Notice

Medical knowledge is constantly changing. Standard safety precautions must be followed, but as new research and clinical experience broaden our knowledge, changes in treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current product information provided by the manufacturer of each drug to be administered to verify the recommended dose, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on experience and knowledge of the patient, to determine dosages and the best treatment for each individual patient. Neither the Publisher nor the author assume any liability for any injury and/or damage to persons or property arising from this publication.

Preface

With each subsequent edition of *Total Burn Care*, my objective has remained the same: *Total Burn Care* is designed as a text on the management of burned patients, not only for surgeons, anesthesiologists, and residents but also nurses and allied health professionals. This book has served as a sophisticated instruction manual to guide those with less experience through difficult experiences in burn care. Our hope for the future is that through multidisciplinary collaboration, scientists and clinicians will pursue solutions to the perplexing problems that burn survivors must encounter.

Contributions have been selected from a small number of institutions in order to provide a unified approach. We have allowed some repetition of concepts and techniques throughout the text so that each chapter can be self-contained in its discussion of its main topic. Themes covered elsewhere in the literature have been condensed and the bibliographies selected to assure the reader ready access to the expanded literature on current burn care.

New material is added to this book, as with every edition, reflecting the varied physiological, psychological and emotional care of acutely injured burn patients evolving through recovery, rehabilitation, and reintegration back into society and daily life activities. Almost all chapters have been totally rewritten and updated. There are many new chapters and sections in this edition, along with demonstrative color illustrations throughout the book.

The scope of burn treatment extends beyond the preservation of life and function; and the ultimate goal is the return of burn survivors, as full participants, back into their communities.

I would like to express my deep appreciation to many respected colleagues and friends for their contributions to the third edition of *Total Burn Care*. Grateful acknowledgment is given to the many authors whose time and expertise made this book possible, especially to the Shriners Hospitals for Children staff.

Sincere appreciation goes to Tiaá Bourgeois, for her excellent secretarial assistance.

I am grateful to the Elsevier publishing staff for their support and cooperation in maintaining a high standard in the development and preparation of the third edition. I wish to recognize Ms. Sharon Nash, Senior Development Editor who guided this book throughout the development process.

Finally, I would like to thank my wife, Rose, for her invaluable support.

A special thank you to Lewis Milutin, whose photographic skills produced countless of the priceless pictures presented in the book, and to Dr. Juan P. Barret, first Editor of the *Color Atlas of Burn Care*, for allowing us to reprint photos from the Atlas. The following figures were reproduced. (Plates 2.1, 3.8, 3.7, 3.9, 5.7, 5.8, 5.9, 5.10, 7.25, 7.22, 7.21, 6.26, 7.26, 7.20, 7.17, 7.30, 7.31, 7.32, 7.33, 5.38, 7.8, 7.9, 7.10, 7.11, 7.12, 7.13, 7.14, 7.15, 7.16, 7.28, 7.29, 7.27, 7.23, 7.24, 8.10, 8.2, 8.3, 8.4, 8.5, 8.6, 8.7, 7.44, 7.45, 7.35, 7.38, 7.34, 7.37, 7.42, 7.43, 7.41, 8.27, 4.41, 1.2.1.4, 6.13, 4.21, 6.14, 4.30, 4.19, 4.35, 3.8, 4.59, 8.31, 7.35, 4.57, 4.63, 8.39, 9.48, 8.39, 8.42, 6.95, 6.89, 5.39, 5.31, 9.45, 9.46, 1.1.2.2, 1.1.3.3, 1.3.3.1, 1.4.1.4, 1.4.1.5, 1.3.3.2, 1.3.4.4, 1.3.4.4, 1.4.1.6, 1.4.1.7, 3.13a, 3.13b, 3.12, 6.64, 10.12, 10.13, 9.11, 9.10, 10.44, 10.46, 10.28)

Summary	7

The treatment of burns is over 3500 years old with the first direct evidence found in the cave paintings of Neanderthal man. Documentation in the Egyptian Smith papyrus of 1500 BC advocated a salve of resin and honey.¹ In 600 BC, the Chinese used tinctures and extracts from tea leaves. Nearly two hundred years later Hippocrates described the use of rendered pig fat and resin which was impregnated in bulky dressings. This was alternated with warm vinegar soaks augmented with tanning solutions made from oak bark. Celsus, in the first century AD, mentioned the use of wine and myrrh, a lotion probably used for its bacteriostatic properties. Galen, who lived from AD 130–210, used a vinegar and open wound exposure technique.¹ The Arabian physician Rhases recommended the use of cold water for the alleviation of pain associated with burns. Ambroise Paré (AD 1510–1590), who advocated a variety of ointments and poultices from medieval excremental alchemy, effectively treated burns with onions, and described a procedure for early burn wound excision. Guilielmus Fabricius Hildanus, a German surgeon, published *De Combustionibus* in 1607 in which he discussed the pathophysiology of burns and made unique contributions to the treatment of contractures. In 1797, Edward Kentish published an essay describing pressure dressings as a means to relieve burn pain and blisters. Around this same period of time, Marjolin identified squamous cell carcinomas that developed in chronic open burn wounds. In the early 19th century, Dupuytren² reviewed the care of 50 burn patients treated with occlusive dressings and developed a classification of burn depth that remains in use today (Figure 1.1). He was perhaps the first to recognize gastric and duodenal ulceration as a complication of severe burns, a problem that was discussed in more detail by Curling of London in 1842.³

Dr Truman G Blocker Jr demonstrated the value of a multi-disciplinary team approach to burn care and used this team approach on April 16, 1947 when two freighters loaded with ammonium nitrate fertilizer exploded at a dock in Texas City, killing 560 people and injuring more than 3000 (Figure 1.2). Dr Blocker mobilized the University of Texas Medical Branch in Galveston and soon truckloads of casualties began arriving. This ‘Texas City Disaster’ is still known as the deadliest industrial accident in American history. For 9 years, Drs Truman and Virginia Blocker followed more than 800 of these burn patients and published a number of papers and government reports. The Blockers became renowned for their work on burns with both receiving the Harvey Allen Distinguished Service Award from the American Burn Association. He was also recognized for his pioneering research in burns and treating children ‘by cleansing, exposing the burn wounds to air, and feeding them as much as they could tolerate.’ In 1962, his dedication to treating burned children convinced the Shriners of North America to build their first burn institute for children in Galveston, Texas.⁴

Most of the major advances in burn care have occurred within the last six decades. Between 1942 and 1952, shock, sepsis, and multi-organ failure caused a 50% mortality rate in children with burns covering 50% of their total body surface area.⁵ Recently, burn care in children has improved survival such that a greater than 95% total body surface area burn can be survived over 50% of the time.⁶ Improvements have been made in resuscitation, control of infection, support of the hypermetabolic response, nutritional support, prevention of stress ulcers, treatment of major inhalation injuries, early closure and coverage of the burn wound, effective use of anabolic agents, and the multidisciplinary team approach to burn care and rehabilitation.

Andrew M Munster became interested in measuring the quality of life after a severe burn in the 1970s, when excisional surgery and other improvements had led to a dramatic decrease in mortality (Figure 1.3). First published in 1979, his Burn Specific Health Scale became the foundation for most modern studies in burn outcome. The scale has since been improved, updated, and the scales, originally designed for adults, extended to children.

Fluid resuscitation

The foundation leading to our current fluid and electrolyte management began with the studies of Frank P Underhill who, as Professor of Pharmacology and Toxicology at Yale, studied

Fig. 1.1 Dupuytren.

Fig. 1.3 Andrew M Munster.

Fig. 1.2 Truman G Blocker Jr.

Fig. 1.4 Oliver Cope.

20 individuals burned in a 1921 fire at the Rialto Theater.⁷ Underhill found that blister fluid had a composition similar to plasma and could be replicated by a salt solution containing protein. He suggested that burn patient mortality was due to loss of fluid and not, as previously thought, from toxins. In 1944, Lund and Browder estimated burn surface areas and developed diagrams by which physicians could easily draw the burned areas and derive a quantifiable percent describing the surface area burned.⁸ This led to fluid replacement strategies based on surface area burned. Knaysi et al.⁹ proposed a simple 'rule of nines' for evaluating the percentage of body surface area burned. In 1946, Drs Oliver Cope and Francis Moore were able to quantify the amount of fluid required for ade-

quate resuscitation by analyzing young adults who were trapped inside the burning Coconut Grove Nightclub in Boston (Figure 1.4 and Figure 1.5). They postulated that the space between cells was a major recipient of plasma loss, causing swelling in both injured and uninjured tissues in proportion to the burn size.¹⁰ Moore concluded that additional fluid, over that collected from the sheets and measured as evaporative water loss, was needed in the first 8 hours after burn to replace 'third space' loss. He then developed a formula for replacement of fluid based on the percent of the body surface area burned.¹¹ Kyle and Wallace showed the heads of children were relatively larger and the legs relatively shorter than adults and modified the fluid replacement formulas for use in

Fig. 1.5 Francis Moore.

Fig. 1.6 Baxter.

TABLE 1.1			
Formula	Crystalloid volume	Colloid volume	Free water
Evans	mL/kg/% burn normal saline	1.0mL/kg/% burn	2.0 liters
Brooke	1.5 ml/kg/% TBSA lactated Ringer's	0.5 mL/kg/% TBSA burn	2.0 liters
Parkland	4 mL/kg/% TBSA	None	None
Modified Brooke	2 mL/kg/% burn first 24 hours		
Hypertonic (Monafo)	250mEq/L Na ⁺ in volume to maintain urine output @ 30mL/hour		
Warden	Lactated Ringer's + 50 mEq NaHCO ₃ (180 mEq Na ⁺ /L for 8 hours)		
SBH-Galveston	5000 mL/m ² burned + 1500 mL/m ² total	None	None

children.¹² Evans and his colleagues made recommendations relating fluid requirements to body weight and surface area burned.¹³ From their recommendations, normal saline (1.0 mL/kg/% burn) plus colloid (1.0 mL/kg/% burn) along with 2000 mL D5W to cover insensible water losses was infused over the first 24 hours after burn. One year later, Reiss et al presented the Brooke formula¹⁴ which modified the Evans formula by substituting lactated Ringer's for normal saline and decreasing the amount of colloid given. Baxter and Shires developed a formula without colloid, which is now referred to as the Parkland formula (Figure 1.6).¹⁵ This is perhaps the most widely used formula today and recommends; 4 mL of Ringer's lactate/kg/% TBSA (total body surface area) burned/24 hours after burn. All of these formulas advocate giving half of the fluid in the first 8 hours and the other half in the subsequent 16 hours after burn (Table 1.1). The greatest quantity of solute

is given in the first 24 hours after burn. After that, more hypotonic solutions are given to replace evaporative water loss. Baxter and Shires discovered that after cutaneous burn, fluid is not only deposited in the interstitial space but marked intracellular edema also develops. The excess disruption of the sodium–potassium pump activity results in the inability of cells to remove excess fluid. They also showed that protein, given in the first 24 hours after injury, was not necessary and postulated that, if used, it would leak out of the vessels and cause edema to exacerbate. This was later substantiated in studies of burn patients with toxic inhalation injuries.¹⁶

After a severe thermal injury, fluid accumulates in the wound. Unless there is an adequate and early fluid replacement hypovolemic shock will develop. A prolonged systemic inflammatory response to severe burns can lead to multi-organ

dysfunction, sepsis, and even mortality. It has been suggested that for maximum benefit, fluid resuscitation should begin as early as 2 hours after burn.^{17,18} Fluid requirements in children are greater with a concomitant inhalation injury, delayed fluid resuscitation, and larger burns.

Control of infection

Another major advancement in burn care that has decreased mortality is the control of infection. Between 1966–1975, 60–80% of patients with burns over 50% of their total body surface died of bacterial sepsis. With the introduction of efficacious silver-containing topical antimicrobials, burn wound sepsis rapidly decreased. Early excision and coverage further decreased morbidity and mortality from burn wound sepsis. In 1965, Carl Moyer¹⁹ initially used 0.5% silver nitrate soaks as a potent topical antibacterial agent for burn wounds.

Mafenide acetate (Sulfamylon), a drug used by the Germans for treatment of open wounds in World War II, was adapted for treating burns at the Institute of Surgical Research in San Antonio by microbiologist Robert Lindberg and surgeon John Moncrief.²⁰ This antibiotic would penetrate third-degree eschar and was extremely effective against a wide spectrum of pathogens. Simultaneously, Charles Fox²¹ in New York, developed silver sulfadiazine cream (Silvadene), which was almost as efficacious as mafenide acetate cream. While mafenide penetrates the burn eschar quickly, it is a carbonic anhydrase inhibitor which can cause systemic acidosis and compensatory hyperventilation and may lead to pulmonary edema. Because of its success in controlling infection in burns combined with minimal side effects, silver sulfadiazine has become the mainstay of topical antimicrobial therapy. Nystatin in combination with silver sulfadiazine has been used to control *Candida*²² at Shriners Burns Hospital for Children in Galveston, Texas. Mafenide acetate, however, remains useful in treating invasive wound infections.²³

Hypermetabolic response to trauma

Major decreases in mortality have resulted from a better understanding of how to support the hypermetabolic response to severe burns. This response is characterized by an increase in the metabolic rate and peripheral catabolism. The catabolic response was described by Sneve²⁴ as exhaustion and emaciation and he recommended a nourishing diet and exercise. Cope et al.²⁵ quantified the metabolic rate in patients with moderate burns, and Francis Moore²⁶ advocated the maintenance of cell mass by continuous feeding to prevent catabolism after trauma and injury. Over the last 20 years the hypermetabolic response to burn has been shown to cause increased metabolism, negative nitrogen balance, glucose intolerance, and insulin resistance. In 1974, Douglas Wilmore and colleagues²⁷ defined catecholamines as the primary mediator of this response. He showed that catecholamines were 5 to 6-fold elevated after major burns, causing an increase in peripheral lipolysis and catabolism of peripheral protein. Hart et al.²⁸ further showed that the metabolic response rose with increasing burn size, reaching a plateau at a 40% TBSA burn. Bessey, in 1984, demonstrated that the stress response

required not only catecholamines but also cortisol and glucagon. Wilmore et al.²⁹ examined the effect of ambient temperature on the hypermetabolic response to burns and found that burn patients desired an environmental temperature of 33°C and were striving for a core temperature of 38.5°C. Thus, warming the environment from 28° to 33°C decreased the hypermetabolic response substantially, but did not abolish it. Wilmore suggested that the wound itself served as the afferent arm of the hypermetabolic response and its consuming greed for glucose and other nutrients, at the expense of the rest of the body, stimulated the stress response.³⁰ He felt that heat was produced by biochemical inefficiency, later defined by Robert Wolfe,³¹ as futile substrate cycling. Wolfe et al. also demonstrated that burned patients were glucose-intolerant and insulin-resistant³² with an increase in glucose transport to the periphery but a decrease in glucose uptake into the cells.³³

Nutritional support

Shaffer and Coleman advocated high caloric feedings to burn patients as early as 1909 while Wilmore in 1971 supported supranormal feeding with a caloric intake as high as 8000 kcal/day. P William Curreri³⁴ retrospectively looked at a number of burned patients to quantify the amount of calories required to maintain body weight over a period of time (Figure 1.7). In a study of nine adults with 40% TBSA, he found when given a maintenance feeding at 25 kcal/kg plus an additional 40 kcal/% TBSA burned per day, their body weight could be maintained during acute hospitalization. Sutherland³⁵ proposed that children should receive 60 kcal/kg body weight plus 35 kcal/% TBSA burned per day. Herndon et al.³⁶ subsequently showed that supplemental parenteral nutrition increased both

Fig. 1.7 P William Curreri.

immune deficiency and mortality, and recommended continuous enteral feeding as a standard treatment for burns.

Stress ulcers

Nearly 150 years ago, Dupuytren and Curling defined acute gastrointestinal ulcers as major problems after burn. Czaja, McAlhany, and Pruitt³⁷ at the Institute of Surgical Research in San Antonio studied burn patients and found gastric erosions in 86% of all burns over 40% TBSA (Figure 1.8). The incidence of gastric erosion was reduced by scheduling antacids to treat the low pH. This led to the now traditional protocol of measuring gastric pH on an hourly basis and alternating Maalox and/or Amphogel to adjust the gastric pH. This has virtually eliminated gastric ulcers as a problem in patients with a major burn. Continuous enteral feeding also helps maintain the integrity of gut mucosa, decreases bacterial translocation, and minimizes the need for antacids.

Early excision

One of the most effective therapies in decreasing mortality from major thermal injuries has been the early excision of the burn wound and its coverage.³⁸ Jackson and colleagues³⁹ pioneered excision and grafting, beginning in 1954, with burns of 3% TBSA gradually increasing up to burns covering 30% TBSA. Janzekovic,⁴⁰ working alone in Yugoslavia in the 1960s, developed the concept of removing deep second-degree burns by tangential excision with a simple uncalibrated knife (Figure 1.9). She treated 2615 patients with deep second-degree burns by tangential excision of eschars between the third and fifth day after burn and covered the excised wound with autografts which allowed patients to return to work within 2 weeks or so from the time of injury. William Monafo⁴¹ was one of the first

Americans to advocate the use of excision and grafting techniques of larger burns (Figure 1.10). Dr John Burke,⁴² while at Massachusetts General Hospital in Boston, reported an unprecedented survival after massive excision to the level of fascia in children with burns over 80% TBSA and practiced early burn excision throughout the early 1970s and 1980s using a combination of tangential excision for the smaller

Fig. 1.9 Janzekovic.

Fig. 1.8 Pruitt.

Fig. 1.10 William Monafo.

burns (Janzekovic's technique) and excision to the level of fascia for the larger burns (Figure 1.11). He showed a decrease both in length of hospital stay and mortality in massively burned patients. Lauren Engrav et al.⁴³ compared tangential excision versus non-operative treatment in burns of indeterminate depth. Their randomized prospective study, conducted in 1983, showed that deep second-degree burns of <20% TBSA when grafted early, allowed patients to return to work earlier, reduced hospital time, and showed less hypertrophic scarring. Herndon et al.,⁴⁴ in a randomized prospective study, showed a decrease in mortality in massively burned adults with third-degree burns when treated with early excision of the total burn wound as opposed to conservative treatment. He also reported that these massively burned children with 98% TBSA burns have a 50% survival rate.^{45,46}

Skin grafting

Progress in skin grafting techniques has paralleled the developments in wound excision. A Swiss medical student, JI Reverdin, performed reproducible skin grafts⁴⁷ in 1869. The method gained widespread attention throughout Europe, but since the results were extremely variable the method quickly fell into disrepute. JS Davis⁴⁸ resurrected this technique in the United States during the 1930s and reported the use of 'small deep grafts' later known as pinch grafts. Split-thickness skin grafts were accepted during the 1930s due in part to improved and reliable instruments. The Humby knife, developed in 1936, was the first reliable dermatome, but was cumbersome. Padgett and Hood developed an adjustable dermatome which had cosmetic advantages. Padgett⁴⁹ also developed a system for categorizing skin grafts into four types based upon thickness. Tanner and colleagues,⁵⁰ in 1964, revolutionized burn wound grafting with the development of the meshed skin graft and J

Wesley Alexander⁵¹ gave us a simple method of widely expanding autograft skin and then covering it with cadaver skin (Figure 1.12). This has since been the mainstay in the treatment of massively burned individuals. Jack Burke⁵² developed an artificial skin in 1981, which is marketed today as IntegraTM. He first used this artificial skin on very large burns which covered over 80% of the TBSA. David Heimbach led one of the early multicenter randomized clinical trials using IntegraTM.⁵³ The development of tissue cultured grown skin by Bell et al.,⁵⁴ in combination with an artificial dermis, perhaps offers the best opportunity for better outcomes.

Inhalation injury

During the 1950s and 1960s burn wound sepsis, nutrition, kidney dysfunction, wound coverage, and shock were the main focus of burn care specialists.⁵⁵ Over the last 25 years these problems have been clinically treated with more and more success; thus, a greater interest in inhalation injury evolved. A simple classification of inhalation injury separates problems occurring in the first 24 hours after injury, which include upper airway obstruction and edema, from those which manifest after 24 hours. These include pulmonary edema and tracheobronchitis, which can progress to pneumonia, mucosal edema, and airway occlusion due to the formation of airway plugs from mucosal sloughing.^{55,56} The extent of damage from the larynx to tracheobronchial tree depends upon the solubility of the toxic substance and duration of exposure. Nearly 45% of inhalation injuries are limited to the upper airways above the vocal cords while 50% have an injury to the major airways. Less than 5% have a direct parenchymal injury that results in early acute respiratory death.⁵⁵

With the development of objective diagnostic methods the incidence of an inhalation injury in burned patients can now be

Fig. 1.11 John Burke.

Fig. 1.12 J Wesley Alexander.

identified and its complications identified. Xenon-133, scanning was first used in 1972 in the diagnosis of inhalation injury.^{57,58} When this radioisotope method is used in conjunction with a medical history the identification of inhalation injury is quite reliable. The fiberoptic bronchoscope is another diagnostic tool which under topical anesthesia can be used for early diagnosis of inhalation injury.⁵⁹ It also is capable of pulmonary lavage to remove airway plugs and particulate matter.

Shirani, Pruitt, and Mason⁶⁰ reported that smoke inhalation injury and pneumonia, in addition to age and burn size, greatly increased burn mortality. The realization that the physician should not under-resuscitate burn patients with an inhalation injury was emphasized by Navar et al.⁶¹ and Herndon et al.⁶² A major inhalation injury requires 2 mL/kg/% TBSA burn more fluid in the first 24 hours postburn to maintain adequate urine output and organ perfusion. Multicenter studies looking at patients with adult respiratory distress have advocated respiratory support at low peak pressures to reduce the incidence of barotrauma.

The high-frequency oscillating ventilator, advocated by Cioffi⁶³ and Cortiella et al.,⁶⁴ has added the benefit of pressure ventilation at low tidal volumes with rapid inspiratory minute volume which provides a vibration to encourage inspissated sputum to travel up the airways. The use of heparin, N-acetylcysteine, nitric oxide inhalation, and bronchodilator aerosols have been used with some apparent benefit at least in pediatric populations.^{23,65,66}

Inhalation injury still remains one of the most prominent causes of death in thermally injured patients. In children the lethal burn area for a 10% mortality without a concomitant inhalation injury is a 73% total body surface area burn, but with an inhalation injury, the lethal burn size for a 10% mortality rate is a 50% body surface area burn.⁴⁶

Summary

The evolution of burn treatments has been extremely exciting over the last 40 years. It is our hope that the next 10 years will witness the development of an artificial skin which combines the concepts of Burke et al.⁶⁷ with the tissue culture technology described by Bell.⁵⁴ Inhalation injury, however, remains one of the major determinants of mortality in severely burned children and adults. Further improvements in several of smoke inhalation injuries are expected through the development of arterial venous CO₂ removal and extracorporeal membrane oxygenation devices.⁶⁸ Perhaps even lung transplants will fit into the treatment regimen for end-stage pulmonary failure. Our goals continue to strive for a better understanding of the pathophysiology of contractures and hypertrophic scar formation in order to effectively treat scar formation and how to modulate it in a positive manner. Further decreases in burn mortality can be expected; however, continued advances are necessary to understand how to rehabilitate patients and return them to a productive life.

Summary and hopes for the future	12

Major burn injury evokes strong emotional responses in most lay persons and health professionals who are confronted by the spectre of pain, deformity, and potential death associated with significant burns. Severe pain and repeated episodes of sepsis followed by predictable outcomes of either death or a survival encumbered by pronounced disfigurement and disability has been the expected pattern of sequelae to serious burn injury for most of mankind's history.¹ However, these dire consequences have, over time, been ameliorated so that, while burn injury is still intensely painful and sad, the probability of resultant death has been significantly diminished. As illustrated in Table 2.1, during the decade prior to 1951, a 49% mortality rate occurred in young adults (15–43 years of age) with total body surface area (TBSA) burns of 45% or greater.² Forty years later, statistics from the pediatric and adult burn units in Galveston, Texas indicated that the 49% mortality rate accompanied a 70% or greater TBSA for the same age group. In 2006, those mortality figures have improved even more dramatically, so that almost all infants and children, when resuscitated adequately and quickly, can be expected to survive.³ Although improved survival was the primary focus of burn treatment advancement for many decades, that goal has now virtually been accomplished.

Such improvement in forestalling death is a direct result of the maturation of the science of burn care. Scientifically sound analyses of patient data have led to the development of formulas for fluid resuscitation^{4–7} and nutritional support.^{8,9} Clinical research has demonstrated the utility of topical antimicrobials in delaying onset of sepsis, thereby contributing to decreased mortality of burn patients.¹⁰ Prospective randomized clinical trials have determined the efficacy of early surgical therapy in improving survival for many burned patients by decreasing

blood loss and by diminishing the occurrence of sepsis.^{11–16} Basic science and clinical research have contributed to decreased mortality by describing pathophysiology related to inhalation injury and suggesting treatment methods which have decreased the incidence of pulmonary edema and pneumonia.^{17–20} Scientific investigations of the hypermetabolic response to major burn injury have led to improved management of this life-threatening phenomenon, resulting not only in diminished loss of life but also promising improved quality of life.^{21–35}

Melding scientific research with clinical care has been promoted throughout the recent history of burn care, in large part because of the aggregation of burned patients into single purpose units staffed by dedicated healthcare personnel. Dedicated burn units were first established in Great Britain in order to facilitate nursing care.³⁶ The first US burn center was established at the Medical College of Virginia in 1946 followed that same year by the US Army Surgical Research Unit, later renamed the US Army Institute of Surgical Research.³⁶ Directors of both of these centers and later the founders of the Burn Hospitals of Shriners Hospitals for Children emphasized the importance of collaboration between clinical care and basic scientific disciplines.¹ The organizational design of these centers stimulated the formation of a self-perpetuating feedback loop of clinical and basic scientific inquiry.³⁶ Scientists in such a system receive first-hand information about clinical problems while clinicians receive provocative ideas about patient responses to injury from experts of other disciplines. Advances in burn care attest to the value of a dedicated burn unit organized around the concept of a collegial group of basic scientists, clinical researchers, and clinical care givers, all asking questions of each other, sharing observations and information, and together seeking solutions to improve the welfare of their patients (Figure 2.1).

Findings of the group at the Army Surgical Research Institute pointed out the necessity of involving many disciplines in the treatment of patients with major burn injuries and stressed the utility of a team concept.¹ The International Society of Burn Injuries and its journal, *Burns*, and the American Burn Association with its publication, *Journal of Burn Care and Research*, have publicized to widespread audiences the notion of successful multidisciplinary work by burn teams.

Members of a burn team

As illustrated by a perusal of the contents of either of the aforementioned journals and by the contents of this volume, the burn team can include epidemiologists, molecular biolo-

gists, microbiologists, physiologists, biochemists, pharmacists, pathologists, endocrinologists, nutritionists, and numerous other scientific and medical specialists. Burn injury is a complex systemic injury, and the search for improved methods of treatment leads to inquiry from many approaches. Each scientific finding stimulates new questions and potential involvement of additional specialists.

At times, the burn team can be thought of as including the environmental service workers responsible for cleaning the unit, the volunteers who may assist in a variety of ways to provide comfort for patients and families, the hospital administrator, and many others who support the day-to-day operations of a burn center and significantly impact the well-being of patients and staff. The traditional concept of the burn team, however, connotes the multidisciplinary group of direct-care providers. Burn surgeons, nurses, dietitians, and physical and occupational therapists are the skeletal core; most burn units include anesthesiologists, respiratory therapists, pharmacists, and social workers. In recent years, as mortality rates have decreased, interest has intensified in the quality of life for burn

survivors, both acutely in the hospital and for the long term. Consequently, more burn units have added psychologists, psychiatrists, and, more recently, exercise physiologists to their burn-team membership. In pediatric units, child life specialists and school teachers are significant members of the team of care takers as well.

Infrequently mentioned as members of the team, but obviously important in influencing the outcome of treatment, are the patient and the family of the patient. Persons with major burn injuries contribute actively to their own recovery, and each brings individual needs and agendas into the hospital setting which influence the ways in which treatment is provided by the professional care team.³⁷ The patient's family members often become active participants; obviously so in the case of children, but also in the case of adult patients. Family members become conduits of information from the professional staff to the patient; they act, at times, as spokespersons for the patient, and at other times, they become advocates for the staff in encouraging the patient to cooperate with dreaded procedures.

With so many diverse personalities and specialists potentially involved, it may appear absurd to purport to know what or who constitutes a burn team. Yet references to the 'burn team' are plentiful, and there is common agreement on some specialists whose expertise is required for excellent care of significant burn injury.

Surgeons

A burn surgeon is the key figure of the burn team. Either a general surgeon or a plastic surgeon or, perhaps, both with expertise in providing emergency and critical care, as well as the techniques of skin grafting and amputations, provides leadership and guidance for the rest of the team which may include several surgeons. The surgeon's leadership is particularly important during the early phase of patient care when moment-to-moment decisions must be made based on the surgeon's knowledge of the physiologic responses to the injury, the current scientific evidence, and the appropriate medical/surgical treatment. The surgeon must not only possess knowledge and skill in medicine but must also be able to communicate clearly, both receiving and giving information, with a diverse staff of experts in other disciplines. The surgeon cannot alone provide comprehensive care but must be wise enough to know when and how to seek counsel as well as how to give directions clearly and firmly to direct activities surrounding patient care. The senior surgeon of the team is accorded the most authority and control of any member of the team and, thus, bears the responsibility and receives the accolades for the success of the team as a whole.³⁷

Nurses

The nurses of the burn team represent the largest single disciplinary segment of the burn team, providing continuous coordinated care to a patient.³⁶ The nursing staff is responsible for technical management of the 24-hour physical treatment of the patient. As well, they provide emotional support to the patient and patient's family and control the therapeutic milieu

that allows the patient to recover. The nursing staff is often the first to identify changes in the patient's condition and initiate therapeutic interventions.³⁶ Because recovery from a major burn is a rather slow process, burn nurses combine the qualities of sophisticated intensive care nursing with the challenging aspects of psychiatric nursing. Nursing case management can play an important role in burn treatment, extending the coordination of care beyond the hospitalization through the lengthy period of outpatient rehabilitation.

Anesthesiologists

An anesthesiologist who is an expert in the altered physiologic parameters of the burned patient is critical to the survival of the patient, who usually undergoes multiple surgical procedures acutely. Anesthesiologists on the burn team must be familiar with the phases of burn recovery and the physiologic changes to be anticipated as the burn wounds heal.¹ Anesthesiologists play significant roles in facilitating comfort for burned patients, not only in the operating room but also in the painful ordeals of dressing changes, removal of staples, and physical exercise.

Respiratory therapists

Inhalation injury, prolonged bed rest, fluid shifts, and the threat of pneumonia concomitant with burn injury render respiratory therapists essential to the patient's welfare.³⁶ They evaluate pulmonary mechanics, perform therapy to facilitate breathing, and closely monitor the status of the patient's respiratory functioning.

Rehabilitation therapists

Occupational and physical therapists begin at the patient's admission to plan therapeutic interventions to maximize functional recovery. Burned patients require special positioning and splinting, early mobilization, strengthening exercises, endurance activities, and pressure garments to promote healing while controlling scar formation. These therapists must be very creative in designing and applying the appropriate appliances. Knowledge of the timing of application is necessary. In addition, rehabilitation therapists must become expert behavioral managers for their necessary treatments are usually painful to the recovering patient who will resist in a variety of ways. While the patient is angry, protesting loudly, or pleading for mercy, the rehabilitation therapist must persist with aggressive treatment in order to combat quickly forming and very strong scar contractures. The same therapist, however, typically is rewarded with adoration and gratitude from an enabled burn survivor.

Nutritionists

A nutritionist or dietitian monitors daily caloric intake and weight maintenance and recommends dietary interventions to provide optimal nutritional support to combat the hypermetabolic response of burn injury. Caloric intake as well as intake of appropriate vitamins, minerals, and trace elements

must be managed to promote wound healing and facilitate recovery.

Psychosocial experts

Psychiatrists, psychologists, and social workers with expertise in human behavior and psychotherapeutic interventions provide continuous sensitivity in caring for the emotional and mental well-being of patients and their families. These professionals must be knowledgeable about the process of burn recovery as well as human behavior in order to make optimal interventions. They serve as confidants and supports for the patients, families of patients, and on occasion, for other burn team members.³⁸ They often assist colleagues from other disciplines in developing behavioral interventions with problematic patients which allow the colleague and the patient to achieve therapeutic success.³⁹ During initial hospitalization, these experts attend to managing the patient's mental status, pain tolerance, and anxiety level to provide comfort to the patient and also to facilitate physical recovery. As the patient progresses toward rehabilitation, the role of the mental health team becomes more prominent in supporting optimal psychological, social, and physical rehabilitation.

Functioning of a burn team

Gathering together a group of experts from diverse disciplines will not constitute a team.⁴⁰ In fact, the diversity of the disciplines, in addition to individual differences of gender, ethnicity, values, professional experience, and professional status render such teamwork a process fraught with opportunities for disagreements, jealousies, and confusion.⁴¹ The process of working together to accomplish the primary goal, i.e. a burn survivor who returns to a normally functional life, is further complicated by the requirement that the patient and family of the patient collaborate with the professionals. It is not unusual for the patient to attempt to diminish his immediate discomfort by pitting one team member against another or 'splitting' the team. Much as young children will try to manipulate parents by going first to one and then to the other, patients, too, will complain about one staff member to another or assert to one staff member that another staff member allows less demanding rehabilitation exercises or some special privilege.⁴² Time must be devoted to a process of trust-building among the team members. It is imperative that the team communicate — openly and frequently — or the group will lose effectiveness.

The group becomes a team when they have common goals and tasks to be accomplished and when they share, as individual members, overlapping values that will be served by accomplishing their goals.^{43,44} The team becomes an efficient work group through a process of establishing mechanisms of collaboration and cooperation which facilitate focusing on explicit tasks rather than on covert distractions of personal need and interpersonal conflict.^{44,45} Work groups develop best in conditions which allow each individual to feel acknowledged as valuable to the team.^{46,47}

A burn team has defined and shared goals with clear tasks. For the group of burn experts to become an efficient team, skillful leadership that facilitates the development of shared

values among team members and ensures the validation of the members of the team as they accomplish tasks is necessary. The burn team consists of many experts from diverse professional backgrounds; and each profession has its own culture, its own problem-solving approach, and its own language.⁴⁸ For the team to benefit fully from the expertise of the members of the team, every expert voice must be heard and acknowledged. Team members must be willing to learn from each other, eventually developing their own culture and communicating in language that all can understand. Attitudes of superiority and prejudice are most disruptive to the performance of the team.

There will be disagreement and conflict, but these can be expressed and resolved in a respectful manner. Research suggests that intelligent management of emotions is linked with successful team performance in problem solving and in conflict resolution.⁴⁹ When handled well, conflicts and disagreements can result in increased understanding and new perspectives which can, in turn, enhance working relationships⁵⁰ and lead to improved care for the patient.⁵¹

The acknowledged formal leader of the team is the senior surgeon who may find the arduous job of medical and social leadership difficult and perplexing. Empirical studies, with remarkable consistency, indicate that the required functions for successful leadership can be grouped into two somewhat incompatible clusters:

- to direct the group toward tasks and goal attainment; and
- to facilitate the interaction of the group members, enhancing their feelings of worth.^{44,47,51–54}

Task-oriented behavior by the leader may at times clash with the needs of the group for emotional support. During those times, the team may inadvertently impede the successful performance of both the leader and the team as the group seeks alternate means of establishing feelings of self-worth. When the social/emotional needs of the group are not met, the group begins to spend more time attempting to satisfy individual needs and less time pursuing task-related activity.

Studies of group behavior demonstrate that high performance teams are characterized by synergy between task accomplishment and individual need fulfillment.^{44,52} Since one formal leader cannot always attend to task and interpersonal nuances, groups allocate, informally or formally, leadership activities to multiple persons.^{44,45,47,53} The literature in organizational behavior indicates that the most effective leader is one who engages the talents of others and empowers them to utilize their abilities to further the work of the group.^{44,45,53} Failure to empower the informal leaders limits their abilities to contribute fully.

For the identified leader of the burn team, i.e. the senior surgeon, to achieve a successful, efficient burn team, it is

important that the leader be prepared to share leadership with one or more ‘informal’ leaders in such a way that all leadership functions are fulfilled.^{44,45,47,53,55} The prominence and the identity of any one of the informal leaders will change according to situational alteration. The successful formal leader will encourage and support the leadership roles of other members of the team, developing a climate in which the team members are more likely to cooperate and collaborate toward achievement beyond individual capacity.

For many physicians, the concept of sharing leadership and power appears at first to be threatening, for it is the physician, after all, who must ultimately write the orders and be responsible for the patient’s medical needs.⁵⁶ However, sharing power does not mean giving up control.⁵³ The physician shares leadership by seeking information and advice from other team members and empowers them by validating the importance of their expertise in the decision-making process. The physician, however, maintains control of the patient’s care and medical treatment.

Summary and hopes for the future

Centralized care provided in designated burn units has promoted a team approach to both scientific investigation and clinical care which has demonstrably improved the welfare of burn patients. Multidisciplinary efforts are imperative for the continued increase in understanding of and therapeutic responses to the emotional, psychological, and physiologic recovery and rehabilitation of the burned person. Tremendous scientific and technological advances have led to dramatically increased survivability for burn victims.

Our hopes for the future are that by following the same model of collaboration, scientists and clinicians will pursue solutions to the perplexing problems which the burn survivor must encounter. Physical discomforts such as itching still interfere with rehabilitation of the patient. New techniques for controlling hypertrophic scar and for reconstructive surgeries could do much to diminish the resultant disfigurement.⁵⁷ The combined use of anabolic agents^{33,34} and supervised strength and endurance training^{27,28} are currently being investigated as means of enhancing the well-being of survivors of massive burn injury. Further development of psychological expertise within burn care and increased public awareness of the competence of burn survivors may ease the survivor’s transition from incapacitated patient to functional member of society. We hope that burn care in the future will continue to devote the same energy and resources which have resulted in such tremendous advances in saving lives to improving the capacity for preserving optimal quality of life for survivors.

Mass casualties	24
Outcome analysis in burn injury	25

Introduction

In 2001 there were an estimated 157 078 deaths from all injuries and an estimated 29 721 821 persons with non-fatal injuries in the United States which in a total population of 286 400 669 at that time represented an age-adjusted injury death rate of 54.8/100 000 population, and an age-adjusted non-fatal injury rate of 10 378/100 000 population. Data supplied by the CDC National Vital Statistics System indicate that in 2001 there were 3423 (1.2/100 000 population) fatal fire and burn injuries which represented 3.4% of all unintentional fatal injuries. Similarly, data supplied by the National Electronic Injury Surveillance System All Injury Program indicate that in 2001 there were 498 507 non-fatal fire and burn injuries (174/100 000 population) which represented 1.8% of all non-fatal unintentional injuries that occurred that year. There were more fatal fire and burn injuries in men (2056) than in women (1367), but the fatal fire and burn injuries in women represented a greater percentage of all fatal unintentional injuries (3.9% vs. 3.1% for men). Non-fatal fire and burn injury as a percentage of all non-fatal injuries showed essentially no gender difference, i.e. 1.8% for men and 1.9% for women.¹

Unintentional fatal and non-fatal fire and burn injuries represent a variable percentage of all unintentional injuries as related to the population in various age groups. Fire and burn injuries represented 10.3% (1.4/100 000 population) and 3.3% (410.4/100 000 population) of all fatal and non-fatal unintentional injuries respectively in the 0 to 4-year age group, and

12.7% (0.8/100 000 population) and 1.4% (138.9/100 000 population) respectively in the 5 to 9-year age group.

The total number of non-fatal fire and burn injuries in 2001 was greatest in the 25 to 34-year age group, 91 334 (229.4/100 000 population) representing only 2.1% of all unintentional injuries, and the 35 to 44-year age group, 78 968 (174.9/100 000 population) representing only 2% of all unintentional injuries. The highest rate of non-fatal, unintentional fire and burn injury in adults, 274.6/100 000 population, was in the 20 to 24-year age group.¹

The causes of injury in male patients with non-fatal burns were scald/thermal 198 898 (68%), chemical 45 036 (15.3%), electrical 4781 (1.6%), and radiation 39 034 (13.3%), with 6838 (2.3%) unspecified. In that same year, the causes of burns in female patients with non-fatal injuries were scald/thermal 173 205 (76.9%), chemical 25 973 (11.5%), electrical 2405 (1.1%), radiation 16 883 (7.5%), with 6744 (3%) being unspecified. As a percentage of all non-fatal burn injuries in males, scald/thermal injuries were greatest (83%) in the 0 to 14-year age group, chemical injuries were greatest (21.3%) in the 45 to 64-year age group, electric injuries were greatest (3.8%) in the 45 to 64-year age group, and radiation injuries were greatest (19.4%) in the 25 to 34-year age group. In female patients with non-fatal burns, the distribution of scald/thermal injuries appears to be bimodal, with the greatest percentage in the 0 to 14-year and the 65 and above year age groups, i.e. more than 82% in each. In female patients with non-fatal burns the highest percentage of chemical injuries, 13.6%, occurred in the 15 to 19-year age group, electrical injuries, 2.5%, in the 0 to 14-year age group, and radiation injuries, 14.5%, in the 15 to 19-year age group. Fire and burn injuries constitute 10% of all fatal, unintentional injuries in the 0 to 14-year age group, 1% in the 15 to 24-year age group, 3% in the 25 to 64-year age group, and 4% in the 65 and above age group. Fire and burn injuries can also be violence-related, but as such are relatively uncommon and for reporting purposes are grouped indistinguishably with other uncommon causes and are not cited separately.¹

The rank of unintentional fire and burn injury as a cause of fatal and non-fatal injuries varied by both age and sex in the United States in 2001 as indicated in Table 3.1. Only in female patients is burn injury, as 10th, among the 10 leading causes of injury and then only for fatal injuries. The incidence rates of fire and burn injuries for both males and females have progressively decreased over the past two decades.² The incidence rate of fire and burn injuries for males has decreased from

601/100 000 population in 1985 to 276/100 000 in 2000 to 192/100 000 in 2001. The incidence rates for females decreased even more during the same time period, i.e. from 647/100 000 population in 1985 to 284/100 000 in 2000 to 158/100 000 in 2001. In a recent 1-year period, 2000–2001, the incidence rate for all burns decreased from 280/100 000 population to 175/100 000.^{1,2} The magnitude of those changes reported for the one-year period, 2000 to 2001, brings the validity of the data for 2001 into question.

As would be anticipated, the upper limbs, the head and neck, and the lower limbs were the primary body parts most often affected by burns. Forty-five percent of non-fatal burns involve the arm and hand, 25% the head and neck, 16% the leg and foot, 6% the upper trunk, 3% the lower trunk, and 5% other areas. The disposition of patients with unintentional fire and burn injuries seen in emergency departments in 2001 as recorded by the National Center for Injury Prevention and Control was ‘treated and released’ in 480 220 (95.7%) as a reflection of the fact that the vast majority of burns are of very limited extent. In 2001, there were 17 056 (only 3.4%) of the total 501 930 patients with fire and burn injuries seen in Emergency Departments (ED) who were hospitalized or transferred to another treatment facility.¹ That estimate of burn patients admitted to hospitals is approximately one-third of that estimated below because it doesn’t include patients treated in other facilities or admitted without being treated in an ED and because of lack of information on the medical chart.

In 2003 data published as the WISQARS Injury Mortality Report indicate that there were 3875 fire and burn deaths recorded in the United States which represent a crude death rate of 1.33/100 000 population in our total population of 290 810 789 in that year. Fire/burn death rates in individual

states in 2003 ranged from 281 and 267 in Texas and California respectively, to a low of 4 and 1 in Hawaii and Wyoming respectively. The age-adjusted fire and burn death rates in 2003 ranged from 6.14 and 3.23 in Rhode Island and Mississippi respectively, to a low of 0.52 and 0.22/100 000 in Colorado and Wyoming respectively.³

The American Burn Association now maintains the National Burn Repository which contains records of 187 000 patients treated for burn injuries at 70 burn centers in the United States and Canada between January 1991 and 2005. The most recent report from this registry describes the demographics of the population of burns admitted and treated at burn centers in North America during the period 1995–2005 and includes information about associated injuries, site of injury, length of hospital stay, and mortality. The registry data indicate that 70% of the patients were men, and that 63% of the patients were Caucasian, 18% African-American, and 12.4% Hispanic. The 18% registrant rate of African-Americans exceeds by almost 50% the 12.8% African-American segment of the 2004 US population of 294 941 471. The mean age of all burn patients was 33 years with 10% of cases being under 2 years of age, and 14% of cases being 60 years of age or older. The vast majority of burns for which extent was recorded were of limited extent, i.e. 62% involved less than 10% of the total body surface, with 68% of the full-thickness burns involving less than 10% of the total body surface.⁴

The most common etiologies of burn injury were flames and scalds which together accounted for 78.5% of the reported cases. The number of scalds far exceeded the number of flame burns in the 0 to 1.9-year age group and the 2 to 4.9-year age group, but flame burns outnumbered scalds by more than a factor of 2 in all other age groups. Seventy percent of the burns in patients younger than 2 years were caused by scalding and those injuries represented 28% of all scald injuries. Contact with a hot object accounted for 8.1% of burns, chemicals for 3.2% of injuries, and electric current for 4.3% of injuries; 43.2% of the injuries occurred in the home, 8.4% at industrial sites, 16.8% on streets or highways, 4.2% during recreation and sports, 1.8% at schools, and 0.7% on farms. There were an additional 5.7% of burns for whom other rare sites of injury were specified and 19.2% for whom the site was unspecified. Circumstances of injury data indicate that 65% of the burns were sustained in non-work-related accidents, 17% in work-related accidents, 4.9% in recreation accidents, and 5% as a consequence of self-injury, abuse, or assault. Records in which transfer information was reported indicated that 61% of the patients were initially treated elsewhere and then transferred to the reporting hospital.¹

The six surgical procedures most often performed for the registry patients were burn wound excision, skin grafts to other sites, application of wound dressing, venous catheterization, non-excision debridement, and homograft application. Other frequently performed procedures included suture of skin and subcutaneous tissue, insertion of endotracheal tube, arterial catheterization, and application of heterograft skin.¹

Ninety-five percent of the patients entered into the registry survived and were discharged. In the 5% of cases who expired the cause of death was recorded in only 51%, and in 494 cases the cause was listed as ‘treatment withheld.’ The most common cause of death was multiple-organ failure, 32%, followed by

burn shock, 14.6%, trauma wound, 14.2%, pulmonary failure-sepsis, 13.2%, cardiovascular failure, 12.2%, and burn wound sepsis, 4.7%. Inhalation injury was recorded in only 6.5% of burn admissions, but when present length of stay was increased as was mortality reflecting the increased risk of pneumonia and the increased need for ventilatory support.¹

The cost of fire and burn injuries includes both medical costs and the cost of lost productivity. In 2000, total lifetime costs of the 774 376 fire and burn injuries of that year, which included 3922 fatal burns, were 7.546 billion dollars which consisted of medical costs of 1.345 billion dollars and productivity losses of 6.202 billion dollars.²

Epidemiology and demography

Geographic location, presumably because of regional differences in construction and heating devices as well as economic status, influences death rates from house fires. House fire death rates are higher in the Eastern part of the United States, particularly the Southeast, as compared to the West.⁵ There are marked seasonal differences in house fire deaths. From 1991 to 1995, residential fire-related deaths were highest during the cold winter months (December–February) when greatest use is made of heating and lighting devices and lowest in the warm summer months (June–August).⁶ Unattended and/or improperly positioned cooking and heating devices are the leading causes of residential fires.⁷ House fires cause only approximately 4% of burn admissions, but the 12% fatality rate of patients hospitalized for burns sustained in house fires is higher than the 3% fatality rate for patients with burns from other causes. This difference is presumably the effect of associated inhalation injury.^{8,9}

Playing with matches, cigarette lighters, and other ignition devices has been incriminated as the cause of one in ten residential fire deaths.⁵ House fire death rates show little gender prominence except for an increased incidence in males age 2 to 5, a group that has the highest rate of non-fatal burns due to unsupervised play with matches.¹⁰ In fact, among children of 9 years or less, child-play fires are the leading cause of residential fire-related death and injury. Careless smoking, which accounts for one in four residential fire deaths, is the most common cause of such fatalities.² Alcohol and drug intoxication, which contribute to careless smoking behavior by impairing mentation, have been reported to be a factor in 40% of residential fire deaths and appear to contribute to the high weekend frequency of house fires.¹¹ Arson is the second most common cause of residential fire deaths.¹² Defective or inappropriately used heating devices, which are the third most common cause, account for one in six residential fire deaths overall, and an even greater proportion in low-income areas.¹² The effect of low income on fire and burn deaths is also related to residence in older buildings, crowded living conditions, and absence of smoke detectors. Nearly 800 children, age 14 and less, died as a consequence of fire- and burn-related injury in 1996.¹³ Flames and burns were considered to be responsible for one-fourth of all fire-related deaths in children. As a reflection of the effect of economic status, minority children age 0 to 19 are more than three times as likely to die in a residential fire as white children.¹⁴ As income increases, racial differences in house fire death rates decrease.¹⁵

During the 5-year period, 1991 to 1995, the residential fire-related death rate in the United States decreased from 1.3 to 1.1 per 100 000 population.⁶ That change and the further decrease since then has been attributed to the combined effects of improved building design, the use of safer appliances and heating devices, and the increased use of smoke and fire detectors. Data from the Centers for Disease Control Behavioral Risk Factor Surveillance System (BRFSS) indicate that the presence of smoke alarms in households in the United States is high, i.e. more than 78% of households in all 50 states. In 1995, 93.6% of all US households claimed to have at least one smoke alarm.⁶ There are almost half as many fire-related deaths in homes with smoke alarms as compared to homes without those devices.^{16,17}

In 1998, the Centers for Disease Control and Prevention (CDC) formed a collaboration with the US Consumer Product Safety Commission, the United States Fire Administration, and other governmental and non-governmental agencies with a stated goal of eliminating residential fire-related deaths by 2020. As a part of the larger effort, the CDC provides funds to 16 states to participate in the Smoke Alarm Installation and Fire Safety Education Program. That program, which involves installation of smoke alarms and general fire safety education, emphasizes strong partnership with local fire departments and collaboration with target communities selected on the basis of greatest risk for fire-related injury. During the program's lifetime 280 000 homes have been canvassed and over 212 000 smoke alarms have been installed in more than 160 000 high-risk homes. At 6 month follow-up, more than 90% of the alarms were functioning and program evaluation indicates the likely saving of 610 lives as a result of activation of a program alarm.¹⁸

The economic consequences of residential fires are also great. In 1995, property damage and other direct costs attributable to such fires were estimated to exceed four billion dollars.¹⁹ The healthcare costs of burn injuries are also prodigious. Each year in the United States 60 000 to 80 000 people require in-hospital care for burns. The average cost of hospital care of a patient injured by flame and/or smoke inhalation ranges from \$29 560.00 to \$117 506.00 with much higher costs incurred by patients with extensive burns. The length of hospital stay ranges from one day to hundreds of days (mean 8.7) and for patients 80 years and above is more than twice as long as that for children under 5.²⁰ The estimated cost of a fire-related death, which includes the loss of future productivity ranges from \$250 000.00 to 1.5 million dollars.^{21–23}

Unlike fire deaths, the precise number of burn injuries which occur in the United States is unknown. Twenty-one states require that burn injuries be reported, but two require that only burns associated with assaults or arson be reported, and seven require that only larger burns (usually those involving more than 15% of the total body surface area) be reported.²⁴ Consequently, the total number of burns as noted above has to be estimated by extrapolation of data collected in less than one-half of the states to the entire population. Such estimates have ranged from 1.4 million to 2 million injuries due to burns and fires each year.^{5,25} Because of the general improvement in living conditions in the United States, an annual incidence of approximately 1.25 million is considered to be a realistic estimate at the present time.²⁵ The majority of those burns are of limited extent (more than 80% of burns involve less than 20% of the total

TABLE 3.2 AMERICAN BURN ASSOCIATION MAJOR BURN INJURY CRITERIA

1. Second- and third-degree burns greater than 10% of the total body surface area in patients under 10 or over 50 years of age
2. Second- and third-degree burns greater than 20% of the total body surface area in other age groups
3. Significant burns of face, hands, feet, genitalia, or perineum and those that involve skin overlying major joints
4. Third-degree burns greater than 5% of the total body surface area in any age group
5. Inhalation injury
6. Significant electric injury including lightning injury
7. Significant chemical injury
8. Burns with significant preexisting medical disorders that could complicate management, prolong recovery, or affect mortality (e.g. diabetes mellitus, cardiopulmonary disease)
9. Burns with significant concomitant trauma (may require initial treatment in a trauma center)
10. Burn injury in patients who will require special social and emotional or long-term rehabilitative support, including cases of suspected child abuse and neglect

body surface area).²⁵ However, as recently as the 1980s, it was estimated that in the United States 270–300 patients per million population (67 500–75 000) per year sustained burns which, because of extent, associated injury or comorbid conditions required admission to a hospital.²⁷ In light of the overall decrease in the incidence of burns, it is currently estimated that only 170–230 patients per million population (50 592–68 448) will require admission to a hospital annually.^{21,26}

A review of 1994 Pennsylvania statewide hospital discharge data identified 3173 cases with a fire or burn diagnosis for a rate of 263 per million population.²¹ Sixty-eight percent of the patients were males and 70% of the patients were white. Hospital discharge rates showed three distinct peaks, i.e. patients of less than 5 years, patients between 25 and 39 years, and patients 65 years and older. The discharge rate for males was slightly more than twice that of females and the rate for blacks was more than twice that for whites. Scalds and hot substances were the cause of the burn in 58% of the patients. Fire and flame sources accounted for 34% of the burns (clothing ignition 15%, conflagration 12%, and controlled fire 7%). Two percent of the burns were self-inflicted and 2% were the consequence of an assault.

