Liver damage and morphological changes	361
Hepatic acute phase response	366
Summary	375

Liver damage and morphological changes

After a thermal injury a variable degree of liver injury is present, and it is usually related to the severity of the thermal injury. Fatty changes, a very common finding, are per se reversible and their significance depends on the cause and severity of accumulation (Figure 26.1a–e).⁵ However, autopsies of burned children have shown that fatty liver infiltration was associated with increased bacterial translocation, liver failure and endotoxemia and thus delineating the crucial role of the liver during the postburn response (unpublished observations).

In a recent study in 102 children, 41 females and 61 males with a total body burn size of $58 \pm 2\%$, third-degree burn was $45 \pm 2\%$, we found that liver size and weight significantly increased during the first week postburn ($+85 \pm 5\%$), peaked at 2 weeks post burn ($+126 \pm 19\%$), and was at discharge increased by $+89 \pm 10\%$, $p < 0.05$. At 6, 9 and 12 months liver weight was increased by 40–50% compared to predicted liver weight. In addition liver protein synthesis was impaired over a 6-month period with a shift from constitutive hepatic proteins to acute phase proteins.⁶ Liver enzymes were significantly elevated over the first 3 weeks postburn, normalizing over time. However, in a larger clinical trial we found that the hepatic acute phase response is not limited to a short period of time. In contrast, we found that the synthesis of constitutive hepatic proteins was decreased over a period of 8 weeks, while acute phase proteins were increased during the same time period, indicating the perseverance of the hepatic acute phase response.

Immediately after burn the damage of the liver may be associated with an increased hepatic edema formation. We have shown that the liver weight and liver/body-weight significantly increased 2–7 days after burn when compared to controls. As hepatic protein concentration was significantly decreased in burned rats we suggest that the liver weight gain is due to increased edema formation rather than increases in the number of hepatocytes or protein levels. An increase in

edema formation may lead to cell damage, with the release of the hepatic enzymes (Table 26.1).⁷

Liver function tests and diagnostic tools

The so-called liver function tests evaluate liver activity by assessing the degree of functional impairment. They do not provide a pathological diagnosis and the extreme functional reserve of the organ occasionally produces normal results in the face of significant lesions. Many of these tests do not measure a specific function of the liver, and other organ systems may be implicated. False-positive results for each of the tests are found in about 10% of hospital controls. False-negative tests also occur in about 10% of most tests.^{1–5} Diagnostic tools are:

- Ultrasonography: diagnosis of morphological changes and blood flow (duplex).
- Computed tomography (CT scan): morphological lesions (with the use of vascular enhancement).
- Magnetic resonance imaging (MRI): vascular lesions or intrahepatic focal lesions.
- Scintigrams: dynamic measures.
- Angiography: vascular patterns for the diagnosis of morphological changes.
- Needle biopsy of the liver: pathological diagnosis.

Enzymes

The three enzymes that achieve abnormal serum levels in hepatic disease and have been studied widely are alkaline phosphatase, serum glutamic oxalacetic transaminase (SGOT), and serum glutamic pyruvic transaminase (SGPT). SGOT is present in the liver, myocardium, skeletal muscles, kidney and pancreas. Cellular damage in any of the above-mentioned tissues results in elevation of the serum level. In reference to the liver, the most marked increases accompany acute cellular damage regardless of cause, and extremely high levels are noted in patients with hepatitis. SGOT is only moderately increased in cirrhosis and biliary obstruction. SGPT is more particularly applicable to the evaluation of liver disease, since the hepatic content greatly exceeds myocardial concentration. Elevations accompany acute hepatocellular damage. Lactic acid dehydrogenase (LDH) levels may also be elevated. Serum alkaline phosphatase is found in many tissues, including the liver, bile ducts, intestines, bones, kidneys, placenta, and white blood cells, provides an elevation of the patency of the bile channels at all levels, intrahepatic and extrahepatic. Elevation is demonstrated in 94% of patients with obstruction of the

Fig. 26.1 (a) Histological section of a fatty liver after thermal injury at autopsy. The liver appears to be yellow and enriched with fat. (b) Massive enlargement of the liver in burn patient with greater than 90% TBSA. Liver was 2.68 × expected at autopsy. (c) Admission chest radiograph shows normal lung expansion. (d) Chest radiograph 2 days prior to death shows loss of thoracic domain. (e) At autopsy, liver is enlarged with central lobular necrosis.

TABLE 26.1 LIVER WEIGHT, LIVER WEIGHT/100g BODY WEIGHT, AND LIVER PROTEIN CONTENT FOR CONTROL AND BURNED RATS

	Control days postburn				Burn days postburn			
	1 (n = 5)	2 (n = 5)	5 (n = 5)	7 (n = 5)	1 (n = 14)	2 (n = 14)	5 (n = 14)	7 (n = 14)
Liver weight (g)	13.0 ± 0.9	12.4 ± 0.8	13.2 ± 0.3	13.1 ± 0.4	13.1 ± 0.5	15.3 ± 0.7*	13.6 ± 0.4	13.6 ± 0.5
Liver weight/body weight (%)	3.4 ± 0.1	3.4 ± 0.3	3.8 ± 0.2	3.9 ± 0.2	3.5 ± 0.1	4.1 ± 0.1*	3.6 ± 0.1	3.7 ± 0.1
Liver protein content (mg/mL)	0.98 ± 0.01	0.97 ± 0.01	1.04 ± 0.02	1.0 ± 0.01	0.88 ± 0.02*	0.90 ± 0.02*	0.92 ± 0.01*	0.88 ± 0.01*

Data presented as means ± SEM. *Significant difference vs. control at corresponding day, $p < 0.05$.

extrahepatic biliary tract due to neoplasm and 76% of those in whom the obstruction is caused by calculi. Intrahepatic biliary obstruction and cholestasis also cause a rise in the enzyme level. In the presence of space-occupying lesions such as metastases, primary hepatic carcinoma, and abscesses, the alkaline phosphatase level (ALP) is also increased. The overall correlation between metastatic carcinoma of the liver and an elevated enzyme level is as high as 92%. Sixty percent of patients with primary hepatic carcinoma also demonstrate a significant increase. ALP is also elevated in several non-hepatic disease states, such as bone tumor, pregnancy, and growth.

Liver damage has been associated with increased hepatocyte cell death.⁷ In general cell death occurs by two distinctly different mechanisms — programmed cell death (apoptosis) or necrosis.⁸ Apoptosis is characterized by cell shrinkage, DNA fragmentation, membrane blebbing, and phagocytosis of the apoptotic cell fragments by neighboring cells or extrusion into the lumen of the bowel without inflammation. This is in contrast to necrosis, which involves cellular swelling, random DNA fragmentation, lysosomal activation, membrane breakdown and extrusion of cellular contents into the interstitium. Membrane breakdown and cellular content release induce inflammation with the migration of inflammatory cells and release of pro-inflammatory cytokines and free radicals, which leads to further tissue breakdown. Pathological studies found that about 10–15% of thermally injured patients have liver necrosis at autopsy.^{9,10} The necrosis is generally focal or zonal, central or paracentral, sometimes microfocal, and related to burn shock and sepsis. The morphological differences between apoptosis and necrosis are used to differentiate the two processes.

A cutaneous thermal injury induces liver cell apoptosis.⁷ This increase in hepatic programmed cell death is compensated by an increase in hepatic cell proliferation, suggesting that the liver attempts to maintain homeostasis (Figure 26.2). Despite the attempt to compensate increased apoptosis by increased hepatocyte proliferation the liver cannot regain hepatic mass and protein concentration (we found a significant decrease in hepatic protein concentration in burned rats). It has been shown that a cutaneous burn induces small bowel epithelial cell apoptosis.¹¹ In the same study the authors showed that small bowel epithelial cell proliferation was not increased, leading to a loss of mucosal cells and hence mucosal mass.¹¹ Similar findings were demonstrated in the heart.¹² Burn

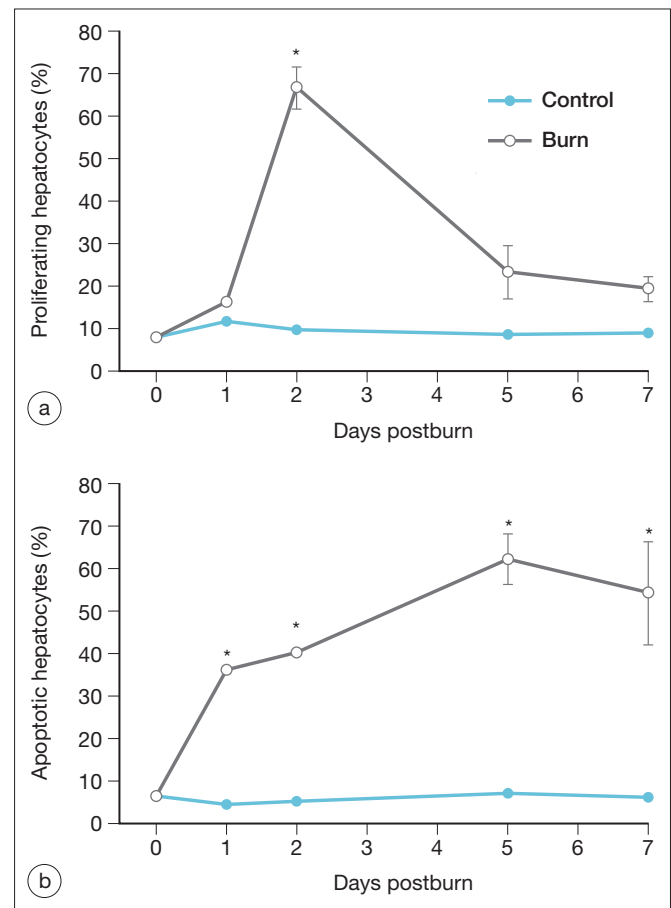

Fig. 26.2 (a) Percent of proliferating cells measured by PCNA. *Significant difference between burn vs. control, $p < 0.05$. Data presented as means ± SEM. (Burned animals $n = 7$ and controls $n = 2$ per time point). (b) Apoptotic cells measured by TUNEL assay 1, 2, 5 and 7 days after burn expressed as positive apoptotic hepatocytes per 1000 hepatocytes. Burned rats had significantly higher rates of hepatocyte apoptosis when compared to controls. Data presented as means ± SEM. (Burned animals $n = 7$ and controls $n = 2$ per time point.) *Significant difference between burn and control, $p < 0.05$.

induced cardiocyte apoptosis; however, cardiocyte proliferation remained unchanged, causing cardiac impairment and dysfunction.¹²

The mechanisms whereby a cutaneous burn induces programmed cell death in hepatocytes are not defined. Studies

suggested that in general hypoperfusion and ischemia-reperfusion are associated to promote apoptosis.^{13–15} After a thermal injury it has been shown that the blood flow to the bowel decreases by nearly 60% of baseline and stays decreased for approximately 4 hours.¹⁶ It can be surmised that the hepatic blood flow also decreases, thus causing programmed cell death. In addition pro-inflammatory cytokines such as IL-1 and TNF- α have been described to be an apoptotic signal.^{17,18} We have shown in our burn model that after a thermal injury serum and hepatic concentration of pro-inflammatory cytokines such as IL-1 α/β , IL-6 and TNF- α are increased.¹⁹ We therefore suggest that two possible mechanisms are involved in increased hepatocyte apoptosis: decreased splanchnic blood flow and elevation of pro-inflammatory cytokines, initiating intracellular signaling mechanisms. Signals that may be involved encompass many signals that play an important role during the acute phase response (see below).

Therapeutic possibilities could be the administration of anabolic growth factors, such as GH, IGF-I or HGF, which all have been shown to be anti-apoptotic.^{19–22} In exerting an anti-apoptotic effect these growth factors could improve hepatic morphology, function, and thus homeostasis after a thermal injury.

Biliary formation

Bile secretion is an active process, relatively independent of total liver blood flow, except in conditions of shock. Bile is formed at two sites:

- the canalicular membrane of the hepatocyte, and
- the bile ductules or ducts.

Total unstimulated bile flow in a 70 kg man has been estimated as 0.41–0.43 mL/min. Eighty percent of the total daily production of bile (approximately 1500 mL) is secreted by hepatocytes and 20% is secreted by the bile duct epithelial cells. The principal organic compounds in bile are the conjugated bile acids, cholesterol, phospholipid and protein. As bile passes through the biliary ductules or ducts it is modified by secretion or absorption of epithelial cells. The highest cells in the biliary ductules have functions and architecture in common with both hepatocytes and ductular cells, and are called cholangiocytes. The best characterized hormone to stimulate bile secretion is secretin. The bile is then being secreted into the gallbladder, whose only function is to concentrate and store bile during fasting. Approximately 90% of the water in gallbladder bile is absorbed in 4 hours. Cholecystokinin appears to be the principal physiological stimulator of gallbladder concentration. Cholinergic stimulation causes contraction of the gallbladder and relaxation of the sphincter of Oddi, which means that bile is secreted into the intestine. Most of the bile salt is being absorbed into the enterohepatic circulation. The liver extracts the bile acids and transports them back to the canalicular membrane where they are resecreted back into the biliary system. Total bile pool size in humans is 2–5 grams and undergoes this circulation 2–3 times per meal and 6–10 times a day, depending on the dietary habit. In addition, 0.2–0.6 grams are lost in the stool per day, and this quantity is replaced by newly synthesized bile acids.³

Bilirubin is a breakdown product of heme and is almost completely excreted in the bile. With hepatocellular disease or extrahepatic biliary obstruction, free bilirubin may accumulate in blood and tissues. Approximately 75% of bilirubin is

derived from senescent red blood cells. Bilirubin circulates bound to albumin, which protects tissue from its toxicity. It is rapidly removed from the plasma by the liver through a carrier transport system. In the hepatocyte, bilirubin is conjugated with glucuronide and secreted in bile. Conjugated bilirubin may form a covalent bond with albumin, so called delta bilirubin. In the intestine, bilirubin is reduced by bacteria to mesobilirubin and stercobilirubin, collectively termed urobilinogen. These are both excreted in the stool. A part of urobilinogen is oxidized to urobilin, which is a brown pigment and gives stool its normal color.

In trauma and sepsis intrahepatic cholestasis occurs frequently and appears to be an important pathophysiological factor without demonstrable extrahepatic obstruction. This phenomenon has been described in association with a number of processes, such as hypoxia, drug toxicity, or total parenteral nutrition.²³ The mechanisms of intrahepatic cholestasis seem to be associated with an impairment of basolateral and canalicular hepatocyte transport of bile acids and organic anions.²⁴ This is most likely due to decreased transporter protein and RNA expression, thus leading to increased bile. Intrahepatic cholestasis, which is one of the prime manifestations of hepatocellular injury, was present in 26% in one clinical study.¹⁰ All of these were concurrent with sepsis. The cellular damage observed in sepsis is most likely the result of decreased hepatic blood flow than direct cellular damage.²⁵

Energy, carbohydrate, insulin, and lipid metabolism

(See Chapter Metabolic responses to burn injury.)

Most of the body's metabolic needs are regulated in some ways by the liver. The liver expends approximately 20% of the body's energy and consumes 20–25% of the total utilized oxygen, which is due to the remarkable hepatic architecture and the blood supply. The hepatocellular organelles in plasma membranes permit specific functions and, at the same time, interrelate with an extracellular matrix, which facilitates metabolic exchange between blood and hepatocytes.² The liver does not only conduct a large number of functions but also manufactures many substances, which serve other organs or tissues. The liver collects such substrates to meet the fuel requirements of other tissues in response to multiple metabolic signals. It is the only organ producing acetoacetate for use by muscle, brain, and kidney, but not itself. The energy-related functions of the liver are regulated by hormones, other agonists and substrates coming to and from the liver.

The liver has a central role in energy metabolism: it supports as a glucose source energy requirements of the central nervous system and red blood cells. During the fed state, results of intestinal carbohydrates digestion, glucose (80%), galactose and fructose (20%), are delivered to the liver. The latter two are rapidly converted into glucose. Glucose absorbed by the hepatocyte is converted directly into glycogen for storage up to a maximum 65 grams of glycogen per kilogram of liver mass. Excess glucose is converted to fat. Glycogen is also produced by muscle, but this is not available for use by any other tissues. During the fasting state, this glycogen is the primary source of glucose. However, after 48 hours of fasting, liver glycogen is exhausted, and proteins mobilized primarily from muscle, mainly alanine, are converted by the liver to glucose.

Lactate, by anaerobic metabolism, is metabolized only in the liver. Ordinarily it is converted to pyruvate and subsequently back into glucose. This shuttling of glucose and lactate between liver and peripheral tissue is carried out in the Cori cycle. The brain does not participate in the cycle and a continuous source of glucose for the brain must come at the expense of muscle proteins.

In liver disease the metabolism of glucose is often deranged. Frequently, in patients with cirrhosis the portal-systemic shunting causes decreased exposure of portal blood to the hepatocytes, producing an abnormal result of the oral glucose tolerance test (OGTT). Hypoglycemia is rare in chronic liver disease since the synthetic capacity of hepatocytes is preserved until late in the disorder. In fulminate hepatic failure, however, there is extensive loss of hepatocyte mass and function, and hypoglycemia supervenes as gluconeogenesis fails.

Glycogenesis, glycogen storage, glycogenolysis, and the conversion of galactose into glucose all represent hepatic functions. Hypoglycemia is a rare accompaniment of extensive hepatic disease, but the amelioration of diabetes in patients with hemochromatosis is considered an indication of neoplastic change. The more common effect of hepatic disease is the deficiency of glycogenesis of resulting hyperglycemia. An hepatic enzyme system is responsible for the conversion of galactose into glucose, and abnormal galactose tolerance tests are seen in hepatitis and active cirrhosis. In rare instances a familial deficiency in this enzyme system accounts for spontaneous galactosemia accompanied by an obstructive type of jaundice that appears after the first week of life and subsides when lactose is removed from the diet.

There are three sources of free fatty acids available to the liver: fat absorbed from the gut, fat liberated from adipocytes in response to lipolysis, and fatty acids synthesized from carbohydrates and amino acids. These fatty acids are etherified with glycerol to form triglyceride. The export of triglycerides is dependent on the synthesis of very low density lipoproteins. In cases of excess supply of fatty acid, there is lipid accumulation in the liver because there is an imbalance of triglyceride relative to very low density lipoproteins. This is seen in obesity, corticosteroid use, pregnancy, diabetes and total parenteral nutrition. Simple protein malnutrition or protein-calories imbalance may also result in fatty change of liver, based on decreased export of triglycerides, because of limited supply of precursors for hepatic synthesis of lipoproteins.

Synthesis of both the phospholipid and cholesterol takes place in the liver, and the latter serves as a standard for the determination of lipid metabolism. The liver is the major organ involved in the synthesis, esterification, and excretion of cholesterol. In the presence of parenchymal damage, both the total cholesterol and the percentage of esterified fraction decreases. The biliary obstruction results in the rise in cholesterol, and the most pronounced elevations are noted in the primary biliary cirrhosis and the cholangiolitis accompanying toxic reactions to the phenothiazine derivatives.^{3,4}

Vitamin metabolism

The liver has many important roles of uptake, storage, and mobilization of vitamins. Most important are the fat-soluble vitamins A, E, D, and K. The absorption of these is dependent on bile salts. The vitamins appear in the thoracic duct 2–6

hours after oral administration. Vitamin A is exclusively stored in the liver, and excess ingestion of vitamin A may be associated with significant liver injury. A role for storage of vitamin A in the Ito cells has been suggested. The initial step in vitamin D activation occurs in the liver where vitamin D₃ is converted 25-hydroxycholecalciferol.

Of particular surgical significance was the discovery of vitamin K. This vitamin is essential for the gamma-carboxylation of the vitamin K-dependent coagulation factors II, VII, IX and X. These factors are inactive without gamma-carboxylation.^{3,4} Vitamins play an important role in wound healing, energy, metabolism, inflammation and antioxidants. Postburn hypermetabolism causes a vitamin deficiency requiring substitution.²⁶

- There are decreased vitamin A levels in burn patients. This is maybe due to a reduction of retinol binding protein (RBP, see proteins section), which is a vitamin A transporter. Vitamin A has been shown to enhance wound healing; thus its substitution is important for dermal wound repair.
- Vitamin E encompasses antioxidant properties and in animal experiments its administration has been shown to reduce lung injury. After a thermal injury its concentration is decreased; thus its substitution is suggested.
- Vitamin D, with its crucial function in the ossear cascade, is also decreased after burn injury; however, its substitution has not been proven.
- Thiamin and riboflavin are vitamins that affect energy and protein metabolism and wound healing. Both factors are decreased after trauma. Thiamin serves as a co-factor in the Krebs cycle and for the oxidation of glucose; thus its need is related to the energy intake. Thiamin is further necessary for the lysyl oxidase function to form collagen. Riboflavin is involved as a co-enzyme in oxidation–reduction reactions. Riboflavin is decreased after burn and an increased need for burn victims has been shown.²⁶
- Folic acid is depleted after a burn and can lead to impaired synthesis of DNA and RNA. Inadequate supplies of vitamin B₁₂ and the indispensable amino acid methionine, impair folate utilization. Thus, a deficiency of either of these nutrients can produce signs of folate deficiency.
- Vitamin B complex with B₆ and B₁₂ serve as co-enzymes in the energy and protein metabolic process. Vitamin B₆ is involved in amino acid metabolism, vitamin B₁₂ in the catabolism of odd-chain long fatty acids. Both should be substituted in the form of a multi-vitamin complex, as both are decreased in the postburn hypermetabolic response.
- Vitamin C plays an important role during the postburn hypermetabolic response. During that period oxygen free radicals, such as superoxide, peroxide and hydroxyl, may cause increased postburn vascular permeability. Vitamin C administration, a free radical scavenger, has thus been suggested to be beneficial in terms of reducing microvascular permeability and thus required fluid volume. In recent studies vitamin C has been described to enhance wound healing in skin, bones and other tissues.

Table 26.2 gives a therapeutic guideline for vitamin substitution according to our institute.²⁷

Coagulation and clotting factors

The liver produces multiple coagulation factors, which can be altered or are defective in the state of liver disease. In the state of jaundice vitamin K resorption is decreased, resulting in a decreased synthesis of prothrombin, or when the liver is severely damaged, in the state of hepatocellular dysfunction prothrombin is not synthesized at all. The diagnosis of pathological prothrombin synthesis is made by the prothrombin time. Decreases in factors V, VII, IX and fibrinogen also have been noted in hepatic disease.⁴ Homeostasis of clotting is complex and has been recently investigated in thermally injured patients.²⁷ Thrombotic and fibrinolytic mechanisms are activated after burn and the extent of activation increases with the severity of the thermal injury. Most homeostatic markers fall during the early shock phase of burns due to dilutional effects, loss and degradation of plasma proteins. Clotting factors return to normal levels after the aggressive resuscitation period. Later in the postburn course, thrombogenicity has been suggested as being increased due to a decrease in anti-thrombin III, protein C, and protein S levels, while fibrinolysis activation occurs via increases in tissue plasminogen activation factor, thus leading to an increased risk of thrombosis. The hypercoagulable state places many thermally injured patients at risk for disseminated intravascular coagulation (DIC). DIC has been described postmortem in 30% of the examined cases. At our institute, heparin is administered as a prophylaxis for deep venous thrombosis and thus for the onset of DIC (Fraxiparine 0.5 mL s.c.). If needed, fresh frozen plasma is therapeutically administered to improve coagulation.

Hepatic acute phase response

Proteins

The acute phase response is a cascade of events initiated to prevent tissue damage and to activate repair processes; the release of pro-inflammatory cytokines by phagocytic cells,

fibroblasts, and endothelial cells leads to the systemic phase of the acute phase response. The systemic reaction affects:

- the hypothalamus — which leads to fever,
- the pituitary–adrenal axis — which leads to the release of steroid hormones,
- the liver — which causes the synthesis and secretion of acute phase proteins,
- the bone marrow — which promulgates further hematopoietic responses, and
- the immune system — which allows the activation of the reticuloendothelial system and the stimulation of lymphocytes.

However, a crucial step in this cascade of reactions involves the interaction between the site of injury and the liver, which is the principal organ responsible for producing acute phase proteins and modulating the systemic inflammatory response.

After major trauma, such as a severe burn, hepatic protein synthesis shifts from hepatic constitutive proteins, such as albumin, pre-albumin, transferrin, and retinol-binding protein, to acute phase proteins.^{1–5,7} Acute phase proteins are divided into type I acute phase proteins, such as haptoglobin and α_1 -acid glycoprotein, mediated by IL-1-like cytokines (IL-1 α / β , TNF- α / β) and type II acute phase proteins, such as α_2 -macroglobulin and fibrinogen, which are mediated by IL-6-like cytokines (IL-6, IL-11).⁷ The up-regulation of acute phase proteins represents a redirection of the liver in order to fulfill immune functions, coagulation and wound healing processes (Figures 26.3 and 26.4).^{2,3,8,9}

In contrast to acute phase proteins, constitutive hepatic proteins are down-regulated.^{28–32} After a thermal injury, albumin and transferrin decrease by 50–70% below normal levels.^{29–32} Studies have shown that two mechanisms are responsible for the decrease of constitutive hepatic proteins:

- the liver re-prioritizes its protein synthesis from constitutive hepatic proteins to acute phase proteins. This could be shown in many studies in which the mRNA synthesis for constitutive hepatic proteins is decreased.
- the other mechanism for decreased constitutive hepatic protein concentration is the capillary leakage and the

TABLE 26.2 MEDICATION GUIDELINE FOR VITAMIN AND MINERAL SUPPLEMENTATION²⁶

Vitamins and minerals	0–2 years	2–12 years	> 12 years
Multivitamin	Poly Vi Sol 1 mL	Poly Vi Sol 1 mL	Vi Deylin 5 mL or Theragran
Ascorbic acid	250 mg QD	250 mg QD	500 mg QD
Folic acid	1 mg QMWF	1 mg QMWF	1 mg QMWF
Vitamin A	2500 U	5000 U	10 000 U
Vitamin E	5 mg	5 mg	10 mg
Zinc sulfate	55 mg	110 mg	220 mg
Elemental iron	<30 kg dose = 2 mg/kg/dose PO TID >30 kg dose = 65 mg PO TID or FeSO ₄ 325 mg PO TID		

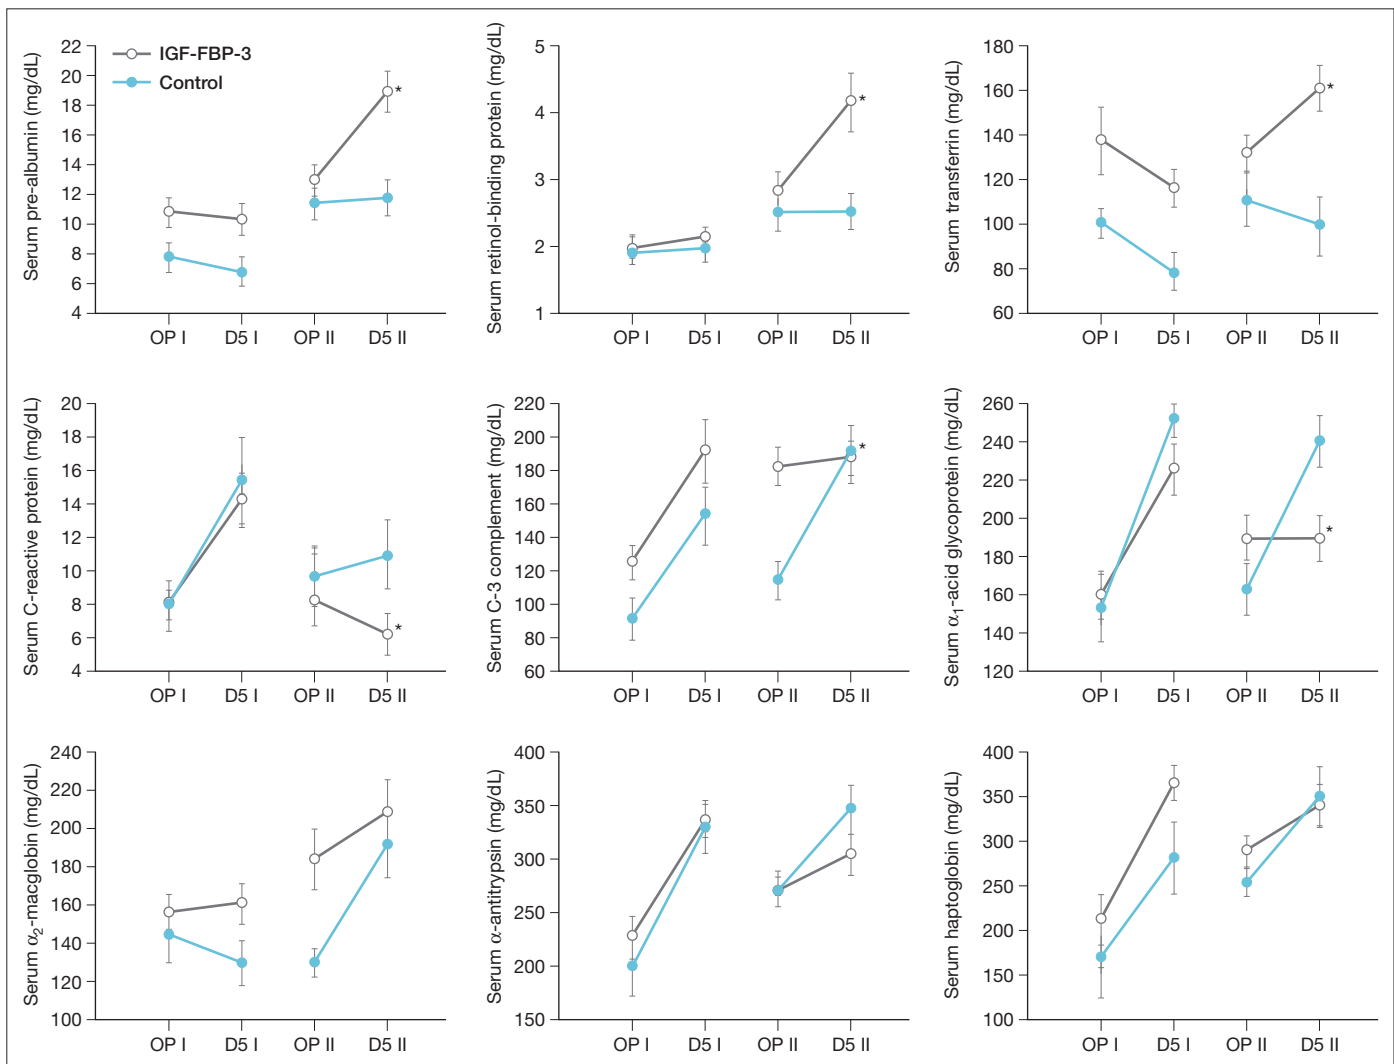

Fig. 26.3 Serum constitutive hepatic proteins (upper line), type I acute phase proteins (middle line), and type II acute phase proteins after thermal injury. The figures depict a clinical study in which the complex IGF-I/BP-3 was determined. All pediatric patients received after saline (control) from OP I to D 5 I. After this first control period patients received either IGF-I/BP-3 or saline OP II to D 5 II. Upper line: all constitutive hepatic proteins were decreased after burn (period I and II). IGF-I/BP-3 increased constitutive hepatic proteins during the second study period, as saline did not. Normal levels: pre-albumin: 25–45 mg/dL, retinol-binding protein: 3–6 m/dL, transferrin: 203–430 mg/dL. Middle line: all type I acute phase proteins are increased after thermal injury during the control and the study period. IGF-I/BP-3 decreased type I acute phase proteins when compared to controls. Normal levels: C-reactive protein: <5 mg/dL, C-3 complement: 50–90 mg/dL, α_1 -acid glycoprotein: 55–140 mg/dL. Lower line: type II acute phase proteins are also increased after burn and stay elevated. IGF-I/BP-3 had no effect on type II acute phase proteins when compared with controls. Normal levels: α_2 -macroglobulin: 100–150 mg/dL, α -antitrypsin: 150–250 mg/dL, haptoglobin: 50–300 mg/dL. Values are presented as means \pm SEM. *Significant between IGF-I/BP-3 vs. controls, $p < 0.05$.

loss of these proteins into the massive extravascular space and burn wound.

Albumin and transferrin, however, have important physiological functions as they serve as transporter proteins and contribute to osmotic pressure and plasma pH.^{29,30} Their down-regulation after trauma has been described as potentially harmful and the synthesis of these proteins has been used as a predictor of mortality, nutritional status, and severity of stress and as an indicator of improved recovery.^{30,33–35} As albumin could be drastically decreased after burn injury we administered human albumin to maintain albumin levels at 2.5 mg/dL at our institute. Other studies discussed albumin

substitution controversially and suggested not to substitute albumin.

The therapeutic guideline at our institute is: serum albumin is measured daily at 4:30 a.m. If serum albumin concentrations are less than 2.0 g/dL, albumin is supplemented based upon age and body weight to maintain colloid osmotic pressure at 2.0 g/dL. Children <2 years of age and <20 kg body weight receive 6.25 g/day exogenous albumin over 6 hours, children 2–9 years old weighing >20 kg but <40 kg receive 12.5 g/day over 6 hours, and children 10–18 years old weighing >40 kg receive 25 g/day. Total albumin infused, albumin infused per day and grams of albumin infused per meter square burn are recorded.

Fig. 26.4 Signal cascade of the hepatic acute phase response. Type I acute phase proteins, such as haptoglobin and α_1 -acid glycoprotein, are mediated by IL-1-like cytokines (IL-1 α/β , TNF- α/β) and type II acute phase proteins, such as α_2 -macroglobulin and fibrinogen, are mediated by IL-6-like cytokines (IL-6, IL-11). In several studies the biphasic time course of pro-inflammatory cytokines has been demonstrated. Immediately after burn IL-1, IL-6, IL-8 and TNF- α increase 2- to 10-fold above normal levels, decrease slightly after approximately 12 hours, increase again, and then start to decrease. Cytokines bind to their receptors, activate intracellular signals by tyrosine phosphorylation, for the type I acute phase response c-jun/c-fos, hepatic nuclear factor-kappa B (NF- κ B) or the CCAAT/enhancer-binding-proteins (C/EBPs). The intracellular signal cascade for type II has been shown to be a tyrosine phosphorylation and activation of intracellular tyrosine kinases (JAKs), latent cytoplasmic transcription factors, STAT1, STAT3, and STAT5 (signal transducer and activator of transcription), or mitogen-activated protein (MAP). These signals activate transcription, translation and expression of acute phase proteins. Particularly, IL-6 has been speculated to be the main mediating cytokine. IL-6 activates glycoprotein 130 (gp 130) and the JAK kinases (JAK-1) leading to activation of STAT 1 and 3 translocating to the nucleus. Intranuclear, the genes for acute phase proteins are turned on.

Mediators of the acute phase response

Mediators of the acute phase response are cytokines. Type I acute phase proteins, such as haptoglobin and α_1 -acid glycoprotein, are mediated by IL-1-like cytokines (IL-1 α/β , TNF- α/β) and type II acute phase proteins, such as α_2 -macroglobulin and fibrinogen, are mediated by IL-6-like cytokines (IL-6, IL-11).²⁸ In several studies the biphasic time course of pro-inflammatory cytokines has been demonstrated. Immediately after burn IL-1, IL-6, IL-8 and TNF α increase 2- to 10-fold above normal levels, decrease slightly after approximately 12 hours, increase again, and then start to decrease. Animal and human studies demonstrated that cytokines can either approach normal levels within 2 days after trauma or can be elevated up to 2 weeks after thermal injury. Cytokine elevation has been shown to be dependent upon the extent of the burn and concomitant injuries.

The signal cascade of cytokines is the following: the cytokines bind to their receptors, activate intracellular signals by tyrosine phosphorylation, for the type I acute phase response c-jun/c-fos, hepatic nuclear factor-kappa B (NF- κ B) or the CCAAT/enhancer-binding-proteins (C/EBPs).³⁵⁻⁴⁷ The intracellular signal cascade for type II has been shown to be a tyrosine phosphorylation and activation of intracellular tyrosine kinases (JAKs), latent cytoplasmic transcription factors, STAT1, STAT3, and STAT5 (signal transducer and activator of transcription), or mitogen-activated protein (MAP).^{28,36-48} These signals activate transcription, translation and expression of acute phase proteins. Particularly, IL-6 has been speculated to be the main mediating cytokine. IL-6 activates glycoprotein 130 (gp 130) and the JAK-kinases (JAK-1), leading to activation of STAT 1 and 3 translocating to the nucleus. Intranuclear, the genes for acute phase proteins are turned on (Figure 26.4).

The aim of the acute phase response is to protect the body from further damage, and the aim will be achieved when all elements of the acute phase response coalesce in a balanced fashion. However a prolonged increase in pro-inflammatory cytokines and acute phase proteins has been shown to be associated with a hypercatabolic state, increased risk of sepsis, multi-organ failure, morbidity and mortality.³³⁻³⁵ Therefore, an important therapeutic approach to improve trauma mortality may be the modulation of the acute phase response by decreasing acute phase proteins and pro-inflammatory cytokines and increasing constitutive hepatic proteins.³³⁻³⁶ The use of antibodies against pro-inflammatory cytokines such as tumor necrosis factor (TNF), interleukin-1 β (IL-1 β), or their receptors showed promising results *in vitro* and in animal models by increasing survival rates in the state of septicemia.⁴⁹⁻⁵¹ However, when these approaches entered clinical trials it became evident that these promising animal data couldn't be found in humans. A possible explanation that the anti-inflammatory agents used failed to control the exaggerated synthesis of pro-inflammatory cytokines may be because they focused on only one pathway or mediator in the inflammatory cascade, leading to a compensation through other pathways.⁵³⁻⁵⁵ Another cause of the failure may have been that the anti-inflammatory cascade did not undergo intensive studies. It has not been until recently that investigations speculated about the importance of a balance between pro- and anti-inflammatory agents.^{54,55} Two studies demonstrated that non-survivors with pancreatitis had decreased interleukin-6 (IL-6) to interleukin-10 (IL-10) ratios when compared with survivors.^{54,55} The relevance of cytokine ratios in the pathogenesis and the prediction of trauma, sepsis and shock still need to be defined; however, individual effects have been investigated. A prolonged and increased inflammatory response contributes to multi organ failure and mortal-

ity.^{33–35} The overexpression of pro-inflammatory cytokines, such as IL-1, IL-6 and TNF, inhibit the growth hormone–insulin-like growth factor-I (IGF-I) axis and increase the hypermetabolic response with resulting increases in morbidity and mortality.^{56–58}

In contrast to pro-inflammatory cytokines, anti-inflammatory cytokines appear to have protective characteristics. Interleukin-2 (IL-2) and interferon- γ (IFN- γ) are signals in the TH-1 response and play a critical role in initiating and maintaining cellular immune responses, in the defense against intracellular pathogens.⁵⁹ Interleukin-4 (IL-4) and interleukin-10 (IL-10) are TH-2 cytokines, characterized by production of B-cell activating cytokines.⁵⁹ TH-2 responses enhance the production of antibodies, which are crucial for the humoral immune response, e.g. in preventing disseminated infections. Administration of IL-10 can protect against lethal doses of endotoxin in mice and decreases the release of endotoxin-induced IL-6 and IL-1.^{34,60,61} Thus, IL-10 administration may ameliorate the endotoxemic shock and may improve survival. The effect of anti-inflammatory cytokines in burns still need to be defined.

Currently research focuses on new mediators and their modulation. Wang and Tracey showed that hypermobility-shift group protein-1 (HMG-1) is a late mediator responsible for lethality in the state of septicemia.⁶² They suggest that blocking HMG-1 maybe a new approach to improve survival. Another group showed that macrophage inhibitory factor (MIF) plays a crucial role in the pro-inflammatory cascade and its attenuation may also improve survival after massive trauma.⁶³ Despite the research focusing on attenuating the pro-inflammatory acute phase response the optimal treatment for severely injured trauma patients needs to be defined. Our group has been studying the effect of growth factors, such as growth hormone (GH), hepatocyte growth factor (HGF), insulin-like growth factor-I (IGF-I), and insulin-like growth factor-I in combination with its principal binding protein-3 (IGF-I/BP-3), on the hepatic acute phase response and cytokine expression as a physiological approach to attenuate the pro-inflammatory cascade.^{19–22}

Growth factors

Over the last years our group has investigated the effect of growth factors, such as growth hormone, hepatocyte growth factor, insulin-like growth factor-I, and insulin-like growth factor-I in combination with its principal binding protein-3 on the hepatic acute phase response. Our hypothesis was that physiological anabolic agents would improve constitutive hepatic protein synthesis and thus equilibrate the pro- to anti-inflammatory hepatic response. We have shown that the growth factors tested all had different effects on hepatic cytokine and protein synthesis.^{19–22}

Recombinant human growth hormone (rhGH)

The effect of rhGH on the hepatic acute phase response has been tested in animal models and pediatric burn patients.^{19,20,64} Data showed in burned children that GH modulated the acute phase response by decreasing both serum TNF- α and IL-1 β . Decreases in serum TNF- α and IL-1 β were associated with decreased type I acute phase proteins serum amyloid A (SAA) and C-reactive protein (CRP). rhGH did not affect IL-6 con-

centration and neither its dependent acute phase proteins haptoglobin, α_1 -antitrypsin, or α_2 -macroglobulin. The mechanisms by which rhGH modulates the acute phase response are not entirely defined; however, it has been demonstrated that rhGH binds to its cell surface receptor (GHR) and leads to tyrosine phosphorylation of CCAAT/enhancer-binding-proteins (C/EBPs), the AP-1 family of transcription factors, intracellular tyrosine kinases (JAKs), octamer-binding-proteins and STATs (signal transducer and activator of transcription).^{42,44,48,63–69} These signal transcription factors translocate to the nucleus where they can interact with specific DNA sequences to modulate the gene expression of c-fos/c-jun and nuclear factor-kappa B (NF- κ B), which regulate the expression of constitutive hepatic and acute phase proteins.^{70,71} Interestingly, cytokines regulate constitutive hepatic and acute phase protein expression through a similar cascade.²⁸ IL-1-like cytokines bind to their receptors, leading to an activation/phosphorylation, which results in activation of cellular signals AP-1, NF- κ B and C/EBP β .²⁸ The stimulation of these signals leads to an activation of the transcription and translation of type I acute phase protein genes. Given the fact, that rhGH decreases IL-1-like cytokines, it is unknown whether rhGH decreases type I acute phase proteins through a direct down-regulation of AP-1, NF- κ B or C/EBP β , or through modulation of the IL-1-like cytokine expression which decrease these cellular signals and consecutively type I acute phase proteins.^{44,70,71}

rhGH administration increased endogenous albumin levels, reducing the amount of required exogenous substitution to maintain normal serum albumin levels. Similar to acute phase proteins, the mechanisms by which rhGH increases endogenous albumin concentrations are unknown; however, rhGH might exert this effect through activation of C/EBP α .^{44,73} C/EBP α is a trans-activator of liver specific genes such as albumin and its mRNA concentration decreases during trauma and stress and can be considered as a negative regulated acute phase gene.^{42–44,73–75} Recently, C/EBP α mRNA levels, which are decreased after trauma, were shown to increase with rhGH.⁴⁴ Thus, a stimulation of the α isoform may consecutively lead to a stimulation of constitutive hepatic proteins, such as albumin and retinol-binding protein.⁴⁴

Despite the advantages seen with rhGH administration Takala et al. reported increased mortalities in septic adult patients.⁷⁶ We have not found any evidence that rhGH increases mortality in pediatric burned patients; however, based on Takala et al.'s data, rhGH should not be given in septic patients or patients with multi organ failure (MOF). Another side effect of rhGH that has been recently delineated is an increase in hepatic triglyceride concentration and development of a fatty liver.^{19,77} rhGH administration over 10 days increased hepatic triglyceride concentration by nearly 50% in burned rats.¹⁹ The mechanisms have been discussed in clinical studies, where the authors speculated that rhGH increased peripheral lipolysis and, due to a lack of transporter proteins (LDL, HDL), triglycerides accumulate in the liver.⁷⁷ We demonstrated in pediatric burn patients that rhGH increased free fatty acid concentration when compared to placebo, indicating that rhGH stimulates peripheral lipolysis and, subsequently, free fatty acid concentration.⁶⁴

In summary, rhGH modulates the acute phase response by affecting pro-inflammatory IL-1-like cytokine expression

followed by decreased type I acute phase proteins and increasing constitutive hepatic proteins. No effect on IL-6-like cytokines and type II acute phase proteins could be demonstrated. Given the fact that the acute phase response is a contributor to mortality after trauma, rhGH administration appears not to cause an increase in mortality in severely burned children as described by Takala et al. in trauma and septic patients as rhGH does not cause an increased and prolonged acute phase response.⁷⁶

Hepatocyte growth factor

Hepatocyte growth factor (HGF) has been shown to accelerate hepatic regeneration and improve hepatic function in rats after trauma.⁷⁸ HGF and its receptor *c-met* (HGFR) are known to modulate the acute phase response in primary hepatocyte cultures.⁷⁹ HGF stimulates *in vitro* synthesis of constitutive hepatic proteins and decreases the synthesis of acute phase proteins.^{79,80} Within 30–60 minutes of injury plasma HGF is elevated, presumably sending a strong mitogenic signal to the hepatocytes, which are already primed by interleukin-6 (IL-6), tumor necrosis factor- α (TNF- α), or insulin.⁸¹ The cause of the increase in plasma HGF is currently unknown; however, it has been postulated to be due either to increased production of HGF in extrahepatic organs, such as lung, spleen, kidney, or gut, or to a decrease in hepatic HGF excretion.^{81,82} The rapid increase in HGF stimulates hepatocyte mitogenesis, motogenesis, and DNA synthesis.⁸¹ HGF administered to normal rats only stimulates a small number of hepatocytes to enter the DNA synthesis cycle, indicating that hepatocytes in normal livers are not ready to respond to mitogenic signals without the priming events that switch them into a responsive mode.⁸¹

We have shown that HGF administration stimulates constitutive hepatic proteins after burn injury *in vivo*.²¹ In fact, serum transferrin reached normal levels 7 days after injury with HGF treatment, whereas in saline-treated animals serum transferrin remained low. Serum albumin levels decreased; however, beginning at day 2 after burn, HGF attenuated this drop in serum albumin. The exact mechanisms by which HGF stimulates constitutive hepatic proteins are unknown; however HGF is capable of stimulating the synthesis of C/EBP α , which regulates constitutive hepatic proteins.⁶⁸

In contrast to recent *in vitro* studies, where the authors demonstrated that HGF decreased acute phase proteins, we showed *in vivo* that HGF increased serum α_2 -macroglobulin (type II acute phase protein), with no effect on α_1 -acid glycoprotein and haptoglobin (type I acute phase proteins).^{79,80} Type II acute phase proteins are mediated through IL-6-like cytokines, including cytokines such as IL-6 and IL-11.²⁸ IL-6 secreted by Kupffer cells in the liver is capable of regulating the synthesis of transcription factors that have response elements in the 5'-flanking region of the HGF gene that may be potentially utilized in inducing HGF gene expression at the transcriptional level.^{81,83–85} Therefore, IL-6 appears likely to substantially and quickly up-regulate HGF mRNA and HGF mRNA receptor expression.⁸³ However, the interaction between HGF and IL-6 *in vitro* has been shown to be complex and controversial.^{79,84,87} In our study, we demonstrated that administration of rhHGF stimulated serum IL-6, along with an increase in its dependent type II acute phase protein, serum

α_2 -macroglobulin and TNF- α .²¹ TNF- α is another important mediator during the acute phase response, which has been shown to modulate type I acute phase proteins and to stimulate IL-6, HGF and HGF-receptor gene expression.^{78,81,83,86,87} TNF- α is a pro-inflammatory cytokine, associated with increased catabolic activity and mortality.⁸⁸ However, a recent study suggested that increased TNF- α concentrations after liver injury play an important role in the early signaling pathways of liver regeneration.⁸¹ In support of this hypothesis, we found that serum and hepatic gene expression for TNF- α was significantly elevated with HGF. This finding suggests that HGF stimulates IL-6, TNF- α and type II acute phase proteins. Increased TNF- α could not be shown to contribute to any detectable adverse side effects; however, one may speculate that body weight loss may be due to elevated TNF- α .

HGF exerted beneficial effects after thermal injury by increasing liver weight, liver weight per 100 g body weight and higher total hepatic protein content compared to rats receiving saline.²¹ HGF, furthermore, demonstrated no increase in liver triglyceride content, a phenomenon associated with thermal injury.^{20,77} These findings are most likely due to the strong mitogenic effect of HGF on hepatocytes.

HGF has been shown to have some beneficial effects and be a potential therapeutic agent; however, more studies need to be done before this growth factor can be applied in patients.

Insulin-like growth factor-I in combination with its principal binding protein-3

Insulin-like growth factor-I is a 7.7-kDa single chain polypeptide of 70 amino acids with sequence homology to proinsulin.⁸⁹ In the system 95–99% of IGF-I is bound and transported with one of its six binding proteins IGFBP 1–6.⁹⁰ The majority of IGF-I is bound to IGFBP-3. Administration of the IGF-I/BP-3 complex as a therapeutic agent provides several advantages over the administration of IGF-I alone, because when IGF-I is already bound to IGFBP-3, it rapidly transforms into a ternary complex which confers decreased serum clearance and it allows the delivery of significantly larger amounts of IGF-I without inducing hypoglycemia and electrolyte imbalances. In general, IGF-I has been shown to improve cell recovery, wound healing, peripheral muscle protein synthesis, and gut and immune function after thermal injury.^{91–93} Recent evidence suggests that IGF-I is instrumental in the early phases of liver regeneration after trauma and modulates the hepatic acute phase response in burned rats.²²

As administration of IGF-I in therapeutic dosages causes adverse side effects a new complex has been recently developed, in which IGF-I is bound to its principal binding protein-3 (IGFBP-3) in a 1:1 molar ratio. This complex has been shown to be safe and efficacious.²² Thus, we investigated the effect of IGF-I/BP-3 in thermally injured pediatric patients.⁹⁴ IGF-I in combination with IGF-I/BP-3 decreased pro-inflammatory cytokines IL-1 β and TNF- α , with subsequent decreases in type I acute phase proteins, C-reactive protein, complement C-3 and α_1 -acid glycoprotein.⁹⁴ As we did not observe an increase in IL-6 or type II acute phase proteins we suggest that IGF-I effectively decreased IL-1 β and TNF- α without compensatory elevation of IL-6 and type II acute phase proteins. Decreased acute phase protein and pro-inflammatory cytokines concentration was associated with increased synthesis of

constitutive hepatic proteins, such as pre-albumin, retinol-binding protein, and transferrin.⁹⁴

IGF-I appears to have anti-apoptotic, pro-mitogenic effects on multiple cell lines, such as hepatocytes, small bowel epithelial cells, and hematopoietic progenitor cells.⁹⁵⁻⁹⁷ Therefore, IGF-I seems to affect extra- and intracellular signaling pathways. Recent studies demonstrated that IGF-I decreases the C/EBP β subtype, which increases after trauma and regulates cytokine and protein synthesis.⁷⁴ In contrast IGF-I increases the C/EBP α subtype, which decreases after trauma and regulates constitutive hepatic protein synthesis.⁴⁷ IGF-I has been furthermore shown to affect nuclear factor- κ B (NF- κ B). NF- κ B controls the transcriptional regulation of many pro-inflammatory cytokines and acute phase proteins which contain NF- κ B response elements in their promoter region.^{28,38,40} NF- κ B has also been shown as one of the most potent anti-apoptotic transcription factors in several organs. We have recently demonstrated that IGF-I increases hepatic NF- κ B concentration and decreases hepatocyte apoptosis after trauma.⁹⁷ IGF-I further affects nitric oxide, JAK/STAT, Gp 130 and many more transcription and translation factors.^{46,47} We therefore suggest that IGF-I plays a major role after trauma by maintaining organ homeostasis and function. In thermally injured children rhIGF-I in combination with its principal binding protein modulates the hepatic acute phase response by decreasing pro-inflammatory cytokines IL-1 β and TNF- α , followed by a decrease in type I acute phase proteins. IGF-I/BP-3 had no effect on IL-6 and type II acute phase proteins (Figure 26.3). Decreases in acute phase protein and pro-inflammatory cytokine synthesis were associated with increases in constitutive hepatic protein synthesis. Attenuating the hepatic acute phase response with IGF-I/BP-3 modulated the hypermetabolic response, which may prevent MOF and improve clinical outcome after a thermal injury without any detectable adverse side effects. Data shown would make IGF-I/BP-3 an ideal therapeutic agent; however, recently our group found that IGF-I/BP-3 increased the risk for peripheral neuropathies, thus limiting the use of this agent (unpublished observations).

Insulin

In our first study we determined the effect of insulin therapy on inflammation, hepatic function, structure and hepatic mRNA and protein cytokine expression during the hypermetabolic cascade post burn.⁹⁸ Rats received a thermal injury and were randomly divided into the insulin or control group. Our outcome measures encompassed the effect of insulin on cytokines, hepatic proteins, hepatic pro- and anti-inflammatory cytokines mRNA and proteins, hepatocyte proliferation including Bcl-2 and hepatocyte apoptosis with caspases-3 and caspases-9. We found that insulin significantly improved hepatic protein synthesis by increasing albumin and decreasing C-reactive protein and fat, while insulin decreased the hepatic inflammatory response signal cascade by decreasing hepatic pro-inflammatory cytokines mRNA and proteins IL-1 β and TNF at pre-translational levels (Figure 26.5). Insulin increased hepatic cytokine mRNA and protein expression of IL-2 and IL-10 at a pre-translational level when compared with controls. In addition, insulin affected hepatic signal transcription factors and attenuated on a molecular level inflammation (Figure 26.6). Insulin increased hepatocyte proliferation along

with Bcl-2 concentration, while decreasing hepatocyte apoptosis along with decreased caspases-3 and -9 concentration, thus improving liver morphology (Figure 26.7). From this animal study we concluded that insulin attenuates the inflammatory response by decreasing the pro-inflammatory and increasing the anti-inflammatory cascade, thus restoring hepatic homeostasis. The subsequent study examined whether the observed effects of insulin are limited to a thermal injury or whether insulin exerts positive effects during other pathophysiological states. We chose the model of endotoxemia (LPS administration).⁹⁹ Endotoxemic rats were divided to receive either saline or insulin. Hepatic morphology and function was determined by measuring the effect of insulin on liver proteins, enzymes, hepatocyte apoptosis and proliferation including caspases-3 and -9 and Bcl-2. Intrahepatic ATP, glucose and lactate concentrations were determined by bioluminescence. To determine possible molecular and biochemical mechanisms the effect of insulin on hepatic cytokine mRNA and gene profile analysis was performed. Insulin significantly improved hepatic protein while it attenuated hepatic damage as shown by decreased AST and ALT. Improved liver morphology was probably due to decreased hepatocyte apoptosis along with decreased caspase-3 concentration and increased hepatocyte proliferation along with Bcl-2 concentration. Insulin decreased the hepatic inflammatory response signal cascade by decreasing hepatic IL-1 β , IL-6 and MIF. Bioluminescence showed that insulin improved hepatic glucose metabolism and glycolysis. Gene chip analysis revealed a strong anti-inflammatory effect of insulin on inflammatory mediators. These data provide insight that insulin improves hepatic integrity, glucose metabolism and function by increasing cell survival and attenuating the hepatic inflammatory response in endotoxemic rats. In order to confirm our animal data we went on and conducted a human study.¹⁰⁰ Thirteen thermally injured children received insulin to maintain blood glucose at a range from 120 to 180mg/dL; fifteen children received no insulin with blood glucose levels also at range from 120 to 180mg/dL and served as controls. Our outcome measures encompassed the effect of insulin on pro-inflammatory mediators, the hepatic acute phase response, fat and the IGF-I system. Insulin administration decreased pro-inflammatory cytokines and proteins, while increasing constitutive hepatic proteins. Burned children receiving insulin required significantly less albumin substitution to maintain normal levels compared to control. Insulin decreased free fatty acids and serum triglycerides when compared to controls. Serum IGF-I and IGFBP-3 significantly increased with insulin administration. In conclusion, several studies have shown that insulin attenuates the inflammatory response by decreasing the pro-inflammatory and increasing the anti-inflammatory cascade, thus restoring systemic homeostasis, which has been shown critical for organ function and survival in critically ill patients. Insulin appears to be a safe and efficacious drug to affect hepatic dysfunction. Even more so, as tight euglycemic control has been shown to be advantageous over low-dose insulin treatment. Studies in this area are warranted.¹⁰¹

Propranolol

A new therapeutic option to attenuate hepatic swelling and dysfunction appears to be a non-selective β_1/β_2 blocker. Beta

Fig. 26.5 Serum pro-inflammatory cytokines after a 30% TBSA thermal injury. (a) Serum TNF. Insulin prevented an increase of serum TNF on days 1 and 2 when compared with controls. Normal serum TNF: 0–2 pg/mL. (b) Serum IL-1 remained elevated during the study period. Insulin decreased serum IL-1 concentration on days 1, 2 and 7 after trauma when compared with animals receiving saline. Normal IL-1: 0–20 pg/mL. (c) Insulin significantly decreased serum IL-6 concentrations 1 day after burn compared to controls, which were almost 300 times elevated above normal levels. Normal IL-6: 0–10 pg/dL. (d) Macrophage inhibitory factor (MIF) was found to be increased immediately after burn, but further increased over the study period by almost 100% in the control group. Insulin significantly decreased serum MIF 5 and 7 days after trauma. Normal MIF: 0–20 pg/mL. *Significant difference between insulin and control, $p < 0.05$. Data presented as means \pm SEM.

blockade results in a decrease in urinary nitrogen loss, decreased peripheral lipolysis and whole body urea production,¹⁰² decreased resting energy expenditure, and improved skeletal muscle protein kinetics.¹⁰³ Furthermore, propranolol preserved fat-free mass when compared to controls.¹⁰³

Another study from our group showed that propranolol decreased hepatic fat storage by limiting fatty acid delivery in severely burned pediatric patients.¹⁰⁴ In addition, we showed that propranolol decreased peripheral lipolysis and improved insulin responsiveness.¹⁰⁵ Recently we further showed that propranolol has a profound effect on fat infiltration of the liver. The effect of propranolol on attenuating, and even reversing, hepatomegaly is shown in Figure 26.8. In control patients 39 of 45 livers increased in size during acute hospitalization, whereas only 4 of 35 livers with propranolol therapy increased in size ($p = 0.0001$ between groups). We propose that propranolol reduces hepatomegaly by inhibiting lipolysis and reducing liver blood flow, in turn delivery of fatty acids to the liver. The effect of propranolol on the hepatic acute phase response, systemic inflammatory reaction and immune system is being examined in current clinical studies at our institute. In summary, for a long time hepatic dysfunction was tolerated without any treatment option. In the field of burns, it appears that there will be new treatment options available to successfully attenuate the hypermetabolic hepatic acute phase response.

Enzymes

Liver enzymes, such as aspartate aminotransferase (AST) and alanine aminotransferase (ALT), are the most sensitive indicators of hepatocyte injury. Both AST and ALT are normally present in low concentrations. However, with cellular injury or changes in cell membrane permeability, these enzymes leak into circulation. Of the two, the ALT is the more sensitive and specific test for hepatocyte injury as AST can be also elevated in the state of cardiac arrest or muscle injury. Serum glutamate dehydrogenase (GLDH) is also a marker and is elevated in the state of severe hepatic damage. Serum alkaline phosphatase (ALKP) provides an elevation of the patency of the bile channels at all levels, intrahepatic and extrahepatic. Elevation is demonstrated in patients with obstruction of the extrahepatic biliary tract or calculi. In general, serum levels are elevated in hepatobiliary disease.¹⁰⁶

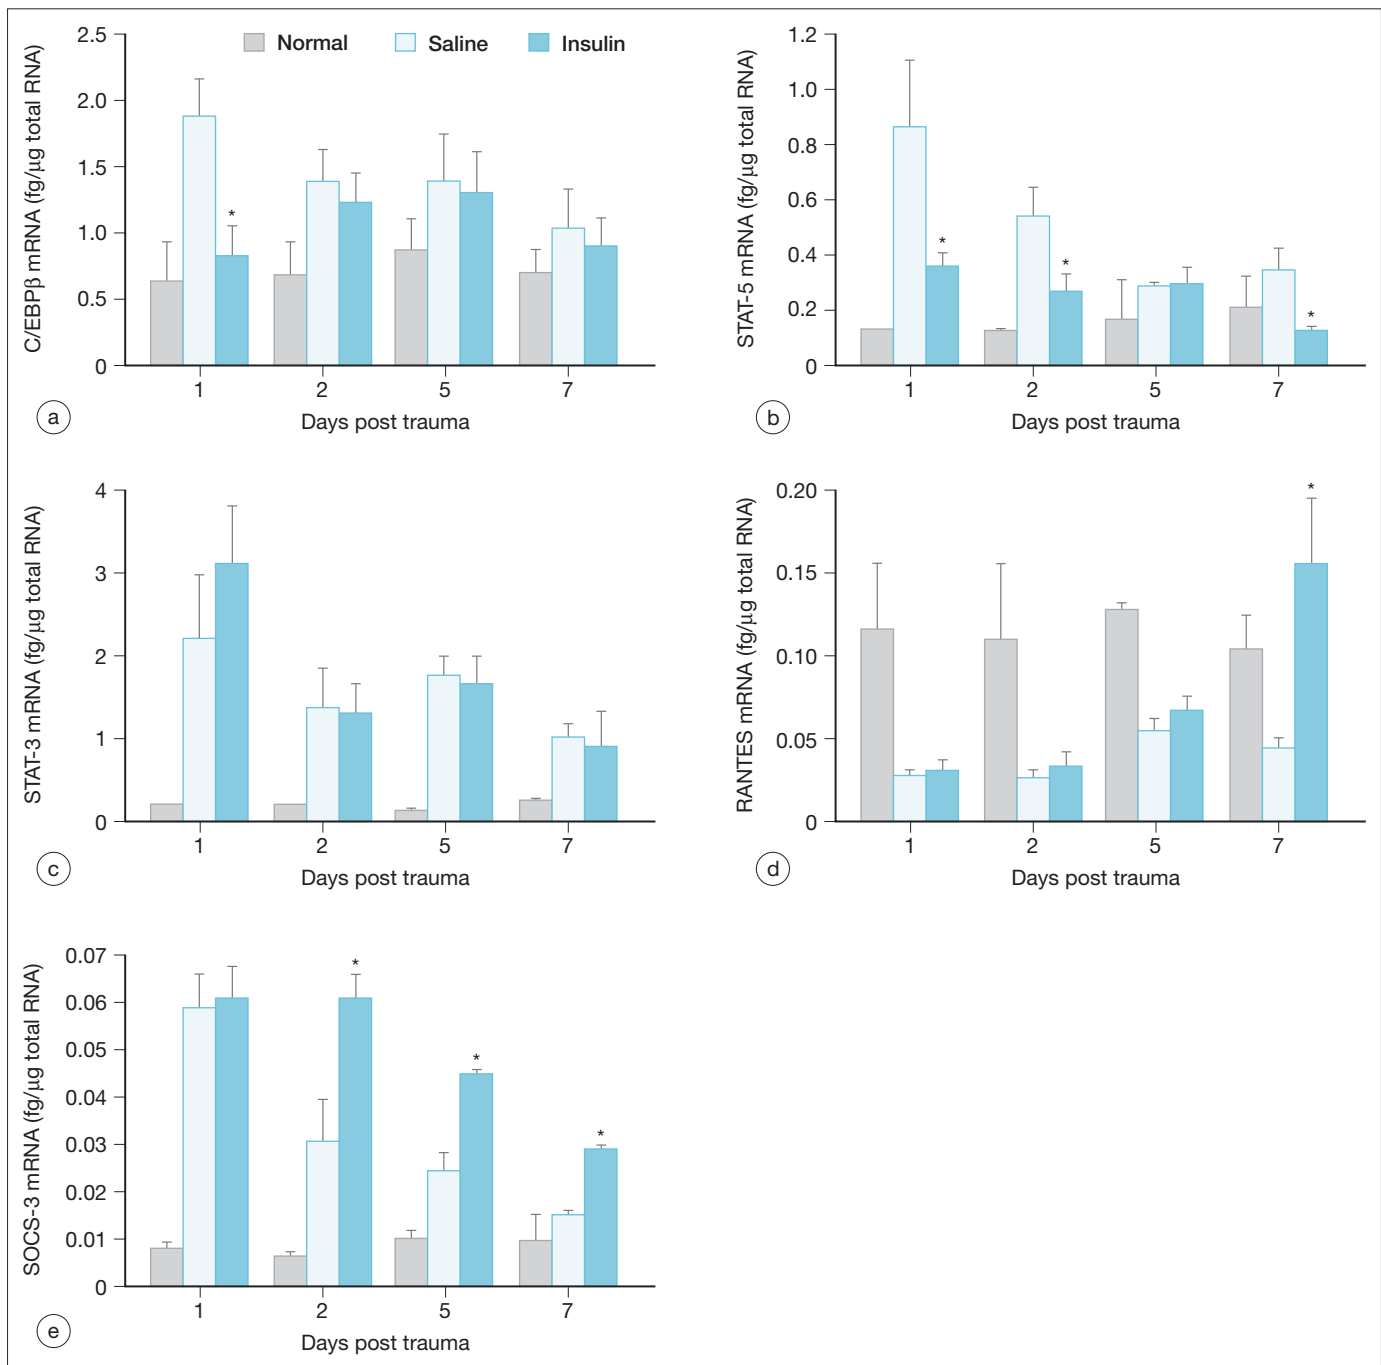

Fig. 26.6 Hepatic mRNA expression of signal transcription factors quantified by light cycler analysis. (a) C/EBPβ mRNA expression increased after burn and remained elevated during the study period. Insulin decreased hepatic C/EBPβ mRNA expression on the first day after thermal injury. (b) Hepatic STAT-5 mRNA expression increased after the burn trauma. Insulin significantly decreased STAT-5 mRNA expression on days 1, 2 and 7 when compared to controls. (c) Hepatic mRNA expression of STAT-3 increased after trauma, but differences between controls and insulin could be shown. (d) Hepatic RANTES mRNA expression was decreased with the thermal trauma. Insulin increased RANTES mRNA, which approached normal levels 7 days post trauma compared to rats receiving saline. (e) SOCS-3 mRNA was found to be increased with burn injury. Insulin further increased hepatic mRNA expression of SOCS-3 2, 5 and 7 days after burn. *Significant difference between insulin and control, $p < 0.05$. Data presented as means \pm SEM.

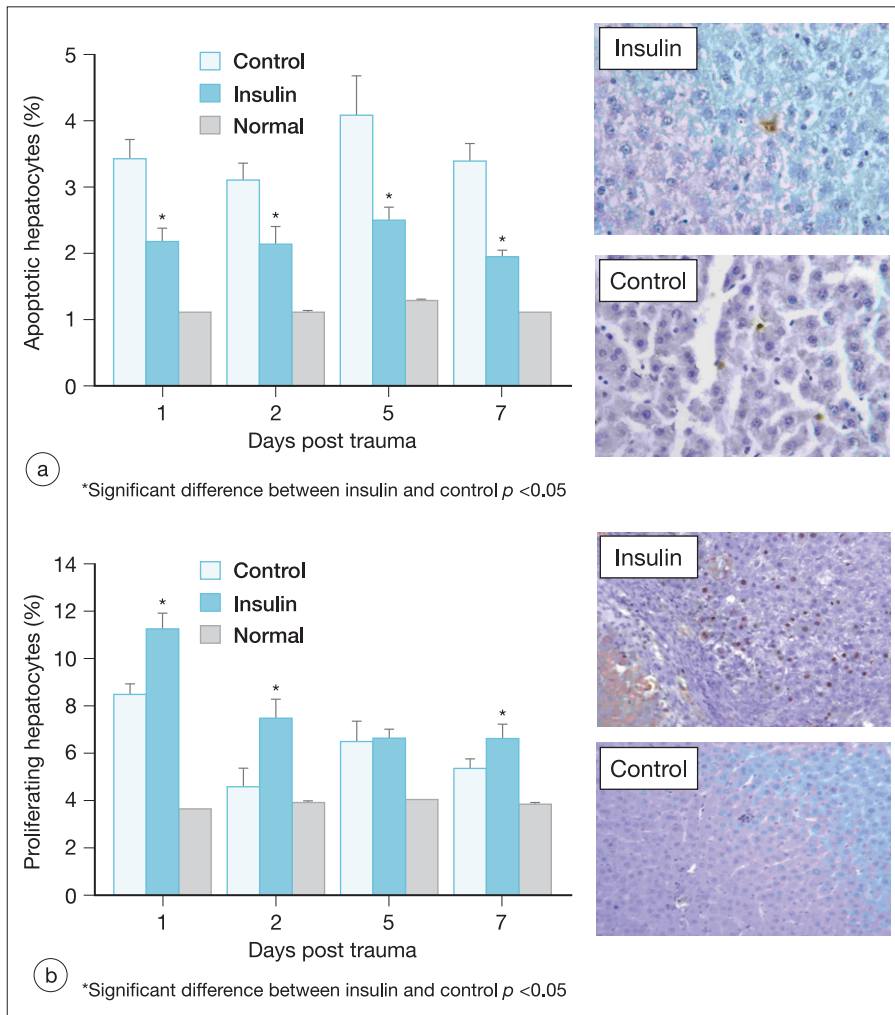

Fig. 26.7 Hepatic morphology determined by measuring hepatocyte proliferation, apoptosis and resulting hepatocyte net balance. (a) Thermal injury caused a significant increase in hepatocyte apoptosis by the biological factor 4 compared to normal. Insulin decreased apoptosis on all study days by 50% compared to controls, $p < 0.05$. Beside the figure, two representative histological sections stained for apoptosis. While in control sections many apoptotic hepatocytes could be identified, only few were found positive in the insulin sections. (b) Hepatocyte proliferation increased in the control and the insulin immediately after burn and remained elevated throughout the entire study period. Insulin had a mitotic effect on hepatocytes and significantly increased proliferation compared to controls on days 1, 2, and 7 after thermal trauma. Beside the figure, two representative histological sections stained with Ki67 for proliferation. While in control sections few proliferating hepatocytes could be identified, many hepatocytes were found positive in the insulin sections.

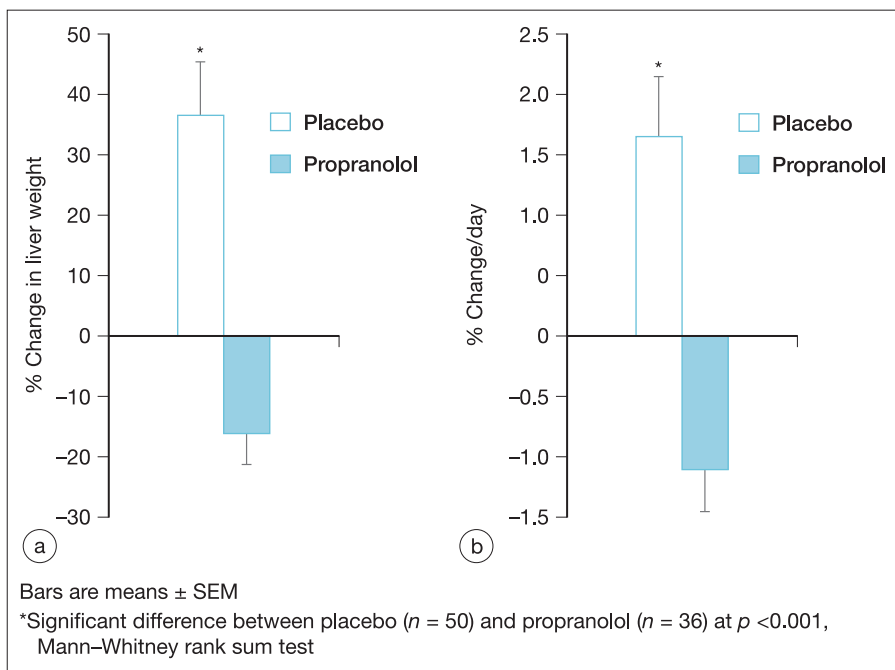

Fig. 26.8 (a) Percent change in liver weights. *Significant difference between placebo ($n = 50$) and propranolol therapy ($n = 36$) at $p < 0.001$. Confidence intervals for differences are 30.242, 75.358. Mean \pm SEM days after burn until the first measurement was 12.8 ± 1.3 days (range, 2–28 days). (b), Percent change per day in liver weights. *Significant difference between placebo ($n = 49$) and propranolol therapy ($n = 36$) at $p < 0.0001$. Confidence intervals for differences are 1.927, 4.063. (Reproduced with permission Barrow RE, Wolfe RR, Dasu MR, et al. The use of beta-adrenergic blockade in preventing trauma-induced hepatomegaly. TABLE 26.3 LOCALIZATION OF HEPATIC ENZYMES AND THEIR FUNCTION IN HEPATIC DAMAGE DIAGNOSIS⁹⁷

Localization			
Enzyme	Cytoplasmic	Mitochondrial	Liver specific
AST	+	+	No: heart, muscle
ALT	+	-	Yes
GLDH	-	+	Yes
ALKP	Combination of several isoenzymes	No: bone, growth, pregnancy, etc.	

Reproduced from Jeschke MG, Herndon DN, Vita R, et al. IGF-1/BP-3 administration preserved hepatic hemostasis after thermal injury which is associated with increases in NO and hepatic NF- κ B. *Shock* 2001; 16:373–379.⁹⁷

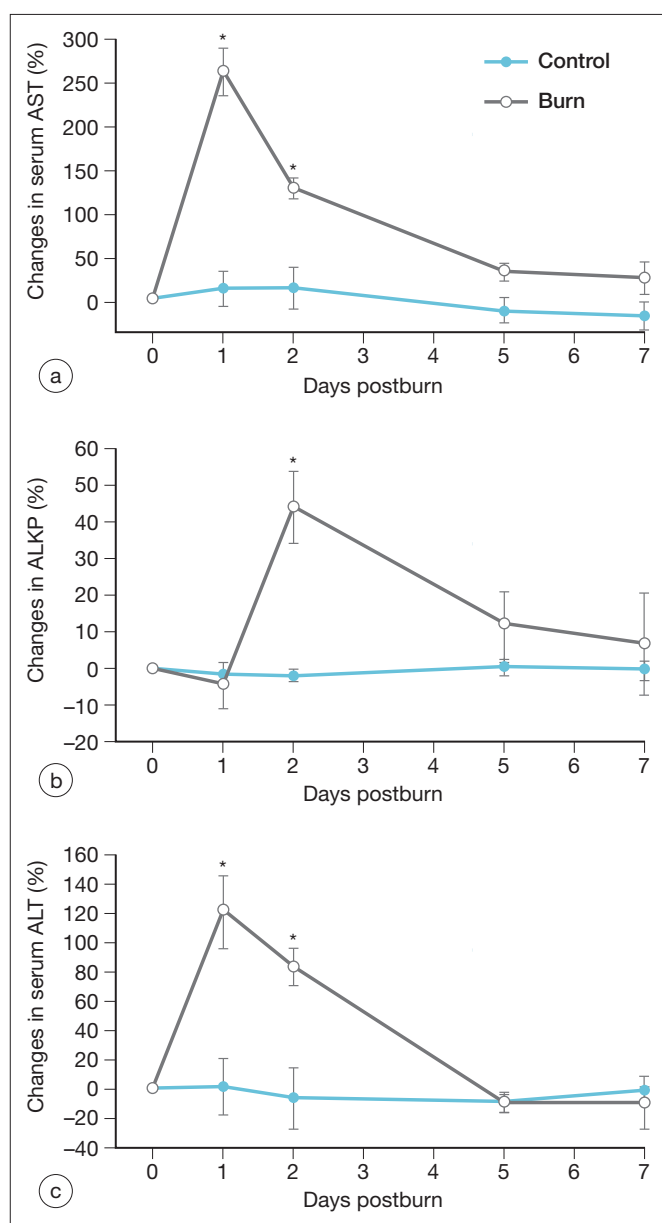

Fig. 26.9 Serum AST (a), ALKP (b) and ALT (c) levels were determined in controls and thermally injured rats. Serum AST and ALT increased during the first day after burn, whereas ALKP increased 2 days after burn when compared with controls. Data presented as means \pm SEM. * Significant difference between burn and controls, $p < 0.05$.

As mentioned earlier liver damage occurs after a thermal injury. The elevation of hepatic enzymes correlates with the severity and extent of the hepatic injury. Small hepatic injury leads to a predominantly elevation of the cytoplasmic enzymes ALT and only little elevation of AST. The so-called de Ritis ratio GOT/GPT < 1 . In a state of severe hepatic damage, mitochondrial bound enzymes are strongly elevated and the de Ritis ratio GOT/GPT > 1 (Table 26.3).¹⁰⁶

Thermal injury causes liver damage by edema formation, hypoperfusion, pro-inflammatory cytokines or other cell death signals with the release of the hepatic enzymes. Others and we have shown that serum AST, ALT and ALKP are elevated between 50 to 200% when compared with normal levels (Figure 26.9). We observed that serum AST and ALT peaked during the first day postburn and ALKP during the second day postburn. During hepatic regeneration all enzymes returned to baseline between 10–14 days postburn. If liver damage persists, enzymes stay elevated. There is no need for therapeutic intervention to decrease elevated enzymes. Enzymes can only be used as markers and the effect of therapeutics can be studied.

Summary

The liver plays a crucial role in the aftermath of a thermal injury. The synthesis of constitutive hepatic proteins, acute phase proteins, cytokines and other mediators makes it a determining factor for survival. A new approach for improving hepatic function may be the use of anabolic, anti-inflammatory agents; however, there is no effective treatment for hepatic dysfunction.

Importance of bone metabolism and function after burn

Burn injury exceeding 40% total body surface area (TBSA) is very disruptive to bone and calcium metabolism. Long-term consequences include an increased risk of fracture postburn resulting from long-term loss of bone calcium and a chronic, progressive vitamin D deficiency with inability of the skin to synthesize normal quantities of vitamin D from sunlight exposure. More immediately postburn, calcium homeostasis is disrupted and patients become magnesium depleted. These are in part consequences of burn-induced hypoparathyroidism and development of end-organ resistance to parathyroid hormone. This chapter will deal in detail with normal homeostasis of calcium, phosphorus, and magnesium, how the burn injury disrupts them and how these disruptions can be managed. It will then go on to discuss the known effects of burn injury on bone structure and bone biology, deal with the consequences of the damage to bone and the management of this problem as it has been worked out to date.

Metabolic functions of calcium, phosphorus, and magnesium

The effects of burn injury on homeostasis of three critical minerals (calcium, phosphorus, and magnesium) have not been studied in great detail. These three minerals play key roles in

metabolism and also are stored in bone, a tissue that is significantly affected by burn injury. All three of these minerals play important roles in intracellular and extracellular metabolism.

Calcium

Calcium (Ca) plays a major role in neuromuscular impulse propagation and membrane depolarization and, consequently, in muscle contractility. Ca may also serve as a second messenger, mediating the secretory release of peptides such as amylase, insulin, and aldosterone via intracellular pathways utilizing calmodulin, an intracellular calcium receptor protein, or protein kinase C. From the standpoint of extracellular metabolism, Ca serves as a co-factor in blood coagulation, specifically in the conversion of prothrombin to thrombin and the activation of several factors in the coagulation cascade. Ca also contributes to plasma membrane stability by binding to phospholipids.¹⁻³

Phosphorus

Phosphorus (P) plays a major role in intracellular energy metabolism. P, in the form of phosphate esters, is a constituent of purine nucleotides, an important source of intracellular energy. Phosphorylation of various metabolic intermediate products is also the means of intracellular energy transfer. In the form of phospholipids, P is also a major structural component of cell membranes.¹

Magnesium

Magnesium (Mg), primarily stored in mitochondria, is a vital co-factor for the function of enzymes involved in the transfer of phosphate groups; and thus, it is important for all reactions which require adenosine triphosphate (ATP) and in reactions involving replication, transcription, and translation of nucleic acids.¹ Extracellular Mg is important in plasma membrane excitability.

Homeostasis of calcium, phosphorus, and magnesium

Calcium

Absorption of Ca is generally well regulated by the body. With high Ca intake, absorption can be as low as 20%, while with low Ca intake, absorption can reach 70%.⁴ The mechanism for this regulation is shown in Figure 27.1. With high Ca intake, there is a transient hypercalcemia followed by a suppression

Fig. 27.1 Vitamin D and calcium metabolism.

of parathyroid hormone (PTH) secretion, and consequently a suppression of PTH-stimulated renal conversion of 25-hydroxyvitamin D, the chief circulating form of the vitamin, to calcitriol, or 1,25-dihydroxyvitamin D. With low Ca intake, the reverse occurs. There is a transient reduction in serum Ca concentration, followed by a rapid, within 5 minutes, rise in PTH secretion. PTH will under normal circumstances stimulate bone resorption and increase renal tubular Ca reabsorption in order to raise serum Ca concentration. Furthermore, it stimulates the renal enzyme 25-hydroxyvitamin D-1- α hydroxylase to convert 25-hydroxyvitamin D to calcitriol. Calcitriol then binds to intestinal epithelial cells and increases transcellular Ca absorption by altering cell membrane phospholipid and by facilitating the intracellular passage of the absorbed Ca by stimulating the cellular synthesis of *calcium binding proteins*. Thus, the efficiency of Ca absorption is improved.

Ca, given intravenously, bypasses the intestinal control mechanism and suppresses PTH production by the parathyroids as well as production of calcitriol by the kidney. The bone stores 99% of the body's Ca.¹

Phosphorus

In contrast to Ca, the intestine plays no significant regulatory role in P absorption. Approximately 80% of dietary phosphate is absorbed and the bone stores approximately 90% of the body's phosphate.

Homeostatic control appears to rest primarily within the kidney.^{5,6} The regulatory mechanisms are most likely PTH-independent.^{5,6} Thus, the renal excretory rate of phosphate

will primarily regulate the serum P concentration and maintain it within a normal range. Fibroblast growth factor (FGF)-23 evolves to be one key regulator of phosphate and vitamin D metabolism in humans.⁷ Studies demonstrated that mutations in the FGF-23 gene cause autosomal dominant hypophosphatemic rickets (ADHR), a phosphate wasting disorder. The exact molecular pathway of FGF-23 mediated actions is currently under intense investigations.⁷

Magnesium

Approximately 60% of the body's Mg is stored in the skeleton,⁹ although not at sites where matrix is calcified. Mg absorption, like P, varies directly with dietary intake, with about 40% of an average daily load being absorbed.¹⁰ The relationship between Ca and Mg absorption is described as inverse, but the mechanism of this is unclear. Renal excretion is the main route of Mg elimination and it may vary with serum Mg concentration.¹¹ Thus, hypermagnesemia and hypercalcemia inhibit renal tubular reabsorption of Mg while hypomagnesemia and PTH increase Mg reabsorption.¹¹

Effect of burn injury on calcium, phosphorus, and magnesium homeostasis

The effects of burn injury on mineral homeostasis have not been studied in great detail. Data from the studies at the University of Texas Medical Branch and the Shriners Burns Hospital in Galveston most completely describe some of the developments in this area.

A study of children burned >30% total body surface area demonstrated that serial measurements of blood ionized Ca were a mean of 5% below the lower limits of normal.¹¹ These levels were associated with serum levels of PTH that were too low for the ionized Ca concentration in the blood indicative that these patients were hypoparathyroid following acute burn injury. Furthermore, administration of a standard amount of PTH failed to produce the expected increases in urinary cyclic AMP and phosphate excretion,¹² providing evidence for PTH resistance in these patients. Mg depletion, encountered in all of the patients studied,^{12,13} is known to impair secretion of PTH in response to hypocalcemia and to result in resistance to PTH infusion. A recent study at our hospital indicates that aggressive parenteral Mg supplementation will replete approximately 50% of the burn victims admitted to our institution. However, Mg repletion failed to improve the hypoparathyroidism.¹³ Therefore, the cause of the postburn hypoparathyroidism remains unknown. Recent data obtained from animal studies show that there is an up-regulation of the parathyroid gland Ca-sensing receptor, which is associated in humans with decreased circulating Ca level necessary to suppress PTH secretion.¹⁴ This phenomenon is known as a *reduced set point* for Ca suppression of PTH secretion. The underlying mechanisms are shown in Figure 27.2.

In data collected from 11 adult patients in the burn unit between December 1989 and January 1992¹⁵ low serum concentrations of ionized Ca, P, and Mg were far more common than high serum levels of these minerals and is consistent with the abnormalities observed in their calcium homeostasis. Six patients had low serum concentrations of ionized Ca, three of them manifesting the hypocalcemia during the first 48 hours

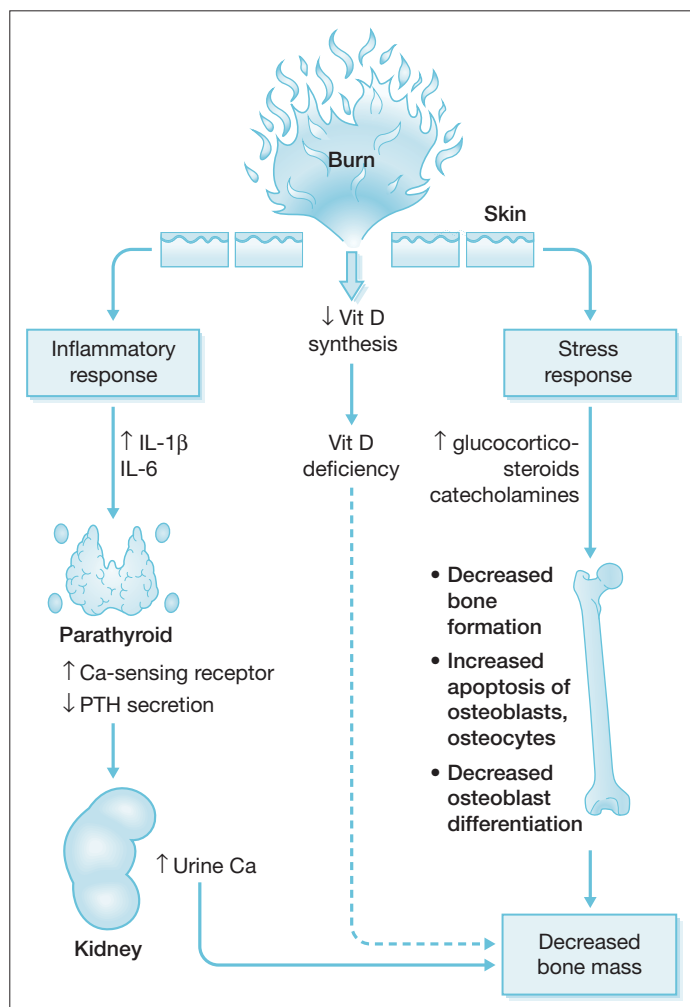

Fig. 27.2 Mechanisms of bone loss after severe burn.

postburn. Four of these patients were hypophosphatemic; this was most prevalent on day 7 postburn. Five of the patients were hypomagnesemic, with this finding most likely to be present on day 3 postburn. In contrast, only one patient demonstrated hypercalcemia and one hyperphosphatemia. No one was hypermagnesemic. In each case, the elevated serum level of either ionized Ca or P was transient. The studies in adults are not as yet as detailed as the studies in children have been in this regard.

Hypocalcemia cannot be diagnosed from determinations of total serum Ca concentration, due to the variability of serum albumin concentrations postburn. Determination of serum ionized Ca concentration should be encouraged, if available, for a more accurate diagnosis. Several possible mechanisms for hypocalcemia have been proposed. One is a shift of Ca from the extracellular to the intracellular compartment, as has been suggested by the accumulation of Ca in the erythrocyte of the burn patient,¹⁶ a manifestation of what is termed the 'sick cell' syndrome. Alternative hypotheses include increased urinary calcium excretion, which has been documented to occur in burned children,¹⁷ but is consistent with the documented hypoparathyroidism.¹² Losses of Ca in tissue exudate could also theoretically contribute to hypocalcemia. While it

has been argued that the amount of Ca in wound exudate is probably insufficient to entirely account for postburn hypocalcemia,¹⁸ there are not enough studies that actually measure Ca content of the burn wound exudate.

While fecal Ca losses can be high in burn patients¹⁸ and the large amount of endogenous corticosteroids produced by burn injury may impair intestinal Ca absorption,¹⁹ there is no evidence to suggest that hypocalcemia is caused by corticosteroid-induced impairment of intestinal reabsorption of Ca secreted into the intestinal lumen. Other proposed mechanisms include reduced bone turnover.^{15,20} The possibility of the reduced set point for calcium suppression of PTH secretion as a contributor to postburn hypocalcemia, while preliminary,¹⁴ is an attractive hypothesis.

Studies investigating the metabolism of 25-hydroxyvitamin D and 1,25-dihydroxyvitamin D in 24 children with massive burns demonstrated a low serum concentration of 25-hydroxyvitamin D at 14 months and up to 7 years after trauma, correlating with low bone mineral density (BMD) z-scores. In contrast, concentrations of 1,25-dihydroxyvitamin D were normal 2 years after burn but showed a decrease to lower levels at 7 years after burn. This process suggests that these patients are becoming progressively vitamin D deficient.²¹

Possible explanations for postburn hypophosphatemia include intracellular accumulation of phosphate, inadequate phosphate intake, excessive urinary phosphate excretion, not likely in view of the documented hypoparathyroidism, or phosphate loss into the extravascular fluid. In a review of the subject, Dolecek¹⁸ found increased urinary phosphate excretion only during the third and fourth weeks postburn in adults, while hypophosphatemia was documented to occur earlier. Thus, it is possible that the increased urinary phosphate excretion, seen later postburn, is more a function of increased tissue breakdown and filtered load than of inappropriate or excessive urinary phosphate losses. There is little documentation of inadequate phosphate intake following burns. Burn victims at our institution have been documented to take in a minimum of 1.6 g phosphate per day in enteral feedings alone.¹⁵ Loss of significant phosphate in the extravascular fluid, excessive secretion of phosphate into the intestine with failure to reabsorb, and intracellular accumulation are all theoretically possible explanations for hypophosphatemia, but remain unproven. Similarly, the cause of sustained hypomagnesemia occurring postburn is unknown, although excessive urinary and fecal losses have been reported in adults¹⁸ and excessive losses in the burn wound have also been described.²²

One potential explanation for acute hypomagnesemia is resuscitation with Ringer's lactate, which does not contain Mg.¹⁴

Rationale for therapy

Because of their importance in the maintenance of bodily metabolic processes, low serum levels of ionized Ca, P, and Mg should be treated (Figure 27.3). Hypocalcemia, especially in the immediate postburn period during the resuscitation effort, can potentiate abnormalities of cardiac muscle produced by hyperkalemia²³ and cause unresponsiveness to repletion in shock.²³ If a patient is not hypocalcemic, there is insufficient evidence of benefit following provision of

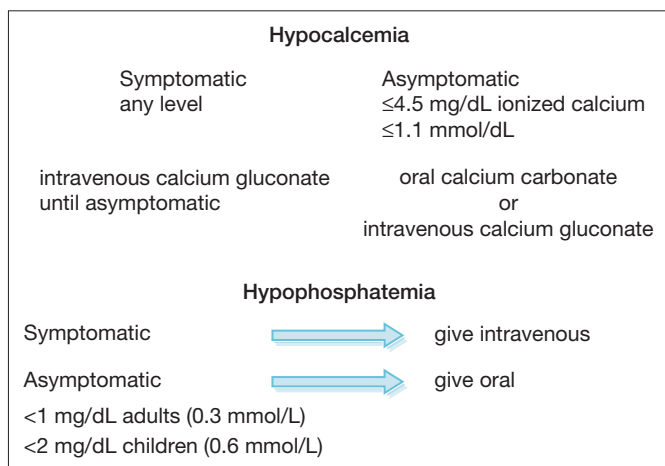

Fig. 27.3 Treatment algorithm for hypocalcemia and hypophosphatemia.

parenteral Ca during resuscitation^{24–26} unless the patient has hyperkalemia, hypomagnesemia, or Ca channel blocker toxicity.²⁷ Similarly, while caution should be exercised during massive transfusion with citrate-containing blood, Ca therapy may not be necessary if the patient is normocalcemic and if hepatic and renal function are only minimally impaired. The liver will clear citrate, which may transiently chelate Ca, at a rate of 1 unit of blood transfused every 5 minutes.²⁸ Only when clinical and electrocardiographic evidence suggests hypocalcemia should treatment be initiated. Ca infusions, when given, should be administered slowly, since rapid replacement of Ca has resulted in cardiac arrhythmias.^{23,28}

Hypophosphatemia may result in tissue hypoxemia due to increased hemoglobin affinity for oxygen and decreased tissue ATP, metabolic encephalopathy, hemolysis, shortened platelet survival time, myalgias, weakness, and possible impairment of myocardial contractility.²⁹ Hypomagnesemia, or Mg depletion with normal serum Mg, can blunt the effect of parathyroid hormone secreted in response to hypocalcemia on target organs and can impair the secretion of parathyroid hormone itself.³⁰ Mg deficiency can also cause generalized convulsions, muscle tremors, and weakness.³⁰

Treatment options to maintain mineral homeostasis

Acute symptomatic hypocalcemia should be treated with intravenous Ca. In adults, 90–180 mg of elemental Ca over 5–10 minutes is given so as to reverse twitching. In infants or children, Ca chloride in a 20 mg/kg dose or Ca gluconate in a 200–500 mg/kg/dose in four divided doses is suggested.^{30,31} Caution should attend the use of parenteral chloride since it may cause phlebitis and/or acidosis. While hypocalcemia is asymptomatic and patients can tolerate enteral feedings, milk and/or infant formula, can provide as much as 3 g/day of bioavailable Ca.¹⁵ If, as we and others have found, hypocalcemia can occur despite enteral provision of such a large quantity of Ca, intermittent parenteral administration of Ca salts will be necessary. While the amounts given to each patient must be determined individually, as an example of what may be needed,

six of our recent patients with burns exceeding 40% TBSA received 0.9 to 15 grams of 10% calcium gluconate per day over the first 5 weeks following burn injury. Treatment was given an average of twice daily on approximately 75% of the days during those 5 weeks.

Symptomatic hypophosphatemia requires parenteral treatment with a starting dose of 2 mg/kg infused over 6 hours and treatment continued until serum P concentrations exceed 1.0 mg/dL (0.3 mmol/L).²⁹ Infants and children with symptomatic hypophosphatemia should receive 5–10 mg/kg infused over 6 hours followed by 15–45 mg/kg given by infusion over 24 hours or until the serum P concentration rises above 2.0 mg/dL (0.6 mmol/L).³²

Our adult patients who tolerated enteral feedings and consumed an average of 1.6 g/day of phosphate should have consumed enough to treat asymptomatic hypophosphatemia.¹⁵ Hypophosphatemia has not been reported to be prolonged in burn patients; however, in such cases where this may occur, parenteral supplementation would be necessary.

Patients who have signs or symptoms of Mg deficiency with serum Mg concentration below 1.5 mEq/L (1.8 mg/dL or 0.8 mmol/L) usually require parenteral therapy.^{30–33} A treatment plan is displayed in Figure 27.3.

Bone

The main Ca storage depot in the body is bone. Both linear growth and bone remodeling are adversely affected by burn injury. Linear growth at the epiphysis of the long bones usually occurs by means of proliferation of cartilage cells with production of extracellular matrix; these chondrocytes and matrix undergo a series of biochemical changes which lead to the appearance of ossification centers, which appear as single expanding foci. As these ossifications expand, cartilaginous tissue is replaced by bone in a vascular supply system, which provides for the delivery of nutrients, hormones, and growth factors.

It has been reported by Rutan and Herndon³⁴ that linear growth velocity is retarded in children with severe burns. The mechanism for this effect of burn injury is unknown, but it has been established that the rate of growth does return to normal.³⁴ The effects of burn injury on bone remodeling are profound and long-lasting. In a study of 12 adult patients with burns of greater than 50% total body surface area, there was a marked reduction in bone formation.¹⁵ In children the findings are more dramatic. Iliac crest bone biopsies from 18 children burned over 40% of their total body surface area revealed even more markedly depressed bone formation²⁰ and a cross-sectional study of children undergoing biopsy a mean of 5 years after suffering a similar-sized burn injury revealed that fully 50% of them had persistent decreased bone formation.³⁵ To put these findings in perspective, it is necessary to discuss the normal process of bone remodeling.

Bone remodeling is a continuous process of breakdown of calcified bone matrix by osteoclasts and formation of new bone matrix by osteoblasts and the mineralization of that matrix by calcium and phosphate forming a mature crystal lattice of calcium phosphate hydroxyapatite. One remodeling cycle takes about 4 months in an adult. Bone resorption and formation are normally biochemically and, perhaps mechani-

cally, linked. All the details of this linkage are not known, but, as an example, parathyroid hormone receptors have been identified on osteoblasts but have so far not been identified on osteoclasts.³⁶ Thus, parathyroid hormone can increase the number of osteoblasts on bone surfaces in both humans³⁷ and animals.³⁸ Therefore, osteoblasts, which are bone-forming cells, must serve as an intermediary in the process of parathyroid hormone-mediated bone resorption. One way in which osteoblasts could act in this direction is to produce a ligand of the receptor activator of nuclear factor- κ B (NF- κ B), (RANK ligand or RANKL), to stimulate osteoclastogenesis in the bone marrow.³⁹

The reduced bone formation following burn injury was first identified on bone biopsies in adults between 9 weeks and 9 months postburn.¹⁵ By administering tetracycline to the patients in two doses separated by 2 weeks, we found that the newly-mineralized bone surface taking up tetracycline was markedly reduced in burned patients compared to age- and sex-matched controls¹⁵ In contrast, the distance between the two tetracycline fluorescent labels in the bone was not significantly reduced. The distance between the tetracycline bands represents the *mineral apposition rate*, and is an index of osteoblast function. The mineral apposition rate when multiplied by the percentage of bone surface taking up tetracycline is the *bone formation rate*,⁴⁰ and is an index of osteoblast number as well as function. Thus, in the adult burn patients, bone formation is reduced possibly due to a reduced number of osteoblasts rather than to reduced osteoblast function. Also consistent with these findings is the reduced amount of osteoid or unmineralized bone matrix, a product of osteoblasts (Figures 27.4 and 27.5). There appears to be a dissociation of bone formation and bone resorption. In children, there is no separation between tetracycline labels,²⁰ indicating that osteoblast function as well as osteoblast number may be impaired. Furthermore, in the children biochemical markers of both bone formation and bone resorption are reduced,²⁰ suggesting lower

Fig. 27.4 Goldner trichrome stain of an iliac crest bone biopsy of a healthy person. The blue-green area represents mineralized bone. The red area represents unmineralized osteoid. Spindle-shaped cells on the osteoid surface are osteoblasts.

bone turnover that is seen with chronic elevation of glucocorticoid production,⁴¹ which has been identified in these patients. Bone biopsies in adults are consistent with these findings.

The consequences of the reduced bone formation include chronically diminished bone mineral density of the lumbar spine.^{17,20} This results in an increased fracture risk¹⁷ and possible reduction in *peak bone mass*.¹⁷ A reduction in peak bone mass would put a burned child at risk to develop adult-onset osteoporosis (Figure 27.6). Cross-sectional studies of bone mineral density of the lumbar spine were performed using dual-energy X-ray absorptiometry (DEXA) in 68 children:¹⁷ 16 were burned between 15 and 36% of total body surface area, 22 were burned over 40% of total body surface area and studied within 8 weeks of their burn, and 30, also with burns over 40% of total body surface area, were studied a mean of 5 years following burn injury. The bone density z-scores (standard deviation scores) were less than -1 in 60% of the severely burned patients and less than -2 in 27% of the same group with no difference between those studied within 8 weeks and

Fig. 27.5 Goldner trichrome stain of an iliac crest bone biopsy of a burned patient. The blue-green area represents mineralized bone. Compared to the previous figure, note that osteoblasts are absent on the osteoid surface.

Fig. 27.6 X-ray as an example of burn-induced osteoporosis 1 year after trauma.

Fig. 27.7 Distribution of lumbar spine bone mineral density (BMD) z-scores of severely burned children compared to a standard distribution curve. Note that the distribution after burn is shifted to the negative side.

those studied a mean of 5 years following burn injury (Figure 27.7). Z-scores were not as low for those receiving moderate burns. These data suggest that the bone density in the severely burned children compared to age-related normal children is decreased¹⁷ and that there is no significant improvement of bone density over time. Longitudinal studies are currently in progress in order to better define the issues causing the prolonged reduction in bone density.

There are several potential contributing factors to this pathology, including the production of pro-inflammatory cytokines, especially interleukins-1 β and -6²⁰ immobilization, which induces bone resorption and decreases formation.⁴² However, while bone resorption maybe transiently stimulated by cytokines and elevated glucocorticoids, which stimulate RANKL production by the osteoblasts, the extent of apoptosis of osteoblasts and the lack of differentiation in the bone marrow, eventually eliminate the production of RANKL and lead to chronic low turn-over disease.⁴¹ Another possible contributing factor is aluminum loading, which can cause reduced bone formation in uremic patients⁴³ and in those receiving total parenteral nutrition.^{44–50}

Treatment options for bone catabolism after severe burn

Studies have been conducted to address bone mass wasting after a massive thermal injury. Attempts to use high-dose recombinant human growth hormone (rhGH), 0.2 mg/kg/day subcutaneously during the course of hospitalization for the acute burn injury led to a rise in circulating levels of insulin-like growth factor 1 (IGF-1). However, serum levels of osteocalcin, a vitamin D- and vitamin K-dependent peptide produced by osteoblasts and which serves as an index of bone formation remained low following a 6-week period of treatment. The failure of rhGH to improve bone formation despite producing a rise in circulating IGF-1 may be attributable to GH-independent high circulating levels of IGF-binding protein-4 (IGFBP-

4), a binding protein that can block access of IGF-1 to local tissue receptors. Similarly, circulating levels of IGFBP-5, a binding protein that can help bind IGF-1 to hydroxyapatite matrix of bone, is initially low following a burn, rising to normal by time of hospital discharge.⁵¹

In contrast, the use of rhGH at a dose of 0.05 mg/kg/day subcutaneously from hospital discharge to 12 months in children after burn resulted in a significant improvement in linear height as well as bone mineral content when compared to placebo treatment. These beneficial observations continued in the second year after burn while the drug was discontinued. No adverse side effects such as rebound phenomena on growth and bone formation once rhGH was stopped were noted. This treatment with rhGH over an extended period during the rehabilitation phase after burn caused a significant increase in serum concentrations of anabolic acting hormones such as growth hormone, IGF-1, and IGFBP-3, while IGFBP-4 remains elevated, suggesting that this protein was not the cause of failure to increase osteocalcin induction as previously thought.⁵² In contrast, serum concentrations of cortisol were significantly decreased in patients who received rhGH. The capacity of anabolic agents to reverse posttraumatic bone catabolism is supported by a study performed in children with a TBSA $\geq 40\%$ receiving oxandrolone, an anabolic steroid, from discharge to 12 months after burn.^{53,54} In this study oxandrolone was given at a dose of 0.1 mg/kg/bid daily and treated patients showed significant improvements in growth percentiles as well as in bone mineral content when compared to patients treated with placebo.⁵⁴ In each case, the increase in bone mineral content was preceded 6 months by a rise in lean body mass, reflective of muscle mass. It is possible that the effects of anabolic agents on bone are indirectly resulting from increased skeletal loading following an increase in skeletal muscle mass.^{52,54} In addition to anabolic agents, therapies used successfully in the treatment of menopause-associated osteoporosis are also shown to be beneficial in burn-induced bone catabolism. In a randomized, double-blind, placebo-controlled clinical trial, severely burned children with a TBSA $\geq 40\%$ received pamidronate at a dose of 1.5 mg/kg intravenously within 10 days of the burn and again 1 week later. At hospital discharge, lumbar spine bone mineral content was significantly improved in patients who received the bisphosphonate pamidronate. While this significant difference continued, total bone mineral content was additionally significantly improved at 6 months after burn. Bone histomorphometry and urine concentrations of Ca and free deoxypyridinoline were not affected by pamidronate. The treatment did not reveal any negative side effects such as hypocalcemia.⁵⁵

In comparison to the past, we now have therapies available to attenuate bone loss after severe burn. Independent from the time phase after burn, these treatment options can be used during the acute hospitalization such as pamidronate or during the rehabilitation in the months after burn such as rhGH and oxandrolone. Future directions include the investigation of additional agents such as vitamin D supplementation on the acquisition of bone mass as it has been shown that serum levels of 25-hydroxyvitamin D correlate with bone density²¹ and that the skin of burned patients is not able to convert 7-dehydrocholesterol to adequate circulating levels of active vitamin D, suggesting an absolute need to supplement this vitamin.⁵⁶

Importance of vitamins and trace elements	387
Homeostasis of trace elements and vitamins and role in burns	387
Effect of therapy on wound healing, fluid requirements, and the immune response	388

Importance of vitamins and trace elements

Trace elements and vitamins are a key part in nearly every cell mechanism of the human body. However, there remains very little understood about the effects of burn injury on trace element and vitamin metabolism and post-burn requirements. The limited research that has been done has concentrated on homeostasis of trace elements and vitamins after burn injury, wound healing in relation to trace elements, vitamins, and the antioxidant properties of various of the trace elements and vitamins. We will examine each of these aspects in the context of available data.

Homeostasis of trace elements and vitamins and role in burns

There are limited data regarding trace element loss following burn injury. The major trace elements studied are zinc and copper, although a limited amount of work has also been done on selenium status post-burn.

Several groups have reported low serum concentrations of zinc and copper, as well as albumin and ceruloplasmin, their respective associated binding proteins.¹⁻⁶ Urine and skin are considered major routes of loss of these elements.^{3,5,7} Thus, Cunningham et al.⁵ and Boosalis et al.⁸ found that patients with moderate to severe burns had excessive urinary zinc excretion associated with reduced plasma zinc levels, especially the plasma subfraction bound to albumin.⁵ Zinc supplementation by means of total parenteral nutrition resulted in hyperzincuria, although not as pronounced as if zinc supplementation were given orally.^{5,8} In contrast, increased urinary copper excretion was not found despite parenteral delivery of supplemental copper, although both plasma copper and ceruloplasmin were reduced. Only a few studies documented an increase in urinary copper excretion.^{1,9} Voruganti et al.⁹ found elevated urinary copper and zinc excretion in severely burned children at admission as well as at hospital discharge. The

pediatric burn patients in this study received up to three times the suggested oral intake of zinc and copper compared to the dietary reference intakes. Thus it would appear as if while there is a consensus that plasma copper and zinc concentrations fall post-burn, the observation of urinary losses of micronutrients such as zinc and copper vary and the functional impact remains unexplained.

With regard to cutaneous losses of zinc, Berger et al.⁷ found that the losses through wound exudate greatly exceeded excretory losses over the first week post-burn. Guo et al.¹ also detected elevated quantities of zinc in wound exudate. These observations have been confirmed additionally in children. Wound zinc and copper concentrations exceeded plasma concentrations in six children with a mean total body surface area (TBSA) of 54%.⁹ The other explanation offered for the uniformly reported fall in plasma zinc levels post-burn is the redistribution of zinc within the body. In a study in which rats given ⁶⁵Zn received a 20% TBSA burn, van Rij et al.¹⁰ reported that there was a rapid uptake of ⁶⁵Zn by spleen, kidney, wound, and, particularly, liver, while there was a decrease in ⁶⁵Zn in brain, muscle, and, particularly, bone. Zinc-binding protein was demonstrated in the liver cytosol, suggesting that there is a flow of zinc to the liver at the expense of plasma, bone and, even wound, after burn injury. Agay et al.¹¹ reported a redistribution of zinc and copper to the liver without significant changes in the muscle and brain. This study analyzed additionally related antioxidant enzymes such as the superoxide dismutase and found a decrease of activity mainly in the plasma after burn. It was also found by Cunningham et al.⁵ that zinc supplementation exacerbates the urinary zinc excretion, suggesting that the body cannot take up the supplemental zinc and perhaps suggesting that rather than zinc depletion, zinc redistribution is largely responsible for the low plasma levels. Consistent with this, zinc is also involved in the inflammatory response and could be redistributed to sites of barrier disruption such as skin to be lost subsequently in the wound exudate.

With regard to copper, it is clear that reduced plasma copper concentrations are associated with reduced circulating levels of ceruloplasmin.^{2,6} Even though ceruloplasmin is an acute phase reactant stimulated by pro-inflammatory cytokines such as interleukin-1,¹² which is known to be elevated in the post-burn inflammatory state,^{13,14} there is also evidence that ceruloplasmin, in addition to copper, can be lost in the burn wound exudate as Cunningham et al.² reported a strong relationship between the size of the open wound and the amount of circulating ceruloplasmin. Gosling et al.⁴ reported that copper

concentration in severe burns varied inversely with burn surface area, in contrast to circulating zinc levels, which showed no such correlation. Furthermore, ceruloplasmin, like albumin, may be extravasated from the intravascular compartment and carry the copper with it.

Loss of zinc and copper following burn injury are of potential significance due to the important roles of each as antioxidants, especially as components of the enzyme superoxide dismutase, and the additional roles of zinc in wound healing, collagen cross-linking, which may affect skeletal calcification¹³ and immune function.¹⁵ Clearly, further studies will be required to elucidate the mechanism of hypocupremia and hypozincemia. Despite the supplementation of zinc and copper in patients after burn, the plasma concentrations remain low, probably requiring a higher intake. In a preliminary study, Voruganti et al.⁹ supplemented pediatric patients with 40% TBSA burn with 22.5 mg zinc per day according to the reference intake given by Pochon,¹⁶ who recommended 10–30 mg of zinc sulfate per day in children with >20% burn surface area. However, this quantity failed to raise plasma zinc levels. Based on this observation, we would recommend at least an intake of 30 mg zinc sulfate per day in these children. Additionally, in the study reported by Voruganti et al.,⁹ the copper intake was 2–3 times higher than the dietary reference intake, which is 3 mg per day for 4–8 years old children and 5 mg per day for 9–13 years old children, without attaining normal plasma concentrations. In parallel with the zinc intake, the intake of copper should be further increased. Appropriate criteria have yet to be determined on which to base adequacy of copper and zinc supplementation.

Another trace element which acts as an antioxidant is selenium. In 1984, Hunt et al.¹⁷ reported that plasma and erythrocyte selenium concentrations were reduced following burn injury, as was urinary selenium excretion. Boosalis et al.¹⁸ confirmed these findings in 1986 and suggested that urinary selenium loss was not the chief explanation for the post-burn selenium deficiency. They postulated that there may be an antagonistic relationship between selenium and the silver that is administered to the burn wounds. A possible redistribution between different organ compartments after burn may be another explanation for the observed changes in selenium levels as reported by Agay et al. in burned rats.¹¹

A trace element that is reported to be elevated following burn injury is aluminum. Klein et al.¹⁹ reported elevated serum aluminum concentration in adults suffering severe burn injury (>40% TBSA), even finding some aluminum deposition in the bones of burn patients as few as 8 days post-burn.²⁰ While aluminum is toxic to bone and is a known inhibitor of bone formation,²⁰ it is clearly not the only contributor to post-burn osteopenia and increased fracture risk. Nonetheless, the sources of aluminum contamination in burn treatment have been published²¹ and attempts to minimize aluminum loading in these patients may hasten their skeletal recovery from burn injury.

Studies of the homeostasis of vitamins following burn injury are sparse. Rettmer et al.²² performed functional testing for thiamin, riboflavin, and pyridoxine in burn patients and found them all to be normal. However, many adult burn victims are alcoholic and will require the standard thiamine supplementation of 50 mg/day. In a study of serum vitamin K levels in

severely burned pediatric patients, Jenkins et al.²³ reported that 91% of the 48 children studied demonstrated circulating vitamin K levels below expected norms. These low levels were correlated with days of antibiotic therapy, percentage body surface area excised, and administration of blood products. However, there was no relationship between serum vitamin K concentration and prothrombin time. Therefore, it is not certain if the low circulating levels of vitamin K are clinically significant. It should be pointed out, however, that osteocalcin, a protein produced by osteoblasts, is a vitamin K-dependent gamma carboxylated protein that is used as a standard index of new bone formation. Osteocalcin is documented to be low in burned children during the same time period covered by the study of Jenkins et al.,²³ i.e. the first 4 weeks post-burn. Thus, the possibility remains open that low circulating vitamin K levels may contribute to low osteocalcin in the serum, although bone formation has been documented to be low by other studies as well (see Chapter 27).

Serum levels of other vitamins have also been measured within 2–3 weeks post-burn. These were vitamin A (retinol), vitamin E (alpha tocopherol), and vitamin C (ascorbic acid). Nguyen et al.²⁴ reported low serum vitamin E levels during the first 14 days post-burn as part of a study examining peroxidation products following thermal injury. Similar findings were noted by Rock et al.²⁵ not only for vitamin E but also for vitamins A and C. However, serum levels of all these vitamins improved with enteral supplementation.

Circulating levels of vitamin D have been low but so has vitamin D-binding protein.^{20,26} Serum calcitriol (1,25(OH)₂-vitamin D) levels have been slightly low, but calcitriol, the metabolically active form of vitamin D, is bound to albumin in serum. Therefore, in light of the post-burn hypoproteinemia it is difficult to assess the short-term significance of the marginally low levels of circulating vitamin D. However, preliminary data suggest that burn patients do develop vitamin D deficiency after they are discharged from the hospital due to the recommendation that they minimize their exposure to sunlight.²⁷ However, it is now reported that skin from burn scars and adjacent areas cannot synthesize normal amounts of vitamin D following exposure to ultraviolet light.²⁷ Thus, vitamin D supplementation is mandatory although the amount required is still under study. A more detailed description of the metabolism of vitamin D is given in Chapter 27.

Effect of therapy on wound healing, fluid requirements, and the immune response

Despite the well-known role that zinc plays in wound healing, relatively little is known of the effects of zinc depletion post-burn on healing of the burn wound. A recent *in vivo* study in rats by Li et al.²⁸ indicated that dietary zinc supplementation by itself may not be sufficient to improve wound healing. However, zinc applied directly to the experimental wound may accelerate healing. This subject is very difficult to evaluate, however, because of the evolving nature of wound management, including artificial skin, antibiotic therapy, and surgical intervention. There has also been a report suggesting that nicotinamide may increase capillary density and rapidity of wound healing in rats.²⁹

With regard to other potentially beneficial effects of supplementation with trace elements of vitamins, there are conflicting studies regarding whether administration of ascorbic acid alters the volume of fluid required for initial burn resuscitation.^{30–32} In a study from Japan by Tanaka et al.,³⁰ infusion of ascorbic acid during the initial 24 hours post-burn in adults burned over 30% TBSA lessened the amount of fluid required to maintain heart rate and blood pressure and cut by 50% the amount of body weight gain. This is consistent with an earlier report by Nelson et al.,³¹ who found that guinea pigs given large quantities of dietary ascorbic acid following burn injury had improved weight gain and reduced metabolic rates compared to controls. In contrast, a study involving infusion of ascorbic acid into dogs given graded scald burns of the paw failed to reduce paw weight gain.³² However, this study was limited to a local burn injury involving the paw and did not take into account other systemic factors that might affect body fluid accumulation after a more extensive burn. In addition, a report by Chen et al.³³ showed that pre-treatment of rats and mice with 1,25-dihydroxyvitamin D (calcitriol) lessens fat pad edema and pulmonary vascular permeability. However, this has limited practical value in that data are not available for human post-burn treatment with calcitriol.

Contradictory reports have also been published with regard to the effects of vitamin E on the immune response. Kuroiwa

et al.³⁴ failed to demonstrate a difference in lymphocyte response to phytohemagglutinin or in ear thickness response to 2,4-dinitrofluorobenzene in guinea pigs following a 30% burn and vitamin E supplements ranging from 0 to 100 mg/kg/day, although those receiving vitamin E supplements were less anemic than those that did not. In contrast, Haberal et al.³⁵ showed in patients with a >20% partial- or full-thickness burn injury, vitamin E supplementation for 3 days resulted in an increased number of circulating T cells compared to normal and in contrast to burn patients who did not receive vitamin E. In agreement with Kuroiwa et al.,³³ Berger et al.,³⁶ studying severely burned adults, reported that supplementation of these patients 30 days post-burn with zinc, copper, and selenium for 8 days failed to alter lymphocyte proliferation to mitogens but the number of pulmonary infections in the supplemented group decreased, resulting in a shorter hospital stay when data were normalized for burn size.

In summary, there is much to learn regarding the homeostasis of trace elements and vitamins in response to burn injury and how changes in the status of these micronutrients affect wound healing, fluid resuscitation requirements, the immune response, and skeletal recovery. This area remains wide open to advances in research that could potentially hasten recovery and improve the quality of life for victims of severe burn injury.

Hypophosphatemia

David W. Mazingo and Arthur D. Mason Jr.

Chapter contents

Etiology of postburn hypophosphatemia	391
Stress response	391
Resuscitation and topical therapy	392
Ulcer prophylaxis	392
Hyperventilation	392
Metabolic support	393
Burn wound physiology	393
Acute phase response and sepsis	393
Other electrolytes	393
Consequences of hypophosphatemia	394
Prevention and treatment of hypophosphatemia	395

Certain humoral and metabolic responses to thermal and mechanical trauma that maintain homeostasis and prevent cellular dysfunction also produce alterations in electrolyte balance. An example is renal retention of sodium during the resuscitative phase of burn injury, which alters sodium balance in the course of preserving intravascular volume. Despite the markedly increased cardiac output and renal plasma flow that occur in the subsequent flow phase, a decrease in blood volume persists and results in sustained elevation of plasma renin activity, secretion of antidiuretic hormone, and sodium retention.¹ Conversely, the severe hypophosphatemia that often follows major injury occurs concomitantly with a 50–100% increase in resting energy expenditure, leading to a possible deficiency in the high-energy phosphate compounds essential for cellular metabolism. Thermal injury induces a precipitous decrease in serum phosphate concentration that reaches its nadir between the second and fifth postburn days. This phenomenon has been recognized for quite some time² and was recently confirmed by the authors in a large series of burn patients.³ Despite aggressive phosphorus supplementation, normal levels of serum phosphorus are rarely reached prior to the tenth postburn day (Figure 29.1). Of 550 patients studied, 175 had serum phosphorus concentrations below 2.0 mg/dL, and of these 49 were below 1.0 mg/dL, with the lower limit of normal serum phosphorus being 3.0 mg/dL. Such hypophosphatemia is not exclusive to thermal injury, having been described following multiple trauma,⁴ head injury,⁵ and elective surgery.⁶ The exact mechanism by which thermal injury or severe stress induces hypophosphatemia is unknown. Several events associated with burn injury, however, affect

phosphorus metabolism, and these may combine to produce hypophosphatemia.

Etiology of postburn hypophosphatemia

Many of the pathophysiological changes and therapeutic interventions that occur during the first postburn week influence serum phosphorus concentration (Box 29.1). Hypophosphatemia does not necessarily imply phosphorus depletion; in the case of burn injury, most patients are healthy prior to injury and presumably have normal phosphorus stores. Nor do simple calculations of phosphate balance explain the dramatic decrease in serum levels; simultaneous reduction of urinary phosphate excretion is observed, suggesting an extrarenal mechanism. The fractional excretion of phosphate, however, increases during the early period of diuresis following burn injury (postburn days 2–4), potentially contributing to the decline in serum levels. The pathophysiological events and therapeutic interventions discussed below are associated with hypophosphatemia in other disease states and in certain experimental animal models, but the extent of their contributions to the postburn decrease in serum phosphorus has not been critically evaluated and is, at present, undefined.

Stress response

In the early postburn period, the classic ‘fight or flight’ response occurs, with elevation of plasma catecholamines, glucose, glucagon, and cortisol. Exogenous epinephrine administration has been associated with the development of hypophosphatemia, and the profound catecholamine release accompanying thermal injury may contribute to the early decrease in serum phosphorus. The mechanism by which this occurs is uncertain but may be a consequence of the accompanying hyperglycemia, resulting in a redistribution of phosphorus from the extracellular to the intracellular compartment (see section on Metabolic support). In acute clinical states of glucagon excess, tubular reabsorption of phosphate is impaired in both the proximal and distal nephron, leading one to expect renal phosphate wastage.⁷ Since urinary excretion of phosphate is usually decreased in the early post-injury period, the importance of hyperglucagonemia remains uncertain. Administration of pharmacological doses of glucocorticoids enhances phosphorus excretion and impairs phosphate absorption by the gut and reabsorption by the kidney. Whether or not the adrenocortical response significantly contributes to the hypophosphatemia after burn injury is not known.

Fig. 29.1 Serum phosphorus levels abruptly decline with a nadir between postburn days 2 and 5. The data were obtained from 550 consecutive burn patients admitted to the US Army Institute of Surgical Research.

PHOSPHATE-BINDING ANTACIDS/SUCRALFATE

ACID-BASE DISTURBANCE

ELECTROLYTE IMBALANCE

- hypokalemia
- hypomagnesemia
- hypocalcemia

CARBONIC ANHYDRASE INHIBITION (MAFENIDE ACETATE)

Resuscitation and topical therapy

Administration of large doses of sodium lactate for initial burn resuscitation may decrease the serum phosphorus concentration by several mechanisms.⁸ Lactate is converted to glucose in the liver, a process requiring high-energy phosphate availability. Additionally, though it does not usually occur clinically, metabolic alkalosis induced by lactate infusion may result in depression of serum phosphorus concentration. Alkalosis is associated with an increase in glycolysis that promotes transfer of phosphorus to the intracellular space. During resuscitation, alkalemia is uncommon and patients are more likely to manifest a mild metabolic acidosis, which is compensated by hyperventilation, resulting in a normal or mildly alkaline

blood pH. Acidosis markedly inhibits renal phosphate reabsorption, resulting in phosphaturia. The contribution of this mechanism to postburn hypophosphatemia is probably minor; early renal phosphate wastage is not observed, perhaps being obscured by diminished glomerular filtration early in burn injury. In addition, the *p*-carboxy metabolite of mafenide acetate strongly inhibits carbonic anhydrase. Such inhibition diminishes proximal tubular reabsorption of phosphate and probably occurs following topical burn wound treatment with mafenide, but the magnitude of the effect is unknown.

Expansion of the extracellular fluid volume is also associated with inhibition of proximal tubular phosphate reabsorption. A tight coupling exists between sodium and phosphate transport across the renal epithelial cell. In patients with burns, mobilization and excretion of the large edema volume usually begins by the second postburn day and continues throughout the next week to 10 days. In contrast to the relative paucity of phosphate excretion during the first 24 hours after injury, when glomerular filtration is markedly reduced, a modest loss of phosphate may occur with diuresis of the edema fluid. In fact, the diuretic phase is associated with an increase in the fractional excretion of phosphate despite a concomitant reduction in the serum phosphate concentration.⁹ Phosphorus excretion during the natriuretic phase of early burn injury is consistent with the tight coupling observed in other diuretic states.

Ulcer prophylaxis

Effective prophylaxis against Curling's ulcers with H₂-antagonists and antacid buffering has been a mainstay of burn care for the past two decades. Significant degrees of hypophosphatemia and phosphate depletion occur during continuous or chronic administration of phosphate-binding agents containing magnesium, calcium, and aluminum. These agents bind not only dietary phosphate but also phosphate secreted into the intestinal lumen, often resulting in a net negative phosphate balance. The severity of such hypophosphatemia clearly depends on the dose of phosphate-binding agents, dietary phosphorus intake, and pre-existing phosphate balance. To reduce alimentary scavenging of dietary and secreted phosphate, buffering with antacids containing aluminum phosphate salts (Al₂PO₄), which do not bind any additional phosphate, may be utilized. Sucralfate, which is also effective in preventing upper gastrointestinal stress ulceration following thermal injury, is not a buffering agent, but as a complex salt of aluminum hydroxide, is capable of binding phosphate. Its administration has also been associated with the development of hypophosphatemia in critically ill patients.¹⁰

Hyperventilation

Respiratory alkalosis is often present during the first week postburn and may be enhanced by anxiety or pain, and even by the inhibition of carbonic anhydrase induced by mafenide acetate burn cream. As fluid resuscitation progresses, respiratory rate and tidal volume progressively increase, resulting in minute ventilation that may be twice normal. Mild hyperventilation induces only a slight decline of serum phosphorus levels; prolonged, intense hyperventilation, however, may

result in serum phosphorus values less than 1.0mg/dL.¹¹ During respiratory alkalosis, phosphorus virtually disappears from the urine, eliminating renal losses as the causative mechanism. Respiratory alkalosis induces a rapid movement of carbon dioxide from the intracellular to the extracellular space. Intracellular pH increases, activating glycolysis and increasing the formation of intracellular phosphorylated carbohydrate compounds. The readily diffusible inorganic phosphate pool supplies the required phosphorus, and serum phosphorus concentrations consequently fall abruptly. The extent to which this mechanism contributes to postburn hypophosphatemia is uncertain.

Metabolic support

Administration of carbohydrates may play a major role in the development of postburn hypophosphatemia. Infusion of glucose solutions or oral intake of carbohydrates produces mild hypophosphatemia in healthy individuals. This decrease in serum phosphate is associated with an increase of inorganic phosphate, ATP, and glucose 6-phosphate in muscle cells. The mechanism by which such carbohydrate administration induces hypophosphatemia is somewhat speculative. Experience with phosphate-deficient total parenteral nutrition and subsequent development of hypophosphatemia has provided some insight into the etiology.^{12,13} As carbohydrates are absorbed, insulin secretion increases, shifting phosphorus from the extracellular to the intracellular space. If phosphate reserve is low, ATP is poorly regenerated since hypophosphatemia inhibits glucose 3-phosphate dehydrogenase. Inorganic phosphates in the intracellular pool become further diminished because of incorporation, initially as newly synthesized ATP, but eventually as triose phosphates when the ATP is consumed in the hexokinase reaction. Glucose utilization by red blood cells requires ATP at the hexokinase and phosphofructokinase steps, but regeneration of ATP does not occur during phosphate deficiency or acute hypophosphatemia due to a block at the glucose 3-phosphate dehydrogenase step. In states of phosphate depletion, the scant phosphate that enters the red blood cell is incorporated into 1,3-diphosphoglycerate, but most is diverted to 2,3-diphosphoglycerate, also preventing complete glycolysis to regain the ATP consumed.

In thermally injured patients, infusion of dextrose-containing solutions usually begins 24 hours postburn, and enteral nutrition, in which most of the calories are supplied as carbohydrates, is initiated within several days of injury. These interventions are temporally correlated with the rapid descent of serum phosphorus concentrations. In other clinical states, severe hypophosphatemia following the initiation of enteral or parenteral nutrition is most commonly associated with the feeding of patients with advanced protein-calorie malnutrition. When total body phosphorus is depleted by starvation, serum phosphorus levels usually remain normal, but carbohydrate administration produces a rapid marked decline in serum phosphorus concentration. If untreated, this may result in multi-system organ dysfunction, respiratory and cardiac failure, or death. Thermally injured patients are usually well nourished prior to burn injury and the clinical scenario of refeeding hypophosphatemia may not apply to them. Similar findings, however, have been described recently in previously well-

nourished surgical intensive care unit patients in whom the initiation of isotonic enteral feedings resulted in a decrease of serum phosphorus from normal levels to approximately 1mg/dL, a level that is considered to be dangerously low and to require prompt supplementation.^{14,15} In addition, the authors have reported that hypophosphatemia in thermally injured patients is exacerbated by the initiation of enteral feeding and occurs regardless of the postburn day when feeding is initiated.³ This further reduction of serum phosphorus during the first postburn week, when levels are already low, may be particularly hazardous and speaks for aggressive phosphorus supplementation prior to and during the initiation of enteral alimentation.

Burn wound physiology

In patients recovering from thermal injury, the burn wound itself may act as a significant phosphorus sink. Despite the overall catabolism accompanying major injury and loss of lean body mass, healing burn wounds and skin grafts are anabolic and require phosphorus for normal repair. In addition, the continued loss of fluid and protein through the burn wound surface is a potential source of unquantified phosphorus loss and may contribute to hypophosphatemia.¹⁶ In a comparison between burn patients and traumatically injured patients, it was shown that urinary phosphorus clearance, fractional excretion of phosphorus and renal threshold phosphate concentrations were not different between the two groups; however, persistent hypophosphatemia persisted in the thermally injured patients. This may further implicate the wound as a source of early phosphorus loss.¹⁷

Acute phase response and sepsis

Burn injury is characterized by an abrupt increase in acute phase proteins as patients enter the hypermetabolic phase of burn injury. These same responses are similar to those observed in the sepsis syndrome. Recently, the development of hypophosphatemia has been characterized in patients with the acute phase response syndrome.¹⁷ Similar findings have been documented in patients with sepsis and infection, and correlation to increase in levels of cytokines such as tumor necrosis factor alpha and interleukin-6 has been made.¹⁸ Similar findings were observed in patients with a variety of infectious diseases, and correlation of high levels of C-reactive protein and white blood cell count was made with the magnitude of hypophosphatemia.¹⁹ Though these reports did not include burn injured patients, one may infer that activation of the inflammatory cascades such as occurs in major thermal injury may contribute to the development of hypophosphatemia.

Other electrolytes

Disorders of electrolyte balance may contribute to the development of hypophosphatemia. Experimental magnesium deficiency in animals may lead to phosphaturia and phosphorus deficiency, but intentional magnesium deficiency in man results in no change or a slight rise in serum phosphate.^{20,21} In chronic alcoholics, however, hypomagnesemia and hypophosphatemia are coexistent. Hypokalemia, which is also exacerbated by

magnesium deficiency, may result in phosphate wasting and hypophosphatemia. The mechanism is uncertain, but may be related to coexistent metabolic alkalosis, diuretic use, or the underlying illness. Changes in calcium and phosphate homeostasis, and in the regulating hormones calcitonin and parathyroid hormone, have been described after thermal injury.²² Coincident with the early depression of serum phosphorus, the fraction of ionized calcium was shown to decrease and remain low, but within the normal range, for the 14 postburn days studied. Urinary calcium output was low, about 4.5 mmol/day, and urinary phosphate output was as high as 30 mmol/day, despite a low serum phosphorus. Serum calcitonin levels were significantly elevated for up to 2 weeks post-injury, whereas parathyroid hormone remained within the normal range. The magnitude of the contribution of the classic regulating hormones of calcium and phosphorus homeostasis to the observed decrease in serum phosphorus after severe injury is not known with certainty. Catecholamines and glucagon are known to induce an increase in calcitonin secretion, and the administration of pharmacological doses of calcitonin results in phosphaturia. A direct effect of calcitonin on phosphate transport in the nephron has been demonstrated. In those burn patients, it was notable that ionized calcium decreased slightly though still within the normal range, despite very high levels of calcitonin and normal parathyroid hormone concentrations. A slight, though statistically significant, increase in parathyroid hormone was observed around the fourth postburn day and may be related, albeit indirectly through calcium regulation, to the observed postburn decrease in serum phosphorus concentration.

Summary

Clearly, multiple factors influence the serum phosphorus level following burn injury. Fluid resuscitation and subsequent mobilization of interstitial edema fluids, catecholamine excess, respiratory alkalosis, the use of phosphate-binding antacids or sucralfate, hypokalemia, hypomagnesemia, and the initiation of enteral nutrition have all been associated with hypophosphatemia in other illnesses and experimental models. All or most of these factors may be encountered in the early treatment of burn patients and the contribution and relative importance of individual factors to the depression of serum phosphorus is difficult to analyze. Most likely, carbohydrate administration, respiratory alkalosis, and diuresis of edema fluid are the more important etiologic factors contributing to hypophosphatemia in the early postburn course.

Consequences of hypophosphatemia

The clinical manifestations of hypophosphatemia (Box 29.2) are mainly those of organ system hypofunction. These responses have been defined through clinical observation and laboratory studies in circumstances in which hypophosphatemia occurred as a relatively isolated event. Phosphorus supplementation has been reported to reverse these abnormalities, suggesting a cause and effect relationship. Hypofunction of organ systems associated with phosphorus depletion has been attributed to a lack of available inorganic phosphate for synthesis of high-energy phosphorus compounds; breakdown of stored ATP occurs, and the inorganic phosphate is diverted to

Box 29.2 Clinical manifestations of hypophosphatemia

CNS

- lethargy, malaise, neuropathy, seizures, coma

CARDIOVASCULAR

- impaired cardiovascular contractility
- decreased response to pressor agents
- hypotension
- acute cardiac decompensation

PULMONARY

- tachypnea
- decreased vital capacity
- respiratory failure

GASTROINTESTINAL

- anorexia, dysphagia

RENAL

- glycosuria, calciuria, magnesuria, renal tubular acidosis

MUSCULOSKELETAL

- weakness, myalgia, arthralgia, rhabdomyolysis

other intracellular pathways. Organ system dysfunction after thermal injury is characterized by early hypofunction and later hyperfunction of most organ systems. Whether hypophosphatemia contributes significantly to the early postburn depression of function that occurs in multiple organs is not known. Clearly, some of the clinical manifestations shown in Box 29.2 are commonly observed in thermally injured patients, while others are not usually associated with such injury. Most patients reported to have had complications of hypophosphatemia have also had a coexistent and severe illness. It is important to remember that prior cellular injury has been prerequisite in most instances in which hypophosphatemia has been implicated as a cause of organ system dysfunction. The following discussions of organ system abnormalities should be interpreted in light of the specific circumstances under which the observations were made.

Cardiac dysfunction

Although the early depression of cardiac function following burn injury has been attributed to an initial decrease in circulating blood volume, the search for intrinsic myocardial depression after burn injury and for mediators of such depression continues. In experimental studies and in clinical material, a correlation between hypophosphatemia and cardiac decompensation has been reported. Cardiac output, measured by bolus thermodilution, was impaired in seven critically ill hypophosphatemic patients and improved significantly with phosphorus supplementation.⁴ In one experimental study, myocardial contractility was impaired by phosphorus deficiency and reversed by phosphorus repletion, suggesting that phosphorus deficiency may be a cause of heart failure in certain clinical conditions.²³ Hypophosphatemic cardiac depression has been described as occurring in 28.8% of surgi-

cal intensive care patients.²⁴ Despite these reports, there appears to be little evidence that hypophosphatemic cardiomyopathy is a frequently encountered clinical entity; most patients in whom this mechanism is invoked have already had a number of other causes for myocardial dysfunction.²⁵

Neuromuscular dysfunction

Varying degrees of areflexic paralysis, paresthesias, sensory loss, weakness, and respiratory insufficiency have been reported to be associated with acute hypophosphatemia, usually induced with feeding malnourished patients.¹² A reduction in available ATP to support respiratory muscle contraction has been suggested as a mechanism for acute respiratory failure, and diaphragmatic contractility has been reported to improve with phosphorus repletion in mechanically ventilated hypophosphatemic patients.²⁶ Profound generalized muscle weakness associated with isolated phosphorus depletion has been observed in both clinical and laboratory studies.^{27,28} In a study of hypophosphatemia and muscle phosphate metabolism in patients with burns or mechanical trauma, no direct correlation was demonstrated between the serum phosphorus concentration and the high-energy phosphate content of muscle cells; all these patients, however, were receiving phosphorus supplementation during the study.²⁹ If acute hypophosphatemia is superimposed on pre-existing cellular injury, potentially reversible muscle cell dysfunction may extend to irreversible necrosis.³⁰ Several authors have reported severe rhabdomyolysis associated with severe hypophosphatemia following burns and major trauma.^{31,32} This spectacular clinical event is rare but may occur to a lesser, subclinical, extent in critically ill patients.^{30,33} Hypophosphatemia as the underlying etiology may often be dismissed since muscle cell destruction results in release of phosphate and elevation of serum phosphorus. In the absence of significant hemochromogenuria, the diagnosis may not even be suspected. Further investigation is required to determine whether this 'asymptomatic' rhabdomyolysis is, in fact, an important clinical entity, or merely an obligate manifestation of critical illness.

Hematologic dysfunction

When untreated, severe hypophosphatemia may lead to red blood cell dysfunction by alterations in cell shape, survival, and physiological function. Lack of high-energy phosphate results in a decrease in erythrocyte 2,3-diphosphoglycerate and subsequent leftward shift of the dissociation curve, with a consequent risk of tissue hypoxia.⁷ Clinical hypophosphatemia, with or without previous phosphate depletion, results in reduced production of 2,3-diphosphoglycerate, erythrocyte ATP, and other phosphorylated intermediates of red blood cell glycolysis. In a variety of experimental and clinical situations, including burn injury and mechanical trauma, red blood cell 2,3-diphosphoglycerate has been shown to be reduced in the presence of hypophosphatemia.^{34,35} In thermally injured patients it has been demonstrated that postburn disturbance of red cell phosphate metabolism may be prevented by administration of phosphorus in the early postburn course.³⁵ Hypophosphatemia has also been associated with decreased red cell survival and decreased red cell deformability, with impaired capillary transit and the potential for further deficiency of tissue oxygenation.

White blood cell dysfunction also has been observed as a result of hypophosphatemia induced by the initiation of phosphate-free parenteral nutrition and was associated with depressed chemotactic, phagocytic, and bactericidal activity of granulocytes.³⁵ A reduction in granulocyte ATP content was also documented and amelioration of these white blood cell abnormalities was coincident with phosphorus repletion. Any correlation between these observations and an increased risk of infection remains speculative for hypophosphatemic patients in general and burn patients in particular.

Summary

Though it is clear that organ system dysfunction may be a manifestation of severe untreated hypophosphatemia, the relationship between these specific abnormalities and those observed in either the hypodynamic or the hyperdynamic phases of burn injury remains unclear. Clinical experience dictates that even when severe hypophosphatemia is avoided, the scenario of early organ system hypofunction and later hyperfunction persists. This is not to say that the marked hypophosphatemia observed following burn injury is part and parcel of the disease process, without bearing on the postburn physiological response, but that thus far, the pathophysiological milieu following thermal injury has not permitted definition of the contribution of hypophosphatemia to the overall postburn response. Until cause and effect relationships are defined through ongoing research, aggressive phosphorus repletion should be approached cautiously following thermal injury. Such therapy does, however, clearly ameliorate red blood cell 2,3-diphosphoglycerate depletion, which, in and of itself, supports treatment.

Prevention and treatment of hypophosphatemia

An unequivocal recommendation to treat hypophosphatemia in thermally injured patients should be supported by evidence that the treatment is of benefit. Such evidence is somewhat lacking in thermally injured patients, but in many analogous instances of hypophosphatemia from other causes, a direct benefit has been ascribed to repletion.

Serum phosphorus levels should be measured daily during the early phase of burn care and intravenous phosphate repletion initiated when levels drop below 2.0 mg/dL (Figure 29.2). Most of the severe adverse effects of hypophosphatemia occur with concentrations below 1.0 mg/dL, and this replacement strategy should prevent the development of clinically significant hypophosphatemia. Correction of severe hypophosphatemia with serum phosphorus levels less than 1.0 mg/dL requires intravenous replacement, usually with solutions of sodium or potassium phosphate containing 0.16 mmol/kg body weight (5 mg/kg body weight) of elemental phosphorus over 6 hours. The dose may be halved for patients with serum phosphorus levels between 1.0 and 2.0 mg/dL.³⁶ Following completion of the infusion, a repeat serum phosphorus determination should be obtained, and further treatment based on the post-infusion plasma concentration. A potential hazard associated with intravenous administration of phosphate salts is hyperphosphatemia, which may induce metastatic deposition of calcium phosphate salts and hypocalcemia. Additionally, when

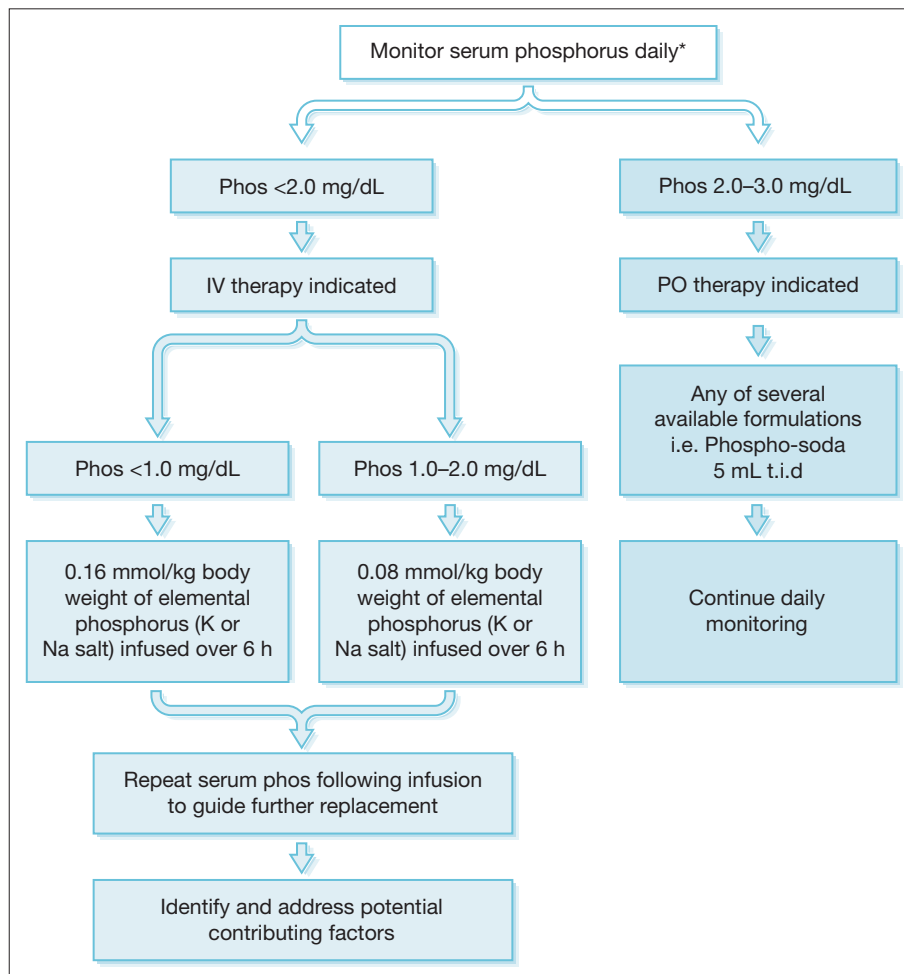

Fig. 29.2 The use of this algorithm permits prompt detection and timely correction of hypophosphatemia following burn injury.

potassium phosphate salts are used, care must be taken to avoid excessive or too rapid administration of potassium. Phosphorus replacement should be carefully monitored and proceed with great caution in patients with impaired renal function or evidence of soft tissue injury or necrosis.

Prevention of hypophosphatemia may be facilitated by beginning oral phosphorus replacement prior to interventions such as the initiation of either enteral or parenteral carbohydrate administration, gastric acid neutralization with phosphate-binding antacids or sucralfate, and the administration of diuretics. The nadir of serum phosphorus concentration typically occurs between 3 and 5 days postburn, during the period of edema mobilization, and the need to initiate phosphorus supplementation should be anticipated in this interval. Additionally, to temper the gastrointestinal losses due to administration of phosphate-binding antacids, substitution of, or alternation with, antacids containing aluminum phosphate should be considered.

For mild asymptomatic hypophosphatemia or for prophylaxis when worsening of hypophosphatemia is expected, oral supplementation with any of several available formulations is recommended. Such oral regimens have been shown to be cost-effective.³⁷ Five milliliters of Phospho-soda, containing 4.2 mmol/mL of elemental phosphorus, is commonly administered three times daily. Correction of other electrolyte abnor-

malities, most notably hypomagnesemia, hypocalcemia, and hypokalemia, as well as maintenance of acid–base normality, may prevent further renal phosphate losses and maintain the extracellular phosphate pool. After the 10th postburn day, the phosphorus delivered in standard liquid enteral formulas and hospital diets is usually sufficient to maintain serum phosphorus levels above 3.0 mg/dL.

Summary

Thermal injury induces a precipitous decrease in serum phosphate concentration that reaches its nadir between the second and fifth postburn days. This phenomenon has been recognized for some time, but interest in the problem has been limited. The organ system dysfunctions induced by hypophosphatemia are in many ways similar to certain of the pathophysiological changes observed following burn injury. The contribution of hypophosphatemia to these manifestations remains undefined. Wound fluid losses, increased circulating catecholamines, intracellular phosphate redistribution, and increased fractional excretion of urinary phosphate, as well as iatrogenic induction of hypophosphatemia through various therapeutic interventions, have been implicated as contributing to postburn hypophosphatemia. There may be other pathways regarding phosphorus regulation that have not been explored in this patient population. Phosphatonins have been

shown to be important mediators of phosphorus homeostasis and could be important mediators in this phenomenon seen in burn patients.⁴⁰ Frequent serum phosphate measurement and

prompt phosphorus replacement when hypophosphatemia is recognized should minimize any sequelae of this potentially deleterious electrolyte deficiency.

Introduction

The metabolic consequences of major burn injury are profound and constitute an ongoing challenge to successful burn treatment. Metabolic rates of burn patients can exceed twice normal and cause tremendous wasting of lean body mass within a few weeks of injury. Failure to satisfy these energy and protein requirements results in impaired wound healing, organ dysfunction, susceptibility to infection, and ultimately death. Provision of aggressive nutritional support is an essential component of burn care, which can reduce mortality and complications, optimize wound healing, and minimize the devastating effects of hypermetabolism and catabolism.

Nutritional therapy is more successful when it is provided within a comprehensive protocol.¹⁻³ Every burn center should develop a multidisciplinary protocol that standardizes the initial and ongoing assessment, initiation, and monitoring of nutritional support for patients with all sizes of burn injury.

This chapter provides practical guidelines for addressing the nutritional needs of burn patients. In attempting to interpret recent research, two difficulties are apparent. First, research dealing specifically with burn patients is far from complete. More data are available from trauma and other ICU populations, and it is often necessary to extrapolate some information from one group to another, which may not always be accurate. While burns have long been considered a paradigm for acute stress, burn injury has some special features which require unique nutritional solutions. We will attempt to discuss these issues as they arise.

Second, results of original research are not always consistent; studies of similar therapies may reach contradictory conclusions, especially in different populations. Such findings often underscore our imperfect understanding of the complexities of nutritional physiology. We will summarize new concepts in this field but also try to distinguish them from 'tried and true' therapies which are widely accepted. The reader is referred to excellent reviews summarizing the evidence for current clinical recommendations.^{1,4} Nutritional support, like many areas in burn care, is a moving target. The reader will need to interpret this chapter, and future readings, in this light.

The hypermetabolism of burn injury

Over 70 years ago, Cuthbertson documented that traumatic injury produced increased energy utilization and accelerated losses of body nitrogen.⁵ In the 1970s, burn patients were found to exhibit the most severe hypermetabolism of any group, with energy expenditure from 60 to 100% above normal following a major burn, and concomitant catabolism of protein stores.^{6,7} These studies also demonstrated the so-called ebb and flow response to injury (see Figure 30.1), in which an initial (12–24 hour) reduction in metabolic rate is followed by a crescendo–decrescendo curve of sustained hypermetabolism that can persist for weeks.

Attempts to nourish burn patients with oral diets often failed due to altered mental status, gastrointestinal dysfunction, and inhalation injury. Even patients who could eat were rarely able to tolerate the amount of nutrition necessary for adequate support. As a consequence, patients with major burns predictably incurred weight losses of 20% or greater within the first few weeks of injury,^{8,9} with associated immune compromise and delayed wound healing. This inanition often proved fatal as patients succumbed to respiratory failure, pneumonia, and systemic infection⁹ (Figure 30.2).

Mediators of hypermetabolism

The hypermetabolism following burn injury is a consequence of several predominant hormonal changes.^{10,11} As described by Long et al.⁶ and Wilmore et al.,⁷ burn trauma stimulates major increases in the catabolic hormones epinephrine, cortisol and glucagon, resulting in greatly accelerated gluconeogenesis, glycogenolysis, and muscle proteolysis.¹² Catabolic hormones counteract the effect of insulin; as a result, blood sugar levels rise, and protein synthesis and lipogenesis are inhibited. Growth hormone is similarly antagonized and less effective.

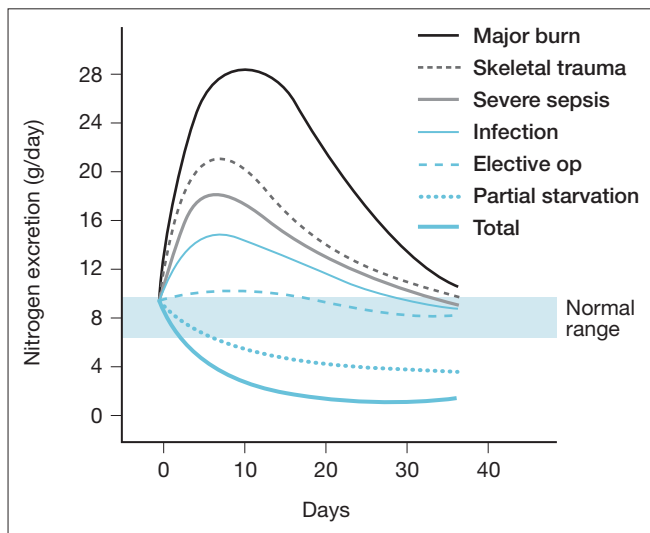

Fig. 30.1 This is a classic illustration of nitrogen excretion following injury compared to starvation and other conditions. Burn injury evokes the most pronounced catabolism of any clinical condition, with nitrogen excretion exceeding 25 g/day (150 g of protein, almost a half-pound of lean body mass!). Notice also the dynamic, 'crescendo-decrescendo' nature of this process: nitrogen excretion (and metabolic rate) rises from near-normal levels just after injury to reach a maximum at 7–14 days postburn, thereafter declining slowly throughout recovery. This illustrates the impossibility of using static formulas to estimate nutritional requirements accurately at every point throughout the course of burn treatment. (Reproduced with permission from Long et al. *Metabolic response to injury and illness: estimation of energy and protein needs from indirect calorimetry and nitrogen balance*. JPEN 1979; 3:452–456.⁶)

Fig. 30.2 Weight loss following burn injury as documented in the era before routine nutritional support. Dramatic losses of lean body mass occur within a week or two of injury, and progress continuously in the absence of effective nutritional support. By 4–6 weeks postburn, patients with major burns have lost 15% of lean body mass or more — a fatal degree of inanition. (Reproduced with permission from Wilmore et al. *Ann Surg* 1974; 180:653–658.⁷)

In this environment, skeletal muscle is the major obligatory fuel for hypermetabolism. In contrast to starvation (in which metabolic rate falls, and lipolysis and ketosis provide energy and protect muscle reserves), burn injury reduces the body's

ability to utilize fat as an energy source. Lipids have limited protein-sparing effect. Instead, a diet composed largely of carbohydrates is required to reduce protein catabolism, and even glucose is limited in its ability to prevent protein wasting.¹³

Although these hormonal changes provide a major challenge to the provision of adequate nutrition, they also provide mechanisms by which hypermetabolism can be reduced to facilitate metabolic support. In recent years, investigators have attempted to ameliorate burn-induced hypermetabolism by several methods, including blocking catecholamines with propranolol, administering counter-regulatory agents such as insulin and insulin-like growth factor-1 (IGF-1), or use of anabolic hormones such as growth hormone, testosterone, or synthetic anabolic agents such as oxandrolone.^{14,15} This rapidly-evolving area of research is discussed in detail in other chapters of this book. Although some of these methods show promise for clinical use, it must be remembered that the hormonal milieu which accompanies burn injury is complex and incompletely understood. Additional research will be needed to confirm the efficacy and safety of these techniques.

Modern burn care and metabolic requirements

Modern methods of burn treatment do not appear to have altered the *nature* of burn-induced hypermetabolism but have significantly reduced its *magnitude*. Maneuvers as simple as maintaining high ambient temperature and relative humidity can reduce caloric requirements by up to 20%.⁷ Antibiotics and routine early burn wound excision have reduced infection and modulated hypermetabolism. Although excisional surgery has not been shown to directly reduce energy expenditure,¹⁶ covering burn wounds with autograft, allograft, or synthetic substitutes certainly shortens the duration of hypermetabolism. Other therapies, including mechanical ventilation and chemical sedation/paralysis, also reduce energy requirements.¹⁷

As a result, numerous recent reports using indirect calorimetry document metabolic rates which, though still increased, are now more likely to approximate 120–150% of normal, rather than the 160–200% previously reported.^{18,19} Nonetheless, both temporal and patient-specific variations in energy expenditure make it difficult to predict requirements for individual patients.

Assessment of nutritional needs

Initial assessment

Patients suffering from systemic diseases such as cancer and AIDS often present with serious pre-existing nutritional depletion which must be addressed before the underlying disease can be treated. A variety of nutritional assessment techniques have been used in population-based surveys, including careful clinical evaluation, serum proteins, anthropometric measurements, tests of immune function, etc.

Pre-existing malnutrition can also exist in burn patients and can compromise wound healing and survival.²⁰ However, extensive initial nutritional assessments may not be necessary

in burned patients for several reasons. Burn injury induces major abnormalities in nutritional indices which confound assessment of pre-burn status: swelling and eschar preclude accurate anthropometric measurements, serum proteins are altered quickly, and immune function is similarly disturbed. A careful nutritional history, calculation of body mass index (BMI), and functional status may be the most meaningful assessments to perform.²¹ Moreover, satisfying *ongoing* requirements is far more important — and probably more difficult to determine — than compensating for *pre-existing* deficiencies. Attempting to ‘catch up’ by providing excess calories and/or protein is ineffective and likely to increase such complications as hyperglycemia, CO₂ retention, and azotemia (see ‘overfeeding,’ below). Therefore, the primary goal of nutritional support in burn patients is to satisfy *ongoing*, burn-specific requirements. Pre-existing deficiencies can be addressed after the acute phase resolves.

Formulas for estimating caloric requirements

Any protocol for nourishing burn patients must begin with estimation of their nutritional needs. An array of regimens for this purpose have been developed.²² One of these, the Curreri formula,²³ has been widely (and successfully) used, though its

accuracy is open to question. To create the formula, Curreri’s group examined only nine patients and calculated backwards to estimate the calories which would have been needed to make up for patients’ lost weight. As will be discussed, this is a dubious assumption at best.

Several popular formulas for adult nutrition are reviewed in Table 30.1.^{23–28} As can be seen, they use different variables to predict different caloric requirements for specific patients, and reach very different estimate of energy needs. Because modern burn treatment has blunted the magnitude of hypermetabolism, older formulas like Curreri’s significantly overestimate energy requirements.¹⁸ Moreover, static formulas inevitably fail to account for the major differences in energy expenditure invariably documented between patients, within individuals, and over time. Dickerson et al. reviewed 46 published methods for predicting energy expenditure in burn patients.²⁹ They found that *none* of the methods reviewed correlated precisely (= 15% error) with measured energy expenditure in a group of 24 patients. Because postburn energy expenditure fluctuates (see Figure 30.1), formulas are likely to result in overfeeding early and late in the postburn course and may underfeed patients during periods of peak energy utilization.

TABLE 30.1 COMMONLY USED FORMULAS FOR ESTIMATING CALORIC REQUIREMENTS IN ADULT BURN PATIENTS

Formula name	Formula ^a	Daily caloric estimate (kcal), 25-year-old male (80 kg; BSA = 2.0m ² with 60% TBSA burn)	Comment
Harris–Benedict ^{2,25}	Basal energy expenditure: Men: 66.5 + (13.8)W + (5)H – (6.76)A Women: 655 + (9.6)W + (1.85)H – (4.68)A Adjust for stress by multiplying BEE by a factor of 1.2–2.0	Basal rate = 1915 If factor is 1.2 = 2299 If factor is 1.2 = 2299 If factor is 2.0 = 3830	The Harris–Benedict formula is an accepted standard for estimating <i>basal</i> energy expenditure (BEE). For burn patients, multiplying BEE by an arbitrary factor introduces significant inaccuracy. A factor of 1.2–1.5 should be sufficient for all but the largest burn injuries
Curreri formula ²³	Age 16–59: (25)W + (40)TBSA Age ≥ 60: (20)W + (65)TBSA	4400	This widely used formula probably overestimates modern energy requirements significantly. A modification for elderly patients is included
Davies and Liljedahl ²⁴	(20)W + (70) TBSA	5800	This formula will grossly overestimate energy requirements for patients with very large injuries
RDI ²⁸	37(W)	2960	‘One size fits all’ is convenient, but inaccurate for most patients, particularly the elderly and obese
Ireton-Jones ²⁶	Ventilated patient: 1784 – 11(A) + 5(W) + 244(S) + 239 (T) + 804 (B) Non-ventilated patient: 629 – 11(A) + 25(W) – 609(O) =	2957 2384	This complex formula permits calculation of energy requirements for trauma and burn patients, and includes a factor for obesity
Toronto ²⁷	–4343 + (10.5 × TBSA) + (0.23 × CI) + (0.84 × HBE) + (114 × T) – (4.5 × PBD)	2782	Another complicated formula which requires ongoing collection of patient data

^aFor all formulas, W = weight in kilograms; H = height in centimeters; A = age in years; S = sex (male = 1, female = 0); T = trauma (present = 1, absent = 0); B = burn (present = 1, absent = 0); O = obesity (present = 1, absent = 0); TBSA = burn size (percent total body surface area); CI = calorie intake the previous day; HBE = Harris–Benedict estimates; T = temperature (°C).

Pediatric formulas

Numerous formulas have also been created to address the energy requirements of burned children; several commonly used formulas are presented in Table 30.2.^{30–34} As needs change with age, pediatric formulas differ by age. Even with this accommodation, however, predictive equations yield very different caloric requirements for the same patients. These formulas share the same inherent limitations of adult formulas.

Indirect calorimetry

In recent decades, improved technology for performance of indirect calorimetry (IC) has permitted routine measurement of energy expenditure at the bedside. IC devices measure the volume of expired gas, along with inhaled and exhaled concentrations of oxygen and carbon dioxide, permitting calculation of oxygen consumption (VO_2) and carbon dioxide production (VCO_2), and thus metabolic rate.³⁵ Measurements made through tight-fitting face masks, hoods, or by connection to mechanical ventilators have proven reliable and reproducible over a wide range of metabolic rates and FiO_2 .

IC can also detect significant under- or overfeeding through calculation of the respiratory quotient (RQ) – the ratio of carbon dioxide produced to oxygen consumed (VCO_2/VO_2).³⁶

The body's metabolism of specific substrates affects this ratio, providing information about metabolic supply and demand. For example, in unstressed starvation, utilization of fat as a major energy source produces an RQ of 0.7 or less;³⁷ in normal metabolism of mixed substrates, RQ = 0.75–0.90; the synthesis of fat from carbohydrate, which typifies overfeeding, results in an RQ of 1.0 or greater. In this way, overfeeding can contribute to difficulty weaning from ventilatory support.³⁸

IC is used widely to measure caloric requirements for burn patients and to detect significant under- or overfeeding.^{39,40} Resting energy expenditure (REE) is usually measured in the early morning with patients at bed rest. Fluctuations in energy utilization associated with activity must be factored into nutritional support, and are usually estimated by increasing measured metabolic rate by 10–20%.⁴¹

Delivering estimated needs: How close is 'close enough'?

Recent studies in ICU patients found that less than 80% of prescribed calories were actually delivered.^{42,43} Enteral nutrition was less successful than TPN, because of more frequent interruptions for diarrhea, tube dislodgement, surgery, etc. In

TABLE 30.2 COMMONLY USED FORMULAS FOR ESTIMATING CALORIC REQUIREMENTS IN PEDIATRIC BURN PATIENTS

Daily caloric estimate (kcal) for patients with 40% TBSA burn						
Formula name	Age (years)	Formula ^a	1 month old 10 kg BSA = 0.5 m ²	3 year old 12 kg BSA = 0.6 m ²	10 year old 30 kg BSA = 1.1 m ²	14 year old 60 kg BSA = 1.6 m ²

Galveston adolescent ³³	≥12	1500 kcal/m ² + 1500 kcal/m ² burn			3360	

^aFor all formulas, W = weight in kilograms; H = height in centimeters; A = age in years; BSA = body surface area; TBSA = burn size (percent total body surface area).
^bWHO pediatric nutrition handbook, 5th edn. Ronald E. Kleinman, ed. American Academy of Pediatrics; 243.

both types of nutrition, hyperglycemia sometimes required reducing nutrition, while dextrose-containing IV fluids added unplanned, ‘empty’ calories. These studies illustrate the ubiquitous practical difficulties of actually giving patients the nutrition that is prescribed for them — difficulties which can compromise the success of nutritional support.

This experience raises an important question: How close is ‘close enough’ in feeding critically ill patients? Despite the limitations inherent in static formulas, the superiority of IC-based nutrition has not been proven clinically.^{1,44} Many patients have been successfully nourished using the Curreri and other formulas, and abundant experience demonstrates that either formulas or indirect calorimetry can be used to nourish burn patients successfully, particularly if this is done within a multidisciplinary regimen of support. Many units use a goal of delivering nutrition within 10% of measured (or calculated) needs as a quality assurance indicator, despite the lack of evidence for such a policy.

Specific nutrient requirements

Carbohydrates

The major energy source for burn patients should be carbohydrates. Glucose is the preferred fuel for healing wounds, and accessory metabolic pathways to provide glucose, including the alanine and Cori cycles, are active in burn patients.

The major complication of carbohydrate feeding under stress is glucose intolerance. Aggressive control of hyperglycemia is emerging as a critically important aspect of optimal patient care. Even patients with relatively normal tolerance may have caloric requirements that exceed the body’s ability to assimilate glucose, which is estimated at approximately 7 g/kg/day (2240 kcal for an 80-kg man).⁴⁵ Patients often require significant amounts of supplemental insulin with aggressive (or ‘tight’) glucose control now recommended (see below). However, refractory hyperglycemia can still occur and require reduction or even discontinuation of nutrition until blood sugar can be controlled. Providing a limited amount of dietary fat reduces requirements for carbohydrates and can improve glucose tolerance significantly.

Table 30.3, discussed below, lists the composition of a number of commonly available enteral nutrition products which should help in understanding the quantities of nutrients required for support.

Requirements and uses of fat

A certain (small) quantity of fat is an essential nutrient. Essential fatty acid deficiency is a well-documented complication of patients given long-term TPN;¹⁰ modern TPN contains significant amounts of lipid for this reason. In addition, providing a substantial proportion of fat calories reduces the required glucose load and associated VCO₂. However, the hormonal environment of burn-injured patients suppresses lipolysis and limits the extent to which lipids can be utilized for energy. For this reason, most authorities recommend that fat constitutes no more than about 30% of non-protein calories, or about 1 g/kg/day of intravenous lipids in TPN.¹⁰

It may be desirable to give even less fat. In an animal model, adverse effects on immune function occurred when diets con-

tained more than 15% lipids.⁴⁶ Some clinical research supports this finding,⁴⁷ leading some authorities to recommend low-fat diets for use in burn patients. Commercially available nutritional supplements are listed in Table 30.3; popular ‘stress formulas’ contain 25–40% of calories as fat, while some ‘specialty’ formulas — for renal failure, respiratory failure, or diabetes — contain even more fat, which limits their usefulness in burn patients. Patients given TPN may be better off if fat is withheld entirely for short periods of time (as little as once weekly),^{1,48} though this may result in aggravated glucose intolerance.

The composition of administered fat may be even more important than the quantity. Most common lipid sources contain mostly omega-6 fatty acids (ω -6 FFAs) such as linoleic acid which are metabolized through synthesis of arachidonic acid, a precursor of pro-inflammatory cytokines such as prostaglandin E₂. Lipids such as fish oil containing a high proportion of omega-3 fatty acids (ω -3 FFAs) are metabolized without elaborating pro-inflammatory compounds. Diets high in ω -3 FFAs have been associated with improved immune response, possible improved outcomes,⁴⁹ and may reduce problems with hyperglycemia.⁵⁰ Most experience with ω -3 FFAs has been obtained with ‘immune-enhancing diets,’ of which they are a major component (see below). Both the optimal composition and dose of fat in nutritional support remain topics of substantial controversy.

Protein

The hormonal environment of burn injury greatly increases proteolysis. Provision of carbohydrate and fat calories is only partially successful in reducing protein catabolism; some loss of lean body mass is obligatory following injury.⁵¹ Increased protein must be supplied to satisfy ongoing demands, and provide amino acids for wound healing, enzymes, immunocompetence, and other functions. When calories are limited, protein will be used as an energy source rather than to replenish lost protein stores. The converse, however, is not true: providing calories in excess of need will not lead to increased protein retention or synthesis — it will just lead to overfeeding with its associated risks. Protein intake above required needs (as in extremely high protein/low carbohydrate diets) also results in protein’s use as a fuel source through gluconeogenic pathways.

Protein catabolism in burn patients can exceed 150 grams/day, or almost a half-pound of skeletal muscle. Although feeding supranormal amounts of protein may not reduce breakdown of endogenous protein stores,⁵² it facilitates protein synthesis, and reduces negative nitrogen balance. In burned children, a diet including increased protein (23% of total calories) was associated with improved immune function, less bacteremia, and increased survival.⁵³ As burn size increases, progressively more protein is required for positive nitrogen balance.^{54,55}

Current recommendations call for 1.5–2.0 grams of protein per kilogram body weight per day for adult burn patients, and up to 3.0 g/kg/day in children.^{39,56} With provision of sufficient non-protein calories, this should result in a calorie:nitrogen ratio of 100:1 or less, typical of the ‘stress’ formulas listed below. Measurement of nitrogen balance and visceral protein markers may be helpful in assessing the adequacy of nutritional support (see below).

TABLE 30.3 COMPOSITION OF COMMERCIALY AVAILABLE ADULT AND PEDIATRIC ENTERAL NUTRITION PRODUCTS (PER 1000KCAL OF FEEDINGS)

I. Adult formulas ^a											
Brand name (manufacturer)	mL/ 1000 kcal	%RD	Carbs		Protein			Fat			Comments
			g	%kcal	g	%kcal	Cal:N2	g	%kcal	ω 6: ω 3	
'Immune-enhancing' and healing adult formulas											
Crucial™ (Nestle)	667	100	90	36	63	25	67:1	45	39	2:1	Elemental, hypertonic, concentrated enhanced with arginine
Impact™ (Novartis)	1000	67	130	53	56	22	71:1	28	25	1.4:1	Widely used 'immune-enhancing' formula; supplemented with arginine; high in ω -3 FFAs
Replete™ (Nestle)	1000	100	113	45	63	25	75:1	34	30	3:1	Inexpensive, high-protein formula
TraumaCal™ (Mead-Johnson)	667	33	95	38	55	22	91:1	45	40	6.3:1	High-protein, concentrated. Relatively high proportion of ω -6 FFAs. Deficient in some vitamins
Standard adult formulas											
Isocal-HN™ (Mead-Johnson)	943	80	117	46	42	17	125:1	43	37	N/a	Isotonic 'all purpose' feeding, without fiber
Jevity™ (Ross)	943	67	146	54	42	17	125:1	33	29	4.2:1	Isotonic, with fiber
'Specialty' adult formulas											
Nepro™ (Ross)	500	52	111	43	35	14	154:1	48	43	N/a	Widely used 'renal failure' formula; low in potassium, phosphorus, protein. Can be supplemented with protein for burn patients
Glucerna™ (Ross)	1000	70	96	34	42	17	125:1	54	49	10.8:1	Low-carbohydrate formula for diabetics; relies on high-fat content, which is of limited efficacy in burn patients
Pulmocare™ (Ross)	667	70	71	28	42	17	125:1	62	55	4:1	Customized formula for pulmonary failure relies on high fat content to avoid excessive VCO ₂ ; limited efficacy in burn patients
Peptamen™ (Nestle)	1000	67	127	51	40	16	131:1	39	33	7:1	Semi-elemental, isotonic

Pediatric Vivonex™ (Novartis)	1250	108–120	163	63	30	12	30	25	Free amino acids, semi-elemental
Compleat Pedatric™ (Novartis)	900	111	130	50	38	15	39	35	

^aAbbreviations: mL = milliliters of formula to contain 1000kcal; % RDI per 1000mL = percent of recommended dietary intake of micronutrients contained in 1000mL of formula. Includes micronutrients not listed; g = grams; %kcal percentage of total calories; Cal:N2 = calorie-to-nitrogen ratio; ω6ω3 = ratio of ω-6 to ω-3 fatty acids. Information from manufacturers' websites as of December 2005.

Glutamine

Several amino acids have enhanced roles in energy delivery following injury. Alanine and glutamine (GLU) are important transport amino acids, created in large quantities from skeletal muscle to supply energy to the liver and to healing wounds.⁵¹ GLU also serves as a primary fuel for both enterocytes and lymphocytes and is thus important in maintaining small bowel integrity, preserving gut-associated immune function, and limiting intestinal permeability following acute injury.^{57,58} While the clinical significance of bacterial translocation in humans remains unresolved, glutamine may reduce passage of intact bacteria, and probably prevents translocation of endotoxin and secondary elaboration of inflammatory mediators by gut mucosa.^{58,59} In addition, glutamine is a precursor of glutathione, an important antioxidant, and also improves elaboration of heat shock proteins, which provide cellular protection following stress and trauma.⁶⁰

GLU is quickly depleted from both serum and muscle following burn injury, which may limit visceral protein synthesis, leading to the suggestion that GLU be considered a 'conditionally essential' amino acid in burns.^{51,61} Importantly, GLU is almost totally absent from parenteral nutrition owing to its instability in solution; this may explain some of the inferiority of TPN, including a higher rate of systemic infections, compared to enteral nutrition.

In a number of clinical trials, GLU supplementation produced some improved outcomes in patients with cancer, AIDS, surgery, trauma, or burns.^{58,62} However, the benefits of GLU supplementation were not consistently seen in comparisons between postoperative and ICU patients, provision of 'low-dose' (<0.20g/kg/day) vs. 'high dose' (>0.20g/kg/day) GLU, or parenteral vs. enteral administration.⁶⁰ The best data supporting GLU supplementation comes from burn patients, in whom provision of 25g GLU/kg/day or more, given parenterally⁶³ or enterally,^{64,65} was associated with reduced infections, improved visceral protein levels, and reduced mortality and

length of hospitalization. This effect of GLU may be relatively specific to burn injuries.

At this time, supplementation of enteral nutrition with GLU for burn patients is not routinely practiced, although this has been suggested.¹ Provision of the large amounts of GLU given in these trials (0.25–0.50g/kg/day) could interfere with delivery of other amino acids, so it might be preferable to give GLU *in addition* to the usual quantity of protein (1.5–2.0g/kg/day in adults) required in burn patients.⁵⁸ Obviously, many questions persist regarding the clinical utility of GLU supplementation in burn care. Further clinical trials of this amino acid will be needed to clarify this issue.

Arginine and 'immunonutrition'

Arginine (ARG) is also important in postburn metabolism. ARG stimulates T-lymphocytes, enhances natural killer cell function, and stimulates synthesis of nitric oxide (NO), which is important in resistance to infection.^{66,67} ARG supplementation of enteral diets has been associated with improved immune responsiveness and wound healing.⁶⁸

Even the earliest efforts to nourish burn patients sought to define an 'ideal' nutritional mixture. Early diets were simply supplemented with eggs or milk.²² Modern efforts have focused on combining components that appear to improve immune function and wound healing. In a study in burned children, a formula enhanced with ω-3 FFAs, histidine, ARG, RNA, and vitamins was associated with reduced infectious morbidity and improved survival.⁶⁹ This experience quickly led to commercial production of similar multi-ingredient 'immune-enhancing diets' (IEDs).

Subsequent studies have evaluated IEDs in a variety of clinical settings; some have demonstrated improvements in immunity and wound healing, and/or clinical parameters, including infection rates, incidence of multiple organ failure, or hospital stay.^{70,71} However, others have not been uniformly favorable. It appears that these diets may have very different conse-

quences in different patient groups, with improved outcomes following trauma or elective surgery,^{72,73} but deleterious or no effects in patients with sepsis or pneumonia.^{1,70,74} Much of the blame for these inconsistent results has been attributed to ARG, the exact dosing of which may influence its effects greatly, as too much could stimulate excessive NO production and exaggerated inflammation.⁷⁵

Little information has been obtained on the use of IEDs in burn patients. One randomized trial comparing a highly publicized IED (Impact™) with another high-protein ‘stress’ solution found no differences in major outcome variables.⁷⁶ Though both solutions contained significant amounts of ω-3 FFAs, they differed in contents of vitamin A, ARG, and RNA; both feedings also contained significantly more fat than the modular tube feeding of Gottschlich et al.⁶⁹

This experience illustrates that our understanding of complex nutritional physiology is still limited and may have been hindered by the rush to create commercially viable ‘cocktails’ for clinical use before understanding the real actions (and interactions) of their components, their optimal doses, and in what settings they might even be harmful to patients. At present, use of IEDs, particularly ARG, is not recommended.¹ This issue must await clarification from future well-designed and large-scale clinical trials.

Branched-chain amino acids

The branched-chain amino acids (BCAAs) leucine, isoleucine, and valine, have been postulated to spare endogenous muscle catabolism by stimulating protein synthesis and serving as energy substrates. In clinical trials in trauma and ICU patients, BCAA-enriched nutrition has been associated with improved nitrogen balance but has had no effect on survival.⁷⁷ In both animal and clinical studies in burn injury, BCAA-enriched feedings have not produced improvements in outcome, protein synthesis, or immune function,⁷⁸ and are therefore not recommended for use.

Micronutrients: vitamins and trace elements

In addition to major nutrients, metabolism of many so-called ‘micronutrients’ — vitamins and trace elements which are important in wound healing and immunity — is also affected by burn injury.⁷⁹ These compounds have not been evaluated extensively in clinical studies, though depressed serum levels of some compounds have been documented following burns. Limited data suggest that supplementation of some substances (vitamin A, vitamin C) may be beneficial. Table 30.4 contains a list of the most important micronutrients, their recommended daily allowances (RDAs), and the contents of several commonly used enteral formulas.

A complete listing of micronutrients and their functions is beyond the scope of this chapter; excellent reviews are available.^{79,80} A few of the most important compounds are now discussed:

- Vitamin A is important in wound healing and epithelial growth. Vitamin A also functions as an antioxidant, and in preventing free radical damage. Decreased levels of vitamin A have been demonstrated following burn injury,⁸¹ and supplementation has been recommended for burn patients.⁸² However, toxicity of vitamin A can also occur.
- Vitamin C or ascorbic acid is essential for synthesis and cross-linking of collagen and thus for wound healing. It also functions as a circulating antioxidant. Some data support vitamin C supplementation in burn patients, and toxicity does not appear to be a clinical problem.⁸⁰ Supplementation of up to 1000mg per day (over 20 times RDA) in burn patients has been recommended.⁸²
- Vitamin D: considerable recent research has demonstrated that bone resorption and osteopenia is a significant problem following burn injury.⁸³ Disorders of vitamin D metabolism, as well as immobilization, may contribute to this problem, which is discussed in another chapter in this book.
- Iron is essential in oxygen-carrying proteins and also acts as a cofactor for a number of important enzymes. Burn patients are prone to iron deficiency, partially due to blood loss, but it should also be remembered that blood transfusions deliver a significant amount of iron.
- Zinc is required for the function of many metalloenzymes. Several aspects of wound healing appear to be affected by the availability of zinc, including DNA/RNA replication and lymphocyte function. Zinc deficiency has been documented during the first several days after burn injury.⁸⁴ Supplementation of up to 220mg/day (15 times RDA) has been recommended.⁸²
- Selenium is important in the function of lymphocytes, and hence, in cell-mediated immunity. Selenium is lost through the skin following burn injury; selenium deficiency in burn patients has been documented.⁸⁵

A recent survey found that many burn centers provide some supplementation of trace elements, though both indications and specific doses vary among units.⁸⁶ Current reviews recommend supplementing at least the micronutrients listed above, and perhaps others.¹¹ However, remember that many commercially available tube feedings contain substantial quantities of these micronutrients (Table 30.4), which can approximate the recommendations for supplementation listed by Mayes et al.⁸² The addition of a daily multivitamin tablet, or liquid multivitamins to tube feedings or TPN, will provide far more than RDA for most of these micronutrients at minimal cost and risk. It is unclear whether additional supplementation is of benefit of burn patients. Remember also that blood transfusions provide substantial amounts of iron, chromium, and some other micronutrients.

Formulas for enteral nutrition

Successful nutrition has been provided to burn patients with very simple concoctions of milk, eggs, and other nutrients.²² However, commercially prepared enteral formulas offer several advantages. They are carefully composed to contain appropriate quantities of all necessary nutrients. Canned enteral diets can be infused through narrow feeding tubes with minimal clogging. Most are reasonably inexpensive, though some specialized formulas can be quite costly. Table 30.3 lists the nutrient composition of a number of popular enteral formulas.

A bewildering array of additional products are available, including fiber-containing diets, elemental diets, supplements,

and specialized diets for patients with renal failure, hepatic failure, glucose intolerance, etc. Many of these products do not meet the nutrient needs for burn patients and often limit protein while providing excess amounts of fat and carbohydrate. As an example, Table 30.5 shows the effects of changing either the volume of enteral nutrition and intravenous fluids (a major source of calories

for some patients) delivered, or switching to one of the 'diabetic' formulas available. Clearly, the choice of formula can greatly influence both the success of nutrition, and the type and magnitude of complications encountered. This illustrates the need to have the burn center dietician involved in evaluating and selecting the products used to feed each patient.

TABLE 30.5 EFFECT OF DIFFERING VOLUME AND TYPE OF ENTERAL NUTRITION ON PROTEIN AND CARBOHYDRATE INTAKE

Example 1 ^a Maintenance feeding and IV			
	Feedings	IV dextrose	Total
mL/h	100	200	300
kcal/d	2400	680	3080
Protein g/d	150	0	150
Carbs g/d	271	240	511
Fat g/d	82	0	82
Example 2 Decrease feeding, increase IV			
	Feedings	IV dextrose	Total
mL/h	50	250	300
kcal/d	1200	1020	2220
Protein g/d	75	0	75
Carbs g/d	136	300	436
Fat g/d	41	0	41
Example 3 ^b Changing formula to Glucerna™			
	Feedings	IV dextrose	Total
mL/h	100	200	300
kcal/d	2400	680	3080
Protein g/d	100	0	100
Carbs g/d	229	240	469
Fat g/d	131	0	131

^aTypical 'maintenance' regimen for a patient with major burns, consisting of 100mL/h of a high-protein 'stress' formula (Replete™), plus dextrose-containing crystalloid solutions to deliver a total fluid volume of 300mL/h. Note that in Example 2, decreasing enteral nutrition, which is sometimes done to reduce glucose intolerance, results in relatively little decrease in total carbohydrate calories.

^bResult of changing enteral products, using a formula designed for patients with glucose intolerance. These formulas are typically high-fat diets, resulting in fewer carbohydrate calories, but more fat and less protein, which is far from ideal for a stressed burns patient. The total amount of carbohydrates 'saved' by this adjustment is about 42 grams, or about three servings of starch per day.

Formulas for TPN

Solutions for TPN must be composed of elemental components that do not require digestion. Dextrose is the main calorie source, and the high concentrations require delivery through central venous catheters. Protein is supplied as prepared amino acid solutions. As mentioned previously, glutamine is not a component of TPN. In recent years, lipid emulsions have been perfected for intravenous use, and lipids can constitute a significant proportion of the calories in TPN.

The exact composition of TPN must be ordered by the physician. This permits exact tailoring of the solution to individual patient needs. Box 30.1 is an example of a protocol for ordering and administering TPN used at the University of Utah using a 'standard' TPN solution (70% dextrose, 15% amino acids, and 20% lipid emulsion). Electrolytes, vitamins, and minerals can

be custom-ordered, or standard 'packages' can be used. Medications such as insulin and H₂ blockers can be added as well.

Methods of nutritional support

Route of nutrition: parenteral vs. enteral

It is ironic that the development of TPN in the 1960s and 1970s actually preceded many enteral nutritional techniques. At the peak of TPN's popularity, it was estimated that over 500 000 patients were treated yearly, at a cost of over 3 billion dollars.⁸⁷ This included burn patients, for whom TPN was widely advocated.^{22,88}

Use of TPN has now been largely replaced by enteral nutrition (EN) for both theoretical and practical reasons. Enteral nutrition directly nourishes the bowel mucosa; some nutrients (e.g. glutamine) may be particularly important in this regard. Also, the presence of even small amounts of nutrients within the bowel lumen stimulates the function of intestinal cells, maintains the architecture of intestinal microvilli and normal mucosal function, and may help preserve normal blood supply to the intestine.⁸⁹ Together, these effects may reduce bacterial translocation and sepsis and preserve gut-associated immune function.⁹⁰⁻⁹² In contrast, TPN appears to be associated with increased secretion of tumor necrosis factor and other proinflammatory mediators.⁹³ Lipids added to TPN may enhance inflammatory response as well, particularly in pulmonary dysfunction.⁴⁸

In clinical trials, early and aggressive enteral nutrition has been associated with decreased infectious complications in trauma and ICU patients.^{94,95} In burn patients, TPN supplementation of enteral nutrition has been associated with substantially increased mortality.^{96,97} This is in contrast to a recent meta-analysis which showed no increased mortality associated with TPN in ICU patients.⁹⁸ The difference in these findings may be due to metabolic characteristics which are unique to burn patients, or may simply reflect more selective use of TPN in burn units, where it is limited to the sickest patients and therefore serves as a surrogate for severity of illness. As reviewed in Chapter 26, fatty infiltration of the liver is enhanced following burn injury; hepatomegaly and cholestasis can become massive, particularly in association with systemic infections.⁹⁹ This appears to be true regardless of the route of nutrition used but may be particularly severe in association with use of TPN.

In addition to maintaining gut integrity, EN provides 'first-pass' delivery of nutrients to the liver, which reduces hyperglycemia and hyperosmolarity. TPN requires central venous access, with the inherent risks of pneumo/hemothorax, bacteremia, endocarditis, air embolism, etc. Last, but by no means unimportant, TPN solutions are a great deal more costly than enteral formulas, require more expensive delivery systems, and more frequent monitoring of glucose and other blood chemistries. For all these reasons, *enteral nutrition should be considered the route of choice for the nutritional support of all burn patients with functioning (or even partially functioning) gastrointestinal tracts.*^{1,100} TPN supplementation of EN is also not recommended, unless intolerance of maintenance EN is prolonged.

Early enteral feeding

A 1984 study in burned guinea pigs demonstrated that immediate EN improved maintenance of small bowel mass and

Box 30.1 A protocol for administration of TPN in burn patients

(Adapted from the 'Adult Parenteral Nutrition Orders', University of Utah)

STEP ONE: CALCULATED REQUIRED ENERGY AND PROTEIN NEEDS:

Example: 25-year-old man, 80kg in weight. Body surface area = 2.2 m².

- Indirect calorimetry indicates energy expenditure of 2400kcal/24 hours. To account for fluctuations in energy expenditure, increase measured value by 20% (480kcal); total = 2880 nonprotein kcal/day.
- Estimate protein requirements at 2.0g/kg/day = 160g protein

STEP TWO: ORDER TPN SOLUTION

- Carbohydrates: carbohydrates are supplied as 70% dextrose (D70), which contains 2.4kcal/mL. To give 75% of nonprotein calories as dextrose, calculate:

$$[(2880 \text{ total kcal}) \times (0.75 \text{ calories as dextrose})] / 2.4 \text{ kcal/mL} = 900 \text{ mL D70}$$

- Fat: The remainder of nonprotein calories will be given as lipid emulsion. This is commonly available as 10% (1.0kcal/mL) or 20% (2.0kcal/mL) solution. To give 25% of nonprotein calories as lipid, calculate:

$$[(2880 \text{ total kcal}) \times (0.25 \text{ calories as lipid})] / 2.0 \text{ kcal/mL} = 360 \text{ mL 20\% lipid emulsion}$$

- Protein: protein is supplied as crystalline amino acid solutions at a concentration of 10% (0.1g/mL), or 15% (0.15g/mL). To give 160g of protein, calculate:

$$(160 \text{ g protein}) / 0.15 \text{ g/mL} = 1067 \text{ mL of 15\% amino acid solution}$$

- Total volume = 900mL D70 + 360mL lipids + 1067mL amino acids = 2327 mL.
- Add electrolytes: these can be ordered as customized additions in any quantity, but a standard electrolyte 'package' contains (per liter of TPN):
 - Sodium chloride: 35 mEq
 - Potassium phosphate: 15 mM (22 mEq potassium)
 - Magnesium sulfate: 8 mEq
 - Calcium gluconate: 5 mEq
- Add vitamins: a standard vitamin 'package' contains approximately 100% of recommended dietary allowances of vitamins A, C, D, E, and B₁₂, pyridoxine, thiamine, riboflavin, niacin, pantothenic acid, folate, and biotin.
- Add trace elements: a standard 'package' contains:
 - Zinc: 2.5 mg
 - Copper: 1.0 mg
 - Manganese: 0.25 mg
 - Chromium: 10 μg
- Add additional water, and calculate infusion rate. If patients require additional fluid, water can be added to the TPN solution as desired. If no additional water is required, then the goal rate for infusion is 2327 mL / 24 hours = 97 mL/h.

STEP THREE: PROTOCOL FOR ADMINISTRATION

- Begin infusion at 20 mL/h via central vein.
- Increase rate every 4–6 hours by 10–20 mL/h until rate of 120 mL/h is achieved.

STEP FOUR: BEGIN MONITORING ON NUTRITIONAL SUPPORT**Blood glucose:**

- As infusion is initiated, measure blood glucose every 4 hours.
- If glucose is ≥120 mg/dL, begin administration of exogenous insulin by 'sliding scale', or continuous drip. Consider oral hypoglycemic agents.
- After goal rate is achieved, measure blood glucose every 6 hours.

Daily:

- Serum electrolytes, blood urea nitrogen, creatinine.

Twice weekly:

- Hepatic enzymes (lactate dehydrogenase, alkaline phosphatase, total bilirubin, transaminases)
- 24-hour urine for nitrogen balance
- Serum transferrin or prealbumin
- Serum phosphorus, magnesium, and calcium

reduced hypermetabolism to levels approximating normal.¹⁰¹ Other studies in animals and humans have not confirmed significant amelioration of hypermetabolism with early EN.^{102,103} However, it appears clear that enteral feedings can be started safely within hours of injury in patients of all ages and that doing so reduces the accumulated 'calorie deficit,' improves nitrogen balance and overall nutrition.^{104–106} Duodenal or jejunal feedings can be continued even during surgical procedures without increased risk of aspiration, which facilitates achievement of caloric goals, and may also reduce infectious complications.¹⁰⁷ For all these reasons, tube feedings should be started as soon as practically possible following injury, and certainly within 48 hours. To enhance success, begin feedings at a rate of 20–40 mL/h (as little as 5 mL/hour in infants) and try to reach the therapeutic goal rate within 24 hours; the schedule is similar to that used for TPN in Table 30.5.

Gastric vs. intestinal feeding

Both gastric and intestinal feedings are widely used for delivery of EN; both have advantages and disadvantages. Gastric feeding can be instituted through large-diameter tubes placed blindly, which simplifies early feeding and minimizes clogging. Blenderized diets and intermittent bolus feedings can also be given into the stomach, reducing expense and the inconvenience of infusion pumps. A major disadvantage is the tendency of the stomach to develop ileus, both immediately postburn and in conjunction with sepsis or stress.

Intestinal feeding requires placement of a tube beyond the pylorus. While this can be done blindly, small enteric tubes have been placed inadvertently into the lung, with catastrophic consequences.¹⁰⁸ Many facilities prefer fluoroscopic or endoscopic

tube placement, which is safer but inconvenient. Naso-enteric tubes are small and comfortable, but clog rather easily and often dislodge and migrate into the stomach. It is controversial whether aspiration is more common with gastric vs. intestinal feedings.^{109,110} Any regimen of EN, however, requires careful ongoing monitoring for intolerance and pulmonary complications.

Many clinicians employ 'pro-motility' agents such as metoclopramide, erythromycin, or cisapride in conjunction with enteral nutrition. These agents, particularly erythromycin, may help enteral tubes pass spontaneously into the small intestine and can also ameliorate gastric ileus and feeding intolerance.¹¹¹

Developing a program of nutritional support

Nutritional support can be provided most effectively by developing a comprehensive protocol that involves all members of the burn team and defines their roles and responsibilities. As stated previously, it has been repeatedly shown in ICU populations that adherence to such protocols increases both the success of nutrition and overall patient outcomes.

The level of support required by various patients differs greatly. For each patient, the goal is to provide adequate nutrition using the simplest and most physiological method. All patients need frequent reassessment to assure that they are achieving nutritional goals, to detect complications, and to determine if support can be simplified or if escalation is required. A simple algorithm for determining the level of nutritional support is displayed in Figure 30.3. Applying such an algorithm proactively may prevent problems from developing.

Patients with relatively small injuries (20–25% TBSA) and who are not intubated will generally be able to eat, though it

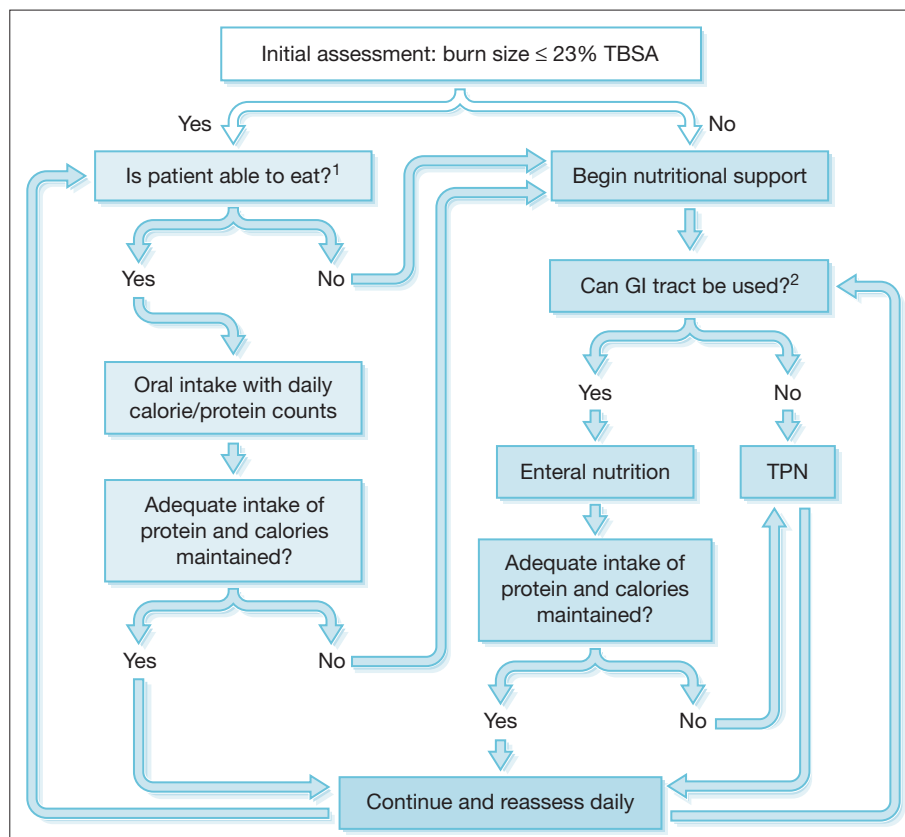

Fig. 30.3 An algorithm for determining the route of nutritional support for burn patients (see text).

¹ On admission, patients may require 3–4 days to tolerate adequate oral intake. Patients who require longer should be considered for nutritional support.

² Patients should be given some enteral nutrition even if they still require TPN for the balance of nutritional support.

may take several days for initial ileus and nausea to resolve. Patients with large partial-thickness burns may have more difficulty due to effects of pain and pain medications. In this circumstance, a few days of inadequate nutrition can be permitted if it appears the patient will soon be able to eat. Patients who are failing to progress with oral intake, who require major surgery, or who develop complications will benefit from the early institution of more formal nutritional support. Early initiation of enteral feeds may actually prevent development of ileus. Patients given TPN should be reassessed frequently for evidence of GI function; patients who cannot tolerate all their nutrition enterally should be given low-rate ‘trophic’ feeds if at all possible. These help preserve small bowel integrity and function, and facilitate gradually increasing enteral nutrition (and decreasing TPN) as the bowel recovers. Similarly, some oral intake should be permitted when possible in patients given enteral nutrition. Oral intake — even sips of liquid — is of great psychological benefit to patients and encourages them to wean from tube feedings quickly as recovery progresses.

Several patient populations merit special consideration in providing adequate nutritional support:

- **Infants/children:** children, like adults, demonstrate increased calorie and protein requirements following burn injury. However, adult enteral products provide high renal solute loads, large protein intakes, and vitamin and mineral levels incompatible with current recommendations for children. Most infants require relatively high fluid volumes and should not receive concentrated formulas; infant formulas are more dilute and generally provide 20 or 24 kcal/oz (0.66–0.8 kcal/mL). Some popular pediatric enteral formulas are compared in Table 30.3. Oral intake in small children is often difficult due to pain, anxiety, and an inability to comprehend the need for adequate intake. Many prefer drinking to eating and offering high-calorie, nutritionally complete fluids is helpful. However, early initiation of enteral nutritional support can meet nutrient needs and reduce the stress associated with pushing oral intake.
- **The elderly:** elderly patients are more likely to have pre-existing nutritional conditions and malnutrition than other adult burn patients.²⁰ Diabetes and its complications — heart disease, poor dentition, etc. — all affect nutritional status and provision of adequate nutrition. Resting metabolic rates decrease with age and may not rise dramatically postburn. Reliance on standard formulas to calculate energy and protein needs will likely result in overfeeding, glucose intolerance, and azotemia. Similarly, many high-protein ‘stress’ products provide excessive intakes of calories and protein for the elderly; using a standard product may be more appropriate in this setting. Examples of such products are included in Table 30.3. The clinician also needs to evaluate the need for restrictions (e.g. potassium, fat) in these patients.
- **Pre-existing conditions:** the increasing prevalence of diabetes, metabolic syndrome, and obesity in Americans affects burn patients as well. Metabolic syndrome (also called syndrome X) is a complex metabolic disorder which includes diabetes, lipid abnormalities,

and hypertension, all associated with insulin resistance, and is often associated with central obesity (‘apple-shaped’ body habitus). The prevalence of syndrome X makes hyperglycemia more common in burn patients, and renders glucose control more difficult.

- **Obese patients** are often falsely presumed to be well-nourished. In fact, they often have poor muscle mass and visceral protein stores, and they continue to need calories for nutrition as metabolic changes limit the body’s ability to utilize stored body fat. Underfeeding will lead to loss of muscle as in other patients. Several formulas exist to estimate calorie needs in obese individuals though the clinical relevance has not been established; indirect calorimetry and nitrogen balance studies can provide more timely information about calorie and protein needs.

Monitoring and complications

Monitoring of nutritional support

Comprehensive nutritional support in burn patients must include ongoing monitoring of its adequacy and success. As mentioned previously, the physiological changes which accompany burn injury render many monitors of nutrition difficult or impossible to interpret. In addition, most of these markers do not correlate highly with outcomes. *Careful assessment of clinical status*, including vital signs, respiratory status, functional improvement, and wound healing, remains the most important aspect of nutritional monitoring. The tests described below are most useful in identifying and monitoring trends (as opposed to point estimates) in nutritional status.

Body weight

Change in body weight is the best predictor of overall nutritional status for the general population, and significant weight loss — particularly rapid and unplanned — is a powerful predictor of mortality.¹¹² However, weight is often misleading in burn patients. Initial fluid resuscitation routinely adds 20–30 kilograms to patients’ weights and much greater increases are common. Theoretically, this fluid will dissipate with diuresis, but the time course for this is unpredictable, particularly if resuscitation volume is high.¹¹³ Fluid increases may mask ongoing loss of lean body mass so that patients can suffer significant inanition and still weigh more than at the time of admission. In addition, fluid shifts associated with infections, ventilator support, hypoproteinemia, and elevations in aldosterone and antidiuretic hormone lead to wide fluctuations in weight that have little to do with nutritional status. Even weeks after injury, patients have increased total body water and have almost always lost more lean body mass than is apparent from weight alone.¹¹⁴ Along with increases in fluid, patients may have increased fat mass without changes in weight. In ICU patients, aggressive TPN did not prevent loss of over 12% of protein mass despite weight gain as fat.¹¹⁵ In burned adults, increasing caloric intake to almost twice measured energy expenditure did not reduce ongoing muscle breakdown; increased caloric intake resulted only in accumu-

lation of body fat.¹¹⁶ In following weights, try to recognize long-term trends more than daily variations, and continue monitoring during the often long rehabilitation phase.

Nitrogen balance

Providing sufficient protein intake is a major goal of nutritional support. Because patients differ widely in their protein requirements, some ongoing monitor of this parameter is desirable. In addition to serum protein measurements (described below), a widely-used test is the assessment of nitrogen balance. Measurements should be obtained at least weekly and require accurate collections of urine for determination of urea nitrogen along with concomitant recording of nitrogen intake. Twenty-four-hour collections are often used, though shorter times can also provide accurate data.¹¹⁷ Nitrogen balance (N_2 bal) can then be calculated by formulas such as the following:¹¹⁸

$$N_2 \text{ bal} = N_2I - (1.25 \times (UUN + 4))$$

where N_2I = 24-hour nitrogen intake.