A smaller subset of approximately 20 000–25 000 burn patients with even more severe injuries, as defined by the American Burn Association (Table 3.2), are best cared for in a burn center.²⁸ Those patients consist of 42 per million population with major burns and 40 per million population having lesser burns but a complicating co-factor.²⁷ There are 126 self-designated burn care facilities in the United States, and 14 in Canada which are distributed in close relationship to population density and are reported to contain a total of 1811 and 125 beds respectively (Figure 3.1).²⁹ As described below, the geographic distribution of burn centers necessitates the use of aeromedical transfer by both rotary and fixed wing aircraft to transport patients requiring burn center care to those facilities from distant and remote areas.

In addition to economic status³⁰ and geographic location^{30,31} the risk of being burned and the predominant cause of burn injury are related to age,³² occupation, and participation in recreational activities.³³ Scald burns are the most frequent form of burn injury overall and cause over 100 000 patients to seek treatment in hospital emergency rooms.^{34,35}

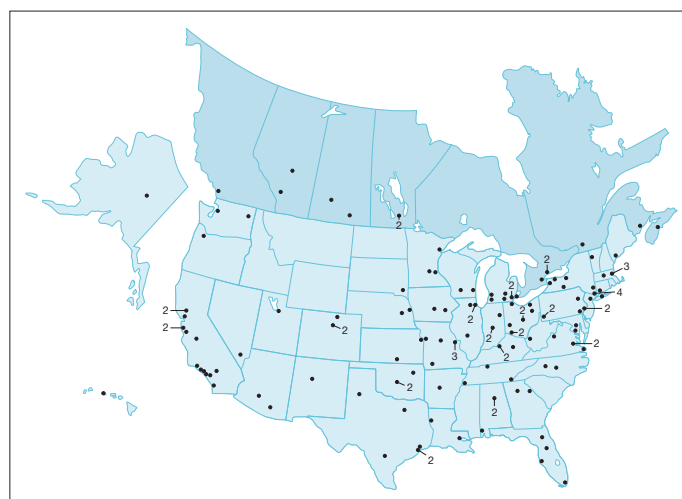

Fig. 3.1 Burn care facilities in North America 2004–2006. The numbers indicate facilities in areas where these are concentrated.

High-risk populations

Children

The number of pediatric burn patients admitted to hospitals is influenced by cultural differences, resource availability, and medical practice. Consequently, the number of pediatric burn patients admitted to a hospital for treatment varies by geographic area from a low rate of 4.4/100 000 population in America (North, Central, and South) to a high of 10.8/100 000 population in Africa. Although the incidence rate for Asia, 8.0/100 000 population, is similar to that for Europe and the Middle East, population size determines that Asia provides care for over one-half of the global pediatric burn population.³⁶

It has been estimated that 83 000 children, ages 14 and under, were treated in hospital emergency rooms in the United States for burn-related injuries in 1997. Of those injuries, 59 000 were thermal burns and 24 000 scald burns.¹³ An average of 16 children with scald burns die each year, and those age 4 and less account for nearly all of those deaths.¹³

Of the children age 4 and under who are hospitalized for burn-related injuries, 65% have scald burns, 20% contact burns, and the remainder flame burns. The majority of scald burns in children, especially those age 6 months to 2 years, are from hot foods and liquids, particularly coffee which may be dispensed at temperatures of up to 180°F (82.2°C), spilled in the kitchen or other places where food is prepared and served.¹³ Hot tap water burns, which typically occur in the bathroom, tend to be more severe and cover a larger portion of the body surface than other scald burns. Consequently, such burns which account for nearly one-fourth of all childhood scald burns are associated with higher hospitalization and death rates than other hot liquid burns.¹³ Ninety-five percent of burns among children due to the operation of microwave devices are scald burns resulting from the spillage of hot liquids or food.¹³

Among children (14 years and less) hair curlers and curling irons, room heaters, ovens and ranges, irons, gasoline, and fireworks are the most common causes of product-related burn injuries.¹³ Nearly two-thirds of electric injuries in children ages 12 and under are caused by household electric cords and extension cords.¹³ Contact with the current in wall outlets causes an additional 14% of such injuries.¹³ Male children are at higher risk of burn-related death and injury than female children, and children ages 4 and under and children with a disability are at the greatest risk of burn-related death and injury, especially from scald and contact burns.¹³ Heavy-for-age boys are more burn prone than their normal-sized counterparts. A recent retrospective study of 372 children admitted to a single burn center from January 1991 through July 1997 confirmed that males who were large for age on the basis of weight or height were over-represented in the burn population.³⁷ Interestingly, that same study indicated that male children at or under the fifth percentile for weight, and male and female children at or under the fifth percentile for height were also over-represented among pediatric burn patients. The authors considered the latter finding to reflect, at least in part, the effect of concomitant malnutrition or neglect.

The occurrence of tap water scalds can be prevented by adjusting the temperature settings on hot water heaters or by installing special faucet valves so that water does not leave the tap at temperatures above 120°F (48.8°C).^{13,38} Thermostatic valves, which shut the hot water off if the cold water fails, are the most dependable.³⁹ The results of a survey in Denmark indicated that the kitchen, not the bathroom, is the most common site of burn injury (39% of burns).⁴⁰ Those burns were most commonly due to contact with hot liquids.

Home exercise treadmills represent a recently identified source of burn injury in pediatric patients. The injuries are a consequence of contact with a moving treadmill, most commonly involved the volar surface of the hand, and in two-thirds of patients required surgical intervention in the form of skin grafting.⁴¹

The elderly

The elderly represent an increasing segment of the population, the members of which have an increased risk of being burned and higher morbidity and mortality rates than younger patients. A recent review of medical records of patients admitted to a

burn center during a 7-year period revealed that 221 of 1557 (11%) admissions were 59 years or older.⁴² Ninety-seven (44%) of that group were women, a reflection of the higher percentage of women in the elderly population. Two-thirds of the injuries were caused by flames or explosions, 20% by scalds, 6% by electricity, 2% by chemicals, and 6% by 'other causes.' Forty-one percent of the injuries occurred in the bedroom and/or living room, 28% out of doors or in the work place, 18% in the kitchen, 8% in the bathroom, and 5% in the garage or basement. Seventy-seven percent of the patients had one or more preexisting medical conditions. Sixty-four patients (29%) had smoke inhalation. In 57% of patients judgment and/or mobility were impaired. Ten percent of patients tested positive for ethanol and 29% for other drugs by toxicology screening. Survival advantage was conferred by younger age, absence of inhalation injury, absence of preexisting medical conditions, and lesser extent of burn. A review of 111 octogenarians admitted to a burn center between 1983 and 1993 revealed that scalds caused 32% of injuries, flames 30%, contact 29%, bath immersion 7%, electricity 2%, and hot oil 1%.⁴³ In 18% a disease such as a stroke was considered to be directly responsible for the burn injury and in an additional 50% of the patients, a preexisting disease was considered to be contributory to the injury event. The average length of stay was almost twice that of younger adults and rehabilitation of survivors was markedly prolonged.

The disabled

The disabled are a group of patients considered to be 'burn-prone.' The majority of burns in the disabled occur at home and are most often scalds. The effects of disability and preexisting disease in those patients are evident in the duration of hospital stay (27.6 days on average) and the death rate (22.2%) associated with the modest average extent of burn (10% of the total body surface area).⁴⁴ A recent report on burn injury in patients, generally elderly patients, with dementia has emphasized the need for prevention measures to reduce the incidence of burn injuries incurred when such patients are performing the activities of daily living.⁴⁵

Military personnel

In wartime military personnel are at high risk for burn injury both combat related and accidental burn injury. The incidence of burn injury, which is related to both the type of weapons employed and the type of combat units engaged, has ranged from 2.3% to as high as 85% of casualties incurred in various periods of conflicts over the past six decades (Table 3.3). The detonation of a nuclear weapon at Hiroshima in 1945 instantaneously generated an estimated maximum of 57700 burn patients and destroyed many treatment facilities which thereby compromised the care of those burn patients.⁴⁶ In the Vietnam conflict, as a consequence of the total air superiority achieved by the US Air Force and the lack of armored fighting vehicle activity, patients with burn injury represented only 4.6% of all patients admitted to Army medical treatment facilities or quarters from 1963 to 1975.⁴⁷ The majority (58%) of the 13047 burn patients treated in those years were non-battle injuries, with only 5536 (42%) being battle injuries. The overall incidence of burns as the cause of injury in all United States mili-

TABLE 3.3 INCIDENCE OF BURN INJURY IN ARMED CONFLICT

Conflict	Casualties

*34% of all casualties from ships.		

tary forces in Vietnam during those years may well have been higher. Allen et al reported that during calendar years 1967 and 1968 a total of 1963 military burn patients from Vietnam were admitted and treated at a burn unit established in a United States Army General Hospital in Japan.⁴⁸ In consonance with the data from US Army hospitals in Vietnam, the burns in 847 (43.2%) of those patients were the result of hostile action. In the Panama police action in late 1989, the low incidence of burn injury (only 6 or 2.3% of the total 259 casualties had burns) has been attributed to the fact that the action involved only infantry and airborne infantry forces using small arms weaponry.

As exemplified by the Israeli conflicts of 1973 and 1982, and the British Army of the Rhine experience in World War II between March 1945 and the end of hostilities in Northwest Europe, the personnel in armored fighting vehicles have been at relatively high risk for burn injury.^{49,50} Burns have also been common injuries in war at sea. In the Falkland Islands campaign of 1982, 34% of all casualties from the British Navy ships were burns.⁵¹ The increased incidence of burn injuries, 10.5% and 8.6% in the Israeli conflicts of 1973 and 1982 respectively as compared to the 4.6% incidence in the 1967 Israeli conflict, is considered to reflect what has been termed 'battlefield saturation with tanks and anti-tank weaponry.'^{43,49,52} The decreased incidence of burn injuries, 8.6% in the 1982 Israeli conflict as compared to the 10.5% in the 1973 Israeli conflict, has been attributed to enforced use of flame retardant garments and the effectiveness of an automatic fire extinguishing system within the Israeli tanks.⁵² Those factors have also been credited with reducing the extent of the burns that did occur. In the 1973 Israeli conflict, 29% of the patients with burns had injuries that involved 40% or more of the total body surface, and only 21% had burns of less than 10% of the body surface. In the 1982 Israeli conflict those same categories of burns represented 18% and 51% respectively of all burn injuries. Modern weaponry may have eliminated the differential incidence of burn injury between armored fighting vehicle

personnel and the personnel of other combat elements. One of every seven and every six casualties had burns in the British and Argentinean forces respectively in the 1982 Falkland Islands conflict in which there was little if any involvement of armored fighting vehicles.^{51,53} Conversely, there were only 36 (7.8%) burn casualties in the total 458 casualties sustained by US Forces in 1990 and 1991 during Operation Desert Shield/Desert Storm in which there was extensive involvement of armored fighting vehicles.

In the current armed conflicts, Operations Iraqi Freedom and Enduring Freedom, the US Army Burn Center has provided care for all of the patients from all branches of the armed forces who has sustained severe burns in the theaters of operation. Surgeons from the Burn Center have provided care at the Center and an Army general hospital in Landstuhl, Germany, at hospitals within the theaters of operation and during aeromedical transfers from the hospital in Europe to the Burn Center in San Antonio, Texas. During the period of March 2003 to May 2004, 109 burn casualties from those conflicts were hospitalized at the Burn Center. Twenty patients (18.3%) had burns of more than 20% of the total body surface and six patients (5.5%) had smoke inhalation injury.

During that same period of time Burn Center flight teams reactivated the Intercontinental Aeromedical Transfer System that had been organized and used effectively in the Vietnam Conflict in the first Gulf War. The teams performed 18 flights to transport 51 war-injured burn patients from the Army hospital in Landstuhl to the Burn Center in San Antonio. Those 18 missions were carried out without a death or life-threatening complication in flight.⁵⁴

Even though the risk of burn injury in the combat population is relatively high, the distribution of burn size in other than armored fighting vehicle personnel is comparable to that in the civilian population, i.e. more than 80% of the patients have burns of less than 20% of the body surface. Even so, the number of burns that can be rapidly generated necessitates that planning for combat casualty care include augmentation of in-theater medical treatment facilities with personnel having burn-specific expertise as was done in Operation Desert Shield/Storm. Changes in both professional staffing and the patient population served at the US Army Burn Center during the period 1 January, 2001 to 1 May, 2006 are reflected in Table 3.4. Lack of on-site pediatrician support forced the Burn Center to cease function as a tertiary referral center for pediatric burn patients and reduce admission of such patients. Conversely military activity, predominantly that in Operation Iraqi Freedom, generated a marked increase in combat-related burns principally as a consequence of the ignition of improvised explosive devices.

Even in peacetime non-combat munitions incidents are common in the US Army. In a recent 7-year period there were 742 noncombat munitions incidents reported in which 894 soldiers were injured.⁵⁵ The most common types of injuries were burns which occurred in 261 or 26.7% of all the patients injured. The high incidence of burn injury in military personnel in both war and peace will generate a subset of extensively burned patients who will require tertiary burn center care to ensure optimum functional outcome and maximum survival.

**TABLE 3.4 ADMISSIONS TO US ARMY INSTITUTE OF SURGICAL RESEARCH BURN CENTER
JANUARY 1, 2001, TO MAY 1, 2006**

Cause of burn	Age groups (years)			Total
	0–15	16–40	>40	
Hot liquids	32	89	69	190
Gasoline, diesel, and kerosene	24	228	151	403
Open flame	7	48	48	103
Structural fires	5	34	68	107
Butane, propane, natural gas explosions	6	60	47	113
Motor vehicle crashes	0	34	18	52
Smoking	0	10	27	37
Bomb, improvised explosive device, gunpowder	1	359	15	375
Contact	4	27	29	60
Electrical or electrical arc	0	60	35	95
Chemical	0	13	11	24
Welding	0	10	9	19
Intentional:				
Self-inflicted	0	8	11	19
Assault	0	8	3	11
Aircraft crashes	0	10	4	14
Train crashes	0	0	2	2
Sunburn	0	2	0	2
TOTAL	79	999	548	1626

Burn etiologies

Burns due to hot liquids may occur in any age group, but 77% of all hot liquid scalds have been reported to occur in children less than 3 years of age. Full-thickness injury is present in less than half of patients with hot water scalds, but present in 58% of patients with hot oil burns. Young children are most commonly injured by their pulling a container of hot water or hot cooking oil onto themselves, while older children and adults are most commonly injured by improper handling of hot oil appliances.^{56–58}

Burns from scalds and contacts with hot materials cause approximately 100 deaths per year.⁵ The case fatality rate of scald injury is low (presumably due to the usually modest extent and limited depth of the burn), but scalds are major causes of morbidity and associated healthcare costs, particularly in children less than 5 years of age and in the elderly. Although deaths from scalds are relatively rare in patients between the ages of 5 and 64, both rates of hospitalization for burn injury and death rates are three times higher for blacks than for Caucasians.⁵⁹

Even though the burns of 30% of all patients requiring admission to a hospital are caused by scalding due to hot liquids,^{60,61} flame is the predominant cause of burns in patients admitted to burn centers, particularly in the adult age group (Table 3.4). The misuse of fuels and flammable liquids is a common cause of burn injury. A recent retrospective review of admissions to one burn center for the multi-year period,

1978 to 1996, identified 1011 (23.3% of 4339 acute admissions) as being gasoline-related.⁶² The average total extent of burn was 30% of the total body surface area with an average 14% full-thickness burn component. One hundred and forty-four of those patients expired. The unsafe use of gasoline was implicated in 87% of patients in whom the cause of the burn could be identified, and in 90 or 63% of the 144 fatalities. The use of gasoline for purposes other than as a motor fuel, and any indoor use of a volatile petroleum product should be discouraged as part of any prevention program. In one epidemiologic study in New York state, the largest number of admissions in the teenage/early adult age group (15–24 years) was related to automobiles. Ignition of fuel following a crash, steam from radiators, and contact with hot engine and exhaust parts were the most frequent causes.⁶¹ In a review of 178 patients who had been burned in an automobile crash, it was noted that slightly more than one-third had other injuries, most commonly involving the musculoskeletal system, and that approximately 1 in 6 had inhalation injury (1 in 3 of those who died).⁶³ A review of patients admitted to a referral burn center revealed that burns sustained while operating a vehicle involved an average of more than 30% of the total body surface and were associated with mechanical injuries (predominantly fractures) much more frequently than those burns incurred in the course of vehicle maintenance activities which involved an average of less than 30% of the total body surface.⁶⁴

Contact burns from motorcycle exhaust pipes are another injury related to the use of vehicles. In Greece the incidence of burns from motorcycle exhaust pipes has been reported to be 17/100 000 person-years, or 208/100 000 motorcycle-years. The highest occurrence was in children. In adults the incidence is 60% higher in females than in males. As would be anticipated, the most frequent location of the burns was on the right leg below the knee where contact with the exhaust pipe occurs. The authors concluded that significant reduction of incidence could be achieved by wearing long pants and the use of an external exhaust pipe shield.^{64,65}

Automotive-related flame burns can also be caused by fires and explosions resulting from 'carburetor-priming' with liquid gasoline; and such burns have been reported to account for 2% to 5% of burn unit admissions.⁶⁶ The burns sustained in boating accidents are also most often flash burns due to an explosion of gasoline or butane and typically affect the face and hands.³³ Bonfire and barbeque burns caused by flash ignition of a flammable liquid which is used to start or accelerate a fire affect those same areas as well as the anterior trunk.⁶⁷

The ignition of clothing is the second leading cause of burn admissions for most ages.⁶¹ The burn injury rate due to the ignition of clothing is influenced by poverty and is inversely related to income. The fatality rate of patients with burns due to the ignition of clothing is second only to that of patients with burns incurred in house fires.⁶¹ Burns caused by ignition of synthetic fabrics which melt and adhere to the skin are commonly deeper than burns caused by other fabrics and typically exhibit a gravity-dependent 'runoff' pattern. More than three-quarters of deaths due to the ignition of clothing occur in patients above the age of 64.⁵ Clothing ignition deaths, which were a frequent cause of death in young girls, have decreased as clothing styles have changed and are now rare among children with little overall gender difference at the present time. From 1975, when it was mandated that sleep wear sizes 0 to 6X successfully pass a standard flame test, until 1999 when that law was repealed, the percentage of clothing burns caused by sleep wear in children age 0–12 decreased from 55 to 27.^{61,68} Sleep wear-related burns are being closely monitored to assess the affect of deregulation of sleep wear garments on sleep wear-related burns.

Work-related burns account for 20–25% of all serious burns. A Bureau of Labor Statistics survey in 1985 indicated that 6% of all work-related thermal burns occurred in adolescent workers (16–19 years).⁶⁹ In a 1986 study in Ohio, it was noted that the majority of hospital-treated burns in the teenage/young adult group occurred on the job.⁷⁰ A study in that same year revealed that 6 out of 10 hospitalized burn injuries in employed men in Massachusetts were work-related.⁷¹ Restaurant-related burns, particularly those due to deep fryers, represent a major and preventable source of occupational burn morbidity, and in restaurants account for 12% of work-related injuries.⁶¹ Almost 700 deaths annually are caused by occupation-related burns.^{72,73}

A recent review of Rhode Island workers compensation claims has identified that the highest claim rate for burn injury was for workers in food service occupations. Evening and night-shift workers were at an increased risk for chemical burn injuries. The overall claim rate for burn injury was 24.3/10 000 workers and ranged from a high of 51/10 000 for workers

younger than 25 years to a low of 16.5/10 000 workers between the ages of 40 and 54.⁷⁴

As would be anticipated, the risk of burn injury due to hot tar is greatest for roofers and paving workers. Of all accidents involving roofers and sheet metal workers, 16% are burns caused by hot bitumen, and 17% of those injuries are of sufficient severity to prevent work for a variable period of time. In the state of California, in 1979, 366 roofers and slaters sustained burn injuries.⁷⁵ The majority of hot tar burns involved the hand and upper limb.⁷⁶ Another occupation associated with an increased risk of burn injury is welding in which flash burns and explosions are the most common injury-producing events.

In the United States in 1988, there were 236 200 patients with chemical injuries of all types treated in emergency rooms. Of those patients, 35 000 or 15% were patients of all ages with chemical burns, and 6500 or 5% were children younger than 5 years with chemical burns. The limited extent of burns due to chemical content is indexed by the fact that only 800, or 2%, of the chemical burns required admission to a hospital. The effect of age (in the very young, removal of the offending agent may be delayed) on the severity of chemical injury is evident in the fact that 400 of the patients requiring admission to a hospital for the care of chemical burn injuries were children younger than 5 years.⁷⁷ The greatest risk of injury due to strong acids occurs in patients who are involved in plating processes and fertilizer manufacture. The greatest risk of injury due to strong alkalis in the work place is associated with soap manufacturing and in the home with the use of oven cleaners. The greatest risk of phenol injuries is associated with the manufacture of dyes, fertilizers, plastics, and explosives. The greatest risk of hydrofluoric acid injury is associated with etching processes, petroleum refining, and air conditioner cleaning. Anhydrous ammonia injury is most common in agricultural workers and cement injury is most common in construction workers. Injury due to petroleum distillates, which cause dilapidation, is greatest in refinery and tank farm workers, while white phosphorus and mustard gas injuries are most frequent in military personnel.⁷⁸

Nearly 1000 deaths are caused annually by electric current. One-third of electric injuries occur in the home and one-quarter occur on farms or industrial sites.⁶¹ The greatest incidence of electric injury caused by household current occurs in young children who insert uninsulated objects into electrical receptacles or bite or suck on electric cords in sockets.²⁷ Low-voltage direct current injury can be caused by contact with automobile battery terminals or by defective or inappropriately used medical equipment such as electric surgical devices,⁷⁹ external pacing devices,⁸⁰ or defibrillators.⁸¹ Although such injuries may involve the full thickness of the skin, they are characteristically of limited extent. Caucasians, apparently because of employment patterns, are almost twice as likely to be injured by high-voltage electric current as are blacks.⁷³ Employees of utility companies, electricians, construction workers (particularly those working with cranes), farm workers moving irrigation pipe, oil field workers, truck drivers, and individuals installing antennae are at greatest risk of work-related high-voltage electric injury.²⁷ The greatest incidence of electric injury occurs during the summer as a reflection of farm irrigation activity, construction work, and work on outdoor

electrical systems and equipment.¹⁰ The current limitation and ineffectiveness of preventive measures is evident in the constancy of occurrence of high voltage injury over the past 20 years. Conversely, the use of ground-fault circuit interrupters and media-promoted awareness have reduced the incidence of low-voltage injuries.⁸²

During the period 1982 to 2002, 263 patients with high-voltage injury, 143 with low-voltage injury, and 17 with lightning injury were treated at a regional burn center. The observed mortality was greatest in the patients with lightning injury, 17.6%, in contrast to 5.3% in patients of high-voltage injury, and 2.8% for patients with low-voltage injury. In the patients with high-voltage injury, 88 required fasciotomy and even so, muscle necrosis occurred in 68 with amputation necessary in 95. Pigmented urine was observed in 96 patients, and renal failure in 7. Arrhythmia was recorded in 38 patients, and cardiac arrest in 2. Neurologic deficit was recorded in 21, cataract formation in 5, and associated fractures were present in 22.⁸² Another recent study reported the outcome of 195 patients with high-voltage electric injury treated at a single burn center during a 19-year period: 187 (95.9%) of the 195 patients survived and were discharged. Fasciotomy was required in the first 24 hours following injury in 56 patients, and 80 patients underwent an amputation because of extensive tissue necrosis. The presence of hemochromogens in the urine predicted the need for amputation with an overall accuracy of 73.3%.⁸³

There are 30 million cloud to ground lightning strikes each year in the United States and each one represents a risk of severe injury and even death. A total of 1318 deaths were caused by lightning in the United States from 1980 through 1995.⁸⁴ Of those who died, 1125 (85%) were male and 896 (68%) were 15 to 44 years of age. The annual death rate from lightning was greatest among patients age 15 to 19 years (6 deaths per 10 million population; crude rate: 3 per 10 million) and is 7 times greater in males than females. The greatest number of deaths caused by lightning, 145 and 91, occurred in Florida and Texas respectively. However, New Mexico, Arizona, Arkansas, and Mississippi had the highest crude death rates of 10, 9, 9, and 9 per 10 000 000 population respectively. Lopez and Holle note that National Oceanic and Atmospheric Administration data identified an average of 93 deaths and 257 injuries caused by lightning occurred each year during the period 1959–1990.⁸⁵ Those authors also cited a study based on national death certificate data for 1968–1985 which reported an average of 107 lightning deaths each year and an annual death rate of 6.1 per 10 million population. Approximately 30% of persons struck by lightning die with the greatest risk of death being in those patients with cranial burns or leg burns. Ninety-two percent of lightning-associated deaths occur during the summer months (May–September) when thunderstorms are most common. Seventy-three percent of deaths occur during the afternoon and early evening when thunderstorms are most likely to occur. Fifty-two percent of patients who died from lightning injury were engaged in outdoor recreational activity such as golfing and fishing and 25% were engaged in work activities when struck. Sixty-three percent of lightning-associated deaths occur within 1 hour of injury. Virtually all lightning injuries and deaths can be prevented by taking appropriate precautions. The recent decrease in

lightning-related deaths appears to be related to a decrease in the farm population, better understanding of the pathophysiology of lightning injury, and improved resuscitation techniques. Analysis of data from the Defense Medical Surveillance System by the US Army and the CDC reveals that the highest lightning-related injury rate occurred in male US military members, stationed near the East Coast or the Gulf of Mexico where lightning occurs frequently, who were subjected to outdoor exposure to thunderstorms. During 1998–2001, 350 service members were injured and one killed by 142 lightning strikes. One-half of the lightning strikes occurred during July and August and three-quarters occurred between May and September; 246 (70.1%) of the lightning injuries involved active duty personnel, with men being 3.3 times more likely to be struck than women. The overall lightning casualty rate for military personnel was 5.8/100 000 person years. Louisiana, Georgia, and Oklahoma had the highest rates of lightning injury, i.e. 39.6, 25.2, and 23.5/100 000 person-years respectively.⁸⁶

Fireworks are another seasonal cause of burn injury. Approximately 10% of patients with fireworks injuries require in-hospital care and approximately 60% of those injuries are burns.⁸⁷ These data can be used to estimate that 1.86 to 5.82 fireworks-related burns per 100 000 persons occurred in the United States during the 4th of July holiday.⁸⁸ Extrapolation of the National Electronic Injury Surveillance System (NEISS) data indicates that 13 263 patients sustained burns in 1992 from fireworks and flares.⁸⁹ Sparklers, firecrackers, and bottle rockets caused the greatest number of burn injuries requiring hospital care.⁹⁰ Nearly 3000 children, ages 14 or less, sustained fireworks-related injuries that required treatment in hospital emergency rooms in 1996.¹³ Burns accounted for approximately 60% of those injuries, and principally involved the hands, head, and eyes. As expected, 75% of such injuries occur in the month surrounding July 4.¹³ Males, especially those age 10 to 14, are at the highest risk for fireworks-related injuries. Children, age 4 and under, are at highest risk for sparkler-related injuries.¹³ A recent report of 7 patients with burns due to snap-cap pyrotechnic devices noted that 6 patients required hospital admission with 4 undergoing split-thickness skin grafting for closure of burns of the leg caused by explosion of multiple devices in one trouser pocket. Proposed prevention measures include reducing the explosive units per package, package warnings, and limiting the sale of the devices to children.⁹¹ At the US Army Institute of Surgical Research Burn Center, only 4 or 0.1%, of 3628 burn patients admitted during a 15-year period had been burned by fireworks.

Burn injury can also be intentional, either self-inflicted or caused by assault. It is estimated that 4% of burns (published range 0.37–14%) are self-inflicted. A retrospective review of 5758 burn patients treated at a regional burn center during a 12-year period identified 51 patients (26 males and 25 females) with a diagnosis of self-inflicted burns.⁹² In 42 patients, in whom the injury was an attempt at suicide, the burn involved from 1% to 84% of the total body surface with an average extent of 22%. Twelve, or 28%, of those patients expired. There were 9 patients in whom the injury was considered a form of self-mutilation. Those injuries typically caused by flames involved 1% to 5% of the total body surface with an average extent of 1.4%. Forty-three percent of all the injuries

occurred at home, and 14 (33%) occurred while the patient was in a psychiatric institution. Seventy-three percent of the patients had a history of psychiatric disease; and these were predominantly affective disorders or schizophrenia in the suicides, and personality disorders in the self-mutilators. Fifty-five percent of the suicides had previously attempted suicide; 66% of the self-mutilators had made at least one previous attempt at self-mutilation. The authors concluded that the very fact of self-burning warranted psychiatric assessment. In a recent study the extent of such injuries was reported to be greater than that of accidental burns with the head and torso more frequently involved than in patients with accidental burns. Consequently the hospital stay was typically longer than that of patients with accidental burns.⁹³ Buddhist ritual burning caused by contact with smoldering incense is a traditional religious form of self-mutilation.⁹⁴ Squyres et al reported their experience in treating 17 people over a 3-year period for self-inflicted burns.⁹⁵ The average extent of burn in those patients was 29.5% of the total body surface; and 59% of them had concomitant inhalation injury. All of those patients had a psychiatric disorder which in 47% of the group, was related to substance abuse. The most frequently employed means of injury was ignition of a flammable liquid.

Assault by burning is most often caused by throwing liquid chemicals at the face of the intended victim or by the ignition of a flammable liquid with which the victim has been doused. Relatively uncommon is the infliction of burn injury by dousing the victim with hot water. Duminy and Hudson have reported their experience with 127 patients who had been intentionally injured with hot water.⁹⁶ The burns in those patients involved from 1 to 45% of the total body surface area with an average extent of 13.7%. The trunk and arms were burned in 116 of the patients, the head and neck in 84, and the legs in 27. The vast majority, 84, had only partial-thickness injuries. Fifty-one of the 94 male patients and 12 of the 33 females had been assaulted by their spouses. In cases of spouse abuse, the face or genitalia are characteristically splashed with chemicals or hot liquids while cases due to abuse or neglect in elderly, disabled, and handicapped adults resemble those in child abuse cases.^{97,98} In India, a common form of spouse abuse is burning by intentional ignition of clothing. When such burns are fatal they have been called 'dowry deaths' since they have been used to establish the widower's eligibility for a new bride and dowry.

Child abuse represents a special form of burn injury most commonly inflicted by parents but also perpetrated by siblings and child care personnel. Child abuse has been associated with teenage parents, mental deficits in either the child or the abuser, illegitimacy, a single parent household, and low socioeconomic status (although child abuse can occur in all economic groups). Abuse is usually inflicted upon children younger than 2 years of age who, in addition to burns, may exhibit signs of poor hygiene, psychological deprivation, and nutritional impairment.⁹⁹ The most common form (approximately one-third of cases) of child abuse thermal injury is caused by cigarettes; such injuries, because of their limited extent, frequently do not require admission to a hospital.¹⁰⁰ Child abuse by burning has also been inflicted by placing a small child in a microwave oven. The burn injuries produced in that manner are typically present on the body parts nearest the microwave

generating element, full thickness in depth and sharply demarcated.¹⁰¹ Child neglect, if not child abuse, is considered to be a factor in burns of the hand, particularly those on the dorsum of the hand, due to contact with a hot clothing iron.¹⁰² Most often scalding causes the burns in abused children who require in-hospital care.¹⁰³ Such injuries are often associated with soft tissue trauma, fractures, and head injury. A distribution typical of child abuse immersion scald burns, i.e. feet, posterior legs, buttocks, and the hands, should heighten one's suspicion of child abuse. The presence of such burns mandates a complete evaluation of the circumstances surrounding the injury and the home situation. The importance of identifying child abuse in the case of a burn injury resides in the fact that if such abuse goes undetected and the child is returned to the abusive environment, there is a high risk of fatality due to repeated abuse. Chester et al. have recently reported that parental neglect is far more prevalent than abuse as a causative factor for burn injury in children. Children with burns that occurred as a consequence of neglect had deeper burns than children with accidental burns and were more apt to require skin grafting for wound closure. Eighty-three percent of the children with burns due to neglect had previously been referred to a child protection agency.¹⁰⁴

Elder abuse can also take the form of burn injury. A congressional report published in 1991 indicated that 2 million older Americans are abused each year, and some estimates claim a 4% to 10% incidence of neglect or abuse of the elderly.¹⁰⁵ A recent retrospective review of 28 patients, 60 years and above, admitted to a single burn center during a calendar year, identified self-neglect in 7, neglect by others in 3, and abuse by others in 1.¹⁰⁶ Adult protective services were required in 2 cases. The authors of that study concluded that abuse was likely to be under-reported because of poor understanding of risk factors and a low index of suspicion on the part of the entire spectrum of healthcare personnel.

Patients may also sustain burns while in the hospital for diagnosis and treatment of other disease.¹⁰⁷ In addition to the electric injuries noted above, chemical burns have been produced by inadvertent application of glacial acetic acid, concentrated silver nitrate, iodine, or phenol solutions, and potassium permanganate crystals. Application of excessively hot soaks or towels or inappropriate use of heat lamps or a heating blanket are other causes of burn injury to patients.¹⁰⁸ Infrared heat lamps are often used in conjunction with acupuncture, but inappropriate intensity of excessive duration of exposure may cause full-thickness skin injury.¹⁰⁹ Much more serious are the burns and inhalation injuries caused by electrocautery or laser devices, explosion of gases (including ignition of flammable material in oxygen), or ignition of the instruments used for endotracheal and endobronchial procedures or anesthetic management.¹¹⁰ Localized high-energy ultrasound may also produce coagulative necrosis as exemplified by full-thickness cutaneous injury and localized subcutaneous fat necrosis of the abdominal wall in a patient who had received focused beam high-intensity ultrasound treatment for uterine fibroids.¹¹¹ A common cause of burn injury, particularly in disoriented hospital or nursing home patients, is the ignition of bed clothes and clothing by a burning cigarette. Smoking should be banned in healthcare facilities, or at least restricted to adequately monitored situations.

A recent retrospective review of 4510 consecutive patients admitted to a burn center between January 1978 and July 1997 identified 54 patients who sustained burns while undergoing medical treatment.¹¹² Twenty-two patients sustained their injuries in a hospital or nursing home, most commonly (12 patients) as a consequence of a fire started by smoking activities. Fifty-eight percent of those patients expired. Another 2 patients were scalded while being bathed in nursing homes and 1 of those patients expired. Thirty-two patients were burned as a consequence of home medical therapy, including 9 vaporizer scald burns, 8 burns caused by ignition in therapeutic oxygen, and 11 caused by inappropriate application of heat. In contrast to other studies, no patients in this series sustained burns from medical lasers.

Burn patient transport and transfer

As noted above, the concordance of burn treatment facility location and population density necessitates that many patients requiring burn center care be transferred from other locations to such institutions. For transfer across short distances and in congested urban areas, ground transportation is frequently more expeditious than aeromedical transfer. Aeromedical transfer is indicated when the patient requires movement from a remote area or when such transfer will materially shorten the time during which the patient is in transit as compared to ground transportation. Helicopters are frequently employed for the aeromedical transfer of patients over distances of less than 200 miles. Vibration, poor lightning, restricted space, and noise make in-flight monitoring and therapeutic interventions difficult, a fact which emphasizes the importance of carefully evaluating the patient and modifying treatment as needed to establish hemodynamic and pulmonary stability prior to undertaking the transfer. When transfer requires movement over greater distances, fixed-wing aircraft are utilized, ideally those in which an oxygen supply is available to support mechanical ventilation. The patient compartment of such an aircraft should be well lighted, permit movement of attending personnel, and have some measure of temperature control.

In general, burned patients travel best in the immediate postburn period as soon as hemodynamic and pulmonary stability have been attained by resuscitation. This avoids the instability caused by infection, secondary hemorrhage, sepsis, or cardiac insufficiency all of which may occur later in the severely burned patient's hospital course.¹¹³ The importance of having an experienced burn physician accompany a patient during aeromedical transfer is indicated by the findings of a study in which the management problems encountered during 124 flights to transfer 148 burn patients were reviewed.¹¹⁴ More than half the patients required therapeutic interventions by the surgeon of the burn team prior to undertaking aeromedical transfer. Such interventions most commonly involved placement or adjustment of a cannula or catheter, modification of fluid therapy, or endotracheal intubation and modification of ventilatory management. In slightly more than one-third of the patients, such interventions were considered necessary to correct physiological instabilities which would have compromised patient safety during the transfer procedure. Six of the 124 patients required an escharotomy to relieve compression

of the chest or a limb caused by a constricting eschar. The therapeutic alterations most commonly needed during the aeromedical transfer procedure itself were changes in fluid therapy, adjustment of a ventilator, and administration of parenteral medications exclusive of analgesics. The medical personnel effecting the burn patient transfer must bring with them all the equipment and supplies needed for pre-flight preparation and in-flight management of the patient.

Physician-to-physician case review to assess the patient's need for and ability to tolerate aeromedical transfer, prompt initiation of the aeromedical transfer mission, examination of the patient in the hospital of origin by a burn surgeon from the receiving hospital and correction of organ dysfunction prior to undertaking aeromedical transfer, and in-flight monitoring by burn experienced personnel ensure both continuity and quality of care during the transport procedure. During the 10-year period 1991–2000, US Army Institute of Surgical Research Burn Care Flight Teams using such a regimen completed 266 helicopter and fixed-wing aeromedical transfer missions to transport 310 burn patients within the continental United States without any in-flight deaths. During the same period, the Institute carried out 12 intercontinental aeromedical transfer missions in which 17 burn patients, were transported with only 1 in-flight death.

Mass casualties

Mass casualty incidents may be caused by forces of nature or by accidental or intentional explosions and conflagrations. Interest in man-made mass casualties has been heightened by recent terrorist activities and the threat of future incidents. The incidence of burn injury in a mass casualty incident varies according to the cause of the incident, the magnitude of the inciting agent, and the site of occurrence (indoors vs. outdoors). The terrorist attacks in which airplanes laden with aviation fuel crashed into the Pentagon and the World Trade Center on September 11, 2001 produced 10 patients and 39 patients respectively with burns requiring treatment at burn centers.^{29,115} The terrorist attack on a nightclub in Bali in 2002 caused an explosion and fire that killed over 200 people and generated 60 burn patients who after triage and emergency care were transported by aircraft to Australia and treated at various hospitals.¹¹⁶ The casualties produced in terrorist attacks often have associated blast injury and mechanical trauma in addition to burns.

Recent non-terrorist mass casualty incidents have been of greater magnitude in terms of numbers of burn casualties. In 1994 an airplane collision caused nearby military personnel to be sprayed with burning aviation fuel. Of the 130 injured soldiers, 43 required transfer to the US Army Burn Center for treatment.¹¹⁷ In The Station nightclub fire in Warwick, Rhode Island in February 2003, 96 people died at the scene and 215 people were injured; 47 of the 64 burned patients evaluated at one academic medical center were admitted for definitive care.¹¹⁸ Lastly, an explosion at a pharmaceutical plant in North Carolina in January 2003 killed 3 and injured more than 30 to an extent that necessitated admission to a hospital. Ten of the injured patients, all with inhalation injury and 6 with associated mechanical trauma, required admission to the regional burn center.¹¹⁹ To deal effectively and efficiently with

a mass casualty situation burn treatment facilities must have an operational and tested mass casualty disaster plan and be prepared to provide burn care to a highly variable number of patients injured in either natural or man-made disasters.

Outcome analysis in burn injury

The importance of extent of injury in determining burn outcome was recognized by Holmes in 1860, and discussions expressing that extent as either a measured area or as anatomical parts of the body surface appeared in the latter 19th and early 20th centuries.¹²⁰⁻¹²² Formal expression of burn size as a percentage of total body surface area, however, awaited the work of Berkow in 1924.¹²³ Though accorded little recognition as such, this single advance in the description of thermal injury, along with the corollary understanding that burn size is a crucial determinant of pathophysiological response, made burns the first form of trauma whose impact could be measured and easily communicated. Techniques based on this understanding produced what were in effect the first trauma indices, making assessment of the relationship between burn size and mortality, direct comparison of populations of burned patients, and rational assessment of therapy possible long before rigorous outcome analysis became feasible for any other form of injury.

The earliest comprehensive statistical technique used for such assessment was univariate probit analysis.^{124,125} This approach, laborious in the days of paper files and rotary calculators, required that the population studied be arbitrarily partitioned into groups which were relatively similar in burn size and age. Such analyses yield equations describing the effect of burn size on mortality which are valid for only the particular age group studied. An early attempt to develop a multivariate evaluation was made by Schwartz, who used probit plane analysis to estimate the relative contributions of partial- and full-thickness burns to mortality. This approach also required arbitrary partitioning of the population.¹²⁶

The advent of computers of suitable power and further development of statistical techniques have reduced the difficulty of analyzing burn mortality, removed the necessity for arbitrary partitioning, and made these techniques much more accessible.¹²⁷ Their use to assess outcome demands understanding of both the techniques themselves and the population being analyzed. The analysis of a population of 8448 patients admitted for burn care to the United States Army Institute of Surgical Research or to its predecessor, the US Army Surgical Research Unit, between January 1, 1950 and December 31, 1991 illustrates the concepts underlying such outcome analysis and depicts the trends in mortality that have been characteristic of most major burn centers in this country.

For validity, an important first step in studies of outcome is to achieve as much uniformity as possible in the population to be analyzed. These patients reached the Institute between the day of injury and postburn day 531 (mean 5.86 days, median 1 day), with burns averaging 31% (range 1-100%, median 26%) of the total body surface. Their age distribution was biphasic, with one peak at 1 year of age and another at age 20; the mean age of the entire population was 26.5 years (range 0-97 years, median 23 years). From this group, 7893

(93.4%) who had flame or scald burns were selected, excluding patients with electric or chemical injuries.

This group included patients who sustained thermal injuries in Vietnam and were first transferred to Japan and then selectively transferred to the Institute. Arriving at the Institute relatively late in their courses, these survivors of temporal cohorts in which some deaths had already occurred exhibited inordinately low mortality. Outcome is inevitably biased toward survival as the postburn time of admission lengthens. To avoid this bias, the analysis focused on the 4870 patients with flame or scald injuries who reached the Institute on or before the second postburn day, excluding later arrivals. Burn size in these patients averaged 34% (range 1-100%, median 29%), and age was again biphasic, with peaks at 1 and 21 years and a mean of 27.1 years (range 0-93 yrs, median 24 years).

One object of the analysis was to evaluate changes in burn mortality during the five decades of experience included in the study. For reliable results, some of the techniques which were used required more subjects than were available in single years; a moving 5-year interval, advancing 1 year at a time, was used to group the data. The number of patients in each of the overlapping 5-year intervals is shown in Figure 3.2. In this and subsequent plots, the data for a 5-year interval are plotted at the first year of the interval, reflecting that year and the succeeding four. The number of admissions meeting the selection criteria was small in the early years of the Institute's experience and rose in somewhat linear fashion during the second and third decades to a sustained plateau of approximately 800 (160/year).

Mean patient age is shown in Figure 3.3. Between 1950 and 1965, most of the admissions were young soldiers; mean age approximated 22.5 years and was relatively stable. During the succeeding decade, this value rose to an irregular plateau centering on 30 years of age, a change reflecting a greater number of civilian emergency admissions and increasing age in the military population.

Figure 3.4 shows the variation in mean burn size during the study interval, and Figure 3.5 shows the roughly parallel mortality. Mean burn size peaked in the two intervals spanning 1969 to 1974 and decreased steadily after that time. Mortality,

Fig. 3.2 Number of patients meeting study criteria. Values are plotted at the first year of each moving 5-year interval.

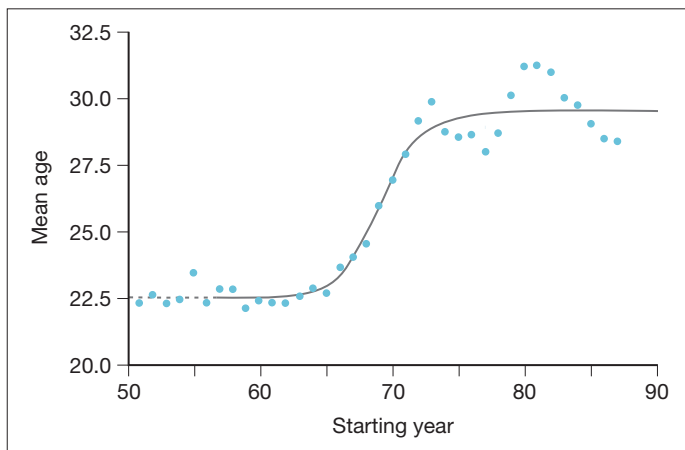

Fig. 3.3 Mean age of study patients.

Fig. 3.4 Mean burn size in study patients.

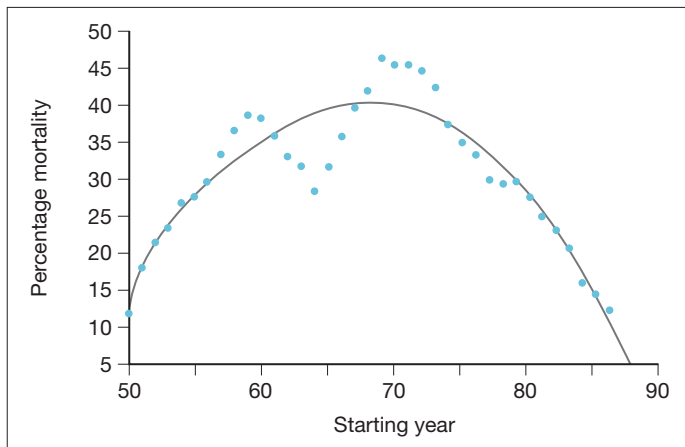

Fig. 3.5 Percent mortality in study patients in each moving 5-year interval.

principally due to burn wound sepsis, peaked at 46% during those years. The two data sets are shown together in Figure 3.6 and suggest a crude index of the results of burn care in this population. There were two intervals in which percent mortality exceeded mean percent burn. The first occurred in the late 1950s and early 1960s, a time when burn wound sepsis

due to *Pseudomonas aeruginosa* was uncontrolled. This was succeeded by a 6-year interval of good control of wound infection following the introduction of topical wound treatment with mafenide. In turn, this was followed by a second interval of poor control in the late 1960s and early 1970s, during which both *Pseudomonas* and a mafenide-resistant *Providencia stuartii* were major causes of sepsis; this endemic was controlled by the mid-1970s following changes in topical treatment and wound management.

Raw percent mortality, even in conjunction with burn size, is never an adequate index of the effectiveness of treatment, since the frequency of death after burn injury is also determined by prior patient condition, age, inhalation injury, and the occurrence of pneumonia and burn wound sepsis. Each of these elements, except for prior condition, can be addressed in analysis, but only burn size, age, and the presence or absence of inhalation injury are known at the time of admission. In the studied group, burn size and age were available for every patient, but data on inhalation injury were missing for patients admitted in the earlier years; we elected to use burn size and age for analysis. This choice does not exclude the impact of the complications, but does confound that impact with those of burn size and age.

For a uniform population of specific age, a plot of the relationship between burn size and percent mortality is S-shaped, or sigmoid — small burns produce relatively few deaths, but as burn size increases mortality rises steeply and then plateaus as it approaches its maximum of 100%. Figure 3.7 illustrates this dose–response relationship for 50-year-old patients admitted to the Institute between 1987 and 1991. Such curves are mathematically intractable and are usually transformed to more easily managed straight lines for analysis. Several mathematical transformations have been used to accomplish this. As previously noted, the one used in early analyses was probit transformation; in the present study, a logistic transformation, illustrated in Figure 3.8, was used. The choice between these is one of convenience as either yields essentially the same information.^{128,129}

The locations of a sequence of such curves for groups of patients of increasing age move first to the right (toward larger burn size) as age increases from infancy to young adulthood,

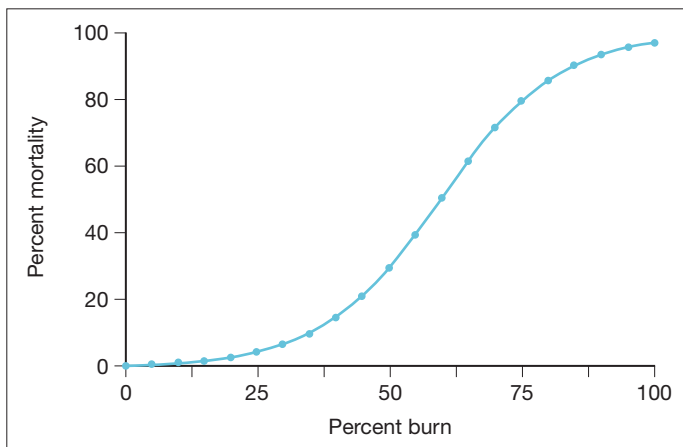

Fig. 3.7 Effect of burn size on percent mortality.

Fig. 3.9 Effect of age on mortality. Effect is minimal at age 21. Note that horizontal intersects share a common effect.