Most formulas contain two constants, which can introduce significant error to calculations. Urinary urea nitrogen (UUN) is increased by 4g/dL (2g/dL is used for children less than 4 years old, and 3g/dL for children 4–10 years) to approximate total urinary nitrogen (TUN). However, TUN may exceed this value in burn patients,¹¹⁹ leading to underestimation of nitrogen losses. The formula provided also multiplies estimated TUN by 1.25, to account for significant loss of protein-rich exudates from burn wounds. Many formulas which estimate nitrogen balance do not account for it. Actual burn wound losses can exceed these estimates, again leading to overly-optimistic estimation of the adequacy of protein intake. Thus these formulas provide only an approximation of actual nitrogen balance.

Attainment of positive or even neutral nitrogen may not always be possible, especially in the absence of exercise. Inactivity causes muscle wasting and increased nitrogen excretion even in healthy people.¹²⁰ In the early postburn period, patients are often bedridden and sedated, and may even be chemically paralyzed; increasing levels of protein intake only result in increased nitrogen excretion. This emphasizes the importance of a comprehensive, team-based plan of care in which nutritional and physical therapy are equally important in maintaining muscle mass.

Serum proteins

The acute response to burn injury shifts metabolic pathways away from maintenance of visceral proteins often cited as 'nutritional markers.'¹²¹ Albumin, an important indicator of *chronic* nutritional status, is of much less value in assessing *acute* changes. In burn patients, serum albumin levels are both immediately and chronically depressed; even successful nutrition will not produce rising albumin levels for long periods. Administration of supplemental albumin, to improve colloid oncotic pressure and control edema, has not improved clinical or nutritional outcomes.^{122,123}

Some other proteins have been advocated as more useful markers of nutrition. Prealbumin (or transthyretin) has a short half-life, making it theoretically more responsive to nutritional changes.¹²¹ However, prealbumin levels also fall quickly post-

injury, and rebound slowly. Levels may correlate with susceptibility to infection, but may not reflect ongoing nutritional status.^{39,124} Serum transferrin, retinol-binding protein, and others have also been used, but their clinical usefulness appears equally limited.^{53,121,125} Measurement of these proteins may be expensive or not routinely available. Protein markers, if used at all, should be interpreted in the context of patients' clinical condition and, like body weight, evaluated serially to indicate trends.

Other parameters

Abnormalities of immune function and susceptibility to infection are major consequences of malnutrition. In the past, markers of immune competence have been advocated for use in nutritional assessment, including total lymphocyte count⁸² and measurement of delayed-type hypersensitivity (DTH) to antigens injected into the dermis.^{126,127} These markers have not proved very useful, particularly in burn patients. Acute thermal injury is itself profoundly immunosuppressive; anergy can also be produced by infection, old age, or other complicating factors and does not itself constitute evidence of inadequate nutrition.

A number of other parameters should be followed routinely in all patients receiving nutritional support. Burn injury produces accelerated evaporative water losses, so hydration should be monitored closely. Electrolyte abnormalities, and levels of phosphorus, magnesium, and calcium should also be assessed regularly. Liver function abnormalities can result from over-feeding but can also indicate other serious conditions which complicate burn treatment including hepatitis and acalculous cholecystitis. The large protein loads required by burn patients result in increased urinary excretion of nitrogenous wastes and predispose to elevations of blood urea nitrogen. Table 30.5 illustrates a protocol for administration of TPN to a burn patient, including the recommended monitoring of nutritional status.

Some new, technically-advanced methods are now available for nutritional monitoring as well. Bioimpedance analysis (BIA) measures the body's resistance to the passage of electrical currents; from this information total body water, and the body's fat-free cell mass can be calculated.^{128,129} Dual X-ray absorptiometry (DEXA) scanning measures precise absorption of radiation by various tissues; it has been used to measure bone density as well as fat-free mass in clinical studies.¹³⁰ Both of these techniques are currently useful primarily in research but may be utilized more widely in clinical care in the future.

As this information suggests, no single laboratory test is universally applicable or reliable for nutritional monitoring of burn patients. A survey of nutrition practices in 46 burn centers¹³¹ indicated that the most commonly-used parameters were body weight (100% of centers), serum albumin (93%), nitrogen balance (70%), transferrin (41%), and prealbumin (26%). In establishing a nutrition protocol, it remains essential to follow clinical course and wound healing, and it is probably reasonable to monitor at least body weight and possibly one or two indices of protein status, such as nitrogen balance, transferrin, or prealbumin. Other tests probably don't add much additional information, and can be reserved for research studies.

Overfeeding

While almost any disorder of fluids, electrolytes or homeostasis can occur with nutritional support, one of the most frequent complications of modern nutrition is overfeeding. As noted previously, it can be difficult both to estimate the nutrition needed by burn patients and to deliver these nutrients successfully. Nutrition is often inadequate in the early postburn period, a time when ileus and nausea interfere with enteral nutrition, and hyperglycemia complicates both EN and TPN. Aggressive efforts to feed patients in the early postburn period can lead to unintended overfeeding as metabolic rate declines and regimens become more successful. Significant overfeeding, especially for long periods, can produce three major complications.

Increased production of CO₂

As noted above, overfeeding carbohydrates results in fat synthesis, increased VCO₂, and elevation in respiratory quotient (RQ). Patients with ongoing respiratory compromise may demonstrate difficulty weaning from ventilatory support. This problem can be particularly severe with use of TPN.¹³² Regular monitoring of RQ with indirect calorimetry will detect this problem. Nutritional support can be tapered to match measured values, or glucose administration reduced by giving a more calories as fat, or both. If it is possible to switch patients on TPN to enteral nutrition: this may be helpful, though overfeeding of enteral nutrition can occur as well.

Fatty liver

Excess carbohydrate or fat administration leads to deposition of fat in the liver parenchyma.¹³³ Some degree of hepatic enzyme elevation is common in burn patients, and this may also be more pronounced with TPN. Enzymes should be monitored regularly, and feeding evaluated carefully if enzymes become elevated above 2–3 times normal. Pronounced elevations can suggest other disorders (hepatitis, acalculous cholecystitis, etc.), and may be unavoidably associated with sepsis.⁹⁹

Azotemia

The large amounts of protein required by burn patients can lead to elevation of blood urea nitrogen (BUN), particularly if dehydration occurs.¹³⁴ Acute renal failure is one of the most dreaded complications of sepsis, with a persistently high mortality rate. Monitor fluid intake, urine output, and blood chemistries frequently in burn patients who require nutritional support. An increase in BUN in excess of 30% above baseline may indicate relative dehydration or overfeeding of protein, particularly if nitrogen balance is positive; reduce the amount of protein being given. Even in established renal failure, patients continue to require large amounts of protein. Protein restriction should be avoided, even if doing so commits the patient to hemodialysis.¹

Hyperglycemia

Hyperglycemia is extremely common following critical illness. Approximately 10–20% of patients admitted to ICUs have pre-existing diabetes. Far more important, however, is that up to 90% of all ICU patients develop elevated blood glucose values during their hospital stay.¹³⁵ In burn patients, insulin's

effects are overwhelmed by catabolic hormones, causing relative insulin resistance and hyperglycemia which can be both profound and sustained — the 'diabetes of injury.' Prolonged elevations in blood sugar are clearly associated with immune deficiency and increased susceptibility to infection; this may also be true for acute hyperglycemia.¹³⁵ And, since infection exaggerates glucose intolerance, infection and hyperglycemia often potentiate each other.

Recent evidence has emphasized the value of maintaining glucose levels as close to normal as possible. In a landmark study, surgical ICU patients randomized to a regimen of 'intensive' glucose control (maintaining glucose levels at 80–110 mg/dL), compared to more traditional control (180–200 mg/dL) had substantial reductions in multiple organ failure, infection, renal failure, polyneuropathy, length of stay, and mortality.¹³⁶ This experience has been confirmed repeatedly.^{137,138} In addition to lowering blood sugar, insulin exerts a number of beneficial effects of its own, including reducing circulating levels of C-reactive protein and other pro-inflammatory compounds,^{139,140} which may explain some of the benefits shown in these studies.

Thus, meticulous control of blood sugar is emerging as a cost-effective way to improve outcomes in critical care. It is reasonable to assume that similar benefits can be expected in burn care, though there are as yet no large studies in burn patients. Many units are now adopting comprehensive protocols for intensive monitoring and treatment of blood sugar values; an example from our burn center is given in Figure 30.4. Because hyperglycemia is often resistant to therapy, effective glucose control may require substantial insulin doses, glucose monitoring, and nursing time, even in patients not receiving nutritional support. Hyperglycemia is both more common and more severe with TPN as opposed to enteral nutrition, and this alone constitutes a powerful argument for avoiding parenteral nutrition. Reassessing patients' calorie needs (with changes in clinical status and/or over time) and reducing the quantity of infused calories if appropriate is probably the first step in managing hyperglycemia. A number of other adjuncts can contribute to effective blood sugar maintenance as well, including controlling infections, increasing patient activity, and restricting oral intake of sweets. Oral hypoglycemic agents and anabolic agents may ultimately prove to have major benefit in this effort.¹⁴¹ Adherence to strict policies for blood sugar monitoring and control is likely to emerge as a major focus of quality assurance in burn care in the years to come.

Complications of enteral nutrition

Enteral feeding complications fall into two categories: metabolic and mechanical. Major metabolic complications of nutritional support are reviewed in Table 30.6. Mechanical complications include misplaced feeding tubes, gastric distension, nausea, and aspiration. All tube placements should be verified prior to use, and clinicians must monitor gastrointestinal function frequently. Surgically-placed gastrostomy or jejunostomy tubes eliminate problems with tube migration, but are associated with (generally low) risks of dislodgement, leakage, and bowel perforation. Some units add blue dye to tube feeds in an effort to detect aspiration more efficiently. Unfortunately, blue dye has a low specificity and sensitivity

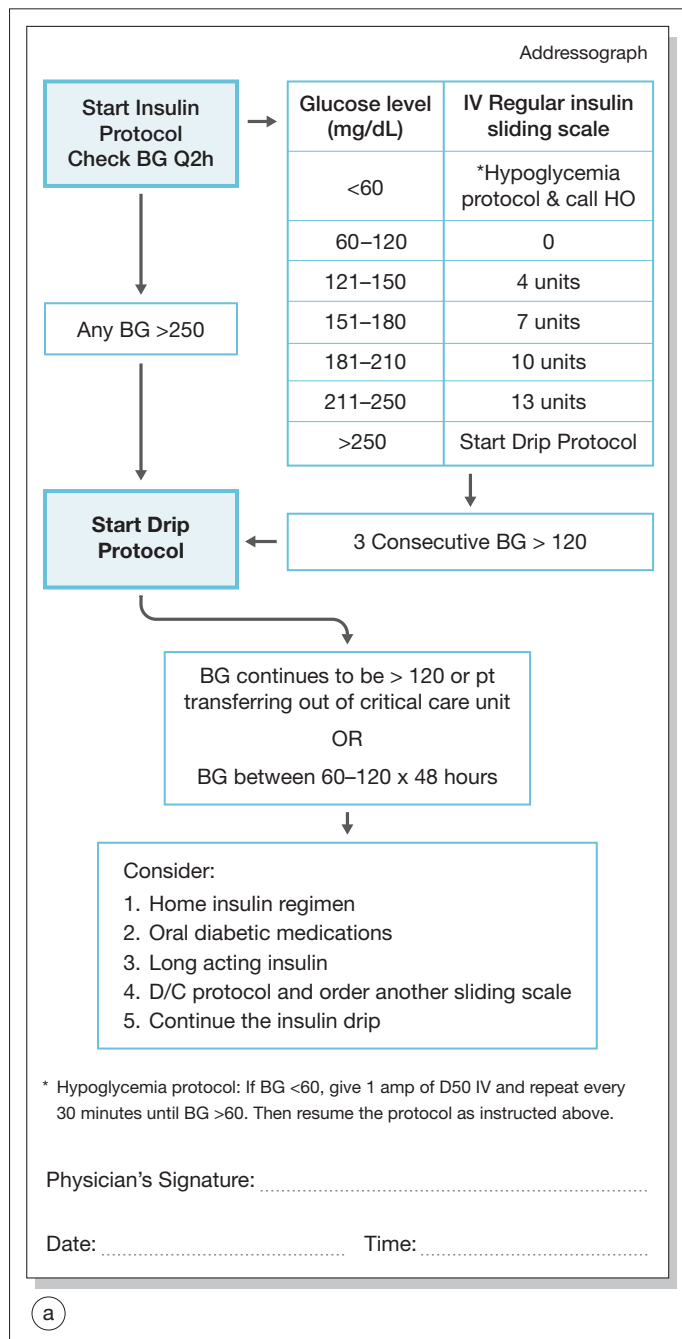

Fig. 30.4 Hyperglycemia Management Guidelines, Burn Intensive Care Unit, University of Utah.

Insulin drip protocol

Step 1: initiate insulin infusion

- Standard insulin drip: Regular insulin 100 units/100 mL of NS
- Give IV bolus as indicated and initiate insulin drip based on the following table:

Initiation of insulin drip protocol only

Blood glucose	Regular insulin bolus	Regular insulin dose
121–140	0 units	1 unit/h
141–169	6 units	1 unit/h
170–249	8 units	2 units/h
250–299	10 units	3 units/h
300–399	10 units	4 units/h
400–500	10 units	5 units/h
>500	10 units	6 units/h

Important note:

All patients receiving IV insulin drip therapy must have a continuous source of glucose (continuous tube feeds OR TPN unless ordered by MD)

Step 2: monitoring

- Check BG Q1h timed such that BG are checked 1 hour after drip initiation or rate change.
- If 3 consecutive BG within 80–120 with no change in therapy, reduce checks to Q2h.
- Then, if 3 consecutive BG within 80–120 with no change in therapy and insulin rate is ≤ 2 units/h, reduce checks to Q4h.

Step 3: ongoing infusion

- Make adjustments based on the following table:

Blood glucose	Infusion rate adjustment
<60	Hold drip. Give 1/2 amp D50. Recheck Q30min, repeat 1/2 amp D50 until BG >60
60–79	Hold drip. Check BG in 1 hour. <i>if BG >80, restart at 1/2 rate prior to holding drip</i>
80–120	No change
121–140	↑ rate by 0.2 unit/h
141–170	↑ rate by 1 unit/h
171–250	Give 8 units regular insulin bolus and ↑ rate by 1 unit/h
>250	Give 10 units regular insulin bolus and ↑ rate by 1 unit/h

Note: If blood glucose <60 on glucometer send sample to the lab for measurement per policy

Step 4: important nursing information

- If BG decreases by ≥ 100 mg/dL from previous level, ↓ rate by 1/2 and recheck in 1 hour.
- If BG ≤ 150 mg/dL and subsequent level decreases by ≥ 30 mg/dL, ↓ rate by 1/2.
- If patient's enteral or parenteral nutrition is discontinued, hold insulin drip and check BG Q2h and restart sliding scale on previous page.

Step 5: discontinuation

- After insulin drip is discontinued, check BG Q2h.
- Begin appropriate insulin sliding scale and/or oral diabetic agents (i.e. home regimen).

An adequate physician order is 'Insulin per Protocol'. Reference protocol copies will be available on the units.

b

TABLE 30.6 METABOLIC COMPLICATIONS OF NUTRITIONAL SUPPORT (PARTICULARLY TPN)

Complication	Description/cause	Frequency	Severity	Diagnosis/treatment
Hyperglycemia	Occurs to some degree in almost all patients on nutritional support; more common and more severe with TPN. Any nutritional support regimen should be started slowly, and monitored regularly	Common	Moderate to very severe	Blood glucose <i>must</i> be monitored regularly in all patients. Insulin added to TPN solution can be helpful; patients may also require a rigorous protocol using supplemental insulin and oral hypoglycemic agents. Sustained hyperglycemia may require slowing/holding TPN until controlled
Hyperosmolarity	Occurs almost exclusively with TPN: prolonged hyperglycemia can cause dehydration, mental status changes; coma	Rare	Can be life-threatening	A complication of untreated hyperglycemia. Close attention to glucose control should prevent this. Treat by stopping TPN, hydrating, controlling glucose
Hyperkalemia	Excessive administration of potassium; often occurs when a 'standard' electrolyte solution is added to TPN without considering patient-specific issues (i.e. renal failure)	Uncommon	Can be life-threatening	Routinely monitor potassium, especially during initiation of TPN. Occurs in association with hyperglycemia, renal dysfunction, sepsis. Severe hyperkalemia (≥ 6.0 mEq/L) causes T-wave elevation, can be fatal. This is a medical emergency, and mandates discontinuation of TPN, or change to a low-potassium enteral formula
Hypokalemia	Low serum potassium. Can occur if electrolytes are not added during TPN ordering. The institution of TPN causes uptake of potassium and sudden hypokalemia. This occurs along with hypophosphatemia and hypomagnesemia — the 'refeeding' syndrome	Uncommon	Moderate to serious	Routinely monitor potassium, especially during initiation of TPN. Institution of aggressive glucose control can cause this. Can cause weakness arrhythmias. Treat by potassium supplementation. Magnesium deficiency can contribute to hypokalemia as well
Hyponatremia/fluid overload	Occurs usually when dilute solutions are used for TPN. Can result in pulmonary failure, ascites, edema. Use of 'peripheral' TPN requires large fluid loads, particularly in children, and should be avoided. Additional fluids given with antibiotics and resuscitation can compound this problem	Moderately common	Moderate to serious	Monitor intake/output, serum sodium. Nutritional support in renal failure should be continued, but may require more frequent dialysis. Severe hyponatremia from any cause must be corrected gradually (≤ 0.5 mEq/L/hour) to avoid severe neurologic complications
Hypernatremia/dehydration	Can occur when insufficient free water is given. Burn patients may have significant requirements over and above the fluids required for TPN	Moderately common	Moderate to serious	Monitor intake/output, serum sodium. Additional free water can be added to TPN or given separately. Persistent hyperglycemia causes obligatory diuresis and dehydration
Hypermagnesemia	Presents with lethargy, weakness, prolongation of P-R and Q-T, AV-block	Rare	Moderate to serious	Usually occurs in the setting of renal failure
Hypomagnesemia	Presents with perioral tingling, weakness, tetany, arrhythmias. Magnesium is consumed during protein synthesis, and institution of nutrition, particularly TPN, can precipitate hypomagnesemia — the 'refeeding syndrome'. Diuretics also cause this	Moderately common	Moderate to serious	Monitor magnesium routinely, especially during institution of nutritional support. May require substantial supplementation

TABLE 30.6—cont'd

Complication	Description/cause	Frequency	Severity	Diagnosis/treatment
Hyperphosphatemia	Usually occurs in the setting of renal failure	Uncommon	Moderate	Renal dysfunction may require removal of all phosphate from TPN and use of phosphate binders, or change to a low-phosphate enteral formula
Hypophosphatemia	Presents with weakness, particularly of jaw muscles, lethargy, obtundation. Often occurs early postburn even without nutrition, but phosphorus is consumed into protein with TPN — part of the 'refeeding syndrome'	Common	Moderate	Monitor phosphorus levels routinely, especially during institution of nutrition. Patients may require frequent monitoring and supplementation
Trace element deficiency	Copper deficiency can cause anemia and neutropenia; zinc deficiency causes skin lesions, hair loss, impaired immunity. Deficiencies of selenium, cobalt, manganese, and others have been described	Rare	Moderate to serious	Trace element deficiencies usually occur only with prolonged TPN. Standard trace element 'packages' contain more than enough for maintenance. Blood transfusions also contain significant amounts of copper, chromium, and some others
Vitamin deficiency	A variety of vitamin deficiencies have been described, almost exclusively in patients on long-term TPN	Rare	Moderate to serious	Fat-soluble vitamins (A, D, E, K) and water-soluble 'B' vitamins should all be included in standardized vitamin 'packages' for TPN supplementation. Individual vitamins can be given as well
Essential fatty acid deficiency	Presents with malabsorption/diarrhea, dry skin, anemia, thrombocytopenia. Hyperinsulinemia prevents fatty acid mobilization, so deficiency can develop in as little as 10 days of TPN	Uncommon	Moderate to severe	Use of medium-chain triglycerides (MCTs) do not prevent this, but modern lipid solutions contain long-chain triglycerides as well. Lipid emulsion should be given at least once weekly
Fatty liver dysfunction	Presents with hepatomegaly, right upper quadrant pain, and elevation of hepatic enzymes. May occur to a mild extent in many patients, but becomes worse with prolonged overfeeding and TPN; can lead to cirrhosis	Common	Mild to severe	Avoid overfeeding, particularly fats. Monitor liver enzymes routinely. More common and more severe in septic patients

for detecting aspiration. Reports of blue dye-associated mortality have led the FDA and others to recommend eliminating blue dye for this purpose.¹⁴²

Bowel necrosis and perforation

Several reports have documented bowel necrosis and perforation as a rare complication of enteral nutrition in the critically ill, including burn patients.^{143,144} It is likely that continued administration of tube feedings in the face of decreased bowel motility causes distension, interfering with intestinal blood supply. Bacterial overgrowth of stagnant tube feedings, and administration of narcotics and antidiarrheal agents also contribute to this complication.⁸⁹ Fever, leukocytosis, tachycardia, and abdominal distension may precede frank peritonitis. Abdominal CT scanning can confirm perforation, which man-

dates laparotomy, and usually intestinal resection. Mortality rates approximate 50%.¹⁴⁴

Diarrhea

Tube feedings are frequently blamed for diarrhea, which can range from a minor problem, to a major source of patient discomfort, morbidity, fluid and electrolyte imbalance, and other complications. Often the cause is multifactorial.¹⁴⁵ The high glucose loads of hypertonic tube feedings may contribute to diarrhea, though diluting feedings has generally not proved helpful in treatment. Enteral medications including antacids, phosphates, antibiotics, and others contribute to diarrhea as well. Infectious causes include cytomegalovirus infection¹⁴⁶ and pseudomembranous colitis caused by *Clostridium difficile*.¹⁴⁷ A prospective study found an association between the

concentration of fat in tube feedings and the incidence of diarrhea;¹⁴⁸ diarrhea was reduced in a group of children fed a low-fat ‘immune-enhancing diet.’⁶⁹ Because the gut’s tolerance of tube feedings is limited, diarrhea is increased with over-feeding, and can be controlled by reducing infusion rate.

A variety of compounds have been suggested for treatment of diarrhea, including opiates (Imodium™, Lomotil™, Paregoric, etc.), bulk agents (Metamucil™), and others. Some clinicians advocate use of fiber-containing tube feedings to reduce this complication. Fiber is a normal component of nutrition, and its presence may help prevent bacterial overgrowth and stasis.¹⁴⁹ However, these compounds have also been blamed for intestinal stasis and bowel necrosis.¹⁵⁰ In addition, fiber-containing feedings sometimes clog small-diameter tubes. In our experience, attempts to control diarrhea with medications are frequently either ineffective or lead to constipation and distension. Infectious diarrheas may be worsened by slowing intestinal transit. Most diarrhea is self-limited and does not require pharmacological therapy. Try altering the tube formula, stopping enteral medications, reducing the infusion rate, or simply waiting a day or two. It may be necessary to hold feedings temporarily to permit refractory diarrhea to resolve, then restart them gradually. Diarrhea unresponsive to simple measures should prompt evaluation for an infectious source inside or outside the bowel.¹⁵¹

Complications of parenteral nutrition

Technical complications of TPN are those associated with line placement and maintenance. These complications can be life-threatening, and demand close attention to protocols for line care. Complications occurring at the time of line placement include pneumothorax, hemothorax, pericardial tamponade, hydrothorax, and catheter misplacement. These complications can also occur later if lines erode through venous structures.

Indwelling central venous lines can cause hemorrhage or air embolism if disconnected inadvertently. In addition, central lines can develop serious infections, including catheter sepsis, septic thrombophlebitis, and even endocarditis; not surprisingly, these infectious complications are more common when catheters are placed through cutaneous burn wounds.¹⁵² Central lines used for TPN are particularly prone to infectious problems, and risk is increased if lines are left in place for long periods, and if they are used for multiple purposes (blood draws, hemodynamic monitoring, antibiotics, maintenance fluids, etc.). Consider changing central venous catheters — especially TPN lines — in any patients with persistent, unexplained fevers, or other evidence of infection.

Metabolic complications of TPN can be both severe and difficult to treat. Because TPN often represents the only fluid and electrolyte therapy given to patients, the body’s ability to compensate for deficiencies/excesses is severely limited, which can allow almost any disorder of electrolyte or vitamin deficiency or excess to develop. In addition, a number of common complications of any nutritional regimen can be either more frequent or more severe when associated with TPN use as opposed to enteral nutrition. Such complications are outlined in Table 30.6.¹⁵³

Conclusion

Although nutritional support following a major burn continues to evolve, several aspects are clear. Enteral nutrition and high protein intake are important, though there is no ‘one-size-fits-all’ solution — needs vary with each individual, and change throughout the course of care. A thorough protocol involving all team members that includes ongoing and systematic assessment can tailor support to changing needs, and provide optimal care to every patient.

Prevention of infection, excision, and early closure of burn wound	426
Pharmacological modulation	428
Possible future pharmacotherapeutic options	429
Gene profiling for the future	430

Introduction

Severe thermal injury leads to a change in patient metabolism that may be seen for more than 12 months after the initial event. The ensuing period of hypermetabolism and catabolism following a burn leads to impaired immune function, decreased wound healing, erosion of lean body mass, and hinders rehabilitative efforts delaying reintegration into normal society. Strategies for attenuating this maladaptive response may be divided into pharmacological and non-pharmacological. Non-pharmacological approaches include prompt, early excision and closure of wounds, pertinacious surveillance for and treatment of sepsis, early commencement of high-protein, high-carbohydrate enteral feeding, elevation of the immediate environmental temperature to 31.5°C ($\pm 0.7^\circ\text{C}$); and early institution of an aerobic resistive exercise program. Several pharmacotherapeutic options are also available to further reduce erosion of lean body mass; these include anabolic agents such as recombinant human growth hormone (rhGH), insulin, and oxandrolone and also beta blockade using propranolol. This chapter will discuss the metabolic changes seen following a major burn and how different treatment options effect outcome (Figure 31.1).

Metabolic alterations following burn injury

The hypermetabolic response

Severe burns lead to a hypermetabolic response far in excess of that seen in any other disease state.¹ Patients admitted with

multiple traumatic wounds have an increase in metabolic rate that rises further when placed on a ventilator to between 30 and 75% that of normal.^{2,3} However, those admitted with burns involving more than 40% of the total body surface area (TBSA) have increases in metabolic rate of between 80 and 200% of normal, leaving the patient with a nitrogen deficit of up to 30g/day.⁴ Initially, over the first 3 days, there is a reduction in metabolic rate — called the ‘ebb’ phase; this is followed by an increase in metabolic rate that lasts for more than 9 months after the burn injury.⁵ The hypermetabolic or ‘flow’ phase is characterized by a hyperdynamic circulation,⁶ increased core temperature,⁷ increased oxygen and glucose consumption,^{8,9} carbon dioxide production,⁹ glycogenolysis,¹⁰ lipolysis,¹¹ proteolysis,^{12,13} and futile substrate cycling.^{14,15} The intensity of the response is dependent on the percentage TBSA burned, body weight at admission, and time from injury to excision of eschar.¹⁶ Moreover, the magnitude of the ensuing catabolic process is dependent on the severity of the hypermetabolism and development of sepsis during hospital stay.¹⁶ The resting metabolic rate of patients with large burns increases in a curvilinear fashion from close to normal predicted levels for TBSA < 10% to twice that of normal predicted levels at 40% TBSA and above. In those patients with burns greater than 40% TBSA the resting metabolic rate at thermal neutrality (33°C) reaches 180% of predicted basal rate during their acute admission, this reduces to 150% once the wounds are fully healed, 140% at 6 months after injury, 120% at 9 months postburn, and 110% after 12 months (Figure 31.2).⁵

This rise in metabolic rate and resulting loss of total body protein results in decreased immune defenses, decreased wound healing, and exhaustion, which hinders rehabilitation.⁵

Mediators of hypermetabolism

The cause of the hypermetabolic response is unclear; however, endotoxin, platelet-activating factor, tumor necrosis factor, interleukins 1 and 6, arachadonic acid metabolites using the cyclooxygenase and lipooxygenase pathways, neutrophil-adherence complexes, reactive oxygen species, nitric oxide and the coagulation and complement cascades have all been implicated in regulating this response.¹⁷ More recently the cortisol releasing factor (CRF) type-2 receptor ligand had been

Fig. 31.1 Major burn injury.

proposed as integral to maintenance of the hypermetabolism associated with burns.¹⁸

The change in regulation of skeletal muscle during the stress response following major trauma is due to the activation of pathways of protein breakdown. Recent studies have shown one of the chief protagonists to be the ubiquitin-proteasome pathway.¹⁹ Ubiquitin is a common 8 kDa peptide found throughout all eukaryotic cells (hence the name). During skeletal muscle degradation it is activated in a stepwise process to covalently attach to other proteins, reducing their ability to disassociate from proteasomes and subsequently leading to degradation of the protein it has attached to. Ubiquitin has seven lysine residues, the use of which confers different functions. Chains of ubiquitin peptides linked via lysine 48 lead to degradation of the target protein by the proteasome.²⁰ However, those linked by lysine 63 appear to confer signaling functions in the nuclear factor-kappaB (NF- κ B) pathway,^{21,22} and act as mediators in DNA repair²³ and the stress response.²⁴ The role of ubiquitin peptides linked by other lysine residues is still unclear. The ubiquitin pathway is stimulated by TNF and the rise in glucocorticoids seen following severe thermal injury.²⁵ The other main reason for the net loss of skeletal muscle is due to an imbalance in the rate of amino acid production secondary to protein breakdown and the ability of the cell to retain and reuse these amino acids.²⁶ A study comparing the protein turnover in patients suffering from massive burns with that in normal individuals found an increase in both muscle protein degradation and muscle protein synthesis in the burns group. However there was an 83% increase in muscle protein degradation compared with a 50% increase in muscle

Fig. 31.2 (a) Association between admission weight and negative protein balance. Data presented as mean \pm SEM.¹⁶ (b) Association between time to primary wound excision and negative protein net balance. Data presented as mean \pm SEM.¹⁶ (c) Influence of burn size $>0.40\%$ total body surface area on catabolism. Data presented as mean \pm SEM. * $P = 0.0001$ by Student's t test.¹⁶ (d) Resting energy expenditure. Indirect calorimetry was used to measure energy expenditure in a resting state at admission, full healing, and 6, 9, and 12 months after burn. At all time points, the energy expenditure was higher than the basal metabolic rate predicted for age-, sex-, weight-, and height-matched individuals by the Harris-Benedict equation. Error bars represent 95% confidence intervals. (Figures (a-c) reproduced with permission from Hart et al.¹⁶ Ann Surg 2000; 232(4):455-465. Figure (d) reproduced with permission from Hart et al.⁵ Surgery 2000; 128(2):312-319.)

protein synthesis. In the same study they found that the absolute values of inward transport of phenylalanine, leucine, and lysine were not significantly different in the two groups. However, the ability of transport systems to take up amino acids from the bloodstream, as assessed by dividing inward transport by amino acid delivery to leg muscle, were 50–63% lower in the patients. In contrast, outward phenylalanine and lysine transport were 40% and 67% greater in the patients than in the controls, respectively.²⁷ These results suggest that the increased protein synthesis seen is secondary to the rise in amino acid concentration; however, this synthetic rate is unable to keep up with the acceleration in protein breakdown. The increased net efflux of amino acids from the cell is facilitated by accelerated outward transmembrane transport and impaired influx due to the hyperdynamic circulation caused by the rise in catecholamine release.²⁷

Hormonal changes seen following trauma

Cortisol levels increase in response to stress in patients, this increase is accompanied by an increase in cortisol binding in skeletal muscle. In a recent study we identified a rise in cortisol following a major burn injury (>40% TBSA); this rise was greater in male patients, but both male and female patients returned to near-normal cortisol levels at around 3 months following injury. The significance of adrenal and sympathetic response to burn injury is described in more detail in the previous chapter, including the hyperdynamic circulation, peripheral lipolysis and increases in fatty infiltration of the liver. These responses can be attenuated by the use of β -adrenergic receptor antagonists such as propranolol.

Alterations in metabolism of carbohydrate, protein and fat

The increase in energy expenditure is mirrored by substrate oxidation resulting from increases in ATP consumption. Increases in catecholamine, glucagon and glucocorticoid production lead to enhanced glycogenolysis and protein breakdown in both the liver and skeletal muscle. This in turn leads to increases in triglyceride, urea and glucose production (gluconeogenesis) which consequently leads to hyperglycemia. The process of substrate cycling leads to increased thermogenesis¹⁴ which raises core and skin temperature to 2°C above that of normal, unburned patients. Raised catecholamine levels also increase peripheral lipolysis and subsequent triglyceride-fatty acid cycling, leading to fatty infiltration of the liver such that the liver weight increases by 120%. This has been associated with an increased incidence of sepsis; however, no causative effect has been found (Figure 31.3, Table 31.1).²⁸

A large proportion of the glucose produced by the liver is directed towards the burn wound, where it is consumed by anaerobic metabolism of inflammatory cells, fibroblasts, and endothelial cells; this in turn produces lactate, which is recycled back to the liver and into gluconeogenic pathways. The catabolism of protein in skeletal muscle produces three-carbon amino acids such as alanine that are also recycled to the liver to contribute to gluconeogenic pathways. The release of catecholamines increases glucagon secretion, which in turn promotes gluconeogenesis. The relative insulin resistance seen

Fig. 31.3 Significant enlargement of the liver and fatty deposition therein are common findings in severe and fatal burns. (Reprinted with permission from Barret JP, Herndon DN, eds. Color atlas of burn care. London: WB Saunders; 2001:133, Plate 8.38.)

TABLE 31.1 LIVER WEIGHT PER BODY WEIGHT FOR NORMAL VS. BURNED PATIENTS (2 MONTHS TO 15 YEARS OF AGE)

	Full-thickness burn (%)	Liver wt/BW (g/kg)	Weight increase (%)
Normal (n = 14)	0	34.3 ± 1.1	
Burn (n = 14)	76 ± 5	75.6 ± 6.0*	120

Burn size and liver weight ratios are means ± SE.
BW = body weight.
*Significant difference at $p < 0.001$.

following a major burn combined with increased hepatic gluconeogenesis leads to hyperglycemia;¹⁰ patients in this situation have been shown to have an increased rate of muscle protein breakdown.²⁹ A study measuring whole body protein flux in normal individuals showed a three-fold increase in the rate of protein catabolism with no accompanying alteration in protein synthesis during a period of hyperglycemia.³⁰ Endogenous anabolic hormone levels change with both IGF-I and IGFBP-3 significantly lower immediately after burn, and neither reaching normal levels after 40 days postburn. Serum insulin levels are significantly increased during the same time period with female patients producing up to 3 times normal levels; however, in the presence of insulin resistance, hyperglycemia remains a problem. Endogenous growth hormone levels also fall 4–5-fold initially and remain below half the normal level during the first 40 days. The result of these levels combined with relative insulin resistance in the burns patient leads to a marked reduction in protein synthetic ability which can only be reversed by restoration of more normal levels from an exogenous source.

Nutritional support

Patients with burns greater than 40% TBSA can lose up to 25% of their body weight in the first 3 weeks following injury if sustained on an oral diet alone. Numerous formulae have

been developed to calculate the requirements of each patient; the caloric requirement is based on size of burn, the total surface area of the patient, the presence or not of sepsis and body weight: $25 \text{ kcal/kg/day} + 40 \text{ kcal/\%TBSA/day}$ would provide enough calories to maintain body weight in an adult patient; for children the requirement is $1800 \text{ kcal/day} + 2200 \text{ kcal/m}^2 \text{ burn/day}$. Ideally this calorific intake should be all via enteral feeding, with parenteral feeding held in reserve for those with prolonged ileus or intolerance of enteral feeding.

Methods

Parenteral vs. enteral

The route of delivery of nutrition is just as important as the composition. Early enteral nutrition is associated with reduced postoperative septic morbidity rates compared with those administered by parenteral nutrition alone.³¹ An increase in mortality, impairment of liver function and reduced immune response has been shown when using both enteral and parenteral feeding combined to reach caloric intake when compared with enteral feeding alone.^{32,33} The use of total parenteral nutrition (TPN) in burns patients increases mortality three-fold and decreases the amount of enteral calories that are tolerated.^{32,33} Therefore it may only be used in the presence of mitigating circumstances where enteral feeding is not feasible such as Ogilvie's syndrome, bowel obstruction, ischemic enterocolitis or a protracted ileus. An attenuation of the catecholamine response and maintenance of gut mucosal integrity with consequent reduction in bacterial translocation has been shown with immediate enteral nutrition but not with parenteral nutrition. The associated risk of vomiting, reported as 2.8% in one study, was not linked to any increase in aspiration pneumonia.

Gastric vs. intestinal feeding

The ileus associated with severe thermal injury is not as common as previously thought; that which derives from mesenteric hypoperfusion prior to adequate resuscitation is reversed once the patient is suitably volume replete. Postburn ileus does not affect the small bowel as profoundly as the stomach. Therefore feeding using a nasoduodenal tube passed through the pylorus, or a nasojejunal tube advanced past the ligament of Treitz, can be initiated as soon as possible and preferably within the first 6 hours following injury (Figure 31.4).^{34,35} This approach also allows continuous feeding during operations and physical therapy sessions. The initiation of immediate enteral feeding allowed the delivery of calculated caloric requirements by the third day postburn.³⁶ Other studies have shown a reduction in hypermetabolism when enteral feeding is commenced immediately after burn injury; this reduction in metabolic rate was associated with prevention of elevations in glucagon, cortisol, and catecholamines.³⁷

Specific requirements

All patients with a significant burn require increased caloric intake and are placed on a high-protein, high-carbohydrate diet. Those with burns in excess of 30% TBSA should be

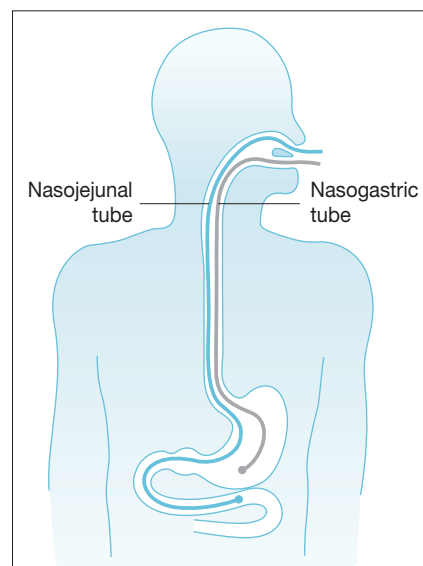

Fig. 31.4 Diagram showing position of nasogastric and nasojejunal tubes.

Fig. 31.5 Measuring resting energy expenditure by the bedside.

placed on tube feeds to allow for constant feeding in the initial period. In order to calculate the caloric requirements of each patient, resting energy expenditure (REE) is measured directly at the bedside by indirect calorimetry using portable calorimeters. The mode of testing should be via ventilator, mouth-piece, mask, or canopy³⁸ (as shown below) and carried out by trained personnel as per the AARC Clinical Practice Guidelines.³⁹ Oxygen consumption and carbon dioxide production are measured and used to calculate the energy expenditure (Figure 31.5).⁹

In pediatric patients with burns in excess of 40% TBSA receiving 1.4 times the measured resting energy expenditure (MREE in $\text{kcal/m}^2/\text{day}$) the body weight is maintained. Optimum nutritional support in a convalescent burns patient should be 1.2 times the MREE.⁴⁰ Any increase in caloric delivery above 1.4 times the MREE results in additional weight gain though solely due to fat deposition (Figure 31.6).⁴¹

In the absence of access to indirect calorimetry there are other formulas to estimate the caloric needs of a burns patient; unfortunately, these normally overestimate the needs considerably. A recent comparison of three such formulas with MREE found that the World Health Organization

× 2 multiplier (WHO × 2) was the closest to MREE × 1.3 (Table 31.2).⁴²

Two of the above equations are then multiplied by a factor to take into account the increased energy requirements due to the burn: WHO × 2 and Harris–Benedict × 2. The Mayes formulas take the burn into account at the original calculation.

- The Galveston formula for estimating caloric requirements in pediatric patients is derived from retrospective analyses of dietary intake, which was associated with maintenance of body weight averaged over hospital admission (Table 31.3).
- The Curreri formula used in Galveston for the calculation of energy requirement in adult patients has been reached following linear regression analysis of weight change vs. predicted dietary intakes in adults at 25 kcal/kg/day + 40 kcal/%TBSA/day⁴³ (Table 31.4).

Carbohydrates

protein) stimulates protein synthesis secondary to increases in endogenous insulin production and improves lean body mass accretion, relative to isocaloric-isoprotein but high-fat enteral diet.⁴⁴ We have reduced the delivery of high-fat diets in our patients due to those findings. We also aim to reduce substrate for lipolysis and the subsequent generation of fatty deposition in the liver, a serious problem in burns patients.

Protein

Sufficient protein intake is vital to maintain lean body mass as the rate oxidation of most amino acids in burned patients can reach as high as 50% higher than rates seen in healthy individuals in a fasting state. Therefore raising protein intake by more than 50% from 1g/kg/day to between 1.5 and 2g/kg/day will ensure adequate supply in adults; the same cannot be said for children, however, who may increase urea production without any beneficial anabolic effect. One study in burns patients showed that a balance between protein synthesis and catabolism could be achieved with a protein intake of 1.4g protein/kg/day.⁴⁵ Additional delivery of protein above 1.5g/kg/day has been shown to only increase urinary excretion of urea.⁴⁶

Particular attention must however be paid to supplementation of amino acids in the diet of those patients with severe burns. Leucine, important in signaling the initiation of protein synthesis,⁴⁷ is oxidized at an increased rate in critically ill patients.⁴⁵ Acute administration of leucine initiates cellular protein synthesis by its activation of the mammalian target of rapamycin (mTOR) cell-signaling pathway; however, a recent study in rats has shown that chronic administration of leucine, via drinking water over 12 days, led to an increase in protein synthesis in adipose tissue, skeletal muscle, and liver without notable adaptive changes in signaling proteins or metabolic enzymes.⁴⁸ Myocardial dysfunction, a common problem associated with severe burns, has been shown to be reversed at least in part by oral administration of leucine in the early postburn period. Enteral glutamine supplementation in adult burn patients has been shown to result in reduced positive blood cultures by a factor of three, prevent bacteremia with *Pseudomonas aeruginosa*, and may decrease mortality rate. However, it had no effect on level of consciousness and did not appear to influence phagocytosis by circulating polymorphonuclear cells.⁴⁹

New areas of development in nutrition for burns

Fat

A novel enteral feed containing an altered lipid profile and enhanced antioxidants moderated the severity of the initial inflammatory response in the lungs of patients developing acute respiratory distress syndrome (ARDS), a common problem among burns patients with smoke inhalation injury. The beneficial effects of the eicosapentaenoic acid, gamma-linolenic acid diet on pulmonary neutrophil recruitment, gas exchange, requirement for mechanical ventilation, length of intensive care unit stay, and the reduction of new organ failures suggest that this enteral nutrition formula would be a useful adjuvant therapy in the clinical management of patients with or at risk of developing ARDS.⁵⁰ However, a follow-up study showed that although enteral nutrition with the experi-

mental diet for at least 4–7 days did not reduce oxidative stress as measured, it did restore plasma levels of beta-carotene and alpha-tocopherol to normal or higher levels and appeared to protect ARDS patients from further lipid peroxidation.⁵¹

Micronutrients/vitamins

Burns patients have been shown to suffer significant trace element deficiencies involving predominantly copper, iron, selenium, and zinc.⁵² Early trace element supplementation has been shown to be beneficial in a study involving patients with burns greater than 40% TBSA. It was associated with a significant decrease in number of bronchopneumonia infections and shorter length of hospital stay.

Altered copper levels seem to be of particular importance in the burn patient. Through its interaction with enzymes such as lysyl oxidase, copper is essential in collagen synthesis and therefore wound healing. It also takes part in antioxidant defense via its action on superoxide dismutase.⁵³ Ceruloplasmin, an acute phase protein induced by IL-1 and IL-6, is normally in short supply during times of copper deficiency and both normally increase in concentration in response to stress. However, following a severe burn of >30% TBSA, copper is lost in large quantities through the burn wound, resulting in a 20–40% reduction from normal levels within the first week postburn.⁵⁴ The copper deficit may remain for many weeks and is inversely proportional to burn size.⁵⁵ Copper deficiency is further associated with the use of silver sulfadiazine, a commonly applied topical agent in burns, is antagonistic to the actions of copper, and further reduces serum concentrations.⁵⁶ Zinc, long known as essential to wound healing, particularly for ulcers, is an indispensable supplement in burns nutrition, although the quantities needed have yet to be clarified. Carbonic anhydrase, DNA and RNA polymerases and proteases all rely on zinc to play a central role in their efforts to improve wound healing and tissue regeneration.⁵⁷ Supplements containing copper and zinc have been shown in an animal model that, given following early wound excision, reduced lipid peroxidation and subsequently the quantities of lipid peroxide delivered to distant tissues.⁵⁸

A study looking at the presence of trace elements in burn wounds found increased levels of manganese, a trace element involved in mucopolysaccharide and glycoprotein synthesis, as well as in the mitochondrial antioxidant defense (Mn SOD), indicating that its antioxidant function might be important during wound healing.⁵⁹

Environmental support

A proportion of the energy generated during the hypermetabolic response is to offset heat losses secondary to evaporation through the burn eschar; this loss of body water can be up to 4000mL/m² TBSA/day. The body tries to raise the core and skin temperature by 2°C secondary to a hypothalamic reset mechanism similar to that seen in cold acclimatization. Therefore the hypermetabolic response may be reduced by warming the ambient temperature to thermal neutrality (33°C) at which point the heat for evaporation is derived from the environment, taking the burden away from the patient. Raising the immediate environmental temperature can reduce the

Fig. 31.7 Effect of ambient temperature on metabolic rate. (Reproduced with permission: Herndon DN. Mediators of metabolism. *J Trauma* 1981; 21:701–705.)

Fig. 31.8 Heating panel shown suspended from the ceiling in an intensive care room. (Reprinted with permission from Barret JP, Herndon DN, eds. *Color atlas of burn care*. London: WB Saunders; 2001:150, Plate 9.48)

magnitude of the hypermetabolic response from 2.0 to 1.4 times the resting energy expenditure in burns >40% TBSA⁶⁰ (Figures 31.7 and 31.8).

Exercise

Initial excision and grafting, followed by prompt treatment of infection and sepsis together with early enteral feeding, are all integral parts of immediate interventions for a patient with severe burns. However, once past the initial acute phase, patients enter into a long period of rehabilitation that normally includes reconstructive operations to increase movement and allow the patient a more normal life. The early institution of a balanced physical therapy program is essential in reducing contractures and restoring metabolic variables. Progressive resistance exercises in convalescent burn patients can maintain and improve body mass, augment incorporation of amino acids into muscle proteins, and increase muscle strength and ability to walk distances by about 50%.⁶¹ It has been demonstrated that resistance exercising can be safely accomplished

Fig. 31.9 Some of the exercise equipment used for the supervised exercise training program.

in pediatric burn patients without exercise-related hyperpyrexia due to inability to dissipate the generated heat.^{62,63} In a recent study one group participated in a 12-week in-hospital physical rehabilitation program supplemented with an individualized and supervised exercise training program while the other group participated in a 12-week, home-based physical rehabilitation program without individualization and supervision of exercise. The results showed a significant improvement in muscle strength, power, and lean body mass in the hospital-supervised exercise group (Figure 31.9).⁶²

Prevention of infection, excision, and early closure of burn wound

Early excision and grafting

Of all the changes over the last few decades in burns treatment it is the introduction of expeditious removal of full-thickness burn wounds that has had the greatest impact on survival and outcome. Conservative treatment of large full-thickness burn wounds followed by skin grafting is a lengthy process associated with a not inconsiderable burden of pain and suffering, severe metabolic derangement, and increased septic episodes, and results in an increased length of hospital stay. Several studies have shown attenuation of the hypermetabolic response in patients of all ages.^{64,65} Early excision together with aggressive enteral feeding has also been shown to be effective in reducing muscle catabolism and improving infectious outcomes in pediatric patients.⁶⁶

Studies have shown that when a large burn wound (>50% TBSA) is excised and covered with autograft, cadaver skin or bio-engineered skin substitute within the first 72 hours following injury, the patient's resting metabolic rate will be 40% less than a patient whose wound is not excised and covered until 7 days post injury.¹⁶ Cross-leg nitrogen studies have shown an increase of 230% in net protein losses when comparing those patients who were excised and covered within 72 hours and those who received delayed primary reconstruction at 10–21 days (Figure 31.10).

Another study involving pediatric burns patients revealed that those admitted early whose burn eschar was removed

Fig. 31.10 Effect of delay to excision and grafting on protein catabolism. (Reproduced with permission from Hart et al. *Ann Surg* 2000; 232(4):455–465.¹⁶)

Fig. 31.11 Indicating that burn wound excision significantly reduced bacterial colonization among patients in the early excision group. * $p < 0.05$ (paired t test), deep versus superficial biopsies. (Reproduced with permission from: Barret JP. *Plast Reconstr Surg* 2003; 111(2):744–750.)

Fig. 31.12 Indicating that patients treated conservatively for 1 week (Delayed exc.) demonstrated greater bacterial colonization than did patients treated with early excision (Early exc.). * $p < 0.05$, delayed excision group versus early excision group. (Reproduced with permission from: Barret JP. *Plast Reconstr Surg* 2003; 111(2):744–750.)

Fig. 31.13 Patients treated conservatively had higher serum levels of C-reactive protein (a) and C3 complement (b) compared with patients in the early burn wound excision group on day 5 postoperatively. Asterisk indicates $p < 0.05$ (unpaired t test) for the early excision group vs. the conservative treatment group. Serum levels of IL-6 (c) and TNF- α (d) were higher in patients treated conservatively 5 days after the injury. Levels of IL-1 β and IL-10 were similar in both patient groups. Asterisk indicates $p < 0.05$ (unpaired t test) for the early excision group vs. the conservative treatment group. within 48 hours of initial injury had reduced incidence of infection and graft loss when compared to those admitted late for delayed excision (day 7). In the same study greater bacterial colonization and higher rates of infection were correlated with topical treatment and late excision (Figures 31.11 and 31.12).

Early excision and prompt coverage is also associated with decreased mortality, reduced length of hospital stay,⁶⁵ less operative blood loss⁶⁷ and fewer septic complications⁶⁸ in children and young adults when compared to conservative serial debridement.

Prompt removal of burn eschar is of paramount importance for the invasively infected burn wound in patients with severe burns and should be performed as early as possible to reduce an increased release of inflammatory mediators and to control the hypermetabolic response during sepsis. A significant reduction in interleukin-6 (IL-6), interleukin-8 (IL-8), tumor necrosis factor- α (TNF- α) and lipopolysaccharide (LPS) has been shown in those patients following the thorough debridement of infected burn tissue.⁶⁹ In a more recent study we were able to show a reduction in C-reactive protein (CRP), C3 complement, IL-6 and serum TNF- α (Figure 31.13).⁷⁰

Effect of sepsis on metabolic response

Sepsis raises the metabolic response to burn by 40% when compared to non-septic patients with burns of a comparable size. This increase in catabolism is seen throughout the acute stay and well into rehabilitation. Consequently, prevention and/or aggressive treatment of sepsis is important in reducing the ensuing mortality and morbidity of increased protein loss. Within the burns setting it is difficult to determine sepsis according to standard protocols. Table 31.5 shows modified scoring systems based upon the American Academy of Chest Physicians (AACP) and the Society of Critical Care Medicine (SCCM) score. Together with an experienced burn clinician, a diagnosis of sepsis can be reached and acted upon (Table 31.5).

Pharmacological modulation

The hypermetabolic response to severe burns leads to a shift in protein kinetics such that there is a marked increase in protein breakdown and a concomitant decrease in protein synthesis. The drop in protein synthesis is sufficient to fall below the rate of protein degradation and so lead to a net loss of protein. The anabolic phase during rehabilitation following a burn injury is due to protein synthetic rates rising above protein degradation.⁷¹ This is an important finding as it shows us that an anabolic state can be achieved during persistent hypermetabolism. Analgesia and sedatives help to ameliorate the pain and anxiety associated with such injuries and hence prevent a rise in the metabolic rate that would otherwise be seen. Pharmacotherapy specific for the hypermetabolic response includes anabolic hormones such as recombinant human growth hormone, insulin, insulin-like growth factor-I (IGF-I), IGF-I and insulin-like growth factor binding protein-3 (IGFBP-3) in combination; anabolic steroids such as testosterone or its synthetic analogue oxandrolone; and adrenergic antagonists such as propranolol or metoprolol.

Analgesia

The metabolic rate of the patient is adversely affected by activity, anxiety and pain secondary to increases in sympathetic nervous system activity. Day-to-day burn care including range of motion exercises, debridement, dressing changes and application of topical antimicrobials, increases the otherwise almost

unbearable pain levels still further. Therefore, prodigious quantities of narcotics and sedatives as well as supportive psychotherapy are helpful in reducing these effects.

Anabolic hormones

Recombinant human growth hormone

rhGH administered via injection at a dose of 0.2 mg/kg during the acute admission resulted in reduced donor site healing time by 25%, reduced length of stay in hospital from 0.80 days/%TBSA to 0.54 days/%TBSA⁷² and led to improved quality of wound healing with no rise in scarring.⁷³ The growth retardation also typically seen following severe burns in pediatric patients was prevented during administration of rhGH during hospital admission.⁷⁴ A favorable attenuation of the hepatic acute phase response⁷⁵ was also seen, with increased concentrations of IGF-I (the secondary mediator of rhGH) and increased albumin production.⁷⁶ When given at a dose of 0.05 mg/kg/day for the first year following burn injury, improvements in height, lean body mass, and bone mineral content were seen. These improvements remained after cessation of the treatment. Additionally, rhGH has a positive effect on immune function by reducing T-helper-2 and enhancing T-helper-1 cytokine production.⁷⁷

The benefits of rhGH are not without some side effects, most notably hyperglycemia during the acute admission.⁷⁸ An increased mortality rate seen in non-burned critical care patients⁷⁹ is not present in burned pediatric patients.⁷⁶ Improved wound healing, reduced tissue wastage, and length of stay in hospital are all major benefits that will improve both the physiological and psychological rehabilitation of the patient. Currently the drawbacks for rhGH are the side effects and mode of delivery. Ongoing investigations are addressing these points, along with trials incorporating beta-blocking agents.

Insulin

Recently it has been restated that severe hyperglycemia in patients suffering from massive burns is associated with an increase in muscle protein catabolism,²⁹ reduced graft take, and an increase in mortality.⁸⁰ Euglycemia, maintained using insulin for non-burned, surgical critical care patients, significantly reduced incidence of infection and mortality.⁸¹ The use of insulin has been shown to significantly reduce donor site healing time from 6.51 (± 0.95) days to 4.71 (± 2.3) days.⁸² A continuous infusion used in burn patients prevents muscle catabolism and conserves lean body mass in the absence of increased hepatic triglyceride production.⁸³ Submaximal doses (3 mU/kg/min) of insulin administered via infusion to burns patients resulted in net protein muscle anabolism without the need for large doses of carbohydrate.⁸⁴ Insulin has been shown to attenuate the inflammatory response by decreasing the pro-inflammatory and increasing the anti-inflammatory cascade, thus restoring systemic homeostasis and reducing the drive of the hypermetabolic response.⁸⁵ Continuous intravenous insulin infusions at doses that will maintain euglycemia (glucose between 100 and 140 mg/mL) after severe burns down-regulates acute phase protein levels⁸⁶ and attenuates muscle catabolism, preserving lean muscle mass.⁸⁷ Recently, insulin administered to burned children was shown to blunt the increase in C-reactive protein, IL-1 β , and TNF- α levels after injury,^{88,89} in the absence of normoglycemia. In another recent

study involving pediatric patients in whom the glucose levels were maintained at between 90 and 120mg/mL, intensive insulin therapy was shown to be safe and effective, reducing infection rates and improving survival.⁹⁰ The mechanisms are unclear for this response; however, it is likely to be caused by inhibition of NF- κ B with stimulation of I- κ B in monocytes.⁹¹ This would result in reduced length and severity of infections and attenuate multiorgan dysfunction associated with burn shock. Although pharmacological doses of insulin have been shown to increase glucose uptake into tissue and this uptake is accompanied by increased amino acid uptake and increased lactate release,⁹² the exact mechanisms are still unclear. Proposed pathways include activation of sodium-dependent transport systems, initiation of protein translation, and direct regulation of proteolytic activities. Metformin may also be used to attenuate hyperglycemia in patients with severe burns, thereby increasing muscle protein synthesis.^{93,94} Other antihyperglycemic agents such as dichloroacetate may also show beneficial results in reduction of postburn hyperglycemia.⁹⁵

Anabolic steroids

Oxandrolone is a synthetic testosterone analogue that can be taken orally, is inexpensive and has only 5% of the virilizing action seen in testosterone. Use of oxandrolone in the burns setting at a dose of 0.1mg/kg bd increases protein synthetic efficiency,⁹⁶ anabolic gene expression in muscle,⁹⁷ and improves lean body mass by increasing net muscle protein synthesis,⁹⁸ thereby attenuating muscle wasting.^{99,100} In severely burned children treated during acute hospitalization, oxandrolone significantly improved net protein synthesis, lean body mass, bone mineral content, synthesis of the hepatic constitutive proteins such as albumin and prealbumin, and attenuated the acute phase reactive protein levels.^{96,101,102} Oxandrolone improved body composition and strength in severely burned children during the 12 months of treatment. Its effect on height and weight continued after treatment was discontinued (Figure 31.14).¹⁰³

Due to the ability of this treatment option to increase lean body mass in an outpatient setting together with the enteral route of administration makes it an ideal medication in the postburn rehabilitation of children. Bone mineral content was also shown to be improved following long term treatment with oxandrolone versus unburned controls.⁹⁶

Catecholamine antagonists

Propranolol has been used successfully to block the effects of endogenous catecholamines that have been implicated as primary mediators of the hypermetabolic response.¹⁰⁴ In the initial stages after burn, levels of catecholamines show a 10-fold increase.^{1,105} The resulting hyperdynamic circulation, increased basal energy expenditure, and catabolism of skeletal muscle proteins are all deleterious for the patient. As described at the beginning of the chapter, catecholamines stimulate lipolysis via the β_2 adrenoceptor. The effects of propranolol in the burn patient include reduced thermogenesis,¹⁰⁶ tachycardia,¹⁰⁷ cardiac work, and resting energy expenditure.¹⁰⁴ The dose used is different for each patient; however, a reduction of heart rate by 20% is seen to produce reduced cardiac work

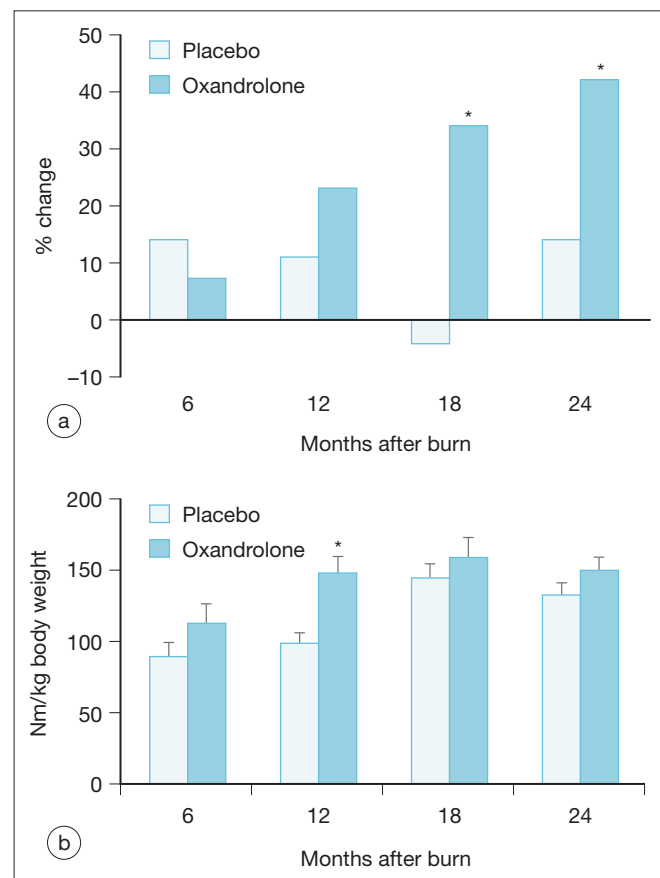

Fig. 31.14 (a) Percent change with time in the number of burned children in the >25th percentile/total for height when compared with values obtained at hospital discharge. *Significant changes in height were observed 6–12 months after oxandrolone was discontinued, $p < 0.05$.¹⁰³ (b) Muscle strength was significantly improved with oxandrolone 12 months after burn. Normal values for healthy children: 182 Nm/kg body weight (SD 40). Data are presented as mean \pm SEM. *Significant difference between oxandrolone and placebo at $p < 0.05$. Reproduced with permission from Przkora R. *Ann Surg* 2005; 242(3):384–391.¹⁰³

load and fatty infiltration (secondary to reducing peripheral lipolysis and hepatic blood flow) (Figure 31.15).¹⁰⁸

Propranolol is shown to enhance intracellular recycling of free amino acids, leading to reduced skeletal muscle wasting and increased lean body mass.¹⁰⁹ The exact mechanisms for the beneficial changes seen in the burns patient following administration of this mixed β_1/β_2 adrenoceptor antagonist remain to be found.

Possible future pharmacotherapeutic options

IGF-I

The beneficial effects of rhGH are derived through IGF-I and IGFBP-3, the levels of which are raised by 100% during treatment, relative to healthy individuals. Therefore an infusion of equimolar doses of IGF-I and IGFBP-3 has been shown to improve protein metabolism in both adult and pediatric burns patients with significantly less hyperglycemia than rhGH alone.¹¹⁰ Interestingly there was no additional benefit seen

Fig. 31.15 Fatty infiltration of the liver following severe thermal injury. (Reprinted with permission from Barret JP, Herndon DN, eds. Color atlas of burn care. London: WB Saunders; 2001:133, Plate 8.39.)

with higher doses of the infusion; using 1 mg/kg/day was sufficient to achieve the desired effect. Attenuation of the type I and II acute phase response was seen following infusion, leading to reduced acute phase protein production and increased constitutive protein production by the liver.^{111,112} Another potential beneficial effect of an infusion of IGF-I/IGFBP-3 has been shown in a human model where there was a partial reversal of the detrimental change in Th1/Th2 cytokine profile.¹¹³ Typically, following massive thermal injury, there is a shift to a predominant Th2 cytokine response,^{114,115} resulting in increases in lymphocyte production of IL-4 and

IL-10, together with decreased production of IL-2 and interferon- γ (IFN- γ). However this combination drug has yet to become commercially available and therefore further studies are required.

Ketoconazole

Ketoconazole is an imidazole antifungal agent. As with other imidazoles, it has a five-membered ring structure containing two nitrogen atoms. Ketoconazole has oral tablet, cream and dandruff shampoo formulations. The oral formulation has been available in the USA since 1981. Like all azole antifungal agents, ketoconazole works principally by inhibition of cytochrome P450 14 α -demethylase (P45014DM) an enzyme in the sterol biosynthesis pathway that leads from lanosterol to ergosterol.¹¹⁶ Ketoconazole inhibits the 11 β -hydroxylation and 18-hydroxylation reactions in the final steps during the synthesis of adrenocorticosteroids¹¹⁷ and may even function as a glucocorticoid receptor antagonist.¹¹⁸

Gene profiling for the future

Ongoing studies to correlate genomic and proteomic changes induced by burn with phenotypic changes and clinical outcomes are being conducted by the Inflammation and the Host Response to Injury Large-Scale Collaborative Research Program. Recent experiments demonstrate that dramatic, tissue-specific alterations in genomic expression patterns occur in a temporal fashion in blood leukocytes, skin, muscle, and fat. Further experiments will elucidate the genomic and proteomic differences in adults who survive a burn versus those who do not. Additional information (data and publications) can be found at www.gluegrant.org.

Introduction	434
Etiology	434
Common ground: mediators	435
Prevention of multisystem organ failure	437
The potential role of nutritional and specific immunomodulators	439

The cure of many diseases remains unknown.
Socrates, circa 400 BC

Introduction

Despite its common occurrence in critically ill burn patients, our understanding of the multisystem organ failure syndrome remains fragmented and incomplete. The cascade of organ dysfunctions which typify the multisystem organ failure syndrome is driven by an unregulated inflammatory state, often, but not always, associated with uncontrolled infection.¹ Other potential 'engines' driving this cascade of organ dysfunctions are an impaired gastrointestinal barrier,^{2,3} the open burn wound,⁴ and inadequate delivery of oxygen to peripheral tissues.⁵ The line between organ dysfunction and failure is admittedly unclear, but a set of organ-specific definitions of failure is helpful and has been developed (Box 32.1).⁶ Approximately 15% of patients admitted to surgical intensive care units have multisystem organ failure,⁷ and perhaps 8% of burn patients ultimately develop the syndrome.⁸

The sequence of failures often follows a predictable course, although the cascade can be modified by various treatments, such as the prophylactic use of H₂ receptor blockers. In burn patients, two cascades have been described.⁸ An early cascade characterized by resuscitation failure, adult respiratory distress syndrome, hemodynamic failure, renal failure, liver failure, gut failure, and infection, and a late cascade typified by pulmonary failure, hemodynamic instability, renal failure, gut failure, and liver failure. Frequently, vasomotor failure and death is seen at the end of both cascades. Mortality increases with increasing numbers of failed organ systems. When three organs have failed, mortality has been reported as 100%, although survival is sometimes seen in patients with even more failed organ systems.⁹ An understanding of the progres-

sion of the syndrome aids in prognostication and facilitates decisions regarding termination of futile efforts.^{10,11} The management of specific organ failures will be presented in the next chapter. The purpose of this chapter is to discuss the etiology and prevention of the syndrome.

Etiology

The etiology of multisystem organ failure remains a mystery under intense investigation. All patients seem to share characteristics associated with an uncontrolled inflammatory state, and there are several proposed 'engines' which drive this uncontrolled inflammation, including sepsis, the open burn wound, the gut, and hypoperfusion.

Sepsis is clearly the most common initiator of the syndrome, and was recognized early on as the primary cause.¹ One single overwhelming infection is not required, as small repetitive infections may initiate the cascade,¹² perhaps by priming immune cells, making them react more intensely to each subsequent stimulus.¹² It was recognized later that many patients with multisystem organ failure did not have infection,¹³ and this led the search for other 'engines'. Endotoxin liberated from the walls of Gram-negative bacteria is a major, but not the only, intermediary,¹⁴ as Gram-positive bacteria cause similar aberrations in oxygen transport and hemodynamics,¹⁵ via similar cascades of mediators.¹⁶

In burn patients the wound may also be a source of the inflammatory mediators leading to multiple organ failure. Certainly, an infected wound will do this, but wound sepsis is decreasing in incidence with the advent of early burn wound excision¹⁷ and most infectious deaths in burn patients today are caused by pneumonia rather than wound sepsis.¹⁸ Complete wound closure, without donor sites, decreases oxygen consumption¹⁹ and presumably ameliorates the inflammatory response to the open wound. Incomplete wound closure does not have this effect.²⁰ Increased levels of circulating mediators such as interleukin-6 (IL-6), IL-8, and tumor necrosis factor (TNF) have been shown to originate from the burn wound²¹ and contribute to the hypermetabolic and inflammatory state seen in burn patients. Interleukin-8 has been demonstrated to be upregulated in the lung after burn injury²¹ and the stimulus for this upregulation, which is associated with pulmonary dysfunction, may come from the wound.²¹

Intensive recent work has demonstrated the importance of gut barrier function and the relation of gut barrier failure to the development of multisystem organ failure.²² Normal barrier function prevents the movement of bacteria and their products

BOX 32.1 Organ-specific definitions of failure (OSF)

If the patient had one or more of the following during a 24-hour period (regardless of the values), OSF existed on that day.

CARDIOVASCULAR FAILURE (PRESENCE OF ONE OR MORE OF THE FOLLOWING):

- Heart rate ≤ 54 beats/min
- Mean arterial blood pressure ≤ 49 mmHg
- Occurrence of ventricular tachycardia and/or ventricular fibrillation
- Serum pH ≤ 7.24 with a P_{aCO_2} of ≤ 49 mmHg

RESPIRATORY FAILURE (PRESENCE OF ONE OR MORE OF THE FOLLOWING):

- Respiratory rate ≤ 5 beats/min or ≥ 40 beats/min
- $P_{aCO_2} \geq 50$ mmHg
- $AaDO_2 \geq 350$ mmHg ($AaDO_2 = 713 F_{iO_2} - P_{aCO_2} - PaO_2$)
- Dependent on ventilator on the fourth day of OSF, e.g. *not* applicable for the initial 72 hours of OSF

RENAL FAILURE (PRESENCE OF ONE OR MORE OF THE FOLLOWING):*

- Urine output ≤ 479 mL/24 h or ≤ 159 mL/8 h
- Serum BUN ≥ 100 mg/dL
- Serum creatinine ≥ 3.5 mg/dL

HEMATOLOGICAL FAILURE (PRESENCE OF ONE OR MORE OF THE FOLLOWING):

- WBC ≤ 1000 cells/mm³
- Platelets ≤ 20000 cells/mm³
- Hematocrit $\leq 20\%$

NEUROLOGICAL FAILURE

- Glasgow Coma Score ≤ 6 (in absence of sedation at any one point in day)
- Glasgow Coma Score: sum of best eye opening, best verbal, and best motor responses. Scoring of responses as follows: (points)

Eye

Open: spontaneously (4), to verbal command (3), to pain (2), no response (1)

Motor

Obeys verbal command (6); response to painful stimuli: localizes pain (5), flexion-withdrawal (4), decorticate rigidity (3), decerebrate rigidity (2); no response (1); movement without any control (4)

Verbal

Oriented and converses (5), disoriented and converses (4), inappropriate words (3), incomprehensible sounds (2), no response (1). If intubated, use clinical judgment for verbal responses as follows: patient generally unresponsive (1), patient's ability to converse in question (3), patient appears able to converse (5)

*Excluding patients on chronic dialysis before hospital admission. Reproduced from Knaus et al., *Ann Surg* 1985; 202:685–693.⁶ with permission.

a tribute to normal barrier function. Although not seen immediately after trauma,²⁴ several insults have been shown to result in increased translocation of bacteria and their products into the portal and lymphatic circulations. Hemorrhagic shock,²⁵ endotoxin administration,²⁶ burns,²⁷ and burn wound sepsis²⁸ have each been shown to result in increased translocation of bacteria from the gut. Gut permeability to macromolecules, such as endotoxin, has been shown to increase with increasing burn wound size using polyethylene glycol 3350 as a tracer.²⁹ Smaller molecules, with lactulose as the tracer, have also been shown to pass more readily through the gastrointestinal membrane after injury.³⁰ The exact mechanism by which bacteria and their products pass through the gastrointestinal barrier is not clear. Both intra- and transcellular processes may be involved.^{31,32} The consequences of loss of the gastrointestinal barrier are profound. Translocating whole bacteria can be a direct source of sepsis or can activate Kupffer cells^{2,3} and promulgate an inflammatory response in conjunction with bacterial products such as endotoxin.

Cellular dysfunction, caused by inadequate oxidative metabolism secondary to hypoperfusion, is another potential 'engine' resulting in multisystem organ failure. In ischemia-reperfusion models, oxygen radicals are generated, resulting in peroxidation of cell membrane lipids and accumulation of activated neutrophils,³³ with progressive cellular and whole-organ dysfunction. It has been proposed that critically ill patients suffer from supply-dependent oxygen consumption because of defects in cellular oxygen extraction and utilization.^{34,35} This results in inadequate aerobic metabolism unless supranormal levels of oxygen are supplied.³⁶ The reality of this proposal is still actively debated.^{37,38} Certainly, a grossly inadequate amount of oxygen available to cells dependent on aerobic metabolism can lead to cellular dysfunction, and this may be followed by organ failures.⁵ Maintaining oxygen delivery at at least normal, and possibly supranormal, levels should help maintain cellular homeostasis and minimize the risk of multiple organ failure.³⁹ Although the requirement for a supranormal level of tissue oxygenation in critical illness is controversial and our ability to predict organ-specific oxygen delivery and consumption from whole-body data is poor,⁴⁰ careful attention to whole-body hemodynamics is an integral part of the management of any critically ill patient.

Common ground: mediators

Sepsis, open burn wounds, impaired gut barrier function, and hypoperfusion are all associated with multiorgan failure. The similarity in the response to these differing events implies that there is some common ground. These processes all probably impact on individual organs via a number of mediators, whose complex interactions are still very poorly understood,⁴¹ but are being unraveled by investigators using blocking antibodies, soluble receptors, and receptor antagonists.⁴² At this point, these mediators, including endotoxin, arachidonic acid metabolites, cytokines, platelet activating factor, activated neutrophils and adherence molecules, nitric oxide, complement, and oxygen free radicals will be reviewed briefly.

Endotoxin, a lipopolysaccharide component of Gram-negative bacterial cell walls, induces many of the symptoms associated with sepsis, including fever, hypotension, the release of

from the gut lumen into the portal and lymphatic circulations. Bacterial densities range from near 0 in the stomach, to 10^4 – 10^5 in the distal small bowel, to 10^{11} – 10^{12} /g of stool in the normal colon.²³ That the normal gut can carry this bacterial load, without the frequent occurrence of Gram-negative infection, is

acute phase proteins, and the production of multiple cytokines including TNF and IL-1.⁴³ Endotoxin also activates complement,⁴⁴ causes activation of the coagulation cascade,⁴⁵ and results in the release of platelet activating factor.⁴⁶ Potential sources of endotoxin include both Gram-negative bacteria in foci of infection and Gram-negative bacteria within the gut when the gut barrier fails.

Arachidonic acid makes up approximately 20% of cell membranes, is released from these membranes in response to a multitude of stimuli which activate phospholipases A₂ and C, and is then metabolized by one of two major enzyme systems (Figure 32.1).

The cyclooxygenase pathway results in production of prostaglandins and thromboxanes, and the lipoxygenase pathway results in the production of leukotrienes.⁴⁷ The prostaglandins and leukotrienes interact with other mediators in a complex fashion, and are later degraded by enzyme systems, which are dispersed throughout the body.⁴⁸

Arachidonic acid, which is metabolized via the cyclooxygenase pathway, results in the formation of prostaglandins and thromboxanes. Prostacyclin inhibits platelet aggregation, thrombus formation, and gastric secretion.⁴⁹ Thromboxane A₂ (TXA₂) causes platelet aggregation, has profound vasoconstricting effects on both the splanchnic and pulmonary microvasculature, and causes bronchoconstriction and increased membrane permeability.⁵⁰ It is studied via its longer-lived but inactive metabolite, TXB₂. Aspirin has its physiological effects by inhibiting thromboxane synthetase.⁵¹

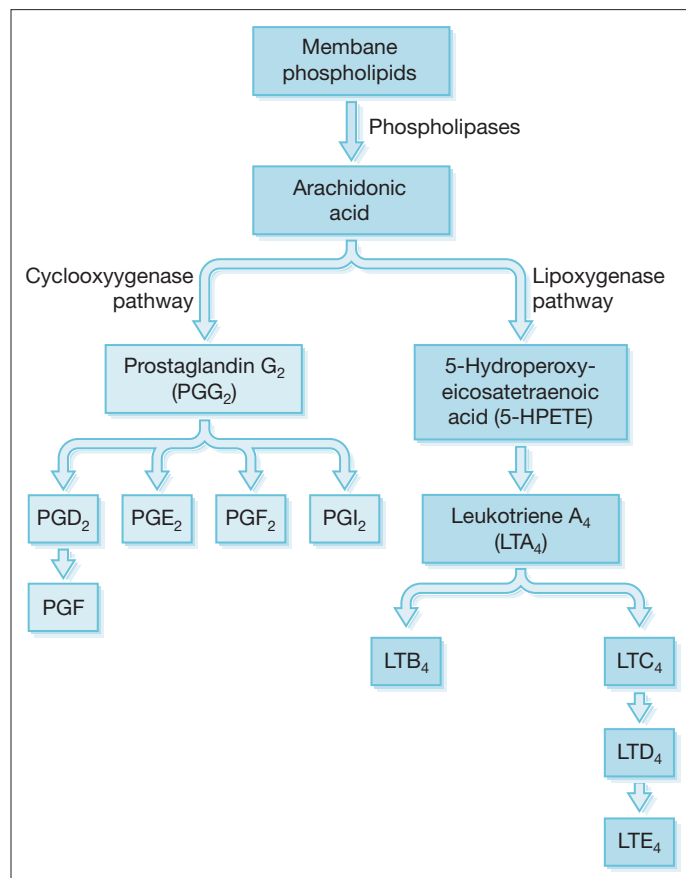

Fig. 32.1 The cyclooxygenase and lipoxygenase pathways of arachidonic acid metabolism.

Arachidonic acid metabolized via the lipoxygenase pathway results in the formation of leukotrienes. There are two types based on their metabolism after the action of 5-lipoxygenase, leukotrienes (LT) C₄, D₄, and E₄ (the sulfidopeptide group) and LTB₄.⁵² Leukotrienes are generated in response to multiple stimuli by several cell types, including neutrophils, macrophages, and monocytes.⁵³ Vessel walls are also capable of generating leukotrienes.⁵⁴ Leukotrienes C₄, D₄, and E₄ have variable actions on vascular tone depending on the presence or absence of other mediators such as cyclooxygenase product.⁵⁵ In addition to their variable effects in redirecting blood flow, LTC₄, LTD₄, and LTE₄ also increase vascular permeability,⁵⁶ and have been described as being elevated immediately prior to the development of pulmonary failure.⁵⁷ The major effect of LTB₄ is an enhancement of neutrophil chemotaxis.⁵⁸ Thus, leukotrienes as a group may be involved in the edema formation and pulmonary and systemic vascular changes that are seen in the multisystem organ failure syndrome.

Cytokines are regulatory proteins that are secreted by immune cells and have multiple paracrine and endocrine effects. There are six major classes,⁵⁹ including interleukins, TNF, interferons, colony-stimulating factors, chemotactic factors, and growth factors. Those which have been most extensively characterized are IL-1, IL-6, and TNF.

Interleukin-1 and IL-6 are elevated in septic states, and high levels are associated with a fatal outcome⁶⁰ and predict systemic infection.⁶¹ Interleukin-1 β causes hypotension and decreased systemic vascular resistance, which may be synergistic with the effects of TNF.⁶² Even better characterized is TNF, the administration of which causes hypotension, cardiac depression, and pulmonary dysfunction in animals.⁶³⁻⁶⁵ When administered to humans, TNF causes fever, hypotension, decreased systemic vascular resistance, increased protein turnover, elevation of stress hormone levels,^{66,67} and activation of the coagulation cascade.⁶⁸

Platelet activating factor is a nonprotein phospholipid that is secreted by many cells including platelets, endothelial cells, and inflammatory cells,⁶⁹ and is a major mediator of the pulmonary⁷⁰ and hemodynamic⁷¹ effects of endotoxin. The major effects of platelet activating factor are vasodilation, cardiac depression, and enhancement of capillary leak. Its complex interactions with other mediators are still poorly understood.

Although tissue injury can occur in the absence of neutrophils,⁷² the inflammatory process results in local accumulation of activated inflammatory cells which release various local toxins such as oxygen radicals, proteases, eicosanoids, platelet activating factor, and other substances. When unregulated, such accumulations of activated cells can cause tissue injury.⁷³ The initial attachment of neutrophils to the vascular endothelium at an inflammatory site is facilitated by the interaction of adherence molecules on the neutrophil and endothelial cell surfaces.⁷⁴

These neutrophil adherence receptors are induced by numerous stimuli but, interestingly, are reduced after major thermal and nonthermal injury,⁷⁵ perhaps explaining in part the increased incidence of infection in such patients. The importance of this adherence mechanism can be seen in patients who are deficient in one of the integrin class of neutrophil adherence receptors, CD-18, who suffer from frequent bacterial infections.⁷⁶ The biology of the transmembrane polypeptides

that govern these complex cell-to-cell interactions is an active area of research⁷⁷ and holds promise for therapeutic interventions in the future.

Oxygen radicals, such as hydrogen peroxide and superoxide anion, are released by activated neutrophils in response to a variety of stimuli.⁷⁸ They are also released when xanthine oxidase is activated after reperfusion in ischemia-reperfusion models. These highly reactive products cause cell membrane dysfunction, increased vascular permeability, and release of eicosanoids.

Nitric oxide, released when citrulline is formed from arginine (Figure 32.2), was only identified as an endothelial product in the middle 1980s.⁷⁹ Its half-life is only a few seconds, as it is quickly oxidized, but it has profound local microvascular effects. Nitric oxide synthesis is stimulated by various cytokines, endotoxin, thrombin, and by injury to the vascular endothelium. It is a potent vasodilator,⁸⁰ but its actions vary depending on the vascular bed and presence of other mediators.⁸¹ Nitric oxide is one of the major mediators of the hypotensive response to sepsis.^{82,83}

Antigen-antibody complexes activate the complement cascade, and complement fragments thus generated can interact with other cytokines to promulgate the inflammatory response.⁸⁴ Diminished levels of a natural inhibitor of C5a have been demonstrated in patients with adult respiratory distress syndrome (ARDS)⁸⁵ and administration of anti-C5a antibody diminishes hypotension in an animal model of endotoxemia.⁸⁶ Complement fragments may be involved in the development of burn wound edema.⁸⁷

Obviously, our understanding of the incredibly complex cellular and subcellular biology, of which multisystem organ failure is but one manifestation, is poorly understood at the present time. This dim understanding highlights the important role that prevention plays in managing the syndrome.

Prevention of multisystem organ failure

Once established, multisystem organ failure is very difficult to reverse, emphasizing the importance of prevention.⁸⁸ Preven-

tion is based on our crude knowledge of the ‘engines’ that drive the process — sepsis, the gut, the wound, and inadequate perfusion (Table 32.1). Dealing with these issues is far more practical than dealing with an incompletely understood complex web of mediators. Also, this complex cascade evolved in numerous species over thousands of generations and interference in the network may do more harm than good. The discussion that follows will address prevention of sepsis via proper wound management and attention to unusual causes of sepsis, support of the gut, and prevention of inadequate oxygen delivery. Subsequently, the potential role of nutritional and specific immunomodulators will be addressed.

Prevention of sepsis

In the burn patient, prevention of multisystem organ failure is greatly facilitated by prevention of wound sepsis via an aggressive surgical approach to deep wounds. The increasing survival of burn patients has paralleled the evolution of this approach to the burn wound.⁸⁹⁻⁹¹ Not only is overt wound sepsis prevented by early removal of devitalized tissue, but multiple smaller septic insults are also prevented, as manipulation of heavily colonized burn wounds is a frequent source of

TABLE 32.1 MULTIPLE ORGAN FAILURE ETIOLOGY AND ESTABLISHED PREVENTIVE MEASURES

Etiology	Prevention
Sepsis	Early excision and biologic closure of deep wounds. Anticipation and early treatment of occult septic foci
Gut barrier failure	Optimize whole-body hemodynamics. +/- Early enteral feedings
Inadequate organ perfusion	Optimize whole-body hemodynamics. +/- Enhanced oxygen delivery

Fig. 32.2 Nitric oxide metabolism. (From Cobb et al.,¹⁸⁹ with permission.)

transient bacteremia.^{92,93} Such multiple occult bacteremias occurring during frequent manipulation of heavily colonized wounds could contribute to the development of multisystem organ failure by priming immune cells, making them react more intensively to each subsequent insult.¹² The role of perioperative antibiotics in minimizing bacteremias in the perioperative period has yet to be defined clearly. However, they are clearly beneficial in patients with injuries greater than 60% of body surface and in any other patient in whom the probability of bacteremia with wound manipulation is felt to be high.⁹⁴ Appropriate perioperative antibiotics are guided by surface cultures. Burn patients are prone to a large number of unusual and often occult infectious complications⁹⁵ which can result in sepsis and potentially contribute to the development of multiorgan failure. Rapid diagnoses and treatment are facilitated by a high index of suspicion.

Intravascular infections such as suppurative thrombophlebitis and endocarditis typically present in burn patients with fever and bacteremia without localizing signs. Burn patients with endocarditis develop a new murmur in only 9% of cases,⁹⁶ and only 10% have been reported to present antemortem.⁹⁷ Of those with septic thrombophlebitis, 68% have no localizing signs and present with fever and positive blood cultures only.⁹⁸ The diagnosis is made in patients without localizing signs only by thorough examination of all sites of prior cannulation, with surgical exposure of any suspicious sites and complete excision of any involved veins.⁹⁹ Vigilant care and scheduled replacement of intravascular devices will minimize the occurrence of catheter-related sepsis. Occult intracompartamental sepsis can also present with fever and bacteremia without localizing signs, and is diagnosed only by careful examination and exploration of suspicious compartments.¹⁰⁰

Pneumonia, seen in approximately 35% of patients with inhalation injury, adds between 20 and 60% to the expected mortality of burn patients.¹⁰¹ Although a difficult diagnosis to make in critically ill patients, pneumonia should be vigilantly anticipated and aggressively treated with appropriate endobronchial toilet and specific antibiotics. The incidence of nosocomial pneumonia increases with longer durations of intubation,¹⁰² emphasizing the importance of judicious use of mechanical ventilation.

Suppurative sinusitis is being recognized with increasing frequency in the intensive care unit, and may be more frequent in patients who are nasotracheally intubated.¹⁰³ Diagnosis may require examination and culture of material obtained by antral puncture, in addition to plain radiographs and computed tomography. Although there is some controversy about the role of the nasotracheal tube in causing sinusitis,¹⁰⁴ treatment involves removing all nasotracheal devices, topical decongestants, and appropriate antibiotics. Surgical drainage is reserved for recalcitrant cases.

Acalculous cholecystitis often presents with generalized sepsis without localizing signs in the burn patient, and, like intravascular infection, is a very difficult diagnosis to make.¹⁰⁵ Recently, bedside placement of percutaneous cholecystostomy tubes under ultrasonic guidance has become an option in the management of suspected cholecystitis in critically ill patients.¹⁰⁶ This technique allows an accurate diagnosis to be made and the condition to be temporarily treated in patients too unstable for immediate operation.

Sepsis accounts for at least half of cases of multisystem organ failure. In perhaps no other area can the vigilance of the burn team have a greater impact in multisystem organ failure prevention than in the early detection and aggressive treatment of occult septic foci.

Support of the gut

Bacteria and their products released when the gut barrier fails may fuel the multiorgan failure syndrome. Gut mucosal integrity suffers when mesenteric flow is inadequate and gut blood flow is decreased after burn injury, a response exacerbated by the release of TXA₂.¹⁰⁷ Thus, support of splanchnic blood flow is an important aspect of multisystem organ failure prevention,¹⁰⁸ and this is best done by careful attention to whole-body hemodynamics. There is no substitute for a carefully monitored burn resuscitation.

The enterocyte may be better supported by intraluminal, rather than parenteral feedings, as gut deprived of intraluminal feedings develops mucosal atrophy.¹⁰⁹ Early enteral feedings are tolerated in the burn patients,¹¹⁰ and may reduce the magnitude of the hypermetabolic response to the injury.¹¹¹ Parenteral feedings do not prevent gut mucosal atrophy as well as isocaloric and isonitrogenous intraluminal feeds,¹¹² although convincing human data are not available to support the clinical significance of this point.

The value of specific nutrients to support the enterocyte is far less clear than the value of providing adequate mesenteric blood flow and perhaps intraluminal nutrition. However, this is an exciting and active area of research. Glutamine, a nonessential amino acid, is the preferred fuel of the small bowel enterocyte¹¹³ as well as other rapidly dividing cells. Sepsis has been shown to decrease glutamine uptake by the small bowel enterocyte, which may result in barrier failure,¹¹⁴ and the addition of glutamine to the nutritional regimen has been theorized to improve barrier function. Glutamine is not a component of commercial parenteral nutritional formulas because of its short shelf life, although the dipeptide is well tolerated parenterally, and has a longer shelf life.¹¹⁵ Although supplemental glutamine may improve protein balance in surgical patients,¹¹⁵ and may partially reverse gut atrophy,¹¹⁶ it has not been shown to improve gut barrier function when given parenterally.¹¹⁷

The role of specific nutrients in support of the large intestinal mucosa is less clear, but butyrate, a fatty acid liberated by fiber fermentation, is a favored fuel of the colonic mucosal cell.¹¹⁸ Enteral pectin may help support the colonic mucosa, but the value of such support in the hypermetabolic burn patient is as yet unclear. Limited work has been done suggesting possible benefit of probiotics for gut barrier support.¹¹⁹

A decontaminated gut lumen might diminish the impact of gastrointestinal barrier failure. Attempts have been made to access the impact of selective decontamination of the gut¹²⁰ and coating enteric bacteria to inhibit their ability to attach to the intestinal mucosa and translocate.¹²¹ Although there is a suggestion that the rate of pneumonia may be decreased by such maneuvers, there is no apparent impact on mortality.

Support of the gut in an effort to prevent multisystem organ failure is certain to have real value. Maintenance of adequate mesenteric perfusion via careful attention to whole-body hemodynamics is crucial. There are some data to support the contention that enteral feedings have beneficial effects on

outcome in injured patients when compared with parenteral feedings, possibly via an enhancement of gastrointestinal barrier integrity.¹²² However, these data require confirmation prior to general application. Data supporting the administration of specific mucosal substrates or gut decontamination are less convincing, but further research in these important areas may show such benefit.

Insuring adequate oxygen delivery

The normal intracellular partial pressure of oxygen is 0.5 mmHg, and this small amount of mitochondrial oxygen allows for the aerobic generation of most of the cell's adenosine triphosphate (ATP). When cells have to adapt to a lower oxygen tension, ATP generation continues at a lower rate by anaerobic channels,¹²³ possibly triggered by the build-up of adenosine diphosphate (ADP). As outlined by Gutierrez, the anaerobic reactions which generate ATP are glycolysis, the creatine kinase reaction, and the adenylate kinase reaction.¹²³ Glycolysis describes the conversion of glucose to lactate with the generation of two ATP molecules. The creatine kinase reaction is the breakdown of the high-energy phosphate storage molecule, phosphocreatine, with the generation of ATP and creatine. The adenylate kinase reaction describes the combination of nucleotides to form ATP and AMP which, although generating ATP, depletes the cells of adenine nucleotides. In conjunction with this conversion to anaerobic ATP generation, the intracellular concentration of hydrogen ion increases, the amount of adenine nucleotides within the cell decreases, and intracellular calcium levels increase with decreased function of the ATP-driven sodium-calcium pump.¹²⁴ There also may be an increase in the liberation of intracellular oxygen free radicals with the activation of xanthine oxidase.¹²⁵ If low oxygen tensions continue, membrane phospholipids may be degraded by the combined effects of elevated calcium, oxygen free radicals, and the decreased synthetic capabilities coincident with decreased levels of ATP.¹²⁶ These effects may be magnified if there is also systemic sepsis as cellular oxygen extraction may be impaired. That such cellular hypoxic dysfunction is involved in the development of organ dysfunction is implied by the fact that cocarboxylase, which enhances ATP generation by ischemic cells, ameliorates some of the metabolic and hemodynamic consequences of endotoxic shock in an animal model.¹²⁷

An understanding of progressive cell destruction and dysfunction which is caused by low intracellular oxygen tensions, coupled with the perception of oxygen extraction abnormalities associated with sepsis, has led to an intense interest in the delivery of supranormal amounts of oxygen to prevent organ dysfunction, as clinical data suggest that inadequate oxygen delivery is associated with the development of multisystem organ failure.¹²⁸ Clinically, it is somewhat cumbersome to measure and follow oxygen delivery, and other markers of the adequacy of tissue oxygenation have been tried, including the use of lactate and the lactate/pyruvate ratio, base deficit, mixed venous oxygen tension and pH, and gut tonometry. However, none of these secondary markers of oxygen delivery have proven to be as reliable as the direct determination of oxygen delivery and consumption by the reverse Fick technique.

Normal physiological oxygen supply dependency is different than the pathological supply dependency seen in septic states.

In this circumstance, supranormal oxygen delivery is said to be required, as extraction is decreased.¹²⁹ The exact reasons for this pathological supply dependency are unclear, but may involve microcirculatory shunting or aberrations of intracellular physiology. It has been proposed that the purposeful delivery of supranormal amounts of oxygen is associated with a decreased incidence of multiple organ failure and increased survival.¹³⁰ The reality of the proposal is still controversial, with data showing no increase in oxygen consumption with transfusion of critically ill children¹³¹ and the absence of a consumption plateau in patients with ARDS.¹³² Also, regional blood flow is poorly predicted by whole-body oxygen delivery and consumption data,¹³³ implying that whole-body delivery and consumption data may be of no value even if pathological supply dependency was real. Normally, oxygen consumption is approximately 25% of oxygen delivery, and delivery can be maximized by optimizing the hemoglobin, partial pressure of oxygen, and cardiac output, which are the major determinants of oxygen delivery, although total flow may be more important than the blood's oxygen-carrying capacity.¹³⁴

Inadequate oxygen delivery clearly leads to organ dysfunction. At a minimum, the clinician should insure that injured patients are resuscitated to the conventional clinical endpoints of appropriate urine output, skin perfusion, blood pressure, and sensorium. In selected critically ill patients, invasive monitoring is justified to document oxygen delivery and consumption, extraction ratio, and the possible presence of supply dependency in which circumstance supranormal levels of oxygen delivery with plateau of oxygen consumption is an appropriate resuscitation endpoint.

The potential role of nutritional and specific immunomodulators

The holy grail of those who study the complex biology of the multisystem organ failure syndrome is an ability to modulate the common pathways that lead to organ dysfunction and death. The three general approaches to this goal are nutritional, nonspecific, and specific immunomodulation.

Nutritional immunomodulation

Three categories of substances show some promise as potential nutritional immunomodulators in burn patients: long-chain fatty acids; arginine, glutamine, and branched-chain amino acids; and nucleotides. Short- and medium-chain fatty acids are commonly utilized for energy, whereas long-chain fatty acids are important constituents of cell membranes and can profoundly influence cell function.¹³⁵ Omega-3 long-chain fatty acids play a particularly important role in the membranes of immunocompetent cells.¹³⁶ There are animal data suggesting that supplementation of the diet with ω -3 fatty acids may improve immune function after burn injury;¹³⁷ however, there are no clear clinical data yet available to support the routine administration of ω -3 fatty acids as a dietary supplement in injured patients.

The potential immunostimulating effects of specific amino acids, particularly arginine, glutamine, and the branched-chain amino acids leucine, isoleucine, and valine, are an active area of research. Arginine is a nonessential amino acid with important functions in the urea cycle and in the generation of

nitric oxide.¹³⁸ It also may have important effects in insuring immune cell competence.^{139,140} Although there are some animal data suggesting improved immunocompetence and outcome after burn with supplementation of arginine,¹⁴¹⁻¹⁴³ human data are not yet adequate to support its routine administration to burn patients. Glutamine, the most common amino acid in the body, and a preferred fuel of rapidly dividing cells, may be conditionally essential in hypermetabolic patients,^{113,114} and its administration has been proposed as a method to support the gut barrier, thereby abrogating the consequences of barrier failure. Early human data suggest that administration of supplemental glutamine may improve amino acid protein economy in stressed surgical patients,¹¹⁵ but there are inadequate data as yet to support the routine administration of glutamine as an immune stimulant.

The branched-chain amino acids leucine, isoleucine, and valine are important energy sources in stressed surgical patients. Although there was an early enthusiasm for the supplemental administration of these substrates, subsequent data have suggested that the supplemental administration of branched-chain amino acids does not benefit stressed surgical patients.¹⁴⁴

Based on limited animal and human data it has been suggested that the administration of adenine nucleotides may have beneficial effects on immune function in stressed patients.¹⁴⁵ Again, at the present time there is inadequate human data to support the routine use of supplemental nucleotides.

The concept of nutritional immunomodulation via supplementation of specific substances is exciting. However, despite preliminary human studies suggesting a beneficial effect of supplemental arginine and ω -3 fatty acids,¹⁴⁶ with additional nucleotides,¹⁴⁵ and glutamine,¹¹⁵ there do not yet exist adequate data to support nutritional immunomodulation as a routine maneuver in the management of burned patients.

Non-specific and specific immunomodulation

It seems intuitively unlikely that there exists a magic immunomodulating bullet that will prevent the development of multisystem organ failure in critically ill surgical patients, particularly if sepsis is uncontrolled, the integrity of the gut barrier is compromised, burn wounds are unaddressed, or patients are inadequately supported hemodynamically. However, such efforts have tremendous potential to facilitate our understanding of cellular and subcellular biology and may, in time, provide a clinical dividend. Efforts at nonspecific immunomodulation have included the use of steroids,¹⁴⁷ immunoglobulin G,¹⁴⁸ and naloxone¹⁴⁹ with no significant impact on patient outcomes. With the exception of steroids for those with suspected adrenal insufficiency¹⁵⁰ and naloxone for those with opiate intoxication, there is no role for these substances in critically ill burn patients.

Although there have been efforts to absorb lipopolysaccharide,¹⁵¹ and to prevent endotoxemia with prophylactic polymyxin B in burn patients,¹⁵² the greatest efforts at specific immunomodulation have been applied to the development of anti-endotoxin antibodies. The earliest clinical efforts used human serum with anti-J5 activity and demonstrated an enhanced survival in patients with Gram-negative septic shock.¹⁵³ Later, two monoclonal IgMs were developed, and

human trials were completed. The first was anti-E5, a murine monoclonal antibody. Clinical trials suggested a benefit in septic patients without refractory shock.¹⁵⁴ Large numbers of treated patients developed antibodies to the murine monoclonal, and although these patients were not retreated, attention turned more toward a human product. A subsequent effort with this murine monoclonal did not show statistically significant improvements in outcome.¹⁵⁵

HA-1A, a human monoclonal IgM, was trailed in a large multicenter effort without statistically significant improvement in outcome, except in a subgroup of patients that had Gram-negative bacteremia and shock.¹⁵⁶ Multiple confounding factors made these marginally beneficial results suspect, leaving the ultimate utility of HA-1A still unclear.

Anti-endotoxin monoclonal therapy, which may have potential to be beneficial if significantly refined, has also been criticized for its expense. It is estimated that it would cost \$24 100 per year of life saved should this technology be used widely.¹⁵⁷ Integrating such advanced and expensive technology into common practice poses tremendous practical problems, and is therefore very unlikely to happen soon when one considers its lack of clear efficacy and high expense.

Significant efforts have also been made toward modifying the actions of arachidonic acid metabolites or eicosanoids, both cyclooxygenase and lipoxygenase products. Numerous animal models of sepsis and endotoxemia exist, and cyclooxygenase pathway blockade with nonsteroidal anti-inflammatory agents has demonstrated improved survival,^{158,159} improved pulmonary hemodynamics,¹⁶⁰ and improved mesenteric blood flow.¹⁶¹ There has been little work documenting outcome improvement in human patients, but it has been suggested that nonsteroidal anti-inflammatory agents improve symptoms associated with endotoxin infusion in normal volunteers¹⁶² and septic patients,¹⁶³ and may improve immune function after surgical trauma.¹⁶⁴ In an animal model, infusion of the vasodilating arachidonic acid metabolite, prostacyclin, ameliorates the pulmonary dysfunction associated with endotoxin infusion.¹⁶⁵ Less work has been done with lipoxygenase pathway inhibitors. Survival is enhanced in a murine model of endotoxin infusion with lipoxygenase pathway blockade.¹⁶⁶ Endotoxin-associated pulmonary dysfunction is diminished in sheep¹⁶⁷ and pigs¹⁶⁸ when this pathway is blocked. The ultimate role of lipoxygenase blockade in human remains uninvestigated.

Cytokines are difficult to measure accurately and their complex interactions are poorly understood. The production of IL-1 receptor antagonist is increased in human endotoxemia,¹⁶⁹ and, in an animal model, its administration enhances survival.¹⁷⁰ However, infusion of IL-1 may improve immune function in humans.¹⁷¹ Clearly our understanding of the complex functions of this cytokine are inadequate to allow intelligent intervention.

Tumor necrosis factor is produced by macrophages and other inflammatory cells when stimulated by endotoxin.¹⁷² In animal models, the physiological effects of both endotoxin infusion and Gram-negative sepsis^{173,174} are attenuated by TNF blockade with monoclonal antibodies. Circulating levels of TNF are high immediately after sepsis begins and then fall, implying that only anti-TNF pretreatment would be beneficial.¹⁷⁵ However, even anti-TNF administration prior to experimental

sepsis¹⁷⁶ and endotoxemia¹⁷⁷ has variable effects, at best, on survival. Again, our incomplete understanding precludes effective intervention.

Interference with the effects of platelet activating factor (PAF) has been shown to decrease neutrophil priming by human burn serum,¹⁷⁸ to improve endotoxin-induced pulmonary dysfunction,¹⁷⁹ to decrease eicosanoid release,¹⁸⁰ and to attenuate thromboxane release and improve survival¹⁸¹ in various animal models of endotoxemia. These exciting initial results, and the availability of several blockers and receptor antagonists, portend a future use for PAF modification.

Efforts to modulate both the adherence and function of inflammatory cells are an exciting area of research, as activated neutrophils clearly play an important role in the development of multiple organ failure. Blockade of neutrophil adhesion receptors with monoclonal antibodies enhances survival in animal models of endotoxic and hemorrhagic shock.^{182,183} Again, our basic understanding is not yet adequate to intelligently modify such important processes.

Oxygen free radicals generated by activated neutrophils or xanthine oxidase may oxidize membrane lipids, forming lipid peroxides, resulting in membrane dysfunction.¹⁸⁴ Native antioxidant systems do exist, but can be overwhelmed. Circulating levels of vitamin E, a natural antioxidant, are low in patients with ARDS.¹⁸⁵ Efforts to modify oxidant activity have included blockade of free radical generation, addition of free radical scavengers, augmentation of host antioxidant defenses, and prevention of amplification of tissue damage by neutrophils.¹⁸⁴ Particularly exciting are free radical scavengers such as superoxide dismutase¹⁸⁶ and spin-trapping nitrones¹⁸⁷ which improve survival in animal models of endotoxic and hemorrhagic shock. But, despite such encouraging initial animal work, such therapy is not yet appropriate in human patients.

The continuous synthesis of nitric oxide (Figure 32.2) plays an important role in the regulation of pulmonary and systemic vascular tone in sepsis¹⁸⁸ and this presents potential opportunities for intervention.¹⁸⁹ Aerosolized nitric oxide has been

shown to be useful in reversing the pulmonary hypertension associated with ARDS¹⁹⁰ and nitric oxide synthesis blockade may improve the hypotension and renal dysfunction associated with sepsis. However, its complex interactions with other cytokines and variable effects on different vascular beds render any nitric oxide-based interventions investigational at the present time.

Recently, recombinant activated protein C (rAPC) has been shown to have a favorable influence in patients with sepsis-induced multiple organ failure, after it demonstrated a 6% absolute reduction in mortality in a large multicenter trial.¹⁹¹ Institutional criteria for administration of rAPC infusion vary, but generally include those patients with vasopressor-dependent septic shock and multiple organ failure of recent onset. Its major complication is bleeding, which has precluded its general use in septic shock in burn patients. However, it may ultimately have a role in septic shock associated with isolated inhalation injury.¹⁹²

Most patients who die in the burn unit after surviving resuscitation succumb to multiple organ failure.¹⁹³ Although modification of the cascade of events leading to multiorgan failure at the cellular and subcellular level is an enticing possibility, our fragmented understanding of these processes mitigates against such therapy in human patients at the present time. That TNF enhances the ability of neutrophils to kill invading bacteria¹⁹⁴ and of rats to survive Gram-negative sepsis,¹⁹⁵ that cyclooxygenase inhibition increases TNF production after burn,¹⁹⁶ that PGE₂ is important in renal autoregulation;¹⁹⁷ and that cytokine levels vary significantly over the course of critical illness¹⁹⁸ makes one loath to interfere in such complex, and poorly understood processes. Vigilant clinical care in the intensive care unit, with the prevention of sepsis, proper management of burn wounds, support of the gut barrier, and careful attention to whole-body hemodynamics is a much more fruitful area in which a vigilant clinician can make a difference. On the near horizon is an exciting new understanding of the molecular mechanisms of critical illness that is likely to lead to effective targeted interventions.¹⁹⁹

Introduction

Acute renal dysfunction is a major complication affecting the thermally injured individual and is commonly associated with a high mortality rate. Currently, the incidence of acute renal failure in burn patients varies between 0.5 and 30% with a reported mortality rate between 73 and 100%.¹⁻⁴ Prior to 1965, there were no reported survivors from acute renal failure following burns.⁵ While advances have been made in the understanding of the etiology of acute renal failure in association with thermal injury, little has been accomplished with the actual treatment. The application of dialysis as a treatment modality has not significantly changed the mortality rate of individuals suffering from acute renal failure.⁶ Therefore, the best treatment for acute renal dysfunction is prevention by understanding the pathophysiology of renal dysfunction in the thermally injured individual. This chapter will review the definition, the etiology, the pathophysiology, the diagnosis, and the treatment of acute renal failure in association with thermal injury (Figure 33.1).

Definition

Historically, acute renal failure has been defined as an abrupt and sustained decrease in renal function. Unfortunately, there is no consensus regarding an absolute definition for acute renal failure. This is exemplified by more than 30 different definitions having been used in the literature creating much confusion and making comparisons between studies impossible.⁷ Although the definitions are numerous, the common theme of all definitions in the literature is an abrupt decline in glomerular filtration rate with the inability of the kidneys to appropriately regulate fluid, electrolytes, and acid-base homeostasis. In an effort to standardize the definition of renal dysfunction, the International Acute Dialysis Quality Initiative group has developed the RIFLE criteria (Table 33.1). The RIFLE criteria

is a classification system that utilizes the glomerular filtration rate (GFR) and urine output to define increasing levels of renal dysfunction. Patients are classified into one of five categories:

1. renal dysfunction,
2. injury to kidney,
3. failure of kidney,
4. loss of kidney function, and
5. end-stage kidney disease

RIFLE is based on the worst value between glomerular filtration rate (GFR) or urine output and the need for sustained renal replacement therapy. The classification system has been clinically validated, with increasing severity grades of acute renal failure corresponded with increasing mortality.⁸ This new classification system should aid in future experimental designs and allow for relative comparisons between studies investigating acute renal failure associated with thermal injuries.

Etiology of acute renal failure

Burn-related renal insufficiency is most commonly observed during the period of initial resuscitation after burn injury or as a component of the multi-organ dysfunction associated with severe sepsis.

The major etiological factors associated with the development of early acute renal dysfunction in the burn individual are hypovolemia or an ineffective perfusion gradient between the glomerulus and Bowman's space. The principal driving force for glomerular pressure/filtration is effective renal blood flow that is controlled by the relative resistance between the afferent and efferent renal arterioles. During early burn resuscitation, decreased glomerular filtration rate can be due to:

- hypovolemia,
- depressed myocardium (cardiac output),
- extrinsic compression via abdominal compartment syndrome, or
- denatured proteins.

Hypovolemia

The most common cause of early renal dysfunction in the thermally injured patient is hypovolemia secondary to extravascular fluid loss from the burn injury. Burns affecting more than 20% total body surface area are of sufficient size to induce decreased renal blood flow from extravascular fluid loss.^{9,10} This concept is supported by the observations of Kim et al. that burn size is an independent predictor of acute renal failure in the burn population.¹¹ The depressed renal blood

flow results in ischemia and cell death. The ischemic insult is known to produce oxygen free radicals that cause direct tubular cellular damage, disruption of tight junctions between cells resulting in obstructing casts which further reduces the effective glomerular filtration rate. Thus, the time the kidneys are ischemic is critically important to the development of acute renal insufficiency. Nguyen et al. found initial management of the burn individual to be critically important to overall survival. Fluid replacement therapy was demonstrated to have a protective affect against acute renal failure.¹² Similarly, the Shriners Burn Institute for Children, Galveston observed that time to initiation of resuscitative fluids was directly related to the incidence of renal dysfunction and overall mortality.¹³ They concluded that early aggressive fluid resuscitation lessens kidney damage, thus preventing renal dysfunction and hence improving overall outcome.

Fig. 33.1 Autopsy specimen from a patient with acute tubular necrosis and renal failure. Note the edema and the alteration of medullary pyramids. Acute renal failure in burn patients carries a high mortality.

Cardiac dysfunction

Cardiac dysfunction is known to result in reduced renal blood flow and thus induces renal insufficiency. While diminished cardiac output following thermal injury has been attributed to decreased preload or hypovolemia, there is increasing evidence of direct myocardial suppression. Myocardial dysfunction after thermal injury is commonly overlooked by physicians due to the concentrated effort to correct the overwhelming state of hypovolemic shock and electrolyte abnormalities.¹⁴ However, an effective burn surgeon must re-establish adequate renal blood flow early by correcting the diminished preload state but be aware of the impact of the burn injury on the entire cardiovascular system. Patients suffering burns larger than 50% total body surface area are subject to decreased cardiac output, increased myocardial workload, myocardial ischemia, and acute cardiac infection from the large area of wounded skin.¹⁵⁻¹⁹ Several authors have suggested theories to explain the decreased cardiac output associated with thermal injury:

- increased sympathetic activity with impaired adrenal response,
- hypovolemia resulting in myocardial ischemia, and
- direct myocardial suppression.^{16-18,20-22}

Of the potential theories, direct myocardial suppression by tumor necrosis factor (i.e. myocardial depressant factor) has gained substantial interest. Tumor necrosis factor is known to be released by myocytes stimulated by endotoxin or direct thermal injury.²³⁻²⁸ The effects of tumor necrosis factor on cardiac function include reversible biventricular dilatation, decreased ejection fraction, and decreased stimulation to catecholamines (Figure 33.2).^{25,29-31} While most early cardiac dysfunction caused by tumor necrosis factor can be reversed by inotropic support, the key is early diagnosis to prevent ineffective renal perfusion and thus prevent the morbidity and mortality associated with renal insufficiency.

Extrinsic compression via abdominal compartment

Burns larger than 20% total body surface area generally require intravenous resuscitative efforts. During resuscitation of a thermally injured patient, the initial volume of fluids utilized should be proportional to the area of burn injury. Despite a physician's greatest effort to monitor endpoints of resuscitation, obligatory intercompartmental fluid shifts will occur during resuscitation.³² These intercompartmental fluid shifts can be specifically hazardous if they occur into fascial bond

TABLE 33.1 THE RIFLE CRITERIA		
	GFR	Urine output
Risk of renal dysfunction	Serum creatinine $\times 1.5$	$<0.5 \text{ mL/kg/h} \times 6 \text{ h}$
Injury to the kidney	Serum creatinine $\times 2.0$	$<0.5 \text{ mL/kg/h} \times 12 \text{ h}$
Failure of kidney function	Serum creatinine $\times 3.0$ or creatinine $>4 \text{ mg/dL}$ when there was an acute increase of $>0.5 \text{ mg/dL}$	$<0.5 \text{ mL/kg/h} \times 24 \text{ h}$ or anuria $\times 12 \text{ h}$
Loss of kidney function	Persistent ARF ≥ 4 weeks	
End-stage kidney disease	Persistent ARR ≥ 3 months	

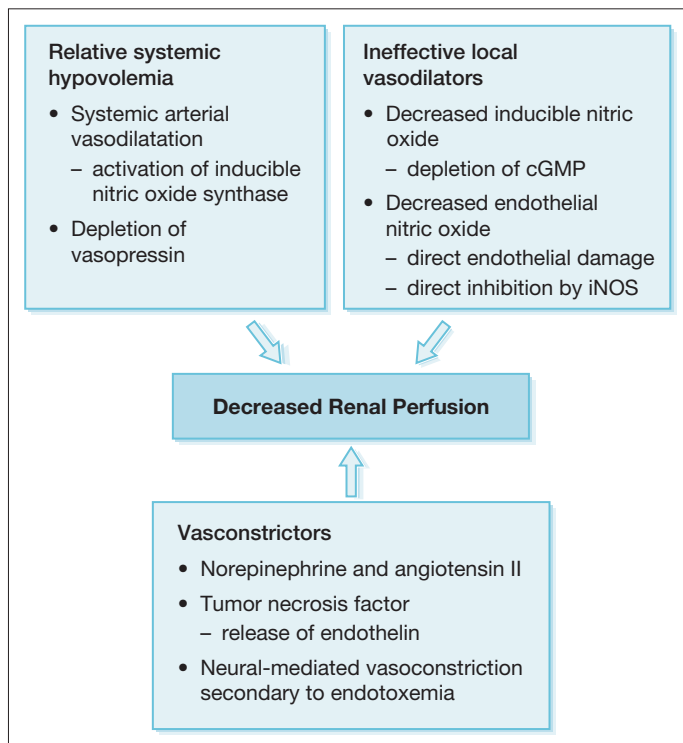

Fig. 33.2 Multifactorial etiology of sepsis-induced acute renal failure.

compartments such as the peritoneal cavity. Numerous studies from the trauma literature have described the adverse physiological effects of increasing intra-abdominal pressure on visceral perfusion.^{33–35} Abdominal compartment hypertension is a known pathological process that occurs during initial burn resuscitation as defined by intraperitoneal pressures greater than 25 mmHg.^{32,36–38} However, the exact incidence of abdominal compartment syndrome, the point of decreased visceral perfusion, is currently unknown during burn shock resuscitation.³² O'Mara et al. demonstrated that the volume and type of fluid resuscitation affects the development of abdominal compartment syndrome in the burn patient. It has been suggested that fluid resuscitation with crystalloid greater than 25 L/kg alerts the clinician to possible abdominal compartment hypertension and to monitor for decreased cardiac output, decreased lung compliance, or decreased renal perfusion — abdominal compartment syndrome.

Denatured proteins

Rhabdomyolysis and free hemoglobin have both been implicated in the development of acute renal failure.³⁹ Of the two, rhabdomyolysis has been implicated to cause renal insufficiency to a greater extent following thermal injury. Rhabdomyolysis can arise secondary to direct thermal affect, compartment syndrome, or following electrical injury. The release of myoglobin or unconjugated hemoglobin into the systemic circulation results in blockage of renal tubules, constriction of afferent arterioles, and the generation of oxygen free radicals.⁴⁰ The generation of oxygen free radicals directly injures the renal tubular cells, contributing to the renal insufficiency. The extent of renal injury is directly related to the

TABLE 33.2 RENAL FAILURE DYSFUNCTION AND SEPSIS

*Sepsis associated with lactic acidosis or altered mental status.
†Sepsis associated with hypotension.

amount of iron-containing molecules released and the state of hydration and degree of acidosis.⁴¹ Fortunately, the incidence of denatured proteins causing burn-associated acute renal insufficiency is low and the overall prognosis is favorable if the pathological source is identified early and appropriate treatment is initiated.⁴²

Sepsis

There have been significant advances made in the treatment of burn injuries since 1965. Early aggressive resuscitation and excision have significantly influenced the course of acute renal failure immediately associated with thermal injury.^{43,44} However, acute renal dysfunction associated with the septic syndrome continues to cause significant mortality.⁴⁵

Sepsis and septic shock are the most common causes of death in the intensive care unit (ICU) and are responsible for approximately 35–50% of the cases of acute renal dysfunction within the ICU. Several authors have found the degree of sepsis to be directly related to the incidence of acute renal dysfunction^{46,47} (Table 33.2). The key to treatment is a basic understanding of the pathophysiology of acute renal failure associated with sepsis. The basis of the physiological changes associated with sepsis-induced acute renal dysfunction is multifactorial in nature but begins clinically with a generalized arterial vasodilatation secondary to a decreased systemic vascular resistance (Figure 33.2). Initially, bacteria or their products activate sepsis-associated mediators (cytokines) locally at the site of direct invasion. In sepsis, the homeostatic balance between production and inactivation of these mediators is altered, allowing for release of these mediators systemically. The systemic effect of this imbalance is a procoagulant state with direct damage to the endothelium and vasoparalysis. It has been theorized that acute renal insufficiency associated with sepsis is the result of each of these pathological processes. The vasoparalysis seen in sepsis results in a relative or profound state of hypotension that activates the neurohumoral axis. The sympathetic nervous system and renin–angiotensin–aldosterone axis responds to the hypotension by increasing the cardiac output to maintain the systemic arterial circulation. However, this systemic response may actually worsen renal perfusion and therefore function by inducing a prerenal state by direct renal arteriole vasoconstriction.⁴⁵ This pathological process is aided by other direct vasoconstrictors (tumor necrosis factor — endothelin) known to be released during sepsis, and the inability of locally secreted vasodilators (endothelial and inducible nitric oxide) to counterbalance these sepsis-associated vasoconstrictors.^{45,48} Finally, as mentioned previously, sepsis induces a procoagulant state by affecting the expression of complement and the fibrinolytic

cascade.^{49–51} This alteration in the homeostasis of coagulation may result in a state of disseminated intravascular coagulation with direct injury to the kidney by glomeruli microthrombi.⁵² The net result is a lack of perfusion to the kidneys during sepsis that will ultimately culminate in acute tubular necrosis secondary to ischemia.

Diagnosis of acute renal insufficiency

The key to the diagnosis of acute renal injury following thermal injury is to have a strong fund of knowledge in the pathophysiology affecting the burned patient throughout their treatment course. Significant renal injury may be present despite normal urine output or significant changes in the biochemical markers of renal injury; therefore, a physician must constantly review the global physiological state of a thermally injured patient and anticipate conditions that may affect the renal system so that a stepwise approach to the diagnosis and treatment may be initiated.

Of the physiological parameters of renal function, altered urine output is probably the first and most recognized sign of renal dysfunction. Urine output has been demonstrated to be a very specific but unfortunately not a very sensitive measure of renal function.⁵³ Most clinicians regard urinary output of little diagnostic value in the evaluation of renal dysfunction since severe renal injury may exist with any pattern of urinary output. The variability is due to the fact that urinary output is not determined by the GFR alone, but by the difference between the GFR and tubular reabsorption. The one clinical scenario in which urinary output may be diagnostic is the presence of anuria (<50 mL/day) or complete cessation of GFR.⁵⁴ The most common cause of anuria, excluding postrenal obstruction, is a severe prerenal condition. While it is true that other conditions (acute cortical necrosis, bilateral arterial occlusion and rapidly progressive acute glomerulonephritis) may cause anuria, their incidence is low and the diagnosis is usually readily apparent due to additional clinical signs.

Although urinary output is commonly non-diagnostic regarding the type of renal injury, both microscopic and biochemical analysis may aid in the diagnosis of acute renal injury and thus guide treatment options.⁵⁵ Microscopic examination of the urinary sediment is an easy and inexpensive initial evaluation of acute renal injury to determine the underlying renal pathology. The combination of normal urinary sediment and oliguric/anuric urinary output would suggest a prerenal condition, whereas the presence of epithelial casts and abundant tubular epithelial cells is pathognomonic for acute tubular necrosis. Similarly, the identification of pigmented casts on microscopic evaluation signifies the diagnosis of myoglobinuria most likely secondary to rhabdomyolysis. If, however, the microscopic evaluation is non-diagnostic, urinary electrolytes will allow for the evaluation of the renal response to the individual's physiological state.

The main goal in evaluating urinary electrolytes of a thermally injured individual is to differentiate between the prerenal and renal forms of acute renal failure. It has been well established that a prerenal state in the presence of a functional nephron is associated with an enhanced absorption of sodium or a low fractional excretion of sodium. The fractional excretion of sodium (FeNa) is defined as:

$$\text{FeNa} = \frac{(\text{urine sodium} \times \text{plasma creatinine})}{(\text{plasma sodium} \times \text{urinary creatinine})}$$

with a value <1% associated with a prerenal condition and a value >1% associated with a renal condition.⁵⁶ While this is the accepted rule, there are conditions that affect renal absorption of sodium and thus have been shown to affect the calculated value (Table 33.3). Additionally, chronic renal insufficiency has been demonstrated to be associated with altered sodium homeostasis and therefore the interpretation of the FeNa in the setting of renal insufficiency is difficult. In this situation, an alternative agent such as urea may be appropriate. Recently, fractional excretion of urea (<35) was suggested to be more specific and sensitive than sodium in distinguishing between prerenal and renal forms of acute renal failure.⁵⁷ The prerenal state does not just affect the homeostasis of sodium and urea; several additional indexes can be utilized to differentiate between the two forms of acute renal failure (Table 33.4).

Ideally, we would have a biochemical marker of acute renal injury that would:

- allow early detection of renal injury,
- identify the nephron segment affected,
- reflect improvement and worsening of renal function, and
- be easily and rapidly measured.⁵⁸

Currently, no such 'ideal' biomedical filtration marker exists. However, creatinine has been utilized as the standard marker for determining the glomerular filtration rate. Serum creatinine is freely filtered across the glomerulus and neither absorbed nor metabolized by the kidney. However, the amount of creatinine excreted is approximately 10–20% greater than the amount filtered. Therefore, the calculated creatinine clear-

TABLE 33.3 FACTORS THAT AFFECT FRACTIONAL SECRETION OF SODIUM

Fractional excretion of urea	<35	>50

ance by definition overestimates the true GRF during normal steady-state conditions.⁵⁹ Creatinine is thus not an 'ideal' marker but a 'reasonable' marker of GRF in a normal host.

The impact of illness appears to have a significant affect on utilizing creatinine as a marker of GFR due to the non-steady-state environment. Plasma creatinine is not only dependent on its urinary clearance but also on its production and volume of distribution within the body. Several studies have demonstrated the impact of illness on each of these parameters^{53,60} (Table 33.5). In critically ill patients, serum creatinine appears to be an inaccurate absolute determinant of GFR. In fact, serum creatinine has been demonstrated to often lag behind the true degree of progressive renal dysfunction and renal recovery.⁵³ Therefore, in these conditions, serum creatinine should be viewed by the degree of change over time, which in turn should grossly reflect the degree of GFR change over time.

Moran and Myers demonstrated the importance of understanding the degree of creatinine change over time.⁶¹ They investigated creatinine kinetics following ischemic postoperative acute renal failure. Based on their observations, they developed hypothetical profiles of acute renal failure and recovery focusing on changes in GFRs and their corresponding changes in serum creatinine. Their work suggested that the two variables are often not inversely related but may often dissociate during acute renal failure and recovery: i.e. a rising serum creatinine is not always indicative of worsening GFR and a decreasing serum creatinine is not always indicative of an improving GFR. What did appear to be prognostic in acute renal failure is the number of days the plasma creatinine continued to rise after the initial ischemic insult. Post-insult day 4 appeared to be significant in determining the state of recovery. An abrupt insult followed by immediate recovery caused the serum creatinine to peak around post-insult day 4. However, if serum creatinine continued to rise beyond post-insult day 4, this indicated that renal recovery had not begun and this was followed by a severe protracted course of acute renal insufficiency. While this study was not conducted in a burn population, the underlying pathophysiology (ischemic) is germane to the burn population, especially after initial resuscitation.

A clinician should understand the limitations of any marker used to calculate or follow GRF during renal injury. While not an 'ideal marker,' creatinine is the gold standard for this calculation. GFR calculations based on creatinine clearance should be made over short time intervals with the serum cre-

Factors	Effect on serum creatinine

Trauma	Increased production
Fever	Increased production
Immobilization	Increased production

atinine value reflecting the mean of the values obtained at the beginning and end of the collection interval.

Treatment of acute renal failure

The key to the treatment of acute renal failure is prompt diagnosis coupled with a rapid reversal of the underlying pathophysiology while preventing iatrogenic injury. If the process is progressive despite initial therapeutic maneuvers, early continuous renal replacement is indicated. This section will focus on the prevention of early and late acute renal injury and the current theories behind renal replacement.

As stated previously, early acute renal failure is secondary to ineffective renal perfusion. Several authors have demonstrated that the timing of initiation of resuscitative fluids is directly related to the incidence of renal dysfunction.^{12,13} Therefore, resuscitative efforts should be begun immediately to re-establish effective renal perfusion. Several resuscitative formulas have been established based on multivariate logistic regression analysis (Table 33.6). Which formula to utilize is unimportant, but the clinician should recognize that these formulas are estimates of volumes of fluids needed over a period of time. The true amount is directly dependent on the patient's own physiological status and degree of injury. A clinician should continuously monitor endpoints of resuscitation to guide fluid therapy and prevent over-resuscitation. If the true volume status (preload) or ability to assess effective renal perfusion is difficult, one should initiate monitoring of central pressures or global volume-related variables (extravascular lung water volume, intrathoracic blood volume). Currently, the best means to measure the degree of resuscitation is unknown; however, recent data suggest monitoring of regional perfusion variables as a more reliable means of correlating the degree of resuscitation than monitoring any single pressure- or volume-related variable.⁶² While establishing an effective circulating volume is of prime importance, an astute clinician should also carefully assess myocardial contractility in every patient to exclude myocardial dysfunction as a contributing factor to ineffective renal perfusion. The universal goal is to reestablish effective renal perfusion through a well thought

TABLE 33.6 BURN FORMULAS FOR ESTIMATING INITIAL RESUSCITATION

Colloid: Evans	NS 1 mL/kg/%burn	1 mL/kg/%burn
Crystalloid: Parkland Modified Brooke	4 mL/kg/%burn 2 mL/kg/%burn	
Pediatric formulas: Cincinnati Shriners Institute for Burn Children Galveston Shriners Institute for Burn Children	4 mL/kg/%burn + 1500 mL/m ² TBSA 5000 mL/m ² BSA + 2000 mL/m ² TBSA	
TBSA = total body surface area. BSA = burn surface area.		

out resuscitation plan based on proven resuscitation formulas and modified by variables correlated with the degree of resuscitation.

The etiology of late renal dysfunction is directly related to the development of sepsis and is multifactorial in nature. Thus the most effective therapy is prevention or early recognition of the septic state (Box 33.1). Every thermally injured patient should be continuously monitored for early markers of sepsis (feeding intolerance, increasing insulin resistance, elevation of acute phase reactants) so that early therapy may be initiated. Once a clinically significant infectious organism is identified, early goal-directed therapy should be initiated. Rivers et al. demonstrated a significant reduction in mortality if early goal-directed therapy is applied to the septic patient.⁶³ This work has recently been acknowledged and summarized in the Surviving Sepsis Campaign published as a consortium agreement of several different governing bodies.⁶⁴ The principle is simple:

- establish early source control while providing effective antibiotic therapy and maximizing global perfusion and thus renal perfusion.

The strategy is effective and important since no renal protective pharmacological agent has been demonstrated to prevent or limit renal dysfunction. The importance of infectious surveillance to minimize the affects of a variety of known pathogens that infect the thermally injured patient cannot be overstated. The goal is to effectively treat local infections and prevent systemic dissemination to avoid the morbidity and mortality of septic shock.

Fortunately due to major advances in burn care resuscitation and the treatment of sepsis, renal failure requiring renal replacement therapy is a rare event.⁶⁵ The reported incidence is approximately 1%, but the overall mortality associated with acute renal failure requiring renal replacement therapy approaches 80%.^{2,3} Burn patients with renal insufficiency are at particular risk for renal replacement therapy due to the large positive fluid balances associated with the initial resuscitation therapy, enhanced catabolism leading to elevated urea levels, and need for substantial nutritional support to maintain a positive nitrogen balance.⁶⁵ Previously, renal replacement therapy has been successfully performed utilizing peritoneal dialysis.⁶⁶ However, this form of therapy has been limited by its clearance rates and the need for catheter insertion through the abdominal wall, which is a common donor site or thermally injured area. Over the past two decades, continuous hemofiltration has become the standard renal replacement therapy for critically ill patients. The technique provides a smooth and continuous control of volume stasis without inducing hemody-

BOX 33.1 Definition of SIRS/sepsis

Documentation of confirmed infectious source
 Heart rate >90 beats per minute
 Body temperature <36°C or >38°C
 Hyperventilation: respiratory rate >20 breaths per minute or PaCO₂ less than 32mmHg
 White blood cell count <4000 cell/mm³ or >12000 cells/mm³ or >10% immature neutrophils

namic instability. It is a proven therapy in the burn population; however, the incidence of bleeding complications is higher compared to traditional renal replacement therapies.⁶⁵

An additional theoretical benefit of continuous hemofiltration is the removal of proinflammatory mediators, which may be associated with the development of multiple organ failure.⁶⁷ The experimental and clinical data suggest that the rate of hemofiltration and biological nature of the filters affect the overall results.⁶⁸ Currently, there is insufficient data to recommend continuous hemofiltration solely on the basis of removal of inflammatory mediators. Future randomized prospective studies will hopefully resolve this theoretical benefit.

Major advances in the treatment of the thermally injured individuals have been accomplished over the past four decades. Early aggressive resuscitation coupled with early excision has significantly reduced the early complications of burn injury including renal insufficiency. This is exemplified by the fact that prior to 1965 there were no reported survivors from acute renal failure following burn injury. While the incidence of acute renal insufficiency following burn injury has been reduced, the disorder is still clinically significant after prolonged delayed initial resuscitation and following the development of sepsis. Therefore, a physician must constantly review the global physiological state of a thermally injured patient and anticipate conditions that may affect the renal system so that a stepwise approach to the diagnosis and treatment may be initiated. Currently, there are no pharmacological agents that prevent or treat acute renal insufficiency. Therefore, the best treatment option is prevention. However, if renal insufficiency develops requiring renal replacement therapy, the therapy should be initiated early to prevent an edematous state and allow for early nutritional support. The future of acute renal injury lies in the development of 'early markers' of acute renal insufficiency to allow for early aggressive treatment of the disorder by maximizing renal perfusion while minimizing nephrotoxic agents.

Introduction

About 500 000 people are burned and seek medical care in the USA every year, most of whom have minor injuries and are treated in the outpatient setting. However, approximately 50 000 burns per year in the USA are moderate to severe and require hospitalization for treatment. Some of these will require critical care for at least part of their hospitalization, and some will require it for months. About 4000 die from complications related to the burn.¹ Burn deaths generally occur in a bimodal distribution, either immediately after the injury, or weeks later due to multiple organ failure, a pattern similar to all trauma-related deaths.

Morbidity and mortality from burns are decreasing in incidence. Recent reports revealed a 50% decline in burn-related deaths and hospital admissions in the USA over the last 20 years.¹ This rate of decline was similar for all burned patients seeking medical care. The declines were likely most affected by prevention efforts causing a decreased number of patients with potentially fatal burns, and improved critical care and wound management for those who sustain severe burns. In 1949, Bull and Fisher reported 50% mortality rates for children aged 0–14 years with burns of 49% of the total body surface area (TBSA), 46% TBSA for patients aged 15–44, 27% TBSA for those aged between 45 and 64, and 10% TBSA for those 65 and older.² These dismal statistics have improved, with the latest studies reporting a 50% mortality for 98% TBSA burns in children 14 years and under, and 75% TBSA

burns in other young age groups.³ Therefore, a healthy young patient with almost any size burn should be expected to survive using modern wound treatment and critical care techniques.

Burned patients generally die from two causes: ‘burn shock’ resulting in early deaths, and multiple organ failure and sepsis, leading to late deaths. With the advent of vigorous fluid resuscitation protocols in the severely burned, irreversible burn shock has been replaced by sepsis and subsequent multiple organ failure as the leading cause of death associated with burns in those who do not die at the scene. Those who do not die precipitously with any risk for mortality will require what is termed *critical care*, a service performed in specialized units containing the equipment, supplies, and personnel required for intensive monitoring and life-sustaining organ support to encourage recovery.

Critical illness in burned patients has typically been equated to sepsis. In a pediatric burn population with massive burns over 80% TBSA, 17.5% of the children developed sepsis, defined as bacteremia with clinical signs of sepsis.⁴ The mortality rate in the whole group was 33%, most of whom succumbed to multiple organ failure. Some of the patients who died were bacteremic and ‘septic’, but the majority were not. These findings highlight the observation that the development of severe critical illness and multiple organ failure is often associated with infectious sepsis, but it is by no means required to develop this syndrome. What is required is an inflammatory focus, which in severe burns is the massive skin injury that requires inflammation to heal.

It has been postulated that the progression of patients to multiple organ failure exists in a continuum with the systemic inflammatory response syndrome (SIRS).⁵ Nearly all burn patients meet the criteria for SIRS as defined by the consensus conference of the American College of Chest Physicians and the Society of Critical Care Medicine.⁶ It is therefore not surprising that severe critical illness and multiple organ failure are common in burned patients.

Patients who develop dysfunction of various organs, such as the cardiopulmonary system, renal system, and gastrointestinal system, can be supported to maintain homeostasis until the organs repair themselves or a chronic support system can be established. Critical care may be defined loosely as the process of high-frequency physiological monitoring coupled with short response times for pharmacological, ventilatory, and procedural interventions. This chapter will describe the organization of specialized burn intensive care units (BICUs),

including requirements for personnel and equipment. The techniques used in BICUs will be described, and then organ-specific management will be addressed.

Burn intensive care unit organization

Physical plant

Optimally, a BICU should exist within a designated burn center in conjunction with a recognized trauma center, thus providing the capability to treat thermal and non-thermal injuries. This unit, however, need not be physically located in the same space as that designated for non-burned trauma patients. In fact, the requirements for the care of wounds in burned patients necessitates additional equipment such as shower tables and overhead warmers, and thus separate space dedicated to the severely burned is optimal. This space may be located in a separate hospital with established guidelines for transfer to the facility.⁷

The number of beds required in the unit may be calculated by the incidence of moderate to severe burns in the referral area, which in the USA is approximately 20 per 100 000 people per year. The Committee on Trauma of the American College of Surgeons recommends that 100 or more patients should be admitted to this facility yearly, with an average daily census of three or more patients to maintain sufficient experience and acceptable access to specialized care.⁷

Most moderate to severe burns requiring admission will require intensive monitoring for at least the day of admission during the resuscitative phase. Thereafter, approximately 20% will require prolonged cardiopulmonary monitoring for inhalation injury, burn shock, cardiopulmonary compromise, renal dysfunction, and the development of SIRS and multiple organ dysfunction syndrome (MODS). In these severely burned patients, the average length of stay in the BICU is approximately 1 day per % TBSA burned. Using an average of 25 days admission for a severely burned patient and 2 days for those not so severely injured, this will require approximately 130–150 BICU inpatient days per 100 000 population. An eight-bed BICU can then serve a population of 1 000 000 sufficiently. Space provided should be at least 3000 ft², including patient beds and support space for nursing/charting areas, office space, wound care areas, and storage.

Personnel

A BICU functions best using a team approach between surgeons/intensivists, nurses, laboratory support staff, respiratory therapists, occupational and physical therapists, mental health professionals, dietitians, and pharmacists (Box 34.1). The unit should have a designated medical director who is a burn surgeon, to coordinate and supervise personnel, quality management, and resource utilization. The burn surgeon will usually work with other qualified surgical staff to provide sufficient care for the patients. It is recommended that medical directors and each of their associates be well versed in critical care techniques, and care for at least 50 patients per year to maintain skills.⁷ In teaching hospitals, two to three residents or other medical providers should be assigned to the eight-bed unit described above. A coverage schedule should be devised to provide 24-hour prompt coverage.

BOX 34.1 Assigned burn unit personnel

- Experienced burn surgeons (burn unit director and qualified surgeons)
- Dedicated nursing personnel
- Physical and occupational therapists
- Social workers
- Dietitians
- Pharmacists
- Respiratory therapists
- Psychiatrists and clinical psychologists
- Prosthetists

BOX 34.2 Consultants for the BICU

General surgery	Pediatrics
Plastic surgery	Psychiatry
Anesthesiology	Cardiology
Cardiothoracic surgery	Gastroenterology
Neurosurgery	Hematology
Obstetrics/gynecology	Pulmonology
Ophthalmology	Nephrology
Orthopedic surgery	Neurology
Otolaryngology	Pathology
Urology	Infectious disease
Radiology	

Nursing personnel should consist of a nurse manager with at least 2 years of intensive care and acute burn care experience, and 6 months of management responsibilities. The rest of the nursing staff in the BICU should have documented competencies specific to the care of burned patients, including critical care and wound care.⁷ Owing to the high intensity of burn intensive care, at least two full-time equivalents are required per ICU bed to provide sufficient 24-hour care. Additional personnel are required for respiratory care, occupational and physical therapy, and other support. A dedicated respiratory therapist for the burn unit is optimal.

Owing to the nature of critical illness in burned patients, complications may arise that are best treated by specialists not generally in the field of burn care (Box 34.2). For these reasons, these specialists should be available for consultation should the need arise.

Equipment

The equipment that must be present or available in the BICU are those items which are common for all ICUs, and some which are specialized to the BICU (Box 34.3). Each BICU bed must be equipped with monitors to measure heart rate, continuous electrocardiography, noninvasive blood pressure, invasive arterial and venous blood pressures, and right heart cardiac output using either dye dilution or thermal dilution techniques. Continuous arterial blood oxygen saturation measurement is also required, while continuous mixed venous saturation monitoring is optional. Equipment to measure weight and body temperature should also be standard. Oxygen availability and at least two vacuum pumps must be present for each bed.

BOX 34.3 Equipment for a fully equipped BICU**STANDARD**

- Monitors (heart rate, electrocardiography, blood pressure, cardiac output, oxygen saturation, temperature)
- Scales
- Ventilators
- ACLS cardiac cart
- Laboratory support (blood gas analysis, hematology, chemistry, microbiology)

SPECIALTY

- Fiberoptic bronchoscopes
- Fiberoptic gastroscopes/colonoscopes
- Dialysis equipment (peritoneal dialysis and hemodialysis)
- Portable plain radiography
- Computed tomography/fluoroscopy/angiography
- Indirect calorimeters

Ventilatory equipment too must be available for all beds. The availability of a number of types of ventilators is optimal, including conventional ventilators with the capability to deliver both volume-targeted and pressure-targeted breaths as well as high-frequency ventilators that are oscillatory and/or percussive in design. An emergency cardiac cart containing advanced cardiac life support (ACLS) medications and a battery-powered electrocardiograph/defibrillator must be present on the unit should the need arise. Infusion pumps to deliver continuous medications and intravenous/intra-arterial fluids must also be readily available. A laboratory providing blood gas analysis, hematology, and blood chemistry must be located on site. Microbiological support to complete frequent, routine bacterial cultures should also be present.

Specialty equipment to be available includes various sizes of fiberoptic bronchoscopes for the diagnosis and treatment of pulmonary disorders, including personnel versed in these techniques. Fiberoptic gastroscopes and colonoscopes for gastrointestinal complications are also necessary. For renal support, equipment to provide peritoneal dialysis and both intermittent and continuous hemodialysis and hemofiltration should be available. Portable radiographic equipment for standard chest/abdominal/extremity radiographs must be immediately available. Equipment for computed tomography, fluoroscopy, and angiography should be available in other parts of the hospital. Indirect calorimeters to measure metabolic rate are preferable. Overhead warmers and central heating with individualized ambient temperature controls must be available for each room.

Hemodynamic monitoring in the burn intensive care unit

Most burned patients follow an anticipated course of recovery, which is ‘monitored’ in the ICU by measuring physiological parameters. Experienced clinicians assess these physiological measures in a repeated and sequential fashion to discern when potential interventions may be initiated to improve outcomes. Oftentimes, no intervention will be required, as the patient is

following the anticipated course. At other times, this is not the case and procedural or pharmacological intervention is necessary. Physiological monitoring is then used further to determine the adequacy of the interventions. The following is a survey of monitoring techniques used in the BICU.

Cardiovascular monitoring

Arterial lines

Hemodynamic monitoring is directed at assessing the results of resuscitation and maintaining organ and tissue perfusion. Currently used measures are only estimates of tissue perfusion, as the measurement of oxygen and nutrient transfer to cells cannot be made directly at the bedside. Instead, global physiological measures of central pressures serve as the principal guides.

Measurement of arterial blood pressure is the mainstay for the assessment of tissue perfusion. In critical illness, this measurement can be made using cuff sphyngomanometers; however, in practice this technique is not useful because the measurement is episodic, and placement of these cuffs on burned extremities is problematic. In addition, blood pressure can be increased in the extremity from the inflation and deflation of the cuff. Diastolic pressures can also be artificially elevated in the elderly and obese. Instead, continuous monitoring for hemodynamic instability through the use of intra-arterial catheters is generally preferable. Lines are typically placed in either the radial or femoral artery. The radial artery is the preferred site for most critically ill patients, because of safety with the dual arterial supply to the hand should a complication occur. However, it has been shown that radial artery catheters are inaccurate in the measurement of central blood pressure when vasopressors are used,⁹ and are notoriously inaccurate in children because of greater vascular reactivity.¹⁰ For these reasons, we recommend femoral arterial blood pressure measurement in burned patients.

In arterial catheters, systolic, diastolic, and mean arterial pressures should be displayed continuously on the monitor screen. Either systolic or mean arterial pressure can be used to determine adequacy of pressure, although a mean arterial pressure of greater than 70 mmHg is considered a more accurate description of normal tissue perfusion. The mean pressure is a more accurate description of central arterial pressure, because as the arterial pressure wave traverses proximally to distally, the systolic pressure gradually increases, while the diastolic pressure decreases. The mean pressure determined by integrating areas under the curve, however, remains constant. The adequacy of the waveform must also be determined, with a diminished waveform indicative of catheter dampening, requiring catheter replacement. Care must be taken to insure that the diminished waveform is not true hypotension, which can be determined using a manual or cycling sphyngomanometer placed on the arm or leg. Exaggerated waveforms with elevated systolic pressure and additional peaks in the waveform (generally only two are found) may be a phenomenon referred to as ‘catheter whipping’, which is the result of excessive movement of the catheter within the artery. Typically, this problem is self-limited, but care must be taken not to interpret typically normal systolic blood pressure values with evidence of catheter whipping as normal, as the effect generally overestimates pressures. Again, use of mean arterial pressures

as the principal guideline for the assessment of blood pressure is optimal as the effects of catheter whipping are then diminished.

Complications associated with arterial catheters include distal ischemia associated with vasospasm and thromboembolism, catheter infection, and arterial damage/pseudoaneurysm during insertion and removal. Although these complications are uncommon, the results can be devastating. Physical evidence of ischemia in the distal hand or foot should prompt removal of the catheter and elevation of the extremity. If improvement in ischemic symptoms is not seen in 1–2 hours, angiography should be considered. Should thromboembolism be found, the clot can be removed with operative embolectomy or clot lysis at the discretion of the treating physician. If during angiography, extensive arterial damage is found with ischemia, operative repair will be necessary.

Catheter infection as evidenced by purulence and surrounding erythema should instigate removal of the catheter, which will often suffice. With continued evidence of infection, antibiotics and incision and drainage of the site should be entertained. Great caution must be exercised if an incision is made over the catheter site to avoid arterial bleeding. If a pseudoaneurysm is encountered after arterial catheterization and removal without signs of distal ischemia, compression with a vascular ultrasound device until no further flow is seen in the pseudoaneurysm will often alleviate the problem without operative intervention.¹¹

Pulmonary artery catheters

Pulmonary artery catheters placed percutaneously through a central vein (internal jugular, subclavian, or femoral vein) and ‘floated’ into the pulmonary artery through the right heart have been used extensively in hemodynamic monitoring in ICUs. By measuring the back pressure through the distal catheter tip ‘wedged’ into an end-pulmonary branch, an estimate of left atrial pressure can be made. In addition, dyes or isotonic solutions injected into a proximal port can be used to determine cardiac output from the right heart. These data are used to estimate preload delivery to the heart, cardiac contractility, and afterload against which the heart must pump, which then directs therapy at restoration of hemodynamics. These catheters are used in ICUs under conditions of unexplained shock, hypoxemia, renal failure, and monitoring of high-risk patients.

Pulmonary artery catheters, while used widely in critical care settings, have come under scrutiny from reports indicating no benefit with their use. A study of 5735 critically ill adults in medical and surgical ICUs showed an increase in mortality and use of resources when pulmonary artery catheters were used. Most of these patients had medical conditions. The authors of this report suggested that their results should prompt a critical evaluation of the use of pulmonary artery catheters under all conditions.¹² An accompanying editorial went so far as to suggest an FDA-mandated moratorium on pulmonary artery catheters until further data were forthcoming.¹³ While this suggestion may be somewhat draconian, it should certainly cause the clinician to question whether using a pulmonary catheter would be of benefit in the particular situation.

Several reports exist in the literature regarding the use of pulmonary artery catheters in burned patients, most in regards

to parameters of resuscitation immediately after the injury. The first report in 1978 on pulmonary artery catheterization in 39 patients concluded that pulmonary wedge pressure was a more reliable indicator of circulating volume than central venous pressures. These authors also noted a consistent depression in myocardial function in the early phase of injury.¹⁴ Other authors have noted similar findings in terms of heart dysfunction using pulmonary artery catheters in children. They concluded that routine use of pulmonary artery catheters is useful in directing therapy during resuscitation, including modifying resuscitation volumes and the use of inotropes.¹⁵ Another report indicated that use of values generated from the pulmonary artery catheter during resuscitation to hyperdynamic endpoints improved survival in severely burned patients.¹⁶ Furthermore, they found that if patients were unable to reach the hyperdynamic parameters measured by the pulmonary artery catheter, they were more likely to die.¹⁷ These studies used historical controls, and their conclusions must be held in this light. In spite of the above findings, pulmonary artery catheters are rarely used during resuscitation in most burn centers, and their use is primarily limited to patients with unresponsive hemodynamic problems.

As mentioned above, the values derived from the pulmonary artery catheter can be used to drive heart function to supranormal levels with intravascular volume and inotropic support under defined protocols to improve oxygen consumption and presumably improve outcomes.¹⁸ While this approach received enthusiasm after the initial report, other studies have not found any benefit with the use of pulmonary artery catheters in the critically ill, and some have found them to be detrimental.¹⁹ The only study in burns is mentioned above, which found improved survival using the technique.¹⁷ Regardless, no well-designed prospective trial investigating whether pulmonary artery catheter-guided supraphysiological resuscitation parameters improve outcomes has been performed in burns, and this practice cannot be widely espoused.

Newly designed pulmonary artery catheters with sensors providing additional data have been used in critically ill patients other than burns. One of these catheters contains an oxygen saturation monitor on its tip, allowing the continuous measure of mixed venous oxygen saturation. The potential benefits of such a measure would be to give earlier notice of cardiogenic compromise, and allow for a more direct measure of whole-body resuscitation. Problems with calibration and position sensitivity, however, have limited its use. Another of these catheters has an implanted rapid response thermistor, and when combined with an electrocardiographic lead measuring P–R interval on a beat-to-beat basis, can give a reasonable estimate of right heart ejection fraction and thus heart function on a frequent basis.²⁰ Another variant of this is a catheter with an implanted heating filament and sensor that uses thermodilution to measure cardiac output every 30 seconds. The accuracy of both these catheters has been verified in clinical studies, but neither has been widely accepted for use.²¹

Base deficit

The base deficit is a value calculated using the Henderson–Hasselbalch equation based on the relationship between pH, pCO₂, and serum bicarbonate:

$$\text{pH} = 6.1 + \log (\text{HCO}_3^-)/(\text{pCO}_2)(0.03)$$

The base deficit is the stoichiometric equivalent of base required to return the pH to 7.40. Base deficit is routinely calculated on blood gas analysis, and provides a reasonable estimate of the degree of tissue anoxia and shock at the whole body level, particularly in hemorrhagic shock. A rising base deficit indicates increasing metabolic acidosis, and may stratify mortality in patients after major trauma.²² The same can be said for the use of base deficit in burn resuscitation.^{4,23} These studies showed a correlation of higher base deficit and increased mortality, and some have suggested this value is a better monitor of resuscitation than the time-honored monitors of urine output and arterial blood pressure.²⁴ Despite its utility as an indicator of shock, base deficit is a nonspecific indicator of metabolic acidosis, and may be elevated with alcohol, cocaine, and methamphetamine use. Interpretation may be difficult under these circumstances.

Transesophageal echocardiography

Transesophageal echocardiography has been used for a number of years as an intraoperative monitor in high-risk cardiovascular patients. It has not been used extensively in other critically ill patients because of the lack of available expertise and paucity of equipment. Since this device can be used as a diagnostic tool for the evaluation of hemodynamic function, it serves to reason that it could be used as a monitor in critically ill severely burned patients. A report documented the use of transesophageal Doppler measurements of cardiac output in a series of severely burned patients undergoing early escharotomy, and found that while it was able to detect changes in cardiac performance, its variation was dampened in comparison to measurements made with a pulmonary artery catheter.²⁵ Another report used it during resuscitation of a child with a 30% TBSA burn, which was successful.²⁶ Another more remote study used transesophageal echocardiography to measure cardiac function after burn, revealing the typical depression in left ventricular function documented using other means.²⁷ Others have found using the same technique that intravascular volume and cardiac contractility are significantly diminished the first day after burn in spite of high-volume resuscitation.²⁸ No study has been done to date investigating whether transesophageal echocardiography is of clear benefit in monitoring hemodynamics in burned subjects.

Arterial hemodilution and intrathoracic blood volume

Cardiac output can also be measured using a transpulmonary approach with a thermistor inserted into an arterial port that can measure thermodilution injected into a central venous line. One report showed reasonable agreement between this technique and standard pulmonary artery thermodilution measurements in severely burned patients.²⁹ The same group of authors showed that measurement of intrathoracic blood volume using a double indicator dilution technique as a measurement of adequate preload in severely burned patients might be a better indicator of adequate resuscitation compared to traditional techniques of urine output and blood pressure. Interestingly, they showed that the volumes given for resuscitation with this method were much higher than those pre-

dicted by the Parkland formula, but that no significant increases in extravascular lung water were seen.³⁰

Mechanical ventilation

The use of mechanical ventilation is central to the function of the BICU. Burned patients are at risk for airway compromise, necessitating endotracheal intubation and mechanical ventilation for a number of reasons. Inhalation of smoke causing damage to the upper airway, development of massive whole-body edema restricting the airway, and hypoxia occur relatively frequently during the initial resuscitation, all of which may require endotracheal intubation and mechanical ventilation. Thereafter, acute lung injury and acute respiratory distress syndrome may intervene, necessitating pulmonary support with ventilators. This section will deal briefly with indications for intubation, common ventilator strategies, and monitoring of mechanical ventilation.

Indications for intubation

Intubation entails passing an endotracheal tube from either the nose or the mouth through the pharynx into the trachea. This tube is then connected to a mechanical ventilator to cause inspiration and passive exhalation through the lungs. Indications for intubation in burned patients are in general to improve oxygenation and ventilation, or to maintain gas exchange during clinical conditions expected to compromise the airway. These indications are as follows (see also Table 34.1):

- Respiratory distress indicated by:
 - tachypnea
 - hypoxia
- Impending need for airway maintenance:
 - initial management of smoke inhalation injury
 - expected massive whole-body edema after resuscitation for a major burn.

Ventilatory modes

The complexity of mechanical ventilators has increased dramatically since the first generation of volume cycle ventilators used in the 1960s. The development of positive end-expiratory pressure (PEEP) to maintain functional residual capacity was followed by development of modes using partial ventilatory support, such as intermittent mandatory ventilation in the 1970s. Efficient microprocessors were then developed that permitted modes of ventilation such as pressure support ventilation, time-cycled pressure control ventilation, and inverse

TABLE 34.1 CLINICAL INDICATIONS FOR INTUBATION

Criteria	Value

Respiratory/ventilatory failure	Impending
Upper airway edema	Severe

ratio ventilation. Most recently, new processors have been used to combine modes of ventilation, such as pressure support and time-cycled pressure control ventilation, and open lung strategies such as airway pressure-release ventilation to some success. However, even with these new developments, the function of mechanical ventilators remains identical to those first used. Whether these new ventilators have had any appreciable effect on mortality remains to be fully elucidated.

The principal difference in mechanical ventilation from spontaneous ventilation, that each of us does every minute of the day, is the effect of positive pressure as opposed to normal physiological negative pressure. The use of positive pressure improves gas exchange by recruiting alveoli and increasing functional residual capacity (i.e. the number and volume of open alveoli at the end of expiration), thus improving ventilation perfusion mismatching and decreasing intrapulmonary shunting of blood past nonventilated lung areas (Figure 34.1). Adverse effects of positive pressure ventilation lie in its propensity to produce trauma to the airways (barotrauma) and its effects on intrathoracic pressure which can impede venous return to the heart and decrease cardiac output.

Control and assist control ventilation

The volume control modes are volume-cycled settings that deliver a preset tidal volume at a minimum respiratory rate and inspiratory flow rate regardless of the patient's own respiratory efforts (Figure 34.2). Of the two, the control mode will not trigger with patient effort. This mode is typically very uncomfortable for patients due to ventilator–patient dyssynchrony, with use limited to patients under general anesthesia. The assist control mode differs in that a breath will be delivered regularly according to a prescribed rate, but it will also deliver a breath upon patient negative pressure effort to open a flow valve, at which time the ventilator will fire allowing the patient to control his or her own ventilatory rate with a preset minimum rate as a back-up. This mode is typically used in heavily sedated patients who cannot generate enough tidal volume under pressure support modes or intermittent mandatory ventilation mode, or in those patients that the clinician wishes to minimize the work of breathing. It must be noted, however, that the work of breathing can be increased dramatically in patients with excessive ventilator triggering. Increasing the minimum number of breaths to match the patient's effort can minimize this effect. When using this mode of ventilation, it is important to monitor lung compliance by measuring serial peak and plateau pressures for diagnostic purposes as well as minimization of barotrauma.

Time-cycled pressure control ventilation

Volume-cycled ventilation delivers a set volume of air regardless of pressure required. In the case of poor lung compliance, such as in acute respiratory distress syndrome (ARDS), the mode could lead to excessive ventilatory pressures leading to significant airway injury. For this reason, time-cycled pressure control ventilation was developed that delivers inspiration at a given flow rate to a preset pressure. The breath is terminated at a set cycle time, not on the basis of volume of flow as is the case with volume-controlled ventilation. Therefore, pressure control has the advantage of limiting inspiratory pressure despite changes in compliance. It also has the disad-

Fig. 34.1 Photos of different ventilators commonly used in burn units in the USA. (a) The most commonly used is the 'servo' type ventilator, which can be set to give volume- or pressure-regulated breaths with or without pressure support or PEEP. The I:E ratios can also be reversed. (b) The second type is the VDR ventilator, which delivers HFPV or CPAP. (c) The third type is the APRV ventilator, which can be set to all the servo settings as well as APRV.

Fig. 34.2 Airway pressure curves illustrating the three mechanical functions: IN, initiation of the cycle; LIM, the preset limit (i.e. pressure or volume) imposed on the positive pressure cycle; CYC, the function (i.e. time or volume) ending the cycle. Each mechanical function is governed by one of four physical factors: volume, pressure, flow, and time. (a) A time-initiated, volume-limited mode. (b) A pressure-initiated (sub-baseline pressure produced by the patient’s effort to breathe), volume-limited mode. (c) A time-initiated, volume-limited, time-cycled mode that extends inspiration beyond the time that the volume is delivered. A plateau is reached after flow has stopped but before the ventilator cycles into exhalation. (Reprinted with permission from Shapiro et al.¹²⁸)

Fig. 34.3 Airway pressure tracings of four volume-cycled modes. The thick solid lines represent ventilator breaths. The thick dotted lines are spontaneous breaths. The thin dotted lines illustrate the spontaneous breathing pattern in the absence of ventilator breaths. IMV, intermittent mandatory ventilation; SIMV, synchronized intermittent mandatory ventilation. (Reprinted with permission from Shapiro et al.¹²⁸)

vantage of a variable tidal volume during dynamic changes in lung compliance which can lead to inadequate excessive minute ventilation if compliance worsens or improves respectively. This puts the onus on the provider to monitor changes in compliance to make appropriate changes in the preset pressure to compensate. This differs from the volume-cycled mode that requires monitoring of peak and plateau pressures. Another disadvantage is that this mode is not as well tolerated by awake patients as other modes.

Intermittent mandatory ventilation

Intermittent mandatory ventilation (IMV) was developed to allow spontaneous ventilation interspersed with volume-cycled or time-cycled pressure control mechanical ventilation. It was developed initially as a method to wean patients from the ventilator by depending more and more on patient effort

Fig. 34.4 Schematic illustration of pressure support ventilation. IN, initiation by spontaneous breath; LIM limit (pressure); CYC, cycle (derived from decreasing inspiratory flow); EX, expiration. (Reprinted with permission from Shapiro et al.¹²⁸)

for ventilation. The addition of a synchronized mode (SIMV) to avoid placing a mechanical breath on top of a spontaneous patient breath greatly improved this mode of ventilation. This mode has the advantage of maintaining some patient work in breathing to preserve respiratory strength when mechanical ventilation is required, and as a weaning tool to progressively increase patient effort while decreasing mechanical support in preparation for discontinuing mechanical ventilation. This method can be problematic in patients with low pulmonary compliance, and the IMV mode may not allow for sufficient spontaneous tidal volumes due to extremely limited inspiratory capacity. The addition of pressure support to augment spontaneous ventilatory efforts can be used (Figure 34.3).

Pressure support ventilation

Pressure support ventilation is a patient-triggered, pressure-limited, flow-cycled ventilatory mode (Figure 34.4). Each pressure support breath is triggered by patient negative pressure effort, at which time a valve opens producing a high-flow, pressure-limited breath. The breath ends when the patient’s inspiratory demand falls below a preset limit, allowing spontaneous respiration and complete patient control. It also differs from the other modes in that it is flow-cycled as opposed to

volume- or pressure-cycled. Because this mode is triggered and completed entirely from patient response, it cannot be used in patients with decreased respiratory drive, such as paralyzed patients and those who are heavily sedated. This mode has a number of advantages because of improved synchrony with patient effort. It can be used to provide full ventilatory support by setting a flow and pressure such that an adequate tidal volume is delivered. It can also be used effectively during weaning by decreasing the pressure incrementally to allow for progressively greater patient effort. Caution must be exercised when decreasing ventilatory support such that a sufficient tidal volume is still delivered to maintain adequate ventilation.

Inverse ratio ventilation

Inverse ratio ventilation is a mode of ventilation which is designed to improve oxygenation at a given level of inspired oxygen. Conventional ventilation uses the times of inspiration and expiration in a ratio of 1:4 or 1:2, giving a longer time for expiration, which is generally a passive process. Inverse ratio ventilation reverses this ratio to give a longer inspiratory time (1:1 or 2:1) by using rapid inspiratory flow rates and decelerating flow patterns during the inspiratory phase. The effect of inverse ratio ventilation is to increase mean airway pressures and thus recruit alveoli in an effect similar to PEEP. Secondly, in severe lung disease, ventilation in the lung is unequal due to peribronchial narrowing. Thus, some underventilated alveoli that are actually open are not able to exchange gases efficiently, increasing the intrapulmonary shunt and decreasing arterial oxygenation. Inverse ratio ventilation can improve this by selective air-trapping, or intrinsic PEEP, in these compromised air spaces. Inverse ratio ventilation can be done either in a volume-cycled or time-cycled pressure ventilation mode, but it is most commonly used with pressure-controlled ventilation to decrease peak airway pressures.

The beneficial effects of inverse ratio ventilation are questionable. It may be that the same effect can be gained by just increasing peak airway pressures with PEEP or peak inspiratory pressures. In fact, studies have showed no benefit of inverse ratio ventilation compared to conventional volume ventilation in terms of oxygenation.³¹ These studies did show some slight improvements in ventilation ($PaCO_2$). Other studies have shown that functional residual capacity is indeed not improved with inverse ratio ventilation, and in fact is detrimental to cardiac function because of increased intrathoracic pressures.³² For these reasons, inverse ratio ventilation cannot be recommended except in the setting of ARDS refractory to other therapies.

High-frequency oscillatory ventilation

High-frequency oscillatory ventilation (HFOV) is a new mode of ventilation which combines features of conventional ventilation with jet ventilation. It delivers subtidal, high-frequency oscillatory breaths at a constant mean-airway pressure (mPAW). It is thought to maintain open alveoli by recruiting collapsed portions of diseased lung by applying the equivalent of continuous positive airway pressure used during conventional ventilation. Optimizing mean airway pressure limits peak pressure, thereby making this a 'lung protective' mode. A recent randomized prospective trial in adult patients with

ARDS demonstrated that HFOV resulted in brief improvement in oxygenation while mortality difference or complication rates were not different.³³ In burned patients, one center reported early success reversing profound hypoxemia in patients with ARDS while facilitating early excision and grafting with intra-operative use.³⁴ HFOV, where available, should be given consideration in burned patients with severe hypoxemia.

High-frequency percussive ventilation

High-frequency percussive ventilation (HFPV) is a pressure-limited, time-cycled mode of ventilation that delivers subtidal pressure-limited breaths at a high frequency (400–800 beats/min) superimposed on a conventional inspiratory and expiratory pressure-controlled cycle (10–30 breaths/min). The purported advantages are to loosen airway exudate and casts for better pulmonary toilet, and to provide adequate gas exchange at lower airway pressures. This method of ventilation has been tested primarily in burned patients with inhalation injury, and was first reported in 1989.³⁵ In this study, HFPV was used as a salvage therapy in patients with inhalation injury and as primary therapy in another group. Improvements in oxygenation and a lower rate of pneumonia were seen. Another study documented an improvement in mortality in burned patients with inhalation injury treated with high-frequency percussive ventilation compared to historical controls.³⁶ Other studies have shown significant decreases in the work of breathing, and lower inspiratory pressures in addition to improvements in oxygenation and the rate of pneumonia.^{36,37} In fact, the use of this mode of ventilation in burned patients has been extended to non-burned patients in some ICUs with salvage of many patients.³⁸ This method of ventilation seems to be particularly efficacious in the treatment of inhalation injury.

Airway pressure-release ventilation

Airway pressure-release ventilation (APRV) is a mode which delivers continuous positive airway pressure with a time-cycled pressure-release phase (to allow for expiration). Advantages of APRV include optimization of mean airway pressure, limitation of peak inspiratory pressures, and integration of spontaneous breathing independent of the ventilatory cycle. These characteristics allow for an open lung with optimal alveolar recruitment and, as a result, improved ventilator-perfusion mismatching. This mode is best utilized in patients who are permitted to spontaneously breathe with negative pressure induced by diaphragmatic contraction that aids in lung recruitment of areas that were previously atelectatic. This is in contrast to conventional positive pressure ventilation where positive pressure from within the bronchus through the volume of air is preferentially distributed down the path of least resistance to areas of the lung that are already well aerated predisposing them to overdistention and barotrauma. Theoretically, this mode of ventilation is thought to be the ideal lung protective strategy. APRV gained popularity in the late 1990s, and is becoming the preferred mode of ventilation in many centers. Small prospective trials have suggested that APRV is associated with fewer ventilator days, improved gas exchange, improved hemodynamic performance, and less need for sedation when compared to conventional modes.³⁹ This mode is being increasingly used in burn units around the world, but to date no trials have been reported in this population.

Inhaled nitric oxide

Nitric oxide is a short-lived gaseous product of endothelial cells that is a powerful local vasodilator. Because it is a gas, this product can be delivered through the endotracheal tube to areas of ventilated lung where it can provide localized pulmonary vasodilation. Thus, areas of ventilated lung can receive more blood flow to decrease intrapulmonary shunting and improve oxygenation. This gas has been used extensively in neonates and children⁴⁰ with hypoxemic respiratory failure with beneficial effect. It has also been used in ventilated burned children to improve oxygenation.⁴¹ Although nitric oxide therapy has received considerable attention as a potential therapeutic option in severe pulmonary disease, no reports to date have documented improved mortality in spite of improvements in oxygenation. For this reason, its use cannot be recommended outside of a clinical trial.

Limiting barotrauma

Barotrauma is a common complication of mechanical ventilation and results in pneumothorax, pneumomediastinum, subcutaneous emphysema, interstitial emphysema, and pneumatoceles. In a volume-cycled mode, elevated peak and plateau pressures have been implicated in inducing barotrauma. Thus, it is conceivable that limiting airway pressures may decrease morbidity. Early reports showed no clear benefit of pressure-limited ventilation,^{42,43} which was accomplished by giving lower tidal volumes more frequently to maintain minute ventilation, and to accept a higher $PaCO_2$ value and lower arterial pH, which is termed permissive hypercapnia. Criticism of these trials lay in their low enrollment and lack of power to show differences. A recent large multicenter trial, however, documented improved survival and increased ventilator-free days in the first 28 days in the ICU in patients with ARDS treated with low-tidal volumes (6 mL/kg predicted body weight) versus traditional tidal volumes (12 mL/kg predicted body weight). In fact, this study was stopped early by the data safety committee because of the benefits incurred to the treated group.⁴⁴ Suspected reasons for the improvements seen

in this trial contrary to the earlier trials was the number of subjects enrolled as well as the defined protocol to limit plateau pressures <30 cmH₂O. Theoretically, the low-tidal volume strategy prescribes to the theory of ARDS which dictates that small healthy areas of lung exist adjacent to diseased and collapsed areas. In the conventionally treated group, higher tidal volumes and pressure are only distributed to open healthy alveoli; therefore the barotrauma of high pressures is delivered to this 'healthy' lung, thus increasing the damage there and thus worsening outcomes.⁴⁵ In burned patients, decreased chest wall compliance, presence of smoke inhalation injury to the upper airways, and massive fluid requirements are just a few variables that make effective gas exchange challenging while optimally minimizing barotrauma. Prospective trials comparing modes of ventilation to minimize barotrauma are lacking in the burn literature, making it difficult to determine which approach is best suited in this population. One recent study showed no statistically significant differences were found between a pressure-limited strategy and a conventional strategy in 61 burned patients for mortality, pulmonary complications, or incidence of pneumothoraces.⁴⁶ It serves to reason, however, that pressure-limited ventilation strategies might be of benefit in burned patients in sufficiently powered studies, although the merits have not been sufficiently tested.

Weaning from mechanical ventilation

Regardless of the mode of ventilation, almost all patients surviving the initial insult requiring mechanical ventilation will arrive at a stage to be weaned off the ventilator. Clinicians continue to debate the advantages of weaning patients with various forms of mechanical ventilation. Some clinicians prefer to use pressure support ventilation (PSV) with or without SIMV because of the ease with which the level can gradually be reduced. Others maintain that intermittent trials with abrupt cessation of ventilator support while maintaining endotracheal intubation ('t-tube trials') result in more rapid weaning (Figure 34.5).⁴⁷ It must be noted that weaning from ventilation depends upon the rate at which the patient recovers

Fig. 34.5 The probability of successful weaning with intermittent mandatory ventilation, pressure support ventilation, intermittent trials of spontaneous breathing, and once-daily trials of spontaneous breathing (Kaplan–Meier curves). After adjustments for baseline characteristics (Cox proportional hazards model), the rate of successful weaning with a once-daily trial of spontaneous breathing was 2.83 times higher than that with intermittent mandatory ventilation ($p < 0.006$) and 2.05 times higher than that with pressure support ventilation ($p < 0.04$). (Reprinted with permission from Esteban et al. *N Engl J Med* 1995; 332–350. Copyright Massachusetts Medical Society.⁴⁷)

from the condition causing mechanical ventilation and the aggression of the clinician driving the weaning process. In practice, either method of weaning from the ventilator (gradual weaning with pressure support or intermittent t-tube trials) will be successful. What will certainly prolong the process is random changes in ventilation parameters without a directed plan.

Monitoring of mechanical ventilation

For patients on mechanical ventilation, the normal physiological regulation of ventilation and oxygenation are often impaired by sedatives and paralytics required for the presence of the endotracheal tube, or due the pathophysiological condition requiring mechanical ventilation. For these reasons, monitoring of ventilation and oxygenation by the clinician is required.

Ventilation

Arterial CO₂ tension remains the most accurate means of assessing ventilation. This is typically measured on blood gas analysis. After assessment of the pCO₂, ventilatory settings to adjust minute ventilation can be made to reach the desired level. Another method that has received attention of late is expiratory end-tidal CO₂ monitoring through infrared measurement of CO₂. This technique allows for continuous online determination of end-tidal CO₂, which is an estimate of arterial PaCO₂. For end-tidal CO₂ to equate with PaCO₂, an assumption of a low alveolar–arterial gradient must be made. In patients with healthy lungs, this gradient is only 2–3 mmHg. In certain trauma patients, particularly those with head injuries, the gradient remains low, and may be used for continuous PaCO₂ monitoring. However, in other critically ill patients, the alveolar–arterial gradient may be in a state of flux, calling into question values received from an end-tidal CO₂ monitor. Factors affecting the alveolar–arterial gradient include cardiac output, airway dead space, airway resistance, and metabolic rate. Each of these may change in a severely burned patient, particularly patients with inhalation injury. For these reasons, end-tidal CO₂ monitoring is not recommended in burned patients for the estimation of PaCO₂.

In general, PaCO₂ varies indirectly with minute ventilation, and thus, this value must be considered when making ventilator adjustments to alter PaCO₂. Minute ventilation is equal to tidal volume multiplied by respiratory rate. Therefore, PaCO₂ can be adjusted downward by either increasing tidal volume or respiratory rate. In general, respiratory rate should be set between 10 and 20 breaths and tidal volume at 6 mL/kg for the initial settings. Adjustments can then be made in minute ventilation to optimize PaCO₂, which is usually 40 mmHg. When making these adjustments, it should be noted that the respiratory rate cannot be increased above 40 breaths/min, and tidal volume should be minimized to avert barotrauma.

When plateau airway pressures are greater than 30 mmHg, the ventilated lung is relatively noncompliant, indicative of ARDS or pulmonary edema. In this situation, ‘permissive hypercapnia’ is a strategy that may be used to decrease barotrauma. This strategy seeks to limit peak and plateau airway pressures by decreasing tidal volumes to allow for respiratory acidosis (PaCO₂ > 45 mmHg, arterial pH < 7.30). This strategy was used to some extent in the trial investigating the efficacy

of pressure-limited ventilation on improving outcomes in critically ill ventilated patients.⁴⁸

Oxygenation

As with the determination of the adequacy of ventilation, oxygenation has been classically determined using the partial pressure of O₂ in arterial blood. In general, a pO₂ value of 60 mmHg has been considered sufficient. Another frequently used monitor is pulse oximetry, which is an optical measurement of oxygenated hemoglobin in pulsatile vessels. Using differences in absorption of red and infrared light, the percentage of oxygenated hemoglobin in the arteries can be calculated. Shortcomings of this technique are that methemoglobin and carboxyhemoglobin are falsely measured as oxygen saturated hemoglobin, which is common initially in patients with smoke inhalation injury. Otherwise, this is a very accurate technique for the determination of oxygen content in arterial blood, as 97% of oxygen is carried to the tissues via hemoglobin. This assertion has been corroborated by *in vitro* studies,⁴⁹ which showed the accuracy of pulse oximetry to within 2–3% of oxyhemoglobin levels. The major limitations of this technique lie in the insensitivity to changes in pulmonary gas exchange. Because of the shape of the oxyhemoglobin dissociation curve, when the SaO₂ exceeds 90% and the PaO₂ is greater than 60 mmHg, the curve is flat and changes in PaO₂ can change considerably with little change in SaO₂. Regardless, it is assumed that an SaO₂ value greater than 92% is indicative of adequate oxygenation. An advantage to oxygen saturation measurements that should not be overlooked is that it is a continuous measure that is immediately available, while blood gas measurement of PaO₂ is by nature intermittent.

Initial ventilator settings to assure adequate oxygenation are usually 40% oxygen in the inspired gas with 5 mmHg PEEP. This amount of PEEP is used to mimic the normal physiological pressures in nonintubated subjects. When oxygenation begins to decline, initial maneuvers are to increase the fractional inspired oxygen (FiO₂) to greater than 40% and possibly to 100%. Concentrations of oxygen greater than 60% are considered toxic to airway epithelium, and other means to increase oxygenation should be employed. This should consist initially of increasing the level of PEEP incrementally until the desired level of oxygenation is reached while keeping the FiO₂ to less than 60%. Once a level of 15–20 mmHg of PEEP is reached, other means of increasing oxygenation will need to be employed. These consist of inverse ratio ventilation, HFOV, HFPV, APRV with and without inhaled nitric oxide, etc., which are described above.

Organ system failure and management

Etiology and pathophysiology

As stated earlier, it has been hypothesized that organ dysfunction commonly seen in the critically ill exists in a continuum with SIRS. Certain patients with SIRS will go on to develop MODS, which is characterized by nonfatal signs of organ system dysfunction, such as renal insufficiency or ventilator dependence. A subset of these patients will go on to develop frank organ failure, termed multiple system organ failure (MSOF), which often leads to death (Figure 34.6).^{5,6} What is

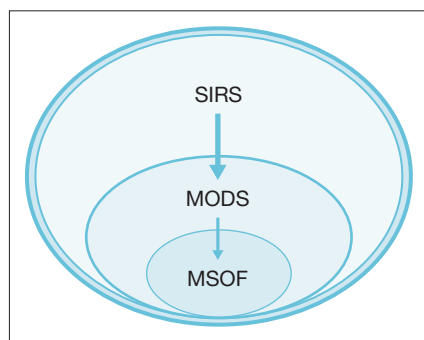

Fig. 34.6 Progression to multiple organ failure. All severely burned patients have the systemic inflammatory response syndrome (SIRS). A subset of these will develop signs and symptoms of multiple organ dysfunction syndrome (MODS). Still fewer will go on to develop multiple system organ failure (MSOF).

BOX 34.4 Theories for the development of multiple organ failure

- Infectious causes
- Macrophage theory
- Microcirculatory hypothesis
- Endothelial-leukocyte interactions
- Gut hypothesis
- Two-hit theory

required for the development of SIRS is inflammation, which in the severely burned emanates primarily from the burn wound. Factors associated with progression from the systemic inflammatory response syndrome to multiple organ failure are not well explained, although *some* of the responsible mechanisms in *some* patients are recognized. Occasionally, failure of the gut barrier, with penetration of organisms into the systemic circulation, may incite a similar reaction. However, this phenomenon has only been demonstrated in animal models, and it remains to be seen if this is a cause of human disease.

A number of theories have been developed to explain the progression to multiple organ failure (Box 34.4). One of these is the infection theory that incriminates uncontrolled infection as the major cause. In the severely burned patient, these infectious sources most likely emanate from invasive wound infection, or from lung infections (pneumonias). As organisms proliferate out of control, endotoxins are liberated from Gram-negative bacterial walls, and exotoxins from Gram-positive and Gram-negative bacteria are released.⁵⁰ Their release causes the initiation of a cascade of inflammatory mediators called cytokines, as well as the recruitment of inflammatory cells that can result, if unchecked, in organ damage and progression toward organ failure. Cytokines are a group of signaling proteins produced by a variety of cells that are thought to be important for host defense, wound healing, and other essential host functions. Although cytokines in low physiological concentrations preserve homeostasis, excessive production may lead to widespread tissue injury and organ dysfunction. Four of these cytokines – tumor necrosis factor alpha (TNF- α), interleukin 1 beta (IL-1 β), interleukin 6 (IL-6), and interleukin 8 (IL-8) – have been most strongly associated with sepsis and

multiple organ failure. The primary detractor to this theory is that many patients, including burned patients, can develop multiple organ failure without identified infection. It seems that inflammation from the presence of necrotic tissue and open wounds can incite a similar inflammatory mediator response to that seen with endotoxin. The mechanism by which this occurs, however, is not well understood. Regardless, it is known that a cascade of systemic events is set in motion either by invasive organisms or from open wounds that initiates the systemic inflammatory syndrome, which may progress to multiple organ failure.

Another theory implicates macrophages and their activity in the development of multiple organ failure. Macrophages activated by inflammation release excessive levels of cytokines and inflammatory mediators into the systemic circulation which cause end-organ damage, and incite further inflammation and macrophage activation. Elevated circulating and bronchoalveolar fluid cytokine levels have been associated with increased risk for SIRS/MODS; however, trials investigating the efficacy of cytokine blockade in patients with multiple organ failure have not improved survival rates in very large studies.

Yet another theory implicates prolonged tissue hypoxia and the generation of toxic free radicals during reperfusion as the primary mediator of end-organ damage. Deficits in resuscitation then would lead to areas of the microcirculation throughout the body that receive inadequate nutrients, and shift to anaerobic metabolism and formation of superoxides from ATP metabolites. The effects of the toxic products of oxygen free radical formation are only now being elucidated. From *in vitro* models and *in vivo* animal models, we know that tissues that initially were in shock and are then reperfused produce oxygen free radicals that are known to damage a number of cellular metabolism processes. This process occurs throughout the body during burn resuscitation, but the significance of these free radicals in human burn injury is unknown. It was found that free radical scavengers such as superoxide dismutase improve survival in animal models; however, these results were not established in patients.⁵¹ Oxygen free radicals oxidize membrane lipids, resulting in cellular dysfunction. Endogenous natural antioxidants, such as vitamins C and E, are low in patients with burns, suggesting that therapeutic interventions may be beneficial.⁵² Serum nitrate levels correlate well with multiple organ failure scores in critically ill patients, implying a role for this constellation of events in SIRS/MODS.

The role of vascular endothelium and leukocyte interactions to cause the changes seen in multiple organ failure has also been suggested. Cytokines and oxidants can convert endothelial cells to a proinflammatory state with upregulation of adhesion molecule expression, leading to leukocyte adherence and neutrophil-mediated tissue damage. Inhibition of this association with monoclonal antibodies has been shown to reduce tissue damage and organ injury in animal models of hemorrhagic shock, and was shown to attenuate skin injury when used during burn resuscitation.⁵³ The relevance of this model to the generation and maintenance of organ failure is yet to be established.

The last two theories revolve around the role of the gut in the generation of organ failure, and the ‘two-hit’ theory of

multiple organ failure. For years, investigators have implicated the gut as the 'engine' of organ failure, which is associated with loss of gut barrier function and translocation of enteric bacteria and their toxic metabolites. Bacterial translocation has been shown to occur in animal models after burn,⁵⁴ as well as in humans.⁵⁵ These bacteria and their products then activate the inflammatory cells described above, culminating in organ failure. The relevance of gut-mediated bacterial translocation to human disease, however, has been hotly debated. No clear studies have shown whether bacterial translocation is the cause of SIRS/MODS, probably because investigators have been unable to control bacterial translocation effectively during shock in humans, and thus a cause and effect relationship cannot be established. The 'two-hit' theory ascribes a summation of insults to the development of organ failure. Each of the insults alone is inadequate to cause the response, but one or more of these insults can 'prime' the inflammatory response system such that another normally insignificant injury causes the release of toxic mediators that end in multiple organ failure.

Prevention

This brief outline of the potential pathophysiology and causes of burn-induced critical illness and multiple organ failure demonstrates the complexity of the problem. Since different cascade systems are involved in the pathogenesis, it is so far impossible to pinpoint a single mediator that initiates the event. Thus, since the mechanisms of progression are not well known and thus specific treatments cannot be accurately devised, it seems that prevention is likely the best solution. The current recommendations are to prevent the development of organ dysfunction, and to provide optimal support to avoid conditions which promote the onset.

Course of organ failure

Even with the best efforts at prevention, the presence of the systemic inflammatory syndrome that is ubiquitous in burn patients may progress to organ failure. Experience with the severely burned dictates that virtually all burned patients will display the signs and symptoms of SIRS, including tachycardia, tachypnea, increased white blood cell count, etc. Thereafter, various organ systems may begin to show signs of dysfunction. Generally, these will begin in the renal and/or pulmonary systems and progress through the liver, gut, hematological system, and central nervous system in a systematic fashion. The development of multiple organ failure does not preclude mortality, however, and efforts to support the organs until they heal is justified.

Renal system

Pathophysiology

Acute renal failure (ARF) is a potentially lethal complication of burns. Despite substantial technical developments in dialysis to replace the function of the kidneys, mortality meets or exceeds 50% for all critically ill patients who develop acute renal failure.⁵⁶ Interestingly, mortality associated with ARF requiring dialysis in the critically ill has not improved significantly for over 30 years. The same can be said for renal failure

requiring dialysis in the severely burned specifically.⁵⁷ The causes of death in these critically ill patients is not uremia because of advances in dialysis, but primarily sepsis and cardiovascular and pulmonary dysfunction.

With the advent of early aggressive resuscitation after burn, the incidence of renal failure coincident with the initial phases of recovery has diminished significantly in severely burned patients.⁵⁷ However, a second period of risk for the development of renal failure 2–14 days after resuscitation is still present, and is probably related to the development of sepsis.

Acute renal failure, usually in the form of acute tubular necrosis (ATN), is characterized by deterioration of renal function over a period of hours to days, resulting in the failure of the kidney to excrete nitrogenous waste products and to maintain fluid and electrolyte homeostasis. It may be caused by a number of factors interfering with glomerular filtration and tubular resorption. In burned patients, the causes can be generally narrowed to renal hypoperfusion, or nephrotoxic insults from pharmacological treatments (e.g. aminoglycosides or intravenous contrast agents) or sepsis (Figure 34.7).

Ischemic renal failure is the more common of the two causes, and is induced by hypoperfusion from an imbalance between vasoconstrictive and vasodilatory factors acting on the small renal vessels during low-flow states. Decreased flow to the renal cells directly alters endothelial cell function, decreasing the production of and response to vasodilatory substances. The renal medulla is the most sensitive portion of the kidney to hypoxia, and the damage is initially to the renal tubular cells. The outer medulla and proximal tubules have high oxygen requirements, and the resulting ischemia causes swelling of tubular and endothelial cells with necrosis, apoptosis, and inflammation evident on histological examination.⁵⁸ These changes lead to further vascular congestion and decreased blood flow, leading to more cell loss and further decrements in renal function.

Structural changes in the tubular cells include loss of polarity and the integrity of the tight junctions.⁵⁹ Integrins are redistributed to the apical surface, resulting in live and dead cells sloughing into the tubular lumen, causing cast formation. The casts then cause increased intratubular pressure and reduced glomerular filtration rate. Loss of epithelial cell barrier and the tight junctions between viable cells causes back-leakage of the glomerular filtrate, further reducing the effective glomerular filtration rate. Arg-Gly-Asp peptides, which prevent adhesion between cells in the tubular lumen and thus decrease cast formation, prevent increases in proximal tubular pressure and mitigate ischemic renal failure in experimental animals.⁶⁰

After the initiating event, tubular function and the glomerular filtration rate decrease to reduce urine production. The progression of ARF is commonly divided into three phases – initiation, maintenance, and recovery – and can be oliguric (urine output <400 mL/day) or nonoliguric (urine output >400 mL/day) in nature. Patients with nonoliguric ARF have a better prognosis than those with oliguric renal failure, probably due in large measure to the decreased severity of the insult and the fact that many have drug-associated nephrotoxicity or interstitial nephritis. The percentage of critically ill patients with ARF who require dialysis ranges from 20 to 60%. Among the subgroup who survive initial dialysis, less

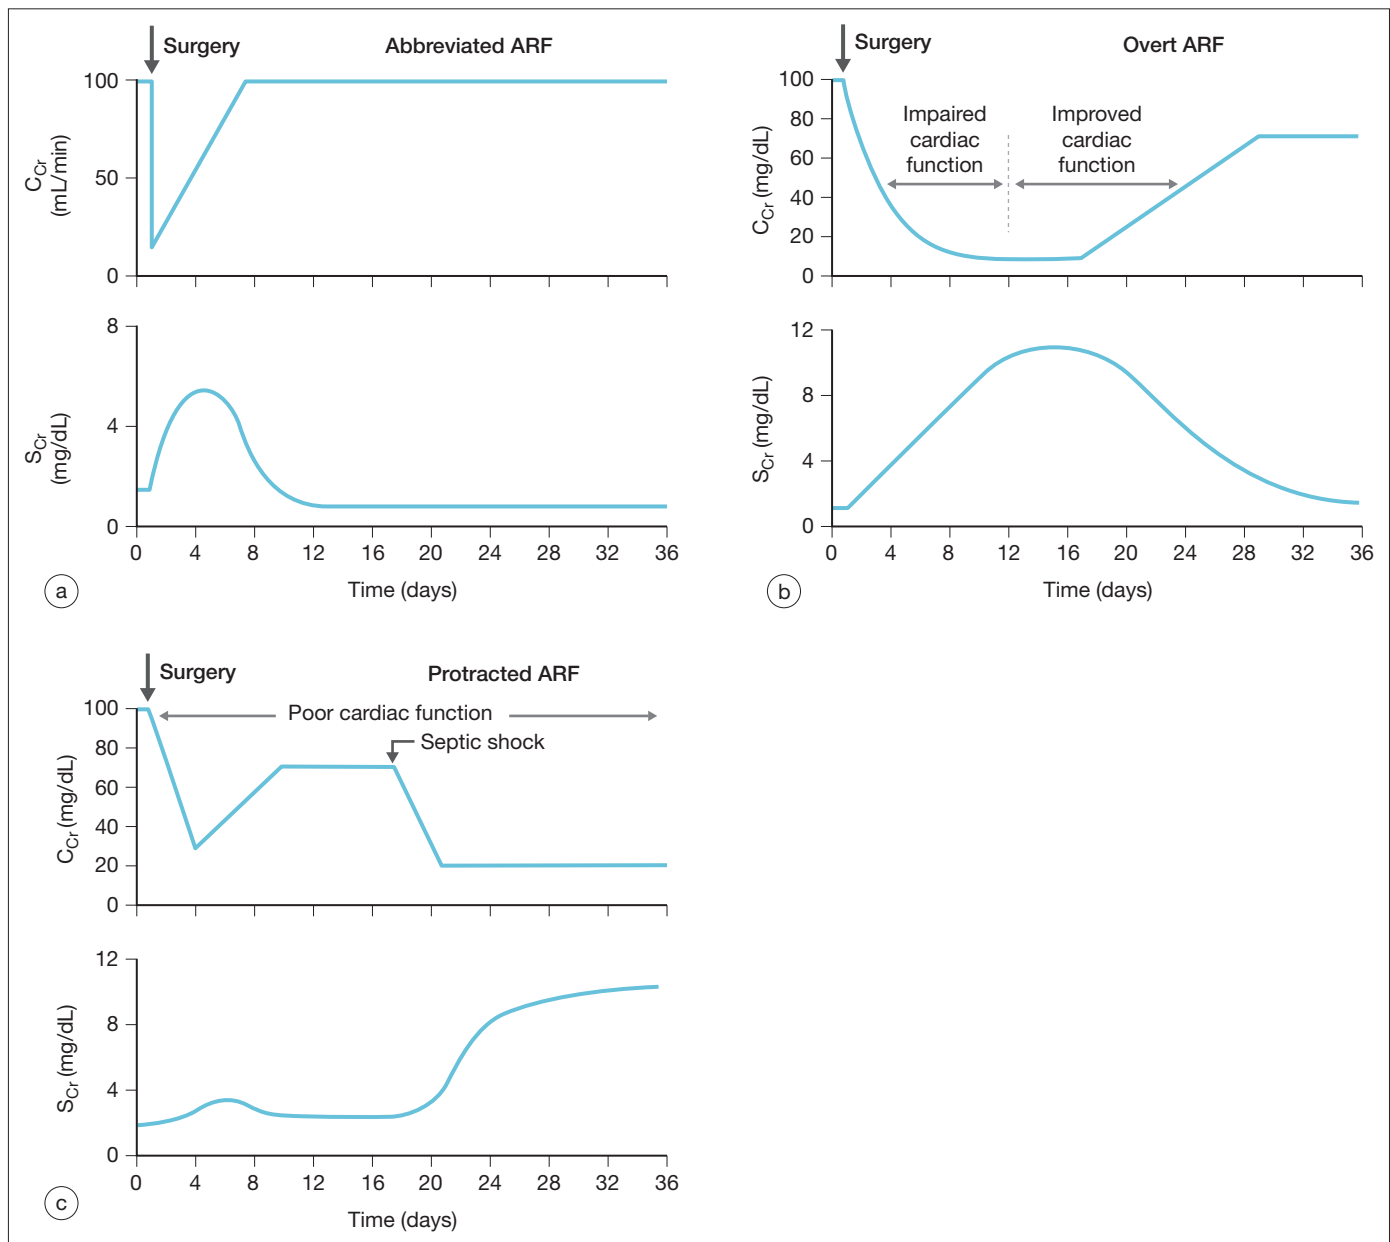

Fig. 34.7 Three patterns of hemodynamically mediated acute renal failure (ARF) occur after major burn. (a) Abbreviated ARF consists of an acute reduction in creatinine clearance (C_{Cr}) with prompt recovery. Serum creatinine (S_{Cr}) may increase even as C_{Cr} is recovering. (b) Overt ARF consists of concurrent mirror image increases in C_{Cr} and S_{Cr} in association with compromised cardiac function followed by recovery. (c) Protracted ARF develops as a consequence of prolonged hemodynamic compromise often complicated by systemic sepsis. (Reproduced with permission from Myers and Moran. *N Engl J Med* 1986; 314:97–105. Copyright Massachusetts Medical Society.¹²⁹)

than 25% require long-term dialysis, demonstrating the potential reversibility of the syndrome.⁶¹

Once ARF is established, pharmacological improvement of renal blood flow will not reverse the injury. Agents such as dopamine, which dilates renal arterioles and increases renal blood flow and creatinine clearance in normal animals,⁶² improves creatinine clearance and the fractional excretion of sodium in stable, critically ill patients for 24 hours, after which the effect diminishes. At 48 hours, no effect remains.⁶³ Other investigators have shown no efficacy of dopamine treatment in preventing acute renal failure in septic, oliguric patients.⁶⁴ Other agents such as calcium channel blockers have been shown to improve vascular tone, and decrease vasoconstriction

associated with radiocontrast agents,⁶⁵ but to date, no studies have been done to document their usefulness in acute renal failure induced by hypoperfusion. Natriuretic peptides also have conceivable benefit, and were shown to improve renal function for up to 24 hours in a group of patients with either ischemic or toxic acute renal failure, including a reduced requirement for dialysis in the treated group.⁶⁶ Another trial showed an improvement in dialysis-free survival in a subgroup of patients with oliguric ATN.⁶⁷ These results, however, were not borne out in other studies.⁶⁸ Recently, the potent dopamine-1 receptor agonist fenoldopam has garnered some interest as an agent to improve renal perfusion. A recent randomized controlled trial demonstrated that low-dose fenoldo-

pam may have some prophylactic benefit when used in septic patients in a mixed ICU population.⁶⁹

Diuretic therapies, such as mannitol and loop diuretics, have been used extensively in patients with acute renal failure to increase urine flow, and protect the kidney from further ischemic damage. Mannitol can decrease cellular swelling in the proximal tubule and increase intratubular flow, thus potentially decreasing intratubular obstruction and further renal dysfunction. Mannitol is recommended along with vigorous volume replacement and sodium bicarbonate for the treatment of early myoglobinuric acute renal failure. Loop diuretics also increase intratubular flow rates, and can convert an oliguric state to a nonoliguric state, thus making clinical management of renal failure easier. Although nonoliguric renal failure is generally associated with a lower mortality rate, there is no evidence that conversion from an oliguric to a nonoliguric state improves mortality. It is likely that those patients who respond to diuretics have less severe renal damage at the outset of treatment; thus the outcomes are better.

Treatment

The initial care of patients with ARF is focused on reversing the underlying cause, and correcting fluid and electrolyte imbalances. Renal failure is heralded by a decrease in urinary output. Volumes of urine less than 1 mL/kg/h may indicate the onset of ARF. This failure may be due to prerenal causes, which is typically decreased renal blood flow from hypoperfusion, or intrinsic renal causes, which are associated with medications or sepsis. Differentiation between these etiologies can be made with laboratory examinations (Table 34.2). Prerenal etiologies are associated with concentrated urine (urine osmolality >400 mOsmol/kg), decreased urinary sodium concentrations, and decreased fractional excretion of sodium. Intrinsic renal causes will be associated with more dilute urine with higher sodium concentrations. These tests should be performed before diuretics are used, as this treatment will increase urinary sodium and decrease urine osmolality even in prerenal conditions. In general, urine osmolality and urinary sodium concentrations are primarily used for these determinations because of the ease of measurement.

Should these tests reveal a prerenal cause, volume replacement should ensue to prevent further renal ischemia. The physical exam and invasive monitoring if deemed appropriate should guide this volume replacement. The decision to administer or remove fluids may prove difficult, however, since both strategies have detrimental consequences if followed inappro-

priately. Although volume replacement is ineffective in restoring renal function once tubular necrosis is established, it remains our most effective prophylactic strategy, and is generally the place to start with the onset of renal failure.

Once renal failure begins, serum creatinine will begin to increase with the decrease in glomerular filtration. However, up to 70% of renal function must be lost prior to significant increases in serum creatinine concentrations, making its use as a screening examination for renal failure suspect. Increases in serum creatinine may also be masked by increased plasma volume associated with aggressive volume resuscitation. Because renal failure is treated best by prevention with early detection, the use of a clinical measure of glomerular filtration rate, such as creatinine clearance (C_{cr}), may be of greater clinical utility early in the course of failure. Creatinine clearance can be measured effectively over short-time periods (2-hour collections), with the only caveat for an overestimation of glomerular filtration rate when compared to inulin. Nonetheless, serial measurements to examine changes in creatinine clearance will improve monitoring for acute renal failure.

After assuring adequate volume status, every effort should be made to prevent other causes of renal injury. All nephrotoxins should be discontinued or avoided. Hyperkalemia that may develop can be treated with resins, glucose and insulin, and sodium bicarbonate in the presence of metabolic acidosis. Medications eliminated through the kidney should be adjusted. Once the diagnosis of ARF is established, consideration can be given for diuretic therapy, especially if it is determined that the patient is volume overloaded. Decreasing the volume of fluid given can also alleviate volume overload in burned patients. These patients have increased insensible losses from the wounds which can be roughly calculated at 3750 mL/m² TBSA wound plus 1500 mL/m² TBSA total. Decreasing the infused volume of intravenous fluids and enteral feedings below the expected insensate losses may alleviate some of these problems. Decreasing potassium administration in the enteral feedings and giving oral bicarbonate solutions can minimize electrolyte abnormalities. Almost invariably, severely burned patients require exogenous potassium because of the heightened aldosterone response which results in potassium wasting; therefore, hyperkalemia is rare even with some renal insufficiency.

Intermittent dialysis remains the standard replacement therapy for severe ARF in the hemodynamically normal ICU patient. The indications for dialysis are edema and volume overload or electrolyte abnormalities not amenable to other treatments. In recent years, continuous renal replacement therapies have emerged as yet another option for critically ill patients with ARF⁷⁰ (Figure 34.8). The advantages of continuous treatment over intermittent include more precise fluid and metabolic control, decreased hemodynamic stability, and the enhanced ability to remove injurious cytokines.⁷¹ Disadvantages include the need for anticoagulation and heightened surveillance. Bleeding problems are particularly prevalent in burned patients during anticoagulation.⁷² Nonetheless, trials to date have not shown any benefit of continuous hemodialysis over traditional intermittent dialysis.

Peritoneal dialysis is another option for burned patients with severe acute renal failure.⁷³ Catheters can be placed at the bedside with near continuous exchanges to improve

TABLE 34.2 LABORATORY TESTS TO DISTINGUISH PRERENAL FROM INTRINSIC RENAL FAILURE

Examination	Prerenal	Intrinsic renal
Urine osmolality (mOsmol/kg)	>400	<400
Urinary sodium (mEq/dL)	<20	>40
FE _{Na} (%)*	<1	>2

*FE_{Na}, fractional excretion of sodium, calculated as $(U/P_{Na} / U/P_{Cr}) \times 100$, where U is urinary concentration, and P is plasma concentration. Na is sodium and Cr is creatinine.

Fig. 34.8 Photograph of a new model dialysis machine that can deliver either intermittent or continuous renal replacement therapy.

electrolyte and volume overload problems. The capital required for this treatment is minimal. Hypertonic solutions are used to remove fluid volume, and the concentrations of potassium and bicarbonate are modified to produce the desired results. The dwell time is usually 30 minutes followed by drainage for 30 minutes. This treatment can be repeated in cycles until the problem is resolved. For maintenance, 4–6 such cycles a day with prolonged dwell times (1 hour) is usually sufficient during the acute phase.

After beginning dialysis, renal function will likely return in survivors, especially in those patients that maintain some urine output. Therefore, patients requiring such treatment may not require lifelong dialysis. It is a clinical observation that whatever urine output was present will decrease once dialysis is begun, but it may return in several days to weeks once the acute process of closing the burn wound nears completion.

Pulmonary system

Mechanical ventilation in the severely burned generally takes place for three reasons:

- airway control during the resuscitative phase,
- airway management for smoke inhalation, and
- for the development of acute lung injury and ARDS.

The first is for airway control early in the course with the development of massive whole-body edema associated with the great resuscitative volumes required to maintain euvolemia. In this situation, the need for mechanical ventilation is not due to lung failure, *per se*, but instead to maintain the airway until the whole-body edema resolves. Once this occurs, usually 2–3 days into the course, extubation can be accomplished. Ventilator management during this phase is routine.

The second primary reason for mechanical ventilation is for airway management early in the course of smoke inhalation. Another chapter in the book will deal specifically with this issue.