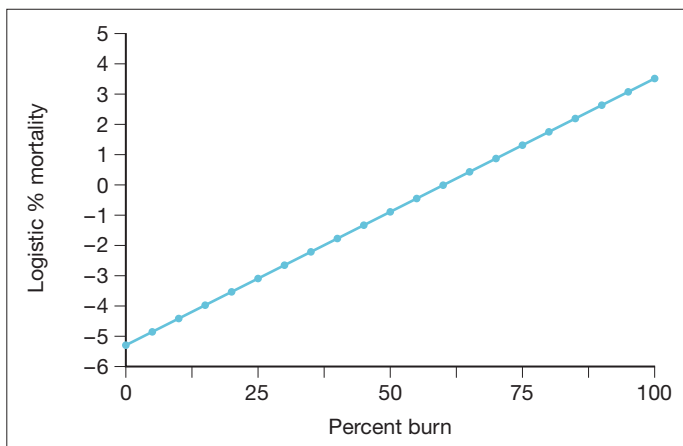

Fig. 3.8 Logistic transformation of ordinate of Figure 3.6.

and then to the left, passing through the infant location at around age 45 and continuing inexorably leftward with increasing age. These differing locations reflect the greater risk of burn mortality at the extremes of age. The cubic curve in Figure 3.9 describes this curvilinear effect of age on mortality; the effect was least at age 21. In this population, the age function was relatively stable over the entire interval of study.¹³⁰ As we have noted, earlier analyses began by dividing the studied population into arbitrary age and burn size groups; probit analysis of the relationship between burn size and percent mortality in each age group then permitted estimation of the LD₅₀, the burn size lethal to half the selected age group. To accommodate both age and burn size simultaneously, without arbitrary partitioning of the population, multiple logistic regression was used in this study, with each member of the population entering the analysis as an individual data point.

The result of this three-dimensional form of analysis is most readily visualized as a plane lying within a cube. Figure 3.10 shows the sigmoid response of mortality to burn size for three discrete ages, and Figure 3.11 shows the curvilinear variation of mortality with age in patients entering this study between 1987 and 1991. A best-fitting plane which covers the tips of

Fig. 3.10 Effect of burn size on percent mortality at three discrete ages (1987–1991).

spikes representing all of the burn sizes and ages of interest is generated by the multiple logistic technique, and it is illustrated for these particular patients in Figure 3.12.

The equation representing this plane is of the form shown below, in which L is the natural logarithm of the odds of mortality and P the expected fractional mortality rate:

$$L = a_1 + a_2(\% \text{ burn}) - a_3(\text{age}) + a_4\left(\frac{\text{age}}{100}\right) - a_5\left(\frac{\text{age}}{1000}\right)$$

$$P = \frac{\exp^L}{1 + \exp^L}$$

The advantage of this approach, as opposed to previously used age and burn size partitioned analyses, is that it permits analysis of an entire population without artificial segmentation, and

Fig. 3.11 Effect of age on percent mortality at three discrete burn sizes (1987–1991).

Fig. 3.12 Plane of percent mortality with age and burn size coordinates (1987–1991).

allows an explicit estimation of expected mortality for each member of the population. Serial applications of the technique were used to assess mortality in each of the moving 5-year intervals of the study.

Figure 3.13 reflects the changes in LD_{50} which were experienced by young adult patients during the five decades of the study. This value, indexing the mean likelihood of survival after burn injury, began to increase in the mid-1970s in all age groups. Many aspects of care changed and improved during the five decades of this study:

- early resuscitation became more widely understood and better practiced;

Fig. 3.13 LD_{50} in moving 5-year intervals in patients 21 years of age. Increasing values indicates improving prognosis.

- the clinical facility was remodeled to permit single bed isolation;
- topical chemotherapy with alternating applications of mafenide acetate and silver sulfadiazine, coupled with the use of a chlorhexidine-based wash solution (Hibiclens), permitted better control of wound infection;
- early wound excision came to be more generally practiced;
- better infection control techniques limited cross contamination of wounds;
- new antibiotics, more effective against Gram-negative organisms, became available;
- inhalation injury and other pulmonary problems became better understood and are now managed with better equipment;
- improved grafting techniques and the use of biological dressings facilitated earlier coverage of large wounds.

In essence, we have learned, through integrated clinical and laboratory research, how to apply ordinary principles of trauma and wound care to this extraordinary injury. No single innovation produced a ‘step’ improvement in mortality, but the aggregate effect has been improved survival.

This improvement is reflected in Figures 3.14 and 3.15, which depict early (1950–1963) and recent (1987–1991) mortality planes, respectively. The improvement is not uniform for all burn sizes or ages, nor would one expect this to be so. Small burns have never been lethal, except at the extremes of age; little improvement in survival could occur with such injuries. At the other extreme, very large burns in older patients have always been lethal and remain so. To define the age and burn size coordinates of the improvement in survival, one subtracts one mortality plane from the other; the result is itself a plane depicting the difference in mortality in age and burn size coordinates (Figure 3.16). The greatest differences occurred in the area of the LD_{80} of the 1950–1963 mortality plane.

In the interval between 1992 and 2002, 2970 additional patients were admitted. Among these, 2430 (82%) had sustained thermal injuries, and 1961 were admitted on or before the second postburn day. Mortality in these patients did not differ significantly from that observed between 1987 and 1991.

Fig. 3.14 Mortality plane for patients admitted between 1950 and 1963. Note location of contour lines in base of cube.

Fig. 3.15 Mortality plane for patients admitted between 1987 and 1991. Note contour locations.

Logistic regression permits simple assessment of the odds ratio for mortality between the individual years and the last year of this span, with appropriate adjustment for age and burn size. Figure 3.17 depicts this ratio, which indexes the effect on mortality of everything beyond burn size and age. Peaks occurred when sepsis was uncontrolled. The lower ratios beyond 1975 reflect the additive effects of changes in treatment, environment, and infection control. No significant differences in the ratio have occurred during the 16 years between 1987 and 2002.

Though this experience conforms with that of most burn centers in the United States, it should be noted that there are still many areas of the world where the survival of patients with burns of more than 40% of the total body surface is rare. Among the patients meeting the present study criteria between 1950 and 2002, 1591 (23%) died. Had the mortality experienced since 1987 prevailed through the whole interval, only a bit more than half this number would have succumbed to their injuries. Mortality now is less than half that characterizing the first decade of the Institute's experience.

Fig. 3.16 Plane of differences in percent mortality between 1950–1963 and 1987–1991. Note location of peak.

Fig. 3.17 Odds ratio of death between individual years and 2002, adjusted for burn size and age.

Fig. 3.18 Estimated age/burn size distribution of 70 000 annual hospital admissions.

As previously noted, estimates of the annual total number of burns in the United States, for which there is little reliable information, range as high as 2 000 000. A more reliable but still imperfect estimate is that between 50 000 and 70 000 acutely burned patients are admitted to hospitals in the United States each year. Figure 3.18 is based on composite data from several sources and depicts an estimate of the age and burn size distribution of these patients. Using the Institute's mortality experience between 1987 and 2002 as a basis for projecting expected mortality yields the data shown in Figure 3.19, which depicts the age and burn size distribution of the expected deaths.

According to this model, patients over 50 years of age with burns of 50% or less of the total body surface account for 19%

Fig. 3.19 Estimated age and burn size distribution of expected deaths among patients depicted in Figure 3.18.

of admissions and 50% of deaths; at the other age extreme, children under 5 account for 19% of admissions but only 12.5% of deaths.

Much has been accomplished in acute burn care during the last half century, and further improvement in outcome will probably occur as inhalation injury and pneumonia come under better control and new wound coverage techniques are developed, but such improvement will be harder won and smaller in magnitude. Preservation of function, reconstruction, and rehabilitation, areas which have received less attention in the past, appear the more likely primary targets of future burn research and may be expected to materially enhance the quality of life for burn survivors.

Burn intervention strategy	35
Evaluating the effect of burn prevention	39

Introduction

The word ‘prevent’ comes from the Latin word ‘praevenire,’ which means to anticipate. The prefix ‘pre’ means before and ‘venire’ means to come. During the last century in the United States, burn treatment had always come before burn prevention. Since burns then as now, represent such a small percent of all traumatic injuries, burn prevention has not been viewed as a high priority health issue by a large portion of society.

Burns are still referred to as accidents by many in the medical community and society in general.¹ Believing that burns and other traumatic injuries are ‘accidents’ (‘accident-prone’ individual) implies the individual has little or no fault in the injury cause. The word ‘accident’ means an event that takes place without one’s foresight or proceeds from an unknown cause, an unfortunate occurrence, or mishap, especially one resulting in an injury. Synonyms include misadventure, mischance, misfortune, mishap, and disaster. The word ‘injury’ is a more appropriate term. It is derived from the Latin word ‘juris’ which means not right. An injury represents damage that occurs as a result of an exposure to a physical or chemical agent at a rate greater than what the body can tolerate. Unfortunately the designation of traumatic injuries as accidents is still perpetrated in the E codes which are the supplementary classification of external causes of injury. An example is E893, Accident caused by ignition of clothing, or E898.1, Accident caused by other, burning by: candle, cigar, pipe or cigarette.

Historical perspective

The medical community in Great Britain in the first decade of the 20th century was well aware that burn injuries and deaths represented a serious public health issue.² Scalds and burns

were noted to occur predominately in children. Unguarded fires and the flammability of flannelette, a cotton garment, were recognized as common causes of burns in children and old women. Legislation was enacted making parents liable to a fine if a child younger than 8 years was injured or died as a result of an unguarded open fire. In a review of over 3600 patients with flame burns and scalds, two-thirds occurred in and around the home, one-third were at work, 50% were children, 82% were the result of clothing fires, cottons were the common fabrics and the number of scalds about equaled that from burns, but the former were more likely to survive.³ Approximately 50% of home accidents were judged to be preventable. Research was conducted on the design and flammability of clothing. Fabrics were treated with tin, antimony, and titanium to make them relatively flame-retardant. Statistics on common locations and causes for home ‘accidents’ identified the kitchen and cooking, scald burns from children pulling over containers with hot liquids, and the use of flammable liquids. Burns as a result of a seizure were recognized. Prevention efforts included education and ‘propaganda’ (film, radio, newspapers, exhibits, and posters), better design of housing and improving living conditions (decreasing overcrowding), safer methods of heating houses (central heating and electric fires), use of non-flammable materials in girls and women clothing, and better design of fireguards for coal fires. Better design of teapots, cups, and cooking utensils rendered them more difficult to tilt over. One author in 1946 expressed quite clearly that carelessness, neglect of normal precautions, and stupidity were human factors associated with burns.⁴ It was recognized that accurate and comprehensive burn data were lacking, but necessary if long-term prevention policies were to be enacted.

Injury control

The five key areas in injury control are:

1. epidemiology,
2. prevention,
3. injury biomechanics (physical and functional responses of the victim to the energy),
4. treatment,
5. rehabilitation.⁵

The major components of epidemiology include measurement of both the frequency and distribution of the injury. This in turn is analyzed and interpreted. Next, risk factors are identified, an intervention strategy is developed and tested, and, lastly, the results analyzed.

Burn injury magnitude

The first step in any prevention program is to identify the how, who, where, and when of the injury. With this information strategic planning and implementation can be directed at reducing the risk of injury or death. In the US in 1995 the leading causes of injury deaths in their order of magnitude were motor vehicle, firearm, poisoning, fall, suffocation, drowning, and finally fire/burn.⁶ In 2003 fire/burns still ranked 6th behind motor vehicle, falls, poisoning, choking, and drowning as leading causes of unintentional injury deaths.⁷ Fires, flames, and smoke were the 5th leading causes of fatal injury in the home. In 1996 the number of fire deaths and injuries were 4990 and 25 550 respectively. On average in the United States in 2003, a fire death occurred about every 2 hours, and someone was injured every 29 minutes.⁸ Smoke inhalation accounted for the majority of fatalities in home fires. In 2001 there were 3423 and 498 507 fire deaths and injuries respectively in the US.⁹ This represented 3.4% and 1.8% of all fatal and non-fatal injuries reported. The rate of fatal and non-fatal fire injuries was 1.2 and 178 per 100 000 populations. In 2002 there were 3363 deaths, a decrease of less than 2%. The number of fire deaths increased progressively with age and peaked at 720 over 75. The number of non-fatal injuries (almost 79 000) was greatest between ages 35 to 44. Males were 1.6 times more likely to die in a fire. Populations in the lowest income levels had a greater risk of dying in a fire than people in higher income brackets. Eighty-six percent of fatalities involved a single fatality, 10% two fatalities and 4% greater than two. Seventy-four percent of fatal fires occurred in any type of structure, and 94% in residential structures or cars. The leading causes of fatal fires in residential property were incendiary/suspicious 27%, smoking 18%, and open flame 16%. The leading areas of fire origin in fatal residential structures were sleeping areas 29%, lounge 21%, and kitchen 15%. Fatal fires were more common in the winter. The time of day when most structure fires occurred was between 10 a.m. and 8 p.m.

It is well recognized that many burns treated in emergency departments are never admitted to the hospital. The National Hospital Ambulatory Medical Survey identified 516 victims of fire, flame or hot substances per 100 000 emergency room visits in 2003.¹⁰ While most of these were not life-threatening, nonetheless most were probably preventable. Unfortunately most prevention efforts are not directed at these victims. This group is worthy of future prevention efforts.

Risk factors

A number of factors must be considered when determining the fire risk to the host. Age, location, demographics, and low economic status represent important factors. The US Fire Administration expresses much of its fire data as relative risk (RR).⁹ A common way to express fire deaths across different populations is to determine the RR of dying or being injured. The RR of a group (say death) is calculated by comparing its rate to the rate of the overall population. A RR of 1 is given to the general population. As a general rule of thumb, many statisticians consider a relative risk of 4 or more as important. If an RR of 4 or greater is used to identify high-risk burn populations, then based on 2001 data, prevention programs should have been

directed at everyone over 85 years (RR 4.6), African-Americans (RR 6.9), and American-Indian males (RR 5.3). The RR of fire deaths in 2001 for all ages, with the exception of 0–4 years and over age 55, was less than 1. The use of RR in injury prevention may well be important when resources are limited.

In 2001 for ages 0–14 there were 599 fire deaths and 2926 fire injuries: 53.4% and 48.5% of deaths and injuries occurred in children less than 5 years. The RR of fire death for children less than 5 years was 1.2, 0.6 for ages 5 to 9, and 0.3 for 10 to 14 years.⁹ The activities of children at the time of a fire injury were asleep (55%), trying to escape (26%), and unable to act, implying not understanding what was happening or how to take action (9%).

Analysis of fatal pediatric (less than 15 years) fires in Philadelphia, age of housing, income, single-parent households, and the number of children under age 15 were significant independent variables.¹¹ Of note the risk was greatest between 12:00 a.m. and 6:00 a.m. The common causes were playing with matches, smoking, and incendiary. The common locations were bedroom and living room. Upholstered furniture, cooking materials, bedding, mattresses, clothing, and curtains were primary materials first ignited in fatal fires. Playing with cigarette lighters, candles or near stoves with hot liquids were frequent scenarios in fatal pediatric burns. The authors stressed that identification of risk factors by analyzing population characteristics by census tract was important for burn prevention.

The 50 and older population from 2000–2050 will grow at a rate 68 times faster than the rate of growth for the total population. The number of people 65 and over is projected to rise from 13% of the total population in 2010 to nearly 20% in 2030. The elderly (over 64 years) obviously represent a high-risk group. In 2001 more than 30% of all fire deaths were in this group.¹² Their risk of dying in a fire was 2.5 times greater than the general population. The leading causes of both fire death and injuries were smoking and cooking. Additional risks included medical conditions associated with physical or mental illness – arthritis and stroke, i.e. the victim is slow or unable to escape the burn event, poor eyesight and hearing, systemic diseases such as diabetes (peripheral neuropathy with decreased or no lower extremity pain perception), Alzheimer's disease (confusion, forgetfulness), psychiatric illness (depression and suicide). Other risk factors in teenagers and adults are alcohol, and medications such as sleeping pills, tranquilizers, narcotics, and synthetic stimulant drugs such as methamphetamines.

Burn prevention involves more than just the burn community. Fire safety engineers and legislators (building code laws) and building inspectors have a vested interest in prevention. An important aspect of fire prevention is the design of fire safe buildings.¹³ To do this both fire and personal characteristics associated with the greatest risks must be identified. These included the ignition factor (misuse of ignited material by children), type of material ignited (sofas, chairs, and bedding) and form of heat of ignition (electrical equipment, matches, lighters, cigarettes); personal factors were condition preventing escape, condition before injury, activity at time of injury, and location of ignition (in room of fire origin, and floor of fire origin).

Burn prevention is a worldwide problem. The United States has one of the highest fire death rates among industrialized countries. It is important to recognize worldwide prevention

efforts.^{14,15} The World Health Organization (WHO) reported that globally burns accounted for 238 000 deaths in 2000. Burns ranked among the 15 leading causes of death in children and young adults (5–29 years). Obviously these figures are suspect, and intuitively appear under-representations. Risk factors included cooking at floor level, open kerosene stoves, high population density, poor house construction, illiteracy, and local cultural practices (homicide by burning). Prevention programs proposed by WHO include raising or enclosing cooking areas, electrification to reduce dependency on candles and kerosene, safe stove design, improved house construction, and obviously installation of smoke detectors.

Injury prevention comes of age

The science of injury prevention took form in the middle of the last century. The energy sources involved in any injury event are classified into five physical agents: kinetic or mechanical, chemical, thermal, electrical, and radiation.¹⁶ A common form of mechanical energy associated with a burn is a motor vehicle collision. Three risk factors associated with any injury are:

1. the vector or energy source and the way it is delivered,
2. the host or injured person, and
3. the environment, both physical and social.

A seminal article in modern injury science was published by Haddon in 1968.¹⁷ He identified three phases of an injury event:

1. Pre-event: preventing the causative agent from reaching the susceptible host.
2. Event: includes transfer of the energy to the victim. Prevention efforts in this phase operate to reduce or completely prevent the injury.
3. Post-event: determines the outcome once the injury has occurred. This includes anything that limits ongoing damage or repairs the damage. This phase determines the ultimate outcome.

Haddon then created a matrix of nine cells which enabled the three events of the injury to be analyzed against the factors related to the host, agent or vector and environment¹⁸ (Table 4.1). This matrix is a very useful tool for analyzing an injury-producing event and recognizing the factor(s) important in its prevention. Haddon also proposed 10 general strategies for injury control (Table 4.2). Risk factors and potential intervention strategies can be identified.

Burn intervention strategy

The emergence of the science of prevention has turned attention away from individual ‘blame’ and the attitude that society

TABLE 4.1 THE HADDON MATRIX FOR BURN CONTROL

	Agent or vector	Host	Environment	
			Physical	Social
Pre-event	Fire-safe cigarette	Control seizure	Non-slip tub surface	Legislation – factory preset water heater thermostats
Event	Sprinklers, smoke detectors	Flame-retardant cloths	Fire escapes	Fire drill education
Post-event	Water	First aid antibiotics	EMS	Emergency and rehabilitation services

Matrix adapted from Haddon W, Advances in the epidemiology of injuries as a basis for public policy. Public Health Reports 1980; 95:411–421.¹⁸

TABLE 4.2 GENERAL STRATEGIES FOR BURN CONTROL

Prevent creation of the hazard (stop producing fire crackers)
Reduce amount of hazard (decrease chemical concentration in commercial products)
Prevent release of the hazard (child-resistant butane lighters)
Modify rate or spatial distribution of the hazard (vapor-ignition resistant water heaters)
Separate release of the hazard in time or space (small spouts for hot water faucet)
Place barrier between the hazard and the host (install fence around electrical transformers, fire screen)
Modify nature of the hazard (use low conductors of heat)
Increase resistance of host to hazard (treat seizure disorder)
Begin to counter damage already done by hazard (first aid, rapid transport and resuscitation)
Stabilization, repair rehabilitation of host, example (provide acute care — burn center and rehabilitation)

General Strategies for Burn Control from Haddon W, Advances in the Epidemiology of Injuries as a Basis for Public Policy. Public Health Reports 1980; 95:411–421.¹⁸

has no part in the promotion of prevention to the concept that sociopolitical involvement is necessary.¹⁹

All burn injuries should be viewed as preventable. Public health is defined as the effort organized by society to protect, promote, and restore the people's health.²⁰ The public health model of injury prevention and control is divided into:

- surveillance,
- interdisciplinary education and prevention programs,
- environmental modifications,
- regulatory action, and
- support of clinical interventions.

Primary prevention is preventing the event from ever occurring. Secondary prevention includes the acute care, rehabilitation, and reducing the degree of disability or impairment as much as possible. Tertiary prevention concentrates on preventing or decreasing disability. Disability prevalence and productive activity loss are important outcome measures. There are both active and passive prevention strategies. Passive or environmental intervention is automatic; little to no cooperation or action is required by the host. This is the most effective prevention strategy. Examples include building codes requiring smoke alarms, sprinkler installation, and factory adjusted water heater temperature. Active prevention measures are voluntary, emphasize education to encourage people to change their unsafe behavior, and require repetitive educational measures to maintain individual action. Herein lays its weakness. Project Burn Prevention was a program funded by the Consumer Product Safety Commission (CPSC) in 1975.²¹ It was undertaken to determine if a burn prevention program would decrease burn deaths by utilizing an educational program and media messages involving a large population base. The author concluded that there was no reduction of burn incidence or severity in their study with either the school education program or media campaign. Education to bring about and maintain personal responsibility was not sufficient. Active prevention is the least effective and most difficult strategy to maintain, especially over a long period. Examples are a home fire drill plan, and wearing goggles and gloves when handling toxic chemicals. Passive strategies are not always successful; a water heater thermostat may be raised by a homeowner and a sprinkler system or smoke alarm must be maintained. Once surveillance data have been established and collected, then prioritizing high-risk burn groups is necessary in order to identify intervention strategies.

The Four Es of Intervention comprise Engineering, Economic, Enforcement, and Education.²²

- Engineering — focuses on the physical environment (product safety design) and the vector. Examples include fire-resistant upholstery and bedding, child-resistant multi-purpose lighters (including cigarette), and insulated electric wire.
- Economic — influences behavior, i.e. monetary incentives such as insurance rate reduction if a home has smoke alarms or sprinklers.
- Enforcement — influences behavior with laws, building codes, and regulations. Requiring fire escapes, sprinklers/smoke alarms in motels, hotels, and homes.
- Education — influences behavior through knowledge and reasoning. Examples include pamphlets, public

television programs, CPSC News Alerts. These active measures are the least effective.

In any prevention program the results must be evaluated.²³ If a prevention program does not achieve the stated goal(s) possible reasons include:

- the technique or measurement used may be inappropriate to identify the reduction caused by the prevention strategy;
- faulty program design;
- study design may have been good, but the program was carried out inappropriately.

With this background in epidemiology and prevention of injuries, important areas of challenge and opportunity in burn prevention both past, present, and future will be discussed.^{24,25}

Flammable clothing

In the decade of the 1940s, publicity surrounding children sustaining burns to their legs as a result of the ignition of Gene Audry cowboy suits or 'chaps' (made of highly flammable-brushed rayon) awoke both the medical and lay community in the US to the dangers of flammable clothing.²⁶ This was soon reinforced when burns resulting from 'torch sweaters' worn by girls began to suddenly appear. Extensive research was conducted to determine fabric flammability.^{27,28} Wool burns very slowly and doesn't ignite. It melts with a red glow, retracts from the heat source, and finally extinguishes itself. On the other hand, cotton burns like a torch and is completely destroyed in a matter of seconds. Raised cut materials were known to be very flammable. While rayon ignites easily, it does not burn as intensely as cotton. A combination of cotton and wool burns less than either by itself. Silk produces a red glow but usually goes out quite quickly. Nylon simply melts but will cling to the underlying surface. Loose-fitting clothing, particularly if the individual is in an upright position and air currents are created by moving, tends to make the burn worse. A close nap or closely woven material is more flame retardant than loose weave textiles.

In 1953 legislation regulating the manufacture and sale of wearing apparel of highly flammable clothing (the Flammability Fabrics Act) was passed in the US. As a result of the act contracts were awarded to Burn Units to collect epidemiologic data regarding flammable fabric burns, flammability testing methods were improved and standardized, and flame-retardant fabrics were developed. The initial act covered only fabrics that came in contact with the body and therefore excluded industrial fabrics. The act was amended in 1967 to include articles of wearing apparel and interior furnishings such as paper, plastic, rubber, synthetic film, and synthetic foam. In the US the chemical agent tris was the common additive used to make flame-retardant clothing. Tris was banned in 1977 by the CPSC not because of the lack of scientific proof of its effectiveness but because a 'two-year feeding study' in rodents conducted by the National Cancer Institute revealed that the agent caused cancer.^{29,30} Did tris and flame-retardant sleepwear result in a decline of clothing flame burns?³¹ Analysis of 6000 burns admitted to 15 burn centers in the United States between 1965 and 1969 revealed that 86% of all flame burns involved fabrics.³² In 1977 McLoughlin et al. reported a decrease in sleepwear burns at the Shriners Burns Institute in

Boston, MA.³³ It was recognized though that accurate national statistics to support their experience were lacking. Other explanations were proposed – the change in referral patterns of patients, improved public education on the hazards of sleepwear, behavior changes not directly related to the flammability of sleepwear, changes in clothing design, and finally that burn injuries were still occurring but were less severe. Clothing burns involve three factors – flammability, the behavior of the wearer, and the heat source.³⁴ During this same period, make-up of clothing changed. By 1985, 87% of children's sleepwear was made of synthetics and only about 13% of sleepwear was made of cotton. In 1996 sleepwear standards for children were amended by the CPSC. The amendments permitted the sale of tight-fitting children's sleepwear and sleepwear for infants aged 9 months or under, even if the garments do not meet the flammability standards ordinarily applicable to such sleepwear. This conclusion was based on staff findings that there were virtually no injuries associated with single-point ignition incidents of tight-fitting sleepwear, or of sleepwear worn by infants under 1 year. Sleepwear for children 9 months or younger and tight-fitting garments (up to size 14 and not exceeding specified measurements for specific areas of the body) could now be sold even though they don't meet the flammability standards ordinarily applied to such sleepwear. The commission emphasized that sleepwear standards were designed to protect children from burn injuries if they came in contact with an open flame such as match or stove. Flame-resistant or snug-fit clothing does not apply for sleepwear in sizes of 9 months and under because infants wearing these sizes are 'insufficiently mobile to expose themselves to sources of fire.'³⁵ What about the children that don't voluntarily expose themselves to an open flame? The safest sleepwear is a snug-fitting, flame-resistant garment. In 1999 a rash of clothing burns occurred in girls, ages 2½ to 11, wearing large loose-fitting cotton T-shirts as nightdresses. The victims had been either playing with either matches or a lighter.³⁶

Snug-fitting cotton and flame-resistant garments are the safest choices for children's sleepwear. Loose-fitting clothes have a large airspace between the fabric and skin. The oxygen promotes the flame. In order to meet CPSC requirements, flame-resistant implies garments don't ignite easily and must self-extinguish quickly. Snug-fitting clothes that comply with CPSC guidelines are made of fabrics that aren't flame-resistant, but don't create 'an unreasonable' risk of burn injury because they limit the airspace under the garment. The CPSC requires all snug-fitting children's sleepwear from 9 months through size 14 to have a label that reads: 'Wear Snug-Fitting, Not Flame Resistant.' A hangtag reads 'For child's safety, garment should fit snugly. This garment is not flame resistant. A loose-fitting garment is more likely to catch fire.'

The reader is encouraged to read the excellent review of sleepwear flammability and legislation in both the US and the United Kingdom by Horrocks et al.³⁷ The CPSC is requesting of all burn units/centers to notify the National Burn Center Reporting System (NBCRS) any burn injury in children (15 years and younger) if the clothes they were wearing ignited, melted, or smoldered. The CPSC also wants the garment sent to them. There is no specific number of cases needed to reopen hearings by the CPSC to reconsider changing sleepwear standards.

Hot water burns

Unintentional injuries are the leading cause of deaths in children. While the majority of scald burns in children aren't fatal, the exact incidence is unknown. Heretofore there has not been accurate data available. But with the institution of the American Burn Association's National Burn Repository inpatient data regarding all aspects of burn injury will be available. Unfortunately many hot liquid burns are small and don't require hospital admission. All tap water scald burns should be preventable. In 1983 the Washington state legislature required all new home water heaters be preset to 49°C [120°F].³⁸ The time of exposure to this temperature is sufficiently long that the victim, usually a child or elderly disabled person, is able to be removed or can climb out of the water before a severe burn can occur. An educational program was instituted to inform people to voluntarily decrease the water temperature. Follow-up in 1988 revealed there had indeed been a reduction in hot water-caused pediatric burns. Voluntary reduction of thermostat temperatures to a safe level by manufacturers has not been uniformly successful. Mandatory regulations to lower water heater temperature would be the most effective strategy, but until society is educated and convinced of its benefit, change will be slow.^{39,40} Other prevention methods to reduce tap water scald burns include inserting shut-off valves in the water circuit to detect temperatures over a certain level, and the use of liquid-crystal thermometers in bathtubs to alert the caregiver of the water temperature.^{41,42} Unfortunately prevention of spill burns, which represent the largest percentage of pediatric burns, is more problematic. Most spill scald burns won't be prevented by adjusting hot water thermostats. Negligence on the part of the caregiver(s) is the key issue. Preventive measures must depend on education, but how successful will behavior modification be when people forget to keep hot liquids such as coffee, soup, tea, grease or electric cords attached to pots, or deep fryers out of the reach of children? Success can be achieved through a combination of education, legislation and/or litigation regarding product safety.⁴³⁻⁴⁵ Examples include ovens with a door that can be opened and climbed on by a child and an oven that is not secured to the wall. The child's weight on an open door can tip the oven forward, spilling hot liquids. Numerous active scald prevention programs have been reported. The effectiveness of active prevention has been called into question regarding effectiveness.⁴⁶ Education campaigns directed at parents and burn safety to modify behavior have been shown effective over a short period of time only. Unfortunately weaknesses of many studies include short follow up, small sample size, and no controls. Identifying why specific prevention measures are unsuccessful is as important as why some are successful. Not all scald burns involve children. Product design and installation are important. Burns occurring during bathing as a result of seizures are not uncommon.⁴⁷ Avoidable risk factors identified were shower levers were easily knocked out of position, absence of water temperature safety features, and confining shower cubicle.

Fire-safe cigarettes

A cigarette when left unattended and not even puffed can burn as long as 20–40 minutes. In 1993 30–45% of residential fire deaths were caused by the careless use of cigarettes. In 1996

smoking was the cause in 4.8 % of the 191 729 residential fires, 10.6 % of all fire injuries, 17% of the deaths, and 4.1% of the \$2.6 billion lost.⁶ Statistics collected from 1986–1987 revealed that positive blood alcohol levels were 7.8 times more common in fire injuries than non-injuries. Consumption of 5 or more drinks per occasion was associated with an increased risk of a fire fatality. The odds ratio of a fire injury in a house where members collectively smoked from 1 to 9 cigarettes per day was 1.5 relative to households with no smokers, from 10–19 cigarettes per day the odds ratio was 6.6 and if greater than 20 cigarettes per day the odds ratio was 3.6. Their data revealed that smoking appeared to be the more important risk factor.

Although the number of adults smoking decreased by 8.6% from 1965 to 2002, residential smoking fires still represented a major cause of fire deaths and injuries.⁴⁸ Four percent of residential fires were caused by smoking in 2002, but smoking accounted for 19% of fire fatalities and 9% of fire injuries. Tobacco material was responsible for approximately 14 450 residential fires, 520 deaths, 1330 injuries, and \$371 million in residential property damage. Smoking was associated with the highest number of deaths (25 per 1000 fires), and the next highest was children playing (14 per 1000 fires).

It is no surprise that most smoking fires started in the bedroom or living/family room areas of a house. The items first ignited were upholstered furniture, trash, mattress or pillow, and bedding. The time of day of residential smoking fire deaths and injuries were 2 a.m. and 6 a.m. and 12 p.m. to noon respectively. Falling asleep, alcohol, and substance abuse were common associated factors.⁴⁹ Smoke alarm performances in residential smoking fires revealed: alarm present and operated — 39%, present and not operating — 25%, no alarm present — 36%. Alarm performance in fatal fires was — 43%, 25%, 32%.

The concept of a fire-safe cigarette was explored in the early part of the 1920s. The first federal bill mandating fire-safe cigarettes was introduced in 1974. The legislation passed the Senate but failed in the House of Representatives.⁵⁰ For the most part the concept remained dormant until 1984 when the Cigarette Safety Act created a technical study group on cigarette and little cigar fire safety.⁵¹ This group was to determine if a fire-safe cigarette could be made and would it be commercially feasible. A number of cigarette design changes have the potential to make cigarettes less fire-prone. These include reduced tobacco density, paper porosity, cigarette circumference, and addition of citrate.⁵² Two important facts emerge regarding cigarette-related burns:

1. Burn data on non-fatal cigarette fire injuries are lacking on the national level.
2. Legal liability of tobacco companies might be the most effective means of decreasing both non-fatal and fatal burns associated with cigarettes.

Unfortunately litigation against tobacco manufactures has not been very common. On January 11, 2000 Philip Morris companies announced the development of a cigarette with ultra-thin concentric paper bands that are applied to the traditional paper. The bands are referred to as 'speed bumps' and cause the cigarette to self-extinguish if it is not smoked. This is because no oxygen gets to the burning ember. This technology was first reported more than a decade ago. The production of a safe cigarette should not be voluntary, but be required by

law. The state of New York implemented legislation requiring all cigarettes sold in the state after June 28, 2004 have reduced ignition propensity (RIP).⁵³ The US government has not yet passed fire-safe cigarette legislation. Canada passed fire-safe cigarette legislation in 2004. It was the first country to do so. Everyone is encouraged to read the article titled 'How the tobacco industry continues to keep the home fires burning' by Andrew McGuire.⁵⁴

Carbon monoxide poisoning

Carbon monoxide (CO) inhalation is the leading cause of fatal poisoning in the industrialized world.⁵⁵ Burn injuries and fatalities are often associated with CO intoxication. Whenever a carbon-based fuel, gas, oil, wood, or charcoal is burned carbon monoxide is produced. Obviously open flames are the most common source. These include charcoal grills, gas water heaters, stoves, and lanterns. Carbon monoxide generating appliances, such as space heaters, are often used during power outages. Their use may be weather related or because home heating is shut off for financial reasons – the latter often occurring in the low-income households. If the heating source is either used improperly or ventilation is inadequate or faulty, CO levels can become toxic. The number of deaths as a result of CO poisoning is unknown because many victims may not have blood levels drawn or death may be attributed to an associated burn. In a phone survey conducted in 1003 households in the US, 97% of responders had a smoke alarm, and only 29% had a CO detector.⁵⁶ Is price a factor in the low prevalence? The cost for a single unit can be as low as \$10 and \$75 for a combined smoke and CO detector. A CO alarm near all sleeping areas represents an effective prevention strategy. Should any home with a smoke detector have a CO detector? Based on the success of smoke alarms, the answer is yes. But future research is needed to answer conclusively a number of questions – are they necessary, what type of CO sensor, and what level of CO gas activates the alarm, specifically the level for both a caution and dangerous or hazardous level? It is important to remember the life span of carbon monoxide detectors varies from 2 to 5 years. In addition the 'test' feature on many detectors only checks the functioning of the alarm and not the status of the detector.

Smoke detectors/alarms

Without question the use of smoke alarms has had the greatest impact in decreasing fire deaths in this country. In 1966 the percent of residential fire deaths in homes with an operating smoke alarm was 13%, 11.5% deaths occurred in homes with a non-operating alarm, and 38.5% in houses without an alarm.⁶ Smoke alarm performance was not much better in one- and two-family dwellings fire fatalities — 10% had operating alarms, alarms present but not operating 10%, and no alarm 42%. Socioeconomic factors associated with lack of functioning smoke detectors include living in a non-apartment dwelling, an annual income of less than \$20 000, being unmarried, and living in a non-metropolitan area, and homes with children younger than age 5. Smoke detector ownership was most often associated with not living in public housing, higher education (completing high school), maternal age (not a teenager), practice fire drills, and larger homes.^{57–59}

In 1985 McLoughlin published Smoke Detector Legislation.⁶⁰ Her conclusions were smoke detector installation in new houses *appears* to be effective when mandated by a building code. Malonee et al. in 1996 collected data on a smoke detector give-away program in Oklahoma City, OK.⁶¹ The target area for intervention had the highest rate of injuries related to residential fires in the city. The number of injuries per 100 000 population was 4.2 times higher than the rest of the city. Ten thousand-one hundred smoke alarms were distributed to 9291 homes. Over the next 4 years the annualized injury rate per 100 000 population decreased by 80% in the target area, as compared to only 8% in the rest of the city. The authors concluded that target intervention with a smoke alarm give-away program reduced residential fire injuries. Smoke alarms represent intervention before the burn event occurs. Building codes mandating installation in new homes have been proven to be a practical solution. While ‘retrofit’ laws would appear to be unenforceable, yet the practical solution is to require installation when a house is sold or an apartment rented. Installation in existing homes represents the ultimate goal, but this won’t be accomplished by legislation. Maintenance of alarms is just as difficult.

In 2000 DiGuseppi and Higgins questioned the benefit of injury education to promote smoke alarm usage.⁶² Twenty-six published trials, 13 randomized, were reviewed. The conclusion was ‘counselling and educational interventions had only a modest effect on the likelihood of owning an alarm.’ Programs that gave away and installed smoke alarms appeared to decrease fire injuries, but the trials were not conclusive and the results were to be interpreted with caution. DiGuseppi et al. conducted a randomized controlled trial to determine the effect of giving free alarms on fire rates and injuries.⁶³ The design was similar to the previously discussed study in Oklahoma City: 20 050 alarms, batteries, fittings, and fire safety brochures were distributed and free installation was offered. No alarms were given to the control group. Follow-up was 12–18 months after distributing alarms. The conclusion of the study was giving free smoke alarms did not reduce fire injuries. Many alarms had not been installed or maintained. Obviously a give-away program isn’t the entire answer and more research is necessary. Rowland et al performed a randomized controlled trial to determine what type of fire smoke alarms were most likely to remain working and how the alarm was tolerated in households with smokers.⁶⁴ It was conducted in 2145 inner-city London households. The alarms had either ionized or optical sensors. Both sensors are very sensitive to small smoke particles; 93% of 2145 households had alarms installed; 15 months later 54% had working alarms. Reasons were a missing alarm (17%), missing battery (19%), and disconnected alarm (4%). The pattern was similar in households with smokers. Important conclusions by the authors were:

1. an alarm with an ionization sensor, lithium battery, and a pause button were most likely to remain a working alarm;
2. an alarm was less likely to work in a household with one or more smokers;
3. installing smoke alarms may not be effective use of resources.

Although evidence regarding how effective alarms are under specific circumstances is lacking, they surely represent the

most effective device yet introduced to decrease both fire injury and death.^{65–67} Unfortunately even though the public knows the benefits of a smoke alarm, it is painfully clear how difficult it is to implement this preventive measure. Facts reported by the US Fire Administration’s National Fire Data Center for Residential Structure Fires in 2000 revealed no smoke alarm was present in 53% of residential fires, present and operating in 32%, failed to operate in 6.7%.⁹

Fire sprinklers

Sprinklers complement smoke detectors.⁶⁸ Sprinklers are an intervention strategy that works during the event. They are the most effective method for fighting the spread of fires in their early stages Automatic fire sprinklers have been in use in the US since the later part of the 19th century. They are the most effective way of limiting the spread of fire in the early stages. As far back as 1993 the National Fire Protection Association (NFPA) estimated smoke alarms alone could reduce fire deaths by 52%; sprinklers alone could reduce fire deaths by 69% and the combination by 82%. In 1996 residential sprinklers were found in less than 2% of residential fires.⁶ The NFPA estimates that occupants with a smoke alarm in the home have a 50% better chance of surviving a fire than those without a smoke detector. Adding sprinklers increases the chances of surviving a fire to nearly 97%. One sprinkler is adequate to control fire in over 90% of the documented sprinkler activations in all residential fires. In 1978 San Clemente, California was the first jurisdiction in the United States to require residential sprinklers in all new structures. In 1985 in Scottsdale, Arizona required a sprinkler system in every room of all new industrial, commercial, and residential building. In 1999, 34% of public assembly properties where fires occurred in the US were equipped with sprinklers, compared with 7% of residential properties.⁶⁹ The costs for installing fire sprinkler systems in buildings 6 to 8 stories high ranges from under \$1.00 to about \$2.00 per square foot in most new construction and from about \$1.50 to \$2.50 per square foot for retrofitting sprinklers in existing buildings. At the present time, cost of a home sprinkler system in new construction is targeted at approximately \$1.00 to \$1.50 per square foot.⁷⁰ Table 4.3 lists components of a hotel/motel fire safety program if the structure is over 75 feet.⁷¹ Sprinklers typically reduce both chance of dying in a fire and the average property loss by one-half to two-thirds compared to where sprinklers are not present. NFPA has no record of a fire death of more than two people in a public assembly, educational, institutional or residential building where the area was completely fitted with working sprinklers. It is estimated that 75% of high-rise and 50% of low-rise hotels have sprinkler systems. In hotels less than three stories, sprinkler requirements may not apply. As of January 2006 no new statistics were found regarding sprinkler installation. Over 200 communities in the US have residential sprinkler laws.

Evaluating the effect of burn prevention

Three important issues reappear in injury prevention literature:

1. implement what is already known, not necessarily proven,
2. passive strategies are more effective than active ones,

TABLE 4.3 COMPONENTS OF A HOTEL/MOTEL SAFETY PROGRAM (FROM HADDON¹⁸)

Fire sprinklers
Smoke/fire detectors
Automatic alarm system
Manual alarm system (pull-boxes in stair wells and near elevators)
Fire department standpipes (a vertical pipe usually noted in stairwells that acts as a reserve in order to secure a uniform pressure in a water-supply system)
Emergency lights
Emergency exit system
Exits signs
Pressurized stairways (a fan blows air in from the exterior, thus creating a positive pressure in the stairway to keep smoke from entering into the stairway and blocking exit path. This is unnecessary if the stairway is open to the exterior of the building.)
Smoke control systems
Portable fire extinguishers
Staff fire emergency response plan
Staff training
General Strategies for Burn Control, Haddon W, <i>Advances in the Epidemiology of Injuries as a Basis for Public Policy</i> . Public Health Reports 1980; 95:411–421. ¹⁸

- new programs and their results must be subjected to more rigorous evaluation.^{72,73}

Successful burn prevention includes collecting, analyzing, and then interpreting burn statistics especially mortality and even more importantly morbidity. The American Burn Association's Burn Data Repository represents a very valuable resource for everyone involved in burn prevention. Heretofore, most burn prevention has been done on a local level and without a national perspective in mind.⁷⁴ The ongoing collection of data will allow

- identification of magnitude and type of burn injury,
- monitoring the trend of specific areas of burn injuries and their prevalence,
- identification if new injury problems arise,
- development of methodologies to evaluate burn prevention or intervention efforts.

Many successful burn prevention programs have been developed on the local level using locally generated data. Behavior

modification on a local level can be instituted more quickly than waiting for national societal initiatives and legislation. Unfortunately local efforts affect only a few. Prevention research should generate information which can be useful on a national level. There must be rigorous methods of evaluating research so the conclusions may be shared. Many burn prevention programs have had an insufficient number of subjects, no controls, inadequate or short follow-up periods, no control for confounders and of utmost importance, few use mortality and morbidity as outcome measures.⁷⁵ While it is difficult to conduct prospective, randomized, double-blinded studies (Class I research), nevertheless rules of good scientific research should be followed.⁷⁶ Studies with a single hypothesis should be conducted over an adequate length of time. The prevention goal should be realistic and achievable and the results must be carefully analyzed.⁷⁷ Resources must not be wasted collecting and analyzing data unless prevention initiatives are planned. The incidence of both burn injuries and deaths is decreasing throughout the United States; no single burn unit or community will have a large enough patient population to conduct meaningful prospective studies. Peck and Maley determined the population requirements necessary to conduct adequate statistical studies.⁷⁸ To undertake a study showing a decrease in injuries by 50% and 10% (alpha level of 0.05 and power of 0.08) requires a population of 9330 and 295082 subjects respectively. A 50% and 10% reduction in burn deaths would require a population of 4672000 and 148175000 subjects respectively. Wanda et al. published a review article on the effectiveness of prevention interventions in house fire injuries.⁷⁹ Various types of intervention programs were reviewed. These included school, preschool, and community education programs, fire response training programs for children, office-based counseling, home inspection programs, smoke detector give-away campaigns, and smoke detector legislation. The important conclusion was morbidity and mortality data must be used for outcome measures. There was wide variability regarding study design, data sources, and outcome measures.

Coordination of prevention strategies on a national level is necessary. Passive prevention programs are most effective, but are slow to implement. Active prevention isn't always easy, requires time, significant organizational support, and money. Unfortunately in the US it is unusual for a fire department to spend more than 5% of its budget on fire prevention.⁸⁰ Active and passive measures are not mutually exclusive and both must be utilized. All burns *should* be preventable, unfortunately the aphorism 'it is easier said than done' is true.

National response systems	61
International applications	63

Introduction

Worldwide, burns cause significant morbidity and mortality for humankind. Geography greatly impacts the resources available for disaster response and humanitarian action. These resources and actions influence the suffering and survival rate. An isolated significant burn occurring in a resource-rich country leads to a swift response and treatment, generally initiated in a matter of hours. When a similar burn occurs in a remote area or in a resource-poor country, the risk of death and disability is exponentially greater. During a burn disaster or humanitarian catastrophe, systems and resources are potentially and often overwhelmed, equalizing what would generally differentiate resource-rich and resource-poor environments. Lessons learned from disasters, humanitarian emergencies, and wars have the potential to lead to personal and systems improvement. Therefore, preparation for burn disasters and humanitarian crises based on prior disaster management and experience benefits the individual healthcare provider, the healthcare system and most of all, the burned patient, regardless of the geographic location on earth.

The concepts of disaster management and humanitarian aid are central to the discussion that follows. Most simply defined, a disaster occurs whenever need exceeds resources.^{1,2} Often, outside assistance is required to restore balance to an overwhelmed system. Outside assistance takes many forms — transferring patients to another facility or another country, activating a national emergency plan or requesting assistance from international organizations. Many other definitions of disasters exist and apply specifically to burn disasters. Masellis describes a disaster as a ‘serious and immediate threat to public health’.³ He divides the management of rescue operations into thermal agent (fire) disaster and burn disaster that are linked by the common causal force — fire (Figure 5.1). A

fire disaster is a serious and sudden vast ecological breakdown in the relationship between man and his environment on such a scale that the stricken community needs extraordinary efforts to cope with the disaster, and often requires outside help or international aid.⁴ A burn disaster can be defined as the overall effect of massive action from a known thermal agent on living people. It is characterized by an excessive number of seriously burned patients with a high rate of disability and death.^{3,5} A fire causing 25 or more deaths is termed a fire catastrophe.⁶

Burn disasters are usually medical disasters for communities, states and infrequently countries, calling for medical planning, resource allocation, communication, and delegation. These disasters may become humanitarian emergencies when there is significant mechanism or when they disrupt infrastructure, government, social function, and economic resources such that the public health as well as the medical health of a community is at risk. Burn disasters can also be part of ongoing humanitarian crises, such as in Iraq where there are already stressed systems in place with very little additional capacity to deal with even a small number of burn casualties.

Public health planning for burn disasters for the most part is involved in supporting medical infrastructure and encouraging disaster planning for such emergencies. Most burn disasters will be local but when burn disasters become catastrophic (as in the event of a large explosion, use of a dirty bomb or a nuclear attack) then application of public health to the large populations becomes more important. Risk analysis reveals that these events are very unlikely but that the outcome would be disastrous. Hopefully, public health infrastructure and planning designed to prevent and react to most disasters will support the event of a large burn disaster but for many countries these systems are untested.

Burn disasters provide a true interface between medical and public health planning. While medical treatment and intervention is always part of public health planning and response, it is often a small portion of overall preparation and response for a disaster or humanitarian emergency. In natural disasters and humanitarian emergencies the public health focus includes security, provision of clean water and sanitation, prevention of disease and vaccination programs, housing, nutritional support, and medical care. In a majority of the burn disasters to date, with the exception of perhaps the 1906 San Francisco fire,⁷ medical response and evacuation have been the appropriate response. But preparedness for a large-scale burn disaster remains as important in the post 9–11 world as it was during the Cold War.

Burn disasters of large scale may lead to humanitarian emergencies. These are disaster situations created and/or contributed to by political, military, economic, and sometimes natural constraints but uniformly impact greater communities and result in a collapse of infrastructure, economy, and an absence or depletion of resources.⁸ Since first coined as Complex Humanitarian Emergencies (CHEs) in the post-Cold War era, these crises have evolved to being simply called humanitarian emergencies and have been characterized as catastrophic public health emergencies, with high levels of violence, long-lasting and widespread, with major violations

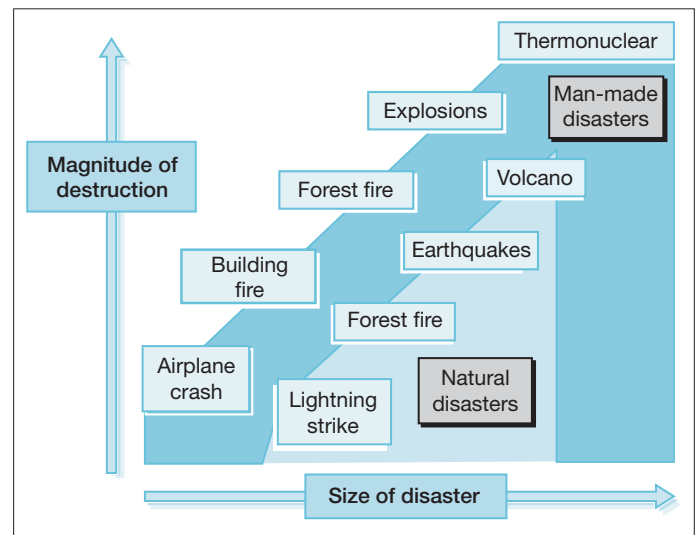

Fig. 5.2 Burn disaster sources and magnitude of destruction.

of the Geneva Conventions and Universal Declaration of Human Rights.⁹ It is within this context that burn injuries commonly occur, and frequently lead to burn disasters as the health systems already in crisis are easily overwhelmed. In the current complex emergencies of Sudan, Afghanistan, and Iraq, civilians and combatants alike have been caught in the cross-fire of the ongoing war, and have been targeted by insurgents with car and suicide bombs that have resulted in uncountable burns and burn deaths. Finally, terrorism and a shift in war strategies, from conventional to asymmetrical, have contributed to the burn disasters of the 21st century.¹⁰ The events of September 11, 2001 led to many burns and while the New York City and Washington DC systems were not as overwhelmed as anticipated, the lessons learned in the aftermath of these tragedies have contributed to the overall approach of burn disaster preparedness and management for this century.^{11,12}

The utilization of resources for burned patients, the most complex form of trauma, is extraordinarily high as well, when compared to other injured victims.¹³ Treating two or three burn patients has the ability to stretch the capacity of even the best prepared, modern facility. Burn disasters involving 20 or more patients has the potential to overwhelm healthcare systems and require intervention from multiple well-equipped facilities and external resources.¹⁴ Fortunately disasters involving multiple burn casualties are uncommon,^{13,15} nevertheless, the potential for overwhelming burn casualties and effects on resources demand planning and preparedness.

Burn disasters and humanitarian crises are most frequently man-made as opposed to natural disasters (e.g. a volcanic eruption, lightning strike, earthquake) and, in general, are comparatively confined to a limited geographical area (Figure 5.2). The initial information needed in order to respond to a disaster revolves around a definition of the event and the geography in question. This includes information about the location as well as means of access to the location, such as points of egress from a room, a building, a field, a town or a

country.¹⁶ In the modern, resource-rich world, earthquake-related flame burns and scalds are infrequent, but when they occur they are usually combined with mechanical trauma.¹⁷ Prior to automatic gas line fail safes and protection of hazardous materials in industrialized countries with protective regulations, fire following earthquake was second only to collapse of masonry buildings as the leading cause of fatalities.⁵ In under-developed areas of the world where construction is rapid, insecure and where building regulations are non-existent, fire following earthquakes still leads to a majority of casualties and fatalities. The large fire that occurred following the San Francisco earthquake of 1906 was responsible for many of the fatalities.⁷ But even recently, the 1989 Loma Prieta earthquake¹⁸ and the 1994 Northridge earthquake,¹⁹ led to many structural fires, incidents of localized fires, and spills of volatile or explosive mixtures that resulted in fires. Explosions are common and widespread and may also cause mass burn and trauma casualties. Remote areas in resource-rich countries and most areas of resource-poor countries exponentially amplify the problems with logistics, evacuation, and treatment of burned victims and raise their morbidity and mortality.

The most recent burn disasters, in Bali and Rhode Island, revealed further lessons learned.^{14,20,21} In the Bali disaster the challenges of treating expatriates, easily reachable by the resources of Australia, exposed yet another concept in evacuation and response in a country under threat of terror. Burns in Iraq, of both Americans and Iraqis, illustrate the contrast of resources and the perils of the daily threat of terrorism.¹⁰

Advances in science and technology have increased the risk of accidents that result in a transfer of thermal energy to people located nearby. The possible number of casualties from such accidents increases as more powerful sources of energy are harnessed.²² Because of growth in the fields of transportation and technology, we are now confronted with a potentially rapid growth in the absolute number of burns in a mass disaster as well as heightening the possible dangers surrounding the use of thermic energy of unprecedented power such that the magnitude and consequences could be appalling.^{23–26} The potential for modern-day fire catastrophes involving urban areas, high-rise buildings, large crowds collected at community events, and worldwide terrorism poses a serious challenge to fire technology and to society.⁶ Such disasters normally exceed the resources of local healthcare providers and facilities,²² especially as it relates to burns.

Every burn center needs a burn disaster plan.²⁷ The burn center disaster response must be integrated into the disaster planning of the hospital and its emergency department and trauma service, the prehospital system, the state emergency management system, and perhaps a national disaster plan.^{15,27,28} Many hospitals, communities, states, and countries, however, will either not prepare disaster plans or will not execute the plan during an emergency. This chapter will review the epidemiology of burn disasters and humanitarian crises, elucidate public health tenets particularly as they relate to preparing a burn disaster plan for a response that will prevent or mitigate consequences, and examine the challenges of the disaster response to a real burn disaster or burn disaster exercise from two perspectives: the resource-rich or Western response and the resource-limited perspective.

Epidemiology of disasters and humanitarian crises

Epidemiology has proved most promising in disaster management.⁴ Disaster epidemiology links data collection, analysis of the disaster, analysis of risk factors for adverse social and health effects, clinical investigation of the impact of diagnostic and therapeutic methods, the effectiveness of various types of the assistance, and the long-term influence of relief operations on restoration of pre-disaster conditions.⁴ Disaster medicine is the study of collaborative applications of various health disciplines to the prevention, immediate response to, and rehabilitation of health problems that arise from a disaster.⁴ For this kind of scientific approach and technical underpinning, special studies, surveys and applied research, social and natural science investigations, and managerial applications are necessary⁴ (Table 5.1). Training people for disaster management requires courses on disaster health in addition to innate humanitarian compassion.⁴ Practical application of disaster medicine is a continuous cycle of planning for disasters, exercising the plan, utilizing the practiced plan should a disaster arise, and examining the response to either an exercise or a real disaster in detail in an after-action assessment (Figure 5.3).

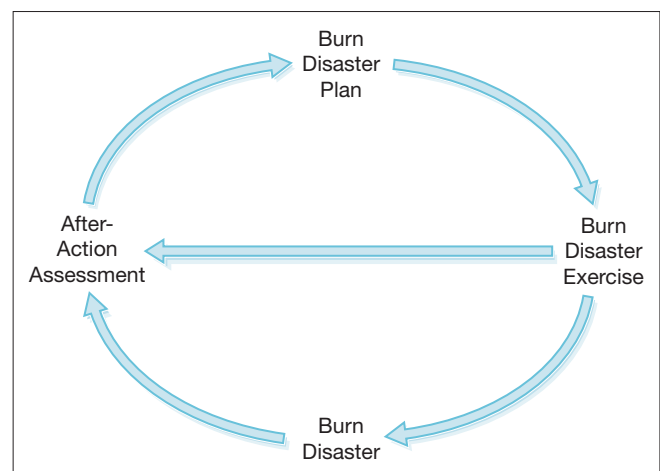

Fig. 5.3 The cycle of burn disaster management.

The incidence and distribution of burn disasters and burn injury during natural and man-made disasters was well described in the 20th century.^{7,15,29–31} Despite the potential for mass disasters, conflagrations became less frequent in the United States during the last half century^{6,15} while the incidence of major fires in Europe increased in recent years.³¹ The 21st century brought many changes including the dawn of terrorism on a scale previously unknown, and a paradigm shift in the conduct of warfare.^{10,32} Both of these realities have impacted the epidemiology of burn disasters since the year 2000. Natural events still contribute to burn disasters, and nowhere more so than in resource-poor regions of the world where the infrastructure is limited, and the fire and burn injury lessons learned and applied in the resource-rich countries have not been activated. By far, most burn disasters today are man-made and many of them intentionally applied. War and terrorism have contributed significantly to the burn disasters that have occurred since the turn of the century and will continue, it seems, for the foreseeable future. The new strategies of asymmetrical warfare alone contribute to burn disasters on a regular basis within Iraq.¹⁰

The large-scale burn disasters of the last century have been examined, published and the lessons learned have often led to changes in public policy, public health education campaigns, and robust disaster plans in resource-rich regions of the globe.¹⁵ Burn injury following natural disasters has been identified, the incidence of these injuries studied, and planning for response in the initial post-disaster phase impacted.⁵ The most common natural disaster contributing to burn injuries are earthquakes, which historically have led to some famous fires including the 1906 San Francisco fire.⁷ These sentinel fires have led to changes in public opinion and important advances in fire prevention.⁶ Changes in building codes and other regulatory interventions have resulted in a significant decrease in fires and burns following earthquakes, but in resource-poor and developing countries, construction codes and government regulations are frequently not enforced and, therefore, in these settings fires and burns may frequently contribute to morbidity and mortality. Other natural disasters may lead to downed power lines and chemical spills that may also result in burns. Early surveillance following hurricane Katrina and the floods that followed uncovered burn injuries in the early days following the event.³³

Burn injuries during humanitarian emergencies including conflict scenarios are known to occur, but many incidents occurring in these settings often go unreported for many reasons. Medical aid in humanitarian emergencies is often provided by relief organizations, or in some cases such as Iraq, is provided to limited degree by a weakened infrastructure and a dwindling number of overworked health professionals. Recording medical events and outcomes is often a low priority in these settings.

The incidence and distribution of burn injury during natural disasters and complex humanitarian emergencies are important to this discussion. Population's increases and shifts, and global environmental changes have led to an increase in natural disasters worldwide.³⁴ In the 21st century the impact of humanitarian emergencies continues to provide significant challenges to the humanitarian community due almost entirely to the ongoing and unresolved crisis in Iraq,¹⁰ with violence,

trauma, and death being reported daily in the civilian and military populations.

The epidemiology of any injury is impacted by the environment where the disaster occurs. In most cases, the incidence of burn injury following a disaster tends to be higher in developing areas of the world where population density is high and prevention and preparation for such disasters is limited by resources, education and often the political will to intervene.¹ However, recent experiences in New Orleans, Louisiana, United States, revealed that even with well-developed disaster plans in place and adequate healthcare infrastructure, morbidity and mortality, including burn injury occur following natural disasters due to human and systems failures, unexecuted plans, and abandonment.³³ In addition, studies suggest that the severity of injuries among those admitted to hospitals show that either victims were able to escape rapidly and, thus, sustained relatively small burns (<30% total body surface area [TBSA]) to exposed areas of skin, or that timely escape was impossible and victims were engulfed and sustained lethal injuries (>70% TBSA).³¹ One explanation is that a great number of victims are trapped in indoor fires and failed to escape. The morbidity and elevated immediate death rate in indoor disasters was mainly due to hypoxia, inhalation injuries, intoxication, and inhalation of poisonous compounds.^{35,36} The effect of hydrogen cyanide and carbon monoxide has been postulated as a cause of incapacity and inability to react, and accounts for high indoor death rates.³⁵ No rescue people reached the severely injured in time.³⁵

Burn disasters, while uncommon when compared to other natural disasters and humanitarian emergencies, are important due to the number of casualties per event, mortality rate, and economic cost of these emergencies. Burn disasters not related to natural disasters, war, and terrorism include explosions and the subsequent fires that ensue following train crashes, air crashes, underground disasters, and liquefied petroleum gas explosions.^{31,35,37,38} The extreme end of the continuum of explosions and resultant burns is a nuclear event. It is such an incident, even in resource-rich parts of the world, that the magnitude of a nuclear occurrence transforms burn disasters,^{23,24,26} which are approachable with adequate infrastructure, resource allocation and planning, into humanitarian crises.

Public health implications

Most burn disasters are local, impacting a small section of the population, even though the mortality rate from the event is high. When burn disasters cannot be avoided or they are intentionally deployed and become catastrophic, the tenets of public health must be employed. Public health planning for burn disasters for the most part is in supporting medical infrastructure, guiding medical resource planning, and encouraging disaster plans for such emergencies. Application of public health principles to large populations becomes important. Although risk analysis reveals that these events are very unlikely, the outcome of such an event would likely change the overall function — social, economic, and public health infrastructure for the foreseeable future.

A plan for response and mitigation must be in place (Table 5.2). Such plans vary depending on where in the world the

disaster occurs, and what resources are available. Burn disasters that occur in the United States and much of Europe are addressed systematically, and plans for surge capacity and other mass causality issues have often been addressed beforehand. In the resource-poor regions of the world, however, infrastructure is often incomplete and resources for a large-scale and rapid response are severely limited. In this case, external support and resources from international humanitarian aid disaster relief organizations are required immediately, and any delay in delivery of supplies, equipment, and personnel will adversely impact mortality rates and individual outcomes. Such scenarios must be considered, since burn disasters or other natural disasters that have the potential for many burn injuries occur more frequently in these underdeveloped areas, if only due to the vast populations that are living in these regions. For truly effective disaster management, the key is prevention and preparedness rather than a *post hoc* fire fighting type of emergency response.^{4,40} This section reviews the public health aspects of prevention, preparation of a disaster plan, exercising the plan, and mitigation of the consequences of a burn catastrophe through descriptions and examples of burn disasters.

Prevention

Prevention, a most important tenet of public health, provides the best possible outcome (i.e. avoiding a burn disaster). But preventive measures were usually lacking in all disasters investigated and mistakes were observed, frequently.³⁵ Even in countries where long-term protection and prevention is governed by regulations, fire and building codes and education programs, systems fail and fires occur leading to burn injury. In the case of terrorism, the disaster by definition cannot be

prevented due to the intentional and unpredictable nature of the strategy for promoting fear and creating instability. During the height of the Cold War when the threat of a nuclear disaster loomed as a realistic possibility, it was only the reality of world destruction and diplomacy that kept the threat in check. Prevention was only theoretical.

Ironically, the most notable immediate reward for good burn disaster planning is the template that is established for burn prevention programs. Initially, the level of prevention achieved depends on the number and effectiveness of public education and information programs that have been pursued.⁴¹ The role of health education is to facilitate the learning of behavior patterns that will reduce risk factors and increase protection factors by means of identification of motivational elements related to behavior.⁴¹

Secondly, prevention must address the risk, environment, resources, and rational for fire and burn reduction technologies. Inspection of public buildings at the time of their initial construction and after any remodeling is necessary in order to ensure proper fire prevention methods. Failure to observe this axiom was crucial in the Stardust disaster⁴² and Station fire.^{20,21} Attention should be paid to methods of egress, as well as fire-fighting capability such as water hose reels and fire-resistant materials.⁴² Posting fire escape plans within rooms of public buildings, providing adequate fire egress instructions and facilities, having fire drills in public facilities (schools, office building, hospitals,⁴³ operating rooms,⁴⁰ ships, airplanes,⁴⁴ racetracks,⁴⁵ etc.) are important aspects of training as well as prevention. There must be proper liaison between disaster planning departments and fire services. A fire department has to ensure that they have proper equipment to fight fires and rescue victims from all facilities and locations in their catchment area, including high-rise buildings, hospitals, schools, campsites, and recreational areas. They should be aware of buildings and locations with hazardous materials, fuel, and explosives as well as forest conditions and other fire hazards in their area. Inspections must include adherence to statutory building regulations and the laws that make these regulations effective. Fire services and local authorities must be adequately staffed, properly equipped, and appropriately trained. The payoff return for prevention is thought to be substantial, but the measurement of effectiveness and cost-effectiveness is an assessment of what could have happened and didn't because of intervention and, therefore, hard to quantify.

Preparation of the disaster plan

Preparation is the next important tenet in the overall public health infrastructure when considering burn disasters and humanitarian crises. Planning for a large-scale disaster requires preexisting public health and medical infrastructure, and the cooperation of local, state, and national agencies. In the worst-case scenario planning will need to interface civilian and military authorities, which will be the norm in disaster planning for many countries and will provide additional challenges for countries such as the United States, where the military rarely intervenes in disaster response.²⁸ Disaster preparedness focuses not only on structuring the response but on laying a framework for recovery as well.³⁹ In the case of burn disaster planning these principles all apply, and specialized burn treatment teams and facilities must take part in the plan.

The disaster plan is the best tool for preparedness. A comprehensive disaster plan is intended to provide optimal treatment of victims of a major catastrophe when there are too many patients to be treated by routine emergency services.⁴⁶ The number of people injured in a burn disaster is defined as the sum of the number admitted to hospitals with burns and the number killed outright.^{31,35} For rural and wilderness areas, that number may be as few as one or two. For a modern urban burn center, in a large tertiary hospital, the ability to care for a larger number of burned victims may be enhanced. Eventually, however, even the resources of a sophisticated burns center in a multi-specialty hospital within a mature trauma system in a resource-rich environment will become exhausted, and the previous planning, preparedness, training, response, relief, rehabilitation, and reconstruction for a major burn emergency or burn disaster situation will be overwhelmed.² The solution will require either secondary triage of burned victims to other more distant burn and tertiary facilities (Figure 5.4) or transportation of staff, supplies, and equipment to the site of the disaster.¹³ The management of mass burns remains a highly complex problem of organization.²⁵ The characteristics and principles of a burn disaster are shown in Table 5.3.

Fundamental planning

All disasters share common elements and therefore should be designed as a continuum to include all disaster types and scenarios.¹ However, disaster scenarios should be considered individually so that the unique elements of the scenarios can be addressed, along with the common processes.^{13,25} Plans for burn disasters must be integrated into overall local, regional, national, and international disaster plans.²⁷ Burn disasters will require integration of medical assets and systems when they are relatively small or local, and must expand quickly to encompass all aspects of a comprehensive disaster plan when large, continuing, or catastrophic. Effective disaster planning will not only lessen property loss and social disruption caused by disaster impacts but will also reduce suffering and the distress of casualties.⁴⁷ Despite evidence available from past

disasters, adequate provision for the management of burned casualties is still lacking in most disaster plans.³¹ Of the 14 disasters studied by Arturson, only in the San Juanico tragedy was a disaster plan in place.³⁵ Disaster planning should emphasize that most burns are either minor or very extensive.⁴⁷ New developments in the organization of emergency medical service systems dictate that new approaches to disaster planning preparedness are essential in order to implement current concepts of emergency medical care delivery.^{1,16,48} The important aspects of modern disaster management from the medical perspective include:

- The utilization of medical triage and treatment protocols in order to effect control and transportation of patients.

Masellis M, Ferrara MM, Gunn SWA. Fire Disaster and Burn Disaster: planning and management. <i>Ann Burns Fire Disasters</i> 1999; 12(2):67-82. ³

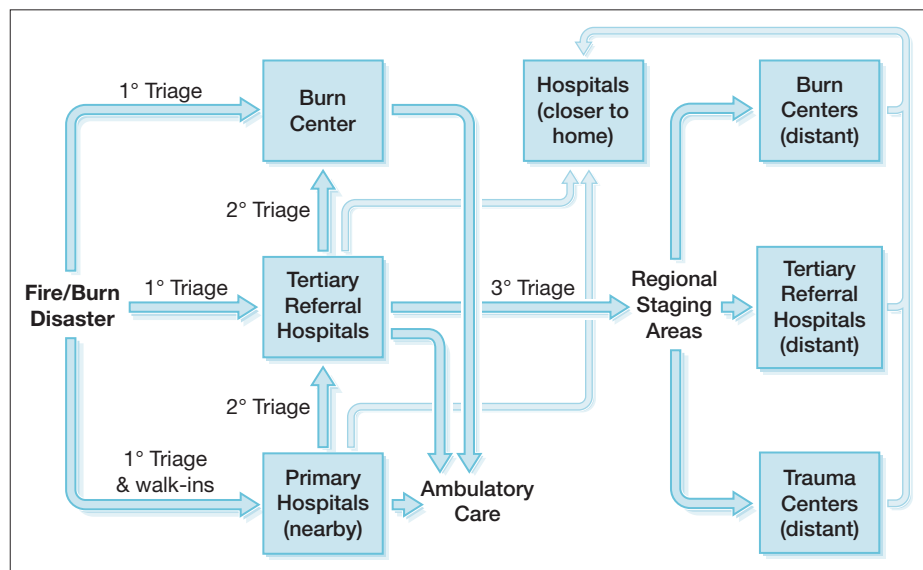

Fig. 5.4
Triage scheme for a fire/burn disaster:
1° = primary; 2° = secondary; 3° = tertiary.

- Early notification of all hospitals that could potentially receive patients.
- Transportation of patients to appropriate hospitals utilizing an existing point-of-entry plan.

This enables burn victims to be preferentially transported to facilities with burn treatment capability and available beds.¹⁶ Three distinct phases of relief operations are necessary: immediate assistance, first aid, and organized relief. Immediate assistance is provided in the first 2–3 hours by people on the spot (trained volunteers, physicians, and nurses) and is fundamental to the prognosis of fire disaster victims. A timely, rational, safe, and effective intervention is the main guarantee *quo ad vitam* for the victims of a fire disaster.⁴ A more complex body of organized relief may not be able to reach a disaster scene for at least 6 or 7 hours. When burn casualties exceed the local ability to provide adequate care, a major disaster should be declared so that all facilities can prepare for upcoming casualties.¹³ Outside or even international assistance should be requested immediately. When a sovereign nation faces a disaster, international law requires that assistance be requested. It is only in the face of a humanitarian crisis that aid may be provided without national consent if the international community deems it is appropriate and necessary.

Effective disaster management can only be accomplished when a thorough disaster planning process has been conducted.⁴⁹ Such a process must include all elements and all recognized emergency response and relief agencies that could play a role in responding to a disaster.^{16,48,50,51} The most important outcome of a planning exercise is that each of the agencies be educated as to the roles and responsibilities of the others so that essential links between agencies can be established.¹⁶

Communication

Communication during a disaster always presents unique opportunities. Sometimes sophisticated systems are available and sometimes the disaster destroys these systems and alternative and more primitive systems must be used. For planning purposes, redundancy and development of fail safe systems should be the solution. Online voice communication with a burn center, burn coordinator, burn surgeon, a trauma center, and trauma surgeon is important. Disaster plans should utilize existing reliable communication venues and have the ability to expand (i.e. bring in additional equipment and staff). Communications must be fast, practiced, and limited in scope. A point-of-entry plan ought to communicate the type of disaster: burns, burns and other trauma, trauma, spinal cord injuries, acute medical complications, poisoning, behavioral crises, neonatal patients, or pediatric victims. A consideration that impacts on incident management is the existence and utilization of a centralized reporting and notification mechanism,¹⁶ such as the enhanced 911 centralized communication system in the United States for fire, police, and emergency medical services. The system should have the capability to contact metropolitan area ambulance services and hospitals individually or collectively through the centralized communication system. This feature allows for central collection of hospital bed availability data, relay of relevant information on the status of the disaster to hospitals, centralized coordination of the disaster response, and direction of ambulances carrying triaged patients to appropriate facilities.¹⁶ The benefits of a

comprehensive system with a centralized communications component are shown in Table 5.4.

A central data bank that stores up-to-date information on the capacity of each burn center to accept patients is imperative for disaster management. Valuable information is also provided concerning hospital capability, intensive care/burn intensive care availability, equipment availability (fluidized beds, etc.), and technical procedures. The information should be utilized on a daily basis for the distribution of burns within the geographical area under non-disaster circumstances. Such a system can then be extremely useful in the event of a disaster when the distribution of patients is urgent. The French telematic data bank for burns also includes an epidemiologic file that forms the basis for prevention campaigns. It is compatible with the International Society for Burn Injuries and the European organization.⁵² The German system that is used on a daily basis responds extremely well. It was not used primarily in the Ramstein air disaster which caused criticism of their disaster management. It *was* used for secondary triage and for consultation on burned patients. The United States' system, National Disaster Management System (NDMS), was activated during Operation Desert Storm and was used by some regions for the distribution of burned patients. Operation Iraqi Freedom again stimulated tracking of daily availability of burn beds.⁵³ Currently the Assistant Secretary of Defense surveys burn centers electronically in the United States on a weekly basis in concert with the American Burn Association.⁵⁴ This data is available should casualty rates exceed the capacity of Department of Defense's burn center and can be used for mass casualty incidents.⁵³ The Italian ARGO satellite system combines a coordination center, data collection center, transportation center, and burn centers into a meshed sub-network. It is expandable and allows the organization to care for severely burned patients. The telecommunication system has high standards of reliability and survival to guarantee continuity of communications from and to a disaster area. It is divided into telephone, fax, video telecommunications networks, and a territorial data collection network. The information is continually updated and links with a national organization capable of rapid mobilization of carriers for the transport of patients. The ARGO satellite system allows immediate contact between spe-

cialized burn centers and the physicians treating patients in the disaster area so that support is available for staff in the field. It functions as a radio telephone in an ambulance and as an ordinary portable telephone carried by a physician.⁵⁵

Clear, concise, honest communication with the media is important during any disaster. Embracing and embedding a public relations plan is vital.^{56,57} The media can serve a very useful purpose in spreading the message for needed resources and in recording the events and responses for the after-action reports and lessons learned. Ignoring the media in the planning stages will surely disrupt the other important aspects of disaster management in the exercises and in the event of a real burn disaster.

The disaster scene

The initial task for a disaster plan is to forecast methods to identify all burned victims. A search and rescue effort involved in a disaster primarily revolves around finding, extricating, and/or transporting victims, including the injured and the dead as well as the non-injured.⁴⁷ Fire services are well positioned and structured to undertake this search and rescue role. They may need to be augmented with heavy rescue units and additional personnel. There should be significant pre-disaster planning and training for organized search and rescue, involving the fire service and a variety of local groups. Seldom does one specific community group assume complete responsibility. Timeliness is essential and stress inherent. Widespread damage to structures will result in large numbers of casualties and trapped people within an immediate disaster zone. It can be anticipated that people who are trapped will attempt to free themselves, and untrapped survivors will go to their aid. A concentrated effort to rescue trapped persons during the first few hours after a disaster will yield greater dividends in lives saved than any larger or more highly developed effort made later.⁴⁷ A larger burn disaster may require that trained rescuers operate solely in a supervisory role while large numbers of untrained workers are added to a trained nucleus in order to rapidly expand rescue capability.

Advanced planning includes availability of well-trained leadership for disaster situations.³⁵ Sorting or triage is performed most effectively by a clinician experienced in the care of burns, as doctors without such experience frequently overestimate the proportion of the body surface burned.^{13,59} Expert triage may minimize the requirement for specialized burn beds³² since moderate to severe burns, which are best cared for in specialized burn centers, seem to be fewer in numbers following severe fire disaster.^{27,35} The French burn system, for example, incorporates this philosophy into a uniform triage system.⁵²

Most disaster plans emphasize a restriction of treatment, at the site or in the emergency department/accident ward, to lifesaving measures and initial prioritization with early transfer to more sophisticated resources where reassessment can take place.⁵⁸ Delays in the dispersal of casualties may be avoided by prior planning, especially if international transfer of patients is envisioned.³¹ Recent incidents involving mass burn casualties have demonstrated that the specific needs of severely burned victims demand a comprehensive plan that follows the guidelines of the Advanced Burn Life Support

(ABLS) course for initial care, assessment of burn size and depth, resuscitation, evaluation for other injuries, care of the burn wound, etc.⁵⁹

Specific details for an incident command system that were developed for fighting forest fires in California, USA, are generally useful for organizing and implementing action for all fire and burn disasters, irregardless of size or complexity.⁴⁸ The essential figure is usually a firefighter, but other people may be involved.⁶⁰ When this system is adapted to the burns center or hospital environment it is called the Hospital Emergency Incident Command System (HEICS) and the design is compatible with the larger incident command structure.

All burn disaster response plans should include activation for explosions and industrial accidents, such as those that occur at petrochemical industries, foundries, and the like.⁶¹ The preparation phase is characterized by mapping the industries at risk of potential flammable or toxic substances most frequently used in an area and which transit avenues are used for egress. This requires the collaboration of other experts such as engineers, chemists, physicists, toxicologists, etc., in order to coordinate all necessary data for potential fire disasters and effective disaster planning. A training phase should be carried out in close collaboration with agencies and people likely to be involved in self-protection, extinguishing of a fire, and rescue of burned victims. A didactic phase through organized meetings of volunteer personnel is required.⁶¹ Burn centers and hospitals whose catchment area includes oil rigs or hazardous materials should plan for appropriate contingencies.⁶²

A disaster plan may have to be tailored to meet the specific needs of an area or a site. In a fire disaster, the number of people involved may be so high that it is impossible to consider all victims for immediate transfer to existing specialized burn centers. Because of the limited number of beds available and because a disaster may occur some distance away,^{35,63–65} the organization and establishment of a field hospital may be required. To be effective, a field hospital must have easy transport, rapid assembly, and the possibility of administering complete and effective treatment to patients. Multi-unit nomadic tents may offer the best facilities.^{64,65} The reduced weights of these tents, their ease of packing, and their limited bulk represent considerable advantages, especially with regard to transportation and rapidity and simplicity of assembly. The modular composition means that their size can be adapted according to the effective needs of a disaster situation.⁶⁵ The organization and establishment of a field hospital must be based on a very precise predetermined plan that defines all the logistic and sanitary activities of a field hospital that are required to manage a disaster immediately and long term.⁶⁵ The United States Air Force Expeditionary Medical Support (EMEDS), a system of tents and equipment, from Michigan, the Carolinas and Kansas were used after hurricane Katrina to temporarily replace damaged medical facilities. The EMEDS can be transported on flatbeds with trucks or by large aircraft. Although it took some period of time to mobilize the EMEDS to the site and deploy them, the concept worked well and EMEDS could be valuable assets for a large scale fire/burn disaster.

Evacuation

Evacuation considerations depend on the number of victims and their conditions, identification of toxic substances, and

other factors. Emergency transport of burned victims may be sporadic and *de novo* in a fire disaster, but more often it will involve medical rescue services such as fully equipped ambulances, helicopters, fixed wing aircraft, and water rescue craft. Most victims are transported by ground vehicles (ambulances, private vehicles, commandeered buses, trucks, etc.). For fire disasters that are up to 100 miles from medical facilities, the use of helicopter services that are fully equipped flying ambulances, often permanently based at hospitals and used exclusively for emergency purposes, are an invaluable mechanism for transport. Numerous factors have led to the creation and development worldwide of medical air rescue services and, in particular, to the widespread use of helicopter services.⁶⁶ Over 300 hospitals in the world have their own helicopter ambulances and fixed wing aircraft used exclusively for emergency transport.⁶⁶ The Italian model of helicopter rescue service is acquiring growing recognition.⁶⁶ The Italian medical evacuation is made through a single nationwide telephone number in Italy that connects qualified multilingual personnel, including physicians and other specialists, to local rescue services, hospitals, civil and military authorities, and other organizations involved in disaster relief. A sophisticated software program provides, in real time, all necessary information for rescue operations within a specific region, and if the need arises, for inter-regional coordination and transport.^{66,67}

The main aim of a helicopter rescue service is to guarantee prompt arrival (maximum time 20 minutes) of a medical team specialized in resuscitation and provided with all the equipment normally available in a hospital intensive care unit. The necessary emergency therapy can be carried out on the spot or continued during transport of a patient. The transport is not necessarily to the nearest hospital, but to the hospital best equipped to receive a patient.^{66,68} The communication coordination system (called emergency operations centers [EOCs] in United States' disaster systems), activated by the regional operative headquarters, coordinates transportation by ground, helicopter, or a fixed-wing aircraft for long-distance transport.

Under most circumstances, transportation must be carried out in coordination with other rescue organizations. The transport of a victim to the nearest hospital for more thorough assessment and lifesaving treatment (e.g. airway management) may occur pending possible placement in a specialized burn center. This phase is often difficult because of lack of beds for burned patients in a region, especially in the case of those requiring extensive care, and must be planned in the transportation phase of a disaster plan.⁶⁹

Timing and coordination of transport of burned patients is critical⁷⁰ and delays may occur, especially if national or international transportation by air is envisioned, unless communication and cooperation are assured by prior agreements.³¹ The personnel and material conditions, as well as the mode of transport, should be an integral part of every burn disaster plan. A burn team must consider the consequences of aero-medical transport in order to determine whether it is safe for a burned patient or what measures should be used in order to effect a safe transfer.^{68,70,71} Burn casualties can best tolerate transfer on the day of the accident, so long as it does not take more than 60 minutes; and later transfers should take place by the end of the third or fourth post-burn day before sepsis

can fully develop.²⁵ The result of an extensive traffic jam must be anticipated in a disaster plan since it may hinder the arrival of patients as well as physicians and staff who are not on duty, but who are inbound to staff or relieve current staff.⁷² Long delays in transportation of patients have been the rule in most disasters.³⁵

Facilities/surge capacity

Burned patients are best cared for in burn centers.²⁷ But the relative scarcity of specialized facilities and expertise for the treatment of extensive burns is of particular concern, such that involvement of distant burn centers may be anticipated following large disasters.³¹ Even a moderate-sized disaster might fill all available burn beds and saturate the total burn capacity of a wide area. It is vital to plan for supporting hospitals in a primary inner circle and for the designated burn centers and tertiary hospitals in an outer circle to be included^{20,21,35,69} (see Figure 5.4). Following very large disasters, optimal care of severely burned victims will be achieved only if distant burn centers are also involved.⁷³ Prior awareness of the location and capacity of specialized facilities will enhance the successful dispersal of casualties.⁷⁴

The role played by specialized burn treatment units is significant.^{25,27} Burn centers seldom plan to have low levels of occupancy that would enable them to accommodate mass burn casualties, so the emergency plan for a burn center must include emergency evacuation of existing burn, trauma, surgical, and other patients to make beds available for mass burn casualties. As a 'rule of thumb,' a burn center disaster plan should plan for expansion by one-half the number of burn beds or about 10–15 additional burn disaster patients.^{27,75} The hospital must establish a control center (EOC, as part of the HEICS strategy),^{20,27} discharge or move patients to alternate care, organize beds for the incoming mass casualties, and pull in extra staff, often without the knowledge of how many casualties to expect. Multiple injuries, including burns and inhalation injuries, may occur in mass casualties from explosions. A burn center should receive logistical support from the sponsoring hospital in order to provide the best treatment for a large number of burned casualties. Logistical support requires work from the hospital staff who are concerned with sterilization, pharmacy, medical and nursing care, radiological diagnosis, and intensive care.⁷² Even little things, such as availability of urine dosimeters, are important!

Traditionally, hospitals have seen their role, during a burn disaster, as related to the medical management of patients admitted to them because of an incident. An expanded role has included sending teams of physicians and nurses to disaster scenes in order to aid in triage and medical management.^{76,77} The role of a hospital in disaster management can be expanded further to include a strong focus on leadership within the medical component of a disaster. On-site medical management can be organized in one of two ways:

- via 'proceed-out teams' of physicians who go directly to the scene; or
- through medical direction given by radio to trained prehospital life support teams at the scene.¹⁶

Another responsibility that may be given to a hospital is the coordination with and medical guidance of the fire, rescue,

police, and public safety components of a disaster response.¹⁶ Few major hospitals have full comprehensive specialty services, including burn units. Sophisticated disaster plans should recognize such limitations and obtain prior consent for referral (comprehensive prearranged transfer agreements with burn centers, trauma centers, and other hospitals).^{27,46} Within a hospital, the disaster plan must bring additional operating rooms online as needed for semi-urgent care of burned victims, while reserving one or two for lifesaving procedures that may be required. The goal is to match hospital resources with the needs of burned victims. In some cases, this will be driven by priorities; in others, a first-come-first-served basis will be installed. All elective admissions and all elective operative cases must be cancelled, immediately.

As an alternative to designated burn centers, patients with smaller burns may be managed in a general hospital without any particular facility for the management of burns.⁷⁸ In this case, a hospital disaster plan must be activated. The reception area and initial treatment area ought to be available for the majority of burned victims. Additional personnel should be summoned. A hospital is obliged to clear hospital beds, particularly on surgical wards and intensive care units, by transfer or discharge. If the expertise, supplies, and equipment are not adequate, secondary triage to adequate facilities and burn centers is necessary.

Personnel

Staffing is a basic requirement for the medical treatment during burn disasters. In the event of a large-scale disaster interrupting infrastructure, it must be assumed that personnel attrition will occur, and appropriate measures employed to compensate for staffing shortages. Advanced plans should be made for personnel recruitment from the community — pool staff, locums, reactivation of retired staff.

An overall disaster plan must ensure that a sufficient number of people have adequate training for initial resuscitation of burned victims. Often the medical and hospital staff who are willing to help have little experience in burn care. Training of personnel is rare, especially concerning communication links.³⁵ Guidance in preventive measures typically is absent, and disasters display the lack of training of personnel to cope with a tragedy.^{35,79} Education concerning simple management of minor and moderate burns should be given on a broad basis to doctors and nurses outside of burn care facilities.³⁵ The Advanced Burn Life Support Course is an excellent tool for training such individuals.⁵⁹ Burn center staff must be available for advisory and consultation services by telephone or telex.²⁵ Today, some burn centers have telemedicine or televideo medicine capabilities which allows burn surgeons and knowledgeable burn personnel to view and consult on acutely burned patients. Such systems permit better decisions on which burned patients will be better served in the burn center and which can be reasonably cared for, locally. In addition, the camera and telemedicine brings remote or resource-poor environments into closer proximity with the burn center, often enabling consultation and follow-up for burned patients. Such a system was used following the Ufa train incident.⁸⁰ The burn center in Salt Lake City, Utah, United States uses televideo on a daily basis for advice and consultation as well as follow-up, saving the expense of unnecessary transfers and long-distance

travel for follow-up. A similar system is planned for Arizona, United States and will incorporate triage and distribution in times of disaster as well as a method of dissemination of basic knowledge of burn care throughout a vast area, including many rural and resource-poor environments. Expert triage is important, but healthcare professionals must be able to work effectively in primitive conditions together with other emergency helpers.³⁵ When admitting patients and rendering qualified specialized medical aid at a hospital, the participation of mixed physicians teams (surgeon, burn specialist, resuscitation, therapist, etc.) is advisable.

A plan must use personnel wisely and efficiently. Using a single caregiver, usually a nurse, with each patient is optimal. That person, then, stays with a burned patient through all of the initial steps of care and insures intravenous (IV) fluid administration, pain control, tetanus toxoid administration, airway maintenance, ventilation, and documentation.

Often the first thing that is asked by a burned patient is to contact relatives.⁸¹ This task should be delegated to someone other than hands-on caregivers for the burn casualty, capable of understanding the burn injury and empathetic with relatives and friends. The handling of families, as well as mass media,^{56,57} must be an integral part of every disaster plan. Major mass burn disasters, such as the Piper Alpha and Ramstein tragedies, involve the wounded and relatives from many countries.^{62,81-83} Multilingual support personnel are essential under these circumstances.

Research on human behavior in critical situations has identified three different kinds of reaction: rational action, panic, and resignation. The two normal reactions when a way of escape is apparent are rational action and panic.⁸⁴ When positive action will lead to safety, resignation is a pathologic form of behavior. It is difficult to plan for the psychological reactions to a fire/burn disaster. The two main elements of this drama that have to be understood are the actual fire and the mass of people.⁸⁴ Nevertheless, experts with psychological training should be utilized for the development of psychological support for burn victims, their families and friends, rescue workers, and healthcare workers. Immediate sessions for debriefing of the rescue workers should be put in place.¹ Psychological support for healthcare workers will be necessary because of their high levels of stress and extended hours of work. The psychological support teams in the fire and burn disaster simulations can help a team rehearse the decisions that must be made in the care of large numbers of burn casualties so that the team is less likely to suffer emotional stress at the precise moment when technical skill and emotional equilibrium are most needed.⁸⁴

Supplies/equipment

A disaster plan must be tailored to the supplies and equipment that are available. In resource-rich environments, commercial supplies and equipment may be stored and warehoused on or near the hospital or burn center. But 'just in time' management systems that move supplies and materials to the hospital as they are needed on a daily basis have decreased on-site supplies and equipment in favor of more cost-effective methods of having suppliers drop ship or furnish what is needed on a daily or very short-time delay basis. That means that as local resources are consumed more rapidly to care for the surge

capacity of the burn disaster, resupply may not be able to keep up with the new local demand. Therefore, burn center and hospital disaster plans must be tailored to match the local supply system and knowledge of how to overcome the shortages in any system and speed up resupply is mandatory. Sometimes adoption of resource-poor environmental strategies may be necessary. For example, clean sheets may be torn into strips and used for bandages and various available topical antibiotics and creams may be substituted to the ideal commercial rolled gauze and topical antibiotic creams. Fiberoptic bronchoscopy may be useful in the early diagnosis of inhalation injury, but may not be available for use during a disaster.⁷² An alternate plan for an individual hospital may be the need to transport some burn victims to facilities that have the capability of proper care due to the availability of appropriate equipment. That facility is usually a designated burn center. Problems in rendering aid in such extreme situations exemplify the necessity of having an organization with a separate department of catastrophe medicine.^{3,35} A plan must assure that the management of individual patients will be optimal under a variety of organizational structures and supply capabilities. Compromises may be necessary in extreme circumstances, but the ideal is to develop a plan to avoid them whenever possible (i.e. patients with eyelid/facial burns are seen within 4 hours by an ophthalmic surgeon who has proper supplies; equipment or sufficient supplies and equipment are available to start physiotherapy within 48 hours).⁷⁸ Even when personnel are available, there may be a lack of specific materials. A practical kit for various procedures in the first few hours after severe burns is helpful.⁸⁵ It must incorporate the following basic features:⁸⁶

- easy to transport to the scene of a disaster;
- easy to keep in good condition at a medical/surgical post;
- long-lasting;
- simple to use;
- robust and lightweight enough for air transport.

The contents of an emergency kit should be an integral part of a disaster preparation and be approved by burn experts on a planning committee. Preparing a kit that includes all the necessary supplies for initial care of burned patients is a significant investment of time and money to initiate and maintain. Having the kits available and stockpiled and kept up to date at a regionalized or centralized location (i.e. National Stockpile Center) would be more cost-effective and serve a wider need. Air dropping a kit was lifesaving for immediate surgical treatment and resuscitation of burned victims in remote areas without direct access to rescue teams or made up for deficiencies in medicines and medical supplies in hospitals that have admitted people with severe burns who were not immediately transferable to other hospitals.⁸⁷ Pre-positioned supplies were of significant benefit at Landstuhl Army Hospital during the Ramstein air disaster.

Education

An educational program must be based on a precise method that starts with analysis of a problem of health and safety and then encompasses epidemiological, behavioral, and educational diagnoses.⁶¹ Health education and training programs assume particular importance in burn disaster planning. They

must include the clinical, technical, and operational aspects of a disaster. Implementation of these plans must follow well-defined programs of teaching at schools, starting with primary school level, through education at civil defense courses, periodic refresher courses for physicians, nurses, volunteers, Red Cross/Crescent personnel, fire brigades, police, etc., in addition to periodic exercises with simulated fire disasters that involve the general population and local rescue forces.^{67,88} Training methods may use brochures, stickers, coloring albums, posters, notices, and a variety of audiovisual means, particularly videotapes. Videotapes can recreate and simulate situations and propose actions for assistance to victims.⁸⁸ An interactive video using ordinary documentary film with educational elements can train a student in prevention as well as every element of burn care. Multimedia presentations improve a user's attention and achieve greater educational effectiveness than a usual mono-medium message; and they should be used in initial as well as refresher courses.⁸⁸

Educational interventions to train healthcare providers for burn disasters must cover a broad range of topics; however, learning needs may vary by practice setting, work experience, and previous exposure to disaster events. Therefore, 'one size does not fit all,' and continuing education programs (the most frequently utilized method of updating knowledge skills among the healthcare professionals) may need to be tailored to meet the unique learning needs of each audience.⁸⁹

Exercising the plan

It is important to exercise a disaster plan through coordination of simulated disasters (see Figure 5.3) involving all of the relevant public safety agencies, prehospital ambulance providers, hospital-based personnel, and proceed-out teams.^{16,40} As one team reported: 'The whole operation went very smoothly. This was partly because the staff had been through several "dummy runs" of a detailed civil accident procedure and partly because they had several hours to prepare for the first casualties to arrive'.⁴⁹ Entire systems must be tested in training programs so that they are made intelligible to the public, supported by management resources, implemented properly, and promulgated to all potential first rescue workers.⁸⁸

Where current disaster plans had been well rehearsed, effective dispersal, immediate care, and secondary transfer of severely burned patients was efficient and resulted in good outcomes.⁹⁰ When the plans are not rehearsed and expert triage is not present at the disaster site, the burden of triage falls on the nearest hospital.^{20,91} There is good evidence for developing an integrated disaster response system and for exercising that response system to prepare health care, disaster relief, and humanitarian aid workers for a proper reaction to these rare events. Mass casualty training is common in countries with adequate public health and medical infrastructure and adequate resources. There is little such coordination, planning, exercises or response in many resource-poor countries.

Mitigation

When natural disasters occur in a geographic distribution and in a predictable but chaotic pattern, another public health tenet, mitigation, will lessen the impact of the events. Planning aimed at mitigating the effects on people (in terms of suffering,

TABLE 5.5 FACTORS THAT INFLUENCE THE EVOLUTION OF A DISASTER

From Masellis M, Ferrara MM, Gunn SWA. Fire Disaster and Burn Disaster: planning and management. *Ann Burns Fire Disasters* 1999; 12(2):67–82.³

disability, and risk to life) must be related to a more complete evaluation of involved damage.³ The operational rescue plan must be developed along three lines: immediate care, medical rescue within 3 hours, and use of specific equipment and means for the rescue of burned patients. Factors that influence the evolution of a disaster are shown in Table 5.5.³

The disaster response

The overall disaster response combines the public health reaction providing for the basic needs of the population impacted, but not burned to dealing with the dead, as well as supplying the medical response to individual burned patients. The initial effort is to get the right patient to the right place at the right time with the right treatment, no matter how limited the resources may be. The first steps of that process are to triage patients appropriately (burned victims to burn centers in particular) and apply initial lifesaving treatment according to the resources available.

Triage

Triage, the sorting out and classification of casualties of war or other disasters, traditionally into three categories, to determine priority of need and proper place of treatment, is an important concept. Burn disasters are no exception. Triage for these events must be adjusted to accommodate the circumstances in which the burn disaster occurs. Initial triage for the Rhode Island night club fire in the United States occurring in February 2003 was set up at an inn across from the night club from which ambulances and helicopters began to ferry people.²⁰ The injured patients exceeded the capacity of the regional trauma center, and ultimately 15 area hospital facilities assisted in treating the 215 patients evaluated.²¹ The Bali burn disaster resulted in the transfer of patients out of Indonesia and into Australia for treatment. Burns occurring from explosions in Iraq frequently overwhelm the very limited resources of the local hospitals and if Coalition military medical personnel have the capacity for assistance or transport, these patients may be treated in military hospitals or in neighboring countries.¹⁰ If not, the severely limited resources result in minimal treatment and a poor outlook for patient survival.

The specifics of triage, therefore, depend on the location of the disaster, the accessibility of the area, the resources of the country, and the possibility of evacuation. Triage is always dependent on resources available. Therefore, it is helpful to consider triage for a burn disaster occurring in three distinct settings:

- A developed country with good medical infrastructure, communication, and disaster planning.
- A response occurring in a remote and/or severely resource-poor situation.
- A military supported response.

These three considerations illustrate that resources dictate the number and condition of patients that will be treated aggressively and those that will receive palliative care (expectant), etc.

Triage in a resource-rich environment

Triage ought to be conducted in a simple, straightforward, and experienced manner. Triage should be prognostic with a view toward singling out those among the burned who are likely to survive.²⁵ The two most important aspects of triage have to do with who will perform triage and where. The initial triage will most likely be at the site of a burn disaster by bystanders followed shortly thereafter by other first responders. The triage area is an important consideration. Because of the nature of some burn disasters, it is important to establish triage stations somewhat removed from an immediate scene.¹⁶ This would be in response to hazards to the rescue and triage personnel such as bomb threats and potential explosions, interference by a crowd, or simply the fact that better facilities for triage are nearby and available. A safe triage area must be secured so that additional burn victims are not created because of lack of scene safety. The lobby of a hotel might serve as a good triage area, since it has good access and egress, appropriate space to work, and serves as a known location to all rescue workers and medical personnel.²⁰ Sorting should, ideally, be performed at the site by an expert in burns.^{13,84,92} Expert triage may minimize the requirement for specialized burn beds.³¹ Few casualties with burn wounds of 30–70% TBSA (14% of those admitted) were encountered following fire disaster.³¹ Since bed availability in specialized centers is limited, it is clear that accurate triage is essential.³¹ With lack of sophistication at the scene, burn victims may be taken to the nearest hospital emergency department or accident ward for triage¹⁶ before they are transported to tertiary verified burn centers.^{16,58,83,84,93–95} The rapid evacuation of casualties to nearby hospitals is a realistic aim for all but the most isolated locations, aided by the fact that most burn victims are themselves initially mobile and cooperative⁵⁰ (see Figure 5.4).

The organization of salvage work is affected by the number of casualties, the seriousness of their injuries, and the general conditions of a disaster.²⁵ The actual triage of patients will be influenced not only by the total number of casualties and bed availability but also by such factors as depth and locations of wounds, complications such as inhalation injury, and extremes of age.^{31,52} With effective triage, the demand for care in a specialized burn center can be minimized for small minor burns. In the case of the Ramstein air disaster, the triage sites formed *de novo* where large numbers of patients were encountered, medical personnel congregated naturally, and supplies could

be obtained for initial resuscitation. The patients were then carried a short distance to staging areas for helicopter pick up or for ambulance or bus loading. In the Ramstein disaster, complete triage on the scene was not possible. The triage response of emergency services at the air base was criticized,^{35,82,83} mainly because most of the victims were transported by a 'load and go' system to nearby hospitals who were used to patients being treated in the prehospital setting by trained anesthesiologists.

Patients must be triaged into categories for systematic referral to appropriate facilities. The triage category is based on the severity of injury and the potential for salvage. The overall goal is to do the most good for the most people. In general, when resources are unlimited and a disaster plan incorporates additional resources, even the most severely injured burn victim will receive optimal care if the triage is accomplished in the most favorable manner. Where resources are limited, triage may require a method for selecting casualties on a true priority basis. It may mean developing an expectant category for those so severely injured that they are not likely to survive (Figure 5.5).

The problem of triage can be simplified and facilitated by a flexible adaptation of certain formulas. The gravity of burns can be expressed in terms of the extent of TBSA burned and age of the patient. In Czechoslovakia, the sum of age and extent of burn that is greater than 90 has established an empirical 50% chance of survival. By flexibly bringing this number up or down, depending on the overall situation, one can extend or narrow the number of burn casualties who ought to be transported first.²⁵ Immediate triage is

essential in the presence of large numbers of burned patients. It has been observed that if a long period elapses before rescue teams can start triage and resuscitation, most of the severely injured die and many of the initially moderately injured develop serious complications.³⁵ Triage may identify five important groups for victims of burn disasters^{13,59} (Table 5.6).

Field triage in a large-scale disaster, catastrophe or resource-poor environment

The Ural mountain train-gas pipeline explosion (Ufa train disaster) was a classic example of the need for field triage and secondary triage. During the initial stages following the Ufa train accident, victims were evacuated to nearby settlements where first aid was rendered, aseptic bandages placed, and fluid resuscitation started. During the second stage, victims were evacuated by medical vehicles and helicopters to Ufa and Tschelyabinsk. Total evacuation took 16 hours and 45 minutes, and 806 people were admitted to hospitals and burn centers.²² Helicopters from a nearby military training base airlifted survivors to hospitals in the regional cities of Ufa, Asha, Gorky, and Chelyabinsk. Aeroflot organized a series of special flights, evacuating 160 of the most badly burned, including 37 children, to hospitals in Moscow.^{93,94} In the Ramstein air disaster, rapid initial transport to supporting hospitals was instituted, but further transport to designated hospitals and burn centers was not thought to have been carried out properly. The result was that some hospitals and burn centers were overloaded with patients while nearby hospitals and burn centers did not get any patients at all.^{35,82,83} Secondary or tertiary transfers

Fig. 5.5 Triage decision table of benefit-to-resource ratio based on patient age and total burn size. (From Gamelli RL, Purdue GF, Greenhalgh DG, et al. Disaster management and the ABA plan. *J Burn Care Rehabil* 2005; 26(2):183–191).²⁷

TABLE 5.6 TRIAGE CRITERIA AND CARE PLANS

Triage criteria	Care plan
Minor burns/non-critical sites: <10% TBSA for children <20% TBSA for adults	Dress wounds; tetanus prophylaxis; outpatient care
Minor burns/critical sites (hands, face, perineum)	Admit, early operations, special wound care, short hospital stay
20–60% TBSA burned	Requires intravenous fluids/careful monitoring; burn unit trained personnel
Extensive burns (>60% TBSA burned); inhalation injury/associated trauma; associated medical illnesses	Mortality high; may be placed in expectant category; pain medication; psychological support
Minor burns; inhalation injury; associated injuries	Administer oxygen; measure carboxyhemoglobin; + or – intubate; ventilate; care of associated injuries
Griffiths RW. Management of multiple casualties with Burns. <i>Br Med J</i> 1985; 291:917–918. ¹³	

could have relieved the problem. The result of good secondary triage is that none of the institutions will be overly taxed in providing disaster response; this will allow uninterrupted care of all patients, including the patients who are already in a facility.