The third is the development of hypoxemia. Severe burns are known to be associated with hypoxemia and the development of acute lung injury (ALI) and its more severe counter-

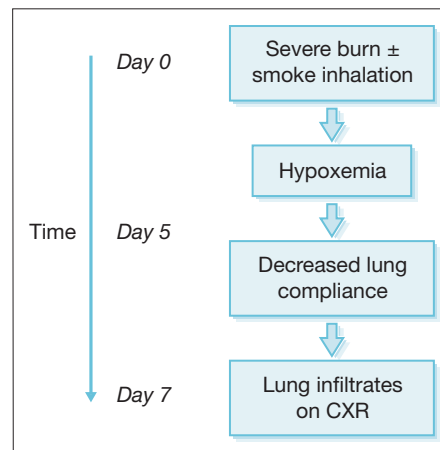

Fig. 34.9 Typical timeline for progression to ARDS. Patients are typically intubated for airway compromise and operative intervention. At day 4 or 5 after severe burn, oxygenation will deteriorate, requiring higher inspired concentrations of oxygen. These measures will soon fail with the introduction of decreased lung compliance requiring higher inspired airway pressures. Only then will infiltrates begin to appear on the chest x-ray (CXR).

BOX 34.5 Definitions of acute lung injury and acute respiratory distress syndrome

- Acute onset
- Bilateral infiltrates on chest radiography
- Pulmonary artery wedge pressure <18 mmHg
- Acute lung injury (ALI) if P_aO_2/F_iO_2 is <30 but >200
- Acute respiratory distress syndrome (ARDS) if P_aO_2/F_iO_2 is <200

part, ARDS. The clinical manifestations are dyspnea, severe hypoxemia, and decreased lung compliance with radiographic evidence of diffuse bilateral pulmonary infiltrates (Figure 34.9). These conditions exist as a continuum from ALI, which is a mild form, to its most severe form, which is dense ARDS. These conditions have been defined by the American–European Consensus Conference Committee, and are listed in Box 34.5. These definitions are relatively simple, and are used in other critically ill populations. The rest of the discussion will be related to ALI and ARDS.

Epidemiology and pathophysiology

ALI and ARDS occur as a result of injury to the lung, which can be direct through smoke inhalation or pneumonia, or indirect through mediators associated with sepsis. Until recently, most studies of ALI and ARDS reported mortality rates between 40 and 60%.⁷⁴ The majority of deaths were attributable to sepsis or multiorgan dysfunction.

Recently, two reports suggest that mortality in ARDS has been decreasing, with a group from Seattle reporting a 67% decrease in mortality for 1987–1993 compared to a period from 1983 to 1987. Another group in the United Kingdom reported a 50% decline in mortality over a similar time period. Explanations include more effective treatment of sepsis, changes in methods of mechanical ventilation, and improved support of the critically ill. No reports of improved mortality have been forthcoming in the severely burned with ARDS.

ALI and ARDS occur because of damage to the endothelium and lung epithelium. It is speculated that the products of inflammation, such as cytokines, endotoxin, complement, and coagulation system products, induce the changes that are characteristic of ALI and ARDS. The acute phase of ALI is characterized by influx of protein-rich edema fluid into the air spaces as a consequence of increased permeability of the alveolar–capillary barrier. The importance of endothelial injury and increased vascular permeability to the formation of pulmonary edema is well established.⁷⁴ Epithelial injury is also of great importance. In fact, the degree of alveolar epithelial injury is an important predictor of outcome.

The normal alveolar epithelium is composed of two cell types. Flat type I cells make up 90% of the alveolar surface, and these cells are easily injured. Cuboidal type II cells make up the remaining 10%, and are more resistant to injury. Type I cells function to move gases from the interstitium to the alveoli. Type II cells function to produce surfactant, participate in ion transfer and fluid movement, and proliferate/differentiate to type I cells after injury.

Loss of epithelial integrity has a number of consequences. Under normal conditions, the epithelial barrier is much less permeable than the endothelial barrier; therefore its loss contributes to alveolar flooding. Also, loss of type II cells disrupts epithelial fluid transport, impairing the removal of edema from the alveolar space. Lastly, loss of type II cells reduces the turnover and production of surfactant, causing a loss of surface tension in the alveoli and contributing to alveolar collapse.

Neutrophils are likely to play a role in the pathogenesis of ALI. Histological studies of lung specimens obtained early in the course demonstrate marked accumulation of neutrophils in the alveolar fluid.⁷⁵ These neutrophils can be recovered from bronchoalveolar lavage fluid from affected patients,⁷⁶ demonstrating a clear association between neutrophil accumulation and lung injury. However, it must be stated that ALI and ARDS develop in patients with profound neutropenia,⁷⁷ and some animal models of ARDS are neutrophil independent, intimating that neutrophils may be nothing more than bystanders in the inflammatory process.

The effects of ventilator injury on the development and progression of ALI and ARDS are just now coming to light. Previous studies focused on the potential damaging effects of high oxygen concentrations on lung epithelium.⁷⁸ Recent evidence suggests that mechanical ventilation at high pressures can injure the lung,⁴⁴ causing increased pulmonary edema in the uninjured lung and enhanced edema in the injured lung.⁷⁹ Alveolar overdistention and cyclic opening and closing of alveoli associated with high ventilatory pressures is also potentially damaging to the lung.

After the development of ALI and ARDS, some patients have a rapid recovery over a few days.⁸⁰ Others progress to fibrotic lung injury, which is observed as early as 5–7 days into the course of the disease.⁷⁵ The alveolar space becomes filled with mesenchymal cells, extracellular proteins, and new blood vessels.⁸¹ The finding of fibrosis on histological analysis correlates with increased mortality.⁸²

In the nonfatal cases of ARDS, the lung heals by proliferation of type II epithelial cells, which begin to cover the denuded basement membrane and differentiate into type I epithelial

cells, thus restoring normal alveolar architecture and increasing the fluid transport capacity of the alveolar epithelium. This proliferation is associated with a keratinocyte growth factor and an hepatocyte growth factor.⁷⁴ Alveolar edema is resolved by active transport of sodium from the distal airspace into the interstitium by intact alveoli.⁸³ Soluble protein is removed primarily by diffusion between alveolar cells, and insoluble protein is eliminated by endocytosis and transcytosis by alveolar epithelial cells and phagocytosis by macrophages.⁸⁴

The severely burned are unique among patients that develop ALI and ARDS. Because direct injury to the lung from smoke inhalation is common, oftentimes patients will present with respiratory insufficiency and relative hypoxia caused by increased capillary permeability, ciliary dysfunction, and interstitial edema associated with the chemical injury of smoke. A few days later, the damaged and necrotic respiratory mucosa begins to slough, causing bronchial plugging and atelectasis, further worsening the clinical condition. However, it is not usually until 4–8 days into the course of injury that severe hypoxemia and ARDS develop in burned patients, a scenario not unlike other types of patients who develop ALI and ARDS, such as after abdominal sepsis or multiple blunt trauma. It serves to reason that smoke inhalation is associated with the development of ARDS, but perhaps this association is related to the inflammation associated with the injury in addition to that rendered by the burn wound. In fact, it was recently shown that the degree of inhalation injury was not associated with the development of ARDS in burned patients.⁸⁵ It may be, then, that smoke inhalation and ALI/ARDS are two separate conditions which are inter-related.

Treatment

The treatment of ALI and ARDS is largely supportive until the healing processes described above can be accomplished. A careful search for potential underlying causes should ensue, including attention to potentially treatable causes such as intra-abdominal infections, pneumonia, line sepsis, and invasive burn wound infection. An improved understanding of the pathogenesis of ALI has led to the assessment of several novel treatment strategies,⁷⁴ including changes in mechanical ventilation strategies, fluid management, surfactant therapy, nitric oxide treatments, and anti-inflammatory strategies.

Potential treatments

The most appropriate method of mechanical ventilation for ALI and ARDS has been controversial for some time. Older strategies recommended supraphysiological tidal volumes of 12–15 mL/kg, which, as stated previously, may contribute to further alveolar damage. This was recognized in the 1970s, which led to studies of extracorporeal membrane oxygenation to reduce tidal volumes to 8 mL/kg. However, this strategy failed to decrease mortality.⁸⁶ Similar studies have been performed in severely burned patients, with no effect on mortality.⁸⁷ Recently, a National Institutes of Health (NIH) study group reported a 22% decline in mortality in patients with ALI and ARDS treated with tidal volumes of 6 mL/kg compared to those treated with conventional volumes of 12 mL/kg. In this study, peak airway pressures could not exceed 30 cmH₂O in the lower tidal volume group, and a detailed protocol was used to adjust the fraction of inspired oxygen and PEEP.⁴⁴

These results were different from previous smaller studies showing no improvement with pressure-limited ventilation.⁴³ Potential reasons for the discrepancy between the NIH study and the others are as follows:

- the NIH study had the lowest tidal volume of the three studies,
- respiratory acidosis was allowed in the NIH study with sodium bicarbonate treatment if necessary to maintain homeostasis, and
- the NIH study had more patients, and thus may have been more sufficiently powered to show differences between treatment groups.⁷⁴

Positive end-expiratory pressure has clearly been shown to benefit patients with ALI and ARDS;⁸⁸ however, the most optimum level has been controversial. The best documented effect of PEEP is to increase functional residual capacity, or the number of open alveoli at the end of expiration.⁸⁹ However, the use of prophylactic PEEP therapy in patients at risk for ALI showed no benefit for the treatment group compared to controls.⁹⁰

A more recent study of PEEP therapy aimed at raising the level of PEEP above the lower inflection point on pressure–volume curves to prevent alveolar closure in addition to low tidal volumes and pressure-controlled inverse ratio ventilation showed improved mortality compared to a control group managed with conventional ventilation.⁹¹ Drawbacks to this study were the unusually high mortality (71%) in the control group, and improvements in mortality for the treatment group compared to controls could only be determined at hospital day 28, which was not appreciated at hospital discharge. Nonetheless, the potentials for benefit of this therapy have warranted further studies, which are underway.

Surfactant therapy has been suggested for patients with ALI and ARDS, which should decrease alveolar surface tension, and maintain open alveoli. This therapy was proved effective in neonates with respiratory distress;⁹² however, a study done in adults with ARDS showed no effect on oxygenation, duration of mechanical ventilation, or survival.⁹³ Newer preparations of surfactant with recombinant proteins and new approaches to instillation such as bronchoalveolar lavage and tracheal administration are being evaluated in clinical trials.

Inhaled nitric oxide is an effective pulmonary vasodilator with effects localized to ventilated areas of the lung, thus directing more blood to the functional areas of the lung. The conceivable effect, then, is to diminish the fraction of blood shunted through the lungs without oxygenation, thus improving pulmonary venous oxygenation. Observational studies suggest that inhaled nitric oxide might be beneficial in the treatment of ARDS by improving oxygenation without increased ventilatory pressures and reducing barotrauma. However, randomized trials testing this hypothesis have been disappointing. In a recent study, inhaled nitric oxide therapy did not reduce mortality or decrease the duration of mechanical ventilation. Improvements in oxygenation were seen; however, the effects were not sustained.⁹⁴ Treatment with less selective pulmonary vasodilators such as sodium nitropruside,⁹⁵ and alprostadil (prostaglandin E₁)⁹⁶ have not been shown to be beneficial.

Glucocorticoids have been used in the treatment of ARDS because of the inflammatory nature of the disease. However,

these agents were not shown to be of any benefit when given at the onset of the condition.⁹⁷ More recently, glucocorticoids have been used in the later fibroproliferative phases of the disease to good effect.⁹⁸ Preliminary studies in a small population have shown improved oxygenation, decreased ventilator dependence, and decreased mortality with no increased risk of sepsis in nonburned patients.⁹⁹ This type of therapy may be treacherous in burned patients at risk for invasive burn wound infection, but might be considered upon complete burn wound closure.

Cardiovascular system

Principles

Treatment of cardiovascular responses after burn requires an understanding of cardiovascular physiology and the effects of treatment. One of the hallmarks of serious illness is the direct link between cardiac performance and patient performance. The four determinants of cardiac function and thus tissue perfusion of blood at the whole-body level are the following:

- ventricular preload or end-diastolic muscle fiber length;
- myocardial contractility or strength of the heart muscle;
- ventricular afterload, or the degree of resistance against which the heart must pump; and
- heart rate and rhythm.

A thorough comprehension of the effects of each of these components on heart function is required in order to initiate effective treatments for burned patients with cardiovascular abnormalities.

Preload

Preload is defined as the force that stretches the cardiac muscle prior to contraction. This force is composed of volume that fills the heart from venous return. Because of the molecular arrangement of actin and myosin in muscle, the more the muscle is stretched with incoming venous volume, the further it will contract. This is best demonstrated on a Frank–Starling curve (Figure 34.10), which was first described by Otto Frank

Fig. 34.10 Frank–Starling curve. The solid line depicts the pressure–volume relationship of the heart, showing that as pressure to the heart (preload) increases, the volume pumped by the heart increases. Immediately after burn, contractility diminishes, shifting the curve downward (dashed line). It still must be noted that with this change, the volume pumped by the heart still increases with increased pressure (preload), validating the use of increased atrial pressure as a means of increasing cardiac output after severe burn.

in a frog heart preparation in 1884; Ernest Starling extended this observation in the mammalian heart in 1914. The relationship demonstrated in the Frank–Starling curve justifies the use of preload augmentation by volume resuscitation to increase cardiac performance. However, when the end-diastolic volume becomes excessive, cardiac function can decrease, probably by overstretch of the muscle fibers such that the contractile fibers are pulled past each other, thus reducing the contact required for contractile force. The preload required to decrease cardiac function in experimental settings is in excess of 60 mmHg, which is rarely encountered in patients.

Preload is measured clinically by either central venous pressure or by pulmonary artery wedge pressure obtained with a pulmonary artery catheter. Of these, the pulmonary artery wedge pressure is the best estimate since it assesses the left side of the heart.

Cardiac contractility

The force with which the heart contracts is referred to as cardiac contractility. It is directly related to the number of fibers contracting, and will be diminished in patients with vascular occlusive disease of the myocardium who lose muscle fibers from infarction and ischemia, and in burned patients during the acute resuscitation.¹⁰⁰ Calculating the left ventricular stroke work from pulmonary artery catheter-derived values provides the best estimate of cardiac contractility, and can be calculated with the following formula:

$$LVS\text{W} = SV (\text{MAP} - \text{PCWP}) \times 0.0136$$

where LVSW is left ventricular stroke work, SV is the stroke volume (cardiac index / heart rate), MAP is mean arterial pressure, and PCWP is pulmonary capillary wedge pressure.

Afterload

Afterload is the force that impedes or opposes ventricular contraction. This force is equivalent to the tension developed across the wall of the ventricle during systole. Afterload is measured clinically by arterial resistance as an estimate of arterial compliance. Arterial resistance is measured as the difference between inflow pressure (mean arterial) and outflow pressure (venous) divided by the flow rate (cardiac output):

$$\text{SVR} = (\text{MAP} - \text{CVP})/\text{CO}$$

where SVR is systemic vascular resistance, MAP is mean arterial pressure, CVP is central venous pressure, and CO is cardiac output.

Heart rate and rhythm

For the heart to function properly, the electrical conduction system must be intact, so as to provide rhythmic efficient contractions to develop sufficient force to propel blood through the circulatory system. For example, if the heart rate approaches 200 beats/min, the heart will not have time to fill completely, thus decreasing myocardial fiber stretch and decreasing heart function. Also, if frequent premature ventricular contractions are present, the heart will not perform as well for similar reasons. Heart rate and rhythm are monitored continuously as a routine in all critically ill patients using electrocardiography.

Effects of burn on cardiac performance

Severe burns affect cardiac performance in a number of ways. The first is to reduce preload to the heart through volume loss into the burned and nonburned tissues. It is for this reason that volumes predicted by resuscitation formulas must be used to maintain blood pressure and maintain hemodynamics. In addition, severe burn induces myocardial depression characterized by a decrease in tension development and velocities of contraction and relaxation.¹⁰¹ Cardiac output is then reduced. These effects are most evident early in the course of injury; however, they are followed shortly thereafter by a hyperdynamic phase of increased cardiac output caused primarily by a decrease in afterload through vasodilation and an increase in heart rate. Deficits in myocardial contractility are for the most part maintained.

Hemodynamic therapy: preload augmentation

When hypotension or other signs of inadequate cardiac function (i.e. decreased urine output) are encountered, the usual response is to augment preload by increasing intravascular volume. This is a sound physiological approach based on the Frank–Starling principle, and should be the first therapy for any patient in shock. Intravascular volume can be increased with either crystalloid or colloid to increase the central venous pressure and pulmonary capillary wedge pressure to a value between 10 and 20 mmHg. The adequacy of this therapy can be monitored by the restoration of arterial blood pressure, a decrease in tachycardia, and a urine output greater than 0.5 mL/kg/h.

Some caution must be exercised when augmenting preload for hemodynamic benefit in burned patients. Excessive volume administration may lead to significant interstitial edema and volume overload with the development of peripheral and pulmonary edema. These changes can lead to conversion of partial-thickness burns to full-thickness injuries in the periphery, and can cause significant respiratory problems. Judicious use of fluid administration after hemodynamics are restored with spontaneous diuresis will usually alleviate this problem; however, at times, pharmacological diuresis will be required.

Hemodynamic therapy: inotropes

If volume replacement is insufficient to improve hemodynamics in burned patients in shock, inotropes may be required. These inotropes generally consist of adrenergic receptor agonists, although phosphodiesterase inhibitors that increase intracellular cAMP levels to increase myocyte Ca^{2+} levels or digoxin that acts to increase myocyte Ca^{2+} levels by inhibiting the Na^+/K^+ pump can also be used to improve myocardial contractility.

Dopamine is a commonly used inotropic agent which has both α -adrenergic and β -adrenergic properties. The α effects are seen primarily at higher doses (10–20 $\mu\text{g}/\text{kg}/\text{min}$), while the β effects are seen at all doses. Therefore, dopamine can be thought of as an ‘inoconstrictor’, because it has both inotropic and vasoconstrictive properties. Other inotropes in this class include epinephrine and norepinephrine. One caveat to the use of these inoconstrictors is that myocardial oxygen consumption increases, which may affect areas of the heart that are ischemic.

At low doses, dopamine also produces splanchnic and renal vasodilation through specific dopamine receptors. It is thought that these vasodilatory effects can be used to optimize renal function through antagonism of α -receptor-induced vasoconstriction. However, this practice has recently been questioned. Dopamine has also been used in burned patients to increase left ventricular stroke work during myocardial depression seen during resuscitation.¹⁴

Dobutamine is another commonly used inotrope which has effects limited to β -adrenergic stimulation; thus, cardiac contractility is increased without vasoconstriction. The effect is to improve cardiac output generally without specific splanchnic or renal effects.

Agents with primary effects on the α -adrenergic receptor can be used to induce vasoconstriction and increase blood pressure. These agents consist of norepinephrine and phenylephrine, and can be used effectively during septic shock or neurogenic shock to increase vascular tone. In burned patients, it is felt that these agents will cause vasoconstriction of the skin circulation and the splanchnic circulation to preserve blood flow to major organs such as the heart and brain. This redistribution in blood flow can cause conversion of partial-thickness skin injuries to full-thickness and result in ischemic injury to the gut. The use of specific vasoconstrictors must be weighed against these effects.

Another vasoconstrictive agent that is being used with more popularity is vasopressin, which is a very potent vasoconstrictor mediated through its own receptor independent of the adrenergic receptors. Levels of vasopressin have been shown to be low in septic shock and physiological replacement at 0.02 mg/kg without titration is used in some units to increase mean arterial pressure to good effect.

Effects of β -blockade on cardiac performance after severe burn

One of the responses to severe burn is a dramatic increase in catecholamine production that has been linked to a number of metabolic abnormalities, including increased resting energy expenditure,¹⁰² muscle catabolism, and altered thermoregulation.¹⁰³ The effects of this sustained catecholamine surge on the cardiac system are to increase heart rate and therefore myocardial work. Propranolol, as a nonspecific β -blocker, has been used to decrease heart rate and myocardial work in severe burns.¹⁰⁴ Propranolol can be given through both the intravenous and oral routes to equal effect on heart rate and myocardial work without detrimental effect on cardiac output or response to stress.¹⁰⁵ Propranolol administration also decreases peripheral lipolysis¹⁰⁶ and muscle catabolism,¹⁰⁷ which are additional beneficial effects. Consideration should be given to further trials with the use of propranolol to improve outcomes in burned patients.

Gastrointestinal system

Pathophysiological changes in the gut after cutaneous burn

The gastrointestinal response to burn is highlighted by mucosal atrophy, changes in digestive absorption, and increased intestinal permeability. Atrophy of the small bowel mucosa occurs

within 12 hours of injury in proportion to the burn size,¹⁰⁸ and is related to increased epithelial cell death by apoptosis.¹⁰⁹ The cytoskeleton of the mucosal brush border undergoes atrophic changes associated with vesiculation of microvilli and disruption of the terminal web actin filaments. These findings were most pronounced 18 hours after injury,⁵⁴ which suggests changes in the cytoskeleton, such as those associated with cell death by apoptosis, are processes involved in the changed gut mucosa. Burn also causes reduced uptake of glucose and amino acids,¹¹⁰ decreased absorption of fatty acids, and reduction in brush border lipase activity. These changes peak in the first several hours after burn, and return to normal at 48–72 hours after injury, a timing that parallels mucosal atrophy.

Intestinal permeability to macromolecules that are normally repelled by an intact mucosal barrier increases after burn.¹¹¹ Intestinal permeability to polyethylene glycol 3350, lactulose, and mannitol increases after injury, which correlates to the extent of the burn. Gut permeability increases even further when burn wounds become infected.¹¹² A study using fluorescent dextrans showed that larger molecules appeared to cross the mucosa between the cells, while the smaller molecules traversed the mucosa through the epithelial cells, presumably by pinocytosis and vesiculation.¹¹³

Changes in gut blood flow are related to changes in permeability (Figure 34.11). Intestinal blood flow was shown to decrease in non-resuscitated animals, a change that was associated with increased gut permeability at 5 hours after burn.¹¹⁴ This effect was abolished at 24 hours. Systolic hypotension has been shown to occur in the first hours after burn in animals with a 40% TBSA full-thickness injury. These animals showed an inverse correlation between blood flow and permeability to intact *Candida albicans*.¹¹⁵

Clinical changes in the gut after burn

Given the changes in the gut to burn described above, it is common to see some evidence of gut dysfunction after burn evidenced by feeding intolerance,¹¹⁶ and mucosal ulceration and bleeding particularly in the stomach and duodenum. Enteral feeding is one of the most important means of providing nutrition to burned patients and has led to a decrease in mortality,¹¹⁷ but at times the gut will not cooperate. Reduced motility and ileus are common, at times requiring parenteral nutrition to meet caloric needs. At the present time, there is no specific treatment for burn-induced ileus, but it seems that early enteral feeding will prevent some of these potential complications.

Stress ulceration of the stomach and duodenum, on the other hand, can be prevented effectively with antacid therapy. In the 1970s stress ulceration leading to life-threatening hemorrhage was common. The mechanism of injury is related to an imbalance between protective factors such as mucus production, protective prostaglandin output, and bicarbonate secretion, and injurious factors such as decreased blood flow and acid production. Gastric ulcers develop in the watershed zones between capillary beds which are worsened by gastric acid-induced injury.

Antacid therapies and early enteral feeding have dramatically decreased the incidence of gastrointestinal ulceration and life-threatening hemorrhage after severe burn,¹¹⁸ such that this complication is very rare in modern burn units. A number

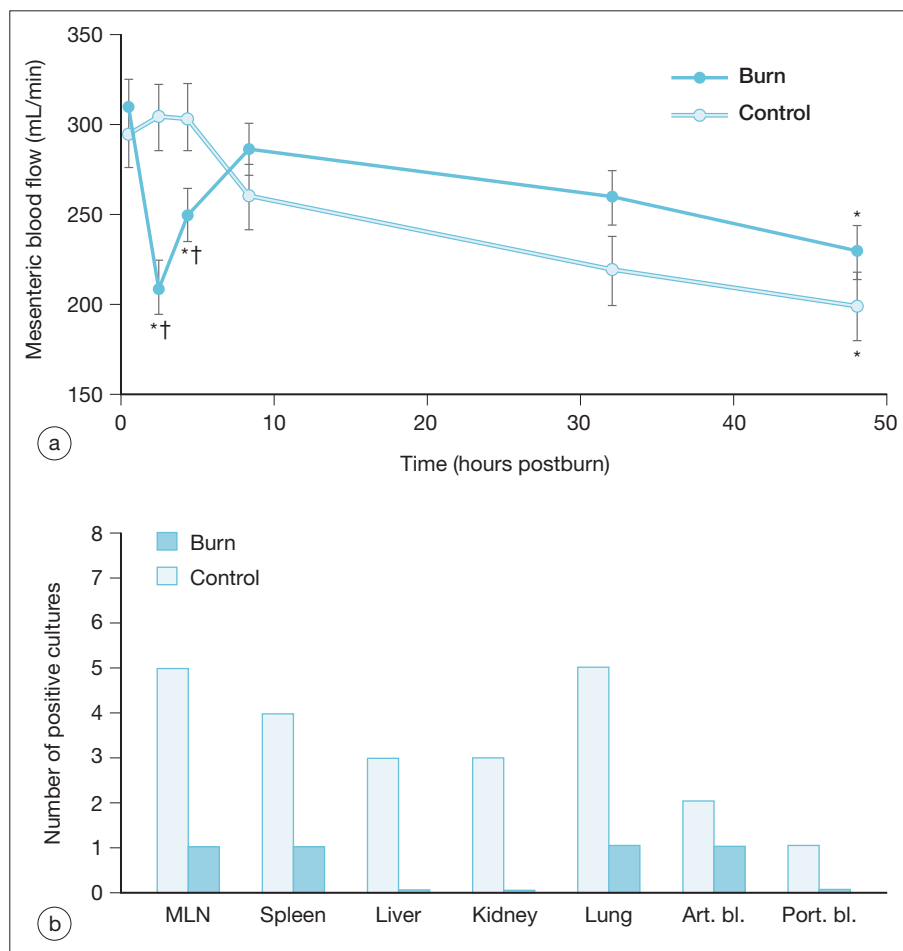

Fig. 34.11 (a) After a severe burn in pigs, superior mesenteric blood flow (solid line) decreased abruptly, then recovered with resuscitation. * $p = 0.05$ vs. baseline, † $p = 0.05$ vs. unburned controls (dotted line). (b) Bacterial tissue culture results from mesenteric lymph nodes (MLN), spleen, liver, kidney, lung, arterial blood (Art. bl.), and portal blood (Port. bl.) after sham injury (open bars) and severe burn (solid bars). of types of therapies including gastric antacids, cimetidine, ranitidine, and sucralfate have been tested in various combinations or alone, all of which are equally effective. Some have even suggested that early enteral nutrition alone is sufficient.¹¹⁹ A survey of critical care physicians found that most use histamine-2 antagonists such as ranitidine for stress ulceration prophylaxis, followed by sucralfate.¹²⁰ Regardless, it can be concluded that some type of prophylaxis against gastrointestinal hemorrhage is required in the severely burned, and will be very effective in preventing this complication.

Endocrinopathies

Hyperglycemia and insulin resistance are common in the critically ill, and the burned patient is no exception. In 2001, Greet van den Berghe reported in a landmark trial that intensive insulin treatment with continuous infusions of insulin aimed at normalizing blood glucose levels between 80 and 110 mg/dL improved mortality, and decreased bloodstream infections and acute renal failure.¹²¹ Even more recently, she showed again that this treatment reduced renal insufficiency, ventilator requirement, intensive care unit length of stay, and mortality in those in the ICU for more than 3 days.¹²² These studies are among the first to show some benefit of a treatment for all critically ill patients. Other investigators have shown the benefit of insulin treatment in burned patients,¹²³ particularly in terms of muscle mass.¹²⁴ Further evidence is accumulating for other beneficial

effects, and it has become the standard of care to avoid hyperglycemia in burned patients in the ICU with continuous insulin therapy. It remains to be seen whether the effects are mediated directly through insulin activity, if the effect is indirect through the avoidance of hyperglycemia, or both.

In another landmark trial, cortisol levels were found to be low in many critically ill patients and a mortality benefit accrued with physiological replacement with hydrocortisone.¹²⁵ This was followed by a trial of hydrocortisone in all critically ill patients with ARDS, and a mortality benefit was again seen.¹²⁶ These studies highlight that hypocortisolemia is at least associated with septic shock and hypotension, and that replacement with hydrocortisone at 50 mg every 6 hours improves outcomes. The same was seen in burned patients in the ICU.¹²⁷ It must be noted, however, that the benefits seem to be limited to those with relative adrenal insufficiency assessed by corticotropin stimulation. Regardless, in the case of hypotension not related to hypovolemia in burned patients, cortisol levels and adrenal stimulation should be performed to determine if relative adrenal insufficiency exists, and treatment with hydrocortisone should ensue.

Summary

Improved critical care of the severely burned has decreased mortality over the past two to three decades. This has been in part through the development of specialized units for care of

burned patients which are equipped with the personnel and equipment to deliver state-of-the-art care. Better understanding of the processes of critical illness and multiple organ failure has led to effective prevention strategies and treatment modal-

ities. Further advances in the understanding of mechanisms of the progression from SIRS to multiple organ failure will engender new breakthroughs that can be expected to further improve the outcomes of burned patients.

Acute care

Healthcare continues to change. It is described as rapid, overwhelming, chaotic, and problematic. Thus, some models of healthcare service are creating a flattening of the traditional organizational pyramid. It is replaced by decen-tralized decision-making and professional autonomy at the bedside. These changes require different skill sets to address the needs of facilitating and advancing clinical work. It requires a more professional and emotional maturity from practitioners regarding their relationship to their own work and their willingness to change their practices.

There are new issues in nursing practice today: clinical judgment and evidence-based practice. Nurses operate in an age of accountability where quality and cost issues drive healthcare. The public demands high-quality results (better outcomes). Evidence-based practice integrates providers' clinical expertise with the best evidence. It helps nurses structure how to make accurate and timely decisions. It improves the odds of doing the right thing at the right time for the patient. Closing the gap between research and practice affects all aspects of medical care. Workplaces must support the use of evidence-based practice (EBP) by creating structures and processes, building the infrastructure to support EBP.

Practicing nurses today need strong and effective clinical leadership. In today's settings, every nurse is a leader, using knowledge and skills to make decisions, and accepting accountability for competent care and safe patient outcomes. Transformational leadership is well suited to nursing in the clinical environment. It repositions staff nurses from the bottom of the organization pyramid to the center. Each nurse emerges as a leader when the clinical situation demands. Power is not given away, but rather partnerships develop between nurses at the bedside and management. Management becomes a partner and resource as opposed to a controlling force. Attractive work environments for professional people recognize the

contributions of each individual and value the power necessary for each partner to participate fully.

Introduction

The care of the burn patient is most challenging for the nurse. Care begins with the immediate resuscitation of the patient in the emergency department and continues until the patient is completely rehabilitated. During the initial resuscitation the role of the nurse is to assess and monitor the patient's hemodynamic alterations. Fluid resuscitation and nursing management of fluid resuscitation are adequately discussed in Chapter 9 in this book. Therefore this chapter will cover other areas where the nurse's care and management are crucial.

Pulmonary priorities

Inhalation injury continues to be the most serious and life-threatening complication of burn injury today. Early diagnosis and treatment greatly impact the outcome of care.

Impaired gas exchange is a potential problem for patients who have face and neck burns and/or inhalation injury. Inhalation injury may include carbon monoxide poisoning, upper airway injury (heat injury above the glottis), lower airway injury (chemical injury to lung parenchyma), and restrictive defects (circumferential third-degree burn around the chest). Upper airway edema causes respiratory distress and is the primary concern during the initial 24–48 hours postburn phase. Tracheobronchitis, atelectasis, bronchorrhea, pneumonia, and adult respiratory distress syndrome (ARDS) may occur during the acute, postburn stage either related or unrelated to inhalation injury.

Nursing care of a patient with inhalation injury begins with a detailed history of the accident. Inhalation injury is suspected when the accident occurred in a closed space. Close observation of the patient and frequent respiratory assessments are made throughout the initial and acute phase postburn. Initially, the patient is observed for hoarseness and stridor, which indicate narrowed airways. Emergency equipment is placed at the bedside to facilitate intubation if necessary. Observing the frequency of cough, carbonaceous sputum, and increased inability to handle secretions may indicate possible inhalation injury and the potential for impaired gas exchange. Other important observations include respiratory rate, breath sounds, use of accessory muscles to aid in respiratory effort, nasal flaring, sternal retractions, increased anxiety, and complaint of shortness of breath. Disorientation, obtundation, and coma may be due to significant exposure to smoke

toxins such as carbon monoxide or cyanide. These conditions are managed emergently with 100% oxygen.

Bronchoscopy may be done early to diagnose inhalation injury as well as facilitate airway clearance. Humidified oxygen should be readily available and applied to patients who have evidence of impaired gas exchange (especially pediatric patients). Aggressive nasotracheal suction may be indicated if the patient has difficulty with managing secretions either because of the increased amount of secretions and/or the decreased effectiveness of the cough. In addition, aggressive pulmonary toilet, including turning, coughing, and deep breathing, up and out-of-bed rocking in mother's arms may be done regularly and frequently. Elevation of the head of the bed, unless contraindicated, will also support and possibly improve ventilation. Trends and changes should be correlated with laboratory results and shared with the team.

Another complication is circumferential third-degree burns around the chest and neck, which often cause restrictive defects. The increased amount of edema combined with decreased chest excursion may greatly decrease tidal volume. This condition may progress and can become life-threatening, in which case chest escharotomy may be necessary to release the constricting eschar. The procedure may be done at the bedside or in the operating room. Equipment includes sterile drapes, scalpel, and Bovie (to control bleeding).

Intubation and mechanical ventilation may be required to improve gas exchange. Tube placement should be checked and documented frequently and verified daily by x-ray. Securing the endotracheal tube requires a standard technique for stabilization and prevention of pressure necrosis. Adequate humidity is necessary to prevent secretions from drying and causing mucous plugging. Remember to provide pre/post-suctioning hyperoxygenation. Sterile technique is used when suctioning to prevent infection. Attention to the details of oral hygiene will provide comfort for the patient and may reduce the occurrence of ventilator-associated pneumonia related to colonization in the oral pharynx.¹

Criteria for extubation depend on why the tube was inserted initially, but, overall, stable vital signs and hemodynamic parameters will support the plan for extubation. The patient should be awake and alert in order to protect the airway; therefore, pain medications may be reduced before extubation. Ventilatory measurements and blood gas analysis should be within normal limits.

Immediately following extubation, the nurse must be alert for signs and symptoms of respiratory distress, administer suction as needed, monitor blood gas measurements, provide optimal positioning for ventilation, as well as provide reassurance and support to decrease anxiety.

Age, burn size, and the presence of inhalation injury and pneumonia have been identified as major contributors to mortality.² Thus, vigilant nursing care (frequent nursing assessments, aggressive pulmonary toilet, etc.) combined with anticipating potential problems and being prepared to deal with the problems will add to the team effort and possibly improve the patient outcome.

Burn wound care

The primary goal for burn wound management is to close the wound as soon as possible. Prompt surgical excisions of the

eschar and skin grafting have contributed to reduced morbidity and mortality in severely burned patients.³⁻⁵

Wound care in the burn unit has become an art of burn nursing practice. It can be extremely challenging and complicated and, for a new nurse, it can be the most difficult and misunderstood part of burn nursing. The complexity exists because there are many different wounds that require different interventions in relation to time postburn or time postoperative. Wound assessment and care is a learned skill that develops over time. The expert burn nurse must teach these skills to new burn nurses in the hydrotherapy area, and operating room, and at the bedside.

Wounds may consist of eschar, pseudoeschar, skin buds, autograft, donor sites, hypermature granulating tissue, blisters, and exposed bone and tendons. Besides the many kinds of possible wounds, there are many topical antibacterial agents available for managing wounds. These choices raise many decisions for the team to address. Topical antimicrobial creams and ointments include mafenide acetate, silver nitrate, silver sulfadiazine, petroleum and mineral oil-based antibacterial products, and Mycostatin powder. Wounds may be treated in the open fashion (topicals without dressings) or closed fashion (topicals with dressings or soaks). Also there are many, many techniques for applying dressings to every area of the body to withstand exercise, ambulation, and moving around in bed. Biological dressings such as homograft or heterograft may be used as temporary wound coverage. Dressings may also be synthetic or biosynthetic or silver impregnated. Selection is based on the present condition of the wound and the expected outcome.

Secondary goals of wound care are to promote healing and to maintain function of the affected body part. These goals are accomplished by preventing wound infection, treating wound infection, preventing graft loss and tissue necrosis, providing personal hygiene, and maintaining correct positioning and splinting throughout hospitalization. To prevent burn wound infection, the burn nurse must use clean technique: cleanse the wound with soap and water; debride the wound of loose necrotic tissue, crusts, dried blood, and exudate; and apply topicals and/or dressings and change as often as ordered. The nurse must inspect the wound for evidence of infection: cellulitis, odor, increased wound exudate, and/or change in exudate; change in wound appearance; and increased pain in the wound. The physician should be notified so that changes in wound care can be made. Cultures and biopsies may be ordered to identify the type and count of organisms and treat with a specific systemic antibiotic and/or topical dressing and/or soak. The wound is often the source of sepsis in the bloodstream. The five cardinal signs of sepsis are: hyperventilation, thrombocytopenia, hyperglycemia, disorientation, and hypothermia.⁶

Preventing graft loss is another wound care challenge for nursing. Usually the patient returns from the operating room in a position that is maintained for 3 or 4 days. Any interaction with the patient during this time of graft immobilization requires creativity and care in order to prevent shearing of the graft. Postoperative dressings on the thighs and back are protected with polymycin, fine-mesh gauze to prevent soiling by feces and to minimize cleanup. The dressings are continuously monitored for increased drainage and odor, which would indicate possible wound infection. If infection is suspected, then

the postoperative dressings may be removed early for a closer inspection of the wound.

Donor sites will also require additional care to prevent infection. Of course, the care postoperatively depends on the coverage of the donor site. If the donor site is covered with fine-mesh gauze, the initial care is to ensure homeostasis and adherence of the gauze to the wound. Therefore the post-op pressure dressing remains intact for 6–12 hours and is then removed. The focus of managing the donor site is to keep the wound dry. If grafts/donor sites are on the back or backs of the legs, the patient is placed in a Clinitron bed for 4–5 days to promote drying. If the donor site remains wet, additional drying techniques (hair dryers, external heaters) may be used periodically during the day.⁷

If the donor site is covered with a synthetic or biological dressing, the same principles apply. Basically, apply a pressure dressing to ensure adherence to the wound for a short period of time postoperative and then expose to the air to support drying of the wound. A bed cradle is used to keep bed linen from contacting the wounds. The location of the graft, donor site, and eschar may all be on the same extremity, which again requires creativity to accomplish all three interventions of care.

Nurses today must accept the challenge of preventing pressure ulcers in major burn patients. No longer is it OK to treat the ulcer as though it is a burn wound. We need evidence to support our nursing practices to prevent pressure ulcers in burn patients because they have many risk factors that predispose to the development of pressure ulcers. Initially, hypovolemic shock with blood flow shunted away from the skin to preserve vital organ function is a factor. Additional injuries may add to the increased risk for pressure ulcers, such as: inhalation injury, which may require intubation and use of paralytic agents to manage the airway. As fluid resuscitation is begun, massive edema in both burned and unburned areas may occur. The edema is maximized at about 2–3 days postburn, which also decreases the blood flow to the skin and adds weight to all parts of the body.

Maintaining systemic hydration can continue to be a problem long after the patient has received adequate resuscitation for burn shock. Continued fluid therapy to replace fluid loss through the burn wound is essential. If systemic hydration is not maintained, even normal skin may be at risk. To complicate this situation, the quantity of fluid lost through the burn wound may increase the moisture on normal skin adjacent to the burn wound. This moisture may cause the normal skin to break down and predispose the skin to further compromise.

Many burn-injured patients will make repeated trips to the operating room for surgical excision of the burn wound and grafting, with graft taken from unburned areas. These procedures may require the patient to be anesthetized for long periods of time. Patients are at risk for pressure ulcers in the operating room, which necessitates the use of pressure-reducing devices. Likewise during these operative procedures the patient may lose large quantities of blood and/or may develop septic shock, resulting in decreased tissue perfusion. Vasopressors, antibiotics, and fluid resuscitation are the usual treatment for septic shock. The low-flow states and the use of vasopressors may also result in decreased tissue perfusion and increased risk of pressure sore formation.

Post surgery the patient is often immobilized with large bulky dressings and splints to protect the graft. These dressings need to be put on with enough pressure to stop the bleeding from the grafted wound and the donor site. But if the dressings are applied too tightly, or if edema develops after dressing application, this pressure may cause increased pressure on the skin.

Throughout the acute phase of care the burn patient is predisposed to pain and anxiety. Pain in the burn wound and fear of pain causes patients to try not to move. Careful titration of anxiolytics and narcotics can result in an alert patient that is relatively pain free but requires intense attention to detail from the nursing staff.

To prevent wound bed desiccation, soaks are used to maintain moisture in the grafted wound and to aid in decreasing wound colonization with bacteria. This moisture, when in contact with adjacent normal skin, may increase the risk of tissue breakdown.

Inadequate nutrition prior to or after the burn injury is potentially a significant problem. The hypermetabolic response in the burn-injured patient leads to protein malnutrition if caloric intake is compromised. To reduce the risks of systemic infection and to promote wound healing, enteral hyperalimentation is most frequently used and the patient is fed by nasogastric or nasojejunal tubes.

In summary, the physiology of the burn injury combined with many of the therapies and treatments during hospitalization impacts the burn patient's risk for pressure ulcers. Burn patients are among the high-risk populations for pressure ulcer development.

All patients, except those with skin grafts postoperatively, will benefit from a bath or shower. Large acute burns are placed on a shower cart and the wounds are gently showered with warm water. The overhead heater is on and the room temperature is 85°F (29°C) or above. Large acute burns are not immersed in a tub of water, so as to prevent autocontamination and electrolyte imbalance.⁸ Time in the hydrotherapy area can be used for careful observation of the wound as well as personal hygiene such as shampoo, mouth care, face care, and perineal care.

The hydrotherapy area affords an excellent opportunity for teaching the patient and family about wound care and dressing application. As the patient gets closer to discharge, families are required to do more of the care. The trend for earlier release from the hospital poses additional challenges for nursing since it reduces the time available to prepare the patient for discharge. The better the patient and families are educated, the better the outcome will be. Early involvement with patient and family helps identify potential obstacles at discharge and facilitates care coordination in the discharge process.

Metabolic and nutritional support

Hypermetabolism, or metabolic stress, is the direct response to a burn injury. The amount of stress increases proportionally to the extent of the injury and strongly influences a patient's nutritional requirements. This response can magnify the normal metabolic rate by 200%. Malnutrition, starvation, and delayed wound healing will result if calories are not provided consistently to meet nutritional requirements. Children require

more calorie and protein replacement than adults, because they have additional nutritional demands to support growth and development.

Monitoring output and managing nutritional intake are among nursing's primary responsibilities. An accurate record of intake and output is critical to patient care because potential problems can be detected early and alternate options of care can be individualized to help the patient achieve his/her goals. Accurate weights, daily or as ordered, are also important. Remember to record whether dressings, splints, or linens are included in the weight. Obviously, including additional elements does not reflect an accurate weight, but trends in weight either up or down may be identified and may be helpful in the overall management of the patient.

Typically, when patients cannot consume enough calories by mouth, then enteral feedings are begun. Sometimes enteral feedings are started before the patient is given the option of eating because the amount of calories is so great and/or the condition of the patient is unstable. Parenteral nutrition is used when enteral fails. The goal is to provide adequate nutrients, calories, and protein. A nasogastric tube is inserted initially and used to decompress the stomach until bowel sounds return. Then tube feedings are started at a very low volume per hour to act as a buffer against ulcer formation. The nasogastric tube allows for checking hourly gastric residuals, gastric pH, and guaiac. If the gastric pH falls below 5, or if the guaiac is positive, Maalox and Amphigel are given every 2 hours, alternately every hour.

Aspiration of stomach contents is a potential complication and always a concern. Gastric residuals are checked before suctioning to prevent the patient from vomiting and possibly causing aspiration. Another precaution is to keep the head of the bed elevated somewhat. A Dobhoff tube is also inserted initially, and feedings are begun as soon as 6 hours postburn. The rate starts slow and is advanced as tolerated to meet the calculated amount of nutritional replacement. Tube feedings continue until the patient can take the required amount of calories by mouth.

Another potential problem with both tubes is dislocation; therefore, it is important to check placement periodically throughout the day. When gastric residuals start climbing, it may be because the Dobhoff tube has slipped into the stomach or the patient is septic. Because tube feedings may become the source of contamination, routine care should include sterilization of the blender and limiting to 4 hours the amount of time that tube feedings can be hung at the bedside. The tubing and container should be changed every 4 hours (Mary Jaco, personal communication, 2004).

Sometimes when patients are encouraged to begin taking food by mouth, it will help to stop the tube feedings during the day and feed only at night. Not scheduling painful activities around meal-time and providing frequent mouth care will also contribute to improved oral intake.

Regular bowel patterns are expected in the postburn period. Patients are given many medications during hospitalization that may contribute to either diarrhea or constipation. Patients are expected to have at least one bowel movement per day. If not, then a bowel evacuation regimen should be initiated. If diarrhea is the problem and the volume exceeds 1500 mL/day, then bulking agents and/or

antidiarrhea medication may be useful to promote routine bowel elimination.

The importance of monitoring and documenting the many parameters of intake and output cannot be overemphasized. Established clinical protocols and guidelines facilitate the implementation and evaluation of the nutritional program.

Other strategies to support the hypermetabolic phenomenon of the burn patient are to keep the room temperature above 85°F (29°C) and to keep the room door closed to prevent drafts across the room. Also frequent rest periods must be provided during the day. Nursing generally makes the schedule of activities for the day, so including frequent rest periods is just as important as anything else that needs to be done during the day. Adequate sleep during the night is also very important: it oftentimes is what makes the difference between a good day and a bad day. A quiet comfortable environment without sensory overload (lights and noise) is essential for the patient to sleep.

Nurses are the grand communicators of progress and/or problems. Nurses work closely with dietitians, physicians, patients, and families to ensure that optimal metabolic and nutritional support is achieved during the postburn period.

Pain and anxiety assessment and management

The expected outcome for pain and anxiety management is for the patient to achieve a balance between successful participation in activities of daily living and therapies and being comfortable enough to rest and sleep as needed. The ultimate goal is for the patient to be satisfied with the pain management plan as it is implemented. Assessment of pain and anxiety provides a baseline for evaluation of pain and anxiety relief measures. Pain and anxiety scales are essential to quantify painful episodes and to evaluate effectiveness of medication. Knowing when and how much to intervene is guided by knowing the baseline pain and anxiety rating for the individual. Patients and families should be given information upon admission on how to use the assessment scales and to identify an acceptable level of pain and anxiety. The assessment scales should be age appropriate. Common pain assessment scales include the visual analog scale, color scale, adjective scales, and faces scale. A pain history may provide valuable insight into how to individualize the pain management plan. Assessment of pain in the pre-verbal child (0–3 years of age) includes crying, irritability, lethargy, depression, facial grimacing and tensing, increased heart rate and blood pressure, abnormal sleep/wake patterns, and withdrawal of a body part when touched.

Intravenous administration of opioids and anxiolytic agents is essential to manage pain and anxiety during the initial stage of injury due to the altered absorption and circulation volume following a major burn injury. A PCA (patient-controlled analgesia) pump is useful on children older than 5 years of age and adults. It is important to manage background pain as well as procedural pain for which medication should be given 15–30 minutes prior to a painful procedure. Constipation is frequently a complication of pain management; thus, a bowel management program should be instituted at the same time. Relaxation, guided imagery, music therapy, hypnosis, and therapeutic touch are adjunct techniques to complement analgesia and reduce anxiety.⁹ Emotional support and patient and

family education decrease fear and anxiety, thereby enhancing the pain management plan.¹⁰

Patient/family education

In order for nurses to be competent teachers, they must be competent practitioners with solid theoretical foundations. Continuing education is key to maintaining competency of a staff as educators of patients and families. Reinforcement of the educational process (assess, plan, implement, evaluate, and document), characteristics of patient population, updates on educational strategies, age-appropriate interventions, and ways to evaluate learning are topics that will sharpen educator competency.

Discharge planning and education begins upon admission. It begins with a thorough assessment of the patient's life prior to the injury. Identifying knowledge deficits and barriers to education, prioritizing strategies for education, providing supplemental educational handouts and/or classes as well as developing a plan for evaluating the effectiveness of the teaching opportunity are integral parts of the educational process.

Assessment provides essential information for planning an educational program to meet the specific individual needs of each patient and family. It is also done periodically during different stages of the educational process to determine if the plan remains valid or changes need to be made.

The assessment findings become part of the educational plan, in that the plan is tailored to meet the needs and concerns of the patient and family. The plan includes the learning objectives, the strategies for education, and the learning materials. All of these parts of the educational goal are agreed upon by the patient/family and the educator.

Implementation of the plan is the next step, followed by a thorough evaluation of the effectiveness of learning and/or determination of whether the education goal is being accomplished. Alterations in the original plan may be needed any time during the educational process depending on unforeseen situations or changes in conditions that were not anticipated.

The plan and how it was implemented and evaluated are documented on a multidisciplinary education documentation form. All disciplines document the educational encounters on the same form (required by JCAHO).¹¹ The benefits are many. This process ensures communication of educational topics among the team members, provides a historical account of education, and documents progress and/or changes in the plan. It benefits the patient and family by making them competent in their role as care provider when discharged from the hospital. Knowledge allays anxiety about the unknown and aids in compliance with recommended care after discharge, improving the long-term outcomes.¹² Patients and families can be empowered to become active participants in the burn care team early in the postburn course through a well-structured educational plan.

Rehabilitation of the burn-injured patient

A major burn is one of the most devastating injuries, both physically and emotionally, known to man. After weeks of being an invalid, undergoing repeated surgeries, fighting infection, having the body ravaged by the metabolic consequences of injury, and enduring pain and anxiety, the patient now faces

months of continued physical therapy to regain the level of function that they had known before the injury. Most patients who have sustained a major burn will continue to have a higher than normal metabolic rate and find that they do not have the stamina to easily regain their lifestyle.¹³ In children, bone metabolism is affected and these children are more prone to fractures.¹⁴ Although these patients must continue to exercise to prevent contractures, they may not have the physical strength to actively participate in such programs. Likewise, these patients frequently become depressed, as they face an altered self-image and fear that they will not be able to return to a normal life. For the adult, the concerns of whether they will be able to return to work or have to change their occupation is also a factor. What is the role of the nurse at this phase of treatment? Although nurses have been very involved in the care of the patient in the early phases of care, many nurses do not see how they can continue to be involved. The transition from the hospital to home care is often difficult for both the patient and family. It is important prior to discharge that the patient and family be educated in the care of wounds and healed skin before they leave the hospital. They also need information about the normal depression that occurs post-hospitalization and resources in their home community to which they have access. This is where the nurse case manager becomes an integral part of the patient care team. Nurse case managers that are hospital based can begin to work with the patient and family soon after admission to assess the patient's future needs and coordinate these with outside agencies to ensure that the transition goes smoothly. Often case managers from workman's compensation carriers or health maintenance organizations (HMOs) are involved during the early phase as well. Coordination of activities between case managers is important to provide seamless care. With children, it is important for the nurse case manager to begin working with the school nurse or community health nurses to provide for this seamless transition in care.

Although the rehabilitation therapist plays an important role in providing referrals to community therapists and psychologists, and social workers frequently make referrals to community mental health providers, the nurse case manager should be involved in the overall coordination of these and other services to foster a unified approach. The free flow of communication between all providers is necessary for optimal rehabilitation of the patient.

Work-hardening programs for adults

Work-hardening programs have been shown in adults to more rapidly return the patient to their optimum level of functioning.¹⁵

These programs may be available through community rehabilitation facilities, vocational rehabilitation agencies, HMOs hospitals or health centers with cardiac rehabilitation programs or through Workmen's Compensation carriers. The major concern for the nurse case manager and the burn team is which patients need these programs and at what point the patient will benefit the most from such intensive programs.

Assessment

Burn patients, like those recovering from coronary heart disease and surgery, find themselves deconditioned. Even 3

weeks of bedrest in a healthy subject can result in a 25% decrease in maximal oxygen consumption. Thus, burn patients who are hospitalized for 2 or more weeks may need to be considered for such programs. Burn patients should be first assessed for risk factors associated with coronary heart disease. Such risk factors include:

- age and sex,
- elevated blood lipids,
- hypertension,
- cigarette smoking,
- physical inactivity,
- obesity,
- diabetes mellitus,
- diet,
- heredity,
- personality and behavior patterns,
- high uric acid levels,
- pulmonary function abnormalities,
- ethnic race,
- electrocardiographic abnormalities during rest and exercise,
- tension and stress.

Cardiac stress testing is usually recommended prior to beginning an exercise program. If the patient has several risk factors, the exercise program can be tailored to fit the patient's needs.¹⁶

Planning

What is available? Often the major issue is what is available and who will pay for this care. When an adult is injured on the job, this is often arranged and paid for by the compensation carrier, since they have a vested interest in returning the patient to work as soon as possible.

Implementation

Once the details are worked out the next hurdle is to get buy-in from the patient and family. Some programs require the patient to be in a facility some distance from their home; this may present issues for both the patient and family. Similarly, if the program is in the local community, daily visits to the rehabilitation facility may pose transportation issues, especially if the patient is unable to transport him or herself. These details can usually be worked out with cooperation of all caregivers and the family involved. Motivation and determination are often the most difficult factors to overcome. This is especially true if the patient is suffering from depression. The nurse case manager can be very instrumental in rallying the burn team and caregivers in the community to help the patient and family to see this as a way to return the patient to more normal function.

Evaluation

Success in such programs requires that all involved have the same goals and that these goals result in measurable outcomes. The goal of such programs is not only to increase the patients tolerance to exercise but also to improve their psychological and social functioning and to return the patient to work or to the same level of functioning pre-injury.

Extensive exercise in children

Children may suffer from the same deconditioning as adults, especially if they have suffered 40% or greater burns. Cucuzzo et al. have shown that children with greater than 40% burns have bone demineralization.¹⁷ Treatment of these patients with long-term anabolic steroids and intensive exercise programs can return the patient's metabolic status and bone remineralization to normal much sooner.

Assessment

Children seem to do better if they are at least 4 years old when they begin this exercise program. The best time to start such a program is approximately 6–9 months postburn. With most patients this is after they have had 2–3 months away from the hospital after discharge from their initial injury. Like adults, individualized programs considering their current general state of health is necessary. When children enter these intensive exercise programs it is important for the parent or a responsible adult member of the family to be involved. This may be a significant factor in when the patient is able to start such a program. Similar results can be obtained in younger children through active play and exercise accompanied by music therapy. The use of activities set to music can increase stamina and actively stretch scar tissue and increase joint mobility.

Planning

Although cardiac rehabilitation programs and the like may be readily available in most major towns and cities in this country, often they do not take children. Children's hospitals often have rehabilitation units or outpatient programs for children that can offer similar programs to the adult cardiac programs. Children's hospitals are usually found in major cities; thus, these programs may not be as accessible as programs for adults. In some communities, school-age children may be able to obtain help within the school sport programs, especially if they have qualified athletic trainers. Children aged 4–6 may have more difficulty finding programs outside of children's hospitals. Some early childhood intervention and pre-kindergarten program may be available for younger children.

Another question is who pays for this care? Unlike the adult with insurance or workman's compensation insurance, children are often without funding for this rehabilitative care. State programs for children with special need (i.e. Title V programs) are one avenue to explore. Other sources of funding may come from private or public charities, school-mandated programs, or vocational rehabilitation programs for the older teenager.

Implementation

Motivating the child and parent can be a major task. Often the parent and child have spent weeks or months during the acute phase of care away from home. If there are other children in the home or if the parent normally works outside the home, the parent may not feel that he/she can be away from home an additional 2–3 months. The child may also not want to leave the safety of the home environment. Thus motivating the child and parent is often difficult. Helping the parent see this as a valuable program will require the whole burn team to work together with the patient and family.

Evaluation

The outcome of these programs for the child can be measured in increased exercise tolerance and improved psychological and social adjustment. A major function of these programs is to convince the child and parent that the patient is a normal child and can succeed mentally and physically. If the child returns home and can keep up with his/her peers, this alone improves the child's self-esteem.

Reconstructive surgery

Assessment

The role of the nurse in the reconstructive surgery phase is to be an advocate for the patient and family. Education of the patient and family throughout the course of burn care is an important nursing function. Many people have unrealistic expectations for reconstructive surgery. The nurse's role in the outpatient clinic or physician's office is to listen to the patient and family and to understand their hopes and expectations. Often when the surgeon discusses what should or could be done to improve the patient's appearance or function, the patient and family member are reticent to ask questions or to describe what they want. Patient's priorities are often different from the surgeons and this leads to dissatisfaction. Most surgeons prefer to wait until the scar has matured to begin reconstructive surgery. Occasionally, if the scar tissue is interfering with function, correction of the scar will be attempted. This is especially true in children where scar tissue may cause bone deformity if left until it has matured. In children, some reconstructive procedures are best postponed until the child has matured. Usually, surgery is best accepted by the child at the beginning of high school or just prior to starting further education. Although it is difficult to continue to be supportive of the patient and family during the scar maturation process, the nurse's role is one of education, support, and encouraging

the patient to continue with exercise, splints, and pressure garments, if ordered.

Planning

Once again, the nurse case manager can be instrumental in helping the family find the funding and resources to provide reconstructive surgery for the patient. If the patient is working or in school planning, the procedures should accommodate the patient's school or work schedule as much as possible. For children, funding through Services for Children with Special Needs may be available. Working with insurance companies and HMOs can be tricky if the surgery is presented as cosmetic rather than corrective surgery.

Implementation

Preparing the patient for surgery is the responsibility of the nurse and physician. Providing the patient with realistic expectations is often difficult. Many times, immediately after the surgery, the area will look worse and the patient may feel dissatisfied and depressed. Preoperative preparation of the patient and family may allay some of these issues. Surgery, itself, is frightening enough for the patient and family. In children, this can be especially frightening because it may bring up memories of their original burn treatment and the pain associated with this treatment. Postoperatively, the nurse should teach the patient and family how to care for the wound to prevent infection and further scarring.

Evaluation

Whose body is it anyway! A line from a famous play actually sums up the evaluative process for reconstructive surgery. As professionals, we may see great improvement in the patient's condition after surgery. But if the patient is not satisfied with his or her appearance, little has been gained by the surgery. This is the reason that the patient and family must have realistic expectations prior to surgery.

Introduction

Burn injuries are the third most common injury causing death in children, following motor vehicle crash and drowning accidents.¹ Burn injuries have the greatest length of stay (average of 7.8 days) for all hospital admissions due to injuries.² Approximately 1.25 million people are burned in the United States every year. Fortunately, most burns do not require hospitalizations; however, 60 000 to 80 000 patients sustain severe enough burns to demand hospital admission.^{3,4} Of those, 40% are children younger than 15 years.⁵ About 5500 burn patients die each year,³ and approximately 2500 of them are children.

House fires injure or kill over 10 000 people per year. House fires are among the leading causes of burn-related deaths in children at a rate of 12%; they are the leading cause of injury-related deaths for black children between the ages of 1 and 9 years. Children between 0 and 5 years of age are at a greater risk as a disproportionate number of fire deaths occur in homes. Deaths among preschool children are at a rate of more than twice the national average (29.6 deaths/million children) or an average of 20% of the total percentage of all home fire deaths.

Scalds are another common burn injury in children 2 years and under. Scald injuries may be due to household accidents or deliberate abuse. These may include spilling hot coffee or water, children reaching up to counter tops pulling pot handles or cords attached to cooking appliances and spilling the contents onto themselves, unknowingly putting body parts under a hot water faucet or climbing into a hot tub without realizing the water was too hot, and intentionally or unintentionally

being placed into or brought in contact with a hot substance by another individual.

Great improvements have been made in the reduction of mortality related to thermal injuries over the past few decades. Advances in fluid resuscitation, early surgical excision and grafting of the burn wound, infection control, treatment of inhalation injury, nutritional support, and support of hypermetabolic response to injury have contributed to a 50% decline in burn-related deaths and hospital admissions in the United States.³ This overall improvement in mortality is most perceptible in the pediatric population. In 1949, Bull and Fisher reported the expected 50% mortality rate for 49% total body surface area (TBSA) burn size in children aged 0 to 14.⁶ This has improved to 50% expected mortality in 98% TBSA burn in the same population group.⁷

The burn injury produces overwhelming physiological and psychological challenges to a child. The unique anatomical and physiological attributes of the child require the attention of physicians and nurses who are trained not only in burn care but also in the specifics of pediatric care. The most obvious differences between adults and children are in size and body proportion. Shorter lengths, tighter angles, and smaller diameters of various anatomical structures and spaces make certain manipulations more difficult. These differences also require the provision of special equipment and supplies, which reflect the configurations of pediatric anatomy. In addition to anatomical differences there are also many physiological differences between children and adults, which must be considered and will be discussed concerning the treatment of the pediatric burn patient.

Initial evaluation

A patient must be immediately removed from the source of burn and clothing and jewelry removed immediately as these burning items can prolong the burning process. Pouring cool water to minimize the depth of the burn can cause hypothermia in large burns and should be avoided. After the burning process is stopped, the patient should be kept warm by wrapping with a sterile sheet or blanket, if available, or clean sheet or blanket. If the burn involves chemical burns, the patient should be removed from the chemical immediately and the wound irrigated with copious amount of water at least for 30 minutes to dilute the chemicals.

Burn patients should be treated as a trauma patient and any other traumatic injuries diligently ruled out. Any potential life-threatening injuries should be identified and treated.

The airway should be assessed first: 100% oxygen should be administered and oxygen saturation monitored using pulse oximetry. Arterial blood gas and carboxyhemoglobin are obtained when appropriate. A full-thickness circumferential chest burn can interfere with ventilation. Chest expansion should be observed to ensure equal air movement. If the patient is on a ventilator, airway pressure and P_{CO_2} should be monitored. If ventilation is compromised, escharotomy of the chest should be performed to allow better chest movement and improve ventilation. Wheezing, tachypnea, stridor, and hoarseness indicate an impending airway problem due to inhalation injury or edema, and immediate attention is required.

A cuff blood pressure measurement may be difficult in patients with burned extremities. These patients may need an arterial line to monitor their blood pressure especially if they require a long transfer. A radial arterial line may not be reliable in patients with extremity burns and may be difficult to secure. A femoral line may be more reliable and easy to secure. These should be secured with sutures. Persistent tachycardia should alert a practitioner for a missed injury. Accurate and rapid determination of burn depth is vital to the proper management of burn injury.

A nasogastric tube is placed in all patients with major burns, as the majority of children develop gastric distension or ileus. A bladder drainage catheter is placed to monitor urine output accurately as a measure of successful resuscitation.

Resuscitation

In the hours after a serious burn, there is a systemic capillary leak that increases with burn size. Capillary usually regains competence after 18–24 hours if resuscitation has been successful. Intravenous (IV) access should be established immediately for the administration of resuscitative fluid. Increased times to beginning resuscitation of burned patients results in poorer outcomes, and delays should be minimized.⁸ It is crucial that venous access be obtained early postburn, even though such access may be extremely difficult to obtain. Due to the small circulating volume, delays in resuscitation for periods as short as 30 minutes can result in profound shock. Peripheral IV access is preferred and may need to go through burned skin if necessary. When peripheral IV is not available due to extremity burns, a central venous line may be secured. Either subclavian or femoral line can be obtained but femoral venous access may be easier to obtain in edematous patients. Small-bore catheters limit the rates at which fluid can be administered; therefore, children with large burns require two large-bore IVs so that sufficient fluid can be given. The presence of two IVs also provides a safety margin if one infiltrates to allow continued resuscitation while the ‘safety’ line is re-established.

When vascular access is unobtainable in small children (less than 6 years old), the intraosseous route is a viable option and it is relatively easy to obtain. Children can be administered fluid volumes in excess of 100 mL/h directly into the bone marrow.⁹ Intramedullary access can be utilized in the proximal tibia until IV access is accomplished. There is a very rare incidence of embolic complications with this procedure. A 16–18 gauge bone marrow aspiration needle can be used to cannulate the bone marrow compartment, although spinal

needles and even butterfly needles can be pushed through the soft bone of a child. Although previously advocated only for children younger than 3 years of age, intraosseous fluid administration can be safely performed in children under 6 years of age, if the bone is sufficiently soft to allow needle penetration.¹⁰ The anterior tibial plateau, medial malleolus, anterior iliac crest, and the distal femur are preferred sites for intraosseous infusion. The needle should be introduced into the bone, taking care to avoid the epiphysis, either perpendicular to the bone or at a 60° angle with the bevel facing the greater length of bone (Figure 36.1). The needle has been properly inserted when bone marrow can be freely aspirated. Fluid should be allowed to infuse by gravity drip. The needle should be well secured to prevent inadvertent removal. The use of pumps should be discouraged in case the needle is dislodged from the marrow compartment.

Due to their small body weight to body surface area ratio, fluid losses are proportionally greater in children. Normal blood volume in children is approximately 80 mL/kg body weight and neonates, 85–90 mL/kg, compared to the adult whose normal blood volume is 70 mL/kg. Evaporative water losses in a 20% TBSA burn in a 10 kg child are 475 mL or 60% of the circulating volume, while the same size burn in a 70 kg adult causes the loss of 1100 mL or only 25% of the blood volume. Although fluid losses after a burn injury are directly proportional to the burned surface area, the commonly used

Fig. 36.1 Intraosseous line placement in the proximal tibia (a) and distal femur (b). (Redrawn with permission from Fleisher and Ludwig.⁶⁰)

'rule of nines', useful in adults, adequate in adolescents, does not accurately reflect the surface area of children under 15 years of age (Figure 36.2). The standard relationships between surface area and weight in adults do not hold true in children, as infants possess a larger cranial surface area with less area in the extremities than adults. Most routinely used resuscitation formulas were developed using adult patients and are almost exclusively weight-based. Since the linear relationship

between weight and surface area does not exist in children (surface area varies to weight as a 2/3 function), use of these formulas in children results in under- or over-resuscitation (Table 36.1).

Therefore pediatric burned patients should be resuscitated using formulas based on body surface area, which can be calculated from height and weight using a standard nomogram (Figure 36.3) or formulas (Table 36.2). The most commonly

Fig. 36.2 The 'rule of nines' altered for the anthropomorphic differences of infancy and childhood.

TABLE 36.1 RESUSCITATION BY THE PARKLAND FORMULA ONLY COMPARED TO MAINTENANCE FLUID REQUIREMENTS ALONE

Example	% Burn	Calculated needs		Replacement burn loss	
		Resuscitation*	Maintenance†	mL	mL/kg/%
1 year old	15	600	800	-200	-1.33
10 kg	30	1200	800	400	1.33
0.48 m ² BSA	60	2400	800	1600	2.67
	90	3600	800	2800	3.11
4 years old	15	990	1200	-210	-0.85
16.5 kg	30	1980	1200	780	1.58
0.68 m ² BSA	60	3900	1200	2760	2.79
	90	5940	1200	4940	3.33
12 years old	15	2400	2250	1150	1.92
40 kg	30	4800	2550	2550	2.12
1.13 m ² BSA	60	9600	2250	7350	3.06
	90	14400	2250	12150	3.38

*4 mL/kg/% burn.
†2000 mL/m² BSA.

Fig. 36.3 Standard nomogram for the determination of body surface area based on height and weight. The example depicted is for a child of 100 cm in height and 23 kg in weight. (Reprinted with permission from Eichelberger.⁶¹)

TABLE 36.2 FORMULAS FOR CALCULATING BODY SURFACE AREA (BSA)

Dubois formula	$BSA (m^2) = ht (cm)^{0.725} \times wt (kg)^{0.425} \times 0.007184$
Jacobson formula	$BSA (m^2) = [ht (cm) + wt (kg) - 60]/100$

used resuscitation formula in pediatric patients calls for the administration of 5000 mL/m² total body surface area (TBSA) burned plus 2000 mL/m² TBSA for maintenance fluid given over the first 24 hours after burn, with half the volume administered during the first 8 hours and the second half given over the following 16 hours.¹¹ The subsequent 24 hours, and for the rest of the time their burn is open, call for 3750 mL/m² TBSA burned or remaining open area (for evaporation from wound) plus 1500 mL/m² TBSA (for maintenance requirements). This need decreases as a patient achieves more wound coverage and

healing. As in the adult patient, resuscitation formulas offer a guide to the initial starting point for the amount of fluid necessary for replacing lost volume in children and the amount of fluid should be titrated according to effects.

Loss of renal medullary concentrating capacity is usual secondary to washout of the medulla during resuscitation and immature kidneys' inherent inability to concentrate. Hyponatremia is a frequently observed complication in pediatric patients after the first 48 hours post-injury. Frequent monitoring of serum sodium is necessary to guide appropriate salt or water supplementation. Children of less than 1 year of age may require more sodium supplementation due to higher urinary sodium losses. Further, potassium losses should usually be replaced with oral potassium phosphate rather than potassium chloride as hypophosphatemia is frequently observed in this population.¹² Calcium and magnesium losses must also be supplemented.

An indwelling urinary catheter is essential for burns greater than 20%. During the early phase of resuscitation urine output should be assessed as frequently as every 15 minutes and titrated appropriately. Fluid administration should be titrated to achieve a urine output of 1 mL/kg/h in children and 2 mL/kg/h for infants. If the patient is making more than that, IV fluid should be titrated down. Other endpoints should also be followed, such as mental status, heart rate, blood pressure, and capillary refills. One can also follow the trend of either lactic acid or base deficit and see the resolution. Initial fluid boluses should be administered in amounts appropriate for the size of the child and should represent no more than 25% of the total circulating volume (10 mL/kg). If urine output is less than minimal, it may be more appropriate to increase the rate of IV fluid rather than giving bolus.

Intravenous resuscitation fluid should be isotonic and replace lost electrolytes. Lactated Ringer's (LR) is the most commonly used solution for the first 24 hours postburn. Electrolyte loss in the wound correlates better with LR. Children less than 1 year of age should also receive maintenance fluid containing dextrose solution to prevent hypoglycemia as their glycogen stores are limited.

Mortality

In a review of 103 children with >80% TBSA burns over a 15-year period, it was found that 69 survived with an overall mortality of 33%. Mortality was greatest in children under 2 years of age and in burns >95% TBSA (Figures 36.4 and 36.5).⁸ Another major predictor in mortality was the length of time to intravenous access (Figure 36.6). Burns that received resuscitation fluids within the first hour had a significantly higher chance of survival.⁸ The mortality rate also increases significantly with smoke inhalation injury. In no pediatric patient, no matter how large the burn, how young or with what type of inhalation injury could it be accurately predicted whether they would live or die at the time of admission.⁸

Fig. 36.4 Mortality in burns >80% total body surface area for various ages.

Assessment of resuscitation

Evaluation of the efficacy of resuscitation is difficult in children. The routine clinical signs of hypovolemia for the adult burn patients – low blood pressure and decreased urine output – are late manifestations of shock in the pediatric patient and tachycardia is omnipresent. Children have remarkable cardiopulmonary reserve, often not exhibiting clinical signs of hypovolemia until more than 25% of the circulating volume has been lost and complete cardiovascular decompensation is imminent. Mental status, pulse pressures, arterial blood gases, distal extremity color, capillary refill, and body temperature reflect volume status. Capillary refill is a good indicator of volume status in burned children. Decreased capillary refill should warn a practitioner of imminent danger. A child with normal blood pressure and acceptable heart rate, but with cool clammy extremities, obtundation, and a delayed

Fig. 36.5 Mortality for increasing burn size.

Fig. 36.6 Time to intravenous access in survivors and non-survivors. Mortality increases with delays in starting an intravenous line and instituting volume resuscitation.

TABLE 36.3 NORMAL PEDIATRIC VITAL SIGNS

Age	Minimum heart rate (beats/min)	Systolic BP (mmHg)	Respirations (breaths/min)	Minimal hemoglobin (g/dL)	Minimal hematocrit (%)
<2 years of age	100–160	60	30–40	11.0	33.0
2–5 years of age	80–140	70	20–30	11.0	33.0
6–12 years of age	70–120	80	18–25	11.5	34.5
>12 years of age	60–110	90	16–20	12.0	36.0

capillary refill, is a child in dire danger. Measurement of arterial blood pH with attention to base deficit or lactic acid is of particular importance in this age group, reflecting decreased tissue perfusion.

Children frequently develop a reflex tachycardia after even the most trivial injury due to an overexuberant catecholamine response to the trauma or anxiety. Systolic blood pressures of less than 100mmHg are common in children younger than 5 years of age (Table 36.3). Young children with immature kidneys have less tubular concentrating ability than adults, and urine production may continue in spite of hypovolemia. Arterial pH, lactic acid, or base deficit can be followed to assist resuscitation.

Volume overload must be avoided. Volume overload can lead to pulmonary edema, right heart failure, abdominal deep muscle compartment syndromes, and cerebral edema in burn patients. Although children possess a large cardiopulmonary reserve, the young heart is less compliant, and stroke volumes plateau at relatively low filling pressures, shifting the Starling curve to the left. Cardiac output is almost completely dependent upon heart rate, and the immature heart is more sensitive to volume and pressure overload. Cardiac output can be measured using a PiCCO monitor, which is less invasive than a Swan–Ganz catheter and only requires an arterial line and a central venous line. Transthoracic or transesophageal echocardiograms should be utilized early to assess the cardiac function in patients who are failing or not responding to the conventional therapy. Children are particularly prone to the development of edema from both vasogenic and hydrostatic sources. Vasogenic edema occurs within the early postburn period when vascular integrity is impaired. Of particular concern is the development of cerebral edema. Care should be taken in order to maintain head of bed elevation, particularly during the initial 24–48 hours postburn and avoid hypercarbia. The maintenance of intravascular osmotic pressures decreases the likelihood of edema development. Salt-poor albumin can be expected to remain in the intravascular space if administered after 8 hours postburn in amounts necessary to maintain serum albumin levels at more than 2.5g/dL. Albumin deficit can be calculated using the formula:

$$[2.5\text{g/dL} - \text{current serum albumin (g/dL)}] \times [\text{wt (kg)} \times 3]$$

The deficit can be administered as 25% albumin and given in three divided doses gradually.

Evaluation and management of airways

The smaller aperture of the pediatric trachea predisposes it to obstruction. Equal amounts of airway edema in pediatric and adult airway results in significantly disproportionate increases in amounts of resistance and decreases in cross-sectional area. A 1mm increase in tissue thickness of a 4mm diameter pediatric trachea results in a 16-fold increase in resistance with a 75% decrease in cross-sectional area. The same edema in an adult airway would increase the airway resistance threefold and reduce airway area by 44%.¹³ Therefore early intubation is advocated. As edema develops promptly following injury, airway evaluation and management must be given priority in pediatric patients. During emergent conditions when edema is present, inability to secure the airway with an endotracheal tube is a clear indication of the need for surgical airway control.

Potential hemorrhage and edema formation make emergency intubation difficult. Early intubation should be considered when a long transfer is anticipated or a patient has a large burn which likely will develop airway edema with a large amount of fluid resuscitation. Concurrent placement of an endotracheal tube over the bronchoscope should be considered at the time of bronchoscopy. A readily available estimate of airway diameter is the width of the patient's little finger, an age-based formula $(\text{age} + 16)/4$ or the use of Broselow tape.

Following placement of the ET tube, it must be adequately secured. With a child, oozing wounds and moist dressings, this can be a difficult task. One successful approach is to attach the ET tube with tape around the back of the head both above and below the ears. An additional piece of tape over the top of the head, secured to the tape behind the head, will prevent accidental extubation in most children.¹⁴

Inhalation injury

Inhalation injury, and its sequelae of infection and pulmonary failure, are major determinants of mortality after burn injury.

The mortality rate of children with isolated thermal burns is 1–2%, but it increases to approximately 40% in the presence of in-halation injury.^{15,16} Carbon monoxide poisoning coupled with hypoxia is the most frequent cause of death due to ‘smoke inhalation’. Any flame-related injury, particularly if it is confined in closed space, should be evaluated for an inhalation component. If inhalation injury is suspected, arterial blood gas and carboxyhemoglobin level should be obtained and the patient placed on 100% oxygen. Children may be spared some of the overt signs of inhalation injury due to their short stature and proximity to the floor-level cool air. As with adults, the only definitive method to diagnose an inhalation injury is through direct visualization of the airway and early examination of arterial carboxyhemoglobin level. Signs of potential inhalation injury include facial burns, singed nasal hairs, carbonaceous sputum, abnormal mental status (agitation or stupor), respiratory distress (dyspnea, wheezing, stridor, hoarseness), or elevated carboxyhemoglobin level >10%.¹⁷ Carboxyhemoglobin levels must be calculated from the time drawn, back to the time of the accident or for O₂ given as described in the chapter on this subject. A carboxyhemoglobin level >60% has more than 50% chance of mortality (Table 36.4).

Common treatment modalities for inhalation injury include airway maintenance, clearance, and pharmacological management (Table 36.5). A recent study has shown that a group of children treated with a regimen of nebulized heparin and acetylcysteine had a significant decrease in reintubation rates, atelectasis, and mortality when compared to a control group.¹⁸

Hypermetabolism

Children with burn injury demonstrate a remarkable increase in metabolic rate. No other disease state produces as dramatic an effect on the metabolic rate as burn injury.^{19,20} This hypermetabolism is thought to slow wound healing and prolong generalized weakness. This prolonged metabolic dysfunction can lead to loss of lean body mass and increase morbidity. Marked wasting of lean body mass occurs within a few weeks of injury.

The hypermetabolic response increases with increasing burn size. There is an upregulation of catabolic agents, such as cortisol, catecholamine, and glucagons,²¹ which induces a hyperdynamic cardiovascular response, an increased oxygen consumption, energy expenditure, proteolysis, lipolysis, and glycogenolysis, loss of lean body mass and body weight, delayed wound healing, and immune depression.^{22,23}

Pharmacological agents have been used to attenuate catabolism and to stimulate growth in burn injury. To further minimize erosion of lean body mass, administration of anabolic hormones such as growth hormone, insulin, insulin-like growth factor-1 (IGF-1)/IGF-binding protein-3 (IGFBP-3), oxandrolone or testosterone and catecholamine antagonists such as propranolol have been used in pediatric burns. These agents contribute to maintenance of lean body mass and promote wound healing.^{24–29}

Thermoregulation

Core body temperature is consistently elevated after a major burn. A hypothalamic reset induced by various inflammatory cytokines and pain causes this elevation even in the absence of infection. The temperature reset is thought to be an adaptive mechanism to bolster host defense against potential pathogens. Burned patients strive for temperatures of about 38°C. Depressed or ‘normal’ temperatures are more likely indicative of overwhelming sepsis or exhausted physiological capabilities to maintain temperature and should be viewed as an ominous sign. After major thermal injuries, routine methods of heat conservation are inadequate due to the extensive heat loss through convection and evaporation. Infants and toddlers, with their increased surface area/volume ratios, less insulating fat, and lower muscle mass for shivering, are particularly susceptible to hypothermia.

Hypothermia produces numerous consequences. The heart is particularly sensitive to temperature, and ventricular arrhythmias are not uncommon. Hypothermia also increases the susceptibility of the myocardium to changes in electrolyte concentrations. The oxyhemoglobin dissociation curve is shifted to the left by lowered body temperature, impairing peripheral oxygenation. In extreme cases, hypothermia

TABLE 36.4 CARBON MONOXIDE POISONING

Carboxyhemoglobin (%)	Symptoms
0–10	Normal
10–20	Headache, confusion
20–40	Disorientation, fatigue, nausea, visual changes
40–60	Hallucination, combativeness, convulsion, coma, shock state
60–70	Coma, convulsions, weak respiration and pulse
70–80	Decreasing respiration and stopping
80–90	Death in less than 1 hour
90–100	Death within a few minutes

TABLE 36.5 AIRWAY MAINTENANCE, CLEARANCE, AND PHARMACOLOGICAL MANAGEMENT

Turn side to side	q 2h
Sitting or rocked in chair	As soon as physiologically stable
Ambulation	Early
Chest physiotherapy	q 2h
Suctioning and lavage (nasal/oral tracheal)	q 2h
Bronchodilators	q 2h
Aerosolized heparin/acetylcysteine	q 2h alternating
	Heparin 5000–10000 units with 3 mL NS q 4h
	Alternated with acetylcysteine 20% 3 mL q 4h

produces central nervous system and respiratory depression, coagulopathies, and loss of peripheral vasomotor tone.

Every effort should be made to reduce the heat loss experienced by pediatric patients. Ambient temperatures and humidity should be maintained at 30–33°C and 80%, respectively, in order to decrease energy demands and evaporative water losses. Wet dressings should be avoided or at least wrapped, and wet bedding promptly changed so as to decrease evaporative or conductive cooling. The patient should be positioned so that drafts are avoided, including the inlets and outlets for air-conditioning and heating ducts. Bathing or showering should be expeditiously completed, avoiding undue environmental exposure.

Nutritional support

Nutritional support of the hypermetabolic response in severely burned patients is best accomplished by early enteral nutrition. Early institution of enteral feeding can abate the hypermetabolic response to burn.^{30,31} Patients with smaller burns are immediately placed on a high-protein, high-caloric diet to support their metabolic response. Those with larger burns (>30%) are placed on enteral feedings.

Almost immediate enteral nutrition can be initiated via a transpyloric feeding tube. Most children will tolerate enteral feedings as early as 1–2 hours postburn, if not immediately. Several studies have demonstrated the efficacy of early alimentation and the additional salutary effects.^{32,33} Enteral feedings can be given through a flexible Silastic duodenal feeding tube, bypassing the stomach, which may be experiencing decreased peristaltic action.

Early enteral feeding preserves gut mucosal integrity and improves intestinal blood flow and motility.³⁰

Milk has been demonstrated to be one of the least expensive and best tolerated of all enteral formulas. Additionally, it is palatable and easily recognized by children when they are able to take oral feedings. Because of the low sodium content of milk, sodium supplementation may be necessary. Hyperosmolar feedings, commercially available, should be diluted because of the high incidence of subsequent diarrhea if used full strength. It is diluted to 1/2 or 3/4 strength. Diarrhea is particularly troublesome in children because of their increased sensitivity to volume deficits.

Several formulas are available to estimate caloric requirement in burn patients. Since caloric demands are related to burn size, caloric support should be given in amounts calculated based on body surface area. A series of different formulas based on body surface area have been developed at Shriners Hospitals for Children, Galveston to meet the differing requirements of the various age groups.^{34–36} The Curreri formula has likewise been amended to reflect the differing demands of the pediatric group (Table 36.6).

Growth

Hypermetabolism and muscle protein catabolism persist long after the wound is closed.³⁷ Protein breakdown continues 6–9 months after severe burn. There is almost a complete lack of bone growth for 2 years after injury. This results in long-term osteopenia, which may adversely affect peak bone mass accumulation in children.^{38,39} Severely burned children with a burn size of >80% have a linear growth delay for years after injury.⁴⁰

TABLE 36.6 NUTRITIONAL REQUIREMENTS FOR CHILDREN

	Galveston	Modified Curreri
Infant	2100 kcal/m ² + 1000 kcal/m ² burn	BMR + 15 kcal/% burn
Toddler		BMR + 25 kcal/% burn
Child	1800 kcal/m ² + 1300 kcal/m ² burn	BMR + 40 kcal/% burn
Adolescent	1500 kcal/m ² + 1500 kcal/m ² burn	

In severely burned patients, nail and hair growth are attenuated during the acute postburn period, and bone growth is slowed.^{41–43} Dampened height and weight gain velocities have been documented in children during the first 3 years postburn, thereby rendering these burned children slighter and shorter than their age-matched peers.⁴⁴

Nutritional support of acute burn patients becomes an essential part of treatment during their hospitalization.

Wound closure

One of the more important advances in the last 20 years has been the development of early excision and early wound closure. Improvements in the treatment of burn wounds and utilization of antimicrobial dressings have dramatically decreased the incidence of fatal sepsis in burned patients.⁴⁵ Two decades ago third-degree burns were treated by removing small amounts of eschar at a time, approximately 10–15%, followed by grafting. Commonly, eschar was allowed to separate with lysis by bacterial enzymes. This led to a high incidence of invasive infection and wound sepsis and prolonged length of hospital stay with increased mortality. Today massive excision can be easily managed in children, providing results of decreased mortality and decreased length of hospital stay.^{46,47} Early excision even in the first 24 hours is safe and effective.⁴⁸ Performing early excision within the first 48 hours can significantly reduce blood loss.⁴⁹ By using skin substitutes such as allograft skin, xenograft, and Integra (Figure 36.7), the burn wound can be covered and protected for many weeks until enough donor site is available for grafting (repeat autografting is performed when the donor site is healed for reharvesting). Cultured epidermal autografts (CEA) is available for massive burn injuries (Figure 36.8). Although it is an effective way to cover large burns with limited donor sites, it may not be the most cost-effective approach. A group of patients treated with CEA had greater hospital costs, a longer length of stay, and more reconstructive admissions than conventional treatment with meshed autograft skin.⁴⁶ Cultured skin substitute (CSS) is currently undergoing investigative study and holds promise. CSS, consisting of autologous cultured keratinocytes and fibroblasts attached to collagen-based sponges, may reduce the requirement for donor skin and number of autograftings in massive burns.

Scald burns in young children are best managed with delayed treatment. Unless the wound is clearly third degree, the scald injury should be conservatively managed for approximately 2 weeks to allow the wound to heal or demarcate (Figures

Fig. 36.7 Dermal and skin substitutes can be used as temporary cover for severe burns. Integra, a bilaminar skin substitute, can replace homografts as temporary cover. The Silastic superficial layer can be removed after 3 weeks and a super-thin autograft then placed on top. The entire wound can be covered with Integra, which is subsequently autografted when donor sites are available. (Reprinted with permission from Barret J, Herndon DN, eds. *Color atlas of burn care*. London: WB Saunders; 2001: 107, Plate 6.95.)

Fig. 36.9 Superficial and small areas of deep second-degree scald burns before topical treatment: 25% total body surface area. (Reprinted with permission from Barret J, Herndon DN, eds. *Color atlas of burn care*. London: WB Saunders; 2001: 79, Plate 5.39.)

Fig. 36.8 The cultured epidermal autografts are ready to use 18–21 days later. Extreme care with handling is needed because of the fragility of the cultured cells. (Reprinted with permission from Barret J, Herndon DN, eds. *Color atlas of burn care*. London: WB Saunders; 2001: 106, Plate 6.89.)

Fig. 36.10 Deep second-degree burns treated for 10 days with silver sulfadiazine. Note that the edges are regenerating. Pseudo-eschar challenges the evaluation of the wounds. Foul smell, discoloration, surrounding cellulitis, and eschar separation are signs of infection. (Reprinted with permission from Barret J, Herndon DN, eds. *Color atlas of burn care*. London: WB Saunders; 2001: 77, Plate 5.31.)

36.9 and 36.10). This conservative treatment results in less wound excised, less blood loss, and less apparent scarring.⁵⁰ Treatment methods for the conservative care of scald burns were analyzed. Scald injuries greater than 20% TBSA (mean 31%) were randomized to treatment with allograft skin versus topical antimicrobial therapy. Treatment with allograft led to decreased time to healing and decreased pain.⁵¹ In another study, patients greater than 40% TBSA burn (mean 65%) were randomized to allograft skin or topical antimicrobial. Patients who received treatment with allograft skin had a significantly decreased length of stay.⁵² The current recommended treatment for second-degree burns, primarily scalds less than 30% TBSA, is immediate application of Biobrane. Biobrane can be safely used in children, even in infants less than 2 years of age. When applied within 48 hours of injury there is no

difference in infection between Biobrane and topical antimicrobials. Further, application of Biobrane versus topical antimicrobials leads to decreased pain, decreased length of hospitalization, and decreased healing time.^{53,54}

Pain management

Children do not always express their pain in the same way as adults.⁵⁵ Children may display pain through behaviors of fear, anxiety, agitation, anger, aggression, tantrums, depression, withdrawal, and regression.^{56,57} How the child's experience of pain from the burn injury and anxiety from the hospitalization are clinically managed will have lasting psychological effects for many months and years to follow. A severe burn injury brings many weeks of surgeries, dressing changes, and

exercises that can cause intense pain. Pain can also exist as a constant state throughout the hospitalization. Morphine sulfate is the most commonly used analgesia. It should be given intravenously, and not intramuscularly. Fentanyl can be also used. Fentanyl Oralet can be used successfully for dressing changes (10 µg per kg). Most outpatients are treated with hydrocodone/acetaminophen.

Rehabilitation

Rehabilitation is a key component to success of burn treatment and starts at the time of the admission. During the acute phase of burn care, splints are used to minimize joint deformities and contractures. Splints are used continuously except during a therapy session. They are fabricated to each patient's needs and used from day 1 of hospitalization. Bedside therapy, including passive and active range of motion, is started early. Early mobilization should be practiced. Early ambulation after the grafts has taken and early physical and occupational therapies are important to success of rehabilitation of burned children. Patients with leg grafting are kept bedrest after the operation, but on postoperative day 4, they are gotten out of bed and started on ambulation. Early therapy and ambulation are keys to success of long-term rehabilitation of burned children. When patients are discharged from their acute care hospitalization, they undergo rigorous therapies, including stretching, and range of motion and strengthening exercises.

In general, deep partial-thickness burn wounds requiring 3 or more weeks to heal will likely produce hypertrophic scars. The longer it takes to heal, the more likely are scars. Using dressings that exert constant pressure on the healing wound and pressure garments exerting constant pressure on the healed wound are the most effective ways of decreasing the incidence of hypertrophic scar formation. Pressure garments may be worn up to 2 years or until scars mature.

Prevention

Prevention remains the single best way to manage pediatric burn injuries. National prevention and education efforts have positively impacted the number of pediatric burns each year. Lowering the temperature set point on hot water heaters and teaching families to check the bath water temperature before placing a child in the bath has decreased hot water scald injuries. Prevention groups have worked with gas hot water heater companies and the Consumer Product Safety Commission (CPSC) to provide education to raise gas water heaters 12 inches off the ground, which significantly reduces the risk of accidental explosions and fires.⁵⁸

Much work still needs to be done in the area of 'child fire play'. Three-fourths of 'child fire play' involves matches or lighters. All matches and other ignition sources must be placed out of reach of children. A positive step toward prevention occurred in 1994 when CPSC placed into effect a child-resistant lighter to protect children under 5 years of age. The importance of placing smoke detectors in multiple areas in a house has received much public education over the last several years. Current prevention education focuses on children, and especially infants that are not able to remove themselves from a fire. Since the CPSC has reduced flammability standards on children's sleepwear in 1997, there has been an increased incidence of sleepwear-related burn injuries in children.⁵⁹ One way to protect infants and children is to dress them in fire-resistant sleepwear and clothing to protect them from a burn injury if a fire does occur.

Children have no idea of the dangerous situations they place themselves in. Educating children as early as possible that fire is dangerous is imperative. Providing safe environments for our children and providing appropriate education to them is the responsibility of healthcare providers, the adults that care for them, and the community at large.

Introduction

The geriatric patient, usually defined as over 65 years of age, now constitute about 10% of the major burn population, with an anticipated progressive rise as the geriatric population in the United States continues to increase. Improvements in the quality of life over the past 50 years in developed countries have increased the average life span by nearly 30 years.¹ The proportion of the population in the United States over 65 years of age is expected to increase from 12.4% in 2000 to 19.4% in 2030, with a projected increase from 420 million to 973 million elderly citizens.² This trend presents a special challenge since the elderly will constitute an ever-growing segment of the average surgeon's practice and will influence clinical and ethical decisions along with healthcare costs. The elderly and the very young pediatric population are most likely to succumb to severe burns.³⁻⁶ It has been reported that nearly 12 deaths per day result from residential fires with infants, toddlers, and the elderly representing the high-mortality population.^{4,5} Children less than 5 years of age and adults over 65 years of age have a mortality from burns that is six times the national average.⁶ Treatment of the elderly burned patient remains a greater challenge compared with middle-aged and younger patients, due to lower physiological reserves, higher underlying co-morbidities, reducing the margin for error.⁷ The number of elderly people seeking medical attention for minor burns is also increasing, making the recognition of the physiological and metabolic changes which occur with age even more important for the burn care professional.⁸⁻¹⁰

Epidemiology

Contact with flame is the main (65%) cause of burn injury, while one-third of injuries are due to cooking accidents — scalds in 15% and contact with hot objects close to 15%.⁸⁻¹¹ The latter cause is much more prevalent in the elderly, reflecting increasing psychological and physical disability. This fact is also reflected in the statistic that the rate of fire-related deaths in an individual over 75 years of age is four times the national average. The male to female ratio is nearly even compared to the 5 to 1 male to female ratio for the young adult burn victim. This ratio is explained by the fact that 95% of burns in elderly people occur in the home compared to less than half for the younger adult. Prevention therefore must be focused on the home. Prevention should also focus on the fact that 30% of geriatric patients are the victims of self-neglect and at least 10% are the victims of elder abuse.¹¹

Outcome

As expected, mortality and morbidity is higher for the geriatric patient with a burn.¹⁻⁵ Mortality in a young adult with a burn 80% total body surface area (TBSA) is 50%; in a person aged 60–70 years a burn 35% TBSA has a 50% mortality and in a person over 70 years old, a 20% TBSA burn will have a 50% mortality.^{9,12} Pereira et al.¹³ analyzed 1674 patients admitted to the Shriners Burn Hospital, Galveston, Texas, between 1989 and 2005 as well as 179 autopsies conducted during this period, to study mortality trends and primary causes of death in the entire spectrum of age over time. The data demonstrated that mortality has indeed reduced in all age groups over the last decade, including the elderly (>65 years) group. Gender dimorphism was noted in mortality in patients over 65 years of age. Lung injury and sepsis was the commonest primary cause of death noted at autopsy. Increase in weights of heart, lung, spleen, and liver were noted in all age groups postmortem. These data indicate that chronological age alone is not an independent cause of mortality and morbidity after severe burns.

Furthermore, the long-term disability is much greater in the geriatric patient. Approximately 50% of elderly patients with a major burn return to a home environment within the first year^{8,9,14} compared to nearly 90% for the younger adult. The increased risk factors present in this population explain these outcome statistics. It is also possible that the increased complications seen in the elderly burns result from a more cautious and less-aggressive treatment regimen. This is due to

existing beliefs among clinicians that elderly burn patients tolerate eschar excision less than their younger counterparts, resulting in a greater delay in excision of burned tissue.¹⁵ However, it is important to recognize that despite these risk factors the elderly burn patient has been repeatedly demonstrated to tolerate multiple and early surgical procedures, and early wound closure corresponds to a better outcome.^{16–18}

Risk factors

There are a number of well-recognized risk factors, present in elderly people, which will lead to increased morbidity after a burn. Some of the more prominent factors are shown in Box 37.1.

Decreased cardiopulmonary reserve

Aging is known to decrease pulmonary reserve for both gas exchange and lung mechanics.¹⁹ Elderly people are more prone to pulmonary failure, which is the major cause of death in all burns. The presence of atherosclerosis, coronary artery disease, and previous myocardial infarcts are also common.

Chronic illness including malnutrition

A number of disease states are commonly seen, such as adult-onset diabetes and a previous or current cancer. Some degree of protein-energy malnutrition is found in over 50% of elderly burn patients on admission. Malnutrition increases morbidity and mortality after a burn and may well increase the elder's risk for burn injury.^{20–22} Micronutrient deficiency is particularly prevalent. A well-recognized alteration in the gastrointestinal tract is a decrease in the ability to breakdown whole proteins and to tolerate a carbohydrate load, which leads to inadequate calories and protein.²¹ Daily protein requirements are higher in the elderly than in the younger population.²¹

Decreased lean body mass

There is a progressive decrease in lean body mass with aging.²³ The lean mass or body protein compartment is responsible for all the physiological and metabolic activity needed for survival, and any significant decrease is detrimental since a burn injury characteristically leads to catabolism-induced loss of lean mass. Any pre-existing loss will result in increased morbidity, especially the early onset of immune deficiency, weakness, and impaired healing.^{22,24,25} The cause of the loss is multifactorial. Impaired nutrition, decreased activity, and a decrease in levels of the endogenous anabolic hormones, human growth hormone, and testosterone with age are all causative.^{19,22}

BOX 37.1 Risk factors in elderly people

- Chronic illness, e.g. adult diabetes
- Cardiovascular disease, e.g. previous infarct
- Pulmonary reserve decreased with age
- Unintentional weight loss
- Decrease in lean body mass
- Impaired nutrition with presence of deficiency states in energy, protein, and macronutrients
- Decreased endogenous anabolic hormones
- Skin aging (thin, decreased synthesis)

Decreased anabolic activity leads to a longer recovery time as well as causing the restoration of muscle to be very slow. Of importance is the fact that elderly people respond to exogenous anabolic stimuli such as testosterone analogs, human growth hormone, and resistant exercise in a similar fashion to the younger population. Therefore, exercise, high protein nutrition, and anabolic agents are essential for recovery.^{26–28}

Aging skin and wound healing

There are significant changes in the skin with aging which are responsible for the greater percent of deep burns in the elderly, even after scalds, compared to a younger patient.^{29–31} A 50% decrease in the turnover rate of the epidermis is present after age 65, as well as a flattening of the rete pegs and fewer epidermal-lined skin appendages. These properties will significantly decrease the healing rate of a partial-thickness burn.^{29–31}

In addition, there is a progressive thinning of the dermis and a decrease in both collagen content and matrix, especially glycosaminoglycan. The latter is responsible for loss of skin turgor. In addition, there is a decrease in vascularity and in the key resident cells, i.e. macrophages and fibroblasts. The thinner dermis with less blood flow explains the greater amount of deep burn, and the decreased cellularity explains a decrease in all phases of healing^{29–31} (Box 37.2).

Treatment

In general, treatment is identical to that for the younger patient except for the fact that massive burns are more commonly managed expectantly.

Initial resuscitation

In general, more fluid is required to resuscitate the same burn size to avoid hypovolemia.³² The reason is likely the decreased skin turgor which decreases the resistance to fluid accumulation or edema production. Another possible factor is some impairment in cardiac function. Early ventilatory support is more commonly required due to decreased lung reserve and earlier fatigue.

Wound management

The same aggressive approach at wound closure used in the younger patient applies to the elderly. Removal of the burn wound is essential to survival.^{16–18} Since older patients do

BOX 37.2 Aging of skin

- Decreased epidermal turnover
- Decrease in skin appendages
- Thinning of dermis
- Decreased vascularity
- Decreased collagen and matrix
- Decreased fibroblasts, macrophages

tolerate operative procedures, a conservative approach is not warranted. However, thinner skin grafts are necessary due to the thinner dermis, and a longer healing time is expected.²⁹

Metabolic and nutritional support

Although elderly patients do not generate the degree of hypermetabolism seen with younger patients, the catabolic response is comparable, necessitating a 1.5 g/kg/day protein intake.^{33,34} Since many older patients already have a lean mass deficit evidenced by prior weight loss,¹³ the goal of nutritional support must not be ‘maintenance’ alone, but rather replacement therapy, especially of protein and micronutrients, as pre-existing deficiency states are common.^{22,23} Nutrient supplements are invariably required. As most supplements are protein hydrolysates, the gut is more capable of absorbing the peptides and amino acids compared to the breakdown of whole proteins in food.^{35,36} Anabolic agents can be valuable adjuncts to optimal nutrition.^{37,38}

Anabolic agents such as insulin and oxandrolone have been studied in improving postburn hypercatabolism in the pediatric population and their use could be extended to the elderly considering the reduction in endogenous anabolic hormones in this group post-injury.⁴⁵ Continuous infusions of the anabolic peptide insulin, with tight euglycemic control, in victims of major thermal injury prevents muscle catabolism and preserves lean body mass, without increasing hepatic triglyceride production.^{39,40} Lower dose infusions at 9–10 U/h, promotes substantial muscle anabolism without the need for additional large doses of carbohydrate.⁴¹ Maintenance of euglycemia with insulin for non-burned patients in surgical critical care units, substantially diminished infection and the mortality rate and is a critical hormonal manipulation in the acute setting.⁴² Insulin infusions are suited to the closely monitored environment of the burn intensive care unit but are impractical in the rehabilitative outpatient setting. Testosterone restoration is an effective therapeutic maneuver in both male and female burn victims. However oxandrolone, a synthetic analog, is preferable since it possesses only 5% of testosterone’s virilizing androgenic effects and has a per oral formulation available. Oxandrolone improved net muscle protein synthesis in healthy young men⁴⁵ and was later found to effectively improve lean body mass in burned patients, especially emaciated subjects whose treatment had been delayed.^{37,43} The effects were independent of age.⁴⁴ Treatment of acute pediatric burn patients with oral oxandrolone (0.1 mg/kg twice daily) enhances efficiency of protein synthesis, increases anabolic gene expression in muscle, and significantly increases lean body mass at 6, 9, and 12 months after burn and bone mineral content 12 months after injury versus unburned controls.⁴⁰ Recombinant human growth hormone has been successfully used in pediatric patients; however, has several adverse side effects, particularly during acute care in burned patients, most notably hyperglycemia, and has shown an increased mortality rate in critically ill, non-burned adults in Europe.^{46,47} We therefore do not recommend its use in the elderly.

Pain, sedation, and comfort care

There is increasing evidence that the geriatric burn patient is undertreated for pain due to the misconception that there is less pain with age.⁴⁸ Both pain and anxiety further increase

catecholamine levels, which is deleterious. Management of standard drug therapy is affected by the decreased clearance of many of these agents with aging, requiring decreased dosages⁴⁹ (Table 37.1). Evidence from investigations of experimental pain suggests that there is an increased response in the elderly to high-intensity stimuli and a reduced pain tolerance to high-intensity stimuli.⁵⁰ Undertreated postoperative pain in the elderly does seem to increase the incidence of delirium.⁵¹ Also, although the initial burn injury and sepsis-related complications principally determine the extent of the metabolic response in burn victims, obligatory activity, background and procedural related pain, and anxiety also greatly increase metabolic rates. Judicious maximal narcotics support, appropriate sedation, and supportive psychotherapy are mandatory to minimize their effects.⁵² Another area of potential benefit is the use of a proactive geriatrics consultation team. Involving the geriatrician early reduced the perioperative incidence of delirium by one-third due to targeted recommendations based on predefined areas of high risk. Comfort care only measures need to be strongly considered for elderly patients with likely fatal burns. Age, burn size, and pre-existing health problems dictate which patients should have comfort care. Since these factors are evident very early, this approach should not be delayed to avoid excessive suffering by patient and family.⁵³

Perioperative optimization

Aging leads to many changes in the cardiovascular system that makes hemodynamic stability more difficult to achieve, leading to increased adverse outcomes. Coronary artery disease is prevalent and is estimated to exceed 80% in patients over 80 years.⁵⁴ The incidence of congestive heart failure may be as high as 10% in the elderly.⁵⁵ The revised cardiac risk index helps stratify patients into risk groups and helps to identify those in whom additional cardiac evaluation might be indicated.⁵⁶ Patients at risk for a perioperative myocardial event either by the revised cardiac risk index or who have other risk factors (e.g. peripheral vascular disease, unexplained chest pain, diabetes, ECG abnormalities, etc.) should undergo further evaluation. For patients unable to exercise at all, pharmaco-

TABLE 37.1 COMMONLY USED DRUGS REQUIRING DECREASED DOSES IN ELDERLY PATIENTS*

Drug	Comments
Barbiturates (should be avoided in elderly)	Paradoxical pharmacological response often leading to restlessness, agitation, or psychosis; decreased rate of elimination
Benzodiazepines	Increased sensitivity to pharmacological effect; some benzodiazepines may be metabolized more slowly
Narcotic analgesics	Increased sensitivity to analgesic effects: possibly impaired clearance
Tricyclic antidepressants	Increased incidence of cardiac and hemodynamic adverse effects; urinary retention and other anticholinergic effects; decreased drug clearance

*Decreased dose in part due to decreased renal function in the elderly.

logical stress perfusion imaging using dipyridamole, adenosine or dobutamine provides comparable prognostic information compared with exercise perfusion imaging. A normal stress perfusion scan or a normal stress echocardiogram is associated with <1% combined perioperative death or infarction rate. Patients with minor perfusion abnormalities undergoing lower-risk operations may not require catheterization, but should be considered for prophylactic β -blockers and aspirin before operation. High-risk subgroups of patients based on clinical risk factors and individuals with positive non-invasive tests should undergo cardiac catheterization. Patients with significant cardiac lesions should have definitive coronary revascularization via angioplasty before large body surface area burns are excised. Increasingly the potential benefits of using β -adrenergic blocking agents in the perioperative period are being studied.^{57–59} The rationale is that perioperative ischemic events are related to an exaggerated postoperative sympathetic response leading to increases in heart rate.^{57,58,60,61} β -blockade has an added advantage in the burn patient. Severe thermal injury is associated with persistent hypermetabolism that can last for up to 9–12 months post injury,⁶² with deleterious consequences in the acute and the convalescent phase. The resting metabolic rates in burn patients increase from near normal for burns less than 10% TBSA to twice normal in >40% TBSA involvement.⁶⁰ Previous studies have demonstrated that catecholamines play a key role in the initiation of the various cascades leading to postburn hypermetabolism.^{66,67} Once initiated, these cascades, their mediators and their by-products appear to stimulate the persistent and increased metabolic rate seen after severe burn injury. Blocking the triggering of these cascades at the onset by blocking the action of catecholamines at the receptor level attenuates this response and decreases suprphysiological thermogenesis,⁶³ tachycardia, cardiac work⁶⁴ and resting energy expenditure.⁶⁶ Severely burned subjects treated with propranolol titrated to produce 20% reductions in baseline heart rates, diminished obligatory thermogenesis, tachycardia, cardiac work, resting energy expenditure, reduced fatty infiltration of the liver and increased muscle–protein balance.⁶⁴ However no study has directly focused on the geriatric patient. Furthermore, the drawback of β -blockade in the elderly is that the aging cardiovascular system has a decreased response to β -receptor stimulation. This decrease together with anesthetic agents may have additive effects in the setting of prophylactic β -blockade administration and lead to deleterious and profound hypotension intraoperatively. Despite being well tolerated, as demonstrated by Mangano et al.,⁵⁷ many practitioners still withhold β -blockers in the elderly for fear of drug-related complications. Individualized dosing of β -blockers as suggested by Raby et al.⁶¹ to control myocardial ischemia postoperatively may be more beneficial due to different coronary anatomy and ischemic thresholds among patients. This target-based approach may decrease the incidence of drug-related side effects. Further investigations will be necessary to evaluate the most appropriate therapeutic regimen that will reduce perioperative ischemia, cardiac morbidity, and postburn hypermetabolic response in the elderly burn survivors.

Pulmonary complications are more strongly linked to coexisting comorbidities than to chronological age.⁶⁸ Because of the prevalence and importance of chronic obstructive pulmonary

disease (COPD) and asthma in the elderly, physicians need to have a high index of suspicion for these conditions during the perioperative evaluation. Perioperative chest x-rays should be ordered selectively. The value of pulmonary function tests remains controversial. With the appropriate diagnosis, aggressive pulmonary rehabilitation including exercise training, patient education, nutritional counseling, smoking cessation, and optimization of medication have been shown to be effective for the elderly patient.⁶⁸ Aggressive use of antibiotics, judicious use of bronchodilators, adequate hydration and postural drainage and chest physiotherapy are also liable to reduce the incidence of pneumonia.

Rehabilitation

The elderly patient needs to be aggressively managed in the rehabilitation phase to avoid any further loss of function or strength, which will be difficult to recover. As previously described, the geriatric patient is capable of restoring muscle strength with resistance exercise and therefore should not be managed conservatively.⁶⁹ As with children, providing support and guidance for family or caretakers is an integral part of care. The patient will depend on these individuals for their well-being on discharge.^{70,71}

Intentional burns in the elderly

Identifying elder abuse is harder than identifying child abuse. Children cannot legally live alone and must attend school, whereas the elderly often live alone, interacting predominantly or exclusively, with the very family or carers who enact their abuse.⁷² The abused elderly may collude with their abusers (unwittingly or purposefully), keeping their abuse secret due to shame or guilt, especially if children are responsible, or fear of reprisal if they are dependent on the abuser.^{73,74} There is evidence that 80% of elder abuse comes to light only when someone other than the victim or a relative becomes involved.⁷⁵ Most forms of intentionally inflicted burns have a higher associated morbidity and mortality than equivalent accidental burns, in part due to comorbidity from other physical or substance abuse or from psychological problems that pre-existed and contributed to the inflicted burn or that result from it. Unlike with children, in dealing with elder mistreatment the duties of a doctor to report suspected abuse may produce ethical difficulties with respect to confidentiality, when competent elderly victims of abuse do not want it reported. The initial priority of the examining doctor is to identify life-threatening conditions and treat them, and thereafter, to identify and promptly and completely record symptoms and signs of abuse or neglect (including photographs). A deliberately inflicted burn on another human being represents a criminal act and as such must be reported. Intentionally inflicted burn injuries are not simply physical injuries and are best managed within a multidisciplinary team of specially interested and prepared healthcare, social service and legal professionals.

Conclusion

Surgical decision-making in the burned elderly patient requires consideration of the patient's physiological age, preburn

functional status, degree of impairment from comorbid conditions, and clear treatment goals. No patient should be denied an operation on the basis of age alone, since decline in organ function with aging is predictable for the population as a whole but less so for an individual. Currently, no 'score' can improve decisions based upon sound clinical judgment after a thorough evaluation and discussion with the patient and the family.

Favorable outcomes in the elderly burned patient should pertain more to relief of suffering and maintaining independence and quality of life rather than expanding life span. And finally, clear and repeated communication between the burn team and patients or their surrogates remains a critical aspect for guidance of therapy and the achievement of acceptable outcomes.

Gastrointestinal pathology	504
Vascular access complications	508
Summary	510

Introduction

A multitude of surgical complications can occur in burn patients depending on the size and depth of burn injury. Burns, sustained as a result of concomitant blunt trauma (e.g., vehicle explosion), can present with multiple organ system injuries, requiring thorough systemic assessment and management according to the Advanced Trauma Life Support (ATLS) guidelines. Patients with large total body surface area (TBSA) burns generally require prolonged hospital stay with numerous debridement and skin grafting procedures and are at risk for potential surgical complications involving various organ systems. The gastrointestinal (GI) tract complications include stress gastritis and ulceration, acalculous cholecystitis, superior mesenteric artery (SMA) syndrome, and pancreatitis. Additionally, despite pharmacological advances in prevention of stress gastritis and ulceration, it remains as the most common cause of GI tract bleeding in burn patients. Burn injury-induced enterocolitis as a result of transient ischemia-reperfusion injury to the gut is a serious GI tract complication, which can progress to full-thickness necrosis of involved segment. Abdominal compartment syndrome can also occur during acute phase of massive fluid resuscitation in large TBSA burned patients. Moreover, burn patients are susceptible to common GI tract pathology such as appendicitis and intussusception (in toddlers) during their prolonged hospitalization. Other potential complications include conditions associated with vascular access procedures, which are frequently performed in large TBSA burn patients. Major burn injury significantly affects hemodynamic status, requiring central venous as well as arterial pressure monitoring. Various catheter-related complications are frequently encountered in burn intensive care units. A variety of non-thermal surgical problems can occur in burned patients.^{1,2} The cause for occult systemic sepsis is frequently attributed to GI tract pathology such as ischemic bowel, acute cholecystitis, abscess and gastric perforation resulting in significant morbidity and mortality, especially with delay in diag-

nosis and treatment. In our own experience at Shriners Hospital for Children at Galveston, common surgical problems encountered were enterocolitis, gastroduodenal ulceration, septic thrombophlebitis, mesenteric ischemia with bowel necrosis, small bowel obstruction, and arterial vascular injury with distal limb ischemia. These secondary and sometimes fatal complications in burn-injured patients deserve immediate recognition and treatment. Major burn patients need diligent care and attention throughout their hospital course to avoid complications arising from other organ systems. This chapter reviews the frequently encountered general surgical problems in burned patients with respect to diagnosis and management.

Burns and multiple traumas

Blunt trauma

Burn injury in association with multiple trauma poses an unusual and often vexing challenge for the surgeon. There are few published data pertaining to this topic, primarily due to the regionalization of burn care in areas not commonly associated with trauma centers. Approximately 24% of military burn casualties and 2–7% of civilian burns are associated with other traumatic injuries.^{3–5} Mortality is obviously related to burn size and depth, but is also directly related to the number and severity of associated multiple organ injuries. Of 2914 major burn patients admitted over a period of 10 years to Los Angeles County and University of Southern California burn center, combined injuries accounted for approximately 5% of admissions with an overall mortality of 13%, nearly twice that of burns without associated trauma. In addition, the presence of inhalation injury further compromised the prognosis, carrying a mortality of 41% in the group of patients with major burns, multiple trauma and smoke inhalation.⁶

Knowledge of the mechanism of the burn injury aids in predicting the full scope of concomitant traumatic injuries. For example, motor vehicle crashes account for the majority of multiple injured burned patients. Industrial accidents and attempts to escape house fires, explosions, and electrical burns with falls account for the other majority of victims. One group found that 88% of burned patients injured in motorcycle crashes and 36% of those injured in other motor vehicles crashes have additional injuries other than burns.⁵ Motor vehicle crash victims that require extrication from the vehicle and those that are ejected typically have the most severe injuries. Those trapped or unconscious in or near a burning vehicle

are obviously in danger of severe inhalation injury. The most frequently encountered organ system injuries in motor vehicle crash victims in order of frequency are musculoskeletal, head and neck, abdominal, thoracic, and genitourinary system. Attempts to escape from the building during a fire commonly lead to falls resulting blunt trauma with potential multiple organ injuries. The median lethal height for this mechanism of injury is 40 feet (four building floors) and spinal injuries may be overlooked.⁶ Spinal cord lesions are seldom complete and they may not necessarily present with obvious evidence of associated vertebral fractures.^{7,8} High-voltage electrical burns rarely occur at ground level and are, therefore, often accompanied by falls, resulting in multiple injuries. In addition, tetanic contractures resulting in fractures, massive neurovascular, orthopedic and soft-tissue destruction are frequently seen with major electrical burn injury.

Primary assessment

In burned patients with multiple organ injuries, the spectacular appearance of the burn injury may unduly shift the caregiver's attention away from the seemingly underwhelming associated injuries, resulting in delay of diagnosis and subsequent increased morbidity and mortality. The initial assessment of patients with combined thermal and non-thermal injuries should focus on airway, breathing, and circulation, as recommended by the ATLS guidelines from the Committee on Trauma of the American College of Surgeons. The burn injury itself is usually not immediately life threatening, but rather asphyxia, airway obstruction, impaired breathing from neurological injury, exsanguination, tension pneumothorax or cardiac tamponade pose more ominous threats. Thoracic injuries such as rib fractures, pneumothorax and hemothorax should be managed as in any other trauma patients with blunt thoracic injury. Thoracostomy tubes, if possible, are placed away from burned skin to decrease the risk of infectious complications such as empyema. Although rare, empyema with loculated fibrous thoracic collections is best handled with minimally invasive thoracoscopic approach. Pericardial tamponade resulting from heavy impact to anterior chest wall can be detected by focused assessment with sonography for trauma (FAST) exam and managed with pericardiocentesis or a pericardial window.

Associated injuries

Approximately 5% of civilian combined injury patients have associated intraabdominal trauma.^{6,9} The diagnosis of intra-abdominal injury may prove difficult, as the abdominal examination is often unreliable in the face of a severe burn. In addition, the usual practice of monitoring changes in vital signs and hemoglobin to detect intra-abdominal injury may be unreliable since these changes may be significantly affected by the intravascular volume shift from severe burn. Tools such as diagnostic peritoneal lavage (DPL), computed tomography (CT) scan or ultrasonography (FAST exam) that are currently used to evaluate trauma patients with blunt or penetrating mechanisms should also be considered when evaluating a burned patient with suspected intra-abdominal injury. In a prospective, randomized study, the sensitivity, specificity and accuracy of these diagnostic modalities in victims of blunt abdominal trauma were similar and the diagnostic studies

were actually complementary in minimizing the incidence of missed injuries.¹⁰ It is imperative to avoid 'negative' celiotomies, while promptly detecting all significant intra-abdominal injuries that could compromise the overall outcome of the patient. However, once the decision has been made for surgical abdomen, extreme care must be taken to avoid abdominal wall complications such as dehiscence and infection. Dehiscence of abdominal wounds in burned patients is frequent, independent of whether or not the burn wound was traversed.¹¹ If abdominal wall closure demonstrates significant tension, retention sutures should be utilized. Occasionally, a temporary abdominal closure using silo sheet or organ bag may be required due to massive bowel edema for delayed abdominal wall closure. Although DPL is now rarely used due to advances in CT imaging, when necessary, closed rather than open technique for DPL should be used. Diagnostic laparoscopy can be a helpful, non-invasive method to accurately determine injuries such as bowel perforation or ischemia that are difficult to diagnose with CT alone. However, adequate intra-abdominal insufflation for laparoscopy is often difficult to achieve in patients with eschar in the trunk area.

Vascular injuries may be difficult to diagnose due to the appearance of the burned skin, soft tissue edema, compartment syndrome, or hypotension. Although angiography continues to be the gold standard in the diagnosis of major vascular injuries, the invasive nature of the exam and necessity of moving patients to the angiography suite pose a significant burden and risks. On the other hand, ankle-brachial index (ABI) and a Doppler ultrasound are non-invasive bedside techniques to assess adequacy of arterial blood flow; however, the results can be difficult to interpret, especially for ABI when extremities are burned full-thickness. Although extremely rare to face significant vascular injury requiring graft placement, potential problems with contamination of either autologous or synthetic grafts need to be weighed, and the liberal use of prophylactic muscle flaps for graft coverage has proven to be helpful. As is standard in all trauma patients, the cervical spine should be considered unstable until a complete evaluation has been performed. True unstable cervical spine fractures should be treated with traction via halo or tongs, which may be placed through the burn, if accompanied with compulsive site care and early burn wound excision. When necessary, intracranial pressure monitoring via a bolt placed through healthy skin is preferred over a ventriculostomy. If a neurosurgical procedure is required, debridement of the scalp and non-viable tissue is completed at the same time as the craniotomy. Orthopedic injuries, primarily fractures, are the most common associated injuries in thermally injured patients. The burn surgeon and the orthopedist make decisions regarding the optimal management of these patients jointly. Therapeutic decisions are based upon the following considerations:

- stability of the fracture,
- need for excision and grafting of the burn,
- access required for adequate burn wound care, and
- early aggressive physical therapy after the injury.

Although fractures away from the burns may be managed with reduction and casting, in cases where fractures are associated with severe soft-tissue damage, internal fixation should be carried out prior to bacterial colonization of the wound (within 24–48 hours). In a review of 101 thermally injured patients

with orthopedic injuries, 75% of the patients had definitive orthopedic procedures within 24 hours of their injuries. Early, aggressive fracture treatment has resulted in decreased orthopedic complications without additional risks of infection, poor fracture healing, or amputation.^{9,12–15} All open fractures must have incision and drainage in the operating room within 24 hours of the injury. Skeletal traction is used infrequently due to resultant patient immobility; however, it may be a good option in patients with severe hemodynamic instability. Antibiotic coverage is provided as deemed appropriate to the orthopedic injury. A majority of dislocations may be managed with closed reduction but when open reduction through a burn wound is inevitable, the wound is closed to the level of the fascia without drains.^{14,16}

Child abuse

A mechanism of injury of particular interest is that of non-accidental trauma, as seen in cases of abuse and assault. Assault-provoked burn injuries carry a 7–16% risk of other associated injuries. Burn injury is found in 10–25% of documented cases of child abuse and most occur in children under 3 years.¹⁷ Inconsistent history involving the burns, delay in seeking medical attention, history of previous trauma and specific patterns of the lesions (bilateral stocking glove pattern, sharply delineated edges of the burn, dependent location, tide or splash marks, and marks left by cigarettes, irons, heaters and curling devices) should alert the healthcare giver to possible child abuse.¹⁸ A skeletal survey may confirm the presence of old fractures of ribs and long bones also suggestive of non-accidental trauma. In children with an altered state of consciousness or developmental delay, head CT scan is a reliable diagnostic tool to detect abusive head injury. In addition, an ophthalmological examination may reveal retinal hemorrhages, typical of the ‘shaken baby syndrome.’¹⁹ This topic is extensively discussed in Chapter 61.

Gastrointestinal pathology

Pathophysiology

Burn wounds of sufficient size (>30% TBSA burns in adults) initiate a generalized physiological response, which affects other organ systems, including the GI tract. The GI tract has long been recognized as an internal target of systemic shock and disruption of gut mucosal integrity is thought to be the initiating focus for sepsis in burn patients. These physiological changes include splanchnic hypoperfusion due to massive intravascular fluid loss along with vasoactive hormones, hypermetabolism leading to profound catabolic state and malnutrition, and immunosuppression with a breakdown of mucosal barriers to bacterial invasion in the GI tract. Combinations of these derangements initiate various organ system dysfunctions, resulting in non-thermal complications of burn injury. Massive burn injury results in diffuse capillary leak, hypovolemia, and release of vasoconstrictive agents, which cause selective decrease in splanchnic blood flow^{20,21} (Figure 38.1). The splanchnic hypoperfusion shown to occur in the early postburn period^{22,23} along with inadequate fluid resuscitation contribute to significant tissue hypoxia. In the GI tract, burn injury can result in decreased blood flow to the gut by

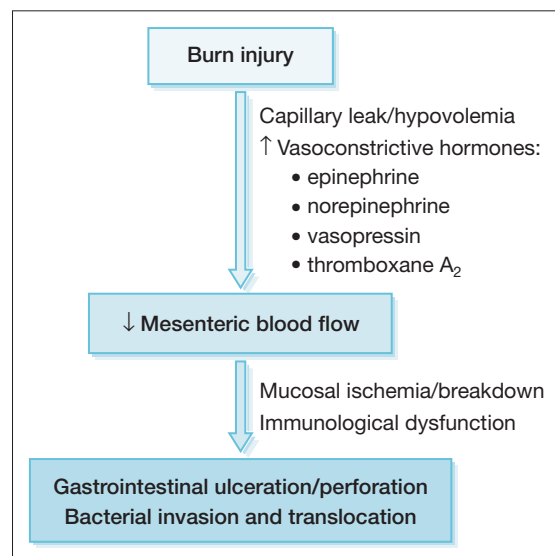

Fig. 38.1 Pathogenesis of mucosal barrier disruption. Massive burn injury induces diffuse capillary leak syndrome leading to decrease in intravascular volume along with outpouring of vasoconstrictive hormones. Subsequent decreased splanchnic circulation contributes to mesenteric ischemia, mucosal atrophy, enterocolitis and intestinal necrosis. Gut mucosal barrier disruption along with immunological dysfunction can lead to systemic inflammatory response.

one-third despite maintaining adequate cardiac output with fluid resuscitation.²² A 40% flame-burned pig model showed an early reduction in superior mesenteric blood flow associated with intestinal mucosal hypoxia, acidosis and increased bacterial translocation despite adequate fluid resuscitation.²⁴ Sepsis and burn injury have additive effects on intestinal integrity.²⁵ Multiple factors can influence intestinal blood flow and this may be improved by enteral feeding.²³ Further, an increased plasma level of thromboxane B₂, a vasoactive inflammatory mediator, has been noted both in the acute phase (3 days postburn) and during sepsis.²⁶ A selective reduction in blood flow to liver, small intestine and kidney during massive burns contributes to surgical complications. Hypoperfusion with ischemia insult to gallbladder can result in bile stasis, leading to acalculous cholecystitis.²⁷ Ischemia-induced injury to GI tract mucosa can produce ulcer formation (Curling’s ulcer) and enterocolitis severe enough to cause full-thickness necrosis and even intestinal perforation.²⁸ Poor perfusion to kidney and liver can also result in organ dysfunction and failure. In addition to complications involving GI tract organs, decreased perfusion to burn wounds results in poor wound healing and increased incidence of wound infection.

The hypermetabolic response to burn injury altering immunological function also significantly contributes to non-thermal complications in burned patients. The hypermetabolic response causes a profound catabolic state, deterring wound healing and immunological function. The activation of the hypothalamic–pituitary axis, sympathetic outflow, and the acute phase response take place, resulting in fat and protein breakdown and increase in gluconeogenesis.²⁹ Defective fibroblast function also contributes to impaired wound healing. Leukocyte dysfunction and reduced cellular immunity cause immunologi-

cal compromise. Blunting this hypermetabolic response has been thought to be critical to improve the overall recovery of burn patients.^{30–33} Growth hormone administration, which blunts hypermetabolic response in burn patients, has recently been reported to enhance small bowel homeostasis during burns by significantly increasing gut mucosal villus height and cell number.³⁴ Early enteral feeding has been shown to blunt hypermetabolic response.^{31,32,35} The combination of transient mesenteric hypoperfusion along with hypermetabolic response to burns has been shown to contribute to breakdown of gut mucosal barrier, subsequently leading to bacterial translocation from the gut, initiating systemic inflammatory response and, ultimately, sepsis. Numerous studies have demonstrated the link between massive cutaneous burn injury and bacterial translocation.^{36–40} Early mucosal atrophy that occurs after burn injury has been found to be a major contributing factor for impaired gut barrier function. An increase in intestinal epithelial cell turnover in mice has been shown to result from both apoptosis and proliferation of gut epithelial cells.⁴¹ Furthermore, an increase in intestinal apoptosis that occurs after cutaneous burn injury does not appear to be the result of mesenteric hypoperfusion alone, but is speculated to be related to pro-inflammatory mediators produced by the burn wound.⁴² Intervention aimed at preventing splanchnic hypoperfusion along with hypermetabolic response to burn injury may prevent immunological dysfunction and GI tract complications that are associated with severe burns.

Stress gastritis

The decreasing trend of stress gastritis and/or gastroduodenal ulceration in burned patients reflects both improvement in the treatment of acutely burned patients and the success of specific prophylactic measures. The incidence of acute gastroduodenal disease was previously reported to be as high as 86%, depending on the method of diagnosis (routine endoscopic evaluation, presence of gastrointestinal bleeding, postmortem).⁴³ Since the introduction of aggressive fluid resuscitation, antacid, early enteral feeding and proton pump inhibitors, the incidence of clinically significant gastroduodenal ulcer disease in burned patients (Curling's ulcer) has significantly decreased, fallen below 2%,⁴⁴ with a mortality of less than 0.2%.⁴⁵ The exact pathogenesis of Curling's ulcer remains unknown; however, reduced mucosal blood flow along with production of deleterious prostaglandins is thought to contribute to ulcer formation.⁴⁶ These lesions tend to be encountered more frequently in patients with larger burns and in the presence of sepsis.⁴⁷ Gastric ulcers are characteristically multifocal, and duodenal ulcers are usually solitary, with 15% of patients having combination of both gastric and duodenal ulcerations. Hemorrhage is the predominant presenting sign, and is often massive. Perforation is less common and is seen in about 12% of the patients.

A significant number of patients with major burn injury may develop mucosal changes within 72 hours of the burn, and with subsequent septic episodes and hypoxemia it may progress to ulceration. Multiple factors are implicated as potential causes of stress ulcers in burned patients,⁴⁷ including mucosal ischemia, increased acid production, increased acid back-diffusion, energy depletion, bile reflux, and direct mucosal injury due to the presence of intraluminal tubes. The state of

mucosal perfusion is dependent upon a complex interplay of local and systemic factors, and inadequate perfusion may contribute to breakdown of mucosal barrier function to acids. The prevention of stress ulcers in thermally injured patients requires eliminating or minimizing these factors. Aggressive fluid resuscitation aids in maintaining adequate mucosal blood flow. The administration of H₂ receptor antagonists or proton pump inhibitor is also important in reducing stress ulcer formation. Although these pharmacological agents have been shown to be effective against ulcers,⁴⁵ early enteral feeding is the most effective approach in the prevention of stress hemorrhage in burn patients.⁴⁸

Proper treatment of established stress ulcers includes those measures currently in use for prevention. More aggressive medical therapy includes combinations of intravenous (IV) vasopressin, somatostatin, and/or endoscopic cautery. Surgical options should be utilized early in order to prevent the profound effects of bleeding and hypotension on a maximally stressed burned patient. Specific surgical indications include massive bleeding (>2.5 liters in adult, >50% blood volume in child), ongoing uncontrolled blood loss, and evidence of a perforated viscus. If operative repair is necessary, vagotomy with antrectomy is considered as the operation of choice.⁴⁷ The overall mortality for patients requiring operative intervention remains significant at 50%. Although Curling's ulcers are far less frequent than in the past, they remain a potential hazard to all burn-injured patients. The current low incidence of stress ulceration is due to successful aggressive burn injury management and the use of specific preventive measures, especially early enteral feeding.

Acalculous cholecystitis

Acute acalculous cholecystitis is a rare complication of burn injury, as it is typically identified searching for source of sepsis in critically ill patients. The incidence is estimated at 0.4–3.5% in burned patients.^{49,50} Predisposing factors for acalculous cholecystitis include extensive burns (>40% TBSA burn), multiple transfusions, sepsis, a history of total parenteral nutrition, and a history of narcotics usage.⁴⁹ It is associated with high mortality, and the appropriate treatment depends on the patient's overall stability. Proposed etiologies are bile stasis, altered bile composition, acute gallbladder hypoperfusion due to third space fluid loss, and systemic sepsis.^{49,51} The lack of enteral feeding, resulting in decreased cholecystokinin level, along with narcotic use contributes to bile stasis. Multiple blood transfusions that are frequently required in major burned patients alter the composition of bile. Systemic sepsis with the resultant effects of circulating vasoactive mediators upon local tissue perfusion also leads to local ischemia of the gallbladder wall, inflammation, gangrene, and even perforation in unrecognized cases. The common histological finding in acalculous cholecystitis consists of intense injury to blood vessels within the muscularis and serosa.

Acute acalculous cholecystitis commonly presents with fever, right upper quadrant abdominal tenderness, leukocytosis, and elevated liver enzymes. These findings also commonly pre-exist in severely burned patients; therefore, a high index of suspicion is required for prompt diagnosis. The significant rates of gangrenous gallbladder and perforation are noted to be 33–100% and 12%, respectively.⁵² Ultrasound exam is the

preferred diagnostic study demonstrating thickened gallbladder wall, pericholecystic fluid, and intraluminal sludge. A positive cholecystoscintigraphy (HIDA scan) can also confirm the diagnosis but is often unavailable and may be difficult to obtain for critically ill patients. Once the diagnosis of acalculous cholecystitis is confirmed, cholecystectomy via laparoscopic approach should be considered for burned patients.⁵⁰ Patients who are extremely ill may be considered for ultrasound-guided percutaneous cholecystostomy placement.⁵³ Clinical response rates with this technique range from 56 to 100%.^{53,54} In a recent review of 163 patients who underwent percutaneous cholecystostomy, over 80% of patients were able to undergo removal of the cholecystostomy tube and did not require a cholecystectomy.⁵⁵ Caution must be employed when utilizing this technique, as the incidence of gangrenous cholecystitis is significant in thermally injured patients, and a lack of clinical response after percutaneous cholecystostomy should prompt the surgeon to proceed with a cholecystectomy.

Superior mesenteric artery syndrome

Superior mesenteric artery (SMA) syndrome occurs when the third part of duodenum is extrinsically compressed by the superior mesenteric vascular pedicle. SMA syndrome is usually precipitated by rapid and substantial weight loss, leading to a loss of retroperitoneal fat. In burned patients, weight loss through malnutrition, loss of abdominal wall muscles, and a recombinant position contribute to the severity of the duodenal compression. With aggressive immediate early enteral feeding, SMA syndrome is now rarely encountered in acute burn patients. Bilious emesis and intolerance to tube or oral feedings are common at presentation. The diagnosis is established by an upper gastrointestinal series demonstrating a dilated stomach and proximal duodenum with extrinsic compression of the third portion of the duodenum. Management of SMA syndrome is primarily medical, by enhancing caloric intake by utilizing a nasojejunal enteral feeding or parenteral nutrition. Surgical procedures are rarely indicated, but when they are necessary, the operative goal should be bypassing the point of obstruction caused by superior mesenteric vascular pedicle. In a reported series of 37 of 3536 patients treated for SMA syndrome over a 12-year period, 18 patients were successfully managed medically with nasogastric decompression and intravenous nutrition.⁵⁶ Operative intervention (side-to-side duodenojejunostomy) was necessary in 30%, either for failed medical therapy or perforated ulcer. There were 3 postoperative deaths and 8 deaths following medical therapy alone for an overall mortality rate of 27%. A more recent report found that the average burn size for pediatric patients experiencing SMA syndrome was 64% TBSA and weight loss ranged from 10 to 30%.⁵⁷ The decrease in the incidence of SMA syndrome in recent years is attributed to more aggressive enteral nutritional support limiting weight loss to less than 5% of pre-burn weight. In general, enteral feeding, beyond the point of obstruction utilizing a fluoroscopically or endoscopically placed nasojejunal enteral feeding tube, should be administered as initial line of therapy.⁵⁸ Recently, a minimally invasive laparoscopic approach has been used to relieve the duodenal obstruction in patients with SMA syndrome.⁵⁹

Enterocolitis

Splanchnic hypoperfusion occurs as a result of hypovolemia and circulating vasoactive mediators and the degree of intestinal insult is a product of the severity and duration of ischemia along with reperfusion by resuscitative efforts. Complications of intestinal injury span from mucosal barrier breakdown with subsequent bacterial translocation to full-thickness intestinal necrosis with perforation. The pathogenesis of enterocolitis is multifactorial. Ischemia-reperfusion injury to the gut as well as the presence of virulent bacteria and fungi in the immunocompromised state contribute to intestinal complications. Desai et al.²⁸ reported a series of burned patients with both clinically recognized ischemic intestinal complications (incidence 1%) and those identified only at autopsy (incidence 55%) with an overall survival of 30%. Children actually fared better with a survival rate twice that of their adult counterparts. When intestinal ischemic injury occurs, multiple operations are frequently required, with one series reporting up to 41 interventions for 16 patients.^{28,60} These patients also commonly experience systemic sepsis. Nearly 75% of burned patients with bowel ischemia at autopsy had documented sepsis at the time of their death.²⁸ These results show both the high incidence of sepsis and mortality associated with intestinal ischemic complications in burned patients.

Ten of 2114 patients with burn injury have been shown to experience ischemic necrotic bowel disease in one study.⁶¹ The patients with ischemic bowel disease had a higher mean TBSA burn (53%) compared to that of the patients with other GI tract problems (22%). The patients with ischemic bowel disease typically demonstrated dilated bowel loops, intolerance to tube feedings, high gastric residual volumes, and even radiological evidence of pneumatosis intestinalis. Severity of thermal injury, the presence of systemic infection, and altered intestinal flora secondary to systemic antibiotic therapy contributed to increased ischemic intestinal complications.⁶¹ Although the overall incidence of clinically recognized intestinal ischemic complications in thermally injured patients is low (1–3%), early recognition and intervention requires a high index of suspicion. Signs and symptoms may be falsely attributed to the burn wound and lead to a delay in recognizing intra-abdominal pathology. Thermally injured patients who develop sepsis and intolerance of enteral feedings should be treated immediately with bowel rest and broad-spectrum antibiotic coverage. Abdominal radiographs frequently demonstrate massively dilated multiple bowel loops without organized pattern (Figure 38.2). Persistent, relatively fixed dilated bowel loops is an ominous sign for necrotic intestine. Failure to respond to conservative treatment mandates surgical intervention. At operation, frank necrotic intestinal segments should be resected (Figure 38.3); however, indeterminate areas of necrosis, particularly when they involve extensive lengths, should be reexamined at a second-look operation within 24–48 hours. The primary goal of surgical intervention is to eliminate obviously non-viable bowel, while preserving as much intestine as possible to avoid risks of developing short bowel syndrome.

Pseudomembranous colitis is caused by the overgrowth of toxigenic strains of *Clostridium difficile*, which derives its virulence from an alteration of the intestinal bacterial flora.

Fig. 38.2 Diffuse distention of multiple loops of bowel. Relatively-fixed dilated appearance of bowel loops over time suggests progression of intestinal complication to involve an ischemic segment.

Fig. 38.3 Necrosis of distal half of small bowel. This patient underwent resection of necrotic bowel with exteriorization of proximal small bowel as ileostomy, which was later reversed uneventfully.

In a reported series of 112 thermally injured patients, the overall incidence of *C. difficile* colitis was 8% with mean burn size in these patients of 47% TBSA.⁶² Pseudomembranous colitis occurs most commonly as a result of systemic antibiotic therapy, although oral or even topical administration of antibiotics has also been linked to development of pseudomembranous colitis and toxic megacolon. Topical silver sulfadiazine, used commonly in all burned patients, has been shown to cause toxic megacolon, which may then progress to colonic perforation.⁶³ The clinical features of colitis, such as fever and

leukocytosis with abdominal pain, distention, and diarrhea, must be promptly recognized. Major burned patients are at high risk for pseudomembranous colitis since they are frequently treated with multiple antibiotics for documented systemic infections and for prophylaxis during excision and grafting. The presence of heme-positive or grossly bloody stools should immediately alert one to further investigate an overgrowth of *C. difficile* with a toxin assay. Eliminating unnecessary systemic antibiotic therapy is the key to prevention of this disease; however, when it occurs, oral vancomycin or metronidazole is the appropriate treatment. Metronidazole can also be administered intravenously as effective therapy.

Ileus

Sepsis, electrolyte imbalance, narcotics, and renal failure are common causes for generalized ileus in burn patients. In the presence of ileus, management of enteral feeding becomes a delicate issue to avoid intestinal complication. Patients will obviously experience abdominal distention and pain; this can also be further complicated by the overuse of narcotics in an attempt to alleviate pain. In particular, intestinal ileus may represent as an early indicator of systemic sepsis in burn patients and, therefore, the etiology for ileus should be carefully explored. In addition to small intestinal ileus, pseudo-obstruction of the colon (Ogilvie's syndrome) is commonly encountered in burn patients.⁶⁴ Presenting symptoms include abdominal distention with constipation or diarrhea. Diagnosis is established by a plain abdominal radiograph, which typically shows massive colonic distention. Signs and symptoms are usually minimal or attributable to the burns. Optimal therapy should be based on the degree of cecal distention. Distention <10 cm in its greatest diameter is treated conservatively with saline enemas, rectal tube decompression; colonoscopy-assisted decompression is the preferred option for persistently dilated cecum lasting more than 3 days or distention >10 cm. However, a special consideration must be used to appropriately adjust the 'acceptable' size of cecal distention based on patient's size and weight, especially in pediatric patients. An operative intervention is rarely necessary with the creation of a cecostomy or occasionally with resection accompanied by diversion.

Pancreatitis

Acute pancreatitis can occur in burned patients. The pathogenesis is usually idiopathic but may be attributable to ischemia, sepsis, and medications. The diagnosis may be difficult and masked by overwhelming burn injuries. Symptoms of epigastric abdominal pain along with hyperamylasemia confirm the diagnosis. Treatment is similar to pancreatitis in non-burn patients, consisting of supportive care such as bowel rest, fluid resuscitation, and IV nutrition. The exact roles of enteral versus parental nutrition as well as use of antibiotics remain greatly debated. Abdominal ultrasound examination of the biliary tract should be performed to determine presence of gallstone. Occasionally, detailed work-up with abdominal CT scan is necessary to identify complications such as pseudocyst formation, pancreatic necrosis, and pancreatic abscess. Operative intervention is rarely indicated unless infective complications occur.

Feeding tubes

The importance of enteral nutrition in critically ill patients, including burns, has been clearly established. Parenteral nutrition is associated with increased risks for complication such as line sepsis, intestinal atrophy and bacterial overgrowth. However, the excessive caloric intake required in a burned patient, coupled with appetite suppression and/or inability to consume oral intake, necessitates alternative means of delivering calories than the simple oral route. Nasogastric, nasojejunal, gastrostomy, and jejunostomy tubes can all deliver enteral nutrition but each of these options has its own unique advantages and disadvantages. Selecting the inappropriate enteral formula can also cause diarrhea and malabsorption, which complicates wound healing and local wound care, especially in the areas of perineum. An advantage of the nasogastric tube is avoidance of potential complications associated with a procedure (i.e. endoscopic or open abdominal approach). Nasogastric feeding tubes are soft, thin, and pliable, and they avoid the gastric, pulmonary, and nasal complications of large decompression nasogastric tubes. However, these tubes are difficult to maintain, and can inadvertently be displaced or migrate into the pulmonary tree, resulting in potentially serious complications of aspiration. A nasoduodenal or nasojejunal feeding tube placed under fluoroscopic guidance with its tip well beyond the pylorus has become a standard practice for many burn centers. This method is especially useful in major burn patients, who frequently experience gastric ileus during immediate postburn period. Immediate enteral feedings are initiated at the same time the gastric decompression is accomplished with the nasogastric tube. However, these feeding tubes require careful titration of formula volume to avoid abdominal distention, diarrhea or discomfort.

A surgically placed gastrostomy tube can be maintained for long periods and requires minimal experience to manage,⁶⁵ however, the surgical site care may be complicated by the presence of burn wound. In addition to high risk for burned wound breakdown at the gastrostomy, a lack of subcutaneous tissue makes them more susceptible to complications such as gastric prolapse (Figure 38.4). Although alternate techniques

Fig. 38.4 Gastric prolapse at gastrostomy site. Gastrostomy through the area of full thickness burns is at high risk for gastric prolapse.

of placement such as percutaneous endoscopic⁶⁶ and laparoscopic assisted⁶⁷ methods are now available to minimize the morbidity associated with surgically placed gastrostomy, it still requires diligent care to avoid complications related to the gastrostomy tube itself. In general, laparoscopy-assisted feeding tube placement has become a standard approach for pediatric patients. However, relatively non-compliant abdominal wall due to full-thickness burns in the torso area can create difficulty achieving adequate insufflation of the abdominal cavity. Further, a gastrostomy tube is not an adequate method for effective gastric decompression. Although jejunostomy feeding can eliminate a risk of gastroesophageal reflux associated with gastric tube feedings, it also carries the disadvantage of requiring an operative procedure. The pathophysiology of diarrhea in tube-fed burn patients has been extensively examined. In one study, tube feeding osmolality, anti-stress ulcer medication or hypoalbumenia did not have an adverse effect on intestinal absorption. A low-fat (<20% of caloric intake), vitamin A-enriched (>10 000 IU/day), early enteral support program maximizes conditions to promote tube feeding tolerance.⁶⁸ Increased incidence of diarrhea occurred in older patients, >40% TBSA burns, patients receiving antibiotic treatment, or late initiation of tube feedings (>48 hours post-burn). Given these findings, enteral feeding should be initiated early after burn injury, specifically formulated to avoid diarrhea. Even in pediatric patients who required laparotomy for abdominal compartment syndrome, surgical intervention did not preclude the safe postoperative delivery and advancement of enteral feedings.⁶⁹

Others

Massively burned patients generally require prolonged hospital stay; therefore, they are also susceptible to common GI tract pathology such as appendicitis. The limited ability to discern history and abdominal exam findings may create some difficulty for prompt diagnosis. Imaging modalities such as ultrasound and CT scan are readily used to ensure accuracy of diagnosis. Although laparoscopic appendectomy has become a standard approach, restrictive abdominal cavity to gas insufflation in burns patients with major burns to the trunk area prohibits minimally invasive approach. In pediatric burn patients, bleeding per rectum, especially in toddlers 1–3 years of age, should alert the possibility of ileocolic intussusception. Ultrasound exam can frequently identify this condition; however, non-operative enema reduction may be more difficult to attempt for this group of patients. At operation, intussusception is manually reduced, appendectomy is performed, and the viability of involved bowel segment thoroughly assessed (Figure 38.5). A critical nature of prompt diagnosis to prevent necrosis or perforation was also emphasized in a recent case report of an 18-month-old infant with intussusception.⁷⁰

Vascular access complications

Adequate venous access is imperative to administer aggressive fluid resuscitation during the critical acute postburn period. Although peripheral venous access with large-bore catheters is the preferred route for resuscitating trauma patients, the placement of peripheral venous lines can be extremely difficult

Fig. 38.5 Ileo-ileal intussusception in a burn patient. Persistent intolerance of enteral feedings with high gastric residuals along with 'current' jelly-like stool was noted in a 19-month-old infant. (a) Ileo-ileal intussusception at mid-ileum. (b) Manual reduction revealed necrotic ileal segment requiring resection with primary anastomosis.

in major burns involving the extremities. Therefore, central venous lines have become the standard practice in major burn patients to provide secure vascular access for administration of fluid and blood products as well as perioperative monitoring of intravascular volume status. However, central venous line placement is associated with potentially serious complications. A particular attention should be given to the use of various available cannulation sites depending on the size of the patient, as well as taking into consideration clinical conditions of burn wounds. Arterial monitoring is frequently necessary in critically ill burn patients. At Shriners Hospital for Children at Galveston, femoral arterial catheterization has become routine for hemodynamic monitoring in major burn patients. The potential risks for complications from femoral arterial access

are obviously far greater than for radial and/or pedal arterial catheterization.

Suppurative thrombophlebitis

The incidence of suppurative thrombophlebotic complications in burn patients has been estimated to range from 0.4% to 7% with significant risk in patients with >20% TBSA burns.⁷¹⁻⁷⁴ A review of 2103 patients over 10-year period showed that 25 patients (1.2%), with a mean age of 40 years and 49% TBSA burns, were found to have significant pulmonary thromboembolism.⁷¹ An increasing experience with catheter-related septic central venous thrombosis has been reported. Not all of these infections occur in association with venous thrombosis, and specific risk factors for developing suppurative thrombophlebitis include both burn injury and prolonged intravenous catheterization. Factors such as prolonged catheterization (>72 hours), concentrated IV solutions, venous cut-down, lower extremity catheters, emergency IV access have all been associated with increased risk for septic thrombophlebitis.⁷⁵ The presentation of suppurative thrombophlebitis is often occult with approximately 20% of patients showing no local clinical signs.⁷⁵ In burned patients, occult suppurative thrombophlebitis is most frequent; only 36% of patients was reported to exhibit local signs in one study.⁷³ Burned patients frequently display a positive blood culture and clinical sepsis without obvious source. Thorough examination of all catheter sites must be performed to identify catheter-related sepsis. The absence of pus at the site or within the vein does not necessarily rule out suppurative thrombophlebitis.⁷⁵ Proper exploration of an infected vein requires surgical cut-down and expression of vein contents. If pus or clot is found, the vein segment should be excised to a normal-appearing vein (usually at the first uninvolved tributary). If exploration is negative at one site, then sequential exploration of other sites is necessary until the source of infection is identified. Aside from surgical excision, systemic IV antibiotics must be administered. The most commonly found organisms in infected veins in burned patients reflect those cultured from a burn wound.⁷³ In non-burned patients, *Staphylococcus*, *Klebsiella*, and *Candida* are found in descending order of frequency.⁷⁵ Catheter-related septic central venous thrombosis has increasingly been recognized in the burn population as it parallels the increased use of central venous catheters in these patients. Typically, patients with septic central venous thrombosis demonstrate positive catheter tip culture, blood culture, and ongoing bacteremia after catheter removal. The majority of patients also show local evidence of disease manifested by ipsilateral upper extremity swelling.⁷⁶ Catheter-related thrombosis can be managed by removal of catheter alone; however, if significant obstruction of flow is present, full systemic heparinization may be required. Surgical intervention is rarely required. In order to minimize the incidence of these catheter-related complications of thrombosis or infection, the current standard practice for central venous access at Shriners Hospital for Children at Galveston consists of meticulous aseptic care at the catheter insertion site along with regularly scheduled catheter site change. Central venous catheters are changed over a guidewire placed through an existing catheter every 3 days and a new central venous cannula on a fresh site is placed every 6 days.

Thoracic complications

With frequent use of central venous access in major burn patients, the risk for potential thoracic complications associated with placement of central venous lines must be recognized. Although the overall incidence is quite small (1–4%), any thoracic complications can potentially lead to life-threatening conditions. Pneumothorax is caused by lung parenchyma injury during venipuncture of central veins, and can be treated with observation or small chest tube placement. However, if unrecognized, especially in patients receiving positive ventilatory pressure support, it can rapidly progress to tension pneumothorax with hemodynamic compromise. In order to reduce the risk of puncturing the lung parenchyma during attempted central venous line placement, it is crucial to be familiar with the central venous anatomy in the neck and chest areas. Especially in small pediatric patients, percutaneous access to subclavian veins may require a more acute cephalad angle of approach under the clavicle due to its venous anatomical differences when compared to adults.^{77,78} Proper shoulder roll should be placed to maximally enhance the space between the first rib and the clavicle for easier access to subclavian veins. A patient should be adequately sedated and given sufficient pain medication to avoid any movement during the procedure.

Bleeding related to placement of central venous catheters varies in location and can be local, mediastinal, intrathoracic, or pericardial. Local hemorrhage occurs typically in patients with a coagulopathy but should be controlled with local pressure. Hemorrhage into the thoracic space can occur at the time of catheter insertion or after the catheter has been in place, from erosion through the vein wall. Blood may accumulate into the mediastinum, pleural space or pericardium. The most common situation leading to venous wall perforation occurs during an insertion of a percutaneous introducer sheath over a guide wire. As the sheath is introduced, it can fail to negotiate a path of a vein and traumatize the vein wall. If the injury is small, it can resolve on its own with thrombosis formation; however, in cases of larger venous tear, rapid bleeding into thoracic cavity can occur and emergent thoracotomy may be necessary. In order to reduce the risk of bleeding complication, many burn centers rely on guidance of fluoroscopy and/or ultrasound during the insertion of central venous lines. Pericardial tamponade can also occur with high mortality. Bleeding or infusion of fluid into pericardial space can rapidly compromise the cardiac function and results in hemodynamic collapse. Patients typically manifest hypotension, muffled heart sounds, and distended neck veins (Beck's triad). However, the classic triad of symptoms is rarely all present and a physi-

cian must have a high index of suspicion in order to recognize this condition early. Echocardiograms can confirm the clinical suspicion and pericardiocentesis or pericardial window can return the cardiac function to baseline.

Distal limb ischemia

Arterial monitoring is frequently required in patients with major burns, especially during the perioperative period. Although radial and pedal arterial cannulas are routinely placed without significant complications, they can be associated with problems such as hematoma and pain. Occasionally, a larger and more proximal femoral artery is considered for access, but this site should only be used with extreme caution due to potentially serious complications that can occur. Especially in pediatric burn patients, the femoral artery can be very small and a catheter within the vessel can result in near complete occlusion of blood flow to distal aspect of the limb. If this occurs, the catheter should be immediately removed and a Doppler flow study should be obtained to assess for the presence of intimal flap. Recently, magnetic resonance arteriography has been utilized as a diagnostic tool with excellent yield. Conservative treatment, with optimizing hemodynamics and occasional systemic heparinization, are usually adequate to restore blood flow. Surgical intervention is rarely necessary and can potentially result in further compromise of the integrity of arterial blood flow. Most importantly, arterial cannulas should be removed as soon as its potential benefit of invasive monitoring is no longer present for the care of major burn patients.

Summary

Surgical problems secondary to burn injury can cause devastating physiological responses. Physicians must have a high index of suspicion to identify any associated nonthermal injuries when evaluating patients with major burn injury. When presented with patients with multiple organ injuries, the protocols for ATLS should be followed, ensuring the airway, breathing, and circulation. Injuries to other organ system should be handled in a systemic fashion with involvement of appropriate consultant surgeons. A multitude of gastrointestinal complications can occur during the course of prolonged hospitalization for major burn patients. Ulcers and other complications must be prevented when possible and detected and treated when present. Finally, medical professionals must be constantly on the alert for problems related to intravenous catheters and tube feedings, as related infections and complications can be fatal.

Electrical burns

Introduction

Electricity is now an indispensable part of civilization, invisible and often taken for granted. Unfortunately, electrical burns are the most devastating of all thermal injuries on a size for size basis, usually involving both the skin and deeper tissues. They primarily affect young, working males, often have legal involvement and are the most frequent cause of amputations on the Burn Service. In addition to power company linemen and electricians, construction workers, laborers and crane operators are at special risk.¹

Electrical burns have multiple acute and chronic manifestations not seen with other types of thermal injury. Morbidity, length of hospital stay and number of operations are much higher than expected, based on burn size alone.

Pathophysiology

Electrical burn severity is determined by voltage, current (amperage), type of current (alternating or direct), path of current flow, duration of contact, resistance at the point of contact and individual susceptibility. Electrical burns are classified as low-voltage (<1000 volts) and high-voltage injuries (1000 volts and higher). Low voltage burns are generally localized to the area immediately surrounding the injury while at high voltage, the cutaneous burn is associated with deep, underlying tissue damage very closely resembling a crush injury.² Nearly all burns occurring indoors, except in specialized industrial settings, are of the low-voltage type. While the victim or witness(es) often knows the voltage involved, the amount of current is unknown, with current flow related to voltage by Ohm's Law:

$$\text{Current (I)} = \text{Voltage (E)} / \text{Resistance (R)}$$

Animal experiments have demonstrated that resistance varies continuously with time, initially dropping slowly, then much

more rapidly until arcing occurs at the contact sites. Resistance then rises to infinity and current flow ceases.³ Temperature measurements, taken simultaneously, showed that rate of temperature rise parallels changes in amperage. Tissue temperature was the critical factor in the magnitude of tissue damage. Interestingly, there was no increase in temperature distal to the contact points.

In North America, more than 90% of all electrical burns are caused by 60 cycle-per-second commercial alternating current, which reverses its polarity 120 times per second. Only an occasional low- or high-frequency industrial injury is encountered. With one half of the time spent positive with respect to ground and one half spent negative, the verbiage 'entrance' and 'exit' wounds are archaic, as one does not know whether a given point on the body contacted the wire or the ground. These terms should be replaced by 'contact points.' A descriptive term such as blow-out type injury describes concentration of current and not its causation (Figure 39.1).

The path of current makes a significant difference in pre-hospital fatalities, but in patients reaching the hospital alive, current path determinations are often less than precise and meaningful. The patient may have no, one, or many visible contact points and an untold number of invisible contacts. An example of this is the surgical electrocautery where the large grounding pad contact site is not visible (hopefully). Despite some misconceptions, the term 'electrocution' does not apply to these living patients, as electrocution is defined as 'to kill by electric shock.'⁴

Alternating current causes tetanic muscle contractions, which may either throw victims away from the contact or draw them into continued contact with the electrical source creating the potential for continually increasing severity. Altered levels of consciousness, reported in about one half of high voltage victims, also contribute to prolonged periods of contact.⁵ Resistance at the point of contact varies from very low values for sweat-soaked hands or skin in the summer to more than 100000 ohms for heavily calloused hands or feet during very dry winter weather. Individual susceptibility is a non-quantifiable term to explain why two or more individuals exposed to the same situation have extremely varied injuries.

The burn injury has the potential to cause three different components: the true electrical injury caused by current flow, an arc injury resulting from the electrical arc generated as the current passes from the source to an object, and a flame injury caused by ignition of clothing and/or surroundings. Electricity arcs at temperatures of up to 4000°C create a flash-type injury,⁶ most often seen in electricians working with metal objects in

Fig. 39.1 High-voltage contact point with a blow-out type injury of the chest wall.

close proximity to an electrical source. These injuries, when occurring without actual current flow through the victim, are treated and classified in the same manner as any flash burn.

The exact mechanism of electrical injury continues to be the subject of much research, very often appearing clinically to be a multifactorial combination of both thermal and non-thermal causes. Electricity flowing through tissue generates heat, much as it does flowing through the wire of a toaster, with Joule's law defining the amount of power (heat) delivered to an object:

$$\text{Power (J-Joule)} = I^2 (\text{Current}) \times R (\text{Resistance})$$

Tissue resistance (from lowest to highest) is nerve, blood vessels, muscle, skin, tendon, fat, and bone. Theoretically, current flow would be distributed in proportion to resistance, with tissues having the highest resistance generating the most heat. However, in the animal model, the body acts as a single uniform resistance rather than a collection of different resistances; i.e. it behaves as a volume conductor.³ Deep tissues appear to retain heat so that the peri-osseous tissues, especially between two bones (i.e. tibia–fibula, radius–ulna) often sustain a more severe injury than superficial tissue. The associated macro- and microscopic vascular injury appears to occur nearly immediately and is not reversible.⁷

Direct and indirect electrical destruction of cells also play a role in tissue injury. This appears to be especially important for nervous system cells as their injury is not well explained by heating alone. Cells maintaining their integrity with a sodium-potassium-ATPase pump operating at -90 millivolts direct current, certainly have the potential for disruption with high voltage alternating current. Breakdown of cell membranes is one of the mechanisms by which cell damage can occur.⁸ This process of electroporation of cellular membranes may explain the injury not apparently caused by heat.⁹

Acute care

Severity of injury is inversely proportional to the cross-sectional area of tissue able to carry current. Thus the most severe

Fig. 39.2 Characteristic contracted arm and hand following high-voltage contact to the hand with extensive myonecrosis to the entire forearm.

injuries are seen at the wrists and ankles, with decreasing severity proximally. In hand-foot current flow, 30% of the resistance is in the ankle and 25% in the wrist.¹⁰ The extremities are the most frequently injured body parts, with severe injury often occurring in the arm and hand (Figure 39.2) As current follows the path of least resistance, it may generate small deep arc injuries in the axilla, groin, popliteal and ante-cubital fossae as seen here.

Electrocardiographic monitoring

While ventricular fibrillation is the most common cause of death at the scene of injury, virtually any cardiac arrhythmia can be precipitated by an electrical injury. Arrhythmias are treated using the same indications and modalities as for medical causes. In the authors' experience, new-onset atrial fibrillation has been the most common arrhythmia seen in patients reaching the hospital alive. All have responded to appropriate medical management.

Direct myocardial injury may also result. This injury behaves more like a traumatic myocardial contusion than a true myocardial infarction, not having the hemodynamic or recurrence consequences of atherosclerotic myocardial infarctions. Housinger et al. have shown that creatine kinase (CK) and MB-creatine kinase (MB-CK) levels are poor indicators of myocardial injury in the absence of ECG finding of myocardial damage, especially in the presence of significant skeletal muscle injury.^{11–13} Myocardial damage and arrhythmias are manifested very soon after injury.¹⁴ All patients should be monitored during transport and in the emergency room. Rather than a policy of more prolonged cardiac monitoring for all patients, a selective policy makes most efficient use of expensive medical resources, without patient risk.^{1,14}

Indications for cardiac monitoring

- Documented cardiac arrest
- Cardiac arrhythmia on transport or in ER
- Abnormal EKG in ER (other than sinus brady- or tachycardia)
- Burn size or patient age would require monitoring.

Myoglobinuria

The presence of pigmented (darker than light pink) urine in a patient with an electrical burn indicates significant muscle damage. Myoglobin and hemoglobin pigments present risk of acute renal failure and must be cleared promptly. While low levels are of little clinical concern, grossly visible urinary pigmentation requires rapid response to minimize tubular obstruction (Figure 39.3). The urine dipstick is too sensitive for both pigment and hematuria to serve as a guide for treatment. Evaluation of the serum to differentiate myoglobin from hemoglobin depends on the fact that the smaller myoglobin complex is cleared by the kidney at a threshold below visibility, while hemoglobin as a polymer bound to albumin, has a much higher renal threshold. Differentiating between the two is of little clinical significance, however, as both require prompt clearance and must be treated. Urine with a color darker than light pink is promptly treated with two ampules of mannitol (25 g) given IV push, followed immediately by two ampules of sodium bicarbonate, also given IV push. Ringer's lactate is administered at a rate sufficient to grossly clear the urine of pigment. The rationale of this protocol is to create a rapid, osmotic diuresis with initial alkalization to minimize pigment precipitation in the renal tubules. If adequate organ

perfusion is maintained, repeat administration of mannitol and bicarbonate is not required. Loop diuretics are not as efficient as mannitol. The required urinary output is generally very high for several hours following injury, followed by significant reduction in urine requirements, as venous return from the injured part to the central circulation is thrombosed. Using this protocol, the authors have had a zero incidence of acute renal failure in 187 consecutive patients with grossly visible urinary pigment.

Resuscitation

The hidden injury associated with an electrical burn makes the use of burn resuscitation formulas based on body surface area burned inaccurate, except to establish a minimum volume required. In the absence of gross myo/hemoglobinuria, the goal of resuscitation is to maintain normal vital signs and a urine output of 30–50 mL/h with Ringer's lactate whose rate is adjusted on an hourly basis to achieve those goals.

Traumatic injuries

Approximately 15% of electrical burn victims sustain traumatic injuries in addition to their burn, a rate nearly double that of other burn patients. Most of these injuries are caused

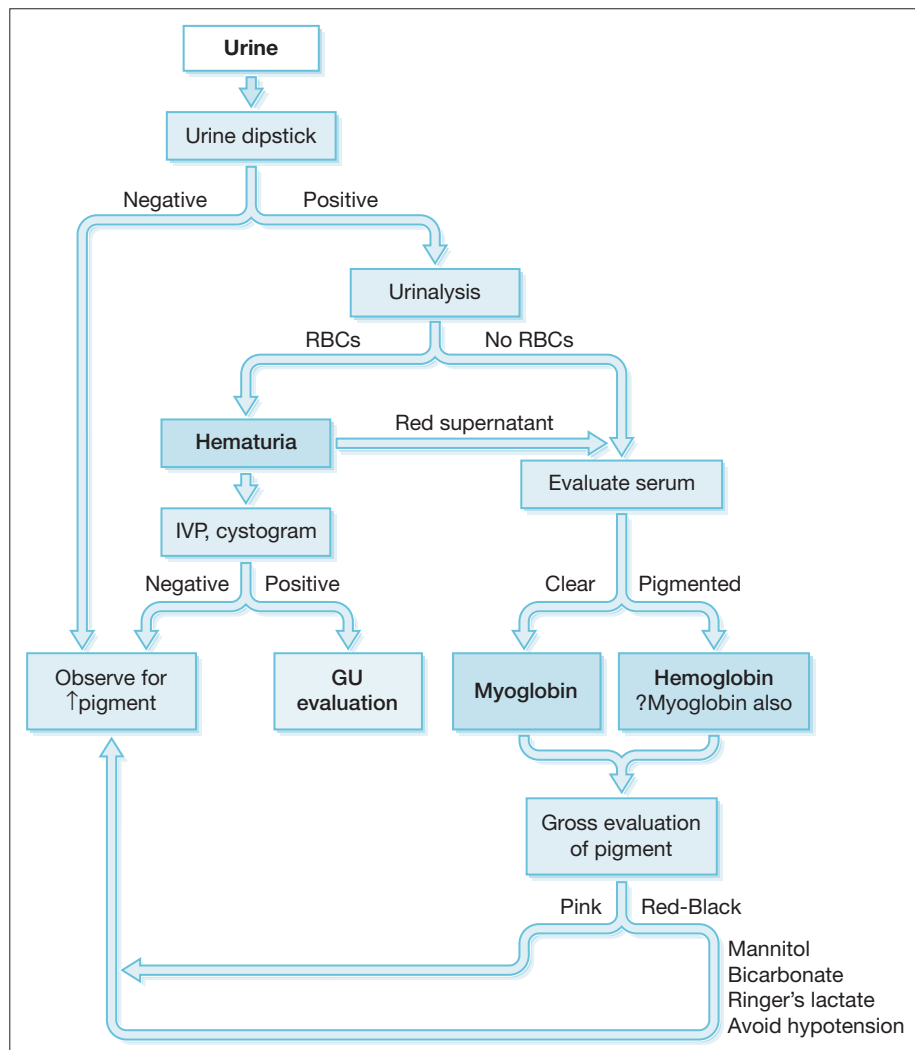

Fig. 39.3 Work-up and treatment of pigmented urine.

by falls from a height or being thrown against an object, with some resulting from the tetanic muscle contractions associated with the electrical shock itself; forces strong enough to cause compression fractures.¹⁵ A careful history and physical examination should select those patients who require a full trauma evaluation.

Compartment syndrome

Patients with high-voltage electrical injuries of the extremities are at risk for development of compartment syndromes during the first 48 hours post injury. Damaged muscle, swelling within the investing fascia of the extremity, may increase pressures to the point where muscle blood flow is compromised. Loss of pulses is one of the last signs of a compartment syndrome, unlike the early loss of pulses occurring in a circumferentially burned extremity requiring an escharotomy. A high index of suspicion is paramount for the early diagnosis (either by serial examinations of the affected extremities or repeated measurements of compartment pressures) and prompt treatment of these increased compartment pressures. While a very aggressive approach to fasciotomies has been advocated in the past, significant morbidity attends a fasciotomy and its closure. Mann et al. has made a convincing argument for a conservative course regarding the indications for fasciotomies, that is for the usual clinical signs of compartment syndrome, progressive nerve dysfunction or failure of resuscitation with other patients undergoing exploration and aggressive debridement on the third to fifth postburn day.¹⁶ Elevated CK levels have been correlated to the extent of muscle damage, with the authors advocating early decompression and aggressive surgical managements in patients with strongly elevated CK levels.¹⁷

Four compartment fasciotomies of the lower leg and anterior/posterior fasciotomies¹⁸ of the upper extremity are performed in the operating room under general anesthesia. Rarely, medial and lateral fasciotomies of the thigh and upper arm are required to completely release all damaged areas. Incisions can be made with either a knife or electrocautery, with care taken to assure complete release of all affected muscle groups. Coverage of the ensuing wound is with a biologic dressing such as porcine heterograft¹⁹ and the extremity is kept elevated to hasten resolution of edema. At this initial operation, we place a silk suture in the muscle at the proximal limit of gross necrosis in order to determine progression of visible damage. While a great deal of discussion concerns the progressive nature of electrical burns, ultimate division of the muscle is seldom more than 1 cm proximal to that seen at a careful initial evaluation. The initial operation is followed by a second look operation in 24–48 hours with debridement/amputation and the earliest possible closure. Fasciotomy wound closure is facilitated by use of traction on the affected skin edges by carefully placed sutures, vessel loop tensioning²⁰ or commercially available tensioning devices. Skin grafting is minimized if fasciotomy closure is appropriately planned. In order to minimize operating time and blood loss at the initial operation primary amputations are not generally performed, except to remove mummified, contracted extremities.

Wound care

Local burn care is performed using mafenide acetate (Sulfamylon[®]) on the thick eschar of the contact points, because of

its excellent penetration. Silver sulfadiazine is used for microbial control on the deep flash/flame components and a biologic dressing used on more superficial areas. Surgical excision is begun 2–3 days postburn either as a second look operation following fasciotomy or as the first procedure in patients not requiring fasciotomies. All obviously necrotic tissue is removed, while tissues of questionable viability are retained and re-evaluated every 2–3 days until wound closure can be achieved. A very conservative course of tissue removal and wound closure with a combination of skin grafts and/or flaps for soft tissue coverage gives the best functional results. An ongoing program of physical therapy and functional splinting is begun the day of admission and continued throughout the hospital stay. Serial neuromuscular examinations are performed to document neurological status. Regional anesthesia is best avoided to minimize medicolegal complications should late neurological dysfunction arise.

Diagnosis

Multiple diagnostic modalities have been investigated attempting to speed up the process of identifying the extent of deep tissue necrosis. Radionuclide scanning with xenon-133²¹ and technetium pyrophosphate^{22,23} have been shown to be accurate predictors of tissue damage. Hammond showed that scanning did not decrease hospital stay or number of operations required.²³ Magnetic resonance imaging provides poor sensitivity for evaluation of muscle damage in non-perfused areas. Gadolinium-enhanced MR imaging demonstrates potential viability in zones of tissue edema and good correlation with histopathology.^{24–26} While very sensitive and specific, diagnostic scans often add little to direct clinical evaluation and create logistical problems of their own. For all practical purposes, the use of the above cited techniques are expensive and unnecessary.

Problem areas

Contact points on the scalp, chest, and abdomen provide additional specific management problems. The scalp must be carefully searched for these lesions as scalp burns are rarely painful and are easily missed on cursory physical examinations (Figure 39.4). Scalp burns which spare the galea are managed by excision and skin grafting directly onto the galea, while wounds that penetrate to the outer table of the skull or deeper require a different approach. Exposure of non-viable calvaria has historically been approached by providing a viable wound bed after removing the dead bone with an osteotome or a dental-type burr. Drilling multiple holes in a close set pattern, deep enough to cause bleeding from viable cancellous bone is another method to develop granulation tissue which eventually covers the entire area. The latter method is still useful in situations where a patient's advanced age or large burn size precludes more aggressive approaches to wound closure. All of the above methods require weeks to months of wound care before the wound is ready for autograft coverage. The best and most expedient approach to these deep skull burns is a rotation scalp flap(s) over the burned area. Split-thickness skin grafts cover the resulting adjacent defect. This provides rapid closure and is associated with minimal morbidity (Figure 39.5).²⁷ Skin expansion of the hair-bearing area can be performed 12–18 months later to obliterate the areas of alopecia.

Fig. 39.4 Contact point on scalp with deep necrosis through galea. Patient had no complaints of pain.

Fig. 39.5 Rotation scalp flap to cover deep necrotic contact point.

Larger scalp defects are closed with free flaps anastomosed to appropriate vessels lying outside the zone of injury.

In addition to the myocardial effects of electricity enumerated above, thoracic injury to the deep structures including the phrenic nerve and direct thermal injury to the heart may occur. Chest wall injuries present special closure problems (adjacent or remote soft tissue flaps) for coverage of exposed bone and cartilage. Costal chondritis is the most frequent complication of deep chest wall burns, becoming a source of long-term morbidity, requiring multiple debridements.

Abdominal wounds provide the potential for internal injuries both directly under contact points and remotely as the result of late ischemic necrosis.^{28,29} Patients must be frequently evaluated for changes in their abdominal examination and/or feeding tolerance. Deterioration mandates laparotomy. Repair of large abdominal wall wounds requires careful planning and often a multidisciplinary team for optimal results.

Lightning injury

Approximately 100 000 thunderstorms occur in the USA each year with lightning killing more people than any other weather phenomena, causing about 80 fatalities per year with Florida and Texas having the most deaths.^{30–32} While lightning strikes involve millions of volts of electricity, the spectrum of burn injury is extremely varied, from minimal cutaneous burn to significant burns equal in depth to commercial high voltage electricity. Major cutaneous injury is rare unless a nearby object is turned incandescent, causing a flash/flame-type injury, as when a bag of golf clubs on the victim's back is struck. The pathognomonic cutaneous sign of a lightning strike is a dendritic, arborescent or fern-like branching erythematous pattern on the skin (Lichtenberg figure) which appears within an hour of injury and fades rapidly, much like a wheal and flare reaction.³³ Full-thickness isolated burns on the tips of the toes has also been reported as being characteristic. Both findings are useful in determining the cause of injury in the patient found down under uncertain circumstances.³⁴

Lightning may cause both respiratory and cardiac standstill for which CPR is especially effective when promptly initiated.³⁵ The ears should be carefully examined as injuries are frequent, ranging from ruptured tympanic membranes (most common) to middle and inner ear destruction.³⁶

Neurological complications are relatively common and include unconsciousness, seizures, paresthesias and paralysis which may develop over several days after injury. The term keraunoparalysis has been used to describe the latter symptom complex and is associated with vasomotor disorders. Fortunately these are usually transient. Surgically treatable lesions including epidural, subdural and intracerebral hematomas may occur, mandating a high index of suspicion for an altered level of consciousness.³¹ The prognosis of many lightning-caused neurological injuries are generally better than for other types of traumatic causes, although subtle neurological changes may persist, suggesting a very conservative, watchful waiting and supportive approach with serial neurological examinations after an initial CT scan to rule out correctable causes. A recent study by Muehlberger et al. with follow-up to 12.3 years after injury showed that none of their 10 patients had long-term neurological or psychological deficits.³⁷ Differences in long-term outcomes may be more related to effectiveness of CPR than the injury itself.

Low-voltage burns

Low-voltage direct current causes both direct injury and thermal injuries most often due to the heating effect of electricity turning a ring, wristwatch, bracelet or necklace incandescent resulting in a deep circumferential thermal burn. These are treated in the same manner as other thermal burns.³⁸ Mechanics and persons working on automobiles are at greatest risk for this injury as automotive electrical systems are the most common source of low-voltage–high-amperage electricity.

Low-voltage alternating current injury is usually localized to the points of contact, although with prolonged contact, tissue damage may extend into deep tissues with little lateral extension as seen in high-voltage wounds. These wounds are treated by excision to viable tissue and appropriate coverage based on wound depth and location.

Burns of the oral cavity are the most common type of serious electrical burn in young children.³⁹ Most of these injuries result from the child chewing on an electrical cord or on the male–female plug interface between two cords. Injuries involving only the oral commissure are initially treated very conservatively as the extent of injury is difficult to predict (Figure 39.6). Simple wound care is performed as an outpatient.^{40,41} The most serious complication is bleeding from the labial artery, occurring 10–14 days after injury. Families are instructed to digitally compress the labial artery if bleeding occurs and return to the ER. Following healing, treatment varies by the severity of injury. Gentle stretching and the use of oral splints give good cosmetic and functional results in most patients, with reconstructive surgery being reserved for the remainder. Severe microstomia is corrected by mucosal advancement flaps. Burns of the mid-portions of mouth heal very poorly and require a much more aggressive surgical approach with carefully planned reconstruction.^{42,43}

Complications

The primary early complications of electrical injury include renal, septic, cardiac, neurological, and ocular manifestations. Renal failure and sepsis are preventable by adequate resuscitation and rapid removal of necrotic tissue, while cardiac damage is recognized and treated on admission. Neurological deficits may be present on admission or develop days to weeks after injury.

Cataract formation is the most frequent ocular complication of electrical injury, although ocular manifestations may affect all portions of the eye.^{44,45} The exact pathophysiology appears to be unknown, but ocular changes may affect as many as 5–20% of patients with true electrical burns. Saffle reported on

Fig. 39.6 Low-voltage contact burn of the mouth, most often involving the commissure.

seven patients with 13 cataracts, noting a high rate of bilaterality and little association with voltage or location of contact points, although often thought of as being more frequently associated with contact points of the head, neck and upper trunk.⁴⁶ Seventy-seven percent eventually progressed to the point where surgical therapy was necessary, the results of which were uniformly good. Lag time before appearance may be as short as 3 weeks and as long as 11 years after injury.⁴⁷

Neurological complications are protean in their diversity and may present either early or late (occurring up to 2 years after injury). Neuromuscular defects including paresis, paralysis, Guillain–Barré syndrome, transverse myelitis or amyotrophic lateral sclerosis can be caused by electrical injury.⁴⁸ A study by Grube puts the incidence into perspective.⁵ Of 64 patients with high-voltage burns, 67% developed immediate central or peripheral neurological symptoms. One third had peripheral neuropathies with one third of those persistent. Twelve percent had delayed onset of peripheral neuropathy with 50% of those resolving. They reported no late onset, central neuropathies. Ko reported on 13 patients with delayed onset of spinal cord injuries postulating on a vascular cause of the deficit.⁴⁹ The most common peripheral defect is a peripheral neuropathy, with weakness being the most commonly found clinical finding.⁵⁰ In general, resolution of early-onset lesions is much better than for late onset, spasticity is more frequent than flaccidity, and function is affected more than sensation. Sympathetic overactivity with changes in bowel habits, urinary and sexual function is the primary autonomic complex complication. Although the exact mechanism of nerve injury has not been explained, both direct injury by electrical current and/or a vascular cause receive the most attention. To date, imaging studies, including angiography and MR imaging, have not been helpful in either predicting or evaluating the extent of deficit. Very often, neuropsychological status is abnormal. In a study comparing electrical burn patients with non-burned electricians, Pliskin showed significantly higher cognitive, physical and emotional complaints not related to injury or litigation status.⁵¹ A full neurological examination must be performed on admission, documenting initial presentation. Consistent long-term follow-up with careful neuromus-

Fig. 39.7 Heterotopic ossification arising at the cut ends of a forearm amputation and requiring excision.

cular examinations becomes an important part of patient care. Electrodiagnostic evaluation may be helpful in delineating the defect. Early involvement of an experienced, interested physiatrist is important in assessing long-term needs and participating in the creation of a therapy plan.

Heterotopic ossification occurring at the cut ends of amputation sites is unique to the electrically burned patient. This occurs in about 80% of patients with long bone amputations, but not in patients with disarticulations or small bone amputa-

tions. Ossification was severe enough to require surgical revision of the bone end in 28% (Figure 39.7).⁵² This is easily accomplished by opening the stump incision and using a bone rongeur to remove the soft heterotopic bone and reclosing the stump.

Although electrical burns are only about 3% of all burn injuries, they consume enormous amounts of resources, requiring a carefully planned team approach for optimal care.

Introduction

Severe cases (of electrical injury) coming for reconstruction present a formidable problem of flexion contracture and loss of many tendons and nerves, new pedicled skin and grafted-in tendons and nerves usually being necessary. One encounters inside the limb the same type of destruction and cicatrix as is found after any severe infection.

Sterling Bunnell, 1948

This chapter will focus on the multitude of surgical and reconstructive problems that result from electrical injury. The spectrum of electrical injuries is complex due to various factors determining manifestation, severity, and distribution of the resulting tissue damage. In common with other types of trauma, especially burn injuries, the consequences of electrical injuries may affect a wide range of physiological functions. Its distinct features warrant a differentiated approach to this unique kind of trauma. The resulting tissue loss and the damage to essential structures of the involved body areas often require extensive plastic-reconstructive procedures.

Although the incidence of low-voltage burns steadily declined over the last decades, most probably due to progress made in the field of home and occupational safety education and equipment, electrical injuries still account for 3–5% of all admissions to major burn centers.^{1,2} Electrical fatalities are relatively uncommon and most of them occur accidentally. Advances in reconstructive operative techniques resulting in higher rates of limb salvage in other causes of trauma so far have not achieved similar results in electrical injuries. Therefore, although earlier reported limb amputation rates of up to 71% decreased over the last decades with the increasing ability to reconstruct anatomic parts and restore function, limb salvage remains a surgical challenge.^{3,4}

Diagnosis and acute treatment

Diagnosis and acute treatment of electrical injury have been described in Chapter 39. However, several important characteristics need to be emphasized.

Assessment of tissue damage

The correct assessment of the extent of tissue damage is difficult. The percentage of burned body surface area grossly underestimates the injury to underlying tissue. Electrical burns may appear as mere pinpoint marks. In contrast, fatal electrocution may even take place without any visible skin burns in case of a large contact area. In a series of 59 patients with high-voltage injuries, the extent of visible burns showed no correlation to any other complications or sequelae.⁵ The actual cutaneous resistance depends on contact size, pressure applied during contact, the magnitude and duration of the current, and the moisture status of the skin (Table 40.1).

In contrast to thermal burns, deposition of metallic iron and copper is found on the epidermis after electrical injuries as electrolysis occurs in the extracellular fluid of the skin. These metal condensations produce a black coating of the skin resembling an eschar.

Clinical determination of tissue viability is based on inspection and the demonstration of muscle contractility. As yet, there are no other diagnostic tools available to accurately assess the extent of tissue damage in the early phase following electrical injuries. The value of magnetic resonance imaging (MRI) for the detection of non-perfused non-edematous muscle is debated.^{6,7} Serial measurement of skin temperature, muscle perfusion scintigraphy, Xe-133 clearance test, and radionuclide arteriography with labeled microspheres show no significant advantages.⁸ Angiography, although not providing information on tissue viability, demonstrates the absence of tissue perfusion, and may lead to an early indication of limb amputation.⁹

Rhabdomyolysis and myoglobinuria

Rhabdomyolysis leads to hyperkalemia, calcium deposition in damaged muscle cells, release of intracellular phosphate and eventually hypocalcemia. Destroyed muscle cells release myoglobin, resulting in myoglobinemia. Hemolysis also often occurs with electrical injury, resulting in concurrent hemoglobinemia. Thus urine measurements of hemochromogens cannot be used as a guide to adequate therapy.^{10,11} Serum levels of creatinine and creatinine phosphokinase (CPK) are used as indicators of rhabdomyolysis. It is important to note that the

TABLE 40.1 DEPENDENCY OF CUTANEOUS RESISTANCE ON SKIN MOISTURE⁶

	Resistance
Dry skin	100 000 Ω
Wet skin	2 500 Ω
Skin immersion	1 500 Ω
Rubber soles	70 000 Ω

Reproduced from Ohashi et al. Burns 1998; 24:362–368.

destruction of 2 g of skeletal muscle can already yield a 10-fold increase of the normal CPK level. After a muscle injury the CPK level will peak by 24 hours and return to baseline within 48–72 hours. This diminishes the diagnostic value of serum and urine chemistry testing.^{11,12}

Renal failure

Myoglobinuria has traditionally been considered a major risk factor for the development of acute renal failure. Recently, patients with electrical injuries have been shown to have a surprisingly low risk for renal failure.¹³ In 162 patients, only 14% had myoglobinuria and none developed renal failure. Suggested criteria to evaluate the risk of acute renal failure after electrical injury include: prehospital cardiac arrest, full-thickness burns, compartment syndrome, and high-voltage injury. Presence of at least two criteria should instigate immediate treatment, as the time-frame to prevent the progression to acute renal failure is limited to a few hours postinjury. Renal complications after low-voltage injuries are rare.

Cardiac monitoring

Among the estimated 1300 deaths that occur annually in the United States from electrical injury (including lightning strike), 30% of the patients present with cardiac complications. The complex mechanisms of cardiac tissue affection by electrical current implicate a wide range of cardiac complications of electrical injury. The majority of ECG abnormalities are sinus tachycardia and non-specific changes in the ST-segment and the T-wave.¹⁴ Death from electric injury most commonly results from current-induced cardiac arrest.

Various degrees of heat generation, direct cellular destruction (electroporation) and effects on excitation–contraction coupling mechanisms such as ion shifting make predictions of the clinical course difficult. Keeping that and the wide range of possible trauma mechanisms in mind (low/high-voltage injury, current flow direction through the body, duration of exposure, pre-existing comorbidities, etc.) it is clear that algorithms for cardiac monitoring of electrically injured patients need to be critically discussed and are best viewed as an orientation for the physician.

However, the current literature review allows the following recommendations: if an initial ECG shows no abnormalities, the delayed development of cardiac problems is very unlikely, irrespective whether the patients sustained high- or low-voltage injuries.^{15–17}

TABLE 40.2 RECOMMENDATION FOR CARDIAC MONITORING IN THE ABSENCE OF OTHER INJURIES

Admission and cardiac monitoring	Discharge
Loss of consciousness ³⁶	Asymptomatic patient ³⁷
Extensive burns ³²	Normal initial ECG ³⁸
Current passing through the thorax ³⁴	Uneventful 4-hour observation ³⁹
Cardiac dysrhythmias ³⁶	Voltage less than 240/260 in adults ^{37,38} Voltage less than 120/240 in children ^{30,39} PP. 1257–1259 (PC65)

Conversely, the presence of dysrhythmias or conduction abnormalities on initial presentation, electrical injury in children, or if the projected path of the current flow crosses the thorax on initial presentation, warrants prolonged cardiac monitoring.^{18–21} Depending on the nature of the current-induced arrhythmia, pharmacotherapeutic and/or invasive interventions may be necessary to prevent life-threatening arrhythmias and re-establish normorhythmia. Table 40.2 outlines recommendations for cardiac monitoring of electrically injured patients based on central clinical findings and specific features of the trauma mechanism.

Apart from specific therapeutic measures of cardiac complications, acute treatment of patients with electrical injuries adheres to guidelines of ABLIS[®], ATLS[®], and current practice of intensive care medicine. This includes the maintenance of a patent airway, effective ventilation, and systemic circulation to provide adequate tissue perfusion and oxygenation. The reduced extent of visible skin burns may lead to underestimation of resuscitation fluid requirements. The patients must be continuously monitored for signs of neurovascular compromise, and deranged tissue perfusion and oxygenation. Pulse oximetry may be useful for this purpose.

Surgical debridement

In the last decades, the concept of progressive tissue necrosis has led to the treatment strategy of early debridement and fasciotomy, followed by serial debridement and delayed wound closure. However, extensive studies have failed to support the notion that electrical injury causes progressive ischemia secondary to electrically induced endothelial damage.^{22–24} In serial arterial angiograms of electrically injured extremities no vascular changes could be found.²⁵ The observed changes may more likely be explained by vascular changes similar to ischemia–reperfusion injury with immediate cessation of capillary blood flow in response to current passage. This event is followed by vascular spasms lasting for extended time, with subsequent vasodilatation and restoration of flow.^{26,27} Although still controversial, these findings may shift the acute treatment paradigm.

While there is little discussion about the early time point of debridement, several recent studies question the need of extensive and total necrectomy and advocate the approach of

delayed soft tissue coverage. ‘Conservative debridement’ consisting of removal of charred and obviously necrotic tissue has been promoted in a study on 40 patients.²⁸ In this study partially damaged tendons, muscles, and nerves were preserved, and wound closure was achieved by immediate flap coverage. Patients treated in this manner with immediate soft tissue coverage had a significantly better outcome compared with a control group who underwent serial debridement procedures. Similar results were found in a study using early free-flap coverage for electrical injuries, suggesting that careful limited initial debridement is an adequate measure.²⁹ According to this study overly extensive and repeated debridement to ensure viability of all remaining tissue appears not only unnecessary but also quite likely harmful. It appears safe to abandon these strategies and to perform an early extensive, but selective debridement in order to preserve continuity of functionally important structures (Figure 40.1). Available options for wound closure encompass the total range of plastic reconstructive procedures, from skin grafts and local flaps to free tissue transfer.³⁰ Limb salvage with functional preservation of vital structures should be attempted and may require revascularization using segmental vein grafts or segmental cable grafting of nerves. Pedicled flaps should be considered in cases of suspected arterial compromise.

Despite the encouraging results of the studies recommending early soft tissue reconstruction by all means it should be noted that for the extent of electrical injury no scoring system has been established so far. Therefore, the comparison of different studies using both aggressive debridement alone or selective debridement and early soft tissue coverage is difficult with respect to the severity of tissue damage treated. Alterna-

tive approaches to salvage upper extremity function such as the temporary ectopic implantation of an undamaged hand have been reported, but cannot be considered standard of care.³¹

The condition of the individual patient and the level of tissue destruction varies considerably and determines the available therapeutic options.

Compartment syndrome

Muscle compartment pressure should be monitored clinically and by invasive pressure measurements. In contrast to blunt trauma, pain is not a reliable indicator of increased compartment pressure due to the high incidence of electrical nerve injury. When compartment pressures exceed 30 mmHg, surgical decompression by open fasciotomy becomes necessary to prevent ischemic muscle injury. In case of lower compartment pressure, progression may be prevented by administration of nonsteroidal anti-inflammatory drugs (NSAIDs) and antioxidants, protective splinting, and rest without elevation of the affected extremities. However, general operative decompression in high-voltage injuries of extremities appears not to be warranted. In a cohort study, Mann et al. found an increased amputation rate of 45% with immediate operative decompression compared with patients undergoing selective fasciotomy, and they recommend fasciotomy only in case of progressive peripheral nerve dysfunction, manifested compartment syndrome, or other major injuries.²² With a fixed neurological deficit, however, surgical decompression shows no influence on outcome.³² If the clinical situation remains doubtful, however, the performance of open fasciotomy with early debridement may be preferred (Figures 40.2 and 40.3).

Fig. 40.1 Electrical burn from a domestic water heater (220V). The 13-year-old girl manipulated the device while being immersed in the bathtub. She sustained third- and fourth-degree burns of the digits (a). Debridement revealed full-thickness injuries involving tendons, nerves, and phalangeal bones (b), which necessitated primary amputation (c).

Fig. 40.2 High-voltage injury from an overhead power line (30 000V). The teenager climbed a train and was struck by an arc without touching the power line. The spectrum of injury included third- and fourth-degree burns and deep tissue necrosis of the forearm (a). After fasciotomy due to impending compartment syndrome (b). Coverage with free latissimus dorsi flap after 'conservative' debridement. Significant functional deficits after 4 years (c).

Reconstructive challenges

When treating a patient with severe electrical injury the plastic reconstructive surgeon encounters many surgical challenges. The anatomic regions most often concerned are the head and the extremities, especially the upper extremities. Bearing that in mind the appropriate reconstruction is of utmost importance for the functional outcome and the resulting quality of life of the injured person.

Head: scalp, skull, and mouth

The head is a common injury site in electric burns. The resulting injury usually appears as a circular area with a central full-thickness damage of the scalp, often reaching through galea, periosteum, and sometimes bone. Exposure and necrosis of bone may consequently lead to osteomyelitis and even an epidural abscess. Treatment strategies depend on the extent of the injury to the bone. In case of only a partial necrosis of the bone the outer table of the skull can be tangentially removed with a high-speed bone drill and the viable diploic cavity exposed. In case of sufficient vascularization the exposed bone can be grafted immediately or, when blood supply is questionable, grafted when suitable granulation tissue has developed.³³ A vacuum sealing system of the wound may be of significant efficiency in growing adequate amounts of granulation tissue. When the initial wound debridement is delayed, necrotic and infected bone might become the source of a full-thickness skull defect. However, with grafting of skin on partially debrided viable bone the lack of a subcutaneous or galea layer often causes long-term problems such as ulceration and scar formation. Full-thickness injury of the skull theoretically requires a complete excision of the necrotic bone to prevent infectious complications. However, this poses the patient at risk for a neurosurgical procedure and requires coverage of the excised area by a rotation flap or even a microvascular graft. Another approach suggested is the partial debridement followed by definitive flap coverage of the exposed bone. This, however, requires early debridement and the prevention of localized bacterial colonization and infection.^{34,35} Fortunately, involvement of the dura occurs rarely. This usually requires an extensive free flap procedure.³⁶ We preferably use the latissimus flap connected to cervical vessels, occasionally using interpositional vein grafts. This reduces the risk of perfusion problems considerably. When these options are not available, the use of acellular human dermis to reconstruct the dural defect followed by split-thickness skin grafting after vascularization may be an option.³⁷

In children, especially in toddlers, common sites of low-tension injury include the mouth and occur usually in the area of the oral commissure, affecting the commissure, the lips, and the tongue. The injury happens when the child bites into a cord or a light switch, or touches the male end of an improperly connected cord. The injury usually results in a localized partial necrosis of the lips and the commissure, the subsequent contracture results in microstomia. The treatment strategies, conservative versus early surgical intervention, are debated. The more aggressive early approach of excision and reconstruction results in faster healing, shorter length of hospital stay, and

Fig. 40.3 High-voltage injury from a power line (50000V). Presentation with primary loss of perfusion, loss of function, and compartment syndrome. Initial operation with fasciotomy, revascularization of the radial artery and necrectomies. On the following days adequate perfusion with a patent radial artery without coexisting veins. Coverage with groin flap on day 6. Venous congestion and subsequent malperfusion was temporarily treated with leeches. Secondary amputation on day 10 due to late occlusion of the radial artery.

fewer surgical procedures.^{38,39} However, in this sensitive age group, early excision and reconstruction may also result in a tightened lower lip, and consequent inhibition of normal mandible growth.^{40,41} The conservative management, which is favored by us, performs the reconstructive procedure after maturation of the burn wound scar. Thus the extent of the damage is more apparent and the reconstruction can be performed electively.⁴² Oral splinting has been advocated during the initial healing period to decrease the need for reconstructive surgery. However, this more likely reduces scar contractures, so the planned reconstructive procedure can be performed after scar maturation.⁴³⁻⁴⁵ The risk of acute hemorrhage by erosion of the oral arteries after sloughing of the

necrotic tissue appears low in our patient population. With adequate caution and education to the patient, this does not prohibit the conservative approach.

Thorax and abdomen

Electrical injury to the trunk commonly is of minor concern. However, high-tension injuries can cause damage to underlying parenchymatous organs such as the lung. Clinically this may lead to atelectasis and edema, requiring aggressive ventilator support. Intra-abdominal injuries are uncommon, but may require treatment like penetrating injury. When exploration during escharectomy and debridement reveals necrotic underlying muscle and fascia, exploratory laparotomy may be

indicated. Potential bowel injury may require segmental bowel resection. Reconstructive options for the closure of chest or abdominal wall defects include direct closure or placement of a synthetic mesh covered by local fasciocutaneous or musculocutaneous flaps. However, the potential negative effects of direct closure on intra-abdominal pressure with subsequent development of an abdominal compartment syndrome or compromise of respiratory function must be considered.

Extremities

Electrical injuries to the extremities, especially to the arms and hand, are more common in adult members of the workforce. The actual effects and the sequelae depend on the current, the path of the current, and the patient's medical condition. Often the electrical source is grasped by the hand, leading to entry wounds at the hands and upper extremities and exit wounds at the lower extremities. As the resistance and thus the local energy production are dependent on the tissue mass and the cross-sectional diameter of the injured body part, high-tension injuries often lead to extensive tissue damage and loss of the involved extremity. Despite aggressive treatment strategies with early debridement and decompression of neurovascular structures, the likelihood of amputation is high.^{22–24,46} Even if amputation can be avoided, the resulting outcome may be a non-functioning extremity. With the phenomenon of kissing lesions, extensive tissue damage may occur with resulting thermal necrosis of muscle, tendon, nerves, and blood vessel. The superficial injury may appear innocuous, but the operative debridement shows deep tissue destruction often mandating limb amputation. The role of initial debridement cannot be overstated as remaining non-viable tissue leads to infection and tissue loss. In our view the early debridement of non-viable tissue prevents this fatal development. Imminent or suspected compartment syndrome should always trigger open fasciotomy to prevent further compromise to the involved extremity. With involvement of the hand and the wrist region in form of an 'arcing phenomenon' release of the Guyon canal and the carpal tunnel, in addition to fasciotomy of the forearm, appears necessary. The reconstruction and coverage at this injury site may require microvascular reconstruction using nerve cable grafts for the median or ulnar nerve and vein grafts for reconstruction of the radial and ulnar artery in combination with coverage by free flaps. However, these options require sufficient soft tissue coverage and absence of any infection. If in doubt, it appears wise to perform a simple skin grafting procedure followed by elective secondary flap coverage and nerve cable grafting. Other regions of selective destruction in the upper extremity are elbow and axilla. The visible amount of tissue damage does not correlate with the destruction found on exploration. The underlying neuro-vascular structures, such as brachial artery, median and ulnar nerve or the brachial plexus in the axilla, are at risk. Debridement often leaves a vast tissue defect, which may be covered by rotation flaps from anterior or posterior chest wall in the axilla. Microvascular free flaps at the level of the elbow are rarely used. For extensive defects on the hand and forearm, pedicled groin flaps provide good coverage providing independent blood supply. The groin flap also

avoids a vascular 'steal phenomenon' as it can be seen after microvascular free flaps in such severely injured extremity.

Despite all surgical options available, when exploration and initial debridement yield vast irreversible destruction of vital structure, the decision for amputation is justified and should be made early.

Amputations

Although distressing to the patient, amputation often remains the only option. The main objective for the surgical procedure is the achievement of a stably covered stump, allowing early fitting and adaptation of prosthetic devices. The optimal level of amputation is determined by the extent of remaining viable tissue and the intention to create sufficient stump length for function and cosmetic appearance of a prosthesis. In electrical injury involving the lower extremity this often requires higher amputation than initially anticipated in order to achieve sufficient stability of the stump and thus allow early prosthetic fitting and ambulation. The local situation often is similar to peripheral vascular disease and the amputation techniques should be appropriately chosen. However, open (guillotine) amputation should be avoided whenever possible. Split-thickness skin grafting onto open stumps is an additional but less preferable approach as breakdown of the skin occurs more often in grafted areas, especially at graft borders or at point where grafts adhere to underlying bone and further surgical interventions will be required. However, if valuable stump length can be maintained by skin grafting it should be attempted since secondary plastic surgical correction and specific prosthetic fitting are available.

In the upper extremity more length should be preserved, as the resulting weight bearing load to the stump is less compared to the lower extremity. This allows for better control of the prosthesis by the patient and thus enhanced functionality. In the forearm the muscle length of the flexor–extensor system should be preserved to improve function. In long forearm stumps atraumatic handling of tendons and muscles is necessary to preserve pronation and supination. Upper arm amputations should be made to preserve as much length as possible as this eases subsequent kineplastic procedures for a functional prosthesis. As in the forearm, muscular length of the flexor–extensor system is maintained by joining them over the bone end. Although it is technically feasible to maintain extremity length by coverage with a free flap this appears only useful in upper extremity amputation where the functional implications warrant such large-scale operation and the load on the stump is reduced.

Despite the availability of sophisticated modern myoelectric prostheses the old techniques of surgical rehabilitation should be kept in mind. This includes the Sauerbruch kinematomyoplasty of the biceps humeri muscle and the Krukenberg plasty of the forearm, which provides sensible chopstick-like stumps. Especially, for upper arm amputations distraction-osteogenesis procedures (Ilizarov technique) provide valuable options to lengthen a short amputation stump.

Peripheral nerve injury

Peripheral nerves are very sensitive to electric alterations, and even minor injury may cause transient dysfunction. Clinical

findings may be anesthesia, paresthesia, or dysesthesia of usually short-term duration. In rare cases minor electrical injury may cause temporary autonomic dysfunction and trigger a complex regional pain syndrome (sympathetic reflex dystrophy). Treatment for reflex sympathetic dystrophy should be initiated early and include elevation of the extremity to reduce edema formation, active exercise, non-steroidal anti-inflammatory drugs, and adequate pain relief. The autonomic dysfunction may be influenced by α -adrenergic antagonists, Ca-channel blockers, and low-dose diazepam medication, or may require intravenous regional blocks and sympathetic ganglion blockade.⁴⁷

Electrical injury of the upper extremity commonly results in peripheral nerve injury of median and ulnar nerve. The clinical findings may resemble upper extremity compression syndromes or peripheral neuropathy.^{48,49} Nerve lesions may be caused by secondary factors such as incorrect positioning and splinting, constricting dressing, or delayed inadequate escharotomy or fasciotomy. Due to the accompanying severe muscle loss and scarring, the extent of pure nerve damage is sometimes difficult to determine.

Direct damage to peripheral nerves occurs following the before-mentioned mechanisms of local heat production depending on cross-sectional resistance or the proximity of peripheral nerves to underlying bone. The local thermal effect affects vascularity and perfusion perineural tissue by producing thrombosis, necrosis or hemorrhage of epineural vessels. Delayed development of fibrosis and therefore a delayed onset of symptoms are not uncommon. Other mechanisms of nerve injury are development of focal axonal degeneration following axonal excitation,⁵⁰ or electroporation, which more likely affects myelinated axons.^{51,52}

Complications

Central nervous system

Approximately 60% of all patients with high-voltage injury present with immediate neurological complications, loss of consciousness being the predominant symptom.⁵³ The involvement of the spinal cord has been described in 2–27% of patients with an entry point of the current located in the head region.^{54–56} The incidence of a delayed paralysis progressing to tetraplegia followed by partial remission has been described.⁵⁷ However, the cause and mechanism of this phenomenon remain unclear.

The neuropsychological effects of electrical injury have been described, mainly in case reports and retrospective studies. Typical consequences and complaints are related to physical, cognitive, and emotional changes.^{58,59} The existing problems could not be directly attributed to physical manifestations of injury, and are similar to problems associated with prolonged stress, sleep deprivation, or after blunt head injury. In a study on 481 professional electricians, 97% reported having experienced an electrical shock at some point in their career.⁶⁰ The low incidence of neuropsychological dysfunction in this study differed from other findings about the nature and progression of a characteristic neuropsychological syndrome

of electrical injury.^{59,61} Although the development of transient and progressive neuropsychiatric complications is possible and undisputed, the actual specific effects of electrical injury are difficult to determine. Other confounding factors such as the posttraumatic stress disorder, the grief reaction to disfigurement or extremity loss, and the disposition of the individual, all influence systematic evaluation.

Cataracts

An increased incidence of cataract formation has been described after electrical injury. The incidence in different reports varies from 1% to 8%.^{62,63} Patients with head and neck wounds appear to be most at risk. However, the path of the current and the location of the entry point were not related to the development of ocular sequelae. Cataracts may also occur without injury to the head and appear even years after injury. Common initial complaints are blurred vision or diminished visual acuity.⁶⁴

Skeletal injury

Besides direct tissue destruction through electrical energy, additional trauma can be indirectly inflicted by electric current. Fractures occur due to secondary falls or with forceful tetanic muscle contractions. These are mostly seen in the shoulder,⁶⁵ wrists,⁶⁶ femurs,⁶⁷ and the spine,⁶⁸ and may require open reduction and internal fixation. Late sequelae of electrical injury similar to severe thermal burns include major joint contractures and limited function of the extremities.

Another common late complication of electrical burns is heterotopic calcification in periarticular tissue of large joints, especially elbows. Causative factors include forced passive mobilization, secondary articular bleeding, and calcium precipitation and deposition in damaged or degenerating muscle and connective tissue. Particularly for electrical injury, heterotopic bone formation also occurs in amputation stumps of long bones. This, as well as the common formation of bone cysts in the amputation stump, may lead to secondary skin erosion, inflammation, and difficult adjustment of prosthesis. In both situations surgical excision and wound closure may provide adequate therapy.⁶⁹

Summary

Electrical injuries result in deceptively large tissue loss, often leading to amputation of involved extremities. After initial resuscitation, early debridement, necessary decompression of neurovascular structures, and early wound closure are essential to successful restoration of function. Extensive surgical procedures including free soft-tissue transfer may be necessary to achieve wound closure, and to save and restore limb function. Sometimes, however, early amputation may provide easier and earlier recovery and reintegration into daily life. Long-term complications such as central nervous sequelae, cataracts, and heterotopic ossification must be considered and addressed early in the rehabilitation process.

Diagnostic methods and management	532
Frostbite care protocol	533

Frostbite is a traumatic injury that is caused by the failure of the normal protective mechanisms against the thermal environment that classically results in localized tissue temperatures falling below freezing, although cold-induced injury can result from non-freezing environmental insults. Cold-induced injury continues to be a relatively frequent injury in the United States due to increasing interest in out-of-door winter recreational activities as well as the high prevalence of homeless and socioeconomically disadvantaged individuals in large urban centers.^{1,2}

One of the earliest cases of frostbite has been found in a pre-Columbian Chilean mummy from about 3000 BC.³ Much knowledge about the incidence and circumstances surrounding this injury has been derived from the extensive military experiences of the past.⁴ Hannibal lost nearly half of his army of 46 000 soldiers during a 2-week crossing of the Pyrenean Alps due to frostbite injury. During the Revolutionary War, it is recorded in 1778 that Washington lost 10% of his army to cold-related casualties during a single winter.⁵

The first modern published report of cold-induced injury did not occur until 1805,⁶ and Baron Larrey produced the first systematic medical observations of frostbite during the Russian campaign of 1812–1813.⁷ As Surgeon General of Napoleon's forces in Russia, Dominique Larrey was able to produce classic descriptions of frostbite and trench foot, and to identify the severe effects of refreezing that occurred with bonfire thawing and subsequent marching in frigid conditions. With this information, Larrey made therapeutic recommendations that were adhered to for more than 150 years of military medicine. This included the use of friction massage with snow or ice rather than rapid thawing over an open fire as he had seen more severe injuries subjected to such freezethaw-freeze conditions. He also noted that the number of cold-induced injuries was much greater during periods of wet, near-freezing conditions as opposed to similar periods when conditions were dry, but below freezing. He described the loss of all but 360 troops

due to cold in a division of 12 000 men. Larrey reported essentially the total loss of one-quarter million troops within a 6-month period due to cold and starvation. Over the past century, military medical experience has only been somewhat better. It is estimated that World Wars I and II and the Korean conflict included one million frostbite injuries. The United States Army reported 90 000 cold injuries during World War II. German troops underwent 15 000 amputations during the winter of 1942,⁸ and Greek troops 25 000 amputations due to frostbite alone during the course of the war.⁹ High-altitude bomber crews suffered from frostbite more than any other injury.¹⁰ Modern military cold-induced injury data continue to accrue.^{11–16} Interestingly, the Vietnam War and other military conflicts fought in tropical climates produced substantial non-freezing cold injuries in soldiers exposed to wet environments in the temperature range of 35–40°F (1.6–4.4°C).^{10,17,18} Although there has been little epidemiological data in the civilian population, significant numbers have accumulated in relatively few series.^{19,20} This significant body of military and emerging civilian data stimulated first basic laboratory investigations, starting with Merryman^{21–23} and, subsequently, clinical research that has taken us from the empiric recommendations of Larrey to the rapid rewarming²⁴ recommendations of Mills^{25,26} and others.²⁷ Such efforts have paved the way to more systematic investigation and eventually to refinement of patient care practices.

Physiology of temperature regulation

In the human, temperature regulation is achieved through a complex interaction of heat production, loss, and conservation mechanisms that require both autonomic and voluntary functions. Normal body temperature ranges from 36.2 to 37.7°C. Any impairment of autonomic or voluntary behavioral functions may result in dysregulation of thermal homeostasis. Control of thermal homeostasis resides in the central nervous system. Core blood cooling will result in hypothalamic–pituitary axis stimulation of catecholamine release, peripheral vasoconstriction, and inhibition of sweating to conserve heat as well as thyroid hormone release with upregulation of oxidative metabolism and shivering for an increase in heat production. Core temperature, which may be measured by rectal thermometer, is generally expected to be 0.5°C higher than surface temperatures, which may be measured orally or tympanically. Peripheral extremity skin temperature is expected to fluctuate much more widely. In a warm environment, temperature of the distal extremities may substantially exceed

core temperature, while the reverse may be true in the heat conservation mode in a cold environment.²⁸ Acral blood flow may vary from 0.5 to 100 mL/min/100 g of tissue.²⁹ When blood flow falls below this range, eventual tissue necrosis may occur. With environmental conditioning the maximal blood flow may exceed 100–122 mL/min/100 g of tissue. Such range in peripheral blood flow response affords the core body temperature substantial thermal homeostasis at a relatively cheap metabolic price, but the cost is at the expense of the extremities. The primary function of this response is to maintain core blood temperature. Sir Thomas Lewis described a vasomotor response in cold environments and termed it the ‘hunting reaction’.^{30–33} In this response, vasoconstriction alternates with vasodilation in 5–10-minute cycles. The cycling is somewhat irregular and results in non-uniform changes in peripheral temperature, but this cycling both conserves core heat and allows extremity viability. The hunting reaction is more pronounced in people indigenous to colder climates. There appears to be maintenance of higher extremity temperature with more rapid cycling and rewarming.³¹ Voluntary behaviors may be important in protection of extremities from cold injury and, as such, mental status impairment can constitute a substantial risk for frostbite in the cold environment.³⁴ Consequently, alcohol and drug intoxication have been roundly implicated among the risk factors for cold-induced injury.^{35–39}

Pathophysiology of cold-induced injury

A number of factors have been associated with the development of frostbite. One well-recognized factor is that of ethanol consumption. Valnicek et al. reviewed their 12-year experience in Saskatchewan with patients admitted for frostbite and identified ethanol use in 46%, psychiatric disorders in 17%, vehicular trauma in 19%, vehicular failure in 15%, and drug abuse in 4% of patients.³⁸ Overt or covert manifestation of psychiatric disease³⁹ as well as neurovascular factors such as smoking and diabetes mellitus, homelessness, fatigue, improper clothing, previous cold weather injury, high altitude, extremes of age, and male gender,^{19,40} have all been cited in cold injury. A number of physical factors appear to play a role in the development of frostbite. The duration and efficiency of tissue cooling understandably have a marked effect on the extent of cold injury. Moist or wet skin is substantially more susceptible to frostbite than dry skin.⁴¹ Efficiency of thermal conduction is important as evidenced by the effectiveness of metal contact as opposed to fabric or wood contact. Windchill is a principle of physiological importance that was demonstrated by Paul Siple who was well-known for his physiological observations with the Antarctic Byrd expeditions.⁴² He developed formulas, taking into account the effects of temperature and wind speed on tissue cooling, that are a basis for the wind chill charts published by the US Air Force. Thus, exposed skin may suffer similar injuries exposed to air at 0°F in calm conditions or to a 15 mile-per-hour breeze at 25°F.²⁶ Although high-altitude conditions have been associated with cold injury, there has been no independent risk factor associated with this environment.⁴¹ The physical state of skin can have an effect on the development of cold injury. Water in the stratum corneum can predispose to water crystallization in the skin and deeper tissue.⁴³ This may explain recommendations of using oil or

ointment on exposed skin at risk for frostbite and the practice of polar explorers to avoid washing during expeditions. The nature of clothing also plays a significant role. Mills²⁵ documented the association of ill-fitting boots and the development of frostbite. Similarly, some authors have touted the relationship of snug-fitting or damp clothing and cold-induced injury, reporting the effect of clothing on circulation or the thermal conduction of moisture compared to dry air by a factor of 25.⁴⁴ Cigarette smoking is cited as a cause of local circulatory compromise. This has been demonstrated with smoking nude models as well as random skin flaps.^{45,46} Chronic smoking does not appear to have an effect on cold-induced injury. Lastly, a history of previous cold injury places the patient at substantial risk for frostbite:^{47,48} not only the incidence of injury but also the extent may be increased with previous exposure.⁴⁴ There is no real evidence of tolerance or indigenous adaptation to the cold environment that is intrinsically protective against frostbite.^{16,49}

The injury associated with frostbite is attributed to two broad mechanistic categories: the first is that of direct cellular damage and death due to the cold insult, and the second is the more delayed process mediated by progressive tissue ischemia.^{50–56} The immediate effects of frostbite are evidenced by formation of extracellular ice crystals. These crystals cause direct injury to the cell membrane, resulting in cellular dehydration due to a change in the osmotic gradient.^{22,57} The rate of cooling is reported to have an effect on the development of extracellular or intracellular ice crystals.⁵⁸ Rapid cooling results in intracellular freezing, which causes more severe cellular damage and cell death, while a slower rate of cooling produces extracellular ice crystals. This slower process, nevertheless, results in transmembrane osmotic shift that drives water from within the cell and produces intracellular dehydration. This dehydration causes changes in protein^{59,60} and lipid conformation, as well as changes in pH and other biochemical processes such as electrolyte concentration that are deleterious to intracellular homeostasis.^{61–64} As temperature continues to fall, intracellular crystals develop regardless of cooling rate^{20,65} with a loss of the linear relationship of temperature to metabolism,^{31,66} decreased DNA synthesis⁶⁷ and the vascular response that has been called the ‘triple response of Lewis’, which is characterized by localized reddening of the wheal and may indicate release of histamine from injured cells.⁶⁸

Microvascular pathophysiology may be even more important in outcome than the direct thermal injury to the cell. This was suggested by studies showing survival of full-thickness skin subjected to freezing and thawing that progressed to necrosis when left *in situ* but survived when transplanted to a normal, uninjured recipient site.⁵⁰ Zacarian identified a number of processes that may play a role in the microcirculatory changes of frostbite. There appears to be a transient vasoconstriction of both arterioles and venules with subsequent resumption of capillary blood flow. Concomitantly there have been microemboli observed.⁶⁵ With thawing, the capillaries demonstrate restoration of blood flow, but this diminished within minutes. Complete cessation of blood flow is often seen within 20 minutes after rewarming of frozen tissue. Such similar changes have been seen with random skin flap models after reperfusion which has suggested reactive oxygen species as mediators of injury.⁶⁹ Within 72 hours there is a significant

de-epithelialization in the capillary bed and deposition of fibrin. Examination of the endothelial ultrastructure has shown swelling, fluid extravasation, vascular endothelial cell dilation and significant projection of the cell into the vascular lumen prior to cell lysis.⁷⁰ There is regional variation in the extent of injury with venules being most profoundly affected,⁷¹ with the hypothesis that, as evidenced by lower flow, stasis must play a role in this pathophysiological process.

Pathobiochemistry of frostbite has been closely compared to the inflammatory response in the burn wound.^{27,72} Inflammatory mediators such as eicosanoids in burns,^{73–76} in burn blister fluid,^{77,78} as well as bradykinin⁷⁹ and histamine⁸⁰ draw parallels with findings in cold-induced injury. This has prompted investigators to hypothesize a model similar to that of Jackson including zones of necrosis and stasis.⁸¹ Similar to their burn blister analysis, Robson and Heggors examined the fluid in frostbite blisters and found high levels of prostaglandin F₂ and thromboxane B₂. These agents or their precursors have been implicated in vasoconstriction and leukocyte adherence.⁷² The inhibition of these eicosanoids has had a salutary effect in animal models.^{82,83} Clinical efficacy has been suggested by the use of thromboxane inhibition.²⁰ It appears that this process is significantly different than the previously proposed mechanism of vasospasm, thrombosis, and fibrin deposition.² Much about this mechanism has yet to be elucidated, including the nature of microemboli that have been observed.⁸⁴

Signs and symptoms of frostbite injury

Most frequently, the patient is basically unaware that frostbite injury is occurring. The association of hypothermia and the use of substances known to alter mental status may contribute to this problem. Typical distribution in 90% of patients is acral, with others suffering injuries to ears, nose, cheeks and penis.^{13,19,38,40} The patient may note insensitivity and clumsiness of the affected part. This complex of symptoms rapidly reverses upon rewarming. Insensitivity is rapidly replaced by severe pain during and immediately after the rewarming process. The pain is often described as throbbing in character, sometimes requiring parenteral opioids for relief. Pain symptoms increase for the first few days and gradually abate during the following 3 weeks. Assessment of injury must be deferred until rewarming of the affected part is complete.

A condition often termed 'frostnip' may be present in which there is not true tissue injury; the condition may be manifested by numbness and pallor of exposed skin. This will often affect skiers and others exposed to cold winds for brief periods of time. Rewarming results in near-complete resolution of symptoms and physical findings, with the possible exception of some hyperemia, edema, and tingling in the region. The non-freezing manifestation of mild cold injury is often termed chilblains, pernio, kibes or cold urticaria. These are often chronic in nature with itching and erythema as more prominent findings. True frostbite, on the other hand, always involves some degree of tissue injury. Classification of severity of cold injury can be helpful in planning medical management. It must be emphasized that clinical appearance will evolve over a period of time after rewarming. Even after rewarming, the initial appearance is often deceptive.^{11,19} Most injuries appear hyper-

emic after rewarming regardless of the degree of involvement. The development of skin blebs is a time-dependent process that often requires many hours to days. Sensation returns during this period, which is often replaced by bothersome tingling and pain. This may develop into severe neuropathic pain that can be aggravated by warm environments and dependent position of the injured member. After 12–24 hours the character of the blebs becomes apparent and an assessment of the degree of involvement may be helpful in planning management of the injury. Traditional classification is similar to that of the burn injury. First-degree injury is superficial without formation of vesicles or blebs. There may initially be an area of pallor with surrounding erythema that evolves into general edema and erythema without long-term sequelae. Second-degree injury has associated light-colored blisters and subsequent peeling. This often correlates with dermal involvement but has a generally favorable prognosis. Third-degree frostbite typically has dark or hemorrhagic blisters that evolve into thick, black eschar over 1–2 weeks. Fourth-degree injury involves bone, tendon or muscle and will result in definite tissue loss. Exactness in depth of injury cannot be expected and some favor more general classification of superficial (first- and second-degree injury) or deep (third- and fourth-degree) frostbite injury. Poor prognostic findings include hemorrhagic blisters and a woody or nondeforming tissue consistency. Preservation of pinprick sensation and light-colored and large blebs predict less risk of tissue loss. Long-term symptoms include hypersensitivity to cold, sensory deficits, chronic pain, and hyperhidrosis.¹ Growth abnormalities and heterotopic calcification have also been described as long-term complications of frostbite.^{33,85}

Diagnostic methods and management

The time-dependent evolution of the clinical manifestations of frostbite and the inability to assess tissue involvement deep to the skin are significant limitations in the prompt management of this injury. A number of imaging methods have been explored in an attempt to decrease the duration of disability and the length of stay in hospitals. Plain radiographs can demonstrate soft-tissue swelling or, as time progresses, tissue loss, bone demineralization or periosteal inflammation. Arteriography has constituted the traditional method for assessment of distal perfusion, but its usefulness is limited by the same factors as clinical assessment in the early phases of injury.² The usefulness of laser Doppler flowmetry in frostbite injury is presently unknown. Radioisotope scintigraphy has emerged as an early diagnostic modality.^{86–89} Magnetic resonance imaging is now being proposed as a method to evaluate even individual vessel status and as a means to identify a line of demarcation earlier in the clinical course.⁹⁰

Only a few general principles of frostbite care are generally accepted. Larrey's methods of rubbing the affected area with snow or with vigorous massage have only recently fallen out of usage in the main medical community. Mills and others at the Arctic Aeromedical Laboratory have documented the results of thawing and refreezing with the resultant worsening of outcome.⁴⁸ Thus it is recommended that partial or slow rewarming during transport should be avoided. Rapid rewarming means warming at the temperature of 40°C with a protocol such as that based upon the work of McCauley et al.²⁷

Frostbite care protocol

- Admit frostbite patient to a specialized treatment unit.
- Transfer of acute frostbite patient should be avoided unless necessary for specialized care with great care to protect patient from further cold exposure.
- Immediate rapid rewarming should be performed at a temperature of 40–42°C for 15–30 minutes or until rewarming is complete.

After complete rewarming:

- White blisters are debrided and topical treatment with *Aloe vera* (Dermaide aloe) q6h is initiated.
- Hemorrhagic blisters are left intact.
- Injured parts are elevated and splinted as required.
- Tetanus prophylaxis is followed.
- Appropriate analgesia is administered.
- Ibuprofen 400 mg PO q12h is administered.
- Antibiotic prophylaxis is administered as appropriate.
- Hydrotherapy or gentle wound care is provided daily.
- Photodocumentation is essential upon admission, at 24 hours, and at every 2–3 days during hospitalization.
- Outpatient care must be tailored to patient situation to maintain adequate wound care and appropriate medical follow-up.

A number of adjunctive therapeutic modalities have been suggested with some experimental rationale, but there is minimal clinical evidence in support of the therapies. Sympathectomy has been examined with mixed results.^{91,92} The series by Taylor is of interest with favorable outcomes in a small number of patients. Although suggestive of more rapid resolution of edema and possibly decreased tissue loss, there is no randomized controlled study to answer this question. As is suggested by basic science investigation, the use of anticoagulation does not appear to have any clinical application in frostbite.⁴⁹

Dextran has been thought to have some theoretical utility because of the appearance of microemboli in this disease process. These have been poorly characterized, but basic

animal experiments have demonstrated some decrease in tissue loss with the administration of dextrans.⁵⁰ Again, this has not been examined in a rigorous fashion clinically.

Vasodilators have been used widely in the past. Intra-arterial reserpine has been used successfully for vasospasm but there are no clinical data to recommend its use for frostbite at the present time. Other efforts to improve tissue oxygenation such as hyperbaric oxygen have likewise been inconclusive and no substantial clinical or laboratory investigation has been produced recently.

In the past decade, the use of thrombolytic agents has been examined in a collected series of patients⁹³ as well as in an animal model.⁹⁴ A multicenter trial will be necessary to measure the effects in a controlled fashion.

Surgical intervention is often required with frostbite injury, but as the adage has been often repeated, 'Frostbite in January, amputate in July',⁹⁵ a conservative approach is needed in the present management scheme. Mills described the need for early escharotomy or fasciotomy in certain individuals, but this is indeed rare.²⁶ He likewise suggested that skin grafting after development of healthy granulation tissue may decrease the amount of postfrostbite pain. Meticulous debridement and gentle but thorough wound care is important in the maintenance of the frostbitten part which is an effort to allow complete demarcation prior to amputation. This is not always possible and surgical intervention may be needed for control of infection as well as wound closure after clinical wound demarcation or as guided by technetium scintigraphy. The need for improved treatment of frostbite has become widespread, with this disease being seen more frequently in the general population over the past few decades. There has been some fascinating progress in the understanding of this injury process, but clinical investigations are presently lacking in most aspects of care for the frostbite injury. Biochemical intervention and improved imaging methods can help to speed the recovery and enhance the ultimate functionality of these patients.

General principles of management	537
Specific agents	538

Introduction

We live in an increasingly dependent world on chemical agents. Our cars are powered by petroleum distillates in the combustion chambers of the engine and chemical reactions in the batteries, our gardens are fertilized by specially enriched products, and our houses are kept clean by powerful agents to dissolve and remove. This makes chemical burns more commonplace in the household, yet industrial applications to provide these chemicals are also expanding. Whenever the news of an armed conflict with a country not armed with nuclear weapons is broadcast, the possibility of chemical weapons is included. The variety of chemical exposures is so vast, that a short chapter cannot describe all of the agents and their treatments, but this chapter can provide general principles for the treatment of chemical injuries (Figures 42.1 and 42.2). The importance of understanding these principles is underscored by the fact that while only 3% of all burns are due to chemical exposures, approximately 30% of burn deaths are due to chemical injuries.¹

Pathophysiology

All burn wounds, whether due to chemical or thermal sources, have in common the denaturation of proteins. The structure of biological proteins involves not only a specific amino acid sequence, but also a three-dimensional structure dependent on weak forces, such as hydrogen bonding or Van der Waals' forces. These three-dimensional structures impart the biological activity on the proteins, and are easily disrupted by outside influences. Heat energy breaks these weak bonds to unfold and denature proteins, just as changes in pH or dissolution of surrounding lipids that may stabilize a protein disrupt its function. Direct chemical effects on a reactive group in a protein will similarly render it ineffective. In addition, chemical agents may act in a systemic fashion as their elements are circulated throughout the victim, with potential metabolic toxicity.

Severity of a chemical burn injury is determined by several factors:

- strength (concentration),
- quantity of burning agent,
- manner and duration of skin contact (progression),
- penetration, and
- mechanism of action.

Broadly classified, there are six mechanisms of action for chemical agents in biological systems:²

- *Reduction*: Reducing agents act by binding free electrons in tissue proteins. Examples include hydrochloric acid, nitric acid, and alkyl mercuric agents.
- *Oxidation*: Oxidizing agents are oxidized on contact with tissue proteins. The byproducts are also often toxic and continue to react with the surrounding tissue. Examples of oxidizing agents are sodium hypochlorite (Clorox, Dakin's solution), potassium permanganate, and chromic acid.
- *Corrosive agents*: Corrosive substances denature tissue proteins on contact. Typically, eschar formation and a shallow ulcer represent their injury. Examples of corrosive agents include phenols and cresols, white phosphorus, dichromate salts, sodium metals, and the lyes.
- *Protoplasmic poisons*: These agents produce their effects by binding or inhibiting calcium or other organic ions necessary for tissue viability and function. Examples of protoplasmic poisons include 'alkaloidal' acids, acetic acid, formic acid, and metabolic competitors/inhibitors such as oxalic and hydrofluoric acid.
- *Vesicants*: Vesicant agents produce ischemia with anoxic necrosis at the site of contact. For example, substances such as cantharides (Spanish Fly), dimethyl sulfoxide (DMSO), mustard gas, and Lewisite.
- *Desiccants*: These substances cause damage by dehydrating tissues and at the same time are involved in exothermic reactions to release heat into the tissue. Examples here include sulfuric and muriatic (concentrated hydrochloric) acid.

Within these groups, there are different categories of compounds, each with their own characteristics. This method of describing burn injuries as acid or alkali is less accurate than describing the classes by how they coagulate proteins. Although the mechanisms of action for individual acids or alkali may differ, the resulting wounds are similar enough to warrant consideration as separate groups.³ Acids act as proton donors in the biological system, and strong acids have a pH < 2. The best predictor of ability of an acid to cause injury,

Fig. 42.1 Acid burn to foot illustrating coagulation of blood vessels ('coagulative necrosis').

Fig. 42.2 Alkali splash burn to face.

however, is the amount of neutralizing material to correct the pH of the acid to neutral.⁴ Alkali, or basic material, capable of producing injury typically has a pH > 11.5.⁵ In general alkaline material causes more injury than acidic compounds because acids cause coagulation necrosis with precipitation of protein, while the reaction to alkali is 'liquefaction' necrosis allowing the alkali to penetrate deeper into the injured tissue.⁶ The alkalis dissolve and unite with the proteins of the tissues to form alkaline proteinates, which are soluble and contain OH ions, allowing further reactions deeper into the tissues.⁷ Organic solutions will tend to dissolve the lipid membrane of cell walls and cause disruption of cellular architecture as their mechanism of action. Inorganic solutions would tend more to remain on the exterior of cells, but may act as vehicles to carry the above-mentioned agents that denature proteins or form

salts with proteins themselves. It is important to consider that the introduction of a chemical agent into a biological system does not result in a simple organic chemistry reaction, but a complex variety of chemical changes across the spectrum of substrates present in a human cell.

General principles of management

The most important aspects of first aid for chemical burn victims involve removal of the offending agent from contact with the patient. This requires removal of all potentially contaminated clothing and copious irrigation. Important principles in the irrigation of chemical burn patients involve protection of healthcare providers to prevent additional injuries. Further, the wounds should not be irrigated by placing the patient into a tub, thereby containing the chemical and spreading the injurious material. Irrigation should be large volume, and 'to the floor' or out an appropriate drain. Lavage of chemical injuries is meant to dilute the agent already in contact with the skin, and prevent additional agent from being exposed to the skin. Early, copious lavage has been shown to reduce the extent and depth of full-thickness injury.⁸ No measure of adequacy of lavage has been developed, but monitoring of the pH from the effluent can provide quantifiable information as to adequacy of lavage, but quite often after a period of 30 minutes to 2 hours of lavage may be necessary, and clinically the input of the patient is important to tell that the symptoms of the injury have been reduced signal the end of lavage. The adage 'dilution as the solution to the pollution' applies.

Material Safety Data Sheets (MSDS) are mandated to be available for all chemicals present in the workplace. These can be valuable resources for potential systemic toxicity and side effects of an agent. Plant safety officers should be available at all times to provide this information in cases of industrial accidents. Further assistance is available from regional poison control centers for household chemicals or unidentified agents.

One of the most controversial areas of chemical burn treatment involves the use of neutralizing agents. In theory, they should effectively remove the active chemical form in a wound and provide relief from further injury. However, because of the wide range of chemicals potentially involved, their correct use cannot be assured, so they are generally discouraged. The practical problems encountered with their use are exothermic reactions (i.e. when an acid is used to neutralize an alkali solution, the resulting reaction may liberate a large amount of heat), causing further thermal damage on top of the pre-existing chemical injury. When the burning agent is known and an appropriate antidote is known, there is some benefit demonstrated in its use.⁹ Despite this, no agent has been found to be more effective than plain water for irrigation.¹⁰

General principles of trauma management are followed (the ABCs). Airway patency is assured, followed by adequate air movement, and maintenance of hemodynamics. Despite the increasing awareness of chemical burns, no one center has undertaken a study of the resuscitative needs of a chemical burn victim, and hence we rely on the conventional thermal burn formulas for resuscitation. Monitoring of urine output remains paramount to assessment of adequacy of end-organ

perfusion and hence resuscitation. Systemic disturbances of pH are potential complications and must be monitored until electrolyte trends are stabilized.

The typical large-volume lavage required to adequately dilute chemical exposures puts the victim at potential risk for hypothermia, both from evaporative cooling losses and the use of unwarmed lavage fluid. First aid performed in outdoor decontamination areas can compound the possibility of hypothermia. Recognition of these risks can prevent added complications.

Principles of wound care for chemical burns are typically the same as for thermal injuries. Early excision and grafting of obvious non-viable tissue is advocated, particularly in light of the observation that chemical burns tend to heal more slowly than thermal burns. Topical application of antimicrobials can be useful for partial thickness injuries. With the development of temporary wound coverings, such as Biobrane™, it is tempting to use this technology in the setting of chemical injuries, but there is no significant experience to support this use.

Specific agents

Acetic acid

Table vinegar, a dilute solution of acetic acid is usually harmless. Glacial or nearly 100% pure acetic acid acts as a metabolite by forming esters with proteins of metabolic pathways.

Strong alkali

Lime, sodium hydroxide and potassium hydroxide are common alkali agents that burn. They are present in many household cleaning solutions, and have historically been commonly ingested as well as causing cutaneous burns.

Dry residues of alkali (e.g. lime) must be brushed away to reduce the total amount of alkali present; then copious irrigation is undertaken. Attempts to neutralize alkali are not recommended.

Alkali injury to the eye is particularly devastating. These compounds penetrate the cornea quickly causing scarring, opacification of the cornea, and perforation.¹¹

Assorted acids

Acids tend to cause hard, dry eschars on contact with skin, sparing deeper tissue. In fact, tannic acid has been described as a treatment for thermal injury,¹² and even Native Americans have used unrefined products in the treatment of burns since pre-history. Many of these compounds are absorbed as protoplasmic poisons and are renal and hepatic toxins.

Alkyl mercuric compounds

Skin reaction with these substances releases free mercury, which can be found in blister fluid. With time, this mercury is absorbed, which can cause systemic effects. After blisters are debrided, repeat washing to lavage the blister fluid contents away is necessary.

Cantharides

‘Spanish Fly’ is used as an aphrodisiac that acts as a vesicant upon contact with the skin. This leads to the formation of multiple, small blisters.

Cement

Cement acts both as a desiccant and an alkali. It penetrates clothing and combines with sweat, causing an exothermic reaction. The dry powder is very hygroscopic and will cause desiccation injury if not hydrated or washed away. Cement is calcium oxide, which becomes calcium hydroxide upon exposure to water. Injury results from the action of the hydroxyl ion.¹³

Chromic acid

Contact with chromic acid, a powerful oxidizing agent used to clean other metals, will cause protein coagulation. The lethal dose for ingestion is between 5 and 10g, and results in gastroenteritis, followed by vertigo, muscle cramps, peripheral vascular collapse, and coma. Water lavage is again the primary treatment for exposure, but in an industrial setting where this acid is used; washing with a dilute solution of sodium hyposulfite, followed by rinsing in a buffered phosphate solution may be a more specific antidote. Dimercaprol may be used at 4mg/kg IM every 4 hours for 2 days followed by 2–4mg/kg/day for 7 days total to treat the systemic effects.

Dichromate salts

A highly corrosive substance with similar symptoms of systemic toxicity as chromic acid. Lethal dose is 50–100mg/kg. Emergency treatment is by lavage, but more specific treatments include lavage with 2% hyposulfite solution or a buffer of 7% potassium dihydrogen phosphate and 18% disodium hydrogen phosphate.

Dimethyl sulfoxide (DMSO)

This is a powerful organic solvent, with the ability to carry non-lipid soluble compounds quickly across cell membranes. It is used commonly in ‘alternative medicine’ as a relief for joint pain itself, but commonly is the vehicle for other agents. If implicated in a cutaneous injury, it is likely the dissolved substance, rather than the DMSO itself causing injury.

Formic acid

All patients injured by formic acid should be hospitalized due to multiple systemic effects of this metabolic poisoning agent. These problems include metabolic acidosis, intravascular hemolysis with hemoglobinuria, renal failure, pulmonary complications, and abdominal pain with necrotizing pancreatitis and vomiting.¹⁴

Hydrocarbons

Prolonged contact with petroleum distillates results in dissolution of lipid cell membranes and resulting cell death.¹⁵ These burns tend to be superficial and heal spontaneously.¹⁶ Systemic toxicity includes respiratory depression and, when lead additives were present, systemic lead poisoning was common. The present epidemic of ‘huffing’ or inhaling volatile hydrocarbons has produced a syndrome of neurological damage as well.

Hydrochloric acid/muriatic acid

Muriatic acid is the commercial grade of concentrated hydrochloric acid. Once in contact with the skin, it denatures proteins into their chloride salts. Most significantly, hydrochloric acid fumes can cause inhalation injury with a sudden-onset pulmonary edema.

Hydrofluoric acid

Hydrofluoric acid (HF) is a commonly used acid with industrial applications. It is used as a cleaning agent in the petroleum industry and glass etching. It is also one of the strongest inorganic acids known. Hydrofluoric acid is particularly lethal due to its properties both as an acid and as a metabolic poison. The acid component causes coagulation necrosis and cellular death. Fluoride ion then gains a portal of entry that then chelates the positively charged ions like calcium and magnesium.¹⁷ This causes an efflux of intracellular calcium with resultant cell death. The fluoride ion remains active until it is completely neutralized by the bivalent cations, including penetration to bone. This may exceed the body's ability to mobilize calcium and magnesium rapidly enough and muscle contraction and cellular function, dependent on these cations, will become dysfunctional. Fluoride ion is also a metabolic poison and inhibits the Na-K ATPase, allowing efflux of potassium as well.¹⁸ These electrolyte shifts at nerve endings are thought to be the cause of the extreme pain associated with HF burns.¹⁹

HF burns are classified based on the concentration of the exposure according to a system developed by the National Institutes of Health-Division of Industrial Hygiene.²⁰ Concentrations greater than 50% cause immediate tissue destruction and pain. Concentrations of 20–50% result in a burn becoming apparent within several hours of exposure. Injuries from concentrations less than 20% may take up to 24 hours to become apparent. Studies on the protective properties of skin correlate well with this scheme, as there was noted to be some protection for a period at all acid concentrations; then the still undefined barrier broke down, allowing the HF to penetrate.²¹ Interestingly, the barrier was disrupted by nicks in the skin and organic solvents, suggesting that some lipid element is lost as the wound turns from superficial to full thickness.

The systemic symptoms typical of hypocalcemia or hypomagnesemia are generally absent. Serum calcium levels and electrocardiogram are important monitors of patient status.²² Once the cardiac dysrhythmias develop, they are hard to restore to a normal rhythm.²³ Compounding the problem of hypocalcemia, the fluoride ion may be acting as a metabolic poison in the myocardium to promote the irritability. The typical electrocardiographic change is Q-T interval prolongation. The fluoride ions can be removed by hemodialysis or cation exchange resins.^{24,25}

Treatments of HF exposure are designed to neutralize the fluoride ion and prevent systemic toxicity. Topical calcium gluconate gel (3.5 g of 2.5% calcium gluconate mixed with 5 oz of water-soluble lubricant is applied to the wound 4–6 times each day for 3–4 days) can be used after the wounds have been copiously irrigated.²⁶ Calcium gluconate injections into the area of the wound (0.5 cc/cm² of 10% calcium gluconate) have also been used with good success.²⁷ Pain relief with these treatments is often swift, and it is felt that return of symptoms indicate need for repeat treatment. Calcium chloride delivers more milliequivalents per cc of solution, but is contraindicated in subcutaneous injection due to its tissue irritating properties. Burns to the hand with HF are common in workplace accidents, and present special problems; how to deliver large amounts of calcium to limited areas. Palmar fasciotomy may be needed to relieve the pressure after tissue injections.²⁸ Another option is intra-arterial injections of dilute calcium salts (10 cc of 10%

calcium gluconate or calcium chloride in 40 cc of 5% dextrose) into the radial artery that would supply the injured area.²⁹ Infusion continues until the patient is symptom free of pain in the injured extremity. This technique is commonly described, but there is not wide clinical acceptance, owing to the difficulty and risk of peripheral arterial cannulation while infusing an agent potentially causing distal ischemia. Injury to eyes by HF is treated with copious irrigation with water or saline, not calcium chloride, which is associated with increased corneal ulceration.³⁰ After the acute period is over, the eye may irrigate with 1% calcium gluconate every 2–3 hours and recovery usually occurs in 4–5 days. Pulmonary reaction to HF vapor may persist for up to 3 weeks after exposure. Nebulized solutions of calcium gluconate and intermittent positive pressure breathing device support are recommended.³¹

Hypochlorite solutions

These are potent oxidizers delivered in alkaline solution used as bleaches and household cleaners. Commonly available solutions are 4–6% and are lethal only when a large surface area is involved; however, exposure to 30 cc of 15% solution is potentially fatal. Systemic manifestations of toxicity include vomiting, dyspnea, and edema of the airway, confusion, cardiovascular collapse, cyanosis and coma.³²

Nitric acid

A strong acid that can combine with organic proteins to produce organonitrates which act as metabolic poisons.

Oxalic acid

This is a potent metabolic poison that combines with calcium to limit its bioavailability. After exposure, serum calcium should be monitored closely, as well as signs of cardiac or respiratory muscle dysfunction: 0.5 g oxalic acid exposure or ingestion may be fatal.

Phenol (carbolic acid)

This substance was originally used as an antiseptic, but its use declined after serious side effects were noted. It is bound irreversibly to albumin after exposure and ingestion of as little as 1 g may cause death. Cardiovascular effects include ventricular arrhythmias,³³ and skin necrosis also results from prolonged contact.

Industrial use of this compound and its derivatives (resorcinol or 1,3-dihydroxybenzene) has shown the most common adverse effects to be dermatitis and depigmentation of the skin.³⁴ Acute poisonings are potentially fatal, so prompt action is necessary with copious irrigation to decontaminate the wounds.³⁵ Polyethylene glycol (PEG molecular weight 300 or 400) has been shown to be of potential benefit,^{36,37} but large-volume lavage should not be delayed while PEG application is begun.

Reports in the literature indicate intravenous sodium bicarbonate may be of use to prevent some of the systemic effects of phenol.³⁸ The mechanism is not clear, as phenol is not dissociated from the albumin by this treatment.

Phosphoric acid

An industrial acid used in strong concentrations. Lavage followed by electrolyte monitoring (phosphorus is a strong calcium binder) is the treatment of choice.

Phosphorus

Phosphorus has both military and civilian uses. It is an incendiary agent found in hand grenades, artillery shells, fireworks and fertilizers.³⁹ White phosphorus ignites in the presence of air and burns until the entire agent is oxidized or the oxygen source is removed (for example, as with immersion in water). The wounds are irrigated with water, the easily identifiable pieces of phosphorus are removed from the wound, and soaked dressings are applied for transport. Ultraviolet light can be used to identify embedded particles through phosphorescence, or a solution of 0.5% copper sulfate can be applied which will impede oxidation and turn the particles black to aid in their identification and removal. Hypocalcemia, hyperphosphatemia, and cardiac arrhythmias have been reported with phosphorus burns.⁴⁰

Potassium permanganate

This is an oxidizing agent that is highly corrosive in dry, crystalline form. It is poorly absorbed, so systemic effects are rare.

Sulfuric acid

Sulfuric acid and its precursor sulphur trioxide are strong acids and desiccants with many industrial applications. Copious irrigation and early excision are the treatments of choice.⁴¹

Vesicant chemical warfare agents (lewisite, nitrogen mustard)

These agents were historically used during the trench warfare of World War I. They affect all epithelial tissues, including skin, eyes, and respiratory epithelium. Symptoms described after exposure to mustard gas include burning eyes and a feeling of suffocation associated with a burning throat.⁴² This is followed by erythema of the skin in 4 hours with blisters developing in 12–48 hours. Severe pruritis develops, particularly in the moist areas, such as the axilla and perineum. When the blisters rupture, they leave painful, shallow ulcers. Exposure to larger quantities of these agents produces coagulative necrosis of the skin with either no blistering or ‘doughnut blisters’ surrounding a central necrotic zone.⁴³ Secondary respiratory infection and bone marrow suppression often lead to death. Lewisite (2-chlorovinyl-dichloroarsine) is the best known arsine. It is more powerful than the mustards and the symptoms occur sooner. Phosgene oxime is another common agent in chemical warfare. It is the most widely used halogenated oxime and has the immediate effect of stinging, likened to contact with a stinging needle.⁴⁴ Affected areas quickly become swollen with blister formation, and eschars develop over the next week, but wound healing is slow (over 2 months). Eye involvement is extremely painful and can result in permanent blindness. Inhalation leads to hypersecretion and pulmonary edema.

Treatment primarily includes prophylaxis against exposure, and those administering aid to victims should be suitably protected with respirator, butyl rubber gloves, and boots. Clothing is removed from the victims and large-volume lavage of the skin is undertaken. Eyes are irrigated with water or ‘balanced salt solution.’ Symptomatic relief of itch is provided with benzodiazepines, antihistamines, or phenothiazines. Blisters are debrided and dressed with topical antimicrobials (but silver sulfadiazine neutralizes dimercaprol). Dimercaprol is a chelating agent that is an antidote for lewisite poisoning, available as an ointment, eyedrops or intramuscular preparation. There is no specific antidote for nitrogen mustard, but sodium thiosulfate and cysteine may be helpful to reduce the effects if administered early.⁴⁵ Early excision and grafting has not been shown to be of benefit with nitrogen mustard burns, but the deeper lesions seen with the other agents seem best suited to treatment as if they were full-thickness thermal burns. The blister fluid from nitrogen mustard injuries does not contain active agent and is hence harmless.⁴⁶ Symptomatic treatment of ocular and respiratory complications is undertaken. Agranulocytosis or aplastic anemia can result from exposure to these agents, as was seen in Iranian casualties from the Iran–Iraq war.⁴⁷ Transfusion of blood products was not helpful,⁴⁸ and in the appropriate setting, bone marrow transplantation may be considered. Other marrow stimulators (e.g. granulocyte maturation colony-stimulating factor of lithium carbonate) have not been tried.

Ingestions of caustic substances are common in young children as they begin to explore their environment and get into the household chemicals, or in adults as a suicide gesture. In a 15-year review of chemical burn injuries at our institution, we identified 154 chemical burn injuries, with 26 patients involved with ingestion injuries (17% incidence), but significantly 14 patients under age 4 years (unpublished data). Management of these injuries is not necessarily undertaken in a specialized burn unit, but can be handled by a general surgeon, or foregut surgery specialist. Similar principles apply, with neutralization, lavage, and avoidance of vomiting which might re-expose tissue to the offending agent. Early endoscopic evaluation of the oral pharynx, esophagus and stomach/proximal duodenum with endoscopy will help to define extent of injury before scarring eliminates access to these structures. Particularly vulnerable areas include compromise of the upper airway due to the concentrated exposure in this area and subsequent risk requiring intubation. In general, endoscopic gastrostomy tubes should be considered early in the course of treatment to provide feeding access to the stomach and a guide string should be left in the lumen of the esophagus. The reader is referred to an appropriate general surgery text for the current management of this problem.

Introduction

In the aftermath of 9/11, with the threat of constant and unrelenting terrorism, the possibility of employment of nuclear weapons, crude nuclear devices, attacks on nuclear facilities and use of chemical agents cannot be ignored. Such attacks may result in types of injuries in previously unimaginable numbers. Given the devastating medical consequences that would follow the use of such weapons, the training of medical personnel will be a crucial factor in the effective management of such casualties, should the unthinkable ever occur.

Only 4 months after Roentgen reported the discovery of x-rays, Dr John Daniel observed that irradiation of his colleague's skull caused hair loss. Since this finding was reported in 1896, many biomedical effects of radiation have been described.¹ Knowledge of nuclear physics was rapidly amassed in the early part of the 20th century, leading eventually to the Manhattan project and the development of the atomic bomb. The last 50 years has also seen widespread deployment of energy-generating nuclear reactors, and the expanding use of radioactive isotopes in industry, science, and healthcare.² More recently, major industrial accidents of note at Three Mile Island in Pennsylvania, Chernobyl in the Ukraine and at Goiania, Brazil have resulted in potential or real radiation injuries to hundreds of people.

Exposure to ionizing radiation can follow one of three patterns:

1. small-scale accidents, as might occur in a laboratory or from an x-ray device in a hospital setting;
2. large industrial accidents (such as those mentioned above), stretching the need for treatment beyond available resources; and

3. detonation of a nuclear device in a military conflict where resources are totally overwhelmed or unavailable and associated multiple and combined injuries also exist.

This chapter first describes the terminology used in standard measurement of radiation exposure and discusses the frequency of radiation accidents, injuries and fatalities. The effects of exposure to ionizing radiation and triage and care protocols are considered according to known and projected prognostic factors. The complications that arise specifically with this injury and the supportive measures that need to be taken will be addressed.

Vesicant agents are characterized by their ability to produce cutaneous blisters resembling 'burns.' Although most physicians are unlikely to encounter casualties of chemical weapons, the proliferation of these agents has increased the risk to both military and civilian populations. They are likely to require expertise found in burn centers and for this reason an account of the management of these injuries is included in this text. Finally, the problem of mass casualties is examined, and recommendations for management are made.

Radiation injuries

Terminology

Damage to biological tissue by ionizing radiation is mediated by energy transference. This can be the result of exposure to electromagnetic radiation (e.g. x-rays and gamma rays) or particulate radiation (e.g. alpha and beta particles or neutrons). The severity of tissue damage is determined by the energy deposited per unit track length, known as linear energy transfer (LET).³ Electromagnetic radiation passes through tissue almost unimpeded by the skin and are called low LET since little energy is left behind. In contrast, neutron exposure has high-LET, resulting in significant energy absorption within the first few centimeters of the body. Alpha and low-energy beta particles do not penetrate the skin, and represent a hazard only when internalized by inhalation, ingestion or absorption through a wound.

Radiation dosing can be expressed in several ways (Table 43.1):

- The roentgen (R) is the unit of exposure and is related to the ability of x-rays to ionize air. It is defined as the quantity of low-energy x-rays or gamma rays required to produce 1.61×10^{15} ion pairs per kilogram of air.
- The curie (Ci) or becquerel (Bq) is the unit of activity (rate of decay) of a radioactive material. One curie

TABLE 43.1 RADIATION UNITS AND CONVERSION FACTORS

Old unit	New unit	Conversion factor
Rad (rad)	Gray (Gy)	1 Gy = 100rad
Rem (rem)	Sievert (Sv)	1 Sv = 100rem
Curie (Ci)	Becquerel (Bq)	1 Bq = 2.7×10^{-11} Ci

equals 3.7×10^{10} decays per second, a definition originally based on the rate of decay of 1g of radium.⁴ The becquerel is a smaller but more basic unit and equals one decay per second.

- The rad is the unit of absorbed dose of radiation and corresponds to an energy absorption of 100ergs/g. A newer international unit, the gray (Gy), is now in use and is defined as 1Joule (J) of energy deposited in each kg of absorbing material, and is equal to 100rads.⁵

Not all radiation is equally effective in causing biological damage, although it may cause the same energy deposition in tissue. For example, 1Gy of neutron radiation will not have the same effect as 1Gy of gamma or x-radiation. For this reason, a unit of dose equivalence was derived that allows radiations with different LET values to be compared. One such unit is the rem (acronym of roentgen equivalent man). The dose in rem is equal to the dose in rads multiplied by a quality factor (QF).⁶ The QF takes into account the linear energy transfer and has a different value for different radiations; for x-rays it is 1.0, for neutrons 10. The international unit, now more widely in use, is the sievert (Sv). One sievert equals 100rem; 1rem equals 10mSv. This allows radiations with different LET values to be compared, since 1Sv of neutron radiation has the same biological effect as 1Sv of low LET gamma or x radiation.

Incidence

A significant radiation accident is one in which an individual exceeds at least one of the following criteria:⁷

- Whole body doses equal to or exceeding 25 rem (0.25Sv).
- Skin doses equal to or exceeding 600rem (6Sv).
- Absorbed dose equal to or greater than 75rem (0.75 Sv) to other tissues or organs from an external source.
- Internal contamination equal to or exceeding one-half the maximum permissible body burden (MPBB) as defined by the International Commission on Radiological Protection (this number is different for each radionuclide).
- Medical misadministrations provided they result in a dose or burden equal to or greater than the criteria already listed above.

Radiation accidents within the United States should be reported to the federally funded Radiation Emergency Assistance Center/Training Site (REAC/TS). This is operated by Oak Ridge Institute for Science and Education (ORISE) at Oak Ridge, Tennessee and can be contacted by calling (865) 576-

1005. A radiological emergency response team of physicians, nurses, health physicists, and support personnel provides consultative assistance on a 24-hour basis and has the capability of providing medical treatment, whenever a radiation accident occurs. REAC/TS also maintains a Radiation Accident Registry System.

The number of accidents, number of persons involved, as well as the number of fatalities, in the United States and worldwide is shown in Tables 43.2 and 43.3. There have been a total of 134 fatalities recorded by the Registry worldwide.⁷ The majority of the radiation deaths occurred as a result of the Chernobyl accident in 1986 (>40). The classification of radiation accident by device for the period 1944 until March 2005 and their frequency distribution is illustrated in Table 43.4 and Figure 43.1.⁷ The majority of radiation accidents are due to radiation devices. This may be an accelerator; however, most devices involved in accidents are encapsulated, highly radioactive sources used for industrial radiography. Next most frequent accidents are radioisotope accidents that involve radioactive materials, which are unsealed such as tritium, fission products, radium and free isotopes used for diagnosis and therapy. Uncommon criticality accidents occur when enough fissionable material, such as enriched uranium is brought together to produce a neutron flux so high that the material undergoes a nuclear reaction (becomes critical).

The most devastating radiation injuries and fatalities yet seen, however, resulted from detonation of nuclear weapons at Hiroshima and Nagasaki during World War II. Since 1945 nuclear weapon technology has developed enormously and current strategic thermonuclear warheads dwarf those weapons used in Japan.⁸

Perhaps a more likely weapon of terrorism will involve the use of a radiological dispersal device (RDD). The term dirty bomb generally refers to conventional explosive packaged with radioactive material that is scattered over a wide area when detonated. It is believed that these devices would probably elicit more harm by public fear and panic than by serious injury.⁹ Perhaps a greater threat might be the use of radioactive material placed in a public place without use of explosives, as illustrated by the event in Goiania, Brazil where 249 people were affected by radiation when cesium-137 was unwittingly released by scrap metal workers.

Pathophysiology

The detonation of a nuclear device over a population center will produce an extremely hot, luminous fireball, which emits intense thermal radiation capable of causing burns and starting fires at considerable distance. This is accompanied by a destructive blast wave moving away from the fireball at supersonic speed and the emission of irradiation, mainly gamma rays and neutrons.¹⁰ The result of a combination of thermal and radiation injuries is said to have a synergistic effect on the outcome. Several animal experiments have demonstrated a significant increase in mortality when a standard burn wound model is irradiated, over and above that expected from either injury alone.^{11,12}

Thermal effects

Exact information about the cause of fatalities in a nuclear blast is not available, but from the nuclear attack on Japan, it has been estimated that 50% of deaths were due to burns and

some 20–30% was flash burns.¹³ The clinical picture may range from an erythema of the exposed areas (most commonly face, hands, arms and legs), to a charring of the superficial layers of the skin. Secondary flame burns may be present following the ignition of the victim's clothing or environment. The physicians at Hiroshima and Nagasaki observed that the 'flame' burn wound seemed to heal at first. However, between 1 and 2 weeks later, a serious relapse occurred. Wound infection set in; there was a disorder in granulation tissue formation; a gray, greasy coating would form on the wounds. Thrombocytopenia resulted in spontaneous bleeding both into the wound and elsewhere. Histologically, the normal collection of leukocytes delineating a necrotic area were found to be absent due to agranulocytosis and gross bacterial invasion was evident;¹⁴ both these changes obviously affecting the prognosis of these otherwise relatively small injuries.

Radiation effect

Damage to biological tissue by ionizing radiation is mediated by energy transference. The transference of this energy can damage critical parts of the cell directly or indirectly by formation of free radicals (such as the hydroxyl radical). The primary targets are cellular and nuclear membranes and DNA.¹⁵

The morbidity of radiation is dependent on its dose, the dose rate and the sensitivity of the cell exposed. Cells are most sensitive when undergoing mitosis so that those that divide rapidly such as bone marrow, skin and the gastrointestinal tract are more susceptible to radiation damage. Radiation to an organ such as brain or liver, which has parenchymal cells with a slow turnover rate, results in damage to the more sensitive connective tissue and microcirculation.

The overall effect on the organism depends on the extent of the body surface involved, duration of exposure and homogeneity of the radiation field. It is convenient to consider radiation injuries as localized or whole body (acute radiation syndrome).

Localized injury

In a localized injury a relatively small part of the body is affected without significant systemic effects.¹⁶ The skin and subcutaneous tissue alone may be involved following exposure to low-energy radiation. Exposure to high-energy radiation may injure deeper structures.

Radiation damage depends on the dose of exposure and several progressive features are observed in skin: erythema is equivalent to a first-degree thermal burn and occurs in two stages. Mild erythema appears within minutes or hours following the initial exposure and subsides in 2–3 days. The second onset of erythema occurs 2–3 weeks after exposure and is accompanied by dry desquamation of the epidermal keratinocytes. Epilation (loss of hair) may occur as soon as 7 days post injury. It is usually temporary with doses less than 5 Gy but may be permanent with higher doses.

Moist desquamation is equivalent to a second-degree thermal burn and develops after a latent period of about 3 weeks with a dose of 12 to 20 Gy. The latency period may be shorter with higher doses. Blisters form, which are susceptible to infection if not treated.

Full-thickness skin ulceration and necrosis are caused by doses in excess of about 25 Gy. Onset varies from a few weeks to a few months after exposure. Blood vessels become telangiectatic and deeper vessels occluded. Obliterating endarteritis results in fibrosis, atrophy and necrosis. Skin cancers may be evident after months or years.

The acute radiation syndrome

The physiological effects of whole-body radiation are described as the acute radiation syndrome (ARS). The clinical course usually begins within hours of exposure. Prodromal symptoms include nausea, vomiting, diarrhea, fatigue, fever and headache. There then follows a latent period, the duration of which is related to the dose. Haematopoietic and gastrointestinal complications follow this. The ARS can be subdivided into three overlapping subsyndromes, which are related to the dose exposure.

Haematopoietic syndrome

This may occur after an exposure of between 1 and 4 Gy. The bone marrow is the most sensitive and pancytopenia develops. Opportunistic infections result from the granulocytopenia and spontaneous bleeding results from thrombocytopenia. Hemorrhage and infection is the usual cause of death.

Gastrointestinal syndrome

This requires a larger dose exposure usually in the range of 10 to 12 Gy. Severe nausea and vomiting associated with bowel cramps and watery diarrhea occurs within hours of irradiation. There is a shorter latent period of 5–7 days, which reflects the turnover time of the gut epithelium (3–5 days). The epithelial damage results in loss of transport capability, bacterial translocation with sepsis, bowel ischemia and bloody diarrhea. Large fluid imbalances can result in hypovolemia, acute renal failure and anemia from both bleeding and the loss of erythropoiesis. Critical exposure will lead to rapid deterioration with unrelenting bloody diarrhea, fever, refractive hypovolemic shock, sepsis and death.

Neurovascular syndrome

An exposure to a dose of 15–30 Gy or greater can cause an immediate total collapse of the vascular system superimposed on the aforementioned syndromes. This may be due to the massive release of mediator substances, nitric oxide abnormalities or destruction of endothelium.¹¹ This syndrome can progress rapidly with variable neurological symptoms, respiratory distress, cardiovascular collapse and death.

Triage

Triage is the initial classification of casualties into priority groups for treatment and is essential in the management of large numbers of casualties. Those patients unlikely to survive should not be allowed to overwhelm available resources, so that adequate treatment reaches those most likely to survive. In most circumstances, ionizing radiation is not immediately life threatening and any associated injury should be treated first. Once lifesaving measures has been carried out and the patient stabilized, assessment of radiation exposure can proceed.

If large-scale casualties are encountered, triage may, of necessity, seem to be draconian. In conventional warfare with limited medical resources, 50% of soldiers with thermal injuries of up to 70% TBSA will be expected to survive (Table 43.5). This survival rate should be bettered in a smaller civilian major accident. Thus burns alone over 70% TBSA should receive expectant treatment and those under 20% can have their treatment delayed. If there has been a significant exposure to radiation as well as a thermal injury, individuals with over 30% TBSA burns are unlikely to survive without the use of major resources.¹⁷

Treatment

The treatment of any burn requires massive support from a dedicated team. This will be available for small accidents. With larger accidents or a nuclear attack, the number of victims could swamp the services; treatment facilities may be destroyed; normal supply channels would be drastically reduced, if present at all; production, distribution and transportation of supplies may be greatly impaired and local care workers may also be the victims.¹⁸

First aid

The victims must be evacuated from the source of radiation in order to limit the exposure. Normal resuscitation procedures must be followed (i.e. airway, breathing, circulation, etc.). Contaminated clothing must be removed and the skin wounds decontaminated by copious but gentle irrigation with water or saline. The goal of decontamination is to dilute and neutralize particles without spreading them to unexposed areas. Thus patients should not be immersed in tubs. Irrigation should be continued until a dosimeter such as a Geiger–Muller counter indicates a steady state or minimum radiation count has been reached.

Intact skin may also be irrigated with a soft brush or surgical sponge preferably under a stream of warm tap water. If this is inadequate, a second scrubbing with mild soap or detergent (pH 7) for 3–4 minutes is recommended. This is followed by application of povidone-iodine solution or hexachlorophene soap, which is then rinsed again for 2–3 minutes and dried. If the patient is known to have had less than 100rem he/she can be followed as an outpatient. Exposures greater than 100rem require full evaluation in hospital. Patients with exposures over 200rem or who have symptoms of ARS should preferably be sent to specialist centers with facilities to treat bone marrow failure.¹⁹

Assessment

The assessment of thermal injury has been covered in preceding chapters. Exposure to radiation can be estimated clinically, by noting the onset of symptoms of ARS, supported by biological parameters. A complete blood count, including platelets and differential count, should be performed immediately and repeated at 12–24 hours if indicated by a change in the absolute lymphocyte count. If the patient sustains a fall in lymphocyte count of 50% or a count less than 1×10^9 /liter in a time period of 48 hours post exposure, a moderate dose of radiation has been encountered.²⁰ Levels of serum amylase and diamine oxidase (produced by intestinal villi) may be useful biological dosimeters of the future. Amylase levels are only reliable when the salivary glands have been exposed and diamine oxidase has not yet been fully assessed in humans. Lymphocyte chromosomal analysis allows very accurate measurement even at low levels of exposure. However, the need for the test to be performed in cell cultures in laboratories over 48 hour incubation would render this test impractical with large numbers of casualties.²¹

General care of the irradiated patient

Where possible a history should be obtained from the patient or others. Factors such as age, concurrent medical problems, smoke inhalation and multiple trauma will affect the prognosis. With this in mind a full physical examination is carried out to exclude other injuries. Victims of radiation exposure may not appear to differ clinically from the thermally injured and should receive the same care. Those exposed to lethal doses of radiation will exhibit early signs of radiation sickness and should be triaged accordingly.

All patients should be given adequate analgesia. Opiates or opioids are the drugs of choice. They must be titrated to effect and administered by the intravenous route. Early nausea and vomiting will be distressing and must be treated with available antiemetic drugs. Prochlorperazine has to be given by intramuscular injection but the newer agent, ondansetron, may prove successful as it is used against the similar symptoms encountered in radiotherapy and chemotherapy. It can also be used in children.

Patients with thermal burns in excess of 40% TBSA or with associated inhalation or major trauma should be treated expectantly in the mass casualty situation. They should be made comfortable, given adequate analgesia and/or sedatives if available and thought appropriate. Resuscitation should be the same as that for an uncomplicated thermal injury. Any resuscitation formula can be used, but it must be closely monitored and altered as necessary to maintain an adequate urine output. The fluid requirement will be increased as fluid is sequestered into damaged internal organs especially the gut. Fluid losses from diarrhea and vomiting may also be excessive and need to be replaced. Intravenous fluids may be limited and the victims may be advised to take oral fluids consisting of balanced salt solutions and maintain a large urine output. A number of oral fluid replacement formulas exist although the best known, Moyer's solution, can be readily formulated by mixing a teaspoon (5mL) of sodium chloride and a teaspoonful of sodium bicarbonate in a liter of tap water.

TABLE 43.5 SURVIVAL RATES WITH MAJOR RESOURCES AVAILABLE

Burn alone	<70% TBSA	50% survival
Burn alone	>70% TBSA	Probably fatal
Burn plus radiation	<30% TBSA	May survive
Burn plus radiation	>30% TBSA	Probably fatal
TBSA, total body surface area.		

Care of the burn wound

The patient is bathed gently to remove loose non-viable skin, the remnants of burnt clothing and any other external debris, which may be contaminated with radioactive material. After the patient has been cleaned, decontaminated and debrided, the extent of any thermal burn and its depth can be ascertained more accurately. The major problems that will be experienced with a radiation burn and/or thermal injuries are those associated with sepsis, fluid balance and the non-healing wound. Mild erythema may require little treatment; however, it is important to avoid further irritation of the skin by exposure to abrasive decontamination, irritating solutions and sunlight. With a slightly higher radiation dose causing dry desquamation, a bland lotion and loose clothing to alleviate itching may be all that is required. Deeper burns with moist desquamation are treated like conventional thermal injuries. Topical chemotherapeutic agents can be used and regularly applied as described elsewhere. Burns are best treated closed because of the high risk of sepsis in immunosuppressed patients whose wounds are susceptible to dehydration, colonization and portal entry of organisms. Early tangential excision and split skin grafting provides early wound closure, decreased burn wound colonization and sepsis and shortened hospital stay.^{22,23} This technique is recommended by the authors and probably has advantages where the potential to develop septic wounds is great. Information regarding the grafting of radiation burns is not yet available but is probably best delayed. Dubos et al.²⁴ performing early excision and grafting of burns in irradiated monkeys have shown that healing occurred fully by the end of the second week, although histologically there was a slight delay in the healing process. The procedure however is not without risks. Blood loss in excess of 300 mL per %TBSA excised presents an increased anesthetic hazard. In irradiated tissue that is severely injured, definitive management usually involves resection of damaged tissue and replacement with well-vascularized non-irradiated tissue, usually from a distant site.

Hyperbaric oxygen therapy (HBO) may be combined with surgical treatment potentially to enhance wound healing in irradiated tissue. The mechanism of action is not certain but appears to be related to the creation of a high oxygen gradient across the irradiated tissues, which stimulates capillary ingrowth. Hyperbaric oxygen treatments have been devised using an empirical approach.²⁵ A single treatment or 'dive' consists of 90 minutes in the chamber breathing an oxygen-rich mixture at 2.4 ATA (atmosphere absolute). Soft-tissue defects are usually treated with 30 dives. When combined with surgery a '20/10 protocol' is used in which the operative procedure is 'sandwiched' between 20 preoperative and 10 postoperative dives.

Treatment of complications

Hematological

Blood and platelets are administered to maintain an adequate hemoglobin concentration and a platelet level of 20×10^9 per liter. If surgery is contemplated this level should be raised to 75×10^9 per liter. All blood products should be irradiated to avoid graft versus host disease.

Bone marrow transplantation is the treatment of choice following total body irradiation. It should be performed between 3 and 5 days post exposure as the immunosuppression is at its peak.

An important goal of medical treatment is to stimulate the proliferation and differentiation of residual hematopoietic stem and progenitor cells (HSPC). Administration of anti-apoptotic cytokine combinations such as stem cell factor, Flt-3 ligand, thrombopoietin, and interleukin-3, may assist recovery, if administered early.²⁶ Moreover, hematopoietic growth factors such as granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF) have also been recommended^{27,28} based on demonstration of improved survival in irradiated primates and reduced neutropenia in humans following accidental irradiation.

Infection

The immunosuppression associated with irradiation makes the victim susceptible to exogenous and endogenous pathogens. Exogenous infection can be limited by adequate aseptic technique and nursing the patient in a sterile environment. Monitoring the patient adequately will allow the early diagnosis of sepsis and its treatment before it becomes well established. The antibiotic chosen should reflect the current pattern of susceptibility and nosocomial infections in that particular unit at that time. Combination therapy will be required where there is a profound neutropenia. With the large fluid losses and shifts, gentamicin is not recommended unless there is no other choice. Therapeutic levels will be difficult to obtain without risking toxicity and there are now safer broad-spectrum antibiotics (imipenem, ceftazidime and ciprofloxacin). If Gram-positive infection is suspected, vancomycin or the newer and safer teicoplanin should be administered. If there is an inadequate response, an antifungal agent must be added. The use of fresh frozen plasma, gamma globulin solutions and monoclonal antibodies is at present speculative, but if resources allow and the patient's condition is not stabilizing, these agents should be considered.

Cardiovascular collapse

This complication may occur due to the exposure, sepsis, fluid loss or hemorrhage. The patient should be given adequate fluid resuscitation, the airway must be protected and oxygen therapy instituted. Sedation and mechanical ventilation will decrease the oxygen debt that will inevitably occur. Inotropic support may become necessary and should be started as early as possible accompanied by the relevant cardiovascular monitoring. Invasive cardiovascular monitoring will aid in the treatment of volume replacement, but invasive intravenous lines must be inserted in aseptic conditions, kept meticulously clean, changed regularly and removed when no longer indicated. Agents that manipulate the release of nitric oxide may become available in the near future and may turn out to be the agents of choice in the treatment of septic shock.

Occupational exposure

In clinical practice there are concerns that relatively low levels of radiation delivered over a long period of time might induce cancer and/or exert genetic or teratogenic effects. The radiation dose can be limited by reducing the duration of exposure or by increasing the distance from the source of radiation. Since distance and radiation intensity obey the inverse square law, the latter is particularly effective. While the efficacy of

shielding devices will be determined by the type and thickness of the material and the energy and type of radiation, Table 43.6 illustrates the effectiveness of these devices when used at diagnostic x-ray energies. It should be noted that the bodies of others provide very effective shielding.

Cumulative doses of radiation can be recorded on radiation badges containing photographic emulsion. The personnel dosimeter is relatively cheap and accurate but has limitations. The smallest exposure that can be measured is 10 millirem; film badges can be exposed by heat, giving false readings, and they are analyzed only at monthly intervals.

Summary

Treatment of radiation injury, whether or not it is combined with other injuries, requires specialized knowledge and resources. The combination of radiation injury with associated injuries appears to have a synergistic effect on outcome. Significant increases in mortality occur because of immunosuppression secondary to radiation exposure in patients already vulnerable to infections. For localized radiation injury, it is often difficult to assess the level of severity quickly and with accuracy, because of the delay between exposure and appearances of lesions, and because of hidden lesions in underlying tissues. Medical treatment deals with inflammation, moist desquamation, and chronic pain; the most favorable time for surgical intervention is difficult to specify. Full intensive care support is needed for whole-body irradiation causing ARS, and is available only if small numbers are involved. Those that survive and show signs of regeneration of tissues will warrant late surgical intervention. Aplastic anemia, immunosuppression, hemorrhage, and sepsis will be major problems for survivors. The improving therapy of bone marrow transplantation is the treatment of choice. Large numbers of casualties will necessitate expectant treatment only. Evacuation of survivors will take days and a natural selection will take place.

Vesicant burns

Vesicant agents are characterized by their ability to produce cutaneous blisters resembling 'burns.' They have posed a major military threat since the use of sulfur mustard [bis (2-chloroethyl) sulfide] in the trenches of World War I. Since this time various nations have deployed chemical weapons and terrorist organizations have used it in public places.²⁹ More recently, the conflict between Iraq and Iran in the 1980s displayed the most open and widespread use of chemical weapons

on a battlefield in recent decades. Chemical weapons were believed to have been deployed by Iraq in the 1990 Persian Gulf War when nerve gas and blister agent were detected in the theater of operations.^{30,31} Although sulfur and nitrogen mustard is the most important vesicant militarily, the vesicant category includes other agents, such as lewisite and phosgene oxime. These compounds affect not only skin but all epithelial tissue with which they come into contact, particularly the eyes and respiratory tract. Although most physicians are unlikely to encounter casualties of chemical weapons, the proliferation of these agents has increased the risk to both military and civilian populations. They are likely to require expertise found in burn centers and for this reason an account of the management of these injuries is included in this text.

Mechanisms of action

The mechanism of action of mustard has eluded identification; however, most of the toxic effects are believed to be related to alkylation of DNA and critical target molecules. The DNA cross-links, which prevent replication and repair of DNA ultimately, lead to cell death. The dermal epidermal separation, which causes the skin lesions, is believed to be due to release of proteases and other enzymes. Breakage of anchoring filaments connecting the basal cell layer to the basement membrane results in a blister with the basement membrane on its dermal side. There are three main hypotheses to explain the biochemical processes leading to enzyme release.

The first proposes that strand breaks in the DNA activate the nuclear DNA repair enzyme poly (ADP-ribose) polymerase. This initiates a cascade of reactions in which cellular stores of nicotinamide adenine dinucleotide (NAD) are depleted, glycolysis is inhibited, and the hexose monophosphate shunt is stimulated. This is thought to lead to induction and secretion of proteases.³²

The second hypothesis proposes a mechanism based on an interaction between mustard and the intracellular scavenger glutathione (GSH).³³ This is thought to inactivate thiol proteins, including calcium and magnesium adenosine triphosphatases, which regulate calcium levels. Elevation of cytosolic calcium concentration activates production of proteases, phospholipases and endonucleases, which break down membranes, cytoskeleton and DNA leading to cell death. A separate consequence of depleted GSH could also be lipid peroxidation with the formation of lipid peroxides toxic to cell membranes.³⁴

The third hypothesis involves lipid peroxidation where the principal toxic consequence of GSH depletion is the formation of toxic lipid peroxides with resulting cell membrane disruption.

The exact mechanism of action of the other agents is unknown although lewisite has been shown to inhibit several important enzyme systems, such as the pyruvate dehydrogenase complex.

Clinical features

Early symptoms ascribed to mustard gas include an ocular burning sensation and a feeling of suffocation associated with a burning throat.³⁵ After 4 hours, erythema is seen; in 12–48 hours, blistering appears accompanied by severe pruritus which has a predilection for moist areas such as the axilla and

TABLE 43.6 THE EFFECTIVENESS OF SHIELDING DEVICES

Device	Transmission

Human body wearing lead apron	0.1%
Portable lead shields	<1%

perineum. The blisters tend to rupture, discharging an amber serous fluid and leaving painful shallow ulcers. Greater exposure produces coagulative necrosis of skin, with either no blistering or 'doughnut blisters' surrounding a central necrotic zone.³⁶ This will be accompanied by severe conjunctivitis, corneal erosion and necrotizing bronchitis. A secondary respiratory infection may develop over the next few days which coupled with associated marrow suppression could prove fatal. Following absorption of large amounts of mustard other systems may be affected. Severe stem cell suppression may lead to pancytopenia and involvement of the gastrointestinal tract can have effects ranging from nausea and vomiting to severe hemorrhagic diarrhea. Excitation of the CNS, resulting in convulsions, has been reported.³⁷ Mustard may also affect other organs, but rarely do these produce clinical effects

Lewisite (2-chlorovinyl-dichlorarsine) is the best known arsine. It is more powerful than the mustards and symptoms occur sooner. Eye irritation is produced immediately and sneezing, salivation and lacrimation occur sooner. Non-lethal chronic exposure may lead to arsenical poisoning.

Exposure to phosgene oxime, the commonest halogenated oxime, has the immediate effect of stinging, and is likened to that on contact with a stinging nettle.³⁸ Within a minute, the affected area becomes swollen and solid lesions resembling urticaria are seen. An eschar will form after 1 week, but healing is often delayed beyond 2 months. Contamination of the eyes is extremely painful and may result in permanent blindness. Inhalation causes irritation and coughing, hypersecretion, and pulmonary edema.

Treatment for exposure to a vesicant agent

The only prophylaxis against these agents is butyl rubber gloves, boots and a respirator. The clothing of a victim must either be removed or decontaminated with Fuller's earth powder. Eyes can be irrigated with water but, if available, 1.26% sodium bicarbonate solution or 0.9% saline should be used. Upon reaching a treatment facility, patients must have all their clothing removed if this has not already been done, and all the exposed areas must be cleansed with copious water lavage. Attendants should also be suitably protected and contaminated clothing must be placed in special bags.

Current treatment of vesicant agents centers around symptomatic relief. Itching can be treated with sedatives (benzodiazepines or phenothiazines), and antipruritic agents. Dimercaprol (British antilewisite), a chelating agent, is a specific antidote for lewisite poisoning. It is of note that it is incompatible with silver sulfadiazine. It is available as an ointment for skin lesions, as drops for eye applications (5–10% in oil), and in an intramuscular preparation for systemic toxicity. Other chelating agents are:

- DMSA – mesodimercaptosuccinic acid,
- DMPS – 2,3-dimercapto-1 propanesulfonic acid sodium, and
- DMPA – N-(2,3-dimercaptopropyl) phthalamidic acid.

These have a higher therapeutic index, are water soluble, and are effective orally. There is no specific antidote to mustard poisoning and no pretreatments or treatments exist that provide practical or effective protection against mustard toxicity.³⁹

There are also no standardized methods for the treatment of mustard injury. For patients experiencing cutaneous injuries, erythema requiring more than 5% TBSA in non-critical areas (face, hands, perineum) require hospitalization. The systemic fluid derangement is less than that seen with thermal burns; however, patients should be carefully monitored. Fluid requirements in Iranian casualties during the Iran–Iraq war appeared to have been relatively independent of TBSA.

Blisters should be deroofed and dressed with topical antimicrobials. The mustard blister fluid is harmless.⁴⁰

Favorable outcomes have now been demonstrated in the pig model by use of various debriding techniques and resurfacing with split-thickness skin grafts. Such methods have included laser,⁴¹ dermabrasion,⁴² sharp surgical excision,⁴³ and enzymatic debridement.⁴⁴

Proposed strategies for the development of improved therapies have been discussed in detail by Graham et al.⁴⁵

Affected eyes should be irrigated, treated with antibiotics, and inspected at the earliest time by an ophthalmologist. Respiratory injury requires symptomatic treatment according to its severity. Inhalation of high-dose steroids is controversial at present. Severe exposure will lead to agranulocytosis or aplastic anemia.⁴⁶ The pancytopenia seen after 7 days with the Iranian casualties did not appear to be helped by transfusion of relevant blood products. Bone marrow transplantation may prove useful, although of little practical value with large numbers of casualties. The effect of bone marrow stimulants such as oxymethalone and lithium carbonate is unknown but may be considered. Fluid replacement may be carried out dynamically with adequate cardiovascular monitoring. The maximum fluid loss occurs during blister formation and not necessarily in the first 24 hours.

Long-term effects of acute exposure

Individuals who sustain mustard injury may experience difficulties even after the initial effects of the injury have subsided. Destruction of melanocytes leaves hypopigmented areas, otherwise hyperpigmentation tends to predominate. Acute and severe exposure can also lead to chronic skin ulceration, scar formation and the development of skin cancer.

Recurrent or persistent corneal ulceration can occur after latent periods of 10–25 years. Chronic conjunctivitis and corneal clouding may accompany this delayed keratopathy.⁴⁷

Clinical follow-ups on 200 Iranian soldiers who suffered injuries from mustard during the Iran–Iraq War indicate that about one third had experienced varied respiratory ailments, such as chronic bronchitis, asthma, recurrent pneumonia, bronchiectasis and even tracheobronchial stenosis, more than 2 years after exposure. Some 12% of all British soldiers exposed to mustard in World War I were awarded disability compensation for respiratory disorders believed to have been due to mustard exposures during combat.⁴⁸

Summary

The vesicant agents are perhaps poorly named since they have the ability to affect all epithelial surfaces, particularly the eyes and respiratory surfaces, and not just the skin. The most important vesicant is sulfur mustard, which acts as an alkylating agent, causing a series of clinical reactions ranging from

vesicles to severe skin necrosis. Systemic effects are seen with high doses and the combination of depressed bone marrow activity and respiratory involvement often proves fatal. There is no effective antidote, and treatment depends on prevention of contact and local therapy to achieve wound healing, which tends to be slow. There is no risk to the caregiver from the blister fluid which contains no active agent.

Mass burn casualties

Burn-injured patients should ideally be managed individually with treatment tailored to their personal needs. However with mass casualties, following monumental disasters, whether natural or otherwise, lack of experienced staff, paucity of equipment and insufficient time to perform all relevant tasks, may make this an impossible goal. Nevertheless, every medical facility should be prepared at a moment's notice to cope with such situations. The handling of mass casualties is not confined to hospitals and the success of medical support will depend on adequate planning. It is informative to consider past disasters where mass casualties have involved large numbers of burned patients.⁴⁹ These have fared badly over the last 30 years and have included the circus fires in Niteroi, Brazil⁵⁰ in 1961 and at Bangalore⁵¹ in 1981, and the camping ground explosion in 1978 at Los Alfaques⁵² where more than 400, 100, and 200 victims died, respectively. European disasters have been smaller but have included the Bradford Football Stand fire⁵³ in 1985, and the Ramstein Air Show disaster⁵⁴ in 1988. Clinical management must continue throughout the chain of evacuation and can be divided for descriptive purposes into that occurring at the site of injury, the receiving (trauma or accident and emergency) center and the specialist burns unit. At each site the overall management of large-scale burn disasters revolves around the three principles of triage, treatment and transport.

Principles of triage

Triage is the process by which casualties are sorted on the basis of treatment priorities. It must first facilitate the application of maneuvers that are lifesaving.⁵⁵ The ABCs of trauma management are carefully followed so that a patient with an airway or breathing problem takes priority over a patient with a circulatory disability. Remember, the overall severity of the injury is determined by the combined effect of different injuries. For instance, the priority of a 40% burn will be increased if there is an associated fracture which may contribute to overall fluid loss. In a mass casualty situation, the patient with the most severe injury or greatest threat to life is not necessarily the patient that receives first priority. Consideration must be given to likelihood of survival, to optimize available resources. Furthermore, if patients' needs exceed available resources (equipment and personnel) they may be given a lower priority for triage until the necessary resources are secured. It is important to note that the triage should be performed by the person with the greatest experience of the types of injuries expected.

Management

Clinical management must continue throughout the chain of evacuation and can be divided for descriptive purposes into

that occurring at the site of injury, the receiving (trauma or accident and emergency) center, and the specialist burns unit. At each site the overall management of large-scale burn disasters revolves around the three principles of triage, treatment and transport.

On site Triage

Casualties at the site of the accident are triaged according to:

- The general condition of each patient, the extent and depth of the burn injuries and a patient's ambulatory status.
- Availability of facilities and personnel in the adjacent hospitals.

All patients undergoing triage must be adequately labeled. This will enable them to be identified according to their group. Large colored labels that are waterproof should be attached to each victim. The label will denote the triage group, treatment, drugs administered, and time given. Cases can be graded as follows:⁵⁶

- A. Ambulant patients with less than 10% burns — wounds are dressed and treatment is continued as an outpatient unless there is a reason for admission, i.e. extremes of age, deep burns requiring surgery, areas requiring special nursing.
- B. 10–30% burns — after first aid these patients can be moved to distant hospitals initially, so as not to overload burn centers.
- C. Serious burns involving 30–50% TBSA — these patients may be saved by energetic measures and should be transferred immediately to specialist centers for optimum treatment of shock and respiratory problems.
- D. Patients with more than 50% TBSA burns, especially those with respiratory burns and the elderly, are unlikely to survive. These patients should be transferred to the nearest hospital but admitted to a separate ward.

In any disaster it is advisable to group similar injured casualties in the same installations. Certain hospitals near the disaster should be designated as 'burn centers' and all cases requiring immediate and intensive care should be sent to these institutions.

Treatment

At this level, treatment of casualties may be limited to maintenance of airway, management of respiratory problems, commencement of intravenous infusions, protection of the burn wound, and analgesia. Escharotomy should be carried out for full-thickness circumferential burns, and antitetanus prophylaxis given.

Transport

The transportation of the burned patient between the site of injury and the receiving hospital is known as primary transport. The initial call will reveal the location; the number of injuries; the approximate time of the incident. This information will aid in decisions regarding the personnel, vehicles, equipment, and protective clothing that must be sent. On arrival at the scene, vehicles must be parked where

they are out of danger and not blocking essential access or exits.

Most burn patients can be safely transported provided that they are properly stabilized and accompanied by competent medical personnel. The patient's physiology should be monitored throughout the journey.⁵⁷ Treatment including additional analgesia must be continued en route as necessary. Transfer itself can exacerbate the existing deleterious physiological changes. The parameters that should be monitored continually during transfer are listed in Box 43.1.

Accepting hospital

Triage

Cases greater than 70% TBSA probably will not survive in the mass casualty situation. They should be made comfortable with adequate analgesia and sedation if thought necessary. They should be treated after patients in the more salvageable groups (see above).

Treatment

Mass nuclear casualties have been dealt with previously. When supplies and facilities are overloaded, compromises will be necessary. These are:

- Plasma and blood products are reserved for cases with associated trauma. Electrolyte solutions are effective in uncomplicated burns for the first 24 hours.
- Local wound care. Exposure method may be useful in this situation.
- Grafting. Lack of operating space may be a problem. Patients whose wounds can be covered by a single grafting procedure take priority to allow early discharge.

With larger burns temporary biological cover may be necessary until space becomes available.

Away from the site of the disaster, opportunity is taken to carry out the 'secondary survey', a full examination from head to foot. A full history is recorded and an assessment of the extent of the burn and associated injuries is included. A respiratory evaluation based clinically, together with arterial blood gases and fiberoptic bronchoscopy (if practical), enables an early decision on whether patients require intubation and ventilation. This decision can be made by analysis of frequent arterial PO₂ measurements on a constant FiO₂ to detect early shunting. A pulse oximeter may provide a more practical substitute for arterial catheterization.

If the casualty is unconscious, attention must be paid to the possibility of associated head and neck injury, pneumothorax

and carbon monoxide poisoning.⁵⁸ The burn wounds are then cleaned with a mild antiseptic solution and debrided. The extent and depth of burns are then estimated, which, together with the weight of the patient, can be used to guide intravenous fluid resuscitation along well-established formulas. Success is measured by careful cardiovascular monitoring, aiming to produce a urine output in the range of 0.5 mL/kg/h in adults and 1.0 mL/kg/h in children.

Ideally each patient should have their fluid requirements calculated on an individual basis. However, when large numbers of casualties are involved, problems can occur in applying the standard formulas.⁵⁹ To obviate this problem the Burns Calculator has been developed⁶⁰ to assist non-experienced personnel to prescribe fluid to adults and children over the first 8 hours.

Transport

Transfer from the receiving hospital to the burns unit is known as secondary transport; it is established that full assessment and resuscitation before moving the patient is invaluable in preventing cardiovascular and respiratory disasters.^{61,62} A full examination may reveal other injuries, e.g. ruptured spleen, that could prove fatal if not diagnosed. Biochemical and hematological parameters are optimized. For example, abnormal potassium predisposes to arrhythmias. Equally, transferring a hypoxic patient increases the morbidity and mortality. Airway problems need managing definitively before transport. Any suggestion of airway involvement must alert the need for intubation. There is no place for intubated patients breathing spontaneously during transfer. Adequate analgesia, sedation, and muscle relaxation should be given so that pain, anxiety, or restlessness does not interfere with the clinical picture. Attention must be paid to the wound, the immobilization of fractures and need for escharotomy before transport is commenced. All the necessary drugs and equipment needed during transfer must be available. It is wise to assume that the journey time will be twice that normally encountered so that enough drugs and oxygen are available in case of delays. All documents, including drugs and fluids administered, must be taken with the patient. A contemporaneous record of events during the journey must be kept.

Tertiary referral center

At the burn center, the patient is reassessed. Physiological stabilization is obtained and those with lesser injuries may be transferred to peripheral hospitals with their treatment plan so as to reduce the strain on the facilities of the burn center. Similarly, cases found to require grafting at a later date can be sent back to the unit so that a two-way traffic is established. It is important that only those needing the tertiary center remain there. Transportation between tertiary referral centers is very similar to that already mentioned.⁶³

Summary

In mass casualty situations involving burns, local resources may not be able to cope with the large and unexpected number of victims. The system is therefore so stressed that treatment must be prioritized. Patients with the most urgent needs are given the earliest care. This may differ from non-mass casualty situations in that the most critically injured may be placed in

Box 43.1 Parameters to be monitored continually during patient transfer

- Respiratory rate and pattern
- Heart rhythm and rate
- Capillary refill time

- Level of consciousness
- Blood and fluid Loss
- Oxygen saturation
- Drugs and fluids administered

an expectant category, to allow resources to be distributed to as many victims as possible. The objective is to provide a protocol for assessment of injured patients, and transportation to appropriate hospital facilities.

Conclusion

Planning for mass casualties is important. Well-trained personnel, preset protocols, specialized transport, and adequate supplies of documents, drugs and equipment will ensure

minimal mortality and proper use of facilities. Paradoxically, the threat of chemical and thermonuclear injury is heightened by the breakup of the Soviet Union, producing a glut of weapons specialists on the world employment market. Also small chemical industries can produce dangerous chemicals with ease and minimal cost. Healthcare workers serving a civilian population or military force have the obligation to learn the basics of management of radiation and chemical injury to achieve the greatest good for the greatest number of injured.

Severe exfoliative disorders	554
Skin and soft-tissue infections	561
Conclusion	563

Introduction

Acute, severe exfoliative, and necrotizing diseases of skin and underlying structures may cause significant morbidity in the afflicted patient. The problems associated with these diseases, such as wound infection, sepsis, adequate nutrition, and pain, are similar to those seen in patients with major burns. Burn centers provide expertise in the treatment and management of critically ill patients with skin loss from all causes, not solely from thermal injury. This chapter describes the pathophysiological processes of severe exfoliative skin disorders, their diagnosis, and the specialized treatment offered by burn units.

Severe exfoliative disorders

Erythema multiforme minor (EM), Stevens–Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN) are severe exfoliative diseases of skin and mucous membranes. There is great controversy on the classification of these exfoliative skin disorders and the terminology is confusing. Erythema multiforme minor is characterized by skin lesions isolated to no more than one mucosal surface. Erythema multiforme major involves two of more mucous membranes and may affect internal organs with systemic symptoms. However, most authors consider erythema multiforme major, SJS, and TEN to be the same disease entity, differing only by the area of involved skin. In this classification, SJS is considered to affect less than 10% total body surface area (TBSA), whereas TEN covers greater than 30% TBSA, leaving a zone of overlap between 10 and 30% TBSA, which is referred to as SJS/TEN.^{1,2} The most common characteristics of these disease entities are defined in Table 44.1.^{3,4} The incidence of TEN is estimated at 0.4–1.2 cases per million persons per year. The incidence of SJS has been reported to be 1–7 cases per million persons per year.^{5–9} These exfoliative disorders occur in all age groups; however, the incidence is increased in the elderly and females.^{3,10–13} In addition, TEN is seen more often in patients with HIV infection¹⁴ and in bone

marrow transplant recipients.¹⁵ Mortality of TEN ranges from 25 to 80%. However, reports are variable and usually based only on small patient populations.^{16–18} Death may occur early in the course of the disease, with sepsis being the most frequent cause. *Pseudomonas aeruginosa* and *Staphylococcus aureus* are the predominant organisms involved.¹⁶ Pulmonary embolism and gastrointestinal hemorrhage are other causes of death.^{10,16} The prognosis of SJS/TEN is worse than that of a burn victim with the same extent of skin loss.¹⁶ Mortality is increased significantly in those patients at the extremes of age, and in relation to the percentage of denuded skin and serum urea nitrogen levels.^{16,19} SJS is associated with a mortality rate of 0–38%.^{11,20} Erythema multiforme rarely causes death.²⁰

Etiology

TEN and SJS both appear to be caused by immunological reactions to foreign antigens. TEN, as the more severe entity, has a much higher percentage associated with antecedent drug therapy. Drugs are implicated in 77–94% of cases of TEN.^{6,21} Antibacterials and antifungals (36%), anticonvulsants (24%), analgesics and nonsteroidal anti-inflammatory agents (38%), and even corticosteroids (14%) have been implicated.^{21,22} Attempts to identify drugs suspected of having caused exfoliative necrolysis by skin test and laboratory tests seldom have been rewarding.¹⁶ Upper respiratory tract infections, pharyngitis, otitis media, or viral illness are frequently reported.^{10–12,23–25} *Mycoplasma pneumoniae* and herpes viruses (cytomegalovirus, Epstein–Barr virus, herpes simplex, and varicella zoster) have been implicated in the cause of EM and SJS, but not TEN.^{11,26,27} It can be difficult to differentiate some prodromal symptoms as due to viral or other infectious agents, or due to the primary disease process. Recently, the incidence of HIV infection in patients with toxic epidermal necrolysis has risen.^{14,28} Whether this increase is due to their immunocompromised state or to the increased prescription of high-risk drugs, particularly sulfonamides, is debated. No history of drug ingestion or preceding illness may be noted in these patients. Many of these cases may actually suffer from lack of patient recall of current medication because of the severity of the underlying disease or the patient's age. Idiopathic cases, not related to drugs, accounted for only 3–4% of TEN.^{6,7}

Morphology/histopathology

An early skin biopsy is essential for diagnosis. Skin manifestations vary from patient to patient and with the age of the lesion (Figure 44.1). Skin lesions may evolve to different stages of development with recurrent attacks of EM in a single patient.²⁹

TABLE 44.1 CHARACTERISTICS OF ERYTHEMA MULTIFORME, SJS, AND TEN

	Erythema multiforme	Stevens–Johnson syndrome	Toxic epidermal necrolysis
Prodrome	Absent	High fever, malaise	High fever, malaise
Acute phase	4–8 days	4–8 days Sensation of skin burning or tenderness	Sudden onset, 1–2 days Sensation of skin burning or tenderness
Skin lesions	Symmetrical, primarily located on the extremities, some target lesions without blisters	Variable distribution, individual vesicles on an erythematous base <10% TBSA Nikolsky's positive	Diffuse generalized epidermal detachment, absence of target lesions, large confluent plaques >30% TBSA Nikolsky's positive
Mucosal involvement	Limited to one surface, usually oral	Severe, two or more surfaces involved	Severe, two or more surfaces involved
Histopathology	Dermoepidermal separation, mononuclear perivascular cell infiltrate, small areas of epidermal detachment associated with target lesions	Dermoepidermal separation, more intense dermal infiltrate, areas of epidermal detachment	Epidermal necrosis, dermoepidermal separation, minimal dermal inflammatory infiltrate, large areas of epidermal detachment
Recovery	1–4 weeks	1–6 weeks	1–6 weeks
Mortality	0%	0–38%	25–80%

Fig. 44.1 Toxic epidermal necrolysis (TEN) is characterized by massive sloughing of the epidermal tissue.

Advancing edges of the target lesions show scattered necrotic keratinocytes in the epidermis and only mild dermal inflammation. In older lesions and central zones of target lesions, the dusky appearance corresponds to areas of extensive keratinocyte necrosis, often with the formation of subepidermal bullae and dermoepidermal separation. The surrounding erythematous zone shows papillary dermal edema, vascular dilation with endothelial cell swelling, and perivascular mononuclear cell infiltrate.¹³ Extravasated erythrocytes may be seen in the surrounding papillary dermis. The reticular dermis is normal.

Epidermal and dermoepidermal suppressor/cytotoxic T-lymphocytes in addition to dermal infiltrates of helper T-lymphocytes have been demonstrated.^{30–32} Hertl has confirmed that these epidermal cells are cytotoxic T-cells.³³ Langerhans cells appear to be reduced in the epidermis, although numer-

ous dermal macrophages are observed.³⁴ A more intense dermal cell infiltrate is present in SJS, especially in postherpetic cases.^{26,30} Dendritic lymphoid cells are observed, opposed to damaged dermal macrophages and necrotic keratinocytes. Further, at the point where the cytoplasmic processes contact the keratinocyte, the plasma membrane of the keratinocyte is absent.³⁴ Aberrant expression of HLA-DR on keratinocytes has been observed, a phenomenon which has been observed in many other inflammatory skin disorders.^{31,35}

Immunofluorescence microscopy has demonstrated IgM and C3 along the dermoepidermal junction and dermal vessels in cases of postherpetic SJS and EM.^{26,30} There have been only two reports of basal cell immunofluorescence in TEN.^{34,36} The pathogenesis of TEN is not completely understood. Type IV delayed hypersensitivity reaction, type II cytotoxic reaction, keratinocyte cytotoxicity mediated by lymphocytes, drug-related nonimmunological mechanisms, and keratinocyte apoptosis mediated by receptors of the TNF superfamily are possible mechanisms which amplify predisposing factors of infection and genetic susceptibility.^{14,37–39} Positive patch tests in patients with TEN have been used to support the delayed hypersensitivity hypothesis.³² This view is somewhat at odds with the fact that HIV patients display increased frequency of TEN.^{14,40}

Suppression/cytotoxic T-cell infiltrates are observed in the epidermis in TEN^{32,34} and graft versus host disease.⁴¹ It is hypothesized that cytotoxic T-cells recognize drug metabolites which are complexed with the MHC-I molecule on the surface of keratinocytes, migrate into the epidermis, react with keratinocytes, and cause epidermal necrolysis. The occurrence of sicca syndromes in patients with TEN and graft versus host disease further supports the autoimmune theory.⁴² The observation of blebbing of the keratinocyte plasma membrane in TEN is considered a reliable morphological finding of cytotoxic T-lymphocyte cytotoxicity.³⁴ Further, the observation that

cyclophosphamide aids TEN patients supports this theory, as cyclophosphamide is known to inhibit cytotoxic T-lymphocyte activity.³⁴ Type II cytotoxic reactions involve the binding of either IgG or IgM antibodies to a cell-bound antigen. The antigen–antibody complex then activates the complement cascade and results in the cell destruction. This mechanism is not generally supported since nuclear fragmentation, common to keratinocytes of toxic epidermal necrolysis patients, is not a consequence of complement-mediated cytolysis.^{34,36,43} Keratinocyte apoptosis as the primary mechanism in the pathogenesis of TEN has been favored recently.³⁸ This event is thought to be mediated by ligand/receptor interaction of the tumor necrosis factor (TNF) superfamily (as TNF α /TNF receptor or FasL/Fas interaction).^{38,44} In SJS, keratinocyte DNA fragmentation has been found in about 90% of cases associated with dermal perforin-positive lymphocytes.³⁹ Nonimmunological mechanisms include keratinocyte injury by either drug, drug metabolite, or toxic products derived from a drug in the epidermis.^{14,28,45}

Clinical features

A prodromal phase of TEN/SJS is identified frequently and usually consists of low-grade fever, malaise, and cough, all of which may suggest a respiratory tract infection. These symptoms may precede any cutaneous manifestation by 1–21 days, but usually last for 2–3 days.^{2,11} Additionally, patients may present with conjunctivitis, sore throat, and generalized, tender erythema. This may evolve from morbilliform eruptions or discrete erythematous or purpuric macules.³⁷ Later, vesicles and large bullae emerge from areas of erythema. Patients may exhibit diffuse red erythema immediately followed by epidermolysis.¹⁶ On light digital pressure, the epidermis desquamates in sheets: Nikolsky's sign is positive (Figure 44.2). Generally, a lag period of 1–3 weeks is observed from initiation of drug until skin eruption, which may be shorter on reexposure of a previously sensitized individual.^{1,2}

Two or more areas of mucosa involvement are typical of SJS or TEN. Mucosal involvement precedes skin lesions by 1–3 days in one-third of cases.^{13,46} Several sites are usually affected, in the following order of frequency: oropharynx, ocular, genitalia, and anus. Most TEN patients have multiple mucosal lesions, and they generally persist longer than cutaneous lesions.¹⁶

Complications

Toxic epidermal necrolysis is frequently associated with serious complications. The skin re-epithelializes from the dermal elements without scarring. Some patients experience hemodynamic instability and shock, and secondary full-thickness necrosis of the skin may develop; however, abnormal pigmentation is common (Figure 44.3). Nail plates are frequently lost and nail regrowth may be abnormal or absent.¹³ Mucosal membrane erosions may result in cicatricial lesions causing phimosis in men and vaginal synechiae in women. Oropharyngeal involvement is common and often results in severe dysphagia⁴⁷ (Figure 44.4). Although mucocutaneous erosions are the most common features of TEN/SJS, the disease may present with multisystem involvement. The onset of intestinal symptoms generally occurs concurrently with the cutaneous lesions.⁴⁸ Epidermal and epithelial sloughing may extend into the gastro-

Fig. 44.2 (a–c) Nikolsky's sign. Epidermal separation induced by gentle pressure on the skin surface.

Fig. 44.3 One-year post-TEN, wounds are completely closed with minimum of residual scarring but with abnormal pigmentation.

Fig. 44.4 TEN patient demonstrating significant oropharyngeal involvement. (Arrows demonstrate membraneous conjunctivitis.)

intestinal mucosa, and may induce esophagitis with frequent subsequent stricture formation.⁴⁵ Gastrointestinal erosions macroscopically resemble ulcerative or pseudomembranous colitis and massive hemorrhage requiring resection has been reported.^{10,16,23} Intestinal involvement worsens the prognosis.^{16,48} Respiratory tract involvement occurs and is associated

Fig. 44.5 Ocular involvement in TEN is common and can lead to blindness. Early and aggressive ocular care must be initiated to prevent pseudomembranes.

with increased mortality.^{47,49} These complications include diffuse erythema to extensive confluent tracheal and bronchial erosion covered by fibrinous exudate.^{37,47} Epiglottal swelling, necessitating intubation, has been reported.⁴⁷ Desquamation of alveolar lining cells also has been reported and these patients require frequent tracheobronchial toilet.⁴⁸ Subclinical interstitial edema is often noticed and 30% of cases progress to frank pulmonary edema and respiratory decompensation.^{13,50} Bronchopneumonia was found to be the most frequent complication, occurring in 50% of patients.^{20,23,49} Pulmonary embolism is an important cause of death in patients with TEN.¹⁶ Renal manifestations like glomerulonephritis and acute tubular necrosis,⁵¹ as well as hepatitis and hepatocellular necrosis, have been described.^{13,37} Hypoalbuminemia, increased erythrocyte sedimentation rate, leukocytosis, thrombocytopenia, and normochromic and normocytic anemia are common.^{20,47} Leukopenia is a frequent and poor prognostic sign.^{12,13,16,23} This is due, in part, to depletion of the T-helper/inducer lymphocyte population (CD4+).⁵² Ocular sequelae are the most severe long-term complications and occur in half of the survivors. Pseudomembranous or membranous conjunctivitis resulting from coalesced fibrin and necrotic debris can lead to opacification, secondary infection, and blindness⁴ (Figure 44.5). Conjunctival scarring may result in lacrimal duct destruction, leading to reduced tear production and keratoconjunctivitis sicca, a Sjögren-like syndrome. Ectropion, entropion, trichiasis, and symblepharon can also occur.^{11,42}

Management

Toxic epidermal necrolysis is a life-threatening disease and such a patient is best managed in an intensive care burn unit where vigorous fluid resuscitation, nutritional support, wound care, physical therapy, and social services are provided routinely in a multidisciplinary team approach.^{10,12,17,18,23,24,37}

Surgical approach

Debridement of necrotic epidermis and coverage of the large wound surface with biological or synthetic dressings are essen-

tial.^{10,53–55} Sloughed epidermis should be removed in order to reduce bacterial growth and the risk for infection. The exposed and tender dermis should be covered. Debridement is best undertaken under general anesthesia as soon as diagnosis by histology is established. Blood loss associated with debridement is minimal, so over-resuscitation must be avoided. Synthetic dressings, such as Biobrane™, and biological dressings, such as homograft (cadaver allograft) and porcine xenograft skin, greatly reduce the pain, decrease fluid loss, promote healing, and reduce the risk of wound infection and sepsis (Figure 44.6).^{10,53–56} Biobrane™ is readily available as a commercial shelf product; however, in our own experience it is associated with increased local infection when covering greater than 40% TBSA wound areas (Figure 44.7). Porcine xenograft adheres well to the skin and is commercially available in large quantities.^{54,55} Homograft is more likely to become vascularized and therefore reduces the number of graft changes.^{10,57} However, this must be weighed against the potential poor cosmetic results of vascularized homograft (Figure 44.8). Grafted areas must be immobilized and protected from shear forces. In children, Steinmann pins to suspend extremities may be useful.⁵⁴ In both adults and children, continuous rotation or air fluidized (Clinitron) beds frequently are used.

Topical therapy

As separation occurs at the dermal–epidermal junction, varying depths of viable dermis remain. If this dermis can be protected from toxic detergents, desiccation, mechanical trauma, and wound infection, then rapid re-epithelialization by proliferation of basal keratinocytes from the skin appendages will occur.⁵³ However, bacterial proliferation on the unprotected wound surface with invasive infection leads to full-thickness skin necrosis. Hydrotherapy and topical antimicrobials provide debridement and infection control which should be initiated early in the course of the disease.^{11,25} Effective topical antimicrobial agents include silver sulfadiazine cream,²⁹ silver nitrate solution,^{13,23,25} chlorhexidine gluconate solution,¹³ and polymyxin-bacitracin ointment.¹¹ Silver sulfadiazine is widely used but may exacerbate the disease process

Fig. 44.6 As with many partial-thickness wounds, biological dressings do much to encourage re-epithelialization and reduce the pain associated with these wounds.

Fig. 44.7 Application of Biobrane™ to left upper extremity after debridement of TEN patient.

Fig. 44.8 Homograft vascularization occurring over a second-degree thermal injury, resulting in a poor cosmetic result.

due to its sulfonamide component. Additionally, an inhibitory effect on epithelialization and leukopenia requiring discontinuation has been observed. Silver nitrate solution does not contribute to the ongoing drug reaction, and epithelialization is not inhibited. However, silver nitrate solutions are hyponatremic, and thus associated with approximately 350 mmoles of sodium loss per day per meter square treated. Therefore, serum electrolytes and osmolarity must be carefully monitored. For patients with contaminated wounds due to delayed initiation of treatment, silver nitrate soaks can reduce contamination and prepare the wound for eventual biological dressing. Chlorhexidine gluconate and polymyxin ointment are effective against Gram-negative organisms, including *P. aeruginosa*, with low incidence of sensitivity. Moreover, chlorhexidine gluconate also shows bactericidal effects against Gram-positive organisms.

Immunomodulation therapy

As mentioned previously, the pathophysiology of TEN appears to be initiationally immunologic. Therefore it is logical to consider immunosuppressive therapy as an early treatment modality for TEN. The following sections will briefly review the literature with regards to use of corticosteroids, cyclosporine A, intravenous immunoglobins, and thalidomide.

Corticosteroid therapy

Corticosteroid treatment of toxic epidermal necrolysis has promoted much controversy. In regard to the delayed hypersensitivity reaction or antibody-dependent cytotoxicity theories of pathogenesis, corticosteroids would seem to be an appropriate form of medical therapy.^{37,58} However, the practice of administering continuous high-dose corticosteroid in an attempt to stop the progression of the disease is widely rejected.^{11–13,37,41,45,59,60} Rational assessment of the benefit of corticosteroids administration is not possible due to the lack of randomized, controlled, prospective trials. Many authors feel that steroids enhance the risk of sepsis,^{23,54} increase protein catabolism, delay wound healing,¹⁶ cause severe gastrointestinal bleeding,^{16,23} prolong hospitalization,⁶⁰ and increase mortality.^{12,23,61} Lyell states that the indication for the use of steroids in the treatment of toxic epidermal necrolysis is vague.⁴⁵

One study found no decrease in the progression of SJS with steroids, but instead found significant morbidity.⁶¹ In a prospective, although not randomized, study, increased survival (66%) was seen in matched patients who did not receive steroids compared to only 33% survival in those who did receive steroids.²³ Pediatric SJS patients treated with steroids had a longer hospital stay and a complication rate of 74% compared to 28% in those without steroids.⁶⁰ Another study demonstrated 80% mortality associated with steroid therapy, which was reduced to 20% when steroids were withheld.¹² In several studies, patients with antecedent glucocorticoid therapy before the onset of TEN showed no significant survival benefit,^{62,63} and corticosteroid use itself has been linked to an increased risk for developing TEN.²² Currently, the body of evidence suggests that the treatment of TEN with corticosteroids has no significant benefit and may in fact be detrimental.^{59,64} Therefore corticosteroids cannot be recommended in the treatment of TEN.

Cyclosporin A

Cyclosporin A is an agent that has the properties of both being a powerful immunosuppressant and antiapoptotic. The mechanism of action is inhibition of the synthesis of interleukin-2 by selective inhibition of calcineurin, thus arresting the proliferation of T helper cells. To date, there have been nine individual cases and one case series of the use of cyclosporin A in the treatment of TEN.⁶⁵ In the only case series, Arevalo et al. observed a significantly shorter time to disease arrest (24–36 hours) and time to re-epithelialization when compared to historical controls.⁶⁵ Although intriguing, the currently published studies do not have similar methodologies, varying with regards to the dosage administered, route of administration, and duration of therapy. Furthermore, cyclosporin A therapy has been associated with a septicemia rate of 55%.⁶⁴ Therefore; a well-performed prospective clinical trial is warranted prior to advocating the use of cyclosporin A in the treatment of TEN.

Intravenous immunoglobulin

It has been suggested that the Fas-Fas ligand interaction may be responsible for the apoptosis seen in TEN.⁶⁶ Through a series of experiments, Viard et al. observed, *in vitro*, that TEN patients expressed lytically active Fas ligand and that the action of this ligand could be blocked by both a monoclonal antibody and human immunoglobins.⁶⁷ These observations suggest that human immunoglobins may contain a Fas blocking antibody and therefore may be useful in the treatment of TEN. Unfortunately, clinical data are less impressive, with some case series suggesting a benefit while others demonstrate less encouraging results.^{66–70} As in the case with cyclosporin A, a controlled multicenter clinical trial is required prior to advocating the use of human immunoglobins routinely in the treatment of TEN.

Thalidomide

The primary mechanism in the pathogenesis of TEN is keratinocyte apoptosis. Accordingly, tumor necrosis factor A has been implicated in the pathogenesis of TEN. Thalidomide, a potent inhibitor of tumor necrosis factor A, would appear to be a logical therapeutic agent in the treatment of TEN. Unfortunately, Wolkenstein et al. had to prematurely terminate a randomized clinical trial of thalidomide versus placebo in the treatment of TEN due to excess mortality in the treatment group. Ten of 12 patients expired in the thalidomide group compared to 3 of 10 in the control group. The authors theorized that thalidomide may have paradoxically increased the production of tumor necrosis factor in the treatment group, a previously reported phenomenon of thalidomide administration. Therefore, thalidomide as a treatment for TEN should not be initiated, owing to the detrimental effects, but does demonstrate the usefulness of randomized, double-blinded, placebo-controlled clinical trials.

Until these treatment modalities have proven their efficacy in controlled trials, the gold standard of treatment for TEN patients consists of a multidisciplinary approach, such as used in severe burns, focusing on wound care, infection control, and prevention of complications. The specific requirements of these patients are best met in an intensive burn care unit, so

early referral to a burn center is strongly recommended. Guidelines for the transfer decision may rely on the referral criteria for severe burn injury established by the American Burn Association (see also algorithm in Figure 44.9). The multidisciplinary burn team for specialized treatment of patients with extensive skin loss with trained critical care physicians, surgeons, critical care nursing specialists, respiratory therapists, and physical and occupational therapists is able to provide the best acute care as well as early and adequate rehabilitation.

General management

Drugs suspected of having initiated the disease should be discontinued immediately. Administration of pain medication is of high priority and antipyretic agents may be required. The empirical use of broad-spectrum antibiotics may be necessary if neutropenia exists, as these patients are prone to septic complications. The white blood cell count generally returns to normal levels after 2–5 days. The cause of this immunosuppression is unclear; it may be part of the primary disease or a secondary event.⁵⁸ Neutropenia is the only complication in which ‘prophylactic’ antibiotics are indicated. Otherwise, systemic antibiotics only should be used for documented infections or suspected sepsis. Oral nystatin prevents intestinal overgrowth of *Candida* and decreases the risk of *Candida* sepsis.^{23,58} Frequent monitoring of urinary tract, respiratory tract, skin, and catheters allows early detection of systemic infection and identification of organisms.

Intravenous replacement of fluid losses through the exposed body surface is required. However, as patients do not develop the massive edema and fluid losses evident in burn patients, fluid resuscitation formulas commonly employed in the management of thermal injuries overestimate the actual need.^{13,37,53–55} Ringer’s lactate solution is given at a rate determined by close monitoring of the patient’s condition and urine output. Once wound coverage is accomplished, fluid requirements usually decrease. Central line placement should be avoided, if possible, to reduce the risk of infection and sepsis.

To further minimize this risk, lines should be placed in areas of uninvolved skin. Invasive devices are removed as soon as possible, and oral and nasogastric routes are utilized at earliest convenience. Environmental temperature should be raised to 30–32°C to reduce metabolic energy expenditure. Heat shield and infrared lamps are beneficial in patients’ rooms, bathrooms, and operating rooms.

Stress ulceration prophylaxis is advisable. Mouth erosion, resulting in severe dysphagia, can be alleviated by the use of viscous lidocaine or cocaine rinses, and thus ease oral administration of nutrients and fluids. Oral debris should be removed and the mouth sprayed with antiseptic several times a day.⁵⁹ Pulmonary involvement requires close supervision, with careful toileting including bronchoscopy, incentive spirometry, mobilization, and coughing to prevent infections and complications. If mechanical ventilatory support is necessary, the prevention of bronchopulmonary infection gains even more importance. Daily monitoring by blood assessment, including blood gas analysis, chest x-ray, and bacteriological culture, are required to initiate timely antibiotic therapy or ventilatory support. Measures to prevent thromboembolism, such as low-dose or low-molecular-weight administration of heparin, should be instituted on admission.

Ocular involvement should be assessed daily by an ophthalmologist. Conjunctival crusting can be minimized by the application of saline eye drops every hour. Any adhesions should be broken using a blunt instrument, and bland eye drops or ointment applied frequently.^{11,53} Documented ocular infections are treated with organism-specific antibiotic therapy. After recovery, special ophthalmological follow-up is needed to prevent and address ocular long-term sequelae. Lacrimal duct obstruction may be detected early by performing Schirmer’s test.^{11,59}

During hospitalization, patients with TEN and SJS may demonstrate limitations in mobility, decreased strength, postural and gait deviation, contractures, and impaired coordination. Therefore, patients should be treated and closely followed throughout the course of the disease by a physiotherapist.⁶⁴

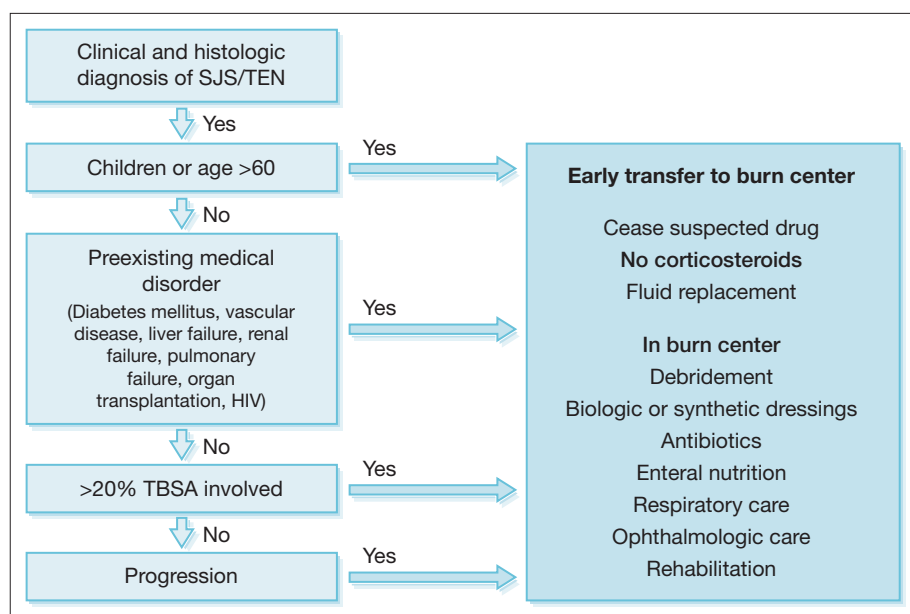

Fig. 44.9 Algorithm for management of SJS/TEN.

Nutritional support

Enteral nutrition should be started on admission. Due to the frequent presence of oral mucosal ulcerations, patients may be reluctant to take nutrition orally, and thus require a nasogastric tube placement. Unlike burned patients who have significantly elevated metabolic rate, these patients appear to have metabolic rates only slightly above basal requirements.^{53,58} Weight stabilization and a positive nitrogen balance have been achieved in adults with 2500kcal/day.⁵³ If gastrointestinal function becomes impaired or sepsis intervenes, requirements may increase. Total parenteral nutrition should be avoided, but initiated if enteral intolerance persists.

Skin and soft-tissue infections

Staphylococcal scalded skin syndrome, necrotizing fasciitis, and purpura fulminans are examples of a group of conditions characterized by extensive soft-tissue loss, rapid onset of critical illness, and death. Early, accurate diagnosis is essential to initiate appropriate action, such as extensive surgical excision in the case of necrotizing fasciitis or crepitant soft-tissue infections. Burn care centers with their acute and reconstructive capacities have much to offer these patients with extensive skin loss.

Staphylococcal scalded skin syndrome

Staphylococcal scalded skin syndrome is the severe condition caused by exfoliative staphylococcal toxins and is characterized by systemic signs and symptoms and generalized involvement of the skin (Figure 44.10). It is important to make a diagnosis early, particularly to differentiate it from TEN, which has a different management and much greater mortality. Staphylococcal scalded skin syndrome is predominantly a disease of infancy (Ritter's disease) and early childhood, with most cases occurring before the age of 5 years.⁷¹ Newborn nurseries are often the sites of outbreaks. Attendant staff may be infected or colonized with *Staphylococcus aureus* strains producing epidermolytic toxin, thus emphasizing the importance of standard hygienic measures. Adult staphylococcal scalded skin syndrome is rare and usually associated with compromised renal function. Mortality is generally only 4%, but can be much higher in adults (40%) depending on underlying diseases.^{71,72}

Two distinct epidermolytic toxins (ETA and ETB), are responsible for the blistering in staphylococcal scalded skin syndrome.⁴⁵ ETA is heat-stabile, whereas ETB is heat-labile and encoded by a bacterial plasmid. Most toxigenic strains of *S. aureus* are identified as group 2 phage.⁷³ The exfoliative toxin is metabolized and excreted by the kidneys, leading to a predisposition of patients with renal immaturity (children) or renal compromise. The exfoliative toxins produce blistering by disrupting the epidermal granular cell layers through interdesmosomal splittings but without epidermal necrosis and with very few inflammatory cells. The exact mechanism of action of the toxins has not been determined, although it is felt that the toxins directly affect desmosomes. One might be proteolytic disruption of desmosomes with the toxin or part of its sequence acting as a serine protease.^{71,74,75}

Diagnosis of staphylococcal scalded skin syndrome can be made rapidly with a skin biopsy. The characteristic intraepi-

Fig. 44.10 Staphylococcal scalded skin syndrome is characterized by diffuse, erythematous lesions with bullae formation (see left forearm). Epidermis is shed in sheets with minimal abrasion. The wounds are partial-thickness and heal without surgical intervention.

dermal level of splitting is seen, with the split occurring at the granular layer level (stratum granulosum) with no epidermal necrosis or inflammatory cells in the corium.⁷³ Immunofluorescent studies of the skin are negative.⁷³ A Tzanck preparation from a scraping of the base of a freshly denuded area will reveal the affected cell population, i.e. acanthocytic keratinocytes.⁷³ Bullae, denuded skin and blood are usually sterile, however, and staphylococci can usually be cultured from nares, conjunctiva, or pharynx.⁷⁶

Management

Onset may be marked by fever, malaise, and irritability. Scarletiform erythema is often accentuated in flexural and periorificial areas.⁷¹ The skin is generally tender to touch, and sheets of skin may peel away in response to minor trauma (Nikolsky's sign). Blisters appear within 24–48 hours of rupture, leaving a characteristic moist erythematous epidermal base. Severe mucosal involvement is not a typical feature. With diagnosis antibiotics should be started, and semisynthetic penicillinase-resistant penicillin analogs are indicated (e.g. methicillin or oxacillin), since the majority of group 2 staphylococci show resistance to penicillin. Administration of steroids to these patients is contraindicated.⁷³ After screening for colonization, decontamination of colonized areas, especially the nasopharyngeal region in patients and nursing staff, may be advisable to prevent further spread. Fluid resuscitation is usually required at a lesser volume compared to a burn patient with a similar involved body surface area. Fluid substitution should be guided by urine output, hemodynamic parameters, electrolyte, and colloid status.

Until skin barrier function is restored, patients should receive appropriate wound dressings to prevent secondary wound infection. Topical agents are soothing and bacteriostatic. It needs to be pointed out that the wound initially is not colonized or infected, so alternatively, large areas can be more effectively managed with biological or synthetic dressings. They have the advantage of eliminating the need for frequent

dressing changes which can be particularly traumatic for young children. Mortality usually is low, but may occur in very young and adult patients, usually from sepsis or electrolyte imbalance on the basis of underlying disease.⁷³ Complete wound healing is usually observed within 7 days, and scarring and altered pigmentation are not common.

Necrotizing fasciitis and bacterial myonecrosis

Necrotizing fasciitis is a soft-tissue infection which is characterized by widespread necrosis of fascia and subcutaneous tissue which may progress to muscle and skin necrosis. Overall mortality may still be as high as 50%.^{72,77} Most cases of necrotizing fasciitis are due to polymicrobial infection including both anaerobic Gram-positive cocci and Gram-negative bacilli.⁷⁷ *Streptococcus*, *Staphylococcus*, *Enterococcus*, and *Bacteroides* are commonly found. Infection with many bacterial species may result in bacterial myonecrosis. However, gas gangrene by *Clostridia* spp. results in severe systemic toxicity and higher mortality than necrotizing fasciitis. A deep contaminated wound frequently precedes the severe soft-tissue infection. Streptococcal myositis has a mortality rate of between 80 and 100%.⁷⁸ Risk factors for both necrotizing fasciitis and bacterial myonecrosis have been identified as diabetes mellitus, intravenous drug use, age greater than 50 years, hypertension, and malnutrition/obesity. The presence of three or more of these risk factors was found to give a predictive mortality rate of 50%⁷⁹ (see Figure 44.11).

Diagnosis

Early diagnosis is of extreme importance and consequence. Initial presentation is deceptive as the findings may be localized pain and edema without discoloration of the skin. Later, induration and erythema may be evident. Paresthesia of overlying skin and eventual dusky discoloration and local blistering may occur in the later course. Severe toxemia may develop, usually out of proportion to the local signs. Severe systemic alterations are characteristic of myonecrosis. Gas inclusion may be evident in subcutaneous tissues on x-ray. CT and MRI may help in the diagnosis and provide information on the nature and extent of the infection.⁸⁰ Frozen section biopsies may provide early histological evidence of infection.⁸¹ Gram stains and microbiological testing are very important diagnostic tools and guide antibiotic treatment. However, a definite distinction between necrotizing fasciitis, myonecrosis, and other soft-tissue infections often can only be established during surgery.

Management

The key to successful management of necrotizing infections is early diagnosis and radical surgical intervention. Surgical exploration involves complete excision of all necrotic tissues. If more than one operation for debridement of infected necrotic tissue is needed, mortality increases from 43 to 71%; this outcome drastically highlights the importance of adequate initial necrosectomy.⁸² In patients with many risk factors, early amputation of the extremity, especially in cases of myonecro-

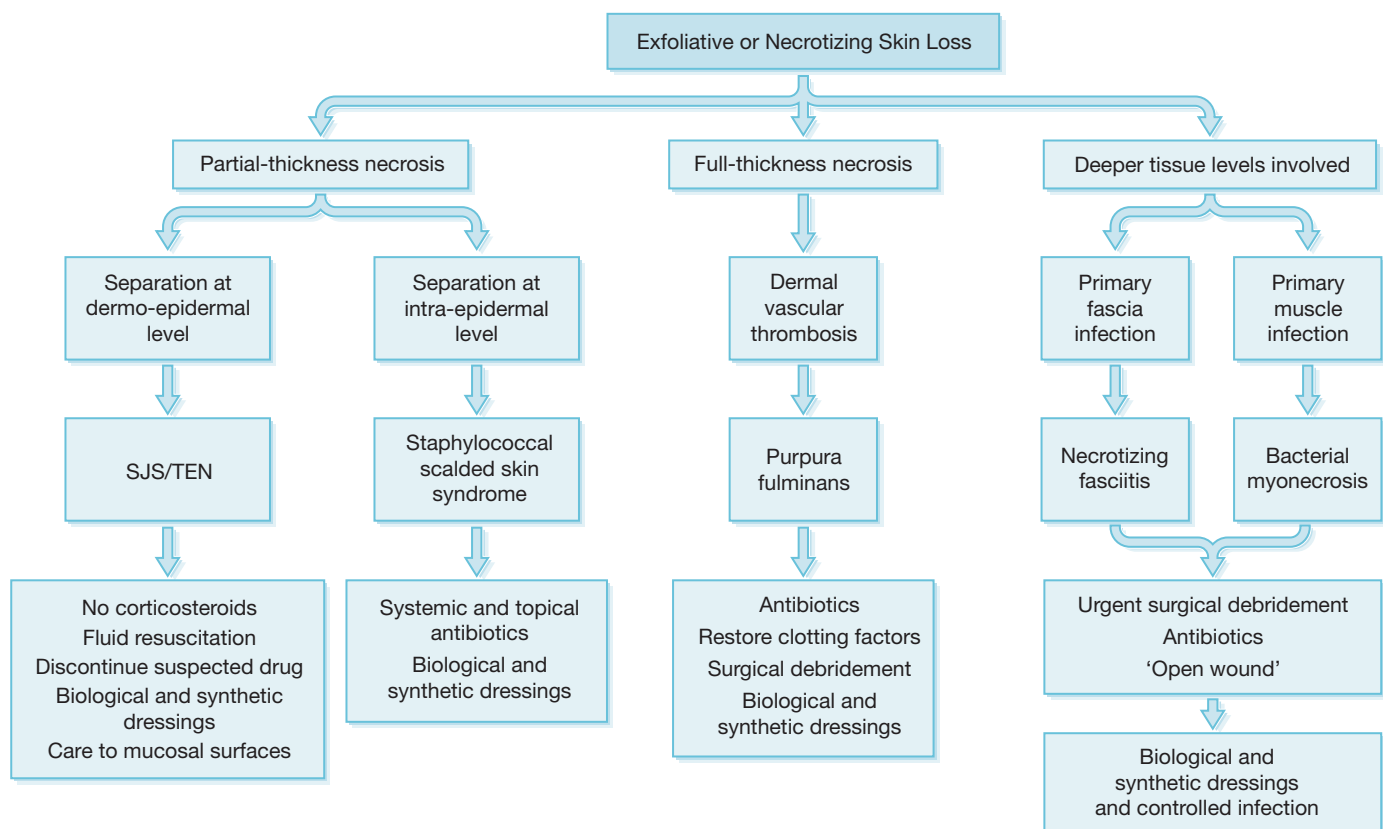

Fig. 44.11 Flowchart of management of exfoliative and necrotizing conditions of the integument.

sis, should be considered. Broad-spectrum antibiotics are started preoperatively, although high-dose penicillin is appropriate for clostridial infections. However, antibiotic treatment is no substitution for surgical intervention. Adequate fluid resuscitation and nutritional support are also required. Wounds are packed open with antiseptic-soaked dressings, which need to be changed frequently. Kaiser and Cerra have reported unsatisfactory results with either early application of porcine xenografts or burn wound topical antimicrobials.⁸³ Complete control of local and systemic infection is required before wound closure is addressed.

As in burns, secondary infections must be prevented by proper wound management, Biological or synthetic dressings offer the advantages of decreased pain, decreased fluid loss, and prevention of secondary infection. Frequently, large areas of skin and soft-tissue loss result from this disease and will eventually require extensive surgery to achieve adequate closure. Some authors advocate the use of hyperbaric oxygen and claim that it results in decreased mortality and reduced need for debridement; however, most of these reports are case reports or uncontrolled trials and adequate prospective controlled trials in patients are still lacking.^{84,85} In animals, hyperbaric oxygen therapy alone did not improve survival or bacterial colonization, but did show adjuvant effects to antibiotic treatment.⁸⁶ In summary, hyperbaric oxygen therapy, if available, should not delay radical surgical debridement and should be used as an adjunct to radical surgery and antibiotic therapy.^{85,87}

Purpura fulminans

Purpura fulminans is a term that describes an acute syndrome of rapidly progressive hemorrhagic necrosis of the skin due to dermal vascular thrombosis associated with vascular collapse and disseminated intravascular coagulation (DIC).⁸⁸ It may occur in individuals with dysfunction of the protein C anticoagulant system, with acute severe infection, or idiopathically without any coagulation dysfunction or infection.

It has been associated with systemic infection by *Meningococcus*, Gram-negative bacilli, *Staphylococcus*, *Streptococcus*,

and *Rickettsia* organisms. Skin necrosis begins in a region of dermal discomfort, which rapidly progresses to evanescent flush, followed by petechiae. Hemorrhagic bullae progress to frank skin necrosis. The process generally involves the skin and subcutaneous tissues, without involvement of muscle. Skin involvement is frequently an early manifestation of the disease process. Skin biopsy will, therefore, allow an earlier diagnosis.⁸⁸ Mortality in the acute phase is 18–40%.⁸⁹

Management is directed at halting progression of the underlying infectious disease, preventing secondary infections, and removing non-viable tissue. Early heparin administration and replacement of clotting factors have proven useful to stop intravascular clotting.⁸⁹ Shock from blood extravasation and sepsis require extensive volume replacement. Limb vascular and compartmental pressure should be monitored closely to enable early escharotomy and/or fasciotomy, when needed. Skin lesions resulting only in blisters should be treated with topical antimicrobials (e.g. silver sulfadiazine) to prevent secondary infection. Non-viable tissue should be removed as soon as the patient's condition allows. Small areas can be covered with autografts but, as large areas are frequently involved, allograft or xenograft skin coverage may be required. Limb amputations may be frequently required due to vascular compromise, as well as revisions for progression of disease.⁹⁰ Isolation of the affected patient, as well as monitoring and prophylactic treatment of patients and staff, may be necessary to prevent further spread and outbreaks of the disease, especially in case of meningococcal infection.

Conclusion

Inflammatory and infectious conditions of the skin and underlying tissues represent a major diagnostic and therapeutic challenge. The team approach to their care is essential, and wound management is paramount. Burn units are ideally suited to deal with patients with these conditions and should be considered as the appropriate site of referral for these critically ill patients.

The burn autopsy	575

Introduction

'Burns are not a simple injury, but a very complicated disease.' This statement, published by J Long in 1840 and cited by Dr Linares in the first edition of this book, holds true with additional force in 2006.¹ Massive destruction of viable tissue, which occurs in burn injury, and injury to the airways by inhalation of toxic products of combustion, stimulate complex reactions which are only beginning to be understood. Burn injury is frequently complicated by malfunction of every organ system. The nature of this malfunction is often clarified by examination of the body after death. Postmortem examination also has the potential to reveal adverse effects of therapy, which might not be clear during life. An important example of this is that the treatment of burned skin with tannic acid was popular until degeneration of the liver was described in autopsies of burned patients treated with tannic acid. The causative link was later confirmed experimentally.² In addition, every death after burn injury has medicolegal implications. Postmortem examination often contributes substantial evidence in this regard. The process of analysis of an entire case from the point of view of pathogenesis often clarifies the nature of the patient's most significant problems. This chapter systematically reviews the observations made at autopsy in patients who have died after burn injury. Where possible, hypothetical interpretations of the mechanisms of disease are suggested. Often the interpretation includes comparison of autopsy findings with results of animal experiments. To quote

Dr Linares on this method, 'Pathology combines anatomy, physiology, and theories of disease, and it is a point of convergence for medicine and the biological disciplines.' The observations reviewed here include our experience of approximately 300 autopsies performed on burned children at the Shriners Burns Hospital in Galveston from 1966 to the present.

To introduce the sections that follow, the major medical problems that complicate burn injury are summarized here. The degree of disruption of normal physiological processes after burn injury is extreme. Immediately after burn injury, massive loss of intravascular fluid into the burned tissue begins to occur.^{3,4} Unless this fluid loss is replaced by the physician very promptly and carefully, serious *hypovolemia* develops.⁵⁻⁷ The consequences of hypovolemia often include the death of neurons in the brain, focal necrosis of the intestinal epithelium, and necrosis of the proximal tubules of the kidneys. The neural and endocrine responses to the traumatic injury may lead to recognizable lesions in the stomach and in the heart. Thermal injury to skeletal muscle, or lack of perfusion of muscle, may lead to local exudation of fluid and development of such high pressure in muscle compartments that arterial perfusion is prevented. This 'compartment syndrome,' unless relieved by prompt surgical intervention, leads to necrosis of muscle throughout the compartment.⁸ The consequences of massive necrosis of muscle often include secondary injury to the lungs, due to release of reactive oxygen species, and myoglobinuria, with secondary renal damage.⁹ At the time of injury, patients frequently inhale sufficient carbon monoxide to compromise the oxygen-carrying capacity of the blood. The resultant tissue *hypoxia* can cause death at the scene, and if the patient survives, it can be sufficient to lead to irreversible neuronal injury and brain death. Hypoxia, sometimes related to carbon monoxide intoxication, also contributes to cardiac and renal injury. In addition, when fires occur in closed spaces, the 'flashover' process consumes all available oxygen, so that the patient's environment may contain too little oxygen to sustain life. Occasionally a burn victim is found without pulse or respiratory effort, probably as a consequence of hypoxia, and is revived by cardiopulmonary resuscitation. In such cases ischemic and hypoxic injury may be profound in multiple organs, and there may be significant 'ischemia/reperfusion injury' to the lungs after resuscitation. Patients injured in house fires often suffer injury to the respiratory tract caused by inhalation of toxic products of combustion.¹⁰ This *smoke inhalation* injury stimulates an intense inflammatory reaction, which can lead to obstruction of airways and further tissue injury. This problem is discussed below in the section on the

respiratory system. *Infection* is the next major risk experienced by patients after burn injury. Necrotic skin provides an excellent environment for proliferation of bacteria and fungi, and as long as necrotic tissue remains, the risk of infection remains high. Injury to the intestinal epithelium by hypoxia or ischemia leads to translocation of intestinal bacteria into the portal circulation. In addition, patients all experience substantial immunosuppression, partly as a result of excessive secretion of endogenous glucocorticoids and release of cytokines into the circulation, which leads to ineffective host defense. *Coagulopathy* may be a very serious complication of burn injury. It may lead directly to tissue ischemia, or the resultant hemorrhage may lead to secondary hypovolemia. Patients often require transfusion of very large quantities of blood products during their treatment.

Disease processes involving multiple organ systems

Hypoxia and ischemia

All cells require a constant supply of oxygen and metabolic substrates, such as glucose, to remain viable. This is largely because animal cells exist in a state of dynamic equilibrium that requires membrane transport to maintain integrity. In hypoxia, when the supply of oxygen is insufficient, cells generate a limited amount of metabolic energy by anaerobic glycolysis, releasing lactic acid. With ischemia, when the flow of blood is insufficient, this metabolic perturbation is complicated by a lack of supply of glucose and other fuels, and the extracellular fluid composition may change dramatically. Tissues vary greatly in their sensitivity to injury by hypoxia or ischemia. In general, tissues with the greatest metabolic activity are the first to lose viability under conditions of hypoxia and ischemia. These tissues include the neurons of the central nervous system, the myocytes of the heart, the epithelial cells of the small intestine, and the proximal tubular cells of the kidney. The location and extent of necrosis in these organs depends on the severity and duration of the ischemic or hypoxic injury.

After ischemia and hypoxia have led to irreversible injury and death of selected cell types or whole segments of organs (infarcts), responses are initiated that may lead to further injury of remote organs. Cellular necrosis stimulates an intense acute inflammatory reaction, probably initiated by activation of the complement cascade, degranulation of mast cells, and other processes. This reaction surrounds an infarct, or proceeds throughout a region of tissue injury if the local circulation is sufficient. Monocytes recruited to the regions of injury secrete cytokines in large quantities, and polymorphonuclear neutrophils activate their antibacterial mechanisms. Cytokines have effects throughout the body, and superoxide released by neutrophils has important distant effects. In addition, in endothelial cells injured by hypoxia, the enzyme xanthine dehydrogenase is converted to xanthine oxidase, which releases superoxide during degradation of adenosine, which in turn is released by necrotic cells.^{11,12} Superoxide, released into the circulation by this metabolic process and by neutrophils, can injure the lung by damaging both endothelial and epithelial cells and allowing protein-rich fluid to exude into alveoli. The inflammatory reac-

tion to thermal tissue injury also stimulates an intense influx of neutrophils, which undoubtedly contributes to this injury by releasing superoxide. In experimental models of burn injury, as well as in models of ischemia–reperfusion injury, the lungs have been shown to be injured by these processes.¹³ Endogenous antioxidants such as glutathione are depleted, and conjugated dienes appear, indicating that cell membrane injury due to lipid peroxidation has occurred in the lung.¹⁴

Infection and sepsis

The skin normally provides a highly effective barrier against invasion of tissues by infectious agents. Necrotic tissue provides an excellent culture medium, and the body surface is inevitably exposed to multiple potential pathogens. Patients who are treated for deep burn injury with traditional debridement and washing for several days generally arrive at this institution with large quantities of multiple microorganisms growing in the necrotic skin. The bacteria appear to proliferate initially in areas that have insufficient circulation to develop a significant inflammatory response. As large numbers of bacteria accumulate, those with high pathogenic capacity invade the adjacent viable tissue, produce further necrosis, and gain access to the circulation. This is the condition of burn wound sepsis, which historically has been the leading cause of death in burn patients. In Dr Linares' published series of 115 autopsies, sepsis was present in 73%, as documented by positive blood cultures and demonstration of invasive infection of viable tissue.^{15,16} In 80% of these fatal cases of sepsis, the burn wound was the source of the infection. The pathogens that were most important were *Pseudomonas aeruginosa*, *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Escherichia coli*, *Enterobacter*, and *Candida* species. Burn wound sepsis is suspected clinically when a burn wound is the site of proliferating microorganisms exceeding 10⁵/g of tissue, and there is histological evidence of active invasion of subjacent unburned tissue.¹⁷ In our institution, the wounds of burn patients, especially the open areas, are routinely sampled for quantitative culture and for histological study when excision and grafting procedures are done, and whenever clinical examination suggests the possibility of tissue infection. The histological classification used and its rationale are discussed below under the integumentary system. Once septicemia occurs, there is a generalized reaction that often includes hypotension, tachycardia, increased hyperthermia or hypothermia, and poor perfusion of the intestines and other viscera.¹⁸ In the case of Gram-negative bacteria, endotoxin stimulates monocytes via their CD14 receptors to become activated and set up a cascade of release of proinflammatory and anti-inflammatory mediators that affect all organs and tissues in the body.^{19–21} Coagulopathy is another important complication of sepsis.²² Once bacteria gain entrance to the general circulation, it becomes possible for foci of tissue infection to develop at distant sites. This is most likely to occur in sites of tissue necrosis or on cardiac valves, or in the lungs. Abscesses in distant organs can allow the infection to resist eradication by specific antibiotics, and thus allow sepsis to develop again after initially effective therapy. The risk of infection is proportional to the severity of the burn, the time before the initiation of fluid therapy, the presence of metabolic alterations, the development of immunological deficiency, the concurrence of trauma, the local evolution of wounds, and the age of a patient.

An infection may begin in a burn wound, the respiratory system, the gastrointestinal tract, the urinary tract, the blood vessels, or from localized infection in any other area of the body. Although most serious infections in burn patients appear to be due to endogenous flora, and many derive from wound infections present at the time of admission, nosocomial infection is a constant hazard.^{23,24}

The problem of burn wound sepsis is amenable to therapy. The strategy of excision of the potentially infected burn wound as early as possible, together with judicious administration of effective antibiotics, has greatly reduced the number of deaths due to infection. Coincident with the institution of early excision and grafting of burn patients in our institution, the incidence of burn wound sepsis as a cause of death declined dramatically.²⁵ The problem of sepsis has not disappeared, however. Certain organisms can evade the best current efforts at management, and have caused death in recent cases, including bacteria resistant to nearly all available antibiotics, and invasive fungi. Those patients who are referred for therapy more than 1 week after burn injury often have extensive invasive wound infection and sepsis, which may be difficult or impossible to eradicate.

Coagulopathy

The burn wound has procoagulant effects, and may induce coagulation throughout the circulation (DIC, disseminated intravascular coagulation).^{26,27} Tissue necrosis, particularly lethal injury to endothelial cells, with exposure of subendothelial collagen, and release of tissue thromboplastin, can activate coagulation and lead to coagulopathy. Generation of thrombin within the circulation not only leads to generation of fibrin peptides but also stimulates acute inflammatory reactions including increased vascular permeability and upregulation of adhesion molecules on neutrophils and endothelial cells.²⁸ Generation of fibrin degradation products may be sufficient to interfere with normal thrombosis, and thrombocytopenia can develop in response to abnormal intravascular fibrin generation.²⁹ Activation of the kinin system can stimulate further abnormal vascular permeability and hypotension.²¹ Consumption of coagulation factors can lead to abnormal bleeding, which can cause extensive tissue injury secondarily. It is important to note that the acute phase response to burn injury includes increased synthesis of fibrinogen and factor VIII. During the first 3–10 days after burn injury, patients often have greater than normal clotting activity. This may increase their susceptibility to development of DIC, especially if sepsis supervenes. It also implies that laboratory testing of levels of fibrinogen and factor VIII may yield normal values even in the presence of abnormal consumption of these factors. When disseminated intravascular coagulation occurs in the patient's terminal course, as was the case in a majority of the autopsies reviewed by Dr Linares, microscopic fibrin thrombi are seen in many organs at the time of autopsy. These microthrombi are seen most commonly in the lungs, the skin, the kidneys, and the gastrointestinal tract.^{15,30}

Integumentary system

The skin is the site of initial injury in burn patients, and many of the events that lead to dysfunction or failure of other organs

begin in the skin. Thermal injury rapidly produces irreversible injury and cell death in epidermal keratinocytes, in the epidermal appendages including hair follicles and their attached sebaceous glands and sweat glands, and in the connective tissue cells of the dermis. In many cases, the burn wound excised within 48 hours of injury shows that the entire dermis and all of the hair follicles are necrotic, but that much of the subcutaneous adipose tissue remains viable. It appears that the greater insulating capacity of adipose tissue protects it to some extent. In some cases, of course, necrosis due to the initial thermal injury may extend deep into the subcutaneous tissue. In extreme cases, the underlying skeletal muscle may become necrotic as a result of thermal injury. Necrosis of skeletal muscle is especially prominent in some cases of electrical injury, in which more heat may be generated adjacent to bone than near the body surface. An interesting observation is that there is often a band-like infiltrate of degenerating polymorphonuclear neutrophils in the midst of a totally necrotic dermis. This suggests that the boundary between necrotic and viable tissue may have extended deeper after the initial burn injury and its inflammatory response. There is experimental evidence that burn wounds often evolve from an initial level of necrosis to a deeper level of necrosis, even from second to third degree, as a result of poor perfusion of the tissue immediately deep to the initial burn injury.³¹ This process of vascular stasis deep to the burn is undoubtedly due in part to the rapid loss of intravascular fluid from the damaged capillaries and venules just below the necrotic burn wound. In addition, there is evidence that neutrophils contribute to this process of burn wound extension, most likely by adhering to endothelium and to each other, with resulting obstruction of the microvasculature.³²

It is important to assess the presence and extent of infection within the burn wound, both in the excised wound during therapeutic procedures, and by biopsy of suspicious areas in open foci after grafting procedures. A high index of suspicion serves the burn patient well. Biopsy and excision specimens in our institution are routinely sampled and studied histologically with stains for bacteria (Brown and Hopps) and fungi (methenamine silver). Within large excision specimens, samples are taken from sites of especially deep tissue injury and sites that show abnormal discoloration of dermal or subcutaneous tissue. When infectious microorganisms are found, it is important to determine their location with respect to the boundary between living and necrotic tissue. This boundary may be irregular. It is generally distinct and marked by inflammation in wounds several days old, but may be indistinct in very fresh specimens, as karyolysis takes several days to develop in burn wounds. As noted above, wound infections generally begin with colonization of the skin surface and proliferation of organisms on the surface, often with extension into hair follicles, followed by growth within the necrotic tissue. Both the coagulum on the surface and the necrotic epidermis and dermis are considered part of the burn eschar. Growth within necrotic tissue is considered evidence of tissue infection, however, and potentially more dangerous than growth on the surface of necrotic skin. Even when quantitative cultures show more than 10^5 bacteria per gram of tissue, when careful histological study shows that the organisms are limited to the skin surface or the superficial necrotic tissue, the risk

of sepsis appears to be low. Such growth on or in necrotic tissue, however, does set the stage for invasion of viable tissue. The finding of clusters of bacteria or fungi within viable tissue does imply a serious risk of sepsis and further tissue invasion. As a rule, bacterial invasion of viable tissue is readily apparent by histological study of appropriate tissue samples, and often includes a zone of tissue necrosis surrounded by intact tissue (Figure 45.1a). Invasive fungal infection presents a somewhat different pattern, in that there is often a wavefront of necrosis that accompanies fungal invasion. Thus fungal infection that extends to a boundary between necrotic and viable tissue is considered evidence of fungal invasion of viable tissue (Figure 45.1b). On this basis, infections identified within burn wounds are reported as surface colonization, invasion of necrotic tissue, which may be superficial or deep, and invasion of viable

Fig. 45.1 (a) This micrograph of Gram-stained tissue shows a dense aggregate of filamentous Gram-negative rods in the wall of a vein in the chest skin of a patient who presented with severe wound infection due to *Pseudomonas aeruginosa*. (b) This micrograph of tissue stained with the periodic acid Schiff stain (PAS) shows a portion of a burn wound of the skin in a patient who presented with focal fungal invasion of viable tissue. Branching fungal hyphae extend near the border of the viable tissue.

tissue. The responsible surgeon is called immediately when invasion of viable tissue is found. If the level of clinical suspicion is especially high, frozen sections have been found useful for this determination, using a tape transfer device to facilitate handling of these difficult specimens, with confirmation of the results with routine sections on the following day.

Respiratory system

In recent years respiratory failure, defined as inability to maintain adequate oxygen saturation while administering 100% oxygen by ventilator, has been the most common immediate cause of death in patients at the Shriners Burns Hospital in Galveston. The causes and mechanisms of respiratory failure are multiple, and will be addressed separately, although more than one mechanism operates in many cases. Direct thermal injury to the trachea and bronchi probably does not occur, except in cases of burn injury due to exposure to large quantities of steam. Patients also may develop problems related to the airways such as pneumothorax or interstitial emphysema, aspiration of gastric contents, pulmonary embolism, and non-specific pulmonary edema due to increased venous pressure. In Dr Linares' series of 115 burn autopsies, every patient had severe lung lesions of various kinds.³³

Infection

In most patients who die with respiratory failure, postmortem cultures of lung tissue are sterile. However, in those patients who have sepsis at the time of death, extensive infection of the lungs is commonly present, and it may represent a terminal event. As is true of sepsis in general, fatal pneumonia is most often seen as a consequence of infection with a highly resistant bacterial strain, an invasive fungal infection, or in a further compromised host with renal failure or some other additional cause of immunodeficiency. Virulent and antibiotic-resistant strains of *Pseudomonas* may produce an angioinvasive infection in the lung, with massive proliferation of bacteria within the walls of pulmonary arteries and ischemic necrosis of segments of lung tissue (Figure 45.2)³⁴ This pattern is similar to that of ecthyma gangrenosum of the skin.^{35,36} A similar angioinvasive pattern of pulmonary infection can be seen with generalized infection due to *Aspergillus* or similar filamentous fungi.

Diffuse alveolar damage

This process affects the pulmonary parenchyma in all lobes and segments, and begins with exudation of protein-rich fluid into alveolar spaces. This proteinaceous exudate, representing the exudative phase of the acute inflammatory reaction, is a consequence of damage or increased permeability of both capillary endothelial cells and the epithelial type I cells of the alveolar lining. Within hours, the exudates form the hyaline membranes that are a histological hallmark of this disease process (Figure 45.3a). Within a few days, the exudate begins to undergo organization by spindle-shaped fibroblasts, and collagenous fibrosis develops, which obliterates alveoli and greatly thickens the septa between alveoli (Figure 45.3b). Macrophages accumulate within alveoli, and alveolar epithelial type II cells multiply. In the late stages, there is severe interstitial fibrosis.

Fig. 45.2 (a) This photograph of a slice of lung tissue taken at autopsy shows numerous round light tan nodules of firm necrotic tissue scattered on a dark red background. This was a patient who developed disseminated infection from burn wounds infected with multiple antibiotic-resistant *Pseudomonas aeruginosa*. (b) This low-magnification micrograph of tissue stained with hematoxylin and eosin (H&E) shows a typical round nodule of necrotic tissue surrounded by intact tissue with congestion and hemorrhage and a minimal acute inflammatory reaction. (c). The tissue Gram stain reveals numerous long Gram-negative rods occupying the muscular wall of a pulmonary artery branch.

Fig. 45.3 (a) This micrograph shows prominent hyaline membranes in H&E-stained lung tissue from a 2-year-old patient who died 8 days after a large scald burn. This represents the exudative phase of the acute respiratory distress syndrome (ARDS). (b) This micrograph shows proliferation of fibroblasts within alveolar spaces, representing the proliferative phase of ARDS. The patient survived 1 month after a large flame burn with clinical evidence of smoke inhalation injury.

There are multiple pathogenetic mechanisms that may be responsible for this process, but it is not clear which of these are most significant in patients with burn injury.^{37,38} The burn injury itself stimulates activation of complement, liberating peptides including C5a and C3a, which could, in spite of their short half-lives, directly stimulate vascular leakage in the pulmonary bed. More likely, these and many other peptides activate circulating neutrophils, which produce secondary injury to the vascular and epithelial membranes in the lung.^{39,40} Conversion of xanthine dehydrogenase to xanthine oxidase in the burn wound, muscles or other tissues can cause release of superoxide into the venous circulation, stimulating endothelial injury and oxidative stress in the lung.¹¹ The neutrophils reacting to the burn wound also undergo an oxidative burst, contributing to the release of superoxide into the circulation. This

process is greatly enhanced if the patient's course is complicated by ischemic injury of muscle compartments, limbs or other organs. Lipid peroxidation is a recognized consequence of burn injury. Superoxide can also react with nitric oxide, produced in the lung, to form peroxynitrite, a highly toxic substance.⁴¹ Thrombin peptides, released during thrombosis of blood vessels in the wound, can also activate neutrophils.⁴² The kinin system can be activated during thermal injury, with its systemic consequences. When patients develop sepsis, additional pulmonary damage can be produced by release of pro-inflammatory cytokines and augmentation of the processes that lead to inflammatory injury of the lung.^{15,43} Neuropeptides including substance P may have a role in increasing vascular permeability in the airways.^{44,45} Finally, the presence of oxygen in high concentration within the lung can itself lead to injury, and this injury can be manifest in the form of diffuse alveolar damage.⁴⁶⁻⁴⁸ Despite this plethora of mechanisms that can lead to pulmonary injury in burn patients, many patients with massive burn injury do not develop clinically apparent respiratory difficulty. The conditions most strongly associated with this form of pulmonary injury are delayed fluid resuscitation, limb ischemia, and, of course, sepsis.

Smoke inhalation injury

Patients often inhale products of combustion in house fires, and the toxic effects of these gases and fumes directly injure tissues with the lung. These patients are recognized clinically during bronchoscopy by observing prominent hyperemia of the tracheobronchial mucosa, and small particles of carbonaceous soot within the airways. Associated findings include facial burns and singed nasal hairs. These patients usually do not require ventilator therapy for several days, but are at high risk of developing respiratory failure later, which responds poorly to ventilator therapy and may prove fatal even when the burn injury is small. The mortality of burn injury has been found to be increased substantially when inhalation injury is present as well.⁴⁹⁻⁵³ Experimental studies in sheep and dogs have partially clarified the mechanisms of smoke inhalation injury.⁵⁴⁻⁵⁷ The immediate reaction to inhalation of toxic smoke, in animals, includes detachment of numerous ciliated columnar cells from the tracheobronchial epithelium, secretion of stored mucus by airway secretory cells and glands, and a dramatic increase (10-fold or greater) in tracheobronchial blood flow.⁵⁸⁻⁶⁰ Within a few hours, an intense acute inflammatory reaction develops, with exudation of numerous neutrophils into the airways (Figure 45.4a), and release of protein-rich fluid that may coagulate within airways, forming occlusive 'casts' containing mucus and desquamated cells. After 48 hours, the exudate of neutrophils, which is most intense in the trachea at earlier times, fills many terminal bronchioles (Figure 45.4b), and begins to extend into the lung parenchyma, together with mucus. This inflammatory reaction resolves in the experimental animal, and the epithelium slowly regenerates. However, autopsy evidence suggests that in human patients, exudation of neutrophils, protein and mucus into the airways may persist for more than a week (Figure 45.4c). The lost airway epithelium does not regenerate for long periods of time. Perhaps because of failure of the mucociliary escalator, mucus can be seen to accumulate around terminal bronchioles focally. This lesion is illustrated in Figure 45.4d.

Multiple mechanisms may be responsible for the respiratory disease evoked by inhalation of toxic smoke.⁶¹ As in the case of diffuse alveolar damage, the available evidence indicates that neutrophils may be responsible for much of the injury, but the locus of injury appears to be different, centered on the airways rather than the pulmonary parenchyma. Factors that may be likely to lead to selective damage to the airways include local release of neuropeptides by afferent C-fibers in the airways, and activation of proinflammatory processes in reaction to injury to the airway mucosa, including local production of interleukin-8.⁶²⁻⁶⁵ Local production of nitric oxide and other reactive nitrogen species apparently has significant deleterious effects in this form of acute lung injury.^{66,67} Local activation of thrombin during the formation of fibrin clots, and local production of endothelin-1 may further enhance the inflammatory reaction in the airways.^{68,69} Secretory cells appear to be especially sensitive to smoke inhalation injury. Recent experimental studies in sheep have demonstrated that activation of poly-adenosyl-ribose polymerase contributes to lung injury after burn and smoke inhalation injury.⁷⁰ Obstruction of small bronchi and bronchioles is thought to lead to failure of ventilation of multiple small segments of lung tissue, and inappropriate vasodilation in these poorly ventilated segments may well lead to shunting of flow through unventilated lung tissue and contribute to the failure of adequate oxygenation.⁷¹ Treatment with either nebulized heparin or tissue plasminogen activator has been found to reduce the degree of injury in the ovine model, demonstrating the importance of fibrin formation in this model.^{72,73} Segmental atelectasis and prominent vasodilation in focal areas are features of smoke inhalation injury seen in experimental animals, and also in patients examined at autopsy after burn injury and smoke inhalation injury. Obstruction of bronchi and bronchioles by mucus, fibrin and cell debris contributes to respiratory malfunction in experimental animals, and similar obstructive material is seen in human lung tissue at autopsy.^{71,74,75} As is the case with diffuse alveolar damage, the toxic effects of high concentrations of oxygen may complicate the reaction to injury.

Cardiovascular system

Despite the tachycardia and increased cardiac output common to patients with burn injury, structural lesions of the heart have been uncommon in our autopsies done on a pediatric population. Cardiac dilation and clinical evidence of poor myocardial contractility do develop in some patients after burn injury. Cardiac hypertrophy is common, probably in reaction to tachycardia and catecholamine stimulation. Bacterial endocarditis occurs in occasional patients with sepsis complicating burn injury. Non-bacterial thrombotic endocarditis (marantic endocarditis) has also been seen, and also may give rise to embolic complications (Figure 45.5a and b). This lesion has been seen more often in patients who had extensive wound infection and clinical signs of sepsis due to *Acinetobacter* species. When the endocardial region of the left ventricle is examined at autopsy, small foci of necrosis associated with local hemorrhage are observed in some cases. Contraction band necrosis is often the only evidence of myocardial injury (Figure 45.5c). These lesions may reflect poor perfusion of a

Fig. 45.4 (a) This micrograph shows an H&E-stained section of the trachea of a sheep experimentally injured under anesthesia by insufflation of cooled cotton smoke through a tracheostomy 3 hours prior to sacrifice. Numerous polymorphonuclear neutrophils are flowing into the trachea through a gap in the epithelial lining. (b) This micrograph shows neutrophils largely obstructing a small bronchiole in a sheep 48 hours after smoke inhalation injury. (c) This micrograph shows obstructive material in a bronchiole in an autopsy sample from a human patient who lived for 7 days after a large flame burn. (d) This micrograph shows mucus and neutrophils in lung parenchyma in an autopsy specimen from a patient who lived 5 days after a flame burn associated with smoke inhalation injury. Upper airway mucus is frequently seen in terminal airways and adjacent parenchyma in the lungs of burn patients who have had ventilator treatment.

tissue with high metabolic demand during terminal episodes of hypotension. In some cases, they may represent the effects of endogenous or exogenous adrenergic stimulation. Rona and his associates have demonstrated that β -adrenergic agents, at high doses, stimulate development of small foci of myocyte necrosis and hemorrhage in the subendocardial region of the heart.^{76,77}

Urinary system

Patients with extensive burn injury, if resuscitated adequately during the first few hours after injury, may have normal renal function throughout their hospital course. It is not uncommon, however, for renal failure to develop, especially when the

initial fluid resuscitation was not optimal, or when patients have episodes of sepsis. In such cases, the autopsy frequently reveals evidence of acute tubular necrosis, the morphological expression of which depends upon the timing of the injury.⁷⁸ In Dr Linares' autopsy series, evidence of acute tubular necrosis was present in 86% of the cases, and all of these patients had clinical evidence of renal failure.³³ The morphological features of acute tubular necrosis include edema of the entire kidney with substantial increase in weight, and necrosis of proximal tubular cells with karyolysis, karyorrhexis and sloughing of the injured cells from the tubular basal lamina. Within 48 hours, these events are followed by regeneration of surviving renal tubular cells, which flatten, become basophilic, and undergo mitosis as they migrate to reconstitute the epi-

Fig. 45.5 (a) This is a close-up photograph of a small lesion on the tricuspid valve of the heart in a patient with non-bacterial thrombotic endocarditis who died of sepsis. (b) An H&E-stained section of this lesion shows that it is composed of fibrin. (c) This micrograph shows acute contraction band necrosis in heart muscle cells in a small area in the left ventricular subendocardial region.

thelial lining. Renal failure was an independent factor associated with increased mortality in the analysis of prognosis in patients with greater than 80% TBSA burns in our institution.⁷⁹ Patients with renal failure seem to be at especially high risk for the infectious complications of burn injury.

Digestive system, hepatobiliary tract, and pancreas

The association of duodenal ulcers with burn injury, described by Curling, is a classical lesion that still occurs in patients with burn injury.⁸⁰ In a pediatric population treated prophylactically with inhibitors of gastric acid secretion, these lesions are distinctly uncommon. Local mucosal necrosis and hemorrhage, early manifestations of this process, are seen with some frequency. Such defects in the mucosa are often multiple, typically small and round, and can be associated with significant hemorrhage from the exposed blood vessels deep to the lesions. They heal rapidly and rarely lead to serious complications.

The intestinal tract is especially susceptible to ischemic and hypoxic injury, and lesions related to poor perfusion are often found at the time of autopsy. Decreased blood flow in the splanchnic circulation is a well-established physiological consequence of endotoxemia.^{17,81} Thus sepsis is associated with an increased risk of intestinal injury. Hypoxic or ischemic injury of the intestinal epithelium, which may be very limited, can lead to translocation of intestinal flora into the mesenteric lymphatic circulation and into the portal venous circulation.^{82–85} Additional factors favoring the escape of bacteria from the intestine include alterations in the bacterial ecology of the gut.⁸⁶ Hypotension and hypoxia, then, can also be causes of sepsis. In our autopsy experience, formation of abscesses or foci of tissue infection in the intestinal tract was uncommon, except when many organs including the skin were heavily infected in patients with generalized sepsis. The intestinal lesion most commonly seen at autopsy consists of transverse streaks of hemorrhage in the small intestine in a ‘ladder’ pattern, associated with focal necrosis of folds of mucosa. This lesion is called superficial hemorrhagic necrosis.⁸⁷ Perhaps surprisingly, perforation of the intestinal tract is an uncommon occurrence in patients with burn injury. Pseudomembranous colitis does occur occasionally (Figure 45.6a).

The liver is enlarged at the time of autopsy in most children who succumb to burn injury, often to double or triple its normal weight. The increase in liver weight is rather consistent as a function of time after injury.⁸⁸ Occasionally such hepatomegaly is thought to compromise ventilation. The lesions often seen in the liver at autopsy include steatosis, with deposition of large and small lipid droplets in hepatocytes (Figure 45.6b) and congestion, often with centrilobular necrosis. This pattern of central necrosis may be a consequence of reduced splanchnic blood flow in patients with sepsis. Intracellular cholestasis is commonly observed in patients with burn injury. The basis for this abnormality is not clear, although multiple physiological derangements could be expected to lead to cholestasis.^{89–91}

Pancreatitis is a frequent complication of burn injury in children. The lesions most often seen at autopsy are focal necrosis of pancreatic tissue, focal hemorrhage and focal fat necrosis (Figure 45.6c). This abnormality is clinically silent in

Fig. 45.6 (a) This autopsy photograph illustrates pseudomembranous colitis in the cecum. (b) This micrograph of H&E-stained liver tissue shows moderate steatosis in a 6-year-old patient who lived for 1 month after a large burn and whose liver was 2.2 times heavier than normal. (c) This cross-section of a patient's pancreas at autopsy shows foci of hemorrhage and several small bright yellow foci of fat necrosis. The patient succumbed to disseminated bacterial infection. (d) This is a micrograph at low magnification showing the extensive loss of lymphoid tissue in the appendix that is typical of children hospitalized for burns who live more than 1 week.

most cases, but is associated with transient elevations in amylase and lipase.

Lymphoid system

Depletion of lymphocytes from lymphoid tissues throughout the body is a consistent feature seen at autopsy in patients with burn injury. The abnormalities were well described by Dr Linares in 1978.⁹² The thymus is consistently very small, even in young children. The lymph nodes often lack germinal centers, and may be strikingly depleted of lymphocytes. Sinus histiocytosis is often present, and pyroninophilic cells resembling plasma cells are often prominent, in the portions of the node normally occupied by B cells. The splenic white pulp is deficient, sometimes strikingly so. The gastrointestinal lymphoid tissue of the terminal ileum is generally atrophic, in spite of its normal prominence in children, and the appendix often shows a striking lack of normal lymphoid tissue in its wall (Figure 45.6d). These abnormalities of lymphoid tissue corre-

late with the deficient immune responsiveness typical of patients with extensive burn injury. To some extent they may represent the effects of high levels of endogenous glucocorticoids in burn patients.

Musculoskeletal system

Lesions of skeletal muscle are uncommon in burn patients, but are ominous when they occur. Occasionally, direct thermal injury extends into deep muscle, and at times this injury can be so severe that adequate debridement is not practical. Electrical injury often is associated with extensive necrosis of muscle. When invasive bacterial or fungal infection extends into muscle, again, it may not be feasible to treat adequately by excision of the infected tissue, and the infection may be resistant to antibiotic therapy and likely to disseminate. Atrophy of skeletal muscle occurs as part of the catabolic state of burn patients, and represents a challenge for those involved in rehabilitative efforts.

Central nervous system

When the brain and spinal cord are examined carefully at autopsy, abnormalities can be found in the great majority of patients who die after burn injury. The commonest lesion is degeneration or loss of neurons in the portions of the cortex most susceptible to hypoxic and ischemic injury. These lesions can be a result of hypovolemia during resuscitation, shock developing as part of the syndrome of sepsis, or as a consequence of respiratory failure. Of course, extensive hypoxic brain injury may occur in patients who are asphyxiated during the initial burn injury. Some patients who require cardiopulmonary resuscitation at the scene of injury develop massive cerebral edema and brain death several days after the initial injury, reflecting the response to extensive hypoxic-ischemic injury in the brain. Severe hypoxic brain injury also can occur in burn patients who are deprived of oxygen during the progress of a house fire, or who are poisoned by carbon monoxide at the scene of the burn. Occasionally prolonged delay in fluid resuscitation of a patient with a large burn is associated with hypoxic-ischemic brain injury and brain death. Another special case is the patient who has direct thermal injury to the brain. Such lesions, which occur occasionally in young children, can be detected by radiological imaging studies, and are represented at autopsy by small foci of tissue necrosis on the cortical surface, surrounded by a hyperemic reaction.

The burn autopsy

As long as patients continue to develop complications of burn injury that are difficult to manage, and as long as the pathogenesis of these complications remains uncertain, careful post-mortem examination of patients who do not survive will

continue to contribute to patient care. There is a paradox here. Tissue injury occurs due to elevated temperature, a very simple physical alteration. However, there is no disease with more complex clinical and physiopathological derangements than an extensive burn. Observations made at the time of autopsy often clarify the nature of the problems that led to the patient's demise. Sometimes the findings lead to suggestions for changes in procedure that may lead to improved patient safety. Often a causal sequence of events can be reconstructed by including the clinical evidence and the autopsy findings. Infectious processes, for example, often can be traced from their sites of origin, in the skin or elsewhere, to the fatal conclusion. The emergence of unusually resistant bacterial strains can be traced. The autopsy should always be approached from the point of view of using both clinical and autopsy evidence to better understand the reactions of the patient to the burn injury and to the treatments provided. In other words, the burn autopsy can provide not only an appropriate morphological analysis but also a dynamic interpretation of the pathogenesis of the disease processes of importance in an individual patient. When approached in this way, investigation of patient deaths becomes a valuable learning experience for all those who participate in it. Not infrequently, unexpected lesions are found which were likely to have been significant in the patient's course. Of course, the circumstances of burn injury may have legal implications, and documentation of the patient's injuries and careful interpretation of the hospital course can have the beneficial effect of providing factual evidence where only supposition would be available otherwise. We advocate a policy of carrying out complete autopsies on all patients who die after burn injury, whenever possible, including microscopic study and consultation with specialists, in collaboration with the local medical examiner or coroner.

Conclusion	592

Introduction

The ultimate goals of all burn team members are to heal the patient's wounds with the least scarring and to maximize the functional and cosmetic outcome. The management of the burn wound depends on the depth and extent of the injury. Those wounds that are superficial need to re-epithelialize. Smaller but deep wounds heal by scar formation and contraction. These processes are beneficial at times but detrimental at other times. Understanding how these wounds heal will help with choosing an appropriate treatment. Larger wounds require grafting. By understanding how a graft heals, one can optimize the outcome. It is clear that all patients with burns greater than 20–25% total body surface area (TBSA) develop systemic changes that influence their survival. The burn wound is a major source of inflammatory mediators that lead to hypermetabolism, muscle wasting and, potentially, dysfunction of multiple organ systems. The best way to treat these systemic problems is to eliminate the source of the inflammatory mediators by expeditiously removing the source of the mediators and covering the wound. The strategies for covering these massive wounds will be discussed in this chapter. The factors that influence wound healing will also be described. Finally, much of our time is devoted to the management of scars. While relatively little is known about reducing scar formation, more options are available to us compared to the past. Hopefully, we will gain further insights into the control of scar formation in the future.

There are several basic principles that the burn team must remember when treating a wound:

1. The goal is to maximize the functional and cosmetic outcome of the burn.
2. Optimizing initial wound care will minimize the need for scar management and reconstructive surgery. (Do it right from the start.)
3. If a burn heals within 2 weeks, then scarring is minimal. If the wound has not healed within 2 weeks, then grafting is probably indicated.
4. Topical agents do heal a wound but, instead, reduce infection risks. In addition, they do not eliminate bacteria. Target the topical agent for the wound type and the likely bacterial flora.
5. Make treatment simple (especially in the outpatient setting):
 - Sterile techniques are unnecessary. Use clean techniques.
 - The patient may get into the shower or tub.
 - Caregivers should wash their hands and use clean barriers (gowns, gloves) in the inpatient setting.
 - At home, barrier techniques are probably not indicated. Hand washing is still important.
 - Try to minimize pain.

The goal of this chapter is to describe the types of wound healing in order to develop better principles of wound management that will lead to the best possible outcome for burn patients.

Types of burns

In order to optimally treat burn wounds, one must first know the types of burn injuries that exist. The type of healing that is involved in each type of wound changes depending on wound depth. Skin can be simply considered to consist of two major components, the epidermis and dermis (Figure 46.1). The major function of the *epidermis* is to keep invading organisms 'out' and keep water 'in.' At the base of the epidermis are the basal cells, which are the only keratinocytes of the epidermis that can proliferate and migrate. These cells are attached to a basement membrane that separates the epidermis from the dermis. The basal cells differentiate as they leave the basement membrane and eventually die and slough in the more superficial layers of the epithelium. The detachment, migration away from the basement membrane, differentiation, and sloughing is the normal life cycle of the keratinocytes. The *dermis* adds the strength to the skin, since it is made of collagen and other extracellular matrix (ECM) proteins. The dermis also contains a vascular and neural plexus. The vascular plexus

Fig. 46.1 This drawing demonstrates the major layers of the skin. The epidermis has a basal cell layer of keratinocytes that have the potential to migrate and proliferate to cover a wound. The dermis contains adnexa (hair follicles, oil glands) that contain epithelial cells that migrate on to the open wound and re-epithelialize it. The type of healing that occurs after a burn depends on which layers of the skin are damaged. A 1° burn does not extend deeper than the basal layer of the epidermis. A 2° burn involves the dermis and a 3° burn extends beneath the dermis and into the fat. A 4° burn involves tissue beneath the fat.

is vital for temperature control, and the neural plexus gives the skin the ability to sense the environment. The neural network also produces the sharp pain that results from superficial burns. The dermis also contains the skin adnexa (hair follicles, oil glands, sweat glands) which are lined by epithelial cells. These adnexa are essential for the healing of superficial burns.

The depth of burn has traditionally been divided into first degree (1°), second degree (2°), third degree (3°) and fourth degree (4°) (Figure 46.1). A 1° burn does not extend below the basal cell layer of the epidermis. These burns are dry, red and painful. The 2° burn extends into the dermis and is characterized by being moist, painful and red with blanching. The wound is moist because of the loss of the barrier function of the epidermis. The pain and blanching redness exist because the dermal nerves and blood supply persist. A 3° burn extends completely through the dermis and into the subdermal fat. These burns are dry, less painful and do not blanch because the dermal nerves and blood supply are destroyed. These burns can be almost any color (white, tan, black, brown, red) and tend to be leathery as result of the 'eschar' produced from

the coagulated proteins that result from the burn. The eschar should not be confused with the 'scab' that develops over time on a 2° burn. This scab is the result of fibrin and cellular deposition from the exuding wound fluid. Finally, a 4° burn is one that extends to fascia, bone, tendon, muscle or other tissue beneath the subcutaneous fat.

Types of tissue repair

Re-epithelialization

Since 1° and 2° burns leave behind remnants of epithelium the major form of healing for these types of wounds is re-epithelialization. For 1° burns, such as sun burns, the basal cell layer of keratinocytes persists. The basal cell layer simply differentiates to recreate the multiple layers of the epidermis. This process is usually complete within 3–4 days. Little treatment is needed to manage these wounds other than possibly a moisturizer.

Once the burn extends into the dermis (2°), then the entire epidermis has to be reconstructed from the skin adnexa. Fortunately, the skin adnexa (hair follicles, sweat glands, oil glands and others) are lined with epithelial cells. There are several stimuli for the basal keratinocytes at the wound edge and the adnexal epithelial cells to migrate on to the surface of the wound.¹ First, the loss of basal cell–cell contact leads to signals for the keratinocytes to migrate. In addition, growth factors that target epithelial cell growth and migration are released from the wound to stimulate migration. Growth factors that specifically target epithelial cells include epidermal growth factor (EGF), transforming growth factor- α (TGF- α), keratinocyte growth factors-1 and -2 (KGF-1 and KGF-2).^{2–6} Other growth factors stimulate keratinocyte growth and migration either directly or indirectly in addition to having other wound healing activities (transforming growth factor- β [TGF- β] and interleukin-1 [IL-1]).^{6,7} Finally, if keratinocytes come in contact with specific proteins, then they are stimulated to migrate. For instance, basal cells are content to stay put if they are in contact with proteins that are in the basement membrane (such as laminin or collagen type IV). When they come in contact with proteins found in the wound, such as fibrin, fibronectin, or collagen type I, then they are stimulated to migrate.⁸ All of these stimuli are produced in a 2° burn or split-thickness skin graft (STSG) donor site.

Keratinocytes migrate from the original wound edge and from the skin adnexa, and travel over the viable wound bed (Figure 46.2). If there is a moist and viable surface, then the cells can migrate most rapidly. As the epithelial cells march up from the adnexa, whitish dots (epithelial buds) appear on the reddish background of the wound (Figure 46.3). When the cells regain contact with other migrating keratinocytes (covering the wound), then they differentiate and form all of the layers of the epidermis. The wounds with the highest concentration of skin adnexa heal the fastest. This is why the scalp heals within 4–5 days while areas lacking hair, such as the lower legs in older people, take longer to re-epithelialize. If the wound dries and forms a 'scab' (composed of fibrin, dead neutrophils and other debris), then the keratinocytes have to 'cut' their way along the viable surface by releasing proteases and other enzymes. If a thick scab does develop, then light

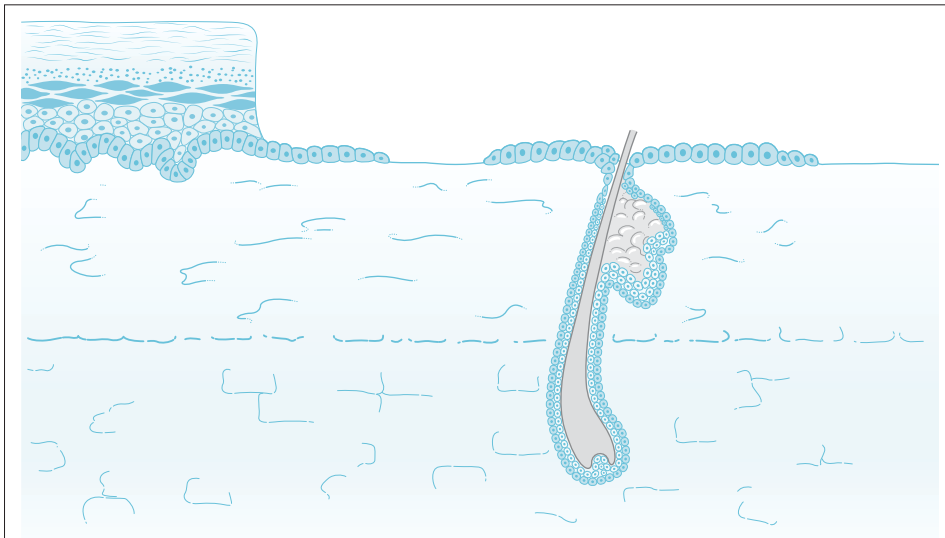

Fig. 46.2 A diagram of re-epithelialization. Basal cells of the epidermal edge migrate across the viable wound bed. In addition, skin adnexa, such as hair follicles, also contain epithelial cells that migrate onto the surface and participate in the resurfacing. If the surface is moist and free of fibrinous exudate, then re-epithelialization proceeds faster.

Fig. 46.3 Epithelial buds are the white dots in the middle of the red wound in this superficial burn that is re-epithelializing.

debridement will assist with healing. One must be careful, however, to avoid pulling off the new epithelium.

It has been shown that maintaining a moist environment leads to more rapid re-epithelialization than if the wound is allowed to dry. Many ointments and dressings have been designed to assist with optimizing healing of these superficial wounds. For instance, an ointment such as bacitracin prevents drying while at the same time decreasing Gram-positive organisms. Dressings have also been designed to maintain the moist environment. These ‘biologic dressings’ are designed to cover the wound and maintain the optimal environment until re-epithelialization is completed. Transparent polyurethane dressings were designed with this in mind. Other dressings are designed to stick to the wound and allow for healing. Bio-brane™, which has a layer of type I collagen, sticks to the wound until re-epithelialization is complete. TransCyte™ uses the same principle but has fibroblasts in the dressing that release a variety of growth factors. Other biologics have been used to improve wound healing in chronic ulcers. Derma-

graft™, a ‘three-dimensional, allogeneic, human neonatal dermal fibroblast culture grown on a biodegradable scaffold that is cryopreserved’, and Graftskin™, a ‘living skin equivalent’ consisting of a dermis (with fibroblasts) and keratinocytes, have been used to treat diabetic ulcers with success. Some of the older biologic dressings are porcine skin and human allograft. All of these biologic dressings have many advantages as well of disadvantages. These agents stick to the wound and allow for protected re-epithelialization under the dressing. The biologic dressings that contain live cells also have the advantage of releasing growth factors and other agents that may accelerate healing. One problem is the cost of using these new technologies. Some of the viable biologics can cost thousands of dollars just to cover a relatively small area. These costs must be balanced with the advantages of each dressing. A jar of bacitracin may reduce costs by a factor approaching hundreds to a thousand times less.

Another approach to accelerating healing of superficial burn wounds and STSG donor sites has been to apply exogenous growth factors. At one time there was a great deal of interest in applying these cytokines to a wound to accelerate re-epithelialization. Many animal studies have demonstrated accelerated healing of superficial wounds.²⁻⁶ Several controlled, randomized, prospective and double-blinded clinical trials have been performed using different growth factors.⁹⁻¹¹ Most of the trials were performed using small donor sites on opposite sides of the body and revealed that a statistically significant improvement in tissue repair was found. Unfortunately, what proved to be statistically significant was not clinically relevant. Wounds would heal a day or two faster compared to the control. Since the healing of small donor sites does not impact length of stay, the benefit did not justify the cost. It is difficult to greatly accelerate healing of small donor sites. The healing of donor sites in massive burns, however, often appears to be slower than that of small wounds. Herndon’s group has treated children with relatively large burns (>40%) with systemic human recombinant growth hormone and found that the time to reharvesting of donor sites was significantly shortened.¹² With the requirement for multiple reharvests, the length of stay per percent burn was also significantly short-

ened. The decreased length of stay more than counteracts the increased cost of the recombinant protein.

While discussing re-epithelialization one must also consider repigmentation. Melanocytes reside in the basal cell layer of the epithelium. After a 2° burn pigment is lost. This is also true for split-thickness donor sites (which heal by the same re-epithelialization process). Like keratinocytes, melanocytes reside in the adnexa of the dermis. After re-epithelialization one will notice that brown dots of repigmentation will gradually appear. The sizes of the pigmentation areas gradually enlarge and coalesce to repigment the area. With deeper burns melanocytes are eliminated and pigment can be lost. This can be a significant problem for people with increased skin color. There is also a tendency for skin grafts to hyperpigment while donor sites frequently will not match the surrounding skin. Unfortunately, we do not have very good options for treating pigmentation problems. There are quinolone creams that may lighten color but they are difficult to control and often do not match the surrounding areas. People have tried to replace pigment with tattoos with poor outcomes. There are those who will dermibrade an area and then regraft the area for return of pigment. This technique may also lead to other scarring problems.

Scar formation

A second form of healing involves re-creating the 'tough' component of the tissue. For skin, the body attempts to form a 'new dermis.' During this process new connective tissue (the ECM) that gives tissue its strength is created. In simpler forms of life, and in the fetus, skin and other tissues can be regenerated. In mammals (at least after birth), wounds close by creating a less than perfect scar. No one knows why mammals scar instead of regenerating the original tissue but one can guess that in our contaminated world that more expeditious closure at the expense of regeneration may have been an evolutionary compromise for controlling bacterial invasion. Scar formation is both essential (to prevent dehiscence) and a hindrance in that excessive fibrosis is an ultimate complication of many disease processes (contractures, hypertrophic scars, keloids, pulmonary fibrosis, cirrhosis, arthritis, plus more). Investigators are trying to understand the controls of these processes. Much more is known about the factors that turn on the process than is known about what turns off the process. These factors will be discussed in this section.

Scar formation is usually divided into three phases. The three phases were originally determined by measuring the tensile strength of incisions over time (Figure 46.4). During the first 4–5 days after closing an incision, little change in wound strength is noted. During this time, inflammatory cells invade the incision, so it is called the *inflammatory* or *lag phase*. After this period, there is a rapid increase in collagen content in the incision that is associated with a rapid increase in tensile strength. This phase is called the *proliferative* or *collagen phase*. Two key events occur during this phase, the deposition of the ECM and the ingrowth of new vessels. Finally, there is a prolonged phase where the incision continues to gain strength (up to approximately 80% of the original skin) but there is no increase in collagen content. Also during

Fig. 46.4 The phases of scar formation are based on the changes of tensile strength and collagen deposition in an incision. For the first 4–5 days after closing an incision, there is little increase in strength. During this *inflammatory phase*, inflammatory cells prepare the wound for the arrival of fibroblasts. Once the fibroblasts arrive in the *proliferative phase*, there is a rapid increase in tensile strength as collagen content increases. After 2–3 weeks, there is no more increase in collagen content but the incision strength continues to increase in the *maturation phase*.

this *maturation phase*, the wound tends to become less cellular and vascular until a quiescent, white scar is formed.

The inflammatory phase prepares the wound for the subsequent repair process. The main role of this phase is to eliminate invading organisms and remove foreign tissue. The inflammatory phase is divided into vascular and cellular components. All of the components of healing are controlled by the release of local and systemic mediators. In the *vascular response*, there is a release of local catecholamines that induce vasoconstriction in an attempt to control bleeding. In addition, when platelets and coagulation factors are exposed to proteins outside the vessels (collagen type I, thrombin, tissue factor, Hageman factor) hemostasis is initiated. After bleeding is controlled, different mediators (histamine, serotonin, kinins, nitric oxide, prostaglandins and leukotrienes) induce vasodilation and increased permeability. The increase in permeability allows for the leakage of serum proteins and water into the local wound area. When the wound is large enough, such as after a burn that is greater than 20% TBSA, then the mediators 'spill over' into the systemic circulation and cause the total body edema that we are familiar with in major burns.

In the *cellular response*, multiple signals are released to attract inflammatory cells to the wound. Platelets contain multiple growth factors in their alpha granules that attract the cells. Other factors such as complement (C3a and C5a) and clotting factors (thrombin and fibrin) are chemotactic for inflammatory cells. The first cells to arrive in the wound are neutrophils. These cells are mainly responsible for killing invading organisms. They release many mediators, such as proteases and oxygen radicals, that can be destructive to tissues if produced in excessive amounts. Several investigators also implicate an excessive neutrophil response that is responsible for the 'systemic inflammatory response syndrome' (SIRS). Studies that were performed in the 1970s, however, suggest that neutrophils are not essential for the healing process.¹³

Macrophages (and monocytes) have been found to be the major regulators of the healing process.^{14–17} When these cells

were eliminated from a wound, very little tissue repair took place. Macrophages release multiple cytokines and growth factors that stimulate the migration and proliferation of fibroblasts, keratinocytes, endothelial cells and other cells involved in tissue repair. The list of growth factors released by these cells has become quite large and is best reviewed in other publications.¹⁷ Macrophages are found in the wound in relatively high numbers after 3–4 days. In the incision, fibroblasts follow very soon after the arrival of macrophages. The role of lymphocytes in the healing process is less clear. Lymphocytes release multiple cytokines that influence macrophages.^{18,19} Tissue repair is not greatly affected, however, in mice with severe-combined immunodeficiency (lacking lymphocytes).²⁰ As discussed below, lymphocytes do release interferons (IFNs) that appear to have antifibrotic tendencies.

Once fibroblasts arrive in the wound, the proliferative phase begins. Two events occur in the proliferative phase: the *synthesis of the extracellular matrix* (ECM: collagens and other matrices) and *re-creation of a blood supply* (angiogenesis, vasculogenesis and arteriogenesis). Fibroblasts are the cells that produce the majority of the ECM. Since collagen is the major strength of tissues, its biosynthesis has been well studied and will only be briefly mentioned here. There are excellent reviews that describe the details of collagen production.^{21,22} There are at least 19 types of collagen. All collagens can be divided into fibril-forming and non-fibrillar collagens. All collagens have at least some component of amino acid triplet repeats of 'glycine-X-Y,' with the 'X' often being proline and the 'Y' frequently being hydroxyproline or hydroxylysine. The peptide chains then form into a triple helix that gives collagen its strength. One of the most important biochemical reactions in the biosynthesis of collagen is the hydroxylation of proline or lysine. The enzyme 'protocollagen hydroxylase' required for

this reaction requires oxygen, iron (Fe^{++}), α -ketoglutarate, and most importantly vitamin C. In vitamin C deficiency (scurvy), hydroxylation does not occur and the triple helix fails to form. The malformed collagen collects within the fibroblasts and healing is markedly impaired. There are many other steps in the biosynthesis of collagen where abnormalities can occur. Another key stage is during the creation of inter-collagenous bonds that help bind fibrils of collagen together. Lysyl oxidase, the enzyme required for this process, can be blocked by such agents as penicillamine and β -aminopropionitrile (BAPN). The role of these agents and the other steps in collagen synthesis are reviewed elsewhere.^{23–25} The deposition of the other ECM components also is essential for normal healing. The role of these other proteins includes glycosaminoglycans (GAGs) and elastins. Their synthesis will not be covered here.

In order to create the ECM, fibroblasts require oxygen and nutrients. In order for healing to continue, a new blood supply must be created. A great deal has been learned about the creation of a new blood supply, and the process has become quite complex. Three processes occur in the creation of a new blood supply: vasculogenesis, angiogenesis, and arteriogenesis. In addition, vascular myogenesis (recruiting the smooth muscle cells to surround the vessels) must also occur. Excellent reviews give more detail.^{26–28} Most of new vessel development involves angiogenesis and arteriogenesis. With *vasculogenesis*, undifferentiated precursor stem cells to endothelial cells (angioblasts) arrive in the site of injury and differentiate to form new vessels. This type of vessel development is important in embryogenesis but does not appear to be as involved after birth. The stem cells do persist into adulthood and thus there is a potential for vasculogenesis to occur.

Angiogenesis involves sprouting of endothelial cells from postcapillary venules (Figure 46.5). Several stimuli can acti-

Fig. 46.5 Neovascularization of a wound involves three components. *Angiogenesis* involves the release of angiogenic factors from cells (macrophages) in a hypoxic environment. These angiogenic factors stimulate endothelial cells to release collagenases and proteases that digest the basement membrane. Endothelial cells then migrate towards the angiogenic stimuli. The migrating endothelial cells eventually form a lumen at the original vessel. During *arteriogenesis*, smooth muscle cells migrate along the newly formed vessel to recreate the muscle layer. A third type of process is called *vasculogenesis*. This process of angioblasts migrating into a tissue to initiate new blood vessel formation dominates embryonic development but appears to play a lesser role in adults.

vate the process. Low oxygen levels and lactic acid are two stimuli that can induce the process.^{29,30} In addition, there are multiple angiogenic factors (such as fibroblast growth factor-2 [FGF-2] and vascular endothelial growth factor [VEGF]) that stimulate endothelial migration and proliferation.³¹⁻³⁴ After an injury, hypoxia and lactic acid are commonly present. In addition, macrophages release angiogenic growth factors in response to the hypoxic environment. The endothelial cells lining the postcapillary venules release proteases that digest the basement membrane. The endothelial cells then migrate towards the chemotactic signals (the concentration gradient of growth factors). As the endothelial cells migrate, endothelial cells in the original venule proliferate to replace those that have migrated away. As the sprout migrates towards the stimulus a lumen is formed to create a new vascular pathway. Recent data also suggest that angiogenesis involves other methods to modify the primitive vascular complex by causing the sprout to divide by intussusception or creating transendothelial cell bridges..

For larger vessels, *arteriogenesis* completes the process by adding the smooth muscle wall of the vessel. The process of *vascular myogenesis* involves the migration of smooth muscle cells along the perimeter of the endothelial sprout. Growth factors, such as platelet-derived growth factor-BB (PDGF-BB), are involved in this process. The smooth muscle cells stabilize the new vessel and at the same time limit its growth.

The process of neovascularization is important for other fields besides wound healing. Many tumors produce increased angiogenic factors or have mutated angiogenic receptors. A great deal of research is being performed to understand this process. Investigators have also found inhibitors of the angiogenic process (such as angiostatin)^{35,36} that may be useful for cancer chemotherapy and possibly scar control.

The final phase of scar formation is *maturation*. During this phase, in an incision, there is no net increase in collagen content, despite an increase in tensile strength. When studying these wounds, collagen synthesis is occurring but there is an equal rate of collagen breakdown by collagenases. Collagen tends to be broken down where it is not needed and it is increased along lines of stress. In essence, fibroblasts are attempting to reorganize the scar to the most efficient configuration possible. In addition, intermolecular bonds are formed between collagen fibrils which tend to increase the strength of the protein (especially collagen type I, the most common collagen in the scar). Lysyl oxidase is the key enzyme that is required for this process. Any inhibition of the enzyme will lead to a weaker scar. If there is an imbalance between collagen synthesis and breakdown, then pathological healing occurs. If there is too little synthesis or excessive collagenase activity, then healing can fail, wounds weaken or chronic wounds develop. Studies have demonstrated that there is both a decrease in growth factor synthesis and increased collagenase activity in chronic, non-healing ulcers.³⁷⁻⁴⁰ On the opposite extreme, if the balance is shifted to excessive collagen deposition, then hypertrophic scarring or keloids may form. Unfortunately, the controls of the collagen synthesis/breakdown balance are not well understood and are the topics of many investigations.

During the maturation process, the wound goes from being highly cellular and vascular to one that is relatively acellular

and avascular. For burn patients, we know that the burn wound tends to get redder and more raised before it matures. The duration of the maturation process can vary depending on how long the wound remains open. Wounds that heal rapidly, such as a sunburn, tend to remain red for a very short time. Those that are open for weeks tend to require 1–2 years to fade out and flatten. The controls of the maturation process are just starting to become known and are discussed below.

The wounds that the burn team handles do not follow the simplified healing of an incision. With large wounds, all three phases tend to blend together (Figure 46.6). If one examines the histology of a 10-day open wound, the center is full of inflammatory cells. The original wound edge tends to be less cellular and has a great deal of collagen deposition. At the edge of the migrating epithelium, there appears to be a transition between inflammation and wound maturation. In essence, all of the three phases of healing are blended together with the edge of the migrating epithelium being the center of transition. In the center, where the wound is exposed to chronic bacterial invasion, there is a persistent stimulus for inflammation (thus the presence of the inflammatory phase). This tissue is full of inflammatory cells, immature vessels and collagen. When the inflammatory response is not eliminated, the tissue becomes the moist, red and raised ‘granulation tissue’ that we are familiar with. Once the epithelium marches across the wound, then the inflammatory stimuli are eliminated and fibroblasts tend to predominate. In addition, there appears to be a signal from the epithelial cells that induces apoptosis in the nearby inflammatory cells^{41,42} As one follows the wound farther behind the migrating epithelium there appears to be fewer and fewer fibroblasts. In essence, the wound covered with an epithelium appears to be going through a maturation phase.

The relationship between wound coverage and maturation has been known for a while. Deitch, et al. noted that wounds that healed within 2–3 weeks tended not to scar.⁴³ If exposure persisted for longer periods, then the wounds tended to develop hypertrophic scarring (Figure 46.7). Other investigators have demonstrated that the apoptosis was induced in fibroblasts

Fig. 46.6 In large open wounds, the phases of scar formation blend together. In the middle of the open wound there is a continuous inflammatory stimulus. Inflammatory cells persist in this area. When the epithelium covers the wound, the inflammatory cells undergo apoptosis and disappear. Fibroblasts dominate this part of the wound, which resembles the proliferative phase in an incision. Farthest from the center and nearest to the original wound edge, maturation of the wound is evident with a less cellular and more organized collagen pattern being found.

Fig. 46.7 Wounds that stay open longer than 2 weeks tend to develop hypertrophic scarring. As an example, the central area remains open at 2 weeks after a scald burn (a). The same area ultimately developed hypertrophic scarring (b).

after epithelial closure^{41,42,44} or coverage of a wound with a flap.⁴⁵ Apparently, the epithelium has signals that regulate the amount of scar formation. If the wound is left open for too long, then the usual controls that prevent an excessive scar are lost. Several investigators have demonstrated that TGF- β is a likely candidate for a factor that is involved in excessive scar formation.^{46–49} Tredgett's group has demonstrated that patients with hypertrophic scars tend to have increased serum levels of TGF- β 1.^{48,49} He and others have demonstrated that different isoforms of interferon (IFN) may reverse the effects of TGF- β 1.^{50–52} Others have found that elimination of TGF- β 1 (by knockout technology) leads to the eventual death of the animal from overwhelming inflammation.^{53,54} The lymphocytes are involved in the regulation since elimination of both TGF- β 1 and lymphocytes leads to the elimination of the inflammatory response.²⁰ One hypothesis is that in its attempt to control inflammation and at the same time wall off the inflammatory source by inducing fibrosis, TGF- β 1 regulation may be lost.⁴¹ Interestingly, Ferguson's group has shown that only the TGF- β 1 and TGF- β 2 isoforms appear to induce scarring, while TGF- β 3 has antiscarring effects.⁵⁵ Eventually, we will be able to understand the controls of collagen deposition enough to greatly reduce excessive scar formation. More on this topic is covered later in this chapter.

Contraction

The final type of healing is *contraction*. This process must be differentiated from contracture, which is the pathological result of the long-term shrinkage of a scar. Contraction is the relatively rapid, mechanical reduction in size of a wound.^{56,57} The classical example of contraction occurs in open wounds in rodents. If one creates a sizeable open wound in a mouse, the wound edges 'pull' together to heal the wound within 10–14 days. An open wound will actually contract to 80–90% of the original wound size. The rest of the wound closure occurs by creation of a new scar and re-epithelialization. Most likely, the process of contraction evolved as a rapid and efficient way

to close an open wound. It certainly makes more sense for a wound to shrink rapidly than for it to regenerate over a much longer period.

Contraction also occurs on wounds in people. The wounds that contract the most are those that tend to be surrounded by loose skin. Small, open wounds on the buttocks (as for the small but deep electric burns) are amenable to contraction. The elderly, with their much looser skin, also can have wounds that can be left to contract. In areas where the skin is tight, such as over the dorsal fingers or ankles, wounds tend to resist contraction. These wounds tend to take much longer to heal and lead to scarring problems.

There are three phases of contraction, just as there are for scar formation. Initially, there is a 'lag period' while waiting for new fibroblasts to enter the wound. Then there is a phase of rapid contraction that is followed by a slower and more drawn-out contraction phase. The contraction of the wound is the result of specialized fibroblasts that contract to shrink the wound. These fibroblasts express α -actin, one of the key components of muscle, so they are called 'myofibroblasts.' There is considerable debate as to whether these cells are just a different phenotype of fibroblasts or whether they are a different type of cell. That debate is not essential for this chapter. As fibroblasts synthesize their collagen, they maintain contact so that millions of cells are intertwined with the new matrix. As the cells contract through an actin/myosin interaction process, the ECM which is attached to the wound edge also contracts.

Scar contracture is a more gradual process, which to some extent involves the same process. Contracture occurs over months as opposed to weeks for contraction. Scar maturation involves the continual remodeling of collagen. During the synthesis of the new collagen along lines of stress, fibroblasts probably contract in an attempt to continually shrink the wound. If there is little resistance, as for those patients who do not participate in a therapy program, then the scar contractures can be profound. Lips can be pulled to the chest and fingers extended to the forearm. Fortunately, the forces of contracture can be counteracted with stretching and massage. Compliant patients may end up with little functional abnormality. The ability of something to splint the contraction also applies to thicker grafts. Thin grafts have little resistance to shrinkage while thicker grafts shrink less. The splinting ability also applies to the surrounding tissue. Areas where the skin is tight, such as over the forehead tend not to shrink. When a graft is placed on looser skin, then the contraction process is more noticeable. While there is a great interest in the control of the contracture process, relatively little is known at this time. Hopefully, the future will bring better preventive treatments.

Types of wound coverage

Different strategies are required for closing different-sized wounds. The goal should always be to obtain the most cosmetic and functional wound closure the first time. Small and clean wounds may be treated by *primary closure*. A small burn wound or scar can be excised and re-approximated with sutures or staples. This closure tends to lead to relatively narrow scars. The limitation on this type of closure is the

tension of the wound and whether it is relatively free of contamination. If there is a concern about the bacterial load, a *delayed primary closure* can be performed. These wounds are left open and treated with dressing changes for 4–5 days and then closed. Since this period is during the inflammatory (lag) phase, then little inhibition in wound strength occurs. For larger wounds, the tension of a closure can lead to a scar that widens over time. Placement of tissue expanders beneath nearby healthy skin may be used as a strategy for ‘stretching’ the healthy skin to accommodate a larger wound. The best example of this technique is for the removal of burn alopecia (baldness) from the scalp. Surgeons can cover the scalp with as little as one-third of the hair-bearing skin. If a wound is too large or dirty to be closed, then a *secondary closure* is an option. This term is a euphemism for ‘allowing the wound to heal on its own.’ This strategy is useful for relatively large burns in older patients (with loose skin) and those who could not tolerate an operative treatment. Sizeable areas on the trunk or thighs heal amazingly well in these high-risk patients.

There are many other strategies for covering larger areas of skin loss. Burn caregivers routinely deal with these types of wounds. Open wounds that need to be closed can be closed with a skin graft. Areas that are functionally important (such as fingers and hands) or cosmetically important are best treated with a sheet graft. If possible, the thickest graft (full-thickness skin graft [FTSG]) should be used if the skin is readily available.⁵⁸ As stated before, the thicker the graft, the less the contraction. One must balance the need for a thick graft with the potential scar that a donor site may make. One strategy is to use the thickest skin for split-thickness skin graft (STSG) donor sites. The back has very thick skin and tends to scar less than other areas.⁵⁹ Another strategy is to use the scalp for a donor site. The scalp matches the color of the face nicely and if not taken too thickly will not transfer hair. The scalp heals extremely rapidly and the hair hides the donor site. It is important to know that many donor sites leave a mark and many produce hypertrophic scars. One strategy is to harvest skin from areas that are relatively hidden with clothes.⁶⁰ Instead of harvesting skin down the length of a thigh one can harvest skin circumferentially around the upper thigh so that shorts would cover the region. If possible, one should avoid harvesting skin from the upper back and chest since these areas are often exposed when wearing normal clothing, especially for women.

There are three phases of skin graft healing.⁶¹ Initially, the graft survives by diffusion of nutrients from the wound bed. Since the skin ‘imbibes’ nutrients from the wound bed, this phase is called the *phase of imbibition*. If any barrier forms between the wound bed and the graft (such as a hematoma, a seroma, pus, or non-viable tissue from inadequate excision), then the graft dies. Since the graft is only held in place by the natural fibrin, there is little resistance to shear, so staples, sutures, fibrin glue or complete immobilization are required. After 2–3 days, blood vessels invade the graft in the *phase of neovascularization*. New blood vessels invade the graft by angiogenesis (as described above) and by a process of ‘inosculation,’ where old capillaries in the wound bed are said to ‘hook up’ with those in the graft. Any shear at this time leads to hematoma formation and loss of the graft. Gradually, new

collagen bridges form between the wound bed and the graft in the final *phase of maturation*. This process takes months, with the graft tending to get thicker and more vascular for 3–4 months before finally fading out over the ensuing months (Figure 46.8). This maturation process parallels the maturation phase described earlier and can take 1–2 years for completion.