Once patients are re-triaged to a specialty burn center, a surgeon directing a major disaster plan may not be able to personally see and assign priorities to a large number of patients because the true priority cannot be assigned until the last patient has arrived. Therefore, a first-come-first-served policy may be effective, reserving some resources for severe emergency problems. The better the prehospital communications the less likely unnecessary overload or misappropriation of resources will occur. To reexamine each of the patients thoroughly by removing all dressings is distressing for the patients and time-consuming for surgeons. Surgeons, therefore, may make hurried and incomplete examinations from which some minor mistakes may result. Further, the senior surgeon directing the surgical management of a major accident should stay out of the operating theater, freeing himself of all routine commitments for the day until the last patient has left the operating theater.⁴⁶ The senior surgeon must, however, keep control of the surgical needs of the patients, interface with relatives, and arrange for transfers of patients to other hospitals if an overload occurs in the receiving hospital and also to eventually transfer patients closer to their homes when their care can be directed safely and appropriately from a hospital closer to home (see Figure 5.4).

Forty-seven patients from the Ramstein air disaster were re-triaged at the Homburg-Saar trauma center using Plan A (natural disasters, fires and explosions/departments of surgery, anesthesia, and radiology), Level II (20–50 victims, activates additional staff and an executive team of department chairs) of their hospital disaster plan. Forty-two patients arrived together on a bus less than 1 hour after the crash and activated the main secondary triage. Secondary triage took place in the triage zone of the trauma center by six emergency room shock teams. Twenty-four victims had deep dermal or full-thickness burns up to 90%. Eleven had additional trauma. Twenty-two

were classified second priority and 8 with minor injuries went home after first aid treatment in the outpatient department. Patients were prepared for transfer to nearby hospitals; but this proved to be unnecessary. Four intensive care units were reinforced with additional staff. Six burned victims were transferred by helicopter to German and American burn centers during the following 48 hours. After discussion with burn center physicians, 5 patients with severe injuries (burns in combination with other injuries) were not transferred and expired of multiple organ failure.⁸³ A thorough burn disaster plan addresses the contingency of disproportions between capacities and facilities as well as the ethical problems in mass burn disasters.^{24,96} Secondary triage or tertiary triage may occur when burn victims can be repatriated to their domestic hospitals. Eleven of the 22 hospitalized patients at the Homburg trauma center following the Ramstein air disaster were transferred to their domestic hospitals.

Medical response

A disaster plan is especially important for burned patients; and thus, it may be helpful to illustrate the operation of such plans through examples from actual major burn disasters. Most burn disasters and burn casualties occur in more urban or at least populated areas.^{35,64,72,79,83,84,97} The Ural train-gas pipeline catastrophe was an exception.^{22,93,95,98–100} Thus, the arrival of the first casualty will usually occur shortly after an incident; and the flow thereafter will be proportional to the number of casualties, the distance of the incident from the receiving facilities, the ease of triage, and the transportation available. The aim of all health workers concerned with mass burns is to give each burned patient the same care they would receive if they were the only patient burned and to save and cure as many of those afflicted as possible.²⁵ There may be overriding conditions that may make this impossible. It is imperative when this situation occurs that a reassessment of secondary triage to other burn care facilities be entertained. The operation of a rescue plan must take into account the types, kinds, and numbers of burn victims and the type of intervention required.³

Putting the disaster plan into action

Triage, communication, treatment, staffing, supply, and transport are the basic problems that confront healthcare workers caring for mass burns. Immediate care is usually delivered by people on the scene of a disaster — relatives, friends, and passersby — people who may have witnessed the disaster or people who have arrived immediately at the scene. Their help is an automatic reaction derived from affection, friendship, or a spirit of human solidarity.³ In the case of burn disasters, the first responders must know how to approach a fire, how to enter a burning building that may be full of smoke or toxic fumes, how to rescue a person whose clothes are on fire, how to treat burn wounds initially and associated trauma immediately, and how to provide medical relief.¹ One of the most troublesome confounding problems is establishing the number of casualties and the size of their burns.

Often the major management problem is a lack of information from the site of the accident.⁵⁸ The focus of patient assessment and care responsibilities shifts from hospitals to the scene of a disaster where triage, evaluations, and medical management of multiple casualties occur.^{16,101} Burn disaster activities should all be coordinated centrally through one resource center utilizing a centralized communication hub with central medical emergency direction capabilities (called EOCs in the United States) (see Table 5.4).

On-scene patient management is generally organized in two distinct phases: patient triage and ambulance staging.¹⁶ On-scene management, when organized and conducted properly, allows for controlled treatment of patients, optimal allocation of resources, and maximization of the utility of these resources for patients.¹⁰² Guidelines for immediate care of burn victims are shown in Table 5.7.

Organized relief refers to the mobilization of all civil defense and military forces that are ready to intervene in the event of a burn disaster.^{49–51} These forces arrive at the scene of an accident as rapidly as possible, but usually not within the first 3 hours. They are equipped with the necessary means and structures to enable them to perform their rescue action during the first 48–72 hours after a disaster until all the people have been evacuated.³ These forces are trained to manage the general details of fire disasters. Special units are composed of

personnel trained in the emergency care of severely burned patients and equipped with specific means and materials. These units should be in charge of preliminary triage, preparing a preliminary evacuation plan, contacting dispatching stations, selecting means of transport, organizing first aid posts, and clearing the area of the dead.³

All assistance to patients who have been exposed to fire and have extensive burns or inhalation injury must be specific, precise, considerate, and timely.⁸⁸ Using an established Burns Mass Disaster plan enabled improved mortality for 10 badly burned victims that were airlifted to a burns center, 1000 kilometers away in the Miri Bank explosion.¹⁰³

Control/communications center

A region-wide disaster network should be developed, linking the communications of multiple hospitals so that each could receive all communications relevant to a disaster from the central communications center. Air and ground transportation units would be included in the link. This requires rigid communications discipline in order to ensure that only pertinent voice communication is transmitted. Priority triage of victims can be accomplished by radio contact between central communication physicians and referring physicians in local hospitals. Through this system, secondary patient triage, hospital notification, and medical control of patients coming from a disaster, as well as mobilization of ground and aeromedical transportation, can be affected. Burned patients can be secondarily transferred to burn centers with available beds, equipment, and personnel so that optimal care can be delivered to each patient.

Accounting for patients is the main function of the control/communication center after initial communications between a disaster scene and facilities have diminished. Transmittal of pertinent information regarding the condition of those patients being transferred from one facility to another tertiary care facility is important. Equally important is to accurately account for the dead. This information is crucial for handling families and friends. Appropriate communication to the media is an issue of public trust, but must follow approved public relations protocols.⁵⁶ A central data bank of patient information, including patient's pictures, may be helpful for directing relatives and friends to the correct facility. Preserving patient confidentiality versus their identity must be balanced.

Treatment

Initial care: details of the initial and continuing treatment of burned patients is the prerogative of other chapters in this textbook. A burn disaster scenario simply emphasizes the importance of the ABCs. The first order of treatment is to ensure an adequate airway and ventilation for each burned victim. This is most often a problem in patients with inhalation injury or mechanical trauma to the face, neck, or chest. Patients with respiratory problems must be identified immediately at the disaster scene and those with inhalation injuries must be noted very early in order to reduce mortality and morbidity.⁷⁸ Intubation and ventilation may be required at the scene or at any time thereafter for inadequate airway or breathing. Firemen are usually the best-trained rescue personnel and are capable of initiating care to burned victims. The kind of assistance provided by the first rescuers is of primary importance

for the prognosis of casualties. First responders must carry out the first triage of urgent cases, taking into consideration a high number of poly-traumatized patients. They must also initiate all medical and surgical procedures necessary for preliminary resuscitative therapy and initial local treatment of burns.³

Patients with all but minor burns should receive prompt fluid replacement in order to counteract the loss of protein-rich fluid into interstitial tissues.¹³ In the Ufa train disaster, first aid was rendered to victims at the site of the accident by local inhabitants and the medical staff of hospitals located in nearby settlements. Within 12 hours, 25 teams of emergency first aid personnel from the city of Ufa and civil defense medical brigades provided additional care. Effective early management extends the time available for dispersal of casualties.³¹ The two fundamental conditions for prognosis are the time interval between the accident and commencement of infusion therapy and the quality of therapy administered.¹⁰⁴ Effective fluid therapy during the first 24 hours provides an interval in which transfer of patients may be organized.³¹ Fluid therapy should be based on the simplest, most expedient effective way of treating a problem. The extent of a burn should be assessed in terms of the percentage of the TBSA using the rule of nines⁵⁹ or the patient's hand (fingers together) as representing 1%.¹³ In the enormous gas explosion in Belgium in 2004 depth of burn was determined with the assistance of laser Doppler imaging and a newly developed color-coded Lund and Browder chart adapted daily and correlated with daily digital photography. This was helpful in planning fluid resuscitation, wound care, and operative intervention.¹⁰⁵ The sum of the partial-thickness and full-thickness burns is used when calculating fluid requirements. The Baxter–Shires formula of 4 ml Ringer's lactate/kg body weight/ 1% TBSA second- and third-degree burn/24 hours is an effective estimate and should be started within half an hour for adults with burns greater than 20% TBSA, for children with burns greater than 10% TBSA, and patients up to the age of 4 years with burns greater than 5% TBSA. Diuresis at 0.5–0.7 mL/kg/h should be maintained.²⁵ The substitution of IV resuscitation by enteral therapy is possible for small burns.²⁵ No colloids should be administered for the first 24 hours. (Additional information on fluid resuscitation can be found in Chapter 8.)

Junior staff can set up IV infusion, administer analgesics, obtain baseline blood samples and radiographs, arrange photographic documentation, begin monitoring fluid balance, and prepare chronological documentation.¹³ Adequate resuscitation was the key to a better survival rate among similar groups of patients whose medical treatment was otherwise the same in two burn units in Spain.^{35,106} The Ufa train disaster provided an example of the consequences of a long delay in fluid resuscitation.³⁵

Initially, burned areas should be simply covered with a clean sheet or clean transparent conforming plastic sheets of material. If a patient must remain for a period before triage, the initial facility may wish to cover a wound with dressings impregnated with silver sulfadiazine or some other effective topical agent and gauze to hold the creams/ointment in place for the transfer. The efficient work of a nursing staff in treating patients with topical antimicrobials before an exact diagnosis of depth and extent of burns is known wastes time, because

the wounds will need to be uncovered in order to allow the receiving medical staff to confirm the diagnosis of size and depth of burn.⁷² One must exercise judgment as to how long to leave a burn wound unprotected from topical antimicrobials so that a physician can evaluate the burn wound. Physicians may well be consumed in lifesaving measures for other burned victims for some extended period. The same could be said for the need for escharotomies. Detailed assessment of casualties will obviously take some time. Such assessment is, therefore, only practical in a clinical environment where personnel and facilities are available for management of fluid therapy and for treatment of urgent complications.³¹ Early debridement of burn tissue is not necessary initially, but can be carried out within the first 5 days post burn once a patient has reached an appropriate facility. The management of burns should involve debridement and wound coverage as soon as possible.⁷² However, this is a function of the tertiary receiving hospital/burn center and should only be considered as part of the eventual care of the patient, not the initial resuscitation.

Methods of treatment must be modified, and medications must be standardized and reduced to basics.³⁵ Initially, no prophylactic antibiotics are administered, but prophylaxis against stress ulcers should be given. Although antibiotics are not used in many burn centers for prophylaxis because of the development of resistant organisms,¹⁰⁷ in a situation where a large number of patients with burns arrive at a general hospital, which would be unlikely to have an endogenous supply of resistant organisms (or the capability of early detection of burn wound sepsis), it would seem advisable to use prophylaxis.⁷⁸

Psychological considerations

An effort should be made to reduce psychological interference that might hinder the organization of rescue work and burn care. Initially, people must trust their rescue workers and be guided by them. This assists in the escape from disaster and lessens the psychological impact. The best psychological first aid is to assist and organize escape from a disaster. During and immediately after a fire/burn disaster, civic education in schools, by mass media and through other means of communication, may help lessen the psychological impact of a disaster on a community. Psychological support must be tailored to the situation of a fire/burn disaster. As in the case of the Ramstein air disaster, the audience at the air show was family-oriented with many school children witnessing the holocaust and experiencing the panic of the event. Therefore, great energy was spent in psychological debriefs in the schools where the children attended and in other public forums.

Patients admitted to a hospital should have supportive psychological counseling given early, throughout their hospital stay, and for follow-up after discharge in order to minimize the late emotional disturbances.⁷⁸ Professionally trained teams of experienced rescue workers help to control emotional problems such as panic caused by a fire disaster.⁵⁸ Most of these patients will have major emotional problems.^{62,81} They are agitated, anxious, very dependent, and out of action. Their faces are not looking good. They have seen their friends go up in flames. Some survivors had heard hundreds of men screaming that they were going to die. Psychologists and social workers were drafted to offer emotional and practical help to

survivors and brief families, as well as support the nurses looking after them.⁸¹ It is only later, as the drama of the first days dies down, that nurses start to feel the strain. Talking among the healthcare givers about an incident helps.⁸¹ Psychological support for victims, relatives, rescuers, and health workers must not be forgotten.¹⁰⁸ Advisors from Bradford and Kent, who had developed special services to help the bereaved in response to the Bradford fire and the Zeebrugge ferry disasters, were available to help.⁸¹ Apart from the casualties themselves, the greatest concern was for the bereaved relatives, most of them with no body to grieve over and no ritual funeral rites to help them mourn. Many bereaved families were desperate to speak to people in the hospitals in order to find out all they could about missing relatives, now presumed dead.⁸¹ Professionals must be available to help these people during and after a disaster. Psychological training must be given by expert psychoanalysts using group work techniques.⁸⁴

Staffing

Initial staffing

Medical staff on duty must be able to undertake emergency care of initial victims prior to arrival of additional staff, as was the case with the Hipercor victims when traffic conditions delayed the arrival of off-duty burns and surgical staff as well as additional hospital staff to care for burned patients.⁷² This can create an overwhelming task for healthcare providers. In the Ufa train disaster the average number of patients per healthcare team was 12–15.²² Within a very short period, initial medical people (physicians, nurses, and members of voluntary organizations) must respond to victims of a burn disaster site. These medical personnel are supported by public and private organizations in the area, hospitals, casualty departments, clinics, fire brigades, and police; and they are coordinated by local authorities.³

When admitting patients and rendering qualified, specialized medical aid at a hospital, the participation of mixed physician teams is advisable.²² The Disaster Medical Assistance Teams (DMATs), Burn Specialty Teams (BSTs), and United States Army Institute for Surgical Research Special Medical Augmentation Response Teams (SMART) employ this concept.^{13,27,59,109} A senior surgeon should calculate the number of hours of operating room time required for proper care of all patients. A priority must be established for initial care and for any dressing changes and re-operations that are required. From that calculation, staffing requirements for the operating rooms, as well as for postoperative anesthetic care, intensive care, and ward care can be established. A senior surgeon should act as coordinator and get surgeons working as soon as patients arrive, keeping two operating theaters reserved for lifesaving operations.⁴⁶ Such calculations will drive the requirements for equipment and supplies and, with some foresight, drive the re-supply rate.

In the San Juanico tragedy, in which about 7000 people were injured, 2000 were hospitalized, 625 had severe burns, 300 died immediately, 250 died in hospitals later, and 60 000 were evacuated. Seven thousand (7000) people were involved in the rescue work during the first 48 hours. Of these, 200 were firefighters, 1000 were physicians, 1300 were paramedics, 1800 were nurses, 2000 were military personnel, and 750 were drivers and helicopter pilots.^{35,79}

Volunteers will come! Assistance from volunteers may occur spontaneously from a crowd or community as it did at Ramstein and Piper Alpha or respond to a formal request as in the Ufa train disaster.

You'll see the basic goodness in people when this sort of thing happens. Everyone rallies around. They don't think of payment. We had no problem with staffing, people just appeared. Although only a skeleton staff was on duty, the switchboard was flooded with nurses offering their services.⁸¹

Volunteers may need supervision and oversight to assure that they do not become overwhelmed or psychologically dysfunctional.

At Ramstein, the townspeople in Landstuhl heard the jet airplanes stop flying and many helicopters start flying and sensed a disaster. They responded to the Landstuhl Army Hospital and served as clean-up crews, traffic control, stretcher-bearers, and many other functions without being asked and often without any supervision. They just did the right things to help the effort.

Relief staffing

Relief personnel must replace or be assigned to the effort before the initial staff becomes exhausted. With so many serious cases, often the usual number of staff must be doubled. Usually there is no difficulty in finding them. Nurses often volunteer their services and the response is great.⁸¹ A plastic surgeon who had been attending a burn conference heard news of the Piper Alpha disaster and along with six other burn specialists from all over the country came to help treat burns.⁶² At Ramstein, off-duty hospital personnel augmented the initial staff and provided the relief staff needed to care for burned and mechanically traumatized victims.

Supply

Replenishing supplies used up in the care of many burned patients initially comes from warehousing facilities at or near the burn unit or hospital. Transport of additional supplies becomes crucial since the care of burned patients has high resources requirements for IV fluids, pain medications, topical antibiotics, and the like. If resupply cannot be affected, including 'just-in-time' supply systems, then there will be a decline in the care of burn victims or a need for secondary triage to a facility equipped and supplied to provide optimal care. Just-in-time supply systems may deplete usually resource-rich hospitals and burn centers, rendering them no different than a resource-poor environment.

Transportation

Coordination and mobilization of necessary transportation mechanisms (i.e. ground ambulance, aeromedical helicopter, and/or fixed-wing aeromedical transportation) and avoidance of calling in unneeded ambulances to a scene, which tends to confuse scene management, are essential.¹⁶ The same control may be necessary for leapfrogging facilities to not overload one hospital at any given time.¹¹¹ Most patients will be transported by ground vehicles, particularly if a disaster is in an urban area. In the MGM Grand Hotel fire in Las Vegas, the ambulances lined up in appropriate staging areas controlled

From Landiscina M, Bile L, Bollini C, et al. The burn patients and medically assisted helicopter transport. In: Masellis M, Gunn SWA, eds. The management of mass burn casualties and fire disasters. Dordrecht: Kluwer Academic; 1992; 251–252. With kind permission of Springer Science and Business Media.

by the on-scene fire command, while helicopters staged autonomous daring rescues. Remoteness of areas, traffic congestion, and the need for secondary triage may provide good reasons for aeromedical transfer. For a helicopter service in Italy, 2.5% of approximately 2500 flights concerned the secondary transport of burn victims while 0.5% provided direct medical assistance to burned patients at the scene of accidents.¹¹² Careful preparations by a hospital requesting transfers can be performed prior to air medical evacuation (Table 5.8). The size of a helicopter (or airplane) affects the optimal therapeutic access to various anatomical parts, monitoring of a patient, ventilatory assistance, and the number of patients that can be transported at one time. Larger helicopters with advanced instrumentation and excellent air speed effect the transportation during adverse meteorological conditions.¹¹²

Occasionally, the burn center may need to be evacuated, also. Such a plan was exercised at the Galveston Shriners' Hospital for Children during hurricane Katrina in August 2005. The patients, guardians, and staff were transferred to sister Shriners hospitals by medical jet. The repopulation of the hospital inpatients and acceptance of new acute burn referrals began approximately 40 hours after the all clear to return signal was given.¹¹³

After-action assessment

Disaster management must include the overall assessment of the consequences of a disaster. This assessment must be as accurate as possible whether it refers to a presumed or actual event.³ Awareness of the scale and nature of past disasters may aid in the formulation of new plans for dealing with mass burn casualties in the future.³¹ Uniform language and a framework to report and analyze disaster incidents is important and will contribute to evaluations that are more accurate.¹⁶ The study of 10 major fire-related public transport aircraft accidents led to changes in cabin interior materials and potential filters that could provide satisfactory respiratory protection.¹¹⁴ Modifications and revisions to disaster plans and disaster management can be effectively accomplished by initiating a mechanism of post-incident evaluation of disaster exercises and actual disaster responses. The central coordination of the response can be the focal point for this evaluation, which must include all of

the emergency medical services and the resources involved in a disaster response.⁷⁶

There is no doubt that the extensive after-action reports of the MGM Grand Hotel fire followed closely by the Las Vegas Hilton fire changed fire safety and fire prevention of high-rise hotels and buildings, forever. This resulted in pressurized fire escape systems, fire control centers in hotels, hospitals, and public buildings, fire sprinkling systems, extensive smoke alarm systems, and evacuation notices in hotels, hospitals, and public buildings among other things.

All of the agencies and individuals involved in a burn disaster should be assembled routinely, immediately following incidents in order to critique the events while the facts are clear in the minds of the providers.¹⁶ Information included in these sessions, although sometimes subjective, is usually quite candid and complete; and when combined with taped and written recordings of the incidents, it provides important lessons about the strengths and weaknesses of the management of the response.¹⁶ Relevant lessons learned include the knowledge that all public service agencies are integrally involved in successful management of a burn disaster and must be kept informed of current burn disaster plans. A multi-agency mass disaster plan that had been formulated and rehearsed in preparation for the Pan American Games was used when a pilotless aircraft struck a hotel.¹¹⁵ Such a critique depends on reliable information for successful management of the next disaster. From an in-depth review, individual facilities are able to effect changes such as directing online communications to an admitting office, preparing intensive care units and operating rooms, as well as establishing a person with authority to make decisions for the hospitals' ability to accept patients without questioning their fiscal resources. Major internal changes can be effected, based on data and corrections made, to allow a hospital to accept burn disaster victims at any hour that a disaster may occur. The practical benefit of these evaluation sessions is the fact that changes in disaster plans and operational management are made based on information learned during a disaster response critique.^{16,109} Critiques often identify problems on notification of hospitals and burn centers concerning the nature and extent of injuries, as well as the number of patients they should expect. Organized relay of pertinent patient information to hospital staff or mobilization of appropriate physicians, specialists, and staff is key. Matching patients with specific injuries, such as burns, to facilities capable of treating these specific problems, such as burn centers, is the mark of a well-designed and effectively managed disaster plan. In addition, forensic information is obtained that may be useful for disaster planning as well as for industrial change.^{115,116} Follow-on studies and after-action reports have helped structural and mechanical engineers understand the differences in conflagration destruction between modern integrated steel and glass and older concrete column and beam high-rise building fires.

Some important, but previously unknown, statistics have been generated from after-action reports. The total number of injured patients was more than six times higher and the number of casualties admitted to hospitals was nearly 20 times greater following outdoor disasters than indoor disasters.³⁵ The immediate death rate at the site was very high (74%) in indoor fires compared to outdoor disasters (35%), but the hospital death rate was lower following indoor disasters.^{31,35} Sixty

percent of burn victims of indoor disasters sustained burns covering less than 30% of their TBSA.³⁵ In a significant number of patients with very extensive burns (greater than 70% TBSA), they occurred after outdoor fires, while very few were admitted with extensive burns after indoor fires.¹³ Those who failed to escape from indoor fires died rapidly from a combination of hypoxia and inhalation of poisonous compounds.^{117,118} Such a mechanism was probably the initial cause of death in the Beverley Hills Supper Club fire, but the conflagration then destroyed the evidence by severely burning the dead as determined in the after-action reports. The after-action reports of the accidental release of chlorine toxic gas from a train tank car derailment showed that burn disaster planning could be exercised effectively for inhalation injuries.¹¹⁹ The poor prognosis of burn victims with large burns sustained in mass disasters has been emphasized and is reflected in the high mortality following outdoor disasters.^{15,31,106,120} The number of burn victims admitted with burns in the 30–70% TBSA range was consistently low, which is more important since patients with this burn size potentially obtain the greatest benefit from referral to a burn center.^{27,31} In an indoor disaster of another kind, the MGM Grand Hotel fire in Las Vegas resulted in 300 hospital admissions for smoke inhalation, but no burn injuries.¹²¹ After-action reports will allow analysis of the environmental impact of the disaster, the vulnerability of the territory, and the information, education, and participation of the population.⁴² In emergencies, human behavior is a decisive factor in the creation of dangerous or harmful situations and it plays a basic role in the evolution of the effects of a disaster.⁴² Retrospective studies are less helpful, but can direct future planning of burns mass disasters.¹²²

The positive effect of a previous disaster on the preparedness of the people involved is substantial.¹²³ A disaster plan must incorporate details of disasters occurring in several scenarios. These plans may be unique to an individual area, but all should include preparations for explosions.^{35,43, 58,72,79,95,98,106,124} Particular procedures regarding both medical assistance and general behavior, and those that rescue workers have to perform, must include educational campaigns, refresher courses, and training sessions aimed at citizens of every social extraction starting at school age.³ As an example, burn disaster from a forest fire would depend on the fire typology; and the variability depends on meteorological conditions.

Prior disasters and international responses to them underscore the need for a coordinated response to major burn disasters and the positive results of international cooperation.^{22,125} The disasters in Armenia and Chernobyl emphasized to the Soviet Health Ministry officials the importance of having contingency plans made in advance of any accident. That experience led to the rapid triage and transport of victims from the accident site to medical centers in surrounding towns following the Ufa train disaster. The Soviet experience during the Ufa incident demonstrated that such an organization of public health services permitted the rendering of aid to the majority of victims in a rapid and appropriate time frame.²² The Italian military have demonstrated their role in disaster relief.^{50,51} Physicians and other staff members who are not familiar with burn care must have some means to assess the extent of burns and initiate therapy. Vitale et al. have prepared a clinical file and protocol for general doctors and for non-specialized hos-

pital physicians to assist burn patients.¹⁰⁴ Such a file should be incorporated into every disaster plan. Placing ideal or consensus disaster plans with descriptions of duties of various personnel on a government website for wide electronic distribution, either before (to help with local disaster planning) or during a disaster (to help poorly or non-trained personnel), is a necessary current procedure. Such documents should be simple and easy to understand and use. These recommendations may have national or international applications. The lessons learned provide a framework for burn disaster management, should a group be asked to provide assistance in the future.¹²⁵ All of these data are important in planning for the next burn disaster.

National response systems

There is good evidence for an integrated disaster response system and for exercising to prepare healthcare and humanitarian workers for response to rare events. Mass casualty training is common in countries with adequate public health, medical infrastructure, and resources. There is little such coordination, planning and response in many countries. Examples of national disaster plans serve as the template for other countries to develop or strengthen their national disaster response.

In 1986 the United States sent a team to Germany to study the Ramstein air disaster. This team was composed of members of the Department of Defense and the American Burn Association. The primary objective was to prepare an after-action report of lessons learned for the Department of Defense, separate, but in concert with that of the United States Air Force. The secondary, but equally important, objective was to study the German national system that had handled the Ramstein air crash so well and provide a model for the United States to incorporate a burn disaster component into the national disaster plan of the National Defense Medical System (NDMS).

The disaster plan involved dividing the United States into workable units which the American Burn Association had already begun through its regionalization program. The objective of the regionalization program was to allow burn centers in sections of the United States to work together to improve the daily care of burned patients. The initial emphasis was to provide a common language for burn centers and non-burn center emergency departments. The Advanced Burn Life Support course⁵⁹ was in its infancy, but provided the initial education required to improve the overall burn care in the United States. The onus was on individual burn centers and burn center directors to provide expertise in burn care and to promulgate burn education throughout their catchment area. Working together the burn centers and burn center directors in a given area would adopt mechanisms similar to the German national burn distribution system that would allow transport of the burned patient to the nearest available burn center. Expanding that concept was the initial development of the regional and national burn disaster plan.⁶⁹

In the subsequent 20 years the United States and the American Burn Association have formulated a disaster management plan that, perhaps, can be used as a template for other countries' burn disaster plans and as an outline for international cooperation.^{27,59} The key background facts are:

- Burn injuries are common in mass disasters and terrorist attacks.
- Burn center care is the most efficient and cost-effective care for burn injuries.
- Burn centers are not the same as trauma centers.
- Burn centers are a unique national resource.
- The American Burn Association has the capacity to be a key component in national disaster readiness for mass burn casualties.²⁷

The definitions, supporting documentation, and key policy statements were published in 2005.^{27,59} It defined a mass burn casualty disaster as any catastrophic event in which the number of burn victims exceeds the capacity of the local burn center to provide optimal burn care. It went on to define surge capacity as the capacity to handle up to 50% more than the normal maximum number of burn patients when there is a disaster. Primary triage is the triage that occurs at the disaster scene or at the emergency department of the first receiving hospital; however, primary triage should be handled according to local and state mass casualty disaster plans. By federal legislation, state disaster plans must incorporate burn centers into such plans. In the American Burn Association's primary triage policy, a burned patient should be triaged to a burn center within 24 hours of the incident. The disaster site incident commander should call the nearest verified burn center regarding available capability and alternate site burned center information. Furthermore, the American Burn Association's recommended triage decision diagram that is specific for burn casualty disasters is shown in the Figure 5.5.^{27,59} Secondary triage is the transfer of burned patients from one burn center to another burn center when the first burn center reaches surge capacity using pre-established formal written transfer agreements. Secondary transfer is implemented within the first 48 hours of the incident by the burn center director when the burn center's surge capacity is reached.

The magnitude of the disaster will determine whether the involvement of local, state, or federal agencies is necessary. It is imperative that all elements work in concert. The disaster response in the United States is multi-tiered and ranked as follows:

- Local response disaster plan.
- State response disaster systems.
- National Disaster Medical System (NDMS):
 - Disaster Medical Assistance Teams (DMATs).
 - Burn Specialty Teams (BSTs).
- Military support to civil authorities:
 - United States Army Special Medical Augmentation Response Teams (SMARTs).

NDMS, a section of the Federal Emergency Management Agency (FEMA) in the Department of Homeland Security, manages and coordinates the federal medical response to major emergencies and federally declared disasters, including natural disasters, technological disasters, major transportation accidents, and acts of terrorism. NDMS can be activated by:

- The governor of an affected state may request a presidential declaration of disaster or emergency.
- A state health officer may request NDMS activation by the Department of Homeland Security.
- The Assistant Secretary of Defense for Health Affairs may request NDMS activation when military patient

levels exceed Department of Defense and Department of Veterans Affairs capabilities.

- At the request of the National Transportation Safety Board.²⁷

NDMS has three functions:

- Medical response to the disaster site.
- Patient movement from the disaster area to unaffected areas of the nation (responsibility of the Department of Defense — global patient movement requirements center of the United States transportation command, Scott Air Force Base, Illinois).
- Definitive medical care in unaffected areas.

DMATs provide care during a disaster and are composed of physicians, nurses, technicians, and administrative support staff.²⁷ BSTs are specialized DMATs designed to be deployed along with a DMAT to provide burn expertise and augment existing local capabilities.^{27,110} The team may assist the evaluation and resuscitation or help direct triage and transferred efforts. The BST is led by an American Burn Association member and is composed of approximately 15 burn experienced personnel, including the following:

- One surgeon (team leader).
- Six registered nurses.
- One anesthesia provider.
- One respiratory therapist.
- One administrative officer.
- Five support personnel selected based on mission requirements.²⁷

Military support to civil authorities is the final tier in the nation's disaster response system. Among the many SMART team resources are the two United States Army, Institute of Surgical Research, Brooke Army Medical Center, Fort Sam Houston, Texas, burn SMART teams. The mission of the SMART teams is to provide short duration medical liaison to local, and state, federal and Department of Defense agencies responding to disasters, military–civilian cooperative actions, humanitarian assistance missions, weapons of mass destruction incidents, or chemical, biological, radiological, nuclear, or explosive incidents. These teams were particularly useful to the William Randolph Hearst Burn Center in New York following the September 11, 2001 disaster and the days beyond.¹¹

Another aspect of the national burn disaster plan that was learned from the German system was a determination of bed availability. The American Burn Association's central office, working with United States Department of Health and Human Services Office of Public Health Emergency Preparedness established and maintained a real-time burn bed availability program for the nation. Initially, the American Burn Association worked with United States Army Institute of Surgical Research on a burn bed resource capability project. During times of crisis, a real-time burn bed resource capability reporting system is available. This model was further refined into a tracking system for the daily availability of burn beds for national emergencies,⁵³ which is currently surveilled electronically on a weekly basis by the Assistant Secretary of Defense for Health Affairs.⁵⁴

The American Burn Association has added a number of action items on disaster preparedness to assist disaster planning at all levels.²⁷ And thus the United States finally has a

comprehensive national disaster plan that incorporates burn disasters, is sophisticated, and serves as a model for other national disaster plans. The burn disaster subcommittee of the Committee on Organization and Delivery of Burn Care of the American Burn Association continuously updates this national burn disaster plan with recommendations. While the burn disaster plan speaks specifically to burn injuries, disasters with combined burn and trauma may require transfer to a trauma center for appropriate care. Clearly, when burn centers are overwhelmed, trauma centers serve as the next echelon of disaster relief.

Trauma systems

Burn centers should be integrated into large hospitals that are able to obtain assistance from several other specialty units from within the hospital.⁷² Trauma centers must begin to fill the gap that exists between resources for emergency medical systems and a disaster response.¹⁶ With leadership from trauma systems, meaningful planning can be accomplished among pre-hospital emergency medical systems, hospitals, and the public safety community.¹⁶ This shift in disaster management responsibility from the public safety sector to the medical community incorporates advances made in the organization of emergency medical services.¹⁶

International applications

During the past two decades the response to burn disasters has improved greatly. The Ufa train disaster,^{22,95} the Bali nightclub fire¹⁴ and Operation Iraqi Freedom¹⁰ have demonstrated that national boundaries no longer restrict burn disaster management. International cooperation during times of burn disasters, including repatriation of burn victims to their home country or to another country for optimal burn care, is a realistic expectation. Nations and non-governmental agencies look upon burn disasters as an opportunity to augment resource-poor countries and areas. Even though burn care is not optimal in all countries or even within parts of any country, the ability to move burned patients long distances, safely,^{68,70,71} and transport assistance in the way of trained personnel, supplies, and equipment has changed the expectations for burn disaster management in burn disasters and humanitarian crises.^{27,95}

Not all fire disasters result in mass burn casualties.¹² However, when a mass casualty event occurs involving a significant number of burned patients, an international response will be necessary to respond to the resources, materials, and manpower requirements,^{22,93} and to compensate for the destruction of systems and resources and/or the inability for the system to surge further. This is likely to be the usual situation in resource-poor countries, where local infrastructure is absent or unable to respond to the needs of multiple burn victims. This was the case in Bali. Not only did Australia provide response teams to aid in the immediate aftermath but they also evacuated many of the critically ill patients to facilities in Australia for the advanced care they required.¹⁴ The joint work of the Soviet and United States physicians during the Ufa train explosion demonstrated the efficacy of international cooperation. In planning for the care of victims of future disasters, such international cooperation should be illustrious.¹²⁵

After needs were assessed in the Bashkir train-gas pipeline disaster, two pediatric burn teams were sent to assist in the care of burned children. These teams integrated with the host nation's medical personnel to care for the burn victims.^{94,95} The United States team arrived 2 weeks after the disaster.⁹⁴ The cooperative effort allowed an increased frequency of dressings and more aggressive, rapid, and complete debridement of wounds. New techniques were introduced such as the use of a free hand skin graft knife, an air-driven dermatome, a skin graft mesher, and the use of dilute epinephrine solution for topical control of bleeding. Additional splints were made. One aspect of the burn care at Children's Hospital Nine was the role of parents providing much of the care of their children. They were present virtually all of the time on the wards. For those children whose parents were missing or children orphaned because of the disaster, others acted as surrogates. They fed the children, changed the beds and clothing, transported them around the hospitals, and received them directly from the dressing and operating rooms still partially anesthetized.^{94,95} Soviet medical and paramedical staff slowly realized the large number of patients involved, the extent of their injuries, and the logistics of their care. The result was acceptance of medical help offered by burn care teams from the United States, United Kingdom, France, Israel, and Cuba, which illustrated the importance of having access to international medical support following disasters of such magnitude that local (regional and national) medical resources were exhausted.³⁵ Full and immediate use should be made of colleagues called out under a major disaster plan or they will disappear.

As of the United States team joined the burn surgeons at Children's Hospital Nine in caring for children from the Ufa train disaster, certain ideas and materials also necessarily came along. Project Hope provided over 7000kg of badly needed medical supplies, drugs, and equipment, all of which arrived during the 2 weeks while the United States team was in the former Soviet Union. Such material aid permitted the Soviet surgeons to carry out usual therapy more effectively and the United States team to introduce some new ideas and techniques.⁹⁴ The Brooke Army team brought tons of much-needed supplies with them as well.¹²⁵ Authorities need to act on guidelines that provide for the stockpiling of specific mobilization materials in the most convenient location, the management of ambulance services, traffic control, the use of local and regional mass media, and the general means of transportation.³ At Ramstein, contingency supplies specifically for a mass disaster were brought in and used for the care of burned patients.

A bonus lesson learned from after-action reporting was that burn teams working together could exchange new ideas and techniques with colleagues from other parts of the world who are not familiar with such techniques.^{22,80} The effect of the combined efforts of the Soviet and United States Army medical teams who worked together at the largest hospital in the city of Ufa was that the team was able to effectively care for a large number of patients. Prior to this event, neither the hospital nor the Soviet physicians working at the hospital had had significant burn care experience.²² Other follow-on studies directed comparative studies of the microbial spectrum of burn wounds and medicinal sensitivities of the microorganisms.¹²⁶

Introduction	67
Who can be managed as an outpatient?	67
Treatment	70
Outpatient treatment of moderate and major burns	77

Introduction

Although there has been a remarkable decline in the incidence of burn injuries during the past several decades, currently in the United States each year about 700 000 individuals sustain a burn injury that requires treatment by a healthcare professional. Among these victims it is estimated that approximately 35 000 are admitted to hospitals. There are about 4500 fire- and burn-related deaths each year.¹ Therefore, thermal trauma typically results in an injury of low mortality in which the majority of care can be safely rendered in an ambulatory setting.

The outcome of burns treated in the outpatient setting is usually good. If, however, care is suboptimal, protracted morbidity or compromised function can result. The goals of therapy are to minimize pain and the risk of infection, achieve wound healing in a timely fashion, preserve physical function, minimize cosmetic deformity, and affect physical and psychosocial rehabilitation in the most expeditious manner.

Who can be managed as an outpatient?

When a patient with a burn is first evaluated, information is immediately available from which an accurate prognosis can be derived. For instance, a valuable easily remembered estimate of the probability of death from burn injury was published in 1998.² Using stepwise logistic regression analysis of 1665 patients, the authors identified three risk factors for death: age greater than 60 years; burns on more than 40% of the total body surface area (TBSA); and, the presence of inhalation injury. The mortality prediction for the presence of none of these risk factors is 0.3%; for the presence of one risk factor it is 3%; for two it is 33%; and, for all three it is approximately 90% (actual, 87%).

In addition to these risk factors, there are other factors — and a huge dose of common sense — which help determine

the initial treatment venue. These include depth of the burn; premorbid diseases; and, co-morbid factors such as associated trauma, distribution of the burn, and injuring agent. When outpatient care is an option the patient's social situation needs to be assessed. In some instances, it may be prudent to initiate care in a hospital so that potential complicating medical problems can be sorted out or the possibility of non-accidental trauma can be excluded.

Age

Patients between 5 and 20 years of age have the most favorable survival outcome from burns. The LA₅₀ (percent of total body surface area at which 50% of the patients live and 50% die) for this age cohort is 94.5% TBSA of burn.³ Younger individuals, especially infants, have an increase in morbidity as well as mortality from burn injury. In this group, child abuse or neglect must be included in the psychosocial analysis.^{4,5} The peak incidence of non-accidental burn injury is 13–24 months of age.⁶ Burns that are particularly suspicious are those whose appearance suggests an injury from a cigarette, hot iron, or immersion in hot water. The latter injury is identified by a stocking/glove distribution of the burn and a sharp linear demarcation between the burned and unburned skin (Figure 6.1a,b). Scalding which has occurred in an institution or in the presence of a caregiver other than one who has a biological relationship to the victim should also heighten one's suspicion. Even with trivial injury, if the burn was sustained under suspicious circumstances or the history does not correspond with the nature or distribution of the burn, the patient should be admitted to a hospital for their protection. Cases of suspected abuse or neglect must be referred to the appropriate social services agency.

Any patient over the age of 70 years with burns is in danger of dying regardless of the extent of the burn. The LA₅₀ for this age group is 29.5% TBSA of burn.³ Therefore, admitting the older patient to a hospital to assess their response to the injury can prove invaluable before treatment is continued as an outpatient.

Extent of the burn

The larger the percent of body surface area involved by the burn, the worse the prognosis. The percent of the body surface area can be roughly estimated by using the 'rule of nines'⁷ or more accurately by the technique of Lund and Browder (Table 6.1).⁸ A helpful adjunct in estimating the area of burn is to use the surface area of the patient's hand. This area, which approximates 1% of the TBSA,

Fig. 6.1 a,b Two cases of non-accidental trauma with immersion pattern scald burns. Note the sharp transverse linear demarcation between the burned and unburned skin.

includes the palm together with the fingers and thumb extended and adducted.

Any burned patient who requires intravenous fluid resuscitation should be admitted to a hospital. This includes adults and older children with burns in excess of 15% of the body

surface area, as well as younger children (under 5 years of age) and infants with burns in excess of 10% of the body surface area.⁹ In some instances, due to premorbid dehydration caused by physical activity, an arid or semi-arid climate, alcohol, or diuretics, some patients with smaller burns may

need supplemental intravenous fluids for optimal care. In the authors' practice, patients with small area burns that need intravenous fluid are often held for several hours or overnight in an observation area in the Emergency Department until their pain is controlled and fluid needs are met. Then care is continued as an outpatient.

Depth of the burn

The deeper the burn the worse is the prognosis. However, depth of small-area burns is less important in determining the need to initiate care in a hospital than the extent of the burn.

When a burn is first evaluated it is often difficult to determine its depth. The superficial injury of sunburn or its equivalent is easy to identify. Likewise, it is easy to discern a waxen, dry, inelastic, insensate, cadaveric-appearing wound as a full-thickness burn. However, it is difficult to distinguish the subtle differences between a superficial partial-thickness burn, which will heal spontaneously within 3 weeks, and a deeper partial-thickness burn which will take longer to heal. This is especially true for weeping wounds in which the blisters have ruptured. Initially, these wounds appear superficial and are perfused. However, with time, as the injured small blood vessels in the wound thrombose, the wound takes on an ischemic, cadaveric appearance of a deeper injury.^{10,11} This change does not reflect invasive infection but merely the natural evolution of the wound.

Premorbid diseases

Preexisting medical conditions often have a profound influence on the clinical course and outcome of a burn injury. While any medical disorder may have an adverse effect, there are a number of conditions that occur frequently among the burned and which may play a significant role in causation or outcome. For instance, any condition or habit that alters an individual's mental state may lead to a burn injury. These include seizure disorders, senility, and psychiatric illnesses as well as the use of sedatives, controlled substances, illegal and recreational drugs, and alcohol. These usually obligate hospital admission. Medical conditions that are known to enhance morbidity of patients with burns include renal failure, congestive heart failure, cardiac dysrhythmias, hypertension, chronic obstructive pulmonary disease, diabetes mellitus, sequelae of alcoholism, morbid obesity, conditions which require the use of steroids, and other diseases which compromise the immune system.¹² The clinical status of any of these disorders must be determined and their potential influence on the outcome assessed before determining whether the patient can be safely managed as an outpatient.

Co-morbid disorders

Respiratory complications

Inhalation injury and carbon monoxide poisoning substantially magnify the burned patient's risk and may occur even with no or trivial cutaneous injury.^{13,14} In addition, upper airway obstruction can be caused by the edema produced from burns of the oropharynx or the flux of fluid into the soft tissues of the upper airway resulting from deep burns of the face and/or neck. The full-blown adverse sequelae of these complications may not be immediately apparent.¹⁵ Therefore, if the

history of the accident or distribution of burns suggests any of these three complications, a period of monitored observation is warranted. Overnight observation is usually sufficient.

Associated trauma

Burns frequently occur with other forms of trauma. If the burn involves only a small area of the body, the associated trauma will dictate whether a patient needs to be admitted to a hospital.

Distribution of the burn

The location of the burn may have a profound effect on the patient's activities of daily living, and dictate the setting in which the patient receives care. For instance, the edema from a small-area superficial burn of the face may result in swelling of the eyelids, hampering the patient's vision (Figure 6.2), or burns that involve the lips or the oral cavity may inhibit efficient oral alimentation. Likewise, burns of the hands, feet, or those involving the perineum or adjacent areas may severely limit an individual's autonomy. While burns in these areas may not necessarily demand care in a hospital, there must be consideration of the assistance available to the patient when contemplating outpatient ambulatory care.

Because of fluid flux into the tissues beneath a burn, patients with circumferential burns of an extremity are in danger of ischemia of underlying and distal tissues from increased tissue pressure.¹⁶ Except for those with very superficial burns all patients with circumferential burns of an extremity should be monitored for evidence of elevated tissue pressure. Since the clinical signs of compartment syndrome and ischemia in a burned extremity are unreliable,¹⁷ the authors advocate measuring the tissue pressure by a direct method and uses the Stryker® Intracompartment Pressure Monitoring System. A tissue pressure above 40mmHg is the indication for surgical decompression of the injured limb. Alternatively, a Doppler ultrasonic flow meter can be used to assess the circulatory status of the extremity.¹⁷ A muffled first arterial sound and/

Fig. 6.2 Swelling caused by a burn that healed spontaneously without scar. For several days the edema of the eyelids prevented the patient from seeing.

or the absence of the second arterial sound is regarded as sufficient evidence of pathological elevation of the tissue pressure.

Burns across joints do not, for that reason alone, require admission to a hospital.

Injuring agent

Electricity

Patients exposed to low-voltage electricity, arbitrarily defined as less than 1000 volts (the most frequent source being household currents of 110 or 220 volts), are in great danger of dying at the accident scene from a cardiac dysrhythmia, usually ventricular fibrillation.¹⁸ Following low-voltage electrical exposure, the most frequent residual electrocardiographic abnormality is a non-specific change in the ST-T wave segment¹⁹ and the most troublesome dysrhythmias are among the atrial fibrillation-flutter group.²⁰ If the electrocardiogram is normal or becomes normal during observation, the chances of a subsequent dysrhythmia or cardiac arrest are virtually nil.

The tissue damage from low levels of electrical energy is usually small and most patients do not need to be admitted to a hospital. Occasionally, however, the damage to a child's lip, tongue, gums, and dentition from sucking on a defective energized electrical cord may preclude efficient oral alimentation. In this circumstance, hospital admission to establish satisfactory oral intake is probably wise. With an electrical burn of the lip, the injury is often deep enough to cause necrosis of the superior or inferior labial artery. The injured artery is prone to rupture between the fourth and seventh post-burn day. Therefore, the patient or caregiver must be warned of this possibility and instructed on the first aid measures for hemorrhage control.

Patients who sustain tissue damage from contact with high-voltage electricity generally require admission.

Chemicals

Although chemicals cause tissue damage by chemical reactions and not from heat, their care falls in the purview of burn care surgeons. Brushing off dry chemicals or copious lavage with water of wet chemicals are the appropriate emergency treatments.^{21,22} No one knows how long lavage should be continued, but up to 1 hour has been recommended.²³ One guide is the presence of pain. The supposition is that, as long as there is pain, the chemical remains active and continues to cause damage.

In some instances, there are specific antidotes for the pain caused by a chemical. For example, with hydrofluoric acid, the injured tissues should be injected with calcium gluconate.²⁴ Hydrofluoric acid also serves as a good example of the many chemicals that are absorbed into the body with the potential to cause organ injury. Exposure of concentrated hydrofluoric acid to as little as 3% of the body surface area can result in a fatal dysrhythmia from hypocalcemia caused by the binding of calcium by the absorbed fluoride ion.²⁵ Since it is impossible to remember the systemic sequelae of all the chemicals to which an individual might be exposed, the physician should identify the chemical and seek information from the local poison control center.

After emergency local wound care, the treatment of the residual wound from a chemical is the same as the treatment for any wound.

Social circumstances

Patients whose injuries may be non-accidental need to be admitted to a hospital for their protection.

Before a patient is discharged from emergency care, the physician should ascertain that there are satisfactory resources available for supervision and care, and a way in which the patient can readily access medical care. Therefore, the distance the patient lives from care needs to be taken into consideration. For outpatients a visiting nurse can be invaluable in providing wound care and monitoring for wound complications, as well as assessing the patient's physical progress and social situation.

Treatment

Cooling the burn

The first objective in burn wound care is to dissipate the heat. As long as the temperature in the tissues is above 44°C injury continues.²⁶ The first step is to remove the source of heat. Both clinical and experimental evidence indicate a beneficial effect from immediate active cooling of the wound to dissipate heat.²⁷ Cool tap water or saline at about 8°C (46.4°F) applied in any practical manner (e.g. compress, lavage, or immersion) is as effective as any other product or method.²⁸⁻³⁰ Colder substances, such as ice, may be detrimental.³¹ The period of time that is required for active cooling is brief.³² Typically, by the time most patients present for care, the tissues have already cooled spontaneously.

Active cooling also has several potential advantages beyond dissipation of heat. First, cooling stabilizes skin mast cells, decreasing histamine release and, thereby, decreasing edema of the wound. Secondly, in the first several hours after the injury, cooling is an effective way of controlling the pain of partial-thickness burns.^{33,34} In cooling for pain control, cool, but not ice-cold,^{35,36} moist compresses are applied to the painful wound. This method is applicable in the management of virtually all patients whose wounds can be safely cared for in an ambulatory setting. Because of the limited surface area of burn among most of those patients treated as outpatients, the detrimental systemic effects of active cooling, e.g. hypothermia from accelerated heat loss, should not occur. However, since water conducts heat 23 times faster than air, it makes good sense to monitor the patient's core temperature during active cooling of the wound. A limit to the surface area that is cooled is arbitrary, but a practical limit is about 10% of the TBSA.

Pain control

Burn wounds are painful. The most severe pain occurs with partial-thickness wounds devoid of epidermis. Initially it is intense and can prove to be unbearable. The pain spontaneously moderates after several hours but intensifies when wounds are manipulated during dressing changes, wound care, and physical activity. While eschar-covered burns may be insensate, when the eschar separates spontaneously or is

removed, the exposed viable tissues are painful when cut into, cauterized, or manipulated.³⁷

Narcotics are typically used as first-line treatment. In the emergency setting, small incremental doses of morphine can be given intravenously and titrated to effect. Subsequently, acetaminophen with codeine or oxycodone or similar analgesics, alone or in combination, are usually effective. Provided alteration of platelet function is not a concern, nonsteroidal anti-inflammatory drugs (NSAIDs) can be used. Analgesics can be supplemented with short-acting benzodiazepines, such as midazolam, to enhance sedation and provide anxiolysis. Most patients will require supplemental analgesics for wound dressing changes, physical therapy, and sleep.

Clearance of these classes of drugs is accelerated among those who regularly abuse alcohol or controlled substances.^{38,39} Therefore, remarkable amounts of analgesics and sedatives may be required.

If a patient's pain cannot be controlled by oral medication, the patient may need to be admitted to a hospital. In the hospital setting, effective pain control can usually be obtained by the patient-controlled analgesia method. Even with patient-controlled analgesia, supplemental analgesia and sedation will often be required when wound dressings are changed.

Topically applied or injected local anesthetics are not recommended in the management of burns.

Local burn wound care

Loose, devitalized tissue is gently trimmed away, a practice known as *épluchage*. This process should not cause pain or bleeding.

Blisters

Recommendations for the management of blisters are varied and range from leaving blisters intact,⁴⁰ to removing the blistered skin immediately,⁴¹ or delaying removal.⁴²

Those who advocate removal of blistered skin cite laboratory studies that show that the blister fluid exhibits several potentially detrimental effects.⁴¹ Immune function is depressed by impairment of polymorphonuclear leukocytes and lymphocytes. Blister fluid adversely affects neutrophil chemotaxis, opsonization, and intracellular killing. Inflammation is enhanced by the presence of metabolites of arachidonic acid in the blister fluid. A plasmin inhibitor in the blister fluid decreases vascular patency. Finally, blister fluid may provide a medium for the growth of bacteria. Based on these considerations, the case can be made that blistered skin should be removed to facilitate healing.