Since grafts require a viable wound bed, flap techniques have been developed to cover difficult wound beds where exposed bone or tendon exist. A flap contains its own blood supply and thus does not depend on the ‘imbibition’ from the wound bed. Flaps also have the benefit of being thicker than skin grafts and thus tend to prevent contraction. One must remember that a flap leaves a defect that must be closed. A local flap involves transfer of a nearby tissue by rotation, advancement or transposition. Part of the skin must stay attached to the original donor site until a new blood supply develops from the recipient site. A ‘random’ flap has its blood supply maintained by the dermal plexus. Other flaps, such as a groin flap, have an axial vessel that ‘travels’ with the tissue. Myocutaneous flaps utilize the underlying muscle in transfer since the skin derives its blood from that muscle. Finally, free flaps are myocutaneous flaps that have their main vessels separated and re-attached to distant vessels. For a more detailed review of flaps, check plastic surgery textbooks.

Cosmetically and functionally, sheet grafts are the best type of skin graft for covering large areas of the body.⁶² One must remember that the seams between sheets of skin behave like incisions and thus leave linear scars. One should try to place seams so that scarring is minimized. For instance, placing a seam across the flexion surface of a joint will increase the tendency to develop a contracture. One can also break up seams by creating ‘darts’ that lead to a zig-zag seam instead of a linear one.⁶³ The goal should be to minimize all seams. This can be done by using newer dermatomes that harvest 6 inch wide skin or harvesting long and curved pieces of skin that allow for a graft to ‘wrapped’ around the face, for instance. By reharvesting donor sites, relatively large areas can be covered with sheets of skin without significant donor site morbidity. The author has covered as much as 55% TBSA of a patient with sheet grafts. Unfortunately, as wounds cover more of the body surface area, different strategies are required for wound coverage. *Meshing* skin grafts has become the standard method for covering large areas. The size of the mesh can be increased to cover larger and larger areas. Healing of the mesh graft requires not only skin graft ‘take’ but also the interstices must heal by scar formation, contraction and re-epithelialization. These grafts lead to a permanent mesh pattern, because of this required interstice healing.

Once massive wounds are encountered, then new strategies are required. It is clear that the large burn wound leads to a massive and continuous systemic inflammatory response syndrome (SIRS) that is a major contributor to patient mortality. Most burn surgeons believe that the source of the inflammatory stimulus should be expeditiously excised and covered with some type of permanent or temporary material which functions as skin. Some feel that the wound should be closed within hours while others feel that the wound should be closed within days. Most cover the wound with as much autograft as possible and then they use some other form of coverage. The

Fig. 46.8 During the maturation of a skin graft, the graft and donor site tend to get redder and thicker before fading into the more supple and naturally colored mature wound. At 5 days after grafting (a) both the graft and donor site are pink and dry. At 4 months (b), the wound has become thicker, tighter and redder. If the patient continues therapy and massage, the wounds begin to smooth out and become less red at 8 months (c). The mature wound becomes flat, supple and loses its redness (d).

‘gold standard’ has been to use allograft (cadaver skin) as a temporary wound cover. If fresh skin is available, then the skin will ‘take’ as a viable skin transplant until the body rejects. Patients with massive burns, however, are significantly immunosuppressed, so rejection may take several weeks to months. During that time, the donor sites can be recropped as they heal to gradually replace the allograft.

Other strategies have been developed. Cultured epithelial autografts can be grown from the patient’s skin and massively expanded to cover the entire body.⁶⁴ Unfortunately, the lack of a dermis leads to prolonged fragility and significant scarring, so most believe that a ‘dermis’ is required along with an epithelium.⁶⁵ One strategy has been to place allograft and, then, when the cultured epithelium has been prepared, apply

it to the dermal allograft.⁶⁶ Since it has been found that the epithelium is the major source of the immune reaction, and not the dermis, this technique is possible.

Others have developed dermal substitutes that can be used with very thin autografts.^{67–69} One of the most commonly used dermal substitutes is Integra™, which is a dermis that is created from collagen type I and chondroitin-6-sulfate. The dermis is covered with a silicone ‘epithelium’ that reduces water loss and bacterial invasion. The dermal substitute is applied to the excised wound and allowed to vascularize. After 2–4 weeks, the silicone can be removed and a thin, meshed autograft is applied over the surface. More recent reports have described placing Integra™ on harder-to-heal areas such as bone and tendon with at least some success.⁷⁰ Other dermal substitutes

exist. AlloDerm™ is a freeze-dried human dermis that can be applied beneath a thin autograft. This product has been used to create a ‘thicker’ dermis with less donor site morbidity. The advantage of this product over Integra™ is that the thin autograft can be applied at the same time as the initial grafting. There is some risk of having less ‘take’ in this situation. TransCyte™ is silicone/nylon membrane that has allogeneic neonatal fibroblasts cultured in its ECM. This material is sold as both a dermis and as a temporary dressing that releases growth factors and thus can accelerate healing of superficial burns. It has not been used as a dermal substitute very often and is usually applied as a biologic dressing to accelerate epithelial healing.

Several others have described developing composite skins that are composed of a viable dermis (often containing fibroblasts) and cultured keratinocytes.^{71–73} These ‘skins’ are available on the market as allogeneic products (Apligraf™), while investigators are using biopsies from patients to grow a new composite skin. Recent reports suggest that there are excellent graft takes with some types of composite skin.⁷⁴ There is an entire chapter devoted to the use of skin substitutes. All of these ‘skin substitutes’ do have the problems of being expensive and have lower resistance to infection than autografts. Great progress has occurred and, someday, autografting may be a procedure of the past.

Factors affecting wound healing

Age

The basic components of tissue repair do not change throughout the life of an individual. There are some relatively minor differences that are dependent upon age but for the most part healing occurs efficiently throughout life. The most profound differences of tissue repair occur before birth. In the 1980s, surgeons began to experiment with trying to operate on fetuses to treat congenital abnormalities such as diaphragmatic hernias. They discovered that incisions produced in the fetuses healed without a noticeable scar. Soon, many investigators were studying fetal healing in an attempt to determine the factors that were involved in ‘scarless’ tissue repair.^{75,76} It became clear that there was a period when healing transformed from scarless to ‘scar forming.’ That gestational time was consistent for each species and occurred before birth. Prior to that period, an incision would regenerate to the normal ‘scarless’ architecture of the surrounding tissue. It was discovered that TGF- β was lacking during scarless healing but was present later during the creation of a scar. In addition, there appeared to be a paucity of inflammatory cells with scarless healing, but increased inflammation during the creation of a scar. Another finding in the early fetal wound was a higher concentration of hyaluronic acid than that which was found in the more mature animals. Teleologically, these findings make sense. During the period of fetal organ growth and differentiation, the animal exists in an environment of minimal risk from outside invasion. The fetus can afford to ‘take the time’ to regenerate that tissue. If a wound developed later in life, then that organism needs to be ready for fighting outside invaders. The development of an inflammatory response is essential to survival. Unfortunately, in order to rapidly close a wound and

fight invasion, the body sacrifices regeneration for a more expeditious but less than perfect scar. There is a great deal of research on fetal wound healing that cannot be covered here but many reviews exist for those interested.^{75,76}

There is feeling among many burn team members that the very young child heals differently than the adult. I have heard several physicians state that younger children tend to take longer to mature their wounds than adults. To examine the question of whether scar maturation was different in younger children versus teenagers, the time to maturation was followed for different ages in children.⁷⁷ We found that there was no difference in scar maturation in the very young when compared with teenagers. I have also heard that therapy is of no assistance in the prevention of scar contractures in children. While different strategies are necessary for children, their scars can be modified by occupational and physical therapy. Wounds in children can mature very nicely. One problem with children is that their bones tend to grow faster than their scars do. They must be followed as they grow since they may develop contractures that may need reconstructive surgery later in their teen years. One difference does exist, however: the thickness of the skin is thinner for the very young child. Strategies to utilize thicker skin, such as from the back, do help with avoiding donor site scarring.⁵⁸

At the other extreme, the very elderly patient tends to have looser and thinner skin. Any experienced burn caregiver will know that a burn that appears to be superficial in an elderly person will often tend to ‘convert’ to third degree. The burn does not ‘convert’ but, instead, the skin is much thinner and thus the wound is deeper from the start. Another problem with the elderly is that the blood supply to some areas of the skin decreases. Along with the decrease in vascularity, the same area will often have decreased hair and other skin adnexa. (The classic signs of vascular insufficiency to an extremity are decreased hair density, and thinner, more fragile skin.) These changes, along with relative hypoxia, lead to delayed healing. The thinner skin in the elderly must be kept in mind when planning grafting procedures. It is not uncommon for the recipient site to have excellent graft take but to have the donor site fail to heal. Donor sites should be harvested as thinly as possible. In addition, using dermal substitutes that allow for the use of ultra-thin donor sites should be of benefit. It is covered elsewhere in this text, but one must also be aware that the elderly patient has much less ability to survive larger burns when compared with younger patients. Relatively small burns often lead to multiple organ failure and critical illness that impairs tissue repair. Many elderly burn patients are treated non-operatively since their operative risks are prohibitive.

Not all healing is impaired in the elderly. The older patient does have looser skin that allows for contraction of larger wounds. Larger wounds can be allowed to contract with less disfigurement. For example, I have treated a 90-year-old woman with a tea spill to the thigh without grafting. A large open area on the anterior thigh healed over months without range of motion problems. Her family was taught care and she was discharged in their care within days of admission. The ultimate treatment of any elderly patient does require different strategies when compared to the younger patient.

Nutrition

The importance of adequate nutrition for the healing of wounds has been known for over a century. Studies at the beginning of the last century proved that healing was impaired with either total protein-calorie or just isolated protein malnutrition.^{78,79} These studies have been repeated hundreds of times.^{80,81} The aggressive nutritional support of burn patients has contributed to not only improved healing but also improved survival. While growth factors potentially may improve healing during malnutrition, there is no substitute for aggressive nutritional support. One should assess the nutritional state of the patient prior to the injury. Those patients who were malnourished prior to their burn will be at higher risk for complications and death.

There have been many investigations to determine whether the addition of specific nutrients may improve healing. Certain amino acids have been given in excess to animals to determine whether healing could be augmented. Several amino acids (methionine, cysteine, arginine) have provided statistically significant improvements in tissue repair, but whether their addition leads to clinical improvement is not clear.^{82,83} Arginine has been shown to improve collagen deposition and tensile strength.⁸⁴ In addition, it stimulates the immune system and thus may benefit the patient. Several 'immune-stimulating' tube feeding formulas include arginine. Glutamine is another nutrient that has been found to protect the enterocytes of the gut. The amino acid has not been proven to improve tissue repair.⁸⁵

Other nutrients such as vitamins and trace elements are essential for wound healing. The importance of vitamin C has already been discussed. Without vitamin C, collagen synthesis is impaired at the same time as collagen breakdown continues.⁸⁶ Since the balance between collagen synthesis and breakdown is lost, old incisions may break down. The other important vitamin for tissue repair is vitamin A. Vitamin A has been found to accelerate tissue repair and even may reverse the healing deficit after radiation or steroid treatment.^{87,88} The vitamin is pro-inflammatory and stimulates fibroblast function. Some of the B vitamins may also improve some aspects of wound healing.⁸⁹ The one vitamin that is commonly felt to improve healing but has no studies to support that contention is vitamin E — at least one study has demonstrated that vitamin E fails to accelerate tissue repair.⁹⁰ While it may not have profound effects on healing, vitamin E is essential for other aspects of burn treatment.

Trace elements are also known to improve healing. Zinc is the most notable mineral that has been found to reverse healing defects.⁹¹ The mineral is essential for many enzymes that are involved in tissue repair. The commonly used Unna boot contains zinc oxide. Zinc deficiency also leads to impaired tissue repair. Copper is essential for lysyl oxidase, the enzyme that is required for crosslinks between collagen molecules.⁹² A recent report suggests that a copper deficiency led to impaired healing in a burned patient.⁹³ Other trace elements may play a lesser role in tissue repair. Most burn centers supplement patients with extra vitamins and minerals. Whether the extra supplements help burn patients has not been proven. It does appear that extra vitamin C may be helpful for reducing fluid requirements during resuscitation.⁹⁴

Infection

It is well known that infection has profound effects on tissue repair. Surprisingly, infection does not *always* lead to impaired healing but some studies have demonstrated that contaminating a wound with bacteria does lead to impaired tissue repair.⁹⁵⁻⁹⁷ However, others attempted similar experiments but found that tissue repair was improved.⁹⁸⁻¹⁰⁰ It appears that if minor contamination occurs, then inflammation is augmented and the result is improved healing. If, on the other hand, large amounts of virulent bacteria are present then the host is overwhelmed and the infection is destructive. The same may be true for skin graft take. Robson has stated that if a wound bed has greater than 10^5 bacteria, then a graft will not take.¹⁰¹ Lesser numbers tend not to have an effect.

The systemic effects of infection also affect tissue repair. An abscess distant from the wound has been found to impair tensile strength.¹⁰² However, at least a portion of the decrease was attributed to impaired nutritional intake. But on the whole, it is most likely that sepsis does lead to altered tissue repair. Experience suggests that donor sites heal poorly and graft take is decreased in profound sepsis. Just the burden of a large burn wound appears to decrease the rate of donor site closure.

Associated illnesses

There are several systemic problems that have adverse effects on tissue repair. The most recognized disease affecting healing is *diabetes mellitus*.¹⁰³⁻¹⁰⁵ Diabetes can affect healing by several causes:

- First, the disease leads to both macrovascular and microvascular disease. The altered perfusion may lead to impaired nutrient and oxygen delivery.
- Secondly, the peripheral neuropathy of diabetes mellitus contributes to the tendency to develop ulcers. Insensate feet will not feel minor injury so that a minor irritation may turn into a more serious wound. Loss of the normal reflexes of the muscles that maintain the arch of the foot may lead to increased pressure areas, especially over the second metatarsal.
- Finally, the wounds in diabetic patients tend to have a higher propensity to become infected. A minor wound frequently becomes infected and more extensive. Diabetic patients tend to have a higher risk for amputation when compared to patients without the problem.

Fortunately, there is a growth factor (Regranex™ [PDGF-BB]) available to treat these wounds and which does appear to help healing.¹⁰⁶

Other diseases do affect healing:

- Obviously, any vascular abnormality that leads to tissue hypoxia has adverse effects.^{29,30,107}
- In addition, uremia¹⁰⁸ and liver failure¹⁰⁹ have adverse effects on tissue repair.
- Malignancy has been known for a long time to have adverse effects on wound healing.^{110,111} It is likely that the body shunts nutrients away from the wound and to the cancer. In addition, cancer patients tend to have anorexia and weight loss, both of which contribute to impaired wound closure.

Any other disease that impairs nutrition will predispose the patient to altered healing.

Cytotoxic treatments (steroids, chemotherapy, radiation)

Any agent that impairs cellular proliferation will lead to some impairment in tissue repair:

- Steroids are the most notable class of drug that leads to altered healing.^{112,113} Steroids decrease the inflammatory response and decrease collagen production. The inhibition of collagen production is occasionally used as a strategy to decrease scar formation in those patients with a tendency towards hypertrophic scarring. Its efficacy varies from patient to patient; however, growth factors have been found to reverse some of the adverse affects of steroids.^{114–116}
- Most chemotherapy agents lead to impaired healing.^{117,118} These agents are designed to kill rapidly proliferating cells. Unfortunately, the cells required for tissue repair must also grow rapidly. The agents affect healing if given systemically and can lead to chronic non-healing ulcers if they extravasate into the subcutaneous tissues. Growth factors have had some beneficial effects in animal studies.¹¹⁹
- Finally, radiation leads to similar problems as for chemotherapy agents.^{120,121} The effects can also be improved with topical growth factors.¹²²

Other drugs may have effects on healing but are not of major clinical importance.

Methods of stimulating wound healing

For years people have been trying to stimulate wound healing. Most of the time healing progresses at a reasonable rate and does not need to be accelerated. Healthy people rarely have healing problems and do very well without factors that stimulate healing. Those patients, however, with impairments such as diabetes, malnutrition, infection, treatment with cytotoxic agents are the ones who would benefit from a wound that heals more rapidly.¹²³

There have been literally thousands of publications that have studied agents that improve healing in animals. Very few have made it past the preclinical studies to become therapeutic agents for augmenting tissue repair. (See the nutrition section above, describing the studies relating to the addition of nutritional factors.)

Growth factors

The major thrust of improving healing has been through the addition of growth factors. Growth factors are natural cytokines that attract cells into the wound, stimulate their proliferation and induce the production of extracellular matrix.

Recombinant proteins

Initial studies involved harvesting growth factors from patients' own cells. Platelet releasates were the most common source for growth factors.¹²⁴ With the development of the ability to mass-manufacture any protein, recombinant growth factors were produced. Currently, Regranex™ (recombinant human PDGF-BB) is available and has been proved to be efficacious for diabetic ulcers.¹⁰⁶

The use of this growth factor for clinical wound healing stimulation has not been very extensive. Recombinant

proteins are expensive and have not been embraced by clinicians.

Gene therapy

A current focus for inducing growth factor activity in the wound has been through gene therapy. There have been numerous studies that utilized different vectors for delivering a gene (usually a growth factor) into a wound.^{125–136} Most known growth factor genes have been delivered to wounds and have been found to stimulate tissue repair in animal models.

There have also been clinical trials that utilize gene therapy for treating many diseases. One recent review suggested that there were hundreds of gene transfer protocols.¹³⁷ There have, however, been major setbacks in the use of gene therapy for human disease. In 2003, there were two publications that revealed that gene therapy techniques have the potential for major complications. In one study, two children developed lymphoproliferative disorders after retroviral gene transfer to their hematopoietic stem cells.¹³⁸ In the most disturbing case, an 18-year-old patient died from a systemic inflammatory response syndrome and ultimately, multiple organ failure after gene transfer for ornithine transcarbamylase deficiency.¹³⁹ Despite these setbacks trials are proceeding. There are two publications that describe the use of adenoviral-mediated gene overexpression of PDGF-BB to treat diabetic foot ulcers and venous stasis ulcers in clinical trials.^{140,141} The results of the clinical trials have not been published so we will have to wait to determine whether this technology will lead to a new way of accelerating wound healing.

Combined gene therapy and skin substitute technologies

Another strategy for stimulating healing in the burn wound is to combine gene therapy and skin substitute technologies.^{142–144} Since autogenous skin substitutes must be initiated from a biopsy and then cells must be grown in culture, there is ample opportunity to transfect them to augment or reduce a specific gene. There are studies that have used cultured keratinocytes or fibroblasts to increase production of PDGF-A, FGF-7, or KGF. This technology would allow for the skin substitute to release pharmacological doses of growth factors and stimulate angiogenesis, keratinocyte migration or collagen deposition. It would also be conceivable that a skin substitute would allow for the production of a factor that would minimize hypertrophic scarring.

Stem cells

The most recent interest in research has been the investigation of the role of stem cells in many areas of medicine. Wound healing in burns using stem cells has also been investigated.¹⁴⁵ In a recent publication from Lancet, fetal skin constructs have been reported to improve healing.¹⁴⁶ They utilized a bank of fetal skin cells from one donor and placed them on native horse collagen. The constructs were applied to eight patients for each dressing change for 1–3 weeks. They had complete healing with minimal hypertrophy. One must wonder, however, whether this application is really an elaborate way of delivering growth factors to a wound. It can be imagined that the cost of such a treatment would make its use unlikely.

A group from Russia has described using bone marrow mesenchymal stem cells in a similar type of treatment.¹⁴⁷ Both

reports lead to the speculation that stem cell research to improve healing in burns is a feasible treatment for the future.

Scar control

A great deal of knowledge has been gained about the factors that accelerate healing. Growth factors and other agents have been developed to reverse healing abnormalities of all kinds.

The factors that ‘turn off’ the healing process have not been well elucidated. Failure to control healing leads to excessive scarring that affects other organs beside the skin. The same processes lead to impaired cardiac function after a myocardial infarction, pulmonary fibrosis, cirrhosis, arthritis and many other fibrotic diseases. If one were able to control scar formation, then a great number of diseases would have better outcomes.

The mechanisms involved in ‘turning off’ of scar formation are starting to be elucidated (Figure 46.9). In order to stop the

Fig. 46.9 The extent of scar formation appears to be regulated through the signaling of a key growth factor — TGF- β . Multiple factors affect signaling of this growth factor. First, there are signals that emanate from the migrating epithelium that inhibit the signals that induce scarring. TGF- β activity is highly regulated through multiple checks and feedback loops. There are different stimuli that up-regulate or down-regulate its activity. Once TGF- β is synthesized, the protein exists in a latent form as a proprotein. In addition, the latent TGF- β is ‘protected’ by latent TGF- β -binding protein (LTBP). Several factors have the potential to activate TGF- β : decreased pH, proteolysis (plasmin, urokinase), thrombospondin, $\alpha\beta 6$, or binding by the IGF-II/mannose-6-phosphate (man-6-P) receptor. Inflammation tends to increase TGF- β activity through signaling through leukocytes such as macrophages. Lymphocytes produce interferons (IFNs) that inhibit the effects of TGF- β . TGF- β signaling may be inhibited by proteins or antibodies that interfere with receptor binding. There is also a type III receptor (betaglycan or endoglin) that binds some isoforms of TGF- β without inducing a signal. Once bound to the active receptors (TGF- β IIIR which then interacts with TGF- β IIR), intracellular serine kinases are phosphorylated. Signaling then proceeds with Smad2 or Smad3 becoming phosphorylated. Smad2 or Smad3 then bind with Smad4. Smad2 may be more involved with fibrosis while Smad3 may be more essential for the control of inflammation. The Smad2/3-Smad4 combination then enters the nucleus for binding to specific binding sites on the DNA. Ultimately, binding to these genes leads to transcription and translation of new proteins. One may also block collagen synthesis by providing antisense oligonucleotides that interfere with translation from mRNA to protein. Finally, there are inhibitory Smad proteins (particularly Smad7 for TGF- β) that block Smad signaling.

healing process, inflammation must stop. It is clear that covering a wound with an epithelium is required to begin stopping the inflammatory response. As long as there is exposure to foreign antigens and organisms the body will continue to 'try to protect' the organism with an inflammatory response. Studies have demonstrated that the epithelium induces apoptosis (programmed cell death) in inflammatory cells as it marches across a wound.^{41,42} In addition, as a wound is covered with a graft or flap, apoptosis is induced in fibroblasts and other inflammatory cells.⁴⁵ The signal produced by the covering epithelium has not yet been elucidated but studies suggest that factors that affect apoptosis are produced in the migrating keratinocytes.¹⁴⁸ More studies are needed to understand how the epithelium influences the ultimate scar.

We do know that if a wound is left open for too long, then it has a tendency to develop hypertrophic scarring.⁴³ Several investigators have demonstrated that TGF- β plays a role in the extent of scar formation (Figure 46.9).⁴⁶⁻⁴⁹ Those patients with a greater tendency to scar have higher serum levels of TGF- β 1.^{48,49} One study has revealed that antibodies to TGF- β 1 can reduce the amount of scarring that is present in a rat wound.⁵⁵ Interestingly, TGF- β 3 may have antiscarring effects.⁵⁵ In addition, interferons may reverse the tendency towards hypertrophic scarring. Both interferon- γ and interferon- α 2b have been found to reverse some of the scarring tendencies in patients.⁵⁰⁻⁵² Also, tension that is produced in a scar contracture increases TGF- β 1 and collagen production. Reducing the tension in a scar band by performing a release will decrease TGF- β 1 expression.¹⁴⁹

Newer techniques have been developed to counteract TGF- β 1 signaling (Figure 46.9).¹⁵⁰ Using an antibody against the protein is one strategy that might be effective. As stated before, an antibody to TGF- β 1 has been shown to reduce the extent of collagen deposition in a rat.⁵⁵

Instead of interfering with the protein, another strategy is to inhibit TGF- β 1 activity at the receptor.¹⁵¹ One study has examined the possibility of inhibiting scar formation by adenovirus-mediated overexpression truncated TGF- β receptor II. The publication suggested that overexpression of a non-functional receptor to bind TGF- β did inhibit scar formation.

Other studies suggest that hypertrophic scar cells have an impaired ability to undergo apoptosis.^{152,153} Strategies are being promoted to develop technologies to induce apoptosis in these cells. One interesting strategy has been to treat wounds with antisense oligonucleotides that actually inhibit mRNA signaling.¹⁵⁴⁻¹⁵⁷ Antisense oligonucleotides bind to mRNA and prevent translation of that specific protein. The antisense technology has been used to block collagen, TGF- β and other proteins to inhibit collagen synthesis.

Other strategies use agents that block key proteins in the cell cycle. A couple of publications have shown the potential of blocking p21 to inhibit healing.^{158,159}

Research has now gone past the role of growth factors and has studied the role of cell signaling in scar control. Nice studies from Ashcroft have revealed that intracellular proteins involved in signaling of TGF- β 1 are related to scar control.¹⁶⁰ After binding to the TGF- β receptor, signaling occurs through a family of proteins called Smads. There are two potential proteins, Smad3 or Smad2, that can be used for signaling. If Smad3 is eliminated then there are signs of good healing but less inflammation.^{161,162} It appears that signaling through Smad3 tends to increase fibrosis while signaling through Smad2 induces an inflammatory response. The relative amount of signaling between Smad2 and Smad3 may ultimately influence the extent of scarring. It is conceivable that therapies that direct intracellular signaling could lead to better scar control.

Another intracellular protein, Smad7 acts as an inhibitor of TGF- β signaling.^{163,164} Up-regulation of this protein could lead to improved control of hypertrophic scarring after burns. Hopefully, more therapeutic agents will be available in the future.

Despite these advances there are only a few current clinical modalities used for scar control in patients. Scar massage and stretching (therapy) appear to very efficacious. Patients who are compliant with a therapy program do much better than those who are not.

Silicone is another product that is available for the treatment of scarring. The exact mechanisms of how silicone works are not clear.^{165,166} Providing pressure on to the scar through hard materials or stretchy cloth (garments) has been used for decades to reduce hypertrophic scarring. There are some studies being published that suggest that pressure garments are not effective, but there are also many years of experience that suggest that they are very helpful. Hopefully, third-party support for garments is not lost before well-controlled studies are completed to answer the question of their efficacy.

Conclusion

Understanding the principles of wound healing is essential to the adequate treatment of burn patients. The skin is the first barrier to the outside world. If enough of the skin is lost, then any other defense will be overwhelmed. In addition, we now know that the wound is not an isolated event that affects only the local tissues. An open wound leads to a profound systemic response that, if large enough, will lead to major systemic changes and potentially the ultimate failure of the organism (through multiple organ failure). Our job as caregivers of the burn patient is to heal the wound as expeditiously as possible, while at the same time maintaining the best cosmetic and functional outcomes as possible. The best way to succeed in completing that goal is to have as good an understanding of tissue repair as possible.

Molecular and cellular basis of hypertrophic scarring

Paul G. Scott, Aziz Ghahary, JianFei Wang, and Edward E. Tredget

Chapter contents

Introduction	596
Chemical composition and organization of the extracellular matrix	596
The hypertrophic scar fibroblast phenotype	598
Modulation of fibroblast behavior by fibrogenic and antifibrogenic cytokines	600
The T-helper-2 cell response to burn injury	601
Fibrocytes	603
Summary	604

Introduction

The postburn hypertrophic scar presents as a raised, erythematous, pruritic and inelastic mass of tissue. If left untreated the collagen within its dermal matrix may undergo a reorganization leading to the development of contractures, and thus adding functional impairment to the discomfort and cosmetic problems already suffered by the recovering burn patient (Figure 47.1). The undesirable physical properties of hypertrophic scar tissue can be attributed to the presence of a large amount of extracellular matrix that is of altered composition and organization, compared to normal dermis or mature scar. This matrix is the product of a dense population of fibroblasts (and other cell types) maintained in a hyperactive state by inflammatory cytokines such as transforming growth factor- β (TGF- β) and other factors, some of which may be physical in origin. Eventually most hypertrophic scars undergo at least some degree of spontaneous resolution: a process that may have led to some of the conflicting descriptions of the histology, cell biology or chemistry of hypertrophic scar that have appeared in the literature from time to time. This chapter will review what is known about the molecular and cellular characteristics of the postburn hypertrophic scar and how these help to explain its development and properties, drawing comparisons with normal wound healing and mature scars. While it would be misleading to suggest that the etiology of this debilitating condition is completely understood, it is nevertheless our hope that the better understanding of its pathogenesis that is now emerging will lead eventually to more rational and successful, non-surgical treatments.

Chemical composition and organization of the extracellular matrix

Collagen

Collagen is the predominant extracellular matrix protein in both normal dermis and hypertrophic scar, where it is responsible for the tensile strength of the tissue. However collagen constitutes a smaller proportion (about 30% less of the dry weight) of hypertrophic scars because there are greater increases in other components such as the proteoglycans and glycoproteins¹ (see below). The major genetic form of collagen in skin and scars is type I, which characteristically assembles into thick fibrils, fibers and fiber-bundles. In normal dermis there are smaller amounts of type III (10–15% of the total) and very small amounts of type V and type VI collagens. Pure types III and V collagens assemble *in vitro* into thin fibrils^{2–4} but are found in tissues mainly in heterotypic fibrils mixed with larger amounts of type I collagen.^{5–7} Both types III and V collagens are considered to reduce the diameters of the collagen fibrils of which they form part. Hypertrophic scars generally contain thinner collagen fibrils than normal dermis (averaging around 60 nm in diameter compared to 100 nm).⁸ This difference might be explained by the higher proportions of types III and V collagens, reported to be about 33%^{9,10} and 10%,¹¹ respectively. Type III collagen appears in healing wounds within a few days after injury¹² and its persistence at high levels in hypertrophic scars is probably a reflection of their biological immaturity. Type VI collagen does not assemble into fibrils, but rather into thin beaded filaments, 5–20 nm wide, that are seen to run perpendicular to the fibrils and possibly to link them together.¹³ These may constitute the interfibrillar elements that have been described in hypertrophic scar.¹⁴

In the light microscope, it can be seen that much of the collagen in hypertrophic scars is arranged in ‘whorls’ or ‘nodules,’ rather than the thick fibers or fiber-bundles that are characteristically oriented parallel to the surface in normal dermis.⁸ In some specimens (e.g. Figure 47.2) there are extensive regions of almost hyaline appearance where little organization of the fine-fibered collagen is apparent. In the electron microscope the narrow collagen fibrils in these regions are seen to be more widely spaced than in normal dermis or mature scar and to be ovoid or irregular in cross-section.¹⁴ The interfibrillar space in fibrous connective tissues is occupied mainly by

Fig. 47.1 Hypertrophic scarring in a 34-year-old white man, 8 months following a 60% total body surface area burn involving the face, upper extremities and hands. (From Scott et al.,³⁶ with permission.)

matrix macromolecules of two other classes: the proteoglycans and glycoproteins.

Proteoglycans and glycoproteins

Proteoglycans influence physical properties of connective tissues such as turgor, resilience and resistance to compression, while glycoproteins such as fibronectin and tenascin are involved in cell-matrix adhesion and have effects on cell behavior mainly through this mechanism. Proteoglycans also influence cellular activity, but through a variety of mechanisms including both positive and negative modulation of growth factor activity. The morphology of collagen fibrils and

their organization are profoundly affected by the nature and amounts of proteoglycans present in the connective tissue.

Proteoglycans consist of one or more glycosaminoglycan chains, which are linear polymers of anionic disaccharides, covalently attached to a protein core. In the most common glycosaminoglycans (dermatan sulfate, chondroitin sulfate, heparan sulfate and hyaluronic acid), one unit of the repeating disaccharide is a uronic acid. Early chemical analyses of hypertrophic scars revealed elevated concentrations of uronic acid (and hence glycosaminoglycans).¹⁵ Since it is the anionic polysaccharide glycosaminoglycan chains that are mainly responsible for the water-holding capacity of connective tissues,¹⁶ it

Fig. 47.2 Hematoxylin and eosin-stained sections of normal skin (a) and a hypertrophic scar containing a nodule (b) (original magnification $\times 10$).

is not surprising that hypertrophic scars are hyperhydrated relative to normal dermis or mature scars. However, the 2.4-fold increase in glycosaminoglycan content (and presumably osmotic pressure) is disproportionately high relative to the 12% increase in water content.¹ Since the collagen fibers normally restrict swelling of connective tissues, it may be proposed that the high concentration of glycosaminoglycans in hypertrophic scars is responsible for their enhanced turgor.

Following the initial analyses of total glycosaminoglycan content in hypertrophic scars, it was reported that the nodular areas were virtually devoid of dermatan sulfate (the major glycosaminoglycan in normal dermis) and contained instead chondroitin sulfate, which is usually only a minor component.¹⁷ The corresponding changes in the proteoglycans were defined more recently, when it was reported that hypertrophic scars contain on average only 25% of the amount of the small dermatan sulfate proteoglycan decorin (the major proteoglycan found in normal dermis) and 6-fold higher concentrations of a large proteoglycan resembling versican.¹ This latter proteoglycan, which carries 12–30 chondroitin sulfate chains, is normally present only in the proliferating zone of the epider-

mis and in association with elastin in the dermis.¹⁸ Decorin and versican, as detected by immunohistochemistry, show a strikingly inverse distribution in the nodules,¹⁹ thus explaining the earlier observations on the distribution of the glycosaminoglycans: dermatan and chondroitin sulfates.

Decorin is implicated in the regulation of collagen fibril formation and in the organization of fibrils into fibers and fiber-bundles.^{20,21} In the decorin-null mouse, collagen fibrils were found to be variable in diameter and irregular in outline.²² This latter characteristic was earlier described for the collagen fibrils in the nodules of hypertrophic scar⁸ and may be explained by the virtual absence of the decorin that normally defines and delimits the fibril surface. A second small proteoglycan, biglycan, present in lesser amounts than decorin in normal dermis, is found at elevated levels in postburn hypertrophic scars.^{1,19} In most connective tissues biglycan is found close to the cell surface²³ but in hypertrophic scars it is associated with the collagen in the extracellular matrix,¹⁹ possibly because there is little decorin to compete for the restricted number of proteoglycan core protein binding sites on the collagen fibrils.²⁴

The differences in proteoglycan proportions and distributions between normal dermis and hypertrophic scars could in principle result either from altered biosynthesis or altered degradation. There is evidence for the former mechanism, since fibroblasts cultured from postburn hypertrophic scar contain less decorin mRNA and synthesize less of the protein than do normal fibroblasts.²⁵ It was shown by *in situ* hybridization that there are relatively few cells expressing mRNA for decorin in healing burn scars until about 12 months after injury.²⁶ Surprisingly, in fibroblasts cultured from hypertrophic scars there were no differences in contents of mRNAs for versican or biglycan, suggesting that other factors such as transforming growth factor- β (see below) were influencing fibroblast behavior and responsible for the elevated amounts of these two proteoglycans in the scars.²⁵

As hypertrophic scars mature, the collagen fibrils become coarser and better organized and there is an increase in immunohistochemically detectable decorin (Figure 47.3). At about 12 months after injury, a time when many scars start to resolve spontaneously,²⁷ there is a large increase in numbers of cells expressing decorin, suggesting that this proteoglycan may play an active role in the resolution.²⁶ Mature scars show contents of collagen, proteoglycans and water that are indistinguishable from those in normal dermis.¹

The results of early chemical analyses of hexose and sialic acid contents¹⁵ showed that hypertrophic scars contained elevated concentrations of glycoproteins, at least part of which is fibronectin.²⁸ This extracellular matrix macromolecule has effects on cell attachment and activity (reviewed in Hynes²⁹) that could be important in the development and organization of hypertrophic scar but its role does not appear to have been investigated directly.

The hypertrophic scar fibroblast phenotype

Many laboratory investigations have been based on the premise that the fibroblasts that can be grown from tissue explants retain the hypertrophic scar phenotype in culture. This is at least partly justified since these cells show characteristics that

Fig. 47.3 Immunohistochemical staining for decorin in normal skin from the abdomen of a 39-year-old female (a), postburn hypertrophic scar from the neck of a 4-year-old male, 5 months (b) and 12 months (c) after burn injury and postburn mature scar from the neck of a 22-year-old female, 216 months after burn injury (d). Bars = 10 μ m. (From Sayani et al., *Histopathology* 2000; 36:262–272.²⁶ with permission.)

would be predicted from what is known about the tissue. Some strains of hypertrophic scar fibroblast synthesize more collagen³⁰ and fibronectin³¹ than do normal dermal fibroblasts and all strains investigated make less decorin,²⁵ collagenase^{32,33} and nitric oxide.³⁴ Rather less consistent are the reports of altered cell replication rates *in vitro*. Since hypertrophic scars have a greater density of fibroblast-like cells than normal dermis or mature scar,²⁶ it might be predicted that these cells

would divide more rapidly in culture but the consensus is that population doubling times are unchanged or slightly longer.^{31,35,36} Possible explanations for this apparent anomaly are the absence *in vitro* of stimulatory cytokines, such as transforming growth factor- β (see below), that are present in the tissue,^{19,37} or that the cells that grow out of the explants are approaching the end of their replicative life span. There have been reports of enhanced incorporation of bromodeoxy-

uridine into hypertrophic scar fibroblasts *in vitro*³⁸ but labeling with tritiated thymidine led Oku and colleagues to conclude that most fibroblasts in hypertrophic scar are dormant, although there may be a small population of more rapidly proliferating cells.³⁹

Myofibroblasts and delayed apoptosis in hypertrophic scars

The presence of myofibroblasts, cells characterized by an indented nuclear envelope and well-developed stress-fibers, has been considered pathognomonic for fibrous tissue that is prone to undergo contracture.⁴⁰ Hypertrophic scar tissue contains elevated numbers of cells identified as myofibroblasts on morphological criteria.⁴¹ Myofibroblasts are now usually identified by their positive staining for α -smooth muscle actin,⁴² and such cells are especially prominent in palmar fascia in Dupuytren's disease⁴³ and in hypertrophic scar but not in keloid.⁴⁴ All fibroblasts probably have contractile ability, as seen in experimental model systems such as the fibroblast-populated collagen lattice where myofibroblasts do not appear until contraction is complete.⁴⁵ Moreover, cells with the morphological characteristics of myofibroblasts can be induced in skin by the application of tension in the absence of wounding.⁴⁶ Nevertheless, electroinjected antibodies against α -smooth muscle actin block the contraction of the fibroblast-populated collagen lattice,⁴⁷ indicating that this minor actin isoform (normally accounting for about 14% of the total actin in fibroblasts) is an integral component of the contractile apparatus.

The reduction in cellularity that accompanies the conversion of granulation tissue into scar tissue, or of hypertrophic scar into mature scar, is associated with induction of apoptosis (programmed cell death).⁴⁸ (See Perl et al.⁴⁹ for a brief review of this complex process.) The myofibroblast has been suggested to be a terminally differentiated pre-apoptotic cell.⁴⁰ However, this suggestion appears inconsistent with reports that organization of α -smooth muscle actin into stress fibers protects fibroblasts against the induction of apoptosis,⁵⁰ and with the different distributions of α -smooth muscle actin staining and apoptotic cells in skin wounds in guinea pigs treated with interferon- α 2b.⁵¹ The prevalence of myofibroblasts in hypertrophic scar may actually be a sign of a delay in the normal onset of apoptosis in the healing wound and this delay may be responsible at least in part for the hypercellularity.

Influence of extracellular matrix on fibroblast survival

The extent and strength of interactions between attachment-dependent cells such as fibroblasts and epithelial cells and the underlying extracellular matrix are important factors determining cell survival. Detachment of such cells often leads to apoptosis, a phenomenon for which the term 'anoikis' (Greek for homelessness) was coined.⁵² In this context the high concentration of fibronectin in hypertrophic scars might be important, since binding of the α 5 β 1 integrin to this adhesive glycoprotein has been shown to inhibit Chinese hamster ovary (CHO) cells from undergoing apoptosis.⁵³ Results obtained with the fibroblast-populated collagen lattice model *in vitro* also support the paradigm that the extracellular matrix regulates fibroblast behavior in healing wounds ('outside-in signaling'). In the anchored lattice, which resists deformation in all

but the short vertical dimension, fibroblasts continue to proliferate, while in floating or stress-relaxed collagen lattices that are rapidly reorganized, they are triggered to undergo apoptosis.^{54,55} The overabundant glycosaminoglycans in postburn hypertrophic scars, through their contribution to tissue osmotic pressure and turgor, might inhibit reorganization of the collagen matrix by the fibroblasts.⁵⁵ Alternatively (or additionally), reorganization of the matrix may be impaired as a result of its chemical stabilization (cross-linking) by tissue transglutaminase, an enzyme that is expressed in greater amounts by hypertrophic scar than by normal dermal fibroblasts.⁵⁶ Either mechanism could delay the onset of apoptosis. Treatment of hypertrophic scars with pressure therapy has been used for many years and is generally considered beneficial. It has been shown that such treatment promotes the reorganization of postburn scar tissue and the disappearance of α -smooth actin staining myofibroblasts, probably by accelerating the onset of apoptosis.⁵⁷ A similar phenomenon is seen in the scars of burn patients treated with systemically injected interferon α 2b.⁵⁸

Modulation of fibroblast behavior by fibrogenic and antifibrogenic cytokines

Two general mechanisms might be suggested to account for the altered phenotype of fibroblasts in hypertrophic scars. The first, and simplest, is that thermal injury selectively destroys certain cells, for example those in the superficial dermis, while the second, and more extensively investigated possibility, is that the proliferation and/or activities of certain subsets of fibroblasts are affected by fibrogenic cytokines present in the wounds. These two mechanisms are not mutually exclusive. Some of the activities of the cytokines in healing wounds are shown in Figure 47.4.

Fig. 47.4 The fibrogenic and antifibrogenic factors that modulate fibroblast function during wound healing. (From Tredget EE, Nedelec B, Scott PG, Ghahary A. Hypertrophic scars, keloids and molecular basis for therapy. *Surg Clin North Am* 1997; 77:701-730, with permission.)

Transforming growth factor- β

The best-characterized fibrogenic cytokine is transforming growth factor- β (TGF- β), actually a family of (in mammals) three closely related proteins (for review see Roberts and Sporn⁵⁹). Cellular sources of this cytokine include degranulating platelets, macrophages, T-lymphocytes, endothelial cells, smooth muscle cells, epithelial cells and fibroblasts, i.e. all the major cell types participating in wound healing.⁵⁹ Transforming growth factor- β 1 is a potent chemoattractant for monocytes⁶⁰ and fibroblasts.⁶¹ It stimulates fibroblasts to synthesize collagen, fibronectin, and glycosaminoglycans,^{62–64} down-regulates decorin synthesis while up-regulating production of versican and biglycan,⁶⁵ enhances neovascularization⁶⁶ and modulates production of a variety of proteinases and their inhibitors.^{67,68} Subcutaneous injection of TGF- β 1 into newborn mice stimulates formation of granulation tissue⁶⁶ and accelerates healing of incisional wounds in rats.⁶⁹ Many of the effects of TGF- β 1 on mesenchymal cells may be mediated by connective tissue growth factor. This protein, which stimulates the proliferation of fibroblasts and synthesis of extracellular matrix proteins,⁷⁰ is coordinately expressed with TGF- β in several fibrotic conditions.⁷¹

Transforming growth factor- β stimulates the expression of α -smooth muscle actin in fibroblasts and may delay the onset of apoptosis by this pathway.⁵⁰ Fibroblasts cultured from hypertrophic scar synthesize more TGF- β 1 than do normal dermal fibroblasts⁷² and the protein has been detected in the scar by immunohistochemistry.^{19,37} The serum of recovering burn patients contains levels of TGF- β 1 about twice those in control patients.⁷³ All these observations, and evidence implicating it in other fibrotic conditions (reviewed in Ghahary et al.⁷⁴), point to the probable involvement of TGF- β in post-burn hypertrophic scarring.

The activity of TGF- β in connective tissue may be modified by interaction with components of the extracellular matrix, such as the proteoglycans. Decorin has been shown to bind to TGF- β and to neutralize at least some of its activities^{75,76} and mature postburn scars stain intensely for TGF- β that appears to be co-distributed with the decorin.¹⁹ Consequently we suggest that decorin, which is massively re-expressed in healing burn wounds starting around 12 months after injury,²⁶ down-regulates TGF- β activity and promotes the natural resolution of hypertrophic scarring.

Insulin-like growth factor-1

Other cytokines that may play a role in hypertrophic scarring include insulin-like growth factor-1 (IGF-1). Like TGF- β 1, IGF-1 is expressed locally in response to tissue injury,^{77,78} including postburn hypertrophic scar tissue.⁷⁹ Insulin-like growth factor-1 is mitogenic for fibroblasts and endothelial cells, stimulates collagen production by osteoblasts,⁸⁰ lung⁸¹ and dermal⁸² fibroblasts and in growth plate chondrocytes,⁸³ and reduces expression of collagenase by dermal fibroblasts.³³ The remarkable similarity in activities of IGF-1 and TGF- β 1 can be explained by the observation that IGF-1 induces transcription of the gene for TGF- β 1, so that at least some of its actions on fibroblasts might be mediated through this indirect mechanism.⁸⁴ Expression of IGF-1 in uninjured skin seems to be restricted to epidermis, sweat and sebaceous glands⁸⁵ but in a healing burn wound these elements are disrupted and epithelial cells migrat-

ing towards the wound surface could possibly secrete IGF-1 in proximity to fibroblasts and affect their activity.

Interferons

The interferons (IFNs) are naturally occurring cytokines that were originally detected as proteins expressed in response to viral infection⁸⁶ but which may have therapeutic application in the treatment of hypertrophic scars and keloids. There are two main classes of interferon: type I comprising IFNs- α and - β (produced by leukocytes and fibroblasts, respectively), and type II (IFN- γ , produced by activated T-lymphocytes). They are distinguished by the degree of their amino acid sequence similarity and by their receptors and intracellular signaling pathways.⁸⁶ Treatment of fibroblasts *in vitro* with either type of interferon inhibits cell proliferation and reduces expression of type I and III collagens,^{87,88} fibronectin⁸⁹ and TGF- β .⁷³ Interferon- α 2b, but not IFN- γ , also induces the expression of collagenase, suggesting that it may possibly be of greater benefit than the latter in the treatment of fibroproliferative disorders where an excessive amount of collagen is present.⁹⁰ Treatment of fibroblasts *in vitro* with IFNs reduces the rate of contraction of collagen lattices,^{91,92} probably by down-regulating the expression of the genes for the major β and γ isoforms of actin.⁹³ Administration of IFN- α 2b to guinea pigs through osmotic mini-pumps reduces the rate of wound closure and the frequency of α -smooth muscle actin-positive cells, and increases the frequency of apoptotic cells in healing wounds at late stages.⁵¹

Although keloids in patients treated with IFN- α 2b showed only limited improvement,^{94,95} early (phase II) trials in postburn hypertrophic scar patients have shown promising results, associated with a reduction in scar height, increase in scar suppleness and reduced levels of circulating methylhistamine and TGF- β .⁷³ In these same patients there was an increased frequency of apoptotic cells following treatment with IFN- α 2b.⁹⁶ Induction or augmentation of apoptosis by IFNs has been demonstrated in activated T cells, squamous cell carcinoma cells and non-melanoma skin cancer cells.^{97–99} It does not appear to have been previously shown in fibroblasts but is consistent with the report that IFN- γ down-regulates α -smooth muscle actin.¹⁰⁰

Given the evidence, reviewed above, that interferons can modify fibroblast behavior both *in vivo* and *in vitro*, the question naturally arises of whether depressed intrinsic levels of these cytokines might play a role in the pathogenesis of aberrant scarring. McCauley et al. isolated peripheral blood mononuclear cells (PBMC) from black keloid patients and from a control group of patients who had suffered equivalent trauma but not developed keloids.¹⁰¹ After appropriate stimulation, PBMC from the keloid patients secreted less IFN- α and IFN- γ but more IFN- β . Cytokine production by T-cell clones that could be grown from active hypertrophic scar tissue and scars undergoing remission, were compared by Bernabei et al.¹⁰² In both cases clones producing IFN- γ predominated but the amounts of this cytokine released were 4–6 times lower in clones from scars undergoing remission. It was suggested that the IFN- γ , a potent pro-inflammatory cytokine, was responsible for the prolonged inflammation in active hypertrophic scars.

The T-helper-2 cell response to burn injury

It has long been recognized that hypertrophic scars are heavily infiltrated with lymphocytes, often forming perivascular

cuffs.⁸ These cells are surrounded by a proteoglycan-rich matrix that they may have secreted themselves.¹⁰³ The largest population of lymphocytes in hypertrophic scars is activated (CD4+) T-helper cells, found especially in the subpapillary dermis but also in the epidermis and reticular dermis.¹⁰⁴ There are also increased numbers of macrophages and Langerhans' cells but B-lymphocytes are not seen. Two subsets of T-helper cells (Th1 and Th2) can be differentiated by the cytokines that they synthesize.¹⁰⁵ Th1 cells secrete IFN- γ , interleukin-2 (IL-2) and tumor necrosis factor- β (TNF- β) and are principally involved in cell-mediated immunity, whereas Th2 cells secrete IL-4, IL-5 and IL-10 and induce antibody production. The activation of naïve mouse CD4+ T-lymphocytes to secrete TGF- β is promoted by the Th2 cytokine IL-10 and the amounts of TGF- β secreted are greater in T-cell populations from IFN- γ null mice and lower in IL-4 null mice.¹⁰⁶ For an extensive review of the evidence linking the type of T-cell response to the development and mechanism of fibrosis, see Wynn.¹⁰⁷ In burned mice there is depletion of splenocytes synthesizing IFN- γ and IL-2 (Th1 cytokines) and an increase in synthesis of IL-5 (a Th2 cytokine).¹⁰⁸ There is evidence for a similar 'Th2 response' in human burn victims. Stimulated PBMC from patients with 25–90% surface area burns showed diminished production of IL-2.¹⁰⁹ Increased production of IL-4, accompanied by decreased IFN- γ , was subsequently reported in a group of burn and major trauma patients.¹¹⁰ Interleukin-4 has been reported to be even more potent than TGF- β at promot-

ing collagen synthesis by fibroblasts.¹¹¹ A link between the type of Th response to injury and the severity of fibrosis has been demonstrated: hepatic fibrosis is much more severe in BALB/c mice, which show a Th2 response to chemically induced liver injury, than in C57BL/6 mice, which respond with a Th1 cytokine profile.¹¹² Moreover, shifting the Th2 response toward a Th1 response by treatment with a neutralizing antibody to IL-4, or with IFN- γ , ameliorated fibrosis in the BALB/c mice. Intradermal administration of IFN- α 2b has been reported to be ineffective in preventing the recurrence of resected keloids¹¹³ and this treatment might therefore be expected to be minimally effective for the treatment of hypertrophic scarring. It is nevertheless possible that systemic administration of IFN- α 2b to recovering burn patients does affect the T-helper cell phenotype and that its beneficial effects are mediated in part through this mechanism.^{73,114} We have recently reported results of a longitudinal study on recovering burn patients that supports the hypothesis that there is 'locked on Th2 response' to burn injury.¹¹⁵ Cytokine synthesis by T-cells was assessed from the time of injury to 1 year after injury, during which time many burn patients develop hypertrophic scarring. Within 1 month of injury, few interferon- γ (IFN- γ) positive T cells (Th1) were found in association with low serum IL-12 levels (Figure 47.5a,b) and no detectable serum IFN- γ . By 2 months, IL-4 positive Th2 cells were significantly increased as compared to normal controls (Figure 47.5c). In burn patients who later developed hypertrophic

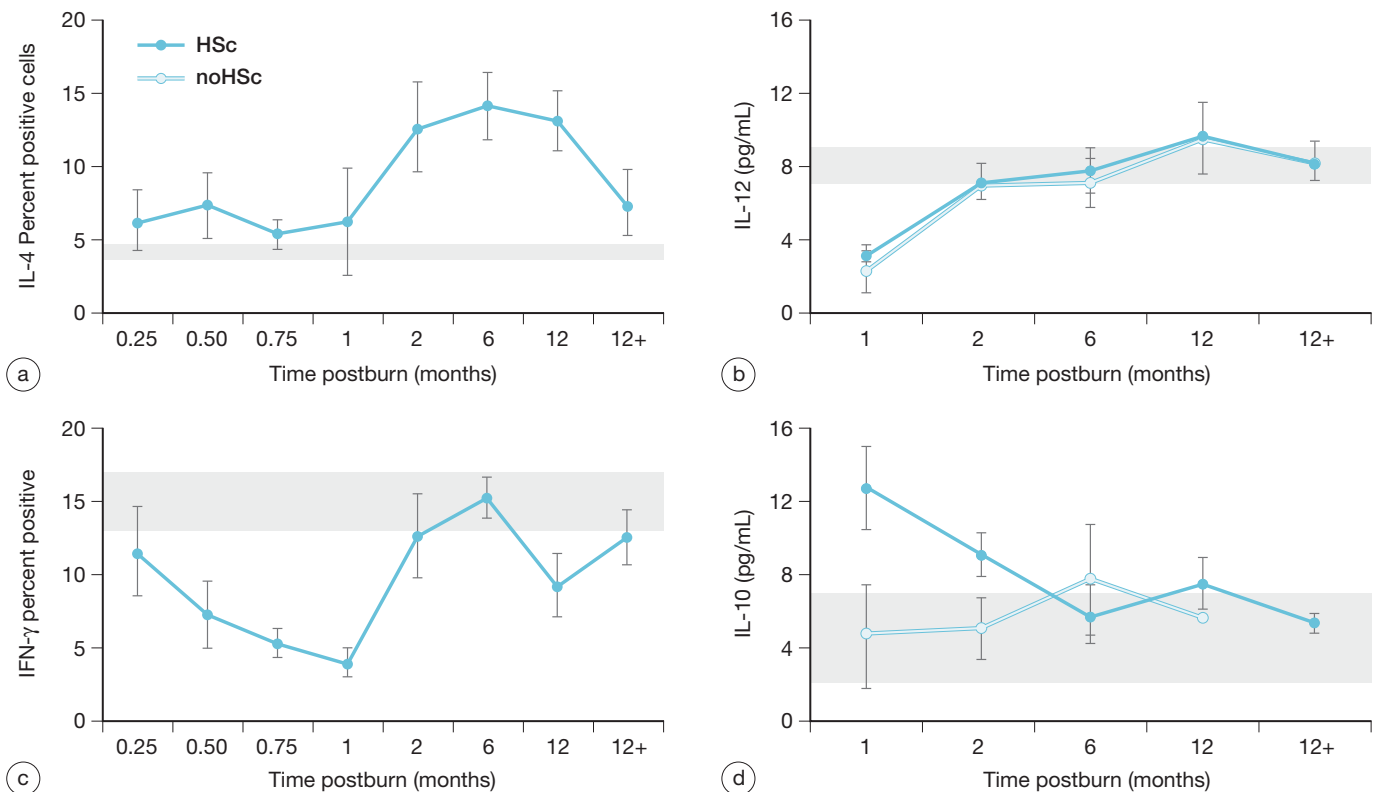

Fig. 47.5 Cytokine production by lymphocytes from burn patients as a function of time after injury. The percentages of lymphocytes producing IFN- γ (a) or IL-4 (c) were estimated by flow cytometry analysis of cells stained for intracellular cytokines using fluorescent-labeled antibodies ($n = 22$). (b,d) Time course of IL-12 (b) and IL-10 (d) production by peripheral blood mononuclear cells (PBMC) cultured from burn patients who developed hypertrophic scar (HSc) and those who did not (noHSc), measured by ELISA ($n = 16$). The values measured for cells from normal human volunteers are shown in the shaded boxes (mean \pm SD). (From Tredget et al., *Interferon Cytokine Res* 2006; in press¹¹⁵ with permission.)

scarring, serum IL-10 (Figure 47.5d) and TGF- β levels were also significantly increased early after injury, as compared to normal volunteers and to a subset of burn patients who did not develop hypertrophic scarring. These elevated levels of IL-10 and TGF- β returned to normal after 6 months. Activated peripheral blood mononuclear cells (PBMC) contained mRNA for IFN- γ only in normal volunteers or patients without hypertrophic scarring, whereas IL-4 mRNA levels were increased in the PBMC of burn patients with hypertrophic scarring. In tissues, IL-4 mRNA was increased in the hypertrophic scars, whereas IFN- γ mRNA was reduced, as compared to normal skin and mature scar. Increased numbers of CD3+ and CD4+ cells were present in hypertrophic scar tissues as compared to normal skin, together with increased staining for the fibrogenic cytokine TGF- β . These longitudinal studies in human burn patients strongly suggest that hypertrophic scarring is associated with a polarized Th2 systemic response.

Fibrocytes

Blood-borne cells that are rapidly recruited into wound chambers in mice, adopt a spindle shape and synthesize collagen, were identified in 1994 and termed ‘fibrocytes’.¹¹⁶ These cells, believed to constitute 0.1–0.5% of peripheral blood leukocytes, exhibit characteristics of both fibroblasts and monocytes. They synthesize extracellular matrix molecules such as collagen types I and III and fibronectin, while expressing certain surface antigens, such as CD11b, CD34, and CD45, that are characteristic of cells derived from the bone marrow (for a review see Metz¹¹⁷). In addition to possibly forming some of the extracellular matrix in healing wounds, fibrocytes may be involved in antigen presentation,¹¹⁸ cytokine production¹¹⁹ and the stimulation of angiogenesis.¹²⁰ They may also be a source of myofibroblasts and contribute to wound closure.^{121,122}

Fibrocytes, identified by their staining for CD34, have been reported in various experimental and naturally occurring fibrotic conditions, including bleomycin-induced pulmonary fibrosis,^{123,124} renal fibrosis,¹²⁵ and liver fibrosis.¹¹⁹

Fibrocytes may contribute to the pathogenesis of postburn hypertrophic scarring. Adherent, spindle-shaped cells, synthesizing type I collagen, can be cultured with higher efficiency from the peripheral blood mononuclear cell population of burn patients than from normal subjects.¹²⁶ These cells develop in culture from adherent CD14+ leukocytes under the influence of transforming growth factor- β (TGF- β), and possibly other cytokines, secreted by non-adherent CD14– lymphocytes. The efficiency with which they develop is positively correlated with the serum level of TGF- β in the donor,¹²⁶ and this cytokine has been found to be persistently elevated in burn patients.⁷³ During culture these fibrocytes lose cell surface proteins such as CD34 (which is also expressed by other cell types including vascular endothelial cells). Therefore to detect and quantify fibrocytes in tissue, a more stable and specific marker is desirable. Both adherent (‘fibrocyte precursor’) and non-adherent lymphocytes contain LSP-1 (leukocyte-specific protein-1, formerly known as ‘lymphocyte-specific protein-1’) but this particular cytoskeleton-associated protein is upregulated in fibrocytes from burn patients and completely absent from fibroblasts.¹²⁷ Moreover, LSP-1 is expressed by cultured fibrocytes for at least 28 days (unpublished data), during which time 80% of the cells lose CD34 expression.¹²³ Fibrocytes in human scar tissue can therefore be identified, and distinguished from other lymphocytes and from fibroblasts, by dual staining with antibodies directed against LSP-1 and procollagen type I (Figure 47.6). Although such cells probably constitute only a small proportion of the collagen-producing cells in hypertrophic scar, they are more abundant than in mature scar and none were seen in normal dermis.¹²⁷ Recent work in our laboratory (unpublished data) has shown that fibrocytes from

Fig. 47.6 Dual immunofluorescent labeling of fibrocytes in scar tissue. Cryosections of hypertrophic scar (a–c) and mature scar (d–f) were stained with antibodies to leukocyte-specific protein-1 (LSP-1) (green color) and the N-terminal propeptide of type I procollagen (red color). In double-exposure photomicrographs fibrocytes (arrowed in c) are visualized in hypertrophic scar by the colocalization of LSP-1 and procollagen (yellow color). (From Yang et al., *Wound Rep Reg* 2005; 13:398–404.¹²⁷ with permission.)

Fig. 47.6 – cont'd.

burn patients, but not those from normal subjects, can secrete factors stimulating the proliferation, migration and contractility of normal dermal fibroblasts. Fibrocytes may therefore play an important, albeit indirect, role in the pathogenesis of post-burn hypertrophic scar.

Summary

The postburn hypertrophic scar consists of a mass of hypercellular and disorganized connective tissue overlain with a thickened epidermis. Within the connective tissue much of the collagen is arranged in whorls and nodules, rather than the thick fibers and fiber-bundles running parallel to the surface that are characteristic of normal dermis. This derangement of the collagen, together with the very high content of glycosami-

noglycans, accounts for the inelasticity and turgor of the tissue which might be further stabilized by cross-linking by tissue transglutaminase. The hypercellularity characteristic of hypertrophic scar probably results from a blockade in the induction of the programmed cell death (apoptosis) that normally accompanies scar maturation, consequent upon altered cytokine profiles and signals from the extracellular matrix. Abnormalities in the extracellular matrix may themselves result from the selection and stimulation of subpopulations of fibroblasts, synthesizing increased amounts and altered proportions of specific types of collagen and proteoglycan, and reduced amounts of proteolytic enzymes (for example collagenase), that are normally responsible for the remodeling phase of wound healing. A polarized T-helper-2 cell response to burn injury, leading to increased levels of circulating and

local fibrogenic cytokines, such as transforming growth factor- β , and decreased antifibrogenic cytokines such as the interferons, may mediate these shifts in phenotype. A recently

recognized blood-borne cell, the fibrocyte, may accumulate in hypertrophic scar and modulate the activity of the many fibroblasts within it.

Delayed wound closure by second intention and wound contraction	609
The pathophysiology of burn wound healing	609
Factors that may alter normal wound healing	612
Hypertrophic scarring	612
Possible implications for future modes of therapy	616
Pathogenic concepts and gaps in knowledge	616
Summary	617

Introduction

Scarring secondary to burns leads to a multitude of adverse medical consequences including loss of function, restriction of joint mobility, restriction of growth, altered appearance and adverse psychological effects. Studies have begun to reveal the processes of intercellular communication via peptides, such as cytokines and growth factors, that initiate and regulate the process of wound healing. This chapter reviews current knowledge of the process of wound healing in humans and animals, with special emphasis on abnormal long-term responses to thermal injury.

Prehistoric and historic perspectives

Wounds due to combat, hunting injuries, accidents and thermal injuries undoubtedly were the leading causes of death in humans for millennia. On the other hand, prolonged survival of large full-thickness wounds is a recent phenomenon. Several complex biological responses to injury to the skin have evolved over time, but there has been no evolutionary pressure to evolve appropriate responses to very large wounds. There are records of human attempts to improve wound healing in the most ancient texts from Mesopotamia and Egypt. When the prophet Jeremiah asked 'Is there no balm in Gilead? Is there no physician there?' (Jeremiah 8:16, King James Bible) he bemoaned the absence of the expected skill in treatment of open wounds about 2600 years ago. Guido Majno, in his excel-

lent book 'The healing hand: man and wound in the ancient world,' has explored what can be learned from archeology and paleontology regarding wounds and their treatment in ancient times, and has even gone on to do experimental studies of the beneficial properties of substances such as honey that were widely used to treat wounds.¹ He also provided a very accurate brief description of the process of wound healing in lay terms (pp. 1–6), and this elegant overview:

... long before the birth of anything that could be called experimental medicine, wounds also functioned as natural experiments, multiplied millions of times. They were treated with dressings, and in the long run the better dressings stood out. In this permanent battle between man and bacteria, it is thrilling to watch the birth of the first antiseptics ... (preface, p. viii)

In the development of modern medicine, the advances in wound treatment advocated by Ambroise Paré (1510–1590) stand out, together with the campaign for antiseptics of Joseph Lister (1827–1912), and the development of antibiotics as well as the development of the modern methods of treatment described in this book.

Incisional wounds with primary closure

The essential components of wound healing are easily understood, and represent the simultaneous activation in the wound of tissue repair by fibroblasts and small blood vessels, and an inflammatory response initiated by vascular leakage and entry into the wound of circulating polymorphonuclear neutrophils, lymphocytes and monocytes.² When a sharp incision is closed while still sterile, there is only minimal vascular leakage and inflammation, and the predominant reaction to injury occurs in the fibroblasts present in the dermis and subcutaneous tissue. These resting connective tissue cells are rapidly activated to secrete collagen, which quickly bridges the small remaining gap to restore the resistance of the skin to tearing. Vascular continuity is restored by budding and remodeling of blood vessels, and the basal keratinocytes of the epidermis divide briefly to restore the complete structure of the epidermal barrier. All that remains to indicate the site of injury is a linear ribbon of dense collagen with little flexibility that marks the site of the incision, as well as some small scars that mark the sites where sutures were inserted. This process of incisional wound healing was well described in humans by Russell Ross and his colleagues in Seattle.^{3,4}

Delayed wound closure by second intention and wound contraction

If the epidermis and dermis are incised or removed and the edges of the wound remain separated, inflammatory and reparative events are much more prominent. Extensive leakage of blood plasma by damaged small blood vessels maintains an outward flow that serves to keep the wound clean, but causes deposition of coagulated fibrin and other desiccated proteins on the wound surface. Conversion of fibrinogen into fibrin fills the gap in the epidermis and provides a gelatinous matrix capable of sustaining migrating cells. Thrombin stimulates expression of interleukin-6 in connective tissue cells as well as production of important cytokines by infiltrating cells.⁵⁻⁷ Degranulation of platelets during the process of coagulation releases platelet-derived growth factor (PDGF), as well as several other proinflammatory cytokines.⁸ Degradation of fibrin releases peptides that stimulate fibroblast proliferation and secretion and division of vascular endothelial cells, and production of cytokines by other cells.^{9,10} The resting fibroblasts of the dermis, together with circulating stem cells, divide rapidly in the wound bed and secrete large quantities of collagen and proteoglycans, particularly those typically present in skin during fetal life, with predominance of type III collagen.^{11,12} Simultaneously, the endothelial cells of small blood vessels proliferate rapidly and form numerous small capillary loops that extend upward toward the surface. Together, these cells form a mass of granulation tissue that covers the wound. All these activities of fibroblasts and endothelial cells are stimulated by cytokines and other peptides secreted by monocytes and lymphoid cells that infiltrate the wound bed. Certain proteins and peptides that are normally present in blood plasma also stimulate and enable formation of the wound matrix, notably fibronectin and vitronectin.¹³⁻¹⁵ Numerous polymorphonuclear neutrophils also enter the wound bed, where they phagocytize and kill bacteria and fungi, which are always present in the outside world and gain entry to the dermis and subcutis through the open wound. Next, the fibroblasts develop interconnections among themselves and produce contractile machinery of actin and myosin within the cytoplasm of each cell.¹⁶ Then these interconnected myofibroblasts contract to shrink the size of the open wound, pulling adjacent intact skin to cover the wound bed. This process of wound contraction is more dramatic in experimental wounds of rodents than in human wounds. The effects of wound contraction in applying tension to surrounding tissues, however, are sometimes very clear in humans as well. Simultaneously with these processes, the basal keratinocytes of the cut edges of the epidermis change to a migratory and secretory phenotype, and begin to invade the wound bed between the granulation tissue layer and the scab of dried proteins on the surface.¹⁷ Cell division of keratinocytes occurs near the cut edge of the wound to supply cells for this migration. Once they make contact to seal the center of the wound, the migrating keratinocytes change their phenotype again and restore the normal laminated structure of the epidermis and produce a new basal lamina.^{18,19} Melanocytes also seem to develop migratory properties during healing of large wounds, since they establish a degree of pigmentation in the healed wound that approximates the pigmentation of the uninjured skin. It should be noted that only the epidermis regenerates to resemble the normal struc-

ture. Hair follicles, sweat glands and other epidermal appendages do not regenerate. Thus the part of the wound that was closed by epithelial migration remains dry, hairless and flat. The restored dermis in a fully healed scar is composed of collagen type I fibers running in straight lines adjacent to one another parallel to the surface, providing good strength (though somewhat less than the native skin) but far less elasticity and flexibility than the connective tissue of the normal dermis.

The pathophysiology of burn wound healing

The biophysics of thermal injury

Cells of human skin are susceptible to killing when their temperature is increased, largely because of the sensitivity of the cell surface membrane to disruption outside fairly narrow limits of temperature. Burns also can lead to pyrolysis and disruption and oxidation of tissues. Among the various cell types present in the skin, some are likely to be more sensitive to killing by elevated temperature than others. The degree of temperature elevation at a given site in the skin also depends on the rate of heat transfer within the tissue. The thermal conductivity of the dermis is greater than that of the subcutis, since fat is a good insulator. Perhaps for this reason, thermal injury often leads to necrosis of the entire dermis with little cell death in the subcutis, as seen in wound biopsies. Hair follicles in some sites typically extend well beyond the dermis into the adipose tissue of the upper subcutis, and eccrine sweat glands are also seen in the subcutaneous fat (Figure 48.1). Despite the presence of adipose tissue around them, often hair follicles are entirely destroyed by burns even though there is little or no apparent necrosis in the upper subcutis. In the most severe burns, however, the entire subcutis may become necrotic, and cell death may occur in the underlying fascia and skeletal muscle or even in underlying internal organs.

First-degree or superficial injury of skin

Superficial burn wounds are those in which part or all of the epidermis is lost, but the epidermal basal lamina remains intact and the dermis is uninjured. In these areas, only epidermal regeneration is required, hair follicles and sweat glands remain intact, and healing can occur with little or no disfigurement.²⁰

Second-degree or partial-thickness injury

In partial-thickness wounds, the entire epidermis and the upper part of the dermis become necrotic. If the wound is left intact, the presence of a large quantity of devitalized tissue requires prolonged activity of macrophages to clear the necrotic debris. Granulation tissue forms underneath the necrotic dermal tissue, and epidermal migration occurs under the eschar formed by dead tissue, leading to restoration of the epidermis, and production of dermal connective tissue in the form of a thin scar. The deep portions of the hair follicles remain viable, and the keratinocytes lining the hair follicles become migratory and undergo mitosis behind the migrating cells, eventually covering the surface with new epidermis.^{17,21} In severe cases, loss of hair follicles may lead to insufficient regenerative activity to cover the surface.²²⁻²⁴

Fig. 48.1 Photomicrographs of normal skin, stained with hematoxylin and eosin. (a) The hair follicles often extend through the dermis into the subcutaneous adipose tissue. The epidermis forms irregular rete ridges at its base. (b) The reticular dermis of normal skin has an orderly arrangement of collagen fibers with no preferred orientation. (c) With the Movat pentachrome stain, normal collagen fibers stain yellow-orange, and delicate interconnecting black elastin fibers are present between collagen fibers.

Third-degree or full-thickness injury

In full-thickness burns, thermal injury extends deep enough to destroy the entire hair follicle including its root, and some of the upper subcutaneous tissue may also become necrotic. In this case regeneration of the epidermis from hair follicles is not possible, and the wound can develop an epidermal covering only slowly as the epidermis lateral to the wound spreads out over the entire wound surface.² During this time, the necrotic tissue in the wound bed is at risk of infection, and extensive activity of tissue macrophages is required to remove it.

Changes in vascular permeability

In order to review current understanding of the processes important in wound healing, each process will be considered separately. Changes in local blood vessels are the earliest component of the response to injury, and are essential for the succeeding steps. Plasma exudation is due in part to increased permeability of venules to proteins due to local release of substance P from local sensory nerve endings and histamine from mast cells. In burn injury, there is an added component of plasma leakage that occurs for a few hours throughout the body in response to unknown stimuli. Of course, both plasma and red blood cells enter the wound through broken or necrotic blood vessels. Infection triggers further plasma exudation by constantly stimulating and prolonging the vascular phase of acute inflammation. In addition, the newly formed capillaries of granulation tissue allow passage of plasma proteins and fluid until they mature. Certain plasma proteins, notably fibronectin and vitronectin, are important in stimulating reparative responses in the wound.

Granulation tissue and the proliferative phase of wound healing

Massive proliferation of fibroblasts and vascular endothelial cells is characteristic of the early phase of wound healing. These cells, the fine fibrils of collagen, and the gel provided by multiple mucopolysaccharides and proteoglycans, make up the granulation tissue that is a major feature of all wounds that remain open. The most important of many peptides that stimulate fibroblast growth appear to be transforming growth factor beta (TGF- β) and basic fibroblast growth factor (FGF-2), while the most important peptide that stimulates growth of endothelial cells appears to be vascular endothelial growth factor (VEGF).²⁵⁻³¹ In order for wound contraction to occur, it is important for fibroblasts to form networks within the dermis that allow the wound to contract. As Donald Ingber has pointed out, interactions between the extracellular matrix and the cellular cytoskeleton are important in controlling cellular differentiation and function.³²⁻³⁴ Apparently, when wound healing is abnormal and hypertrophic scars develop, there is disruption of this process of interlinking of fibroblasts to form a meshwork that supports tension parallel to the surface, since nodules of collagen develop.

Influx of circulating inflammatory cells and stem cells

Many circulating cells actively migrate into wound beds and play important roles in defense against bacteria and fungi, clearance of devitalized tissue components, and stimulation of

later phases of healing of the dermis and epidermis. Based on experiments with partially selective ablation of individual cell types, the cells most important in stimulating and maintaining tissue repair appear to be the T lymphocytes and monocytes.³⁵ Monocytes, which differentiate into tissue macrophages, are responsible for synthesis and release of many of the cytokines important in wound healing, together with connective tissue cells and epithelial cells. In addition, recent research has shown that circulating stem cells enter healing wounds, where they can differentiate to form fibroblasts and other connective tissue cells needed to restore tissue integrity.^{36,37}

Migration of keratinocytes to cover the wound (epiboly)

When the epidermis is transected, changes take place rapidly in the basal cells of the epidermis adjacent to the wound. The signals that induce these changes are not clear and may include responses to changes in mechanical stresses. The process of epidermal regeneration has been well studied and clarified by the studies of Kenneth Stenn and his colleagues.^{17,38,39} Altered basal keratinocytes send out thin sheets and undergo amoeboid motion over the wound bed, but under the non-viable eschar and/or scab, secreting a provisional matrix as they go.^{40,41} Development of this migratory phenotype is stimulated by the plasma protein vitronectin, and requires the presence of albumin as a cofactor.^{17,39,42} Cell division occurs to support this migration, not among migratory cells, but among their precursors in the residual epidermis. Similar processes stimulate migration and replacement of epithelial cells from hair follicles in partial-thickness wounds. After a complete sheet of epithelial cells is established over the entire wound surface, the keratinocytes that previously migrated over the surface begin to divide and eventually create a multilayered stratified squamous epithelium with a granular layer and keratinization. Epidermal cells secrete substantial quantities of interleukin-1 beta (IL-1 β) and other cytokines.^{43,44} The new proliferative epidermal basal cells also secrete a new basal lamina composed of laminin, type IV collagen and bullous pemphigoid antigen, adhere tightly to that basal lamina, and develop attachments of type VII collagen between the basal lamina and the underlying fibers of type I collagen in the scarred dermis. Just after the newly formed epithelial layer completely covers the wound, the phenotype of the connective tissue cells in the matrix undergoes a series of changes, and much less fibronectin is found in the wound matrix.¹⁸ The stimuli responsible for these changes in the dermal wound matrix are still unclear.

Collagen matrix formation and maturation

As shown by the work of many researchers, scars gradually increase in their strength, as measured by their resistance to tearing, but scars never reach the strength of normal dermis. During this process, the delicate fibers of newly secreted collagens I and III are replaced by large collagen I fibers that are oriented parallel to each other and the skin surface (Figure 48.2). Maturation of collagen fibers is largely a chemical process of remodeling that involves covalent crosslinking of adjacent polypeptide chains. Collagen fibers normally form and are degraded continuously in normal skin as well as in scars, but the processes that control the rates of formation and

Fig. 48.2 (a) In a normal flat scar, the epidermis is flat and does not have any rete ridges, and the dermis is replaced by collagen fibers that are oriented parallel to the skin surface. (b) A Movat pentachrome stain of a normal scar shows mature collagen fibers stained yellow-orange, and does not demonstrate any elastin fibers.

degradation and the orientation of the mature fibers are not fully understood.

Cytokines and other peptides

Many short polypeptides, mostly cytokines and growth factors, are responsible for the changes in cells that lead to wound healing and the termination of wound healing processes, and the formation and organization of a scar. Among the most important are the transforming growth factor beta family (TGF- β), basic fibroblast growth factor (FGF-2), platelet-derived growth factor (PDGF), and vascular endothelial growth factor (VEGF).⁴⁵⁻⁵² Frequently, the response of a particular cell type to a particular peptide depends not only upon binding of cell surface receptors by the right peptide but also upon simultaneous signals from other cellular receptors. Thus

the network of peptide signaling is complex, and the range of possible cellular responses is large enough to allow generation of complex structures with considerable fine-tuning.^{48,53} There are also many opportunities for reparative processes to go wrong, to proceed in an unbalanced fashion, or to fail to complete an appropriate cycle of activation and regression.

Factors that may alter normal wound healing

Changes in blood supply and perfusion

Development of methods to study local blood supply by ultrasonic measurement has led to the discovery that there is usually a zone of greatly increased blood flow below a burn wound, which is not surprising as part of a local inflammatory response to tissue injury. Above this zone of hyperemia is a zone of tissue ischemia in which blood flow is less than normal. Remarkably, during the first 24 hours after a burn wound, the zone of ischemia typically becomes deeper, indicating that ischemic injury actually leads to an increased depth of tissue necrosis compared to that produced by the immediate thermal injury.⁵⁴ Experiments in animals have shown that neutrophils are involved in this process of ischemic injury deep to a burn wound.⁵⁵ Altered blood flow may lead to vascular thrombosis in a burn wound, also contributing to the risk of ischemic tissue injury. In normal skin, there is a plexus of arteries and veins immediately below the dermis in the upper layer of subcutaneous adipose tissue. This subdermal plexus is at risk of thrombosis in deep partial-thickness burns and in full-thickness burns, and it is vulnerable to damage in the process of tangential wound excision, with further loss of blood supply to the wound.

Compromised wound healing and requirements for optimal wound healing

Long clinical experience has demonstrated that wound healing is greatly slowed and impaired when essential ingredients for construction of the scar, or an adequate energy supply, are not available. Vitamin C deficiency and protein-calorie malnutrition are characterized by deficient wound healing, and provision of sufficient calories and reversal of the usual protein catabolism are major goals of general burn care. Diabetic vasculopathy is associated with deficient wound healing, demonstrating the importance of an adequate microcirculation. Heart failure similarly compromises wound healing. Radiation, cigarette smoking, and hypoxemia also have been associated with delayed wound healing.⁵⁴ Advanced age is associated with increased mortality from large burns, but does not in itself prevent good wound healing.^{20,56}

Biological responses to wound excision and grafting

The current standard of treatment in our institution is early excision of the burn wound, normally within 24 hours of admission, with removal of all necrotic tissue, using either tangential excision to leave most of the subcutaneous fat, or fascial excision which removes the entire subcutis. The wound is initially covered with meshed cadaver skin from the skin bank. Within a few days autografting is done using meshed

partial-thickness grafts from unburned regions. Over the face and the hands, unmeshed sheet autografts are often used to obtain the best cosmetic results. The epidermis of the cadaveric homograft slowly degenerates, but the dermal matrix often is incorporated into the healing wound. The interstices of the autograft fill with granulation tissue derived partly from the underlying fibrous or adipose tissue, and partly by migration of fibroblasts from the strands of autograft. The epidermis of the autograft migrates over the granulation tissue matrix and under the fibrin layer, and reconstitutes the epidermis, but without any follicles or other epidermal appendages. The pattern of the meshed grafts is usually visible in the healed wound. The incorporation of dermal connective tissue elements from the donor site may enhance the pliability of the final scar. Occasionally, epidermal inclusion cysts develop within grafted burn wounds, which may grow and rupture. These cysts could develop from residual hair roots that had lost their connection to the surface, from aberrant migration of epidermal cells during wound resurfacing, or from compression of residual hair follicles within the autograft by expanding connective tissue. Tiny bits of hair shaft are sometimes encountered in burn scars, associated with giant cell foreign body reactions, perhaps representing hairs left behind after necrosis of the hair follicles that produced them.

Wound infection

Bacterial infection frequently complicates wound healing, despite the presence of migrating neutrophils and macrophages that work to kill bacteria within the wound. The risk is increased in burn patients, since large amounts of necrotic tissue and cell debris are present in the wound, providing a good culture medium for bacteria. When infection occurs, the inflammatory component of wound healing is amplified, and the processes of conversion of granulation tissue to a dense scaffolding of collagen, wound contraction, and regeneration of the epidermis are delayed. Frequently the wound suppurates, oozing creamy yellow pus. Some bacteria cause additional tissue necrosis, and some bacteria can invade into normal tissues, leading to enlargement and deepening of the original wound. In response to the bacterial infection and the enhanced inflammatory reaction, the cytokine milieu of the wound is altered.⁵⁷⁻⁵⁹ Grafts placed over wounds with residual infected tissue typically do not take, and when large numbers of bacteria are present deep in the wound bed there is always the hazard that the bacteria may enter the bloodstream, incite septicemia, and colonize and invade remote tissues. These processes, which were common in the era before antibiotics and before the practice of early wound excision became common, are now being seen again in cases of infection with highly antibiotic-resistant strains of bacteria, particularly *Pseudomonas* and *Acinetobacter*.

Hypertrophic scarring

Hypertrophic healing

In most patients with large burns in our institution, healing of the burn wounds is complicated in some areas by development of elevated, thick, firm, reddish scars that itch constantly. These occur more commonly in wounds that had become

infected or took longer than usual to become fully covered. They may cover large areas, but generally do not extend beyond the original burn wound. These abnormal wounds also are associated with more severe wound contraction. There are often abnormalities of skin pigmentation, either depigmentation or hyperpigmentation (Figure 48.3). In the majority of affected cases, these hypertrophic scars enlarge for a period of months, then gradually regress over a period of a few years, eventually becoming flat scars with no further symptoms. Special problems associated with scars of the head and neck are discussed in Chapters 54 and 55. The largest hypertrophic scars are surgically excised, often with creation of Z-plasties or sheet grafting to release scar contractures. Usually, new hypertrophic scars do not occur after excision of the original hypertrophic scar. Many of the patients at our institution are Mexican nationals with predominantly Native American ethnicity. However, in our experience this type of hypertrophic scarring occurs in about 75% of Caucasian patients as well as in African-American and Hispanic patients.⁶⁰

Clearly, this experience is quite different from that described in the literature with keloids, which have been described as frequently occurring spontaneously or in response to puncture wounds or clean incisions that were closed primarily.^{61–63} They extend beyond the initial site of injury, respond poorly to medical therapy, persist for many years, and usually recur after surgical excision. There is often a positive family history of keloidal scarring, and keloids are 10–15 times more common in dark-skinned people of African ancestry than in northern Europeans and their descendants. Elaborate patterns of raised scars are a symbol of status in many African tribes, leading one to wonder whether this practice may have exerted selective pressure during human evolution.

Histological features of hypertrophic scars

Numerous hypertrophic scars have been examined histologically in our laboratory, including scars removed during plastic surgical procedures to release wound contractures, and also samples taken for research purposes. The abnormal elevated scars consistently show several distinct differences from uncomplicated flat scars. The most striking is the presence of rounded whorls of immature collagen that consist of delicate thin collagen fibrils, rich in type III collagen, small blood vessels, and plentiful acidic mucopolysaccharide. These nodules are often sharply demarcated from the surrounding scar tissue, which may be composed of similar material or of mature thick collagen fibers that are oriented parallel to each other and to the wound surface, typical of mature scars. Although they are clearly visible with routine H&E staining, these dermal nodules are most distinctly seen with the Movat stain, which stains mucopolysaccharides blue-green and mature collagen fibers yellow-orange (Figures 48.4 and 48.5). The nodules of hypertrophic scars vary in size from 0.5 mm to more than 1 cm in diameter, and appear to be sometimes spherical and sometimes ovoid or cylindrical in shape. The abnormal dermal tissue is very firm, almost like cartilage in its firmness and cutting properties, and may reach a thickness of several centimeters. Both normal and hypertrophic scars are characterized by lack of elastin, which is also visible using the Movat stain. However, there are often residual elastin fibers in the deepest part of the dermis below zones of

Fig. 48.3 Typical appearances of hypertrophic scars of burn patients. (a) The hypertrophic scar is raised above the surrounding normal skin, has sharp borders, and is very firm to the touch. This scar recurred after complete excision. (b) Hypertrophic scars often have patterns corresponding to meshed grafts, and often are hyperpigmented, as shown here, or hypopigmented. (c) This round firm lesion developed from a minor burn on the patient's ear. It did not recur after excision.

Fig. 48.4 Photomicrographs of hypertrophic scars. (a) Within the dermis there is a rounded nodule of collagen that has a sharp border and is distinct from the surrounding scar tissue. (b) The border of a collagenous nodule in a hypertrophic scar. In the surrounding scar tissue, collagen fibers are oriented parallel to the skin surface. Within the nodule, collagen fibers are very thin and are oriented circumferentially.

Fig. 48.5 (a) This Movat-stained slide shows a minimal hypertrophic scar consisting of a single round nodule between hair follicles. The nodule stains light green, in contrast to the yellow-orange color of the surrounding mature collagen fibers. The greenish color reflects a larger quantity of sulfated proteoglycans within the collagen nodule. (b) At higher magnification, numerous small blood vessels can be seen within a large, green-staining nodule from a hypertrophic scar.

hypertrophic scarring, and sometimes there is a narrow zone of normal elastin fibers above the hypertrophic scar, perhaps derived from the applied skin grafts. Occasionally, small rounded nodules of hypertrophic scar tissue are seen scattered between intact hair follicles (Figure 48.5a). It is not unusual to see residual eccrine sweat glands in the adipose tissue beneath a large hypertrophic scar, suggesting that hypertrophic scars may often originate in deep partial-thickness burns. In addition, in a minority of these abnormal scars, an additional histological feature is seen, consisting of very broad, hyper-eosinophilic collagen fibers oriented parallel to each

other, but at varying angles with the skin surface. In some cases such broad, dense fibers dominate the wound. Generally, they are surrounded by whorls of circularly oriented, immature collagen typical of hypertrophic scars (Figure 48.6). These are the features that have been described as typical of the histology of keloids. However, in our patient population, typical keloids are distinctly unusual, and there is no evidence to suggest that the patients with these thick, eosinophilic collagen fibers have a worse prognosis or a delayed course of maturation of their hypertrophic scars than other patients with abnormal scars. Thus, in our experience with the histology of

Fig. 48.6 (a) Some otherwise typical dermal nodules in hypertrophic scars contain very broad, hypereosinophilic collagen fibers similar to those typical of keloids. This specimen is from the patient shown in Figure 48.3c. (b) The typical appearance of the thick, dense collagen fibers that stain intensely with eosin can be seen at higher magnification.

scars from large burns in children, the histological features typical of keloids are seen as part of the spectrum of hypertrophic scarring.

The distinction between hypertrophic scars and keloids was first made by Mancini and Quaife in 1962, and was further described by Peacock et al. in 1970.^{64,65} The thick, hypereosinophilic collagen fibers typical of keloids were first described by Blackburn and Cosman in 1966, and subsequently by Ehrlich in 1970 and many others.^{66,67} The features typical of hypertrophic scars were first described by these authors and by Linares, Kischer and others.⁶⁸⁻⁷¹ All of these authors noted that there was considerable overlap in the histological appearances of hypertrophic scars and keloids, and no claim was made that the histological features were diagnostical. Since both hypertrophic scars and keloids represent abnormal reactions to injury in the skin, characterized by abnormal regulation of the processes involved in wound healing, it has been suggested by many authors that they might share common mechanisms, yet the groups of affected patients are quite distinct. The literature on hypertrophic scars and keloids was thoroughly reviewed in 1999 by Niessen.⁷²

Multiple concepts have been proposed to explain the origin and development of hypertrophic scars and keloids. For purposes of this discussion, it may be best to assume that the etiology and pathogenesis of hypertrophic scars is different from that of keloids, and to limit our discussion to hypertrophic scars. It is sometimes difficult to be certain in reviewing the literature which findings really pertain to which group, since the clinical characteristics of the patients who were the sources of the experimental material are often not given in detail. At this institution, our experience is much more extensive with hypertrophic scarring than with keloids.

A number of differences have been described between normal scars and hypertrophic scars. Hypertrophic scars contain more type III collagen, more fibronectin, and more hyaluronic acid, all characteristic of the early phases of wound

repair, than normal flat scars. They appear more vascular, and studies of cutaneous blood flow by Doppler sonography have shown consistently higher flows in hypertrophic scars. Hypertrophic scars contain significantly more T cells and macrophages than normal scars. Larger numbers of mast cells have been found in hypertrophic scars, and indeed a clinical history of atopy and higher levels of circulating IgE have been found in patients with hypertrophic scars. Recently, larger numbers of epidermal Langerhans cells have been identified in association with hypertrophic scars.^{73,74}

Immunohistochemical staining has demonstrated additional striking differences between hypertrophic scars and normal scars. Staining for α -smooth-muscle actin has consistently demonstrated this contractile protein within fibrocytic cells in the characteristic collagen nodules of hypertrophic scars. The sulfated proteoglycans of hypertrophic scars are quite different from those of normal scars, in that much less decorin is present, and versican is predominant in the rounded nodules. More immunostaining for VEGF is seen in hypertrophic scars. Larger numbers of small nerve fibers have been identified by immunostaining in hypertrophic scars. Recently, studies have been done in which bone marrow-derived stem cells have been identified in fibroblasts and other tissue components of healing wounds in animals. Thus far, these stem cells have not been described in human hypertrophic scars. These findings may provide important clues as to the pathogenesis of hypertrophic scarring, but at this time they are difficult to incorporate into a single hypothesis. Study of the biology of hypertrophic scars has been complicated by the lack of a suitable animal model, and by the scarcity of relevant material from human scars, as well as by confusion as to the proper identification of cases of hypertrophic scarring. However, study of cell culture models has yielded important information on biological processes that may be important in human hypertrophic scars, and potential animal models are being developed.

Experimental models of hypertrophic healing

The first animal model of keloids was described in 1959, based on immunization of experimental animals with autologous skin, followed by induction of wounds.⁷⁵ Extensive work has been done with implantation of human scar tissue into the athymic nude mouse, a model that allows testing of potential therapies and modification of the biological milieu *in vivo*.^{76–79} It is even possible to irradiate the mouse and transplant human bone marrow to study interactions between immune reactions involving human cells and the human skin grafts. Adult horses have been described as having abnormal wounds clinically similar to hypertrophic scars, but these lack the typical histological features of hypertrophic scars in humans. Recently, Engrav and his colleagues in Seattle have developed a model in the female red Duroc pig that seems to mimic most of the features of human hypertrophic scarring.^{80–83} It will be of great interest to test interventions that might modify the development of hypertrophic scars in that model.

Phenotypic abnormalities of hypertrophic scars

There have been many studies of the functions and molecular biology of fibroblasts derived from hypertrophic scars and keloids in tissue culture. It does appear from these studies that there is a significantly different phenotype of fibroblasts from hypertrophic scars that persists in culture. Hypertrophic scar fibroblasts have been found to secrete collagen more rapidly than fibroblasts derived from normal skin or normal mature scars. More secretion of TGF- β has also been described.⁸⁴ Several groups have described abnormal control of proliferation, collagen secretion or peptide secretion in fibroblasts derived from keloids in response to cytokine stimulation or treatment with glucocorticoids. However, in most of these studies the regulatory responses of hypertrophic scar fibroblasts were similar to those of fibroblasts from normal skin.

The reduction in cellularity that accompanies the conversion of granulation tissue into scar tissue during normal wound healing is due to apoptosis (programmed cell death). Studies have demonstrated that the advancing edge of epithelium induces apoptosis in fibroblasts and other inflammatory cells by an as yet unknown signal.⁸⁴ Even the epithelium of a graft or flap used to cover wounds acts similarly.⁸⁵ Hence the presence of excessive myofibroblasts in postburn hypertrophic scars may indicate a delay or reduction in the normal onset of apoptosis. This delay has been reflected in the differential expression of apoptosis-modulating proteins, i.e. an increase in antiapoptotic proteins such as bcl-2 and c-jun and absence of antiproliferative proteins such as p53.⁸⁶

Genotypic abnormalities of hypertrophic scars

DNA microarray technology has enabled us to look more broadly at patterns of gene expression and to explore relationships in gene expression in hypertrophic scars.^{87,88} Preliminary results from these studies suggest that there may be common patterns of gene expression in hypertrophic scars compared with normal skin. Forty-four genes were found to be overexpressed and 124 were underexpressed in a study of hypertrophic scars compared with normal scars.⁸⁷ Some notable genes that have consistently shown more than 2-fold increases in gene expression in hypertrophic scars include collagen types

X and XVI, thrombospondin-4 and matrix metalloproteinase 16 (MMP-16). In a recent study from our institution, cultured fibroblasts from hypertrophic scars showed a greatly reduced response to IL-6 compared to fibroblasts from adjacent normal skin, suggesting that decreased receptor activation might be a factor in hypertrophic scarring.⁸⁹ Better appreciation of altered patterns of gene expression in hypertrophic scars could lead to better delineation of its causes, and help to develop future therapy directed at specific gene targets.

Possible implications for future modes of therapy

Our ability to control hypertrophic scar formation is limited, and no available therapy has been consistently effective. Therapeutic induction of apoptosis is currently being researched as an antifibrogenic therapy for rheumatoid arthritis and lung fibrosis, and might find a place in treatment of hypertrophic scarring. Apoptotic agents such as bcl-2, FLIP, recombinant TRAIL, FasL and C2-Ceramide are now in or on the brink of human clinical trials,⁹⁰ and could be utilized in postburn hypertrophic scar modulation. Recent developments in wound healing research are beginning to unveil the mechanisms behind fetal scarless wound healing. In fetal wound healing there are prominent differences in cytokine profile, specially that of transforming growth factor beta (TGF- β). This cytokine has three isoforms, TGF- β 1, TGF- β 2 and TGF- β 3. While TGF- β 1 and TGF- β 2 have been shown to produce fibrotic scarring, TGF- β 3 has been shown to produce scarless healing.⁹¹ Thus manipulating the level of cytokines at the time of injury or immediately after injury could affect the type of scar formation. This could be achieved using any of several techniques, including application of recombinant proteins or neutralizing antibodies or transient gene therapy.

Pathogenic concepts and gaps in knowledge

Understanding of the biology of hypertrophic scarring has been hampered by multiple factors, including problems in gaining consensus on the definition of the lesion and the lack of a suitable animal model. As a consequence, it has not been possible to test hypotheses by altering the course of the disease. Multiple concepts of pathogenesis have been proposed. None has yet gained wide acceptance, and none has been experimentally excluded. It does seem clear that development of a hypertrophic scar represents an abnormality in control of the normal processes of wound healing. The abnormality may occur early, as Dr Linares suggested, or late.⁶⁰ The normal processes that limit collagen secretion and begin to restore a connective tissue matrix apparently fail in hypertrophic scars. One might suppose that the normal processes by which tensions in the matrix signal cellular responses have become defective in hypertrophic scars.^{32,34} Myofibroblasts are more prominent in hypertrophic scars than in normal or mature scars, and they are thought to play an important role in excessive wound contraction. These myofibroblasts may derive from resting dermal fibroblasts, or they might arise from pre-existing pericytes, as suggested by Kischer.⁹² They also might represent bone marrow-derived fibrocytes in increased numbers.³⁷ The fibrous nodules of hypertrophic

scars might represent persistence and uncontrolled growth of a separate population of connective tissue cells, perhaps related to the perifollicular cells that normally express versican. Since burn patients have higher circulating levels of glucocorticoids and interleukin-6 than normal individuals, a selection process might operate that would tend to allow proliferation of cells resistant to the usual effects of these agents to suppress fibroblast proliferation. A recent suggestion was made that less vitamin D₃ is made in patients with strongly pigmented skin.⁹³ Finally, abnormal macromolecular expression by the covering epithelium may lead to abnormal development of the dermal scar, or fail to suppress inappropriate fibroblast functions.⁹⁴ Clearly, it continues to be important to develop and test many

hypotheses until the problem of hypertrophic scarring is finally solved.

Summary

Healing of burn wounds requires activation of several host processes, including fibrin clotting and lysis, deposition of an immature connective tissue matrix and its reorganization into a mature scar, and epithelial outgrowth and interaction between the epidermis and the dermal matrix. In many burn patients, excessive scar tissue forms, with adverse consequences. Continued study of this problem will continue to be important until more effective modes of treatment are developed.

Exercise for the outpatient	640
Summary	649

With severe burn injuries, as perhaps with any other order of trauma, there is an urgent need for immediate and aggressive initiation of patient-specific rehabilitation programs. The distribution and depth of the burn clearly predict the patterns of deformity and joint contractures and mandate the establishment of therapeutic goals and the initiation of treatment as soon as possible. The more extensive the burn is, the greater the rehabilitation challenge becomes. A seriously burned extremity in an otherwise modestly burned patient is much easier to restore to function than an extremity similarly burned in a patient with full-thickness burns involving multiple sites. Among seriously burned patients, the immediate and primary focus will always be preservation of life and wound coverage. Basic treatment priorities, however, do not preclude the development and implementation of an aggressive rehabilitation program.

The short-term rehabilitation goal is to preserve the patient's range of motion and functional ability. Long-term rehabilitation goals include the return of the patient to independent living and to train patients on how to compensate for any functional loss suffered as a result of the burn.

This chapter addresses positioning, splinting, casting, skeletal suspension, traction, prosthetics and orthotics, scar management, exercise, performance of activities of daily living (ADL) and patient and caregiver education utilized in burn rehabilitation along the continuum of care.

Positioning and splinting of the burned patient for the prevention of contractures and deformities

Positioning of the burned patient is vital in bringing about the best functional outcomes in burn rehabilitation. Positioning programs should begin immediately upon admission to the burn center and continue throughout the rehabilitative process. The role of the burn therapist is invaluable in designing a

positioning program, which counteracts all contractile forces without compromising function. In planning and implementing an effective patient-specific positioning program the therapist should be aware of the patient's total body surface area (TBSA) of burns, the depth of all injuries, respiratory status and associated injuries such as exposed tendons/joints or fractures. Individualized positioning programs are monitored closely for any necessary adjustments depending on the patient's medical status. The quote that 'the position of comfort is the position of deformity' applies to every burned patient who sustained a serious injury.

Anti-deformity positioning can be achieved through multiple means. Splinting, mechanical traction, cut out foam troughs and mattresses, pillows, strapping mechanisms, serial casting and in some cases through surgical application of pins. The burn therapist needs to be aware of physician-specific protocols and work closely with the entire burn team to design the most effective positioning program. Orthotics and splinting devices are vital in burn rehabilitation as they are utilized extensively to obtain appropriate positioning of the entire body and to counteract the contractile forces that lead to deformity. No matter how the burn therapist approaches splinting (material choice, design, and application schedules) the goal is to achieve the best functional outcome at the completion of rehabilitation. When fabricating a splint or an orthosis the burn therapist must be aware of the anatomy and kinesiology of the body surface to be splinted. Also, the therapist should be well aware of all mechanical principles of splinting as they relate to pressure, mechanical advantage, torque, rotational forces, first-class levers, friction, reciprocal parallel forces and material strength.¹

Positioning and splinting must be designed in a way to:

- Allow for edema reduction.
- Maintain joint alignment.
- Support, protect and immobilize joints.
- Maintain and/or increase range of motion.
- Maintain tissues elongated.
- Remodel joint and tendon adhesions.
- Promote wound healing.
- Relieve pressure points.
- Protect newly operated sites (grafts/flaps).
- Stabilize and/or position one or more joints, enabling other joints to function correctly.
- Assist weak muscles to counteract the effects of gravity and assist in functional activity.
- Strengthen weak muscles by exercising against springs or rubber bands.¹

All devices should:

- Not cause pain.
- Be designed with function in mind.
- Be cosmetically appealing.
- Be easy to apply and remove.
- Be lightweight and low profile.
- Be constructed out of appropriate materials.
- Allow for ventilation in preventing skin/wound maceration.¹

Head

In aiding with facial edema reduction, the head may be positioned by elevating the head of the bed at 30–45° if the patient's hips are not involved. In cases where the hips are burned the entire bed may be elevated at the head of the bed with the use of shock blocks (wooden blocks 12–16 inches high with recessed slots for bed legs). This will avoid positioning the hips in the flexion contracture position (Figure 49.1). In the cases where the ears are burned they may be protected from wrapping on pillows with ear cups made of thermoplastic materials or foam.² An ear conformer may be constructed to prevent the rim of the ear from contracting toward the head. Internal ear canal splints may also be fabricated and serially adjusted as the circumference of the canal increases. A nasal obturator may be required to maintain the nostrils open. These obturators may be serially adjusted as the circumference of the nostril increases. Mouth splints are utilized for the prevention of oral microstomia. These devices are custom-made by the therapist or they may be obtained commercially. Mouth splints may be fabricated static or dynamic for the horizontal or vertical opening of the mouth.^{3–6} In cases of severe microstomia where compliance is an issue, an orthodontic commissure appliance which attaches to the teeth may be fabricated by an orthodontist.⁷ The use of stacked tongue blades is an acceptable technique to aid in reversing oral microstomia. Ongoing research looks at the development of a microstomia device that circumferentially opens the mouth according to its anatomy (Figure 49.2). Facial scar hypertrophy may require fabricating a high thermoplastic transparent mask such as the Uvex™ and W-clear™ masks or a silicone elastomer face mask.^{8–10} A semi-rigid low thermoplastic opaque

Fig. 49.1 Wooden blocks are utilized to place the bed on an incline to help with edema reduction and prevent hip contractures.

mask may also be fabricated depending on the state of scar maturation.

Neck

The neck is positioned in neutral or in slight extension of approximately 15° without any rotation. The amount of neck extension must not be so great that traction on the chin causes the mouth to open. Positioning may be achieved with a short mattress supine, a rolled towel or foam cushion placed behind the upper back on the scapular line. Pillows should be avoided in the cases of anterior neck burns as they may lead to flexion contractures. In the case of anterior neck burns a conforming custom thermoplastic collar may be fabricated (Figure 49.3).¹¹ A soft neck collar or a Watusi-type collar may also be fabricated.^{10,12,13} It has been observed that in some cases acute patients rotate or laterally flex their neck on one side, which may lead to a lateral neck contracture (torticollis). If the patient is to remain in bed for a while, a dynamic head strap mechanism may be fabricated to counteract the lateral neck contractile forces and bring the neck in the neutral position. For the prevention of torticollis the therapist may fabricate a lateral neck splint which conforms to the head of the patient, the lateral neck and anterior/posterior shoulder (Figure 49.4).

Spine

Contracture resulting from unilateral or asymmetric burns of the neck, axilla, trunk and groin will cause lateral curvature of the spine (scoliosis). The level and amplitude of curvature will vary with the site and severity of the contracture. In addition, pelvic obliquity accompanying asymmetric hip or knee flexion contracture will impose a lateral lumbar curve. As long as the patient is recumbent, lateral curvature can be prevented by maintaining straight alignment of the trunk and neck (Figure 49.5). However, the curve is often insidious in onset and will not be recognized until the patient begins to walk. Trunk list observed early in the ambulation period can be simply a transient accommodation to pain and wound tightness, but a persistent list may herald the development of scoliosis. Other subtle signs of spinal curvature are asymmetry of shoulder levels, scapular asymmetry, asymmetry of dependent upper extremity alignment to the trunk and asymmetry of pelvic rim levels. Once there is an established asymmetric contracture it is difficult by therapeutic means to stretch it out, so it is probably better to deal surgically with a deforming scar early than to permit even minor scoliosis to persist.

Exaggerated thoracic kyphosis secondary to anterior chest and neck burn is difficult to prevent because the recumbent position cradles the back and encourages protraction of the scapulae. The two-plane contracture extending from chin and neck to thorax and from shoulder to shoulder anteriorly pulls the chin down, flexes the neck and pulls the scapulae forward. Protraction of the scapulae alone may cause a normal thoracic kyphosis to appear to be exaggerated. However, if the protraction posture is not corrected, it tends to become habitual, and the final result features a prominent and rounded thoracic spine (Figure 49.6). As this spinal deformity in its genesis is linked to neck and shoulder contractures, the measures for its prevention and correction are discussed in the section dealing with neck and shoulders.

Fig. 49.2 Horizontal, vertical and circumferential mouth-opening devices are utilized to correct oral microstomia.

Fig. 49.3 An anterior neck conformer helps prevent neck flexion contractures.

Fig. 49.4 (a) A dynamic head strap mechanism aids in positioning the neck in neutral position during a prolonged ICU bed confinement. (b) A lateral neck splint is utilized to prevent lateral neck flexion contractures (torticollis).

Fig. 49.5 Scoliosis resulting from a left chest, abdomen and left lateral trunk injury.

Fig. 49.7 Foam arm troughs are utilized for positioning the shoulders in bed.

Fig. 49.6 Scar contracture has flexed the neck and protracted the scapulae. A full-thickness injury to the anterior neck, chest and shoulders resulted in thoracic kyphosis due to a neck flexion contracture, and scapular protraction.

Exaggeration of spinal lumbar lordosis is rarely related to overlying burn of the back. On the other hand, full-thickness burns of the abdomen are occasionally deep enough to compromise or even eliminate abdominal muscle function. In this circumstance the pelvis, for lack of support of anterior motors, will roll forward and lumbar lordosis will increase. The hamstring and gluteus maximus muscles, though strong posterior stabilizers of the pelvis, cannot compensate for loss of abdominal muscle power. If all abdominal muscles are lost, viscera will protrude, shifting the center of gravity forward. To compensate and achieve balance the patient must lean backwards, further increasing the lumbar lordosis. There is no way to prevent this sequence if abdominal muscle function is lost and,

Fig. 49.8 A three-piece airplane splint may be fabricated to accommodate wound dressings and promote healing while maintaining the shoulder abducted.

since surgical correction often is not practical, the only treatment recourse may be sturdy external abdominal support to relieve the burden of protruding viscera.

Shoulder girdle/axilla

Elevation of the arms should be in the coronal plane with the glenoid humeral joint at approximately 15–20° of horizontal flexion. Abduction in the coronal plane places the glenohumeral joint in relative extension and uncovers the head of the humerus, rendering it more prone to anterior subluxation if the position is chronically maintained. Also, abduction in the coronal plane may cause excessive tension to the brachial plexus over time, resulting in a neuropathy such as radial nerve palsy. Positioning may be achieved with splints, pillows, bedside tables, foam arm troughs and thermoplastic slings suspended from an overhead trapeze mechanism (Figure 49.7). Airplane splints are custom fabricated or obtained commercially for the prevention of axillary contractures. To accommodate wound dressings and promote healing, a three-piece airplane splint may be fabricated (Figure 49.8). This splint

positions the patient's arm in abduction by connecting the elbow and the lateral trunk troughs with a thermoplastic custom-made rod. Commercially available airplane splints come equipped with a mechanism that allows for adjustments depending on available shoulder abduction ranges.^{10,11,13} A figure-of-eight axillary wrap may be fabricated during the rehabilitative phase of recovery to provide pressure and stretch the axillary skin surfaces (Figure 49.9).

Elbow/forearm

Severe burns involving the elbow may result in flexion contracture and threaten posterior exposure of the joint. Full extension is the protecting position for the elbow. If the joint is exposed posteriorly, extension may need to be rigidly maintained for several weeks. If the joint is not exposed, mobilization into increasing flexion range can begin very soon after the burn. The elbow is integral to the so-called delivery system for the hand, and elbow range to full or near-full flexion is more important for overall function than range to full or near-full extension.

Radial head rotation for pronation and supination is less often affected by the burn injury than flexion and extension. The pronators and supinators are frequently injured in electrical accidents where bone, being a poor conductor, heats destroying the muscles closest to it. Forearm rotation is essential for accurate hand placement and the rehabilitative program must seriously address that function. Depending on the location and severity of the injury the forearm may be positioned in neutral or in slight supination. Static elbow splints may be soft or custom-fabricated of thermoplastic materials. An anterior elbow conformer may be fabricated over the burn dressing or a 3-point elbow extension splint which avoids contact with wounds or fresh grafts/flaps may be constructed. Dynamic elbow extension or flexion splints may be utilized to provide prolonged gentle sustained stretch and aid in the correction of contractures.¹⁴ Forearm dynamic pronation/supination splints may be custom-fabricated or obtained commercially for the correction of contractures.^{10,11,13}

Fig. 49.9 A figure-of-eight axillary wrap provides a constant stretch of the axillary skin surfaces.

Wrist/hand

The usual posture of the unsupported burned hand is wrist flexion, metacarpophalangeal (MCP) extension, interphalangeal (IP) flexion and first metacarpal extension and adduction. MCP extension is imposed to some degree by dorsal swelling of the hand and the overall posture may be the position of greatest comfort. If the hand rests unsupported on the bed, all features of the deformity may be positionally reinforced with the first metacarpal being pushed farther into extension and adduction. The overall appearance is that of an intrinsic minus or claw deformity (Figure 49.10).

If, in the acute burn phase, the wrist is securely supported in extension, the metacarpophalangeal joints of digits 2 through 5 will tend to fall into flexion because of gravity if the forearm is pronated or the hand elevated and because of the reciprocal tendering action between digital flexors and extensors. The first metacarpal will likewise fall forward into flexion. Wrist extension is, thus, basic to control of hand and digit position and to prevention of hand and wrist deformity.

Fig. 49.10 (a) Edema following a full-thickness burn of the dorsum of the hand — imposed metacarpophalangeal extension and interphalangeal flexion. (b) The deformity resulting from the persistence of this position is that of a claw hand.

Among the digits, the second and fifth most easily drift into MCP extension because each has a proper extensor and has relative functional freedom from the third and fourth digits. The fifth is occasionally pulled into extreme abduction and extension by scar contracture. The thumb may become similarly displaced and to a lesser degree the index finger. The severe displacement of these digits gives a grotesque, but characteristic deformity (Figure 49.11).

For adults, adolescents and older children preventive static positioning with a custom thermoplastic splint can be relatively efficient. There are, however, two common faults in custom splints that are designed to gain MCP flexion and to position the thumb in flexion and abduction. If the transverse fold of the splint is not proximal to the MCP joints of digits 2 through 5, the splint will impede rather than favor MCP flexion. If the thumb component of the splint applies volar rather than medial pressure the MCP joint will extend and the metacarpal will become correspondingly more adducted. The first MCP joint should be maintained in slight flexion and pressure from the splint should be applied just to the medial surface of the digit. Any degree of first metacarpal adduction contracture increases the likelihood that the proximal phalanx will be pushed into hyperextension and eventually into subluxation by the splint. The optimal position for the burned hand and wrist includes 0–15° wrist extension, 50–70° MCP joint flexion and neutral IP joint position. The thumb should be positioned in a combination of palmar and radial abduction with the first MCP joint slightly flexed as mentioned above. This positioning, which resembles the intrinsic plus position of the hand, is achieved through a burn hand splint fabricated by the therapist (Figure 49.12). Superficial hand burns should not be splinted in order to allow for frequent movement and the freedom to function independently. In the case of circumferential hand burns, a hand extension splint may also be fabricated to prevent flexion contractures and cupping of the palm. The flexion and extension splints are alternated depending on the burn center's protocols. A 'sandwich' hand splint may be fabricated which includes the volar burn hand splint with a dorsal platform over the IP joints in order to prevent flexion

Fig. 49.11 Severe wrist flexion and digital extension deformities of the right upper extremity.

of the digits. The splint may be secured with an elastic bandage or with Velcro® strapping (Figure 49.13).¹⁵ Individual static finger splints may include a gutter splint for the prevention of flexion contractures or a boutonnière deformity, a thumb c-bar for the prevention of syndactyly in the first web space, a figure-of-eight digit splint for the prevention/correction of swan neck deformity and a distal IP joint extension splint for the prevention of mallet finger deformity. Dynamic splinting of the hand may include MCP extension or flexion splints, proximal/distal IP flexion or extension splints, thumb outriggers, digital knuckle benders or flexion/extension spring-loaded splints (Figure 49.14). The therapist must monitor dynamic splinting closely and make frequent adjustments to the outriggers in maintaining a 90° angle of pull at all times. Wrist splints may be fabricated dorsally, volarly or in the cases of a deviation contracture they may be constructed on the medial or lateral aspect of the joint. The therapist should design these splints having in mind the importance of the wrist

Fig. 49.12 The intrinsic plus position hand splint (burn hand splint) positions the hand appropriately to prevent contractures and preserve function.

Fig. 49.13 The 'sandwich' hand splint prevents PIP flexion contractures.

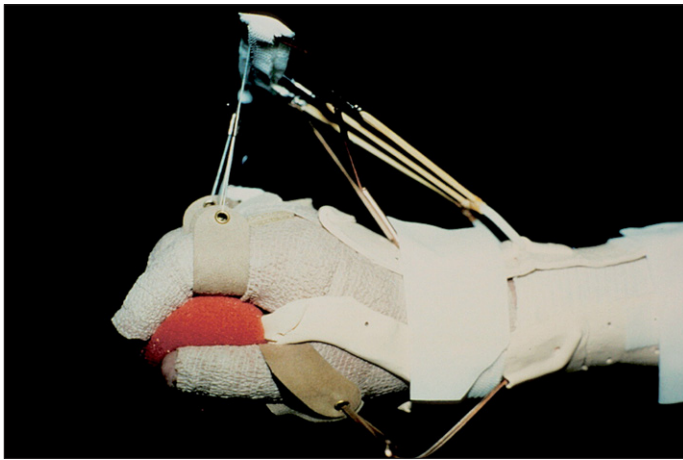

Fig. 49.14 A dynamic MCP extension splint promotes functional use of the hand.

joint in the performance of activities of daily living. A dynamic wrist splint may be utilized which provides a prolonged stretch in counteracting any contractile forces. In treating the edematous hand, it is important to position the hand above the heart level at all times, to aid edema reduction. Elevation should not compromise the vascular supply to the hand.^{10,11,13}

Hip

When anterior burns extend from the abdomen to the thigh, hip flexion is the position of comfort. If the hip is fixed in any degree of flexion, posture will be modified. Bilateral symmetric contractures impose increased lumbar lordosis or knee flexion or both. Asymmetric contracture will cause pelvic obliquity and scoliosis. In adults and older children thighs are more likely to be held in adduction than in abduction, whereas in pre-ambulatory infants the secondary component of the contracture is abduction. Thus, for the hips the preventive position is full extension, 0° rotation and symmetric abduction of 15–20°. If elevation of the upper body is needed for edema reduction then the entire frame of the bed is elevated with the use of wooden shock blocks placed at the head of the bed. Soft mattresses should be avoided as they may promote hip flexion. Hip positioning is accomplished with the use of abduction pillows and other strapping mechanisms eliminating hip rotation. If the patient wears bilateral foot splints then connector bars may be utilized on the splints to bring about the desired bilateral hip positioning stated above. Hip flexion contractures may be serially corrected with an anterior hip spica or with a 3-point hip extension splint (Figure 49.15).^{10,11,13} Subtle hip flexion contractures can be easily overlooked when the patient stands, there being only a slight increase in lumbar lordosis or forward or lateral shift of the trunk. If established hip flexion contractures are not surgically corrected, body posture is likely to be permanently altered with scoliosis or exaggerated lordosis.

Knee

Burn injury to the anterior or posterior surface of the lower extremity that crosses over the knee joint may result in knee flexion. Deep anterior burns may expose the joint, occasionally destroying the patellar tendon. Deep posterior burns

Fig. 49.15 An anterior hip spica splint is utilized to prevent anterior hip flexion contractures.

result in bridging scar formation. The appropriate position for the knee is full extension to be maintained by splint or skeletal traction until there is efficient quadriceps function and the patient is ambulatory. Thereafter, night splints must be used until scar contracture is no longer a threat. Knee splints may include a posterior custom-made thermoplastic knee conformer or a soft knee immobilizer.

Persisting bilateral knee flexion contractures will impose hip flexion. Persisting unilateral contractures may impose pelvic obliquity and scoliosis. As with the hip, posture alteration may be so subtle as to be overlooked. Correction of even a slight contracture should be a surgical priority as should elimination of a soft bridging scar band that does not prevent complete willful knee extension but causes the patient habitually to hold the knee in slight flexion.

Foot/ankle

Ankle equinus is the most frequently occurring deformity involving the foot. Initially it is related more to gravity and failure to support the foot at neutral at the talotibial joint than to the early effect of the burn. Loss of deep and superficial peroneal nerve function will compound the problem by encouraging the foot to drift into inversion as well as equinus because of loss of dorsiflexion and eversion motors. In the end, the total deformity for the unsupported foot may be ankle equinus, hind-foot inversion, and forefoot varus and equinus. Ankle equinus quickly becomes a resistant deformity so that within a few days or even hours the foot can no longer be positioned at 90° of dorsiflexion in the neutral ankle position. Eventually the contractures of scar, muscle and capsular structures combine to fix the deformity.

Equinus deformity and the attending inversion and forefoot varus can be prevented by accurate and unyielding support of

the foot in neutral alignment or slight dorsiflexion. If the patient must be nursed prone, the feet must be allowed to fall free from the mattress. Static splinting if not performed correctly by an experienced therapist is often unsuccessful because of the patient's desire and tendency to plantarflex strongly, displacing the splint and leading to ulcers of the heel, malleoli, toes and where the splint edges touch the skin. A stable footboard may be effective if the feet are kept securely and totally against it. For large burns and particularly for circumferential burns of the lower extremities, skeletal suspension incorporating calcaneal traction will support the foot at neutral if the traction pin is placed in the calcaneus well behind the axis of ankle motion. A balanced traction system demands that the knees be supported in flexion with tibial pins at the level of the tibial tubercle. Calcaneal pins will not prevent forefoot equinus. If traction must be employed for several weeks, proximal pull dorsal pins in the first or first and second metatarsals may be required for support of the forefoot. Transmetatarsal pins are useful as well when calcaneal traction alone is not sufficient to correct equinus.

Minor established equinus deformity can be corrected with a standing and walking program. At the outset graduated heel lifts may be used to accommodate to the deformity. If the patient must be bed confined, skeletal traction through the calcaneus may be the quickest and most efficient way to correct the deformity. Traction is effective even if scar contracture contributes to the deformity. Serial corrective casts or posterior splints alone are useful mainly for minor contractures. For the treatment of circumferential foot/ankle burns anterior foot splints are also fabricated and their application is alternated with the posterior foot splints in preventing plantar or dorsal foot contractures.^{10,11,13} The Multi Podus® System foot splints may be utilized for the positioning of the burn foot/ankle as they relieve heel pressure in preventing pressure ulcers (Figure 49.16). For fixed, unyielding deformity, scar release combined with tendoachillis lengthening with or without posterior capsulotomy is a standard surgical procedure that yields inconsistent results. The correction achieved is often just to neutral or to slight dorsiflexion. The Ilizarov technique has been used

Fig. 49.16 The Multi Podus splint is utilized to position the burned feet appropriately and prevent heel and malleoli skin breakdown.

with generally satisfactory immediate results in severe cases.¹⁶ No matter how correction is achieved, if there are no dorsiflexion motors and if the range of ankle motion is only a few degrees, ankle fusion may in the end yield the best functional result.

The most common intrinsic deformity of the foot is extreme extension of the toes due to dorsal scar contracture. This deformity is insidious in onset and is difficult to prevent as there is no type of non-skeletal splinting that will hold the toes flexed. In its extreme, the deformity includes dorsal metatarsophalangeal (MTP) subluxation which may involve one or all toes depending on the location of the scar. The metatarsal heads become prominent on the plantar surface and walking may be painful. Correction of the deformity requires dorsal surgical release of the contracture, manual correction of the deformity and in severe cases intrinsic or extrinsic pinning of the digit or digits in an overcorrected position, i.e. MTP and interphalangeal flexion. The deformity will commonly if not inevitably recur to some degree unless the patient, after the operation, is able to achieve in all digits active MTP flexion.

Dorsal scar contractures extending from leg to foot to toes may pull the foot into marked inversion if the scar is medial or into eversion if the scar is lateral. The fifth and first toes may be separately displaced by the same scar bands. These contractures must always be surgically corrected. Their persistence will lead to bone deformity in a growing child and will permanently adversely affect foot and ankle function. Even slight inversion, whether imposed by scar contracture or motor weakness, will increase pressure on the lateral border of the foot, leading to callous formation and a painful inefficient gait. Occasionally, the base of the fifth metatarsal is so offensive as to require partial surgical osteotomy.

When there is both anterior and posterior scar contracture, the talus will remain aligned with the calcaneus in a relatively plantar flexed position as the midfoot and forefoot are pulled into dorsiflexion. The result is so-called rocker bottom foot with the head of the talus being the principal weight-bearing feature. This deformity once established defies correction by usual surgical means because of the shortage of soft tissue and because vessels and nerves cannot be stretched to accommodate to the corrected position. The Ilizarov technique may offer a partial solution to the problem. Removal of the head of the talus may give a reasonable weight-bearing surface. With chronic painful ulceration, amputation is the best treatment.¹⁶

A Unna boot may be applied at time of skin grafting to the lower extremity and contribute to early patient ambulation. The Unna boot is a bandage impregnated with calamine lotion and zinc oxide which, when applied over the grafted lower extremity (6 layers), hardens to a semi-rigid dressing resembling a plaster cast. This cast-like total contact dressing provides uniform support to the fresh skin graft and when reinforced with a thermoplastic or plaster splint is facilitates early ambulation. A Unna boot may be applied for up to 7 days post grafting although it could be removed earlier for the inspection of the skin graft. If removed, a new Unna boot needs to be fabricated depending on the burn center's lower extremity postoperative immobilization protocol.¹⁷

Typical burn care positioning protocols describe the supine position in great detail. More emphasis is now being placed on

the use of side-lying and prone positioning for patients with large burns who must be immobilized for extended periods of time due to newer grafting techniques that cover larger areas with fragile skin substitutes. When designing a program for these patients the traditional joint angles are maintained, and the supporting surfaces are modified to maximize surface area while protecting bony prominences.

Side-lying may be used on a rotating basis for patients at risk for sacral or scapular skin breakdown. In a preventive program, the rotation is right side to supine to left side. The order is then reversed on a 1- to 2-hour schedule. Full side-lying at 90° from supine should not be allowed for any significant length of time due to excessive pressure over the greater trochanter. A more appropriate position for side-lying is approximately 30–40° from the supine position, which distributes pressure more evenly between the head of the femur and the lateral portion of the sacrum.

The mechanics of a side-lying position can be accomplished using pillows or wedges made of foam or wood. Pillows are typically used to prop up a patient in side-lying and require direct handling of the patient. The advantage of foam or wooden wedges is that they can be placed directly under the mattress with less manipulation of the patient. As the rotation schedule is completed the wedge can either be removed for the supine position or transferred to the opposite side of the mattress to achieve side-lying on the opposite surface.

Prone positioning systems are usually the position of last resort (Figure 49.17). They are reserved for patients who are not successfully being managed in supine or side-lying. There may be non-healing grafts or wounds in the rectal region that increase the risk of sepsis due to the introduction of fecal matter. Other common candidates for this protocol include those with sacral pressure ulcers or posterior trunk grafts that are not healing.

There are a host of issues that must be considered when instituting a prone program. Airway is always the first issue that must be considered when designing a prone positioning mattress. The supporting surface is cut from a solid open-cell foam mattress that is placed on a wire mesh bed frame. Airway concerns are addressed first and the patient is evaluated for mode of respiration. Nasal and tracheal intubation are issues

Fig. 49.17 Patients may be positioned in prone in order to protect posterior grafts from shearing.

to consider, but are not contraindications for the prone position. A trough should be provided so that direct access can be obtained for routine airway care and if breaths are needed using an Ambu-bag. If the airway becomes compromised the prone position should be abandoned immediately until proper respiration is established.

The facial opening should be cut in a manner that maximizes weight distribution without allowing the head to enter into the opening. Using this protocol places direct weight-bearing pressure on the brow ridge, zygomatic arches, and the anterior mandible. These structures should be monitored closely and the patient should be educated that breakdown is likely to occur due to the limited subcutaneous tissue protecting the face. If burn scars are encroaching on the eyelids then the corneas should be evaluated as well. Corneal abrasion can be avoided with due diligence and prevention of the foam from contacting the unprotected eye. Countersinking a gel cushion into the upper portion of the foam mattress can protect the forehead and brow-ridge.

The sternum, pelvic region, and patellae are protected with the use of an air-cell mattress that is inserted into the mattress in a length-wise manner. The air-cell segments are typically supplied in standard lengths and may not reach from the sternum to the ankles. If there is an unsupported area between the distal portion of the air-cell mattress and the dorsum of the foot, then the area can be supported with open cell egg-crate type foam. The feet are supported at the distal end of the mattress with a foam footboard. Extra precautions should be taken to evaluate the elevation of the great toe from the supporting bed frame.

In the prone position all of the traditional joint alignment suggestions are maintained with the possible exception of the elbows. Shoulder mobility dictates the style of mattress that can be made for the individual burn patient. If the patient has greater than 115° of abduction, then the mattress is modified to horizontally adduct and externally rotate the shoulder while flexing the elbow to allow for elevation of the hands. This minimizes edema in the hands and allows for greater function once the prone position is no longer needed. If the shoulders have limited abduction then a 'butterfly' cut is used to allow for horizontal adduction of the shoulder to protect the brachial plexus with the hands remaining slightly dependent. This will result in some hand edema, which can be addressed with pressure wrapping (Coban™ glove) and active exercise.

Serial casting

Serial casting is frequently utilized in burn rehabilitation for the correction of significant contractures. Joints with over 30° of contracture respond well to casting. The applied cast provides total contact with circumferential and evenly distributed pressure. The prolonged gentle sustained stretch provided by the cast aids in tissue elongation without causing microtrauma to the surfaces targeted for the correction of contractures (Figure 49.18). Casting is a relatively simple, fast and painless intervention and provides an alternative to dynamic splinting when patient compliance is an issue (i.e. pediatrics).

Plaster casting bandages come in different widths and may also be cut in strips by the therapist prior to casting a patient. Plaster casts are inexpensive, lightweight, easy to fabricate and allow for ventilation down to the skin surface (plaster is porous when cured), thus avoiding skin/wound maceration.

Fig. 49.18 Serial casting provides prolonged gentle sustained stretch and aids in tissue elongation and correction of contractures without pain.

Plaster is fast setting when reacting with warm water. Disadvantages of this technique include the decreased water resistance of plaster and breakage if not constructed strongly enough to withstand the patient's own muscle strength.

Fiberglass casts are an alternative technique to plaster casts. Fiberglass bandages are fast setting when reacting with water, they are lightweight and the casts are stronger (mostly preferred for lower extremity walking casts). Because of fiberglass's abrasive properties, therapists must wear gloves prior to handling it.

Recently, non-latex polyester materials such as Delta-Cast™ are utilized as alternatives to plaster and fiberglass. These materials, which resemble fiberglass, are very lightweight, flexible and because of their elastic properties they conform very well. They may be univalve so they can be applied and removed for cleaning and exercise.¹⁸

A light dressing and padding on the bony prominences should be applied prior to either casting technique. Prior to casting the therapist should consider therapeutic heat, massage and stretching of the joints about to receive a cast. When casting is completed the patient should feel a gentle but not painful stretch. The first cast should be removed at approximately 24 hours and thereafter depending on the patient's tolerance it could be applied up to a week at a time. In cases of casting over wounds the cast should be removed at 1–2 days in order to avoid complications in wound healing.^{19,20}

Skeletal suspension and traction

Skeletal suspension and traction systems have been used to a limited extent in burn management for a number of years. The early reports of Larson²¹ and Evans^{22–24} described the use of skeletal suspension for positioning and for extremity elevation for open wound management and of skeletal traction for prevention and correction of contractures. The later reports of Harnar²⁵ and Youel²⁶ deal mainly with the management of hand burns with the skeletally anchored digital traction splints bearing the names banjo, halo, and hay rake (Figure 49.19).

The adaptation of skeletal suspension and traction systems to burn management grew out of earlier experience with traction to correct the elbow and knee contractures of patients

Fig. 49.19 (a) Banjo external fixator. (b) Functional position external fixator.

with rheumatoid disease and of traction and suspension as definitive means for treating certain extremity fractures. In its earliest application to burn management, skeletal suspension was used for extremity elevation only to facilitate wound care. From this experience evolved better-defined traction systems, including those expressly designed for hands and feet. Rehabilitation therapists may remove the patient from the traction apparatus as indicated for exercises and ambulation and reapply the traction at the completion of treatment. Positioning within the traction is often changed by nurses and therapists by altering the amount of the traction weights, thus

preventing the affected joints from being locked into one position over time (Figure 49.20).

In the suspension mode for both upper and lower extremities, distal weight is such as to maintain desired position of the extremity when the patient is asleep or inactive, but is not so great as to prevent active motion or functional exercise. In the traction mode, weight must be sufficient for constant uniform pull to correct a contracture or to maintain surgically gained positioning. With lower extremity suspension or traction, a proximal tibial pin is always required to control rotation of the extremity and to prevent hyperextension of the knee. In the management of a patient with extensive burns, lower extremity weights for the proximal tibia and calcaneus can be alternately increased or decreased to favor flexion or extension of the knee. In the upper extremity, elbow flexion can be gained just by decreasing the distal weight. Occasionally when there is an elbow extension contracture, it is necessary to insert an olecranon pin for traction to gain elbow flexion.

Prosthetic and orthotic intervention

The prosthetist's role

To date, little has been published regarding prosthetics relating to thermal injury, yet patients with burn injuries can present interesting problems which are simultaneously the same as with other patients and yet unique. Patients who have suffered severe burns have complex, long-term problems and considerable self-care to provide. The challenge to the orthotist and prosthetist is to design a device which is maximally useful to a patient who may have multiple limitations. To be useful, a device must be as easy to use as possible. Simplicity often determines whether the device is successful or discarded by a patient.

Fig. 49.20 Skeletal traction is utilized for positioning of extensive burns and for the protection of delicate grafts through suspension. Rehabilitation therapists may remove the traction and ambulate or exercise patients as needed. Traction weights may be changed to achieve different positions within the traction system and help shift the weight of patients in bed.

Planning for function

Prosthetic rehabilitation begins with surgery and progresses to splinting, exercise therapy, preparatory, and then definitive prosthetics. Surgeons performing amputations must be familiar with optimal levels for function and growth. Consultation with rehabilitation team members prior to surgery regarding the planned surgical level, weight-bearing areas and alternatives can provide useful information in providing a patient with optimum function while using a prosthesis.

Additional multiple involvement

Many burned patients have severe limitations in the function of intact extremities which affect their ability to utilize a prosthesis. Their limitations and strengths are important considerations when planning treatment. For example, functional status has been improved in patients with considerable knee instability secondary to burn trauma by performing trans-tibial rather than above-knee amputation, stabilizing the knee with prosthetic components, and allowing knee stability to improve over time with the formation of scar tissue. Salvaging part of the forearm where there is an active elbow flexor and no extensor, or even extremely limited range of motion, can provide increased function both with and without a prosthesis compared to a higher amputation level with better skin coverage. Limited function of the contralateral extremity, especially the hand, will affect decisions regarding amputation, amputation level, and reconstructive surgery. Severely burned patients may need to use their remaining functioning extremities differently than patients without total body involvement. Prosthetic rehabilitation should enhance adaptations.

Prosthetic components

Standard prosthetic texts are useful in providing broad basic information and explanation of the many components available and their use.^{27,28} Components for various regions are described below.

Hand

Improved techniques of plastic surgery of the partial hand have greatly reduced the need for partial hand prostheses other than those for cosmesis. On the other hand, opposition posts can be useful for patients awaiting further surgical improvement.

Transradial

- Wrist flexion units, especially when there is contralateral upper extremity involvement.
- Distal cushions in below-elbow sockets.
- Padding — which can be attached to a harness ring so as to distribute pressure from straps.
- Rapid adjust buckles for donning and doffing for patients with limited range of motion at the glenohumeral joint.
- Cross-chest straps for patients with protracted scapulae and/or scarring and poor definition in the deltopectoral area.
- Utilization of 'preflexion' of the forearm relative to the socket or wrist flexion units at the mid forearm to compensate for limited range of motion (Figure 49.21).
- Transhumeral and shoulder level.

Fig. 49.21 Wrist flexion units can be used to accommodate upper extremity range of motion limitations. The prostheses can provide wrist flexion and rotation. A secondary flexion unit can be applied at mid forearm for increased flexion.

- A flexible thermoplastic inner socket provides reduction in shear stress at trim lines and enhanced adjustability and socket replacement.
- For extremely short transhumeral and shoulder level cases, chest expansion is rarely useful for activating the elbow lock. Other means, such as attaching the elbow lock cable to a waistband, may be necessary.
- Electronics have been used rarely due to physiological and environmental factors.

Lower extremity

Choice of prosthetic components for the lower extremity is based on a patient's functional ability and physiology pertaining to the maintenance of skin integrity. When these criteria are satisfied, cosmesis is addressed. Severely burned patients may exhibit muscle weakness not usually seen at the same amputation levels in the non-burn patient. These should be noted and compensation such as increasing stability of a prosthetic knee through alignment or components should be provided.

Trans tibial

Proximal weight-bearing components, such as knee joints/thigh lacer or ischial-gluteal weight-bearing brims can be helpful with patients who have problems tolerating full weight bearing on the amputation stump or who have the sagittal plane leverage which a below-knee residual limb can provide but lack the frontal plane stability at the knee. They also assist a patient with diminished strength. For partial feet, several types of prostheses have been utilized. Pressure, especially for dorsal foot burns, should be incorporated into the prosthesis or the shoe so as to inhibit hypertrophic burn scar formation. Where bony overgrowth and bone spurs occur, the use of extra socket depth with replaceable distal cushions is helpful. Use of suspension sleeves with and without suction valves has been rewarding.

Above the knee

Neoprene-type suspension belts are well tolerated. Suction, especially suction using 'hypobaric sheaths,' can work if no excessively deep scarring is present. Where scarring is present, the sockets are contoured to the shape presented. Ischial con-

tainment with utilization of large surface areas, increased stump to socket stability, and flexible inner sockets are routinely prescribed.

Socket fitting

With early fitting, some skin problems will be encountered, but these have not been of major significance. Silicone gel or urethane socket inserts have been used successfully, for mature skin/burn scar but they create extra bulk, weight, and replacement expense (especially with still-growing pediatric patients). They are used when other methods are unsuccessful. Distal cushions made from the usual prosthetic materials such as silicone foam are used. On occasion, patients have removed the distal cushions on their own, and no distal edema problems have been noted.

Initial prosthetics

Initial and early prosthetic treatment of an upper extremity amputee includes splinting for the prevention of contracture. A splint may be extended past the distal end of a residual limb to match the length of the whole limb, thus assisting a patient in retaining the concept of length. This is especially useful for patients whose active participation in a rehabilitation program is delayed. A preparatory prosthesis is provided when early definitive fitting is not prudent, e.g. when reduction of stump volume is anticipated or when fitting over a bulky dressing is necessary. For young children, a socket with harness/cable and PVC tube extension has been used.²⁹ The distal tube is filled with plastic resin, drilled, and tapped to accept a prosthetic device. Friction is provided through a set screw on the side of the distal tube. Wrist flexion units can be added, but they add weight and require maintenance, as well as careful training by an occupational therapist. Unless this component significantly increases a patient's function, it may be more of an irritant than an aid. Standard figure-of-eight harnessing can be used to attach a prosthesis. To distribute pressure, pads are placed under the harness from C7 to the distal scapular area and extend laterally the width of the back.

Preparatory weight-bearing treatment is provided through an air bag system, utilizing air bags designed for stabilization of a lower extremity. Containers have been fabricated from laminated plastics or polypropylene, using neoprene on the distal end or a solid ankle cushion heel foot with adapters built into the containers (Figure 49.22). Treatment usually begins on a tilt table, progressing to standing and then ambulation in the parallel bars. Most below-knee prosthetic devices are self-suspending. A belt with straps attached to the containers (when fabricated) has been used for above-knee cases. When a patient experiences hypersensitivity at the amputated sites and the skin at those sites is very fragile, a hybridized prosthesis/orthosis (prosthesis) may be fabricated. This allows for early ambulation by having patients shift their weight from side to side (Figure 49.23). In the cases where bilateral amputations occur above the knee, an Ilizarov external fixator may be applied to lengthen the femoral bones bilaterally and prevent hip contractures. A 2–3-inch gain bilaterally will eventually make the fitting of prosthesis much easier. Prosthetic pylons may be attached to the orthotic fixators in order to allow for some weight bearing before the lengthening and healing of the bones is completed (Figure 49.24).

Fig. 49.22 This girl is walking on a set of preparatory temporary prostheses which employ air bags surrounding the partially healed residual limbs. These air bag prostheses allow the patient to begin weight bearing and practice walking before full healing has occurred.

Fig. 49.23 When the skin at the residual limb is too fragile to permit weight bearing, a special prosthetic/orthotic device such as this can allow a patient to begin walking by shifting their weight to a proximal site (in this case the ischium) when it cannot be borne distally.

Definitive prosthetics

Knowledge about a patient's prosthetic ability, work, and recreational activities will have been accrued by the time of definitive fitting. Most patients welcome the opportunity to provide feedback regarding changes in components or changes for function and fit with the definitive prosthesis. Information is provided to a patient regarding available options. Some patients will sacrifice cosmesis for hi-tech, maximum function such as a thermoplastic socket with a frame for a hydraulic knee and energy return foot with no cosmetic covering. Others will part with some function in order to achieve a desired level of cosmesis. The current array of the available prosthetic socket/weight-bearing and suspension combination, as well as application and use of the many component combinations, is beyond the scope of this chapter. In general, the simplest system which provides the most functional-cosmetic level is accepted by the amputee as the best choice.

Some patients will continue to use their preparatory prosthesis for extended periods of time while other areas of the body are treated. Prior to definitive fitting, body weight, residual limb volume, wear and use patterns should be stable in order to optimize the long-term result with the definitive prosthesis. Return clinic visits should include prosthetic evaluation. Children may require length adjustments even prior to definitive fitting. Other patients may leave the hospital with the prosthetic knee locked and may need additional therapy and prosthetic alignment for improved ambulation with swing phase knee flexion. The overall process of prosthetic evaluation and fitting is described in Figure 49.25.

Fig. 49.24 When a bilateral amputation occurs at the proximal femoral level a prosthesis cannot readily be fitted. An orthotic external fixator can be used to lengthen the bones and reduce contractures. In this case, prosthetic pylons were attached to the orthotic fixators in order to allow some weight bearing before the lengthening and healing process were complete.

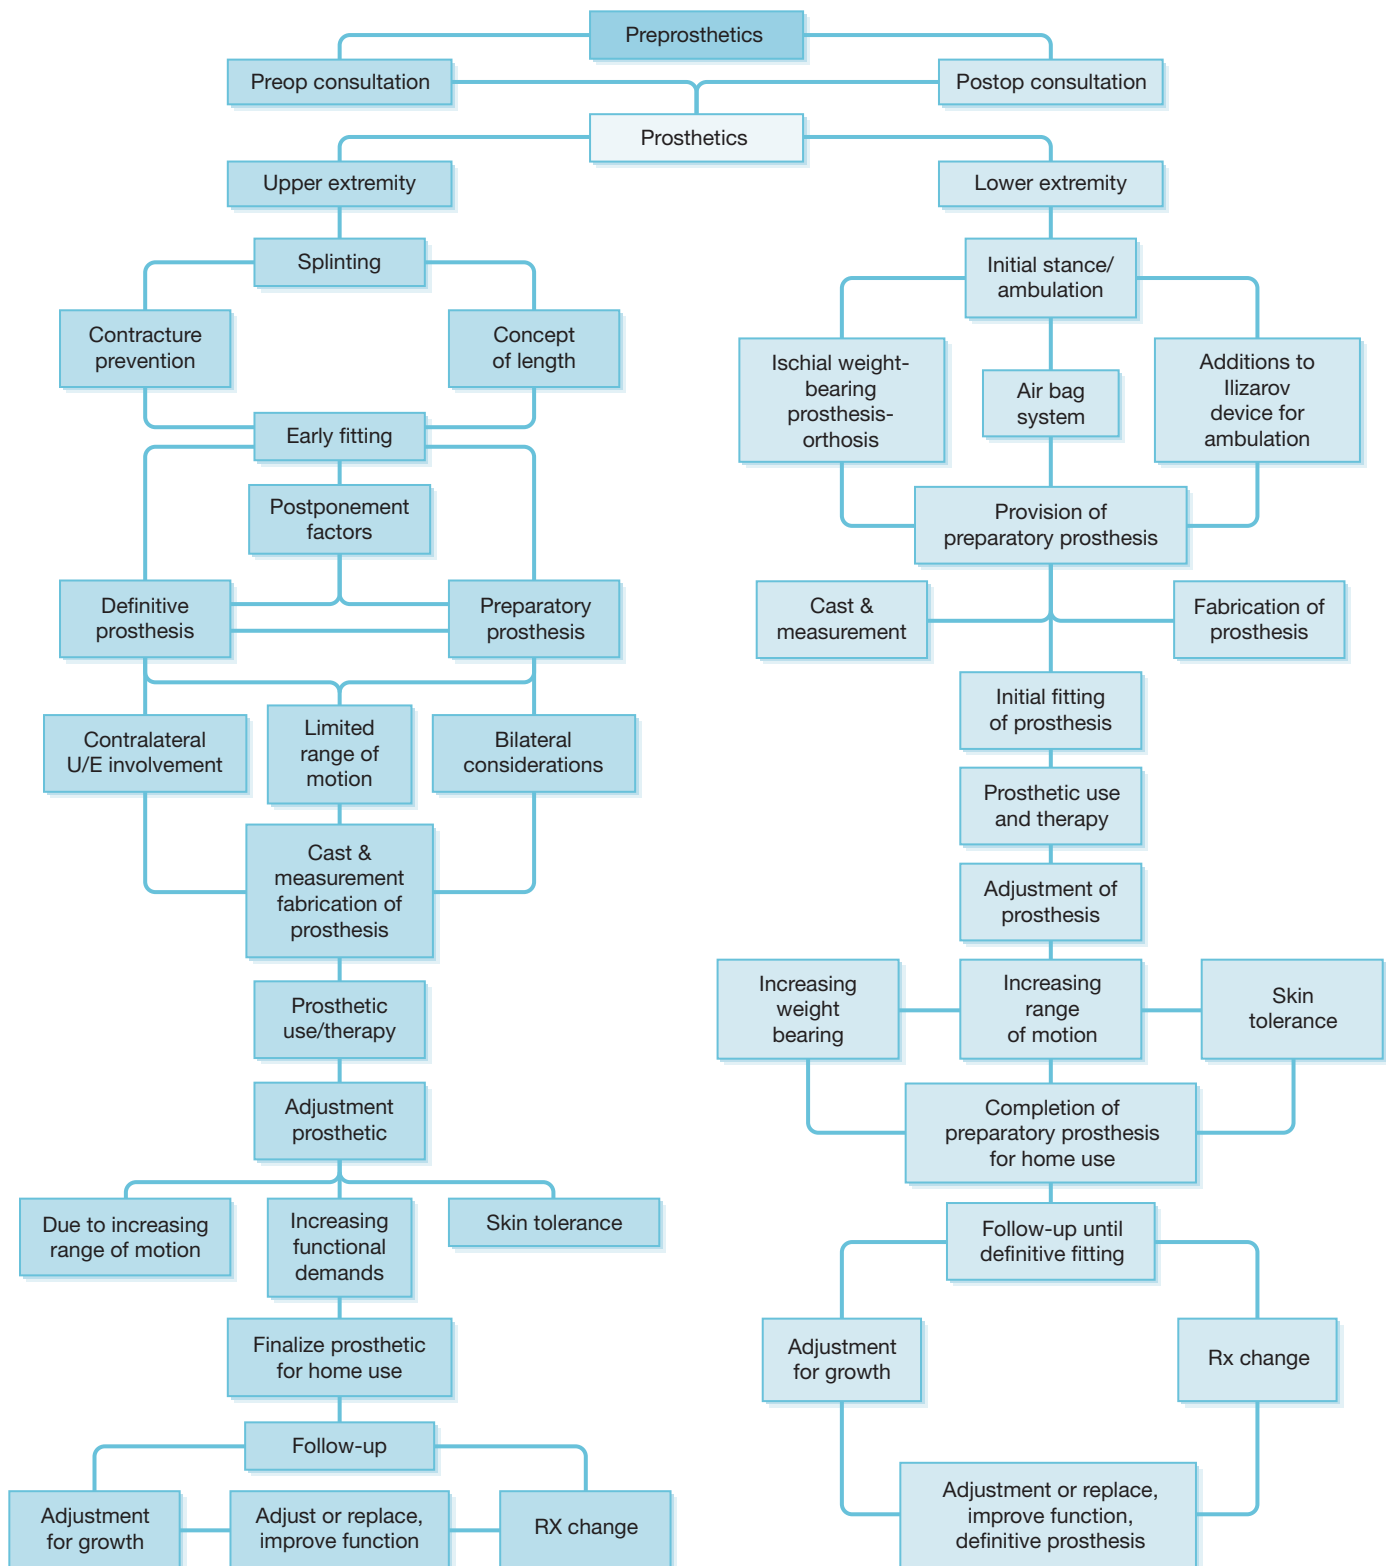

Fig. 49.25 Algorithm showing the process of prosthetic evaluation and fitting.

The orthotist's role

The role of the orthotist in treating the burn patient is similar to treating any other patient with orthopedic deficits. Soft-tissue deformities involving structural and mechanical properties are addressed by the same forces which are harnessed and

applied to any orthotic user. Treating the burn patient for his orthotic needs may, however, pose a significant challenge to the orthotist in the cases where fitting of an orthosis may be complicated by poor skin integrity, fragile and/or sensitive skin, and fluctuation in the volume of the extremity to be

treated. Additional factors which may have an influence on the type of the orthosis used may include the patient's neurological status, pressure points due to pressure garment presence, projected duration of the orthotic utilization, geographic location or a patient's proximity to a clinic for follow-up visits and orthotic modifications, and language/cultural barriers which may affect the compliance with an orthosis.

Orthotic treatment of the lower extremity

The approach of the orthotist in treating the injured foot depends on the extent of the burn injury. Orthotic shoes, which are the fundamental component of most lower extremity orthotics, may be utilized with some modifications in correcting deformities of the burned foot. Modifications of these shoes may include arch pads, molded foot thermoplastics, tongue pads, and metatarsal bars. The orthotic shoes should distribute all forces to the foot appropriately and should reduce pressure on sensitive or deformed structures and encourage total surface weight bearing along the plantar aspect of the foot. Inserts for plantar foot support such as the University of California Biomechanical Laboratory (UCBL) type may be utilized as indicated.

During the preambulation stage the patient may be fitted with those orthoses; if properly utilized, they can position the ankle joint appropriately, and assist in preventing or correcting plantar/dorsal contractures and inversion/eversion of the foot.

Leg length discrepancies are seen frequently in the cases of severe lower extremity burn injuries and they should be addressed with a shoe lift. The ankle-foot complex is difficult to address, especially in the case of a severe thermal injury. In most cases, the resultant deformity is the equinovarus foot. Both conventional and thermoplastic systems may be designed to treat the equinovarus or equinovalgus foot. Such systems may include a metal ankle-foot orthosis (AFO), polypropylene plastic posterior AFO (solid ankle or with an articulation), an AFO with stirrup attachment, an AFO with stirrups and patellar tendon support. A dorsiflexion spring assist may be incorporated in the AFO to aid weak ankle motion. Different straps such as a valgus correction strap may be attached to the AFO for the correction of specific problems. Interface materials, such as silicone, Plastizote® and Aliplast®, can be incorporated into an AFO to provide protection of the soft tissue, provide for total surface weight bearing, and to accommodate any anatomical anomalies that may be present (Figure 49.26). In the event that a return of range of motion is anticipated, an AFO could be fabricated that can be modified as the patient progresses. The ankle joints can be incorporated into the AFO, however, left solid and articulated at a later date.

During more complicated cases, and depending on the anatomy and function of the lower extremities, a knee-ankle-foot orthosis, hip-knee-ankle-foot orthosis or a trunk-knee-ankle-foot orthosis may also be designed for the best functional outcome.³⁰

Burn scar management

History

The burn wound like any other wound heals by the formation of scar at the injured site in order to replace the destroyed

Fig. 49.26 Specialized materials may be required to accommodate anatomical anomalies that may be present. Standard ankle-foot orthoses can be fabricated utilizing silicone materials to accommodate excessive scarring and limb loss.

tissues. Scar is defined as the fibrous tissue replacing normal tissues destroyed by injury or disease.³¹ In the case of a burn injury the scars, if not managed appropriately, have the potential of becoming thick and raised, resulting in scar hypertrophy. Hypertrophic scars are not cosmetically appealing and if they cross any joints they may restrict function. Pressure therapy for scar management is a very old and established component of a recovering burn patient's continuing rehabilitation program. Extensive historical notes on the earliest references to scarring are provided by Linares and colleagues who attribute the first full medical description of scars to Petz in 1790.³² They also state that the first medical reference to the use of pressure for treatment was written by Johnson in 1678 referring to the work of Ambroise Paré in the 16th century.³² Other historical events noted by Linares et al. are: first known accounts of the use of pressure for treatment of children in 1859; use of elastic bandages in 1860; adhesive plaster for pressure in 1881; and use of traction to treat scars in 1902. Linares' review includes descriptions of Nason's work in 1942 in which he noted that ischemia produced by pressure arrests the overproduction of scar tissue, 'where the imprint of the elastic of an undergarment or a belt may be seen — no keloid is present.'³² Another historical review by Ward³³ reveals that Blair in 1924 reported the positive influence of pressure on healing wounds. Nason's application of the 'constant pressure' principle included developing a type of neck splint made of a piece of dental impression compound or a piece of heavy felt strapped tightly over the scar for 6–8 weeks and possibly longer. Later, various splints were developed utilizing pressure and immobilization.³⁴ In the 1960s Drs Silverstein and Larson observed the influence of pressure on healing burns. Their observations led to the manufacture of customized pressure garments that revolutionized scar management in the 1970s which continues to date with some modifications.^{32,33}

The scar

As the burn wound progresses toward healing, or after skin grafting operations take place, scars begin to form. Generally,

the deeper the burns are the higher the risk is for the development of hypertrophic scars. Also, the longer a wound remains open the higher the chances for hypertrophic scar formation are.^{34,35} As the wound begins the healing process, collagen fibers develop to bridge the wound, forming an immature (active) scar which appears as a red, raised and rigid mass.³⁶⁻³⁹ Abston reported that pressure therapy during maturation led to a flatter, softer and a more devascularized scar.⁴⁰ Burn scars may take up to 2 years or longer to mature. Factors contributing to the formation of hypertrophic scars may include: wound infection, genetics, immunological factors, repeated harvesting of donor sites, altered ground substance, age, chronic inflammatory process, location of the injury, and tension.⁴¹ Scar hypertrophy may be evident at 8–12 weeks after wound closure.⁴²

Scar assessment

In order to better study the process of scar maturation, ongoing research is looking at alternative techniques in assessing the state of scars. Hambleton and colleagues studied the thickness of scars with ultrasonic scanning. This method, which is completely non-invasive, allows for a comparison of the thickness of dermal tissue in the traumatized area with that in the normal skin at regular intervals following initial healing.⁴³ Darvey et al. described a technique for the objective assessment of scars utilizing a video camera image on a computer and quantitatively analyzing the color of the scars using a custom-written computer program.⁴⁴ Esposito used a modified tonometer to measure skin tone which correlates to skin pliability and tension.⁴⁵ Bartell and co-workers used the elastometer properties of normal vs. injured skin. In his study Bartell showed that scars, if left untreated, will show improvement over time.⁴⁶ The Vancouver Burn Scar Assessment developed by Sullivan and colleagues is a subjective way of rating the burn scar pigmentation, vascularity, pliability and height.⁴⁷ Hosoda utilized laser flowmetry to determine the perfusion of hypertrophic scars vs. non-hypertrophic scars.⁴⁸ Other studies suggest that laser Doppler flowmetry and monitoring of transcutaneous oxygen tension may in the future be ways of determining scar maturation.⁴⁹

Treatment of hypertrophic scars

To this date hypertrophic scars remain very problematic and difficult to manage. Even though the mechanism of scar maturation is not yet well understood, clinically the accepted protocol to treat hypertrophic scars includes the use of pressure therapy, which should be instituted early on in the maturation process of the burn scar. Means of pressure therapy include pressure garments, inserts, and conforming orthotics. Once the skin has healed enough to withstand sheering, massage and heat modalities may be utilized as an adjunct in scar management. The use of pressure in effectively depressing scars was well documented by Drs Silverstein and Larson in the 1970s; their observations and studies sparked the near-universal use of pressure garments. When an active scar is compressed, it blanches, which indicates decreased blood flow in the area.⁵⁰ Less blood leads to decreased oxygen in the tissues, which in turns leads into decreased collagen production, which brings a balance between collagen synthesis and collagen breakdown (lysis). When a balance in the production

and breakdown of collagen is established, the resultant scar appears flatter.⁵¹ Kealey et al. conducted a prospective randomized study to compare efficacy of pressure garment therapy in patients with burns. Patients were randomly assigned to receive either pressure garment therapy or no pressure garment therapy. Assessment of the maturity of scar included use of the Vancouver Burn Scar Assessment Scale. The results on 113 patients studied in the follow-up revealed no significant differences between groups when age, body surface area burned, length of hospital stay or time to wound maturation were compared.⁵² In addition to this study, other studies have reported problems related to lack of adherence and discomfort, blistering, ulceration or scar breakdown, swelling of extremities and skeletal and dental deformity due to excessive pressures which often leads to stoppage of treatment, significant side effects and deformity.⁵²⁻⁵⁸

On the other hand, studies have also reported benefits of pressure garments.⁵⁹⁻⁶¹ The reader is referred to various recent excellent review articles on the efficacy or lack of efficacy of pressure garments in the management of hypertrophic burn scars.^{62,63} Reasons for the absence of unequivocal evidence is that garments must be worn continuously for a least 23 hours a day, making compliance or adherence difficult.^{55,64,63} In addition, the optimal pressure that must be applied to the scar for treatment is not known.^{55,65-67} Thus, the studies and debates continue, and, at least until more evidence is gathered, pressure therapy with the familiar elastic garments is still prescribed. Patients and families would no doubt feel relieved if the data eventually show that pressure does not make a significant difference in long-term outcomes. However, it should be noted that the studies thus far include neither the examination of burns over joints nor do they include burns of the hands, neck and face. In addition, none of the studies to date address the use of pressure in the form of splints, another source of discomfort and tension for burned children and their families.

None of the known studies yet have broached the face with an attempt to determine the efficacy of pressure versus no pressure. Facial pressure garments in children may pose problems due to interference with growth.^{68,69} We recommend that these patients should be closely monitored for normal facial and dental development by physicians including dental specialists. The elastic hood and underlying silicone face pad present special problems for patients, and some extreme challenges for the adults trying to assist a burned child or adolescent. The elastic mask and hood, covering head, face, and hair, effectively hides the identity of the person wearing it. It is perceived by children as sinister, associated with 'bad men' or monsters, and most children who have worn this garment can relay stories of being ridiculed by strangers who did not know the purpose of the garment. Emotional expressiveness, usually apparent in facial movements, is hidden by the hood. More than one child has explained non-adherence with the prescribed wearing of the elastic mask with a statement similar to 'I want my friends to see me laugh.' A study by Groce et al. compared the elastic mask and hood with silicone pad to the transparent silicone face mask and found no significant differences between the amount of pressure applied by each to the forehead, cheeks, and chin.⁷⁰ Many children have expressed a preference for, and seem to wear more readily, the transparent

mask. This study should make it easier for them to be granted their choice — an important event during a time when so much is happening to them outside of their control. Please see text on Reconstruction for further details.

Pressure therapy

As long as the scars are active they may be influenced by pressure therapy. However, not all burn scars require pressure. Patients with burn wounds which heal within 7–14 days do not need pressure therapy. Those patients whose wounds heal within 14–21 days are closely monitored for pressure therapy needs and may be generally advised to use pressure garments prophylactically. A wound that heals after 21 days will require the use of pressure garments.⁵¹ The correct amount of pressure in suppressing the hypertrophic scar has not yet been determined. Pressure of as little as 10 mmHg may be effective in remodeling the scar tissue over time. Pressures over 40 mmHg, however, may be destructive to tissues and cause paresthesias.⁴² Early forms of pressure therapy include the use of elastic bandages directly applied on the newly healed skin or on top of the burn dressings. The use of conforming thermoplastics along with elastic bandages may also be utilized as means of early pressure therapy.⁷¹ Once the wounds are almost or completely closed, tubular elastic bandages such as Tubigrip™ may be utilized. These tubular bandages are offered in different sizes and accommodate all anatomical circumferences. Care should be taken in applying these tubular bandages so that the fragile skin or the freshly applied skin grafts do not shear, or the minimal dressing underneath is not disturbed. The burn therapist should be aware that these tubular bandages are materials made of a single elastic thread spiraling through the weave of the fabric, and disturbance of the continuous elastic by cutting holes into it will alter the pressure gradient provided by these materials. The tubular elastic bandages should be doubled over the skin surface area treated in order to provide adequate pressure.⁷² Early pressure application over the hand and digits can be accomplished by the use of thin, elastic and self-adherent wraps such as Coban™ (Figure 49.27). This form of pressure is excellent for adult and pediatric patients for controlling edema and aids in the early scar management of hands when the shearing forces of a glove cannot be tolerated. Small children are excellent candidates for Coban™ gloves vs. a garment glove because of compliance issues, comprehension of instructions in assisting with the application of a custom glove and difficulties in obtaining accurate measurements for a custom glove. Coban™ may be applied over the burn dressings or directly onto the healed digits. The burn therapist needs to be aware that if Coban™ is wrapped too tight it may deform the interosseous structures of the healing hand. However, if Coban™ is wrapped too loose it may encourage swelling of the hands when used in combination with arm elastic garments. Coban™ strips are pre-cut approximately twice the length of the digits to be wrapped. Each strip is wrapped in a spiral fashion beginning at the nail bed of each digit, overlapping half of the Coban™ width and ending in the adjacent web space. Each fingertip needs to be exposed so that blood circulation can be monitored at all times. The Coban™ is stretched from 0–25% of the entire elasticity of each strip. Once all web spaces are covered, the rest of the hand is wrapped with Coban™, extending approxi-

Fig. 49.27 A Coban™ wrap can be used to decrease edema and aid in the effective management of hand scar hypertrophy.

mately 1 inch past the wrist joint. No skin areas should be visible once the Coban™ glove is completed. If small hand areas remain uncovered, a small piece of Coban™ is stretched over the area and adheres to the rest of the Coban™. When the glove is completed, the therapist should very superficially lubricate the entire glove with lotion in order to eliminate the adherent effect of the Coban™ and allow for the functional use of the hand. Coban™ should be removed on a daily basis by the therapist or the caregiver. Removal of Coban™ should be done carefully by cutting off or unwrapping each digit strip individually to avoid disturbing any small wound healing. The use of prefabricated interim pressure garments is widely accepted and utilized in burn rehabilitation. These garments are available commercially by different companies and they include pieces for the entire body. Interim garments which are made of softer materials introduce the burn patient to circumferential pressure and protect the newly healed skin. Another reason for using these garments prior to ordering custom-made garments is to allow for the patient's weight to stabilize (post acute hospitalization) and any remaining edema to subside. In some cases where obtaining custom-made garments on regular intervals (approximately 12 weeks) is not an option the recommendation should be that interim garments should be the choice for long-term pressure therapy. Once the patient's weight has stabilized, edema has subsided and the skin is able to withstand some shearing (approximately 3–4 weeks post wound closure), measurements are taken for the fabrication of custom-made pressure garments (Figure 49.28). Today several companies specialize in the fabrication of these garments. Clinically, custom therapeutic pressure for the prevention, control and correction of scar hypertrophy averages 24–28 mmHg, which is approximately equal and opposing to the capillary pressure (25 mmHg). At this pressure level, many researchers believe that scars may be altered.⁷³ In order for pressure therapy to be effective, pressure garments need to be worn at all times, day and night. They should only be removed for bathing and on occasion during exercises should they interfere with movements. Each order is duplicated so one set of garments can be worn while the other is being washed. Today,

Fig. 49.28 Custom-made pressure garments may be fabricated for the entire body.

pressure garment companies offer multiple colors of materials and for the pediatric population cartoon characters may be sewed on the garments to make them cosmetically appealing and improve the patients' compliance.⁷⁴ The burn therapist should choose a reputable company that provides excellent service and support for the patient and the therapist. The company's willingness and flexibility to manufacture non-standard garments, availability of special options, cost and turnaround time should be taken into consideration when selecting the burn center's pressure garment provider.⁷⁵

Inserts

Inserts are widely utilized in burn rehabilitation as an adjunct to achieving effective pressure over certain anatomical locations where pressure garments do not provide adequate pressure. These locations include concave body areas such as the face, neck, antecubital fossae, sternum, palm of the hands, web spaces, upper back and arches of the feet. These materials come commercially prefabricated or may be custom-made by the burn therapist or the medical sculpture technician. Inserts come in different forms such as silicone gels, elastomers, putties mixed with a silicone catalyst, skin care silastic pads, foam and even in the form of hard thermoplastic materials contouring to different anatomical locations. The experienced burn therapist chooses the appropriate insert material best suitable for the patient according to the stage of scar maturation and skin sensitivity. Generally, pressure therapy begins with a soft, thin and elastic insert and progresses to a more rigid insert in depressing the more unyielding burn scar. Inserts need to be worn underneath pressure garments, starting with a few hours of application and progressing as tolerated, toward a 24-hour application. They should be removed frequently for cleaning (warm water and soap), drying and application of

Fig. 49.29 Silicone elastomer inserts for the dorsum of the hand and web spaces are utilized for the prevention of syndactyly and depression on scar tissue.

cornstarch to avoid scar maceration and skin breakdown. Patients may be allergic to certain insert materials so the burn therapist may try different inserts until one is found to be best tolerated by the patient's skin. In cases of scar maceration, blisters, skin breakdown, contact dermatitis and a rash or an allergic reaction, inserts should be removed until healing occurs. Silicone, a polymer based on the element silicon, appears to be the trend in the treatment of hypertrophic scars. To date, the mechanism of how silicone affects the burn scar is not known. Clinically, silicone has been observed to depress the height of hypertrophic scars, prevent shrinking of fresh skin grafts (hard elastomer silicone pads vs. silicone gel pads), and increase the pliability of a scar, thus allowing for increase in the range of motion of affected joints. Patients report that silicone is soothing to the skin and aids in decreasing pain. Silicone, being occlusive, may cause the collection of excessive moisture and cause skin maceration if not removed frequently for cleaning and drying. Its disadvantages are that it is very expensive and short-lived.⁷⁶⁻⁷⁸ The therapist should look for silicone gel pads with a non-shearing protective medium on the non-skin surface in order for the gel to last longer. Also, buying larger-size gel pads and cutting them to fit the patient's need may be a cost-effective method for today's shrinking clinic budgets.

Other insert materials include liquid silicone elastomer, which when mixed with a catalyst form a solid but elastic insert (Figure 49.29). The experienced therapist could create custom inserts for difficult anatomical locations such as the face and web spaces using this technique. Prosthetic Foam™ is a liquid-based silicone elastomer which, when mixed with a catalyst, solidifies in the form of a very pliable foam insert that works best for the palm of the hands where function needs to be preserved while pressure is applied. These foam inserts also work best for applying pressure to contour surfaces on the face (around eyes, mouth, nose) while protecting these sensitive areas from excess and rigid pressure. Elastomer putties such as Otoform K™ or Rolyan Ezemix® form semi-rigid but still elastic inserts for different areas of the body where the scar can tolerate more pressure such as in the web spaces to prevent

syndactyly.⁷⁷ Early on in scar management, a soft foam such as Plastizote®, Velfoam™ or Betapile™ may be utilized to apply gentle pressure to the very fragile and sensitive scar.

High thermoplastic transparent masks were developed in 1968 by Padewski to be applied directly to the face to prevent, control and reverse scar hypertrophy. These masks require the moulaging of the patient in creating a negative facial mold. A positive mold of the face is fabricated with the use of plaster. The patient's positive facial mold is then 'sculptured' in an attempt to recreate the patient's non-burned face. A high thermoplastic material such as Uvex™ or W-Clear™ is then pulled over the positive mold in order to create the hard plastic mask (Figure 49.30a). Holes for the eyes, nose and mouth are cut. The mask is worn under pressure garments or with a head strapping mechanism. In cases of significant scar hypertrophy on the face, the positive mold is 'sculptured' sequentially over a period of time in order to avoid excessive pressure over facial scar leading to skin breakdown. A silicone elastomer face mask may be created utilizing the existing positive facial mold and is worn under facial pressure garments (Figure 49.30b). The use of the clear and silastic masks is preferred over the use of just a facial garment as they provide conforming pressure around facial openings (eyes, nose, and mouth). Frequently, the burn therapist manufactures the clear mask to be worn during the day and the silastic mask along with the facial garment to be worn at night.^{32,79–81}

Burn scar massage

Once the burn scars have matured enough to tolerate sheering forces, massage may be incorporated into the scar management regimen. Scar massage is an effective modality for maintaining joint mobility in the case of contractures. It aids in softening or remodeling the scar tissues by freeing adhering fibrous bands, allowing the scars to become more elastic and stretchy, thus improving joint mobility. Initially, the therapist may utilize a non-frictional massage applying mostly stationary pressure to skin blanching and mobilizing the skin surface

without friction. Utilization of lubricants during this massage technique should be avoided. As the skin begins to tolerate frictional massage, the scar tissue is manipulated in rotary, parallel and perpendicular motions, using a lubricant and pressing the skin to blanching. Clinically, massage is found to alleviate itching. It is also used for desensitization purposes. An electrical massager with a heat attachment may be used along with lubrication, as heat and massage in combination may increase scar pliability. Massage should be performed at least twice daily (3–5 times preferred) for 5–10 minutes on each treated body surface. The burn therapist should frequently assess the skin condition in avoiding further injuries. The patient and/or family are instructed on home massage techniques and electrical massagers may be issued for home use. Other therapeutic modalities for scar management may include the use of heat. Heat relaxes tissues and makes them pliable in preparation for mobilization. Heat modalities may include hot packs, paraffin wax, fluidotherapy and ultrasound. Even though the use of therapeutic heat as an adjunct to rehabilitation is well documented, therapeutic heat modalities are infrequently being utilized in burn rehabilitation.^{82,83}

Burn scar management is a complicated and lengthy process and for it to be successfully completed the patient and caregivers should be committed to follow the therapist's recommendations. Extensive training should take place addressing the use and care of pressure garments, inserts, lubrication and other therapeutic scar management procedures to be performed by the patients and their caregivers. Lubricants which do not contain perfume and other skin irritants should be selected and applied at least (2–3 times daily) to the healing skin. Lubricants with sun protection factor (SPF) of at least 15 are recommended.⁸⁴ Written instructions with pictures and diagrams along with videos addressing scar management should accompany the patient home upon discharge from the hospital. Follow-up visits to the burn or rehabilitation clinic for the assessment of overall recovery to include garments, inserts and other home therapeutic interventions are needed for the patient to successfully complete his/her burn rehabilitation. The therapists' knowledge, creativity and continuing research in improving the currently existing scar management techniques may be the key to positive outcomes in pressure therapy.

Therapeutic exercise

Therapeutic exercise is motion of the body or its parts to relieve symptoms or to improve function.⁸⁵ The need for therapeutic exercise to enhance mobility of the burn patient begins acutely and continues throughout the months of healing. Even though painful and extensive therapy is required during the long rehabilitation process, the results are for the most part dependent on the patients' and families understanding, involvement and dedication to the treatment.⁸²

The goals of therapeutic exercise in burn rehabilitation are to:

- reduce the effects of edema and immobilization;
- maintain functional joint motion and muscle strength;
- stretch the scar tissue;
- return the patient to optimal level of function.

Fig. 49.30 (a) A Uvex™ clear face mask provides pressure to the face so as to prevent scar hypertrophy and to preserve facial features. (b) A silicone elastomer face mask provides pressure to the face in preventing facial scar hypertrophy and preserving facial features.

Exercise for the patient

Exercise sessions depend upon the patient's physical, psychological, and medical status. In the conservative treatment of burn wounds, a vigorous physical therapy program is instituted immediately so as to maintain function.⁸⁶ Postoperatively, exercises involving autografted skin over joints are usually discontinued for 4–5 days. Escharotomies, fasciotomies, heterografts, and synthetic dressings are not contraindications for exercise.⁸⁷ Early mobilization to decrease edema, proper exercise techniques, and accurate documentation of function are more important than the type of wound closure.⁸⁶

Scar contracture and joint mobility limitations are the result of the shortening of immature connective tissue. Therapy aims to prevent deformity and the subsequent limitation of movement. In circumferential burns, both the flexor and extensor surfaces are at risk of contracture. Therapeutic exercise in conjunction with splinting should promote agonist and antagonist movements around those joints in order to maintain mobility.⁸⁸ Treatments are tailored to each individual patient, with independent living being the ultimate goal throughout the rehabilitation continuum.

Exercise activities can typically be divided into four categories: stretching, strengthening, cardiovascular, and functional activity exercises.

'Stretching' exercises are performed with a slow, prolonged force. Gentle, sustained stretch is more effective than multiple repetitive movements in gaining length of burned tissues. An indication of effective stretching is that the scar tissue blanches. If scars extend across more than one joint, each joint should be stretched individually, and then the skin stretched as a whole unit across the involved joints. 'Passive' exercise is a form of stretching exercise which is performed without voluntary muscle contraction. It is a slow, gentle stretch provided by an outside force with the prime result being the stretching of tissue. The use of a continuous passive motion (CPM) device has been documented to be an effective modality for improving joint range of motion.⁸⁷ Rehabilitation advances have shown CPM treatment to be a viable option because of its benefits to soft tissue remodeling, joint nutrition, wound healing, and venous dynamics.^{89,90} Active and active-assistive exercises should become the focus of the session in lieu of passive stretch once the patient has achieved full range of motion. All passive exercise should be performed cautiously when there is evidence of bone or tendon exposure.

'Strengthening' exercise improves the muscle's ability to perform work. 'Active' exercise is performed independently by a patient. This is the form of exercise most recommended because it stretches healing skin and provides strength-inducing benefits. Frequent exercise performed actively (with voluntary muscle contribution) by a patient promotes the greatest increase in movement. 'Active-assistive' exercises utilize the same principles; however, a patient is 'assisted' by an outside force (therapist or assistive device) to achieve the full range of motion. A patient will achieve improvements in strength and range of motion, but not equal to those provided by active exercise. Active-assistive exercises are suggested for those patients who are too weak to perform a full range of motion exercise independently. In 'resistive' exercises, manual or mechanical resistance is applied to a movement. A variety

of modalities offer resistance, ranging from traditional weights to innovative combinations of rubber bands. Resistive exercises can begin in an 'assistive' fashion with minimal resistance and assistance provided to complete the range of motion.

'Cardiovascular' exercises are designed to improve a patient's overall endurance level. These activities are performed for prolonged periods of time with minimum resistance and can be designed to involve activities which are enjoyable for the patient.

'Functional' exercises include those activities which incorporate all types of the above-mentioned exercises. They are designed to improve the coordination and performance of patients in tasks which are relevant to activities of daily living. For example, feeding requires both coordination and strength as well as stretching to take the hand to the mouth. Performing functional activities is generally rewarding to patients. The goal(s) and purpose of these activities are clearly defined and understood. Completion of these tasks requires concentration and appears to distract a patient from the pain of movement. Functional tasks also seem to provide a feeling of accomplishment and encouragement to a patient who wants to regain independence.

Therapeutic exercise begins immediately after the burn. For a patient being treated conservatively, movement helps maintain strength and range of motion, and aids in circulation and healing. For a patient who has been grafted, isometric exercises can be performed during the immobilization period. The benefit of isometric exercise is that a patient does not 'forget' how to contract the muscle, a common phenomenon with periods of prolonged immobilization. Isometric exercise also helps in maintaining muscle strength. When skin grafts have become stable, active exercise may begin. Active exercise is initially performed by allowing a patient to limit the intensity by pain. It is followed by passive stretching exercise and strengthening to maintain mobility.

Exercise can be performed with dressing and wraps in place. Care should be taken when dressings are applied so that joint range of motion is not restricted. Dressings which have been correctly applied will minimize discomfort and promote movement, while dressings applied too tightly will limit mobility, increase pain, and may create pressure-induced neuropathies. Exercise can also be performed while the patient is in the tub, where the buoyancy of the water and the absence of confining dressings can make exercise less painful. Exercise is initially painful and the very first repetition is often the most difficult. Discomfort is due to stretching skin which has lost its natural lubricating mechanism and has become dry and tight. Movement itself decreases pain. Each subsequent repetition will be easier as the skin stretches, and the muscle pumping action of active movement helps resolve edema, thus significantly reducing pain.

Specific movements can be targeted to prevent burn scar contracture. We find that the patients tend to position themselves in a comfortable position, which most frequently is the position of contracture. Based on knowledge about typical contractures, the following movements are encouraged: neck extension and lateral flexion, shoulder abduction and flexion, elbow extension and supination, metacarpophalangeal flexion, interphalangeal extension, wrist extension, knee extension,

ankle dorsiflexion, and metatarsophalangeal flexion. Exercise sessions may be indicated three to four times daily for more involved areas. Patients should be encouraged to exercise between therapy sessions.

To walk or ambulate again following a severe burn is an important goal shared by patients of all ages. However, we believe ambulation should happen on the fourth day after every operation.

The benefits of ambulation include:

- maintenance of range of motion;
- maintenance of strength in the lower extremities;
- prevention of thromboemboli;
- maintenance of bone density via weight bearing;
- promotion of independence in functional activities.⁸⁸

Ambulation exercises may also help prevent decubiti, provide mild, cardiovascular conditioning, and increase appetite. In addition, ambulatory patients have fewer problems with lower extremity contractures and physical endurance.⁸⁷

All wounds must have the proper dressings prior to ambulation. Lower extremity burn wounds should be wrapped with elastic bandages in order to facilitate capillary support. Wrapping will decrease edema and therefore decrease pain and promote healing. The extremities should be wrapped distal to proximal from the toes to the groin crease. The foot should always be included to avoid distal edema. Those extremities that have had skin grafting generally have less graft loss when there is a second elastic wrap to provide further support. Lower extremity donor sites are less painful when wrapped with elastic bandages. Wrapping which incorporates the figure-of-eight pattern has been reported to provide better pressure than the spiral wrap, perhaps due to increased vascular support.⁹¹

As with other exercise, proper positioning facilitates proper gait.⁸⁸ The patient who has been allowed to assume a position of comfort will have difficulty extending the hips and knees during ambulation. The ankle may be tight, limiting plantigrade position when in the upright position. If the joints are in the normal alignment, the amount of pain and energy are greatly reduced.

In preparing for ambulation, therapists may use a tilt table with patients who lack the capacity to stand and mobilize their lower extremities (Figure 49.31).⁹¹⁻⁹⁴ There are a variety of reasons why erect positioning may prove difficult. For example, prolonged bedrest, which influences blood pressure or ankle tightness, may inhibit plantigrade position. However, therapists should keep in mind that a tilt table represents a mostly passive introduction of gravity to the body and does not promote proper alignment of the musculoskeletal system. Creative efforts and aggressive techniques are sometimes necessary to encourage ambulation in patients that first appear incapable or unprepared to begin erect weight-bearing exercise.

Patients that present with fragile tissue over the terminal end of a lower extremity amputation site may initially appear incapable of walking for fear of damage to the weight-bearing surface by compressive or shear forces. This issue can be resolved with the use of a bypass orthosis that shifts the force of weight bearing to the ischium by using a quadrilateral ischial containment socket with metal uprights that connect directly to a foot mechanism. This protocol can be introduced

Fig. 49.31 The tilt table may be utilized prior to ambulation for those patients who may have difficulty assuming the upright position.

on a tilt table and then progressed to a walking program as the individual's condition warrants.

Patients tend to perform much better when given an achievable goal such as walking a specific distance or to a certain place. Children do well when provided with a desired incentive such as a toy or a game. Frequent rest periods may be necessary secondary to decreased endurance levels or pain. Patients should be encouraged to ambulate further distances each day. Care should be taken to avoid prolonged periods of standing so that hypotension does not develop. The lower extremities, even when properly wrapped for support, will show signs of venous insufficiency when dependent for too long a period of time. The use of assistive devices, i.e. crutches or walkers, is discouraged because the legs need the muscle pumping action to prevent edema.⁹⁰ Exercise and ambulation are integral parts of the rehabilitation of burn patients. Both allow a patient to resume a lifestyle as active and independent as possible.

Exercise for the outpatient

This section describes methodology used in designing an exercise-training program for persons with severe burns that have been discharged from the hospital. Exercise training is defined here as 'a planned, structured and repetitive body movement done to improve or maintain one or more components of physical fitness.'^{95,96} The evidence for the use of exercise in the outpatient setting and the methodology presented here is based primarily on the outpatient exercise program that is implemented in severely burned children at Shriners Hospitals for Children in Galveston, Texas and in some severely burned adults.⁹⁷ This exercise program is supplemented by physical

and occupational therapy. The program has proven beneficial in children 7–18 years of age.^{97–99} Recently, effects of a music- and movement-based exercise program on children younger than 7 years of age has been assessed in a pilot study at Shriners Burns Hospital in Galveston, Texas. The effects include increases, as well as maintenance, of range of motion in children that participated in a movement and music program versus those that did not. The principles in designing an exercise program in children and adults with severe burns is based largely on guidelines offered to healthy, non-burned children and adults (Figure 49.32).^{95,96,100–104}

Exercise evaluation

It is important to perform an initial evaluation of risks factors and/or symptoms for various chronic conditions concomitant to the burn. These include pre-existing conditions such as chronic cardiovascular, pulmonary and metabolic diseases. The objective of the exercise evaluations is to obtain information to optimize safety during exercise testing and training and also to develop a sound and effective exercise rehabilitation program.

Health screening before exercise evaluation should begin with the collection of subjective data. This should include evaluation of exercise or sports interests, objectives, level of activity prior to burn, functional limitations (e.g. loss of digits, lower body bilateral amputee), and other pertinent information. To our knowledge, there are no burn-specific physical activity questionnaires. However, simple questionnaires for assessing pre-burn physical activity exist and can be modified to fit a specific given population.^{105–107} This evaluation can consist of muscle strength, cardiopulmonary and muscle joint flexibility testing. The information gathered during the subjective and objective evaluations can then be used to design a structured exercise program or plan to be carried out at home or at an exercise facility. Finally, a plan to periodically re-evaluate subjective and objective data, and the exercise program should be incorporated.

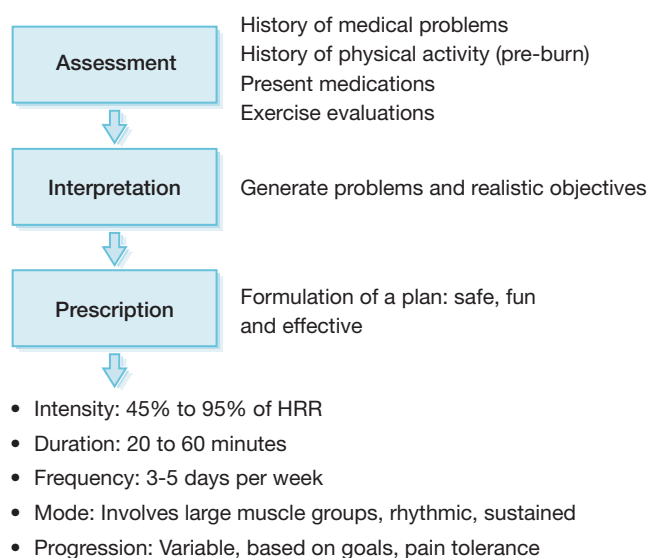

Fig. 49.32 Basic diagram depicting various components involved in the design of an exercise program.

Subjective data: Characterization of limitations or problems of a patient should be done. Obtaining a history of pre-burn physical activity or habits, present medical complaints, symptoms and limitations is crucial to develop a sound exercise program. Symptoms or limitations which may affect exercise tolerance may include pain during ambulation, weakness in ambulation, itching, joint contractures, amputations, shortness of breath, or ease of fatigability. In addition, you should note present medications and note possible effects of these. Following the evaluation of subjective data, an exercise evaluation to gather objective data on the patient's exercise or physical capacity should be performed.

Objective data: Assessment of objective data includes age, height and weight, percent TBSA burn, and percent full-thickness burn. Variables before, during, and after a cardiopulmonary exercise test (CPET) should be obtained if possible. These include heart rate, blood pressure, Borg's rated perceived exertion (RPE), basic electrocardiogram (ECG), and spirometry.^{108,109} However, if a CPET is not possible, an exercise program that is effective can also be designed. Assessment of upper and lower body muscle strength should also be done. This includes assessment of peak strength levels (if possible), as well as determining the loads or weights that will be used during the resistive component of the exercise program. The assessment of peak muscle strength can be accomplished during knee or elbow extension but can also be accomplished during a handgrip.^{97,110,111} These tests involve peak-to-maximal efforts and good communication between patient and tester must exist. In addition, there is a developmental mental maturity that must exist in order for many of these objective data to be maximally helpful. We recommend a chronological age of 7 years and above, though children as young as 3–4 have also been tested successfully.¹¹² Finally, major muscle/joint flexibility should be assessed using measures such as sit-and-reach or goniometry for range of motion. Other types of tests may include neuromuscular tests such as gait analysis, balance time or reaction time. Finally, assessment of functional performance can also be done such as sit-and-stand scores, timed walk/jog and or lifting. The results of these evaluations will be used to identify major problem areas, to write an exercise prescription or to design the exercise program, and to assess progress during and after an exercise program.

Components of an exercise program

An exercise program typically consists of a warm-up phase, an endurance phase, recreational activities (optional), and a cool-down phase. While aerobic training activities should be done 3–5 days per week, complementary flexibility and resistance exercises may be performed at a lower frequency (2–3 days per week).¹¹³ Flexibility exercises can be included as part of the warm-up or cool-down, or done at a separate time. Resistive training is often performed on alternate days as aerobic training; however, both types of activities can be combined into the same workout session. Typically the warm-up period will be of approximately 5–10 minutes, though it can be longer. This will be followed by a stimulus or endurance phase of 20–60 minutes, and a cool-down period of approximately 5–10 minutes. Aerobic and resistance training should be prescribed in specific terms of intensity, duration, frequency, and mode of exercise. Each of these terms will be

discussed in greater detail later. An optional recreational game may occasionally substitute the endurance phase. However, because of potential difficulties in setting an appropriate intensity for an appropriate length of time, it is suggested that it be done as a complement to the endurance phase. If a recreational activity is added to the endurance phase, then the shortening of the endurance phase should be carefully considered though maintaining a minimum of 20 minutes.

Warm-up stage

Prior to the endurance phase, a variety of very light exercises, low-intensity calisthenics, should be done to improve the transition from rest to the endurance phase of the exercise session. The emphasis at the onset of an exercise session is to gradually increase the level of activity until the proper intensity is reached to begin the endurance phase. Stretching exercises to increase the range of motion of the joints involved in the activity were previously included in the warm-up. However, recently, evidence has been introduced to contraindicate the inclusion of stretching during the warm-up period.^{114,115}

In fact, evidence suggests that a pre-exercise warm-up that consists of only light aerobic exercise to increase body temperature is adequate for increasing flexibility before an exercise session.⁹⁶ For example, patients might walk moderately fast during the endurance phase, but might conclude the warm-up period with slow, easy walking. However, a moderate walk (e.g. 3.5 mph) can be a warm-up for a patient that jogs at 5.5 mph during the endurance phase. Heart rate may be monitored or assessed if needed to ensure that the warm-up activity is not too strenuous.

Endurance stage

The endurance phase develops cardiorespiratory or aerobic fitness and includes 20–60 minutes of continuous or intermittent (minimum of 10-minute bouts accumulated throughout the day) aerobic activity. Duration depends on the intensity of the activity; thus, moderate-intensity activity should be conducted over a longer period of time (30 minutes or more), and, conversely, individuals training at higher levels of intensity (i.e. vigorous exercise) should train for at least 20 minutes or more.¹¹³ The most effective exercises for the endurance phase employ large muscle groups in activities that are rhythmic or dynamic in nature. Sports such as soccer, basketball or tennis also have aerobic conditioning potential if a sufficient amount of time for inducing aerobic improvement is achieved (minimum of 20 minutes total). On the other hand, activities like golf and bowling are unlikely to elicit a cardiovascular training effect, but are enjoyable and may yield health-related, as well as psychosocial, benefits.

Recreational activities

The inclusion of enjoyable recreational activities during (or immediately after) the endurance phase often enhances compliance with the exercise program. Rules of the games may need to be modified to adjust skill level requirements, competition, and to ensure safety. The outcome of the game (winning or losing) should be of lesser importance than the safety, participation and enjoyment of the patient. It is important to remember that recreational activities complement the endurance phase and should not consistently replace it. Recreational

activities may also promote development or improvements in psychosocial health, by increasing the amount of social interaction.

Cool-down stage

At the end of the activity session, about 2–5 minutes of cool-down activities – slow walking and stretching exercises – are recommended to gradually return HR and BP toward resting levels. This period includes exercises of diminishing intensities; for example, slower walking or jogging, calisthenics and stretching exercises. This part of the exercise session is viewed as important in reducing the chance of a hypotensive episode after the exercise session, as well as other cardiovascular complications.¹¹⁶

Exercise prescription

Some basic exercise physiology principles should be kept in mind when designing an exercise program for burned patients. Two such principles are: the progressive overload principle, and the specificity principle. The progressive overload principle refers to the observation that a body system must be exercised at a level above which it is presently accustomed in order for a training effect to occur.⁹⁵ The system or tissue gradually adapts to this overload. The typical variables that comprise the overload include the intensity, duration and frequency (days per week) of exercise. The principle of specificity refers to the concept that the training effect is specific to the muscle fibers involved in the activity. Specificity also refers to the types of training in a very specific manner to produce a very specific adaptation or outcome. If a muscle is engaged in endurance types of exercise, the primary adaptations are in the capillary and mitochondrial number, which increase the aerobic capacity of the muscle. These principles are applicable to burned patients; however, it must be noted that a high intensity of exercise is not needed (low to moderate intensity) to achieve health-related benefits. On the other hand, to achieve athletic performance or competitive-related goals, moderate to high levels of intensity will be required. Another consideration that should be kept in mind when designing an exercise program is the age of the population. Prepubescent children are very different in their physiological and mental response to exercise training than postpubescent children. Older adults also have different health and physical problems than younger adults. It is for these reasons that medical exams, as well as exercise evaluations, are strongly recommended prior to starting an exercise program. It is beyond the scope of this chapter to address these differences and/or problems. However, general guidelines for both children and adults are offered and it is suggested to the reader to seek additional information for population-specific recommendations or position stands on exercise and physical activity, from associations such as the American College of Sports Medicine (<http://www.acsm.org/publications/positionStands.htm>), the American Academy of Pediatrics (<http://www.aap.org/>), the American Medical Association (<http://www.ama-assn.org/>) or the American Heart Association (<http://www.americanheart.org/>).

Aerobic training

Intensity: To improve aerobic fitness, generally the intensity of exercise should be between 65% and 95% of the peak heart

rate or between 45% and 85% of the heart rate reserve (HRR).¹¹⁷ The heart rate reserve is the difference between peak heart rate obtained during a CPET and resting heart rate. The range of heart rate values associated with the exercise intensity needed to induce an improvement in cardiovascular fitness is termed the ‘target heart rate zone.’

The peak heart rate (HR_{peak}) is obtained from the CPET. However, when this not possible, one simple method to estimate HR_{peak} is to use the formula (220 minus age).⁹⁵

The rating of perceived exertion or (RPE) scale can also be used as a guideline in setting the intensity of exercise.¹¹⁸ The RPE is a valuable and reliable indicator of exercise tolerance, but also intensity. This method of monitoring exercise intensity is useful when it is impossible to obtain a HR_{peak} or if patients are on medications which affect heart rate such as β -blockers.

There are currently two RPE scales that are commonly used: the original or category scale, which rates exercise intensity on a scale of 6–20 and the revised or category-ratio scale of 0–10. It is reported that the category-ratio scale uses terminology better understood by the subject, thereby providing the tester with more valid information. It has been found that an aerobic training effect and the threshold for the start of anaerobic training are achieved at a rating of ‘somewhat hard’ to ‘hard,’ which approximates a rating of 12–16 on the category scale or 4–5 on the category-ratio scale.¹¹⁹

Finally, if a patient cannot use the heart rate method or the RPE method, the ‘Talk Test’ can also be used as a highly consistent method to set and monitor intensity of exercise.¹²⁰

The ‘Talk Test’, or the point where speech first becomes difficult, approximates exercise intensity almost exactly equivalent to the ventilatory threshold. One could advise the patient to exercise at an intensity where speech is comfortable. When speech becomes uncomfortable, one can assume, based on previous studies, that exercise intensity is consistently above ventilatory threshold or above the desired intensity of exercise needed for general improvements in fitness.¹²⁰ It must be noted that when setting the exercise intensity, safety and effectiveness are linked. An appropriate intensity should also be well suited to result in a long-term, active lifestyle.

Duration: The duration of an aerobic exercise session is closely linked to the intensity of the activity: i.e. a longer duration of low-intensity exercise can be accomplished than a high-intensity exercise. In general, the duration of exercise for burned patients once discharged, should be from 5 to 20 minutes the first week. This will depend on the functional status of the patient and also pain tolerance.

If the patient tolerates up to 20 minutes, then this duration is appropriate. The objective should be to exercise 20–60 minutes of aerobic activity. This can be accomplished continuously or intermittently throughout the day, with a minimum of 10-minute bouts. Typically a duration of 20–30 minutes at between 40% and 50% to 85% of the heart rate reserve (excluding time for warm-up and cool-down) should induce health and fitness improvements.^{113,121}

In burned patients with extremely low aerobic capacity or endurance, four to six; 5-minute bouts with rest periods between bouts would be a program that would induce benefits. The duration of the exercise sessions (or bouts) can be progressively increased over time. However, as mentioned before, a

high intensity of exercise or very long duration of exercise are not needed to achieve health-related benefits, particularly during the initial stages of outpatient exercise rehabilitation.

Frequency: It is reported that deconditioned persons may improve cardiorespiratory fitness with only twice-weekly exercise.¹¹³ However, it is generally agreed that optimal training frequency appears to be achieved with 3–5 workouts per week. The additional benefits of more frequent training appear to be minimal, whereas the incidence of lower extremity injuries increases abruptly. For those exercising at 60–80% HRR, an exercise frequency of 3 days per week is sufficient to improve or maintain VO_{2peak} . When exercising at the lower end of the intensity continuum, exercising more than 3 days per week is not deleterious. Patients with extremely low functional capacities may benefit from multiple, short (5 days per week) exercise sessions. Clearly, the number of exercise sessions per week will vary depending on the patient’s limitations, but also by the patient and caregiver’s lifestyle.

Mode: The most important consideration in choosing the mode of exercise for the endurance phase of the sessions is to engage large muscle groups in activities that are rhythmic or dynamic. The greatest improvements in aerobic fitness result when exercise involves the use of large muscle groups over appropriate periods of time (Figure 49.33). The mode of exercises includes treadmill walking/running, rowing or cycling. If no treadmill is available, then walk/jog at a track or field is appropriate. Swimming is also an appropriate mode of exercise, though closure of burn wounds should be ensured to minimize infection of wound or the contamination of others. Endurance games are also appropriate modes of exercise.

In the development of the exercise prescription for burned patients, it is suggested that the exercise begins with walking, or cycling. These two activities are easy to tolerate, are safe, intensity is easily set and gives the trainer a better ability to monitor progress for the first few weeks. In contrast, other individuals might progress at a faster rate through walking, jogging and cycling programs because of the nature of the burn, but also because of personality, previous athletic experience or psychosocial health. The risk of injury associated with high-impact activities or high-intensity weight training must also be considered when prescribing exercise modalities, especially for the burned individual. This is particularly important if the patient is overweight or novice. It may be desirable to have the patient participate in different exercise activities (cross-train) to reduce repetitive orthopedic stresses.

Progression of exercise

We recommend starting slowly and safely progressing in duration and intensity, but also in transitioning from early activities to activities that are more difficult to perform. This method of progression decreases the potential for inducing excessive muscle soreness, causing new injuries or aggravating old injuries. The emphasis on slow-to-moderate walking as the primary activity early in the fitness program is consistent with this recommendation, and the participant must be educated to not move too quickly into the more demanding activities. For example, if the individual can walk about 1–2 miles without

Fig. 49.33 Aerobic training should incorporate the use of large muscle groups over appropriate time periods.

fatigue, then the progression to a walk-jog or jogging program is a reasonable recommendation.

The recommended rate of progression in an exercise conditioning program depends on the functional capacity, medical and health status, pain tolerance, location of burns, age, individual activity preferences and goals, and an individual's tolerance to the current level of training. For burned patients, the endurance aspect of the exercise prescription can be divided into three stages of progression: initial, improvement, and maintenance.⁹⁶

Initial conditioning stage

The initial stage should include light and moderate muscular endurance activities (for example, 40–60% of HRR). These exercises typically have a low potential for injury, and induce minimal muscle soreness and pain. Exercise adherence may be compromised if the level or intensity of exercises in the program is initiated too aggressively. The amount of time spent in this stage varies depending on the individual's adaptation to the exercise program. We recommend at least 4 weeks of initial conditioning. The duration of the exercise session during the initial stage may begin with approximately 15–20 minutes and progress up to 30 minutes, at least 3 times per

week. Deconditioned individuals should be allowed more time for adaptation at each stage of conditioning. Age of the individual should also be taken into account when progressions are recommended, as adaptation to conditioning likely takes longer in older individuals, but also in extremely debilitated individuals.¹¹³

Improvement stage

The goal of the improvement stage of training is to provide a progressive increase in the overall exercise stimulus, which will allow for significant improvements in aerobic fitness. The improvement stage of the exercise-conditioning program differs from the initial stage in that the participant is progressed at a more rapid rate. This stage is reported to usually last from 4 to 5 months, during which intensity is progressively increased within the upper half of the target range of 50–85% of HRR. However, our experience in a 12-week training program in children 7–18 years of age indicates that after 3–4 weeks of initial conditioning, some patients are able to start the improvement stage. In this stage, duration may be increased consistently every 2–3 weeks until participants are able to exercise at a moderate-to-vigorous intensity

for 20–30 minutes continuously. During this stage, interval training may also be beneficial, provided the total time engaged in moderate to vigorous exercise is at least 20 minutes.

Maintenance stage

The goal of this stage of training is the long-term maintenance of the cardiopulmonary fitness level developed during the improvement stage. This stage of the exercise program may begin at any time the participant has reached previously agreed objectives. During this stage, the individual may no longer be interested in continually increasing the conditioning stimulus. Also, in this stage, further improvement may be none to minimal, but continuing the same workout routine enables individuals to maintain their fitness levels, as well as develop the healthy exercise habit. At this point, it is suggested that goals of the program be re-examined and new goals or objectives set.

Resistive training

Strength is defined as the ability to produce force, and the ability to produce force over an extended period of time is referred to as muscular endurance. Both muscle strength and endurance impact activities of daily living (ADL) because ADL require a percentage of an individual's muscular capacity to perform these everyday tasks. Severe burns result in extensive and prolonged loss of muscle mass; therefore, resistance training, which increases LBM, should be part of an exercise rehabilitation program for burned individuals.^{97,99}

Similarly to designing the aerobic portion of an exercise program, the resistive training portion of an exercise program follows similar principles of training. Both the overload principle and specificity principle are applicable. Strict rules of proper technique and safety must be observed to reduce potential for injury or accidents. A normal breathing pattern should be maintained, with breath holding avoided. Breath holding during lifting can induce excessive increases in blood pressure, which in individuals with hypertension, diabetes or other medical risks can be dangerous.

Similarly to the aerobic exercise program, testing or evaluation of muscle function precedes the resistive exercise program. This helps individuals identify problem areas, areas in need of required improvement, goal setting and tracking progress of individuals. In addition, muscle strength tests have value in determining back to work status.¹²² Some of these tests involve peak to maximal muscular efforts. These tests can be done on weight machines or using dumbbells.

Typically these tests are done at 100% of one-repetition maximum (1RM), but can also be done at 3RM. For extremely deconditioned individuals or for very young children, modification of these guidelines can involve testing using 3RM up to 12RM if needed. An important point to remember is that safety of the individual is crucial. Therefore, correct technique during all testing and training must be observed. The order of exercises or muscle tested is also important. It is recommended that large muscle groups are tested first and alternate between upper body and lower body. For example, a 3RM test may be done in the following order of exercises: bench press, leg press (or squats), shoulder press, leg extension, biceps curl, leg curl, and triceps curl. The three repetitions maximum (3RM) load can be determined as follows. After an instruction period on

correct weight-lifting technique, the patient or individual warms up with lever arm and bar (or wooden dowel) and is allowed to become familiar with the movement. After this, the patient lifts a weight that allows successful completion of four repetitions. If the fourth repetition is achieved successfully and with correct technique, a 1-minute resting period is allowed. After the resting period, a progressively increased amount of weight or load is instructed to be lifted at least four times. If the patient lifts a weight that allows successful completion of three repetitions, with the fourth repetition not being volitionally possible, because of fatigue or inability to maintain correct technique, the test is terminated and the amount of weight lifted from the successful set is recorded as their individual 3RM. This weight is then used to determine the amount of weight or load that will be used during the first 1–2 weeks (of for example, a 12-week program) as baseline loads.