Conversely, these authors recommend leaving burn blisters intact. Blisters form in the stratum spinosum layer of the epidermis. An intact blister usually indicates a superficial partial-thickness wound, which will heal spontaneously within 3 weeks. If, under these circumstances, the blistered skin is removed, the wound is converted from an absolutely painless one to a painful, open wound exposed to colonization by bacteria and potential infection.⁴⁰ An infection in a burn wound covered by an intact blister rarely, if ever, occurs. Therefore, these authors prefer to leave blisters intact, and recommend that they be dressed for protection and not necessarily covered with medication.

If the blister remains intact and the wound is a superficial partial-thickness burn, spontaneous resorption of the fluid will usually begin in less than 1 week. The blistered skin will gradually wrinkle and collapse onto the healing wound surface. If the blister has ruptured, often the devitalized skin can be used as a protective dressing for the wound. Whether the blistered skin has remained intact or it has been used as a protective cover, at about the 10th day post burn, these authors inspect the underlying wound to determine its potential for healing spontaneously within the next 10 days. If it is unlikely that the wound will heal spontaneously within that time frame, surgical intervention to facilitate wound closure is undertaken.

Persistence of the blister, with no signs of spontaneous resorption of the fluid after 7–10 days, usually signifies that the underlying wound is either a deep partial-thickness or full-thickness wound.

There is often concern about large blisters in locations that limit range of motion or interfere with an efficient dressing. This concern most often occurs with a heat contact burn on the palm of the hand, a common injury among toddlers. Since contraction is a property of healing of all wounds, these authors prefer to decompress these blisters, leaving the blistered skin to protectively cover the wound. Then the palm, the thumb, and fingers can be dressed to be maintained in full extension with gentle pressure on the web spaces and the digits in moderate abduction until the danger of contraction is past. This is accomplished by several dressing methods. The hand can be immobilized in full palmar extension using an occlusive dressing consisting of triple antibiotic ointment on *Adaptic*® and padded with dressing sponges, including in the web spaces to maintain moderate abduction of the digits, and incorporating these dressings in a wrap of *Coban*®. A more secure technique is to use semi-rigid casting tape, referred to as 'Soft Cast' (3M™ Health Care, St. Paul, MN). This material consists of a polyurethane resin incorporated in a knitted fabric. Exposure to water activates the resin with a set time of 3–4 minutes. Curing is completed in about 10 more minutes. It can be removed by unwrapping or cutting it with a bandage scissors without the need to use a traditional cast saw. This is a tremendous advantage when treating young children. The technique for applying the 'Soft Cast' is shown in Figure 6.3a–h. The author keeps these casts in place for intervals of 3, 4, 7 (the most frequent interval), or 10 days, repeating the application as long as necessary to prevent contraction of the healing skin.

Cleansing the wound

For cleansing and to remove residual dirt, the wound can be gently washed with room temperature or tepid (100°F) normal saline or water with a mild, bland soap. Antiseptic solutions should not be used. The senior author's service uses *Shur-Cleans*® Skin Wound cleanser, which is composed of poloxamer 188 (polyethylene-polypropylene glycol), a surfactant, 20%, and USP water, 80%. *Shur-Cleans*® is a sterile cleansing solution designed for use on wounds of the skin in all areas, even around the eyes. According to the manufacturer it effectively removes contaminants from wounds without inducing tissue trauma.

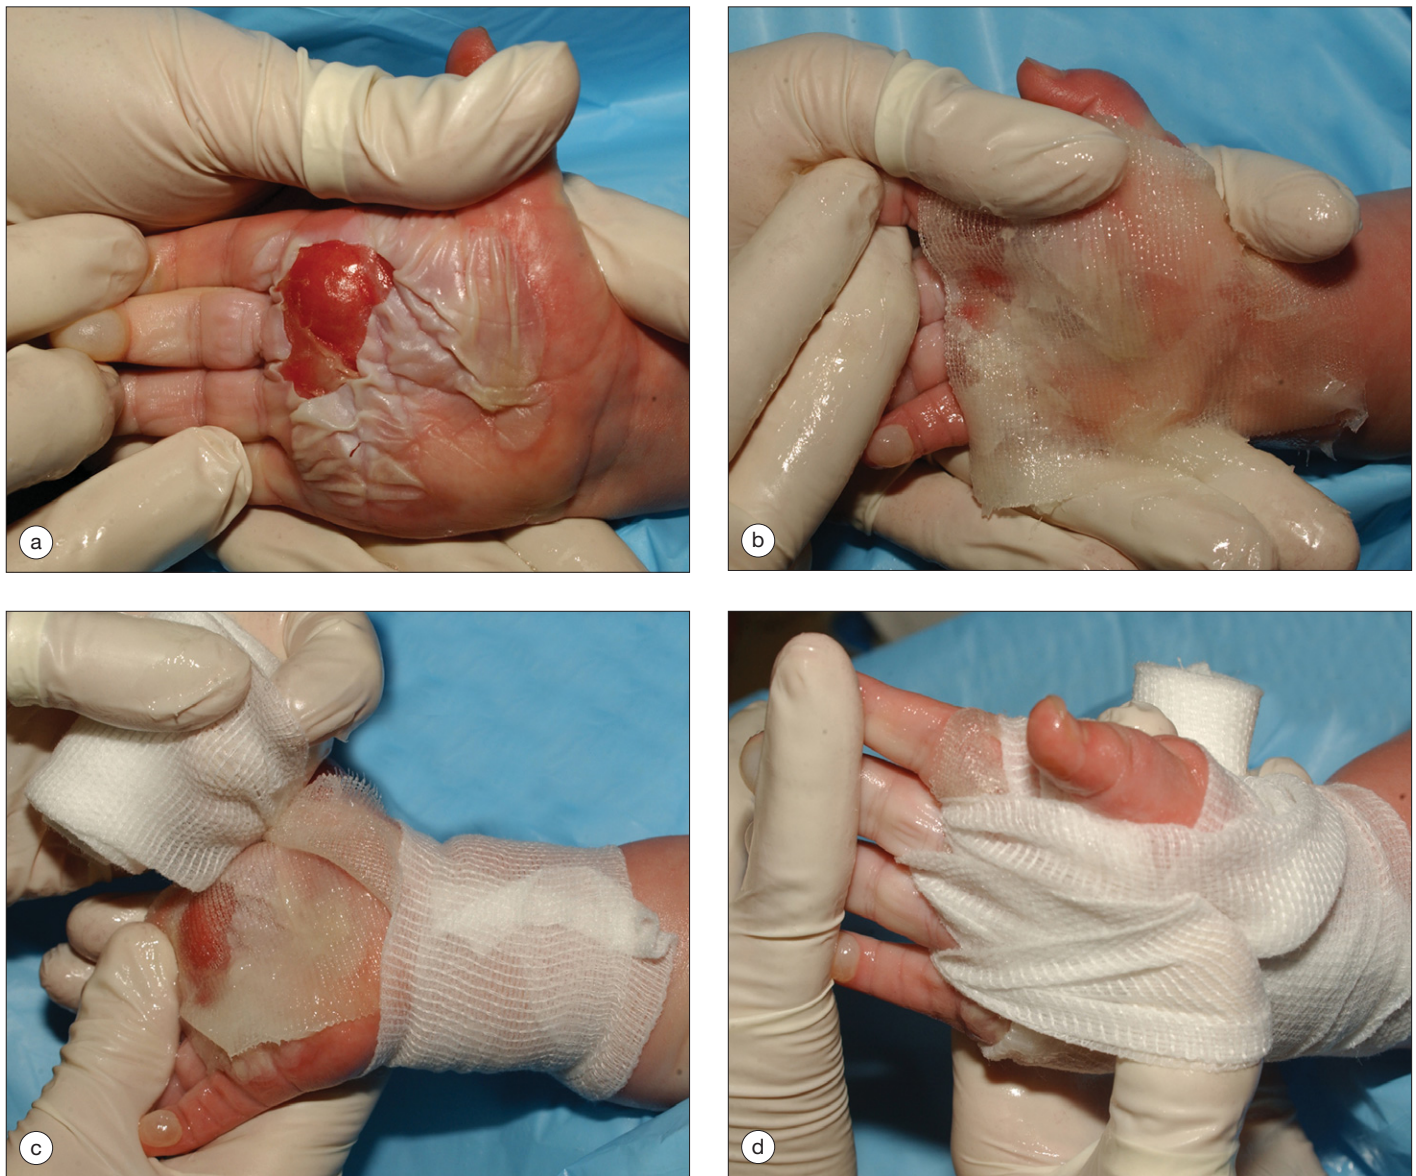

Fig. 6.3a–h ‘Soft’ casting technique to maintain optimal extension of the hand.

(a) Heat contact burns of the palm and tips of fingers. (b) Wound dressed with Adaptic® and triple antibiotic ointment. (c) Kling® wrap started by securing it around the wrist. (d) King® wrap threaded between fingers to prevent interdigital web formation.

In the treatment of burns from tar and asphalt, after cooling to dissipate heat, the solidified tar and asphalt can be removed by solvents that have a close structural affinity to these substances. Therefore, substances related to petrolatum (an oleaginous colloid suspension of solid microcrystalline waxes in petroleum oil) are effective. Medi-Sol™ Adhesive Remover is a citrus-based non-toxic, non-irritating Category I Medical Device solvent authorized by the FDA for use on the skin. It is an effective product for the removal of tar and asphalt.⁴³ It can be obtained from Orange-Sol Medical Products Division (1400 N Fiesta Blvd, Bldg. 100, Gilbert, AZ 85233-1000, phone 480-497-8822) or by using an internet search for ‘Medi-Sol.’ Medi-Sol™ Adhesive Remover is liberally applied and then removed by gentle wiping. Polysorbates alone or in combination with topical antibiotics⁴⁴ and topical antibiotics

in petrolatum base⁴⁵ can be used but are less effective, and repetitive applications are usually required.

Topical agents

There is a long tradition of applying substances to burn wounds in an attempt to prevent infection.⁴⁶ A large variety of antiseptics, antibiotics, and topical antibacterial (antimicrobial) agents have been advocated. Most of these agents have adverse local or systemic effects, or impede wound healing, or both. Additionally, there is no published evidence that the use of any topical agent designed to prevent or control infection will favorably influence the outcome of small burns.⁴⁷⁻⁴⁹ In spite of this, many physicians feel obligated to apply one of these agents to the wound. All published comparative studies show no advantage of these agents over petrolatum-impregnated

Fig. 6.3a–h—cont'd

(e) A strip of Webril™ is placed in the thumb/index finger web space preparatory to laying a strip of plaster-of-paris to maintain optimal abduction of the web space. (f) Application of the plaster-of-paris strip in the thumb/index finger web space while holding the metacarpal phalangeal joint of the thumb in optimal abduction. Because the metacarpal phalangeal joint of children is fragile, special care needs to be taken to avoid hyperextension of it. (g) Soft Cast® wrap being applied while maintaining thumb, thumb/index finger web space in optimal abduction and fingers in full extension until the Soft Cast® material sets. (h) Dressing being completed with a wrap of Coban®.

gauze.⁵⁰ However, if the treating physician believes that the use of a topical antimicrobial agent is desirable, and most do, there are several choices. Among topical antibacterial agents introduced for the treatment of burns during the past five decades, 1% silver sulfadiazine has been the most popular. However, its silver component makes it an antiseptic and, therefore, an inherent property is delay in wound healing. In comparative studies of partial-thickness burn wounds covered with dressings that do not contain antiseptics, e.g. TransCyte®,⁵¹ Biobrane®,⁵² and collagenase ointment with polymyxin B sulfate/bacitracin powder,⁵³ 1% silver sulfadiazine delayed spontaneous reepithelization of the

wound. However, if the wound surface is covered with eschar, 1% silver sulfadiazine, among topical antiseptics recommended for burn wounds, has the fewest side effects and is probably the current best recommendation. If the patient is allergic to sulfa products, silver sulfadiazine should not be used. Because sulfonamides are known to increase the possibility of kernicterus, silver sulfadiazine is not used on pregnant women, nursing mothers, and infants less than 2 months of age. Because silver sulfadiazine impedes epithelization, it should be discontinued when healing partial-thickness wounds are devoid of necrotic tissue and evidence of reepithelization is seen.

Alternatively, there has been increasing interest in the use of combinations of antibiotics in ointment for the treatment of small-area burns. These drugs have no clinically discernible detrimental effect on wound healing. These antimicrobial combinations include triple antibiotic ointment (neomycin, 3.5 mg/g; bacitracin zinc, 400 units/g; and polymyxin B sulfate, 5000 units/g) and polysporin (polymyxin B sulfate, 10000 units/g; and bacitracin zinc, 500 units/g). These antibiotic combinations have efficacy against the Gram-positive cocci and some of the aerobic Gram-negative bacilli that most frequently colonize small burn wounds. Occasionally, small superficial pustules caused by yeast develop on the surrounding uninjured or newly regenerated skin. Discontinuing the antimicrobial agent usually results in clearing of these lesions. The use of a topical antibiotic ointment usually decreases or eliminates the unpleasant odor often associated with the use of petrolatum-impregnated gauze alone. The senior author now uses these agents almost exclusively in the management of small-area burns when a topical antimicrobial is used.

Dressing the wound

Because there are virtually no objective studies on the subject, dogmatic recommendations for dressing small burn wounds cannot be made. Dressings serve three purposes:

- 1) to absorb drainage;
- 2) to provide protection and a measure of isolation of the wound from the environment; and
- 3) to decrease wound pain. In most instances these authors prefer to dress wounds and make the following suggestions.

Superficial partial-thickness burns, the equivalent of sunburn, with intact epidermis, require neither topical medication nor a dressing.

For relatively small superficial partial-thickness burns devoid of epithelium, it is generally conceded that topical antibacterial agents are not necessary.⁴⁷⁻⁴⁹ Non-medicinal white petrolatum-impregnated fine mesh or porous mesh gauze (Adaptic®), or fine mesh absorbent gauze impregnated with 3% bismuth tribromophenate in non-medicinal petrolatum blend (Xeroform®) are satisfactory wound covers. If the burn is deeper and contains adherent necrotic tissue, a topical antimicrobial agent may be used.

For practical reasons, most burns of the face are treated without dressing. These wounds may also be treated without topical medication, allowing the wounds to dry and form a crust. Because the dry wound is often uncomfortable and heals more slowly than moist wounds, many physicians prefer to use a thin layer of bland ointment combined with a topical antibiotic, e.g. Baciquent® (bacitracin in anhydrous lanolin, mineral oil, and white petrolatum). The ointment is applied to the wound after gentle cleansing with water once or twice daily, or more frequently as needed, particularly in a dry climate. Bacitracin has activity against Gram-positive bacteria. Occasionally it causes a contact dermatitis that impedes wound healing.

Since one purpose of dressings is to absorb drainage, the thickness of the dressing is determined by the amount of drainage generated between dressing changes. In weeping superficial partial-thickness wounds, the amount of drainage is greatest soon after the injury. As the character of the wound

changes and healing begins, drainage decreases. Lint-free, coarse mesh gauze, usually starting with about 20 thicknesses, is preferred by the authors.

The dressing is held in place with a gauze bandage (e.g. Kling® or Kerlix®) wrapped with sufficient tightness to hold the gauze in place but not so tightly as to impede circulation. Many use Flexinette® to secure the dressing. Stockinette, semi-impervious to liquid, can be used as an outer layer to help prevent the drainage from soaking through the dressing. As an alternative, a cohesive flexible bandage (Coflex®, Coban®, Cowrap™) can be used as an outer layer to hold a dressing securely in place and prevent drainage from seeping through. Joints are dressed to facilitate range of motion and fingers are dressed separately. However, among infants and young children, an effective way to hold the hand and fingers in extension is with a multilayer covering of one of the cohesive flexible bandages. This kind of a dressing functions as a 'soft' splint.

The frequency with which dressings are changed is arbitrary and dictated by the volume of drainage or the physical condition of the dressing. Recommendations range from twice daily, to as infrequently as once a week. Those who advocate twice-daily dressing changes do so based on the use of topical antimicrobials whose half-life is about 8 hours. Those who use petrolatum, antibiotic combinations in ointment, or bismuth-impregnated petrolatum gauze recommend less-frequent dressing changes, some extending the period to as long as 5 or 7 days.^{50,54}

For inpatients, the authors prefer once-daily or every other day dressing changes to permit daily inspection and cleansing of the wound. Moreover, among inpatients after about 24–48 hours, wound dressings are often saturated or disheveled. Daily dressing changes may be used in the care of outpatients even if the patient or another layperson is responsible for the inspection, cleansing, and redressing of the wound. Cleansing of the wound can often be incorporated into general body cleansing each day. The person responsible for wound care should be instructed in the clinical manifestations of wound infections.

In the management of burns among pediatric outpatients, the senior author now has an extensive and satisfying experience with the use of triple antibiotic ointment and dressing changes done at 3-, 4- or even 7-day intervals. In many instances these dressings are changed and the progress of healing checked at clinic visits. Therefore, parents do not need to deal with the disquieting chore of changing their child's dressings and inflicting pain on them.

Biologic wound dressings

The author does not believe it is necessary or advantageous to use human cadaver allografts, xenografts, or allogenic amnion in the management of burn patients who qualify for ambulatory care. However, in certain circumstances, amniotic membranes may be plentiful and therefore useful.

Allogenic amnion

Allogenic amnion, the innermost layer of the fetal membrane, has been used as a biologic wound dressing since 1910.⁵⁵ Although fragile and technically difficult to handle, allogenic amnion is particularly effective when used as a protective

dressing on partial-thickness burn wounds. It also has a good track record when used to protect and preserve a clean excised wound for subsequent autogenous skin grafting.⁶² When harvested, amniotic membranes are invariably contaminated and carry a biologic risk that can never be totally eliminated. The amnion is washed, sterilized with gamma irradiation and preserved in glycerol, by lyophilization or deep freezing. The risk of biologic transmission can be diminished by systematic serologic testing of the donor for syphilis, AIDS, and hepatitis at the time of harvesting the membrane and 6 months later.⁶²

Synthetic tissue-engineered wound dressings

The use of synthetic wound coverings is becoming more popular in the treatment of superficial partial-thickness burn wounds. The purported advantages are less pain, use of less pain medication, shorter wound healing time, improved compliance with scheduled outpatient visits, and lower costs.

Biobrane®

There are two prospective randomized clinical trials of small numbers of patients that show that in the treatment of superficial partial-thickness burns the use of Biobrane® results in less pain, a lower pain medication requirement, and shorter healing time when compared to those patients treated with 1% silver sulfadiazine.^{56,57}

Biobrane® is a bilayer fabric composed of an inner layer of knitted nylon threads coated with porcine collagen and an outer layer of rubberized silicone, pervious to gases but not to liquids and bacteria.⁵⁸ Wounds on which Biobrane® is to be applied must be carefully selected. They must be fresh, not infected, free of eschar and debris, moist, have a sensate surface, and demonstrate capillary blanching and refill. It is applied snugly to the cleansed wound overlapping itself or fixed to unburned skin with sterile strips of adhesive tape. The key to the successful use of Biobrane® is adherence to the wound. Therefore, the burned area must be dressed or splinted, especially across a joint, to prevent shearing of the Biobrane® from the wound surface. Satisfactory adherence usually occurs in about 4 days. If, at follow-up, the Biobrane® is found to be loose, the non-adherent area can be trimmed away and new Biobrane® applied. If sterile fluid accumulates beneath the synthetic dressing, it can be aspirated. However, if the fluid is purulent, the Biobrane® must be opened to permit complete drainage. Biobrane® is left intact until the wound has reepithelialized. Then it can be gently teased away. If the wound surface has even a thin veneer of residual necrotic tissue, Biobrane® will not adhere.

Hydrocolloid dressings

Hydrocolloid dressings are described as wafers, powders, or pastes composed of materials such as gelatin, pectin, and carboxymethyl-cellulose. They provide a moist environment favorable for wound healing and a barrier against exogenous bacteria. In comparison to wounds treated with 1% silver sulfadiazine, those treated with hydrocolloid occlusive dressings had more rapid wound healing, less pain, and needed fewer dressing changes.^{59,60} As a result, the cost of care was lower. Hydrocolloid dressings have been effective in the treatment of small-area partial-thickness burns and are especially useful in

the terminal phase of spontaneous healing of small burns. There are a number of products made by different manufacturers that are probably suitable, e.g. Cutinova® Thin (Beiersdorf-Jobst), DuoDerm® CGF Border Sterile Dressing (ConvaTec), RepliCare® Hydrocolloid Dressing (Smith & Nephew, Inc.), Restore® Wound Care Dressing (Hollister). Hydrocolloid dressings may be left in place for several days at a time.

TransCyte®

TransCyte® (Smith & Nephew, Inc.), a bioengineered skin substitute composed of human newborn fibroblasts cultured onto the nylon mesh layer of Biobrane®, is used as a dressing applied as soon as practical to eschar- and debris-free partial-thickness burn wounds. It is left in place until the wound heals. In clinical trials, TransCyte®-covered partial-thickness burn wounds healed faster than paired wounds treated with 1% silver sulfadiazine.^{51,61}

Other wound dressing/covering materials

Publications are replete with technologic advances and innovations for wound dressings with the purported goal of enhancement of spontaneous wound healing or protection of the wound until it can be closed with skin grafts or with tissue-engineered delivery systems which contain cultured autogenous keratinocytes with or without fibroblasts.⁶² This effort has resulted in several available products, including: Tissue Tech autograft system (Fidia Advanced Biopolymers S.r.l., Padua, Italy); Hyaff-NW (Fidia Advanced Biopolymers S.r.l.); Laserskin (Fidia Advanced Biopolymers S.r.l.); Apligraf (Organogenesis, Canton, MD); Epicell CEA (Genzyme, Cambridge, MA); Integra (Johnson and Johnson, Ratingen, Germany; Integra Life Sciences Corporation, Plainsboro NJ, USA); Alloderm (Life Cell Corporation, Woodlands, TX); Terumo (Terumo, Tokyo, Japan);⁶³ and, Pelnac (Kowa Company, Tokyo, Japan).⁶⁴ While the results of use of these products may be encouraging, a major limitation in their use is undoubtedly their high cost. However, among most of those treated as outpatients the area of burn wound requiring skin grafts is relatively small. Therefore, the use of these innovative products is unnecessary and standard techniques of surgical wound debridement and skin grafting suffice. Most of the clinical information about the efficacy of these products is anecdotal. However, information in medical publications can be accessed through the cost-free National Library of Medicine's online service: <http://www.nlm.nih.gov/>. On the search screen use the name of the product and burns as the subjects.

Elevation of the burned part

One of the most effective ways to reduce the incidence of infection in burns is to eliminate edema from the burned part. Burn injury elicits a flux of fluid into the tissues immediately subjacent to the wound. Additionally, there is a great tendency for the patient to hold the injured part immobile in a dependent position. To eliminate edema, the injured part should be exercised regularly and, when not in use, maintained slightly above the level of the heart. Merely elevating a leg off the floor to the level of the hip when in the sitting position is not sufficient. Holding the burned

forearm flexed and dependent in a sling will enhance edema. Specific instructions and a demonstration of the proper position should be explicit. Patients with small burns who experience persistent edema beyond 3 days are spending too much time with the part dependent.

The most efficient position for the injured part is just slightly above the level of the heart. To elevate the burned part higher does not further enhance removal of excess tissue fluid. However, for every incremental elevation of the part there is an incremental decrease in the arterial perfusion pressure.⁶⁵

When burns involve the lower extremity, walking and holding the leg in the dependent position often elicit severe pain. To diminish this effect, support, such as with a rubberized elastic bandage (Ace Bandage®), applied from the level of the toes to above the burn, should be used. This will also aid in reducing the accumulation of edema during walking.

Instructions and follow-up care

Before patients are released from emergency care, they are instructed in wound care, positioning, physical therapy, the clinical manifestations of infection, a convenient way to access medical care (usually by telephone), and given pain medication.

The authors often examine patients within the next several days. This allows re-inspection of the wound, assessment of the patient's compliance with instructions, and reinforcement of the principles of wound care. Often, because of pain during emergency care, the patient is distracted from fully understanding instructions. If concern remains, more frequent visits are scheduled until the physician is certain that care is being followed appropriately. After that, the patient can be seen at weekly intervals.

Definitive wound closure

A primary objective in burn care is to have all wounds healed within 1 month. Usually, this goal is easily achieved in an ambulatory setting. Burn wounds that heal spontaneously from the depth of the wound within 3 weeks have an excellent result. When this occurs, the skin functions normally with good elasticity, a nil incidence of hypertrophic scarring (scars that are red, raised, and indurated), and little, if any, alteration in pigmentation. The longer spontaneous healing takes, the worse the result. With longer healing periods, there is an increasing likelihood of developing hypertrophic scarring⁶⁶ and unsightly alterations in pigmentation. In addition, wounds that take a very long time to heal spontaneously may have unstable epithelium.

It is the surgeon's responsibility to make certain that burn wounds either heal spontaneously or are closed surgically in a timely fashion. If it is apparent that a wound will not heal spontaneously within 3 weeks, a better outcome^{67,68} can usually be anticipated by surgically removing the residual necrotic tissue and any granulation tissue by tangential excision⁶⁹ and applying a skin graft. In many instances it is obvious immediately or within several days as to whether spontaneous healing will occur within 3 weeks. Among wounds in which the subtle differences between superficial and deep partial-thickness

burns are not initially discernable, by 2 weeks after injury it is usually apparent whether or not the wound will heal spontaneously within the next 7–10 days. At about 10 days after injury, those wounds which are devoid of necrotic tissue and have evidence of squamous reepithelization will usually heal spontaneously within the desirable time frame. The beginning of reepithelization can be detected by seeing tiny opalescent islands of epithelium scattered throughout the wound. Inspection with a magnifying lens is helpful.

Infection and use of systemic antibiotics

There is no evidence that systemic antibiotic prophylaxis will decrease the incidence of infection in small burn wounds.⁷⁰ Antibiotics should be used only when there is evidence of infection.

The burn itself elicits inflammation. Therefore, the early manifestation of infection in the wound may be quite subtle. Mild erythema, edema, pain, and tenderness, all classic signs of infection, may be present without infection. However, when these manifestations increase over baseline, especially in the presence of lymphangitis and fever, treatment for infection should be instituted. Mainstays of treatment for infection include elevation and rest of the infected wound to control swelling and systemic antibiotic therapy. If the infection progresses the patient should be admitted to a hospital and antibiotics given intravenously.

Infections in the outpatient setting are usually caused by common skin flora. Those most frequently implicated are staphylococci. If there is evidence of infection, a culture of the surface of the wound should be obtained to identify the offending organism and narrow the spectrum of antibiotic therapy. While some burn care physicians advocate the use of burn wound biopsy quantitative culture rather than a wound surface culture,⁷¹ the authors have not found biopsy cultures to be necessary in the treatment of outpatient burns.

Among patients with burns treated in an ambulatory setting, it is quite unusual to develop systemic sepsis. However, patients should be instructed to take their temperature twice daily, once in the morning shortly after they get up from sleep, and again late in the afternoon before they eat supper. Localized infection will be reflected in fever in the afternoon or evening. Sustained fever is suggestive of systemic sepsis. Temperatures above 38°C, especially if accompanied by symptoms of malaise and anorexia, should be reported to the physician and the patient called in for an examination.

A change in the appearance of the wound during the first several days is more likely to result from a decrease in perfusion of the wound than from wound infection. This occurs as the blood vessels injured by heat clot off. This is frequently observed with scald burns. Any further burn wound discoloration, such as the appearance of gray or black spots, especially if there are other manifestations of infection, should raise concern for invasive infection. This rarely occurs among those treated as outpatients. However, if it does occur, the patient should be admitted to a hospital, the wound biopsied for histologic and microbiological studies,⁷² and treatment for infection instituted.

Burns, even minor ones, are regarded as tetanus-prone wounds.⁷³ Tetanus prophylaxis should be provided unless the patient has received tetanus immunization within 5 years.⁷⁴

Pruritus

Itching is an annoying, often unrelenting manifestation of healing and healed burn wounds.

Most burn patients develop pruritus. The incidence is higher among children. The lower extremities are most frequently affected and more frequently than the upper. The face is seldom involved.⁷⁵

Post-burn itching interferes with everything. Scratching often results in repetitive superficial wounding of both skin grafted and spontaneously healed wounds. Triggered and enhanced by environmental extremes, especially heat, physical activity, and stress, pruritus is most intense in the period immediately after wounds are healed. In most instances, it gradually diminishes and eventually stops. There are a few patients in whom it persists beyond 18 months. Patients with prolonged and chronic itching may harbor a psychogenic component.

The sensation of itch is most likely a primary sensory modality rather than, as widely held in the past, a forme fruste of pain.⁷⁶ Histamine, whose synthesis is known to be increased in healing and inflamed wounds,⁷⁷ as well as bradykinin and a series of endopeptides, have all been implicated in the genesis of itching.^{78,79} Because the precise mechanism of pruritus is not known, the likelihood is that there are multiple causative factors.

Since there are no controlled trials defining the best treatment, management is by trial and error. However, antihistamines, cool compress, and lotions are the cornerstones of most attempts to relieve burn-related itching. The antihistaminic diphenhydramine hydrochloride is the most frequently prescribed first treatment.⁸⁰ This drug has an added benefit of providing mild sedation. Other antihistamines, such as cyproheptadine hydrochloride, may also be tried. Analgesics of any kind may be helpful by altering perception of itching in the central nervous system. Combinations of antihistamines and analgesics may be tried. Hydroxyzine hydrochloride, a drug used to provide relief from anxiety and emotional tension, is used by many to help ameliorate itching. Many patients find comfort in an air-conditioned environment. Cool compresses also may temporarily interrupt the itching cycle. A variety of topical agents, including aloe vera,⁸¹ which has anti-inflammatory and antimicrobial properties, and skin moisturizing creams, such as Elta®, Vaseline Intensive Care®, Eucerin®, Nivea®, mineral oil, cocoa butter, and even lard, have been effective. Any odorless lotion free of alcohol is probably helpful. In addition, many patients prefer loose, soft clothing made from cotton.

The staff at the Shriners Burns Hospital, Galveston, Texas, uses the following protocol for the treatment of itching:

Step 1: Use moisturizing body shampoo and lotions.

Step 2: Diphenhydramine 1.25 mg/kg/dose PO q 4 h scheduled.

Step 3: Hydroxyzine 0.5 mg/kg/dose PO q 6 h and diphenhydramine 1.25 mg/kg/dose PO q 6 h. Alter-

nate medication so that patient is receiving one itch medicine every 3 hours while awake.

Step 4: Hydroxyzine 0.5 mg/kg/dose PO q 6 h and cyproheptadine 0.1 mg/kg/dose PO q 6 h and diphenhydramine 1.25 mg/kg/dose PO q 6 h. Alternate medication so that patient is receiving one itch medicine every 2 hours while awake.

Phillips and Robson⁸² advocate using penicillin in pruritus management. They observed that post-burn hypertrophic scars were much more frequently colonized with beta-hemolytic streptococcus, *Staphylococcus aureus*, and *Staph. epidermidis* compared to matched healed wounds without hypertrophic scarring. Therefore, to decrease the inflammation caused by these microorganisms, a root cause of itching, they used the following regimen: low-dose oral penicillin, 250 mg twice daily, to control the beta-hemolytic streptococcus, and aloe vera cream applied topically. As noted above, aloe vera has both anti-inflammatory and antimicrobial properties.

Traumatic blisters in reepithelialized wounds

As the wounds reepithelialize, the delicate thin layer of epithelium is fragile and easily damaged. Itching and other mild forms of trauma may cause small blisters. Patients need to be cautioned about this potential and assured that the epithelium will gain strength and that this will not be a long-term problem. If these blisters rupture, leaving small superficial wounds, the wounds may be left exposed to form a crust. Alternatively, Adaptic® or Xeroform® and a light dressing or one of the hydrocolloid wafer products may be used.

Rehabilitative physical care

Measures to preserve strength and restore function should be incorporated into the initial treatment plan.⁸³ Before leaving emergency care, the patient's physical activity should be discussed and a program for range of motion exercises and muscle strengthening outlined, both verbally and in writing.

At each subsequent follow-up visit, function and strength should be assessed. If there is lack of compliance or if the patient's function begins to deteriorate, the patient should be referred for supervised physical or occupational therapy, or both. If the injury extends across a joint, or involves the hand or distal portion of the lower extremity, it is advisable to have therapists involved from the outset. When there are burns of the face that have the potential for facial dysfunction, it may be prudent to have the patient evaluated and treated by a speech pathologist.

The potential for development of contractures and hypertrophic scars among the burned treated as outpatients is the same as for those treated as inpatients.⁸³ The principles of prevention and treatment of these complications apply in both settings.

Outpatient treatment of moderate and major burns

Some patients classified as having moderate or even major burn injuries (Table 6.2)⁸⁴ are suitable for treatment in the

TABLE 6.2 CLASSIFICATION OF BURN SEVERITY

Minor burn
15% TBSA or less in adults
10% TBSA or less in children and the elderly
2% TBSA or less full-thickness burn in children or adults without cosmetic or functional risk to eyes, ear, face, hands, feet, or perineum
Moderate burn
15–25% TBSA in adults with less than 10% full-thickness burn
10–20% TBSA partial-thickness burn in children under 10 and adults over 40 years of age with less than 10% full-thickness burn
10% TBSA or less full-thickness burn in children or adults without cosmetic or functional risk to eyes, ears, face, hands, feet, or perineum
Major burn
25% TBSA or greater
20% TBSA or greater in children under 10 and adults over 40 years of age
10% TBSA or greater full-thickness burn
All burns involving eyes, ears, face, hands, feet, or perineum that are likely to result in cosmetic or functional impairment
All high-voltage electrical burns
All burn injury complicated by major trauma or inhalation injury
All poor-risk patients with burn injury
TBSA, total body surface area.

ambulatory setting.⁸⁵ The purported advantages include less cost, less chance of exposure to antibiotic-resistant microorganisms, and a more psychologically comfortable environment for the patient. In spite of these benefits, caution should be exercised in selecting patients with moderate and major thermal injury for early discharge from the hospital. On the other hand, as convalescence progresses, many of these patients can have the terminal phase of their acute burn care completed safely as outpatients.

The conditions that need to be met in order to consider ambulatory care for any patient include: intravenous fluid resuscitation must be completed; there must be no ongoing complication; there must be no wound or systemic manifestation of sepsis; adequate enteral nutrition must be established; and pain control must be satisfactory with medication taken by mouth. Additionally, arrangements need to be made for wound care and physical and/or occupational therapy.

Patient assessment prior to transport to a specialized burn care unit from a referring hospital	91
Summary	91

Introduction

Advances in trauma and burn management over the past three decades have resulted in improved survival and reduced morbidity from major burns. The cost of such care, however, is high; it requires conservation of resources such that only a limited number of burn intensive care units with the capabilities of caring for such labor-intensive patients can be found — hence, regional burn care has evolved. This regionalization has led to the need for effective pre-hospital management, transportation, and emergency care. Progress in the development of rapid, effective transport systems has resulted in marked improvement in the clinical course and survival for victims of thermal trauma.

For burn victims, there are usually two phases of transport. The first is the entry of the burn patient into the emergency medical system with treatment at the scene and transport to the initial care facility. The second phase is the assessment and stabilization of the patient at the initial care facility and transportation to the burn intensive care unit.¹ With this perspective in mind, this chapter reviews current principles of optimal pre-hospital management, transportation, and emergency care.

Pre-hospital care

Prior to any specific treatment, a patient must be removed from the source of injury and the burning process stopped. As the patient is removed from the injuring source, care must be taken so that a rescuer does not become another victim.² All

caregivers should be aware of the possibility that they may be injured by contact with the patient or the patient's clothing. Universal precautions, including wearing gloves, gowns, masks, and protective eye wear, should be used whenever there is likely contact with blood or body fluids. Burning clothing should be removed as soon as possible to prevent further injury.³ All rings, watches, jewelry, and belts should be removed as they can retain heat and produce a tourniquet-like effect with digital vascular ischemia.⁴ If water is readily available, it should be poured directly on the burned area. Early cooling can reduce the depth of the burn and reduce pain, but cooling measures must be used with caution, since a significant drop in body temperature may result in hypothermia with ventricular fibrillation or asystole. Ice or ice packs should never be used, since they may cause further injury to the skin or produce hypothermia.

Initial management of chemical burns involves removing saturated clothing, brushing the skin if the agent is a powder, and irrigation with copious amounts of water, taking care not to spread chemical on burns to adjacent unburned areas. Irrigation with water should continue from the scene of the accident through emergency evaluation in the hospital. Efforts to neutralize chemicals are contraindicated due to the additional generation of heat, which would further contribute to tissue damage. A rescuer must be careful not to come in contact with the chemical, i.e. gloves, eye protectors, etc., should be worn.

Removal of a victim from an electrical current is best accomplished by turning off the current and by using a non-conductor to separate the victim from the source.⁵

On-site assessment of a burned patient

Assessment of a burned patient is divided into primary and secondary surveys. In the primary survey, immediate life-threatening conditions are quickly identified and treated. The primary survey is a rapid, systematic approach to identify life-threatening conditions. The secondary survey is a more thorough head-to-toe evaluation of the patient. Initial management of a burned patient should be the same as for any other trauma patient, with attention directed at airway, breathing, circulation, and cervical spine immobilization.

Primary assessment

Exposure to heated gases and smoke from the combustion of a variety of materials results in damage to the respiratory tract. Direct heat to the upper airways results in edema formation, which may obstruct the airway. Initially, 100%-humidi-

fied oxygen should be given to all patients when no obvious signs of respiratory distress are present. Upper airway obstruction may develop rapidly following injury, and the respiratory status must be continually monitored in order to assess the need for airway control and ventilator support. Progressive hoarseness is a sign of impending airway obstruction. Endotracheal intubation should be done early before edema obliterates the anatomy of the area.³

The patient's chest should be exposed in order to adequately assess ventilatory exchange. Circumferential burns may restrict breathing and chest movement. Airway patency alone does not assure adequate ventilation. After an airway is established, breathing must be assessed in order to insure adequate chest expansion. Impaired ventilation and poor oxygenation may be due to smoke inhalation or carbon monoxide intoxication. Endotracheal intubation is necessary for unconscious patients, for those in acute respiratory distress, or for patients with burns of the face or neck which may result in edema which causes obstruction of the airway.³ The nasal route is the recommended site of intubation. Assisted ventilation with 100%-humidified oxygen is required for all intubated patients.

Blood pressure is not the most accurate method of monitoring a patient with a large burn because of the pathophysiologic changes which accompany such an injury. Blood pressure may be difficult to ascertain because of edema in the extremities. A pulse rate may be somewhat more helpful in monitoring the appropriateness of fluid resuscitation.⁶

If a burn victim was in an explosion or deceleration accident, there is the possibility of a spinal cord injury. Appropriate cervical spine stabilization must be accomplished by whatever means necessary, including a cervical collar to keep the head immobilized until the condition can be evaluated.

Secondary assessment

After completing a primary assessment, a thorough head-to-toe evaluation of a patient is imperative.⁷ A careful determination of trauma other than obvious burn wounds should be made. As long as no immediate life-threatening injury or hazard is present, a secondary examination can be performed before moving a patient; precautions such as cervical collars, backboards, and splints should be used.⁸ Secondary assessment should examine a patient's past medical history, medications, allergies, and the mechanisms of injury.

There should never be a delay in transporting burn victims to an emergency facility due to an inability to establish intravenous (IV) access. If the local/regional emergency medical system (EMS) protocol prescribes that an IV line is started, then that protocol should be followed. The American Burn Association recommends that if a patient is less than 60 minutes from a hospital, an IV is not essential and can be deferred until a patient is at a hospital. If an IV line is established, Ringer's lactate solution should be infused at 500 mL/h in an adult and 250 mL/h in a child 5 years of age or over. In children younger than 5 years of age no IV lines are recommended.⁴

Pre-hospital care of wounds is basic and simple, because it requires only protection from the environment with an application of a clean dressing or sheet to cover the involved part. Covering wounds is the first step in diminishing pain. If it is approved for use by local/regional EMS, narcotics may be

given for pain, but only intravenously in small doses and only enough to control pain. Intramuscular or subcutaneous routes should never be used, since fluid resuscitation could result in unpredictable patterns of uptake.⁴ No topical antimicrobial agents should be applied in the field.^{4,9} The patient should then be wrapped in a clean sheet and blanket to minimize heat loss and to control temperature during transport.

Transport to hospital emergency department

Rapid, uncontrolled transport of a burn victim is not the highest priority, except in cases where other life-threatening conditions coexist. In the majority of accidents involving major burns, ground transportation of victims to a hospital is available and appropriate. Helicopter transport is of greatest use when the distance between an accident and a hospital is 30–150 miles or when a patient's condition warrants.¹⁰ Whatever the mode of transport, it should be of appropriate size, and have emergency equipment available as well as trained personnel, such as a nurse, physician, paramedic, or respiratory therapist.

Assessment and emergency treatment at initial care facility

The assessment of a patient with burn injuries in a hospital emergency department is essentially the same as outlined for a pre-hospital phase of care. The only real difference is the availability of more resources for diagnosis and treatment in an emergency department. As with other forms of trauma, the primary survey begins with the ABCs, and the establishment of an adequate airway is vital. Endotracheal intubation should be accomplished early if impending respiratory obstruction or ventilatory failure is anticipated, because it may be impossible after the onset of edema following the initiation of fluid therapy. Securing an endotracheal tube may be difficult because traditional methods often do not adhere to burned skin, and tubes are easily dislodged. One method of choice includes securing an endotracheal tube with woven tape, umbilical cord, under the ears as well as over the ears.¹¹ While doing assessments and making interventions for life-threatening problems in the primary survey, precautions should be taken to maintain cervical spine immobilization until injuries to the spine can be ruled out.

Following a primary survey, a thorough head-to-toe evaluation of a patient should be done. This includes obtaining a history as thorough as circumstances permit. The history should include the mechanism and time of the injury and a description of the surrounding environment, such as whether injuries were incurred in an enclosed space, the presence of noxious chemicals, the possibility of smoke inhalation, and any related trauma. A complete physical examination should include a careful neurological examination, as evidence of cerebral anoxic injury can be subtle. Patients with facial burns should have their corneas examined with fluorescent staining. Routine admission laboratories should include a complete blood count, serum electrolytes, glucose, blood urea nitrogen (BUN), and creatine. Pulmonary assessment should include arterial blood gases, chest X-rays, and carboxyhemoglobin.¹²

All extremities should be examined for pulses, especially with circumferential burns. Evaluation of pulses can be assisted by use of a Doppler ultrasound flowmeter. If pulses are absent, the involved limb may need urgent escharotomy for release of

the constrictive, unyielding eschar (Figure 7.1). In circumferential chest burns, escharotomy may also be necessary to relieve chest wall restriction and improve ventilation. Escharotomies may be performed at the bedside under IV sedation using electrocautery. Midaxial incisions are made through the eschar but not into subcutaneous tissue of the eschar in order to assure adequate release. Limbs should be elevated above the heart level. Pulses should be monitored for 48 hours.¹²

If pulses are still present, but appear endangered, chemical escharotomy with enzymatic ointments (Accuzyme, collagenase, Elase) can be effective. Enzymatic escharotomy in hand burns may be preferred since surgical incisions risk exposure of superficial nerves, vessels, and tendons. Enzymatic escharotomy is indicated only during the first 24–48 hours post-burn, and it should be used only in combination with a topical antimicrobial agent or sepsis can occur. With enzymatic escharotomy, there is usually a spike in temperature, which subsides after the enzyme is removed.

Evaluation of wounds

After the primary and secondary surveys are completed and resuscitation is underway, a more careful evaluation of burn wounds is performed. The wounds are gently cleaned, and loose skin and in large wounds blisters, greater than 2 cm, are debrided (see care of outpatient burns, Chapter 6). Blister fluid contains high levels of inflammatory mediators, which increase burn wound ischemia. The blister fluid is also a rich media for subsequent bacterial growth. Deep blisters on the palms and soles may be aspirated instead of debrided in order to improve patient comfort. After burn wound assessment is complete, the wounds are covered with a topical antimicrobial agent and appropriate burn dressings or a biological dressing is applied.

An estimate of burn size and depth assists in making a determination of severity, prognosis, and disposition of a patient. Burn size directly affects fluid resuscitation, nutritional support, and surgical interventions. The size of a burn wound is most frequently estimated by using the rule-of-nines method (Figure 7.2). A more accurate assessment can be made of a burn injury, especially in children, by using the Lund and Browder chart, which takes into account changes brought about by growth (Figure 7.3).^{4,9} The American Burn Association identifies certain injuries as usually requiring a referral to a burn center. Patients with these burns should be treated in a specialized burn facility after initial assessment and treatment at an emergency department. Questions about specific patients should be resolved by consultation with a burn center physician (Box 7.1).^{4,13}

Fluid resuscitation

Establishment of IV lines for fluid resuscitation is necessary for all patients with major burns including those with inhalation injury or other associated injuries. These lines are best started in the upper extremity peripherally. A minimum of two large-caliber IV catheters should be established through non-burned tissue if possible, or through burns if no unburned areas are available. Ringer's lactate solution should be infused at 2–4 mL/kg/% total body surface area (TBSA) which is burned.^{1,4,9} Children must have additional fluid for maintenance.¹⁴

Taking into account the increased evaporative water loss in the formula for fluid resuscitation for pediatric patients, the

(a) Chest escharotomy site.¹² (b) Escharotomy site on finger. (c) Lower limb escharotomy. (Figure 7.1a Reproduced from Herndon DN, Desai MH, Abston S, et al. Residents Manual. Galveston: Shriners' Burns Hospital, and the University of Texas Medical Branch 1992:1–17).

Fig. 7.2 Estimation of burn size using the rule-of-nines. (From Advanced Burn Life Support Providers Manual. Chicago, IL. American Burn Association 2005. Reproduced with permission from American Burn Association.⁴)

initial resuscitation should begin with $5000\text{ mL}/\text{m}^2/\%$ TBSA burned/day + $2000\text{ mL}/\text{m}^2/\text{TBSA}/\text{day}$ 5% dextrose in Ringer's lactate. This formula calls for one-half of the total amount to be given in the first 8 hours post-injury with the remainder given over the following 16 hours (Box 7.2).¹⁴

All resuscitation formulas are designed to serve as a guide only. The response to fluid administration and physiologic tolerance of a patient is the most important determinant. Additional fluids are commonly needed with inhalation injury, electrical burns, associated trauma, and delayed resuscitation. The appropriate resuscitation regimen administers the minimal amount of fluid necessary for maintenance of vital organ perfusion; the subsequent response of the patient over time will dictate if more or less fluid is needed so that the rate of fluid administration can be adjusted accordingly. Inadequate resuscitation can cause diminished perfusion of renal and mesen-

teric vascular beds. Fluid overload can produce undesired pulmonary or cerebral edema.

Urine output requirements

The single best monitor of fluid replacement is urine output. Acceptable hydration is indicated by a urine output of more than $30\text{ mL}/\text{h}$ in an adult ($0.5\text{ mL}/\text{kg}/\text{h}$) and $1\text{ mL}/\text{kg}/\text{h}$ in a child. Diuretics are generally not indicated during an acute resuscitation period. Patients with high-voltage electrical burns and crush injuries, with myoglobin and/or hemoglobin in the urine, have an increased risk of renal tubular obstruction. Sodium bicarbonate should be added to IV fluids in order to alkalinize the urine, and urine output should be maintained at $1\text{--}2\text{ mL}/\text{kg}/\text{h}$ as long as these pigments are in the urine.^{1,4} The addition of an osmotic diuretic such as mannitol may also be needed to assist in clearing the urine of these pigments.

Additional assessments and treatments

Decompression of stomach

To combat the problem of gastric ileus, a nasogastric tube should be inserted in all patients with major burns in order to decompress the stomach. This is especially important for patients being transported at high altitudes.¹³ Additionally, all patients should be restricted from taking anything by mouth until after the transfer has been completed. Decompression of the stomach is usually necessary because an anxious, apprehensive patient will swallow considerable amounts of air and distend the stomach. Narcotics also diminish peristalsis of the gastrointestinal tract and result in distension.

A patient must be kept warm and dry. Hypothermia is detrimental to traumatized patients and can be avoided or at least minimized by the use of sheet and blankets. Wet dressings should be avoided.

The degree of pain experienced initially by the burn victim is inversely proportional to the severity of the injury.⁸ No medication for pain relief should be given intramuscularly or subcutaneously. For mild pain, acetaminophen 650 mg orally every 4–6 hours may be given. For severe pain, morphine, $1\text{--}4\text{ mg}$ intravenously every 2–4 hours, is the drug choice, although meperidine (Demerol) $10\text{--}40\text{ mg}$ by IV push every 2–4 hours may be used.¹⁰ Recommendations for tetanus prophylaxis are based on the patient's immunization history. All patients with burns should receive 0.5 mL of tetanus toxoid. If prior immunization is absent or unclear, or if the last booster was more than 10 years ago, 250 units of tetanus immunoglobulin is also given.⁴

Transportation guidelines

The primary purpose of any transport teams is not to bring a patient to an intensive care unit but to bring that level of care to the patient as soon as possible. Therefore, the critical time involved in a transport scenario is the time it takes to get the team to the patient. The time involved in transporting a patient back to a burn center becomes secondary. Communication and teamwork are the keynotes to an effective transport system.

When transportation is required from a referring facility to a specialized burn center, a patient can be fairly well stabilized before being moved. Initially, the referring facility should be informed that all patient referrals require physician-to-

Age	0–1	1–4	5–9	10–14	15
A – ½ of head	9½%	8½%	6½%	5½%	4½%
B – ½ of one thigh	9½%	8½%	6½%	5½%	4½%
C – ½ of one leg	9½%	8½%	6½%	5½%	4½%

Fig. 7.3 Estimation of burn size using the Lund and Browder method.

BOX 7.1 Criteria for transfer of a burn patient to a burn center⁴

- Second-degree burns greater than 10% total body surface area (TBSA)
- Third-degree burns
- Burns that involve the face, hands, feet, genitalia, perineum, and major joints
- Chemical burns
- Electrical burns including lightning injuries
- Any burn with concomitant trauma in which the burn injuries pose the greatest risk to the patient
- Inhalation injury
- Patients with preexisting medical disorders that could complicate management, prolong recovery, or affect mortality
- Hospitals without qualified personnel or equipment for the care of critically burned children

Reproduced from Advanced Burn Life Supporters Manual. Chicago, IL: American Burn Association, 2005.⁴

physician discussion. Pertinent information needed will include patient demographic data; time, date, cause and extent of burn injury; weight and height; baseline vital signs; neurological status; laboratory data; respiratory status; previous medical and surgical history; and allergies.

A referring hospital is informed of specific treatment protocols regarding patient management prior to transfer. To ensure patient stability the following guidelines are offered:

BOX 7.2 Burn fluid resuscitation formula¹⁴

Fluid administration — Ringer's lactate

FIRST 24 HOURS:

- 5000 mL/m² burn + 2000 mL/body area m²; administer half in 8 hours and the remaining half in 16 hours

SECOND 24 HOURS:

- 3750 mL/m² burn + 1500 mL/body area m²; administer half in 8 hours and the remaining half in 16 hours
- Adjust the above rates to maintain a urine output of 1 mL/kg/h

Reproduced with permission from Herndon DN, Rutan R, Rutan T. The management of burned children. *J Burn Care Rehabil* 1993 14:3–8.¹⁴

- Establish two IV sites, preferably in an unburned upper extremity, and secure IV tubes with sutures.
- Insert a Foley catheter and monitor for acceptable urine output (30 mL/h adult, 1 mL/kg/h child).
- Insert a nasogastric tube and ensure that the patient remains NPO.
- Maintain body temperature between 38 and 39.0°C rectally.
- Stop all narcotics.
- For burns less than 24 hours old, only use lactated Ringer's solution. The staff physician will advise on the infusion rate, which is calculated based on the percentage of TBSA burned.