Exercise type: There are many resistance-training exercises. However these can be divided into core exercises or assistance exercises. Core exercises recruit one or more large muscle group (for example, chest, shoulder and back). Assistance exercises typically recruit smaller muscle groups such as biceps, triceps, calves. A good program should typically involve both types of exercises.

Training frequency: The number of days to train varies according to the individual's training status. For severely burned individuals, we recommend 2–3 days per week of resistance training.

Type of contraction: Resistance exercise programs or exercises that emphasize accentuated lengthening or contractions (eccentric) are not recommended for severely burned individuals. These types of contractions have a high potential for acute delayed onset of muscle soreness, while having similar outcomes as concentric or isometric muscle contractions. The muscle soreness if severe enough has the potential for discouraging further participation in exercise activities. The movements during weightlifting should be rhythmic, done at moderate repetition duration.

Amount of load lifted: Commonly, a certain percentage of the 1RM or 3RM is used as guideline for choosing a training load. The amount of load lifted can be as much as 100% of 1RM or as little as lifting no load. We recommend initially during the first week of training, allowing the individual to become familiarized with the exercise equipment and to be instructed on proper weight-lifting techniques. Initially, the weight or load the subjects will lift should be set at 50–60% of their individual 3RM for 12–15 repetitions for the first 1–2 weeks. Thereafter, the load lifted can be increased to 70–75% (8–10 repetitions) of their individual 3RM and continued for weeks 2 or 3 to week 6. After this, the training intensity can be increased to 75–85% (8–12 repetitions) of the 3RM and implemented from weeks 7–12 or longer. We must note that these are guidelines to provide an estimate of training load and have some limitations.¹²³ Another method of determining training load is to perform multiple RM based on the number of repetitions planned for the specific exercise. For example, if 8 repetitions were desired for biceps curl, then one would test the individual by having him or her perform 8RM testing sets.

Number of repetitions: It is believed that muscle strength and endurance can be obtained simultaneously by performing a specific number of repetitions within a certain range (for example 6–10 repetitions). The number of repetitions will depend on load lifted (% of 1RM) and also the objective or goals set at the start of the exercise program. However, we recommend 8–12 repetitions, at a moderate to high intensity to improve both muscle strength and endurance.⁹⁷

Number of sets: There are very limited data in children as to whether 3 sets or 1 set is required to increase muscle strength and hypertrophy. Much of the adult-based literature supports similar responses of muscle strength, muscle endurance, hypertrophy between single and multiple set resistance training programs.^{113,124–127} Finally, it is important to stress two points: (1), the difference in strength gains is typically more pronounced in trained individuals; and (2), both single and multiple training increased strength. The first point is usually not the case with burned patients, and the second point stresses the fact that an increase in strength is expected with resistance training compared to the standard of care in burned individuals.

Exercise order: There are many methods of ordering resistance exercises. One of these is to arrange core exercises, then

assistance exercises.¹²⁸ Another method is to arrange large muscle groups and then small muscle groups.^{129–131} Yet another method, which allows the individual to recover more fully between exercises, is to alternate upper body with lower body exercises. This is especially well suited for deconditioned individuals or untrained individuals.^{129,130} For example, we have successfully implemented in severely burned children, the following order of resistive exercises: bench press, leg press or squats, shoulder press, leg extension, biceps curl, leg curl, triceps curl, and toe raises. These exercises can be done on variable resistance machines or free weights.⁹⁷ Both free weights, bands or variable resistance machines are appropriate for burned individuals wishing to participate in an exercise program (Figure 49.34).

Rest periods: As a general rule, it is important to allow enough time between exercises to perform the next exercise in proper form. The rest period also varies depending on the individual's training status and also specific training objectives.

Progressive overload: In order for improvements to continue over time, it is important to carefully monitor and chart the individual's workouts or loads lifted. Progressive overload can be applied in a variety of ways, such as increasing the weight lifted, increasing the repetitions while keeping load constant,

Fig. 49.34 Resistance training consists of exercises with free weights or variable resistance machines.

or decreasing rest periods. A conservative method termed ‘2-for-2 rule’ is suggested. This rule states ‘if an individual can perform two or more repetitions above his or her assigned repetitions goal in the last set, for two consecutive workouts for a specific exercise, then weight or load should be added to that specific exercise for the next training session.’¹³¹ For example, if the assigned number of sets and repetitions is 3 sets of 8–12 reps in the chest press machine, and the individual performs 12 reps in all 3 sets, after several workout sessions (the specific number of sessions depends on many factors), the individual is able to complete 12 reps in the third set (i.e. the last set) for two consecutive workouts sessions, then in the following training session, the load for that exercise should be increased. The amount of weight (load) that should be added depends on factors such as the physical condition of the individual (strong or weak) and the body area (upper body or lower body). In general, an increase of 1–2 kilograms for a less trained, weaker individual is suggested for upper body exercises, while an increment of 2–4 kilograms is suggested for lower body exercises.¹²³

Example of an exercise program

An example of our exercise rehabilitation program is described below (Table 49.1). The results of this program are published.^{97–99} This program has been successfully implemented at discharge from hospital, but also at 6 months post burn.

Final considerations

- The ultimate goal of an exercise rehabilitation program should be to improve physical function. However, the way or the means in which this is achieved are also

important. An exercise program should be challenging, effective, but also must be safe and fun. It should also promote lifelong healthy habits. This will maximize compliance with the exercise program.

- The American College of Sports Medicine (ACSM) has an extensive list of absolute and relative contraindications to exercise and exercise testing that should be carefully considered when designing an exercise program for adults or children. These contraindications will also pertain to individuals with severe burns.
- Individual goals should be established early in the exercise program. Whenever possible, they should be developed by the participant with the guidance of an exercise professional. The goals or objectives must be realistic, and an intrinsic or extrinsic rewards system should be implemented at that time.
- It is recommended that exercise professionals work together with an occupational and/or physical therapist to avoid duplication of services, as well as to identify areas in need of special attention.
- Based on our clinical experience with children and adolescent patients, individuals with severe burns should participate, as soon as possible after hospital discharge, in a structured exercise program. This program should be supervised and if possible conducted in the presence of a trained professional. However, if this is not possible, the exercise program, with some commonsense guidelines, should offer a choice for safe and effective participation.

TABLE 49.1 BRIEF DESCRIPTION OF THE SHRINERS HOSPITALS FOR CHILDREN-GALVESTON HOSPITAL OUTPATIENT EXERCISE REHABILITATION PROGRAM

Aerobic workout	
Intensity	70–85% of each individual's previously determined individual peak aerobic capacity. However, heart rate and rated perceived exertion is obtained at regular intervals during aerobic exercise
Duration	20–40 minutes
Frequency	3–5 days per week
Mode	Aerobic exercise on treadmills, cycle ergometers, arm ergometers, rowing machines, and outdoor activities such as soccer or kickball
Resistance workout	
Exercise type	Upper and lower body of core and assistance exercises
Amount of load lifted and number of repetitions	The weight or load lifted set at approximately 50–60% of each individual 3RM and lifted for 4–10 repetitions for three sets. During the second week, the lifting load, increased to 70–75% (3 sets, 4–10 repetitions) of their individual 3RM and continued for weeks 2–6. After this, training intensity is increased to 80–85% (3 sets, 8–12 repetitions) of the 3RM and implemented from weeks 7–12
Number of sets	3 sets
Exercise order	Bench press, leg press or squats, shoulder press, biceps curl, leg curl, triceps curl, toe raises, and abdominals
Type of exercises	Eight basic resistance exercises done using variable-resistance machines or free weights: 4 for upper body, 3 for lower body, and abdominals
Rest period	A rest interval of approximately 1 minute between sets

Note: Each exercise training session consisted of resistance and aerobic exercises, with aerobic exercise preceding resistance exercise. This outpatient exercise program is supplemented with outpatient physical and occupational therapy.

- For adults, a careful medical and exercise evaluation should be conducted prior to starting an exercise program. Cardiovascular or pulmonary problems, as well as other conditions, such as diabetes, must be identified prior to starting an exercise program to avoid potential fatal or near-fatal complications.
- It is important to get the burned individual started with an exercise program or a more active lifestyle as soon as possible, but it is never too late to get started, regardless of the time post burn.
- When beginning the exercise program, it is better to start slowly and build up gradually, than to start too fast and risk injury.
- For children, avoid using very intense or maximal (1RM) resistance training or testing. Gradual progression is of utmost importance to avoid injury and to promote exercise adherence.
- The individual should ‘listen’ to his or her body. During and after workouts, the individual (and supervisor) should be alert to signs of a potential health problem as a result of overexertion. Signs may include pain, shortness of breath, dizziness or nausea.
- Be flexible and allow individuals to be flexible. Don’t rigidly stick to a schedule if the patient doesn’t feel up

to it. If he or she is overly tired or under the weather, allow them to take a day or two off.

- Monitor the individual’s progress. Reassess fitness every 6 weeks. You may notice that you need to increase the amount of time you exercise in order to continue improving (if part of the original goals).
- The exercise professional or individual should keep an exercise diary or logbook to help chart progress.
- If the patient loses motivation, try setting new goals or try a new activity (or activities). Sometimes, bringing a friend or family member into the program may help in motivation. Incorporate variety into the exercise routine.
- Lastly, work on conveying to the patient or client that a fun and safe exercise program can result in maintenance of lifelong physical, as well as psychosocial, healthy habits (Figure 49.35).

Patient and/or caregiver education

When patients are being discharged from the acute hospital stay, it is vital that they leave with an individualized home exercise program. In addition, splinting and positioning exercises, activity or daily living performance, scar control measures, and psychosocial issues should be addressed. This

Fig. 49.35 Overall long-term burn rehabilitation should result in lifelong physical as well as psychosocial healthy habits and improvements in quality of life.

program can then be updated and upgraded to allow for progression during the ever-changing phases that the burned individual goes through, in what may be in excess of a 2-year recovery period. During follow-up visits, screening and monitoring of the patient's progress regarding the above categories is performed and the necessary changes are completed. This detailed knowledge of the patient's status will allow the burn team to coordinate the care for the patient so that recommendations can be followed through. Providing the patients with a checklist is a valuable tool to enable patients to assume some control of the rehabilitation process, enable them to track their progress and encourage their continuation of the program. Many patients and their caregivers are often overwhelmed by the rehabilitation program. It takes an extraordinary amount of time and energy to plan and participate in a home exercise/instruction program. Continuous communication among the patient, caregiver and the burn team will ease the patient's transition into recovery.

One way of helping patients with the exercise program is to establish communication with a community-based exercise center, such as a commercial or hospital-based facility. Often, direct and constant communication between a burn hospital's physical therapist, exercise physiologists and/or physician and the community-based exercise facility will maximize the potential for adherence to and the efficacy of such 'home' exercise programs, by adding supervision and structure.

Summary

The rehabilitation after a severe burn, although challenging, can be rewarding to the rehabilitation team. The medical staff must continuously evaluate the interventions provided to ensure each patient's maximum functional outcome. Through experience, education and research, the production of therapeutic interventions that will enhance each patient's recovery and will provide them with a more meaningful, productive life will be made possible.

Musculoskeletal changes secondary to thermal burns

E. Burke Evans

Chapter contents

Changes confined to bone	652
Changes involving pericapsular structures	657
Changes involving the joint	662
Alterations in growth	664

Among trauma states the burn is alone in the ability and tendency of its wound, even as it heals, to create major musculoskeletal deformity. In addition, the protracted burn illness which accompanies severe burns may result in other skeletal change. Box 50.1 presents a classification of musculoskeletal changes secondary to burns; from that, the most commonly occurring and clinically significant alterations have been selected for discussion in detail.

Changes confined to bone

Osteoporosis

Osteoporosis is the most frequently occurring postburn change involving the bone. In Shiele's radiographic study of patients with burns confined to the upper extremities, osteoporosis was found in 24 of 70 patients.¹ Klein's ongoing studies suggest that, among persons with serious burns, reduction of bone mass density is pervasive.² Stated causes of osteoporosis in thermal burns are bed confinement, immobilization, hyperemia,³ reflex vasomotor phenomena,⁴ and adrenocortical hyperactivity.⁵ In Chapter 27 of this book, Klein thoroughly reviews the effects of burn injury on bone metabolism.^{2,6} In this section only what is clinically apparent will be discussed.

The more extensive the burn and the greater the number of complications, the longer the patient will be bed confined and relatively immobile. It is easy to understand that the onset of osteoporosis might be accelerated and its intensity more marked in the burn illness which features a hypermetabolic state. If a single extremity of an otherwise normal person is immobilized for a long period of time because of local trauma, as with a fracture, the bones of that extremity will lose mineral to a degree that loss of density can be easily seen in a plain radiograph. So with burns isolated to the extremities, the bones of the affected extremities become osteoporotic; and, in persons with generalized burns, the bones of deeply burned

extremities may show more profound mineral loss than is observed in non-burned extremities or in the axial skeleton (Figure 50.1). Van Der Wiel et al.⁷ found in an x-ray absorptiometry study of 16 adults with fractures of one tibia that there was eventual loss of bone mineral density in the contralateral femur and in the lumbar spine, but to a lesser degree than in the ipsilateral femur. These findings, though not strictly analogous to those observed in burns, nevertheless point to the occurrence of generalized osteoporosis in other trauma states and the difference in loss of bone density relative to local factors. In fractures or in burns, impaired mobility and local hyperemia could account for this difference.

Another characteristic of the osteoporosis of burns that seems to set it apart is its persistence, not just until restoration of the anabolic state, but for months and years after the burn has healed (Figure 50.2). This phenomenon may be most clearly observed in patients who have survived 90% burns, but Klein records less than normal bone among even moderately burned children as long as 17 months after injury.² It seems obvious that muscle atrophy and/or the failure or inability of the person to return to the preburn level of physical activity surely account in part for this protracted state of reduced bone mineralization.

Probably there is no way to prevent osteoporosis in any patient whose burn is of such severity as to require an extended period of bed confinement. On the other hand, the advance of bone atrophy can at least be favorably modified even among patients with large burns if mobilization and active exercise are initiated soon after the burn. The bones of the axial skeleton, the pelvis, and the lower extremities are most efficiently stressed by weight bearing. Thus, standing is a priority measure. Muscle contraction alone may help to forestall bone atrophy and bone is better stressed if the contraction is resisted. Incrementally increasing resistance during motion or at the termination of an arc of motion or to muscle contraction in an extremity which may not be moved can be supplied by anyone who attends the patient. Isometric muscle contraction can be exacted from even seriously burned patients and is important for bone stress, for maintaining muscle tone and bulk, and for the patient's continuing ready identification of the affected extremity. Passive motion has little or no effect on bone and thus does not figure in the prevention of osteoporosis. Other preventive measures, e.g. closure of the wound and maintenance of nutrition, are routine in critical burn care. Treatment of established osteoporosis involves the more aggressive employment of measures for prevention. There are no long-term studies, however, which persuasively measure the

BOX 50.1 Classification of musculoskeletal changes secondary to burns**ALTERATIONS LIMITED TO BONE**

- Osteoporosis
- Periosteal new bone formation¹
- Irregular ossification¹
- Diaphyseal exostosis¹
- Acromutilation of fingers²
- Pathological fracture
- Osteomyelitis
- Necrosis and tangential sequestration

ALTERATIONS INVOLVING PERICAPSULAR STRUCTURES

- Pericapsular calcification
- Heterotopic para-articular ossification
- Osteophyte formation

ALTERATIONS INVOLVING THE JOINT PROPER

- Dislocation
- Chondrolysis³
- Septic arthritis
- Spontaneous dissolution⁴⁻⁶
- Ankylosis

ALTERATIONS INVOLVING MUSCLES AND TENDONS

- Desiccation of tendons⁷
- Fibrosis of muscles⁸

ALTERATIONS SECONDARY TO SOFT TISSUE

- Muscle and joint contractures
- Malposition of joints
- Scoliosis

SOFT TISSUE INJURY

- Compartment syndrome
- Nerve injury

ABNORMALITIES OF GROWTH

- Acceleration and retardation
- Destruction of growth plate

effectiveness of exercise, diet, medication, or modality in the treatment of osteoporosis in any state.

Osteomyelitis

In burns, bones can become infected by exposure of bone by the burn; by an open fracture accompanying the burn; by extension of infection from a septic joint, introduction of organisms along traction pins, internal fracture fixation devices; or by blood-borne organisms of bacteremia. Considering the apparent great liability of seriously burned patients for developing osteomyelitis, it is surprising that it does not regularly occur. As it turns out, clinically significant osteomyelitis in burned patients is rare. Antibiotics given for the general state may prevent seeding of the bone or may repress any small focus of bone infection.

The cortex of long bones is a good barrier to surface organisms. Even exposure of cortex will have little adverse effects if the blood supply of the bone remains intact. Prolonged

Fig. 50.1 (a) Six months after injury there is the coarsened trabeculation of marked osteoporosis of bones of the left hand and forearm of a 4-year-old male whose 70% full-thickness burn involved head, chest, and both upper extremities. (b) A roentgenogram of the left tibia and fibula obtained on the same date as that of the hand shows minimal atrophy.

exposure will kill the outer layer of the cortex, which will in time sequester, separating at a well-defined cleft between dead and living bone. With minor or moderate exposure, the bone will usually survive long enough for bordering granulation tissue to cover it. For larger defects, it is common practice to drill closely spaced holes through the exposed cortex so as to encourage buds of granulation tissue to emerge from the still vascular medullary canal. Another way to encourage granulation tissue formation over exposed bone is with decortication with an osteotome or burr to expose the capillaries of the inner cortex. With these practices, there seems to be little risk of infecting the bone, no matter how contaminated the rest of the limb. It may be that there is sufficient centripetal pressure to discourage the invasion of organisms when the holes are fresh and that the holes are rapidly sealed by blood clot and advancing tissue. There are no reports of deep bone infection related to cortex drilling.

With open fractures which remain at the base of part of a major soft tissue burn wound, bone infection is probably inevitable. Even so, the infection tends to remain at the fracture site and not to involve the rest of the bone, so that local debridement and stabilization of the soft tissue wound are all that are required for treatment. Dowling reported osteomyelitis of the tibia related to an open bimalleolar fracture in an extensively burned extremity.⁸ On the other hand, osteomyelitis developed in neither of the two open fractures reported separately by Choctaw⁹ and Wang.¹⁰ Three patients have been treated in whom open fractures of the femur complicated thigh burns. Each case required aggressive and repeated debridement. One fracture was treated in traction, while the other two were treated with external fixators. In one of the patients

Fig. 50.2 (a) Advanced osteoporosis in the hands of a 14-year-old male 9 months after 100% TBSA burn. All growth plates are open. (b) Twenty-four months after injury, osteoporosis persists and there is irregular closure of metacarpal and phalangeal growth plates. (c) Eight months after injury, growth plates of distal tibiae and fibulae remain open. (d) Twenty-four months after injury, distal growth plates of tibiae and fibulae are closed. Other major growth plates remain open. Osteoporosis is unchanged.

who was admitted 8 months after acute burn, there was established osteomyelitis of the femur in relation to the exposed fracture. Osteomyelitis did not develop in either of the other patients; in the end, all three had sound femurs.

When traction pins are directed through burned skin for the treatment of fractures or for suspension of a burned extremity, the factors favoring development of infection along the pin track and the formation of cigarette sequestra are:

- the introduction or migration of organisms from the burn wound;
- linear pressure of the traction pin;

- prolonged traction;
- excessive movement of the extremity leading to loosening of the pin;
- sealing of the pin sites.

For traction or suspension, pins may be inserted through acutely burned skin, through eschar, through granulation tissue, or later through ischemic burn scar which may be colonized with uncommon and antibiotic-resistant organisms. No amount of local cleaning is likely to sterilize the surface through which the pin must pass, yet it seems that organisms in sufficient numbers to colonize are rarely introduced in this manner.

Local low-grade infections usually resolve when pins are removed if the pin sites are vigorously curetted of granulation tissue. In one case in which a four-pin custom external fixator was used in the treatment of an open infection of the elbow, there resulted diffuse osteomyelitis of humerus and radius. The infection was controlled with antibiotics and without surgery after the pins were removed. This case was included in Barret's report of skeletal pinning in 41 severely burned children.¹¹ In experience with the use of the Ilizarov system for correction of skeletal deformity in burns, one patient developed a pin track infection of such severity as to require removal of the pin, curettage, and intravenous antibiotics for control of methicillin-resistant staphylococcus.¹²

Hematogenous osteomyelitis and that due to spread from an infected joint are rare. The literature entertains no report of the occurrence of either entity in association with burns. Were bone infection of this sort to be recognized, effective treatment would depend upon the identification of the offending organisms for organism-specific antibiotic regimen.

Fractures

Pathological fractures were at one time common in burn management because of the practices of delayed excision of eschar and of keeping patients in bed until wounds were completely covered. During that time, fractures occurred because of bone collapse when patients first stood or walked after a prolonged period of bed confinement or when stiff joints were manipulated¹³ (Figure 50.3). The bones most commonly affected were the femur at its distal metaphysis and the tibia at its proximal

Fig. 50.3 Pathological fracture of the osteoporotic femur of a 9-year-old girl sustained on the first day she stood after 5 weeks of confinement for 40% TBSA burn.

one. The only treatment required was support of the extremity until the fracture consolidated, usually in 4–6 weeks. Children were more often affected than adults and the fractures usually compressed one cortex, producing an angular deformity which rapidly corrected with growth. More currently, Klein's² study strongly suggests that fractures occur more frequently in burned children than in a matched normal population even months after the acute burn. Now, however, in acute burn management the most frequently seen fractures are those occurring at the time of, or in association with, the burn injury. Falls or violent trauma account for many of the fractures, and the sites are those common to the causes, bearing no relation to the burn itself.

Although fractures complicate burn treatment and occasionally delay mobilization of patients, their management need not be complex. Fractures in extremities not burned can be treated in a routine manner by manipulative reduction and plaster immobilization, by open reduction and internal fixation, with an external fixator, or with skeletal traction (Figure 50.4). Fractures in extremities with first-degree or superficial second-degree burns can be managed in the same way. Deep second-degree and third-degree burns present a different problem only with respect to the early bacterial colonization of third-degree burns and the degradation of deep second-degree burns to full-thickness burns which will, in turn, become colonized. There is thus, a precious window of time when fractures requiring open reduction and internal fixation can be definitively treated without increased risk of infecting the bone; however, fracture reduction and stabilization are so important in the functional management of a severely burned patient that the risk of bone infection should be acknowledged and shouldered at any postburn stage. Skeletal traction can often be the management choice, particularly in children and adolescents, even if the treatment protocol requires that the patient be moved from bed for tubbing, dressing change, or additional surgery. The disadvantages of skeletal traction are the confinement to bed and the imposed relatively fixed position of the affected extremity. External fixators, now in common use, have made it possible to align and stabilize fractures in burned extremities without open operation. In fact, external fixation may be the treatment of choice for open fractures in burns, as it often is for open fractures not associated with burns. There is the added functional advantage of patient mobility. Brooker's extensive favorable experience supports this concept.¹⁴ With both skeletal traction and external fixation, there is an added risk of bone infection because of the path from surface to bone provided by the pins. This is a risk worth taking, and it is minimized by scrupulous pin site care and by removal and replacement of any loosening pin. Frye recognized and discussed the specific and continuous difficulties encountered in the management of fractures and burns.¹⁵

When casts are used for stabilization of fractures in burned extremities, the wound is made inaccessible and there is an abiding fear that the unattended wound will seriously degrade or at best not improve. Those fears may be well founded; however, Wang¹⁰ showed that a bivalved circular cast could be used effectively for an open comminuted fracture of a proximal tibia with overlying deep burns, and Choctaw⁹ reported successful use of a cast for immobilization of an open comminuted fracture after immediate postburn grafting of the

Fig. 50.4 (a) This 15-year-old male sustained closed fractures of the right femur, left tibia and left humerus at the time of a 46% TBSA burn involving mainly trunk and right lower extremity. The femur and humerus fractures were treated in skeletal traction. Suspension of the right lower extremity aided management of circumferential deep burns of that extremity. Lesser burns of the left leg made it possible to treat the minimally displaced fracture of the left tibia in a circular cast. All fractures consolidated in 6 weeks in satisfactory alignment. (b) Fracture of the left humerus as it appeared at the time of admission to the hospital. (c) Five weeks after injury, the fracture showed maturing callus. Traction was discontinued at 6 weeks.

affected extremity. Common sense should dictate which fractures can be treated with circular or bivalved casts or with splints. If a reduced or moderately displaced but aligned fracture is so stable as to require external support only for maintenance of alignment, then cast or splint immobilization should be all that is needed. On the other hand, if a fracture because of instability requires for maintenance of reduction, three-point pressure or molding of the cast material, then it will be better treated by other means.

Dowling⁸ reported osteomyelitis resulting from open bimalleolar fracture in an extremity with extensive deep burns. In neither of the cases reported by Wang and Choctaw did the

bone become infected. There were also no infections among Saffle's⁴² fractures, nine of which were treated by open reduction and internal fixation.¹⁷ With two fractures of the femur, each of which was exposed at the base of a deep chronic burn, aggressive debridement of the wounds and the fracture ends was followed by treatment with skeletal traction in one and by external fixation with the Ilizarov system in the other. Both fractures healed without further complication.

Fractures in burned patients heal quickly. There is no recorded experience which suggests that healing is delayed by the burn. Neither is there any record of failure of union. Callus formation may be abundant.

Among severely burned patients, non-displaced or minimally displaced fractures may not be detected until unusual local pain in an affected extremity prompts radiographic examination or when a radiograph obtained for other reasons reveals the fracture as an incidental finding. These fractures are usually of no functional significance. Modest angular deformity near a joint may be a problem in adults, though not in children. On the other hand, undetected transphyseal fractures in children can be a major functional threat.

Changes involving pericapsular structures

Heterotopic bone

Heterotopic bone formation is a rare but functionally important complication of thermal burns. The incidence in a general burn population is reported to be somewhere between 1 and 3%.^{1,18-21} In select populations, the incidence may be higher as it will be if patients with periarticular calcification are included in the statistics. For example, Tepperman et al. reported a 35.3% incidence among patients referred to a tertiary care center for rehabilitation.²² Jackson made the observation that the incidence of heterotopic bone could be expected to be less in institutions which admit patients with minor burns.²³ Munster's²⁴ radiographic survey of 88 adult and teenage patients with 160 burned upper extremities yielded a 16% incidence of pericapsular calcification; and the 23% incidence reported by Schiele et al.¹ included both heterotopic ossification and calcification. In the early routine radiographic study reported by Evans¹³ periarticular calcification which did not progress to heterotopic bone was excluded from the final calculation of an incidence of 2%. The 3.3% incidence recorded by Kolar and Vrabec²⁵ included patients with pericapsular calcification. Even if heterotopic bone occurs infrequently in thermal burns, it remains that once it develops, it often compromises joint motion and is difficult to treat. In addition, its pathogenesis is still incompletely understood; and, thus, protocols for prevention may in fact miss the mark.

Pathogenesis

The metabolic changes occurring after thermal burn are increased metabolic rate; protein catabolism; ureagenesis; fat mobilization; glucogenolysis; gluconeogenesis; elevated glucose flow; and eventual total body weight loss.^{26,27} There is an accompanying suppression of the immune system which favors wound infection, but, at the same time, favors survival of skin allografts. Infection, failure of skin graft take or anything which delays closure of a burn wound will extend the altered metabolic state. Though it might be assumed that there occurs, along with the metabolic upheaval, an adverse change in connective tissue milieu, the exact nature of such a change is not known. It is also not known what the metabolic changes have to do with the development of heterotopic bone, but it is clear that the burn disease is necessary to its formation. Other factors to be considered in the genesis of heterotopic bone are percentage of burn, location of burn, period of confinement, osteoporosis, superimposed trauma and genetic predisposition. These factors, though identifiable, are not easy to implicate.

Percentage of burn

Most reported cases of heterotopic bone have had a 20% or greater total body surface area burn; however, heterotopic bone has been found in patients with as little as 10% third-degree burn.¹³ Peterson et al.,²⁸ Munster et al.,²⁴ and Elledge et al.²⁰ have reported affected patients with total body surface burns of 8%, 14%, and 12% respectively. In addition, with the now extensive experience with salvage of patients with 80% or greater burns, it is clear that heterotopic bone occurs no more frequently among these patients at the other end of the percentage spectrum than in the general burn population. It cannot be said, thus, that the percentage of burn is a determining factor.

Location of burn

A high percentage, but by no means all, of the reported heterotopic bone has occurred in joints with overlying deep burn. In their initial report, Evans and Smith described heterotopic bone occurring a distance from any third-degree burn involvement.²⁹ Johnston, in his early report, noted that in one of his three patients, the skin overlying one affected joint was not even superficially burned.³⁰ If it be assumed that degradation of connective tissue milieu in burns is a total body phenomenon, it follows that heterotopic bone formation need not be burn-site dependent. Thus, the location of the burn cannot alone be a determining factor.

Period of confinement

Evans and Smith expressed the belief that length of bed confinement was perhaps the most important factor in the development of heterotopic bone.²⁹ At the time of that report, patients with even moderate burns might be kept in bed for several weeks. The consequences of prolonged confinement were loss of active range of joint motion and bone demineralization; it was thought that each of these adverse changes might contribute to the formation of heterotopic bone. Thus, any maloccurrence which necessitated longer confinement could be a factor in the pathogenesis. Kolar implicated wound sepsis as such an independent factor along with the length of confinement.²⁵ Other investigators have not addressed the period of confinement as specifically as Kolar, and there have been no studies of comparative groups of confined and non-confined patients. Thus, it may never be determined whether or not current aggressive practice of early mobilization of patients will have an effect on the incidence of heterotopic bone.

Osteoporosis

Only Schiele et al. have reported a relationship between heterotopic bone formation and osteoporosis.¹ We have noted previously that among their group of 70 adults with burns confined to the upper extremities, 11 of the 16 who developed heterotopic bone had radiographically identifiable osteoporosis. In their series of patients, there were 24 who had osteoporosis. Thus, fewer than one-half of these developed heterotopic bone and there were two in the group that developed heterotopic bone who did not have osteoporosis. If the findings in that study are not altogether persuasive, the matter is further confused by the knowledge that the survivors of extensive total body surface burns who may develop profound

osteoporosis seem to have no greater liability to the formation of heterotopic bone than the general burn population.

Superimposed trauma

In one of the patients reported by Evans and Smith, the elbow of the more often used and minimally burned right upper extremity developed heterotopic bone, whereas the elbow of the less used but more seriously burned left upper extremity did not.²⁹ In the same patient, the right hip spontaneously dislocated. After reduction, that hip developed extensive heterotopic bone in the planes of the rectus femoris and iliopsoas, the muscles stressed by the posterior displacement. The opposite hip developed only a small spicule of heterotopic bone anteriorly at the joint line. Experience with this one patient reinforced the authors' belief that there occurred with burns a general compromise of connective tissue which rendered it particularly susceptible to superimposed trauma and that it was this liability to injury which accounted for the appearance of heterotopic bone at sites of repeated stretching of soft tissue, as at the minimally burned elbow or at sites of recognized abrupt excessive stretching as at the dislocated hip. According to all reports, the elbow is the most common site of heterotopic bone formation in adults and children.^{20,21,25,31-38} Perhaps it is the regular use of this joint which accounts for that orientation. Jackson has pointed out that the elbows are subjected to pressure posteriorly and medially when they are used for leverage or are simply in contact with the bed.²³ He suggests with this observation that external pressure is a factor in the orientation of heterotopic bone to the elbow. There may be other factors as well that favor the elbow. Commonly, the elbow is splinted in extension to prevent flexion contracture. If flexion range is lost, passive stretch and encouragement of active flexion are part of the rehabilitation effort. The posterior structures most affected by this effort are those attached to the olecranon. Thus, it is not surprising that heterotopic bone develops medially in line with and deep to the medial fibers of the triceps. If a flexion contracture develops, the heterotopic bone is commonly in the line of brachialis or biceps attachments to coronoid process and biceps tubercle. And if there is loss of pronation and supination range, stretching may cause heterotopic bone to form in line with the proximal radioulnar ligaments and interosseous membrane. There is an implication here that both the quality and timing of postburn exercise may be important. Gentle passive and active motion should cause less tissue disruption than abrupt passive or active or even chronically repeated motion, and the effect of any mobilization effort must vary with the relative stiffness of the joint and the intrinsic resistance of soft tissue. Thus, the longer a joint is limited in its motion, the stiffer it will become and the greater will be the soft tissue damage with any forced manipulation.

The concept of superimposed trauma as a cause of heterotopic bone is supported by the experimental work of Evans³⁹ and of Michelson and Rauschnig.⁴⁰ Evans found that all burned and non-burned rabbits given a single necrotizing injection of alcohol in one quadriceps muscle readily healed the lesions, whereas rabbits, burned or non-burned, which were given a second same-site injection 7 days after the first, uniformly developed well-defined and histologically identifiable ossicles of heterotopic bone. In this experiment, it was

clear that, in susceptible animals, it was not the burn which made the difference, but the chronicity of the wound. Michelson and Rauschnig determined that forceful or regular active remobilization of rabbit knees, which had been immobilized for 1–5 weeks, resulted in the development of heterotopic calcification and ossification in the muscles which were stretched. The response was more consistent in the quadriceps of the knees immobilized in extension than in the hamstrings of those immobilized in flexion. The longer the period of immobilization and the more vigorous the remobilization, the greater the response. Muscle necrosis was a prominent histological finding.

Superimposed trauma is implicated in the development of heterotopic bone in head-injured patients or those with post-traumatic or infectious transverse myelitis.⁴¹⁻⁴³ In these patients, it is assumed that tissue media are altered by injury to the central nervous system. The secondary injury, as in burns, is periarticular. In post-traumatic myositis ossificans, the development of heterotopic bone depends upon persistence of the muscle lesion and local necrosis and, thus, at least by inference, upon repeated insults to the affected muscle.

The development of heterotopic bone in burns has been associated with the agitation of patients and their resistance to physical therapy.^{29,44} Two affected adults and one affected child in a 10-year study resisted physical therapy programming.³⁹ One adult refused to move and the other was extremely apprehensive. The child was likewise apprehensive and refused to cooperate with the therapist. The development in all three of posterior heterotopic bone in both elbows could have been ascribed both to the difficulty encountered in mobilizing the elbows and to the continual pressure on the elbows in bed.

Genetic predisposition

It is difficult to explain the low incidence of heterotopic bone among great numbers of patients similarly burned except on the basis of some, as yet unidentified, inherited factor. It is known that persons with proliferative non-inflammatory arthritis of the hip are more likely to develop heterotopic bone after total hip replacement than persons who have hips replaced for other reasons. In this instance, the predisposing inherited abnormality is identifiable. Though heterotopic bone formation may occur more regularly among spinal cord-injured and head-injured patients than among burned ones, by no means do all persons with head and spinal cord injuries develop heterotopic bone. The total burn experience at the University of Texas Medical Branch has yielded only two similarly affected siblings. Twin brothers who had 19% and 20% total body surface burns and who were mobile throughout much of their treatment and recovery period developed near identical heterotopic bone of both elbows.⁴⁵ There is, however, no scientific proof that genetic predisposition has anything to do with the formation of heterotopic bone in burns. Nor is there any literature to support the idea that a person who develops heterotopic bone when burned will be liable to develop it if he or she sustains head or spinal cord injury. Vrbicky,⁴⁶ in a comprehensive review of postburn heterotopic bone formation, suggests that a key for the genetic predisposition may be in the human leukocyte antigen (HLA), reporting that a HLA B27 survey showed a 7% HLA distribution in the normal population compared with 70% in a population with heterotopic bone.

Characteristics and behavior

Heterotopic bone associated with burns has been reported to occur about all major joints. The joints most commonly affected are elbow, shoulder, and hip, in that order of frequency. The early manifestations are joint swelling and tenderness not unlike any acute inflammatory process. The patient may call attention to the process by a reluctance to move the affected joint. Onset may be as early as 1 month and as late as 3 months or more after the burn, but it is more likely to be associated with the acute recovery phase of treatment than later. Crawford et al. reported that the clinical diagnosis was made in advance of radiographic changes in 9 of his 12 patients.³¹ Teperman et al.²² and Peterson et al.²¹ found that bone scans could help to make a diagnosis before there were radiographic changes. The earliest radiographic alteration is local periarticular increase in soft tissue density. There follows diffuse stippled calcification in the same distribution in or about the capsule of the joint. It is at this point that the process may reverse itself, perhaps due to the improved state of the patient. Because of this change in course, there may be many patients whose periarticular calcification is never detected. If the calcification persists, it may be assumed that bone will develop by either the intramembranous or the enchondral route or both as it does in animal models.

The flecks of calcification appear radiographically to lie within the capsule, whereas heterotopic bone may involve not only capsular structures but may extend as well into the planes of muscles and tendons. At each major joint there is a more or less characteristic distribution of heterotopic bone which is similar to that associated with patients with head and spinal cord injury. At the elbow, posteriorly, disposed bone extends from the olecranon to the medial epicondylar ridge of the humerus in line with the medial border of the triceps muscle (Figure 50.5a,b). At the joint, it may extend medially to bridge the ulnar groove.^{16,47} The medial, rather than lateral, orientation of the heterotopic bone may be related to the medial position of the olecranon and the greater tension on soft tissue on that side. As Jackson points out, the contact area of the elbow is medial, and continual pressure in this area may have something to do with the orientation.²³ Heterotopic bone on the anterior surface of the elbow develops in the planes of the brachialis and biceps muscles extending from humerus to coracoid process or biceps tubercle. Occasionally, a bridge of heterotopic bone develops between the radius and ulna just distal to the joint. More rarely, bone has been found to fill the olecranon fossa and even to ensheath the entire joint. At the shoulder, bone has been found to extend from the acromion to the humerus in the line of the rotator muscles or deep to the deltoid (Figure 50.5c), to lie anteriorly in the plane of the pectoralis major, and, more deeply, to parallel the subscapularis. Hoffer et al.⁴⁸ reported that heterotopic bone at the shoulder lay anteriorly in the plane of the capsule. At the hip heterotopic bone may extend from pelvis to femur in the planes of rectus or iliopsoas anteriorly or in the plane of the gluteal muscles laterally. Jackson has reported heterotopic bone in the plane of the quadratus femoris.²³ Like the shoulder, the hip may be ensheathed anteriorly with heterotopic bone which appears to originate in the capsule.

When heterotopic bone bridges a joint, it becomes part of the skeleton and may, if loaded, increase in dimension as fully

developed ossicles with mature cortex and medullary cavity. If the bone does not bridge a joint, it will, in children, gradually disappear when the burn wound has healed and the child is healthy. In recovering adults, non-bridging bone will, in time, diminish in size, but it may never completely disappear. The same tendency for heterotopic bone to regress after resolution of disease was noted by Lorber, who reported on two patients with paraplegia secondary to tuberculosis in whom deposits of heterotopic bone diminished in size, after return of motor function.⁴¹ Bottu and Van Noyen⁴⁹ reported a similar experience with a patient who had transient viral meningoencephalitis, and Jacobs reported almost complete resorption of large bilateral deposits of heterotopic bone in a patient who recovered from paralytic measles encephalomyelitis.⁴²

Serum levels of calcium, phosphorus, and alkaline phosphatase have been reported by most authors to be normal or, at best, insignificantly higher in burned patients who have developed heterotopic bone.^{18,24,29,50,51} In addition, there is no convincing evidence that calcium intake affects heterotopic bone formation one way or the other. Evans and Smith's limited routine studies of affected and unaffected patients led the authors to believe that the values of serum calcium, phosphorus, and alkaline phosphatase were so consistently normal as to make further investigation unnecessary.²⁹ One interesting observation was that of Koepke, whose early, but incomplete, studies suggested that those patients who were susceptible had elevation of serum alkaline phosphatase before development of heterotopic bone, but not afterwards.¹⁹

Prevention and treatment

The incidence of heterotopic bone in burns is so low as to make it impractical to administer aspirin or indometacin or other non-steroidal anti-inflammatory drugs which are currently used for patients at risk for development of heterotopic bone after major hip surgery. Rather, the thrust in prevention should be toward reducing the period of bed confinement and the duration of the postburn hypermetabolic state. The now prevailing practice of early wound excision and grafting may, in fact, address both of these problems as nearly as it is possible to do so. Even patients with extensive total body surface burns may be out of bed and walking within the first postburn week. Extremity motion is begun as soon as graft and wound stability permit. With this programming, the incidence and intensity of osteoporosis should be reduced as well.

If certain patients are predisposed to the development of heterotopic bone, then the quality and timing of joint mobilization for those patients may be critical. Stretching edematous pericapsular structures in the early postburn period may very well be hazardous if additional tissue damage is the result; however, maintenance of joint motion and muscle function is part of the early excision and grafting program, and it is certain that the longer joint motion is restricted the more likely it is that pericapsular structures will be damaged by stretching. We should like to think that any secondary injury to soft tissue could be avoided by controlled and assisted active motion, gentle terminal stretch, and terminal resistance.

When a patient is reluctant to move a joint previously moved with relative ease, and certainly when there is evidence of unusual swelling about the joint, radiographs should be obtained to determine if there is pericapsular calcification or

Fig. 50.5 (a) Three months after 94% TBSA burn of a 16-year-old male, resistance to motion, local swelling, and pain of both elbows prompted obtaining roentgenograms, each of which showed spotty linear soft-tissue calcification and ossification along the distal humerus and between the radius and ulna at the level of the biceps tubercle. (b) Six months after burn, elbow flexion and extension were reduced to 10° on the left and to less than 5° on the right. Bridges of immature heterotopic bone extended from the medial epicondylar ridges to the olecranon. Forearm rotation was 0° due to interosseous bridges of heterotopic bone at the level of the bicipital tuberosities. Prognosis for restoring functional range of motion in the elbows is poor. (c) At 6 months postburn, glenohumeral motion on the right was limited to a few degrees by heterotopic bone underlying the deltoid. At the same time, a lesser deposit of heterotopic at the left hip did not limit motion.

ossification. Once heterotopic bone or calcification is recognized, joint exercise should be restricted to gentle passive and assisted active motion only. Crawford et al.³¹ observed that ossification progressed to complete ankylosis in all patients who persisted in moving an affected joint beyond the pain-free range. They concluded that active range of motion exercises and stretching were contraindicated if heterotopic bone or calcification was suspected, but that active range of motion could be safely resumed within pain-free range once the diagnosis had been confirmed. In the series of Peterson et al.,²¹ patients suspected of having heterotopic bone had active range of motion exercises only. Ten regained functional range of motion and eight developed ankylosis.

Surgical excision of heterotopic bone is indicated when joint motion is lost or significantly compromised by bridging bone or exostoses. Evans has suggested that surgery be postponed until the burn wound has healed, scars are soft and associated with no inflammatory response, the patient is healthy, and the offensive bone is radiographically mature, i.e. well defined and not increasing in dimension¹³ (Figure 50.6). This position makes sense considering the behavior of heterotopic bone: i.e. proliferation while there are open burn wounds or active scars and regression with wound healing and scar softening. For removal of heterotopic bone, surgical exposures should be planned with extensible incisions so as to facilitate total excision. When there is a bridge of bone, each end of the bridge should be slightly excavated. When there is attachment at only one end, the cartilaginous or fibrous extension should be removed along with the bone. Capsular sheets of bone should be removed completely. If bridging heterotopic bone is incompletely excised, the bridge is likely to recur. When a joint is

bridged by bone in only one plane, removal of the offending bone will usually restore functional motion and the likelihood of recurrence of the bridge is small. When a joint is bridged in more than one plane, recurrence is more likely and the chance for restoration of functional range of motion is correspondingly diminished. When the local inflammatory process has caused intra-articular synovial proliferation and cartilage destruction, the joint is most likely destined for ankylosis. Removal of the heterotopic bone about a joint so affected may allow more functional positioning of the joint, but it is not likely to arrest the process. On the other hand, extra-articular arthrodesis by a bridge of heterotopic bone may preserve the joint. This is particularly the case at the elbow when there is only one posterior bridge of bone from olecranon to medial epicondylar ridge of the humerus. In this situation, the olecranon is fixed in the trochlea, but the radiocapitellar and radioulnar joints remain functional. In Evans' experience with removal of single bridges at the elbow, joint cartilage was found to be healthy as long as 5 years after ankylosis. Preservation of pronation and supination was credited with maintaining the synovial bath to provide nutrition for the humeroulnar cartilage. Indeed, when pronation and supination additionally are blocked by bridging bone, cartilage degeneration is certain. Evans' further experience with long-term survival of glenohumeral cartilage after ankylosis by bridging bone from acromion to humerus is not as easily explained.

Reported experience with excision of heterotopic bone in burns has not been uniformly favorable. Dias,⁵¹ Hoffer et al.,⁴⁸ and Peterson et al.²¹ reported restoration of functional range of motion in most of their patients with timely excision of heterotopic bone. Gaur et al.³² reported good functional return

Fig. 50.6 (a) A mature sheet of heterotopic bone extends from humerus to olecranon, obliterating the olecranon fossa 11 months after 53% TBSA burn in a 13-year-old female. Elbow flexion and extension range was less than 10%. Pronation and supination were near normal range. (b), (c) Three months after excision of heterotopic bone, the patient had attained 90° of elbow motion and a continuing increase to functional (hand to mouth) range was predicted. Now the patient can extend the elbow and can flex it to 90°.

in 7 burned children with 9 affected elbows. Ring and Jupiter³³ reported good results in a varied population, and Chung et al.³⁴ reported good results with early excision a mean of 9 months after the burn. Other surgeons have reported less satisfactory results. In our own experience, results have varied, as anticipated, with severity of affliction. We have learned that if heterotopic bone recurs after excision, it is worthwhile to excise again if the joint affected remains structurally identifiable. For the most part, however, attempts to improve joint function with second operations have failed. We believe that ultimate failure can be predicted at the time of initial surgery; we are convinced that the single most important factor in successful initial excision is in timing surgery to coincide with the patient's return to good health.

Changes involving the joint

Dislocation

Luxations and subluxations of joints in burned patients may occur as a result of direct destruction by the burn of ligaments and capsules, loss of articular cartilage due to infection, faulty positioning, and eventually scar contracture. In all phases of management, but particularly in the acute phase, positioning is of prime importance in the prevention of joint deformity. The preferred positions, listed in Table 50.1, serve as a guide for the prevention of dislocation of joints and of malposition secondary to scar contracture.

The joints most liable to structural compromise due to exposure by the burn and loss of soft tissue support are knee, elbow, proximal interphalangeal joints of the hand, and metacarpophalangeal joints. These hinge joints have in common a subcutaneous dorsal surface, accounting for their ready exposure.

TABLE 50.1 PREFERRED POSITIONS FOR MAJOR JOINTS

Joint	Preferred position
Neck	Midline in neutral or slight extension
Shoulders	Scapulothoracic retraction and depression 85° of glenohumeral elevation with 20–25° of horizontal flexion
Elbows	Extension
Wrists	Slight extension
Metacarpophalangeal joints 2–5	80–90° of flexion
Fingers	Proximal and distal interphalangeal extension
Thumbs	Carpometacarpal flexion and abduction, metacarpophalangeal flexion 5–10°, interphalangeal extension
Spine	Extension with no lateral deviation
Hips	Extension and slight external rotation in 15° of symmetric abduction
Knees	Extension
Ankles	Neutral
Feet	Neutral

The elbow, for its trochlear architecture, is more intrinsically stable than the other joints in this group. It requires loss of collateral support to render it easily displaceable. The knee, on the other hand, is immediately in danger of subluxation if there is loss of continuity of its central slip, the patellar tendon, even if the retinacula remain intact. In this circumstance, gravity alone will displace the tibia posteriorly in relation to the femur if the patient is recumbent. The hamstring muscles contribute to the displacement force regardless of the position of the extremity. Loss of collateral ligaments compounds the problem, but loss of collateral ligament stability in the presence of an intact patellar tendon and functioning quadriceps constitutes far less a threat than loss of patellar tendon. For the lower extremity, persistent posterior translation of the tibia beneath the femur with inefficient quadriceps pull is potentially a functional disaster.

For both the elbow and the knee the protecting position is extension. These two joints are rarely at risk for articular displacement from contracture alone and, if there is no ligament or tendon loss, extension resting splints will give adequate positional support. When there is soft tissue disruption, splinting may not adequately protect either joint. An external fixator with two pin, four cortex fixation above and below the joint will provide stability and will permit access to the wound. For the elbow, it allows fine adjustment to the normal carrying angle as well. If the knee is accurately reducible at the time of application of the fixator, there is a good possibility that the reduction can be maintained. If the tibia cannot be brought forward completely by manual manipulation, it may be necessary to suspend the tibia through a transverse pin at the level of the tibial tubercle. For static vertical traction, the extremity must be elevated from the bed. For dynamic traction, enough weight must be used to accomplish the same elevation. If the tibia can be brought forward by this means, an external fixator will likely hold the reduction. For the knee to remain stable with the tibia forward, the patellar tendon must be reattached and quadriceps integrity reestablished; otherwise, when the fixator is removed, the tibia will once again begin an incremental posterior shift toward its own point of stability. No amount of external splinting or bracing is likely to prevent that shift.

The proximal interphalangeal joints of the hands are more frequently exposed by burn than any others. If the central extensor slip remains intact, there is less risk of subluxation of the joint. Even if there is loss of continuity of the central slip but preservation of the lateral bands, subluxation is easily prevented if the joint is maintained in extension while soft tissue cover is being achieved. It is with loss of the support of lateral bands and collateral ligaments that the joints become liable to dislocation. With the metacarpophalangeal joints, the tendency to displacement or subluxation may be greater because these joints are functionally multiplanar, while the interphalangeal joints are uniplanar. Happily, the metacarpophalangeal joints are less often exposed than the interphalangeal ones.

The protecting position for the proximal interphalangeal joints is full extension. If only the central slip is lost, the position may be held with an external splint. In states of greater instability it may be necessary to use intramedullary transarticular Kirschner wires to hold the position. The wires, though

reasonably efficient, do not control rotation, and they carry with them a risk of post-treatment joint stiffness. In small children it is impossible to introduce the Kirschner wires through the distal phalanx; thus, it is better, with the distal phalanx flexed to 90 degrees, to place the wire through the corresponding metacarpal head into the proximal and middle phalanges. The short-term transfixation of the joint does not harm the joint, and metacarpal phalangeal flexion is the favored position for functional restoration. Pin traction through the distal phalanges in a skeletally stabilized metal splint is another method for maintaining extension of threatened digital joints.^{52,53} It has the advantages of patient comfort and mobility, secure positioning of hand and upper extremity, easy maintenance of elevation, and easy access for dressings, for additional surgery, and for exercise of lesser affected joints. The system likewise makes it possible to keep digits separated, thus facilitating local care. Traction should not be used if collateral ligaments are not intact. By whatever means attained, the corrected position must be maintained until the joint is covered with graft. Protection should continue with a standard splint or brace until the joint is sound.

The two joints most likely to dislocate because of faulty positioning are the shoulder and the hip. These two ball and socket multiplaner joints sacrifice stability in favor of mobility. This is particularly true of the shoulder, where the shallow glenoid contains at any one time only one-third of the head of the humerus. In burns, the head of the humerus may begin to subluxate forward if, during prone positioning for management of back and buttock wounds, the arms are maintained in full abduction in the coronal plane. In this position the arms are in at least 15–20 degrees of extension from the more secure neutral position in line with the scapulae and the humeral heads are forced forward against the anterior capsule. Even when the patient is supine, full abduction and extension of the arms should be avoided. For short-term management, particularly when the patient gets out of bed every day, this position probably does not threaten the joint. But if the patient is to be bed confined and the position unrelieved for days or weeks, the head of the humerus may begin to subluxate forward. In the extreme situation, the head of the humerus will dislocate to a medial subcoracoid position. In patients with deep burns extending from chin to axillae to chest, the common posture of elevation and protraction of the scapulae may be associated with upward subluxation of the humeral heads. With one patient in whom the right clavicle was sacrificed distally because of the depth of the burn, the head of the right humerus moved forward and then upward because of loss of anterior stabilizers.

The head of the humerus is most secure in the glenoid fossa when the arm is adducted to neutral and internally rotated, a position which is incompatible with wound management of burns of the trunk, neck, and upper extremities. The protecting position which accommodates the need for abduction for axillary burns is elevation of the arms in line with the scapulae. The arm is then approximately 20 degrees forward of the coronal plane or in 20 degrees of horizontal flexion. When the patient is prone, the protecting position can be gained only if the chest is supported on a chest width mattress, folded blankets or towels, or a foam rubber pad, any of which will allow the arms to drop forward. When the patient is positioned this

way, whether supine or prone, the forearms will be pronated and the arms will be in sufficient internal rotation to favor seating of the head of the humerus in the glenoid.

The hip will tend to subluxate posteriorly if the thigh is persistently allowed to remain flexed, adducted and internally rotated during the acute burn phase. For the most part, however, the protecting position of extension to neutral or 180 degrees and 15–20 degrees of symmetric abduction is easy to attain and maintain and is, in fact, the most desirable position for wound management.

If dislocation of the head of humerus or femur is undetected or if reduction is delayed for other reasons, open reduction will likely be required. Reduction of a chronically displaced head of humerus in one seriously burned patient using the Ilizarov technique was hampered by the fragility of the bone. Another head of humerus that had been dislocated anteriorly for several weeks was found at the time of open reduction to have extensive erosion of the articular cartilage.

Infection of a joint may result in its subluxation or dislocation. Hip displacement because of apparent spontaneous dissolution has been described by Evans and Smith.²⁹ Eszter and Istvan⁵⁴ and Cristallo and Dell'Orto⁵⁵ reported similar cases. In none of these cases, however, could it be determined that the joint destruction was due to infection.

Septic arthritis

A joint exposed by a burn or by removal of burn eschar is presumed to be infected. The joints most frequently exposed are the knee, the elbow, the proximal interphalangeal joints of the hand, and the metacarpophalangeal joints, all on the subcutaneous dorsal surfaces. Wrist and ankle are less often affected and other joints rarely. Treatment requires stable positioning of the joint for maximum reduction of wound size so as to facilitate soft tissue closure or grafting and to allow aggressive daily lavage. The position for all of the joints listed except the ankle is extension. The ankle is positioned in neutral. External fixation, intramedullary pinning, or skeletal traction may be required to secure the position. To maintain ankle position it is sometimes appropriate to insert a large vertical Steinmann pin through calcaneus and talus into the tibia. The position should be maintained until the exposed joint is covered with epithelialized granulation tissue or skin graft. Exposed adjacent bone can be shaved or drilled, as previously described, to encourage surface granulation. Drilling is particularly useful at the elbow where the olecranon is regularly exposed. Often, however, granulation tissue will quickly extend the wound margins and effectively close the wound so as to allow split-thickness skin grafting. If the burn is isolated to the joint or if the extremity is not otherwise seriously burned, a local muscle, skin or compound flap may be used to close the joint. Free vascularized flaps are useful and should always be considered if it is anticipated that nerve graft or tendon graft or transfer at the site will be required in the future. Incremental remobilization of the joint may proceed when wound closure is sound. Culture of material from an exposed joint will likely yield a variety of organisms consistent with those of the general burn wound, thus requiring broad-spectrum antibiotic management.

The incidence of hematogenous septic arthritis is obscured by its frequent association with severe burns and because

there are rarely separable clinical signs such as local heat and swelling, elevation of temperature, and elevation of sedimentation rate. Local tenderness and greater than usual pain with motion may focus attention on the affected joint. Aspiration of the joint will confirm a diagnosis. A radiograph is helpful, but in the early phases of infection will show only local cellulitis as increased periarticular soft tissue density. If a patient has been receiving broad-spectrum antibiotics, material aspirated from the affected joint may not grow an organism in culture. Clearly, without organism identification and sensitivity determinations, specific antibiotic therapy cannot be initiated.

We have been of the opinion that debridement and exteriorization of the joint and regular vigorous lavage are as important as antibiotics in the treatment of closed infected joints. We believe now that arthroscopic debridement and closed irrigation should be considered as an alternative method of management whether or not skin over the affected joint is burned. Rarely in burns, a joint may become infected from adjacent metaphyseal osteomyelitis. In this situation joint preservation is the treatment priority, and measures are the same as for septic arthritis of strictly hematogenous origin.⁴⁵ In children most infected joints can be salvaged. Adult joints are less resilient. Persistent joint infection will destroy cartilage and lead to ankylosis.^{28,56} All chronically infected joints are liable to dislocation because of surface destruction and capsular laxity.

Amputations

In burns, major amputations are most often performed because of non-viability of the extremity or because a surviving extremity is rendered useless by scar, deformity or insensitivity. Occasionally, in an extensive burn, a severely burned extremity which might be salvaged in part is sacrificed to reduce the extent of the burn or as a lifesaving measure.

In thermal burns, the level of extremity amputation is determined by the viability of muscles and tendons. The more distal the site the better, and it is important to retain joints even if motion will be restricted. For example, if a forearm or leg must be sacrificed, the elbow or knee should be spared if the more proximal muscles controlling that joint are intact, if the bone bleeds, and if there is the possibility that the remaining tissue of the stump has sufficient blood supply to produce granulations for grafting. Aside from affording a better functional prospect, sparing the joint will provide the surgeon opportunity at a later time to choose an appropriate revision level if the joint does not function. The patient will at that time be healthier and stump closure will be routine. Jackson suggests that it may be technically feasible to cover even non-viable bone with a free flap in order to maintain extremity length.²³

Prostheses can be easily fitted over stumps covered with split-thickness grafts. Ridges of hypertrophic scar will break down if there is friction within the socket of the prosthesis. A scar often softens and flattens because of the constant even pressure of a well-fitted socket; prostheses fitted early over grafted stumps may prevent scar thickening. Breakdown may occur at points where the graft is adherent to bone. This problem may necessitate surgical freeing of the adherent graft and reshaping of the bone. Minor hip and knee flexion con-

tractures complicate the fitting and function of a prosthesis; thus, every effort should be made to maintain full extension of these joints. Late revisions of amputations in children are required when the bone overgrows in length and when offensive terminal exostoses develop. The overgrowing bone can be shortened and the exostoses removed.

It is important, in the early management of upper extremity amputations in infants and young children, to supply temporary prosthetic extensions. This provides functional orientation to a prosthesis, maintains muscle bulk and tone, and encourages continuing bimanual activity at normal extremity length until a prosthesis with appropriate terminal device can be applied. Children quickly acquire prehension and transfer skills if they have an opposable stump and they may reject prostheses if they are not applied early. It is equally important to restore bipedal function as soon as possible. If delay of healing or ulceration of a lower extremity stump prevents early prosthetic fitting, an ischial weight-bearing device which suspends the stump will permit the child to walk in advance of prosthetic fitting. Inflatable plastic air bags provide both even pressure and accurate fit for weight bearing in container sockets. Early prosthetic fitting is desirable in teenagers and adults as well, but is not as critical as it is in children. As in non-burned persons, an upper extremity prosthesis may be rejected at any age if the opposite extremity is fully functional.⁵⁷

Alterations in growth

In 1959, Evans and Smith²⁹ reported that a patient who was 24 years of age when burned had a subsequent 1½ inch increase in height. It was suggested that one explanation for this growth spurt might be local change in hemodynamics with stasis, passive hyperemia, and chronic inflammation. We have not since documented height changes in burned adults, but we have observed children whose growth after burn has seemed to be retarded. If growth plates remain open, it is difficult to explain overall growth retardation except on an endocrine or humoral basis. It is easy, however, to explain extremity length differences on the basis of premature closure of growth plates due to direct involvement of the bone or to severity of overlying burn. Frantz reported lower limb length discrepancy in four patients with foot and ankle burns.⁵⁸ Growth plates closed prematurely in only two of the cases. Jackson described two patients with digital and lower extremity deformity, respectively, due to partial closure of growth plates.²³ In Ritsila's case, contracture alone was apparently the cause of growth retardation in an upper extremity.⁵⁹ It seems reasonable, though hard to prove, that growth in a severely burned extremity would be retarded because of functional impairment. One patient, a 3-year-old boy with 80% total body surface burn and sufficiently deep burns of the right upper extremity to require mid-humerus amputation, demonstrated, 4 years after the burn, failure of development of the right shoulder girdle. The factors operant in this case could be premature closure of growth plates of scapula and clavicle, restrictive scar, and disuse atrophy.

There is yet another confusing aspect of premature closure of growth plates in that within an extremity with total full-thickness burn, only a few of the growth plates will close

prematurely. The explanation for this capricious selectivity is at best obscure. Evans and Calhoun recorded an example of spotty closure of growth plates in a 14-year-old male with 90% total body surface burn.¹² There was complete closure of distal tibial and fibular epiphyses 1 year after burn together with closure of all digital epiphyses in the feet and of several digital epiphyses in the hands. Other major epiphyses were spared (Figure 50.2).

In early experience, abnormal growth plate closure was observed in a 6-year-old girl with 50% third-degree burn which did not involve legs or ankles.⁶⁰ Rapidly destructive septic arthritis of one ankle resulted in closure of the adjacent tibial growth plate.

Only occasionally can growth changes be anticipated because of obvious affection of the bone. More often the changes are subtle. It seems clear, thus, that among seriously burned children, regular height and extremity length measure-

ments must be part of ongoing postburn assessment until it is determined that the extremities and trunk are developing symmetrically and on schedule. Extremity and trunk alignment must likewise be part of the assessment as subtle angular deformity can occur because of partial closure of a growth plate. Jackson's report addresses this problem.²³

So-called growth arrest lines seen in the radiographs of non-burned children, who have serious illness or major trauma other than burns, are commonly observed in burned children. In burns, as in other conditions, these transverse markers of relatively increased mineralization represent normal recovery from an insult to enchondral bone formation due to serious stress. They are of no clinical or functional significance. They are more related to total burn than to involvement of select burned extremities as all major long bones are affected. There is no evidence that growth arrest lines *per se* have any effect on growth.

Chapter contents

Background	667
Growth delay	667
Catabolism	669
Long-term outcomes of children with massive burns	670

Background

Management of burns in children remains a major challenge to medical science, not only in terms of mortality, but in discovering ways to improve their recoveries. The ultimate goal is for young burn survivors to grow into active, self-supporting, happy adults, thereby achieving an optimal quality of life. Though advances in burn care have reduced the high mortality associated with massive burns in children, burn team scientists and clinicians have barely begun to gain knowledge into what the long-term quality of life for these survivors can be.¹⁻⁴ Rehabilitative challenges with such children are numerous, and the best methods of achieving good outcomes for children with severe burns are still being developed.⁵

Treatment of pediatric burns is similar in many ways to that of adults. However, pediatric injuries present unique challenges, both at the time of acute treatment and throughout rehabilitation. Increased experience and new data, gathered in large part from courageous young survivors, have allowed burn team clinicians and scientists to identify many long-term problems associated with large burns. A major problem during convalescence is the prolonged hypermetabolic and catabolic response.

This hypermetabolic response appears to play an early and central role in many of the long-lasting difficulties for children with severe burns. In response to a severe burn, afferent stimuli are activated causing a hypothalamic thermoregulatory re-setting to occur. This results in increased heat production, a faster heart rate and a greater cardiac output, in addition to an exaggerated increase in resting energy expenditure.⁶ The stress response to a severe burn is characterized by a cascade of hormones such as catecholamines, cortisol and glucagon that results in a hypercatabolic state.⁷ The effects of this hypermetabolic, hypercatabolic state are rapid muscle breakdown⁸ and reduced bone formation, resulting in severe osteopenia or osteoporosis⁹ as well as linear growth retardation.¹⁰⁻¹²

One can think of this physical state as the body running at almost twice its normal rate even though the individual is at rest. The patient requires enormous amounts of nutritional intake to keep up with the energy expenditure. Even with adequate caloric intake, individuals in this state lose muscle mass and bone density. Conventional thinking has been that this state should dissipate with full healing of the burn wound. However, in clinical work, we observed that the children fail to develop muscle, to grow, and to gain weight for a period of time extending far beyond wound healing.

Only a few years ago were we able to follow systematically 25 severely burned children for 1 year to ascertain the duration of the hypermetabolic–catabolic state.¹³ Stable isotope metabolic and body composition studies were performed during acute hospitalization, at initial hospital discharge, and at 6, 9, and 12 months postburn. The resting energy expenditure of these children peaked at 1-week post-injury with a metabolic rate of 180% of normal and progressively declined with time. At the 12-month exit from the study, their resting energy expenditure remained 15% above basal metabolic rate. Catabolism persisted for at least 9 months, which was 7 months after complete wound healing.

Knowledge of the duration and extensive harm resulting from the catabolic effects of trauma has also led to efforts to better delineate mechanisms of catabolism¹⁴ and to a vigilant pursuit of early interventions that could attenuate the effects of the hypermetabolic–catabolic response. Factors affecting the convalescence of severely burned children are shown in Figure 51.1. The effect of the hypermetabolic–catabolic response 6 months after burn is displayed in Figure 51.2. Such long-lasting deleterious effects upon the recovery of severely burned children demand that we develop strategies to attenuate the hypermetabolic–catabolic response during and after discharge from acute hospitalization. For most of the issues evolving from massive burn, we are still in the early stages of this process; we are still learning about problems and devising methods of improving treatments. Our progress in developing such strategies is the subject of this chapter.

Growth delay

In 1990, Rutan and Herndon demonstrated a dampened growth curve for both height and weight in male and female pediatric patients who had sustained major thermal injury.¹⁰ The growth velocities were delayed up to 3 years after burn injury. Even

Fig. 51.1 Various burn-induced problems that afflict many severely burned survivors (left side of balance). These problems can last up to 2 years. On the right side are strategies to attenuate these problems.

after the return to normal growth velocities, the burned patients lagged behind age- and sex-matched peers.

Normal linear growth and weight gain in children are dependent upon a number of factors. The prenatal environment, adequate nutritional intake, and an emotionally nurturing household environment are crucial. Long hospitalizations alone have been known to produce profound arrests in growth and development in children. The management of massively burned children includes multiple operations and prolonged hospitalization. In cases of fascial excision, subcutaneous fat layers in the injured area are also removed. Fat stores are further depleted in providing energy for the process of gluconeogenesis from existing protein stores for dietary supply. All the reasons for the growth delay following severe burns are not currently known. However, plasma growth hormone (GH) levels have been shown to decrease in severely burned adults,¹⁵ and it is likely that children experience a similar decrease. Administration of an anabolic agent such as recombinant

Fig. 51.2 The ravaging effects of a severe burn are illustrated in these photos (a, b, c). The body is in a hypermetabolic and catabolic state. This results in loss of muscle mass and bone mass, and is worsened by prolonged inactivity. In addition, there are physical limitations sometimes caused by the loss of digits or extremities and of burn scar contractures.

human growth hormone (rhGH) during the acute treatment of severely burned children has been demonstrated to be extremely beneficial in promoting healing and health.⁷ Studies of GH demonstrate that it can be given safely to severely burned children,¹⁶ and that it accelerates wound healing¹⁷ and reduces tissue wasting commonly seen in the catabolic patient.¹⁸ Using rhGH in the acute treatment of children with severe thermal injuries has been shown to improve net muscle protein synthesis¹⁸ as well as to accelerate wound healing and reduce length of hospital stay.^{17,19} Knowledge gained from such studies suggests improved treatment approaches that can be evaluated. Improvement in each of these areas could contribute to improved growth and weight gain; therefore, administration of GH was perceived as a probable advantageous tool in the management of pediatric burn patients toward normal growth.

Low et al.²⁰ tested the hypothesis that rhGH would ameliorate the growth delay by following, for 3 years, 49 children in a prospective, randomized, masked study. Twenty-six children received 0.2 mg/kg GH during their acute hospitalizations; 23 children received 0.9% saline as placebo during the same time periods of acute hospitalization. Children who were treated with GH during their acute care maintained stature (height for age percentile and height-velocity), whereas untreated children who were not in a growth spurt at the time of burn remained delayed in linear growth at the end of the study 3 years post-injury. Continuing with this study, Low et al. found that the differences in height percentiles had nearly resolved at 5 years postburn.²¹ Short-term (average of 6 weeks) administration of GH did not attenuate the hypermetabolic state; resting energy expenditures remained elevated for both groups of children during the time they were being treated acutely. However, the administration of GH apparently made up for a deficit that commonly occurs following severe burn injury. Children burned during a growth spurt are thought to have the advantage of higher levels of growth hormone available and thus can maintain normal growth without exogenous hormone.

Catabolism

As mentioned previously, the catabolic response decreases lean mass and muscle strength. Lean mass and strength are essential for normal daily activities. Several treatment options have been investigated at our institution.

Exercise

Resistance exercise has an established influence on muscle strengthening and muscle protein synthesis. The beneficial effects of resistance training have been well documented in healthy adults, adolescents, and older children.^{22–26} Ferrando et al. demonstrated in healthy adults that moderate resistance exercise is capable of ameliorating the decreases in skeletal muscle protein synthesis and strength that accompany inactivity.²⁷ The acute stimulatory effects of resistance exercise may last up to 48 hours.²⁸ In burns, resistance exercise alone is also capable of inducing increases in lean mass and muscle strength. Suman et al. demonstrated in severely burned children and adolescents that a 12-week exercise program of resistive and aerobic exercise significantly improved lean mass and muscle

strength relative to standard of care treatment (Figure 51.3).²⁹

Anabolic agents

Recently, Przkora et al. studied the effects of administering 0.05 mg per kg per day of GH from hospital discharge to 12 months after burn to children. The investigators showed that growth and bone mass as well as lean mass were significantly increased in patients receiving GH compared to the placebo group. Furthermore, not only lean mass but also muscle strength was significantly improved in the treatment group. The observed beneficial effects on body composition were associated with significant elevations in anabolic hormones such as insulin-like growth factor-1 (IGF-1). Additionally, serum cortisol, a catabolic hormone, was significantly lower with GH treatment when compared to placebo. The enrolled patients were followed for an additional year and the authors demonstrated a persisting effect on growth and on bone mass in the former GH group 1 year after the treatment was discontinued. No rebound phenomena on body composition or on

Fig. 51.3 (a, b) A structured and supervised program of resistance and aerobic exercises has been shown to be beneficial in attenuating loss of muscle mass and muscle function, as well as improving aerobic capacity in burned victims.

hormone metabolism were noted during the year following cessation of GH.

A difficulty confronted in this study is that GH is administered via daily injections. Although these injections are relatively painless (the investigators have first given them to themselves to be sure of this), they present a daily source of irritation and tension to parent and child. Therefore, we searched for a less-intrusive means to improve body composition. Oxandrolone is an anabolic steroid that has been used in catabolic situations such as hepatitis and AIDS patients and can be administered orally, thus eliminating one source of stress for children and families.³⁰ In a randomized trial Przkora et al. treated severely burned children with oxandrolone (0.1 mg/kg twice daily *per os*) or placebo from hospital discharge up to 12 months after trauma. They found a significant improvement in body composition, including linear growth, bone density, and lean mass. Muscle strength was also significantly improved with oxandrolone. As with long-term GH treatment, no adverse side effects were observed in the year following treatment. Beneficial effects on growth were noted even 1 year after treatment.³¹ Other anabolic agents are likely to have similar benefits. Herndon et al.³² have demonstrated that propranolol attenuates catabolism and hypermetabolism during the acute hospitalization of severely burned children. This finding suggests that long-term administration of propranolol may be beneficial in ways similar to those of growth hormone and oxandrolone and offers possible benefits for mitigating symptoms of post-traumatic stress disorder as well.³³

Exercise in combination with anabolic agents

Because of the positive results obtained with exercise intervention alone and with GH alone, we rationalized that an exercise program that included resistance exercise in combination with GH would provide for a synergistic effect on skeletal muscle protein synthesis by addressing separate stimulatory mechanisms for an extended period of time. Suman et al. studied 44 severely burned children and adolescents who received GH (0.05 mg per kg per day) or placebo for 9 months and either participated in a 12-week exercise program or received standard of care treatment (daily physical and occupational therapy).³⁴ In this study, the mean percent change in lean body mass after 12 weeks was similar for the groups of participants receiving GH alone, exercise alone, or the combination of both. On the other hand, the mean percent change in muscle strength was significantly greater only in the groups receiving exercise, independent of GH. Preliminary results using a higher dose of GH (0.1 mg per kg per day) also yielded similar results; lean mass increased by GH alone, exercise alone, or the combination. However, similar to low-dose GH, muscle strength was only increased via exercise. It is presently unknown what are the effects of higher doses of GH on muscle mass of severely burned children.

We have begun studying effects of oxandrolone in conjunction with the exercise program, and results of preliminary data analyses are very exciting in their promise of enhanced overall well-being for survivors of very large and severe burn injuries. Oxandrolone in combination with exercise increased lean mass significantly more than either the drug or exercise treatment alone. Muscle strength and functional improvement were significantly improved with the combination of oxandrolone

and exercise as well as with oxandrolone or exercise alone. A planned future study will introduce propranolol instead of GH or oxandrolone and follow the same design.

Exercise and young children: because of the difficulties with having young children (i.e. under 7 years of age) use the exercise equipment or cooperate in obtaining certain measures, the exercise studies described above were conducted with children ages 7–18. However, as exercise treatment has proven so beneficial, we have now begun a program using music and movement for young children. Movements are chosen to increase strength, flexibility, and endurance. Children enjoy this ‘play,’ and preliminary data indicate the program to be beneficial to overall development and specifically to maintaining or improving joint range of motion beyond standard of care (prescribed occupational–physical therapy exercises).^{35,36}

Long-term outcomes of children with massive burns

Contrary to what many people expect, long-term outcomes studies indicate that most children who survive severe burns do well. For the past 20 years, doctors at Shriners Burns Hospital in Galveston have followed, longitudinally, children who survived massive injuries, assessing physical and psychosocial adaptation on an annual basis with standardized measures when available. In 1986, assessments of 12 survivors of such massive injuries were reported.³⁷ Of the 12, eight (66%) were found to be well adjusted; four were described as regressed with excessive fear, neurotic symptoms, and somatic complaints. A later follow-up report of eight of the children found satisfactory adjustment in six (75%) and two who were not doing well.³⁸ Four years later, we reported the results of psychosocial assessments of 25 children with 80% total body surface area (TBSA) burned in which the burned children appeared, as a group, to have no more behavioral problems than their age-matched cohorts in a normative reference group.³⁹ The burned children also had positive self-esteem, equal to and sometimes surpassing, that of the non-burned reference group. Examining the impact of physical impairment upon the psychosocial competence of 19 survivors of massive burns, we found the competence scores of the burned children, as reported by both the parents of the children and the children themselves, to be equal to those of the normal, age-matched reference group.⁴⁰ Physical impairment was related to competence only in the area of activity, and not in academic or social competence. Perhaps most surprising to us was that two of the 19 children had ratings of ‘no physical impairment’ based upon range of motion measurements according to AMA guidelines. We concluded that severe childhood burn injury does not necessarily induce onerous physical impairment, and even severe impairment does not necessarily lead to poor psychosocial adjustment.

In a more recent examination of the psychological and behavioral adjustment of 74 of our survivors of massive injury (80% TBSA = 70% full-thickness), we found that 70% of the children and young adults had no significant difficulty; most were doing well and described themselves as being ‘happy’. Most were still in school. Three young adults had married or were living with a committed partner and had become parents.⁴¹

Of 41 who were also assessed for physical functioning, 32 patients were independent with completion of age-appropriate activities of daily living skills. Only the amputation of fingers seemed to impede the self-sufficiency of these individuals.⁴² Although some, like those with finger amputations, required adaptive devices and compensations such as extra time to achieve successful performance, most of these survivors of massive injury had managed the skills required to meet developmental milestones, to develop appropriate autonomy, and to achieve psychological and social well-being.

In a study conducted at our sister institution, the Shriners Hospital in Boston, 80 survivors of burns involving >70% TBSA were evaluated almost 15 years following their injuries.⁴³ The investigators used a quality of life assessment tool to measure achievement in several domains, including general health, psychological health, family function, physical function, and physical role. The scores of these young people were similar to those of the normal population with the exception of physical functioning and physical role. In these areas, the scores were more than 2 standard deviations below the age- and gender-matched norms, indicating that some had continuing serious physical disabilities. Thus, while some children surviving severe burns had, as young adults, lingering physical disabilities, most reported having accomplished a satisfying quality of life.

Another outcomes study of 100 young adults with severe burns treated at the Galveston Hospital also reports that on the standardized self-report measures⁴⁴ and on the assessment of physical impairment,^{45,46} young survivors appeared to be doing well; however, measures that prodded more intensely into their psychological/emotional lives revealed that many of them suffered from difficulties, most often anxieties that were at times debilitating.⁴⁷ It would seem that while burned children may harbor fear, anxiety, and sadness at a private level, at a public level, most of them, even those most severely burned, perform well. In terms of achievement in school, occupationally, and socially, most burn survivors are judged by outside observers to be doing well with only 20–30% having behavioral difficulties significant enough to warrant further clinical attention.^{39–46}

The children in these outcomes studies did not have the benefits of the strategies we now use to deal with the hypermetabolism and catabolism occurring in response to large burns, which makes their achievements even more remarkable. Psychosocial difficulties related to the hypermetabolic response are numerous; fatigue, stunted linear growth, diminished muscle mass and weakness, and bone fragility limit the child's ability to fully participate in many ordinary childhood activities for a prolonged period after returning home even though their wounds were closed. Not only did the children miss many physical benefits of such activities, but they also missed the social interactions and the feeling of 'belonging' that accompany participation. Thus children who already felt stigmatized because of their burn scars and disfigurement, felt increasingly isolated from their peers. For psychosocial reasons, we pushed children to return to school quickly upon return home; but that meant that children with severe burns were attending school during the months when they fatigued quickly and so were hampered in their ability to concentrate and learn. Thus, they were at risk for feeling (and being stig-

matized) as academically incompetent. If arrangements for shortened school days or special considerations were made to assist a child, the child often had to be classified as a 'special education' student — again stigmatizing and further isolating the child.

Decreasing the physical impact of hypermetabolism–catabolism also improves the opportunities for successful psychosocial adaptation following severe burn injury. The young survivors who participate in the 3-month, in-house exercise program also are able to receive regular psychological and psychiatric treatment by our burn team during that time. They and their parents receive regular individual psychotherapy for minimally 1 hour per week. During these sessions, many issues are addressed, e.g. bereavement for others lost in the fire, sadness at losing one's former self, pain, anger, social anxiety, preparing to return to their homes and communities. The children participate in age-matched groups for art therapy and for play activities. Similarly they receive schooling within the hospital school, again matched with other burned children of similar age and educational level for classroom participation. All of these experiences also allow the children to share with each other and to support each other in their difficult work of recovery and rehabilitation. Parents likewise benefit from the support and comfort of other parents who are in similar situations, and parents are well educated about how to assist their children before returning home. Tasks of treatment and issues addressed are essentially the same as described in more detail in Chapter 66. The major differences for the children and families who participate in the in-house program are the regularity with which they are scheduled to see a helping expert and the number and diversity of experts easily available to help on a non-scheduled basis.

For all children surviving massive burn injuries, whether having the advantage of 3 months of special attention or not,

Fig. 51.4 The ultimate objective of strategies to attenuate catabolism, hypermetabolism, and other burn-induced problems should be to improve the quality of life in burn victims. This may be accomplished by offering the burn victims physical and psychosocial rehabilitation strategies to enhance the potential to a full and effective re-incorporation into society.

recognition that many of the difficulties of the first year post-burn are part of the illness of severe burns removes some of the strife from the process of rehabilitation. In the past, burn care professionals and patients and their families, all feeling frustrated, have alternated between blaming themselves and blaming each other for their failures during this first terrible year post-injury. With the evidence that this extraordinary physical disruption continues for most of that first year, the informed team can teach the family about this part of the

illness and assist them in planning to manage this phase just as they have managed the acute phase. Successful management of the hypermetabolic response diminishes the extent and severity of psychosocial obstacles burned children and their families must overcome. Knowledge that many former survivors, in spite of their impediments, have successfully met their challenges to become participating members of their communities allows us to hope for even happier futures for our current patients (Figure 51.4).

Overview of burn reconstruction

Ted Huang

Chapter contents

Reconstruction of burn deformities	674
Summary	685

Burn injuries are a systemic illness of trauma in etiology. The severity of 'illness' is usually assessed, if not by patient survival, by the consequence of burn injuries; i.e. scar hyperplasia/hypertrophy, scar contracture, and structural deformities due to loss of bodily components. Since the bodily deformity is closely related to the magnitude of injuries, restorative procedures are seldom indicated if the depth of injury is superficial and the burned area limited (Figures 52.1 and 51.2).

The possibility of surviving burn injuries has changed dramatically over the past 20 years attributable singularly to an aggressive approach in surgical treatment of burn wounds; i.e. early wound debridement and wound coverage.¹⁻³ It is ironic that the success attained in burn treatment has resulted in a higher number of patients who will need to undergo reconstruction because of an aggressive 'lifesaving' surgical treatment.

Formation of scar tissues at a wound site and contraction of the scar tissues are the normal consequence of an injury. Although the exact mechanisms accounting for the sequential changes in wound healing and scar formation remain incompletely understood, wounds with infection and/or allowed to heal spontaneously, for instances, tend to form scars that are thickened and contracted circumferentially; an observation suggestive of various fibrogenic cytokines such as transforming growth factor β could play an important role in the pathogenesis of these otherwise clinically undesirable consequences.^{4,5}

The thickened and contracted scar tissues, the changes that are 'normal' and 'expected' consequences of the wound healing processes, are microscopically found to be composed of collagen arranged in whorls and nodules. The changes may be observed as early as 3-4 weeks following the injury and they are cosmetically unsightly and functionally disturbing (Figure 52.3).

Reconstruction of burn deformities

General principles

Burn injuries are a traumatic illness affecting every physiological system of the body. In short, each and every physiological

process of the body is altered because of thermal destruction of the skin. The altered physiological processes will affect not only the healing of the original burn wounds but also healing processes of the secondary surgical procedures aiming to restore the consequence of the original injuries. The treatment, under an aberrant physiological circumstance, should aim to repair the burn wounds first. Attempts to restore deformities should be delayed until recovery from the initial phase of injury is complete.⁶

An early treatment of deformity

Of the consequences of burn injuries, hyperplasia and contraction of resultant scars at the wound sites and the contraction of mobile bodily parts (i.e. eyelids, neck, axilla, elbow, hands-fingers, groin, knee and ankle-foot) are two of the most common problems that are in need of attention. The regimen of applying pressure upon scar tissues and of immobilizing joint structures has been advocated to minimize the undesirable consequences of scarring and scar contracture (Figure 52.4).

Although the true efficacy of a non-surgical regimen to control the deformities has not been established, the frequency of secondary joint release among individuals who had 'endured' the morbidities associated with proper joint splinting for a period of no less than 6 months^{7,8} has been noted. The use of pressure dressing, especially in the areas such as upper and lower limbs, with proper splinting of the hand and fingers, is strongly recommended soon following the injury. The regimen of non-surgical management of burn deformity must include daily physiotherapy and exercise to maintain joint mobility and to prevent muscle wasting.

Reconstruction of burn deformities

Objective assessment of deformities by the patients themselves is neither physically nor psychologically possible soon after the accident and while they are recovering from injury. Instead, restoration of physical changes resulting from the injury, in addition to the need to obtain relief of pain and discomfort, are the only concerns of the patient. Medical assessment of physical problems caused by scarring and scar contracture, in this sense, will require detailed understanding of the extent of the original injury and the precise treatment approach used to manage the burned wound. Formulating a realistic plan to restore physical problems and to alleviate pain and discomfort in the area of injury similarly requires in-depth analysis of the physical deformities and psychological disturbance sustained by the patient. Psychiatric, psychosocial, and physiotherapeu-

Fig. 52.1 (a) A 3-year-old boy sustained flash flame burns of the face. The depth of injury was judged to be superficial. (b) The wounds healed spontaneously and the scar formed was judged to be minimal.

Fig. 52.2 (a) A 9-year-old boy sustained flame burns involving 60% of his total body surface. (b) The injury was found to be extensive, requiring staged debridement and skin grafting.

tic cares, in this sense, must be continued while a surgical treatment plan is instituted.

Indication and timing of surgical intervention

For a surgeon, making a decision *how* to operate on a patient with burn deformities is quite simple. In contrast, deciding *when* to operate on a patient with burn deformities can be difficult. The dilemma, however, may be alleviated if a basic principle is understood and followed:

- restoring bodily deformities that impose functional difficulties must precede any surgical effort to restore the appearance.

In short, a surgeon's effort must be concentrated upon restoring the deformed bodily parts essential for physical functions if not for patient survival. An exposed skull or a calvarial defect, contracted eyelids, constricted nares, contracted major joints, and a urethral and/or anal stricture in individuals with severe perineal burns are the prime indications for an early surgical

Fig. 52.3 (a) Scars formed around the injured site can become hypertrophic as quickly as in 3–4 weeks following injuries. (b) The scar was so tight as to interfere with mouth opening.

Fig. 52.4 The use of splints over the mobile joints and pressure garment is an essential component of patient management.

intervention. In contrast, restoration of deformed bodily parts in general, can be delayed. In fact, reconstruction of the nose and the ear, for instance, should not be initiated until its growth pattern has reached the growth peak at 6–8 years of age.

Although the exact scientific basis remains unclear, it is advocated that attempts at reconstructing burn deformities should be delayed for at least 2 years (the time needed for scar maturation). During the interim, the use of pressure garments

and splinting is recommended to facilitate scar maturation and to minimize joint contracture. The true efficacy of a pressure garment in facilitating scar maturation remains undefined. Lack of a reliable method in determining various stages of scar maturation and personal difference in assessing scar appearance could account for the controversy. Splinting a joint imbedded in burned scars with an external device to maintain a proper joint angulation, on the other hand, was found to be effective in reducing the need for reoperation to achieve joint function. However, this was possible only if the patient would have worn the splint faithfully for more than a minimal period of 6 months. A physical exercise regimen to provide vigorous movements of a burned joint was found to be similarly effective in reducing the need for surgical intervention.

The 2-year moratorium on early burn reconstruction, in some instances, is justifiable. Operating on an immature scar characterized by redness and induration is technically more cumbersome; hemostatic control of the wound is difficult and inelasticity and lack of tensile strength, noted in scar tissues, render tissue manipulation more difficult. A high rate of contracture, noted in instances where a piece of partial-thickness skin graft is used for releasing a wound showing active inflammatory processes, may further support the advocacy of 2 years of delay in initiating burn reconstruction.⁹

Our recent change in handling individuals who were in need of reconstruction showed that contracted bodily parts can be effectively reconstructed if a skin flap, fasciocutaneous flap or musculocutaneous flap technique is used. The reconstruction is initiated as early as 3–6 months following the initial injury. This approach is well suited for those encountering functional difficulties because of scarring and scar contracture.¹⁰

The techniques of reconstruction

There are several techniques routinely used to reconstruct bodily deformities common to burn injuries; i.e. unsightly scar, scar contracture, and joint contracture. Principally, they are:

- primary closure technique,
- closure with a piece of free skin grafting technique with or without the use of dermal template,
- closure with an adjacent skin flap technique,
- closure with an adjacent fasciocutaneous (FC) flap technique,
- closure with an adjacent musculocutaneous (MC) flap technique, and
- closure with a distant skin, fasciocutaneous (FC) flap, or musculocutaneous (MC) flap via microsurgical technique.

Primary wound closure technique:

Excision of the unsightly scar with layered closure of the resultant wound is the simplest and the most direct approach in burn reconstruction. The technique is also useful in handling scars that are hyperesthetic and pruritic.

The margins of the scar requiring excision are marked. It is important to determine the amount of scar tissue that can be removed so that the resultant defect can be closed directly. 'Pinching' the edge of a scar at three or four different sites along the length of the scar to determine the mobility of the wound edges is the simplest yet most reliable method of determining the amount of scar tissue that can be removed safely. Leaving a rim of scar tissue is generally necessary, unless the size of the scar is so small that removal and direct closure of the resultant wound would not lead to contour deformity. A circumferential incision is made in the line marked and is carried through the full thickness of the scar down to the subcutaneous fatty layer. While the outer layer of the scarred tissue is excised, 4–5 mm of the collagen layer is left attached to the base. The conventional approach of wedged scar excision will result in a depression along the site of the scar excision, an iatrogenic consequence that could be difficult to amend secondarily. In order to minimize vascular supply interference along the wound edges, undermining of the scar edge should be kept to a minimum. Synthetic sutures are preferred for wound closure (Figure 52.5).

Skin grafting technique:

Free skin graft without incorporating a dermal template — Covering an open wound with a piece of skin graft harvested at a various thickness is the conventional approach of wound closure. Whole components of the skin removed as an intact unit – i.e. epidermis and dermis – is defined as a full-thickness skin graft, and a piece of skin cut at a thickness varying between $\frac{8}{1000}$ of an inch (0.196mm) and $\frac{18}{1000}$ of an inch (0.441mm) is considered to be a partial- or a split-thickness skin graft. The thickness of a full-thickness skin graft is quite variable depending upon the body site. A full-thickness skin graft harvested from the back, for instance, will be $\frac{160}{1000}$ of an inch (4mm) in thickness while the one harvested from the upper eyelid will be around $\frac{35}{1000}$ of an inch (0.8mm). The difference is attributable to the difference in the thickness of the dermis.

While a power-driven dermatome is usually used to harvest a piece of partial (split)-thickness skin graft, a free hand knife could be used to cut a piece of full-thickness skin graft. A paper template may be made to determine the size of the skin graft needed to close a wound. The skin graft is laid down to

Fig. 52.5 (a) The scar formed in the left submental area was pruritic and unsightly. The extent of the excision was marked and the area was infiltrated with 0.25% lidocaine containing 1:400000 epinephrine to achieve hemostasis. (b) The epidermal layer was sharply excised, leaving the dermal layer intact. (c) The wound edges were closed primarily in layers using nylon sutures.

the wound, colloquially termed as ‘wound bed,’ and is anchored into place by suturing the graft to the wound edge to edge at various sites. An apposition of the skin graft with the ‘wound bed’ is essential to ensure an in-growth of a vascular network in the graft within 3–5 days for graft survival as any mechanical barriers – i.e. blood clot or pool of serous or purulent fluid – will restrain the vascularizing processes, leading to graft loss. A gauze or cotton bolster tied over a graft has been the traditional technique to anchor and to prevent fluid accumulating underneath a graft even though there has been no objective evidence to support the efficacy of this maneuver. A quilting technique, instead of the bolstering technique, has been found to be more effective in immobilizing a skin graft and is associated with lesser morbidities (Figure 52.6).

The basis for using a free skin graft of various thicknesses to close all wounds is not entirely clear. It is, however, clear that the use of a thin graft is more appropriate for closing wounds with unstable vascular supplies, particularly if the skin graft donor site is scarce. Although the exact reasons remain undefined, the quality and the presence of dermis could influence the extent of wound contraction. That is, the extent of contraction noted in a ‘wound bed’ is more if a piece of skin graft with minimal dermal inclusion – i.e. a thin partial-thickness skin graft – is used. By inference, the presence of a dermal structure in the ‘wound bed’ could affect wound contracture.

Free skin graft with prior incorporation of a dermal regenerative template — For the past several years, artificial dermal substitutes have been manufactured from alloplastic or xenographic materials; e.g. AlloDerm™, Integra™ (the manufacturing processes was initially described by Yanniss and Burke in 1980); these are biosynthetic two-layered membranes composed of a three-dimensional porous matrix of fibers and cross-linked with bovine tendons and glycosaminoglycan (chondroitin-6-sulfate). This material, when implanted over an open wound, has been found to form a layer of parenchymal structures resembling a dermis, thus providing wound coverage with an autologous skin graft in situations where, previously, immediate closure was not possible. However, the need

Fig. 52.6 A partial-thickness skin graft was used to cover an open wound that had resulted from releasing a contracted wound.

for a staged approach to graft a wound using this technique is considered cumbersome (Figure 52.7).

Skin flap technique:

The approach using a segment of skin with its intrinsic structural components attached to restore a destroyed and/or missed bodily part follows the fundamental principle of reconstructive surgery. This technique, however, will not only cause skin scarring in the flap donor site but also a donor site contour alteration that may be considered cosmetically unsightly. The loss of the skin flap, more commonly encountered in burn patients because of altered vascular supplies to the skin attributable to injuries and surgical treatment, could render this technique unsuitable. Despite the drawbacks, the approach to restore a destructed bodily part with a piece of like tissue is technically sound and the procedure can provide restored bodily function and contour. The recent technical innovation of incorporating a muscle and/or facial layer in the skin flap design, especially in a burned area, further expanded the scope of burn reconstruction as more burned tissues could be used for flap fabrication.

The axial skin flap — The skin in many areas is nourished directly by known cutaneous arteries. A skin flap without regard to its length-to-width ratio requisite may be fabricated if the vascular trees are included in the flap pattern (Figure 52.8)

The z-plasty technique — This technique, in short, is based upon the principle of mobilizing a full segment of skin with its vascular supplies undisturbed, from an area adjacent to the site needing tissue replacement. This is conventionally achieved by interposing two skin flaps of an equilateral triangle – i.e. 60° – that has a common limb drawn in the midst of the scarred area. A scarred and contracted area is released as the flaps are interposed in an opposite direction. Any space defect due to skin and underlying tissue movement is made up for by mobilizing tissues from an adjacent area (Figure 52.9).

The modified z-plasty technique; alias 3/4 z-plasty technique — Two flaps are, unlike in the conventional z-plasty technique, of a right-angled triangle; i.e. one internal 90° angle and the other with a 45° angle. The angle for the triangular flap has decreased from a conventional 60° to 45°; hence the 3/4 z-plasty technique. The limb of the 90° triangle is made in the scarred area resulting from the tissue loss. The second limb of the triangle is made perpendicular to the first one. The angle formed by the second limb of the right-angled triangle and the hypotenuse of the second right-angled triangle is 45°. A triangular skin flap fabricated in this manner is rotated to fill the tissue defect formed by the surgical releasing of the contracted scarred area. The procedure is a variant of the conventional rotational/interpositional skin flap technique by rotating the 45° triangular skin flap singularly to make up the defect (Figure 52.10)

Despite its geometric advantage in flap design, fabricating a skin flap or skin flaps for z-plastic reconstruction burn deformities is not infrequently plagued with skin necrosis. Aberrant vascular supplies to the skin attributable to the original injury and/or surgical treatment could be the factor responsible for the problems. In recent years, the use of a skin flap designed

Fig. 52.7 (a) A piece of Integra™ was used to cover the wound. (b) Erythematous changes noted in the wound indicated satisfactory capillary in-growth. (c) A partial-thickness skin graft of $\frac{8}{1000}$ of an inch in thickness was harvested for wound coverage. (d) The scarred chest area required surgical treatment because of pruritis. (e) The appearance of wound 12 months following the re-grafting procedure using the dermal template + STSG technique. The scar was noted to be soft and pliable.

Fig. 52.8 (a) A triangular skin mark made over the right nasolabial area to mark an axial skin flap fabricated for right lower eyelid reconstruction. (b) The size of skin flap was equal to the size of lower eyelid defect. (c) The triangular flap was rotated cephalad and laterally to fill the right lower eyelid tissue defect. (d) The wounds were closed with dissolvable sutures.

to include muscle or fascia underneath has expanded further the usefulness of conventional z-plasty and the $3/4$ z-plasty technique in burn reconstruction.

Musculocutaneous (MC) or fasciocutaneous (FC) flap technique:

Inclusion of not only the skin but also the subcutaneous tissues and the fascia and the muscle is necessary to fabricate a skin flap to reconstruct a tissue defect in individuals with deep burn injuries. That is, fabricating a flap in a burned area is possible if the underlying muscle or the fascia is included in the design.

Musculocutaneous z-plasty technique — While the skin pattern is identical to the conventional z-plasty technique, the muscle underneath must be included in the flap fabrication. Although physical characteristics of the normal skin – i.e. the skin pliability and expandability – are absent if scarred skin

is included in the flap design, a ‘scarred-skin’ MC or FC flap could be safely elevated and transferred to close an open wound. In practice, an MC z-plasty technique is useful in the neck release and in the eyelid because of the underlying muscle; i.e. platysma and orbicularis oculi muscles are thin, pliable, and easily movable (Figure 52.11).

Fasciocutaneous z-plasty technique — This is a technical modification of the MC z-plasty technique by including the muscular fascia only. Separation of the skin and its subcutaneous tissues from the underlying fascia must be avoided in order not to impair the blood supply to the flap. In practice, the technique is useful in reconstructing contractural deformities around the knee and ankle areas.

$3/4$ Fasciocutaneous z-plasty technique — A 45° triangular FC flap that includes the fascial layer may be fabricated anywhere in the body. The flap is elevated and then turned 90° to cover a tissue defect resulting from releasing a contracted

Fig. 52.9 (a) A tight scar band was noted over the forearm. (b) Two equilateral triangles were marked into a 'z.' (c) Incisions were made to free up two triangle skin flaps. (d) Two flaps were interposed to achieved the release.

wound. Although unburned skin, when used to fabricate a triangular flap, is more versatile, scarred skin with or without subcutaneous tissues may be used for flap fabrication. Suturing the fascia to the skin edge is a useful maneuver to avoid impairing vascular supplies to the dermal structures by accidental separation of the fascia from the overlying skin (Figure 52.12).

Paratenocutaneous z-plasty and $3/4$ paratenocutaneous z-plasty techniques — In instances where fabrication of a composite skin flap is indicated in the distal section of the upper

and lower extremities – i.e. wrist and ankle, the paratenon – a fascial extension of the voluntary musculatures should be included in the flap design and fabrication (Figure 52.13).

Tissue expansion technique:

An extreme stretching of the integument is quite commonly observed in human bodies. The tissue expansion technique follows the same principle except it is carried out intentionally with an inflatable device; i.e. a tissue expander. Because of the excessively active scarring processes more frequently observed

Fig. 52.10 (a) A right-angled triangle with the cathetus marked along the line of contracture and perpendicular to the line of release. (b) Incisions were made to release the contracture and to fabricate a triangular skin flap. (c) The right-angled triangle skin flap was elevated and rotated anteriorly. (d) The triangular flap was rotated 90° to fill the tissue defect that had resulted from the release.

in burn victims, especially during the period soon following the accident, timing of the initiation of the procedure could be difficult and its use may be limited because of the pain and discomfort associated with expansion (Figure 52.14).

Free composite tissue transfer via microsurgical technique:

With the advent of microsurgical techniques, transplanting a composite tissue can be carried out with minimal morbidities. The regimen, in caring for burn victims, however, may be limited because of a paucity of donor materials. It is ironic that

burn patients with suitable donor sites seldom require such an elaborate treatment. Those who are in need of microsurgical tissue transplantation are inevitably without appropriate donor sites because of extensive tissue destruction.

Comments

The regimen of burn treatment has changed drastically over the past 50 years. The center of burn treatment moved from understanding the pathophysiology of burn injuries and mastering the patient resuscitation in the 1950s to learning how to cover a burn wound in the 1960s, even though the principle

of early debridement of the burn wound was clear to the physicians. Reconstructive efforts offered to those who had survived the trauma were mostly limited to the restoration of lost bodily functions and cosmetic reconstruction was simply not offered. The treatment outcome, however, was in most instances, suboptimal because of excessive scarring and scar contracture, the two consequences that limited the outcome of burn reconstruction.

A more aggressive approach in managing burned wounds came in the 1980s. Various pharmacological agents used to control aberrant metabolic processes induced by the trauma, the control of infectious consequences, and safer anesthetic agents, for examples, have contributed substantially to the survival of burn victims. The regimen of an early debridement and wound coverage, initially with biological dressing and later with autologous skin grafts, had further enhanced the

Fig. 52.14 (a) A tissue expander was inserted into the right temporoparietal scalp. The hair-bearing scalp would be expanded to cover an alopecia deformity on the left side. (b) The appearance of the scalp 9 months following the removal of the tissue expander. The alopecia was removed and the defect was covered with expanded hair-bearing scalp mobilized from the right side.

survival rate. It is, however, ironic that this improvement in survival rate has caused an increase of patients in need of reconstruction. That is to say that everyone who now survives burns that would result in scarring and scar contraction needs reconstruction, functional or otherwise.

Unsightly hypertrophic scar, scar contracture, affecting particularly the joint structures, and missing bodily parts are still the most common sequelae of burn injuries today. Although the use of skin grafting and skin flap techniques remain the mainstay of burn reconstruction, the outcomes can still be suboptimal because sometimes these techniques are not effective enough to achieve the desired therapeutic objectives (the correcting of the three sequelae listed above).

The exact timing of initiating reconstruction of burn deformities remains uncertain. Difficulty in obtaining suitable tissues for replacement, the risks associated with surgical procedures that involve scar tissues that are active, and the inability to assure outcomes could account for the uncertainty.

The predicament associated with the timing of intervention, on the other hand, could be due to the techniques used. For instance, the use of flap techniques, particularly the use of techniques such as $3/4$ fasciocutaneous z-plasty and/or $3/4$ paratenocutaneous z-plasty, enable us to reconstruct contractural deformities that involve the major joints as well as eyelid deformities as early as 4–6 months following the injuries.

Questions concerning the ideal approach in managing burn deformities remain unanswered. Although surgery has been

the mainstay of the reconstructive approach for the past half century, these problems, perhaps, should be handled completely non-surgically or with limited use of surgical means. For example, reducing the inflammatory phase following injury and controlling the level of various fibrogenic cytokines could be useful in forming scar tissues considered to be physiomechanically sound yet cosmetically pleasant. The know-how of tissue engineering could lead to the formation of bodily parts that may be used to replace missing body components.

Summary

Reconstruction of bodily deformities due to burns is difficult if not impossible. The difficulty is largely due to a lack of understanding of the pathomechanism of wound healing and scar tissue formation. Furthermore, technical limitations on replacing a missing bodily part further fuels the psychological frustrations of reconstructive surgeons.

The use of a musculocutaneous flap and/or a fasciocutaneous flap, particularly modified to follow the principles of z-plasty or $3/4$ z-plasty, has been found to be effective in restoring bodily functions lost because of scarring and scar contracture. Furthermore, it is conceivable that refinement in microsurgical tissue transfer technique in conjunction with advances made in tissue engineering/body parts formation would render the task of reconstructing burn deformities easy and simple.

Summary	699

Introduction

Although the hand accounts for only 2.5–3% of the total body surface area, it is involved in up to 80% of treated burn injuries.^{1,2} The hand may be burned as an isolated injury, or in conjunction with other body areas, and is rarely spared in burns greater than 60% TBSA. Many hand burns occur at the workplace.^{3,4} Injuries that occur on the work site are more likely to be flame burns or electrical burns. Injuries that occur at home are more likely to be due to scalds, explosions or open flames. Contact burns to the hand and scald injuries are common in small children.⁵

The function of the hand depends upon stability, sensibility, mobility, dexterity and controllable power. The hand requires stable coverage, an adaptable skeletal framework and a gliding balance of multiple tendinous/muscular forces. The function of an individual is very dependent on the use of their hands. Loss of hand function negatively impacts on occupation, activities of living, and social interaction.⁶ Thumb loss alone accounts for a 50% function loss of the whole hand.⁷ Our hands are also an important aesthetic feature of the human form. Many patients, who sustain hand burns, are self-conscious about the resulting deformity.

Management of the burned hand provides many challenges to the treating physician. The priority is to maximize the functional outcome for the patient. The final outcome is dependent on the initial severity of the injury, including surface area involved and depth of burn injury, and avoidance of complications such as ischemia secondary to edema, infection and burn scar contractures.

Acute management of the burned hand

Initial assessment

Before focusing on the hand injury, basic trauma principles should be followed. A primary survey of the injured patient, followed by a secondary survey needs to be completed, as the hand burn often is not an isolated injury but part of a larger thermal injury. Once the more emergent needs of the patient, such as airway, breathing and circulatory problems, have been identified and treated appropriately, the burn wound, as a whole, and the burnt hand need to be evaluated.^{2,3}

A history of the mechanism of injury and surrounding circumstances is very helpful. The injuring agent should be established – for example, flame, grease, chemical, water or electrical – and duration of contact. This will impact the depth of the injury, as certain agents retain heat longer such as grease, and chemical agents can continue to penetrate the skin if not properly irrigated (Figure 53.1). Neuromuscular damage and remote injuries, as well as systemic problems such as arrhythmias and renal failure, need to be considered in electrical injuries. Some chemical agents require specific therapies: notably hydrofluoric acid, which can rapidly cause fatal hypocalcemia. Calcium gluconate needs to be administered locally or intravascularly in this scenario.³ Any first-aid measures undertaken, such as cooling the burn, should be enquired about. Additional trauma, for example a crush injury, also needs to be ruled out. A combination of a burn and crush injury can have more severe consequences than either alone. Tetanus status, hand dominance, occupation, and past medical history are also important.⁸

Physical examination of the hand should include an assessment of the area of burn and the depth of burn. Circumferential areas need to be documented. While the extremes of burn depth – superficial/superficial partial thickness and full thickness – are usually easy to distinguish, it can be difficult to determine the depth of deeper partial-thickness burns. Briefly, superficial/first-degree and superficial partial-thickness/second-degree burns are usually erythematous, painful and blistering. They blanch readily with pressure (Figures 53.2, 53.3, and 53.4). Deeper partial-thickness/second-degree wounds can be pale or erythematous. They are often mottled, and usually blanch on pressure, although this may not be as obvious as with the more superficial burns. Nerve endings are present,

Fig. 53.1 Tar burns to both hands. Acute injury on the left, healed hands on the right.

Fig. 53.2 Superficial burns to the hand. Acute injury on the left, healed hand on right.

Fig. 53.3 First-degree burn to palmar surface of a child.

but may be damaged; hence pain is present but variable in severity (Figures 53.5, 53.6, and 53.7). Full-thickness/third-degree areas are pale to brown in appearance and often leathery. Nerve endings are destroyed; thus the eschar is anesthetic. Coagulated blood vessels may be visible^{2,8} (Figure 53.8). Fourth-degree wounds occur when the underlying soft tissue and/or bone is involved. However, depth classification rarely falls into such clear categories. Depth determination often

Fig. 53.4 Second-degree burn to palm of child with blistering from contact burn.

Fig. 53.5 Deep second-degree contact burn in toddler.

Fig. 53.6 Superficial second-degree burn to dorsum of hand.

proceeds by serial observation of progression of healing (Figure 53.9).

The hand is especially prone to thermal injury. The hand is the only appendage that operates outside of a two-foot circle from our central axis. The dorsal hand has non-glabellar skin,

Fig. 53.7 Deep second-degree burn to dorsum of hand.

Fig. 53.8 Full-thickness hand burn with dorsal escharotomies.

Fig. 53.9 (a) Extravasation injury from antineoplastic agent. (b) Extravasation injury from antineoplastic agent post debridement; the extensor tendons are severely damaged.

which is thin and mobile, allowing for individual joint motions. There is thin areolar tissue coverage overlying the tendons and overlying the surface of the joints. The separation between skin and tendon gets extremely thin, especially over the joints, making extensor tendon and dorsal hood involvement more likely. The palmar aspect has a glabrous, thick, hairless skin-bearing surface. There is minimal mobility, allowing for extreme stability and a high concentration of sensory receptors. Palm skin is heavily anchored to underlying fascia by fibrous septae.³ Thus the extensor apparatus on the dorsum of the hand is more vulnerable to injury than the flexor mechanism volarly. Children have thinner skin, so it requires less burn depth to produce a full-thickness injury.⁵ Soft tissue swelling and circulation of the hand and individual digits should be evaluated. If the hand is very edematous and tense or there is evidence of circulatory compromise, such as coolness, poor capillary refill, anesthesia or increasing pain/severe pain on passive motion in the presence of a circumferential or significant burn to the hand, escharotomies plus or minus release of the fascial compartments need to be considered.² A full motor and sensory neurological examination should be documented.³

Initial care and wound management

After the preliminary evaluation, if escharotomies are indicated, these should be carried out without delay. Subeschar and muscular compartmental pressures can be measured using a needle; however, if clinically indicated, escharotomies are generally completed. Escharotomies can be carried out at the bedside using either cautery or a scalpel. Cautery carries an advantage in that hemostatic control is easier. Full-thickness incisions in the medial and lateral midaxial lines should be made, which should extend just beyond the area of full-thickness burn. The superficial branch of the radial nerve is vulnerable to damage at the wrist. Digital escharotomies can be made in the midaxial line between the neurovascular bundle and the extensor apparatus. This is usually done radially in the thumb and ulnarly in the index, middle and ring fingers to allow preservation of the opposing sides of a pinch grip. In the little finger, the medial escharotomy can be continued down the ulnar side of the finger, or this can be preserved to protect ulnar sensation as it is a border digit, and the radial side released.² Intrinsic musculature is extremely sensitive to the effects of soft-tissue ischemia. Shortening and fibrosis of the intrinsic muscles creates a tendon imbalance and

additional clawing, which is very difficult to correct in the burn-injured hand. Incisions can be made longitudinally in the spaces between the 2nd, 3rd, and 4th metacarpals on the dorsum of the hand and extended into the webspaces (Figures 53.10, 53.11, and 53.12). If decompression is still inadequate, the fascial compartments can be released here. An artery forceps can be passed through the fascia between the metacarpals and spread longitudinally to release this compartment.² Carpal tunnel releases may also be necessary to achieve full decompression of the hand (Figure 53.13). Electrical and crush injuries require a much lower threshold for full decompression. Due to small cross-sectional diameters, children are more prone to compartmental syndromes and digital tip necrosis. However, digital escharotomies are somewhat controversial in children, and not always performed due to concerns about damaging the neurovascular bundle.⁵

The wound should be cleaned and debrided if necessary. Very superficial wounds only require moisturization and can undergo immediate mobilization. Dressings should be comfortable, prevent desiccation and protect against infection. In the hand, they should also allow mobilization. Superficial

partial-thickness wounds that are clean and present early for treatment may have dressings such as Biobrane™, a bilaminar, semipermeable silicone membrane bound to a layer of nylon and containing porcine dermal collagen. It is available in a glove form, and once adherent to the burn wound, no

Fig. 53.10 Full-thickness forearm and hand burns. Dorsal escharotomies are visible.

Fig. 53.12 (a) Inadequate escharotomies resulting in necrosis of the fingers. (b) Necrosis of the fingers.

Fig. 53.13 Upper limb fasciotomies. The carpal tunnel has also been released.

dressing changes are required. After application, for the first 24–48 hours, it needs to be monitored for adherence and any signs of infection. If non-adherent or infected, it needs to be removed. Other options include Mefix™, or topical ointments such as silver sulfadiazine or mafenide acetate. Ointments may be applied within a glove for ease of movement. The wound should be cleaned between applications. Indeterminate depth and deeper wounds are usually treated with topical ointments, such as silver sulfadiazine, until healing is complete or surgery is scheduled.^{2,6}

Elevation of the affected limb is crucial to control the development of edema and to reduce that already developed. Inpatients can have the arm suspended in a sling from an IV pole or bed frame. Outpatients should be provided with a sling and clear instructions.³ Less severe or superficial hand burns may be treated on an outpatient basis. If it is unclear whether or not surgery will be required, often the patient can be treated as an outpatient and readmitted if necessary for surgery. However it is essential to have a compliant patient with regard to elevation of the hand, wound care, physical therapy, and follow-up. Adequate arrangements also need to be in place for dressing changes and analgesia.

Surgical management

If wounds are not healing in a timely manner (2 weeks) with dressings, or it is clearly a third-degree burn, debridement and skin grafting should take place. In the patient with an isolated hand burn or a relatively small total body surface area burnt, definitive wound coverage can take place as soon as the decision for surgical management is taken. However in larger burns with limited donor site availability, survival of the acute burn patient takes precedence over hand function. Initial grafting is generally performed to maximize surface wound coverage of large areas of the massively burned patient. This expedites wound closure and increases probability of survival. Delay in healing results in hypertrophic scars, contracture formation, limitations in motion, decreased strength and endurance and poor overall outcome. In general, deeper burns are managed by surgical intervention as soon as practical, to minimize immobility and to decrease duration of both illness and discomfort. Traditionally, maximization of hand function is the second priority after survival. Therefore, hands take high priority.^{2,3} If the hands are not grafted as part of the early surgical plan, it is imperative to maintain range of motion and good hand position.

The burn should be tangentially excised to healthy, bleeding tissue, with preservation of as much viable tissue as possible, i.e dermis in partial-thickness burns and dorsal veins and paratenon in full-thickness areas. In the case of electrical and crush injuries, a second-look procedure may be advisable as more debridement than initially thought may be necessary. For the dorsum of the hand, sheet split-thickness autograft provides a good cosmetic result, although good results have also been achieved with 1:1 and 1.5:1 meshed split-thickness grafts.^{2,3,5,6} Meticulous hemostasis is necessary, especially when sheet grafts are used, and these should also be inspected frequently in the first 48 hours for hematomas and seromas (Figure 53.14). With the advent of synthetic dermal and skin substitutes, e.g. Integra™, it is possible to excise the hand early

Fig. 53.14 Sheet autograft on the dorsum of the hand.

in large burns and cover the area with the dermal substitute. When neovascularization of the dermal component (a cross-linked collagen and chondroitin-6-sulfate layer) takes place, the silicone top layer can be removed and a thin autograft placed on top approximately 2–3 weeks later.⁹ AlloDerm™, an inert human cadaver Dermis with the cellular elements removed, can also be used.⁶ If these substitutes are not available the excised area can be covered temporarily with porcine or cadaver skin.

The palmar skin is thicker and as a result recovers from burn injury more frequently than the thinner dorsal skin. Conservative management is often continued for 2–3 weeks longer because of this. When it is necessary to surgically treat these burns, the same principles of preservation of as much viable tissue as possible apply. In the large burn, split-thickness grafts may be the only option for wound closure. However in smaller burns, some centers use full-thickness skin grafts to resurface the palm as they give a good cosmetic result and contract less.¹⁰ Others have not found a significant difference in outcome with the two methods.¹¹ Glabrous skin grafts from both plantar and palmar surfaces have also been used with good aesthetic and functional results.¹²

Over the dorsum of the fingers with debridement, the extensor tendons and joints are easily exposed. It may be necessary to stabilize the joints in extension with Kirschner wires (K-wires), until stable wound coverage is achieved.² In fourth-degree wounds, it may be necessary to debride tendons and amputate non-viable digits. Again, maintenance of any potentially viable tissue is advised. Tendon and bone are frequently exposed in the wound in these scenarios. The interphalangeal joints may again need stabilization with pins. The wound can be allowed to granulate and then grafted, or flap coverage can be used. For small areas, local flaps such as the cross-finger flap or dorsal metacarpal flaps can be used; larger areas will need distant flaps, such as the reverse radial forearm flap, the ulnar forearm flap or the two-stage pedicled groin flap, although this can be bulky.^{2,6} Alternatively, the crane principle can be used, where a flap is transposed to cover a defect. At the time of division, the flap is then split into two lamina, with the skin and outer lamina being returned to the original site and the soft tissue now adherent to the wound providing for

a stable platform for skin grafting.³ The radial forearm flap can be used as a fasciocutaneous or a fascial flap. Using this flap or the ulnar-based flap sacrifices a major vessel to the already traumatized hand. Free tissue transfer can also be used; however, this is usually reserved for when other options are unavailable in this scenario. In patients with extensive burns, flaps may not be available, or may sacrifice valuable donor sites. The patient also needs to be medically stable enough to withstand a prolonged procedure.

Hand therapy and splinting

For acute injuries, initial management consists of a simple program of elevation to decrease both edema and pain.² Edema of the hand results in a loss of joint and dorsal skin laxity and impairs flexion at the metacarpal-phalangeal (MCP) joints. Protective splinting may be required to maintain joint and hand posture. Prevention of hand deformities is better than the subsequent treatment. Because the dorsal skin has a great propensity for swelling, edema naturally drives the MCP joints into an extended posture. However, if the hand remains in this posture for too long, the collateral ligaments shorten and tighten. Once the hand gets stiff with an MCP extended posture, the contractural forces of the shortened collateral ligaments can be tough to overcome. In addition, with the MCP joints in extension, increased tension on the balance of the extrinsic and intrinsic tendons drives the IP (interphalangeal) joints of the digits into acute flexion. The hand is naturally moved to a posture of MCP extension/IP flexion during the course of scar contracture and healing. If unchecked, end-stage contracture disease of the burned hand results, called the claw-hand deformity. This deformity is defined by wrist flexion, MCP joint hyperextension, PIP flexion, boutonnière's deformities of the digits (PIP flexion and slight DIP extension), and a thumb adduction contracture.¹³ Active and passive range of motion exercises are begun as soon as possible. Splinting should be done in a position of protection, which places the hand in the best position to help overcome the imbalance of tendon forces working on the hand during the edema phase. The position of protection keeps the collateral ligaments of the MCP joint in a flexed position at 70–90°. When the joint is in full flexion, the collateral ligaments are tight. Wrist extension is maintained at 20–30°, IP joints are held in full extension, and the thumb is kept abducted and slightly opposed.¹ The ideal posture of the thumb is to separate the first metacarpal and second metacarpal heads at a maximum distance. This occurs when the first metacarpal is about 45° from both the plane of the palm and 45° from a line drawn along the first ray extending into the radius. In a severely burned hand, the position of the thumb is very difficult to maintain (Figure 53.15).

A temporary pre-manufactured splint can be placed on the patient with the initial dressing and first assessment. A customized manufactured splint can then be made over the first 1–2 days. Pre-manufactured splints sometimes create pressure points in the hand. Most therapy programs recommend removal of the splints for range of motion activities at least twice a day. Some units have used continuous passive motion as an adjunct.^{13,15} All splinting and ranging programs are designed to maximize active use of the hand, maintaining function and

Fig. 53.15 Hand splint showing protective position of wrist, MCP, and IP joints.

Fig. 53.16 External skeletal fixation holding a grafted hand in position.

protecting posture. Patients should be encouraged to use the hands for self-care activities as this speeds return to functional activities.³ Static splinting is used mainly to hold position between therapy sessions, or if active participation with the range of motion program is not possible. Due to their small size, it can be difficult to maintain position when splinting pediatric hands. However, they are less prone to stiffness following immobilization periods.

Postoperatively, the hand is usually splinted in the protective position until graft review at 4–5 days. K-wires or skeletal traction, using a Steinmann pin through the radius and attaching hayrake or banjo splints, has also been used⁶ (Figure 53.16). Then the program of active and passive movement is recommenced. However, when the dorsum of the hand

is grafted, maximum surface length is achieved when the hand is in the fist position; all joints flexed. Split-thickness skin grafts contract as the scar matures up to 50%, and if a lesser area of skin is grafted (as in the safe or protective position of the hand), this may manifest itself as a greater contractural deformity than might otherwise occur. While the majority of surgeons favor the protective position, the fist position has been used without adverse consequences for the initial immobilization post grafting, with resumption of standard rehabilitation after graft take.¹⁴ When the palm is grafted, it can be splinted with the hand joints in extension until the graft has taken and hand therapy can resume.²

Pressure garments are usually fitted following significant burn injury to the hand. Their purpose is to try to control scar formation, but they can also help in controlling/decreasing edema and improving skin conditioning.¹³ Coban wraps can also be used to help with edema. Desensitization programmes may also be necessary if hypersensitivity of the burned area develops.¹⁶

Reconstruction of established hand deformities postburn

General principles

In spite of early splinting, adequate therapy, and vigilant treatment, postburn hand deformities commonly develop. It is important to remember that for the majority of reconstructive procedures in the hand, the priority is to restore or improve function rather than appearance. The timing of these procedures should be decided on an individual basis, and in order of priority, as several procedures may be needed in some cases. The burned hand may not be an isolated injury for the patient, who may wish or need an alternative deformity to be addressed first, e.g. facial deformities. The hand reconstructive surgeon should coordinate care with the rest of the team looking after the patient and with the patient to develop the individual's reconstructive plan in a way that maximizes use of resources and benefits the patient the most. The choice of reconstructive method may also be affected by the patient's other needs, as use of one area as a donor site for a skin graft or flap may prevent its use in the future for another reconstructive purpose.¹⁶

For the isolated hand deformity, these concerns are less. Nevertheless, patient and procedure selection are still important. Many patients simply adapt to their boutonnière fingers or slight contractures, and are tired of the surgical process following recovery from their acute injury. Other patients are not compliant with their hand therapy and, therefore, will not be good candidates for completing complex reconstructive maneuvers.

The timing of surgery also needs consideration. Traditional teaching was that reconstructive procedures should wait until scar maturation had occurred, at least 6 months and up to 2 years post injury. Many centers now undertake reconstructive procedures once stable wound coverage has been achieved, if there is a clear impairment that can benefit from early intervention.² The surgeon should also take into consideration schooling and work commitments when scheduling surgery. In children, body growth may outstrip that of scarred tissue, and

procedures may need to be repeated as the child grows and deformities redevelop.¹⁶

The key to the plan is an ability to communicate between surgeon and patient. Patients need to understand from the surgeon what is possible and what is realistic. Surgeons need to listen to the patients to determine exactly what they need and what they desire. For some patients, the loss of self-image associated with the burn of the hand or with other burns is so devastating that they may not want additional deformity, but opt for another treatment regardless of advantages or expected gains. For example, a patient who has lost multiple fingers may opt for a metacarpal stacking as opposed to a toe-to-hand transfer simply because the feet are still normal.¹⁶

In formulating the plan for the reconstruction of the burned hand, it is important to take into account the rest of the extremity. In the upper extremity, function of the elbow is critical to adequate positioning of the hand. Given deformity at all three levels, it is often appropriate to do releases of wrist, elbow and axilla, and complete large motion reconstructions prior to attempting finer motion reconstruction of the hand. However, it is also possible to complete all of the releases at a single setting.

Reconstructive methods commonly used

Reconstructive methods range from the very simple excision of a scar and primary closure to complex tendon transfers and microvascular free tissue transfers. The repertoire used depends on the complexity of the deformity and surgeon preference. Deformities involving skin only are easier to reconstruct and carry a higher chance of full functional recovery than those with neurological, tendon and/or bony defects.¹⁷ Principles for reconstruction of burn scar contractures include:

- Incisional release of scars at each joint level to allow for maximum restoration of movement.
- Excisional removal of hypertrophic scars when feasible.
- Restoration of transverse and longitudinal hand arches.
- Release or lengthening of deep tissue contractures, including but not limited to extensor tendons, lateral bands and/or accessory collateral ligaments.
- Stabilization of bones and joints in positions of function with either internal K-wires, external splints or external skeletal fixation.
- Resurfacing of hand and digits with thin pliable acceptable tissues, skin grafts if tendons are protected — flaps if joints or tendons are apparent.
- Use of flaps whenever feasible for reconstruction of web spaces.

Here we will briefly discuss some of the more common techniques. Individual deformities that require a more tailored approach will be discussed in the next section.

- Primary closure: This technique can be used for excision of unsightly/hypertrophic scars or scars that are pruritic or hypersensitive. Unless the area is small, it may require serial excision to achieve closure. If part of the base of the scar is left in the wound, it can avoid contour deformities that are sometimes seen when the entire scar is excised.
- Skin grafting: Here the choice lies between split-thickness and full-thickness grafts. Full-thickness grafts

give a better cosmetic result and contract less, however donor site availability and size limit use. Split-thickness grafts can be utilized with or without a dermal template such as Integra™¹⁸ or AlloDerm™. Skin grafts can be used to resurface the defect created from contracture release. Bolster or quilting techniques can be used to immobilize the graft, as can splinting, until graft take at 4–7 days.

- **Skin flaps:** A segment of skin with its vascular supply in the subcutaneous tissue intact is transferred from its original location to resurface a defect following release of contracture. Flaps can be used over surfaces unsuitable for grafting, e.g. exposed tendon or bone. They can however be bulky, and if the vascular supply is inadequately preserved, can necrose. The donor site will have a scar. Some examples include:
 - **Axial skin flap:** the blood supply is known and included in the flap design.
 - **Z-plasty:** two skin flaps from the area adjacent to the site in question, forming an equilateral triangle (60° angles) with a common limb in the scarred area are interposed. This technique is most suited for isolated linear scars.¹⁷
 - **Modified z-plasty/³/₄ z-plasty:** the scar is released and the defect forms the base of a right-angled triangle, the second limb being perpendicular to the scar release. A second triangular flap is designed with a 45° angle at the tip, using the perpendicular limb of the first triangle as one of its limbs. Its base contains the blood supply and is adjacent to the scar defect. This flap is elevated and then transposed 90° into the defect.
- **Musculocutaneous (MC) and fasciocutaneous (FC) flaps:** in these flaps, the skin, subcutaneous tissue, fascia plus/minus muscle is raised. Skin grafting may be required to close the donor if the flap is large. Care must be taken when elevating to avoid separating the subcutaneous tissue from the fascia and disrupting vascular supply. Scarred skin can be incorporated into these flaps, if the muscle and fascia are included. Some of the many suitable flaps are:
 - **Pedicled flaps:** examples include reverse radial or ulnar forearm flaps. These can sometimes be taken as fascial flaps alone, and then a skin graft placed over the fascia, to minimize donor site morbidity. A major vessel is sacrificed going into the hand if these flaps are used. They are thin, pliable, close to the site of coverage and extremely versatile in their use. Other suitable flaps include reverse digital artery flaps, first and second metacarpal flaps, and the dorsal ulnar artery flap which does not sacrifice the ulnar artery.
 - **Distant pedicled flaps:** the groin flap is the most commonly used. This involves a two- to three-stage procedure. First, attachment, then separation 3 weeks later, plus or minus separation of digits at a later stage, depending on the area resurfaced.
- **Free composite tissue transfer:** this technique involves microsurgical techniques. Use of free flaps requires presence of satisfactory recipient vessels, which must

be documented in postburn hand injuries. Suitable donor sites may be in short supply in the extensively burned patient. Typically, a segment of vessel is chosen for an anastomosis, which is close to the reconstruction but outside the zone of injury. In the burned hand, flaps can be connected into the radial artery and the cephalic vein in the anatomic snuffbox. The most commonly used flaps are:

- **Free radial forearm flap:** this can cover entire surface of hand and digits and is thin and supple. It can be innervated if medial and lateral antebrachial nerves included.
- **Dorsalis pedis free flap:** this can be harvested with tendons, portions of second metatarsal and superficial peroneal nerve if needed, but is not large enough to cover the entire surface of the hand.
- **Temporoparietal fascial flap:** this can cover the entire surface of the hand, and is thin and pliable. It is covered with a skin graft. Donor site morbidity is minimal, but the venous outflow is variable.
- **Lateral arm flap:** for small defects it has similar advantages to the radial forearm flap, but with less donor site morbidity. It can be sensate if the posterior brachial nerve is included.
- **Capsulotomy:** release of the capsular ligaments around a joint. Used when the joint has been contracted so long that release of the skin contracture alone is not enough to release the contracture as the ligaments have shortened. If the appropriate postoperative hand therapy is not followed, the capsulotomy will result in increased scarring and poor functional outcome.¹⁶
- **Arthrodesis:** fusion of the joint. The angle of fusion varies depending on the joint involved. It is fused in the position of maximum function. In general, the angle of fusion increases from radial to ulnar, and proximal to distal from MCP and PIP joints, with the index and middle orientated to oppose the thumb, and the ring and little more flexed. They can be fixed using K-wires or other methods of bony fixation.²
- **Amputation:** if other reconstructive methods have been exhausted, or the patient is unwilling to undergo several procedures or the postoperative rehabilitation, amputation may sometimes be the best option, e.g. an abducted, contracted fifth digit.¹⁶

Reconstruction of phalangeal deformities

- **Flexion deformities:** (Figure 53.17) Usually the flexor tendons are deep enough that release of the band still leaves paratenon intact. Isolated bands of scar on the volar surface of the digits may be treated by z-plasties.^{2,8} Alternatively, the scar band can be excised, and the defect resurfaced with a split- or full-thickness skin graft. These areas may also recontract however. V-V advancement in combination with z-plasties, similar to the trident or ‘jumping man’ flap, has also been described for linear flexion contractures.¹⁹ Local skin flaps from adjacent fingers, such as the cross-finger flap,^{2,8} or the dorsal webspace, may be suitable to cover small defects.²⁰ This method of coverage recontracts less. Periarticular structures, such as the volar plate,

Fig. 53.17 Flexion contracture of the little finger.

Fig. 53.18 Boutonnière deformity of the little finger.

joint capsule and collateral ligaments may also require release. Care is needed to avoid injury to the neurovascular bundles, which can become displaced by the pull of the scar band. As the vessels may have also contracted in chronic contractures, it is important to monitor for signs of ischemia as the vessels may spasm as they stretch, when releasing the contractures.² The finger will need to be splinted or held with a K-wire into extension postoperatively.

- *Boutonnière deformity* (Figure 53.18): This is a deformity resulting from the destruction or weakening of the central extensor slip, which allows the lateral bands to migrate volar to the axis of motion in the proximal IP (PIP) joint. In this position, they flex the PIP joint and extend the distal IP (DIP) joint. If in this position chronically, the PIP joint collateral ligaments and volar plate become tight, and the position is very difficult to correct. Attempts at repairing the central slip can be made, by interweaving segments from the lateral bands to form a neocentral slip, or by rotating back some of the distal central slip and securing it. The PIP joint may not fully correct if flexed for a long period. Also, there is usually poor-quality skin

Fig. 53.19 Release of webspace contractures using z-plasties. Clockwise from the top left.

coverage following the burn injury, so the results of these repairs are poor. Tendon plasty using palmaris longus and a groin flap for coverage, after achieving full range of motion in the joints, has been described with success in one series.²¹ Often the best result for the patient is to fuse the joint at an angle of 25–50°, with the angle increasing toward the ulnar digits.^{2,8}

- *Mallet finger deformity*: If there is a burn over the dorsum of the DIP joint, which damages the extensor tendon, this deformity results. Acutely, the joint can be splinted or held in extension by a K-wire until fibrosis of the tendon occurs. If this is not feasible due to the chronicity of the problem, the joint can be fused in slight flexion.²
- *Webspace contractures*: These are extremely common contractures following hand burns. Numerous techniques have been described for their release. Dorsal hooding is the most common problem. This can be released using a variety of local flaps, such as Y-V advancement, z-plasty, 3/4 z-plasty or the trident or ‘jumping man’ combination and many other variations^{2,22} (Figures 53.19, 53.20, 53.21, and 53.22). As some further web creep may occur, if it is possible mild overcorrection should be done. Contracture of the first webspace, bringing the thumb into adduction, is the most symptomatic of the webspace contractures. For mild cases, especially if there is an isolated scar band, z-plasty or ‘jumping man’ local flaps work well. More severe defects require full release plus or minus release of fascia or adductor pollicis from its insertion (it then needs to be reinserted more proximally on the thumb metacarpal). The defect is usually grafted; however, flap coverage, either local or distant, has been described, particularly if the carpometacarpal joint is exposed.^{2,8,23} The release should be maintained postoperatively. A C-bar splint is commonly used. An external skeletal distractor can also be used to gradually stretch out the webspace over 2–4 weeks.

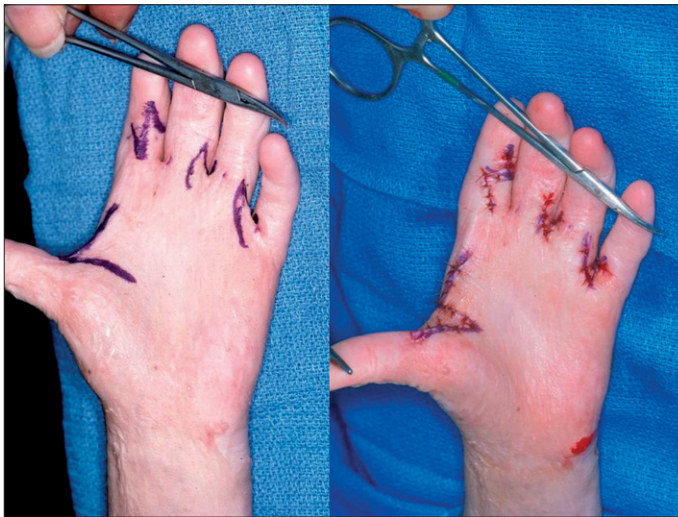

Fig. 53.20 Release of web space contractures using $3/4$ z-plasties.

Fig. 53.21 Release of web space contractures using z-plasties. Preoperative on the left, postoperative on the right.

- *Syndactyly*: This condition can be treated by surgical separation of the digits. The resulting web space defect can be filled by local transposition flaps, e.g. from the dorsum of the adjacent finger, with grafting of their donor sites, as the defect is usually too large to allow primary closure. If local tissue is not available for transposition flaps, the defect should be grafted with a split- or full-thickness skin graft.²³
- *Thumb reconstruction*: Options for thumb reconstruction include metacarpal stacking, distraction osteogenesis and pedicle flaps, pollicization, or toe-to-hand transfers.⁷ The goal in all of these is to provide for pinch or key grip. All are useful and workable, but need to be adapted by the patient's desires and the state of the postburn hand at the time of reconstruction. Partial thumb reconstruction can be completed using island pedicle flaps taken from other digits to provide for a sensate stable pad. This is done, however, with loss of sensation to the donor digit. Free tissue transfer options for simple soft tissue reconstruction of the thumb include wraparound flaps, first web space flaps taken from the foot for base reconstruction, and

Fig. 53.22 (a) First web space contracture. (b) Release of previous first web space contracture using trident flap. Clockwise from top left. (c) Postoperative from release of first web space contracture.

Fig. 53.23 (a) Hand preoperative dorsum and volar surfaces. (b) Preoperative x-ray of the hand in (a). (c) Postoperative view of the same hand as (a) and (b) after thumb stacking procedure.

toe pulp flaps to rebuild a sensate digital tip. All of these are useful for coverage of finger defects as neurosensory flaps and are based upon the first dorsal metatarsal artery and plantar digital nerves. Metacarpal stacking has shown great utility in reconstruction of the first burned hand by providing a viable, accomplishable pinch-grip and even some of the most devastated multiple amputation hands (Figure 53.23). In this procedure, the remnant of the index finger is transferred on to the remnant of the thumb and fixed with K-wires. Flexor tendons and the neurovascular bundle are transferred with the bony remnant.²⁴ This procedure was first used by Littler in multiple digital reconstruction, and repeated in burn patients. Metacarpal stacking provides for a stable vascularized osteocutaneous transfer with concomitant deepening of a first web. Distraction osteogenesis and pedicled flaps do provide for a stable post with coverage. However, their usefulness is limited due to poor sensation and less mobility than with either pollicization or toe-to-hand transfers. Pollicization is most commonly done for congenital deficiencies of the hand where forearm musculature is deficient and nerve and functional retraining occurs at a younger age. Free toe-thumb transfer can provide a good alternative to provide a prehensile digit if other options are not available. Adequate soft tissue cover must be in place first to sufficiently cover vital structures and the thumb web.⁷ Digital transfers in the hand allow for re-establishment of a functioning sensate thumb and provide an opportunity for maximum recovery of thumb function. It requires, however, an intelligent cooperative patient for retraining and the availability of an experienced microvascular team.

Reconstruction of dorsal hand deformities

- *MCP joint hyperextension*: This deformity usually arises from a relative deficit of skin on the dorsal surface of the hand as the skin grafts contract. In severe cases, the MCP joints are subluxed. Once the scar is released or excised, if there is not sufficient gain in flexion, it may be necessary to do dorsal capsulotomies to fully release a tight joint. Aggressive physiotherapy and splinting is required postoperatively.²³ The defect can be skin grafted, or if sufficient unburnt skin is available nearby a $3/4$ z-plasty flap can provide coverage. Other options include regional or distant flap coverage (Figures 53.24, 53.25, and 53.26).
- *Wrist hyperextension*: The deformity here is also as a result of contracture of the dorsal skin cover. After release, the defect can be resurfaced by skin grafting, or if unburnt skin is available nearby, by using a $3/4$ z-plasty which can incorporate paratenon if necessary.

Fig. 53.24 MCP joint hyperextension of fifth digit, released by $\frac{3}{4}$ z-plasty. Clockwise from top left.

Isolated linear scar bands may be suitable to z-plasty release. If tendons are exposed post release without a paratenon cover, a flap will be required for coverage (Figures 53.27 and 53.28).

- *Tendon reconstruction:* Isolated extensor tendons can be reconstructed by attaching the remnant of tendon, if there is one, to the adjacent finger's extensor tendon, or the extensor digiti minimi tendon from the little finger and/or the extensor indicis proprius tendon can be used,

Fig. 53.27 Dorsal wrist contracture released with split-thickness skin graft.

Fig. 53.25 Dorsal hand and wrist contracture.

Fig. 53.28 (a) Dorsal wrist and MCP joint contractures. (b) Dorsal wrist and MCP joint contractures of the hand in Figure 53.25a released with split-thickness skin graft and open capsulotomies. K-wires hold the MCP joints in position.

Fig. 53.26 Claw hand deformity.

as these fingers have two extensor tendons.

If more complex repair is required, palmaris longus or extensor tendons from the foot can be used. Surface coverage will be required postoperatively, and in the burn case, this usually requires a flap. The reverse forearm flaps are suitable. A free dorsalis pedis can also be used, and this has the advantage in that the pedal extensor tendons can be harvested as part of this flap.

Reconstruction of volar hand deformities

- *Palmar contracture*: During release of palmar contractures, it is important not to excise any palmar skin, as this affords the best protection and function for the palm. The scar should be incised and released. Many recommend using a full-thickness skin graft to resurface the defect, citing increased durability and decreased rate of recontraction as the benefits. Not all studies have found this to be so, and one study has not found any significant long-term difference between full- and split-thickness grafts¹¹ (Figure 53.29). The dorsal neurocutaneous island flap has also been used for palmar contractures with good results.²⁵
- *Wrist flexion contracture*: The scar contracture may be released, and the defect skin grafted. Again, if unburnt skin is available adjacent to the defect, a $3/4$ z-plasty flap may be used. If tendons are exposed, flap coverage may be required. However, if the paratenon is preserved, a skin graft will take. Reverse forearm flaps may be suitable to reconstruct the defect over exposed tendons. Abduction and adduction should also be assessed when releasing.

Reconstruction of the neurologically impaired hand

Reconstruction of the hand with neurological injury, such as can occur with crush or electrical injuries, may require the use of nerve and tendon grafts. The sural nerve can be used as a donor graft and palmaris longus, the extensor tendons of the foot and plantaris can be used as free tendon grafts. Flap cov-

Fig. 53.29 Release of palmar contracture with split-thickness skin graft. Clockwise from top left.

erage is required to afford protection to the grafts if inadequate local soft tissue is available.²⁶ Tendon transfers may be necessary in some cases.

Vitiligo

Skin grafting can also be extremely useful for treatment of hypopigmentation of the hand. Hypopigmentation areas can be treated by dermabrasion and epithelial sheet graft application²⁷ (Figure 53.30).

Comment

Success in hand reconstructive surgery relies not only on the surgeon but also on patient compliance with the rehabilitation postoperatively. It is also imperative that splinting and mobilization begin early in the acute phase of the injury. Sensitivity to the needs of the burned hand may often be overlooked in the face of other, more overwhelming, burn injuries. However, neglect of the hand during the acute stage makes reconstruction more difficult. In the burned hand, timing of return to work is a very useful indication of early hand care outcome. Early restoration of function aids the return of the patient to society.

All patients with significant hand burns will have some setbacks and delays in the course of their rehabilitation and retraining. Commonly, despite excellent care and state-of-the-art wound dressings, wound excision and skin resurfacing, patients will continue to be plagued with a number of postburn sequelae and less than optimal outcomes related to the depth of their original injury. These include problems with wound healing and development of deformities. Furthermore, patients who suffer from burns of the hand also can develop significant bouts of depression and post-traumatic stress disorders, which impair the burned survivor's ability to participate fully with the rehabilitation progress.

Summary

Reconstruction of the burned hand begins with acute care. Early therapy, control of edema and adequate positioning are

Fig. 53.30 Uneven pigmentation following burn injury.

integral to the successful outcome of the burned hand. Acute soft tissue coverage is chosen based on limitations versus needs. Successful outcomes require cooperation of patient, surgeon and therapist in formulating an acceptable plan for maximum rehabilitation and recovery of the burned person. Despite adequate care in the initial period, a number of post-burn sequelae and contractures still occur. Digital and hand reconstruction require formulation of a well-thought-out plan.

Options include skin grafts, local and distant flaps, and joint capsulotomies. Microvascular transfer of thin, soft-tissue substitutes provides further options for postburn reconstruction. Postoperative rehabilitation is vital for success of hand reconstructive procedures. Outcome of burned hand treatment is related to function and appearance as determined by return to work, quality of daily living and patient self-acceptance.

Introduction

Reconstruction of the head and neck following burn injuries presents great challenges and great opportunities. Successful treatment requires sound surgical judgment and technical expertise, as well as a thorough understanding of the pathophysiology of the burn wound and contractures. Many disciplines are required to successfully care for patients with burns of the head and neck. These include skilled nursing, experienced occupational and physical therapy, and psychological and social support systems. The surgeon must also have familiarity and expertise with non-surgical treatment modalities such as pressure therapy, steroids, and laser therapy. Realistic expectations on the part of both patients and surgeons are essential to achieve successful treatment outcomes. Burns to the head and neck of a serious nature result in tissue injury with scarring and complete removal of scars is not possible. A scar can only be modified or exchanged for a scar or scars of a different variety. Despite this fundamental limitation, reconstruction of the burned face and neck creates great opportunities for plastic surgery to significantly improve functional and aesthetic deformities resulting in profound improvement for this large group of challenging patients.

Burn injuries constrict and deform the face, distorting its features, proportions and expression.¹ Burns also alter the surface of the facial mask by causing scars and altering texture and pigmentation. The changes to the surface of the skin are deforming but are much less important to facial appearance than are the changes in proportion, features, and expression. The removal of scars should not be the primary goal of facial burn reconstruction. A normal looking face with scars is always better looking than an even slightly grotesque looking

face with fewer scars. Mature scars that result from burn injury will often be less conspicuous than surgically created scars or surgically transferred flaps or grafts. The subtle and gradual transition between unburned skin and burn scar is an excellent example of nature's camouflage and can render scarring remarkably inconspicuous. The principal goal of facial burn reconstruction should be the restoration of a pleasing and tension-free facial appearance with appropriate animation and expression.² If this goal is kept in mind and pursued with persistence and determination, the amount of improvement that can result after severe facial burn injury can be remarkable. Ignoring this basic principle can result in iatrogenic catastrophes during reconstructive surgery of the head and neck following burn injury.

Successful reconstruction of burn deformities of the head and neck requires a well-functioning and extensive team.³ Major burn deformities in this area can be intimidating and overwhelming. Experience and a specialized infrastructure are required to take care of these patients comfortably and successfully. Familiarity with their unique problems and a firm commitment to correcting their challenging deformities is required from all members of the reconstructive team. The care of a patient from the onset of a major burn involving the head and neck to a successful reconstructive outcome requires skill, patience, determination, and enthusiasm from all who are involved.

Acute management

Although the main focus of this chapter is the reconstruction of established facial burn deformities, an understanding of the acute care of facial burn injuries is necessary in order for the surgeon to have an accurate perspective. Excision and grafting of deep second-degree and full-thickness burns has become the standard of care since it was first proposed in 1947.⁴⁻⁶ It remains controversial whether this is the optimum treatment for facial burn injuries. Early excision and grafting of the face is problematic because of the difficulty in diagnosing the depth of the facial burn and accurately predicting an individual patient's long-term prognosis both functionally and aesthetically. The overwhelming majority of facial burns treated conservatively with a moist regimen of topical antibiotics will be healed within 3 weeks. Burns which are clearly full-thickness are best treated by early excision and grafting within 7-10 days to promote early wound closure and minimize contractile forces (Figure 54.1). The problem cases are those where healing has not occurred by 2-4 weeks or longer. Early

Fig. 54.1 (a) Five-year-old Native American girl 3 days after deep second- and third-degree burns to her face. (b) Tangential excision and split-thickness autografting were performed on the 10th postburn day. (c) Five years after facial excision and grafting. She has had a subsequent nasal reconstruction.

tangential excision and grafting has been proposed for these patients in order to achieve more favorable healing with less eventual contracture deformities.⁷ Proponents of conservative therapy argue that early excision and grafting may result in a patient with a grafted face who would otherwise have healed favorably by successfully epithelializing their partial-thickness burn from skin appendages.⁸ Conservative

management has been facilitated by the myriad ancillary techniques currently available to favorably influence the healing of facial burns such as pressure, silicone, silicone-lined computer-generated face masks, topical and interlesional steroids, vitamin E, massage, and treatment with the pulsed-dye laser. Impressive results have been obtained by advocates for early excision and grafting.⁹ Very good outcomes, however, can also

be achieved by being more conservative with this difficult group of patients (Figure 54.2). The majority of acute facial burns are treated conservatively in most burn centers, with early excision and grafting limited to those cases where it is clear that a full-thickness burn injury has occurred.

Pathogenesis

Superficial second-degree burns usually heal without scarring or pigmentary changes. Medium-thickness second-degree burns which epithelialize in 10–14 days usually heal without

scarring, although there can be long-term changes in skin texture and pigmentation. Deep second-degree burns which epithelialize in 14–28 days or longer must be carefully managed for they have a propensity to develop severe late hypertrophic scarring (Figure 54.3). These patients should be closely monitored after initial healing and at the first sign of hypertrophy must be managed with all available ancillary treatment modalities. Pressure garments have been shown over several decades to be effective in suppressing and reversing hypertrophic scarring. Adding silicone to pressure therapy seems to increase its efficacy. Computer-generated clear face masks lined with sili-

cone have improved the ability to deliver pressure to facial hypertrophic scars and are better tolerated by patients (Figure 54.4). When tension plays a role in the development of early hypertrophic scarring, relief of the tension with either focal z-plasty or judicious release and grafting can be very helpful. Full-thickness facial burns should usually be excised and grafted unless focal and small.

Evaluation of facial burn deformities

Facial burn reconstruction should be based on an overall strategy and a clear understanding of the fundamental problems. Many reconstructive techniques have been described in the literature and most can be successful if the strategic goals are appropriate.¹⁰⁻¹² The best reconstructive plan is usually a judicious combination of contracture releases by z-plasty, grafts, and flaps, followed by appropriate scar revision.²

Deep second- and third-degree burns heal by contraction and epithelialization. The more severe the burn injury, the more contraction takes place during the healing process. The changes in facial appearance following a deep second-degree burn injury are dramatically demonstrated in Figure 54.5. Three weeks following a deep second-degree burn, the patient's facial features and proportions remain essentially normal. Six months later, contractile forces have deformed the facies in a pattern that is repeated to a variable degree in virtually all severe facial burns. These changes make up the stigmata of facial burn injury and are listed in Box 54.1. The eyelids are distorted with ectropion, the nose is foreshortened with ala flaring, the upper lip is shortened and retruded with loss of philtral contour, the lower lip is everted and inferiorly displaced, the lower lip is wider than the upper lip in anterior view. The tissues of the face and neck are drawn into the same

plane with loss of jawline definition. The severity of these changes is proportional to the severity of the injury.

Fortunately, the majority of facial burn injuries are not severe and do not involve the entire face. A relatively small number of patients sustain injuries which deeply involve the entire face such as shown in Figure 54.5. It can be helpful to separate patients with facial burn deformities into two funda-

Fig. 54.5 (a) Three weeks following a deep second-degree burn with essentially normal facial features and proportions. (b) Six months later, contraction and hypertrophy have created facial burn stigmata.

BOX 54.1 Stigmata of facial burns

- Lower eyelid ectropion
- Short nose with ala flaring
- Short retruded upper lip
- Lower lip eversion
- Lower lip inferior displacement
- Flat facial features
- Loss of jawline definition

BOX 54.2 Facial burn categories**TYPE I:**

Essentially normal faces with focal or diffuse burn scarring with or without contractures

TYPE II:

Pan-facial burn deformities with some or all of the stigmata of facial burns

mentally different categories as described in Box 54.2. Type I deformities consist of essentially normal faces that have focal or diffuse scarring from their burns and may have associated contractures. Type II deformities make up a much smaller number of patients who have ‘pan-facial’ burn deformities with some or even all of the facial burn stigmata. Although these categories are not rigidly defined and there are some patients who do not fit neatly into one or the other, understanding the fundamental difference between these two groups of patients can help define treatment goals. It can also aid in selecting the most appropriate methods for reconstructive surgery.

Patients with type I deformities have an essentially normal facial appearance despite scars from their burns. In these patients, one must be certain that surgical intervention does not adversely alter normal facial features or create distortion from iatrogenically induced tension. Overall facial appearance should not be sacrificed in an effort to ‘excise scars.’ The best reconstructive options for patients with type I facial burn deformities are usually scar release and revision with z-plasties, full-thickness skin grafts, or tissue rearrangement with local flaps. The pulsed-dye laser can be helpful for decreasing post-burn erythema and treating persistently erythematous burn scars. Full-thickness skin grafts are excellent for focal contractures. Z-plasties in combination with the pulsed-dye laser can be a powerful scar-improving combination (Figure 54.6). Excision of scars and resurfacing operations in aesthetic units and major flap transpositions with or without tissue expansion are rarely indicated.

The much less frequently encountered group of patients with type II facial burn deformities presents a completely different clinical situation. Examples of patients falling into the type II category are shown in Figure 54.7. The surgical goals for this group of patients should be the restoration of normal facial proportion and as much as possible the restoration of the position and shape of normal facial features. The intrinsic and

extrinsic contractures that exist in these patients require large amounts of skin. The correction of these contractures should be carried out in a carefully planned and staged fashion. The sequence of operations is usually the following: eyelids, lower lip and chin, upper lip, cheeks, nose, and then other residual deformities. As each area is reconstructed, the addition of skin results in the relief of tension, which benefits other areas of the face. Excision of normal skin or elastic healed second-degree burned skin is almost never indicated. After facial proportion has been achieved and facial features have been restored to their normal location and shape without tension, scar revision can be carried out to smooth and blend the remaining junctional scars (Figure 54.8).

Normal faces are a mosaic of colors, textures, wrinkles and irregularities. In a face which has undergone major burn injury, a mosaic appearance of scars, grafts, pigmentary abnormalities and other flaws can be attractive as long as the facial features are restored to a normal location and are sufficiently loose and mobile for normal and appropriate facial expression. Cosmetics can be useful for blending and camouflaging areas of pigmentary and texture abnormalities, particularly in females.

Fundamental principles and techniques

Contractures

Burn injuries result in open wounds which heal by either contraction and epithelialization or are closed by skin grafting. Contractures result from both of these forms of wound healing. Contractures are either intrinsic or extrinsic. Intrinsic contractures result from loss of tissue in the injured area with subsequent distortion of the involved anatomic part. Extrinsic contractures are those in which the loss of tissue is at a distance from the affected area but the distorted structures such as eyelids or lips are not injured themselves. Corrective measures should be directed at the cause of the contracture in order to provide optimal benefit and prevent iatrogenic deformities. It is helpful to minimize the amount of skin and scar which is excised when correcting facial contractures. When tension is released, many scars will mature favorably and become inconspicuous. Even long-standing scars will respond to a change in their environment. Healed second-degree burns under tension may be unattractive but when restored to a tension-free state can be superior in function and appearance to any replacement tissue. Minimizing excision also decreases the amount of new skin which must be provided in the reconstruction. Every effort should be made to relieve tension from the face when performing burn reconstruction. Tight faces are never attractive. Tight scars are always hypertrophic and erythematous. Relaxed scars are happy scars.

Aesthetic units

The concept of facial aesthetic units has profoundly affected plastic surgical thinking since its introduction by Gonzalez-Ulloa.¹³ Initially conceived as the ideal approach for resurfacing the face following burn injury, this important concept has been emphasized in virtually all subsequent writings about facial burns. It is important to keep facial aesthetic units in mind during burn reconstruction but the desire to adhere to this concept should not supersede common sense. When small

Fig. 54.6 (a) Hypertrophic scarring of both cheeks, lips and chin 6 months following flame burn. (b) Multiple z-plasties release tension on facial scars. (c) Pulsed-dye laser therapy can be used to decrease erythema. (d) Improved appearance 3 years following burn. No scars have been excised.

unburned and unimportant islands of skin are in an aesthetic unit that is being resurfaced, they can be sacrificed. Otherwise, the excision of normal facial skin is rarely indicated in burn reconstruction. All burned faces to some degree are mosaic. Scar revision with z-plasties is an excellent technique to camouflage scars in a burned face. Mosaic faces which are proportional, tension free, and normally expressive appear much better in real life than they do in images.

Z-plasty

The z-plasty operation is a powerful tool in the surgeon's armamentarium for facial burn reconstruction. The z-plasty

has been used for over 150 years to lengthen linear scars by recruiting lax adjacent lateral tissue.¹⁴ Z-plasty can also cause a profound beneficial influence on the physiology of scar tissue when it is carried out within the scarred tissues rather than after excising them.¹⁵ The physiology of this phenomenon is related to the immediate and continuing breakdown of collagen which occurs in hypertrophic scars following the relief of tension.¹⁶ Z-plasty also narrows scars at the same time that it lengthens them. In addition, the z-plasty adds to scar camouflage by making the borders of the scar more irregular. In order for z-plasties to lengthen a burn scar and restore elasticity, the lateral limbs of the z-plasty must extend beyond the

Fig. 54.7 (a, b) Typical examples of patients with 'pan-facial' burns resulting in type II facial deformities.

margins of the scar. The improvement in the appearance of facial scars following z-plasty and without any scar excision can be dramatic, particularly when combined with pulsed-dye laser treatment (Figure 54.6).

Grafts

Skin grafts are an essential part of facial burn reconstruction. Surgical decisions regarding donor site selection, the use of split-thickness versus full-thickness grafts, the timing of intervention and the postoperative management of grafts often determine the success or failure of facial burn reconstruction. Split-thickness skin grafts contract more than full-thickness grafts, wrinkle more, and always remain shiny with a 'glossy finish' look. Split-thickness skin grafts should be used primarily in the periphery of the face unless the limited availability of donor sites requires their use in more prominent areas. Split-thickness skin grafts can be excellent for upper eyelid releasing and resurfacing. Hyperpigmentation of split-thickness grafts on the face is a frequently occurring problem in dark-skinned patients, particularly of African descent.

The full-thickness skin graft is a reliable workhorse in facial burn reconstruction. The broad, central, conspicuous areas of the face such as the cheeks, upper and lower lips, and dorsum of the nose are excellent sites for the use of full-thickness grafts. The missing or damaged parts in the vast majority of even severe facial thermal burns are the epidermis and the dermis and that is what full-thickness skin grafts provide. After facial burns, the subcutaneous fat may be compressed or distorted by contractures but it is rare that it is lost or injured. Adequate skin must be provided when doing definitive resurfacing operations with full-thickness grafts. Contractures must be overcorrected and postoperative management with conformers and pressure is essential. Full-thickness skin grafts are very reliable when used electively in the face for reconstruction after burns.¹⁷

Flaps

Flaps can be useful for facial burn reconstruction but they must be used judiciously and skillfully, recognizing their problems and limitations. The thickness of skin flaps from all distant donor sites is greater than that of the normal facial skin. The face is tight following burn injury and flaps tend to contract when transferred. They can, therefore, compress or obscure underlying tissue contours. Transposing or advancing flaps from the neck and chest up to the face can easily create extrinsic contractures that adversely affect facial appearance. When flaps have been enlarged by tissue expansion, they are even more dangerous in this regard. Contractures with a downward vector create a 'sad' facial appearance that is distressing to patients. Cervicopectoral flaps provide the best color match in color and texture to facial skin. Distant flaps, whether transferred by traditional technique or microsurgery, share the common flaw of poor match in terms of color and texture.

Tissue expansion

Tissue expanders must be used with caution in the reconstruction of the head and neck. The underlying theme of almost all burn deformities is tension secondary to tissue deficiency. Stretching adjacent tissue in order to carry out scar excision can easily result in an increase in tension and, therefore, create iatrogenic contour abnormalities. The complication rate of tissue expansion in the head and neck area following burn injury is high.¹⁸⁻²⁰ As noted before, care must be taken when advancing or transposing expanded flaps from the cervicopectoral area to the face as it can create extrinsic contractures with a downward vector.

Timing of reconstructive surgery

The timing of reconstructive plastic surgery following facial burn injury falls into three separate phases: acute, intermediate, and late. Specialized burn centers create an ideal patient-care environment where acute care and reconstructive surgery

Fig. 54.8 (a, b) Twenty-nine-year-old firefighter with 'pan-facial' burn deformity causing facial burn stigmata. (c, d) Seven years later following the reconstructive sequence outlined in the text. Facial features and proportion have been restored. Note philtrum reconstruction with composite graft from ear triangular fossa.

can be planned and carried out in optimal circumstances with collaboration among acute and reconstructive physicians and surgeons. The reconstruction of facial burn injuries to the head and neck should optimally begin with the acute care.

Acute reconstructive surgery occurs during the first months following the burn injury and includes urgent procedures which are required to facilitate patient care or to prevent acute contractures from causing permanent secondary damage. Acute reconstructive intervention is most frequently indicated in the eyelid, perioral, and cervical areas. Intermediate reconstructive surgery takes place during the months to years after wounds are closed and the scar maturation process is proceeding. During this phase of recovery, some patients will present

to the reconstructive surgeon after having received their acute burn care at another facility. Timely intervention when indicated is important in this group of patients as it can positively influence further maturation of scars and grafts. Late-phase reconstructive patients present to the reconstructive surgeon with established facial burn deformities many years following their acute injury.

Acute-phase reconstruction

Eyelids

Upper and lower eyelid ectropion can occur from burn injuries to the periorbital region (intrinsic contracture) or may arise secondarily as a result of the contracture of open wounds and

skin grafts at more distant sites (extrinsic contracture). With severe ectropion such as shown in Figure 54.9a, early intervention is mandatory in order to prevent irreversible injury to the cornea. Conservative measures to protect the cornea, such as temporary sutures or contact lenses, are often ineffective. Tarsorrhaphy can cause irreversible iatrogenic injury and should not be used. The best treatment is early intervention with release of contracture and resurfacing with split-thickness skin grafts (Figure 54.9b). Release of even extreme contractures with grafting can be done in the presence of open wounds and effectively restores protective eyelid function.

Perioral deformities

Microstomia occurs from circumferential scarring at the junction between lips and cheek. Perioral scarring from either open wounds or contraction of skin graft suture lines can act as a pursestring, resulting in diminished oral opening (Figure 54.10). This can compromise alimentation and airway access. Microstomia is best addressed by the acute release of the oral commissures taking care to avoid extensive transverse releasing incisions in the aesthetic units of the cheek. Overcorrection can easily result in macrostomia. As soon as adequate oral opening is achieved for feeding and airway access, definitive reconstruction is best left for the post-acute period.

Macrostomia is caused by rapid contraction of open wounds or grafts in the cheek and perioral region, resulting in eversion of the upper and lower lips and lateral movement of the oral

commissures (Figure 54.11). The loss of an effective oral sphincter causes drooling and desiccation of the oral mucosa, and can result in irreversible damage to the dentition. Early intervention with release and grafting of the lower and/or upper lips should be carried out as soon as possible. Definitive reconstruction is best carried out at a later period.

Fig. 54.9 (a) Extreme eyelid ectropion during early acute phase. (b) Successful correction of ectropion with release and graft despite operative wounds.

Fig. 54.10 Microstomia during acute phase as a result of circum-oral contracture.

Fig. 54.11 Macrostomia secondary to contracture of open wounds and grafts with lip eversion and loss of oral competence.

Cervical deformities

Anterior neck contractures in the acute period are best prevented by aggressive splinting and incisional releases and grafting when indicated.²¹ When severe anterior neck flexion contractures occur, early release and grafting is necessary to allow for adequate airway access and to minimize hypertrophic scarring as a result of excessive and persistent tension (Figure 54.12). Although secondary releases and grafts are often necessary, permanent correction of neck contractures with split-thickness skin grafts is frequently possible when

postoperative management includes proper splinting and pressure²¹ (Figure 54.12).

Intermediate-phase reconstruction

The intermediate phase of plastic surgical intervention consists of scar modification designed to favorably influence the healing process in the early months to years following acute wound closure. The treatment options during this period are multifaceted and are continuing to evolve. Significant progress is being made with these types of interventions.

Fig. 54.12 (a, b) Extreme anterior cervical contracture secondary to burns of the entire chest and neck. (c, d) Twenty-three years postburn after release and split-thickness skin grafting. Two additional releases and grafts were required.

It is often recommended that definitive reconstructive surgery be carried out after facial scars and skin grafts are mature, soft, and supple. This process takes at least a year and frequently takes many years to fully occur. The maturation of facial burn scars takes much longer than is generally appreciated by patients and reconstructive surgeons alike. If scars are continuing to improve, it is usually best to allow them to continue to mature. If scars are not maturing favorably, well-timed and well-conceived surgical intervention to favorably influence the scar maturation process can be beneficial. The scar maturation process after facial burns is influenced by multiple factors. The most important factor other than the

initial severity of the injury is the amount of tension present in the face and acting on the scars. Surgical procedures to decrease tension and to favorably alter the direction and contour of scars can achieve significant improvement in scar maturation for many years following a burn. Whenever healing burns cross concave surfaces, there is a tendency for hypertrophic scarring to develop. Examples in the face are the glabella, the nasojugal groove, the crus helicus of the ear, and the infra commissural folds. Relieving tension with z-plasties without scar excision is very effective in correcting hypertrophy (Figure 54.13). Steroids, both topically and intralesionally, can be helpful during this period but must be used sparingly

Fig. 54.13 (a, b) Diffuse, hypertrophic scarring of cheeks, chin, and lips 8 months following flame burn injury. (c, d) Twelve years postburn after treatment with pressure therapy, steroid injections, and multiple z-plasties within the scar tissue. No scar tissue was excised.

to avoid atrophy, telangiectasias, and erythema. Tension can also be relieved by judiciously placed releases and skin grafts. The skin grafts can be of either split-thickness or full-thickness variety. Split-thickness skin grafts are best used where the location of the graft will be inconspicuous or where large amounts of skin are required to relieve the contractures. This is frequently indicated when there are associated neck contractures. Tension from the neck must be eliminated as much as possible to allow for favorable maturation of facial burn scars. The use of full-thickness skin grafts during the intermediate phase of reconstruction should be rare and limited to circumstances where definitive repair is being carried out and there is little chance that further skin will be required in that region. The pulsed-dye laser is a promising adjunctive therapy which can decrease erythema and speed the rate of scar maturation (Figure 54.6).

Late-phase reconstruction

Late-phase reconstructive surgery takes place when scars are mature and the patient's deformities are essentially stable. In some patients, scars will be soft and supple, but in others, even long-standing scars may be hypertrophic and hyperemic many years following the burn injury because of persisting tension or unfavorable orientation. Scars can remain indurated and hyperemic for decades following a facial burn. Reorientation in this late phase with z-plasties and treatment with the pulsed-dye laser can result in remarkable improvement (Figure 54.14). Scar excision can often be avoided with its concomitant increase in facial skin tension and distortion of facial features.

Reconstruction of specific areas of the head and neck

Eyebrows

Eyebrow reconstruction following complete loss is an unsolved surgical problem. Composite grafts of hair-bearing scalp from carefully selected sites in the retroauricular area can satisfactorily transfer hair.²²⁻²⁴ Unfortunately, the hair is scalp hair which grows rapidly and is more projecting than the tangential delicate hair of the normal eyebrow. For complete eyebrow replacement, the technique of composite grafting as described by Brent²² is most useful. For partial eyebrow loss, micro- and mini-grafting of scalp hair can be efficacious. Occasionally, borrowing composite grafts from a contralateral unburned eyebrow is appropriate. Temporal artery island flaps for eyelid or eyebrow reconstruction have been used for many years.^{23,25,26} When used for eyebrow reconstruction, they can be bushy and conspicuous and should be used with caution, particularly when carrying out unilateral eyebrow reconstruction.

Eyelids

Correction of upper and lower eyelid contractures in the late reconstructive period can be a daunting and humbling challenge. The periorbital region is made up of complex three-dimensional anatomy and requires abundant skin to appropriately drape the contours of both the upper and lower eyelids. The slightest amount of excessive tension from either the eyelid skin itself or contractures in adjacent regions such as the forehead or cheek can profoundly and adversely effect

Fig. 54.14 (a) Sixteen-year-old female 11 years following contact burn. Right cheek scar remains erythematous, indurated, and conspicuous. (b) Relaxation and reorientation of scar tissue with z-plasty. (c) Five years later after six treatments with the pulsed-dye laser.

eyelid function and appearance. Reconstructive goals should be restoration of a normally shaped palpebral fissure with appropriate orientation of upper and lower eyelashes at rest and in the open position whenever possible. This often requires extensive releasing incisions extending medial to the medial canthus and lateral to the lateral canthus in order to adequately release all the contracted tissues. When ectropion is the result of a distant contracture, the normal eyelid skin should always be returned to its normal location. Incisions should not be made at the eyelid margin, thereby separating the normal eyelid skin from the ciliary line and replacing it with a graft. When overlying scar is released, care must be taken to prevent injury to the underlying orbicularis oculi muscle. This is often rolled up and contracted and is rarely completely lost. It must be unfolded to its normal flat broad shape and the resulting defect resurfaced with abundant skin graft. Upper eyelid resurfacing is best carried out with split-thickness skin grafts from the best available donor site.²³ Full-thickness skin grafts in the upper eyelid usually transfer a thick dermal component which compromises the delicate contour of the supratarsal fold. Lower eyelid resurfacing may be done with either split-thickness skin grafts or appropriate full-thickness grafts when indicated. For minor contractures of either upper or lower eyelids, the perfect reconstructive material can be obtained from an unburned contralateral upper eyelid. Medial canthal folds are best corrected with z-plasties when there is not a significant tissue deficiency.²⁷

Lower lip and chin

Deformities of the lower lip and chin usually occur in combination. Contracting forces result in inferior dislocation and eversion of the lower lip. In addition, there is compression of the soft-tissue contours of the chin prominence. Release should be carried out at the vermilion scar junction and the lower lip carefully unfurled taking care to prevent iatrogenic injury to the underlying orbicularis oris muscle.¹² The resulting defect is then resurfaced with split-thickness skin grafts or full-thickness grafts when indicated. Restoration of chin contour can be improved with chin implants.

Upper lip deformities

The upper lip is usually shortened and retruded by severe facial burn injuries. Releasing and grafting should be carried out, taking care not to overcorrect the deformity and create a long upper lip.¹² Full-thickness grafts from the best available donor sites are usually the best option for resurfacing. Reconstruction of the philtrum when indicated is best performed by the technique of Schmid²⁸ using a composite graft from the triangular fossa of the ear (see Figures 54.8 and 54.17).

Electrical burns of the oral commissure

Electrical burns of the oral commissure constitute a unique and challenging burn injury to the head and neck. The injury occurs in small children and usually results from placing a live extension cord outlet in the mouth. Most of these injuries are minor and all should be treated conservatively in the acute period. If there has been minimal tissue loss, reconstructive

surgery using local flaps can improve aesthetics.²⁹⁻³¹ When there has been extensive full-thickness loss of skin, vermilion, mucosa, and muscle, as shown in Figure 54.15, reconstruction with a ventral tongue flap can be advantageous.³² Releasing the contracture associated with the deformity can help restore normal mobility and facial expression (Figure 54.16).

Nasal deformities

Burn injuries to the nose result in a broad range of deformities which can be focal and minor or can result in complete nasal amputation. Minor deformities are best dealt with by local scar revision, particularly with z-plasties to relieve contractures, or releases in combination with full-thickness skin grafting. Shortening of the nose with flaring or partial loss of the alar rims is common in more severe facial burns. Local release of the alar lobules with full-thickness skin grafts is a useful technique for minor to moderate contractures. Complete excision of dorsal scar and graft in an aesthetic unit with a full-thickness skin graft is useful for more severe shortening. When the lower third of the nose has been amputated by the burn injury,

Fig. 54.15 (a) Severe oral commissure burns destroy vermilion, mucosa, muscle, and the skin of the lip and cheek. (b) Extensive contracture results with thickening of the leading edge of the commissure.

Fig. 54.16 (a) Sixteen years following devastating right oral commissure electrical burn. Forty-percent of lip circumference is lost and the commissure is thick and immobile. (b) Following tongue flap reconstruction, the commissure is thin and mobile and facial expression is restored.

inferiorly-based, turn-down flaps of the dorsal nasal tissues can provide satisfactory lengthening and improved contour to the tip and alar lobules. More severe cases of nasal deformity can be treated by either dorsal turn-down flaps or other forms of total nasal reconstruction. The dorsal turn-down flap usually requires at least two stages but can be effective in even near total nasal amputation (Figure 54.17). Forehead flaps are usually unavailable in patients who have sustained facial burns severe enough to result in total nasal amputation. Distant flaps can be used with either microsurgical transfer using a radial forearm flap or using the frequently unburned skin of the upper inner arm for a Tagliacozzi flap. If the face is otherwise composed of burn scar and graft, these distant flap nasal reconstructions have the disadvantage of appearing to be ‘stuck on’ and stand out in the midst of the otherwise mosaic appearance of the face. When the face has required resurfacing with flaps, a nasal reconstruction with flap tissue is the best option (Figure 54.18).

Ear deformities

Improved care in the acute phase of burn injury has greatly decreased the incidence of helical chondritis and the resulting associated deformities of crumpled or lost cartilage. Minor ear deformities are often seen in patients with little or no hair loss and can easily be camouflaged. Larger defects can be treated by myriad local reconstructive techniques.^{10,33–35} Subtotal ear amputation (Figure 54.19) often lends itself to reconstruction with a conchal transposition flap and skin graft.³⁶ Complete ear loss can be masked by the use of a prosthesis. Fixation has been improved by the use of osteo-integrated implants but cost and color changes remain problematic. Selected patients can be appropriate candidates for total ear reconstruction using

autologous cartilage and soft-tissue coverage from either temporalis fascia flaps, or expanded local tissue.³⁷ Alloplastic materials should not be used in the reconstruction of postburn ear deformities due to an acceptably high extrusion rate.³⁸

Burn neck contractures

Prevention

Cervical contractures are a major problem in burns involving the chest, neck, and face. The anterior neck skin is thin and the neck is a highly mobile flexion area easily prone to contracture. As noted previously, severe neck flexion neck contractures in the acute phase often require early reconstruction to aid in airway management. Neck contractures should usually be dealt with prior to carrying out facial burn reconstruction as the extrinsic contractile forces from the neck cause facial deformities and can adversely affect the maturation of scars on the face. Preventive methods to minimize cervical contractures during the acute period as burn scars and grafted areas contract include splinting, physical therapy, neck collars, and the use of a three-quarter mattress to encourage neck extension.

Release and grafting

The majority of anterior neck contractures can be satisfactorily treated with release and skin grafting. Extensive contractures usually require split-thickness skin grafting. Focal contractures can be appropriate for full-thickness grafting, which will result in a superior outcome from both a functional and aesthetic standpoint. When neck contractures are exten-

Fig. 54.17 (a) Three-year-old female 10 months following severe facial burn with subtotal nasal amputation. (b) Intraoperative design of a nasal turn-down flap. (c) Split-thickness skin grafting to nasal dorsum following turn-down flap and contracture releases. (d) Fourteen years following turn-down flap after second release and graft.

sive, the lower face and chest are usually a combination of healed skin graft and scar. Split-thickness skin grafts represent 'like tissue' and will blend into the area (Figure 54.12).

Local flap reconstruction

When split-thickness skin grafting is unsuccessful because of recurrent contracture or does not provide a satisfactory aesthetic result, local flap reconstruction of the anterior neck is an excellent technique if there is available tissue. Flaps can either be unilateral or bilateral. When bilateral flaps are available, midline z-plasties secondarily can help to improve neck contour (Figure 54.20). Donor site morbidity is usually minimal

as the upper chest in these patients has frequently been disfigured to some degree by the burn injury.

Distant flap reconstruction

Free flaps have been advocated for the treatment of anterior neck contractures.³⁹ Excellent outcomes can be obtained but require microsurgical technique and create the possibility of complete flap loss. Another potential negative of free flaps to the anterior neck is that they can be thick and bulky, requiring multiple defatting and secondary revisions. The free flap can also appear to be an island in the midst of a broad area of healed graft and burn scar.

Abstract

The involvement of the head and neck can occur in 25–45% of patients with burn injuries. Unfortunately, scalp burns can result in significant burn alopecia. The management of these problems depends on the location and extent of the alopecia. Tissue expansion has become an important part of the armamentarium for correction of this problem with acceptable complication rates. The results of correction of burn alopecia with tissue expansion are an important part of our surgical strategy in the aesthetic reconstruction of cicatricial alopecia.

Introduction

Clinical studies involving soft tissue injuries in patients with large total body surface burns document involvement of the head and neck from 25% to 45%.^{1,2} Scarring is the normal end result of any deep traumatic injury to the skin. Burn injury only represents a segment of traumatic injuries in which scarring may become problematic. Scarring can limit function and can be aesthetically displeasing. The long-term effects of deep burns to the scalp is cicatricial alopecia. The management of this problem depends on these facts:

- the size of the defect,
- its location, and
- the status of the remaining hair-bearing scalp.

The scalp has been a popular donor site for coverage of patients with large total body surface area (TBSA) burns. In 1989, Brou et al. reported a 61% incidence of alopecia in patients with existing scalp burns in which skin grafts were subsequently harvested for wound closure.³ However, only a 2.2% incidence

of alopecia is noted in patients without burns to the scalp who underwent harvesting of scalp grafts for closure of burn wounds.⁴ Yet, regardless of the etiology, burn scar alopecia can pose a significant problem for reconstructive surgeons.

The extensive use of skin grafts, local skin flaps, distant flaps and microvascular free tissue transfer has given plastic surgeons significant tools in the reconstruction of burn patients. However, inherent in each of these techniques are problems with color match and texture. In addition, donor site disfigurement may also play a role. Skin expansion is based on the dynamic nature by which living tissue responds to mechanical stress. Controlled soft tissue expansion offers many advantages over other modalities in the reconstruction of burn patients. The color and texture of expanded skin is a better match to the surrounding tissues than skin grafts or even distant flaps. Donor site morbidity can be minimized. In addition, expanded skin maintains sensibility. Although tissue expansion has numerous advantages, it is not recommended in all situations. Yet, it is such a valuable technique that it has become an integral part of the armamentarium in the reconstruction of burn patients.

Approaches to the correction of burn alopecia

Reconstruction of scalp defects with the use of excision and primary closure has proven to be applicable in regions with small defects.^{5,6} Indeed, serial excisions have been reported to be successful in the correction of burn alopecia if less than 15% of the hair-bearing scalp is involved. Huang et al. reported the successful use of primary excision and/or rotation flaps in the correction of defects covering 15% of the hair-bearing scalp.⁷ Although, these methods remain useful in the correction of small scalp defects, larger defects often require more involved surgical techniques.

Orticochea introduced the four-flap technique for reconstruction of scalp defects. This technique was subsequently modified to a three-flap scalp reconstruction in 1971.^{8,9} These methods have been quite useful in the correction of moderate-size alopecia defects. The primary disadvantage of these techniques relates to extensive blood loss and the excessive scarring which results from mobilization of multiple scalp flaps. In addition, very large defects may not be closed completely.¹⁰ Subsequently, Juri et al., taking advantage of the profuse blood supply of the scalp, used a variety of monopodiced scalp flaps to cover segmental areas of alopecia, especially in the frontal region.^{11–13} The use of this pedicled flap was limited unless the

size of the alopecia segment to be corrected was small. However, Feldman showed increased coverage of patients with significant burn alopecia when horizontal scalp reduction was used in combination with the Juri flap.¹⁴ More recently, Barrera has shown that the use of micrografts and minigrafts can be very successful in the correction of large alopecia segments in 32 burn patients.¹⁵ Because of the size of micrografts (1–2 hair follicles) and minigrafts (3–4 hair follicles), the metabolic rate is quite low, thereby allowing them to survive in scar tissue. This technique may be used in combination with tissue expansion. However, the clinical application of tissue expansion to the closure of large scalp defects without excessive scarring has revolutionized our approach to this problem.

Tissue expansion: historical aspects

Skin expansion is based on the dynamic nature in which living tissue responds to a constant mechanical stress load. Our ability to gain or lose massive amounts of weight demonstrates the ability of the skin to develop independently. Tissue expansion represents a medical application of the normal physiological process for the correction of significant traumatic defects using identical tissue.

As part of the exotic aesthetics of various cultures, tissue expansion has achieved significant social implications in a variety of societies throughout the world. The enlarged lips of the Acaridan women were primarily developed to accentuate their own sense of beauty. The elongated necks that were subsequently produced in the Padaung women of Burma also attest to the exotic aesthetics associated with tissue expansion.¹⁶

However, clinical uses of soft tissue expansion did not gain significance until 1905 when bone lengthening by distraction also resulted in the expansion of soft tissue.¹ These experiments were initially conducted by Codivilla with subsequent follow-up by Putti in 1921.² The first reported clinical case of pure soft tissue expansion was reported in 1957 by Neumann for the reconstruction of a traumatic ear defect by expansion of post-auricular skin using a subcutaneous balloon.¹⁷ This expanded flap was then advanced to cover the cartilaginous framework. Yet the concept of soft tissue expansion to correct traumatic defects did not resurface for another 20 years. In 1975, Radavan and Austed, working independently, re-introduced the concept of soft tissue expansion using a silicone implant.^{18–20} Although Radavan became the first surgeon to gain extensive experience in the use of silicone expanders, Austed first reported the laboratory and research experience with tissue expanders prior to subsequent clinical use.^{18,19}

Biology of tissue expansion

Histological studies of skin

Experimental data on the biology of tissue expanders have resulted from animal experimentation.^{20–22} Subsequent human studies were noted to be similar to the animal data.²³ Initial studies by Pasyk et al. showed that the epidermis lost rete and became thicker. These changes persisted 2 years after expansion. Histological examination of the dermis revealed a thinner dermis, with the most significant thinning occurring in the

reticular dermis. In addition, it was noted that there was an increase in dermal collagen content with disruption of elastic fibers. However, no significant changes in skin appendages were seen. Electron microscopy did not show any significant physiological changes in the skin associated with soft tissue expansion.

Vascular supply of expanded skin

Several investigators have observed a significant increase in vascularity associated with soft tissue expansion both histologically and clinically.^{24–26} Several investigators have noted a significant proliferation of blood vessels associated with tissue expansion.^{24–26} This vascular proliferation occurs primarily at the junction of the capsule and the host tissues. Within days of expansion, small capillaries become distended and the number of arterioles and venules increase. Cherry et al. showed an increase in the surviving length of expanded skin flaps when compared to delayed skin flaps.²⁴ Sasaki et al., using labeled microspheres, confirmed these earlier studies while also documenting an increase in blood flow associated with expanded skin flaps.²⁵ Lantieri et al. believed that vascular endothelial growth factor (VEGF) may play a role in the development of the increased vascularity noted in expanded flaps. This conclusion was based on the fact that the immunolocalization of VEGF only occurred in expanded skin when compared to unexpanded skin.²⁶ The ability of soft tissues to expand is based on several physiological properties. The skin has a constant ability to adapt, although this depends primarily on the amount and distribution of structural proteins and tissue fluids. Collagen fibers become parallel with the stretching of the tissue. Although elastin fibers are important for recoil after stretching, collagen fibers lengthen permanently.

Molecular basis for tissue expansion

Initial studies by several investigations documented an increased mitotic index in the epidermal layer of the skin with expansion.^{20,27} Takei et al. felt that a number of growth factors were involved in this strain-induced cellular activity.²⁸ The process of expansion not only affects adjacent tissue but also a number of cell types. This group postulated that platelet-derived growth factor (PDGF), as well as other growth factors, could stimulate cutaneous cells. While it is well known that transforming growth factor-beta (TGF- β) can influence extracellular matrix production, TGF- β can also enhance fibroblast proliferation. Lastly, membrane-bound molecules may also play a role in the regulation of intercellular signal transduction pathways (Figures 55.1 and 55.2). However, the exact mechanism by which strain influences skin biology is still unclear. Whether we can modulate this response in other ways remains to be seen.

Clinical application of tissue expansion in burn alopecia

The role of tissue expansion in the correction of burn alopecia has slowly become recognized as the gold standard with which other reconstructive methods must be compared. With the increased survival of patients with large total body surface area burns, reconstruction of significant scalp defects has become quite a challenge.

As previously noted, prior to expansion, burn alopecia was managed with serial excision and coverage using local flaps. Huang et al. reported his series of patients with varying degrees of burn alopecia managed with serial incision.⁷ This group classified the extent of burn alopecia in children in an attempt to not only guide our surgical interventions but also to give us some expectations as to what to tell our patients. Patients classified as Group A had alopecia that was less than 15% of the hair-bearing scalp; Group B, the alopecia exceeded 15% but was less than 30% of the hair-bearing scalp; Group

C, the alopecia exceeded 30% but was less than 50% of the hair-bearing scalp; Group D, the alopecia was more than 50% of the scalp. Using this classification system, scar excision is possible to remove alopecia segments up to 15% of the hair-bearing scalp. Currently, if complete excision of the alopecia segment can be carried out in two or three operations, this approach is preferred by many surgeons. If more operations are deemed necessary, alternative approaches are available.

Manders et al. provided a major thrust in the clinical application of tissue expansion for the correction of burn alopecia. This group demonstrated the efficacy and safety of soft tissue expansion in the correction of scalp defects in pediatric patients.²⁹ Despite moderately high complication rates, later reports confirmed the feasibility of tissue expansion in the correction of burn alopecia.²⁹⁻³² Later, McCauley et al. classified burn alopecia based on not only the pattern of the alopecia but also the extent of the alopecia.³³ This classification was designed as a means by which reconstructive efforts could be designed to correct specific types of burn alopecia (Table 55.1)

In this report, patients with types IA and IB burn alopecia were corrected via a single expansion, although overinflation of the scalp expander may be required (Figure 55.3). Patients with type IC and ID burn alopecia required sequential expansion in order to obtain complete coverage (Figures 55.4 and 55.5). Patients that presented with type II burn alopecia were corrected with a single expanded scalp flap. Lastly, patients with type IIB, C or D required multiple expanders if the adjacent alopecia segment could accommodate an expander. Obviously patients with type III and type IV burn alopecia were not candidates for tissue expansion.

The rate at which expansion occurs postoperatively varies. Expansion has been recommended anywhere from 1 week to 2¹/₂ weeks after placement. Injection fractions vary, but 10% of the volume per week is required to complete expansion within a 3-month period. However, individual variations exist, one must be aware of pressure changes which occur with expansion so that flap ischemia and subsequent exposure of the expander does not become a problem. Pietila et al. addressed the issue of accelerated expansion with the 'over filling' technique.³⁴ This group defined overexpansion as expansion to the point where dermal capillary flow is zero by

Fig. 55.3 (a) Seven-year-old male with type IB burn alopecia. (b) Complete inflation of a 500mL tissue expander. (c) One week after correction of alopecia with a single flap advancement. Functional and aesthetic reconstruction of the burn patient. New York: Taylor & Francis; 2005:217–226.)

Fig. 55.4 (a, b) Six-year-old white male with type 1B front temporal burn alopecia. (c, d) Same patient at age 14; 7 years after scalp expansion. (Reprinted with permission from: McCauley RL. Tissue expansion reconstruction of the scalp. *Semin Plast Surg* 2005; 19(2):152.)

laser Doppler flow and patient discomfort is high. Reportedly, fluid was then removed until capillary refill returned and the patient no longer experiences discomfort. They confirmed an average increase of 59% using this technique. However, complications in these patients were not addressed.

Complications of tissue expansion

A number of site-specific studies lends crucial insight into complications associated with expansion of different regions

in the body. Scalp expansion for correction of burn alopecia is well documented.^{32,33,35} As noted in these reviews, the use of tissue expanders for the correction of burn alopecia has revolutionized our thinking about the correction of this problem.^{9,13,36} Of major concern is flap advancement to maintain proper orientation of the hair follicles. Whether or not these wounds are drained does not seem to affect the complication rate of 12–20%.

Complications associated with tissue expanders can be subdivided into those that are major and those that are minor.

Fig. 55.5 (a) Type IC burn alopecia (b) Complete inflation of an 800 mL tissue expander. (c) Three-year follow-up after correction of alopecia. (Reprinted with permission from: Garavito E, McCauley R L, Verbitzky J. Reconstruction of the burned scalp. In: McCauley RL, ed. Functional and aesthetic reconstruction of the burn patient. New York: Taylor & Francis; 2005:217–226.)

Major complications have been reported to be as low as 3% and as high as 49%.^{30–33,37} The major complications are usually defined as those which require removal of the expander (Table 55.2). Such complications may be secondary to infection, exposure of the expander from traumatic extrusion, wound dehiscence, or erosion of the envelope fold or port through the skin.³⁸ Implant failure, which requires removal of the implant, is also considered a major complication as would be ischemia and flap necrosis. Manders et al. reported a major complication rate of 24%.¹⁰ Other investigators have reported similar complications ranging from 17% to 24%.^{31,33} Neale et al.

have shown that with proper protocols and patient selection, the major complication rate (those requiring additional surgery for expander replacement or additional procedures) has decreased from 22% to 12%.²⁴ Minor complications have been documented with these patients and have been defined as poor compliance, intolerance of the injection to fill the expanders, and alterations in the early preoperative plans secondary to incomplete coverage following expansion (Table 55.3). Rates of such minor complications have been reported to be between 17% and 40%, with a mean still in the range of 20%.^{9,31}

TABLE 55.2 MAJOR COMPLICATIONS OF SOFT TISSUE EXPANSION

Complication	Number of patients
Infection	3
Expander exposure	
Dehiscence of incision	5 (two more incipient exposure)
Erosion of envelope fold through skin	1
Erosion of envelope of reservoir through inadequate covering tissue	1 (two incipient)
Manipulated by psychotic patients	2
Implant failure	
Remote port connector	1
Physician assembly may be faulty	1
Injection port may lack proper back	1
Envelope may be perforated by needle	1
Induced ischemia	
Flaps may become ischemic when expanded	1 (recognized and no problem)
Irradiated tissue may not survive elevation	1
Twenty-four percent of expansions were attended by a major complication. Reproduced with permission from: Manders et al. <i>Plast Reconstr Surg</i> 1984; 74:493–504. ¹⁰

Conclusion

Tissue expanders have a permanent place in the armamentarium of reconstructive surgery for correction of soft tissue defects, especially burn alopecia. It also brings a new perspective for correction of complex problems. The techniques have been refined, and although complication rates have improved, they remain moderately high. Yet, the role of tissue expansion in the correction of burn alopecia has been one with tremendous impact. With so many burn injuries occurring to the head and neck, reconstructive procedures, such as those designed to correct alopecia, are becoming more common. The advantages of tissue expansion are numerous: excellent color and

texture match and minimal donor site morbidity (Figures 55.6 and 55.7). The disadvantages are well known and include a protracted time period for completion of the expansion process and a significant complication rate. All patients who are victims of trauma, especially burn injury, want to look and function at their best. Tissue expansion in certain patients offers the chance to replace unstable and unsightly scars with normal adjacent tissue. None of our current reconstructive techniques offer this advantage. As we continue to refine our approach to certain problems using tissue expansion, it is important to communicate to our patients that although the process may be protracted, the end results can be exceptional.

Contractural deformities of the axilla (shoulder), elbow, wrist, knee, and ankle joints	727
Management of axilla (shoulder), elbow, wrist, knee, and ankle joints	728
Surgical management of established contractural deformities	730
Summary	739

Burn injuries, regardless of the etiology, rarely involve a joint. However, the joint function is often impaired because of burns. The joint problems and joint deformities noted in burn patients are mostly due to physical inactivity combined with limitation of joint movement because of scar contracture.

The regimen of burn management, especially during the period immediately following the injury, seldom includes plans to care for the joint; instead, the treatment is focused upon resuscitative efforts to restore fluid balance and to maintain functional integrity of the circulatory and the pulmonary systems. The consequence of joint dysfunction is usually left for later reconstruction.

Contractural deformities of the axilla (shoulder), elbow, wrist, knee, and ankle joints

The factors leading to formation of the contractural deformities

Folding bodily joints in flexion (a so-called posture of 'comfort') is a characteristic body posture seen commonly in a distressed individual. Although the exact reasons are not entirely clear, contraction of muscle fibers at rest and the contractile force difference between the flexor muscle and the extensor muscle may play an important role in the genesis of this body posture. The magnitude of joint flexion, furthermore, increases as an individual loses voluntary control of muscle movement, as frequently occurs in a burn victim (Figure 56.1). Prolonged periods of physical inactivity, associated with burn treatment, and scar tissue contraction around the joint structures as the recovery ensues further impedes the joint mobility.

Incidence of burn contracture involving the axilla (shoulder), elbow, and knee joints

Burn treatment requiring a long period of bed confinement and physical inactivity as well as restriction of joint movement will lead to joint dysfunction. Consequently, every bodily joint (e.g. the vertebral, mandibular, shoulder, elbow, finger, hip, knee and toe) is susceptible to the change. Of various bodily joints involved, the contractural deformities of the axilla (shoulder), elbow, hip, and the knee are relatively common. Factors such as a wide range of joint movement and an asynchronous muscular control are characteristic features of these joints, and, when combined with a high vulnerability to burn injuries, are the probable reasons accounting for the high incidence of deformity encountered. Recent review of the records of 1005 patients treated at the Shriners Burns Hospital in Galveston, Texas over the past 25 years indicated that the elbow was the joint most commonly affected. There were 397 patients with elbow joint deformity, 283 knee contractures, and 248 axillary deformities. The hip joint contracture was the deformity least encountered and was noted in only 77 patients (Table 56.1).

The efficacy of splinting in controlling burn contractures of axilla (shoulder), elbow, and knee joints

Although Cronin in 1955 demonstrated that the neck splint was effective in preventing recurrence of neck contracture following surgical release,¹ the routine use of splinting for burn patients did not become a part of the regimen of burn wound care in Galveston until 1968, when Larson, the former Surgeon-in-Chief, and Willis, the former Chief Occupational Therapist at the Shriners Burns Institute, began to fabricate splints with thermoplastic materials to brace the neck and extremities.²⁻⁵

For more than three decades, a neck brace, a three-point extension splint, and a molded brace fabricated from thermoplastic materials, the prototypes of devices used to splint the neck, elbow and the knee joints, were used in the management of burn patients at the Shriners Burns Hospital and the University of Texas Medical Branch Hospitals in Galveston, Texas. An 'airplane splint' similarly made of thermoplastic materials was also used to splint the axilla during the period where the use of other splinting and bracing techniques, such as a 'figure-of-eight' bandage, is not feasible.

Fig. 56.1 The posture of ‘comfort’ characterized by flexion of shoulder (axilla) and elbow joints, plus hip and knee joints, is assumed by patients under distress, as in burn patients.

Shoulder (axilla)	248
Elbow	397
Hip	77
Knee	283
Total	1005

A study was conducted in 1977 to determine the efficacy of splinting across large joint structures such as the elbow, axilla and knee joints by reviewing the records of 625 patients. There were 961 burns over these joints in this group of patients. Of these, 356 had involved the axillae while 357 and 248, respectively, involved the elbow and the knee joint. The incidence of contractural deformities encountered in these splinted joints was, as expected, low. The incidence of contractures in these joints was 7.3%, provided the patients had worn the splints for 6 months. The effectiveness of splinting was diminished to 55% if splinting was discontinued within 6 months. For comparison, the incidence of contractural deformity ascertained in 219 patients who had never worn the splint was 62% (Table 56.2).

Although splinting and bracing were shown to be effective in minimizing joint contracture, it was not entirely clear if restriction of joint movement would affect the quality of scar tissues formed across the joint surface. The effects were assessed by determining the frequency of secondary surgery performed in this group of patients. Over 90% of 219 individuals who did not use the splint/bracing required reconstructive surgery. In contrast, the need for surgical reconstruction in individuals who wore splints was 25%.⁶

Management of axilla (shoulder), elbow, wrist, knee, and ankle joints

The acute phase of recovery

It is believed that inadequate physical exercise and lack of joint splinting and bracing, while allowing a patient to assume the

posture of ‘comfort,’ are the main factors responsible for the genesis of contractural deformities seen in burn patients during the acute phase of recovery from burn injuries. The deformities, furthermore, are made worse because of skin involvement and burn scar contracture. In order to minimize this undesirable consequence of burn injury, proper body positioning and splinting of the joint structures must be incorporated into the regimen of burn treatment. The treatment should be implemented as soon as the patient’s condition becomes stable.

Bodily positioning and joint splinting

Bodily position: Although a supine position is preferred, the patient may be placed in a lateral decubitus position while confined in bed. The head should be placed in a neutral position with the neck slightly extended. For a patient placed in a supine position, neck extension is achieved by placing a small pad between the scapulae to facilitate the scapular traction. A neck brace may be used if the patient is placed in any other position.

Axillary (shoulder) joint: The axillary (shoulder) joint is kept at 90–120° of abduction and 15–20° of flexion. This generally results in 60–80° of arm elevation. The position is not only useful in protecting the brachial plexus from traction injury but is also effective in maintaining the stability of the gleno-humeral joint. The position is best kept with the use of either a foam wedge, trough or airplane splint. A ‘figure-of-eight’ wrapping over a pad around the axilla, more frequently used for patients during the intermediate phase of recovery from the injury, is effective in maintaining shoulder abduction (it is also useful in preventing excess shoulder flexion).

Elbow joint: Rigid flexion contracture of the elbow is a common sequela in the joint if it is left unattended. In burns of the skin around the olecranon, exposure of the elbow joint is a common sequela if the elbow is allowed to contract freely. Maintaining the elbow in full extension therefore is essential. An extension brace (Figure 56.2), or a three-point extension splint across the elbow joint, is effective for this purpose (Figure 56.3).

Wrist joint: A contractural deformity of the wrist joint is relatively common in individuals with hand burns that were not splinted properly. A cock-up hand splint should be applied to maintain a 30° wrist extension (Figure 56.4).

Fig. 56.2 A splint made of thermoplastic material is used to limit joint flexion.

Fig. 56.3 A 'three-point' extension splint manufactured similar to an orthotic device is used either to extend a contracted elbow joint or to immobilize the joint in full extension.

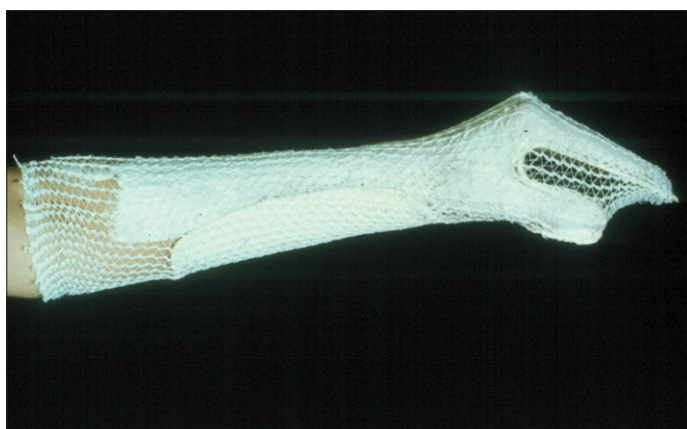

Fig. 56.4 Cock-up hand splint is effective to maintain 30 degree wrist extension.

Knee joint: Flexion of the knee is another posture commonly assumed by a burned victim. Similar to the elbow, uncontrolled flexion of the knee joint will lead to exposure of the joint structure, especially in instances where the injuries involve the patella surface. Maintenance of full extension of

the knee is an essential component of the therapeutic regimen — this is accomplished by means of a knee brace or a three-point extension splint (Figure 56.5).

Ankle joint: In order to minimize a plantar flexion contracture deformity, a common consequence of ankle burns, the joint should be maintained at 90° by applying a posterior splint.

Exercise

Although exercising a burned victim is an integral part of burn therapy, it is seldom implemented until the resuscitative measures are completed and the condition of the patient is considered stable. The primary goal of an exercise routine is the maintenance of the joint's functional integrity and muscle strength. This is attained by, in most instances, manually moving the joint and muscles — passive movement. The frequency and intensity of an exercise regimen, however, may vary depending upon the magnitude of the injury and the extent of joint involvement. The treatment, if possible, should be intensive and is rendered as frequently as possible.

The intermediate phase of recovery

The period from the second month through the fourth month following the injury is considered as *the intermediate phase* of recovery from burn injuries. The burn victims typically have full physiological functions and integumental integrity restored by this time. The cicatricial processes around the injured sites, on the other hand, are still physiologically active — though healing of the burned wound is considered satisfactory. That is, the process is characterized by, in addition to a maximal rate of collagen synthesis, a steady increase in the myofibroblast fraction of the fibroblast population in the wound⁷ (the cellular change believed to account for contraction of the scar tissues). Continuous use of splinting and pressure to support the joints and burned sites, in this sense, is essential in order to control changes caused by the scar tissue formation and contraction.

Bodily positioning and joint splinting

Joint splinting and bodily positioning are similar to the regimen used during the acute phase of burn recovery. That is, the shoulder is kept at 15–20° flexion and 80–120° abduction. A 'figure-

Fig. 56.5 A 'three-point' extension splint can be also used to manage the flexion contractures of a knee joint.

of-eight' wrapping over an axillary pad is used to maintain this shoulder joint position (Figure 56.6). The elbow and knee joints are maintained in full extension by means of a three-point extension splint or brace. A pressure dressing or garment is incorporated into the splint. In instances where the use of a 'figure-of-eight' bandage, pressure dressing and/or garment is not feasible because of recent surgery, devices such as an 'airplane splint' (Figure 56.7), or a three-point extension splint, may be used to splint the axilla, elbow, and the knee joints.

Pressure dressing

A compression dressing, originally incorporated into the treatment of burn wounds of the upper and lower extremities at the Shriners Burns Hospital in 1968 as a means of providing mechanical support to healing wounds, is effective in reducing tissue swelling and in promoting softening of a burn scar. Compression of a burn wound, even though healing is still in progress, is most easily achieved by means of wrapping the extremity in an elasticized bandage. Wrapping of the extremity should begin at the hand or foot. The bandage is moved cephalad in a crisscross fashion. The splint is reapplied over the bandage. It is important to rewrap the extremity three to four times daily. Wrapping an extremity with an elasticized bandage can produce a pressure ingredient of 10–25 mmHg.^{5,8} Pressure dressing should be continued for 12–18 months.

Surgical management of established contractural deformities

Patient evaluation

There are numerous factors that will affect joint movements in burn patients. Although hypertrophy and contraction of

scar tissues and/or contracted skin graft around a joint are the most common causes of joint impairment, changes in the ligamentous structures or the joint itself due to burn injuries can also limit joint mobility. Detailed examination that includes radiographic assessment of the joint structures is essential in order to formulate a definitive treatment plan.

Non-operative or minimally invasive approaches to correcting a contracted and/or stiff joint

Restoration of movements in a contracted and/or stiff joint could be attained by minimally invasive or non-surgical means.²⁻⁶ 'Pushing' and 'pulling' of an extremity that, in turn, 'stretches' contracted scars and tissues around an affected joint is the principle behind this modality of managing a contracted and/or stiff joint. The treatment is found to be especially effective in mobilizing a contracted joint caused by a long period of physical inactivity or, in some instances, of scar contracture.

Although the morbidities associated with this modality of treatment are minimal, breakdown of the skin due to pressure and/or friction resulting from 'pushing' and 'pulling' of a limb can occur.

Axillary (shoulder) contracture: Tight scars formed across the shoulder joint, usually in the area along the axillary folds, often limit the joint movement. The joint stiffness caused by scar contracture may be further aggravated by physical inactivity, especially if the patient is allowed to remain in the posture of 'comfort.'

There are two non-surgical methods commonly used to mobilize a contracted axilla (shoulder) joint. One is 'figure of eight' compression dressing technique and the other is an 'airplane' splinting technique:

Fig. 56.6 An elasticized bandage is used to wrap around the shoulder (axilla) joints in a 'figure-of-eight' fashion to extend and to abduct the shoulder joints. An axillary pad is included in the wrapping to increase the pressure upon the axillary fold.

Fig. 56.7 An 'airplane' splint made of thermoplastic materials is used to maintain the shoulder abduction. The angle of separation may be increased, as the joint becomes more mobile.

- A *'figure-of-eight' compression dressing*: An elasticized bandage is used to wrap over a pad placed in the axillary fold around the shoulder joint in a *'figure-of-eight'* fashion to extend and abduct the shoulder. Continuous wear of the dressing for a period of 3–6 months is necessary to obtain the release — the dressing is removed only for cleansing. The mobility of the joint increases as the scar tissues across the axilla softens but the extent of relief may be limited if the scar is thick and unyielding to the pressure (Figure 56.8).
- An *airplane splint*: The splint is fabricated with a thermoplastic material. The spreading angle is conformed to the extent of the axilla (shoulder) joint held at maximum abduction plus 10–15° of extension. Abduction and extension of the joint, that is elevation of the arm, will be maintained by *'pushing'* the arm away from the upper thorax. Care is needed to protect the skin over the inner aspect of the arm and the side of the chest. The splint is changed regularly as the angle of joint abduction increases. One to 3 months of continu-

Fig. 56.8 (a) A 6-year-old boy sustained burns of the right side of his body extending from the lower neck to the upper thorax that included the axillary crease. (b) He experienced difficulty in extending both the neck and the right arm because of ensuing contraction of scar tissues around the neck and the axilla. (c) A *'figure-of-eight'* dressing was used to maintain the shoulder extension and abduction. The dressing was used for 12 months. (d) He regained the shoulder extension and mobility with the use of pressure dressing.

ous use of this device is usually necessary to achieve the needed release in most instances (Figure 56.7).

Elbow and knee contracture: Flexion contracture is the most common deformity encountered in these two joints. The scar formed across the antecubital and the popliteal fossae frequently aggravates the magnitude of contractural problems in these joints. The following techniques are frequently utilized before surgery to obtain joint movement and joint extension:

- **A three-point extension splint:** The splint is assembled similarly to a prosthetic/orthotic device. Two sidebars hinged at the middle are connected with a bracing trough at the end. A cap pad is attached at the mid-section of the sidebar to fit over the elbow or the kneecap. The splint is placed across the antecubital fossa or the popliteal fossa. Fitting of the splint is adjusted using Velcro straps (Figures 56.2 and 56.3).
Extending the amount of movement of the joint is determined by the extent of the preexisting joint stiffness. The angle of extension is initially determined by the angle of joint contracture. The magnitude of extension is controlled by tightening the olecranon or patella pad. It is increased gradually as the joint gains its mobility. Problems encountered with the use of the ‘three-

point extension splint’ are uncommon. However, breakdown of the skin can occur. Leverage attainable from three-point pressure application may be limited in a young individual because of the inadequate leverage afforded by the shortness of limb length. The skeletal traction technique, in such instances, may be used.

- **A skeletal traction technique:** Utilizing a skeletal traction technique to restore movements in a contracted joint typically requires percutaneous insertion of a Steinmann pin through the radius for the elbow joint and the tibia for the knee joint. The pin is inserted through both cortices at the junction of the proximal two-thirds and the distal third of the radius or tibia. A contracted joint can be mobilized by the continuous and constant ‘pull’ on the long bone of a gravitational force generated by a 10–15 pound weight placed on a pulley device.

For a flexion deformity of the elbow, the patient is placed in a supine position. The pulley traction device will provide a horizontal and then a vertically downward pull (Figure 56.9).

Instead of utilizing a skeletal traction device to loosen a contracted knee, a weight placed around the ankle,

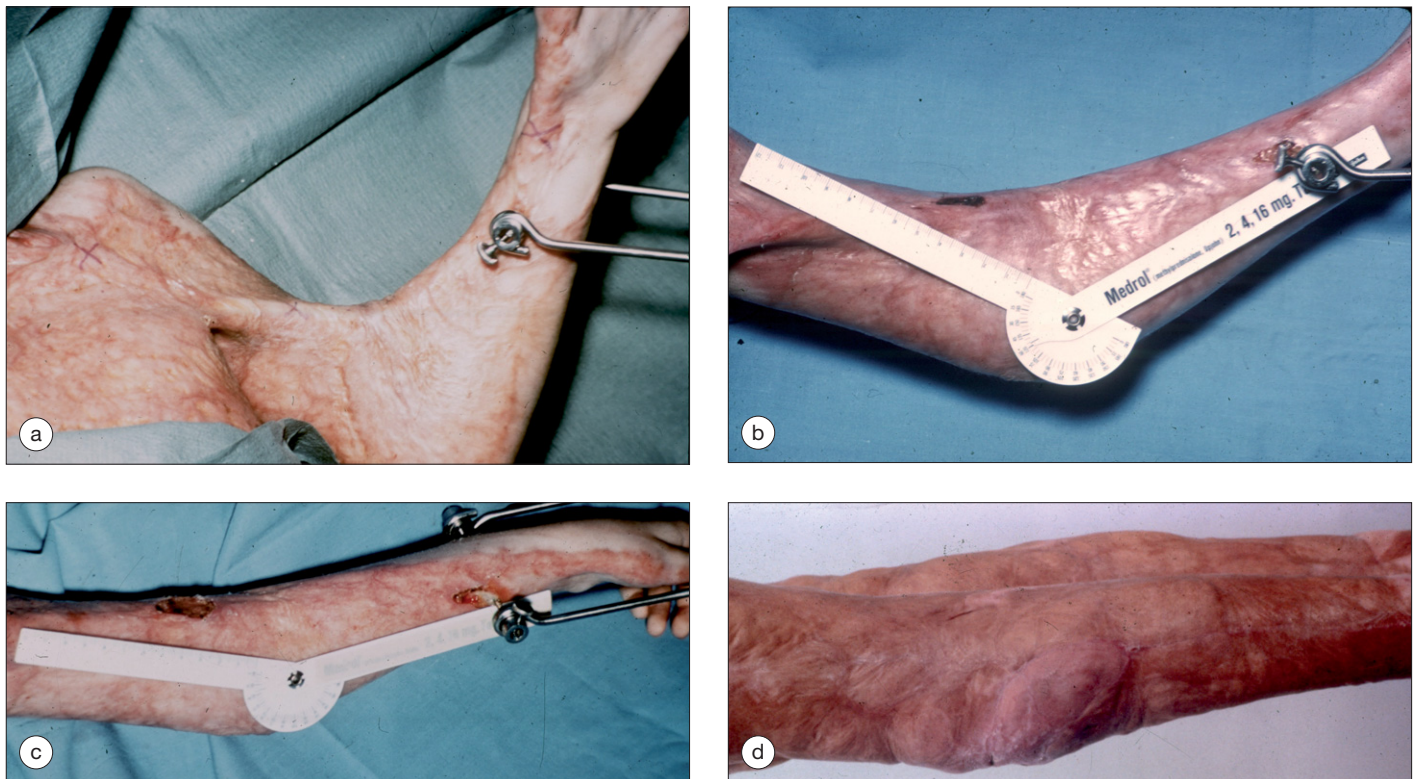

Fig. 56.9 (a) A skeletal traction technique may be used to extend a contracted joint as in this 8-year-old girl. A Steinmann pin was inserted percutaneously through the distal one-third of the radius. The direction of pull was horizontal using 10–15 pound weight. (b) The elbow joint was mobilized in 30–36 hours of constant pull. (c) A near full extension of the elbow joint was achieved in 6 days. (d) This was the appearance of the elbow 2 years after the traction extension treatment for elbow contracture. A minor procedure was, however, needed to release a tight band across the elbow surface.

with the patient in a prone position, may be used to pull on the foreleg. This technique is especially useful in treating individuals with a limited knee flexion contracture. Traction is continued for a period of time and is repeated several times a day (Figure 56.10).

Although morbidities due to infection are uncommon, a continuous and constant force of pull can cause breakdown of the skin located across the joint surface. Any wound thus formed can be temporarily covered with surgical or biological dressings and its closure contemplated once the joint contracture is fully corrected.

Surgical treatment of a contracted joint

Surgical treatment of a contracted joint is contemplated in individuals where the use of non-surgical treatment is ineffective and where functional integrity of a joint is in jeopardy. Surgical intervention, in this regard, is relatively unusual during the acute phase of recovery. Instead, the reconstruction is delayed until the scar tissue becomes fully 'matured,' i.e. flattened and soft.

Pre-surgical evaluation

The patient is seen and the involved joint is examined before surgery. The following features are assessed:

- *The extent of joint contracture* is determined and the passive and active range of joint motion is assessed. Radiographic evaluation may be obtained to delineate the structural integrity of the joint.
- *The magnitude of scarring and scar thickness* is assessed. The scar is usually the thickest across the joint surface.
- *The location and the size of uninjured skin* are delineated. The availability of uninjured skin frequently determines the technique of reconstruction. Skin graft and skin flap donor sites are also ascertained.
- *The point and the axis of joint rotation* are located. The line of incisional release is in alignment with the axis of joint movement.

Reconstruction of contracted joints

Releasing the contracture deformity of the joint

Despite a detailed examination before surgery, the exact cause of joint stiffness can only be delineated with surgery. In practice, contraction of the scar tissues across the joint structure is the most common cause of contractural joint deformities.

- *Release of joint contracture by incising the scarred tissue* — A contracted joint is freed by making an incision in the scar across the joint surface. The incision is placed in line with the axis of joint rotation and initially confined within the width of the scar. It is lengthened as necessary to achieve the intended release. Prior infiltration of the area with lidocaine containing epinephrine in 1:400 000 concentration is useful in obtaining hemostasis and later pain control. The incision, however, must be made with caution to avoid injuring major vessels and nerves. This is

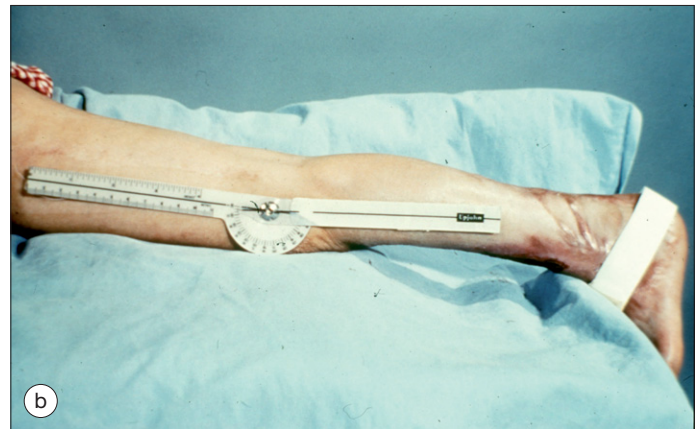

Fig. 56.10 (a) A knee contracture developed in an 8-year-old male youth due to improper positioning and immobilization of the knee joint. There was no direct injuries involving the knee area. With the patient being placed in a prone position, the ankle was strapped with a 10–15 pound weight. (b) The flexion contracture was relieved in 3 days.

achieved by a 'pushing' instead of a 'slicing' motion of the surgical blade to free the scarred tissues. The extent of release is assessed by the improvement of joint motion gained as the scarred tissue is severed.

In rare instances, cicatricial changes could involve the joint capsule and reconstruction of the capsular structure prove necessary.

- *The use of z-plasty technique*⁹ — A contracted area can be lengthened by use of the z-plasty technique. The technique utilizes the principle that a contracted wound is lengthened by interposing two triangular skin flaps mobilized from an unburned area immediately adjacent to the area of release. The lengthening of the wound is maximally attained by interposing two triangular flaps of 60° angle. While the z-plasty technique is an excellent means to ameliorate the problem of wound contracture, it is not possible if the amount of uninjured skin adjacent to the wound is limited.
- *Wound coverage* — there are six basic techniques of wound coverage:
 - (1) Primary closure of the wound.
 - (2) A full-thickness or partial-thickness skin graft.

- (3) An interposition skin flap mobilized from the adjacent area.
- (4) Combination of an interposition skin flap and skin grafting.
- (5) A muscle or skin-muscle flap mobilized from the adjacent area.
- (6) A free skin or skin-muscle flap harvested from a distant site and transferred via a microsurgical technique.

Primary closure of the wound

Wound closure *per primum* following burn scar excision is difficult if not entirely impossible. Inelasticity of the skin surrounding the wound and an inadequate amount of uninjured skin available for mobilization and closure preclude the use of this method. Closure of a resultant wound following release, in practice, would defeat the original objective of the contractural reconstruction.

Skin grafting technique

The use of a piece of skin graft, full or partial thickness, to cover a wound is the most fundamental technique of wound coverage that is technically simple and results in minimal morbidity.

- Operative technique: A partial-thickness skin graft of 15/1000 to 20/1000 in thickness is harvested from an unburned area using a dermatome. The scalp, lower abdomen, and the anterior surface of the upper thigh are the common donor sites. A piece of full-thickness skin graft can be harvested from the lower abdomen, above the suprapubic or inguinal area, without leaving unsightly donor site defects. The subdermal fatty tissues are removed but attempts should be made to

preserve the subdermal capillary plexus (Figure 56.11). The donor defect is usually closed primarily. The graft is cut to fit the defect and the edges are anchored with 3–0 silk sutures. The ends are left sufficiently long to tie over a bolster to immobilize the graft. Several anchoring ‘mattress’ stitches using 4–0 or 5–0 chromic catgut sutures may be placed in the center of the graft to immobilize the skin graft against the base. Hemostasis around the recipient site is essential. Hematoma formed underneath the graft will hinder the ‘take’ of the graft.

- After care: The bolster is usually removed 4–5 days after the procedure. Bodily fluid or blood elements accumulated underneath the graft, i.e. seroma and/or hematoma, are evacuated. This is achieved by making a small ‘nick’ in the graft with a pair of surgical scissors. The fluid is ‘rolled’ out with a cotton tip applicator. The joint is immobilized immediately and pressure dressing is used to minimize the consequence of contracture. Physical exercise is resumed 3 weeks after the surgery.

An interposition flap technique: alias 3/4 z-plasty technique

This technique, known by various names such as ‘three-quarter z-plasty’ technique, a ‘banner’ flap interposition technique, etc., is the most useful method of wound coverage following a releasing procedure for a contracted joint. The technique is based on the principle that an open wound consequential to surgical release may be covered with a skin flap mobilized from an adjacent area. While designing of a flap is technically simple, it requires an area of unburned skin adjacent to the released wound.

Fig. 56.11 (a) A piece of skin with subcutaneous tissues is removed from the abdomen that will be used as a full-thickness skin graft. (b) The subcutaneous fatty tissues were sharply removed with a pair of fine scissors. The capillaries were left undisturbed. (c) A close-up view to show the capillaries that are left in the graft.

- Operative technique: A triangular skin flap is designed in an unburned area adjacent to the wound following release. A vertical limb of the flap, begun at the end of the released wound edge, is set at a 90° angle to the end of the wound. The limb length is equal to the wound length. A triangular flap is formed

by making the width of the flap at the mid-section the same width as the wound. The flap can be based either proximally or distally depending upon the direction of the triangular flap designed (Figure 56.12a). The flap is dissected out and is rotated 90° to cover the defect (Figure 56.12b,c). The flap donor

Fig. 56.12 (a) An interpositional skin flap technique, i.e. a modified z-plasty technique, is useful in reconstructing a flexion deformity around the joint, as seen in this 42-year-old individual who had sustained burn injuries around the upper extremity. A triangular flap based distally on the lateral side of the elbow was designed in an uninjured area adjacent to the scarred joint surface. The length of the flap was equal to the length of scar release. (b) The triangular flap was fabricated. (c) The skin flap was rotated 90° to make up the tissue defect. (d) The donor site was closed primarily. (e) The appearance of the wound 1 year following the reconstruction. (f) Final postoperative view of the reconstructed elbow.

defect is closed primarily (Figure 56.12d,e). The width of flap may be narrow in instances where the size of unburned skin is not enough to fabricate a triangular skin flap sufficiently to cover the wound. The flap, in such an instance, is anchored in the middle of the wound. The two sides not covered

by the flap are closed with a piece of skin graft (Figure 56.13).

- After care: The wound edges are kept clean with antibiotic ointment. Sutures may be removed at day 10. Splinting of the joint is resumed within 4–5 days and joint exercise in 10–14 days.

Fig. 56.13 (a) An interpositional skin flap technique of wound closure may be modified as in this 5-year-old girl who had sustained burns around the right axilla that caused contracture of the axillary joint. (b) The skin defect was so extensive that it could not be covered completely with a single flap. (c) The uninjured skin, raised as a flap, was transferred to the middle of the wound, leaving the areas proximal and distal to the flap to be covered with skin grafts. (d) The appearance of the wound 10 days following the surgery. (e) The appearance of the wound 10 years after the surgery. The flap placed in the middle of the wound had increased in size because of body growth and stretching of the scar tissues.

A muscle flap or skin-muscle flap technique

The technique is utilized in instances when the resultant defect following release is so extensive that coverage of the wound with a skin flap or a skin graft is not feasible.

The latissimus dorsi muscle harvested either as a muscle flap or as a musculocutaneous flap may be used to cover the axilla. The soleus muscle flap or the gastrocnemius muscle-skin flap may be used to cover the wound around the knee joint coverage (Figure 56.14).

Muscle or muscle-skin flap, in practice, is seldom used to reconstruct burn deformities unless vital structures such as the brachial or popliteal neurovasculatures become exposed consequential to releasing procedures. Similarly, microsurgical composite tissue transfer technique is limited in burn scar release. Donor site limitation and technical difficulties encountered in pediatric patients probably account for the infrequent use of this method.

The use of a modified fasciocutaneous (FC) z-plasty technique; alias $\frac{3}{4}$ FC z-plasty technique to reconstruct contracted axilla, elbow, and knee joints

Reconstruction of a contracted joint involving the axilla, elbow, and the knee may be carried out according to the fol-

lowing scheme in most instances once the surgical intervention is determined to be the most appropriate approach in providing relief.

- Ascertain that the scar contracture is the primary reason for the joint contraction.
- Determine the axis of joint rotation.
- A line is drawn to connect the axial point of joint rotation and the center point of contracted scar across the joint.
- A second line that is equal and perpendicular to the length of the release line is drawn. This is the cathetus for the first right-angled triangle.
- A second right-angled triangle (sharing the cathetus with the first one), with the hypotenuse drawn to a 30–45° angle, forms a Z pattern of 90° and 30–45° angles (Figure 56.15a).
- The contracted scar is incised to free the joint. An incision is then made along the drawn common cathetus line. Separation of skin and subcutaneous tissues should be sufficiently deep to identify the fascial layer (Figure 56.15b). The fascial layer is sutured to the skin edge to prevent accidental separation of the skin and the fascia. Dissection is continued underneath the fascia but above

Fig. 56.14 (a) Flexion of the knee was limited because of tight scars around the patella. (b) An incisional release of the tight area across the patella provided the relief of knee contracture. However, it resulted in an open wound of 4–5 cm in size. (c) A medial segment of the soleus muscle was used to cover the defect. (d) The appearance of the knee area 3 months following the procedure.

Fig. 56.15 (a) A right-angled triangle with its cathetus drawn perpendicular to the line of scar release. The triangle has an inner angle of 35° . (b) The fascia layer is identified and is separated from the muscle fibers underneath to fabricate a fasciocutaneous (FC) flap. (c) A right-angled triangle FC flap is fabricated. (d) The defect in the right axilla consequential to the releasing procedures is made up with the flap rotated 90° . (e) The appearance of the axilla 2 years following the releasing procedure.

the muscle fibers to fabricate a fasciocutaneous flap triangular in shape. The extent of proximal subfascial dissection is determined by the mobility of the fabricated triangular flap. The proximal tissue dissection ends once the 90° rotation of the flap, without undue tension, is possible (Figure 56.15c).

- The defect resulting from moving a triangular skin-fascia flap is closed in layers as direct closure of the defect is difficult, especially if the flap donor site is scarred or previously grafted. The wound then may be covered with a skin graft (Figure 56.15d,e).

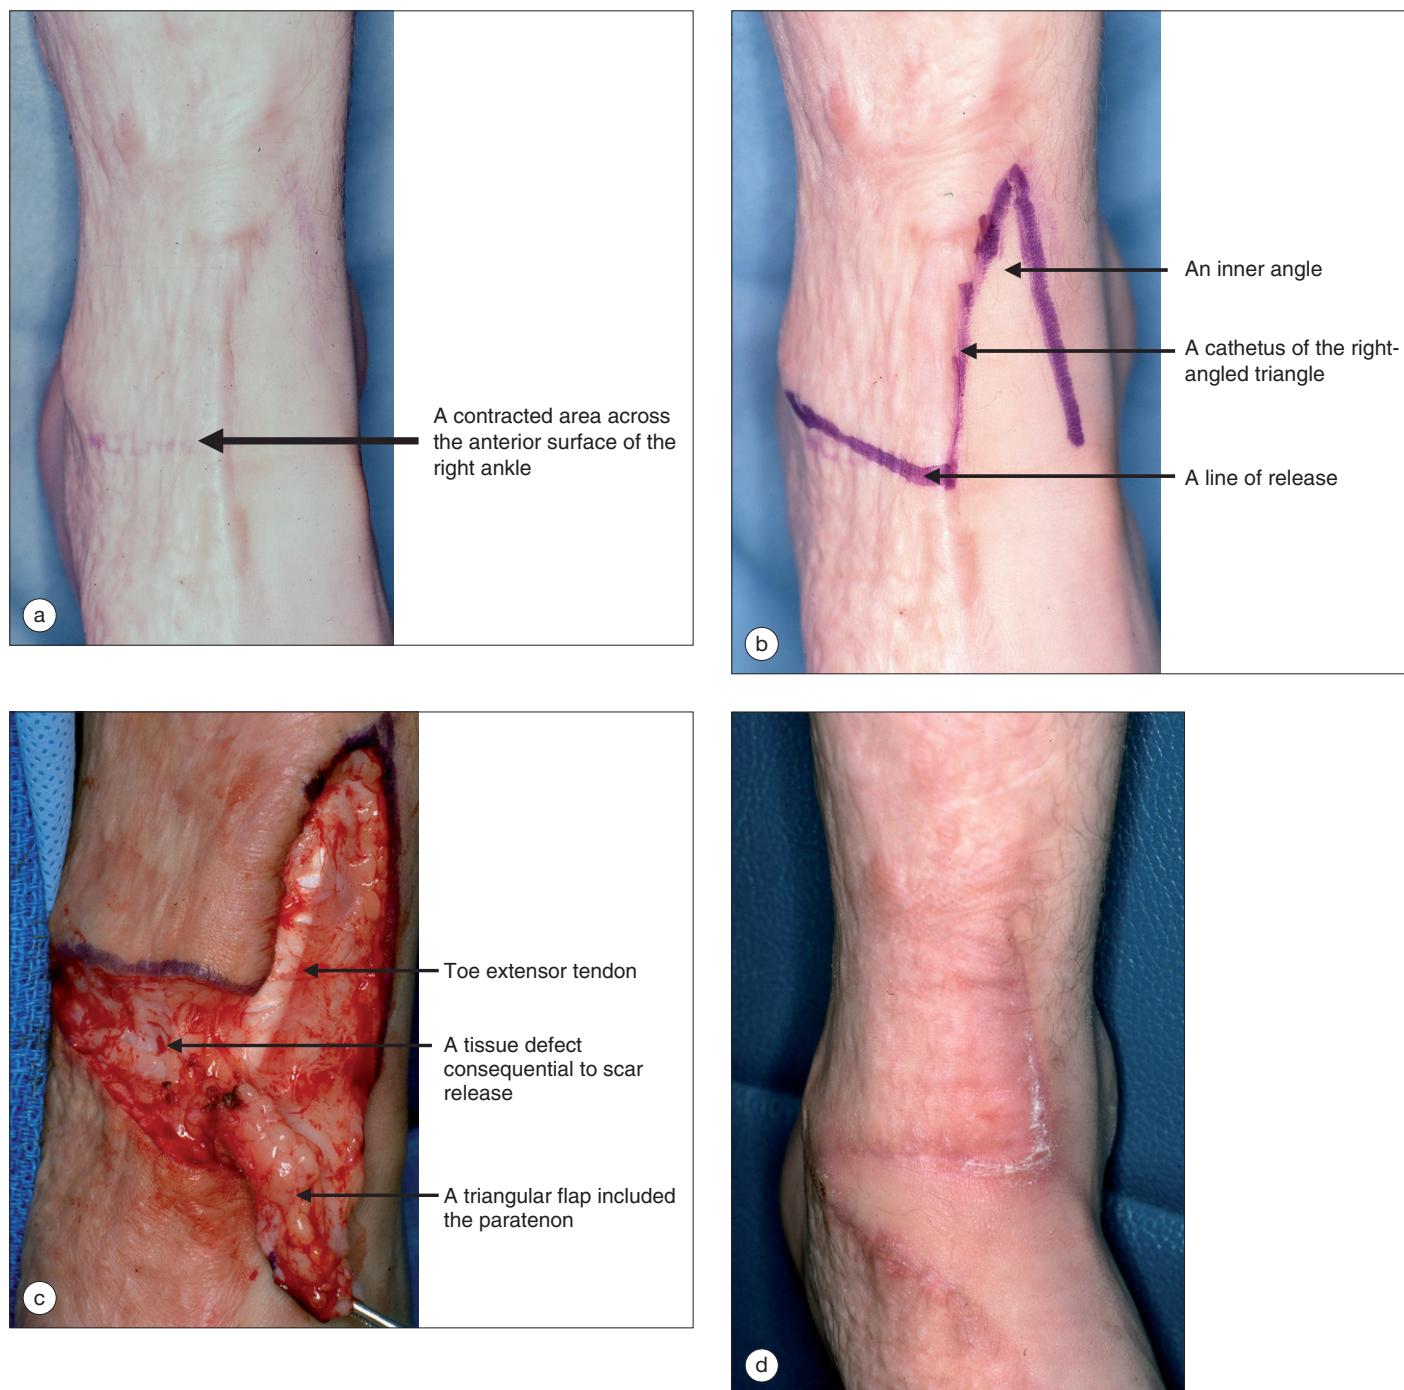

Fig. 56.16 (a) A contracted scar band is noted over the anterior surface of the left ankle. (b) A right-angled triangle is drawn with its cathetus made perpendicular to the contracted area of the ankle. (c) The paratenon is included in the flap fabrication. (d) The ankle surface with the wound healed and the contracture released.

The technique of reconstructing contracted wrist and ankle joints

The indications and the approach in drawing skin lines for z-plasty technique is identical to the maneuver used for other joints. The paratenon instead of the fascia is included in the composite skin flap fabrication (Figure 56.16).

Summary

Contractural deformities of the axilla (shoulder), elbow, wrist, knee, and ankle joints are not uncommon sequelae of burn injuries. Although the injury involving the limbs and the joint structures could account for the deformities encountered, lack of proper positioning and inadequate physical exercise while

recovering from the injuries could further contribute to the genesis of the problems.

The use of appropriate brace, splint and/or pressure dressings is important in minimizing such an undesirable consequence of burn injuries. The treatment for an established joint deformity, on the other hand, requires surgical release of the

contracted skin and scars. Various methods of reconstruction have been described to manage the problems encountered. Specific approaches to managing contractural deformities involving the axilla (shoulder), elbow, hip, and the knee joints have been outlined.

Introduction

Currently, studies have documented that burns of the torso and lower extremities eventually result in a significant number of problems.¹⁻³ Burvin et al. evaluated 421 female patients admitted to their institution over a 3-year period, focusing on female patients with breast burns. Of the 138 female burn patients identified, only 9% had non-isolated breast burns. Interestingly, 66% of the breast burns were secondary to scald injuries.¹ In 1989, Brou et al. evaluated 25 patients with a mean total body surface area burn of 71%.² In this series of patients, 512 reconstructive problems were identified. In the trunk and perineal regions, 70 problems were identified. In 1993, Burns et al. analyzed reconstruction issues associated with 28 patients who survived burns of at least 80% of the total body surface area. In this series, 564 reconstructive problems were noted.³ In each series, approximately 20 reconstructive problems were identified per patient. In the series by Burns et al., the trunk was the most frequently injured area in the torso/lower extremity section. However, the trunk was only second to the hand as the most frequently injured anatomic section. In addition, the breasts were the most frequently injured region within the truncal/perineal region. McCauley et al. noted that subsequent analysis of the donor sites usually revealed that the tissue available for reconstruction was often less than optimal.⁴ Consequently, it became quite clear that a stepwise plan of action for reconstruction could not be followed. Indeed, patient and family desires must be combined with realistic outcomes in order to determine the most judicious and efficacious use of available donor sites. Without question, these issues are of significant concern since it has been recognized that 71% of female patients with burns to the anterior chest wall with involvement of the nipple-areola

complex (NAC) will require surgical intervention to assist with breast development.

Historical issues

Evaluation of the management of burns to the truncal region requires longitudinal analysis of parameters of growth and development in order to assess the efficacy of variations in acute burn wound management. Recently, an increase in the survival of burned patients has been associated with better resuscitation, control of the hypermetabolic response, improved antimicrobial therapy and early excision with closure of the burn wound. Such data are well documented in the burn literature and remain the standard of care today.⁵⁻⁹ Longitudinal assessment of earlier methods of burn care, which included delayed excision and *épluchage*, exhibited an increase in hospital morbidity and mortality of burned patients. Yet, the conservative management of tissue over the torso proved to be quite beneficial in female patients who survived this type of management. In 1989, McCauley et al. documented that with conservative management of burn tissue over the anterior chest wall, involving the NAC it is possible for normal breast development to occur even with nipple loss⁴ (Figure 57.1). This retrospective study, which analyzed burn therapy nearly 20 years earlier, noted that, conservative management of the NAC in these patients was uniformly beneficial. On the other hand, 71% of these patients required incisional releases of the anterior chest wall to assist in breast development. The importance of these studies lies in the observation that, even with loss of the NAC, the breast bud itself is rarely injured.

Several investigations have previously shown that even with the destruction of the NAC, the breast bud may be uninjured.^{4,10} In prepubescent females, since the majority of burns to the anterior chest wall are scald injuries, it is believed that the subcutaneous tissue is still quite viable.^{13,14} This is significant since the mammary gland in children is believed to be located 4–8mm in the subcutis. It is believed to be attached to the overlying nipple by the epithelium of the *parsinfundibularis* of the milk ducts.¹¹ Although burn management prior to 1970 was quite conservative, the longitudinal effects of blunt eschar separation resulted in maximum tissue preservation, which produced flexible, mature burn scars.

Often it is difficult to evaluate the development of young females who have lost their NAC as they proceed to develop in their adolescent years. Many of these patients require fre-

quent follow-up in order to assess the early stages of breast development and to plan surgical correction should entrapment of the breast in burn scar become a problem. During this period of time, pressure garments are often worn in order to assist the maturity of burn scars over developing breast. Many

of these patients may require an incisional release to allow the breasts to develop without distortion (Figure 57.2). Subsequent maturation of skin grafts not only results in blending in with injured tissue but also allows the tissue over the breast to immediately become more relaxed.

Reconstruction of the burned breast

Reconstruction of the burned breast encompasses a variety of techniques.¹²⁻¹⁹ Most reconstructive surgeons view this issue in two parts:

- reconstruction of the breast mound, and
- reconstruction of the NAC.

Choosing the best option available is dependent upon the age at which the patient sustained injury, the type of injury, and the extent of surgical management during the acute phase of treatment. Obvious restriction in the breast development as a result of scar contracture has been the standard indication for surgical intervention. However, the timing for such intervention may vary with each patient.

Traditional methods of breast reconstruction after mastectomy for breast cancer may not be an option in these young girls during their developmental years. Areas of significant burn injury and the lack of tissue bulk may prevent the use of the transverse rectus abdominus myocutaneous (TRAM) flap as a method for reconstruction. The need for bilateral breast reconstruction in many of these patients further complicates the issue. The use of the latissimus dorsi myocutaneous flap is an option and has been utilized by a number of plastic surgeons.^{15,20,21} Some success has been achieved with the use of tissue expansion and subsequent placement of submuscular breast implants.²² Because of significant scarring in the inframammary region in many of these patients, the transaxillary approach may be the best operative approach.

The burned male breast represents a challenge due to a decrease in subcutaneous tissue and lack of desirable outcomes for those who undergo reconstruction of the NAC. Most male patients opt not to undergo NAC reconstruction, thus making the opportunity to reconstruct the male breast rare.²³ Literature on the subject of male breast and NAC reconstruction is limited and significant data are not available. The initial surgical reconstruction of the burned male breast centers on scar excision and contracture release by multiple W-plasty and Z-plasties.²⁴ The male NAC can either be reconstructed using a full-thickness graft from non-hair-bearing scrotal skin or from full-thickness skin grafts from the thigh. Tattooing of the areola should be adequate to define the areola.²³ If attempting to raise the nipple, stacked cartilage grafts can be placed beneath the areolar graft.¹ Although many men opt to forego aesthetic treatment for breast and NAC reconstruction, the option should be made available.

In patients who require global fascial excision of the anterior chest wall, breast development will not occur.

Bilateral breast burns: amastia

As previously stated, patients who have sustained injuries to the underlying breast bud may not develop breasts. During the adolescent years, this becomes a significant issue to young girls. The latissimus dorsi myocutaneous flap may be an option with implant placement in breast reconstruction. The author's approach has been to release the scar contractures using thick split-thickness skin grafts with an inverted T incision. Once the new grafts have matured, a transaxillary approach is then used for placement of submuscular tissue expanders. Once expansion is completed, the expanders are removed and breast implants are then inserted using the transaxillary approach.²²

The use of the transaxillary incision avoids problems which may develop with wound healing if the inframammary approach is undertaken.

The use of tissue expansion and placement of an implant is employed in reconstruction of the burned breast when it is believed that there is adequate skin to result in primary coverage of the prosthesis after placement. Becker introduced the permanent breast expander implant in 1984.²⁴ Tissue expanders are placed in the subglandular or submuscular plane and are expanded incrementally until the desired growth is obtained.¹⁴ In burned patients, who have undergone fascial excisions, placement in the submuscular plane is the only option. Some authors have recommended that reconstruction be delayed several months to allow for scar softening to take place.¹³ Afterwards, the expander can be temporarily deflated to assess tissue laxity.^{16,25} At this point, insertion with a subpectoral breast implant proportional in volume to the tissue expander provides a breast mound that is not under tension. Some common complications that are seen with the use of tissue expander and implants include exposure of the injection port, infections, spontaneous deflation, and capsule formation.²⁵ In such patients, maturity of the tissue over the anterior chest wall is of paramount importance if reconstructive methods are to be successful at a later date. Many of these patients will require tissue expansion and subsequent placement of a muscular prosthesis to give the appearance of developed breasts (Figure 57.3).

The unilateral chest wall burn presents a significant problem. In children, the uninjured side will proceed with uninhibited breast development whereas the burned side may require surgical procedures in order to assist the developing breast.

Mastopexy/reduction mammoplasty

Symmetry of the burned breast is desired and should be the driving force behind breast reconstruction. Correction of asymmetry is complicated and must address skin contractures, nipple dystopia and volume asymmetry.²⁶ The most difficult technical problem has been that of achieving volumetric and geometric equality.²⁷ Assessment of proper volume status between the two breasts can be closely approximated perioperatively, but geometric equality will change over time.

In patients with unilateral breast burns, the uninjured breast serves as a guide for shape and symmetry. Unfortunately, in some patients achieving breast symmetry may be challenging. Occasionally, even as breast development proceeds with the injured breast, its subsequent development may still pose a problem with respect to shape and size when compared to the normal breast. The choices of reduction mammoplasty or a mastopexy on the uninjured breast versus augmentation of the injured breast depends on the extent of the asymmetry and patient desires (Figures 57.4 and 57.6). Sometimes different procedures may be required on each breast to achieve symmetry.

Burns to the breast even after extensive releases with skin grafts maintain a very strong outer envelop for breast support. Thai et al. noted that the thick inelasticity of skin grafts creates a sling that does not become ptotic with age.²⁸ In patients with unilateral breast burns, over time, the contralateral uninjured breast may become ptotic when compared to the reconstructed

Fig. 57.3 (a) A 15-year-old patient who survived a 60% total body surface area (TBSA) burn but necessitated facial excision of deep burns over anterior chest wall. Note lack of breast development. (b) Inverted T incision performed to release chest contractures. (c) Final appearance after removal of expanders, insertion of saline implants and bilateral revision of lateral redundant tissue over the breasts. (d) Right oblique view. (Reprinted with permission from: McCauley et al. *Functional and Aesthetic Reconstruction of the Burn Patient*. New York, Taylor and Francis 2005; 379–392.²²)

burned breast (Figures 57.4). In cases where at least a grade II ptosis is present, a mastopexy of the uninjured breast may be necessary. This procedure not only improves breast symmetry but also improves superior pole fullness.

The development of breast asymmetry and contour deformities are quite common. The burned breast tends to be fuller and does not have the natural ptosis associated with a matured female breast. Mastopexy of the uninjured breast may be performed in order to relieve the grade II or greater ptosis, to realign the NAC, and to give the uninjured breast a fuller appearance. Mudge and McCauley documented significant improvement in breast symmetry and aesthetics using this approach.²⁹

Multiple operations to release the breast from entrapment of burn scars may result in contour deformities. The lack of fullness and accentuated asymmetry of the infraclavicular may require reconstruction using pedicled fasciocutaneous flaps or a latissimus dorsi musculocutaneous flap. Even if the

level of the NACs is similar, medial or lateral displacement of the nipple may be of significant concern to the patient. If breast contracture is a problem, medial or lateral incisional releases and coverage with skin grafts will allow better nipple positioning. On the other hand, if breast contracture is not a problem, isolated repositioning of NAC is indicated. Clearly in patients with macromastia and breast deformities correction of the breast contracture prior to reduction mammoplasty assures optimal results.²⁷

Reconstruction of the nipple-areola complex

Reconstruction of the NAC constitutes the second stage of breast reconstruction. The literature has numerous articles to address this issue.^{30–34} The NAC reconstruction is often delayed until the reconstructed breast mound has had time for scars to mature. This may be 9–12 months after breast mound recon-

Fig. 57.4 (a) A 10-year-old girl with unilateral right breast burns with preservation of the nipple areolar complex. (b) Same patient at age 17 with unilateral macromastia on the left. Note normal breast shape without ptosis on the right side. (c) Postoperative appearance after left unilateral reduction mammoplasty. (d) Patient is satisfied with results, being able to wear a brassiere for adequate support for both breasts. (Reprinted with permission from: McCauley et al. *Functional and Aesthetic Reconstruction of the Burn Patient*. New York, Taylor and Francis 2005; 379–392.²²)

struction. As a rule, reconstruction of the NAC is undertaken when the breasts have fully developed. In the reconstructed breast, several problems may exist: malpositioning of the NAC and partial or total absence of the NAC. In cases of malpositioning of the NAC in the burned breast, Mohmand and Nassan suggested the use of two double U-plasty for correction.³⁰ This technique is quite similar to a z-plasty in which the NAC is transposed inferiorly or superiorly to match the contralateral unburned breast. Of course, the technique can only be performed in patients with no evidence of breast contraction and in patients in which there is minimal displacement of the NAC. Reportedly, there is minimal interference with the sensation of the NAC with this technique.

In situations where the nipple is present but the areola is partially or totally lost, treatment alternatives differ. Partial loss of the areola can be addressed with tattooing of the region to blend in with the color of the remaining areola. In situations where the entire areola is lost, tattooing of the areola or resurfacing with full-thickness skin grafts is useful. The upper inner thigh as a donor site produces excellent contrast with the

surrounding tissues in this situation.³⁵ In unilateral breast burns, the technique utilized may be guided by the color match of the unaffected side. However, in bilateral breast burns with areola loss, either technique provides acceptable results.

Total loss of the NAC presents a difficult problem in the burned patient. Although numerous techniques are available, their role in the reconstruction of the burned breast has yet to be fully evaluated.^{30–32} In the absence of the native NAC, a nipple can be reconstructed from numerous composite graft donors, including toe pulp, postauricular cartilage and skin or the opposite nipple.¹² The use of labial skin to reconstruct the NAC has been replaced with more current procedures. Reconstruction of the NAC using auricular skin and cartilage can be used in patients when nipple sharing is not an option. This technique can yield fair to good results.³⁵ The conchal cartilage is used to simulate Montgomery glands. Free toe pulp grafts as well as composite grafts taken from the second to fourth toe has been utilized in NAC reconstruction. Pensler et al. reviewed different results of various techniques in recon-

structing the burned NAC. They recommended the use of full-thickness skin grafts from the superomedial thigh for reconstruction of the areola. This group also recommended the use of the quadrapod flap for nipple reconstruction if there is adequate surrounding dermis.³¹ This technique appeared to be superior to the composite grafts and the 'double-bubble' technique over a 1-year period. Several authors have been skeptical with respect to the use of skin flaps in reconstruction of the NAC.¹⁰ Since these flaps require normal dermal elements and subcutaneous tissue to maintain viability to the skin, it was felt that the role of skin flaps in the reconstruction of the NAC in the burned patient was limited.

In 1984, Little described the 'skate' flap for NAC reconstruction³⁶ (Figure 57.5). Its use in reconstruction of burn patients has received little attention. However, McCauley and Robson

reported the successful use of the 'skate' flap in reconstruction of the nipple in the burned breast.³⁷ This finding clearly demonstrates the re-establishment of an adequate subdermal plexus in burned patients after resurfacing with skin grafts (Figure 57.6). Virtually all techniques that involve the projection of a nipple will succumb to some degree of flattening. Several factors have been cited for this phenomenon, including surface tension of skin, lack of normal infrastructure, and centrifugal forces.^{25,38,39}

Summary

Problems associated with reconstruction of burns to the truncal region continue to represent a challenge. Entrapment of breast tissue in burn scars in female patients can be eliminated with

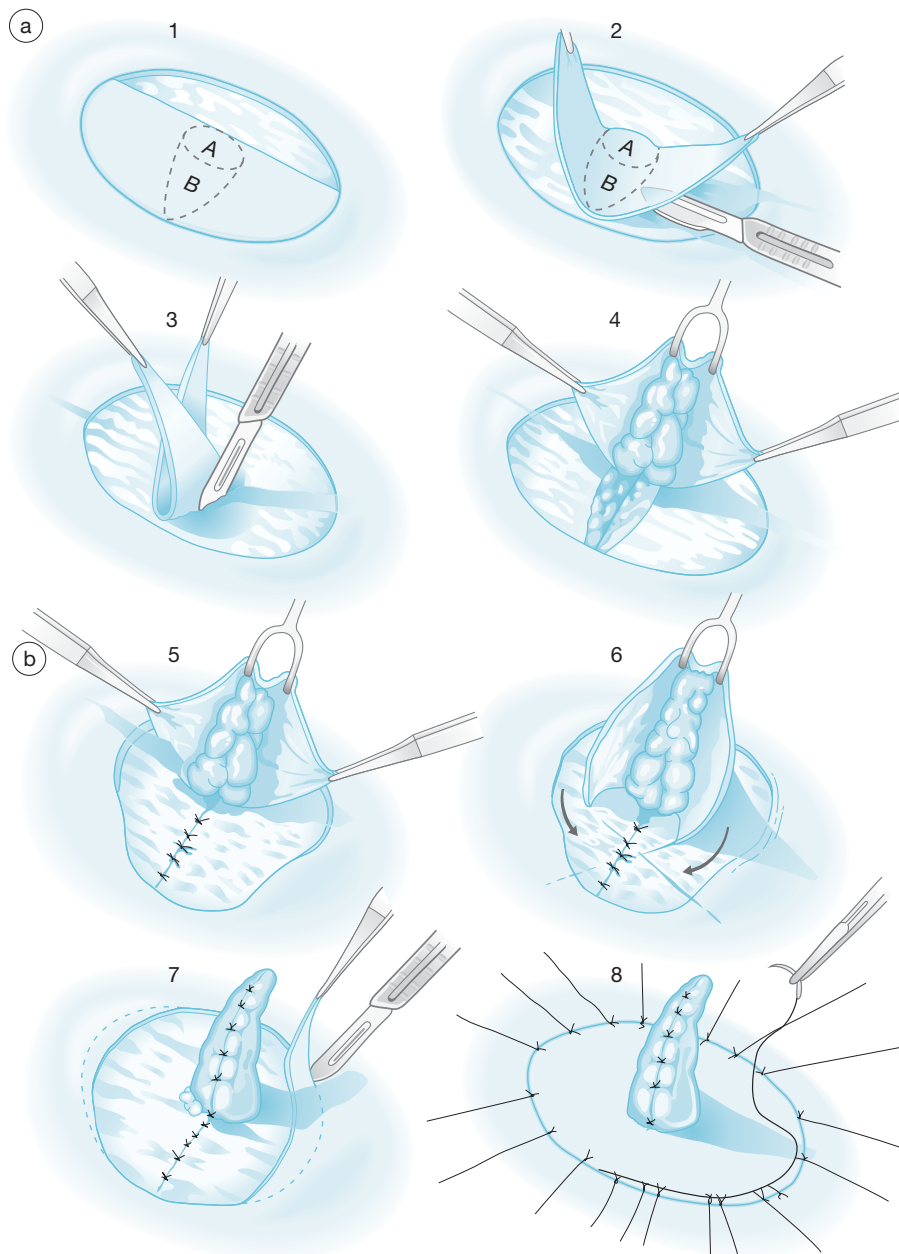

Fig. 57.5 (a) Design of the skate flap as described by Little with elevation of the pedicle. (b) Design of the skate flap as described by Little with reconstruction of the areolar and coverage with a full-thickness skin graft. (Reprinted with permission from: Little³⁶)

Figures 57.6 (a) A 17-year-old female with right-sided breast burns with a slightly smaller right breast noted. Skin grafts were used in the past to assist right-sided breast development. (b) Left pericresant mastopexy performed to lift the nipple-areolar complex with right-sided augmentation. The right nipple-areolar complex reconstructed with a skate flap and inner thigh full-thickness skin graft. (c) Two-year follow-up. Note projection still of the skate flap. skin grafts. Contour problems which are associated with developing breasts may be corrected with the use of skin grafts and/or fasciocutaneous flaps. Improved symmetry of the breast is of significant importance for patients who have unilateral burns of the breast. Reconstructive techniques, including mas-

topexy and reduction mammoplasty, may be required in order to obtain symmetry. In patients requiring fascial excision of full-thickness burns over the anterior chest wall, tissue expansion and subsequent placement of submuscular saline implants have been quite successful for breast reconstruction.

Management of burn injuries of the perineum

Ted Huang

Chapter contents

Management of burns of the perineum during acute phase of injury	749
Reconstruction of established deformities of the perineum and the perineal structures.	751
Summary.	758

Burns of the perineal area are quite uncommon even though the lower trunk and the lower extremities are vulnerable to burn injury. According to Alghanem and Herndon et al., the incidence of perineal burns was about 12 per 1000 admissions.¹ The incidence was reassessed recently by reviewing the records of 5651 patients admitted to the Shriners Burns Hospital between 1976 and 1998. There were only 91 patients identified to have burn injuries of the perineal area. While overall incidence of perineal burns has remained unchanged, boys were found to sustain the injury four times more often than girls in this group of patients. Among 44 boys with genital burns, there were 35 penile burns and 9 with scrotal injuries. In contrast, there were only four patients who had burns of the labial structures. Burns of the vaginal vault were not encountered in this group of patients.

Management of burns of the perineum during acute phase of injury

A conservative approach is used to manage perineal burns:^{1,2} i.e. the perineal area is cleansed daily and the wound is covered with antibiotic dressings. The urethral tract is stented with an indwelling Foley catheter which also decompresses the urinary bladder. The perineal area is neither splinted nor braced. The thighs are maintained at 15° of abduction using a wedge splint to minimize contracture of the hip joint. The burn is given time to demarcate and the wound is often left to heal spontaneously. A non-healing wound is managed with the use of a partial-thickness or a full-thickness skin graft. On rare occasions, a skin flap may be mobilized from the area adjacent to reconstruct defects consequential to full-thickness skin loss of the penis and the scrotum.

Other possible problems seen in the acute phase include necrosis of the penile shaft, testicular necrosis, urethral stricture, and rectal prolapse. Although the Shriners Burns Hospital and the University of Texas Medical Branch Hospitals in Galveston, Texas, have adopted a relatively conservative

regimen to the management of perineal burns, wound care approach, in practice, is quite variable and the exact regimen is often modified depending upon the structures involved.

Burns of the penis

Burn injuries limited to the penis, though possible, are quite rare (Figure 58.1). Concomitant involvement of the penis with burn injuries of the lower trunk and the perineal area, on the other hand, is quite common. The initial regimen of patient management, in addition to resuscitative measures, consists of wound care and urethral stenting. An indwelling Foley catheter of appropriate size is inserted into the urinary bladder to stent the urethral tract and at the same time to monitor the urinary output. The catheter is removed once the swelling around the penile shaft subsides and the wound becomes delineated. No attempt is made to debride the wound at this stage. Instead, it is allowed to demarcate and is often allowed to heal spontaneously.

Loss of skin over the penile shaft and the scrotum

Spontaneous healing is expected in most instances with burn injuries of the penis and scrotum since full-thickness injury of the penile and scrotal skin is relatively uncommon. Skin grafting, a partial thickness or a full thickness, could be used to cover the wound if healing is delayed (Figure 58.2).

In rare instances, a skin flap may be needed to reconstruct structures such as the urethral tract and/or scrotal sac because of the loss of skin coverage. An inguinopudendal skin flap mobilized from the inguinal crease area may be used if a skin graft is judged not to be feasible.³ The use of muscle-skin flaps, such as a gracilis MC flap, is not recommended because such flaps have a high tissue temperature which may interfere with spermatogenesis.

Burn wound of labia majora

Isolated burns of the labial structures are rare. In fact, labial burns are often associated with injuries of the surrounding areas such as the abdomen and inguinal folds. As in the management of male genitalia burns, the injured areas are allowed to heal spontaneously (Figure 58.3). Distortion of the labial structures, mostly due to contraction of the scar tissues in the pubic and inguinal areas, is left for later reconstruction.

Perineal wound coverage

An isolated burn injury of the perineal area is extremely rare. On the other hand, the area will become involved if the lower

Fig. 58.1 An isolated burn injury of the penis is relatively uncommon. This 27-year-old man sustained scalding burns of the penis from an accidental spillage of hot coffee onto the lap.

Fig. 58.3 (a) Burn injuries involving the lower trunk, thighs, and labia. While the lower abdomen and the thighs required skin grafting, the labial injury was left to heal spontaneously. (b) The appearance of genitalia 5 years after the injury.

Fig. 58.2 (a) Burns of the penis are more commonly associated with injuries of the lower trunk/lower extremities. (b) Although skin grafting was needed for wound closure around the perineum, the major bulk of the penile wounds healed spontaneously.

trunk/buttock is injured. The extent of scar contracture varies depending upon the depth of burn. While it may heal spontaneously with minimal scarring, contracture of the perineal area is a common sequela, regardless of methods used to care for the wound (Figure 58.4). The natural inclination to keep

(b) The wound, including the scrotum, was debrided and grafted with a meshed partial-thickness skin graft. (c) The ensuing changes in the genitoperineal area were characterized by scar hypertrophy and contracture. Tight scars formed across the perineum and interfered with thigh movement.

the thighs together and hips adducted during the recovery phase of acute burn injuries seems to aggravate scar contraction.

Anal burns

Burns of the anus are rare, although the anus could become involved in extensive burns of the perineum. If the skin injury around the anal opening is full thickness, the use of a skin flap may be necessary to minimize the consequential of stricture. A piece of skin flap mobilized from the adjacent area will be necessary in grafting the perianal area. Wound coverage with a skin graft is not only technically difficult but also leads to anal stricture when the graft contracts.

Rectal prolapse

Rectal prolapse occurs occasionally in young children with extensive burn injuries with or without perineal involvement. The exact reasons for rectal prolapse occurring in these burned infants remain unclear. However, rectal prolapse may be due to:

- redundant rectal mucosa,
- the structural relationship of the rectum to other pelvic organs, such as sacrum and coccyx, urinary bladder and uterus,
- the lack of muscular support provided by the pelvic musculatures, and
- the anatomical features uniquely special to infants of 1–3 years of age.

A sudden increase in intra-abdominal pressure and malnutrition due to burn injuries could conceivably aggravate the magnitude of the descent of the rectal mucosa through the anal opening.⁴

Clinically, in addition to eversion of rectal mucosa, edematous swelling around the buttocks and perianal area is quite commonly found, even when these areas are burn free. The onset can be quite sudden without any obvious precipitating event. However, it has been observed that an infant's grunting or performance of the Valsalva maneuver can precipitate an eversion of the rectal canal through the anal opening.

The treatment regimen consists of rectal padding and daily cleansing of the perineal and perianal area. Stool softener is added to the dietary regimen to facilitate bowel movement. Spontaneous regression of the prolapse is likely as nutrition improves and tissue swelling subsides (Figure 58.5). Surgical intervention, though in most instances unnecessary, is indicated if the prolapse is not readily reducible due to anal sphincteric dysfunction and/or intussusception.^{4,5}

Reconstruction of established deformities of the perineum and the perineal structures

Cicatricial contracture around the perineum is the most common sequela of perineal burns.^{1,6} In our group of 91 patients, over one-half of them suffered contractural deformity in the perineal area. The magnitude of contracture, furthermore, was exaggerated with the contraction of burn scars in the inguinal crease and inferomedial gluteal folds. Other problems, though relatively uncommon, included complete loss of the penis, anal stenosis, and intractable rectal prolapse.

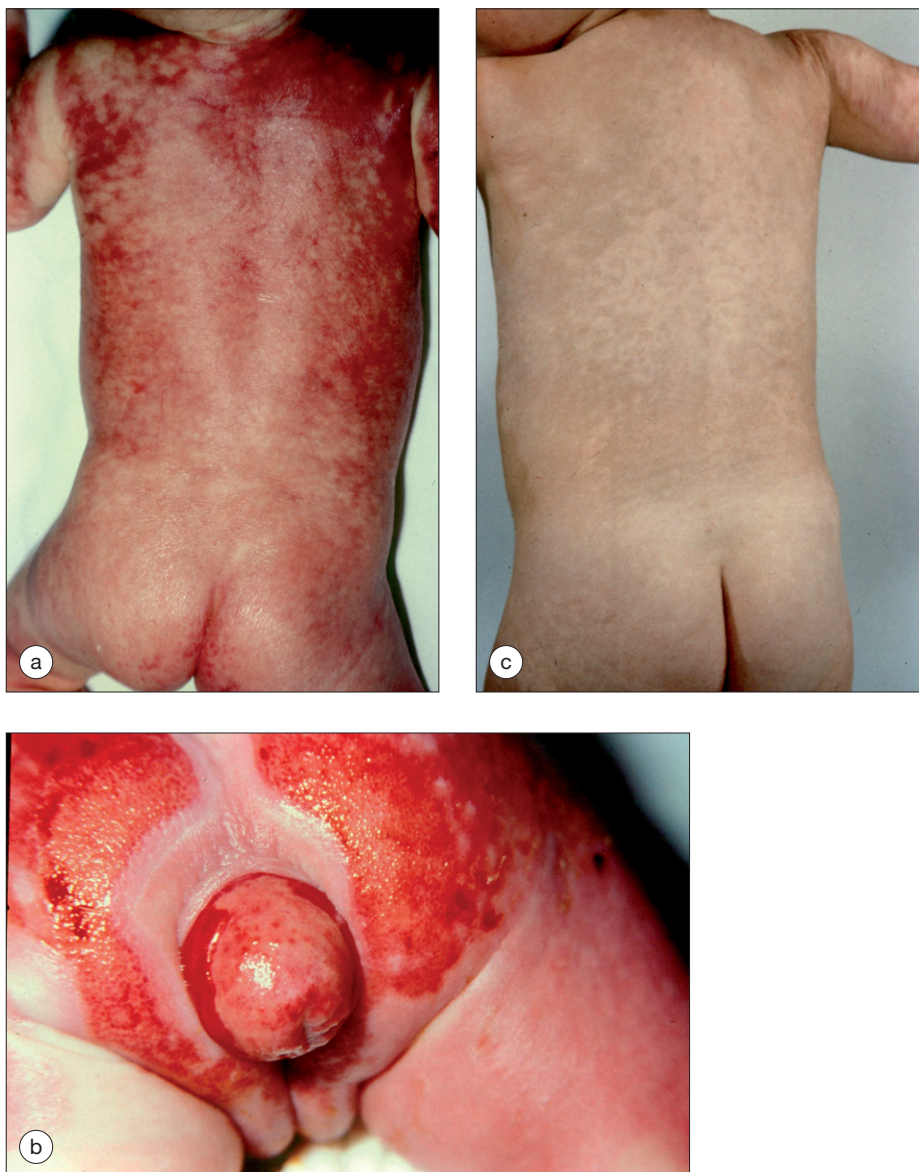

Fig. 58.5 (a) A 2-year-old girl with 65–70% total body surface burns. (b) Prolapse of the rectum appeared 12 days after the accident. The problem was managed non-surgically. (c) The prolapse receded spontaneously 2 months later as she recovered from the burn injury.

There are numerous methods (z-plasty technique, interpositional skin flap technique, incisional release of scarred tissues closed with local skin flap, skin graft) available to reconstruct the deformities. In practice, the technique used to reconstruct perineal and genital deformities varies depending upon the magnitude of scarring, scarred deformity around the perineum, and the extent of functional impediment encountered.

Reconstruction of penile deformity

The task of assessing the exact extent of penile deformities can be difficult. Distortion of the penile configuration attributable to scar contracture could be due to loss of skin or a combination of skin and Buck's fascia loss. In addition, the scarring in the pubic area and/or the inguinal fold could further exaggerate the extent of penile deformity.

Engorging the penile shaft is necessary to assess precisely the extent of penile deformity, as the gross appearance of a flaccid penis can be misleading. That is, it is necessary to make the penile shaft engorged; i.e. creating an artificial penile erec-

tion, in order to determine the extent and the location of scar involvement. Artificial penile erection is created under anesthesia by placing a tourniquet (a piece of 1/4 inch Penrose drain) at the base of the penile shaft. A sufficient amount of physiological saline solution is injected into the corpus cavernosum to induce congestion. The shaft deformity, attributable to the skin loss and/or fascial loss, is delineated once the corpus becomes engorged.

When Buck's fascia is spared injury, the skin defect, resulting from incisional release of the scar, is covered with a full-thickness skin graft. Rarely, when Buck's fascia is involved, surgical release of the facial deformity is necessary. A dermal graft harvested from the lower abdomen may be used to reconstruct the fascial defect and a skin flap (mobilized from the area along the groin crease, as an island skin pedicle flap) used to cover the skin defect.

A complete loss of the penis, although devastating, is extremely rare (Figure 58.6). Reconstruction of the penis is delayed until puberty. The delay is often necessary due to the

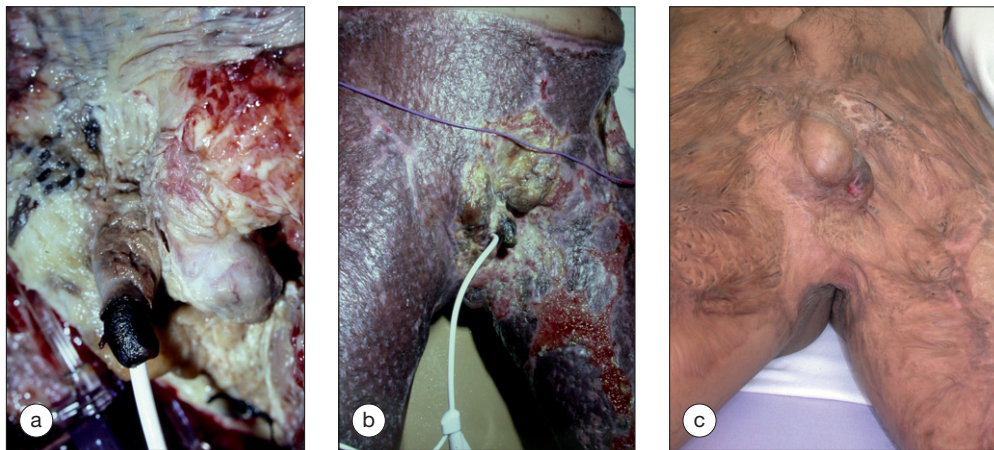

Fig. 58.6 (a) A full-thickness burn of the penis, though uncommon, can occur and the outcome is devastating, as seen in this 10-year-old boy. No attempt was made to remove the penile tissue even though it appeared grossly necrotic. Instead, the wound was allowed to demarcate itself. An indwelling Foley catheter was used to stent the urethra. (b) The patient had lost the phallus entirely. (c) The patient was able to urinate through a short remnant of the penis. Reconstruction of the penile shaft is being planned.

limited amount of soft tissue that can be harvested for genital reconstruction soon after the accident.

There are several methods currently available to reconstruct a neo-phallus. A segment of rectus abdominis MC flap, for instance, may be mobilized from the lower abdomen to form a neo-phallus. In recent years, a forearm osteocutaneous flap transferred to the pubic area via microsurgical technique has been found to be useful in reconstructing a phallus. At the time of phallus reconstruction a urethral tract can be reconstructed either using a piece of full-thickness skin graft or a forearm osteocutaneous flap (utilizing a tube-within-a-tube technique)⁷ (Figure 58.7).

Reconstruction of scrotal deformities

Full-thickness burn injuries of the scrotum result in scar encasement of testicular structures. Reconstruction, therefore, requires surgical release of the scarred areas. A thin skin flap, such as the inguinopudendal flap or a flap mobilized from the adjacent area, however, is needed to cover the resultant defect. A musculocutaneous flap, such as a gracilis MC flap, is not suitable for scrotal reconstruction because of the thickness of the flap and the possible impediment of spermatogenesis (due to the high tissue temperature of the flap). Even though contractural deformity is likely to recur, a skin graft may be used to cover the defect.

Reconstruction of labial deformity

An isolated contour deformity of the labia majora is relatively uncommon. On the other hand, scar contracture occurring in the suprapubic and pubic area, as well as the inguinal fold, could distort the normal configuration of the labia. Therefore, surgical release of the contracted scar tissues is essential to determine the extent of labial deformity. Then the method of reconstructing the deformed labia can be chosen.

To restore a contour deformity caused by skin and subcutaneous tissue loss, a skin flap may have to be mobilized from the adjacent area and to reconstruct a contour deformity due to parenchymal tissue loss, injection of free fat cells (lipoinjec-

tion) could be useful. To inject free fat cells to augment the labial contour, the cells are aspirated from the lower abdomen using the inner cannula of #14 Intracath® needle attached to a 3cc syringe. The syringe is moved in a 'back-and-forth' piston-like manner. The fat cells are injected into the labia using the same syringe but connected with a 19 gauge blunt needle.

Reconstruction of band deformity around the perineum

Scarring and scar contracture of the perineum is a common sequela of perineal burns, especially if allowed to heal spontaneously. Although seldom causing difficulty at a young age, the scars around the perineum could eventually interfere with sitting because of tightness or contraction developed around the buttock. In addition, the patient may encounter difficulty with bowel movement because of gluteal contracture and cicatricial changes involving the anal opening.

The deformity in the perineal area usually results from a tight band in the suprapubic area, or between the ischial tuberosities. Inelastic scars cause inadequate spreading of the buttock and are responsible for the discomfort experienced on sitting (Figure 58.8).

Although a contracted perineal band may be incised to gain release, the task of closing the resultant wound with a skin graft can be difficult as recurrence of contracture is a common sequela. Therefore, a multiple z-plasty technique is the preferred method of reconstruction in such cases.

The technique of multiple z-plasty

The patient is placed in the lithotomy position. Tightness and scar band can be delineated with abduction of the hip joint (Figure 58.9a). A line is drawn in the scar band along the horizontal direction of the band. The length of the horizontal line may extend from one side of the scarred area to the other. A triangular flap with its apex at the end of horizontal line is marked. The angle may vary between 30° and 60° depending upon the uninjured tissues available at both ends of the

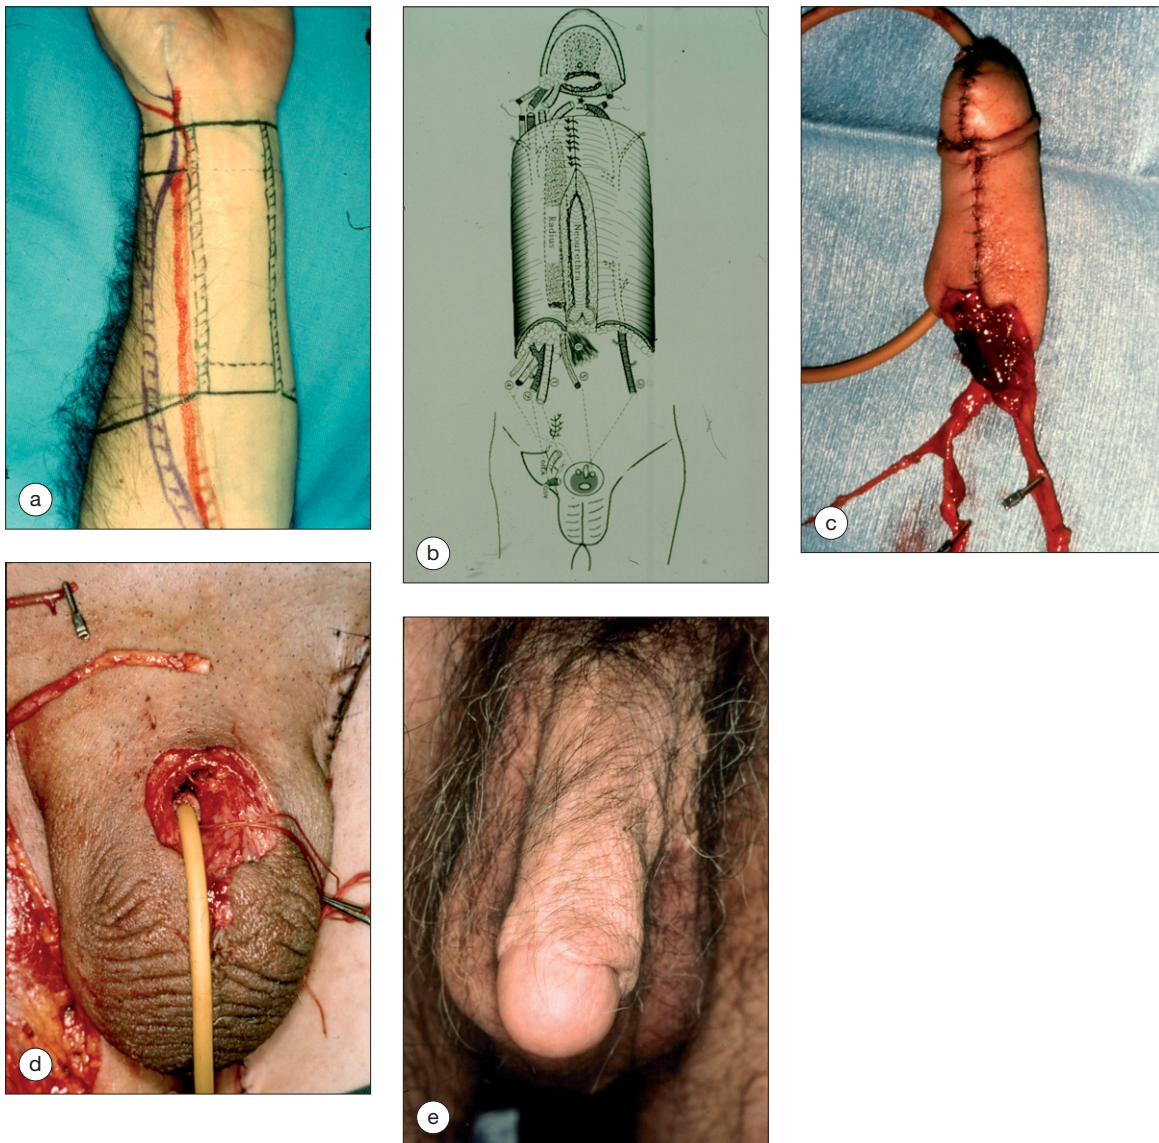

Fig. 58.7 (a) There are various techniques available to reconstruct a penile shaft. A forearm composite flap, one of the methods currently in use, was chosen to reconstruct a phallus structure for a 51-year-old man who had lost his penis because of cancer. (Courtesy of Dr Kenji Sasaki. Reprinted with permission from: Sasaki et al.⁷) (b) As shown in a schematic drawing, a section of the skin with radial artery attached is harvested from the volar surface of the forearm and utilized for penile reconstruction. A tube-inside-the-tube was used to reconstruct the urethral tract. In addition, the pulp from the big toe was used to reconstruct the glans penis. (Courtesy of Dr Kenji Sasaki. (e) A reconstructed penis in a 50-year-old man who had lost the penis because of cancer. (Courtesy of Dr. Kenji Sasaki. Reprinted with permission from: Sasaki et al.⁷)

Fig. 58.8 (a) This 11-year-old boy sustained burns in the lower trunk, thigh areas, lateral scrotal skin, and the proximal penile shaft. (b) Debridement and grafting of the burned wound resulted in tight scar bands across the suprapubic and inter-ischial areas. (c) Tight bands developed in the perineal area.

Fig. 58.9 (a) A tight scar band in the perineal area consequential to burn injuries involving the perineum and the lower extremities. (b) Releasing incisions were placed in the areas away from the anal opening to avoid injuring the anal sphincter. A triangular flap was designed in the uninjured area at each end of the scar band. A releasing incision was set perpendicularly to the direction of the scar band. (c) Each triangular flap was rotated 90° to close the open wound resulting from incisional release.

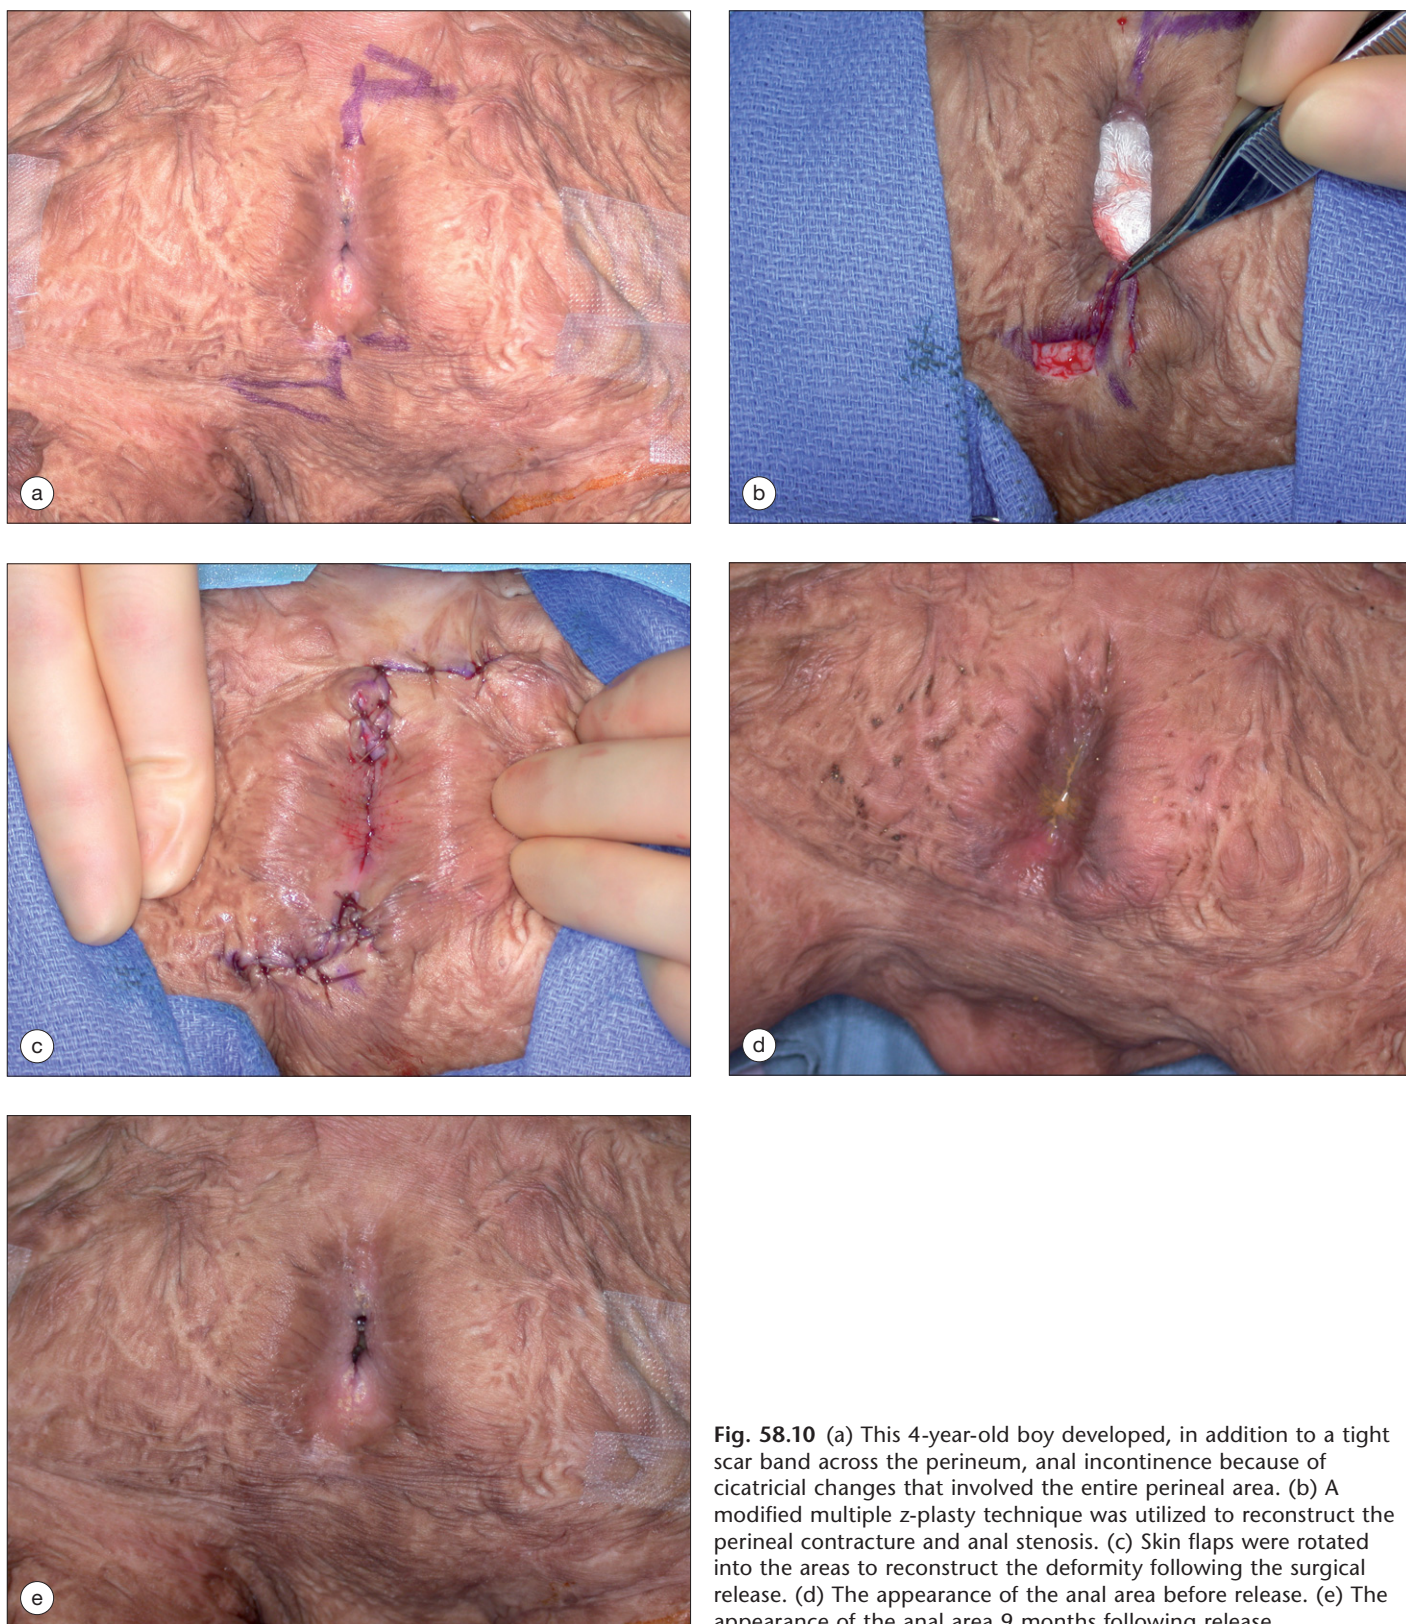

Fig. 58.10 (a) This 4-year-old boy developed, in addition to a tight scar band across the perineum, anal incontinence because of cicatricial changes that involved the entire perineal area. (b) A modified multiple z-plasty technique was utilized to reconstruct the perineal contracture and anal stenosis. (c) Skin flaps were rotated into the areas to reconstruct the deformity following the surgical release. (d) The appearance of the anal area before release. (e) The appearance of the anal area 9 months following release.

horizontal line. The length of the limb of each triangle will be the same as the incision made perpendicular to the horizontal line to release the tight band (Figure 58.9b). Two z-plasties – i.e. two triangular flaps with 30–60° and 90° angles, respectively – are formed as the flaps are raised along the skin markings made. Release of a contracted scar band is achieved by rotating these two flaps at each end (Figure 58.9c).

Although the extent of perineal release may be limited because of scarred tissues surrounding the triangular flaps fashioned, the z-plasty technique is useful in changing the pulling direction of scar tissue, thus diminishing tightness around the perineum.

Reconstruction of anal stricture

While burn injuries rarely involve the entire anorectal canal, it is not unusual that they involve the perianal skin and the external sphincter ani muscle. Stricture of the anal opening due to scar contracture and the cicatricial involvement of the

external sphincter ani muscle are common sequelae. Cicatricial changes around the anal opening can and will interfere with bowel movement.

Treatment requires surgical release of constricted scar bands around the anal opening. An interpositional skin flap fashioned as an island flap, or a modified z-plasty with skin flaps mobilized from the adjacent area, is used to make up the tissue defect (Figure 58.10). The method of using a piece of skin graft to reconstruct the defect is not useful. Application of the graft is difficult and recurrence of stricture is common because of scar contracture.

Reconstruction of rectal prolapse

Although the problem, in most instances, is self-limiting and the prolapse will recede spontaneously as the nutritional status of the patient improves and the burned perineum heals, surgical intervention will be necessary if the rectal prolapse becomes intractable^{4,5} (Figure 58.11).

Fig. 58.11 (a) This 2-year-old boy sustained a third-degree scalding burn that mostly involved the lower extremities. He developed rectal prolapse 10 days after the accident. (b) He underwent a rectopexy procedure because of persistent eversion of the rectal mucosa. (c) The patient regained anal continence 6 months after the surgery.

Summary

Burn injury of the perineum is relatively uncommon. The regimen of treatment during the acute phase of recovery is conservative. The urethral tract is stented with an indwelling Foley catheter and the wound is cleaned daily. Neither a splint nor a brace is used to immobilize the perineal area. The wound is usually left to heal spontaneously. With the rare exception when there is total loss of the penis, the resultant deformity is limited. Disfigurement of

the scrota/labial contour and/or scar bands around the genitalia is the common complaint presented by such patients.

As they interfere with sitting and/or bowel movement, reconstructing scarred deformities is centered upon the release of tight scar bands around the perineal structures. Incisional release and reconstruction utilizing a z-plasty technique or an interpositional skin flap technique is effective in correcting the deformities.

Reconstruction of burn deformities of the foot and ankle

Ted Huang

Chapter contents

Consequences of foot and ankle burns.	759
Reconstruction of the foot and ankle deformities.	759
Summary.	764

Although the exact number of incidents is unknown, the lower section of the lower limb, that is foot and ankle, is frequently burned, especially in individuals who suffer extensive burn injuries. The management of foot burns is similar to the regimen used for other bodily sites — the principle of debridement and wound coverage is followed. The technique of tangential excision of the burned wound with skin grafting, though a preferred surgical modality for burn management, may not be effective because of the difference in integumental make-up of the foot and ankle area. The thinness of the skin overlying the dorsum of the foot and ankle area renders the area more vulnerable to injury while full-thickness burns of the sole of the foot are less likely.

Skin grafting is the most common technique used to cover burn wounds. It is also used to release joint contraction. Despite the troublesome consequences of a deformed foot contour and stiffness of the toe and ankle joints affecting the gait cycle and ambulatory movements, the functional disturbance attributable to a burned foot, in practice, is surprisingly limited.

Consequences of foot and ankle burns

Deformities of the foot and ankle depend on the extent of the initial burn: for example, the scarring and contractural deformities of the toes and the ankle joint are minimal if the burn depth is superficial. The contractural problems, more commonly seen in individuals with extensive burns, have been traditionally managed with the skin grafting technique and splinting and physiotherapy are essential components of the therapeutic reconstruction regimen of burn foot deformities.

Reconstruction of the foot and ankle deformities

General principles

Releasing contracted joint structures to restore the usefulness of the foot is the fundamental approach to reconstruction. The resultant tissue defect, consequential to scar release, can be

covered with skin grafts and/or skin flaps. A Kirschner wire (0.025–0.035 inch) is usually needed to immobilize the joint structures for alignment. The position of the released joint is maintained for a period of 10–14 days. Then the wires are removed and external appliances or shoes are used to maintain the foot position. The techniques of skin grafting and/or skin flap wound coverage, on the other hand, are not infrequently plagued with problems of graft and flap loss because of tissue congestion and altered vascular supplies to the harvested flap.

Scar deformities involving the dorsum of the foot and the ankle

Hypertrophic scar deformities

Formation of a hypertrophic scar over the dorsal surface of the foot and/or ankle is probably the most common problem encountered with burn injuries that are confined to the dorsum of the foot. Contractural deformities of the foot and/or ankle are uncommon because the intrinsic skeletal rigidity of the tarsal and metatarsal bones oppose the pulling force of the scar. Although total or partial surgical removal of symptomatic and unsightly scars may be considered, a non-surgical regimen that would provide proper joint splinting and scar compression by using a high-top shoe, for example, would probably provide the same, if not a better outcome.

Contractural deformities involving the toes

An extension deformity of the toes at the metatarsophalangeal (MTP) joint level, with or without associated dorsiflexion contracture of the ankle, is common if the burns involve the dorsum of the foot and the ankle. This deformity is largely due to scarring and scar contracture following the destruction of the skin over the dorsum of the foot.

Reconstruction of dorsally contracted toes

The contracted toes are released by incising the scar at the level of the MTP joint and/or proximal interphalangeal (PIP) joint. Releasing the scar tissues at the webspace is delayed to minimize the morbidities associated with delayed wound healing.

In children, and in instances where the onset of toe extension contracture is recent, surgical manipulation of the volar plate of the MTP joint capsule is unnecessary. A Kirschner wire (0.020–0.035 inch) is inserted through the proximal phalanx to keep the digit in full extension while maintaining the MTPJ in 45°–60° plantar flexion. The wires are removed 10–14 days later, once the take of skin graft or flap is established (Figure 59.1).

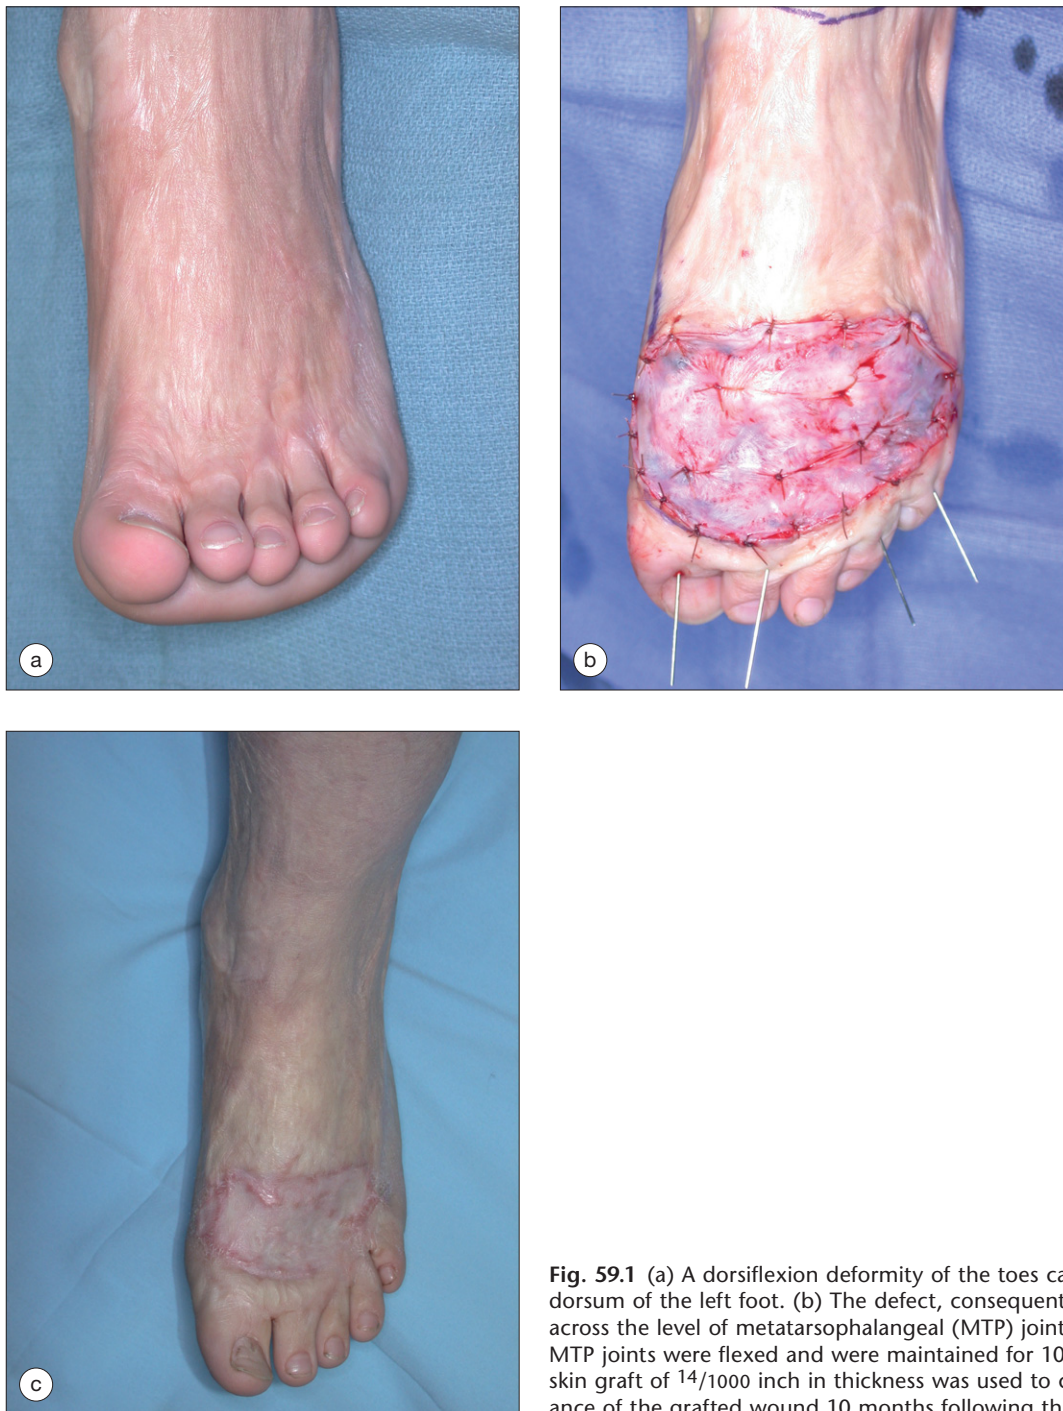

Fig. 59.1 (a) A dorsiflexion deformity of the toes caused by burns involved the dorsum of the left foot. (b) The defect, consequential to a releasing incision made across the level of metatarsophalangeal (MTP) joints, measured 10 cm × 6–7 cm. The MTP joints were flexed and were maintained for 10 days. A piece of split-thickness skin graft of $1^4/1000$ inch in thickness was used to cover the wound. (c) The appearance of the grafted wound 10 months following the procedure.

While it is seldom indicated in children, volar capsuloplasty, involving the volar plate of the MTP joint, may be necessary in adults or in instances where a joint has been subluxed for a long time. Merely releasing and skin graft/flap covering of the wound over the joint structures may not be enough to restore the joint alignment.

In order to minimize recurrent contracture of the toe joints, commonly associated with the use of skin grafting technique, a skin flap mobilized from the area adjacent may be used, particularly in instances where the joint structure is exposed. A $3/4$

paratenocutaneous z-plasty technique achieves coverage of both the joint structures and the wound defect (Figure 59.2).

Contractural deformities of the anterior ankle

Tightness of the ankle joint in foot dorsiflexion is the usual deformity encountered in instances where the burn injury is limited to the anterior surface of the ankle. As in other deformities noted, improper splinting of the foot and the ankle joint, plus scar contracture, are the probable culprits. Although the deformity could be amended with proper foot/ankle splinting,

Figure 59.2 (a) Dorsiflexion contracture developed over the fourth and fifth MTP joint level. An incision was made to achieve needed release. (b) A triangular skin flap with an inner angle of 25°–30° was fabricated from the lateral aspect of the foot. (c) The fascial layer of the abductor digiti V was included in the flap formation. The flap was rotated medially and caudally to cover the defect resulting from release.

surgical intervention may be necessary. Of course, correction of an extremely deformed ankle joint may require, in addition to releasing of contracted scar tissues, reconstruction of deformed periarticular structures. Capsuloplasty and re-routing of the tendons around the ankle joint are oftentimes necessary.

Reconstruction of dorsiflexion contracture of the ankle

Although the skin graft is most commonly used to cover wounds around the ankle, the problem of wound contracture is ever present. It is, furthermore, not a useful means of repairing a wound with an exposed joint and tendons, commonly associated with joint realignment procedures requiring elaborate joint structure reconstruction. However, there are two approaches that are useful for scar release and wound coverage:

- A z-plasty technique is used to release a contractile scar across the ankle joint. However, the conventional approach in which triangular skin flaps are elevated tends to cause vascular supply impairment to the flap, thus causing flap necrosis. Instead, the technique of fabricating a composite skin flap, namely a paratenocutaneous flap, may be used to minimize this undesirable consequence (Figure 59.3).
- The technique of $3/4$ paratenocutaneous (PC) z-plasty, a variant of the PC z-plasty technique, is useful for instances where scarring is more extensive and uninjured skin available for flap fabrication is scarce. A right-angled triangular skin flap is marked with its cathetus perpendicular to the line of scar release. The paratenon is included in the fabrication of the flap, identical to fabricating a PC flap in a z-plasty technique. The flap is rotated 90° to fill the defect resulting from release (Figure 59.4).

Scar deformities involving the sole of the foot

Deep burns, though uncommon, could involve the plantar surface of the foot and the toes. In such instances, plantar flexion of the toes at all joint levels (claw toe deformities) is the most common problem encountered, especially when burns do not involve the dorsal surface of the toes. Plantar flexion of the toes, compounded by contraction of the scar formed in the area, is the most likely cause of this deformity.

Reconstruction of the plantar flexion deformities of the toe

Surgical release of the contracted scar at the level of maximal contraction is usually unnecessary unless the magnitude of contraction is severe enough to render wearing a shoe difficult and/or ambulation is arduous. (A non-surgical regimen of toe-splinting in these cases is not effective.)

The use of a composite skin flap mobilized from the dorsum of the foot, if it is uninvolved, may be feasible. Skin grafting technique, however, is the best modality for reconstruction. Splinting of the foot and toes immediately following surgery is an essential component of the post-surgical care plan as recurrence of the contracture is very likely without this.

Reconstruction of deformities involving the plantar surface of the foot

The problems are mostly related to the breakdown of the graft caused by pressure and shearing when walking. Although a local composite skin flap, if a flap fabrication is possible, could be used to reconstruct a small defect, breakdown of the skin with ulcer formation is inevitable unless the flap is sensate. Restoration of skin sensation to the pressure points is, in this sense, a prerequisite for successful patient rehabilitation regardless of the techniques used.

Reconstruction of specific ankle deformities

Extensive burns of the foot and ankle area, although partially dependant of the magnitude of the burns and scar contracture, could lead to a talipes-like deformity of the foot (talipes equines, varus and valgus). To restore the joint normality, reconstructive procedures will involve not only the release of the capsular structure around the ankle joint but also the lengthening of the tendon of Achilles (for an equines deformity, for example). In practice, the extent of ankle restoration may be limited because of the difficulty in closing an open wound that has resulted from the release of the soft tissues. Use of a skin flap in conjunction with a skin graft may be considered to cover a wound with exposed tendinous and capsular elements.

Fig. 59.3 (a) (Left) Two equilateral triangular flaps are marked over the tight anterior surface of the right ankle. (Center) Two flaps that included the paratenon underneath were fabricated. (Right) Two paratenocutaneous (PC) flaps were interposed to achieve the needed release. (b) (Left) The scar located over the anterior surface of the right ankle as noted in (a), indicated joint contracture. (Center) The appearance of right ankle 3 months following the releasing procedure. (Right) The ankle remained free of contraction 2 years after the operation.

Reconstructing a talipes equines-like deformity

Plantar flexion deformity is most commonly caused by an injury involving the heel. While scar contraction could be the main factor responsible for the deformity, tendo-Achilles shortening (an undesirable consequences of inadequate splinting of the ankle) can further aggravate the deformity. Surgical restoration of ankle mobility will require lengthening of the Achilles tendon. Successful closure of the resulting heel wound with exposed tendon structures necessitates measures such as fasciocutaneous (FC) z-plasty or $3/4$ FC z-plasty techniques (Figures 59.3 and 59.4).

Reconstructing a talipes vera and valgus-like deformity

Although delineation of the exact extent of tissue destruction and scarring causing the joint deformity may be difficult, by releasing the wound, tendon and joint structures are exposed. Inclusion of a surgical plan for wound coverage, in this sense, is essential to minimize the morbidities. A transpositional FC flap technique, alias $3/4$ FC z-plasty, is useful. The technical details of the FC z-plasty and the $3/4$ FC z-plasty technique are described as follows:

Fig. 59.4 (a) (Left) A varus deformity developed in the right ankle due to scar contracture and a tight heel cord. A right-angled triangular skin marking was made in the posterior ankle area in preparation for wound coverage. (Center) A skin flap containing the fascia underneath was fabricated. (Right) The flap was rotated medially to cover a wound resulting from release of the scar and Achilles tendon. (b) (Left) The appearance of the right ankle before release. (Right) The patient is able to maintain the ankle joint properly while walking.

Modified z-plasty technique (includes the paratenon in the flap fabrication): alias $3/4$ paratenocutaneous z-plasty technique

Both techniques are essentially identical to the FC z-plasty and $3/4$ FC z-plasty. They are so termed because the paratenon of the underlying tendon structures is included in the flap fabrication to insure a vascular supply; therefore, in fabricating a flap, the dissection of the tissue must include the paratenon overlying the tendinous structures. A composite triangular skin flap (the skin and the paratenon located underneath) are transposed in a manner identical to other techniques (Figures 59.5 and 59.6).

Comments

The task of managing foot and ankle deformities consequential to burn injuries can be difficult. In recent years there has been a paucity of literature about foot and ankle reconstruction in burn patients. Factors such as patients' lack of desire to undergo reconstruction and/or the advent of physical problems causing a change in treatment priority and the consequential difficulties in patient management may account for the lack of interest shown by physicians in foot and ankle reconstruction in burned patients. The care of these patients, in practice, has been assumed by non-surgical services; a physical therapist is given the task of providing care that will lead

Fig. 59.5 (a) The patient developed a varus deformity of the left ankle. Incisional release of the contracted scar plus tendon transfer was needed to restore the ankle joint alignment. (b) A distally based FC flap was fabricated in the anteromedial aspect of the lower leg and the ankle. (c) The flap was moved caudad to cover the wound where the joint structures and tendons were exposed. (d) The flap donor site defect was covered with a piece of partial-thickness skin graft.

Fig. 59.6 (a) The appearance of left ankle before release. (b) The ankle joint alignment was judged at 9 months after the surgery to be proper.

to the regaining of muscle strength and joint mobility.¹ However, therapeutic goals using physical therapy alone may be unattainable in individuals with permanent structural destruction of the foot and ankle joints — that is, the foot and ankle will remain stiff and walking will be difficult regardless of the intensity and the duration of therapy rendered. It is, therefore, essential that surgeons continue to involve themselves in the care of these patients.

Scar contracture is the most common cause of stiff foot and ankle joints. Surgical release of contracted scar around the joint is, in this sense, the most fundamental and the most common approach used to restore mobility of joints. In practice, maintaining a proper joint alignment is difficult even though the release of scar tissues and surrounding joint structures is complete. This difficulty in restoring joint alignment could be due to structural alteration within the joint capsule caused by the burn injuries and/or protracted abnormal positioning of the joint. Release of ligamentous structures surrounding the joint, however, is seldom needed. Instead, the joint alignment can be maintained easily with the use of Kirschner wires (0.025–0.035 inch) inserted percutaneously, causing ‘re-shaping’ of the altered capsular elements.

Skin grafting is the technique most commonly used to cover an open wound resulting from scar release or joint realignment. However, its usefulness may be compromised if the wound is located in a pressure-bearing area of the foot, e.g. the sole of the foot. Incomplete or inadequate graft sensory re-innervation in a pressure-bearing area, furthermore, will lead to breakdown of the graft. Although various techniques to resurface burned sole have been advocated,^{2–4} their usefulness in burn foot reconstruction is limited. Similarly, the skin materials suitable for covering an exposed tendon and joint structure must have the components of subcutaneous fatty tissue. A skin flap, with an assured vascular supply, that can be mobilized from an adjacent area, is ideal material for wound coverage. (Obviously, if the burn has damaged not only the foot but also the adjacent tissues, this negates the possibility of using the tissues from the area as a flap donor site.) A composite tissue transfer via a microsurgical technique for reconstruction, though clinically appealing, may not be feasible because of a lack of suitable donor sites.^{5,6} In contrast, a local flap technique – e.g. a rotational flap technique and/or an interpositional flap technique – has a logistic advantage over other techniques. However, a flap fabricated in the leg, espe-

cially in the area below the knee, can be plagued with problems of necrosis. Separation of the subcutaneous fatty layer, an essential maneuver in flap fabrication, would inevitably cause disruption of the vascular supplies to the skin. More recently advocated techniques utilizing a musculocutaneous (MC) flap, a perforator flap or reverse flow skin flap,^{7–9} appeared to have technical advantages over a random skin flap. The tissue mobilized, however, is, generally speaking, bulky for the wound coverage and excursion of the flap may be limited. A random FC flap and a random PC flap (a composite skin flap that includes the underlying fascia and/or paratenon) appeared to circumvent the anatomical limitation in flap fabrication. Skin located almost anywhere in the foot and in the lower leg could be used for designing a skin flap for wound coverage. (As we have noted, the use of this technique is possible in a scarred area unless the underlying fascia and/or paratenon has been destroyed.)

Releasing a contracted scarred area is achieved most efficiently by interposing two equilateral triangular skin flaps sharing a common side, the geometric basis for z-plasty technique. A $3/4$ z-plasty technique of tissue release, also known as an interpositional flap technique, a banner flap technique, though it may not be as efficient, is based upon the similar principle that a right-angled triangle is formed with its cathetus made perpendicular to the line of scar release. The internal angle of this triangle may be set at 45° or less. The triangular flap is rotated 90° to make up the tissue defect resulting from releasing of the contracted scar. Although mobilization of the skin flap is simple, surgical dissection of the subcutaneous tissue may compromise the viability of the triangular skin flap. Inclusion of the fascia and/or paratenon in flap design and fabrication, in this sense, assures flap viability and is particularly useful in fabricating a triangular flap with a long cathetus and a narrow internal angle.

Summary

Although the task of reconstructing contractural deformities developed in the foot and ankle is difficult, the basic technique of incisional release with skin graft may be useful. On the other hand, the use of a local rotational skin flap technique, alias $3/4$ z-plasty, is preferred, especially in instances where a flap is needed to cover a wound with exposed tendon and joint structure. The viability of a skin flap is enhanced by including the fascia and/or paratenon in flap design.

Introduction

In seeking optimum health for each patient, ‘total burn care’ aspires to integrated excellence in multiple dimensions. It is a ‘bio-psycho-social-economic-legal-and ethical’ enterprise, and the many hyphens indicate that all the dimensions of care are connected. Too often, the bio-psycho-social-etc. dimensions are assumed to be interconnected like railway cars, with the biological dimension in front, and the ethical hooked on only if necessary at the end, like an optional caboose. This is a misleading assumption. In our experience, ‘total burn care’ is most frequently achieved when it is assumed that *all* the dimensions of burn care are *always* present and in need of regular attention. Moreover, highly integrated, team-oriented, interdisciplinary¹ burn centers practice as if *all* the dimensions of care are *always* interpenetrating, like the length, width, and height of a solid object. In their daily work they assume that no one dimension may be changed without affecting all the others, and they depend on frequent detailed rounds, interdisciplinary staff meetings, and ongoing interviews with patients and families to keep all the dimensions of care ever coordinated and up to date.

In part because the multiple dimensions of burn care are so intimately interrelated, decisions involving the ethical dimension of burn care are extremely common. They are so common, in fact, that care-providers are usually unaware of them. Ethics, after all, is critical thinking about right and wrong, what should or should not be done, etc.² The words ‘should’, ‘should not’ and so forth indicate that ethical matters are being addressed. For example, whenever we decide which of several therapeutic alternatives *should* be recommended, we are making an ethical decision.³ Should we spend more time with patient A than with patient B? Should we catch up on our

journal reading as opposed to getting more sleep? Should we spend more time with our families and less at work? All are ethical decisions. Ethical decision making is therefore like breathing:⁴ ever necessary and ongoing, but regularly automatic unless the problem is serious enough to be singled out for explicit attention.

What is ‘an ethical problem?’ when is it serious?

Often, significant ethical problems are trivialized by mislabeling them as ‘merely problems in communication’.^a A formal yet practical definition is therefore necessary: an ethical problem is present when it involves a conflict of two or more of the following: rights or rights-claims, obligations, goods and/or values.^b For example, disputes about writing a ‘comfort-measures-only’ order for a patient without decision-making capacity and with a very low probability of survival commonly involve a conflict between an obligation and a good: the obligation not to abandon aggressive therapy prematurely, and the good of a maximally pain-free and unprotracted death. In such a case, *the burn team and the patient/surrogate* are ordinarily the major stakeholders and appropriate decision-makers, and we say they are addressing ‘a problem in *clinical ethics*’. On the other hand, consider the burn center’s or healthcare organization’s (HCO’s) responsibility to ICU patients when a safe nurse:patient ratio cannot be consistently met despite the burn center’s best efforts? If discerning ‘what should be done’ in such circumstances requires decision-making at the *managerial level* of the burn center or HCO, a ‘problem in *organizational ethics*’⁵ is the correct term to use.

As indicated, conflicts among rights, obligations etc., are *very* common and vary greatly in difficulty. When should they be taken seriously? An ethical problem is serious when there are stakeholders involved who stand to be affected seriously by the problem or its outcome. Stakeholders working

^a As we shall explain in detail, ‘ethical problems’ shared by stakeholders are, in fact, optimally resolved by communication . . . but by a very challenging, particular, uncommon, and decidedly untrivial species of communication called ethical dialogue.

^b Modified slightly from: May WW. Discerning what’s right in health care at the clinical level. Lecture at U.S.C. Los Angeles, CA: Keck School of Medicine; May 8, 2000. As used here and elsewhere in this chapter, the term ‘values’ refers to considerations (e.g. principles, laws, rules, roles, assumptions, preferences, goals, etc.) giving direction and/or impetus to decision making.

collaboratively without outside help can successfully manage the vast majority of such problems. When are such problems so serious that assistance should be sought from a healthcare ethics committee/consultant (HEC) or its equivalent? There are two answers: the first short and crude, the second longer and more precise. An ethical problem is serious enough to refer to an HEC:

- When you suspect the ‘New York Times sniff-test’ would be positive,^c i.e. you think a hypothetical newspaper reporter might be interested in making the problem or its solution public.
- When there is persistent disagreement among the major stakeholders; and codes, rules, laws and more discussions fail to lead to a resolution within generally acceptable ethical boundaries.

How should ‘clinical ethics’ problems be managed?

In the United States, the ‘informed consent process’ was developed by the American judiciary to safeguard the legal rights and welfare of all the stakeholders participating in ‘bedside’ or ‘clinical’ decision-making. Throughout the USA, this legal process has become the foundation of the healthcare-provider’s approach to avoiding and managing serious ethical problems at the bedside. Its application in the burn center was explained and diagrammed in detail in the first edition of this book,⁶ and what follows should be considered an update and development of what is stated there.

On the vast majority of occasions, there is little or no difficulty achieving agreement and patient consent about a proposed course of burn management. Occasionally, however, the process of obtaining informed consent leads to problems involving disagreements, anxieties and/or controversies about ‘what should be done’. At this point, the participants must give careful attention to the quality of the discussion or ‘ethical discourse’ being used in attempting to resolve the problem. Ethical discourse is a skill requiring practice, like playing a musical instrument. No one becomes good at playing the violin or participating in ethical discourse simply by reading books about the subject, or by letting a consultant take over when things get difficult. Avoidance of, or reluctance to participate in, discourse with stakeholders about ethical problems is like a violin player who avoids practice, or won’t go near the concert hall: both will perform suboptimally when at last forced by circumstances to act.

Contrary to very common practice, ethical discourse at its best is not merely filling your ‘opponent’s’ heads with what you want them to know so they will say what you want hear. Nor is it simply getting your discourse partners to effectively ‘get things off their chests’ so they will feel better and then say what you want to hear. Least of all is it engaging in verbal warfare in an effort to ‘be victorious over your opponents’. At its best, ethical discourse begins by building a ‘safe place for ethical dialogue’, i.e. establishing an interpersonal ‘relation-

ship’ made safe for transparent and self-critical honesty by making active listening and openness-to-learning the norm.⁷

The role of the care-provider in ethical dialogue

The care-provider should *develop the trust* necessary to establish the ‘safe place for ethical dialogue’ described above. To do this, the care-provider should learn the bio-psycho-social-economic- and cultural/religious information required to approach the patient and their family and/or surrogate with empathy for their lives and values. Some religious backgrounds teach us that we have certain limitations to this life and look to the future beyond. Others teach us that within our lives we’ll come back and reflect on what our previous lives have been and also place extreme respect on the departed spirit. Finally, there are people who do not have a religious background and live for different goals and different aspirations. All of these must be considered early on when determining what the caregiver’s relationship and position will be with the patients and their families. Many patients will decide against extremes of treatment and continuing care with the hope of not burdening their family with large hospital bills. Often these issues must be explored with patients before one can feel comfortable with the decision and its justification.

The care-provider must *discover if the patient has ‘decision-making capacity’* sufficient to participate meaningfully in deliberation. To have decision-making capacity, the patient’s (or if necessary, the patient’s/surrogate’s) consent to or refusal of the care-provider’s recommendations must be: *informed* (i.e. comprehending and appreciating relevant information); *free* (substantially free of distorting non-rational/emotional influences); *deliberate* (decided after weighing pros versus cons in the light of his or her value system); *voluntary* (reflecting his or her own intentions); and *expressed* (communicated verbally or non-verbally).⁸ Decision-making capacity is enhanced by optimizing the patient’s physiological stability, consciousness, and pain control as much as possible. It is typically verified by ascertaining orientation, and by asking patients to rephrase the information provided to them in their own words and to say why they have made the decision they have. Determination of decision-making capacity by judicial process (i.e. determination of ‘legal competency’) is rarely necessary. If despite all efforts, the patient is found to be without decision-making capacity, an appropriate surrogate is commonly available among the patient’s family or friends.

The care-provider should *provide appropriate information* about the patient’s diagnosis and the therapy proposed, its nature, prognosis, pros and cons, and similar information about plausible alternatives including forgoing the therapy proposed. Prior investigation of the *patient’s and/or surrogate’s bio-psycho-social-economic-cultural-etc. background* is particularly helpful in the effort to assure clear communication and a common understanding among dialogue partners.

The role of the patient or surrogate

The initial task of the patient is to assimilate the information given by the caregivers. One cannot expect a patient in burn shock to understand or have complete background to understand what medical information is being given to them. There are limitations in their understanding and assimilation of

^cComment made at the 5th Annual Conference of the Los Angeles County Bioethics Network, Marina del Rey, CA: 18 April, 1998.

information that must be taken into account. Also, the patients have the right within their own value system to make a decision with their own best interest at heart. This includes their aforementioned religious or non-religious background, their family and what the needs and wants of their family are. It becomes an obligation of the patient or their surrogate to become a member of the team responsible for the individual. This obligation includes the necessity to reveal information completely and honestly, to become actively involved in their care, and participate constructively and sincerely in ethical dialogue about the issues at hand.

We must also consider previous life experiences. For example, the patient may have had family members or relatives with severe or terminal illnesses, themselves. Such experiences may influence their decision-making. Religious belief may also be a large factor in people's decisions. A clergyman might be involved at any step of the way to involve the patient's religious resources or spiritual support background in order to try to make the decisions about care and continuing treatments. Finally, there is the perception of what it would be like to survive a significant burn. Many people feel that this is not something that one would wish on anyone, let alone suffer through oneself. Patients may feel that they are not going to be a functional member of society, or that they will lose out on many of the things that they had been previously involved in or hope to achieve. Shriners Burns Hospital-Galveston has performed investigations in this area, looking at children as an example of this outcome; the essence is that children who survive large burn injuries end up at least as well off as their peers.⁹ Boys, when they reach maturity, perform better scholastically and have a better self-image than their peers; girls perform at least on an average level with their peers. So, what we are finding is that these people do not become shut-ins but they do survive and thrive. The philosophy is that if you help the person get through the crisis, their own internal tools dictate whether they are going to fail or succeed. If the patient was going to succeed, they will succeed. If the patient fails, they were going to fail regardless of the burn injury. This can be employed and recognized by these data.

How should persistent ethical conflict be managed?

Even when participants make a sincere effort to establish a 'safe place', 'put relationship before decision-making', and perform their roles well, disagreements about conscientiously held positions occasionally persist. At this point, patience and setting aside adequate time to walk through carefully considered steps in ethical decision-making are necessary. Often, to build up their own skills and enhance chances of success, the patient/surrogate or care-providers will ask an HEC to coach them in pursuing a consensus collaboratively arrived at.

In any serious ethical inquiry, three questions must be answered: What seems to be the problem? What can be done? What should be done?³ A seven-step decision-making model (illustrated in Table 60.1) has been found helpful in answering these questions.

In arranging a conference designed to achieve a consensus resolving ethical conflict at the clinical level, every effort should be made to have all the major stakeholders present to

work collaboratively. To discover their current perceptions and level of understanding, to help equalize power, and to model civil discourse, the patient/surrogate and their significant others are asked to speak first as the care-providers listen carefully and respectfully. As indicated by step 1 (see Table 60.1), patients are asked to introduce themselves, explain the conflict as they see it, and indicate what they hope to achieve by the discussion. Thereafter, the care-providers do the same. This step typically takes the most time, but is the most important of all the seven. It 'lets off steam', makes the patient/surrogate and allies feel 'listened to', and optimally leads them to ask for the corrective and supplementary information they need from the care-providers, which (in step 2) they usually can provide or obtain^d. If successfully carried out, steps 1 and 2 transform a potential or actual power struggle into a collaborative search for the answers to the next and then the final question listed on Table 60.1.

The conversation of step 3 may address principles (like respect for persons, beneficence, etc.) but more typically cites relevant laws and rules of the community and or institution, and/or other values ('no unnecessary pain', 'what the patient would want if able to speak', etc.). Step 4 is usually best carried out using a blackboard or equivalent to brainstorm and record all the plausible alternative courses of action. In step 5, the group collaboratively may find a principle, rule, value, etc., or some combination thereof so compelling that the proper alternative is clear; e.g. because it is considered unlawful homicide in most locations, large doses of narcotic primarily intended to stop breathing rather than control pain will be found unacceptable. If the decision is still not clear, steps 6 and 7 will usually lead to a mutually acceptable decision within boundaries acceptable institutionally, legally, and ethically.

Rarely, consensus will elude the most sincere adherence to the seven-step process. If 'time to sleep on the problem', further discussion, efforts to transfer care of the patient, etc.,

TABLE 60.1 THREE QUESTIONS TO BE ADDRESSED WHEN A CLINICAL ETHICS PROBLEM IS SERIOUS AND PERSISTENT, AND THE STEPS APPROPRIATE FOR ANSWERING EACH QUESTION

Question to be answered	Steps for answering each question
A. What seems to be the problem?	Step 1: Disclose/discover conflicting values of stakeholders Step 2: Disclose/discover the relevant information
B. What should be done?	Step 5: Compare alternatives and values: is decision clear? Step 6: If not, assess consequences Step 7: Make decision, collaboratively if possible
Modified with permission from: May WW. Ethics in the accounting curriculum: cases and readings. Sarasota, FL: American Accounting Association; 1990:1.	

^dNote the similarity of these early steps to those of the 'S-P-I-K-E-S' protocol for delivering 'bad news' described by Buckman as quoted by Foley K. A 44-year-old woman with severe pain at end-of-life. JAMA 1999; 281:1937-1945.

fail, appeal to the courts, or (in at least one US state¹⁰) appeal to relevant legislation for relief from responsibility for care of the patient may be necessary.

The patient without decision-making capacity, surrogate or advance directive

In such cases, care-providers typically have no way of knowing or deducing with confidence what the patient's wishes might be in a given set of circumstances. In general, the decision must seek the 'best interest of the patient', but the process required may vary. In some jurisdictions, consultation with another physician, the healthcare institution's administration, and/or HEC, is mandatory. In others, a court-appointed conservator might be required. In all such cases:

- the search for a surrogate should be diligent;
- all relevant medical information must be obtained and reviewed;
- real or apparent conflicts of interest must be disclosed;
- the opinions of the healthcare team, and of one or more physicians in addition to the responsible attending, should be reviewed;
- burden versus benefit must be weighed from the patient's point of view; and
- steps should be taken to ensure the benefit of continued life to a disabled patient is not devalued or underestimated.¹¹

Some institutions also require that consideration of economic impact on healthcare-providers and the healthcare institution be excluded from consideration in such cases. Eventually, a surrogate decision-maker is identified and, hopefully, this is a person who has previously known the patient and their values prior to the accident, who has possibly had discussions about extreme end-of-life issues and can speak on the patient's behalf. The surrogate decision-maker must not make the decision based on what they would want for the patient. However, the surrogate decision-maker must know what that patient would prefer and act as an advocate in this situation since the patient is not able to participate in the decision.

How should 'organizational ethics' problems be managed?

Currently, healthcare decision-making affecting burn care occurs at three levels: in the clinic, in the organization, and in society.⁵ The disciplines designed to improve ethical decision-making at the first and last levels are called 'clinical' and 'societal' ethics, respectively. They discern facts and values for guiding *clinical* or *societal* decisions that affect patient care and have received wide attention in both the media and scholarly journals for years. Recently, attention has been called to the need for discernment of facts and values for guiding *managerial* decisions that affect patient care.^{5,12} For example, at times problems present as difficulties in clinical decision-making, but have their 'root causes' in areas that require decision-making at the managerial level. With dwindling numbers of nurses entering training, fewer and fewer nurses will be available to provide intensive care, and managerial decisions will be required to produce or recruit more nurses and to judge just when it is no longer safe to admit

new patients to beds without adequate staffing. Perhaps rehabilitation services in a given geographical area have not kept up with the ever increasing numbers of patients with large burns who survive but require more, longer, and more expert rehabilitation. Managerial decisions about the distribution of scarce resources will have to be made if adequate rehabilitation is to be available.

Such decisions are ethical: they involve conflicts of rights, obligations, goods, and/or other values. They tend to be less dramatically immediate and more deferrable, but they usually affect more persons and require more resources and follow-up than clinical ethics decisions.¹² They sometimes appear to be made 'in the front office', apparently without satisfactory input from care-providers, patients or other stakeholders, and without availability of extensive literature or assistance from a committee or consultant skilled in ethical analysis and critique applied at the organizational level.

The development of the discipline of 'organizational ethics' is just beginning, and is overdue in the judgment of JACHO¹³ and other authorities.¹⁴ We believe the obligation to be ethical at every level of healthcare decision-making and will become increasingly obvious and pressing with continuing changes in the ways healthcare is delivered. We hope that future editions of this book will report significantly increasing awareness of, and progress in, this level of healthcare ethics. Without such progress, the ability of healthcare ethics to make a difference in practice even at the clinical level will be significantly limited.

Specific problems

Human research

Many of the modern improvements in healthcare, particularly burns, have come through active research protocols. Many advances, including fluid resuscitation, excision and grafting, temperature and nutritional control, and modulation of hypermetabolic response, are based on active research in a clinical setting on human patients. It must be remembered that these are volunteers first and patients must not be coerced into the treatment. Institutions involved in human research must have Institutional Review Boards in place to monitor approved protocols and follow-up on patients and complaints with their research-driven caregivers. Childhood research is an even more scrutinized area because it is the parent, as a surrogate, who is giving consent for the research. It is a difficult area to approach, however, with the thorough monitoring of Institutional Review Boards and the realization children have a great deal to benefit from advances in healthcare. Children should be included in research so that they can get the benefits of progress in medicine and science at the earliest possible opportunity. However, this should not be at the expense of their own rights. Many patients feel that, when asked to participate in research protocols, they have a duty to those who proceeded them and who helped the physicians reach their current level of care. Patients often feel they should try to give something back to the science of medicine. Patients realize that they cannot fully repay their caregivers and may feel they must participate in research in order to help future victims.

Futility

The concept of futility and hopelessness in the care of a patient has changed drastically over the recent past. At one point any burn over a significant size offered no hope for survival.¹⁵ Through efforts in resuscitation, physicians have pushed this survivability to current levels where even in the youngest of age groups extremely large burn victims can function and survive. At the same time, we are finding that there is no simple definition of futility,¹⁶ making simple pronouncements of futility impossible.

Do not resuscitate versus comfort-measures-only versus active withdrawal of treatment

Once the goals of treatment have been agreed upon, decisions about the end-of-life care of an individual patient are to be made. End-of-life care should be a mutual and agreeable choice from the patient with the understanding by the healthcare team that treatment has become inappropriate to the goals agreed upon. Even if these conditions are met, it is important to realize that there is a duty to care for the patient. A do not resuscitate order (DNR) is not equivalent to a do not care (DNC) order.

An allocation of scarce resources

In its simplest terms, this becomes a question of who should survive and what is the price of life in an area where healthcare dollars are less and less available to all people. There is progressive improvement in survival given the concerted efforts of all members of the healthcare team. However, the reality is that society is providing limited funds for the care of burned patients. It becomes a very difficult personal decision of whether the burn unit should focus on saving money and decline treatment of one burn victim to prepare for the next burn or should resources be expended on a patient who perhaps has a poorer possibility of survival. The only problem with holding back on resources is that this next big burn may never come, and one has not provided the full open access of healthcare to the first patient. It can always be said that saving for the future in this situation does not benefit either, and one must advocate the use of the resource; once resources are exhausted, the patient should be redirected. Arguments can be made for both sides; however, if there is no other alterna-

tive for the patient, clearly they must be cared for in their current setting.

A final note: 'ethical preposterism'¹⁷ in burn care'

As conceived in ancient Athens and during most of its history, Western ethics has been an effort to:

- (1) achieve 'the ethical life', i.e. life in all its important dimensions lived at its most flourishing; and
- (2) solve any problems about 'what should or should not be done' during that quest.

The sustained pursuit of excellence in 'total burn care' first achieved momentum in the USA in the mid-20th century. It has always drawn its most primal motivation from the fact that burn patients are arguably the most severely injured and utterly vulnerable of human beings, and therefore deserving of the most tender, skillful, and comprehensive care. Commitment to the safety, healing, rehabilitation, and growth of patients during their return to as flourishing a life as possible, has been the spearhead of the quest since its beginning, and both the fire in its belly and the steel in its resolve ever since. Clearly, burn care is an ethical endeavor through and through, not just when and where 'difficult patients' or 'ethical problems' become evident.

In our introduction we observed that the bio-psycho-social-economic-legal-and ethical dimensions of 'total burn care' are often seen as interconnected like railway cars, with 'bio-' (i.e. the biological dimension) in front, and 'ethical' hooked on only if necessary at the end, like an optional caboose. We believe this to be not only misleading but also an example of 'preposterism'.¹⁷ Taken from the Latin *pre-* (before) and *posterus* (following), that is 'preposterous' which puts the first last, and what should follow first.¹⁸ We believe the ethical dimension of burn care should be habitually seen not as a sometimes-tacked-on caboose, but as a leading and driving locomotive which extends its influence back through all dimensions of the enterprise like a steel backbone. Were that image actually lived out as dreamed by the early founders of the effort, the providers and receivers of burn care could confidently expect to experience a continually improving 'ethical climate' and fewer 'ethical problems', no matter where history might take the train.

Maintaining professional relationships with patient and family	779
Therapeutic interventions with perpetrators	779
Future direction for establishing child safety	779

Introduction

As a subject of scientific investigation, violence, including that occurring within the family, has received much attention from professionals in sociology, mental health, medicine, and law.¹ Yet most health professionals, themselves devoted to healing and comforting others, are reluctant to believe that human beings will cause serious injury to others, especially to those who are significant members of their own family circle and most especially to those who are helpless such as young children or elderly parents. Caregiving professionals value the role of supportive others, and assessing for maltreatment can run counter to career training, values, and interests. The degree of uncertainty in identifying abuse or neglect is uncomfortable, and the family members typically do not validate suspicion. However, the evidence is overwhelming that people do cause injury even to close family members. Sometimes the maltreatment involves burning. Maltreatment to children involving burning has been identified and discussed in the professional literature for many years.² Types of maltreatment include neglect, physical abuse, sexual abuse, and emotional abuse. Although any of the forms of maltreatment may be found separately, they often occur in combination. Neglect is the most common form of maltreatment, occurring in 60% of maltreatment cases, followed by physical abuse, which occurs

in 20% of maltreatment cases.¹ More than one-third of child fatalities are attributed to neglect. Burn injury is common to both neglect and physical abuse. The Federal Child Abuse Prevention and Treatment Act (CAPTA) (42 U. S. C. A. 5106g), as amended by the Keeping Children and Families Safe Act of 2003, defines child abuse and neglect as, at minimum: Any recent act or failure to act, *regardless of intent*, on the part of a parent or caretaker which results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act which presents an imminent risk of serious harm.

Maltreatment of adults by burning is a recognized concern, though infrequently documented in empirical studies.²⁻⁷ Burning as a form of violence against adults likely occurs with much greater frequency than reflected in the literature and has often been unrecognized. Unless adult patients are asked about maltreatment, they are unlikely to volunteer the information.⁵ As burn care professionals become increasingly sensitive to the problem of maltreatment to adults, the reported incidence will probably increase dramatically, replicating the pattern observed with child maltreatment, i.e. the more we ask, the more we will discover.⁷

The authors share the guilt of failing to be attuned to maltreatment in adults in the same way we are alert to that possibility with children. Therefore, our clinical experience with known adult maltreatment by burning is limited to a few flagrant cases. Our experience with child maltreatment is extensive. Since the literature and our own experience are heavily weighted with information about child maltreatment, this chapter also represents that bias. The reader may, at times, be led to believe that the pediatric population is the only target for maltreatment. That is not an intention but rather a reflection of our current knowledge, and we caution the reader, as we remind ourselves, to avoid that misconception.

In this chapter, we have integrated our experience with available information to identify risk factors in the total population and to suggest therapeutic approaches to treating, in addition to the burn wounds, the complex social, interpersonal, and familial issues that both produce injury and complicate the recovery and rehabilitation of the patient. Because burn care professionals are likely to be the only entrée to help for the victims and the perpetrators and because we know what the 'worst case' outcomes can be, we bear the responsibility of finding ways to prevent further harm while maintaining a trusting relationship with the patient and with the patient's family.

Prevalence of maltreatment

During our pediatric hospital's staff orientation, participants are asked to estimate the percentage of children abused and neglected in the United States annually, as well as to estimate the percentage of children abused and neglected by burning. Well-seasoned healthcare professionals routinely underestimate the prevalence. Approximately one and a half million people in the United States are believed maltreated.⁸ Of children in the US suspected to have been abused or neglected, 80% of the injuries involved the skin.⁹ Maltreatment is suspected in as many as 30% of admissions to pediatric burn units, and, the majority of the suspected cases are confirmed by investigating officials to have been caused by maltreatment.^{8–20} This institution's referral rate to investigating officials is 22%. Adult maltreatment by burning is reported less frequently. In one sample of adult burns, 4% of injuries were attributed to maltreatment.⁶

Without intervention, abuse persists. Hultman et al.² found that 36% of the children with suspicious burn injury had been investigated for abuse or neglect prior to the child's burn injury. In addition, 55% of the children with suspicious burn injury had been followed by physicians for significant medical problems: mental retardation, failure to thrive, chronic respiratory infections and otitis media, hypopituitarism, pulmonary stenosis, attention deficit disorder, previous trauma that included skull fractures, and probable Munchausen syndrome by proxy. Given the intense and chronic history reported in Hultman's study, it is hard to hold in mind that the average patient age was 5.²

Thirty percent of the children suffering recurrent maltreatment are eventually mortally injured.¹³ Thus, many children are injured repeatedly in escalating severity, perhaps over years, until they die from maltreatment. At this institution, 43% of the children who had been referred to investigating officials due to suspicious burn injury had additional unrelated reports for suspected maltreatment. Given that the majority of the population is of pre-school age, the children's futures held many more years of potential vulnerability to victimization.

Dynamics of maltreatment

Maltreatment usually occurs as a multigenerational characteristic that is symptomatic of relationships impoverished of nurturance. Central to understanding maltreatment is to understand that perpetrators typically are individuals who were denied adequate parenting and who experienced severe emotional deprivation. The infantile needs of the perpetrator were unmet; the perpetrator has not learned that it is possible to assert oneself appropriately and to meet one's own needs autonomously. Rather, the perpetrator looks to external sources to meet those needs to be cared for and comforted.

In some situations there are two 'perpetrators': i.e. the actor and the overtly passive observer who does not stop maltreatment. Both persons are elements of a psychosocial system that supports maltreatment, and usually both are from similar backgrounds with similar needs.²¹

Maltreatment grows from a non-thinking, passive life position. Abuse can be thought of as expressions of desperation from immature individuals who feel lost and helpless, incom-

petent to care for themselves, and who are in a constant quest for some external source of comfort. Their own experiences of parental maltreatment have taught them to mistrust others so that, as adults, they are typically socially isolated. This further decreases opportunities for comfort or for developing self-efficacy. Feeling helpless and inadequate, and predicting rejection in every interpersonal contact, such people also experience more difficulty in seeking and securing employment, thus frequently incurring a further stress of financial instability.

In an environment devoid of emotional support, perpetrators passively wait for comfort from a spouse, a lover, or a child. When those 'others' fail to gratify the perpetrators' needs or when a change in the situation imposes additional stress, these needful persons react in a child-like, non-thinking way to resolve frustration. Acts or failures to act that result in burn injury are often the end results of intense frustration.²² A child, an elderly person, or a physically dependent adult is commonly an immediate precipitator of stress as well as an easily available target for maltreatment.^{3,22,23}

This perceived helplessness and desperate needfulness also explains some of the other behaviors commonly attributed to perpetrators. They often fail to seek appropriate and timely medical treatment for an injured child, not only because they fear punishment but also because of their learned helplessness and passivity. They discount the seriousness of the injury, as well as their ability to take care of the injury. 'I didn't think it was that bad' is an explanation often given for delay in seeking treatment. By diminishing the significance, they relieve themselves of responsibility to act. When the perpetrator does take the child for help, the perpetrator commonly seeks first a relative or neighbor rather than a physician because perpetrators do not believe in their own ability to decide whether to seek medical treatment. Perpetrators are observed to interact inappropriately with their children because they are preoccupied with having their own needs met. A child who is hurt and demanding is unlikely to reward the perpetrator with feelings of comfort that the perpetrator seeks, and so the perpetrator withdraws from the child. If the child is quiet and compliant, the perpetrator may be observed to ignore the child and sit passively, watching television for long periods until some external force acts as a stimulus to motivate the adult into action.

Justice and Justice,²⁴ in their work with families who mistreat children, identified several erroneous belief systems that are commonly held by perpetrators; these are listed in Box 61.1. Since, as most authorities believe, violence is a multi-generation intra-family pattern, then it is likely that the belief systems attributed to child perpetrators can be extrapolated to perpetrators of adults as well. The issues of dependency, lack of trust, felt inadequacy, frustration, and emotional pain recur in situations describing maltreatment spanning age groups.^{3,24,25}

Assessment begins at admission

As with all patients and families, the therapeutic relationship with patients and families in which maltreatment is suspected is initiated at admission and developed through the process of assessment and treatment. Perpetrators are aware that some-

BOX 61.1 Erroneous beliefs of abusers**ERRONEOUS BELIEF SYSTEMS COMMONLY CONTRIBUTING TO THE FAMILY SYSTEM IN WHICH ABUSE OCCURS (JUSTICE AND JUSTICE, 1990)²⁴**

- If my child cries, misbehaves or does not do what I want, he or she does not love me and I am a bad parent
- My child should know what I want and want to do it
- My child should take care of me like I took care of my parents
- My spouse/lover should know what I want and meet all of my needs
- If I have to ask, it does not count
- You cannot trust anyone

thing is wrong in their lives, although they may be at an impasse in changing their behavior or limited in degree of personal awareness. The need for medical attention and the visible nature of the burn injury have the potential to heighten the caregiver's sense of vulnerability. This crisis can be utilized to bring positive changes for the family. Risk assessment should be discussed with the family members, including the suspected perpetrator. Once the concerns are presented, the individuals have the opportunity to engage in services from which the family could potentially benefit. The family should be apprised of any report to a protective agency and the events to expect thereafter. Remembering that an important factor in the typical perpetrator's character is reluctance to trust, hospital staff are more effective when truthful and forthcoming. Frequent follow-up sessions with the family throughout the course of hospitalization and outpatient treatment are essential to maximizing family change (Figure 61.1). To facilitate a positive relationship, the helping professional must be sensitive to the fear, pain, and sadness that are often the sources of the perpetrators' maltreatment.¹³

Maltreatment indicators

Most non-accidental burn injuries to children occur to the very young, aged 3 years and under, and are scald (Table 61.1) or contact burns^{13–15,17} Maltreated children live in poverty-level households headed by a young, single parent who has two or more children.^{13,14,17,26} Maltreated burned children are reported to require longer hospitalization and to have higher rates of morbidity and mortality from their burns than non-maltreated children.^{27–29}

Suspicion of maltreatment may be prompted by observations of parental behavior. Parents who are not abusive or neglectful typically report the details of the child's injury spontaneously and express concern about the treatment and prognosis. They exhibit a sense of guilt, ask questions about discharge data and follow-up care, visit the child frequently, and bring gifts. In contrast, perpetrators usually do not volunteer information, but are evasive or contradictory; they seem critical of the child and angry with the patient for being hurt. They do not seem to feel guilty or show remorse. They show no concern about the injury, treatment or prognosis. They seldom visit or play with the child, do not ask about discharge

TABLE 61.1 EXPOSURE TIME TO RECEIVE A SEVERE BURN IN HOT WATER

Degrees in Celsius	Degrees in Fahrenheit	Time to second-degree burn	Time to third-degree burn
45	113.0	120 minutes	180.0 minutes
47	116.6	20 minutes	45.0 minutes
48	118.4	15 minutes	20.0 minutes
49*	120.0*	8 minutes	10.0 minutes
51	124.0	2 minutes	4.2 minutes
55	131.0	17 seconds	30 seconds
60	140.0	3 seconds	5 seconds

date or follow-up care, and appear to be preoccupied with themselves and unconcerned about the child.²²

Prospective studies of abuse do not exist, and the ability to predict future injury is limited. However, factors associated with maltreatment have been reviewed retrospectively in a number of studies.^{11,13,15,26,30,31} A comprehensive list of indicators of child maltreatment gleaned from these studies and our own experience is presented in Box 61.2. Utilizing these indicators provides an informed framework from which to begin assessing risk for maltreatment.³² A semi-structured assessment makes for more thorough interview and documentation at minimum. As the information base is enhanced, risk assessment might eventually assist in accurate identification of maltreatment. Hammond and colleagues¹⁹ forwarded this possibility. They demonstrated that two or more endorsed risk factors of their 13-factor assessment significantly increased the likelihood of abuse.

At this institution, number and type of risk factors have been associated with greater risk for maltreatment. The study design was based on comparison between two groups. One group consisted of children with one report to investigating officials, with that report being the one initiated by the burn center staff regarding the burn injury. The other group consisted of children with additional, unrelated reports to investigating officials. The rationale for groupings was that if different people, in different contexts, across time had concern enough to place a report on the child's behalf, the likelihood of accurate identification and an established pattern of maltreatment was greater for those with more than one report to investigating officials. Thus, the characteristics of children with multiple reports may guide professionals regarding level of concern and type of intervention.

Regarding total numbers of risk factors, children with two or more reports to investigating officials averaged 3 more risk factors than those with one report. Those with two or more reports had an average of 8.4 risk factors and as many as 18.

Attention was drawn to 4 risk factors associated with repeated reports to investigating officials: prior burn injury, blaming the child, lack of external support, and acute family

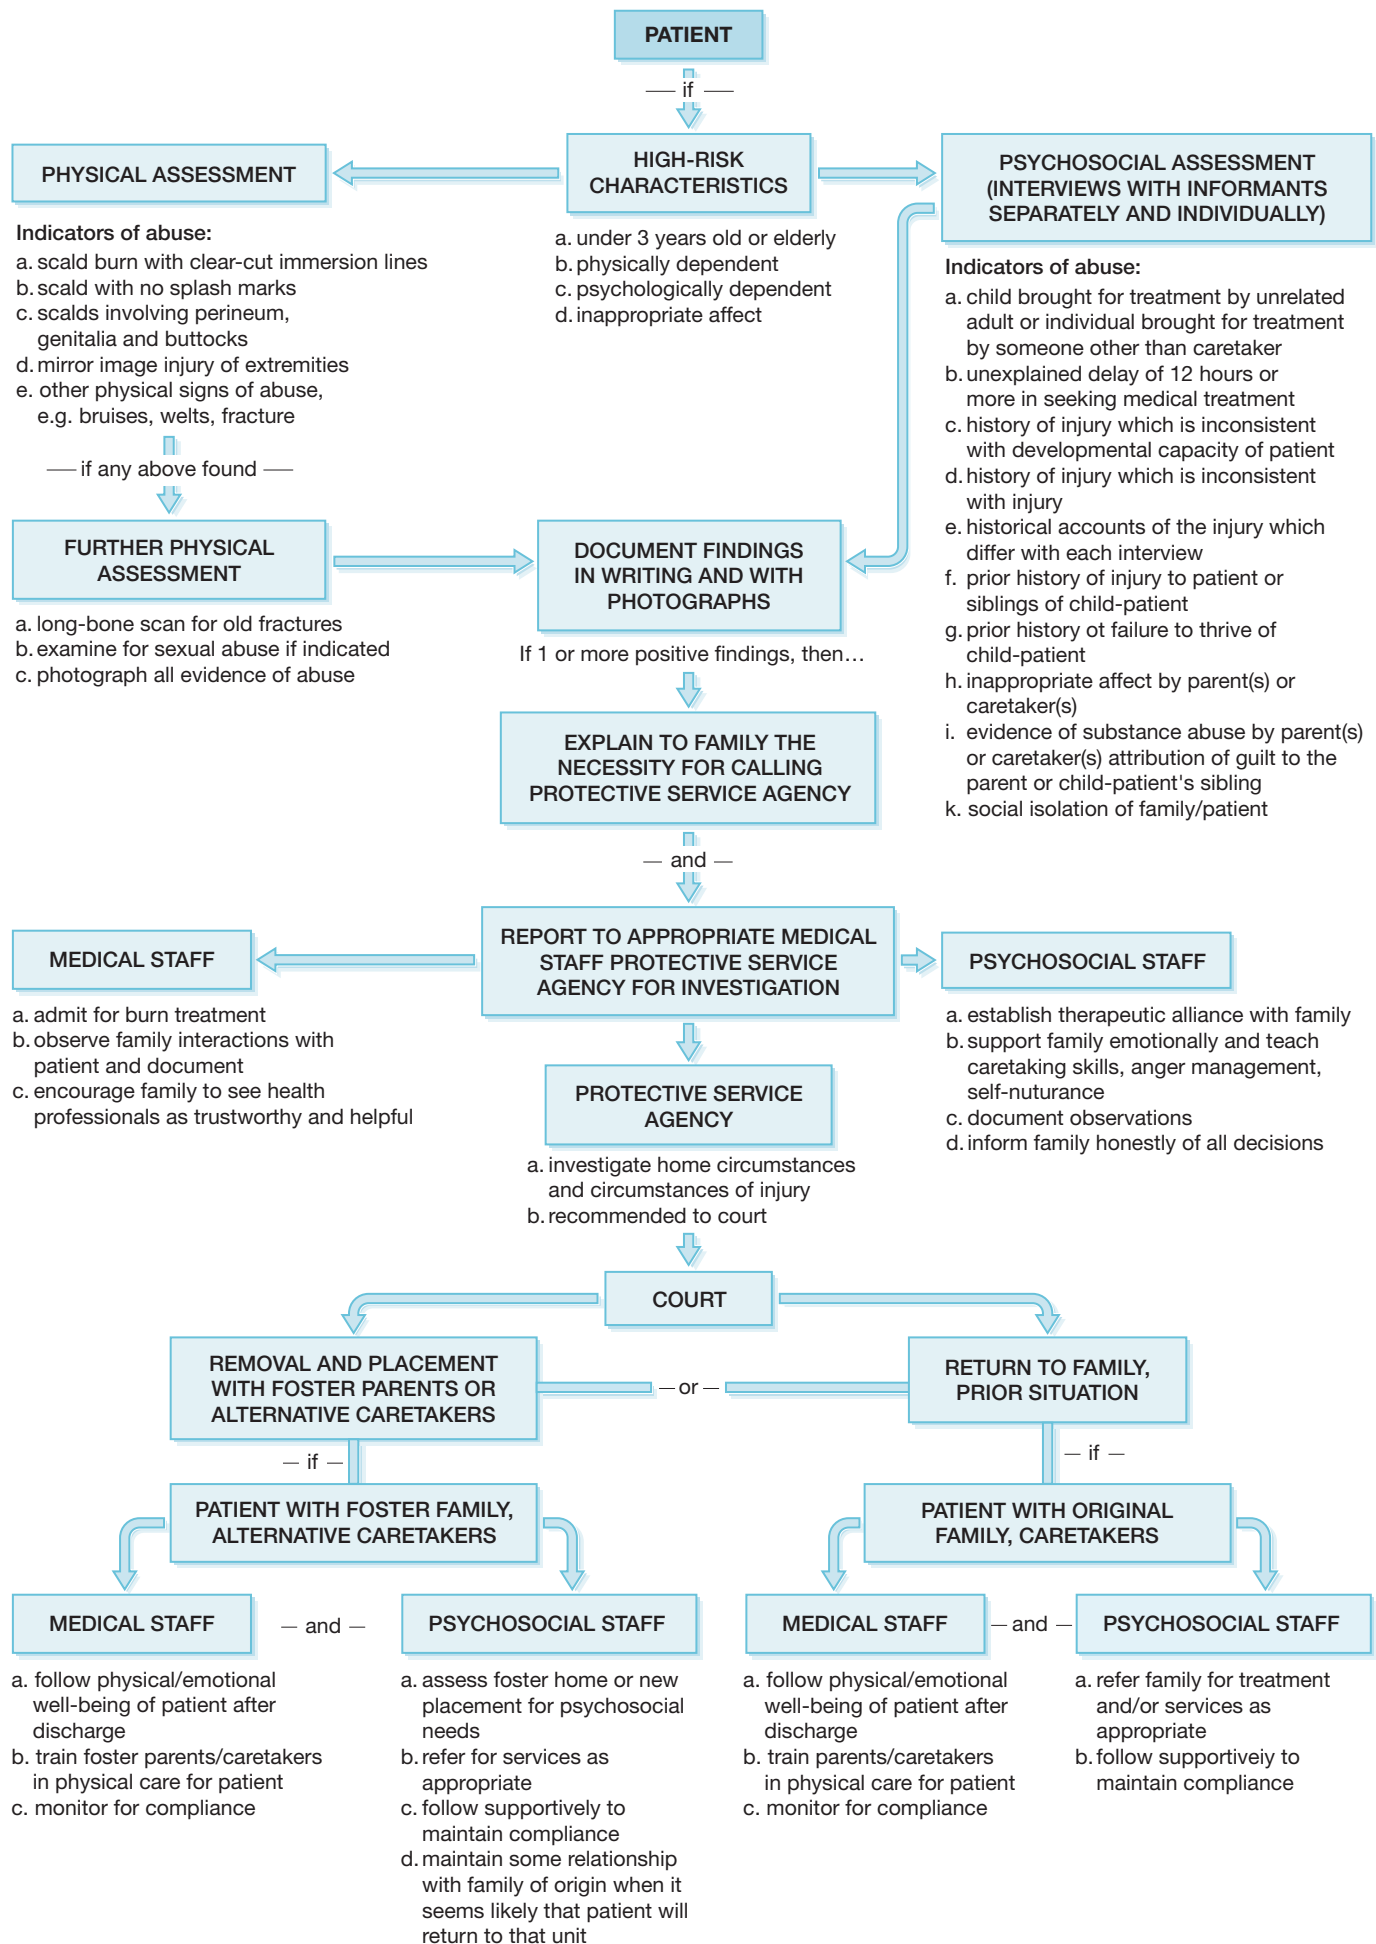

Fig. 61.1 Flow of activities toward treating victims of abuse.

BOX 61.2 Risk factors for abuse/neglect by burning**FORCED — IMMERSION DEMARCATION**

- Symmetrical, mirror image burn of extremities
- Glove-like (burned in web spaces)
- Circumferential
- Minimal splash marks
- Uniform depth
- Full-thickness
- Clear line of demarcation, crisp margin
- Doughnut-shaped scars on buttocks/perineum (spared area forcibly compressed against container, decreasing contact with hot liquid, if container is not a heated element)
- Flexion burns, 'zebra' demarcation to popliteal fossa, anterior hip area, or lower abdominal wall
- Injuries of restraint (e.g. bruises mimicking fingers and hands on upper extremities)¹⁶

INJURY DEMARCATION, OTHER

- In congruent with history of event
- Pattern of household appliance — note whether even pattern versus brushed, imperfect mark
- Scald
- Location of injury: palms, soles, buttocks, perineum, genitalia, posterior upper body
- Cigarette burn, if more than one on normally clothed body parts and if impetigo ruled out

HISTORY OF INJURY

- Evasive, implausible explanation
- Incompatible with child's developmental age
- Changes in story; discovered to be burned — rule out dermatologic epidermolysis bullosa (EB), dermatitis herpetiformis, chemical burn due to analgesic cream, phytophotodermatitis,¹⁷ and birth marks, including Mongolian spots¹⁸
- Under-supervised — inadequate monitoring, impaired person supervising, inordinately young baby-sitter (<12 years of age)
- Burn is older than history given
- Water outlet temperature greater than 120°F
- Mechanism of burn is incompatible with injury (e.g. exposure time, history of event, and degree burn are inconsistent)
- Patient's per-event behavior displeasing to caregiver (e.g. inconsolable, failed to meet caregiver's expectations)
- Toileting events related to history of injury¹⁹
- Burn attributed to:
 - Child or patient, as per caregiver
 - Caregiver who is not present at the healthcare facility
 - Caregiver, as per patient
 - Delay in seeking medical treatment — note estimated time of delay

DEVELOPMENTAL ASSOCIATIONS

- Pre-verbal, non-verbal person
- Vulnerable person (e.g. special need, failure to thrive, elderly)
- Caregiver expectations are inconsistent with patient's development; caregiver overestimates child's developmental skills and safety knowledge; caregiver unaware of patient's developmental capacity
- Patient has symptoms of mental disorder (e.g. ruminating, aggressive)
- Patient displays disturbing behaviors related to attachment (e.g. excessive crying, clinging, apathy/lethargy, excessively withdrawn, listless, unemotional, submissive, polite, fearful, vacant stare)
- Hyper-sexualized language or behavior, as compared to same age peers

CAREGIVER–PATIENT RELATIONS

- History of interrupted caregiver–child bonding
- Adolescent caregiver(s) (e.g. child–child versus adult–child interactions)

- Strained interactions; inappropriate expectations of the patient by the caregiver
- Role reversal (rely on patient for support)
- Inappropriate or lack of caregiver concern:
 - Detached
 - Lack of sympathy
 - Lack of physical contact (e.g. fails to hold or pick up child)
 - Inebriated during visits
 - Infrequent visits

OTHER PHYSICAL SIGNS OF ABUSE OF NEGLECT

- Unrelated injuries:
 - Fractures, dislocations; rupture to spleen, liver, or pancreas; point tenderness; impaired range of motion or function
 - Signs of poisoning
 - Ocular insult (edema, scleral hemorrhage, hyphema, bruise, blue sclera)
 - Swelling, boggy, depressions, cephalohematomas palpable on head or increased intracranial pressure at fontanel
 - Blood, infection, or foreign body in ear
 - Edema, bleeding, septal deviation of nose; foreign bodies in nose; cerebrospinal fluid rhinorrhea from nose
- Unrelated injuries involving the skin: hematomas, soft tissue swelling, lacerations, fingernail markings, scars, bruises (check behind ear), welts, rope burns, strangulation marks, bites, alopecia — note color, size, shape, and location of each (scalp most visible while shampooing)
- Abdominal tenderness, guarding, rebound tenderness, or bruises
- Cardiac instability, tachycardia, murmurs, flow murmurs secondary to anemia, or palpable rib fractures
- Dehydration or malnutrition — note weight, height, and head circumference
- Previous burns
- Unkempt, e.g. severe diaper rash, dirt under nails or in axillae, odoriferous, dirt on plantar surfaces of feet in cold weather
- Inadequate or no immunization record
- Inadequate dental care (e.g. caries); trauma to lips, tongue, gums, frenula, palate, pharynx, or teeth
- Inadequate medical care
- Inappropriate dress
- Assess prior to invasive medical procedures
- Genital, urethral, vaginal, or anal bruising, bleeding
- Swollen, red vulva or perineum
- Foreign body in genital area
- Positive cultures for sexually transmitted diseases — if herpes develops, note whether lesions are on unburned body surface area, on genitals of type II
- Pregnant minor
- Recurrent urinary tract infections, streptococcus pharyngitis, abdominal pain

FAMILY

- Caregiver abused or emotionally deprived during childhood
- Limited disciplinary practices (e.g. only physical punishment)
- Lack of external supports; isolation
- Mental illness; substance abuse; criminal history
- Lack of financial self-sufficiency
- Poor employment history
- Dependent caregiver; unable to cope with daily responsibilities; unorganized
- Violent couples; impulsive; easily frustrated
- Previous Department of Protective and Regulatory Services involvement²⁰
- Prior accidents to dependents
- Acute family stressors
- No primary caregiver

stress. In this sample, having had a prior burn injury was associated with greater risk for recurrent reports to investigating officials. Thus, repeated burn injury to a child should increase the clinician's suspicion of abuse.

Blaming the child describes caregiver's reporting style, in which the caregiver addresses the child's role in the history of injury and minimizes the caregiver role in the history of injury. A commonly stated history of injury involves the bathing routine: the caregiver leaves the bathroom to get a towel, hears the child's cries, and returns to the bath. Some caregivers present an explanation for injury and divert to what the child might have done while not being supervised. For example, caregiver behavior may be justified, e.g. 'I needed a towel' and accompanied by a supposition about the child's behavior, e.g. 'He must have turned on the faucet.' This type of history is associated with limited disclosure and guardedness.

In comparison, other caregivers rehearse the situation, consider their decision-making, express feelings of responsibility, speak of the child in terms of being vulnerable, and consider new home safety practices. For the most part, the caregiver is making 'I' statements, e.g. 'I was not watching my baby.' Presentation style is unguarded and the parent is actively planning.

Lack of external support was associated with repeated reports to investigating officials. Fractious relationships, failure

to establish alliances, and isolation are typically described. External support is observable to some extent across the period of hospitalization. Given that hospital staff is in the role to assist with accessing resources, caregivers tend to disclose support system information.

Acute family stress was associated with repeated reports to investigating officials. Acute family stress dominates the caregiver's disclosure. The crises described are presently occurring. However, the pattern of being in a crisis is chronic and not acknowledged by the reporter. The family environment is chaotic, and the caregiver is commonly 'putting out a fire.' When evaluating risk factors, consideration should be given to the cultural standards of the family's home community. Folk-healing practices should be queried, as well as use of traditional healers.^{11,33} We have seen in the past year two newborns who were burned in hospitals in a country where improperly trained hospital personnel were tending to the infants (Figure 61.2).

Adult maltreatment and indicators

Maltreatment of adults by burning is, as noted earlier, much more rarely reported, probably because the index of suspicion for abuse of an adult is low and therefore injuries are more rarely questioned. Adult victims are also noted to be reluctant

Fig. 61.2 Newborns who were burned in hospitals within the past year.

to report the circumstances of their injuries because of their fear of retaliation or because of shame and embarrassment.²³ Spousal³⁴ and elder maltreatment⁴ are subpopulations within the adult population who are at risk for maltreatment by burning. Two studies describe burn injuries of adults due to violent assault.^{5,6} Associated risk factors in these reports were substance abuse and domestic violence. Although Purdue and Hunt⁶ report that there was no identifiable burn pattern, Krob et al.⁵ described a pattern of scald injury to the anterior trunk and upper extremity. Males and females seem equally at risk for burning by assault.

Bowden et al.² describe a population of older adults made vulnerable by physical or mental impairment who were burned from maltreatment. All but three of their 26 subjects were burned while living in healthcare facilities or institutions. Although this single article identifies maltreatment of the elderly by burning as a problem, frequency of maltreatment is likely greater than presently documented, and maltreatment likely occurs within family settings as well as the institutional settings which dominate this Michigan sample.

Elder maltreatment has been identified as a public concern in the United States only in the last 15 years. Relatively little, however, has been written about the subject in spite of the estimated 2.5 million persons who suffer annually.³⁵ When elder maltreatment does occur within the family, the perpetrator is often an adult child or spouse of the victim. The perpetrators are often intoxicated and were themselves maltreated children.³ Some perpetrators of elder maltreatment are individuals with no prior history of pathology who have become exhausted by the demands of their lives, e.g. caring for an aged parent as well as a spouse and children of their own.^{7,23} Gross neglect is frequently the type of maltreatment sustained by elderly or vulnerable persons, particularly if that person is disoriented or is reluctant to ask for attention and physical care.³⁵ Risk factors of maltreatment for adults are similar to those for children and are listed in Box 61.3.^{2,3,7,23,35}

Reporting and documenting suspected maltreatment

State legislatures in the United States first enacted reporting laws in 1963, and by 1967 every state had laws mandating

professionals who work with children to report suspected maltreatment to designated authorities. A federal law, the Child Abuse Prevention and Treatment Act, was passed in 1974. The laws require professionals to report suspected maltreatment of a child when there is evidence that 'would lead a competent professional to believe maltreatment is reasonably likely'.³⁶ In the case of maltreatment, privileged communication typically only exists for attorney and client. If local laws are not known, staff at the governing protective agency, sourcebooks,³⁷ or the hospital attorneys will be able to provide necessary legal references.

There are no federal programs to specifically address reporting of suspected abuse in adults. Each state has its own set of definitions, reporting laws, and penalties.²³ Professionals who suspect adult maltreatment should be guided by the same principles as in reporting suspicious injury to a child. When maltreatment is suspected, a report must be made to the proper governing adult protective agency. In the United States, the protective agencies operate under the purview of the State Department of Health and Human Welfare. Most states' referrals are made to a statewide intake office. The numbers are located in all phone books. The National Center on Elder Abuse provides information and assistance on elder abuse, including a listing of state elder abuse hotlines. The website is www.elderabusecenter.org and phone number is (202)-898-2586. Child Help USA is a private charity that established and maintains the National Child Abuse Hotline (800)-4-A-CHILD (800-422-4453) and provides a listing of statewide reporting numbers at their website <http://www.childhelpusa.org/report>. Telecommunications Device for the Deaf number is (800)-2-A-CHILD. The US Department of Health and Human Services Administration for Children and Families provides a listing of statewide reporting phone numbers at their website <http://nccanch.acf.hhs.gov/topics/reporting/report.Cfm>.

Healthcare professionals are often reluctant to report suspicious injuries because they feel as if they are condemning a person with uncertain evidence and because they have been trained to maintain patients' confidentiality. However, the medical professional is the sole point of possible intervention for most victims. The purpose of reporting a suspicious injury is to prevent further harm. Making a report is an official trigger requesting further investigation. The ultimate decision about whether maltreatment has actually occurred is left to the investigating officials; however, the professionals reporting the incident must document the observed data to provide the investigating officials and/or the courts the information necessary to intervene appropriately. Professionals should document, for example, observations that render the caretaker's professed ignorance of the cause of injury questionable or that an explanation of cause is implausible given the nature of the injury. Observations of inappropriate behavior or lack of interest in the child's treatment must be documented. Although any single observation may seem unimportant, the pattern of behaviors described by multiple observations may be very significant in obtaining protection for the victim and help for the perpetrator.³⁶ In addition to the documentation of first-hand observations, the following tasks should be delegated:

- Examine the patient for other signs of maltreatment, including a skull and long-bone radiological scan.

BOX 61.3 Indicators of abuse/neglect of adults

- Physical dependence
- Psychological dependence
- Accessibility as a target for abuse as in institutional living or living with a 'caretaker'
- Caretaker(s) with a history of substance abuse, and/or other psychopathology
- Social isolation
- An injury that is not consistent with the story described
- Conflicting reports of the injury
- Scalds with clear-cut immersion lines and no splash marks
- Scalds that involve the anterior or posterior half of an extremity and/or the buttocks and genitals, or a flexion pattern
- Other physical signs of abuse/neglect
- History of related incidents

Clearly state that the radiology consultation is for assessment of occult trauma.

- Photograph any possible evidence.
- If the patient has been referred from another hospital, access information from the staff at that hospital to determine whether they identified suspicious aspects of the injury and whether the injury was reported to an investigating agency. If so, ascertain the number assigned to the patient's case by the investigating agency. This number is needed for subsequent calls related to the patient.
- Interview the patient.
- Interview the family members or caretakers individually and together for thorough histories of the event, sensitive to the differences in the story or changes across time.
- Obtain a thorough family history, the patient's medical history and the developmental capacity of the patient.
- Gather other available collateral information, e.g. medical records from other places of treatment.²⁰

Understanding that abuse does occur and is an expression of the perpetrators pain and sadness can enable the healthcare professional to begin the process of assessment as a critical observer and empathetic interviewer. The interviewer must not respond personally to off-putting behavior from the informant(s) but recognize the behavior as a form of self-protection. Each informant should be interviewed separately, not only to check for conflicting stories but also because there are likely to be tensions between the informants that inhibit the interviewer's ability to establish a relationship with each individual. The informants should also be interviewed together to provide the opportunity to observe tensions, conflicts, and alliances within the family group.

Interviewing the pediatric patient with suspicious injury

Interviews with the child-patient are especially important in cases of suspicious injury. Even children as young as 29 months often relate information with remarkable accuracy.³⁸ An interview with the child alone should be conducted by a professional who has established rapport with the child. The professional can first ask the child to recall specific past experiences which are thought to have no relationship to the current suspected abuse, such as a birthday party or Christmas celebration. The descriptions of these events provide some indication of the child's ability to recall and to describe memories either verbally or in drawings. Questions about the specific events leading to injury should initially be very general: e.g. 'how did you get hurt?' and the child should be encouraged to tell the story freely. Specific questions for clarification should be asked only after the child has told the story. If the child seems unwilling to talk about what happened, the interviewer can suggest the child raise a hand or wiggle a finger to signal that they know something but do not yet want to talk about it. Interviews with a young child are best conducted in several short sessions, giving the child an opportunity to feel safe in the hospital and with the interviewer (Figure 61.3).³⁹

Fig. 61.3 (a) Abuse. Contact burn in which the markings of an iron are clearly visible. (b) Abuse. Classic 'stocking' pattern resulting from feet being immersed in very hot water. The initial history given by the mother of the 21-month-old infant was that an older sibling had turned on the hot water, and the patient herself dipped her feet into the tub.

Interviews with the elderly or handicapped adult patient

When interviewing vulnerable patients, special care must be taken to help them feel safe and comfortable with the interviewer and the hospital setting. The vulnerable adult may be frightened of retribution by the caretaker(s) or afraid of being placed in an institutional setting. The abused adult also may be embarrassed and ashamed of their victimization. If the perpetrator is an adult child, the victim may attempt to protect the perpetrator from detection and punishment. The inter-

viewer must assess the circumstances of the injury and establish a relationship in which the patient can trust the hospital staff to act in the best interest of all concerned, i.e. the patient and the perpetrator(s).

Maintaining professional relationships with patient and family

Working therapeutically with a family suspected of abusing or mistreating the patient requires skill and diplomacy, not only because of a strong tendency on the part of healthcare professionals to align with the victim or be angry with a perpetrator of maltreatment but also because suspected perpetrators often appear off-putting toward the professional staff. Yet, establishing a therapeutic alliance with these families is extremely important, for, no matter how serious the injury, the patient will probably return to that same family, if not at the time of discharge from the hospital, then at a future time.

Therapeutic interventions with perpetrators

Ironically, the professionals of the burn team who identify and report suspected maltreatment also have an exceptional opportunity to intervene in the dynamic process that has led to the maltreatment. During the days or weeks of the patient's hospitalization, the family is placed in a situation of coerced interaction with the burn team. At this time, the family is also in a state of crisis, i.e. their customary defenses have failed to protect them from external scrutiny. In a state of crisis, when their usual belief systems and defensive behaviors are failing, people are more likely to be amenable to new learning and change than during times of equilibrium.⁴¹ Thus, if members of the burn team can interact with the abusive family in ways that invalidate, or at least cast serious doubt upon, the family beliefs, the family system may begin to change. As change is initiated, continued positive support for change can lead to further change.

In order to take advantage of this therapeutic opportunity, the members of the team must relate to perpetrators with honesty and compassion. This does not mean that the team should approve of the behaviors of the perpetrator(s) nor advocate for the perpetrator(s) to be given another opportunity to harm a victim. However, the team members can work with perpetrators in a manner that encourages them to trust professional help. The team members' behavior can demonstrate that relating to others can lead to gratification of their needs for nurturance and comfort. Beneath the hostile suspicious facade of the perpetrator is a frightened and lonely child who feels hopelessly unworthy of kindness. The clinician who is consistently honest, firm, and compassionate can develop a therapeutic alliance with a perpetrator even while explaining that a report is being made to the appropriate agency. The clinician then must assist the family during the process of investigation by honestly informing the family of decisions that are made as a result of the investigation.

Even while explaining that parental rights are terminated or that criminal charges are being filed, a skillful clinician can maintain a therapeutic relationship with the perpetrator(s). By helping the perpetrator(s) perceive the situation, as one

in which there is hope and opportunity to receive help, the clinician can continue a therapeutic relationship that greatly enhances the likelihood that the abusive family will accept further assistance to continue the process of change.

The burn team can work with the community agencies to obtain help for abusive families. Many communities have programs that provide foster grandparents or parent aides, i.e. lay therapists who teach parenting skills and nurture the parent(s).^{22,24} Local self-help groups or telephone crisis intervention services are commonly available. If the burn team has succeeded in developing and maintaining the trust of the abusive family, they are in an advantageous position to encourage families whose prior experiences with social service agencies may have left them suspicious. Even when parental rights are terminated or the patient is removed from the home, the burn team's continued therapeutic support of the perpetrator(s) is advisable since the victim will likely return to that family eventually. In any event, perpetrators of violence against others are a risk to society, and health professionals have an obligation to use their knowledge and skills to diminish that risk.

Future direction for establishing child safety

Accidental attribution for cause of burn injury is easy. Establishing evidence for maltreatment by burning beyond a reasonable doubt is difficult.³ The more that can be known about maltreatment, the more children will be protected. As burn care professionals increase their expertise in the area of child maltreatment, the more they will be able to assist investigating officials. Historically, physician reporting has had an important impact on determinations made by investigating officials.⁴

A primary step toward increasing the knowledge base of maltreatment by burning is the establishment of a national or international database. When events occur infrequently, large sampling is needed. Some of the most dangerous signs of maltreatment occur infrequently. A national database established under a public safety initiative would allow for larger sampling and greater disclosure of information between agencies. One initial step has been accomplished. As of 1995, the American Burn Association initiated collaboration with the American College of Surgeons and created the TRACS/ABA Burn Registry. Ninety burn centers participate and by 2002, the National Burn Repository (NBR) was well established and generated a report. The NBR collects data on some behavioral parameters of burn injury, including suspected self-inflicted injury, child abuse, assault or abuse of adult, and arson. The total of all behavioral parameters monitored through NBR accounts for 4.9% of burn injuries.

Optimally, those participating in a national or international database would develop procedures for consistent assessment and reporting methods. Different forms of maltreatment should be assessed, and at minimum both neglect and physical abuse should be included. Burn centers at which formalized assessment and reporting procedures have been established consistently report high incident rates of suspicious injury. For example, Loyola University Medical Center created thorough procedures for assessment and reporting at 30% of the injuries to the state agency for potential abuse.⁵

Another direction of investigation that may lead to greater expertness would be multidisciplinary studies in which forensic experts, fire dynamics experts, and mechanical engineers

work with the experts in burn injury pathophysiology, the burn care professionals.⁶

Functional sequelae and disability assessment

Chapter contents

Introduction	781
Basic considerations — impairment — disability — handicap	781
Functional outcome	786
Summary	786

Introduction

Advances in acute burn care during the past 25 years, in terms of decreased mortality and decreased length of hospital stay, have been truly outstanding and amazing. In 1971, survival statistics at the Institute of Surgical Research in San Antonio demonstrated an LD₅₀ (lethal dose resulting in a 50% survival rate) with approximately 40% TBSA (total body surface area) burn. Thus 50% of the patients with burns of only 40% died. Now, the LD₅₀ approaches 80% TBSA, and, if no inhalation injury is involved, patients with burn injuries greater than 80–90% of their TBSA routinely survive. In almost every burn unit in the United States, the length of stay has decreased from nearly 3 days/percent burn to less than 1 day/percent burn. The success can be stated simply: patients with larger, more severe burns are surviving; however, are these patients returning to society to become productive citizens? What is the real outcome of massively burned patients? Do pediatric burned patients become functional adults? How do they function socially later in life? What is the long-term effect on the patient's families and society? Are survival and decreased length of stay really the measure of productivity for our specialty? The real product or measurements of customer service is a patient who can successfully return to society and, even more importantly, be a useful, productive individual who can successfully interact socially within a community. Yes, patients with larger and more severe burns are surviving, but this has created new problems for patients' quality of life. Although the problems are magnified in massively burned patients, they exist even in smaller burns. These problems are best demonstrated in a pediatric burn patient with a 95% TBSA burn (Figure 62.1). Cultured keratinocytes were utilized to achieve wound coverage. The child survived; however, when we examined the patient's current and future reconstructive needs, they totaled 33 potential reconstructive procedures. Thus, the reconstructive problems are monumental in a child with very few donor sites.¹ With regard to survival, the results of this

patient are impressive; however, we must ask the question: 'Has the medical expertise in terms of survival progressed past the ability to reconstruct and rehabilitate patients?' Unfortunately, the answer is clearly 'yes'. Are we returning our patients to a society which is not ready financially, psychologically, or socially, to accept them? Again, unfortunately, the answer is clearly 'yes'.

Although the American Burn Association has made rehabilitation a major emphasis, quality work still remains to be done. It is important and imperative that burn centers evaluate the functional outcome of a thermally injured patient. This is important not only for disability assessment but also for evaluation of our medical management. Outcome studies in the 20th century will not only emphasize survival and hospital stay but also patient satisfaction and ability to return to work. The purpose of this chapter is to review the functional sequelae and disability assessment following thermal injury.

Basic considerations — impairment — disability — handicap

The various terms such as 'impairment', 'disability', and 'handicap' appear in laws, regulations, and policies of diverse origin without proper coordination of the ways in which they are used. 'Impairment' refers to an alteration of an individual's physiological, psychological, and anatomical structure or function that interferes with activities of daily living.

'Disability', which is assessed by non-medical means, means an alteration in an individual's capacity to meet personal, social, or occupational demands or to meet statutory or regulatory requirements. Simply stated, impairment is what is wrong with the health of an individual; disability is a gap between what the individual can do and what the individual needs or wants to do. An individual who is impaired is not necessarily disabled. Impairment gives rise to disability only when the medical condition limits the individual's capacity to meet the demands which pertain to non-medical fields and activities. On the other hand, if an individual is able to meet a particular set of demands, the individual is not disabled with respect to those demands, even though a medical evaluation may reveal impairment.

The concept of 'handicap' is independent of both impairment and disability, although it is sometimes used interchangeably with either of those terms. Under the provision of federal laws, an individual who is defined as handicapped has an impairment that substantially limits one or more life activities, including work, has a record of such impairment, or is regarded

Fig. 62.1 A pediatric burn patient with a 95% TBSA burn.

as having such an impairment. As a matter of practicality, however, a handicap may be operationally understood as being manifest in association with a barrier obstacle to functional activity. An individual of limited functional capacity is handicapped if there are barriers to accomplishment of tasks or life activities that can be overcome only by compensating in some ways for the effect of an impairment. If an individual is not able to accomplish a task or activity despite accommodation, or if there is no accommodation that will enable the accomplishment, then in addition to being handicapped, the individual is also disabled. On the other hand, an impaired individual who is able to accomplish a task or activity without accommodation is, with respect to the task or activity, neither handicapped nor disabled. The concept of 'employability' deserves special attention, for, in an occupational setting, if an individual within the boundaries of medical condition has the capacity, with and without accommodation, to meet a job's demands and conditions of employment as designed by the employer, the individual is employable and consequently not disabled. On the other hand, an individual who does not have the capacity or who is unwilling to travel to and from work, to be at work, and to perform assigned tasks and duties, is not employable.

The first critical task in carrying out a medical determination related to employability is to learn about a job, specifically the expectations of the incumbent, with respect to performance, physical activity, reliability, availability, productivity, expected duration of useful service life, and any other criteria associated with qualifications and suitability. Sufficient detailed information from a job analysis will provide a basis upon which a physician determines exactly what kinds of medical information are needed and to what degree of detail to assess an individual's health with respect to demand criteria.

Impairment assessment

Before discussing the medical aspects of evaluating thermally injured individuals, it must be pointed out that no Social Security and Worker's Compensation disability program medical listing exists for burns. Instead, burns must be evaluated under the appropriate body system. Often, more than one system is involved: in other words, musculoskeletal, respiratory, and skin all must be considered in the final decision. Claims must be aimed primarily at resolving the question of onset, whether the impairment can be expected to last 12 months or end in death. The medical evidence needed to document the existence and severity of a medically determinable impairment due to burns must include a history of the impairment, which describes the origin and course of the condition, dates of confinement, nature of treatment, and the claimant's response; current objective findings such as results of examinations, laboratory tests such as blood pressure, electrocardiogram, x-rays, blood tests, range of motion, medical factual data upon which diagnoses are based; and a description of the objective findings of the claimant's limitations and remaining capacities. In other words, how far can the patient walk, which activities cause breath or chest pain, what extent of motion is there in affected parts of the body. Regional specialized burn centers treat many serious burns annually. These centers are excellent sources of medical evidence as they maintain complete detailed records regarding the nature of an injury, treatment, complications, and prognosis. Advances in burn care have improved the survival rate in major burns. Efforts to rehabilitate these survivors and improve their quality of life represent a significant challenge for those involved in their care. The rehabilitation of these survivors is unique and multifaceted, and rarely limited to one system. Many individuals will experience some type of long-term physical impairment or mental limitation, and the rehabilitation process may take years to complete. It must be emphasized that impairments resulting from a burn are not restricted to the skin. Complications may affect any body system; thus, the examiner who is assessing individuals for disability must be attentive to the systemic sequelae of burn injury. The evaluation of a burn victim has some unique features. The necessity to consider such subjective factors as heat and cold intolerance, sensitivity to sunlight, pain, chemical sensitivity, and changes in sweating pattern, as well as the more objective considerations of decreased coordination, sensation, strength, and contracture, lends itself to a unique evaluation.

Disfigurement from scarring, a frequent sequelae of burns, may not affect performance and thereby, in and of itself, causes no impairment. Scarring represents a special type of disfigurement. Again, no percentage of impairment is assigned for the existence of a scar *per se*; however, scars affect sweat glands, hair growth, and nail growth, and cause pigment changes or contractures and may affect loss of performance and cause impairment. Sensory deficit, pain or discomfort from scars needs to be evaluated, as well as the loss of motion of a scar area. An impairment due to disfigurement from scarring may also create behavioral or psychological impairments which subsequently may be rated. The need for intermittent or continuous treatment of the skin with topical agents and pressure garments can impair a person's function and needs to be considered. There is a surprising lack of published literature

which relates to the impairment evaluation of a burned patient. The following are concepts which must be kept in mind when evaluating a postburn patient for impairment and resulting deformities.

Skin

Scars and cutaneous abnormalities which result from the healing of burned tissue may represent a special type of disfigurement. Scars should be described by giving their dimensions in centimeters, and by describing their shape, color, anatomical location, and evidence of ulceration; their depression or elevation, which relates to whether they are soft and pliable or hard and indurated, thin or thick and smooth or rough; and their attachment, if any, to underlying bone, joints, muscle and other tissues. Good color photography with multiple views of a defect enhances the description of scars.

The tendency of a scar to disfigure should be considered in evaluating whether impairment is permanent or whether the scar can be changed, made less visible, or concealed. Function may be restored without improving appearance and appearance may be improved without altering anatomical or physiological function. If a scar involves loss of sweat gland function, hair growth, nail growth, or pigment formation, the effect of such loss on performance of an activity of daily living should be evaluated. Furthermore, any loss of function due to sensory pain, any sensory defect, pain or discomfort in a scar should be evaluated.

Burn scar contracture is probably the most frequently seen cause of impairment in a postburn individual. Every burn, regardless of the depth of injury, heals with some element of contracture. Contractile forces continue long after a wound is healed and can result in severe skin shortage. Inadequate skin prohibits movement to a joint's normal arc of motion and will influence not only the joint underlying the contracture but also those adjacent to the scar. In the early stages of development, burn scar contractures may often be corrected through the use of splints and pressure garments designed to force developing scar tissue into more normal configurations. In spite of the benefits derived from these modalities, they may also function as a type of impairment, both physically and cosmetically. Understanding the splints which individuals must wear and their limitations are important factors in the assessment of disability. Often, surgical means must be employed in order to restore function. When a surgical release of a contracture is performed, the resultant defect can be of considerable size and will require closure by means of a skin graft or flap of tissue. Burn scar contracture frequently requires a series of staged surgical procedures before optimal function and cosmesis are achieved. Recovery from surgical intervention must be followed by an extensive rehabilitation program. If an individual does not participate in a rehabilitation program, contractures will reoccur.

The definition of functional impairment should not be limited to an individual's ability or inability to perform joint range of motion. An extremity can exhibit full active range of motion and still be considered impaired due to poor skin quality. Although much can be done to restore function, the skin is never restored to normal. Scar tissue is less tolerant of the everyday stress imposed on it than normal skin. Scar epithelium is thin, fragile, and prone to chronic ulceration.

Regardless of the location, these chronic open areas will not heal and eventually require skin grafting. This type of lesion can occur at any time, even years after the initial hospitalization. Skin grafts have the same abnormalities as burn scars in that they all involve contracture formation, have loss of sweat gland function, hair growth, and altered pigment formation. Although frequently cosmetically more acceptable, skin grafts are still not normal skin. Physical limitations such as cold and heat intolerance, difficulty with sun exposure, altered sensation, or painful scars may prohibit individuals from performing their past work or other work.

Musculoskeletal

Functional limitation secondary to burn injury usually results from an anatomical alteration about a major joint. The degree to which the function of a joint is affected is greatly influenced by the amount of soft-tissue loss and the degree of pain associated with movement. Full-thickness burns, those involving all layers of skin, may also result in secondary damage to muscle, bone, tendon, and ligaments. In the acute phase of treatment of such injuries, a joint may be exposed, making it vulnerable, and susceptible to a chronic infection (osteomyelitis), instability, and arthritic changes. Ectopic calcification, the abnormal deposition of calcium around the joints, is usually seen in the elbow, but it can occur in any joint. Symptoms include pain with a significant decrease in motion. These changes in joint structure can be verified by x-ray and will require surgery at a later date for correction. Extensive soft-tissue destruction involving the loss of muscle mass, as seen in electrical injuries, will require numerous staged procedures in order to restore function. An individual may never be restored to full function and may be excluded from performing certain types of work which exist in the national economy.

Restriction of normal movement by contracture is not limited to the extremities. When a scar occurs over the trunk or anterior chest, severe and chronic postural changes can result which may cause secondary spinal deformity or altered respiratory functions. Amputations are another leading contributor to postburn impairment. Unlike amputations which are performed for other medical conditions such as peripheral vascular disease, amputation following an extensive thermal injury will often require several staged surgical procedures in order to produce a stump capable of accommodating a prosthesis. It is also important to realize that amputations are not confined to the extremities alone but may also involve skin appendages such as the ears and nose. Complicated stage procedures using local or distant full-thickness skin or muscle-skin flaps are required in order to restore function and cosmesis in these areas. An understanding of how long it will take for an individual's function to be restored is an important factor in deciding about the issue of disability.

Special senses and speech

Impairment to the senses of hearing or vision can occur as a result of a thermal insult, secondary to life-sustaining treatments or as a complication of a healing burn. The loss of central or peripheral vision may begin at the time of contact with a burning agent and can cause the destruction of the eyelids and damage to the cornea. A series of surgical procedures must be performed in order to create a functional eyelid.

Contracture of the eyelids, more commonly the lower, may develop quickly, resulting in incomplete closure of the eyelid, and potential damage to the cornea can result in conjunctivitis or corneal ulceration. In spite of adequate surgical correction, it is common for such injured individuals to have repetitive episodes of recontracture for up to 2 years post-healing, due to ongoing scar contracture process. Perioral burns that result in lip eversion and microstomia, or contracture of the mouth, may eventually impair mastication and result in drooling as well as inhibiting an individual from producing speech which can be heard or understood. Hearing impairment due to the acute burn is rare, but there may be a loss of the external ear, or deafness secondary to the treatment of life-threatening infections with antibiotics.

Respiratory system

Burns that occur in an enclosed space, such as a building structure, often result in some form of inhalation injury to the respiratory system. Impairment may be limited to a temporary need for ventilatory support or extend to permanent respiratory disease. Chronic and recurrent respiratory infections and pulmonary insufficiency may limit an individual's ability to perform their past work or other work in the national economy, especially when toxic chemicals or dust are present in the workplace. Exposure to irritating gases can also worsen pre-existing asthma or result in irritant-induced asthma. Although this form of reactive airway disease usually resolves with time, some individuals may have persistent respiratory impairment that also may require a change in vocation in order to avoid continued exposure to irritants and exacerbation of symptoms.

Furthermore, patients with severe inhalation injuries may require a tracheostomy long after the burn has healed. Closure of the stoma is often delayed for the purpose of intubation and anesthesia in future reconstructive surgeries. Pulmonary function tests are essential in determining respiratory impairment.

Cardiovascular system

A cardiovascular evaluation should include a good history and electrocardiogram. Patients complaining of chest discomfort thought to be of cardiac origin should have a more extensive work-up. There is some evidence of increased incidence of cardiovascular disease in the long-term follow-up of survivors of large thermal injuries.

Neurological system

Neurological impairment caused by a burn may be obvious at the time of admission to a burn center or become clinically apparent up to 2 years following the injury. Patients who are considered at risk include those who have sustained an electrical injury, are predisposed to stroke, or who exhibit signs of peripheral neuropathies secondary to thermal damage. Such patients should be closely monitored for signs of progressive neurological deficit. Electromyography studies will chart the development of degenerative peripheral nerve or spinal cord dysfunction. Dysfunction may be demonstrated in the form of paresis, paralysis, tremor, involuntary movement, or ataxia. Individuals who have suffered an electrical injury may develop a condition characterized by progressive degeneration of fine

and gross motor coordination. Resultant complications can range from inability to perform work-related tasks safely to an inability to perform the routine activities of daily living. It is a disease process which takes place over a significant period of time, and may worsen after an individual has returned to work. In addition to the motor deficits caused by electrical injury, those individuals in whom a current passed above the level of the clavicle have a high incidence of cataract formation with the first 3 years post-injury.

Aside from electrical injury, peripheral nerve injury can also result from deep to full-thickness burns. Symptoms of sensory deficits and pain from nerve injury include anesthesia, dysesthesia, paresthesia, hyperesthesia, cold intolerance, and an intense, burning pain. However, behavioral and psychological issues can make it difficult to assess a patient's true impairment and disability due to peripheral nerve injury. To minimize the subjectiveness of pain-related impairment, only persistent pain that leads to permanent loss of function, in spite of maximum effort toward medical rehabilitation and physiological adjustment, can be classified as permanent impairment.²

Heme and lymphatic

Full-thickness or deeper burns, particularly of the lower extremities, will also cause damage to the lymphatic system. Such injured individuals often demonstrate a lack of normal lymphatic drainage, resulting in chronic edema and the development of stasis ulcers. There can be little or no improvement expected post-healing. External support in the form of elastic garments is necessary to help replace the normal activity of the lymphatic system in reabsorption of fluid. These individuals frequently have difficulty in standing for long periods of time or working in a hot and humid environment.

Digestive system

The digestive system is not usually a problem except in those individuals who have had superior mesenteric artery syndrome, cholecystitis, or peptic ulcer disease during the acute admission. The post-discharge clinical course of these individuals is never predictable; if affected individuals become symptomatic, they should be followed up by a specialist.

Genitourinary system

The genitourinary system may be a problem if deep perineal or buttock burns occurred. Aside from the obvious psychological problems, partial loss of the penis or scarring of the external genitalia may result in difficulty voiding. A badly scarred perineum or buttocks may make sitting in one position for prolonged periods painful and difficult.

Psychological

The advances of surgical techniques involving early excision and grafting as well as the increased ability to prevent infection allow many patients who would otherwise perish to face life shattered by psychological problems as a result of disfigurement. The onset of a thermal injury is a sudden and frightening experience not only to a patient but also to his family members. Because of the unexpected nature of onset, all phases of the patient's lifestyle are abruptly changed. Often,

the full emotional impact is not felt until the time a patient is discharged from the protected environment of a hospital. At this time, the reality of the emotional, physical, and financial burden of a thermal injury are apparent and must be faced. The extent to which a person can psychologically deal with his injuries varies, as do individual personalities. Each case is unique and must be evaluated as such. Studies on the psychological adjustment of survivors of burns generally reflect a biased adjustment to moderate injuries. Few quantifiable data are available concerning the psychological well-being of long-term survivors of severe injuries. Although most authors conclude that victims of burns make satisfactory adjustments, others report symptoms of the psychopathological sort which contradict this optimism.³ Public acceptance is an important problem facing a burn patient. Goffman, in 1963, stated that the way that burn disfigured patients have dealt with the world has generally been shown to be affected by society showing negative responses to visible scars. The burn-disfigured person has to contend with their body image as well as the attitudes of the people and the culture around them. TV and radio have altered not only family standards, but standards of self-perception as well. The young and the beautiful are emphasized. Everyone must be a 'ten'. Patients with burns, like paraplegic or quadriplegic persons, have injuries which can be seen and understood by the public; however, there is also marked ambivalence about a patient with burns as emphasized by the movie industry which has frequently characterized the evil person as being deformed. The 'Phantom of the Opera' is a burn victim, while 'A Nightmare on Elm Street' depicts Freddie Krueger as evil, deformed, and scarred. The burned patient must deal not only with his burn injury but also with society's built-in impressions which are fostered early in life through cartoons, advertising, television, and movies. This is especially important in the pediatric burned patient for whom returning to school can be difficult, to say the least. Recent studies from the Shriners Burns Institutes in Boston and Galveston emphasize that, in pediatric patients with large thermal injuries, most children appear to be satisfied with their quality of life.⁴⁻⁶ This finding was especially true in children with supportive families who had consistent clinical follow-up and early reintegration into society. However, outcome studies on psychosocial impairment are difficult to assess. It is encouraging to see that the Galveston study reported psychosocial adjustment scores within normal limits, with only diminished social competency skills as issues of concerns among their patient group. Unfortunately, in-depth feelings regarding disfigurement and social integration may not surface with the use of present medical evaluation, and further refining and modification, in addition to our current techniques, may be needed to bring out the latent fears and detrimental feelings in these patients.

Impairment evaluation

The physical examination of a burn victim is much the same as the disability evaluation for any patient. With the information gathered from the history and physical examination, and using the tables in the American Medical Association's Guide to the Evaluation of Permanent Impairment,² the physician can arrive at an impairment rating. In addition to the usual range of motion form, a questionnaire regarding the special prob-

lems related to burns is useful (Table 62.1). The American Medical Association's Guide to the Evaluation of Permanent Impairment is difficult, complex, and time-consuming. It is helpful to have members of a rehabilitation department, namely physical therapy and/or occupational therapy, be familiar with this evaluation. A combined approach with either an occupational therapist or a physical therapist to evaluate actual objective determination such as range of motion, and a burn surgeon performing the subjective rating for the skin or psychological status, is useful. The objective measurements due to restriction of active motion and amputations are well outlined in the Guide to the Evaluation of Permanent Impairment. The techniques of measurement are simple, practical, and scientifically sound. For the examination of upper and lower extremities, a large and small portable goniometer are used. The upper extremity, lower extremity, the spine, and the pelvis are considered a unit of the whole person; and tables are available in the manual to determine impairment ratings of the whole person. The subjective rating for skin or psychological determination is not precise. The criteria for evaluating permanent impairment of the skin is divided into five classes:

- *Class I impairment of the whole person is 0–9%.* A patient belongs in class I when (a) signs or symptoms of skin disorder are present, and (b) with treatment, there is no limitation or minimal limitation in the performance of the activity of daily living, although exposure to certain physical and chemical agents might increase limitation temporarily.
- *Class II impairment of the whole person is 10–24%.* A patient belongs in class II when (a) signs and symptoms of skin disorder are present, and (b) intermittent skin treatment is required, and (c) there is limitation in the performance of some of the activities of daily living.
- *Class III impairment of the whole person is 25–54%.* A patient belongs in class III when (a) signs and symptoms of skin disorder are present, and (b) continuous treatment is required, and (c) there is limitation in performance of many of the activities of daily living.
- *Class IV impairment of the whole person is 55–84%.* A patient belongs in class IV when (a) signs and symptoms of skin disorder are constantly present, and (b) continuous treatment is required which may include periodic confinement to the home or other domicile, and (c) there is limitation of performance of many of the activities of daily living.
- *Class V impairment of the whole person is 85–95%.* A patient belongs in class V when (a) signs and symptoms of skin disorder are constantly present, and (b) continuous treatment is required which may include constant confinement to the home or other domicile, and (c) there is limitation of performance of most activities of daily living.

The impairment evaluation is somewhat subjective; however, individual patients can be placed into various categories. The final impairment rating is a combination of the actual objective determinations and the subjective rating for skin and psychological impairment.

Functional outcome

Outcome from thermal injury depends upon many factors other than severity of illness; this may include social status, family support, and patient motivation. A determination of impairment combined with disability is an excellent modality to determine outcome. Presently, we perform formal impairment ratings only when asked by insurance companies, social security, worker's compensation, or the legal system. With emphasis on continuous quality improvement and insurance companies evaluating care by outcome determinations, it is important for burn surgeons to document their outcome. Impairment ratings are time consuming; however, they are an excellent way to evaluate outcomes of care. A systematic approach to evaluating outcomes in this manner should be initiated.

Summary

Disability determination is a difficult and by no means objective procedure. It is not within the scope of this chapter to present all the possible complications and resulting impairments secondary to burn injury.^{5,7,8} There are certain concepts

which must be kept in mind when evaluating a postburn patient for impairment and resulting deformity. Most burn injuries which are significant enough to require admission to a specialized burn care facility will likely result in some type of temporary or permanent disability. Concepts unique to burn patients include:

- the most common complications arise from burn scar contracture and cosmetic deformity, and will require staged surgical procedures for correction;
- rehabilitation may take several years to return a patient to an acceptable level of functioning;
- postburn cosmetic deformity needs to be confined to areas which are socially visible;
- resulting disabilities are not proportional to the extent of cutaneous injury; and
- certain complications, such as neurological degeneration, may not arise until a few years following an injury and are fairly unpredictable.

Many burned patients will have limitations which, individually, fall short of the criteria needed for evaluating disability. It is important to evaluate the comprehensive result of all limiting factors in order to accurately assess the level of disability.

Introduction

Several developments in medicine and burn care have occurred during the last six decades. Patient care, clinical observation, and research have produced important advances in the understanding of the pathophysiology of burns and in the treatment of burn injuries and their complications. As described in the first chapter of this book, the nature of burn injury seemed to require the participation of many different specialties, thus leading to the development of 'burn teams' and 'burn centers'. The result of such collegial effort is state-of-the-art burn care that gathers well-trained personnel with ultimate technology. The drawback of such evolution, though, is complex treatment and a climb in hospital costs. The complexity of burn care in the context of the current health economic era has made outcome measurement, quality assurance, and cost-containment in the burn unit extremely important components of burn care. During the last decade, evidence-based medicine has irrupted in the horizon of outcome measurement and cost-containment in an era of financial restraints and in-depth critical evaluation of the provision of health in modern society. The continuous appraisal that this new approach has introduced in current medicine evidences the lack of available data in many, otherwise, widely accepted therapies.

The present chapter gives an insight into the relevance of outcome measurement as an objective reflection of the quality of care that is provided in burn centers. The development of quality assurance programs is necessary to maintain excellent outcomes while improving cost-containment. Evidence-based burn therapy is reviewed, with a focus on available epidemiological data on approved therapies for the burned population. How programs of quality assurance function and how costs are contained with overall improvement of the quality of care are explained below.

Socioeconomic impact of burns

The first step for any system of self-evaluation and control of the quality of care provided is the recognition of the scope of the problem being evaluated. Incidence and prevalence of the disease or condition investigated are necessary to put the health impact in perspective and to determine the background from which all interventions will be instituted and the efficacy of all treatment or interventions developed to improve or treat the condition or conditions. Data acquisition and epidemiological and statistic treatment of such data are necessary although not always available in the burn population.

Burn injuries continue to plague the economic systems of both developed and underdeveloped countries. In developed countries, severe disabilities secondary to burns produce significant financial losses; in the developing world, loss of life from burns is extremely high. In the United States, there are 1.2 million burns each year, resulting in 60 000 hospitalizations and approximately 6000 deaths. The death toll is highest at the extremes of age; young adults more frequently survive with disabilities that truncate their production in society.¹ Minor burns represent economic loss in the form of sick leaves, and their sequelae sometimes interfere with the productivity of the survivor. Survivors of massive burns are more prone to develop long-term sequelae, and consequences to their families and to society can be devastating.^{2,3}

The overall incidence of burns in developed countries is still relatively high, while the numbers of persons who die from burns is remarkably low. It is reported that 820 per 100 000 persons/year are burned, with 30 per 100 000 persons/year requiring specialized treatment. Admissions to burn centers account for 6.5 per 100 000 persons/year. The gross burn mortality in developed countries (people who die at the scene of the accident plus people who die in specialized units) is only 0.6 per 100 000 persons/year. LD₅₀ (the body surface area burned that kills 50% of people) in the pediatric population^{4,5} and in young adults⁶ is over 90% total body surface area (TBSA) full-thickness burns, and over 40% TBSA full-thickness burns in the elderly.⁶ Burn mortality indices under 4% are common among inpatient populations.

The social cost of minor burns in developed countries is significant. In Western Europe, these costs, including the loss of production at work of the individual, social security cost, and the cost of the entire treatment, are around 7000 euros. For severe burns, social costs are much higher and are to be estimated over 40 000 euros per patient.⁸ These are underes-

timates because the true social costs of long-term disabilities resulting from burn injuries are not yet well determined.

The impact of even the low burn mortality in developed countries is relevant. Beyond the cost of the acute treatment of these severe injuries are the costs of the permanent loss of the individual's productivity at work, social security costs, and insurance costs. When these costs are added, the estimated cost to society upon losing one middle class worker in Western Europe is around 1.1 million euros.⁸

The world view is more dismal. World statistics put burn injuries to the level of a major health problem. Burns described as 'minor' in developed countries produce severe disabilities and even death in developing countries. There are more than 150 000 fire deaths every year in the world, and approximately 30 000 000 people in the world require admission to specialized units. In developing countries, survival of patients with burns over 40% TBSA burned is minimal.⁷

Outcome measures

Outcome measures are the cornerstone of cost-containment and continuous quality improvement in any given health system. They serve to evaluate what works and what does not; they are used for research and for the improvement of clinical practice and to provide higher-quality care in a cost-effective manner.

For a long time, burn mortality has been considered a major outcome measure of the quality of burn care. With the improved survival rates over the last three decades, virtually all pediatric and young adult burn patients should be considered candidates for survival.^{5,9} Improvement in burn mortality has produced a change in the expectations of burn care providers. No longer is survival *per se* a sufficient outcome measure (mortality is being questioned as a true outcome measure in current burn practice¹⁰), but psychosocial adaptation and physical rehabilitation are of prime importance. Rehabilitation, psychology services, and social support departments are now important members of the burn team. Their care, like that of physicians and nurses, begins with the admission of the patient to the burn center and extends for a long period of time after the patient is discharged. The need for some supportive services may extend throughout the patient's lifetime.

Paralleling the development of modern societies, outcome measurements in healthcare systems focus more on rehabilitation and quality of life than on raw incidence, prevalence, and survival rates. When this principle is applied to trauma and burn care systems, there are four main outcome measurements that are to be considered:

1. Burn mortality (raw and relative mortality).
2. Length of stay (LOS).
3. Modulation of the hypermetabolic response.
4. Quality of life.

Burn mortality

As previously mentioned, burn mortality is still one of the major outcome measures in burn centers. It is the most frequently used measure, the data are easily retrieved, and easy to compare among different centers. Although every burn center has its own particular limitations, it is clear that there exists a minimum standard of burn survival (i.e. LD₅₀ of

90% TBSA burned in children and young adults) that should be met given the social and economic situations are provided. In order to achieve the minimal standards of care, it is important to analyze the comparability of results of every burn center. Since local geographic and social parameters vary, the generation of models of probability of death or probit analysis^{11,12} with statistical logistic regression¹³ has proven useful for surveying the outcome of burn victims (Figure 63.1). It has the benefit of comparability,¹¹ but it presents also the benefit of internal control of the burn center, since the logistic model represents the standard of care for that given center. The probability for survival that the model assigns to patients represents the minimum standard. Patients admitted to the burn center with a determined burn injury are plotted in the graphic of probit analysis, and are assigned a probability of death. Afterwards, the real outcome of the patient is compared to the probability for that outcome, and disparities are analyzed on a case per case basis. Relevant data for every new patient are introduced into the logistic regression model, so the probability of survival for the following patient is more accurate. Ideally, the probability of survival should increase with time, reflecting the continuous improvement of the quality of care. The responsibility of the burn team is to continuously improve those results and generate new revised models of probit analysis. The advantage of this analysis is that it includes all the particular social and economic situations of the local geographic area, and on the other hand it is comparable with the results of other centers. One of the main disadvantages is that the prediction is based only on age and TBSA burned.

Other indices, such as the abbreviated burn severity index (ABSI),¹⁴ include the patient's sex, depth of the injury, and

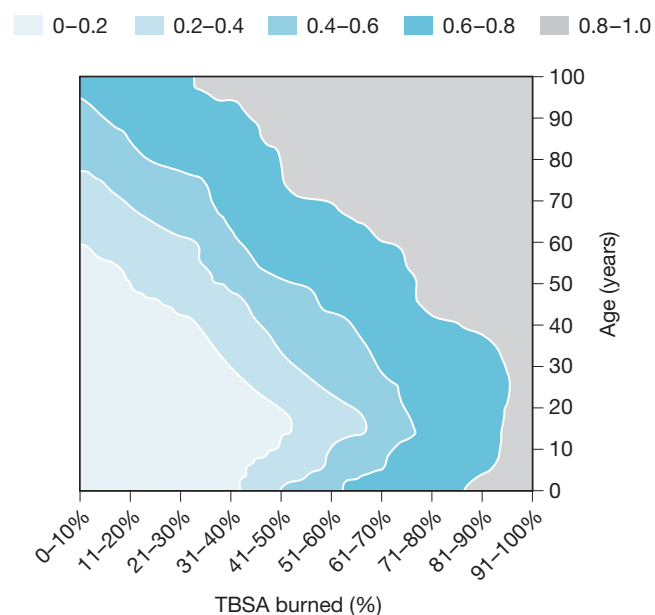

Fig. 63.1 The generation of computer models of death probabilities helps in decision-making and in quality assurance programs. Mortality, though, should not be used alone as an outcome measure, but together with rehabilitation parameters and quality of life.

inhalation injury as risk factors that determine the severity of the burn, achieving a more accurate predictive factor. If additional factors are considered, such as preexisting disease or the abuse of toxic substances, the specificity and sensitivity of the predictors improve.¹⁵ However, even though survival after burn trauma is one of the primary objectives of burn centers, raw mortality and relative mortality (mortality index corrected per age and sex groups in the general population) are no longer the only outcome measures in burn health systems.¹⁰

Length of stay

Length of stay (number of days admitted to hospital) is a relevant indicator for hospital administrators. It is a direct indicator of cost of treatment and its relevance applies to all patients, regardless of their final outcome. As pointed out by Pereira et al.,¹⁰ data on burn survival have been available for decades, but less information has been published on LOS. Length of stay is an indirect indicator of morbidity (uncomplicated patients should leave hospital sooner than complicated patients), although it must be interpreted with caution. Patients may stay longer for rehabilitation despite being healed completely, or, conversely, patients may be discharged home and readmitted soon after as rehabilitation patients to change insurance coding and reimbursement. The best way to standardize LOS to allow easy access and comparison is to express it as a function of burn size (days/%TBSA). It can then be used as an efficiency of burn care provided, with the ratio below 1 (less than 1 day per 1% burn) as a goal for burn treatment. However, it works very efficiently and as good comparison method for massive burns, but it can produce important bias when considering small burns with specific locations (hands, face, genitalia, feet), depths (deep burns requiring flaps), or age (pediatric or geriatric population). We have to assume that certain populations will stay longer than the 'ideal' ratio and administrators and insurance companies should be aware of that.