Following physician-to-physician contact and collection of all pertinent information, the physicians will make recommendations regarding an appropriate mode of transportation. The options are based on distance to a referring unit, patient complexity, and comprehensiveness of medical care required. Options include:

- Full medical intensive care unit transport with a complete team, consisting of a physician, a nurse, and a respiratory therapist from the burn facility.
- Medical intensive care transport via fixed-wing or helicopter with a team from a referring facility.
- Private plane with medical personnel to attend patient.
- Commercial airline.
- Private ground ambulance.
- Transport van with appropriate personnel.

Transport team composition

Because stabilization and care for a burned patient is so specialized, team selection is of the utmost importance. Traditionally, these patients were placed in an ambulance with an emergency medical technician and transported with few efforts made to stabilize the patient prior to transfer. As levels of care and technology have evolved, the need for specialized transport personnel has been increasingly observed. Today most transport teams are made up of one or more of the following healthcare members: a registered nurse, a respiratory therapist, and/or a staff physician or house resident. Because a large number of burned patients require some type of respiratory support due to inhalation injury or carbon monoxide intoxication, the respiratory therapist and nurse team has proven to be an effective combination. The background and training of nurses and therapists differ in many ways, so such a team provides a larger scope of knowledge and experience when both are utilized. Team members ideally should be cross-trained so that each member can function at the other's level of expertise.

Training and selection

Since the transport team will work in a high-stress environment, often with life or death consequences, these individuals must be carefully selected. The selection process should involve interviews with a nursing administrator, a director of respiratory therapy, and a medical director of a transport program.

Minimum requirements for transport team members should include:

- Transport nurse qualifications:
 - a registered nurse;
 - minimum of 6 months burn care experience;
 - current cardiopulmonary resuscitation (CPR) certification;
 - advanced cardiac life support (ACLS) or pediatric advanced life support (PALS) certification;
 - able to demonstrate clinical competency;
 - observe two transports;
 - a valid passport for international response.
- Transport respiratory therapist qualifications:
 - registered/certified respiratory therapist with 6 months burn care experience;
 - licensed by appropriate regulatory agency as a respiratory care practitioner;
 - have current CPR certification;

- have ACLS or PALS certification;
- able to demonstrate clinical competency;
- observe two transports;
- demonstrate a working knowledge of transport equipment;
- a valid passport for international response.

Because all of the care rendered by a transport team outside a hospital is given as an extension of care from a transporting/receiving facility, specific steps must be taken to protect staff and physicians from medical liability and to provide consistent care for all patients. Strict protocols are used to guide all patient care; team members should be in constant communications with an attending physician regarding a patient's condition and the interventions to be considered. Team members must be proficient at a number of procedures, which may be needed during transport or while stabilizing a patient prior to transport. To keep up with current technology and changes, team members should be included in discussions of recent transports and current management techniques, so that they can discuss patient care issues, receive ongoing in-service education, and participate in a review of the quality of transports.

Modes of transportation

Once the need for transport of a burned patient is established, the decision must be rendered concerning what type of transportation vehicle is to be used (Table 7.1). There are two models of transport commonly used: ground (ambulance/transport vehicle), air (helicopter, fixed wing), or a combination of both. Factors to be considered when selecting a mode of transportation are the condition of the patient and the distance involved. The level of the severity of the burn mandates the speed with which the team must arrive in order to stabilize and transport a patient.¹⁵

Ground transport

Ground transport should be considered to cover distances of 70 miles or less; however, sometimes a patient's condition may require air transport, particularly helicopter transport, even though the distance is within the 70-mile range. The ground transport vehicle should be modified with special equipment needed for intensive care transport, and there must be enough room to comfortably seat team members and equipment.

Air transport

Air transport is used primarily when long distances or the critical nature of an injury separate a team from a patient. Air transport, however, does present its own unique set of problems. Aviation physiology is a specialty unto itself, and the gas laws play an important role in air transport and must be taken into consideration.

Dalton's law states that in a mixture of gases, the total pressure exerted by the mixture is equal to the sum of the pressures each would exert alone.¹⁶ This is important when changing a patient's altitude because as altitude increases, barometric pressure decreases. The percentage of nitrogen, oxygen, and carbon dioxide remain the same, but the partial pressures they exert change (Table 7.2).¹⁷

Altitude is an important factor in the oxygenation of a transported patient and constant monitoring by a team is

TABLE 7.1 TRANSPORT CRITERIA: MODE AND TEAM COMPOSITION, BURNS \leq 6 DAYS POST-BURN¹⁵

Weight	% Burn	Distance (miles)	Team*	Transport mode
\leq 3	Any	75	C	Van, helicopter
		76–250	C	Turboprop airplane
		\geq 251	C	Learjet
3.1–20	\leq 10	75	N-RT	Van, helicopter
		76–500	N-RT	Commercial flight or turboprop airplane
		\geq 501	N-RT	Commercial airplane or Learjet
	\geq 10	75	C	Van, helicopter
		76–250	C	Turboprop airplane
		\geq 251	C	Learjet
20 \geq 20	\leq 20	75	N	Commercial flight or turboprop airplane
		76–500	N-RT	
		\geq 501	N-RT	Commercial airplane or Learjet
	\geq 20	75	N	Van, helicopter
		76–500	C	Turboprop plane
		\geq 501	C	Jet

*C, Complete team (doctor, nurse, respiratory therapist); N, nurse; RT, respiratory therapist.
If any of the following criteria exist, the transport shall be changed to the fastest mode with a complete team:

- depressed mental status,
- drug depression,
- respiratory support,
- unstable cardiovascular system,
- presence of associated diseases,
- decreased urine output unresponsiveness to appropriate fluid administration,
- absent or marginal venous access,
- hypothermia unresponsive to corrective measures.

TABLE 7.2 ALTITUDE'S EFFECTS ON BLOOD GAS VALUES

Altitude	Pressure	Tracheal PO ₂	Alveolar PO ₂	Alveolar PCO ₂
Sea level	760	149	103	40
5000 feet	632	122	79	38
10000 feet	523	100	61	36
15000 feet	429	80	46	33
20000 feet	349	63	33	30

required under such circumstances. Boyle's law states that the volume of gas is inversely proportional to the pressure to which it is subject at a constant temperature. This gas law significantly affects patients with air leaks and free air in the abdomen, because as altitude increases, the volume of air in closed cavities also increases.¹⁸ For this reason, all air that can be reached should be evacuated prior to an increase in altitude. Intrathoracic air and gastric air must be removed via functional chest tubes or nasogastric tubes and periodically checked during transport. Other factors that should be considered during air transport are reduced cabin pressure, turbulence, noise, and vibration, changes in barometric pressure, and acceleration/deceleration forces. Physiologic changes which affect a patient and team members include middle ear dysfunction, pressure-related problems with sinuses, air expansion in a gastrointestinal tract, and motion sickness. Utilizing transport vehicles that have pressurized cabins can reduce or eliminate most of these problems.¹⁹

Helicopters and fixed-wing aircraft

Helicopters and fixed-wing aircraft both have advantages and disadvantages related to patient care. Helicopters are widely used for short-distance medical air transport. Medical helicopters, because they are usually based on hospital premises, have no need to use airport facilities or ambulance services and, thereby, reduce team response time. Helicopters are able to land close to a referring hospital. Additionally, helicopters provide ease in loading and unloading patients and equipment.¹⁵ The disadvantages of helicopter transport include its limited range, usually less than 150 miles,²⁰ and its non-pressurized cabin which limits the altitude at which patients can be safely carried. The low-altitude capabilities also subject the aircraft to variability in weather (i.e. fog, rain, and reduced visibility); therefore, helicopter flights experience much more interference due to the weather. Other disadvantages include noise, vibrations, reduced air speed, small working space, lower weight accommodation, and high maintenance requirements.¹⁵

When long distances must be traveled (greater than 150 miles) or when increased altitude is necessary, fixed-wing aircraft are considered as a viable mode of transport for patients. The advantages of using fixed-wing aircraft include: long-range capabilities, increased speed, ability to fly in most weather conditions, control of cabin pressure and temperature, larger cabin space, and more liberal weight restrictions. Disadvantages of fixed-wing aircraft include the need for an airport with adequate runway length, difficulty in loading and unloading patients and equipment, and the pressure of air turbulence and noise.

Equipment

Because medical equipment used in intensive care units has evolved tremendously in the last 10 years, there is no reason that these advances should not be extended to the equipment, which is used in a transport program. Tables 7.3 and 7.4 outline the drugs and equipment used in our successful transport

system. The transport team must be able to provide ICU level care whenever needed. Most hospitals are well stocked and able to provide necessary supplies for initial patient stabilization and resuscitation; however, specialty items relating to the care of burn patients may not be present or adequate to meet the needs of burn victims. It is imperative

that adequate equipment be available to handle any situation that may arise during a transport process (Figure 7.4). Extra battery packs and electrical converters on fixed-wing aircraft are recommended due to long transport times and delays caused by unforeseeable circumstances of weather or logistics.

Portable monitor

A portable ECG monitor capable of monitoring two pressure channels should accompany all patients in transport. This allows for continuous monitoring of heart rate, rhythm, and arterial blood pressure. The second pressure channel may be used for patients with a pulmonary artery catheter or those

Fig. 7.4 Typical equipment used in transport of a patient.

Fig. 7.5 Portable ECG monitor used in transport.

who need intracranial pressure monitoring. This monitor should be small and lightweight but able to provide a display bright enough to be seen from several feet away. The monitor should have its own rechargeable power supply which continuously charges while connected to an alternating current (AC) power supply. One suitable unit is the Protocol Systems Propaq 106 portable monitor (Figure 7.5). This monitor has two pressure channels; it provides a continuous display of ECG, heart rate, systolic, diastolic, and mean blood pressure; it can display temperature and oxygen saturation; and it is also capable of operating a non-invasive blood pressure cuff. High and low alarms for each monitored parameter can be set, silenced, or disabled by a trained operator.

Infusion pump

Continuous delivery of fluids and pharmacological agents must not be interrupted during transport. Infusion pumps can be easily attached to stretchers and are usually capable of operating for several hours on internal batteries. These devices should have alarms to warn of infusion problems and should be as small and lightweight as possible (Figure 7.6).

Ventilator

Size, weight, and oxygen consumption are the primary concerns in selecting transport ventilators. A weight under 5 pounds (2.2kg) is desirable, and a ventilator's dimensions should make it easy to mount or to place on a bed. Orientation of controls should be along a single plane, and inadvertent movement of dials should be difficult.²¹ The ventilator breathing circuit and exhalation valve should be kept simple, and incorrect assembly should be impossible. The TXP transport ventilator (Percussionaire Corporation, Sand Point, ID) is a portable pressure-limited time-cycled ventilator and is approved for in-flight use by the US Air Force (Figure 7.7). The transport ventilator weighs 1.5 pounds (0.68kg), can be set to provide respiratory rates of between 6 and 250 breaths per minute, and provides tidal volumes of between 5 and 1500cc. This ventilator is powered entirely by oxygen and requires no electrical power. All timing circuit gases are delivered to the patient so that operation of the ventilator does not

Fig. 7.6 Portable IV pump used in transport.

Fig. 7.7 TXP transport ventilator.

consume additional oxygen. The I:E ratios are preset at the factory from 1:1 at frequencies of 250 cycles per minute to 1:5 at a rate of 6 cycles per minute. As a result, breath stacking and undesired overinflation due to air trapping may be avoided.²²

Stabilization

One of the primary reasons for a specialized transport team is to be able to transport a patient in as stable condition as possible. Current practice has evolved to embrace the concept that events during the first few hours following burn injury may affect the eventual outcome of the patient; this is especially true with regard to fluid management and inhalation injury. Stabilization techniques performed by the transport team have been expanded to include procedures that are usually not performed by nursing or respiratory personnel. Such techniques include interpreting radiographs and laboratory results and then conferring with fellow team members, referring physicians, and the team's own medical staff in order to arrive at a diagnosis and plan for stabilization. The transport team may perform such procedures as venous cannulation, endotracheal intubation, arterial blood gas interpretation, and management of mechanical ventilators. Team members may request new radiographs, in order to assess catheter or endotracheal tube placement or to assess the pulmonary system's condition. Team members may aid in the diagnosis of air leaks (pneumothorax) and evacuate the pleural space of the lung by needle aspiration as indicated. All of these procedures may be immediately necessary and lifesaving. Cross-training of all team members to be able to perform the others' jobs is recommended in order to safeguard patients in the event that any team member becomes incapacitated during transport. All these skills can be learned via experience in a burn intensive care unit, through formal training seminars, and via a thorough orientation program. Mature judgment, excellent clinical skills, and the ability to function under stress are characteristics needed when selecting candidates for a transport program.

Patient assessment prior to transport to a specialized burn care unit from a referring hospital

Initial assessment upon arrival of a flight team should include a list of standard procedures for determining a burned patient's current condition. First, a thorough review of the patient's history concerning the accident and past medical history must be done. This process provides the transport team with an excellent base from which to begin to formulate a plan of action. The patient will certainly have been diagnosed by a referring physician; however, a transport team often finds problems overlooked in initial evaluations. Since burn care is a specialized field, modes of treatment may vary greatly outside the burn treatment community. Frequently, a referring hospital is not well versed in the treatment of burn victims and should not be expected to display the expertise found among clinicians who work with such patients everyday. Thus, the next step in stabilizing a burn patient is a physical assessment done by a transport team. These procedures should always be

performed in the same order and in a structured fashion. Assessment of a burn patient begins with the ABCs of a primary survey, including airway, breathing, circulation, cervical spine immobilization, and a brief baseline neurological examination. All patients should be placed on supplemental oxygen prior to transport in order to minimize the effects of altitude changes on oxygenation. Two IV lines should be started peripherally with a 16-gauge catheter or larger. Ideally, IV lines should be placed in non-burn areas but may be placed through a burn if they are the only sites available for cannulation. Intravenous lines should be sutured in place because venous access may not be available after the onset of generalized edema. The fluid of choice for initial resuscitation is lactated Ringer's solution.

In addition to initial stabilization procedures, blood should be obtained for initial laboratory studies if not already done. Initial diagnostic studies include hematocrit, electrolytes, urinalysis, chest X-ray, arterial blood gas, and carboxyhemoglobin levels. Any correction of laboratory values must be done prior to transfer and verified with repeat studies. Electrocardiographic monitoring should be instituted on any patient prior to transfer. Electrode patches may be a problem to place because the adhesive will not stick to burned skin. If alternative sites for placement cannot be found, an option for monitoring is to insert skin staples and attach the monitor leads to them with alligator clips. This provides a stable monitoring system, particularly for the agitated or restless patient who may displace needle electrodes. A Foley catheter with a urimeter should be placed to accurately monitor urine output. Acceptable hydration is indicated by a urine output of more than 30 mL/h in an adult (5 mL/kg/h) and at least 1 mL/kg/h in a child.

With the exception of escharotomies, open chest wounds, and actively bleeding wounds, management during transport consists of simply covering wounds with a topical antimicrobial agent or a biological dressing. Wet dressings are contraindicated because of the decreased thermoregulatory capacity of patients sustaining large burns and the possibility of hypothermia. To combat the problem of a gastric ileus, a nasogastric tube should be inserted in all burn patients in order to decompress the stomach. This is especially important for patients being transferred at high altitudes. Hypothermia can be avoided or minimized by the use of heated blankets and/or aluminized Mylar space blankets. The patient's rectal temperature must be kept between 37.5 and 39.0°C.

A clear, concise, chronological record of the mechanism of injury and assessment of airway, breathing, and circulation should be kept in the field and en route to the hospital. This information is vital for a referring facility to better understand and anticipate the condition of the patient. Additionally, all treatments, including invasive procedures, must be recorded, along with a patient's response to these interventions.

Summary

Burn injuries present a major challenge to a healthcare team, but an orderly, systematic approach can simplify stabilization and management. A clear understanding of the pathophysiology of burn injuries is essential for providing quality burn care in the pre-hospital setting, at the receiving healthcare facility,

and at the referring hospital prior to transport. After a patient has been rescued from an injury-causing agent, assessment of the burn victim begins with a primary survey. Life-threatening injuries must be treated first, followed by a secondary survey, which documents and treats other injuries or problems. Intravenous access may be established in concert with local/regional medical control and appropriate fluid resuscitation begun. Burn wounds should be covered with clean, dry sheets; and the patient should be kept warm with blankets to prevent hypothermia. The patient should be transported to an emergency room in the most appropriate mode available.

At the local hospital, it should be determined if a burn patient needs burn center care according to the American Burn Association Guidelines. In preparing for organizing

a transfer of a burn victim, consideration must be given to the continued monitoring and management of the patient during transport. In transferring burn patients, the same priorities developed for pre-hospital management remain valid. During initial assessment and treatment and throughout transport, the transport team must ensure that the patient has an adequate airway, breathing, circulation, fluid resuscitation, urine output, and pain control. Ideally, transport of burn victims will occur through an organized, protocol-driven plan that includes specialized transport mechanisms and personnel. Successful transport of burn victims, whether in the pre-hospital phase or during interhospital transfer, requires careful attention to treatment priorities, protocols, and details.

Introduction and historical notes

Cutaneous thermal injury greater than one-third of the total body surface area (TBSA) invariably results in the severe and unique derangements of cardiovascular function called burn shock. Shock is an abnormal physiologic state in which tissue perfusion is insufficient to maintain adequate delivery of oxygen and nutrients and removal of cellular waste products. Before the 19th century, investigators demonstrated that, after a burn, fluid is lost from the blood and blood becomes thicker; and in 1897, saline infusions for severe burns were first advocated.^{1,2} However, a more complete understanding of burn pathophysiology was not reached until the work of Frank Underhill.³ He demonstrated that unresuscitated burn shock correlates with increased hematocrit values in burned patients, which are secondary to fluid and electrolyte loss after burn injury. Increased hematocrit values occurring shortly after severe burn were interpreted as a plasma volume deficit. Cope and Moore showed that the hypovolemia of burn injury resulted from fluid and protein translocation into both burned and nonburned tissues.⁴

Over the last 80 years an extensive record of both animal and clinical studies has established the importance of fluid resuscitation for burn shock. Investigations have focused on correcting the rapid and massive fluid sequestration in the burn wound and the resultant hypovolemia. The peer-reviewed literature contains a large experimental and clinical database on the circulatory and microcirculatory alterations associated with burn shock and edema generation in both the burn wound

and nonburned tissues. During the last 40 years, research has focused on identifying and defining the release mechanisms and effects of the many inflammatory mediators produced after burn injury.⁵

It is now recognized that burn shock is a complex process of cardiovascular dysfunction that is not easily or fully repaired by fluid resuscitation. Severe burn injury results in significant hypovolemic shock and substantial tissue trauma, both of which cause the formation and release of many local and systemic mediators.^{6–8} Burn shock results from the interplay of hypovolemia and multiple mediators of inflammation with effects on both the microcirculation as well as the function of the heart, large vessels, and lungs. Subsequently, burn shock continues as a significant pathophysiologic state, even if hypovolemia is corrected. Increases in pulmonary and systemic vascular resistance (SVR) and myocardial depression occur despite adequate preload and volume support.^{8–12} Such cardiovascular dysfunctions can further exacerbate the whole body inflammatory response into a vicious cycle of accelerating organ dysfunction.^{7,8,13} Hemorrhagic hypovolemia with severe mechanical trauma can provoke a similar form of shock.

This chapter examines our present understanding of the pathophysiology of the early events in burn shock, focusing on the many facets of organ and systemic effects directly resulting from hypovolemia and circulating mediators. Inflammatory shock mediators, both local and systemic, that are implicated in the pathogenesis of burn shock include histamine, serotonin, bradykinin, nitric oxide, oxygen free radicals and products of the eicosanoid acid cascade (e.g. prostaglandin, thromboxane), tumor necrosis factor, and interleukins. Additionally, certain hormones and mediators of cardiovascular function are elevated several-fold after burn injury; these include epinephrine, norepinephrine, vasopressin, angiotensin II, and neuropeptide-Y. Most certainly other mediators and unknown factors yet to be defined are also involved. Understanding the complex mechanism of the pathophysiologic actions of these mediators may lead to optimally effective therapies are designed. The hope is that an improved early treatment of burn shock, perhaps through individualized fluid resuscitation protocols and methods of mediator blockade, can be developed to ameliorate or eliminate the incidence of organ dysfunction. Effective burn resuscitation and treatment of burn shock remains a major challenge in modern medicine. Extensive efforts have been expended altering mediator release or activity, but have not met with widespread clinical utility.

Hypovolemia and rapid edema formation

Burn injury causes extravasation of plasma into the burn wound and the surrounding tissues. Burn shock is hypovolemic in nature and characterized by the hemodynamic changes similar to those that occur after hemorrhage, including decreased plasma volume, cardiac output, urine output, and an increased systemic vascular resistance with resultant reduced peripheral blood flow.^{6,8,14–16} However, as opposed to a fall in hematocrit with hemorrhagic hypovolemia (due to transcapillary refill) an increase in hematocrit and hemoglobin concentration will often appear even with adequate fluid resuscitation. As in the treatment of other forms of hypovolemic shock, the primary initial therapeutic goal is to promptly restore vascular volume and to preserve tissue perfusion in order to minimize tissue ischemia. In extensive burns (>25% TBSA), fluid resuscitation is complicated not only by the severe burn wound edema but also by extravasated and sequestered fluid and protein in nonburned soft tissue. Large volumes of resuscitation solutions are required to maintain vascular volume during the first several hours after an extensive burn. Data suggests that despite fluid resuscitation normal blood volume is not restored until 24–36 hours after large burns.¹⁷

Edema develops when the rate by which fluid is filtered out of the microvessels exceeds the flow in the lymph vessels draining the same tissue mass. Edema formation often follows a biphasic pattern. An immediate and rapid increase in the water content of burn tissue is seen in the first hour after burn injury.^{15,18} A second and more gradual increase in fluid flux of both the burned skin and nonburned soft tissue occurs during the first 12–24 hours after burn injury.^{7,18} The amount of edema formation in burned skin depends on the type and extent of injury,^{15,19} and whether fluid resuscitation is provided as well as the type and volume of fluid administered.²⁰ However, fluid resuscitation elevates blood flow and capillary pressure contributing to further fluid extravasation. Without sustained delivery of fluid into the circulation, edema fluid is somewhat self-limited as plasma volume and capillary pressure decrease. The edema development in thermal injured skin is characterized by the extreme rapid onset of tissue water content, which can double within the first hour after burn.^{15,21} Leape found a 70–80% water content increase in a full-thickness burn wound 30 minutes after burn injury with 90% of this change occurring in the first 5 minutes.^{16,22,23} There was little increase in burn wound water content after the first hour in the nonresuscitated animals. In resuscitated animals or animals with small wounds, adequate tissue perfusion continues to ‘feed’ the edema for several hours. Demling et al. used dichromatic absorptionmetry to measure edema development during the first week after an experimental partial-thickness burn injury on one hind limb in sheep.¹⁸ Although edema was rapid, with over 50% occurring in the first hour, maximum water content did not occur until 12–24 hours after burn injury.

Normal microcirculatory fluid exchange

An understanding of the physiologic mechanisms of the rapid formation of burn edema requires an understanding of the mechanisms of microvascular fluid balance. Under normal physiologic conditions, blood pressure in capillaries causes a

filtration of fluid into the interstitial space of all tissue. This fluid is then partially reabsorbed into the circulation at the venous end of capillaries and venules, while the remaining net filtration is removed from the interstitial space by lymphatic drainage.^{24,25} Fluid transport across the microcirculatory wall in normal and pathological states is quantitatively described by the Landis–Starling equation:

$$J_v = K_f [(P_c - P_{if}) - \sigma(COP_p - COP_{if})]$$

This equation describes the interaction of physical forces that govern fluid transfer between vascular and extravascular compartments. J_v is the volume of fluid that crosses the microvasculature barrier. K_f is the capillary filtration coefficient, which is the product of the surface area and hydraulic conductivity of the capillary wall; P_c is the capillary hydrostatic pressure; P_{if} is the interstitial fluid hydrostatic pressure; COP_p is the colloid osmotic pressure of plasma; COP_{if} is the colloid osmotic pressure of interstitial fluid; σ is the osmotic reflection coefficient. Edema occurs when the lymphatic drainage (J_L) does not keep pace with the increased J_v (Figure 8.1).

Mechanisms of burn edema

By analyzing the factors interrelating the physiological determinants of transmicrovascular fluid flux (i.e. Landis–Starling equation), edema may theoretically be formed by: increased K_f , P_c , or COP_{if} , as well as by decreased P_{if} , σ , and COP_p . Burn edema may be unique among other types of edema, because it is only in burn edema that all of these variables change significantly in the direction required to increase fluid filtration. Each variable is discussed individually.

Capillary filtration coefficient (K_f)

Burn injury causes direct and indirect mediator-modulated changes of the permeability of blood tissue barrier of the capillaries and venules. Arturson and Mellander showed that K_f , in the scalded hind limb, immediately increases two to three times suggesting that the hydraulic conductivity (water permeability) of the capillary wall increases.²⁶ However, K_f is a function of both hydraulic conductivity and the capillary surface area. Thus, local vasodilation and microvascular recruitment also contribute to the increased K_f . Measuring K_f and the rate of edema formation (J_v) allowed Arturson and Mellander to determine the changes in transcapillary forces necessary to account for the increased capillary filtration. Their calculations indicated that a transcapillary pressure gradient of 100–250 mmHg was required to explain the extremely rapid edema formation that occurred in the first 10 minutes after a scald injury. They concluded that only a small fraction of the early formation of burn edema could be attributed to the changes in K_f and permeability. They further suggested that osmotically active molecules generating sufficiently large osmotic reabsorption pressures are released from burn-damaged cells. However, subsequent studies described below show that very large increases in filtration force are due to increased P_c and particularly to a large decrease in P_{if} of burn-injured skin (Table 8.1).

Fig. 8.1 Landis–Starling equation.

TABLE 8.1 EFFECT OF BURN INJURY ON CHANGES IN THE STARLING EQUATION VARIABLES

Variable	Normal or baseline	Post-burn	Δ	Reference Nos
P_c	25 mmHg	50 mmHg	\uparrow 25 mmHg	46
COP_p	20 to 28 mmHg	15 to 18 mmHg	\downarrow 10 mmHg	50,51
P_i	-2 to 0 mmHg	-100 mmHg non-resuscitated non-perfused skin and -5 mmHg perfused skin	\downarrow 100 mmHg \downarrow 3–5 mmHg	19,52 53,54
COP_{if}	10 to 15 mmHg	13–18 mmHg in burn wound \downarrow and with resuscitation hypoproteinemia in nonburned skin	\uparrow 3 mmHg	51,53,54
σ	0.9	0.5	\downarrow 0.4	46,55,56
K_f	0.003 mL/min per mmHg per 100g (leg)	\uparrow 2 to 3 \times		26,56

Notes: Enhanced microvascular blood flow typically increases capillary surface area. Permeability typically refers to protein permeability of the microvascular exchange vessels, which is often linked to hydraulic conductivity.

Capillary pressure (P_c)

In most forms of shock, capillary pressure decreases as a result of arteriolar vasoconstriction. However, studies in which P_c was measured using vascular occlusion methods, in the scalded hind limb of dogs, showed that it doubled from \sim 25 mmHg to \sim 50 mmHg during the first 30 minutes after burn injury and slowly returned to baseline over 3 hours.⁴⁶ We are unaware of studies that have measured P_c in nonburned skin, but P_c may decrease in nonburned tissue as a result of the documented increase in peripheral resistance.

Interstitial hydrostatic pressure (P_{if})

An initial surprising, but now well-verified finding is that P_{if} in dermis becomes extremely negative after thermal injury. Using a micropipette and tissue oncometer, Lund reported that dermal P_{if} was rapidly reduced from its normal value of

\sim 1 mmHg to less than \sim 100 mmHg in isolated skin non-perfused preparations.¹⁹ This generation of a strongly negative interstitial fluid hydrostatic pressure constitutes a ‘suction force’ or imbibition pressure adding to the capillary pressure in promoting fluid filtration from the intravascular to the interstitial space. *In vivo* measurements show a temporary reduction of \sim 20 to \sim 30 mmHg; presumably, this number is less negative because continued tissue perfusion and fluid extravasation relieves the imbibition pressure. After resuscitation, P_{if} can be increased to a positive value of 1–2 mmHg.^{47,48} On the other hand, Kinsky reported a continued negative pressure providing a partial explanation for the sustained edema for the first 4 hours post-injury (Table 8.1).⁴⁹

Tissue volume and hydration are greatly elevated with a decrease or no change in P_{if} , implying elevated interstitial compliance, which is likely to be the main mechanism that

sustains burn edema for several days. The mechanism behind this negative-pressure generation is in part related to the denaturation of collagen^{47,48} and to changes in the compliance of thermally injured tissue. The release of adhesional forces (β_1 -integrins) between the interstitial matrix fibers and connective tissue cells (fibroblasts) was found to cause an imbibition pressure to develop following different inflammatory reactions.⁵⁷ The cell–matrix interactions and intercellular adhesion are made up of four classes of molecules: the immunoglobulin superfamily, the cadherins, the selectins, and the integrins. Integrins are a group of cell-surface molecules which play an important role in cell–cell and cell–matrix interactions¹⁵⁹ and thus function as mechanoreceptors. Integrins are vital for cell migration and organization of the cytoskeleton. Antibodies towards the β_1 -integrins have been shown to lower P_{if} .¹⁶⁰

The magnitude of the decrease in P_{if} establishes it as the predominant mechanism responsible for both the initial rapid development of edema and the sustained edema.

Osmotic reflection coefficient (σ)

The osmotic reflection coefficient is an index of the proportion of the full osmotic pressure generated by the concentration gradient of plasma proteins across the capillary wall. A value of $\sigma = 1.0$ represents a membrane impermeable to protein; $\sigma = 0$ represents a membrane that is completely permeable to protein. In skin, the normal σ of albumin is reported to be 0.85–0.99.^{25,58} Increased capillary permeability to protein causes a reduced σ , an effective reduction in the reabsorptive oncotic gradient across the capillary wall, and a resulting increase in net fluid filtration. Lymph sampled from burned skin has shown elevated protein concentrations consistent with the large and sustained increases in capillary permeability,^{15,55,58} while a transient and smaller increase in capillary permeability occurs over 8–12 hours post-injury in other soft tissue not directly burned.⁵⁵ Pitt et al. estimated the σ for skin from dog hind paw using the lymph washdown technique and reported a normal σ of 0.87 for albumin and a reduction to 0.45 after scald injury.⁴⁶

Plasma colloid osmotic pressure (COP_p)

The normal plasma protein concentration of 6–8g/dL and its associated COP_p of 25–30mmHg produce a significant transcapillary reabsorptive force partially outweighing the fluid filtration out of the microvasculature.^{14,25} Plasma colloid osmotic pressure decreases in non-resuscitated burn injured animals as protein-rich fluid extravasates into burn wounds, while a significant volume of protein-poor transcapillary reabsorption comes from nonburned tissue such as skeletal muscle.^{14,50,51,59} Plasma is further diluted and p_p is further reduced after crystalloid resuscitation. Zetterstrom and Arturson found that plasma oncotic pressure was reduced to half of the normal values in burn patients. COP_p can decrease so rapidly with resuscitation that the transcapillary colloid osmotic pressure gradient ($COP_p - COP_{if}$) will approach zero or even reverse to favor filtration and edema.^{50,51} Although it is likely that some hypoproteinemia after major burn injury is inevitable, animal and clinical studies that used early colloid resuscitation maintained p_p at higher levels than crystalloid

resuscitation alone.^{7,59,60} The degree of hypoproteinemia and reduced COP_p were reported to correlate with the total volume of crystalloid solutions.⁵⁹ Initial therapy with colloid solution is advocated by some clinicians,⁷ while the majority wait 8–24 hours post-injury, reasoning that some normalization of microvascular permeability in injured tissue must occur before colloid therapy is cost-effective.⁸

Interstitial colloid osmotic pressure (COP_{if})

The COP_{if} in skin is normally 10–15mmHg or about one-half that of plasma in humans.^{14,25} Experimental studies in animals using lymph as representative of interstitial fluid suggest that the colloid osmotic pressure in lymph from burned skin initially increases 4–8mmHg.⁵⁵ However, more direct measurements of COP_{if} using wick sampling^{14,20,51,61} or tissue sampling technique^{14,25} show only modest initial increases in COP_{if} of 1–4mmHg in the early nonresuscitated phase of burn injury. With resuscitation, COP_p falls and then COP_{if} decreases, as the protein concentration of capillary filtrate remains less than plasma despite an increased permeability. Studies show that σ decreases with burns, but never equals zero; thus, some protein sieving remains even in burn skin.⁵⁵ Compared with nonburned skin the COP_{if} remains significantly higher in the burn wound, supporting the view that sustained increases in protein permeability contributes to the persistence of burn edema.^{14,25,49} However, compared with the large changes in P_c and particularly P_{if} , the increased capillary protein permeability is not the predominant mechanism for the early rapid rate of edema formation in injured skin.⁴⁷

Nonburned tissue

Generalized edema in soft tissues that are not directly injured is another characteristic of large cutaneous burns. Brouhard et al. reported increased water content in nonburned skin even after a 10% burn, with the maximum increase occurring at 12 hours postburn.⁶² Arturson reported an increased transcapillary fluid flux (lymph flow) from nonburned tissue and a transient increase in permeability, as measured by an increase in the lymph concentration of plasma protein and macromolecular dextran infused as a tracer.^{15,21,58} Harms et al. extended these findings by measuring changes in lymph flow and protein transport of noninjured soft tissue for 3 days after injury.⁵⁵ They found that skin and muscle permeability (flank lymph from sheep) were elevated for up to 12 hours postburn for molecules the size of albumin and immunoglobulin G, while the microvascular permeability of the lung (lymph for caudal mediastinal node) showed no increase. Maximum increased lymph flow and tissue water content were observed to correlate with the severe hypoproteinemia occurring during the early resuscitation period of a 40% burn injury in sheep.^{8,60} The sustained increase in water content and the elevated lymph flow of the nonburned tissue after the return of normal permeability is likely the result of the sustained hypoproteinemia.^{50,55,58,59}

Demling and colleagues postulated that the edema could be partially attributed to alteration in the interstitial structure.⁶³ They suggested that interstitial protein washout increases the compliance of the interstitial space and that water transport and hydraulic conductivity across the entire blood–tissue–

lymph barrier increased with hypoproteinemia. Several clinical and animal studies have established that maintaining higher levels of total plasma protein concentration can ameliorate the overall net fluid retention and edema.^{7,64} Edema in nonburned areas can also be limited by using nonprotein colloids such as dextran, if the colloid osmotic gradient is increased above normal.^{8,60} However, it is not known if either the correction of hypoproteinemia or the use of either albumin or dextran can lead to improved clinical outcome. It has been reported that the use of colloids has no beneficial effect on edema in the burn wound.^{49,60} Use of hypertonic saline formulations as initial fluid therapies of burn shock can dramatically reduce initial volume requirements and net fluid volume (infused minus urine out).^{65,66} However, a rebound effect subsequently increasing the fluid requirements (and net fluid balance) occurred after early use of both hypertonics and colloids.^{60,65} Retrospective analyses of patients correlating early albumin use versus fluid requirements show significant volume sparing during the first post-burn day, but after 48 hours the affect is not significant.⁶⁷

Altered cellular membranes and cellular edema

In addition to a loss of capillary endothelial integrity, thermal injury also causes change in the cellular membranes. Baxter demonstrated that in burns of >30% TBSA there is a systemic decrease in cellular transmembrane potentials as measured in skeletal muscle away from the site of injury.¹⁰ It would be expected that the directly injured cell would have a damaged cell membrane, increasing sodium and potassium fluxes, resulting in cell swelling. However, this process also appears in cells that are not directly heat-injured. Micropuncture techniques have demonstrated partial depolarization in the normal skeletal muscle membrane potential of -90mV to levels of -70 to -80mV ; cell death occurs at -60mV . The decrease in membrane potentials is associated with an increase in intracellular water and sodium.⁶⁸⁻⁷⁰ Similar alterations in skeletal membrane functions and cellular edema have been reported in hemorrhagic shock^{68,70} and also in the cardiac, liver, and endothelial cells.⁷¹⁻⁷³ Early investigators of this phenomenon postulated that a decrease in ATP levels or ATPase activity was the mechanism for membrane depolarization; however, other research suggests that it may result from an increased sodium conductance in membranes or an increase in sodium-hydrogen antiport activity.^{69,72} Resuscitation of hemorrhage rapidly restores depolarized membrane potentials to normal, but resuscitation of burn injury only partially restores the membrane potential and intracellular sodium concentrations to normal levels, demonstrating that hypovolemia alone is not totally responsible for the cellular swelling seen in burn shock.⁷⁴ A circulating shock factor(s) is likely to be responsible for the membrane depolarization,⁷⁵⁻⁷⁷ but, surprisingly, the molecular characterization of such a circulating factor has not been elucidated, suggesting that it has a complex structure. Data suggests it has a large molecular weight >80 KDa.⁷⁸ Membrane depolarization may be caused by different factors in different states of shock. Very little is known about the time course of the changes in membrane potential in clinical burns. More importantly, we do not know the extent to which the

altered membrane potentials affect total volume requirements and organ function in burn injury or shock in general.

Mediators of burn injury

Burn injury produces a veritable cornucopia of local and circulating mediators that are produced in the blood or released by cells after thermal injury. These mediators play important and complex roles in the pathogenesis of edema and the cardiovascular abnormalities of burn injury. Many mediators alter vascular permeability directly or indirectly by increasing the microvascular hydrostatic pressure and surface area via the arteriolar vasodilation superimposed on an already altered membrane (Table 8.2). The exact mechanism(s) of mediator-induced injury are of considerable clinical importance, as this understanding would allow for the development of pharmacologic modulation of burn edema and shock by mediator inhibition.

Histamine

Histamine is most likely to be the mediator most responsible for the early phase of increased microvascular permeability seen immediately after burn. Histamine causes large endothelial gaps to transiently form as a result of the contraction of venular endothelial cells.²⁷ Histamine is released from mast cells in thermal-injured skin; however, the increase in histamine levels and its actions are only transient. Histamine also can cause the rise in capillary pressure (P_c) by arteriolar dilation and venular contraction. Statistically significant reductions in burn edema have been achieved with histamine blockers and mast cell stabilizers when tested in acute animal models.²⁷ Friedl et al. demonstrated that the pathogenesis of burn edema in the skin of rats appears to be related to the interaction of histamine with xanthine oxidase and oxygen radicals.²⁹ Histamine and its metabolic derivatives increased the catalytic activity of xanthine oxidase (but not xanthine dehydrogenase) in rat plasma and in rat pulmonary artery endothelial cells. In thermally injured rats, levels of plasma histamine and xanthine oxidase rose in parallel, in association with the uric acid increase. Burn edema was greatly attenuated by treating rats with the mast cell stabilizer, cromolyn, complement depletion or the H_2 receptor antagonist, cimetidine, but was unaffected by neutrophil depletion.^{28,33,79} Despite encouraging results in animals, beneficial antihistamine treatment of human burn injury has not been demonstrated, although antihistamines are administered to reduce risk of gastric ulcers.

Prostaglandins

Prostaglandins are potent vasoactive autocooids synthesized from arachidonic acid. They are released from burned tissue and inflammatory cells and contribute to the inflammatory response of burn injury.^{35,80} Macrophages and neutrophils are activated through the body, infiltrate the wound, and release prostaglandin as well as thromboxanes, leukotrienes, and interleukin-1. These wound mediators have both local and systemic effects. Prostaglandin E_2 (PGE_2) and leukotrienes LB_4 and LD_4 directly and indirectly increase microvascular permeability.⁸¹ Prostacyclin (PGI_2) is produced in burn injury and

TABLE 8.2 CARDIOVASCULAR AND INFLAMMATORY MEDIATORS OF BURN SHOCK

Mediators	Central cardiovascular effects (at high concentrations)	Load tissue effects	References
Histamine	↓ Blood pressure Hypovolemia	Arteriolar dilation, and venular constriction ↑ Blood flow ↑ Permeability	27–33
Prostaglandin E ₂ (PGE ₂)	↓ Systemic arterial and pulmonary arterial blood pressure	Vasodilation ↑ Blood flow ↑ Permeability	27,34,35
Prostacyclin (PGI ₂)	↓ Blood pressure	↑ Permeability	27
Leukotrienes LB ₄ LD ₄	Pulmonary hypertension	Vasoconstriction of pulmonary vessels	27
Thromboxane A ₂ (TXA ₂) Thromboxane B ₂ (TXB ₂)	GI ischemia Pulmonary hypertension	Vasoconstriction ↑ Permeability	34,36–38
Bradykinin	↓ Blood pressure Hypovolemia	Vasodilation, ↑ Permeability	27,32
Serotonin		↑ Permeability	31
Catecholamines Epinephrine Norepinephrine	↑ Heart rate ↑ Blood pressure ↑ Metabolism	Vasoconstriction (α ₁ receptors); Vasodilation (β ₂ receptors in muscle); block ↑ permeability due to histamine and bradykinin via β receptors	27,30,39,40
Oxygen radicals: Superoxide anion (O ₂ ⁻) Hydrogen peroxide (H ₂ O ₂) Hydroxyl ion (OH ⁻) Peroxynitrite (ONOO ⁻)	Cardiac dysfunction	Tissue damage ↑ Permeability	27–29,41
Platelet aggregation factor	↑ Blood pressure	Vasoconstriction	42–44
Angiotensin II	GI ischemia ↑ Blood pressure	Vasoconstriction	45
Vasopressin	GI ischemia ↑ Blood pressure	Vasoconstriction	45

is a vasodilator, but also may cause direct increases in capillary permeability. PGE₂ appears to be one of the more potent inflammatory prostaglandins, causing the postburn vasodilation in wounds, which, when coupled with the increased microvascular permeability, amplifies edema formation.^{82,83}

Thromboxane

Thromboxane A₂ (TXA₂) and its metabolite, thromboxane B₂ (TXB₂), are produced locally in the burn wound by platelets.²⁷ Vasoconstrictor thromboxanes may be less important in edema formation; however, by decreasing blood flow they can contribute to a growing zone of ischemia under the burn wound and can cause the conversion of a partial-thickness wound to a deeper full-thickness wound. The serum level of TXA, and TXA₂/PGI₂ ratios are increased significantly in burn patients.³⁶ Heggers showed the release of TXB₂ at the burn wound was associated with local tissue ischemia, and that thromboxane inhibitors prevented the progressive dermal ischemia associated with thermal injury and thromboxane release.^{34,84} A TXA₂ synthesis inhibitor, anisodamine, also demonstrated beneficial macrocirculatory effects by restoring the hemody-

amic and rheological disturbances towards normal. Demling showed that topically applied ibuprofen (which inhibits the synthesis of prostaglandins and thromboxanes) decreases both local edema and prostanoid production in burned tissue without altering systemic production.⁸⁵ On the other hand, systemic administration of ibuprofen did not modify early edema, but did attenuate the postburn vasoconstriction that impaired adequate oxygen delivery to tissue in burned sheep.³⁷ Although cyclooxygenase inhibitors have been used after burn injury, no convincing benefit or routine clinical use, has been reported.

Kinins

Bradykinin is a local mediator of inflammation that increases venular permeability. It is likely that bradykinin production is increased after burn injury, but its detection in blood or lymph can be difficult owing to the simultaneous increase in kininase activity and the rapid inactivation of free kinins. The generalized inflammatory response after burn injury favors the release of bradykinin.⁸⁶ Pretreatment of burn-injured animals with aprotinin, a general protease inhibitor, should have decreased

the release of free kinin, but no effect on edema was noted.⁸⁷ On the other hand, pretreatment with a specific bradykinin receptor antagonist reduced edema in full-thickness burn wound in rabbits.⁸⁸

Serotonin

Serotonin is released early after burn injury.³¹ This agent is a smooth-muscle constrictor of large blood vessels. Antisero-tonin agents such as ketanserin have been found to decrease peripheral vascular resistance after burn injury, but have not been reported to decrease edema.³¹ On the other hand, the pretreatment effect of methysergide, a serotonin antagonist, reduces hyperemic or increased blood flow response in the burn wounds of rabbits, along with reducing the burn edema.⁸⁸ Methysergide did not prevent increases in the capillary reflection coefficient or permeability.⁸⁹ Ferrara et al. found a dose-dependent reduction of burn edema when methysergide was given preburn to dogs, but claimed that this was not attributable to blunting of the regional vasodilator response.⁸⁹ Zhang et al. reported a reduction in non-nutritive skin blood flow after methysergide administration to burned rabbits.⁹⁰

Catecholamines

Circulating catecholamines, epinephrine and norepinephrine are released in massive amounts after burn injury.^{7,91,92} On the arteriolar side of the microvessels these agents cause vasoconstriction via α_1 -receptor activation, which tends to reduce capillary pressure, particularly when combined with the hypovolemia and the reduced venous pressure of burn shock.²⁷ Reduced capillary pressure may limit edema and induce interstitial fluid to be reabsorbed from nonburned skin, skeletal muscle, and visceral organs in nonresuscitated burn shock. Further, catecholamines, via β -agonist activity, may also partially inhibit increased capillary permeability induced by histamine and bradykinin.²⁷ These potentially beneficial effects of catecholamines may not be operative in directly injured tissue and may also be offset in nonburned tissue by the deleterious vasoconstrictor and ischemic effects. The hemodynamic effects of catecholamines will be discussed later in the chapter.

Oxygen radicals

Oxygen radicals play an important inflammatory role in all types of shock, including burn. These short-lived elements are highly unstable reactive metabolites of oxygen; each one has an unpaired electron, making them strong oxidizing agents.⁹³ Superoxide anion (O_2^-), hydrogen peroxide (H_2O_2), and the hydroxyl ion (OH^-) are produced and released by activated neutrophils after any inflammatory reaction or reperfusion of ischemic tissue. The hydroxyl ion is believed to be the most potent and damaging of the three. The formation of the hydroxyl radical requires free ferrous iron (Fe_2) and H_2O_2 . Evidence that these agents are formed after burn injury is the increased lipid peroxidation found in circulating red blood cells and biopsied tissue.^{28,93,94} Demling showed that large doses of deferoxamine (DFO), an iron chelator, when used for resuscitation of 40% TBSA in sheep, prevented systemic lipid peroxidation and decreased the vascular leak in nonburned tissue while also increasing oxygen utilization.⁹⁵ However, DFO may have accentuated burned tissue edema, possibly by increasing the perfusion of burned tissue.

Nitric oxide (NO), when simultaneously generated with the superoxide anion can lead to the formation of peroxynitrite ($ONOO^-$). The presence of nitrotyrosine in burn skin found in the first few hours after injury suggests that peroxynitrite may play a deleterious role in burn edema.⁹⁶ On the other hand, the blockade of NO synthase did not reduce burn edema, while treatment with the NO precursor arginine reduces burn edema.⁹⁷ NO may be important for maintaining perfusion and limiting the zone of stasis in burn skin.⁹⁸ Although the pro- and anti-inflammatory roles of NO remain controversial, it would appear that the acute beneficial effects of NO generation outweigh any deleterious effect in burn shock.

Antioxidants, namely agents that either directly bind to the oxygen radicals (scavengers) or cause their further metabolism, have been evaluated in several experimental studies.^{99,100} Catalase, which removes H_2O_2 and superoxide dismutase (SOD), which removes radical O_2^- , have been reported to decrease the vascular loss of plasma after burn injury in dogs and rats.^{28,99}

The plasma of thermally injured rats showed dramatic increases in levels of xanthine oxidase activity, with peak values appearing as early as 15 minutes after thermal injury. Excision of the burned skin immediately after the thermal injury significantly diminished the increase in plasma xanthine oxidase activity.^{28,29} The skin permeability changes were attenuated by treating the animals with antioxidants (catalase, SOD, dimethyl sulfoxide, dimethylthiourea) or an iron chelator (DFO), thus supporting the role of oxygen radicals in the development of vascular injury as defined by increased vascular permeability.²⁸ Allopurinol, a xanthine oxidase inhibitor, markedly reduced both burn lymph flow and levels of circulating lipid peroxides, and further prevented all pulmonary lipid peroxidation and inflammation. This suggests that the release of oxidants from burned tissue was in part responsible for local burn edema, as well as distant inflammation and oxidant release.⁹⁴ The failure of neutrophil depletion to protect against the vascular permeability changes and the protective effects of the xanthine oxidase inhibitors (allopurinol and lodoxamide tromethamine) suggests that plasma xanthine oxidase is the more likely source of the oxygen radicals involved in the formation of burn edema. These oxygen radicals can increase vascular permeability by damaging microvascular endothelial cells.^{28,29} The use of antioxidants has been extensively investigated in animals, and some clinical trials suggest benefit. Antioxidants (vitamin C and E) are routinely administered to patients at many burn centers. High doses of antioxidant ascorbic acid (vitamin C) have been found to be efficacious in reducing fluid needs in burn-injured experimental animals when administered postburn.¹⁰³⁻¹⁰⁵ The use of high doses (10–20 g/day) of vitamin C was shown to be effective in one clinical trial, but ineffective in another.^{101,102} High-dose vitamin C has not received wide clinical usage.

Platelet aggregation factor

Platelet aggregation (or activating) factor (PAF) can increase capillary permeability and is released after burn injury.^{43,87} Ono et al. showed in scald-injured rabbits that TCV-309 (Takeda Pharmaceutical Co Ltd., Japan), a PAF antagonist, infused soon after burn injury, blocked edema formation in the wound and significantly inhibited PAF increase in the

damaged tissue in a dose-dependent manner. In contrast, the superoxide dismutase content in the group treated with TCV-309 was significantly higher than that of the control group.⁴³ These findings suggest that the administration of large doses of a PAF antagonist immediately after injury may reduce burn wound edema and the subsequent degree of burn shock by suppressing PAF and superoxide radical formation.

Angiotensin II and vasopressin

Angiotensin II and vasopressin, also called antidiuretic hormone (ADH), are two hormones that participate in the normal regulation of extracellular fluid volume by controlling sodium balance and osmolality through renal function and thirst.²⁷ However, during burn shock when sympathetic tone is high and volume receptors are stimulated, both hormones can be found in supranormal levels in the blood. Both are potent vasoconstrictors of terminal arterioles with little effect on the venules. Angiotensin II may be responsible for the selective gut and mucosal ischemia, which can cause translocation of endotoxins and bacteria, the development of sepsis and even multi-organ failure.^{106,107} In severely burn-injured patients angiotensin II levels were elevated two to eight times normal in the first 1–5 days after burn injury with peak levels occurring on day three.¹⁰⁸ Vasopressin had peak levels of 50 times normal upon admission and declined towards normal over the first 5 days after burn injury. Vasopressin, along with catecholamines, may be largely responsible for increased system vascular resistance and left heart afterload, which can occur in resuscitated burn shock. Sun et al. used vasopressin-receptor antagonist in rats with burn shock to improve hemodynamics and survival time, while vasopressin infusion exacerbated burn shock.⁴⁵

Corticotropin-releasing factor

Corticotropin-releasing factor (CRF) has proven to be efficacious in reducing protein extravasation and edema in burned rat paw. CRF may be a powerful natural inhibitory mediator of the acute inflammatory response of the skin to thermal injury.¹⁰⁹

Other approaches to pharmacological attenuation of burn edema

Many reports on edema-reducing strategies using known burn mediator-blocking agents have been previously discussed in this chapter. However, there are other hypothesized approaches to ameliorate or inhibit the fluid extravasation induced by thermal injury. Topically applied local anesthetic lidocaine/prilocaine cream has been reported to be effective in reducing albumin extravasation in small burns in experimental animals.¹¹⁰ The inositol triphosphate analog α -trinositol has also been found effective in reducing postburn edema when administered after injury.^{111–113} Even though α -trinositol showed promising effects in animal experiments and also seemed to reduce pain in pilot clinical projects, its routine clinical application is not established.