Modulation of the hypermetabolic response

Burn patients exhibit a florid inflammatory and hypermetabolic response that is more intense and prolonged than the response of similar critical care and trauma patients. The metabolic rate of a burned person is twice that of an injured one. It causes an hyperdynamic circulatory response with increased body temperature, oxygen and glucose consumption and carbon dioxide production, glycogenolysis, proteolysis, lipolysis and futile substrate cycling. This will lead to wasting of lean body mass, muscle weakness, immunodepression and poor wound healing. It has been an area of intense research in the past decade, and the modulation of this response and the maintenance of lean body mass, a competent immune system, and muscle tone and strength are current outcome measures that can be quantified during hospital course and late in the recovery phase. They are important endpoints that indicate the efficacy of the treatment received and are predictive tools for the assessment of new therapeutic interventions. Furthermore, the modulation of the hypermetabolic response is one of the few areas in burn care with evidenced-based data (see below).

Quality of life measures

Grade of disability

Currently, the grade of disability and the quality of life achieved by burn survivors are also main outcome measures. In modern society, it is not only survival that is important but also the quality of life achieved. Survival at any price may lead to subtotal or total disability, which may be not acceptable for all persons. The latest reports of psychosocial adaptation of patients surviving severe or massive injuries show an optimal response and adaptation in society.^{2,3} Moreover, most burn survivors achieve social adjustment that is within normal limits. It is not unusual for people surviving these catastrophic injuries to develop and attain goals such that the resultant quality of life is better than the pre-morbid condition. In other words, some people would never have carried out important and relevant projects in society had the injury not happened. Physical disabilities are certainly common. In particular, patients whose injuries and sequelae are located in important functional areas, such as hands, elbows and feet, present with important restrictions in day-to-day activities. Nevertheless, social adaptation is also good, and some patients develop lives that are very close to 'normal' living. This is particularly true in pediatric patients, whose capacity for adaptation is great. Rehabilitation services, social services, and psychology departments play an important role in the preparation of patients for day-to-day activities and for coping with society in general. These services are involved early on, during the acute phase, and in the overall treatment plan of patients, so that they can help patients through the acute phase and to make a smooth transition to the reintegration into society (Box 63.1). (For more information see 'Organization of Burn Care' In: Barret JP, Herndon DN, eds. A color atlas of burn care. London: WB Saunders; 2001.)

The physical examination of a burn victim is much the same as the disability evaluation for any patient. With history and physical examination, and using the tables of the American Medical Association's Guide to the Evaluation of Permanent Impairment, a rating of impairment can be made.¹⁶ The techniques of measuring, although complex and time-consuming,

BOX 63.1 Members of the burn team

- Burn surgeons (plastic surgeons and general surgeons)
- Nurses (ICU, acute and reconstructive wards, scrub nurses, anesthesia nurses)
- Case managers (acute and reconstructive)
- Anesthesiologists (experienced in burn anesthesia)
- Respiratory therapists
- Rehabilitation therapists
- Nutritionists
- Psychosocial experts
- Social workers
- Volunteers
- Microbiologists
- Research nurses
- Support services (secretaries, environmental services, medical records, material management, informatics, technicians, etc.)

Adapted from: Barret JP, Herndon DN, eds. A colour atlas of burn care. London: WB Saunders; 2001.

are practical and scientifically sound. A combined approach, with an occupational or physical therapist who makes the objective determination of physical impairment and a burn surgeon who makes the subjective determinations, is advisable. A systematic approach should be followed, including skin assessment, musculoskeletal system, special senses and speech, respiratory system, cardiovascular system, neurological system, hemic and lymphatic systems, digestive system, genitourinary system, and psychological system. After a thorough assessment has been performed, the patient will be placed in one of the categories for permanent impairment and disability (Box 63.2). This evaluation is very important to determine the outcome of burn patients. Impairment and disability assessments are most relevant for insurance companies, social security, worker's compensation, and the legal system. Since the burn team is not only responsible for the acute care but also for continuous quality improvement and the evaluation of outcome characteristics, disability determination is an integral part of modern burn care. Only with such evaluation can the quality of outcomes be improved.

Quality of life

Although disability and impairment assessment is one of the main outcome measures, it alone does not describe the quality of life that patients achieve after burns are healed and all formal treatment is finished. One of the measures that adapts to healthcare systems is the quality adjusted life years (QALY) introduced by Torrance in 1986.¹⁷ One QALY is a measure of all benefits of health treatment that include increase in life expectancy and enhanced quality of life. The increase in life expectancy is measured in number of years, while quality of life is measured on a scale with a maximum of 1 (perfect health). On this scale, 0 corresponds to death. There are negative numbers, since there are health situations that are considered by patients to be worse than death. The QALY are, therefore, the number of years with perfect health which are also compared to the number of years lived in a specified state of health. For example, if a person lived for 70 years in perfect health and died, they would accomplish 70 QALY. Conversely, if a person lived 45 years in perfect health, and then acquired

chronic renal failure, with a quality of life of 0.4 and died at age 70, they would accomplish 55 QALY [45 QALY + 25(0.4)]. There are two sorts of methods to calculate QALY, the 'standard gamble'¹⁸ and the 'time trade-off'.¹⁹ The second method is the simplest and the most used. Patients are confronted with two situations: the situation of disease and/or sequelae for t years and the situation of perfect health for x years followed by death. The utility of any treatment of a chronic condition is represented by x/t . Life expectancy under a certain chronic condition is compiled from medical literature. This time is converted to QALY under perfect health, and the risks of the medical treatment are then evaluated in terms of the effectiveness in producing QALY.

When QALY are applied to burn patients, it is easy to assume that the treatment of severe injuries, which will result in death without treatment, will produce an important number of QALY. Nevertheless, many burn injuries heal with sequelae, so that the quality of life achieved is not that of perfect health, but sometimes quite less than that. Patients that survive life-threatening injuries acquire a high number of years in terms of life expectancy, whereas the total number of QALY is often less than the optimal number. This is confusing since the overall assessment of quality of life that burn patients express in the long run is usually higher than expected.^{2,3} As an example, at the Vall d'Hebron Burn Center in Barcelona, Spain, the overall QALY acquired by all patients (minor and major burns) during 1996, based on an estimation of time trade-off, was 3 QALY per patients.⁸ QALY acquired by burn patients were less than expected, especially in severely burned patients. One of the main problems of QALY assessment as a measure of cost-efficacy and cost-utility is that patients tend to make a short-term estimation of life expectancy and quality of life.²⁰ Burn sequelae are more dramatic in the first months and years after the injury, resulting in a low estimation of QALY.

Other widely used tools are the Short Form 36 (SF-36),²¹ that measures global reintegration and socialization and the Vineland Adaptive Behavior Scales – Survey Form,²² which measures a broad range of functioning in communication, daily living skills, socialization, and motor skills.

Quality assurance

Quality assurance (QA) means a critical appraisal of data collected in the specific system to give assurance to users and to healthcare providers that quality is achieved. Such appraisal should also result in better management, lower complication rates, and better outcomes. The essence of QA is the idea that real quality improvements involve the continuous search for opportunities for all processes to get better.²³ Quality assurance is essential in the modern healthcare system where cost-containment and cost-efficacy are primary endpoints. QA programs provide data to support requests for funding of burn patient care at an appropriate level. They are primordial to suffice the minimal requirements that are to be met by burn centers in order to be endorsed by national societies and state agencies.

The standard QA program is depicted in Figure 63.2 All members of the multidisciplinary burn team (Box 63.1) join together to satisfy common goals and to target all possible

BOX 63.2 Categories of burn impairment and disabilities

- Class I: Impairment of 0–10%. No limitation or minimal limitation in the performance of the activity of daily living. Exposure to certain physical and chemical agents might increase limitation temporarily. Skin disorders are present, but no treatment is necessary
- Class II: Impairment of 10–25%. There is limitation in the performance of some of the activities of daily living. Skin disorders are present and intermittent skin treatment is required
- Class III: Impairment of 25–50%. There is limitation in performance of many of the activities of daily living. Skin disorders are present, and continuous treatment is required
- Class IV: Impairment of 55–80%. There is limitation in performance of many of the activities of daily living. Skin disorders are present, and continuous treatment is required, which includes periodic confinement to home or healthcare institution
- Total impairment

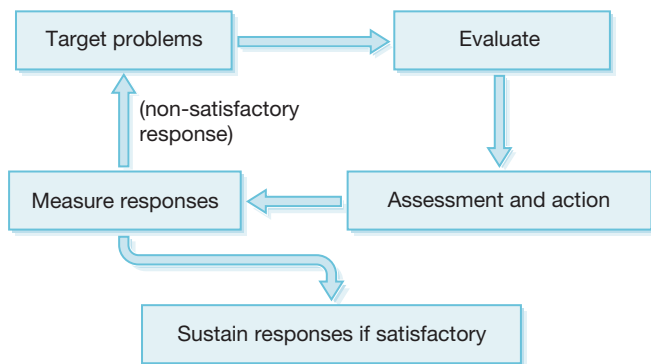

Fig. 63.2 The cycle of quality assurance. The performance of the unit is continuously assessed. When problems are detected, an action is taken after complete evaluation of the situation. The responses and the new performance of the unit are measured again. If the response is deemed adequate, the action is sustained. Should the response not be appropriate, a new cycle begins.

problems encountered in day-to-day work. Should problems arise, an assessment is made; and committees are organized to respond if such a formal response is needed. Actions are carried out in order to solve the problem, and the results of such actions measured. When responses are shown to be effective, the actions and changes in protocols are sustained. Otherwise any new problem that was encountered with the process is targeted for improvement, and actions carried out to address those problems.

Developing a functional QA program requires that the burn team develop clinical protocols and critical care pathways. Although time-consuming at first, this planning saves much time in the long term. Members of the burn team are well acquainted with clinical protocols that begin at the exact time point during patient care. Time points, red flags, and self-stopping parameters are necessary. Protocols are essential for a QA program, since deviations from protocols are easily detected, facilitating evaluation and assessment of the deviations.

Clinical indicators of the overall performance of the unit must be established. It is the responsibility of every member and every department involved in the burn care system to provide the burn team and the QA program with indicators of the well-functioning unit, essentially defining what the unit would be if everything goes very well. Deviation from these performance goals is detected and included in the evaluation system. Outcome measures are the main clinical indicators of the performance of the burn unit as a whole and should be evaluated periodically. Changes in outcomes must be evaluated carefully to detect any malfunction or deviation and develop an appropriate action. Mortality, probit analysis, disability, and quality of life are outcome measures that need to be surveyed constantly. Every specialty involved in burn care must develop their own specific outcome measures that contribute to overall outcome in order to assess, maintain, and constantly improve their contribution to care. Examples of these secondary outcome measures are graft take, pain control, or infection control.

At the Shriners Burns Hospital in Galveston, Texas, QA staff are active and indispensable members of the burn team. Their constant surveillance helps burn patients and burn team

members by assisting to develop protocols and by monitoring achievements according to protocols. They promptly detect deviations so that adequate action can be immediately taken. Their effort assures that no variables will be left to flow without control, so the expected outcome will result. The author finds QA staff to be important back-up aids helping to prevent unwanted surprises.

Finally, QA programs help to maintain cost-efficacy in the burn center. By maintaining outcomes, the investment that society and insurance companies make in the expensive treatment of burn patients is rewarded by provision of state-of-the-art treatment and excellent outcomes. Documentation of such standard of care should result in reimbursement and funding that are maintained if not increased.

Cost-containment in the burn unit

Over the last two decades there has been a continuous change and evolution in health economy. The continuous increase in world population has been joined with an increase in life expectancy, which, along with the decrease in births, has led to an increase in the mean age of population. This is particularly true in developed countries where the population pyramids have reversed their shape. The increasing population of 'elders', along with the economic crisis and the expected increase in costs of healthcare technology and specialists, have provoked an exponential increase in health costs. Economical analysis and cost-containment with an emphasis on cost-efficacy and cost-utility are principal pillars of health economy.

Assessing the maintenance of good outcomes assures that all economic efforts invested in burn centers produce the expected benefits with a positive cost-efficacy effect. Our resources in contemporary society have become limited, so the best outcomes with good cost-efficacy and cost-utility ratios are essential. It is clear that insurance companies and society, in general, seek healthcare systems where less investment still results in the best outcome. It is particularly true in burn centers; reimbursement will peak in centers that provide the best functional outcome in a standard period of time. Contracts flow when good return to productive life is achieved.

Burn treatment presents some particularly relevant differences that make it unique in health economy. In contrast with general costs of tertiary hospital treatments, whose costs peak in human resources, burn treatment costs peak in technology and material costs. These can be as high as 70% of all costs in burn centers, leaving the remaining 30% for wages and salaries of personnel. Materials used in the day-to-day care of burn patients are extremely expensive. However, with cost-containment measures, QA programs, and continuous outcome measures, burn centers can benefit the hospital budget via reimbursement from third-party providers.

In order to maintain a dynamic and viable center, a cost-containment program must be instituted. These programs are defined as all measures directed to produce the best cost-efficacy and -utility ratios; i.e. to maintain costs within expected margins and optimize burn care providing the best outcomes. The main steps of cost-containment programs are:

- data acquisition and outcome measurement;
- treatment protocols; and
- optimization of resources.

Data acquisition and outcome measurement

The first step to control costs in burn centers is the development of a QA program, as previously described, to include data acquisition and outcome measurement. The flow of economic efforts is then bidirectional, from society to patient care and from burn centers to society. All investments made in the burn center are returned to society in the form of excellent outcomes and social reintegration. On the other hand, the knowledge of the most recent outcome figures for the burn unit alert the burn team to know the point of futility of treatment. Expensive efforts to save patients whose burn injuries are fatal increase costs exponentially, decreasing the resources available for other burn patients. It is particularly true in developing countries, where all efforts need to be concentrated only in those patients who will survive.

However, the equal responsibility of the burn team to improve the outcome of burn patients mandates that they push ahead to achieve better survival and better quality of life for their patients. The line that separates futility from constant improvement is vague. The only way to define it and to improve outcomes without increasing futile efforts is with burn research. Experimental and clinical burn research produces new data, which, after critical evaluation of results, will impact and change clinical protocols and pathways.

Evidence-based medicine in burn care

As it has been outlined in previous sections, there has been a burst in wound technology, critical care, and biotechnology during the past two decades. It is not uncommon to be confronted on a daily basis with new technology, pharmaceutical novelties, and expensive new treatments. There has been an exponential improvement in burn care when we compare current survival outcomes with those published 30 years ago. However, paralleling this exponential improvement there is an escalation in treatment expenses, which is not always accompanied by clear data supporting the use of such new technology. In the new era of healthcare, we are confronted with the necessity of providing state-of-the-art burn care while containing burn care expenses. The answer to this ethical and pragmatic dilemma consists of the rationalization of treatment provided supported by clear outcome data. Evidence-based medicine plays a central role in this model of new healthcare, and consists of the provision of treatment based on clear protocols supported by data that warrants cost-efficiency of the therapy used.

Unfortunately, few treatments are evidence-based in burn care, and, most surprisingly, some evidence-based burn care that presents with strong data supporting outcome are not followed by burn practitioners.²⁴ 'The basis of care should be that simple things should always be performed well.' It is not always so, and even in pre-hospital medicine and accident retrieval we find important differences throughout the world, despite being important outcome data supporting what should be done at the accident scene and transport.^{9,25} Another of the few areas where evidence-based burn care has exploded is resuscitation of burn shock. Resuscitation endpoints and monitoring strategies have produced data determining when futility of treatment has been reached, by shifting from fluids and urine output to adequate endpoint monitoring, edema control, adjuvant therapies, and tissue perfusion and oxygenation, supporting the idea

that traditional methods of monitoring are not supported by scientific data, and that it should be performed by constant physiological monitoring.^{26,27} However, despite emerging data on the necessity of shifting to a more monitor-based resuscitation, most burn centers in the world continue to resuscitate based on tradition and old-based resuscitation formulas. Similar behaviors are encountered in the use of human albumin solutions and hyperbaric oxygen treatment. Strong epidemiological data suggest an increase in mortality with the use of albumin among patients with burns,²⁸ and the beneficial effect of hyperbaric oxygen in several surgical conditions is an evidence-based therapy.²⁹ In spite of all this data, albumin is liberally used, and few facilities use hyperbaric oxygen therapy. It seems that tradition and personal belief is stronger than evidence-based therapy in the burn community. A shift in burn treatment towards evidence-based practice is necessary to become cost-effective and provide optimal care.

Treatment protocols and rationalization of pharmaceutical costs

Burn care treatment is expensive. State-of-the-art technology, pharmacological treatments, and skin substitutes are at the top of the price ladder in health treatment. A judicious and clear use of these technologies is clearly indicated for such costs to provide benefit. Clinical protocols and critical care pathways are essential elements to control costs. Protocols and pathways are tools developed after consensus conferences over treatments and diagnostic tests. Experts review the quality and effectiveness of these treatments and techniques, and a consensus is generated about the rationale for the use of old, current, and new technology. Consensus declarations are included in clinical pathways. In this way, well-thoughtout methodology with predicted costs is used to generate outcomes. If no deviations are made and new techniques are not tried without thoughtful consideration, the overall costs of the burn center are contained — provided the annual number of admissions is maintained.

The introduction and testing of new techniques need to be carried out within well-controlled research protocols, and all results need to be critically reviewed. New treatments must be tested versus the standard of care at any given time, and results compared. When better outcomes are achieved with good cost-efficacy results, the new treatment protocol can be general and become standard. As an example, advances that were possible thanks to research supported by the Shriners of North America are prompt eschar excision and immediate wound closure, pressure garments, fluid resuscitation, bacterial translocation control, early enteral nutrition, and improvements in inhalation injury treatment among others. This research was conducted as a comprehensive program of experimental research followed by clinical application in clinical research protocols. Positive results were then applied to routine clinical protocols, improving standard patient care.

Cost-containment, besides QA programs and clinical protocols, is based on rationalization of pharmaceutical costs and optimization of resources. Since more than 60% of all costs in burn centers result from the use of topical and systemic treatments, it is of paramount importance that tight control on the use of such treatments exists. In order to reduce and control costs, it is necessary to use generic drugs in place of trademark (proprietary) drugs when feasible with the same

drug activity. The least-expensive trademark should be used when no generic suffices. However, an expensive treatment should be used if such practice reduces the length of hospital stay. For instance, when the treatment of superficial second-degree burns in children is done with Biobrane™, a more expensive treatment alternative than the traditional treatment with 1% silver sulfadiazine, a significant reduction in pain and hospital stay is achieved. Thus, the overall cost of treatment is reduced, and yet there is a significant improvement in outcome.³⁰ In this situation, the initial treatment with a much more expensive alternative method results in a better outcome, providing a better cost-efficacy ratio.

Optimization of resources

The optimization of resources begins with the organization and calculation of burn unit requirements. In order to calculate the number of personnel required to treat all burns in a determined area, the *method of necessity* is very helpful. To determine the desired number of personnel (RT), one must obtain the catchment population (P), the incidence of burns (I) in persons/year, the number of hours of treatment per day (A), the mean hospital stay in days (L), and the mean number of hours that personnel work in the burn unit (W).³¹ The basic formula is as follows:

$$RT = \frac{P \times I \times A \times L}{W}$$

For example, in a geographic area with a population of 5 million people, a raw burn incidence (patients admitted to the burn center) of 6.5 per 100 000 persons/year, and 1 admission per patient per year, a mean hospital stay per patient of 16.5 days with full time (40 hours/week) personnel working a total of 1960 hours per year to provide continuous care of a patient per 24 hours, the total number of personnel required for the complete treatment of burn patients is 65.6, calculated as follows:

$$RT = \frac{5\,000\,000 \text{ people} \times 6.5/100\,000 \text{ persons/year} \times 24 \text{ hours} \times 16.5 \text{ days}}{1960 \text{ hours}}$$

$$= 65.6$$

The number of beds (NB) dedicated to burn treatment is based on the incidence of burn injuries (I), the mean hospital stay (L), and the ideal index of admissions (IO) estimated as 0.85 (85% of beds used for burn treatment, 15% of beds unoccupied).³² The formula is as follows:

$$NB = \frac{I \times L}{365 \times IO}$$

When this formula is applied to the same example, the number of beds required are 17.3 beds for a geographic area with 5 000 000 population and a burn incidence (admissions to burn center) of 6.5 per 100 000 persons/year:

$$NB = \frac{5\,000\,000 \text{ people} \times 6.5/100\,000 \text{ persons/year} \times 16.5 \text{ days}}{365 \times 0.85}$$

$$= 17.3$$

Although all parameters are well known for all countries and the theoretical burn care needs can be calculated with them, it is common knowledge that burn incidence and the index of admissions suffer important oscillations throughout the year. The calculation of an optimal burn center occupation

at 0.85, which is the index for optimal outcome and cost-efficacy, means that the index of admissions may decrease fewer than 40% in certain periods of the year. Even though it does not affect the actual function of the burn center (it does affect if the index is calculated at 1, with periods of bed occupation over 100%), it makes an important impact in cost-containment, since the maintenance of a full functioning burn center with minimal admissions reduces all benefits, and may produce an important financial loss.

In order to optimize the index of occupation of the burn center, and maintain it at 0.85, it is possible to admit patients at the burn center who present with a spectrum of injuries suitable for treatment at the burn center. Given the nature of burn injuries, the burn team is capable of managing patients with a spectrum of trauma and extensive cutaneous or soft-tissue losses. Box 63.3 compiles all patients suitable to be treated at the burn center. Patients that can be successfully treated and benefit from the technology and expertise of the burn team are trauma patients (general multitrauma and neurological trauma, facial trauma), TEN and dermatoses, plastic surgery patients including free flap reconstruction, and chronic wounds. It must be borne in mind, however, that the burn center is a super-specialized unit created for the care of burns, and that, as such, it may be the only facility for such injuries in that particular area. It is imperative to reach a balance between optimal function and cost-containment with optimal treatment of burn injuries. To achieve that, a set of priorities have to be created for admission to the burn center so the treatment of other injuries and patients do not challenge the admission of severe burn injuries. In Box 63.4, all patients suitable for treatment in the burn unit are divided into three types of priorities. Priority 1 patients include all burn patients whose injuries are categorized as major injuries by ABA standards. These patients have priority over all other patients. Patients included in priority 2 are patients who may be treated in other specialized units of the hospital, but also can be treated with the same standard of care in the burn unit and will benefit from care by the burn team. These patients are admitted on a bed availability basis, with the main idea of maintaining an optimal IO. Patients included in priority 3 are patients who do not present with acute injuries but who may

BOX 63.3 Patients suitable for treatment in a burn center

- Acute burns
- Rehabilitation and reconstructive burn patients
- Toxic epidermal necrolysis and other life-threatening dermatosis
- Blunt and penetrating trauma patients
- Brain trauma
- Maxillofacial injuries
- Upper and lower limb reconstruction
- Craniofacial surgery
- Free flap reconstruction
- Traumatic soft-tissue avulsions
- Pressure sores
- Chronic wounds
- Diabetic and vascular ulcers

benefit from treatment in the burn center. These patients are admitted as elective cases.

When a conflict arises, i.e. there is a shortage of beds and patients included in priority 1 need to be admitted to the burn center, the priority 1 patients have priority over all other patients. Patients included in priority 3 should be moved to another ward in the hospital, followed by patients included in priority 2 if the need for beds is very acute. (Generally, this occurs in response to a major disaster, and the disaster plan will be activated.) It must be borne in mind that all flow of patients must maintain the required standards of care for all patients. The program of optimization should not be carried out until the required standards of care, as demonstrated via QA programs, can be provided.

Other programs of cost-containment that are very effective in maintaining low costs and improving the quality of care are programs to optimize human resources and programs of day care. Human resources in the burn center can be optimized by planning nurses' shifts. Morning shifts are usually the busiest and 8-hour shifts are the most effective. Therefore, morning shifts can be scheduled with the largest number of nurses, while afternoon and night shifts can be staffed by fewer. On the other hand, nurses' shifts with flow capabilities increase the overall performance of personnel in the burn center. Personnel that can staff the nursing wards, outpatient clinics, and social services provide more freedom in the organization and optimization of resources, diminishing costs in the burn center.

Another important change in modern healthcare is the development of day care programs, i.e. major wound care on an outpatient basis and day surgery. Both types of programs diminish the need of admission to the burn center, thereby decreasing costs and increasing performance. This also allows the treatment of other injuries in the burn center, which increases reimbursement via third-party payers and via the budgets of other departments. Patients who present with burn wounds, even large wounds, that do not need admission for other causes and whose injuries are not at risk of infection at home may be treated as outpatients with daily or periodic dressing changes in the day care unit of the burn center. On the other hand, minor burns, with the advent of new and safer techniques of anesthesia, can be successfully treated surgically in day surgery. These two programs require a strict standardization of protocols so only patients who fit the program are included in the day care unit protocol. Patients must be able to reach the burn center at any time, and all risk factors and warning signs need to be explained verbally and provided in writing to the patient and/or to the person who will take responsibility for the care of the patient. Every effort should be made by the burn team to start a program of day care, since the benefits in patient care, quality of life, and cost-containment are spectacular when the program is fully functioning.

Summary

The relevant socioeconomic impact of burns and the particular characteristics of burn injuries made necessary the development of teams to provide dedicated and specialized treatment of burn injuries. The achievement of total burn care and the current excellent outcomes in burn patients have paralleled a continuous increase in the complexity of treatment of burn victims and concomitant increase in costs of treatment. To contain costs and to prevent decline in standard of treatment, it is necessary to develop clinical protocols providing strict guidelines to healthcare providers. Thus, quality assurance programs are developed. Outcome measurement is also a part of quality improvement, since it is the main indicator of the quality of care that is performed at the burn center. Outcome data are part of the data acquisition of QA programs, and outcomes are also improved by the actions of such programs. The climb in costs must be contained with specific measures following an overall plan and by implementation of evidence-based medicine. QA programs provide the tools to assure that measures to control expenses are applied while maintaining the quality of care so excellent cost-efficacy can be obtained. In the modern era of healthcare management, programs of day care, admission of patients without burn injuries to the center, and optimization of resources (technical and human) are of paramount importance to maintain the gold standard of burn care while containing costs.

Introduction

The words ‘burn injury’ trigger, for almost any adult in the world, immediate and vivid images of excruciating pain and suffering. Children are conditioned from early childhood that burn injuries are painful and can cause great harm. Certainly there can be no doubt that complaints of pain are ubiquitous in a burn unit. Burn care professionals should be especially conscious of the management of the pain and suffering endured by their patients. Working to make a patient with burns comfortable is never ending and fraught with frustration. The experience of pain is complex and dependent upon an interaction of dynamic physical and psychological variables. Beecher¹ observed that soldiers burned in battle could perform heroic feats without apparent pain; yet as soon as they were in a safe place their pain was significant. As noted by Choinière the pain expressed by patients with burn injuries varies from day to day and hour to hour (see Figure 64.1).² Such fluctuations make it difficult to dose pain medication appropriately so that under- or over-medicating are avoided.

Although pain is not directly observable, it can be inferred from the patient’s behavior and physical signs such as blood pressure and pulse of the patient, particularly if that patient is a child. The burn care professional must monitor patient behaviors to determine pain level, be they overt indices such as flinching, crying or screaming, or verbal reports of pain level. More interpretation is required to tease out how much of the discomfort is due to pain and how much is a reflection of fear or anxiety. Adding to this confusion is the fear often

expressed by family members, patients themselves, and even well-trained medical professionals that patients will become addicted to opioid analgesics if they are given ‘too much.’ Then, just when the professionals seem to have found a good management plan to facilitate comfort for a particular patient, something often changes to upset the balance of factors, and the patient suffers again. Thus, frustrated caregivers understandably might concede defeat to the issue of pain and focus on working to heal the patient with the certain knowledge that, as the patient heals, the pain and other discomforts will also diminish.

Pathology of a burn injury as it relates to pain

All burn injuries are painful. First-degree or very superficial partial-thickness burns may damage only the outer layers of the skin, the epidermis; but they do produce at least mild pain and discomfort, especially when something such as clothing rubs against the burned area. Second-degree or moderate to deep partial-thickness burns result in variable amounts of pain depending on the amount of destruction to the dermis. Superficial dermal burns are the most painful initially. Even the slightest change in air currents moving past the exposed superficial dermis usually causes a patient to experience excruciating pain. Without the protective covering of the epidermis, nerve endings are sensitized and exposed to stimulation. In addition, as the inflammatory response progresses with the increase in swelling and the release of vasoactive substances, pain is increased.³

Areas of deeper partial-thickness burns may display a confusing pattern of pain over the first few days. These areas may show little or no response to sharp stimuli such as a pinprick; yet a patient may complain of deep achy pain related to the inflammatory response. These wounds are more similar to full-thickness burns with respect to the pain they cause. In a full-thickness burn, the dermis, with its rich network of nerve endings is completely destroyed. This leads to an initial response of a completely anesthetic wound when a sharp stimulus is present. Yet, patients often complain of a dull or pressure type of pain in these areas. Once the devitalized tissue, i.e. eschar, sloughs and is replaced by granulation tissue, a patient again experiences the sensation of sharp pain to noxious stimuli. It is unclear, but increasingly suspect, that some deep burn injuries carry with them a neuropathic pain component; that is, regenerations of nerves and or nerve damage create a form of pain different from tissue damage

Fig. 64.1 VAS scores for different patients show how variable expressions of pain can be from day to day and from one patient to the next. (Reproduced with permission from: Choinière et al. *J Trauma* 1989; 29:1531–1539.²)

known to be a large part of burn injury pain. Two separate patients have described this pain as an insect walking across their skin with spikes on its shoes.

Pain-generating mechanisms during an initial injury

The dearth of information on the mechanisms of pain perception specific to burn injuries leaves many unanswered questions. Some of the best work is that done by Meyer and Campbell^{3,4} who attempted to study this in monkeys and humans exposed to a series of thermal stimuli before and after a 53°C 30-second burn to the glabrous skin of the hand. The nociceptors in the skin stimulate both A and C afferents. Both types of fibers are widely distributed in skin and deeper tissues. Their work indicated that the burn injury resulted in increased sensitivity of the A fibers, decreased sensitivity of the C fibers, and increased pain sensitivity (hyperalgesia) in human subjects. This study would suggest that A fibers rather than C fibers are chiefly responsible for the hyperalgesia related to burn injury. Later studies by Coderre and Melzack⁵ confirm that burn injuries not only make an injured area and surrounding tissue more painful but also cause hyperalgesia, which is a significant problem for many patients. Sensory nerve damage may also play a role in this difficult-to-treat excessive pain. Burn injury is characterized by release of large amounts of inflammatory factors such as interleukins, which probably add to the perception of pain and the hyperalgesia. The hyperalgesia is further enhanced because the burn wound heals slowly over days or weeks. Some of the various surgical and non-surgical therapies that are applied to a wound increase pain during the healing phase. Choinière et al.² utilized the visual analog scale (VAS) on a daily basis and asked patients to rate their worst pain for each day. Patients' scores varied widely from patient to patient. Even for the same patient, overall pain scores varied widely from day to day, but gradually declined towards the end of hospitalization. In an effort to elucidate the predictor of pain in these patients, Choinière et al. compared pain scores with patient's age, socioeconomic status, and educational level and found no significant correlation. Likewise,

no significant correlation was found between the pain scores and burn size.

When further analysis of the Choinière et al. data included the first-degree areas in total extent of burn and the pain measurements were limited to those obtained during the first week postburn, there was a positive correlation of pain with burn size ($p < 0.02$).² In addition they found that pain scores at rest were significantly correlated with extent of first-degree burns ($p < 0.04$) and pain at time of treatments was significantly correlated with extent of second-degree burns ($p < 0.02$). No correlation was found with the extent of third-degree burns. In contrast, Atchison et al.⁶ measured pain scores in children and found a significant correlation between pain scores during the procedure and both the extent of total burn injury and the extent of third-degree burn. More recently, Ptacek et al. described the course of pain over 10 days for 47 patients; they found considerable variability over the course of each day.⁷ There was a general trend down over days. Psychological factors such as anxiety added greatly to the reporting of pain. Also, persons with large burns showed a higher affective (suffering) component to the pain.

Another source of confusion concerning the amount of pain expressed by burn patients is the role played by psychological problems such as anxiety and depression. Choinière et al.² noted that pain at rest was significantly and positively related to levels of anxiety or depression; i.e. with elevated anxiety or depression, pain scores at rest increased. Interestingly, all patients hospitalized more than 3 weeks showed an increase in the depression scores. Although these studies demonstrate the great variability in pain expression in burned patients, they do not identify pain-generating mechanisms, either physiologically or psychologically, in a burn-injured patient. Charlton et al.⁸ used the State/Trait Anxiety Inventory to measure anxiety and reported that the study sample of adult burned patients was not particularly anxious. Other studies have suggested that burned patients have increased levels of anxiety, especially related to treatment and outcome, and that these levels may increase over time.^{9–11} Anticipation of pain related to treatments that occur at least daily can increase a patient's

perception of pain. Anticipatory anxiety related to treatments leads to perception of increased pain, and the increased pain leads to further increases in anxiety. This reaction may explain some findings which suggest that pain increases over time in burned patients.^{12–16} Depression also plays a major role in enhancement of pain.¹⁷ Pain leads to depression and depression enhances the perception of pain.¹⁸ In burn care units where very aggressive pain management is practiced, depression is not a major problem.¹⁹ Further work in these areas is needed to better understand the great variability of burn pain.

Pain as a function of the healing process

As a deep dermal or full-thickness burn wound heals, either by primary intention from excision and grafting or by secondary intention through granulation tissue and scar formation, the injured neural tissue is reorganized.¹⁵ Reflex neural function returns to grafted burn skin approximately 5–6 weeks after the burn has been covered by autografted skin.¹⁶ Active vasodilatation, vasoconstriction, and pain sensation all return at this time. These functions also return to the burn wound which heals through scar formation but may take up to 6 months for complete neural reorganization.

Although rare, causalgia, dysesthesia, and phantom pain syndrome can sometimes develop in healing skin. Phantom limb sensation and pain is going to be more common following traumatic amputation, which is usually the case with burn injury. The incidence of these chronic pain syndromes seems to be related to the healing process. Burns that have been excised and grafted on a clean and uniform vascular bed rarely develop one of these chronic pain syndromes. Wounds that heal by granulation and scar formation seem to be more apt to develop a chronic pain problem because of the continued stimulation of nerve fibers in the area with enhancement of the hyperalgesia. Skin biopsies of granulation tissue have clearly shown neuronal tissue entrapment.¹⁶ Pain, in scar tissue, subsides over time as the scar tissue matures.

Types of pain in burned patients during the acute phase of treatment

As already noted, the pain expressed by patients with burn injuries is extremely variable. In many studies, patients have been asked to rate overall pain, pain at rest, overall procedural pain, and worst pain during the procedure. Such perplexing instructions may account for some of the variability in pain reports. For example, if asked to rate one's overall pain for the day, one would expect this rating to include resting pain, pain during normal activity, and pain during painful procedures. A more reasonable approach may be to ask a patient to rate pain as either procedural or non-procedural (background) pain, with each given an operational definition. Procedural pain can be defined as that related to wound care or stretching of the patient's scar tissue, activities that seem to cause the worst pain for burned patients. Background pain is the discomfort experienced at rest or during mild activity. As the therapies for pain management are discussed later in this chapter, the importance of differentiating procedural and background pain will become increasingly clear.

For many years it was thought that infants did not feel pain because of incomplete myelination of the sensory nerves. Anand and colleagues published data in 1987²⁰ and 1988²¹ to suggest that infants do experience pain as evidenced by a variety of physiological and metabolic responses. Anand and Hickey²² hypothesize that although A fibers are not completely myelinated and may not be efficient in transmission of pain, unmyelinated C fibers take over the transmission of noxious stimuli. This research has demonstrated the need for pain assessment and management in infants and preverbal children as well as older children.

Measurement of pain in burned patients

Although pain cannot be measured directly, it can be quantified by using one of the standardized tools described below. Using reliable and valid tools allows us to gauge the effectiveness of our treatment for any one patient. Assessing pain on a scheduled basis and using the same tool for each assessment gives us information about how pain is experienced by a single patient throughout the burn treatment; we can note patterns that emerge and schedule medications accordingly. Further, standardized tools allow us to compare pain management of one patient with another as well as one burn unit pain management with that of other burn units in order to determine, for example, the effectiveness of a new protocol for pain management. Another important reason for assessing pain regularly and in a standardized way is that it communicates to the patient that we believe she/he has pain, and we are trying to do something about it. This communication reassures the patient, thereby reducing the likelihood that the patient will escalate pain, anxiety, and other related behaviors.

What is the gold standard for the measurement of pain? Gracely²³ reviewed a number of objective modalities for the measurement of experimental pain. He notes that 'pain arises from and is modulated by, a number of mechanisms. These mechanisms are not static but change over time and involve all levels of the central nervous system. In an attempt to understand these mechanisms, several experimental tools have been employed to further elucidate the exact pathways involved in pain transmission and to better understand the therapies used to relieve pain.'

Some of these tools are: cortical evoked potentials; functional brain imaging (PET or positive emission tomography); functional magnetic resonance imaging (fMRI); source analysis of evoked activity; and electrophysiological recording from the human brain. As noted by Gracely, comparing them with verbal judgments of pain magnitude validates these physiological measures: 'This implicitly elevates subjective judgment to the level of a validation standard.'²³ Clinical measurements of pain must continue to rely on standard subjective measures. A tool to use in the clinical setting must be quick and easy to use and useful for frequently repeated assessments.

A major concern in the clinical setting is the use of a consistent pain measurement tool before and 1–2 hours after the administration of a pain-relieving medication. For procedural pain management, the same tool should be used to measure pain at the beginning of a procedure, during the procedure, and post-procedure in order to measure the effectiveness of the pain management regimen used for procedural pain.

Pain measurement techniques for an adult burned patient

A variety of pain measurement techniques have been used with adult burned patients. The more common measures include adjective scales (Table 64.1), numeric scales (i.e. rating pain on a scale of 0–5, 0–10 or 0–100), and visual analog scales (Figure 64.2). Each of these scales measures the sensory component of a patient's pain. Adjective scales and numeric scales are quick and easy to administer because they do not require a visual representation of the scale. The visual analog scale requires a visual representation of the scale to be presented to a patient. Patients must mark or point to the place on the scale that represents their level of pain. This presents a problem for a burned patient whose hands are burned, so some investigators have used a technique of sliding a line or color strip along the scale with instructions to a patient to direct the movement of the slide, stopping at the point representative of the patient's pain. The visual analog scale has been used in a number of studies with a variety of patient samples and has been shown to be a valid method of measuring the sensory component of a patient's pain. The demonstrated validity of the scale allows for comparisons of visual analog pain assessments between studies with different patient samples.

Motivational-affective and cognitive-evaluative components of pain are most frequently measured using the McGill Pain Questionnaire (MPQ).²⁴ The MPQ consists of 20 sets of adjectives which describe all three components of pain: sensory, affective, and evaluative. Qualitative profiles and quantitative scores for each dimension as well as a total pain score can be derived from the selected adjectives. The MPQ has been translated into several languages and has been shown to be a reliable and valid measurement tool. Since it takes 10–20 minutes to administer, it may not be as useful for frequent, repeated measurements. Many studies have employed this measurement on a daily basis to measure either overall or resting pain. Gordon et al.,²⁵ in a prospective multicenter study, asked 40 adult burned patients to rate their pain on 4 scales. These scales were: a visual analog scale, an analog chromatic scale,²⁶ an adjective scale, and a faces scale.²⁷ At the end of the study patients were asked to choose their preferred scale. Patients preferred the faces and analog chromatic scales. Although further research is needed to validate these findings, the preference of patients is another variable to be considered.

Pain measurement techniques for pediatric burned patients

The measurement of children's pain is much more complex than it is for adults, especially for preverbal children. The American Academy of Pediatrics and the American Pain Society issued a joint statement in 2001 that included the recommendation that in a hospital setting 'ongoing assessment of the presence and severity of pain and the child's response to treatment is essential.'²⁸ The assessment of pain in children has included physiological measurements, behavioral assessment, and patient reports of pain. The physiological indicators which have been evaluated are heart rate,²⁹ respiratory rate,²⁹ blood pressure,²⁹ endocrine changes,^{29,30} and changes in PO₂.³¹ None of these shows promise as an indicator for measuring pain in sick children, since all are affected by a variety of stressors, metabolic changes related to a burn, and medications, in addition to pain.

Behavior scales have been devised to measure pain by providing standardized instructions and guidelines for observing behaviors thought to be specific to pain. A number of investigators^{32–37} have looked at infants' cries as measurable behaviors that can be observed in order to evaluate pain. Although these studies demonstrate that length of cry, pitch, intensity, and other characteristics of crying may be used to evaluate pain in infants, the analyses of cry are very time consuming and require elaborate audio equipment. IZARD et al.,³⁸ CRAIG et al.,³⁹ and GRANAU and CRAIG³⁶ have attempted to code facial expressions as measures of pain in infants. Their system characterizes nine facial actions involved in the expression of pain, but its use requires videotaping and detailed analyses of an infant's facial movements. Although this method offers excellent research applications, it, like the detailed analyses of crying, is too cumbersome and not appropriate for the clinical setting. On the other hand, the studies do provide clinicians with information about various facial actions, as categorized by Granau and Craig, which may be helpful in the clinical identification of pain in infants. Other investigators have devised multidimensional scales that include length of cry, facial expressions, and behavioral states in order to measure pain in infants.^{40–42} These scales are easier to use and allow an observer to assess pain as either present or absent without further quantification.

Examples of observational scales which allow for quantification and may be used with toddlers and preverbal children are the CHEOPS (Children's Hospital of Eastern Ontario Pain Scale)⁴³ and The Observer Scale.⁴⁴ The CHEOPS is a scale of six behaviors, each scored on a numeric range; it yields a total numeric score for pain. This scale has been shown to be valid and to have good interrater reliability. The Observer Scale is another standardized instrument that categorizes overall pain or comfort behaviors on a scale of 1–5. The five categories are: laughing, euphoric; happy, contented, playful; calm or asleep; mild-moderate pain — crying, grimacing, restlessness, but can be distracted with toy, food, or parent; and severe pain — crying, screaming, inconsolable.

A burn-specific observational tool was recently developed by Barone et al. at Shriners Hospitals for Children, Cincinnati.⁴⁵ The OPAS (Observational Pain Assessment Scale) is useful in children 0–3 years of age. The scale is depicted in Table 64.2.

TABLE 64.2 OBSERVATIONAL PAIN ASSESSMENT SCALE (OPAS)¹³⁶

Observed behavior	0	1	2
Restlessness	Calm, cooperative	Slightly restless, consolable	Very restless agitated, inconsolable
Muscle tension	Relaxed	Slight tenseness	Extreme tenseness
Facial expression	No frowning or grimacing, composed	Slight frowning or grimacing	Constant frowning or grimacing
Vocalization	Normal tone, no sound	Groans, moans, cries out in pain	Cries out, sobs
Wound guarding	No negative response to wound	Reaching/gently touching wound	Grabbing vigorously at wound

Used with permission of authors.
Assess each of the areas identified in the 'observed behavior' column, rating each behavior using 0, 1 or 2 rating. Add the ratings together for each observed behavior. Document your total score.

Research suggests that simple self-report scales can be used with preschool children. Examples of such scales include the Oucher Scale (photographs of children with various facial expressions).^{46–48} Drawings of faces^{27,49} have also been used with preschool-aged children⁵⁰ and school-aged children (8 years).⁵¹ Preschool children have also used the Poker Chip Tool,⁵² color scales,^{53,54} and a thermometer⁵⁴ to report the degree of pain or hurt. These simple tools allow a preschooler to report pain and are easy to use. One caution with the face scales is that a practitioner must help a child differentiate between physical pain and sadness unrelated to pain. Since there is no evidence that any one of these is more valid than another, it is recommended to pick one and use it consistently. When self-report scales are used in conjunction with observational scales, a practitioner gets a better picture of a child's response to pain and pain therapies.

A school-aged child's cognitive development allows more abstract thinking. In addition to the Faces Pain Rating Scales which they enjoy,⁵⁵ they can use simple numeric scales, 0–5, in the early school years (ages 7–8)⁵⁶ and more complex scales, 0–10 or 0–100, in the later years (age 9–12). Visual analog scales anchored with happy and sad faces⁵⁴ and simple adjective scales^{54,57} also can be used with this age group. In addition to self-reports of pain, observational scales such as the CHEOPS,⁴³ or the Procedure Behavior Check List⁵⁸ can be used with a school-aged child. Again, the important issue is to use one selected scale consistently since no one has been shown to be more valid than others.

Adolescents can think abstractly and can quantify and qualify phenomena and so can use the same scales as adults. One concern with adolescents is that, when they are ill, they tend to regress and thus may require the use of a simpler scale during such times.⁵⁹

Intubated and sedated children provide more challenges in the assessment of pain. The more disabilities that a child has and the more medications that are being given to the patient creates challenges to the clinician. A 2-year-old child who is blind, with only one extremity that is functioning and on numerous medications, presents a huge assessment challenge to the clinician.

'Pain is what the child says it is' reported McCaffery and Beebe in 1989.⁶⁰ What about the case where the nurse documents a lower number than the child says it is because the nurse believes the child is over-rating the score? During a morning assessment while the 10-year-old patient lays in bed,

the nurse asks him to rate his pain on a scale of 1–10 with 10 being the worst possible pain. The child's response is 10. Are we giving the right message if any number other than 10 is documented? Is pain really what the child says it is? In summary, there are many measurement tools for pain assessment across the life span which can be useful to the researcher and the clinician. Box 64.1 presents a list of clinically useful tools according to patient age.

Symptom assessment and management are very important in burn care. The experience of pain may affect the perceptions of other symptoms, including anxiety, fear or itch. Each symptom should be assessed within the context of other symptoms assessments.

Measurement of anxiety

Anxiety is measured in a variety of ways. In 2000, Robert et al. surveyed 64 burn treatment centers to determine how they evaluated and treated anxiety, especially in children.⁶¹ They

found that most centers did not use standardized measures of anxiety. Based on that survey and other information, the Shriners Burns Hospital in Galveston has begun using the Fear Thermometer adapted by Silverman and Kurtines⁶² from the Walk's Fear Thermometer.⁶³ That instrument is illustrated in Figure 64.3.

Taal and Faber introduced a tool to measure burn specific pain anxiety (BSPAS).⁶⁴ This tool is a 5-item scale used to measure anxiety associated with anticipated procedural pain in adult patients.⁶⁵ Initial reliability, validity, and utility studies have been completed.^{65,66} A similar tool is needed for children.

Measurement of itching

The severe itching of burn scars and wounds has not been discussed much in the literature, but clinicians can testify that this phenomenon is a very serious problem. Patients who experience such itching often excoriate new grafts or recently healed skin, thus enhancing their susceptibility to infections. When the pruritus is severe, patients can focus on nothing else. Until very recently there have not been any tools for measuring itch. Now, Field et al.⁶⁷ reported using a visual analog scale of 1–10 to assess itching. Pat Blakeney and Janet Marvin at the Shriners Burns Hospital in Galveston developed an instrument to measure itch called 'itch man' (Figure 64.4). This instrument was based on a patient's drawing of his experience in the hospital.⁶⁸ Children seem to be able to relate to 'itch man,' but validation studies have not been completed. Matheson et al. used a 5-point descriptive itch rating scale in a study comparing effectiveness of shower and bath oil treatments for severe itch.⁶⁹ Validation of this tool was not done but it seemed easily understood by the staff and patients. Clearly, validation studies need to be completed on itch measurement scales just as they have been completed on pain and anxiety measurement scales.

Treatment considerations

Once the pain has been assessed and quantified, treatment can be considered. Three modalities of treatment are effective with pain secondary to burn injury: surgical, pharmacological, and behavioral treatment.

Fig. 64.3 Fear Thermometer to rate anxiety level. (from: Silverman and Kurtines W. *Anxiety and phobic disorders: a pragmatic approach*. New York: Plenum; 1996 with kind permission of Springer Science and Business Media.⁶²)

Surgical treatment of pain

The pain is predominately related to the open wound. Once the wound is closed, the pain subsides. The use of resection and grafting of open burn wounds significantly reduces the burn pain. Open wounds should be grafted as soon as they are clean enough to do so. Even temporary coverage with cadaver skin or pigskin reduces pain in the area of the burn. In the case of second degree wounds, the use of Biobrane®, OpSite®, Tegaderm® or other wound-covering dressings almost immediately eliminates pain in the burn wound site.^{70–73} Duinslaeger et al.⁷⁴ compared methods of treatment of open donor sites. Cultured allogeneic keratinocyte sheets accelerated healing and thereby reduced pain and suffering compared to OpSite® treatment. The cultured keratinocyte sheets cut healing time in half. Pain assessment as early as day 3 revealed lower pain scores in those sites treated with keratinocyte sheets.

Pharmacological management of pain

Pharmacological management of burn pain is the mainstay of therapy. General rules are helpful in governing the use of pain medication. The first tenet is that if the patient says he/she is having pain, he/she is suffering. The second tenet is that analgesics are most effective when given on a regular scheduled basis (not 'as needed' or PRN). Thirdly, pain medication should not be given as an intramuscular injection since injections themselves cause pain and anxiety, and almost never present an advantage over other routes of administration. Lastly, dose and type of medication should be reevaluated frequently to make sure pain is continuously controlled and that the patient is experiencing no serious side effects. The dosing of medication should be adjusted for the general clinical condition of the patients, considering factors of nutritional state, shock, sepsis, age extremes, and concurrent illnesses such as hepatitis. Review articles^{75–84} during the last 10 years recommend a variety of therapeutic modalities for background and

Fig. 64.4 Itch man scale to rate itching intensity in children designed by Blakeney and Marvin.⁶⁸ © 2000 Shriners Hospitals for Children. (Reprinted with permission of Shriners Hospitals for Children.)

procedural pain during the stages of burn treatment. The three stages are:

- the emergency or resuscitative phase (0–72 hours after injury);
- the acute phase (72 hours to 3 or 5 weeks, until the wounds are closed); and
- the rehabilitative phase (from the time of wound closure to scar maturity), a phase that may last months to years.

Table 64.3 provides a matrix summary of therapies that are recommended for procedural and background pain over the three phases of burn care. A variety of routes or methods of administration are also suggested. The routes or methods recommended include the intravenous bolus (IVB), intravenous continuous infusion (IVCI), patient-controlled analgesia (PCA), and orally administered agents on a time interval rather than pain contingent (non-pain contingent; NPC) basis.

Patterson et al. attempted to examine the question if opioid analgesics PRN (i.e. as needed pain contingent) was better or worse than regularly scheduled opioids for young pediatric patients. The study was inconclusive; he found essentially no difference in pattern of medications administered and pain control.⁸⁵ The results were contaminated by a change in practice by the staff when they realized that the scheduled medication could be safely given. This did not

require the patient to have pain in order to receive the medication.

Many patients also require anxiolytic medication along with the analgesic medication. Therefore, included in this table are the anxiolytic agents which are suggested for use by several authors.

Emergency phase

For pain management therapy, the emergency or resuscitative phase applies only to patients with burns greater than 10% total body surface area (TBSA). During the emergency phase, the preferred route for most medications is the intravenous route because of potential problems with absorption from the intramuscular site and stomach due to decreased perfusion. Of the agents recommended for the relief of procedural pain, morphine is the most widely used. For procedures, IVB and IVCI are the most common methods of administration used. For extremely painful procedures in both the emergency and acute phase, fentanyl has a major advantage in that it is shorter acting and avoids oversedation following a procedure as might occur with repeated doses of morphine.

In addition to opioid analgesics, anesthetic agents such as ketamine and nitrous oxide may be used for procedural pain. These two agents, along with anxiolytic agents to be used as adjuncts to pain management, will be discussed later in this chapter.

TABLE 64.3 PHARMACOLOGICAL THERAPIES FOR BURN PAIN RELIEF EMERGENT PHASE

EMERGENCY PHASE		
Procedural analgesics	Background analgesics	Anxiolytics
Morphine (IVB, IVCI)	Morphine (IVCI, PCA)	Diazepam (IV) (Valium)
Meperidine (IVB)	Meperidine (PCA)	Lorazepam (IV) (Ativan)
Fentanyl (IVB, IVCI)	Methadone (PO, NPC)	Midazolam (IV, IVCI) (Versed)
Hydromorphone (IVB, PO) (Dilaudid)		
Nalbuphine (IVB) (Nubain)		
Ketamine (IV) (Ketalar)		
ACUTE PHASE		
Procedural analgesics	Background analgesics	Anxiolytics
Morphine (IVB, IVCI, PCA)	Morphine (IVCI, PCA)	Diazepam (PO) (Valium)
Roxanol (oral morphine)	Codeine (PO)	
Meperidine (IVB, IM)	Meperidine (IVCI, PCA)	Lorazepam (PO) (Ativan)
Fentanyl (IVB, IM)	Methadone (PO, NPC)	
Hydromorphone (PO) (Dilaudid)	Sustained release morphine (PO, NPC) (MS Contin)	
Nalbuphine (IVB) (Nubain)	Acetaminophen (PO, NPC)	
Ketamine (IV, IM) (Ketalar)	NSAIDs (PO, NPC)	
Oxycodone (PO) (Percocet)	Choline magnesium trisalicylate	
Nitrous oxide (IH)		
REHABILITATIVE PHASE		
For severe pain	For mild to moderate pain	Anxiolytics
Hydromorphone (PO) (Dilaudid)	Oxycodone (PO) (Percocet)	Diazepam (PO) (Valium)
Fentanyl (transmucosal)	Non-steroidal anti-inflammatory drugs (NSAIDs) with or without narcotics (hydrocone)	Lorazepam (PO) (Ativan)
Morphine (IVB, IVCI, PCA)	Usually not necessary: acetaminophen, NSAIDs	

Acute phase

During the acute phase, the choice of pharmacological agents used to manage procedural pain encompasses a number of orally administered opioid analgesics. To control background pain during the acute phase, the use of PCA of NPC medication regimens are far superior to the PRN method. PRN regimens often result in undermedication by one nurse and overmedication by the next nurse. A patient may become angry and confused about what to expect regarding pain control and may feel realistically helpless in an environment where others decide whether relief is necessary. Allowing a patient to medicate himself as needed usually results in better and smoother pain control as well as better staff and patient relationships. For a burned patient with extensive hand burns, the control cord can be fitted with a padded pedal-type apparatus that can be positioned so that the patient can press it with a foot, elbow, etc. Occasionally, patients will use the highest dose allowed in order to withdraw from the entire treatment setting. If this occurs, confrontation and negotiation are important to get the patient back to the task at hand.

As noted above, we have few studies of the pharmacokinetics of opioids and anti-anxiety drugs in burned patients. Martyn,⁸⁶ in a review of pharmacological studies in burned patients, describes a variety of pathophysiological changes accompanying burn injury which can alter drug deposition. These changes include cardiovascular changes, alteration in renal and hepatic function, and fluctuations in plasma protein concentration, which may render pharmacokinetic studies of non-burned patients not applicable to burned patients. Since it is difficult to predict precisely how drug responses will be altered, it is important to monitor responses on drug levels more closely so that dosage can be titrated to the individual patient's needs.

Ventilator patient

Special consideration should be given to managing the pain of a patient on the respirator. In these patients analgesia must also provide relief from significant discomfort due to the endotracheal tube. If the patient is fighting the respirator and needs to be sedated to provide adequate function of the respirator and prevention of ventilator-induced lung injury,⁸⁷ then frequent and high doses of intravenous morphine can be given such as 0.03–0.1 mg/kg every hour or higher in order to ensure pain control with adequate sedation. The use of other forms of sedation without opiates may provide sedation without adequate control of pain. This would lead to being able to assess pain only with blood pressure, pulse rate, and respiratory effort. When muscle relaxants are used to facilitate mechanical ventilation it is necessary to assure that adequate sedation and analgesic medications are continuously administered.

Rehabilitative phase

During the rehabilitative phase, most patients complain more of an aching type of pain, similar to arthritic pain. In this case, mild opioid analgesics, acetaminophen, or non-steroidal anti-inflammatory drugs (NSAIDs) may be used for either procedural (exercise) or background pain. Ibuprofen has been used at 10 mg/kg with some positive effect, but many individuals

have gastrointestinal upset with this type of medication. If a procedure will cause severe pain, fentanyl, morphine, hydro-morphone, or one of the other oral opiates should be used.

Age of patient and pain management

Since the pharmacological management of burn pain not only spans the phases of burn care but also must be tailored to meet the needs of all age groups, it is important to comment on pain management in both the very young and the elderly. There is a tendency to give less medication to young children because 'they don't complain of pain'. This opinion is supported by the fact that some children become very withdrawn rather than screaming when they are receiving painful stimuli (e.g. abused children). It is unlikely that a burn is any less painful in a 3-month-old infant than in a 30-year-old adult; thus, the same therapeutic modalities adjusted for age and size are appropriate for burned children. A major issue of treating pain in young children is the safety risk of using opiates. One example is a 1998 report of the Seattle group concerning respiratory depression in 3 children treated with standard doses per kilogram of opiates given to other age groups.⁸⁸ There has been a similar experience at the Shriners Burns Hospital in Galveston. In all cases the respiratory depression responded well to an opiate antagonist such as naloxone. Young children may have an increased sensitivity to the respiratory depressive effects of opiates.⁸⁹

Many times with children it is very difficult to separate out pain complaints from anxiety, post-traumatic stress or even itching. In this case, the first step is to make sure that the pain medication dose and type is appropriate based on the response of most patients, and that it is actually being administered. After ensuring that the pain medication drug and dosage are adequate, then one can begin to examine carefully for the other associated problems that can mimic pain.

At the other extreme of age is the elderly patient. Again, the tendency is to give less medication, either because these patients do not complain as much or because they are thought to be 'more sensitive' to pain medications. A realistic and important concern with the elderly is oversedation. Studies in non-burned elderly people have shown that, with increased age, the efficiency of the clearance mechanism for certain drugs is decreased, and repeated doses may lead to drug accumulation. This would suggest that, when managing pain in an elderly burned patient, it is not that the dose *per se* should be decreased, but that the interval between dosing should be lengthened so as to prevent accumulation and oversedation.

Neuropathic or phantom pain

Some severely burned patients have partial loss of digits or limbs associated with their burns. This adds a different dimension to the management of their pain since these individuals often have sensations of the existence of these digits or limbs for many years after their loss. This type of pain usually does not respond to traditional pain management with non-steroidal acetaminophen or opioid analgesics. This pain is usually neuropathic in nature, and often does respond to the use of tricyclics or anticonvulsants. Doses of imipramine or amitriptyline of 1 mg/kg body weight often are effective. In a recent study, Thomas et al. reviewed 29 patients who had amputations for either burn or electrical injury.⁹⁰ Phantom

limb pain was more common in those with electrical injury than following flame injury. Of the 33% who experienced phantom limb pain, all but one patient's pain responded to amitriptyline. If the pain does not respond to this, then carbamazepine might be utilized in doses which are therapeutic for seizures. Recently gabapentin has been used for neuropathic pain with good effect.⁹¹ Over time, this neuropathic pain seems to become more tolerable and slowly dissipates.

Pharmacological agents used in management of pain

The preceding discussion has focused on the reviews and reports of 'how we do it' or the 'bias' of healthcare professionals in treating burn pain. The following focuses on specific pharmacological modalities in burn pain management.

Lidocaine and related agents

Pedersen et al.⁹² reported the use of EMLA cream, a prilocaine and lidocaine mixture, to burn wounds in a double-blind randomized manner for 8 hours to reduce pain but it did not reduce late hyperalgesia. Beausang et al. in 1999 recommended adding bupivacaine to the epinephrine solution used in preparing the burn wound eschar site and the grafting site.⁹³ Their clinical impression was a reduction of pain. In a similar open-label study of 14 teenage patients, a long-acting local anesthetic (bupivacaine up to 1.9 mg/kg) was infiltrated into their donor sites to reduce pain.⁹⁴ Bupivacaine plasma levels were monitored and found to peak around 8 hours later and stay in a very safe range. Bussolin et al. used a 0.05–0.1% lidocaine with 1:1000000 epinephrine solution as a tumescent local anesthesia up to a maximum dose of lidocaine of 7 mg/kg to infiltrate into the operative area of both the burn excision and the donor sites.⁹⁵ The postoperative pain was essentially non-existent when compared to pain in historic controls who required opiates and/or ketamine to control their pain.

Sympathetic nerve blocks with the same medication are effective for blocking thermal pain.⁹⁶ Cuignet et al. showed with a double-blind design that fascia iliaca compartment block with ropivacaine was very effective in reducing pain at thigh donor sites for burn grafting.⁹⁷ Other similar medications such as lidocaine (1 mg/kg) given intravenously has been reported to cause significant relief of pain for up to 3 days.⁹⁸ Similarly, Cassuto and Tarnow used intravenous lidocaine for generalized pain control without oversedation.⁹⁹ Seizures have been reported following the use of this class of medication even when given topically.¹⁰⁰

One additional issue concerning procedures is the amount of pain created from removing a dressing over the burned area. These removals are usually facilitated by soaking the dressings off but the soaks are sometimes painful. Special dressings such as lipidocolloid dressing¹⁰¹ and moist exposed burn ointment dressing¹⁰² are being developed to reduce that pain.

Opioid analgesics

Of these agents, morphine has continued to be the mainstay for both background and procedural pain management. Long-term use of morphine has several inherent problems. Morphine

binds to more than one receptor class. Morphine use is associated with side effects (respiratory depression and constipation) that limit its use. An additional problem is the rapid development of tolerance to morphine and poor pain control that is seen in a small group of burn patients. Tolerance to morphine is associated with activation of central glutamate pathways (NMDA receptors) and hyperalgesia. Changing to other opiates, such as methadone, or other compounds, such as ketamine, which block the NMDA receptor pathways improves the management of pain no longer controlled with morphine.^{103,104,179} In fact each opiate binds a slightly different pattern of receptors, and therefore it is often useful to rotate opiates in the long-term patient to keep control over the pain.

Other opiates such as hydromorphone (Dilaudid), levorphanol (Levo-Dromoran), fentanyl, and methadone are all excellent oral agents for the relief of moderate to severe pain when given in equianalgesic doses to morphine. Fentanyl comes in a convenient flavored oralet, especially attractive for use with children. The period of peak hydromorphone effect varies widely from 45 to 90 minutes; the combination of lorazepam given 1 hour alone or with hydromorphone given 45–60 minutes before a procedure results in reasonable pain control for the majority of adult patients. As with other opioid analgesics, tolerance may develop rapidly, so the dose of hydromorphone may need to be adjusted frequently. Methadone has a longer half-life than morphine and therefore can provide coverage for a longer time between doses. Also methadone has been noted to give smoother pain relief for children postoperatively than morphine.¹⁰⁵ Methadone is different from morphine both pharmacokinetically and pharmacodynamically. In addition to opioid receptor interaction, methadone also possesses NMDA receptor antagonism activity as well as amine uptake inhibition (similar to imipramine). Methadone has been reported to be effective in patients tolerant to and poorly controlled by morphine. In addition, methadone is a fraction of the cost of most other opioid analgesics.¹⁰⁶ Perry and Inturrisi¹⁰⁷ reported that the pharmacokinetics of morphine in patients with burn injuries were not significantly altered in comparison to non-burned individuals. They found that the $t_{1/2a}$ (apparent distribution half-life in minutes) was 4.3 ± 3.4 (SD) in burned patients vs. $t_{1/2a} 1.7 \pm 1.2$ in normal subjects and that the $t_{1/2b}$ (apparent elimination half-life in minutes) was 98.8 ± 20.8 (SD) in burned patients vs. 176.8 ± 70.3 in normal subjects. Likewise, the apparent central volume of distribution, clearance, hepatic extraction, and plasma binding were similar for burned patients and normals. Osgood and Syzfelbein¹⁰⁸ described a group of acutely burned children in whom the distribution and elimination half-lives of morphine were markedly shortened [$t_{1/2a} = 1.2 \pm 0.39$ (SEM) for burned children vs. 2.2 ± 0.49 minutes in normals; $t_{1/2b} = 36.9 \pm 6.40$ for burned children vs. 126 ± 38.18 minutes in normals ($p < 0.05$)].

Bloedow et al.¹⁰⁹ reported on the pharmacokinetics of meperidine in 11 acute patients (1 week post-injury) and in 5 convalescent patients with burn injuries (about 6 weeks postburn). The meperidine steady-state distribution volume (L/kg) during both the acute and convalescent phases was about half the distribution volume reported in the literature for meperidine in healthy subjects. The meperidine clearance in burned patients (acute 420 mL/min and convalescent 600 mL/min) was slower than would be anticipated in the

presence of known marked increases in hepatic blood flow in burned patients.

Pain associated with dressing change is very important to manage well. In a randomized double-blind placebo-controlled study of 26 adults, Finn et al. concluded that intranasal fentanyl was as effective and safe as oral morphine.¹¹⁰ Also Prakash et al. recently reported using PCA with fentanyl as an effective alternative.¹¹¹

From the published literature concerning the use of opioids in patients with burn injury, one would have difficulty making decisions about the best drug, the best dosage range, or the best route or method (i.e. PCA, PRN, or continuous infusion) of administration of these drugs.^{107–114} Morphine or other opioid analgesics are considered mainstays of pain relief for burned patients, but many reviewers report less than adequate pain relief for burned patients with the use of such agents. The line between enough opioid analgesics to provide pain relief and too much causing respiratory depression is difficult to find. Also experience of the authors has shown that even a PCA regimen must be individualized and frequently adjusted. Important caveats for the use of PCA should include:

- an initial bolus in adults of 0.1 mg/kg of morphine or equivalent dose of other drugs;
- increasing the patient-controlled dose as needed to achieve pain relief (recognizing that tolerance develops at varying rates in individual patients);
- planning for a change in dosing regimens at night to include: (a) giving a bolus dose at bedtime; (b) doubling the patient-controlled dose and lengthening the time interval between doses so that when a patient awakens in pain, he or she does not have to lie awake to push a button several times in order to get adequate medication; and (c) if the increased intermittent dosing is not adequate, being lenient with bolus doses or to start a patient on a continuous morphine drip at night.

The role of synthetic opioid analgesics such as fentanyl deserves special notice. It is becoming more popular since transmucosal fentanyl citrate is now available in a flavored oralet. Fentanyl has desirable pharmacokinetic properties because it acts rapidly, has short duration, and involves no histamine release. It can cause some emesis, however, even with the fentanyl lozenges.¹¹⁵ In non-burned patients the pharmacokinetic data show great variability, especially with the parent compound fentanyl.¹¹⁶ Thus, further pharmacokinetic studies, in non-burned as well as burned patients, need to be completed in order to better understand the efficacy and safety of this class of drugs. In 1998, Sharar et al. did a double-blind study comparing their use at a fentanyl dose of 10 µg/kg with the more classic oral hydromorphone (60 µg/kg).¹¹⁷ They found in a double-blind crossover design study that the fentanyl oralets provided safe and effective control of pain. In fact, the pain scores were improved before wound care and anxiolysis was improved during wound care; at other times, the two treatments were identical. Robert et al. confirmed these findings with a study of 8 children and similar design.¹¹⁸ Later, Sharar's group compared oral transmucosal fentanyl citrate with oral oxycodone and again found the oral transmucosal fentanyl superior.¹¹⁹

α₂ Adrenergic agonists

Recent years have witnessed a dramatic increase in the use of α₂ adrenergic agonists (clonidine and dexmedetomidine) for their sedative, anxiolytic, analgesic, and sympatholytic properties. Noradrenergic pathways within the locus ceruleus of the brainstem help regulate vigilance, wakefulness, and sleep. The locus ceruleus contains one of the highest densities of α₂ adrenergic receptors in the body. Administration of α₂ adrenergic agonists produces decreased brainstem norepinephrine turnover, resulting in increased activity of inhibitory (GABA) neurons, which mediates the sedative and anxiolytic effect of these drugs.^{120,121} α₂ Adrenergic agonists are potent anxiolytics and have been used effectively to treat post-traumatic stress syndrome.¹²² Clonidine is also used in controlling attention deficit disorder.¹²³

α₂ Adrenergic agonists can produce profound analgesia through central mechanisms.¹²⁴ Clonidine and dexmedetomidine have both been found to reduce anesthetic and postoperative analgesic requirements.^{120,121} Dexmedetomidine has been found effective as the sole analgesic in ventilated postoperative patients.^{125,126} Orally administered dexmedetomidine (2.5 µg/kg given 20–30 minutes pre-procedure) produced suitable sedation and allowed placement of peripheral venous catheters in pediatric patients with neurobehavioral problems.¹²⁷ Clonidine is useful in pain and anxiety management, either alone or in conjunction with opioids.^{128–130} It has the advantage of not causing pruritus or respiratory depression. Much data exist concerning its use in adults and children in the preoperative and postoperative setting.^{131–133} Dexmedetomidine has been used to facilitate withdrawal of opioids in critically ill patients.¹³⁴ When administered in higher doses, dexmedetomidine has been used by itself as a general anesthetic.¹³⁵

These drugs are distinguished by several unique features. Profound sedation is possible with minimal effects on respiration.¹³⁵ Patients sedated with dexmedetomidine can often be aroused. The α₂ adrenergic agonists are not controlled substances and there are no reports of substance abuse with clonidine or dexmedetomidine. Use in the ICU has not been associated with withdrawal symptoms even when dexmedetomidine was infused for up to 168 hours at 0.21–0.49 µg/kg/h.

A combination of ketamine and an α₂ adrenergic agonist is particularly effective for procedures. The analgesic effect of ketamine is enhanced by the α₂ adrenergic agonist, allowing lower ketamine doses while at the same time increased heart rate and blood pressure produced by ketamine are moderated.¹³⁷ Clonidine has also been found to reduce emergence problems associated with ketamine sedation.¹³⁸

In most burn patients a combination of morphine and a benzodiazepine (e.g. lorazepam) is effective in providing sedation and analgesia in patients with acute burns. Occasionally, burn patients are poorly controlled with morphine despite geometric increases in doses. In these cases rapidly developing tolerance and a hyperalgesic state make pain management difficult. Clonidine or dexmedetomidine have been found effective in such clinical situations and provided suitable sedation and dramatic reductions in morphine dose.^{139,140}

In our institution pediatric burn patients poorly controlled with morphine and lorazepam have been found to respond to

orally administered (nasogastric tube) clonidine in doses of 2–5 µg/kg (unpublished observations). When more profound sedation of intubated patients is required we have used continuous infusion of dexmedetomidine 0.3–0.7 µg/kg/h after a loading dose of 1 µg/kg intravenously over several minutes.

Non-steroidal anti-inflammatory drugs

Two reports^{141,142} were found concerning the use of NSAIDs in burned patients. Neither of these studies reported on the use of NSAIDs for pain management, but one study by Wallace et al.¹⁴¹ reported a significant reduction in body temperature (0.67°C ($p < 0.01$)) and a decrease in metabolic rate (11.4%; $p < 0.01$) with the administration of ibuprofen, suggesting that this drug may attenuate the metabolic response to thermal injury by blunting the temperature elevation associated with burn injuries. The second study of the pharmacokinetics of ibuprofen when given enterally to burned patients reports the half-life to vary from 1.4 to 5.1 hours, depending on whether the drug was given by enteral tube with tube feeding ($t_m = 1$ hour) or orally with a regular diet ($t_m = 5.1$ hours).¹⁴³ Although ibuprofen was not given for pain control in either study, the results might lead one to ask, concerning the first study, was the decrease in metabolic rate solely related to a decrease in body temperature or was some of the effect a result of better pain control? The second study is important if one is going to use ibuprofen as part of pain management regimen. The results would suggest that different dosing schedules might be necessary if a patient is receiving tube feedings or a regular diet. Non-steroidals, such as ibuprofen, have, in addition to analgesic effects, anti-inflammatory activity, which, in some instances, may be advantageous due to the ability to inhibit prostaglandin biosynthesis. This activity is, however, directly associated with some of the side effects of these drugs which include gastrointestinal bleeding, hypertension, and congestive heart failure. There is disagreement between providers concerning the risk of bleeding from grafts.

Acetaminophen

Because of the significant side-effect profile of non-steroidal and anti-inflammatory drugs such as ibuprofen, acetaminophen has been considered for the management of chronic pain. In 1991, Bradley et al. reported that acetaminophen at a dose of 10–15 mg per kg of body weight given every 4 hours (up to a maximum of 4000 mg/day) was equal in efficacy to ibuprofen at a dose of 10 mg/kg of body weight given every 4 hours (up to a maximum of 2400 mg/day).¹⁴³ In addition, acetaminophen is well tolerated and causes almost no side effects, most particularly gastrointestinal side effects as with ibuprofen. There is some concern about long-term liver problems with this medication when used in high doses such that blood levels reach 50 µg/mL.¹⁴⁴

Meyer et al.,¹⁴⁵ at the Shriners Burns Hospital in Galveston, reported an analysis of 395 consecutive acutely burned pediatric patients who were treated in 1993 and 1994 with a pain management protocol that utilized acetaminophen scheduled at 15 mg/kg every 4 hours as background management with morphine added for breakthrough pain and procedures such as tubbing. The best response was with the younger children

and the smaller burns. Acetaminophen can be easily monitored in the blood, and in the authors' experience, 15 mg/kg every 4 hours did not cause blood levels to exceed 10 µg/mL except in very young children or extremely ill children receiving multiple types of other medications that are metabolized by the liver. One should be aware that, because acetaminophen is packaged in conjunction with hydrocodone in the form of Vicodin® and Loratab®, one should be careful *not* to give acetaminophen in addition to either one of these combination medications.

Medications for anxiety

As mentioned above, anxiety medication should be considered *only* after the patient's pain has been aggressively treated. The medical staff can inappropriately attribute the patient's complaint to anxiety ('just anxious' is a frequently used phrase) when, in fact, the patient is really experiencing pain. The three main antianxiety drugs used in the treatment of burn-related anxiety are lorazepam, diazepam, and midazolam.

Martyn et al.¹⁴⁶ studied the pharmacokinetics of lorazepam in burned patients. After a single dose, there was a rapid decline in concentration due to the high lipid solubility and rapid tissue uptake, leading to a shorter hypnotic effect of the drug. The study compared burned patients to controls matched for age and weight. Interestingly, the elimination half-life was significantly prolonged for burned patients (72 hours vs. 36 hours for control subjects). Therefore, burn patients often need higher than expected doses. Thus, with repeated administration, the tissue could become saturated and then the termination of the effect would depend more on biotransformation by hepatic enzymes. Hepatic enzyme activity has been shown to be quite depressed in patients with burn injuries. Patterson et al.¹⁴⁷ reported that, in a double-blind placebo-controlled study of 79 patients, 1 mg lorazepam did significantly reduce procedural pain ratings in those patients with high baseline pain, but did not reduce baseline trait anxiety.

Based on Martyn's work, we would conclude that lorazepam would be superior to diazepam in treating anxiety in burned patients.¹⁴⁶ Martyn suggests that, in addition to the fact that the clearance of lorazepam is faster than diazepam in burned patients, two other features of lorazepam make it a more acceptable drug for burned patients. First, it is metabolized by conjugation (a cytochrome P450-independent pathway) to a pharmacologically inactive glucuronide metabolite; and, secondly, the unbound volume of distribution is much less than for diazepam that causes clinically effective blood concentrations to persist for many hours, resulting in longer-lasting sedation. Additionally, unlike diazepam, lorazepam is not affected by the concomitant administration of cimetidine. In a recent survey of the use of antianxiety drugs in burned children, 72% received lorazepam at a dose of 0.03–0.05 mg/kg or higher every 4 hours for much of their initial hospitalization.⁸⁴ Lorazepam provided aid in anxiety control with essentially no side effects. Fewer than 1% of the children had hallucinations or delirium associated with rapid changes in dose. The occasional child responds with increased agitation or delirium rather than sedation, an occurrence we have also noticed infrequently.¹⁴⁸

Although the pharmacokinetics of midazolam have not been reported in burned patients, it has characteristics in

non-burned patients that would seem to make it an attractive anxiolytic agent for procedures used to clean burn wounds for those with thermal injury. Midazolam has a more rapid onset than either diazepam or lorazepam; thus, it allows for more rapid titration for effect in an individual patient. The elimination half-life of 2.5 hours is considerably shorter than that of lorazepam (13 hours) or diazepam (36 hours) and should result in a shorter recovery time after a procedure.¹⁴⁹ It is better tolerated when given intravenously. The oral dose is very high and expensive. The anesthetic effect of midazolam is greater than diazepam.^{150,151} Elderly patients have a more consistent response to a given dose.¹⁵² Of the three benzodiazepines reviewed, either lorazepam or midazolam would seem to be more appropriate than diazepam for repeated use in burn care. However, in our experience, we have found diazepam to be very useful in providing background anxiety control when muscle relaxation is desired (for example, to facilitate rehabilitative exercise) in addition to attenuating anxiety. Because of its long half-life, it is ideal for treating the patient during the rehabilitative period when the healing burn wound is very uncomfortable and seems to inhibit doing any activities, including sleep.

Anesthetic agents used in analgesic doses for procedural pain

Nitrous oxide

Nitrous oxide analgesia is now being used in pediatric surgery as an effective alternative to other forms of sedation.¹⁵³ To make it safer, a preset mixture of nitrous oxide and oxygen (Nitonox®) has been developed and shown to be effective in a variety of painful procedures.¹⁵⁴ Filkin et al.¹⁵⁵ reported results from both a retrospective study and a prospective study on the use of 50% nitrous oxide and 50% oxygen for debridement pain. In the retrospective study, the charts of 52 adult male patients, mean TBSA 19% (range 2–85%), were reviewed for the number of treatments, the effectiveness of pain relief, and the frequency of side effects. Only one patient reported no pain relief and requested to discontinue the use of the nitrous oxide. Side effects noted were dizziness, giddiness, increased verbalizations, euphoria, dream-like state, nausea, and non-specific tremors, but they were clinically significant in only two patients. In the prospective double-blind study, all patients were given a standard dose of morphine (0.2 mg/kg) pre-procedure and then randomized to receive either a 50% nitrous oxide–50% oxygen mixture or compressed air for a given study treatment. The study was aborted when 80% of the planned 30 patients requested to withdraw from the study because they did not feel that they were getting consistent pain relief on study days, preferring to use nitrous oxide for all treatments.

A retrospective study by Marvin,¹⁵⁶ in which charts from 130 patients (65 who received nitrous oxide and 65 patients matched for % TBSA burned who did not) were reviewed, found excellent patient acceptance and few side effects. In the study by Marvin, the frequency of specific side effects related to peripheral neuropathy, changes in liver function, and anemia were noted; no patient in either group showed changes in liver function tests while receiving the nitrous oxide mixture. None

of these disorders were similar to the polyneuropathies previously reported in relation to chronic nitrous oxide exposure.^{157–160} Hayden et al.¹⁶⁰ reported one case of progressive myeloneuropathy in burns related to the use of nitrous oxide. The PRN use reported for this patient varies from the once- or twice-daily use reported by Basket,^{161,162} Filkin,¹⁵⁵ and Marvin.¹⁵⁶ It would seem from the report that the patient consumed vastly larger doses. This may well explain the neurological problems seen in this case, which were similar to those described with chronic abuse of nitrous oxide.^{157–160}

The major drawback to the use of nitrous oxide has been its possible toxicity to the staff administering the medication. Adequate gas scavenging equipment should be available to reduce trace gas exposure to caregivers. This is particularly important for pregnant caregivers, since in animals it has been documented to cause spontaneous abortion.^{163,164}

Ketamine

Ketamine is used often with children to manage their pain, particularly for protracted wound debridement. Ketamine also blocks the NMDA receptor which mediates the hyperalgesia associated with morphine tolerance. Therefore it is effective in morphine-tolerant patients. The route of administration has been usually oral, IV or IM. In general it is best to avoid IM injections in treating a child since that causes initial pain. Recently Heinrich et al. has suggested rectal administration in conjunction with midazolam.¹⁶⁵ In adults and adolescent males, ketamine causes considerable dysphoria with unpleasant hallucinations and flashbacks even after complete recovery. However, it is very safe because it preserves airway reflexes. In children, these side effects occur much less often. Simultaneous administration of benzodiazepines seems to reduce these side effects.

Slogoff et al.¹⁶⁶ reported their clinical experience with the use of subanesthetic doses of ketamine for 150 debridement and dressing change procedures in 40 burned patients. Fourteen patients had only one exposure and the remainder had 2–13 exposures. The initial dose was 1.6 mg/kg of ketamine given intravenously. The results showed that patients with one or two exposures had coherent conversation or no vocalization 60% of the time; screaming or vocalization unrelated to stimulation occurred 34% of the time; and vocalizations in response to stimulation, 5%. In the group that received two or more exposures, coherent vocalizations dropped to 40%, while screaming or vocalization unrelated to stimulation increased to 49%; and vocalizations related to stimulation increased to 11%. Involuntary movement was rare in either group: 7% in <2 exposures and 8% in >2 exposures. One patient developed upper airway obstruction, which responded to manipulation of the mandible, and one patient experienced unpleasant emergence reactions after each of four procedures but did not refuse further treatment with ketamine. Significant findings in this study were:

- all patients who had more than two procedures required higher doses ($p < 0.001$);
- the duration of analgesia per dose, min/mg/kg, was less with subsequent doses ($p < 0.001$); and
- the time to complete orientation was less with subsequent doses ($p < 0.01$).

With the increase in dosage after the second exposure, the actual time of analgesia remained constant at about 15 minutes. All patients had complete amnesia for all procedures.

Martinez et al.¹⁶⁷ described a dream state of burned patients treated with ketamine for dressing changes. Twelve of 15 subjects stated that they experienced dreams while under the effects of ketamine. Eight of the 12 described their dreams as pleasant. Subjects were also asked to rate their ketamine experience according to a list of descriptions: seven chose 'frightening', eleven chose 'floating', two chose 'beautiful', eight chose 'helpless', two chose 'powerful', and eleven chose 'confusing'.

Several protocols for the use of ketamine in burned patients have been published.¹⁶⁸⁻¹⁷⁰ Some use nurse-administered intramuscular ketamine 2–3 mg/kg body weight for dressing changes under the order and immediate supervision of a physician.¹⁶⁸ Others use ketamine as an anesthetic, not an analgesic agent.¹⁶⁹ The doses used were 1–2 mg/kg body weight, intravenously, or 8–10 mg/kg body weight given intramuscularly. The procedures required administration by an anesthesiologist. Some use low-dose (1–3 mg/kg body weight) of ketamine administered rectally or orally to produce short periods of analgesia (5–30 minutes) for dressing changes. Repeated use may produce tolerance, so increased doses are required over time. The side effects of ketamine include the production of copious upper airway secretions (necessitating the use of drying agents: atropine or glycopyrrolate), hypertension, pulmonary and systemic arterial hypertension, tachycardia, and postoperative emergency reactions. Ketamine is contraindicated for patients with systemic or pulmonary arterial hypertension, myocardial infarction, ventricular failure, history of cerebral injuries, or psychiatric disorders. Ketamine can produce hallucinations post administration, particularly in adolescent boys. Simultaneous administration of benzodiazepines are thought to reduce this side effect.

More recently, Dimick et al.¹⁷¹ reported on the use of anesthesia-assisted procedures in burned patients. They reported on 109 procedures in 46 patients for staple removal from grafts (34 procedures), massive dressing changes or vigorous debridement (74 procedures), or facial moulage (one procedure). Within 2 hours after the procedure, 72% of patients were able to cooperate fully; and within 4 hours, all were able to cooperate fully. They concluded that anesthesia-assisted procedures in a burn intensive care unit could be performed safely with appropriate professional care and monitoring.

Propofol (Diprivan®)

Propofol is a non-barbiturate hypnotic agent without analgesic activity.¹⁷² It is administered intravenously and is most commonly used as a general anesthesia induction agent. Since it lacks analgesic activity, propofol must be given in doses large enough to cause loss of consciousness to prevent response to painful procedures. It has also been given by continuous infusion in combination with analgesics such as opiates or ketamine. Coimbra et al. reported its use as an adjunct to morphine in a patient-controlled sedation protocol for dressing changes.¹⁷³ They used bispectral index monitoring to follow the patients and found it to provide a safe level of sedation/unconsciousness. It is particularly useful for sedation

and pain control during procedures such as line placement or staple removal. Its onset of action is extremely rapid even with a dose as low as 1.5 mg/kg intravenously.^{174,175} Having non-anesthesiologists administer propofol is not considered a safe practice in some institutions because it depresses blood pressure, respiratory effort, and decreases airway tone and reflexes. Propofol is considered highly effective for procedural sedation. Its use is still approved in the operating room for anesthesia and it is widely used in the ICU for ordinary procedures when proper precautions for airway management are assured.¹⁷⁶

Advantages include a rapid onset of action and a rapid emergence with little cumulative effect after prolonged infusion periods.^{177,178} In addition, there are no reports of drug dependence associated with propofol and, because its abuse liability is low, propofol is not a controlled substance.

Disadvantages include pain on injection. Along with loss of consciousness, propofol causes loss of pharyngeal motor tone which often causes airway occlusion.¹⁷⁹ Propofol also causes depressed respiratory drive, loss of airway reflexes, and hypotension. These changes increase the risk of respiratory complications. As a result, propofol sedation in non-intubated patients should be used only when practitioners skilled at airway management are available. Due to its low aqueous solubility propofol is formulated in a lipid emulsion. At room temperature this lipid emulsion is an ideal growth medium for bacteria. Endotoxic shock and wound infection have been reported in patients after administration of propofol left at room temperature for prolonged periods of time.^{180,181}

Use over 5 days is associated with renal toxicity. This serious complication is referred to as propofol infusion syndrome (including severe metabolic acidosis, rhabdomyolysis, cardiac and renal failure) and has been reported usually after prolonged infusion of high doses in children.¹⁸² There have also been reports of similar problems after shorter periods of infusion and in adults.¹⁸³ As a result of these observations, propofol infusion in the ICU is usually limited to shorter periods (24–48 hours) in older patients. In the pediatric ICU environment, infusions of propofol are limited to 6–12 hour periods.^{174,176} Propofol infusion has been effective during short periods (overnight) as a bridge during the weaning process from other sedatives needed during mechanical ventilation of pediatric burn patients.⁸⁷

Itch medications

Itch is one of the most common sequelae of burn injury. Field et al. reported that pruritus occurs in 87% of patients who have a burn injury.¹⁸⁴ Although it is thought to be secondary to the injury of the skin, the possibility that morphine is adding to the itch needs to be kept in mind. Itch can definitely influence the quality of life and duration of rehabilitation required. Scratching further injures the skin, leading to graft loss and skin breakdown that sometimes requires further grafting. In addition, it is very common for the patient to have a significant problem exercising or sleeping if the itching is intense. Several classes of medications can be used to treat itch. The approaches to treatment are as varied as the presumed causes of the itching.¹⁸⁵ Pruritus associated with burns is poorly understood, so blocking histamine, kinins, proteases, prostaglandins, substance P and 5-HT release and receptors

have all been tried. The first line of defense is a series of moisturizing body shampoos and lotions to alleviate itching due to dry scaly skin. Then, failing that, Preparation H, which contains a caine has been advocated. Topical steroids are not usually used because of the infection risk, until the skin is well healed. They are effective in controlling the itching. Only a small area of skin should be treated with steroids in order to reduce the risk of systemic adrenal suppression. Antihistamine creams such as Benadryl® (diphenylhydramine) cream are available. Other topical medications include colloid and oatmeal baths.¹⁸⁶ Newer topicals are tricyclic antidepressants such as doxipin.^{187,188} The major side effect of this preparation is that too much is absorbed, with resultant oversedation. Recently, gabapentin (10–35 mg/kg/day in divided doses) has been found in a pilot study to help with itching produced by burns.¹⁸⁹ Typical individual: dose is 5 mg/kg during the day and 10 mg/kg for bedtime.

Several non-medication approaches have been used. Massage seems to have a very beneficial effect.¹⁸⁴ In addition, Hettrick et al. reported that transcutaneous electrical nerve stimulations (TENS) considerably reduced the perception of itching in 9 adult patients compared to controls.¹⁹⁰ The most recent method involves the use of laser to reduce pruritus in burn scars.¹⁹¹

Usually the antihistamines are given orally. Using only one antihistamine results in complete relief for only 10% of the patients.¹⁹² Diphenhydramine PO 1.25 mg/kg q 6h is often the first oral medicine used because of its sedative effect as well as helping control the itch. A few children respond better to loratadine, which is much longer lasting. If itch is not well controlled using only one, then another class of antihistamines can be added such as hydroxyzine PO 0.5/kg q 6h. Lastly, if the itch is still not well controlled, an antiseritonic agent, such as cyproheptadine 0.1 mg/kg q 6h, can be added, scheduled so that one of the medications is given every 2 hours. This is targeted against the 5-HT₃ receptors. Care must be made to not use the cyproheptadine with patients who are on serotonergic antidepressants.

Development of protocols for comfort

Interest in pain management of burned patients has been a high priority in the treatment of burns only in the last 10–15 years. Several institutions have developed pain and anxiety management protocols. In 1995, the Journal of Burn Care and Rehabilitation published a special issue devoted to then current practices of systematic treatment of burn pain. In the first edition of this book in 1996, we reported the initial use of a burn pain protocol used at the Shriners Burns Hospital in Galveston.¹⁹³ In 1997 the Boston group, headed by Tompkins, published a 3-year history with a similar protocol.⁷⁵ They incorporated a distinction in treating ventilated acute patients differently from non-ventilated acute patients. Most recently a national consensus on pain management has been reached. Ulmer¹⁹⁴ brought these to the attention of the burn community in a 1998 article. The protocol currently used in the Shriners Burns Hospital in Galveston is being reviewed and updated every few years.⁸⁴ The most recent version is in Box 64.2 and includes management of the most common discomforts of burned patients. It is extremely important to keep trying to improve these protocols as more is learned about the treatment of pain of burn injury.

BOX 64.2 Shriners Burns Hospital (Galveston) comfort protocol for children

BACKGROUND PAIN

Note: Begin bowel prep program simultaneously with beginning opioids

Pre-tub

First choice

PO midazolam 0.3 mg/kg and PO acetaminophen 15 mg/kg

If inadequate,

add PO morphine sulfate solution 0.3–0.6 mg/kg (if >15 kg) or fentanyl lollipop 10 µg/kg

If NPO,

IV midazolam 0.03 mg/kg and IV morphine 0.05–0.1 mg/kg (if >15 kg)

PRE-REHAB THERAPY

On request of therapist,

PO morphine sulfate solution 0.1–0.3 mg/kg or IV morphine 0.02–0.05 mg/kg

If child is very anxious add 0.1 mg/kg diazepam or 0.03–0.05 mg/kg lorazepam

POSTOPERATIVE PAIN

Option A

IV morphine infusion via PCA pump (if >5 years), total dose 10–20 mg/kg/4h

Option B

Attendant-administered bolus, slow IV push morphine 0.03–0.05 mg/kg q 2h (hold if level of responsiveness is decreased)

BACKGROUND PAIN FOR OUTPATIENT

Oral acetaminophen 15 mg/kg q 4h

If inadequate,

add oral morphine solution 0.1–0.3 mg/kg q 4h or MS Contin 0.5 mg/kg PO q 8–12 h

ANXIETY

Lorazepam PO 0.05 mg/kg q 4–6 h

or if muscle relaxation is also desired, diazepam 0.1 mg/kg q 8hr

Note: taper benzodiazepines slowly by reducing dose by 50% every 2 days

ACUTE STRESS DISORDER OR POST-TRAUMATIC STRESS DISORDER SYMPTOMS²²⁹

Imipramine 1 mg/kg and increase slowly to 3 mg/kg as needed or fluoxetine 5 mg if under 6 years of age; for older person begin with 5 mg and increase slowly to 20 mg as needed

ITCH

Use skin moistening shampoos and lotions, topical ointments (not hydrocortisone creams)

Begin with diphenhydramine PO 1.25 mg/kg q 6h; if itch not well controlled, add hydroxyzine PO 0.5/kg q 6h; if itch still not well controlled, add cyproheptadine 0.1 mg/kg q 6h so that one of the medications is given every 2 hours

Non-pharmacological therapies in burned patients

As has been discussed, there is a strong interaction between psychological and physiological factors contributing to the pain experience. Anxiety in particular is prevalent among patients with burn injuries and is known to exacerbate acute pain. Non-pharmacological therapies play an important role in addressing the psychological factors that exacerbate pain as well as having a direct impact on the pain itself.¹⁹⁵

In understanding how non-pharmacological approaches can be used with burn pain, it is important to discuss how behavioral principles contribute to the patient's experience.¹⁹⁶ In terms of classical (stimulus–response) conditioning, patients (particularly children) often will develop a conditioned anxiety response to stimuli associated with painful burn procedures. One study demonstrated that the simple event of a healthcare worker wearing scrubs was enough to elicit a fearful response in burn children.¹⁹⁷ In terms of operant (reinforcement) conditioning, patients can be thought to gain reinforcement by avoiding or escaping painful procedures, perhaps by screaming enough to terminate treatment or to obtain some sort of reinforcement from the staff by showing pain behaviors. Between the stimulus that precedes pain and the pain response that follows, there is the cognitive processing of pain. Such cognitions can be modified as can behavior and influence how much pain a patient experiences. Classical and operant conditioning principles, and modifying internal cognitions, have bearing on how non-pharmacological approaches are applied to burn pain. A series of articles by Thurber and Martin-Herz and colleagues^{198,199} provides an extensive discussion of the theory and application of such principles of pain from pediatric wound care.

Classical conditioning

If the stimuli associated with a painful procedure can be conditioned to evoke anxiety or pain, then a logical goal is to reduce the impact that pre-tubbing stimuli have on the fear/pain response. An obvious environmental intervention is to make the wound care procedure setting as minimally threatening as possible. For children this might involve making the hydrotherapy tank a 'bath tub play area' with age-appropriate floating toys, etc. Our understanding is that some clever children's hospital staffs have turned their MRI scan into a 'cave in a jungle'; obviously such a setting will be less threatening to a child than will be the typical location of such radiological procedures. Similar principles can certainly be applied to burn care.^{198,199}

There are other implications of classical conditioning. The best way to prevent a conditioned pain response is to optimize pain control in the first place. By aggressively and proactively treating pain, the contributions of conditioned anxiety will be minimized. Conversely, once a patient undergoes a procedure with inadequate analgesia, concomitant anxiety can be extremely difficult to treat.

Psychological preparation plays an important role in minimizing anticipatory anxiety. Patients can be provided with procedural or sensory preparatory information.²⁰⁰ With procedural-based preparatory information, patients are explained the mechanics of their procedure (e.g. 'we will unwrap your bandages, wash your wounds and debride necrotic skin, apply

silver sulfadiazine cream and then rewrap your dressings'). With sensory information, patients are prepared as to what they might feel during a procedure ('You will likely feel a pulling sensation as we remove your dressings and a stinging sensation when we wash your wounds with an antiseptic'). Such information is usually helpful to patients, but we should stress that some patients prefer to have as little information as possible, given their particular coping styles.¹⁹⁶

Another approach based on classical conditioning is relaxation training. Patients can be taught deep relaxation and imagery prior to undergoing painful procedures. The rationale is to counteract the anxiety stimulated by pre-procedural stimuli with the relaxation response. If anticipatory anxiety is minimized with deep relaxation, the potential for a cyclical interaction between anxiety and acute pain is reduced. A number of studies have applied relaxation training and stress inoculation techniques, as well as some of the behavioral techniques discussed below to reduce burn pain.^{201–204}

Operant conditioning

The consequences that patients receive for showing pain can have implications for pain control. Since almost all burn procedures are extremely aversive, it will be the natural tendency of patients, particularly children, to be motivated to escape such events. Staff members who allow patients to terminate procedures might be reinforcing, and potentially exacerbating, such escape behaviors. When left unchecked this process can lead to a distressed patient becoming combative rather than tolerating procedures. While such avoidance behavior should (more importantly) alert the staff that analgesia is inadequate, and the many potential pharmacological protocols discussed above should be invoked, it can also occasionally suggest a need for further limit setting. Rewarding a patient with rest once a stage of wound care is completed rather than based on pain behavior can be a useful means to minimize such escalating behavior. Again, however, the goal of a burn team should be to provide enough preparation and analgesia in a pre-emptive fashion that the need for such escape behaviors do not develop in the first place.

Operant conditioning also has implications for the manner in which patients receive pain medication. When patients are medicated in response to pain behaviors they are potentially receiving social reinforcement in terms of attention from the staff as well as the euphoric effects that the drugs might cause. This is one reason that, as mentioned earlier, it is far preferable that patients are medicated at regular time intervals rather than in response to their pain; the latter encourages them to complain more often in order to get the reward.²⁰⁵ A similar application of operant principles is particularly important for the patient who excessively complains about pain out of emotional dependency needs, attention seeking, or in seeking euphorogenic properties of the pain medications. In such patients, provided that adequate levels of pharmacological analgesia have indeed been established, it may be important to extinguish pain behavior, ignoring pain behavior, and simultaneously engaging the patient in distraction unrelated to pain. This is a model more consistent with that used for chronic pain, but one that is occasionally useful for patients with burns that seem to overact independent of how aggressive pain is managed.²⁰⁶

A final application of operant principles has to do with token economies for children. It can be extremely useful to reward children for successful completion of procedures by using star charts or reinforcement schedules of this nature. Thus, a child, upon completing a procedure, may receive a star in a grid that covers a week of burn care. Older children can use an accumulation of points to purchase a desired reward. It is important that children are rewarded for completing procedures rather than for 'being brave' as the latter can serve as a subtle form of punishment to children; in other words, reinforcement should not be withheld if children act out and have a bad day during wound care, as long as wound care is completed.^{198,199}

A particularly useful application of operant principles is to increase therapy activity in patients that are overwhelmed by therapies or appear to have poor motivation. The quota system uses operant principles to reward activity with rest. Patients complete predetermined quotas of activity that are within their capacity, and then are allowed to rest. A baseline determines what is within their capacity. For example, a patient who is trying to walk with burned legs might be instructed to walk until tired for three therapy sessions. The distance walked is recorded for those three sessions, the average is taken, and 80% of that average becomes the starting point. For example, the patient walks 50, 150 and 100 feet during three sessions: 80% of that 100 foot average is 80 feet; 80 feet becomes the starting point. Patients start at 80 feet and increase that amount by 5% (about 5 feet) each session. If they fail to meet a quota, they return to the last successful one. However, they also quit when they reach a program. They do not keep exercising even when they are having a 'good day.' This addresses the problem of pacing and overfatigue. Ehde and Patterson have reported the successful use of the quota with a number of patients with burn injury, both in terms of increasing therapy performance and reducing depression.²⁰⁷

Cognitive interventions

How patients think about their pain can be regarded as a behavior that can be modified and, in turn, can influence the degree of suffering they experience. As such, an important non-pharmacological approach is to draw out the thoughts patients have about their pain and teach them to modify accordingly. A particularly salient example is catastrophizing about pain. Catastrophizing thoughts include those such as 'I cannot stand this pain,' 'I will never get better,' or 'The pain means I will die.' Such catastrophizing thoughts have been associated with greater amounts of pain and less-favorable health outcomes in a variety of studies. Patients can be taught to challenge and reinterpret such thoughts. Along the same lines, it can be useful to teach patients to reinterpret the meaning of their pain sensations. For example, the appearance of skin buds and enhanced pain sensation may indicate that a wound is healing and skin grafts may not be necessary.¹⁹⁶

Under the rubric of cognitive interventions patients may be taught techniques to enhance their ability to cope with pain. Positive self-talk and imagery designed to facilitate coping during periods of pain are examples of this. Thurber and colleagues have described the Two-Process Model of Control as it relates to controlling pediatric burn pain.¹⁹⁹ In terms of

primary control, the patient attempts to modify the objective conditions of the painful procedure, such as negotiating how and when a dressing change will take place. In secondary control, the patient makes adjustments so that he or she can better tolerate the difficult procedures (e.g. positive self-talk, catastrophizing). Thurber et al.¹⁹⁹ and Martin-Herz et al.¹⁹⁸ have published a two-part series on a conceptualization of psychological approaches to burn pain, as well as specific examples for treatment.

Another example of enhancing coping is to give the patient more control during painful procedures. Kavanaugh et al. have described how giving children more control during procedures can reduce the effects of learned helplessness and enhance pain tolerance.²⁰⁸ They reported that children who were provided with the opportunity to participate in and make decisions about their wound care showed lower depression, anxiety, hostility, and stress scores than did controls. Such findings fit well into the paradigm described by Thurber et al.¹⁹⁹

Distraction is another cognitively based approach to pain control. Processing pain requires a certain amount of conscious attention and distracting such patients' attention can enable patients to tolerate pain better. Movies, music therapy, and games have all been used with some success as distraction techniques for burn pain.^{209,210} Music has the additional benefit of inducing a relaxation response. More recently, Hoffman and colleagues have reported on the use of immersive virtual reality (VR) as a powerful analgesic.²¹⁰⁻²¹² Virtual reality can immerse patients' attention in a computer-generated world, and engage them in interaction with that world. These investigators indicate that VR can significantly reduce pain during wound care and physical therapy,^{211,212} even relative to computer game distraction.²¹³

Hypnosis

Hypnosis involves a blend of relaxation, imagery, and cognitive-based approach. The technique deserves special attention because there are a number of reports on its use with burn pain and, when it is effective, its impact on burn pain can be quite dramatic. There are over a hundred anecdotal reports in the literature that indicate that hypnosis can dramatically reduce pain and at least a dozen have been done with pain from burn injuries; such studies however lack control groups, standard measures of pain or information about pain medications.²¹⁴ More recently, tightly controlled studies with reliable measures of pain have supported hypnosis as an effective non-pharmacological approach to burn pain.^{215,216} Patterson and Jensen have reported 12 controlled studies on chronic pain and 17 with acute pain indicating pain reduction; indeed, this modality is becoming far more scientifically acceptable.²¹⁷ Patients with burn injuries are ideal candidates for hypnosis for a number of reasons. In a review of such factors, Patterson et al. listed motivation, regression, dissociation, and hypnotizability as factors that promote hypnotic analgesia on the burn unit.²¹³ Specifically, patients who are faced with the excruciating nature of burn pain are motivated to engage in techniques such as hypnosis. The nature of a burn and its resulting care can cause a patient to become emotionally regressed (i.e. more dependent on the burn staff) and dissociated (i.e. removed from their emotions), and both of these factors seem to be

associated with hypnotizability. Such factors likely account for the frequent dramatic effects that are seen with hypnosis and burn care. On the other hand, hypnosis clearly will not benefit some burn patients, and the degree to which patients are inherently hypnotizable (or not hypnotizable) almost certainly has some bearing on this issue.²¹⁸

Ewin^{219,220} has strongly argued for providing hypnosis within 2–4 hours after a patient sustains a burn injury. He maintains that this approach can serve to impede the progression of the burn as well as facilitate pain control. Unfortunately it is difficult to have a clinician available during this stage of burn care, and Ewin's findings have yet to be tested in other settings. The protocol used by Patterson and colleagues^{216–221} is to provide hypnosis prior to wound care and have nurses provide standard post-hypnotic suggestions during wound care. This approach is efficient for both the hypnotist and the nurses. Patterson et al. have recommended that hypnosis used in this fashion be an adjunct to, rather than replacement for, pain medication.²¹⁶ More recently, investigators have combined immersive virtual reality with hypnosis in order to control burn pain. This approach has the advantage of not requiring a trained hypnotist to be present and appears to work as well as 'live hypnosis.'^{222,223}

Other approaches

There is some evidence that TENS can be effective with burn pain,²²⁴ but we are aware of only one study of this nature. Massage therapy has been reported to be useful in reducing burn pain.²²⁵ We are unaware of any studies on the efficacy of acupuncture on burn pain, although this modality has been useful with pain from a variety of different etiologies. The acute nature and variable distribution of burn pain, may make acupuncture a challenging modality to apply to this problem.

For patients in the post-hospital, long-term rehabilitation phase, non-pharmacological approaches from physical and occupational therapists become critical. Stretching, strengthening, increasing activity, and hot/cold therapy may all become instrumental in enhancing pain control during the rehabilitative stage.

Summary

The state of the art in burn pain management would seem to be based more on personal bias and tradition than on a systematic, scientific approach. In addition, the number of pharmacokinetic studies of pain-relieving drugs of any kind in young children is virtually nil. Since approximately 35% of all burn injuries occur in children under 16 years, with a great majority of these occurring in children under 2 years, we have almost no information on which to base the use of pain-relieving drugs in burned children. It is no wonder that Perry and Heidrick²²⁶ found great disparity in what burn care staff would order or administer to a young child as compared to an adult with burns of similar size and area of distribution on the body. More pharmacokinetic studies in both adults and children with burn injuries must be initiated.

Similar to the lack of conclusive data about the use of the various opioids or anxiolytic agents, is the scarcity of scientific data to recommend any of the non-pharmacological

techniques. However, significant progress has been made just since the last edition of this book 5 years ago. Most burn centers recognize anxiety as contributing to patient discomfort and are beginning to treat both anxiety and pain. Standardized protocols such as the guidelines (see Box 64.2) for starting doses of medication from the Shriners Burn Hospital in Galveston are being put forth.⁸⁴ Non-pharmacological techniques are more frequently included in a center's repertoire of tools for managing anxiety, recognized as a definite adjunct to pharmacotherapy. The major problem currently with these techniques is that they are personnel intensive and therefore are often not offered or reimbursed in the current managed care environment in the USA.

How, then, can we provide the 'best' pain management for a burned patient? Probably the first answer to that question is vigilance in assessment and flexibility in treatment. Patients show great individual variation in their responses to the variety of agents and modalities presented. A successful approach with a burned patient requires that healthcare personnel understand the pain associated with the different depths of wounds, the phase of the healing process, and the components of the pain response. For the burned patient during the initial 3–7 days, the more superficial areas give rise to moderate or severe pain, while the full-thickness areas contribute less to the overall pain response.² Although moderate to severe pain is usually related to procedures or physical therapy, background pain (or pain at rest) is usually described as mild, or very mild, but may be exacerbated by emotional concerns and anxiety. By the second week post-burn, the moderately deep partial-thickness burn with its multitude of skin buds accounts for the majority of the moderate to severe pain. In many burn centers, deep dermal and full-thickness burns are excised and grafted between the 3rd and 10th days postburn. Although this often eliminates the severe pain associated with wound debridement during the 2nd and 3rd week, donor sites are often as painful as the areas of more superficial burns were initially. Dressing changes 3–5 days post-grafting also may be accompanied by the removal of sutures or staples which is usually described by patients as an excruciatingly painful procedure. By the 3rd or 4th week, if the wounds are not mostly healed, anxiety and depression may cause a patient to perceive increased levels of pain. And, within a single phase of recovery and within a single patient, pain frequency and intensity will vary from day to day. A fixed and inflexible approach to treatment is likely to overmedicate on one day and undermedicate the next.

To avoid over- and undermedication in adults, regimens which allow patients to control their own therapy seem most appropriate. This is very important for adults and teenagers, but children also can benefit from having this control. PCA can be used safely by many children and should not be disregarded as a tool on the basis of age alone. For procedural pain, patient-controlled regimens may include self-administered nitrous oxide, PCA, hypnosis, a variety of behavioral approaches, or a combination of these approaches. For background pain, the best control seems to be the use of slow-release opioids or other pain cocktails given on a non-pain contingent basis (i.e. scheduled every 4–6 hours) with the flexibility to supplement this with PRN or 'as desired'

medication. Another approach would be to use PCA with or without a continuous low-dose infusion of narcotics. A variety of non-pharmacological therapies may also help relieve background pain. The most important aspect to remember with all of these regimens, as mentioned before, is flexibility. The other obvious aspect is to remember that a patient is not only the best person to assess his pain but also the best to evaluate the success of the therapies provided.

As challenging as managing comfort is for the healthcare provider, it is equally important to the burned patients. Recent studies suggest both physiological and psychological reasons to successfully manage pain. Kavanagh et al.²²⁸ demonstrated that pain in a burned patient adds significantly to the physiological demands caused by stress. Schreiber and Galai-Gat²²⁹ as well as Ptacek et al.¹⁹ have shown that successful pain management can significantly reduce the occurrence of psychological disorders such as post-traumatic stress syndrome.

Burn care professionals who desire to keep their patients as comfortable as possible can perhaps best prepare themselves by learning to:

- watch and listen to their patients with vigilance;
- use a standardized assessment tool for measuring discomfort on a scheduled basis as well as during moments when the patient is complaining, either verbally or behaviorally, pre- and post-administration of treatment;
- know how discomforts are likely to change as the patient recovers;
- include a variety of pharmacological and non-pharmacological methods for managing discomforts and be prepared to change as the patients' needs change;
- feel comfortable with a process that never ends, but which can bring many moments of relief for the patient and satisfaction for the caregivers.

Psychiatric problems beyond acute hospitalization.	823
Summary.	825

Introduction

The knowledge and skills of a psychiatrist are often needed in the pharmacological management of psychiatric symptoms which commonly occur in conjunction with burn injuries.¹ Psychiatric expertise is also an asset to a burn team in addressing multitudes of psychological issues concomitant to burn injuries. Although a psychiatrist is usually sought as a consultant, a psychiatrist is most helpful to patients and to burn teams as an integrated member of the medical staff.

Preexisting psychiatric disorders and symptoms are relatively common in the histories of burned patients, and frequently appear to have contributed significantly to the etiology of the injury itself.²⁻⁷ Substance abuse,⁸ organic brain dysfunction, attention deficit hyperactivity disorder,⁹ conduct disorder, and personality disorders have been reported as frequently occurring premorbid conditions. One study found alcohol use disorder in 11% of hospitalized burn patients with almost all of those injuries considered preventable.¹⁰ Patients intoxicated at the time of burn injury also suffer a higher rate of complications in their treatment.¹¹ Those abusing flammable inhalants are at particular risk for burn injury.¹²⁻¹⁴ A small, but important, number of patients are admitted with serious burn injuries resulting from purposeful self-immolation.¹⁵⁻¹⁸ In one study of 67 patients with self-inflicted burns, 75% had a prior psychiatric illness and 20% had a previous suicide attempt.¹⁹ A separate study of 11 patients with self-inflicted burns reported that 10 had a prior psychiatric illness with 2 attempting suicide and 2 motivated by hallucinations.²⁰ Of patients with self-inflicted burns, those attempting suicide are more likely to have larger burns and longer hospitalizations than those with the intent of self-mutilation.²¹ As described by Stoddard and Cahners¹⁷ and by Raskind,²² burn patients with suicidal intent present emotional, as well as physical, challenges to a treatment team. A suspected suicide attempt will almost invariably elicit requests for psychiatric involvement in management and treatment of a patient. Less dramatic indicators

of premorbid psychiatric disorders are also identifiable early in a patient's admission and signal the need for psychiatric consultation. Burn patients with a history of any premorbid psychiatric disorders are more likely to have preventable injuries,²³ require longer hospitalization,^{24,25} and have problems with adjustment early in their recovery.^{26,27} The risk of psychiatric complications following burn injury is greater in those patients with a previous history of affective, alcohol or substance use disorders.²⁸ It is therefore important to screen for any preexisting psychiatric disturbance in burn patients.

In addition to premorbid psychiatric illness, other psychological factors have been found to be associated with an increased risk for psychiatric symptoms following burn injury. Taal and Faber²⁹ reported that dissociation and anxiety experienced during the burn injury predicted later psychopathology. Tedstone and colleagues³⁰ found that certain coping styles were predictive of later psychological difficulties. Patients with coping patterns of helplessness, emotion focused, problem focused, focusing on the positive and seeking social support were all at increased risk for subsequent emotional distress. A coping style of acceptance appears to be a protective factor against later anxiety and post-traumatic distress symptoms. In a separate study, avoidant coping or symptoms of anxiety or depression following burn injury were predictive of psychological problems 3 months later, but burn severity was not.³¹ While it is understandable to expect patients with major burns to be at risk, even minor burns can result in significant psychological distress and psychiatric symptoms.³² At the present time, there is no profile that can reliably predict which patients will suffer psychiatric symptoms following burn injury. All patients should be carefully assessed as part of their care.

This chapter will focus on the psychiatric treatment of common mental disturbances that can be expected to occur as part of a symptom complex experienced by any patient who is suffering a serious burn injury. Although preexisting psychopathology alters the expression of a patient's distress and complicates medical management of the patient, the common symptoms described in this chapter are not necessarily indicative of premorbid psychopathology. These symptoms can be very distressing to patient, family, and staff if not well managed by both psychological and pharmacological interventions. The most commonly occurring psychiatric symptoms discussed in this chapter are delirium, organic psychoses, burn encephalopathy, post-traumatic symptoms, sleep disturbances, pain, and depression, which occur during the critical care phase of burn treatment. Psychiatric problems are often noted as part

of the long-term process of recovery from burn injury, i.e. phobias and other anxiety disorders, acute stress disorder (ASD), post-traumatic stress disorder (PTSD), major depression, and dysthymia.

Common psychiatric symptoms

Critical care phase

Delirium, organic psychoses, and burn encephalopathy

Organic factors and premorbid conditions contribute to symptoms during the initial part of treatment. Disorientation, confusion, sleep disturbance, transient psychosis, and delirium are commonly observed among adolescent and adult patients.^{3,33–36} Causes of these symptoms are usually unclear and multifactorial. Hypertension, hypoglycemia, electrolyte imbalance, sepsis, and/or a variety of organic problems can contribute to delirium. The unusual physical surroundings of an intensive care unit heighten the probability of psychoses. The altered state of consciousness may be transitory, wax and wane over several days, or, with large burns, persist for weeks. The picture may be confused further by a suspected occurrence of anoxia. Delirium has been found to occur more often in males who have a history of substance abuse and with burn injuries over 30% TBSA.³⁴ A past history of substance abuse is often suspected as contributing to delirium, particularly with adolescent and adult patients. Inhalant abuse or intoxication at the time of a fire are factors to be considered. Another potential cause of disorientation, hallucinations and agitation may be medications used in the treatment of the acute burn patient. Morton and colleagues³⁷ reported severe psychotic symptoms in a patient following treatment with anabolic steroids. Hallucinations can also be a side effect of anesthesia, especially with ketamine.

In an altered state of consciousness, patients may misinterpret their surroundings, resulting in potentially frightening illusions of reality. Patients may misperceive lines and hoses as snakes. A patient may shout about the fire or the accident, describe symbols of death, monsters, or the devil. A patient may misidentify the people in the room, seeing instead absent friends or dead people, or may identify a treatment team as prison guards. The content of the illusions or hallucinations may be so bizarre and morbid as to suggest a schizophrenia, a brief reactive psychosis, or a psychotic depression (e.g. dead bodies, dead people, or angels). Sometimes patients are so frightened by these visions that they try to escape or become combative. Such psychotic symptoms are understandably frightening to the family of the patient and disconcerting to even experienced staff. Hallucinations are uncommon in children, but when they do occur, the most likely cause is stress, followed by pain and medications.³⁸ Sepsis and metabolic conditions can also result in hallucinations, and are a more frequent cause of this than psychiatric disorder in young burn patients.

In our experience, symptoms of delirium and transient psychosis occur rarely among children under the age of 10 years;³⁶ however, burn encephalopathy, as characterized by lethargy, withdrawal, or coma, is a condition observed in children as well as adults.^{39,40} EEGs in such cases typically reveal diffuse, non-specific slow waves.^{39,41} Causative factors probably are the

same as those for delirium.⁴² Although Andreasen et al.⁴³ report long-term neurological impairment following burn delirium in adults, other studies (and our own experience) do not find residual neurological effects following delirium or encephalopathy.^{33–36,39,40} These symptoms, though apparently short-lived, are upsetting to a patient's family and treatment team when they do occur. Proper treatment must first address organic causes of delirium and/or encephalopathy. Vital signs must be stabilized and blood chemistries and glucose normalized. Also, oxygenation should be checked and sepsis investigated and treated. Pain must be addressed. Then psychotropic medications may be administered.

The use of antipsychotic phenothiazines in an acute burn unit is a common approach to address delirium and/or combative, uncooperative behavior such as pulling off dressings, attempting to get out of bed, or striking out at caretakers.^{44–47} Pharmacological control is preferable to physical restraints, which tend to exacerbate a patient's distress and worsen the symptoms.¹ Haloperidol (Haldol®) is the phenothiazine of choice for adult patients, as it does not have significant cholinergic side effects. The initial dose is 1 or 2 mg of haloperidol, but doses as high as 5 or 10 mg may be administered. Since phenothiazines do not cause respiratory depression, they may be repeated hourly until symptoms begin to come under control. Usually, phenothiazines are administered in two or three doses per day. Pediatric burn patients appear to have a much higher rate of adverse reactions to haloperidol and alternative management of agitation should be considered. In a clinical review of 26 pediatric burn survivors that received haloperidol during acute treatment, 23% had serious side effects.⁴⁸

Chlorpromazine (Thorazine®) and thioridazine (Mellaril®) may be used in place of haloperidol in the dosage range of 25–100 mg per dose. Chlorpromazine and thioridazine have strong sedative effects and interfere with learning, but are less likely than haloperidol to produce associated dystonia, pseudo-parkinsonism, and akathisia. If more than 2 mg of haloperidol per day are used, attention must be given to simultaneous administration of 1 or 2 mg/day of benzotropine (Cogentin®) or 2–5 mg/day of trihexyphenidyl (Artane®) in divided doses. Benzotropine or trihexyphenidyl are used to avoid dystonia, pseudo-parkinsonism, and akathisia.⁴⁵ Occasionally, dystonia takes the form of an oculogyric crisis, which resembles an acute neurological catastrophe⁴⁹ and can be a true medical emergency if respiration is impaired. These reactions are usually alleviated by 50 mg IV diphenhydramine (Benadryl®).

There are two severe side effects for which the patient on phenothiazine must be monitored: neuroleptic malignant syndrome⁵⁰ and tardive dyskinesia.⁴⁵ Neuroleptic malignant syndrome is a potentially life-threatening crisis characterized by fever, muscle rigidity, mental status changes, and autonomic dysfunction. Neuroleptics should be discontinued, and symptoms must be treated aggressively with supportive therapy, as well as benzodiazepines, dantrolene, bromocriptine and anticholinergics. The long-term side effect of greatest concern for patients who receive phenothiazine is tardive dyskinesia. This reaction can be permanent and is characterized by abnormal, involuntary, irregular choreiform and athetoid movements. Usually, a patient is unaware of the writhing and twisting

movements that most often involve the tongue, but can also involve the limbs and the trunk as well. The reaction typically occurs only in individuals who have received phenothiazines for extended periods of time, i.e. longer than 6 months. The risk of occurrence is 2–4% per year over the first 7 years in which phenothiazines are taken. Although it is a very unusual complication in individuals who receive phenothiazines for short periods of time, it has been reported.

Due to the problems which have been associated with phenothiazines, benzodiazepines have been used to a greater extent in recent years for the combative, delirious patient.^{45,51,52} The two most commonly used benzodiazepines are diazepam (Valium®) and lorazepam (Ativan®). Lorazepam (0.03 mg/kg) orally or intravenously, can usually be given every 4–8 hours; for a very combative patient it can be given hourly. A third benzodiazepine which is frequently used is midazolam (Versed®) at 0.05 mg/kg IV, typically used in conjunction with morphine for procedures such as tubbing and staple removal. Midazolam (Versed) is also used for sedation as a continuous infusion for intubated patients. When using the benzodiazepine class of medications, a clinician must balance the desired effects of relaxation with oversedation. Visual and auditory hallucinations may occur if the dose of benzodiazepine is too high. In those cases, it should be reduced or replaced by another type of medication. In cases of excessive anxiety in the presence of adequate pain control, lorazepam can be added to a patient's treatment. Nighttime doses usually enhance sleep. Diazepam in doses of 2–10 mg per dose, depending on the size of an individual, may be used in place of lorazepam if simultaneous muscle relaxation is desired.⁵³ Diazepam has an extremely long half-life, 40 hours, and therefore should be used sparingly (see Chapter 54). To avoid excessive sedation by benzodiazepines, a patient should not be awakened for the next dose.

Acute stress and post-traumatic stress disorder symptoms

A significant number of burn survivors will experience post-traumatic stress disorder symptoms, including intrusive memories of the injury, during their acute recovery.^{54,55} If anxiety is associated with other symptoms of post-traumatic stress, such as hypervigilance or poor sleep, an antidepressant such as a selective serotonin re-uptake inhibitor (SSRI) like fluoxetine (Prozac®)⁵⁶ or a tricyclic antidepressant (TCA) like imipramine (Tofranil®)^{36,57} should be considered. The SSRIs have the advantage of being safer drugs for outpatient treatment since an overdose is unlikely to cause significant cardiac problems as have been attributed to the TCAs.⁵⁸ The usual starting dose of fluoxetine (Prozac) is 10–20 mg for adults, 5 mg for children <40 kg and 10 mg for children between 40 and 60 kg. Typically, the SSRIs are given in the morning rather than the evening as they may interfere with sleep onset. Side effects of SSRIs include gastrointestinal upset, increased agitation, headaches, and sweating. They have, however, fewer instances of anticholinergic side effects such as constipation. A rare but potentially life-threatening side effect is serotonin syndrome,⁵⁹ characterized by at least three of the following symptoms: delirium, agitation, sweating, fever, hyperreflexia, myoclonus, tremor, incoordination, diarrhea and shivering. Severe cases can result in hyperpyrexia, shock or death. The risk of sero-

tonin syndrome increases when patients are on multiple medications that potentiate central nervous system serotonin, such as an SSRI and a monoamine oxidase inhibitor. There is a reported case of serotonin syndrome in a pediatric burn patient who was receiving fluoxetine (Prozac) and linezolid (Zyvox®), a broad-spectrum antibiotic with monoamine oxidase inhibition.⁶⁰

The usual starting dose of imipramine (Tofranil) is 25 mg/day unless the patient weighs less than 25 kg. The beginning dose is 12.5 mg for those under 25 kg. The dose can be increased rapidly over the next few days to a dose of 1 mg/kg. If the symptoms are still uncontrolled, the dose may be increased stepwise to 3 mg/kg, but only with frequent checking of the plasma level and EKG changes with each increment of dose. A steady state is usually not reached until a given dose is maintained for 3–5 days. A dose can be divided and given twice a day, but such division is usually unnecessary. The preferable time of administration is in the evening to aid with sleep. Major side effects of the TCAs are anticholinergic effects (dry mouth and dry nasal passages, constipation, urinary hesitance, and occasional esophageal reflux).⁴⁵ Autonomic complications such as orthostatic hypotension, palpitations, and hypertension have been reported in adolescents with this medication.⁴⁴ Cardiac arrhythmias, associated with a prolonged PR interval, can be life-threatening.^{58,61,62} Sudden death has been reported for teenagers and children receiving desipramine and other TCAs.⁶³ Amitriptyline or doxepin may be used in place of imipramine. The dosages are similar; however, both these medications may cause more sedation than imipramine.⁴⁵

Following clinical reports of increased suicidal ideation in pediatric patients treated with certain antidepressant medications and a review of clinical trial data, the US Food and Drug Administration instructed all manufacturers to include a 'black box' warning with all antidepressant medications.⁶⁴ Pediatric patients and their caretakers must be aware of these risks and clinicians should closely monitor children and adolescents on these medications for possibly increased suicidal ideation and behavior.⁶⁵

Sleep disturbances

Patients with significant sleep problems are common in an acute burn unit.^{66–68} When sleep disturbance with nightmares is associated with post-traumatic anxiety, as described above, antidepressant medications are the drugs of choice. Imipramine (Tofranil)⁶⁹ and doxepin are both sedating antidepressants that are effective treatments for sleep problems in burn patients. Trazodone and nefazodone are alternative medications for insomnia and do not appear to alter sleep architecture as much as other antidepressants. Mirtazapine (Remeron®) is another antidepressant that has been used for insomnia although little is known about its effects on sleep architecture. Sleep problems may be associated with stimulation from the caretaking staff who awaken a patient while checking vital signs and well-being throughout the night. Sometimes lights and televisions are left on throughout the day and night in a patient's room. These environmental factors can be destructive to a patient's sleep-wake cycle. As soon as physiological conditions allow, a patient should be given as much undisturbed sleep time at night as possible, so as to allow natural

sleep cycles to reestablish, and to maintain a normal circadian rhythm. Pain and itch are other problems that can interfere with sleep and should be addressed with appropriate analgesic or antipruritic medications.⁷⁰ If a patient continues to have significant sleep problems, sleep can be induced with diphenhydramine. Diphenhydramine doses of 1.5 mg/kg are often used throughout the day for itching and may be used alone for sleep at night or as an adjunct to other sleep medications. Usually, doses of 25 or 50 mg in the evening are adequate.

Often, post-traumatic symptoms other than sleep disturbances are not evident. In such cases, chloral hydrate may also be used in doses of 1.5 mg/kg, up to a maximum of 1 g per single dose.⁵² Doses of 250 mg are usually adequate for a child; however, we prefer to use benzodiazepine, imipramine (Tofranil), and/or diphenhydramine for sedation and sleep with pediatric patients because deaths have been reported in children taking chloral hydrate for sedation.⁵² Also, in our experience, chloral hydrate does not alleviate nightmares as does imipramine (Tofranil).

Depression

Fluoxetine (Prozac) and the other SSRIs are the first-line medications for treatment of patients with depressive symptoms.^{58,62} TCAs should also be considered in the treatment of depression if the patient does not respond or cannot tolerate treatment with an SSRI. They should be used as described above by following symptoms and monitoring blood levels. Patients should be monitored for hypomania or mania induced by antidepressant medications. When this occurs, the antidepressant dose should be lowered and lithium therapy or other mood stabilizer medication, such as valproic acid (Depakote®) or carbamazepine (Tegretol®) should be considered. Lithium is usually not used in patients recovering from burns because of its effect on sodium concentration.

Pain

Symptoms of depression and agitation are often related to excessive pain and subside with adequate pain management (see Chapter 59). A patient's experience of pain is related to the extent and depth of injury and influenced by individual responses to analgesia, pain threshold, emotional state, cognitive functioning, cultural beliefs, interpersonal interactions, and expectations.^{42,71-76} The experience of pain has been found to be an important mediating risk factor for PTSD in pediatric burn patients.⁷⁷ Chemical analgesics and anesthetics are as important in managing pain with burns as they are with other medical/surgical conditions. Care must be taken to consider the appropriate doses of medication and the most efficacious schedule of administration. Modifications should be continued until good control is achieved.^{78,79} Around-the-clock or continuous administration of analgesics achieves better pain control than PRN administration.^{80,81} This avoids the period of less than therapeutic levels of the drug with increased discomfort prior to the request for medication and ameliorates a patient's anxiety about whether the medication will be allowed. Postoperatively, patient-controlled analgesia (PCA) pumps are very effective in achieving around-the-clock pain control with minimal undesired side effects for adults and for children.^{82,83} The addition of amitriptyline (Elavil®), a TCA, can be effective in controlling neuropathic or phantom limb pain.

In-hospital recuperation

After the initial postburn period, a patient progresses through a series of operative procedures interspersed with days of physical therapy in order to maintain physical activity and range of motion. Immediate operative sites (those grafted and those which donate) are painful. In addition, exercises are painful. A patient's world is one of pain or concern about possible pain in the near future. It must be remembered that many of the treatments and experience of hospitalization may be as traumatic psychologically as the original burn injury, especially for young children.⁸⁴ The patient's expectations for treatment are also very important. Those patients who have low expectation for further improvement and attach higher importance to outcome are at greater risk for psychological distress during recovery.⁸⁵ The major goal of therapy from the psychiatrist's point of view is to control the pain and maximize a patient's participation in recovery, rehabilitation, and other aspects of care.

In addition to the pharmacological treatment described above, designing a psychological milieu that supports comfort and security is a primary task.³⁶ A specific daily treatment schedule is crucial to achieving these goals. The schedule provides specific times for pain medication to insure coverage at times of expected pain (e.g. tubing and physical therapy), but avoids sedation during family, social, and educational activities. Time should be provided in the schedule for fun and diversionary activities. A pediatric patient must have time scheduled for school and play. Patients must be allowed to have expected 'safe' periods without procedures. Whenever possible, the patient, even a young child, should be included in planning the schedule. The schedule should be posted and followed as closely as possible. In order to motivate a patient to participate at a maximum level in rehabilitation, a reward system can be incorporated with rewards consisting of special treats as designated by the patient, such as extra videos or going out of the hospital.

As a latency age child, adolescent, or adult recovers, he/she often wants to talk about the accident. A patient begins a long process of 'understanding' what has happened. Part of this process is learning to look at a 'new' self, literally and metaphorically. As part of the treatment plan, a regularly scheduled meeting with a psychotherapist is established. This special time for 'talking' therapy may vary in content from play therapy with a child or light banter with an adult to serious confrontation with the most difficult emotionally charged issues. The reliability of this safe time in which a patient can complain about everybody and everything, express anger, express fear and sadness, can be very therapeutic. It is important for a patient to have someone other than family who is accepting, safe, and neutral with whom to talk. Communication with the therapist and others may be difficult if the patient is suffering with symptoms of post-traumatic stress disorder or alexithymia, a condition characterized by problems in describing feeling and thoughts.^{86,87} It is also important to take into account the cognitive and emotional development of the patient as it determines the level of ability to use reflection and verbalization in processing what has happened. Younger patients may understandably regress in the face of severe trauma and loss.

A patient's experience in adapting to burn injury can be thought of as a grieving process. A patient has experienced a loss of self. Using a familiar paradigm, we can describe a patient as moving through several stages of adjustment to loss: shock, denial, anger, depression, and finally acceptance.⁸⁸ This formulation is useful in working with a patient about his/her injury. In our experience, shock and denial predominate during the initial hospitalization; anger and depression often last for years as a patient continues in treatment, faces reconstructive surgeries, and confronts a series of social experiences.

Psychiatric problems beyond acute hospitalization

The novice usually expresses a belief that all burned persons need to see a psychiatrist due to the nature of the injury. A number of approaches have been used to determine the incidence of psychiatric difficulties among survivors of major burns. These studies report with surprising consistency that large numbers of survivors do not suffer long-term major psychiatric disorders or psychosocial impairment.^{89,90} Longitudinal studies have found about one-third of burn survivors develop post-traumatic stress disorder within 2 years of their injury.^{91,92} It might be expected that the appearance of the burn scar might influence long-term adjustment, and Fukunishi⁹³ did find cosmetic disfigurement predictive for post-traumatic stress disorder symptoms of avoidance and emotional numbing in women with burn injuries. In contrast, Taal and Farber⁹⁴ found that neither the severity nor the visibility of burn scars influence long-term adjustment, but rather social introversion, which predicted the development of pathological shame.

Our own work has focused on children and adolescents who are at least 1 year postburn and are either outpatients or have returned for further reconstructive surgery. One method we have used has been to survey patients with questionnaires pointed at specific psychiatric symptom complexes. For instance, Koon et al.⁹⁵ surveyed adolescents with the Piers-Harris Children's Self-concept Scale and found that male pediatric burn survivors had significantly higher scores than the normative population. Females described themselves as less popular, although otherwise equal to the norm. Self-esteem did not appear to be related to other burn-related variables (i.e. age at burn or size of burn). With a similar goal of looking for specific symptoms, we hypothesized significant depression and utilized several standardized instruments, including the Suicide Probability Scale (SPS),⁹⁶ to assess depressive symptoms. This study revealed no increase above norm in depression or suicidality, but did reveal significant anger among adolescent burn survivors.

We use a variety of instruments to detect general psychiatric needs among the children that we follow. The Achenbach series of standardized behavioral checklists are useful screening tools.⁹⁷⁻⁹⁹ They offer validity, reliability, and convenience of administration in a setting such as ours where we must assess many clinical variables in a brief period of time. The Child Behavior Checklist (CBCL)⁹⁷ is a 113-item rating of each child's current behavior problems and competencies as perceived by a parent. Complementary to the CBCL are the Teacher Report Form (TRF)⁹⁸ and the Youth Self-Report

(YSR),⁹⁹ which provide assessments of the same behaviors by different observers. Our data from these instruments indicate that about 20–25% of the children and adolescents who survive major thermal injury may develop a variety of significant behavioral problems as indicated, but good adjustment is achieved by the majority of individuals.^{100,101} Blakeney et al.¹⁰² and Zeitlin¹⁰³ reported similar findings of only modest psychological sequelae to pediatric burns in their long-term follow-up study.

Parents usually report more problems than do the children themselves or the teachers.^{100,104} In one study, 60 children with burns (35 boys, 25 girls) were surveyed with the Achenbach instruments at least 1 year after burn injury. The parental perception on the CBCL revealed a statistically significant ($p < 0.05$) increase in problems and decrease in competency for most age groups and both sexes when compared with the normal reference population. In contrast, the TRF and the YSR revealed very few differences from the reference population. Burn size did not account for any of the differences. Item analysis of individual questions revealed excessive endorsement by parents of specific items on all scales compared to their respective reference populations.¹⁰⁵ These results could be explained by increased problems of the children following severe burns that would not be easily observed by persons who do not live with the patient, e.g. nocturnal enuresis or nightmares. Or, perhaps, the parents reporting increased behavioral problems are overly sensitive to any indication of difficulty for their children.

Our investigations have also considered outcomes for the parents of youth burn survivors. The Parental Stress Index (PSI)¹⁰⁶ revealed that parents who reported their children as troubled were themselves more stressed than the normal reference population, not only by their children's behaviors but also in areas unrelated to their children.¹⁰⁷ In addition, on a measure of mood state, the Eight-state Questionnaire (8SQ),¹⁰⁸ mothers who reported troubled children more often felt depressed and guilty than did mothers of well-adjusted children.¹⁰⁷ In a separate study of mothers of children with burns, 52% met criteria for a diagnosis of post-traumatic stress disorder; larger burns were strongly correlated with symptoms in the mother.¹⁰⁹ Fukunishi¹¹⁰ found higher rates of depressive and post-traumatic stress symptoms in the mothers of children with burns than in their offspring. These studies emphasize the need for psychological attention to parents of burned children, as well as to the children themselves.

Using a standardized psychiatric interview for children, Stoddard et al. reported a very high incidence of psychiatric disorders among 30 pediatric burn survivors.^{111,112} In order to make a fair comparison with other populations, these authors compared the burn survivors with a group of survivors of flood trauma and a community sample. Burned children had significantly more phobic disorders, overanxious disorders, enuresis, encopresis, major depression, PTSD, and substance/ethanol abuse than the comparison groups.¹¹² Sleep disorders and psychotic disorders were also slightly more common among the burned children. Even though most burn survivors eventually make good adjustments, they can be expected, at some time during the adjustment process, to suffer psychiatric sequelae which might be attenuated by psychiatric treatment.

Phobias and other anxiety disorders

Many patients continue beyond acute hospitalization to have periods during which they appear extremely anxious and express fear. These periods often recur in association with return to a hospital for reconstructive surgeries. Some are so anxious that they are constantly soliciting their families or others for comfort. Generalized anxiety disorder or overanxious disorder of childhood is characterized in the Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) by the following criteria:

- excessive worry occurring more days than not for at least 6 months about a number of events;
- difficulty in controlling the anxiety;
- the anxiety causes clinically significant distress or impairment in social, occupation, or other important areas of functioning;
- anxiety and worry associated with three or more (only one for children) of the following symptoms (with some symptoms present for more days than not for the past 6 months): restlessness, feeling on edge, easily fatigued, difficulty concentrating or mind going blank, irritability, muscle tension, sleep disturbances.

In a burned patient, difficulty controlling anxiety which is so distressful that it interferes with important functioning, restlessness, and difficulty in concentrating are diagnostic of anxiety disorders since some other symptoms can be related to burn injuries specifically, e.g. being easily fatigued.

Not infrequently, anxiety spills over to other situations and/or becomes focused on specific objects; thus, phobias develop that are characterized by excessive persistent fear in response to specific stimuli. Although adults may express anxiety through 'panic' symptoms such as sweating, palpitations, trembling, or nausea, children may express anxiety by crying, tantrums, freezing, or clinging. A differential diagnosis of these anxiety disorders distinct from PTSD is difficult and requires a careful interview. Burned patients suffering from post-traumatic stress often see the fire or aspects of their accidents whenever they close their eyes; they dream about their traumas. An overanxious patient is afraid of what might happen; the PTSD patient fears what has happened. Most burn patients, certainly those who qualify for the diagnosis of generalized or overanxious disorder, benefit from lorazepam therapy in addition to supportive psychotherapy.

Acute stress disorder and post-traumatic stress disorder

Acute stress disorder and PTSD are the most common psychiatric disorders seen in survivors of major burns.¹¹³ The two disorders are very similar, differing only in how long the symptoms persist. Acute stress disorder symptoms appear immediately following the trauma, last for at least 2 days and resolve within 4 weeks after the trauma. If symptoms persist or appear more than 4 weeks after the trauma, then the appropriate diagnosis is PTSD. These disorders are characterized in the DSM-IV by the following criteria:

- The person has experienced, witnessed, or was confronted with an event which involved actual or

threatened death or serious injury to self or others, and the person's response involved intense fear, helplessness, or horror.

- The traumatic event is persistently re-experienced. Recurrent and intrusive thoughts of the event occur. Burned patients often complain of seeing the fire whenever they close their eyes or when they try to go to sleep. Young children may relive the event over and over again in repetitive play. Nightmares about the event are common; in young children, frightening dreams occur without recognizable content. Feeling as if the event were recurring (e.g. flashback) is reported often. Intense reactivity, psychological and/or physiological, occurs at exposure to internal or external cues that trigger associations with the traumatic incident, e.g. seeing a fire on television.
- There is continued avoidance of stimuli associated with the trauma or numbing of general responsiveness. Persons suffering from PTSD develop flat affect, memory problems, and withdrawal from others. Children's behavior may be regressed; children may lose recently acquired developmental skills such as toilet training or language skills.
- Persistent symptoms of increased arousal, which were not present before the trauma, may develop. These symptoms include sleep disturbance, irritability/anger, difficulty concentrating, hypervigilance, exaggerated startle response, and panic attacks. Patients have periods of feeling afraid and not knowing why.

Nightmares and altered sleep patterns are usually the symptoms first noted. Although one study found no correlation between psychiatric diagnosis emerging during acute hospitalization and later development of post-traumatic disorder,¹¹⁴ the presence of avoidant post-traumatic disorder symptoms during the acute phase of recovery is reported to predict chronic post-traumatic disorder in burn patients.^{91,115-118} In a study of pediatric burn patients, a high resting heart rate, lowered body image, and parental stress symptoms were found to be significant risk factors in development of ASD.¹¹⁹ Many of the other symptoms are described when a more complete history is taken. Patients should be given ample opportunity to explore their feelings and fears about the traumatic event. This process may persist for months. In addition, medications such as the SSRIs and TCAs are helpful in reducing the nightmares and improving the sleep pattern. A study comparing the treatment of ASD symptoms with either fluoxetine (Prozac) or imipramine (Tofranil) among 128 pediatric burn survivors found them to be equally effective, with about 80% response overall, and that the non-responders to one antidepressant usually responded to the other.⁵⁶ Treatment with an SSRI or TCA should be continued for at least 9 months to 1 year following the improvement of symptoms because of the risk of relapse. When medication is discontinued, it should be reduced over time, for suddenly stopping the medicine might cause uncomfortable discontinuation symptoms, although they are not medically threatening. The relatively long half-life of fluoxetine (Prozac) usually protects patients from any discontinuation symptoms, but requires extended vigilance for any drug-drug interactions.

Major depression and dysthymia

Although depression is a reaction most observers would expect of burned patients, it is a rare long-term sequela of burn injury. According to Stoddard,¹¹⁰ fewer than 50% of the children he surveyed had ever suffered major depression; dysthymia, another depressive disorder, occurred in only 10%. Outcome studies of adult burn survivors show a similar prevalence of major depression.^{33,43,120–123}

To diagnose major depression, a patient must have five or more of the following DSM-IV symptoms *for a period of at least 2 weeks, and they must represent a change from previous functioning*:

- depressed mood most of the day (may be an irritable mood in children and adolescents);
- markedly diminished interest or pleasure in most activities;
- significant change in appetite, resulting in either weight loss or gain (for children, failure to make expected weight gains);
- insomnia or hypersomnia;
- feelings of worthlessness or excessive/inappropriate guilt nearly every day;
- fatigue or loss of energy nearly every day;
- diminished concentration or enhanced indecisiveness nearly every day;
- psychomotor agitation or retardation observable by others;
- recurrent thoughts of death, suicidal ideation, suicide attempt or plan.

This is an extremely difficult diagnosis to make during the acute burn period since many of the criteria are linked to physical symptoms. Even beyond the acute phase, the diagnosis is often complicated by grief following the loss of a loved one during a fire, and by sadness at one's altered body. The critical symptoms in a burned patient are depressed mood and anhedonia. Many times a patient's expressed interest in play or plans for the future rule out the diagnosis.

Major depression, with or without grief reaction, should be treated by a team approach. A patient should be involved in scheduled daily activities. Psychotherapy should begin to identify and address appropriate issues. Medication with SSRIs or TCAs, as described for acute and post-traumatic stress, is often helpful. Once the symptoms have responded to medication,

treatment should continue for 9 months to 1 year in order to avoid relapse on discontinuation. When discontinuing medication, it should be slowly reduced rather than stopped suddenly so as to prevent discontinuation side effects.

A smaller percentage of burned patients will develop a milder but more protracted type of depression called dysthymia. This condition must be present for *at least 2 years in adults*, or 1 year in *children and adolescents in order to be diagnosed*. It is characterized by the following:

- depressed or irritable mood,
- appetite changes, sleep difficulties, fatigue, low self-esteem,
- poor concentration or difficulty making decisions,
- feelings of hopelessness.

The same combination of medication and psychotherapy is recommended for dysthymic patients as for major depression.

Summary

Psychiatric symptoms occur commonly as part of the complex systemic response to burn injuries. Psychological and pharmacological treatment are important in the successful recovery of a burned person, and perhaps mitigate against long-term psychiatric sequelae of post-injury. It is important to note that psychological adaptation is a lengthy process occurring over months or years. During the postburn years, it is imperative that the burn team assess the mental and affective states of patients while assessing their physical recovery. Although most burned patients eventually make satisfactory adjustments, many continue for a long time to struggle with self-image, anger, and sadness. These disturbances often seem to be expressed through symptoms that are not easily observed by other than intimate friends and family of a patient.¹²⁴ Sleep disturbance, fear or withdrawal from previous activities are not behavioral disturbances which necessarily insure that a patient will attract psychiatric attention and treatment. They are, however, unhappy responses which can be ameliorated by treatment. It then becomes a responsibility of the expert in burn care and recovery to be aware of frequently occurring disturbed responses, to ask the right questions in order to assess a patient's status, and to assist a patient in receiving psychological and psychiatric assistance.

Manifestations of psychosocial distress	837
Long-term outcome: quality of life	839
Interventions for burn survivors beyond acute care	839
Summary	840

Introduction

Burn treatment extends beyond patient survival to include recovery of optimal function for the whole person. Increased likelihood of physical survival¹ heightens concern for potential psychological morbidity for the burn survivor.^{2–8} Even in emergency circumstances, burn care providers enact treatment plans based on an assumption of future life for the patient. Decisions about treatment are influenced by concerns for preserving function, optimizing cosmetic appearance, and restoring psychological well-being. Psychological and social issues are integral parts of burn treatment from the time of injury through recovery and rehabilitation.

Burn survivors experience a series of traumatic assaults to the body and mind and the fabric of their social network which present extraordinary challenges to psychological resilience. Empirical data regarding the long-term sequelae of burn injury indicate that many adult burn survivors do achieve a satisfying quality of life and that most are judged to be well-adjusted individuals.^{3,4} Similarly, most pediatric burn survivors, even those with the most extensive and disfiguring injuries, do not exhibit serious behavioral problems.^{5–12}

However, 30% of any given sample of adult burn survivors consistently demonstrate moderate to severe psychological and/or social difficulties.^{3,4} The incidence of psychopathology among children is approximately the same as that for adults.^{5–12} A significant minority of adult burn survivors report a diminished quality of life, including dissatisfaction with

appearance and social or occupational difficulties.^{13–17} Burn injury often leads to at least temporary reduction in social involvement¹⁶ and vocational activity, with 50–60% of individuals requiring a change in employment status.¹⁴ Decreased sexual satisfaction, particularly for women, may also occur and appears to relate to physical changes and body image more than burn size or location.¹⁵

Postburn adjustment is affected by quality of adjustment prior to injury, notably preburn psychiatric disorder.¹⁹ It has been demonstrated that even subclinical levels of post-traumatic distress²⁰ and body image dissatisfaction²¹ during the acute hospitalization can independently reduce health-related quality of life for prolonged periods. Importantly, baseline indices of psychosocial strength (absence of preburn psychopathology) and support (marital status and living arrangement) predicts psychological adjustment after a severe burn injury while burn severity (TBSA, burn location, trips to OR) does not.^{18,22,23} For children and adolescents, several studies have found that postburn adjustment is determined primarily by the quality of parental and family support. Family cohesion, organization, and emphasis on spiritual/moral concerns have all been found to relate to positive adjustment of pediatric burn survivors.^{18,23} For adolescent survivors, families of well-adjusted individuals valued and encouraged autonomy within the context of family cohesion.¹⁸

Empirical studies, as well as clinical observations and patient self-reports, support the idea that burn care incorporating psychosocial expertise can facilitate positive psychological adaptation to the challenges of traumatic injury, painful treatment, and permanent disfigurement.^{10,26} This chapter considers aspects of burn treatment that assist the individual in attaining optimal function psychologically, emotionally, and socially (Figures 66.1 and 66.2).

Psychological treatment concurrent with physical treatment

Burn injury treatment and rehabilitation requires interdisciplinary participation, with a complete spectrum of specialists involved to a greater or lesser extent at each phase of treatment. Specialists focus on specific systems or functional domains of each patient at each stage of treatment but the overall approach of the team is integrated and organized both vertically and horizontally throughout the entire process. The *horizontal organization* flows longitudinally, such that variables assessed in earlier phases impact in measurable ways the variables assessed in later phases. We categorize those factors

Fig. 66.1 Burn survivor at her Quinceañera shares the traditional first dance with parent.

which influence burn injury and recovery in terms of six horizontal (i.e. longitudinal) time phases (pre-injury, admission, critical care, in-hospital recuperation, reintegration, and rehabilitation). Burn care also has a *vertical organization* in which each phase is further categorized by the domains of function directly related to health-related quality of life (physiological/anatomical, cognitive, psychological, social). The assessment and intervention provided in these domains involve the entire patient from the cellular level upwards in complexity of organization to the organ system level, then to the cognitive and psychological level and finally to the social system level. The individual's functional ability within each domain is bidirectionally related to the other domains. Each specialist interacts with the patient, with significant others in the patient's social system, and with the other members of the burn care and rehabilitation team. The burn care and rehabilitation team comprises a true interdisciplinary system that operates over six time phases (i.e. horizontal organization) and across four functional domains (i.e. vertical organization).

Clinicians with expertise in human behavior should be involved in the treatment program for all burned patients throughout the process.^{27–31} In this chapter, these experts are called psychotherapists. Every person, however, who interacts with a patient impacts the psychosocial world of the patient. Any caregiver, including the patient's family, may be the instrument of psychotherapeutic intervention.²⁶ The role of the psychotherapist is to consult with caregivers about psychological and social issues and to suggest therapeutic interventions that any or all can act upon.^{27–32} Furthermore, the psychotherapist on a burn team provides direct treatment to patients as

Fig. 66.2 Quinceañera cutting cake with parents.

appropriate to their changing concerns. As the needs of the patient evolve, the intensity of direct psychotherapeutic intervention varies according to those changing needs.

The family of a patient will always greatly influence a patient's recovery and must be considered as part of a patient's treatment plan. For the psychotherapist on the burn team, the family unit is often the 'patient'.^{30–33} Each individual within a family, including the burn survivor, is an essential element of this unit which must adapt to change. The psychosocial issues and therapeutic tasks for the patient and family are much the same across the spectrum of ages from young children through the elderly, regardless of size and severity of injury.^{26,30,31,34,35}

Assisting with death

Treatment plans and programs must be based on an assumption of life beyond the hospital; however, death also occurs on the burn unit, and psychosocial treatment planning includes plans for assisting patients in living to the cessation of life.²⁶ As part of such a plan, the patient's family must be aided in preparing for and enduring bereavement.³⁶ In this event, supporting and enhancing whatever coping strengths the family manifests is the primary task for psychotherapy. Most families initially deny the possibility of death, appearing not to hear an unwanted prognosis. Staff can allow the family to maintain hope while subtly preparing them with honest statements which pose death as an outcome that is possible to accept.²⁶ Comforting the bereft and helping them to care for themselves, physically and spiritually, are essential elements of a plan that facilitates the family's ability to participate in the process. Keeping the family informed about changes in the patient's condition and actively supporting, sometimes instructing, them in continuing their relationships with the dying patient help the patient and family through this difficult event.

At the time of death, the staff can psychologically support the family by assisting them through the necessary paperwork (e.g. signing consents for release of the body or for autopsy) and in allowing them quiet, private time with the deceased loved one before the body is removed. Bereft family members

often want to hold on to something belonging to or representing the deceased. Staff should offer to assist in finding or creating such a tangible object for distraught family members who may not think to make the request. At the Shriners Hospital in Galveston, families typically say they do want a ‘memory’ item. When no such item is readily available, a hand or foot print on paper or a plaster cast model of the patient’s hand or foot seems to bring solace.

Sometimes a patient must be informed about the deaths of others involved in the same situation that brought the patient to the burn unit. Families may be reluctant to tell a loved one such news while they are still in critical condition, but patients need to hear honest answers as soon as they ask questions. It is the role of the psychotherapist to assist family and patient in this difficult situation.³⁷

A death occurring in the context of family acceptance is more easily accepted by staff. Nevertheless, deaths, especially of a patient, are always sad and may elicit a wide range of strong emotions among the members of the burn team. Allowing a time for debriefing and validating the feelings of the staff can be extremely helpful in maintaining the morale of the team as a whole.

Cultural sensitivity

Burn patients come from diverse cultures, and burn care teams must be sensitive to how cultural issues can affect patients and families in all the phases of the recovery process. ‘Culture’ refers to the socially transmitted expectations, beliefs, traditions, and behavioral patterns typical of a given community at a point in time. It is influenced by many factors. Country of origin is influential, but also geographical location within the country, ethnicity, and socioeconomic background are among those factors that together distinguish cultures. Staff must also be aware of their own biases, values, and assumptions that stem from their cultures.^{38,39}

Acculturation is the process in which individuals from one culture embrace patterns, customs, beliefs, values, and the language of the dominant culture.^{40,41} Patients and their families on first arriving at a burn care facility must rapidly adapt to the culture of the hospital environment. Even if the hospital is within their own community, they experience some level of culture shock and acculturation. This process is even more complicated for those who are transported for care to communities far removed from their homes and perhaps in another country. For many, this traumatic situation is also the first time they have traveled to another country, and the first time they have had to deal with differences in language, currency, living accommodations, and foods. Individuals’ concepts of time and space, appropriate hospitality, importance of greetings, how non-verbal gestures are interpreted, and ways of expressing gratitude may differ greatly among cultures. Ideas of what caused the burn injury and what is necessary for healing to occur also are determined by cultural values.^{42,43}

Coping with such a multitude of unfamiliar experiences in a situation that is traumatic under the best of circumstances presents extraordinary stress that can inhibit a patient’s or family’s ability to participate in the recovery process. Such difficulties correctly recognized can be addressed by the burn team so that cultural differences are not impediments to recov-

ery. Cultural traditions can be incorporated into treatment plans to enhance participation toward recovery. It is not necessary for providers to know the beliefs and expectations of every culture, but what is necessary are sensitivity and willingness to learn about cultural differences. Staff can acknowledge their lack of familiarity and pose a question to the patient/family of whether there is anything the team can do to help meet their cultural, spiritual, and religious needs. The question conveys respect for cultural differences and a desire to help through the acculturation process.

Approach to assessment and intervention

Our general approach to assessment and care of burn survivors is described throughout this chapter as we suggest interventions to deal with specific difficulties commonly experienced at each phase of recovery. It is basically a behavioral approach based on learning principles (e.g. operant conditioning, cognitive restructuring, and social learning theories) where maladjusted behavior itself (rather than intrapsychic phenomena, for example) is the target of intervention.⁴⁴ Assessment and treatment are integrally related and both occur simultaneously throughout the recovery and rehabilitation process.

The longitudinal pattern of psychological recovery

Psychological healing occurs across time commensurate with physical healing in a pattern which is relatively predictable and consistent.^{31,45,46} Awareness of this pattern allows caregivers to anticipate the emergence of psychosocial issues and to prepare a patient for coping with those issues. Predicting problematic issues for patients enables them to view their concerns in a context of normal reactions rather than as symptoms of psychological impairment. For convenience in describing this pattern, we have arbitrarily designated a pre-injury phase and five phases of recovery: admission, critical care, in-hospital recuperation, reintegration, and rehabilitation.

Pre-injury adjustment

Psychosocial assessment is begun as quickly as possible upon admission of the patient. However, preburn physical and psychological health, coping skills, and family/social support are closely related to the behavior, distress, and recovery of a patient.^{19,47–50} Size or severity of burn, age at injury, and gender of the survivor are important variables in treatment, but have little documented influence on the eventual outcome for a survivor.^{4,18,49,50} Prior stressful events and coping strategies, risk factors, as well as psychosocial and economic strengths, are included in a good history of a patient’s premorbid lifestyle. A patient’s history and position in the family as well as the family’s strengths and weaknesses are often helpful pieces of information in guiding plans for treatment.

Because patients will be dependent to some extent on family or other caretakers during recovery, it is essential to identify risk factors in the family system.²⁶ Historical risk factors which may predispose individuals to burn injury and which portend poor prognoses are physical illness, substance abuse, psychiatric illness, behavioral problems, poverty, inadequate social support, and heightened family disruption.^{53–55} These factors

are often causally related to the burn injury and to post-injury recovery. For example, a lifetime prevalence of psychiatric disorder is much more common among patients with burn injuries relative to published national data from a representative community sample.⁵⁶ This is particularly troublesome in that this history of psychiatric disorder is significantly related to postburn psychiatric complications and to poorer postburn health-related quality of life.⁵⁶ In addition to these risk factors, every family has its unique difficulties. The trauma of serious injury exacerbates preexisting problems.

Early identification of psychosocial strengths and vulnerabilities, including those which contributed to the circumstances of the burn injury, allow the team to develop treatment and discharge plans which will optimize the patient's recovery. The importance of assessing the circumstances of injury is emphasized in instances of abuse or malignant neglect. In addition, during early assessment interviews with a family, the staff initiates a therapeutic alliance with those who are most likely to be involved in assisting a patient's recovery.

Admission crisis

At the time of admission, patients with burn injuries universally suffer pain and anxiety. Most are experiencing terror, confusion, and psychological shock. Events causing a serious burn injury are frightening, and patients often believe that death is imminent. The hospital environment can also be confusing and frightening. While the physiological emergency is being treated aggressively, the psychological crisis must also be addressed. On admission, the primary psychological tasks are to establish therapeutic rapport, diminish anxiety, and assess the psychosocial strengths and needs of the patient. The first two tasks are addressed immediately by orienting a patient, by assisting the patient to focus on immediate priorities, and by assuring the patient that the burn team is composed of knowledgeable experts who will provide excellent care. The patient's heightened anxiety can be expected to interfere with their comprehension, so it is usually necessary to repeat statements of reassurance. To prevent a patient from becoming emotionally overwhelmed, it may be necessary to — at least temporarily — not talk about trauma-related content perhaps by asking objective, easily answered questions not directly related to the event or injury (e.g. hometown, favorite sports, etc.).⁵⁷

Psychotherapeutic rapport is developed as a patient associates the voice or touch of a therapist with increased comfort. Techniques of hypnotherapy or relaxation with focused imagery can be very helpful in quickly assisting a patient to feel more comfortable. Patients during this crisis can be expected to be cognitively and emotionally regressed, and it may be important to respond to them at that regressed level. Touching patients in a non-threatening manner and in a soothing rhythm is often the most effective way to maintain a regressed patient's focus and communicate reassurance.

Members of the patient's family are also traumatized and may experience difficulty in eating and sleeping for the first several days. They, too, experience difficulty in concentrating and may require frequent repetition of information. They may feel a loss of control, a generalized sense of incompetence and helplessness in providing comfort for the patient. The psychotherapeutic tasks to be accomplished immediately with a

family are similar to those for a patient (i.e. to establish a therapeutic relationship and to diminish anxiety). Both tasks can often be initiated by assisting them in orienting to the hospital and by providing relevant information about the normal responses to trauma. Explaining, for example, that people in this situation often have difficulty for a few days in eating, sleeping, and concentrating, communicates empathy and validates that their distress is acceptable and temporary. Family members are important components of the therapeutic efforts for the patient, and it is important to say this explicitly. This helps to return to them a sense of purpose and control. Even on the day of admission, the staff begins shaping the family behaviors and support network by outlining some immediate concerns. Learning about the injury and its treatment helps to restore a family's sense of competence and provides opportunities for them to experience the reality of their roles in helping the patient.

The manner in which an individual and family will ultimately adjust to long-term sequelae of a burn injury (e.g. deformity, disfigurement) is often determined in the early stages. It is of utmost importance for the treatment team to demonstrate respect for each individual from their first interactions with patients and families.

Critical care phase

From hospital admission until the majority of open wounds are covered, the emphasis in treatment of a burned patient is necessarily on intensive medical and surgical care to resolve physiological crises. This period is psychologically critical as well. A patient experiences great anxiety during much of this time. Fear of death blends into fear of pain and fear of treatment procedures.³¹ A multitude of organic factors stemming from both the injury and its treatment, as well as premorbid conditions, can all contribute to psychological symptoms of disorientation, confusion, sleep disturbance, transient psychosis, and delirium, which are commonly observed among adolescent and adult patients.^{31,58} Pharmacological interventions to manage pain and anxiety should be instituted and, along with psychological interventions, can diminish anxiety and confusion. Repeated statements of orientation to time, place, and person are mandatory. Objects that are familiar and comforting can be placed in the patient's view or so that the patient can touch them. The patient's environment should be as soothing as possible. A schedule which approximates a regular wake/sleep cycle helps a patient begin to feel normal. Visits from family and friends can provide familiarity and reassurance to a patient.

Staff interacting with patients during this phase must be willing to listen to patients' anxieties and reassure them that the nightmares and vivid memories are normal aspects of recovery. Staff can help patients focus on the present time in which they are safe in the hospital and are healing. When a patient is withdrawn or in a coma, staff must remember that the patient may be hearing, although not responding, and must take care to talk to the patient. They must also be discreet in what is said within a patient's hearing range. Patients are often listening to determine what will happen to them; and, in their altered mental states, they may attribute unexpected meanings to what they hear. Although the staff should persist in attempting to orient a patient, they should not argue with the

patient about what is reality. Arguments with a patient who is having vivid illusions, delusions, or hallucinations are usually counterproductive. Psychological interventions are aimed at diminishing anxiety and increasing comfort rather than correcting a patient's perceptions of reality.²⁶

Often, the content of the patient's delirium can be used to facilitate reassurance and relaxation. For example, a man in this phase who believed he was on a boat was combative and remained agitated in spite of psychopharmacological attempts to calm him. The psychologist assisted during procedures by talking to the patient about being on the boat in the same manner used to induce hypnotic trance. As the patient engaged in the description of the boat, the psychologist described calming elements of their imaginary surroundings such as the rhythm of the waves, the cool breeze, the warm sun. For these temporary periods the patient could become calm and could follow the psychologist's instructions to allow procedures. Although the patient was, for several days, disoriented and intermittently agitated, the staff were able to provide the care he needed during this critical phase.

During the critical care phase, family members usually become at ease with the routines of the hospital. They may, however, continue to experience some symptoms of acute traumatic stress, such as intrusive thoughts, difficulties with sleep, or avoidance behaviors.⁵⁹ They remain anxious about their relative's condition and eager for information about their patient's present and future status.^{59,60} In addition, as they accept what has happened, family members begin to think of other concerns which elicit anxiety. They may find themselves thrust by the burn injury into new roles with new responsibilities. Often, especially if the hospital is at some distance from their home, they are without their customary support systems.

It is helpful to provide families with information about what they may expect to observe with their burned relative in the immediate future and to guide family members as they respond to the patient. Families need instruction about how they can be helpful.^{59,60} They may be reluctant to touch the burned person for fear of causing pain and are usually relieved when encouraged to do so. They may feel uncomfortable in talking aloud to a non-responsive patient; the staff can suggest that their voices are extremely important to the patient even though the patient does not respond. The staff must find ways to allow family members to nurture their relative and provide instructions so that the family can begin to become comfortable in caring for the patient's needs. Staff members of critical care units are very busy and may, at moments, want to send the family away so that tasks can be completed more efficiently. However, these first instructions to the family are of critical importance to the future of the patient who needs the expressions of care by loved ones. Taking the time to 'treat' the family is a very important part of treating the patient. In addition, this 'treatment' facilitates the family's resumption of feelings of competence and control, desensitizes them to the sights and odors of the burned person, and encourages the family to join with the burn team in the healing and rehabilitation of the patient.

The burn team must also emotionally support the family's defenses. Often, family members appear to deny or to cling to delusions about the critical nature of the patient's status or the

extent of the patient's injuries. It is important to give a family honest information while allowing them to protect themselves from overwhelming despair.⁶¹ A family must find reason to hope, and the staff can assist them by suggesting realistic and optimistic outcomes. For example, we display in our offices many photographs of burn survivors engaged in a variety of activities such as swimming, going to a prom, wedding pictures, pictures of survivors with their children. The snapshots convey a hopeful message even if nothing is said explicitly about them. Family members of acute patients usually can be observed looking at the photos, and at that point it is easy to discuss which of those survivors had injuries comparable to their relative. The message to be conveyed is that there is hope for a good outcome and that successful recovery requires arduous and painful work over a period of time.

Psychotherapeutic work with the family must also identify and plan for management of those family issues which may impede a patient's recovery and rehabilitation. Some of the common issues are financial support, family alliances, historical family events, and beliefs which influence current perceptions and behaviors. Management plans must support, to the extent possible, the physical and emotional well-being of all the members of the family during a period of time in which the burned patient's needs place unusual and urgent demands on the family system.⁶⁰⁻⁶²

Psychological factors play a significant role in pain and anxiety management. Scheduling of pain and anxiety assessments and the choice of assessment tools used have psychological relevance. Regular, routine assessments of discomfort imply to a patient and a patient's family that the medical staff consider discomfort a valid issue that will be treated. This not only validates a patient's concerns but also sets an expectancy of relief when pain or anxiety is a problem. The use of standardized scales provides the message that to experience a range of pain and comfort responses is normal and allows the patient to participate to some degree in mastering discomfort. When staff assess comfort as routinely as vital signs and indicate that they believe the patients, patients are less likely to feel that they must complain loudly in order to convince the staff that their need for pain relief is legitimate. They also are less likely to feel hopeless and helpless and become depressed.

A supportive milieu that diminishes anxiety also enhances a patient's ability to gain increased comfort with both background and procedural pain. The presence of a supportive person is effective in decreasing pain.⁶³ Encouraging patient participation in self-care has been demonstrated to be effective in assisting a patient to become more comfortable.⁶⁴ In particular, patients who are hypervigilant and reluctant to trust seem to gain mastery over pain when they remove their own dressings or debride their own wounds. Behavioral interventions that enhance a patient's mastery or control, in general, decrease pain and anxiety. For example, adults and children who are developmentally capable of understanding the relationship of treatment to healing better tolerate procedures when told the reason for each procedure.⁶⁵ The choice of words used in explanations of procedures can ameliorate anxiety and reduce the expectancy of pain; for example, one can say 'some people feel a poke; others feel a prick or a tingle — you tell me what you feel' rather than saying 'This is going to hurt now.' Touch can be used as a distraction and to induce

relaxation; continuous, rhythmic repetitive stroking of a non-injured and non-threatening body part accompanied by comforting sounds assists relaxation of many adults as well as children, including infants.⁶⁶ Music therapy can be an excellent adjunct to analgesia. Verbal praise and other tangible reinforcers facilitate learning to cope with painful stimuli by relaxing.⁶⁷

Modeling for and instructing a family in soothing their patient is important. Outside the hospital, family members may know well how to calm their relative, but they may need instruction and/or encouragement from the staff to be comforting within the hospital. Once involved, family members can be valuable assets in providing the ‘placebo’ that relieves a patient’s distress.

Other non-pharmacological interventions also can facilitate comfort. Distraction, deep breathing, progressive relaxation, biofeedback, and virtual reality have all been reported to be effective in decreasing pain and distress associated with burn treatment.^{68,69} Hypnosis induces a relaxed and focused state of awareness which can be extremely helpful in facilitating comfort for adults and pediatric patients and may offer other benefits as well, such as: to increase appetite, to decrease regressive behavior, and to enhance a patient’s sense of well-being, self-confidence, and body image.^{70,71} An inflexible protocol for hypnosis, however, will be no more effective than an inflexible regimen of medications. With each patient, hypnotic inductions and suggestions must be modified to facilitate a patient’s use of imagery. Some patients will respond well to suggestions of imagining a ‘favorite place’; others can more easily imagine switches to ‘turn off’ sensation in selected body parts. Children aged 3 and over respond well to storytelling, with suggestions for comfort and mastery interwoven into the story.⁷²

Providing good pain control enhances the burn care staff’s effectiveness in promoting psychological recovery of a patient by allowing the staff to interact in more pleasant ways with happier patients. Comfortable patients who perceive themselves to have some power are less prone to regressive behavior. They are perceived by staff as more likable which, in turn, reinforces the positive self-regard of the patients.

In-hospital recuperation phase

Paradoxically, as burned patients become physically stronger, open wounds almost healed, and grafting near completion, their continued treatment presents additional and perhaps more difficult challenges to the burn team. Treatment at this stage cannot simply be imposed upon a relatively helpless patient; now the team must succeed in motivating the patient to participate in treatments and to assume responsibility for recovery. The patient who desires optimal recovery must comply with the medical team’s orders and instructions, many of which require significant physical discomfort.

In this phase, patients are just beginning to comprehend the extent of their injury and to realize that their body, changed forever, is no longer congruent with their premorbid self-image. Their anxieties now are increasingly about the future and less about the past and present. Pain continues to be a concern; new experiences of pain must be addressed as patients become increasingly active in rehabilitative exercises. Patients are confronted with the new physical limitations imposed by their injuries; they experience their bodies now as incompe-

tent and disfigured. Patients involved in this struggle shift rapidly in affective behaviors reflecting rapid shifts in cognition. Much of the time, patients experience themselves as the ‘preburn self’ (i.e. the ‘real self’). When the body will not move as it did in the past or when the scarred skin is viewed, a patient remembers and grieves. Patients become aware of their changed appearance as they observe the responses of others and note these responses invalidate their former body image. Their concepts about their social roles may no longer fit with society’s beliefs. Their premorbid identities no longer exist intact and new identities must incorporate remnants of the old, as well as the changed, physical body, thus further stripping them of their identities. In this confusing state, the patient may be expected to act out anger and fear.

In addition to physical limitations, the role of ‘hospital patient’ imposes a loss of control and autonomy on the survivor. After a period of realistic dependence on others, a patient may be frightened and ambivalent about resuming self-care.⁴⁷ The demanding schedule necessary for treatment during this period heightens a patient’s feelings of inadequacy. A patient becomes easily fatigued yet must continue in a schedule of tasks determined primarily by the burn team, thus providing additional evidence of the patient’s loss of autonomy and ability.

Emotional lability and cognitive and behavioral regression are typically observed in patients of all ages during this trying time. Perhaps the most difficult behavior for patient, family, and staff is the patient’s expression of anger. Patients, of course, have many reasons to be angry, and they need to express that anger in order to define and direct it adaptively; however, there are significant limitations upon the availability of situations in which they can express anger. Patients have almost no privacy, nor can they relieve tension through physical activities such as running. Typically, family members and patient care staff, having devoted much time and energy to the patient, are prone to perceive the patient’s angry behavior as a personal and unjust attack by an ungrateful patient. Certainly, the patient will direct rageful temper tantrums toward those who are the safest targets, usually a spouse or parent first and then a nurse or therapist. Angry attacks are best understood as necessary ventilation by the patient rather than sincere evaluations of family or staff.

Expressions of rage are not only upsetting to family and staff; they also frighten patients who themselves perceive this loss of control as evidence of potential destruction of self or others on whom they are dependent. Following an outburst, a patient typically feels guilty and fears withdrawal of love and support by those who were earlier subjugated to the angry behavior. These fears are added to the patient’s fears of being rejected because of the changed appearance. Turning anger now toward self, the patient may feel overwhelmed, hopeless, depressed, and even suicidal. If the hospitalization continues over several weeks, patients experience repetitive frustrations, and tend to feel hopeless and depressed more often. Hopelessness is more likely to result when patients feel as if they have no control over aversive events and eventually give up trying to control what happens to them; such hopelessness over time can lead to chronic depression.⁷³

Psychotherapeutic work at this phase intensifies and is largely focused on working with the rest of the team to help patients combat feelings of hopelessness and helplessness.

Important toward this end is structuring treatment sessions to promote patients' experience of control, achieving success, and feeling rewarded while progressing through difficult procedures. Positive feelings, generated by achieving the goals one has established, increase one's likelihood of repeating the effort. For example, a rehabilitation exercise session based on a work to quota versus work to tolerance basis establishes clear expectations, rewards adequate performance and consistently builds on prior achievements.⁷⁴ Desired behaviors (e.g. pressure garment use, walking on treadmill, reassuring self-statements when looking in a mirror at one's scars) must be reinforced, e.g. by verbal praise or by a time for rest. Since success breeds success it is helpful to begin and end sessions with manageable tasks that generate positive feelings of achievement and mastery. In addition, it can be helpful to 'Always Leave 'em Laughing'. Relaxation, humor, and ending on a good note in general are methods of following the desired response with a rewarding experience.

Much psychotherapeutic work during this phase is accomplished with patient and family together. Families must learn how to assist a patient in adjusting to the new situation, and the family system itself must accommodate to the changed situation. Research has shown the high importance of strengthening the family unit, facilitating family closeness, and supporting their attempts to organize their lives to incorporate the additional duties involved in providing continued care for their patient.^{22-24,50} They must plan and implement adjustments in the family and home environment that will be necessary for the continuation of the patient's recovery and rehabilitation after discharge. Maintaining the integrity of the family unit while making needed adjustments is of high priority and is a challenge. Parents of a burned child must learn to advocate for their injured child but to avoid overprotection by themselves or others. They must encourage the child to perform independently to the limits of physical and age-appropriate ability. Parents and spouses even of adult patients often struggle against desires to protect and infantilize their recovering loved one. Staff can model for the family behaviors that demonstrate respect and courtesy for each family member including the patient.

A psychotherapeutic challenge of this phase is to accept and validate the patient's emotional demonstrations as normal behaviors in the recovery process while also setting limits on the ways in which the emotional upheaval will be expressed. Early in this phase, as the patient begins to ask about the future, the psychotherapist can describe the predictable pattern of emotional vicissitudes indicating that, should such occur, they are normal; they can be endured and managed. The staff must demonstrate positive regard and acceptance of the patient while also helping the patient to exercise control over destructive behaviors. At times, they must impose external limits to protect the patient.

Another psychotherapeutic task with both patient and family is to titrate their denial with graded presentations of reality.⁴⁷ Staff can anticipate and assist a patient in asking questions about future disfigurement and functional abilities, including sexual activity. Without evading questions, psychotherapists give honest but hopeful appraisals that emphasize ability and minimize deformity and disability. For example, as a patient voices an unrealistic belief that time and/or plastic

surgery will return the former appearance, one can state that burned skin will never look like unburned skin and that there will always be some scarring, but that appearance will change with time. Allowing patients to hope, even for unrealistic outcomes, protects them from despair and enables them to continue to believe that there are reasons to endure the pain of rehabilitation.^{30,31} Patients and families should be given the information that rehabilitation may require several years to achieve optimal satisfaction, but that the painful efforts usually obtain good results.²⁶

The therapeutic message to be delivered is that survivors can find ways of achieving whatever goals they set for themselves; the process is lengthy and difficult, and survivors will often feel overwhelmed and hopeless. Expressing sadness and anger is to be expected and accepted; however, such feelings can never be allowed to stop a patient from participating in the necessary regimen to achieve full recovery. Being burned does not relieve a survivor of the responsibility of competence.

Many survivors have endured the process and discovered that they can enjoy their lives even though their early expectations were not, and could not have been, realized. Introducing such a recovered survivor to the recuperative burned patient can be a very helpful intervention at this point.³¹ The more experienced survivor can be heard as a trustworthy authority in a way the unburned professional cannot. Visual images of burn survivors telling their stories and presenting themselves in daily life activities on film or video can aid in accomplishing this purpose.⁷⁵ Groups of patients and/or families of burned patients at varying stages of recovery and rehabilitation have been helpful in providing information, emotional validation, and support as well as reinforcing the concept that it is possible to survive burns and live acceptably happy lives.⁶⁰

Reintegration phase

Although plans for a patient's discharge to outpatient status are developed from the time of admission, very specific plans must be made in the final days of hospitalization. A major objective at this time is to facilitate a patient's reentry and reintegration into life at home. Returning home signifies social interactions with the larger community of extended family, friends, and strangers. Patients as well as family must prepare for those encounters. Goodstein⁴⁷ appropriately labels this the 'social emergency' phase of treatment.

Families and patients alike are often ambivalent about leaving the safe environment of the hospital. Patients, including very young children, fear social rejection or ridicule because of their changed abilities or appearance.^{76,77} Family members will probably feel, and may express, a desire to protect their patient from rejection or ridicule. Family members may also express concerns about their ability to continue the time-consuming physical care of the patient while resuming their usual responsibilities. Patients may doubt their abilities to resume former activities. As discharge approaches, anxieties intensify, and patients can be expected to evidence some regressive behaviors that, in turn, can reinforce the family's doubts.

Psychotherapeutic activities of this phase involve education and preparation of patient and family about the difficulties that can be anticipated at discharge. Patients and families may deny that they will have problems. Rather than accepting their

assurance that problems will not arise, the psychotherapist can characterize such events as normal and 'usual', and proceed, without condescending or judging, to offer suggestions for developing a repertoire of alternative behaviors to address those problems 'just in case' they do experience difficulties. Issues such as recurrence of symptoms of post-traumatic stress, sleep disturbance, irritability, or fear of resuming sexual activities should be discussed during the days prior to discharge. This preparatory verbal rehearsal enhances the probability that the patient/family will be less reluctant to ask for help if problems do occur; if problems do not occur, the staff has the opportunity to congratulate the patient/family on their strengths or skills in coping.

Toward the end of inpatient treatment, patients are expected to resume increased autonomy; caretakers are supported in withdrawing assistance to the degree possible. It is helpful at this point to develop with patients/families a daily schedule to guide them in accomplishing necessary tasks. The burn team relinquishes performance of daily care so that the patient/family can assume care to the extent that they will be required to conduct it at home. The patient and family can benefit from the opportunity to rehearse outpatient care while still able to consult with the burn team for direction and support. Rehearsals are opportunities for all involved to experience difficulties in a safe environment and to plan corrective actions.

Important among these rehearsals are those of interpersonal interactions outside the hospital. Burn survivors have reported their most difficult experience at discharge involved observing the reactions of others.⁷⁸ Patients benefit from the opportunity to experience such reactions before discharge from the hospital. They may leave the hospital for brief outings and return to the hospital for reassurance, encouragement, and praise.⁷⁹ James Partridge of Changing Faces, an organization dedicated to assisting persons with facial disfigurement, recommends a brief social skills training program called '3-2-1-GO!' The program can be provided in the hospital by staff who regularly interact with patients. The patient is asked to plan for uncomfortable social situations by thinking of 3 things to do when someone stares at them, 2 things to say when someone asks them what happened (to cause the scars), and 1 thing to think if someone turns away from them.⁸⁰ Patient/family groups can be extremely helpful in the process of anticipating difficulties at discharge and rehearsing solutions while also providing emotional support.

In addition to preparing a patient and family for discharge, the burn team may also prepare the 'community' to which a patient will return. The 'community' may include extended family, neighbors, church groups, social clubs, a patient's workplace or, in the case of a school-age pediatric patient, the school. Instructing those unfamiliar with burns in what to say or do to ease a survivor's reentry may facilitate reintegration.^{78,79,81}

A few well-organized reentry programs for pediatric burned patients have been described in the literature.^{78,81} Although there is no evidence that adult burn survivors are in less need of assistance with reintegrating into their social worlds, published information about organized reentry programs for adults is scarce.^{79,82} Reentry programs for adults and children involve the same fundamental elements and address the same issues. They educate the community in a developmentally

sensitive fashion. They address both the intellectual and emotional aspects of burn injury, provide generic information about burn injuries and burn treatment, and emphasize a survivor's abilities as well as clarify the ways in which a survivor may need assistance. Homemade videotapes can be sent to target groups ahead of a patient, thus allowing a community the opportunity to see and hear the burn survivor, to anticipate difficulties, and to plan coping responses. Educational information presented in pamphlets or letters can be directed to those who will play key roles in facilitating a patient's transition from hospital to home community. If possible, one or more members of a burn team may visit the home community and speak to targeted groups, answering questions which people may be reluctant to ask of the patient or family. Although there are no empirical data to demonstrate that reentry programs do, in fact, facilitate reintegration, anecdotal reports and clinical experience suggest that survivors have benefited from such efforts.⁸³

Rehabilitation phase, post-discharge

Discharge from acute inpatient treatment does not signify that a patient is well. A burn survivor's wounds are covered with sensitive and fragile skin which is vulnerable to breakdown and requires special care. Dressing changes, exercises, and application of special splints and pressure garments continue. Patients must confront anew their losses and may experience a delayed grief reaction. Upon leaving the protective hospital environment, symptoms of post-traumatic stress that had remitted in the hospital may recur. A survivor must continue the arduous process of tedious, uncomfortable physical treatments while struggling to comprehend and incorporate the multitude of changes into an image of 'self' which the survivor can accept and value.

The process of rehabilitation requires months to years, and patients as well as those around them can become discouraged. It would be extremely valuable to patients leaving the hospital, as well as their social network, employers, and care providers, if there were a set of predictors that could reliably estimate when and to what degree functional improvement could be expected over time. A recent investigation used markers for injury severity (TBSA) and psychological distress (Brief Symptom Inventory's Global Severity Index: GSI) available at discharge to generate benchmarks for postburn impairment.⁸⁴ The objectives were to track functional impairment from discharge and across 2 years of follow-up, and, to predict it using only data available at time of discharge. Participants were from a multisite cohort of adult burn survivors with major burns in a prospective study. To set impairment benchmarks, separate logistic regressions related TBSA (TBSA = 30% versus <30%) and GSI (T-score = 63 versus <63) to SF-36 Physical (PCS) and Mental (MCS) Composite Scales. The PCS benchmark (T-score = 37.25) was strongly related to injury group (TBSA), and, interestingly, corresponded to the mean impairment score in a sample with severe lower limb injury. Similarly, the MCS benchmark (= 32.40) was strongly related to distress group (GSI), and, of note, was equivalent to the mean impairment score in a sample with severe major depressive disorder.

At the time of discharge from the acute hospitalization, the prevalence rates of psychological and physical impairment were quite elevated. The data showed that, in general, physical

impairment rates remained high among those with larger burns (TBSA = 30%). The rate of impairment for this group was 7%, 85%, 49%, 38%, and 29% at preburn, discharge, and at 6, 12, and 24 months postburn, respectively. The rate of physical impairment among those with smaller burns (TBSA <30%) was 9%, 77%, 21%, 16%, and 16% at preburn, discharge, and at 6, 12, and 24 months postburn, respectively. Physical impairment at all 3 postburn follow-ups was predicted by age, number of operations, and by level of physical health and function both before the burn and at discharge.

The data also revealed that, after an initial increase at 6 months, psychological impairment rates then receded over time. The rate of psychological impairment among those with higher distress at the time of discharge (GSI T-score = 63) was 28%, 50%, 38%, 29%, and 35% at preburn, discharge, and at 6, 12, and 24 months postburn, respectively. The rate of psychological impairment among those with lower distress at discharge (GSI T-score <63) was 3%, 10%, 11%, 9%, and 5% at preburn, discharge, and at 6, 12, and 24 months postburn, respectively. Psychological impairment at all 3 postburn follow-ups was predicted by prior alcohol abuse, in-hospital psychological distress, and by psychological function both before the burn and at discharge. The latter information, available at discharge, may help providers inform patients about modifiable factors effecting functional outcome.⁸⁴

The 'enabling-disabling process' and the paradigm of rehabilitation research

The key terms in rehabilitation science are: injury, impairment, functional limitation, disabling condition, and disability. Uniform definitions of these terms are provided in an Institute of Medicine (IOM) report:⁸⁵

- *Injury* (i.e. pathology) is any interference of normal bodily processes or structures.
- *Impairment* is a loss or abnormality of mental, emotional, physiological, or anatomical structure or function.
- A *functional limitation* is a restriction in the ability to perform an action or activity in the manner or within the range considered 'normal' and which is attributable to impairment.
- *Disability* is a limitation in performing socially defined roles expected of individuals within the social and physical environments.

Impairments and functional limitations represent potentially disabling conditions, while disability itself is a function of the interaction between the person's limits and the environment.⁸⁵ The IOM model describes the pathway along which a person with potentially disabling conditions may decline (i.e. experience less access and/or less integration) from injury to impairment, and from impairment to functional limitation. Factors that moderate the relations among these include: biology (e.g. genetic, congenital, pathology), environment (e.g. physical, social, psychological), and lifestyle (e.g. behavior).

- *Enablement* (i.e. the absence of disability) is represented by full social-environmental integration, including access to social opportunities (i.e. roles) and physical space (i.e. absence of physical barriers).

A model for rehabilitation-related research based on the IOM model has been incorporated into the long-range plan of the

National Institute on Disability and Rehabilitation Research (NIDRR).⁸⁶ NIDRR espouses a paradigm for conceptualizing and conducting rehabilitation research that places environmental factors on an equal footing with person factors. The complex interaction of impairments and functional limitations with environmental structure is understood to determine the degree of disability that results from any given potentially disabling condition. Environmental structure is broadly understood as composed of physical space (e.g. architecture, transportation systems), intrapersonal structure (e.g. personality), interpersonal structure (e.g. social support), and socioeconomic structure (e.g. insurance coverage, work, and training opportunities). It is important to note that one's abilities may interact with aspects of the physical and social environments to enable full function in certain environments or at certain times, but allow for only partial integration into other environments and/or at other times.

The goals of rehabilitation science are to develop basic and applied programs of research that preserve or restore function either directly or via technological accommodation, and to enhance access to the physical and social environment by removing barriers to full integration in the community and the workplace.

Regarding burn injury, there are some data to suggest that the most important long-term (more than 2 years post-injury) disability is at the interface of the burn survivor and social environment. A recent study of young adult survivors of childhood burns (mean time since injury, 14 years) found that, although on standardized behavioral scales the young people were rated by others to be doing well, in individual standardized psychiatric interviews, an unexpected high percentage reported symptoms severe enough to warrant diagnoses, especially of anxieties related to social situations.⁸⁷ Similar results were found in a study of adolescents (mean time since injury, 10 years).⁸⁸ In both studies, the young people were rated by a physical therapist to have no physical limitations that prevented their abilities to care for themselves and to participate in ordinary activities, but their anxieties were severe enough to limit their achievement to full capacity. Even if most burn survivors eventually function satisfactorily by external criteria, clinically they may be suffering significant *distress* that is not easily observable. A goal of psychosocial care providers in working with survivors is to understand the sources of survivors' distress and to develop interventions that enable survivors to become full participants in society.

Manifestations of psychosocial distress

Among the most common manifestations of psychosocial distress are: sleep disturbance,^{89,90} depression,⁹¹ body image dissatisfaction,²¹ acute and post-traumatic distress,^{90,92} as well as more heterogeneous symptoms.⁹³ The mean level of psychological distress among those with major burn injuries (37) is reported to be significantly higher than that of a normative sample.²² Evidence indicates that psychological distress in the hospital can have an enduring impact on health and function.^{22,92,94} Psychological distress is closely correlated with poor global quality of life; accounting for substantial variance in concurrently assessed quality of life at 2 (58%), 6 (68%), and 12 (51%) months following a burn injury.⁹³ Psychological

distress while in hospital was found to be associated with significantly greater impairment of physical and psychological function and slower rates of recovery over the course of the first year following a major burn injury even when preburn physical and psychological health and function were statistically controlled.⁹⁴

Acute and post-trauma distress

As described in Chapter 65, acute stress disorder (ASD) and post-traumatic stress disorder (PTSD) following exposure to trauma are common, with a lifetime prevalence in the USA of 7.8%.⁹⁵ Severe burn injury is particularly likely to yield PTSD.^{56,96} ASD and PTSD are characterized by three symptom clusters:

- re-experiencing trauma — intrusive distressing thoughts of the traumatic event or vivid flashbacks of the event;
- avoidance — suppression of trauma-related stimuli;
- hyperarousal — persistent symptoms such as inability to sleep, chronic anxiety, and irritability.

Between 25 and 38% of burn survivors meet criteria for PTSD in the first postburn year, and almost 50% of survivors meet criteria for at least one of the PTSD symptom clusters.^{56,97–99} Post-trauma distress has been found to be associated with greater lengths of acute hospitalization,⁵⁶ enhanced sense of distress, and impaired adjustment to injury.²⁰ It might be assumed that PTSD is related to greater initial injury; however, PTSD among burn survivors has not been found to be related to severity of injury.¹⁰⁰ On the other hand, high levels of acute post-trauma stress symptomatology have been shown to be positively related to perception of more intense pain among hospitalized burn patients.^{96,101}

PTSD can impair long-term adjustment following severe burn injury.¹⁹ Certain aspects of pretrauma adjustment (e.g. history of mood disorder) can influence the risk of developing PTSD following trauma exposure.^{19,102} Individuals with high levels of trait neuroticism appear to be at greater risk of PTSD symptomatology following burn injury while high levels of extraversion appear protective against PTSD.⁹⁷

Body image dissatisfaction

Scarring, disfigurement, deformity, and loss of function that often result from a severe burn injury are likely to lead to significant perceptual and subjective body image changes.¹⁰³ Deformities or disfigurement of the face and other exposed areas may be obvious sources of distress. Disfigurement of areas such as the genitalia may be less apparent, but still highly relevant to body image satisfaction or self-esteem. In any case, changes in appearance or function may result in altered body image perception, a decrease in body image satisfaction, and behavioral avoidance. The association of larger TBSA and facial involvement with body image dissatisfaction of adult survivors may represent the influence of physical injury on psychological disturbance (i.e. physical condition affecting psychological disturbance).²¹ Perhaps those individuals who appraise their injuries as worse because of location (i.e. more physically unattractive because of facial burns) or severity (i.e. larger TBSA) are at greater risk of developing body image dissatisfaction. Conversely, it has been suggested that cognitive and affective factors may interact with objective

aspects of the burn to worsen the appraisal of physical impairment and disability following a burn injury (i.e. psychological disturbance affecting physical condition).

Interestingly, three studies of self-regard by adolescent and adult burn survivors indicate that survivors developed positive feelings of global self-worth even while rating themselves low on the characteristic of physical appearance.^{104–106} They also ranked physical appearance as a less-important domain in their value structures than job competence, romantic appeal, scholastic competence, and a number of other domains. Apparently, the burn survivors in these studies developed the ability to focus on positive characteristics over which they had some control and deemphasize those factors over which they had little or no control. As one young survivor said when explaining why she wanted no further reconstructive surgeries, ‘I’ll just have to get by with my *great* personality!’

Stigmatization and social anxiety

Burn survivors often report stigmatizing behaviors on the part of unburned individuals. The behaviors may be obvious such as staring, teasing, or bullying; or they may be subtle such as avoiding eye contact, ignoring, or expressing pity, but all result in the burn survivors feeling discredited and/or demeaned by others because of their scars.¹⁰⁷ Bull and Rumsey hypothesized that experiencing stigmatization has three specific effects on people with appearance distinctions: poor body-esteem, a sense of social isolation, and a violation of privacy effect.¹⁰⁸ The violation of privacy effect refers to the inability of the person to be anonymous, unnoticed, without undue attention. People of non-impaired appearance do not expect to walk down a street receiving intrusive looks or being approached by strangers who attempt to engage them in conversation regarding their traumatic history. Yet, burned individuals can rarely be anonymous; even the act of ignoring is a form of recognition and rejection. Sometimes the extraordinary attention is meant to be positive, but is none-the-less intrusive and dehumanizing.

Unburned children who are rejected (i.e. actively disliked) or neglected (i.e. socially excluded) by their peers report substantially more social anxiety than their accepted classmates¹⁰⁹ and it is likely true that adults who feel rejected experience social anxiety as well. Social anxiety is a promising construct which may serve as a marker for early identification of risk for developing anxiety disorders¹¹⁰ such as those reported by long-term (more than 2 years post injury) burn survivors in the Meyer et al.⁸⁷ and in the Blakeney et al.⁸⁸ studies. It seems likely that the gestalt of visible distinction, body image dissatisfaction, stigmatization, and social anxiety are keys to understanding the etiology of burn survivors’ distress and to the development of interventions to enable survivors to live with less suffering.

Distress of families of burn survivors

Long-term impact on families of burn survivors has not been well studied, but clinical experience and scanty empirical data indicate the sequelae to be significant. Family members may continue to experience symptoms of post-traumatic stress after a patient has returned home.⁵⁹ Parents of survivors of massive injuries appear extraordinarily stressed even several years after their children’s recoveries.^{6,8} A series of studies at the Shriners Hospital for Children in Galveston found that parents

of recovering pediatric burned patients reported significant depressive symptoms at 2 years post-injury, and they attributed their distress to their burned children.^{111,112} Although parental distress appears to improve with time for most, parents of the most troubled burned children continued across time to be troubled themselves.¹¹² Parents also express concern for their unburned children whom some felt had been slighted of attention and time while the burned sibling presented an extensive drain on the family system. Even free medical and surgical care did not eliminate the burden of direct and indirect costs of burn injury, and many families experience financial difficulties attendant to the injury and treatment of their child.⁶

Long-term outcome: quality of life

After survival is assured, quality of life is arguably the most important outcome to individuals who are seriously ill or injured. Health-related quality of life has been defined as a multifactorial construct that involves an individual's degree of satisfaction and level of health and functioning in several core domains, including: physical-behavioral (e.g. ability to perform self-care behaviors) and psychological well-being (i.e. subjective sense of contentment and the absence of emotional distress), social and role functioning (e.g. ability to fulfill family, work, and community responsibilities), and personal perception of health (i.e. satisfaction with one's health status).¹¹³ Although most attempts to assess outcomes following burns have focused on either physical or psychological status, recent research has begun to focus on the overall quality of life.^{10,17} As with self-report behavioral scales, most long-term (over 2 years) burn survivors appear to have eventually developed satisfactory adjustment and are within normal range on domain subscales of the SF36, a widely used quality of life assessment tool.^{10,113,114} Rosenberg et al.,¹⁷ however, examined the same patients as Baker et al.¹¹⁴ using the Quality of Life Questionnaire¹¹⁵ rather than the SF36 and found that on this questionnaire burn survivors rated their quality of life lower than the normal population in most areas, including general well-being, interpersonal relations, occupational activities, leisure activities, and participation in organized outside activities. These differences obviously reflect a difference in the instruments chosen, but generalizability of the results of the latter study is questionable.

Distresses prolong rates of recovery to satisfactory quality of life. Body image dissatisfaction at time of discharge is associated with prolonged periods of poorer mental health-related quality of life among adult patients following disfiguring injuries.⁹⁷ The impact of body image dissatisfaction on psychosocial quality of life independent of distress, injury, and pre-injury adjustment variables suggests the importance of early identification of populations at risk and the development of early intervention programs.

Post-trauma distress during the reintegration phase is also related to significant extended problems with adjustment during subsequent phases of recovery.^{20,99} These problems are greater for those with post-trauma distress relative both to other burn survivors without significant post-trauma distress and to normative data. Moreover, the effect of post-trauma distress on physical and psychological health-related quality of life is felt even after controlling for pre-injury level of

adjustment, baseline state negative affectivity (e.g. depression, body image dissatisfaction), generalized optimistic-pessimistic expectancies, and injury severity (face burn, TBSA full-thickness). On the other hand, the influence of post-trauma distress on physical adjustment appears to be moderated by generalized optimistic-pessimistic expectancies as well as by aspects of the burn injury itself.⁹⁹ This is consistent with the literature, indicating that negative affectivity or neuroticism (which covaries with state distress and generalized optimism-pessimism expectancies) may exacerbate symptom reporting and disability in physical illness.¹¹⁶

Interventions for burn survivors beyond acute care

Burn survivors and families may need psychotherapeutic attention for months or years as they adapt to new roles. Regular monitoring for psychosocial problems is important, especially for pediatric patients who continue to experience new problems related to burn scars as they mature. Psychotherapists must help patients to define new self-images, incorporating and going beyond body image. In the early months, patients may be encouraged to overcompensate and enjoy the positive identification of 'hero'. Survivors are commended for rehabilitation gains and social accomplishments. Each victory is celebrated. As patients' physical and psychological adaptation stabilizes, psychotherapists must assist patients in resisting the temptation to remain satisfied with the identity of 'heroic survivor'. This role invites survivors to achieve expectations which are unrealistic and to deny unhappiness or anger or pain. The task for psychotherapists is to make explicit the expectation that each burn survivor is a human individual who can be strong and competent, optimistic and autonomous, and also can have moments of sadness, despair, or rage. Guiding patients to accept vulnerabilities and flaws without detracting from the overall positive evaluation of 'self', psychotherapists insist that the person who has been the 'heroic burn survivor' can become a competent, interesting individual who also once survived a serious burn injury.

Most burn survivors who suffer psychological symptoms of distress following discharge from a burn center and who desire treatment must rely on mental health professionals in the community. However, it may be difficult for them to find helpful resources. Of the young adults in the Meyer et al.⁸⁷ study, none were receiving professional help for their difficulties. Such treatment is expensive and often not affordable by the individual, at least in the USA, without insurance or other financial assistance. Many burn survivors do not have insurance either because they are classified as 'uninsurable' or because they cannot afford the premiums. Burn survivors do not always qualify for financial assistance because their 'disabilities' are declared insufficient to require such aid. Even when they can afford such treatment, they may be unable to find a mental health professional to work with them. Mental health professionals who are naïve regarding burn survivors' needs sometimes believe that it is inevitable that scarred survivors will feel depressed and/or anxious; thus, they act as if the survivor (and the helper) cannot expect much in the way of improvement.

As the group of mental health professionals with expertise in burns has increased and psychosocial research has become

more proficient, specific troubles common to many burn survivors have been identified, as enumerated in this chapter. Equally important has been the finding that survivors of even massive burns can achieve potentially satisfying quality of life. Within recent years psychologically based treatment programs with empirically demonstrated efficacy for burned adults and adolescents have been described to treat PTSD,¹¹⁷ acute stress disorder,¹¹⁸ and social skills training for coping with disfigurement.^{119,120} In addition, a number of cognitive-behavioral treatments have been developed and demonstrated to be efficacious for treating or preventing body image dissatisfaction in other populations;¹²¹ and two recent volumes contribute to understanding how disfigurement impacts the individual and the group.^{103,122}

Support groups for burn survivors and their families are ongoing in many burn centers. Additionally, the Phoenix Society, an organization founded by burn survivors for burn survivors, has established a wide-ranging support network for burn survivors and their significant others. A visit to their website¹²³ can be inspiring and informative, providing support, guidance, and accurate information.

Summary

Most burn survivors do eventually adapt well and resume lives of productive activity with satisfactory self-esteem and social

interactions. Empirical data indicate that the first year or so postburn is fraught with discomfort and distress, but much of the difficulty is transient. The process of psychological adaptation continues for several months or even several years. Symptoms of disturbance that linger among burn survivors are likely to be such that only intimate friends and family members will observe them (e.g. nightmares, flashbacks, body image dissatisfaction, social anxiety), so it is valuable for persons with expertise in burn adaptation to periodically assess survivors (especially pediatric survivors who change constantly) to ask about such common symptoms and to provide an opportunity for intervention.

That most burn survivors do amazingly well should never be interpreted as indicative of ease in adaptation. We would never want to diminish the pain and suffering they endure from physical and psychological wounds. As psychotherapists to a large number of burn survivors, we know very well the struggles of survivors. They have moments of true despair and hopelessness, moments of rage, and moments of joy. Probably at some level, burn survivors always feel some sadness about their scars; eventually they attend to other things most of the time and do not obsess over their scars. Fortunate psychotherapists can know them through all extremes – looking for glimmers of hope, validating anger, celebrating victories, and gaining deep respect for resilience of human beings (Figure 66.3).

Fig. 66.3 Color collage. Survivors of severe burn injuries can return to active, interesting, and productive lives in spite of scars and amputations. Recovery is a long and difficult process, challenging the physical and psychological resilience of the individual. Burn care professionals must provide guidance and support to survivors and to their families during the years of recovery. (Reprinted from: Herndon DN, ed. *Total burn care*. London: WB Saunders; 2002.)