Hemodynamic consequences of acute burns

The cause of reduced cardiac output (CO) during the resuscitative phase of burn injury has been the subject of considerable

debate. There is an immediate depression of cardiac output before any detectable reduction in plasma volume. The rapidity of this response suggests a neurogenic response to receptors in the thermally injured skin or increased circulating vasoconstrictor mediators. Soon after injury a developing hypovolemia and reduced venous return undeniably contribute to the reduced cardiac output. The subsequent persistence of reduced CO after apparently adequate fluid therapy, as evidenced by a reduction in heart rate and restoration of both arterial blood pressure and urinary output, has been attributed to circulating myocardial depressant factor(s), which possibly originates from the burn wound.^{11,12} Demling et al. showed a 15% reduction in CO despite an aggressive volume replacement protocol after a 40% scald burn in sheep.¹⁸ However, there are also sustained increases in catecholamine secretion and elevated systemic vascular resistance for up to 5 days after burn injury.^{91,108} Michie et al. measured CO and SVR in anesthetized dogs resuscitated after burn injury.¹¹⁴ They found that CO fell shortly after injury and then returned toward normal; however, reduced CO did not parallel the blood volume deficit. They concluded that the depression of CO resulted not only from decreased blood volume and venous return but also from an increased SVR and from the presence of a circulating myocardial depressant substance. Thus, there are multiple factors that can significantly reduce CO after burn injury. However, resuscitated patients suffering major burn injury also can have supranormal CO from 2 to 6 days post-injury. This is secondary to the establishment of a hypermetabolic state and a systemic inflammatory response syndrome (SIRS).

Myocardial dysfunction

Myocardial function can be compromised after burn injury due to right heart overload and direct depression of contractility shown in isolated heart studies.^{115,116} Increases in the afterload of both the left and right heart result from SVR and PVR elevations. The left ventricle compensates and CO can be maintained with increased afterload by augmented adrenergic stimulation and increased myocardial oxygen extraction. The right ventricle has a minimal capacity to compensate for increased afterload. In severe cases, desynchronization of the right and left ventricles is deleteriously superimposed on a depressed myocardium.¹¹⁷ Burn injury greater than 45% TBSA can produce intrinsic contractile defects. Several investigators reported that aggressive early and sustained fluid resuscitation failed to correct left ventricular contractile and compliance defects.^{116–118} These data suggest that hypovolemia is not the sole mechanism underlying the myocardial defects observed with burn shock. Serum from patients failing to sustain a normal CO after thermal injury has exhibited a markedly negative inotropic effect on *in vitro* heart preparations, which is likely due to the previously described circulating shock factor.¹¹⁹ In other patients with large burn injuries and normal cardiac indices, little or no depressant activity was detected.

Sugi et al. studied intact, chronically instrumented sheep after a 40% TBSA flame burn injury and smoke-inhalation injury, and smoke inhalation injury alone. They found that maximal contractile effects were reduced after either burn injury or inhalation injury.^{120,121} Horton et al. demonstrated decreased left ventricular contractility in isolated, coronary

perfused, guinea pig hearts harvested 24 hours after burn injury.¹²² This dysfunction was more pronounced in hearts from aged animals and was not reversed by resuscitation with isotonic fluid. It was largely reversed by treatment with 4 mL/kg of hypertonic saline dextran (HSD), but only if administered during the initial 4–6 hours of resuscitation.^{123,124} These authors also effectively ameliorated the cardiac dysfunction of thermal injury with infusions of antioxidants, arginine, and calcium channel blockers.^{125–127} Cioffi and colleagues in a similar model observed persistent myocardial depression after burn when the animals received no resuscitation after burn injury.¹²⁸ As opposed to most studies, Cioffi reported that immediate and full resuscitation totally reversed abnormalities of contraction and relaxation after burn injury. Murphy et al. showed elevations of a serum marker for cardiac injury, troponin I, for patients with a TBSA >18%, despite good cardiac indices.¹²⁹ Resuscitation and cardiac function studies emphasize the importance of early and adequate fluid therapy and suggest that functional myocardial depression after burn injury may not occur in patients receiving prompt and adequate volume therapy.

The primary mechanisms by which burn shock alters myocardial cell membrane integrity and impairs mechanical function remain unclear. Oxygen-derived free radicals may play a key causative role in the cell membrane dysfunction that is characteristic of several low-flow states. Horton et al. showed that a combination therapy of the free radical scavengers SOD and catalase significantly improved burn-mediated defects in left ventricular contractility and relaxation when administered along with adequate fluid resuscitation (4 mL/kg per percent of burn). Antioxidant therapy did not alter the volume of fluid resuscitation required after burn injury.¹²⁵

Increased systemic vascular resistance and organ ischemia

Cardiac output may remain below normal after adequate volume replacement in burn patients and experimental animals. Sympathetic stimulation and hypovolemia result in the release of catecholamines, vasopressin, angiotensin II, and neuropeptide-Y after burn injury.^{45,108} These agents cause contraction of the arteriolar smooth muscle, which is systemically manifested by increased afterload and SVR. The increased SVR after burn injury is also partly the result of increased blood viscosity secondary to the hemoconcentration.

Hilton and others performed experiments in anesthetized dogs in which infusion of various peripheral vasodilators improved CO after burn injury.^{114,130} They demonstrated a reduction in the peripheral vascular resistance and augmented CO after verapamil, but the myocardial force of contraction remained depressed. Pruitt et al. examined in a group of burn patients the hypothesis that increased sympathetic activity contributes to CO reduction.¹³¹ They showed a higher CO with treatment using the vasodilator hydralazine along with the reduced SVR.

There are several organs particularly susceptible to ischemia, organ dysfunction, and organ failure when burn resuscitation is delayed or inadequate. These include the kidney and the gastrointestinal tract. Renal ischemia can result directly from hypovolemia and increased sympathetic tone,

but elevations in serum free hemoglobin and particularly myoglobin correlate with increased renal failure.^{132,133} Renal failure rates have dramatically declined due to standardized regimens of fluid therapy, but when therapy is delayed or associated with hypotension acute renal failure is not uncommon.^{132,133}

An occult hypoxia can result from vasoconstriction of the gastrointestinal tract, despite apparently 'adequate' resuscitation.^{107,134} As a consequence of visceral ischemia and reduced mucosal pH, bacterial and endotoxin translocation can contribute to the development of sepsis.

Cerebral edema (and encephalopathies are) is not uncommon after large cutaneous burns, particularly in children, but the exact cause remains unclear. Studies in anesthetized sheep subjected to a 70% TBSA scald show that cerebral autoregulation is well maintained in the immediate postburn period, but 6 hours after resuscitation, increased cerebral vascular resistance reduced cerebral blood flow 50%.¹³⁵

Edema in nonburned tissue

Lungs

In large burns, there is a pronounced increase in pulmonary vascular resistance (PVR) that corresponds with the increased SVR.^{8,60} Pulmonary edema is not an uncommon finding and occurs more often after, than during, the fluid-resuscitation phase of burn injury. Increased capillary pressure secondary to the increased PVR occurs with both pre- and postcapillary vasoconstriction and may contribute to pulmonary edema formation. Pulmonary wedge pressure is increased more than left atrial pressure after experimental burn injury due to postcapillary venular constriction.^{60,136} It is likely that some degree of left heart failure also contributes to the increased capillary pressure. However, hypoproteinemia may be the greatest contributing factor to postburn pulmonary edema.¹³⁷ There is no evidence of increased capillary permeability from analysis of lung lymph sampled in large animal models after 40% TBSA injury, although rat studies suggest that albumin sequestration increases in the lungs after a 30% cutaneous scald.²⁸ Clinical studies of burn-injured patients suggest that, in the absence of inhalation injury, the lungs do not develop edema.^{138,139} This finding is consistent with little or no change in the microvascular permeability of the lung and the fact that lung lymph rate may increase considerably to prevent interstitial fluid accumulation. Pulmonary dysfunction associated with inhalation injury is discussed in a separate chapter.

Edema and abdominal compartment syndrome

Prompt and adequate fluid resuscitation has undoubtedly improved the outcome of burn-injured patients. Despite the treatment advances of burn surgery, massive edema of burned and nonburned tissues continues to be a repercussion of large-volume fluid resuscitation. There is a physiological conflict that exists in the balance between the edema process and hypovolemia. Edema has been previously shown to occur from the massive efflux of intravascular fluid to the interstitial space due to increased capillary permeability, large differences in oncotic pressures, and other forces.

The Parkland formula for burn resuscitation, introduced by Baxter and Shires in 1968, has been the guideline to the cornerstone of early burn care.¹¹⁹ Although the guidelines for burn resuscitation have changed little, fluid management has changed over the past two decades. Engrav and associates compiled data from seven burn centers.¹⁴⁰ The results included 50 patients with $43 \pm 21\%$ TBSA burns in which 16 had documented inhalation injuries. The authors found that 58% of patients with large burns received volumes that greatly exceeded the formula proposed by Baxter. Their patients received close to 6 mL/kg/% TBSA (2 mL/kg/% TBSA greater than the Parkland formula). Urine output also exceeded clinical targets (0.5–1 mL/kg/hour) in 64% of patients. Friedrich and associates¹⁴¹ found that their patients admitted in the year 2000, compared to those in the 1970, received twice the resuscitation volume. In yet another report, the Parkland formula was exceeded in 84% of the burn-injured patients treated.¹⁴² A meta-analysis of 23 clinical trials (1980–2003) using crystalloid burn resuscitation produced similar findings.¹⁴³ Mean fluid infused (5.0 ± 1.2 mL/kg/% TBSA) and mean urinary outputs (1.2 ± 0.4 mL/kg/hour) were both over the burn resuscitation guidelines, suggesting that well over half of all burn patients may be over-resuscitated.

This trend of providing fluid in excess of the Parkland formula has been termed ‘fluid creep.’¹⁴⁴ Over-resuscitation and its resulting edema are not without consequences. The problems of the over-resuscitated burn patient may include eye injuries due to elevated orbital pressures,¹⁴⁵ pulmonary edema,^{146,147} the need for prolonged mechanical ventilation, or tracheostomy,¹⁴⁸ graft failure or the need for fasciotomy of uninjured extremities¹⁴⁹ due to massive edema.

Recently, a new life-threatening complication of generalized edema has been seen with increased frequency and named abdominal compartment syndrome (ACS).^{150,151} Intra-abdominal pressure exceeding 30 cmH₂O is an indication of intra-abdominal hypertension (IAH). ACS is defined as sustained IAH in association with a clinically tense abdomen combined with ventilation aberrations due to elevated pulmonary inspiratory pressures or oliguria despite aggressive fluid resuscitation. ACS may become fatal due to a cascade of physiological events. The syndrome typically leads to multiple organ dysfunction characterized by impaired renal and hepatic blood flow, bowel ischemia, pulmonary dysfunction, depressed cardiac output, and elevated intracranial pressures.^{152,153} ACS can occur after major abdominal trauma or surgery, but this condition in the absence of abdominal injury is known as secondary ACS.¹⁵⁴ Severely burn-injured patients are at risk for this development due to increasingly large volumes of resuscitation fluid, decreased abdominal wall compliance due to eschar, increased capillary permeability with leakage of large plasma volumes, and massive edema formation.

Choice of fluids and generation of edema

A major factor in the increased fluid volumes delivered and the apparent associated morbidity in burn patients may be the decreased use of albumin. This has resulted from two factors. A focus on the growing costs of medical care have showed that

albumin is one of the largest medical costs associated with critical care. Further, a meta-analysis of albumin use over a wide variety of indications suggested no benefit and even a trend towards increased mortality.^{155,156} The meta-analysis was the subject of much controversy and its results were refuted in several more recent meta-analyses, some of a more comprehensive nature.^{157,158} It remains to be seen if closer control of infusion rate using urinary outputs to establish guidelines or if early use of colloids or hypertonics or combinations of these modality can reduce edema and its complications, but it is clear that there is a renewed research focus on edema and the means to minimize it.

Summary and conclusion

Thermal injury results in massive fluid shifts from the circulating plasma into the interstitial fluid space causing hypovolemia and swelling of the burned skin. When burn injury exceeds 20–30% TBSA there is minimal edema generation in non-injured tissues and organs. The Starling forces change to favor fluid extravasation from blood to tissue. Rapid edema formation is predominating from the development of strongly negative interstitial fluid pressure (imbibition pressure) and to a lesser degree by an increase in microvascular pressure and permeability. The type of fluid resuscitation, timing, and total volume infused can influence these fluid shifts.

Secondary to the thermal insult there is release of inflammatory mediators and stress hormones. Circulating mediators deleteriously increase microvascular permeability and alter cellular membrane function by which water and sodium enter cells. Circulating mediators also favor renal conservation of water and salt, impair cardiac contractility, and cause vasoconstrictors, which further aggravates ischemia from combined hypovolemia and cardiac dysfunction. The end result of this complex chain of events is decreased intravascular volume, increased systemic vascular resistance, decreased cardiac output, end-organ ischemia, and metabolic acidosis. Early excision of the devitalized tissue appears to reduce the local and systemic effects of mediators released from burned tissue, thus reducing the progressive pathophysiologic derangements. Without early and full resuscitation therapy these derangements can result in acute renal failure, vascular ischemia, cardiovascular collapse, and death.

Edema in both the burn wound and particularly in the non-injured soft tissue is increased by resuscitation. Edema is a serious complication, which likely contributes to decreased tissue oxygen diffusion and further ischemic insult to already damaged cells with compromised blood flow increasing the risk of infection. Research should continue to focus on methods to ameliorate the severe edema and vasoconstriction that exacerbate tissue ischemia. The success of this research will require identification of key circulatory factors that alter capillary permeability, cause vasoconstriction, depolarize cellular membranes, and depress myocardial function. Hopefully, methods to prevent the release and to block the activity of specific mediators can be further developed in order to reduce the morbidity and mortality rates of burn shock.

Burn shock resuscitation	107
Fluid replacement following burn shock resuscitation	115
Summary	115

Introduction

Proper fluid management is critical to the survival of the victim of a major thermal injury. In the 1940s, hypovolemic shock or shock-induced renal failure was the leading cause of death after burn injury. Today, with our current knowledge of the massive fluid shifts and vascular changes that occur during burn shock, mortality related to burn-induced volume loss has decreased considerably. Although a vigorous approach to fluid therapy has ensued in the last 20 years and fewer deaths are occurring in the first 24–48 hours postburn, the fact remains that approximately 50% of the deaths occur within the first 10 days following burn injury from a multitude of causes, one of the most significant being inadequate fluid resuscitation therapy.¹ Knowledge of fluid management following burn shock resuscitation is also important and is often overlooked in burn education.

Burn shock resuscitation

The history of burn resuscitation began over a century ago; however, complete appreciation of the severity of fluid loss in burns was not apparent until the enlightening studies of Frank P Underhill,² who studied the victims of the Rialto Theater fire in 1921. His concept that burn shock was due to intravascular fluid loss was further elucidated by Cope and Moore,³ who conducted studies on patients from the Coconut Grove disaster in 1942. They developed the concept of burn edema and introduced the body-weight burn budget formula for fluid resuscitation of burn patients. In 1952, Evans¹ developed a burn surface area–weight formula for computing fluid replacement in burns which became the first simplified formula for fluid resuscitation for burn patients. Surgeons at the Brooke Army Medical Center modified the original Evans formula and this became the standard for the next 15 years.

A number of methods for accomplishing adequate volume replacement therapy have been advocated in the more than 40

years since the introduction of the Evans' formula in 1952. This chapter will review the various methods advocated and present the rationale of each. Importantly, properly utilized, each resuscitation formula can be effective in the resuscitation of the burn patient in the immediate postburn period, provided that close attention is paid to the individual's clinical response to therapy and that fluid replacement therapy is modified according to this response. The fact that patients respond to a wide variety of resuscitative efforts is testimony to the fact that burn patients are very resilient and can be overwhelmed only under the most unfavorable circumstances.⁴

Pathophysiology of burn injury

Modern fluid resuscitation formulas originate from experimental studies in the pathophysiology of burn shock. Burn shock is both hypovolemic shock and cellular shock, and is characterized by specific hemodynamic changes including decreased cardiac output, extracellular fluid, plasma volume, and oliguria. As in the treatment of other forms of shock, the primary goal is to restore and preserve tissue perfusion in order to avoid ischemia. However, in burn shock, resuscitation is complicated by obligatory burn edema, and the voluminous transvascular fluid shifts which result from a major burn are unique to thermal trauma.

Although the exact pathophysiology of the postburn vascular changes and fluid shifts is unknown, one major component of burn shock is the increase in total body capillary permeability. Direct thermal injury results in marked changes in the microcirculation. Most of the changes occur locally at the burn site, when maximal edema formation occurs at about 8–12 hours post-injury in smaller burns and 12–24 hours post-injury in major thermal injuries. The rate of progression of tissue edema is dependent upon the adequacy of resuscitation.

Multiple mediators have been proposed to explain the changes in vascular permeability seen postburn. The mediators can produce either an increase in vascular permeability or an increase in microvascular hydrostatic pressure.^{5,6} Most mediators act to increase permeability by altering membrane integrity in the venules. The early phase of burn edema formation, lasting for minutes to an hour, has been thought by some investigators to be the result of mediators, particularly histamine and bradykinin. Other mediators implicated in the changes in vascular permeability seen postburn include vasoactive amines, products of platelet activation and the complement cascade, hormones, prostaglandins, and leukotrienes. Vasoactive substances are also released which may act primarily by increasing microvascular blood flow or vascular pres-

tures, further accentuating the burn edema.^{7,8} Histamine is released in large quantities from mast cells in burned skin immediately after injury.⁹ Histamine has been clearly demonstrated to increase the leakage of fluid and protein from systemic micro vessels, its major effect being on venules in which an increase in the intracellular junction space is characteristically seen.¹⁰ However, the increase in serum histamine levels after burn is transient, peaking in the first several hours post-injury, indicating that histamine is only involved in the very early increase in permeability. The use of H₁ receptor inhibitors, e.g. diphenhydramine, has only limited success in decreasing edema. Recently, the use of an H₂ receptor antagonist has been reported to decrease burn edema in an animal model.¹¹

Serotonin is released immediately postburn as a result of platelet aggregation and acts directly to increase the pulmonary vascular resistance and indirectly to amplify the vasoconstrictive effect of norepinephrine, histamine, angiotensin II, and prostaglandin.¹² The use of ketanserin, a specific serotonin antagonist, in a porcine burn shock model, improved cardiac index, decreased pulmonary pressure, and reduced arteriovenous oxygen content differences compared to a control group in the early postburn period. Serotonin antagonists should be investigated further as possible adjuvant therapeutic agents during burn shock resuscitation.¹³ Prostaglandins, vasoactive products of arachidonic acid metabolism, have been reported to be released in burn tissue and to be at least in part responsible for burn edema. Although these substances do not directly alter vasopermeability, increased levels of vasodilator prostaglandins such as prostaglandin E₂ (PGE₂) and prostacyclin (PGI₂) result in arterial dilatation in burned tissue, increased blood flow and intravascular hydrostatic pressure in the injured microcirculation, and thus accentuate the edema process. Concentrations of PGI₂ and the vasoconstrictor thromboxane A₂ (TXA₂) have been demonstrated in burned tissue, burn blister fluid, lymph, and wound secretion.^{14,15} However, the use of prostaglandin inhibitors has produced variable results in animal studies. Arturson¹⁶ reported a decrease in burn lymph and protein flow with the use of prostaglandin inhibitor, indomethacin. Those results have not been corroborated by other investigators and the role of thromboxane and the prostaglandins still needs to be elucidated.

The activation of the proteolytic cascades, including those of coagulation, fibrinolysis, the kinins, and the complement system, has been demonstrated to occur immediately following thermal injury. Kinins, specifically bradykinins, are known to increase vascular permeability, primarily in the venule. Rocha and co-workers¹⁷ report increased kinin levels in burn edema fluid in the rat. The release of other mediators and the generalized inflammatory response after burns favors the activation of the kallikrein-kinin system, with the release of bradykinin into the circulation.¹⁸ Elevation of proteolytic activity has been demonstrated in both animals and in burn patients.¹⁹ Pretreatment with protease inhibitors significantly decreases free kinin levels but appears to have little effect on the edema process.

The end result of the changes in the microvasculature due to thermal injury is disruption of normal capillary barriers separating intravascular and interstitial compartments, and rapid equilibrium of these compartments. This results in severe depletion of plasma volume with a marked increase in extracellular fluid clinically manifested as hypovolemia.

In addition to a loss of capillary integrity, thermal injury also causes changes at the cellular level. Baxter²⁰ has demonstrated that in burns of >30% total body surface area (TBSA), there is a systemic decrease in cell transmembrane potential, involving nonthermally injured cells as well. This decrease in cell transmitting potential, as defined by the Nernste equation, results from an increase in intracellular sodium concentration. The cause of this is thought to be a decrease in sodium ATPase activity responsible for maintaining the intracellular-extracellular ionic gradient. Baxter further demonstrated that resuscitation only partially restores the membrane potential and intracellular sodium concentrations to normal levels, demonstrating that hypovolemia with its attendant ischemia is not totally responsible for the cellular swelling seen in burn shock. In fact, the membrane potential may not return to normal for many days postburn despite adequate resuscitation. If resuscitation is inadequate, cell membrane potential progressively decreases, resulting ultimately in cellular death. This may be the final common denominator in burn shock during the resuscitation period.

Although the etiology of burn shock is not totally understood, many authors have studied the fluid volume shifts and hemodynamic changes that accompany burn shock. Early work by Moyer,²¹ and Baxter and Shires²² established the definitive role of crystalloid solutions in burn resuscitation and delineated the fluid volume changes in the early postburn period. Moyer's original studies in 1965²¹ demonstrated that burn edema sequestered enormous amounts of fluid, resulting in the hypovolemia of burn shock. In addition, he described the first crystalloid-only resuscitation formula used to treat burn shock. He noted that burn shock recovery occurred in the majority of patients studied, although hemoconcentration remained unchanged and the hematocrit was unresponsive to fluid administration despite adequate resuscitation. This became the first objective evidence that burn shock is not simply due to hypovolemia but is also influenced by extracellular sodium depletion. Baxter and Shires,²² in 1968, using radioisotope dilution techniques, defined the fluid volume changes of the postburn period in relation to cardiac output. They first demonstrated that edema fluid in the burn wound is isotonic with respect to plasma fluid and contains protein in the same proportions as that found in blood. This confirmed Arturson's earlier findings that in major burns there is complete disruption of the normal capillary barrier, with free exchange between plasma and extravascular extracellular compartments. They measured changes in fluid compartment volumes in burned primates and dogs and demonstrated that in untreated (unresuscitated) animals, a 30–50% extracellular fluid (ECF) defect persisted at 18 hours postburn. Plasma volume decreased 23% to 27% below controls, although red cell mass changed only about 10% over the same 18-hour period. Thus, the greatest volume loss was functional intravascular extracellular fluid. Cardiac output was initially depressed very soon after injury to a level of about 25% of controls at 4 hours after a 30% TBSA burn. By 18 hours, however, the cardiac output had stabilized at around 40% of control, despite persistent defects in plasma and ECF volumes. On the basis of studies using different volumes of resuscitation fluids, they arrived at an optimal response in terms of cardiac output and restoration of ECF at the end of 24 hours in a canine model. Clinical studies using similar sodium

and fluid loads immediately followed, confirming efficacy in restoring ECF to within 10% of controls within 24 hours. This became the basis for the Baxter or Parkland formula.²⁰ Mortality was comparable to that obtained with a colloid-containing resuscitation formula.

Baxter went on to demonstrate that during the first 24 hours postburn, plasma volume changes were independent of the type of infused fluid, whether crystalloid or colloid, but at approximately 24 hours post-injury, an infused amount of colloid would increase the plasma volume by the same amount. His findings prove that colloid-containing solutions are an unnecessary component of fluid resuscitation in the first 24 hours. He recommended their use only after capillary integrity was restored, to correct the persistent plasma volume deficit of about 20% as measured externally. While the fluid shifts were being defined by Baxter in terms of crystalloid resuscitation, Moncrief and Pruitt⁴ worked to characterize the hemodynamic alterations that occur in burn shock with and without fluid resuscitation. Their efforts culminated in the Brooke formula modification which utilized 2 cc/kg/% burn during the first 24 hours. Fluid needs were initially estimated according to the modified Brooke formula, but the actual volume for resuscitation was based on clinical response. In their study, resuscitation permitted an average decrease of about 20% in both extracellular fluid and plasma volume, but no further loss accrued in the first 24 hours. In the second 24 hours postburn, plasma volume restoration occurred with the administration of colloid. Blood volume, however, was only partially restored and an ongoing loss of 9% of the red cell mass per day was found. Cardiac output, initially quite low, rose over the first 18 hours postburn, despite plasma volume and blood volume defects. These results were quite consistent with those demonstrated by Baxter in his animal studies. Peripheral vascular resistance during the initial 24 hours was initially very high but decreased as cardiac output improved, and in fact the changes were reciprocal. Once plasma volume and blood volume loss ceased, cardiac output rose to supranormal levels where it remained until healing or grafting occurred.

Moylan and associates²³ in 1973, using a canine model, defined the relationships between fluid volumes, sodium concentration, and colloid in restoring cardiac output during the first 12 hours post-injury. No significant colloid effect on cardiac output was noted in the first 12 hours post-injury. In addition, 1 mEq of sodium was found to exert an effect on cardiac output equal to 13 times that of 1 mL of salt-free volume. This experiment established the fact that any combination of sodium and volume within the broad limits of the study would effectively resuscitate a thermally injured patient.

Arturson's landmark studies in 1979¹⁶ on vascular permeability characterized the nature of the 'leaky capillary' in the postburn period. He demonstrated in a canine model that increased capillary permeability is found both locally and in nonburned tissue at distant sites when the TBSA burn exceeded 25%. He proposed that the burn wound is characterized by rapid edema formation due to dilatation of the resistance vessels (precapillary arterioles); increased extravascular osmotic activity, due to the products of thermal injury; and increased microvascular permeability to macromolecules. The increased permeability permits molecules of up to 350 000

molecular weight to escape from the microvasculature, a size which allows essentially all elements of the vascular space except red blood cells to escape from it. Further studies by Demling and co-workers²⁴ have demonstrated that in 50% TBSA burns, one-half of the initial fluid resuscitation requirement may end up in nonthermally injured tissues.

Resuscitation from burn shock

Fluid resuscitation is aimed at supporting the patient throughout the initial 24-hour to 48-hour period of hypovolemia. The primary goal of therapy is to replace the fluid sequestered as a result of thermal injury. The critical concept in burn shock is that massive fluid shifts can occur even though total body water remains unchanged. What actually changes is the volume of each fluid compartment, intracellular and interstitial volumes increasing at the expense of plasma volume and blood volume. In light of all the studies on different fluid regimens, the question still remains: 'What is the best formula for resuscitation of the burn patient?'

It is quite clear that the edema process is accentuated by the resuscitation fluid. The magnitude of edema will be affected by the amount and type of fluid administered.²⁵ The National Institutes of Health consensus summary on fluid resuscitation in 1978 was not in agreement in regard to a specific formula; however, there was consensus in regard to two major issues — the guidelines used during the resuscitation process and the type of fluid used. In regard to the guidelines, the consensus was to give the least amount of fluid necessary to maintain adequate organ perfusion. The volume infused should be continually titrated so as to avoid both under-resuscitation and over-resuscitation.^{26,27} As for the optimum type of fluid, there is no question that replacement of the extracellular salt lost into the burned tissue and into the cell is essential for successful resuscitation.^{19,21}

Crystalloid resuscitation

Crystalloid, in particular lactated Ringer's solution with a sodium concentration of 130 mEq/L, is the most popular resuscitation fluid currently utilized. Proponents of the use of crystalloid solution alone for resuscitation report that other solutions, specifically colloids, are no better and are certainly more expensive than crystalloid for maintaining intravascular volume following thermal injury.⁴ The most common reason given for not using colloids is that even large proteins leak from the capillary following thermal injury. However, capillaries in nonburned tissues do continue to sieve proteins, maintaining relatively normal protein permeability characteristics.

The quantity of crystalloid needed is in part dependent upon the parameters used to monitor resuscitation. If a urinary output of 0.5 cc/kg of body weight/hour is considered to indicate adequate perfusion, approximately 3 cc/kg/% burn will be needed in the first 24 hours. If 1 cc/kg of body weight/hour of urine is deemed necessary, then of course considerably more fluid will be needed and in turn more edema will result. The Parkland formula recommends 4 cc/kg/% burn in the first 24 hours, with one-half of that amount administered in the first 8 hours⁹ (Table 9.1). The modified Brooke formula recommends beginning burn shock resuscitation at 2 cc/kg/% burn in the first 24 hours (Table 9.1). In major burns, severe hypo-

TABLE 9.1 FORMULAS FOR ESTIMATING ADULT BURN PATIENT RESUSCITATION FLUID NEEDS

Colloid formulas	Electrolyte	Colloid	DSW
Evans	Normal saline 1.0cc/kg/% burn	1.0cc/kg/% burn	2000cc
Brooke	Lactated Ringer's 1.5 cc/kg/% burn	0.5 cc/kg	2000cc
Slater	Lactated Ringer's 2L/24 hours	Fresh frozen plasma 75 cc/kg/24 hours	
Crystalloid formulas			
Parkland	Lactated Ringer's	4 cc/kg/% burn	
Modified	Lactated Ringer's	2cc/kg/% burn	
Brooke			
Hypertonic saline formulas			
Hypertonic saline solution (Monafo)	Volume to maintain urine output at 30cc/h Fluid contains 250mEq Na/L		
Modified hypertonic (Warden)	Lactated Ringer's + 50mEq NaHCO ₃ (180mEq Na/L) for 8 hours to maintain urine output at 30–50cc/h Lactated Ringer's to maintain urine output at 30–50cc/h beginning 8 hours postburn		
Dextran formula (Demling)	Dextran 40 in saline — 2cc/kg/h for 8 hours Lactated Ringer's — volume to maintain urine output at 30cc/h Fresh frozen plasma – 0.5cc/kg/h for 18 hours beginning 8 hours postburn

proteinemia usually develops with these resuscitation regimens. The hypoproteinemia and interstitial protein depletion may result in more edema formation.

Hypertonic saline

Hypertonic salt solutions have been known for many years to be effective in treating burn shock.^{28,29} Rapid infusion produces serum hyperosmolarity and hypernatremia with two potentially positive effects.^{28,32} The hypertonic serum reduces the shift into the extracellular space of intravascular water. Proposed benefits include decreased tissue edema and fewer attendant complications, including escharotomies for vascular compromise or endotracheal intubation to protect the airway. Monafo²⁸ reported that the resuscitation of burn patients with salt solution of 240–300 mEq/L resulted in less edema because of the smaller total fluid requirements than with lactated Ringer's solution. Urine output was the indicator used during resuscitation. Demling and colleagues³⁰ in an animal model demonstrated that the net fluid intake was less if burned animals were resuscitated with hypertonic saline to the same cardiac output compared with lactated Ringer's. Urine output was much higher with hypertonic solution. Interestingly, soft-tissue interstitial edema in burned and nonburned tissue, as reflected by lymph flow, was increased with hypertonic saline similar to that of lactated Ringer's (LR). This can be explained by a shift of intracellular water into extracellular space as the result of the hyperosmolar solution. Extracellular edema can therefore occur at the same time as intracellular fluid defect. This may give the external appearance of less edema. Although several studies to date have reported that this intracellular water depletion does not appear to be deleterious, the issue remains controversial. Shimazaki et al.³¹ resuscitated 46 patients with either LR or hypertonic saline. The sodium infusions were equivalent, but the free water load was greater with

LR; 50% of the latter required endotracheal intubation. The hypertonic serum also delivers a more concentrated ultrafiltrate within the kidney. This increases urine volume and salt clearance without marked increases in the required volume of free water.

There is no consensus regarding the type of osmolarity of hypertonic resuscitation fluid. Caldwell and Bowser³² in 1979 reported a series of 37 patients with greater than 30% burns treated with either LR or hypertonic lactated saline (HLS), but no colloid. Total sodium balance was the same but the HLS group received 30% less free water and the reduced weight gain was maintained for 7 days. Subsequent reports from this institution reported successful HLS resuscitation in the elderly and children but no improvement in late mortality.^{36,39,40}

Bartolani et al.⁴¹ randomized 40 patients to receive LR or HLS. HLS patients received more sodium, but less total fluid than the LR group. The observed higher mortality with HLS was attributed to larger burns in this group.

The role of colloid in association with hypertonic reserve colloid for the second 24 hours, if at all, unless the patient remains poorly perfused after large infusions of crystalloid. Griswold et al.⁴² reported resuscitation of 47 patients with HLS resuscitation. Of these, 29 were also given colloid as albumin or fresh frozen plasma based on burn severity, premonitory state, or poor response to HLS resuscitation. This group had larger burns, greater mean age, and higher incidence of inhalation injury, but required only 57% of the fluid volume predicted by the Parkland formula, compared to 75% of predicted volume in the HLS alone group. Both groups maintained urine volumes of 1 mL/kg/h with no significant difference in hematocrit or serum sodium levels. Jelenko et al.⁴³ also reported in a small series that patients given HLS and albumin required fewer escharotomies, fewer days of mechanical ventilation, and less total fluid than patients resuscitated with LR or HLS

alone. Gunn et al.³³ in a series of 51 randomized patients found no difference in fluid requirements or weight gain if they were given LR or hypertonic saline, if fresh frozen plasma was administered to maintain serum albumin levels above 2 g/dL, but all patients received hypotonic enteral feedings during resuscitation.

Yoshioka et al.³⁴ reviewed 53 patients treated with greater than 30% burns resuscitated with LR, LR and colloid, or HLS. Fluid requirements were 4.8 mL/kg/% TBSA with LR, 3.3 mL/kg/% TBSA with LR and colloid, and 2.2 mL/kg/% TBSA with HLS. The total sodium requirements were increased 30% with LR compared to the other groups. Oxygen extraction, measured as A-VO₂ difference, was improved with HLS, but reduced with LR–colloid, perhaps because of protein leak across the alveoli.

Vigorous administration of hypertonic saline solutions can produce a serum sodium above 160 mEq/dL or serum osmolarity greater than 340 mOsm/dL, followed by a rapid fall in urine output.³⁵ Bowser-Wallace et al.³⁶ and Crum et al.³⁷ have reported 40–50% of patients treated with HLS developed hypernatremia with serum sodium greater than 160 mEq/L requiring switch to hypotonic fluids. Huang et al.³⁸ reported a series of deaths associated with hypernatremia and hyperosmolarity following hypertonic saline resuscitation. Serial determinations of serum sodium and serum osmolarity are required to prevent complications including sudden anuria, brain shrinkage with tearing of intracranial vessels, or excessive brain swelling following rapid correction of serum hyperosmolarity. Current recommendations are that the serum sodium levels should not be allowed to exceed 160 mEq/dL during its use. Of interest, Gunn and associates,³³ in a prospective randomized study of patients with 20% TBSA burns evaluating HSL versus LR solution, were not able to demonstrate decreased fluid requirements, improved nutritional tolerance, or decreased percent weight gain.

Children, have utilized a modified hypertonic solution in major thermal injuries >40% TBSA burn. The resuscitation fluid contains 180 mEq Na⁺ (lactated Ringer's + 50 mEq NaHCO₃). The solution is utilized until the reversal of metabolic acidosis has occurred, usually by 8 hours postburn. The volume administered is begun at a rate calculated by the Parkland formula (4 cc/kg/% burn); however, volume is titrated to maintain urine output at 30–50 cc/h. After 8 hours the resuscitation is completed utilizing LR to maintain urine output at 30–50 cc/h. This hypertonic formula can be used in infants and in the elderly without the accompanying risk of hypernatremia.^{44,45}

Colloid resuscitation

Plasma proteins are extremely important in the circulation since they generate the inward oncotic force that counteracts the outward capillary hydrostatic force. Without protein, plasma volume could not be maintained and massive edema would result. Protein replacement was an important component of early formulas for burn management. The Evans formula, advocated in 1952, used 1 cc/kg of body weight/% burn each for colloid and LR over the first 24 hours. The Brooke formula was clearly based on estimate rather than determined scientifically, but the formula used 0.5/kg/% burn as colloid and 1.5 cc/kg/% burn as LR. The burn budget of Moore similarly used a substantial amount of colloids.³ Con-

siderable confusion exists concerning the role of protein in a resuscitation formula. There are three schools of thought:

1. Protein solutions should not be given in the first 24 hours because during this period they are no more effective than salt water in maintaining intravascular volume and they promote accumulation of lung water when edema fluid is being absorbed from the burn wound.⁴⁶
2. Proteins, specifically albumin, should be given from the beginning of resuscitation along with crystalloid; it should usually be added to salt water.
3. Protein should be given between 8 and 12 hours postburn using strictly crystalloid in the first 8–12 hours because of the massive fluid shifts during this period. Demling demonstrated experimentally that restoration and maintenance of plasma protein contents were not effective until 8 hours postburn, after which adequate levels can be maintained with infusion.⁴⁷ Because nonburned tissues appear to regain normal permeability very shortly after injury and because hypoproteinemia may accentuate the edema, the action advocated by the first school appears to be least appropriate.

The choice of the type of protein solution can be confusing. Heat-fixed protein solutions, e.g. Plasmanate, are known to contain some denatured and aggregated protein, which decreases the oncotic effect. Albumin solutions would clearly be the most oncotically active solutions. Fresh frozen plasma, however, contains all the protein fractions that exert both the oncotic and the nononcotic actions. The optimal amount of protein to infuse remains undefined. Demling⁴⁷ uses between 0.5 and 1 cc/kg/% burn of fresh frozen plasma during the first 24 hours, beginning at 8–10 hours postburn.^{48,49} He emphasizes that all major burns require large amounts of fluid, but notes that older patients with burns, patients with burns and concomitant inhalation injury, and patients with burns in excess of 50% TBSA not only develop less edema but also better maintain hemodynamic stability with the addition of protein.

Slater and co-workers⁴⁴ have recently utilized fresh frozen plasma during burn shock. They use lactated Ringer's, 2 liters for 24 hours, and fresh frozen plasma, 75 cc/kg/24 h (Table 9.1). Although the volume of fresh frozen plasma is calculated, the volume infused is titrated to maintain an adequate urine output. Although the authors are utilizing colloid early in the burn shock period, they emphasize that most burn patients have received LR in significant volumes during field management.

The use of albumin in burns and critically ill patients has recently been challenged by the Cochrane Central Register of Controlled Trials, which demonstrated in critical hypovolemia that there was no evidence that albumin reduces mortality when compared with cheaper alternatives such as saline.⁹⁰ Others using a meta-analysis of randomized, controlled trials found no effect of albumin on mortality and could not find a deleterious effect of albumin.⁹¹ Most burn surgeons agree that in burn patients who have a very low serum albumin during burn shock albumin supplementation is warranted to maintain oncotic pressure.

Dextran resuscitation solutions

Dextran is a colloid consisting of glucose molecules which have been polymerized into chains to form high molecular

weight polysaccharides.⁴⁹ This compound is commercially available in a number of molecular sizes. Dextran, which has an average molecular weight of 40 000 Da, is referred to as low molecular weight dextran. British dextran has a mean molecular weight of 150 000, whereas the dextran used predominantly in Sweden has a molecular weight of 70 000. Dextran is excreted at the kidneys, with 40% removed within 24 hours. The remainder is slowly metabolized. Demling and associates have utilized dextran 70 in a 6% solution to prevent edema in nonburned tissues. Dextran 70 carries some risk of allergic reaction and can interfere with blood typing. Dextran 40 actually improves the microcirculatory flow by decreasing red cell aggregation.⁵⁰ Demling and colleagues⁴⁹ demonstrated that the net requirements to maintain vascular pressure at the baseline levels with dextran 40 were about half those seen with LR alone during the first 24 hours postburn. These authors have used an infusion rate of dextran 40 and saline of 2 cc/kg/h along with sufficient LR to maintain adequate perfusion. At 8 hours an infusion of fresh frozen plasma at 0.5–1.0 cc/kg/% TBSA burn over 18 hours is instituted along with necessary additional crystalloid (Table 9.1).

In the young pediatric burn patient with major burn injury, colloid replacement is frequently required as serum protein concentration rapidly decreases during burn shock. The Shriners Hospitals for Children in Cincinnati and Galveston both routinely utilize colloid during resuscitation of children with major thermal injuries.^{51,52}

Special considerations in burn shock resuscitation

Fluid resuscitation in the thermally injured pediatric patient

The burned child continues to represent a special challenge, since resuscitation therapy must be more precise than that for an adult with a similar burn. In addition, children have a limited physiological reserve. We have demonstrated that children require more fluid for burn shock resuscitation than adults with similar thermal injury; fluid requirements for children averaged 5.8 cc/kg/% burn.⁵³ In addition, children commonly require intravenous resuscitation for relatively small burns of 10–20% TBSA. Baxter⁴⁵ found similar resuscitation requirements in the pediatric age group. Graves and associates⁵⁴ substantiated that children received 6.3 ± 2 cc/kg/% TBSA burn. At the Shriners Burns Hospital, Cincinnati, we have utilized the Parkland formula with the addition of maintenance fluid,

to the resuscitation fluid volume, $4 \text{ mL/kg} \times \% \text{ TBSA burn per 24 hours} + 1500 \text{ cc/m}^2 \text{ BSA per 24 hours}$. This is the formula used to begin burn shock resuscitation and to compare the amount of fluid needed by a particular pediatric burn patient with that needed by an unburned pediatric patient (Table 9.2). This is similar to the results reported by Graves and co-workers⁵⁴ who found that if maintenance fluids were subtracted from the resuscitation fluid requirements, the resulting resuscitation volumes would approach 4 cc/kg/% burn. At the Shriners Burns Hospital in Galveston, fluid requirements are estimated according to a formula based on total BSA and BSA burned in square meters.⁵² Total fluid requirements for the first day are estimated as follows: $5000 \text{ mL/m}^2 \text{ BSA burned per 24 hours} + 2000 \text{ mL/m}^2 \text{ BSA per 24 hours}$.

Recently pediatric burn surgeons have seen a problem of over-resuscitation and a 'saw-tooth resuscitation.' This appears to be due to first responders using the volume resuscitation formula as suggested by Pediatric Advanced Life Support (PALS) which recommends volume resuscitation begin with a fluid bolus of 20 mL/kg of isotonic crystalloid administered over 5 to 20 minutes — this amount is repeated if urine output is not adequate.⁸⁸ This regimen can lead to over-resuscitation. PALS actually recommends a modification of this fluid bolus resuscitation for burns utilizing 2–4 mL/kg/% of body surface area burned per 24 hours.⁸⁸ Education of first responders on the differences between these two fluid regimens is imperative.

Inhalation injury

The presence of inhalation injury increases the fluid requirements for resuscitation from burn shock after thermal injury.^{55,89} We have demonstrated that patients with documented inhalation injury require 5.7 cc/kg/% burn, as compared to 3.98 cc/kg/% burn in patients without inhalation injury. These data confirm and quantitate that inhalation injury accompanying thermal trauma increases the magnitude of total body injury and requires increased volumes of fluid and sodium to achieve resuscitation from early burn shock.

Choice of fluids and rate of administration

It is clear that all the solutions reviewed are effective in restoring tissue perfusion. However, it makes no more sense to use one particular fluid for all patients than it does to use one antibiotic for all infections. Most patients with burns of <40% TBSA and patients with no pulmonary injury can be resuscitated

TABLE 9.2 FORMULAS FOR ESTIMATING PEDIATRIC RESUSCITATION NEEDS

Cincinnati Shriners Burns Hospital	4 mL × kg × % TBSA burn + 1500 cc × m ² BSA	1st 8 hours	Lactated Ringer's + 50 mg NaHCO ₃
		2nd 8 hours	Lactated Ringer's
		3rd 8 hours	Lactated Ringer's + 12.5 g albumin
Galveston Shriners Burns Hospital	5000 mL/m ² BSA burn + 2000 mL/m ² BSA	Ringer's lactate + 12.5 g albumin	

tated with isotonic crystalloid fluid. In patients with burns of >40% TBSA and in patients with pulmonary injury, hypertonic saline can be utilized in the first 8 hours postburn, following which lactated Ringer's is infused to complete burn shock resuscitation. In the pediatric and elderly burn patient population, utilizing a lower but still hypertonic concentration of sodium, i.e. 180 mEq/L, still gives the benefits of hypertonic resuscitation without the potential complications of excessive sodium retention and hypernatremia.

In patients with massive burns, young pediatric patients, and burns complicated by severe inhalation injury, a combination of fluids may be utilized to achieve the desired goal of tissue perfusion while minimizing edema. In treating such patients, we have utilized the regimen of modified hypertonic (lactated Ringer's +50 mEq NaHCO₃) saline fluid containing 180 mEq Na/L for the first 8 hours. After correction of the metabolic acidosis, which generally requires 8 hours, the patients are given LR only for the second 8 hours. In the last 8 hours, a 5% albumin in LR is utilized to complete resuscitation. The resuscitation solution used in Galveston for pediatric patients is an isotonic glucose-containing solution to which a moderate amount of colloid (human serum albumin) is added. The solution is prepared by mixing 50 mL of 25% human serum albumin (12.5 g) with 950 mL in an LR solution.

The monitoring of burn shock resuscitation is initiated by first responders and is generally concluded once the patient's fluid needs have decreased to a maintenance rate, based upon body size and evaporative water loss. Factors influencing monitoring needs include the extent and depth of burn, the presence of inhalation injury, associated injuries, preexisting medical illnesses, and patient age. The monitoring process can be classified based upon the intensity and frequency of observations, as well as the methods employed. While the level of monitoring must be individualized for each patient, one must weigh the risks and benefits of each modality. Young, healthy patients with minor burns may only require the occasional periodic assessment of vital signs, whereas those with more extensive burns and/or other risk factors may require more invasive techniques. A recent survey of 251 burn centers throughout the United States, Canada, United Kingdom, Australia, and New Zealand revealed that only 12% frequently used pulmonary artery catheter (PAC) monitoring during fluid resuscitation in patients with >30% TBSA burns.⁵⁶ Moreover, only 60% of the respondents who addressed treatment goals following PAC insertion indicated that they utilized predetermined physiologic parameters to direct fluid therapy.

Clinical monitoring of burn shock resuscitation has traditionally relied on clinical assessment of cardiovascular, renal, and biochemical parameters as indicators of vital organ perfusion. Heart rate, blood pressure, and electrocardiographic recordings are the primary modalities for monitoring cardiovascular status in any patient. Fluid balance during burn shock resuscitation is typically monitored by measuring hourly urine output via an indwelling urethral catheter. It has been recommended that urine output be maintained between 30 and 50 mL/h in adults,²² and between 0.5 and 1.0 mL/kg/h in patients weighing less than 30 kg;²⁶ however, there have been no clinical studies identifying the optimal hourly urine output to maintain vital organ perfusion during burn shock resuscitation.

Because large volumes of fluid and electrolytes are administered both initially and throughout the course of resuscitation, it is important to obtain baseline laboratory measurements of complete blood count, electrolytes, glucose, albumin, and acid-base balance.⁵⁷ Laboratory values should be repeated as clinically indicated throughout the resuscitation period. These parameters are generally sufficient to assess the physiologic response of most burn patients during burn shock resuscitation. While clinical interpretation of the data should rely on the evaluation of trends rather than on isolated measurements, there have been no studies demonstrating which tests should be performed, how often they should be repeated, or the effect of frequent laboratory testing on the success of resuscitation.

Invasive hemodynamic monitoring permits the direct, and sometimes continuous, measurement of central venous pressure (CVP), pulmonary capillary wedge pressure (PCWP), and pulmonary vascular hemodynamics as well as the calculation of cardiac output (CO), systemic vascular resistance (SVR), oxygen delivery (DO₂), and oxygen consumption (VO₂). The decision to perform such monitoring requires consideration of risks, cost-effectiveness, and impact on clinical outcome. The Swan-Ganz catheter is most commonly utilized in patients in whom routine monitoring is felt to be ineffective, when there is a history of preexisting cardiac disease, or when there are other complicating factors.

PAC-guided therapy has been studied most extensively in trauma and critically ill surgical patients. Kirton and Civetta⁵⁸ performed a critical literature review to determine if the use of the PAC in trauma patients altered outcome. They concluded that hemodynamic data derived from the PAC appeared to be beneficial to ascertain cardiovascular performance, to direct therapy when noninvasive monitoring was felt to be inadequate, or when the endpoints of resuscitation were difficult to define. These findings were echoed at the 1997 Pulmonary Artery Catheter Consensus Conference; however, there was no unanimity that PAC-guided therapy altered mortality in trauma patients.⁵⁹

Studies of PAC use for monitoring burn shock resuscitation are limited. Retrospective analyses of adult patients with extensive burn injuries have concluded that PCWP is a more reliable indicator of circulatory volume than CVP,⁶⁰ and that CO is more accurate in assessing the efficacy of resuscitation than hourly urine output.⁶¹ These findings were supported by Dries and Waxman⁶² who noted that urine output and vital signs monitoring did not correlate with PCWP, cardiac index (CI), SVR, DO₂, or VO₂. They concluded that PAC monitoring may be beneficial in patients at high risk for adverse outcomes due to suboptimal resuscitation. Most recently, Schiller and Bay have reported their retrospective experience in 95 patients treated over a 4-year period during which an attempt was made to maximize circulatory endpoints.⁶³ They concluded that early invasive monitoring facilitated more aggressive resuscitation and resulted in increased survival, and that the inability to achieve hyperdynamic endpoints predicted resuscitation failure.

PAC-guided monitoring has also been used to aid in achieving predetermined therapeutic endpoints during the resuscitation and management of trauma and critically ill patients. In a series of prospective randomized class II trials, Shoemaker et al.^{64,65} demonstrated that patients resuscitated to hyperdy-

dynamic endpoints (i.e. increased CI, DO_2I , VO_2I) had decreased mortality, ICU stay, and ventilator days compared to patients who were resuscitated to normal hemodynamic values. Recent studies by Fleming⁶⁴ and Bishop⁶⁵ have not only supported these conclusions but also demonstrated a decreased incidence of organ failures.

While the data supporting hyperdynamic resuscitation are impressive, there is also strong evidence that such therapeutic goals are not associated with improved outcome. Two trials in critically ill patients^{66,67} were unable to demonstrate any benefit of PAC monitoring on patient outcome. These studies were supported by prospective randomized trials^{68,69} which demonstrated no statistical differences in survival, organ failure, or ICU days between the control and hyperdynamic groups.

In an evidence-based review of these and other citations, Cooper et al.⁷⁰ concluded that the existing literature had inconsistent results regarding the efficacy of goal-oriented hemodynamic therapy. This conclusion was underscored by Elliott⁷¹ who cited a meta-analysis of seven studies in which no significant differences in mortality were noted between control and hyperdynamic resuscitation groups.

The most appropriate endpoints in burn shock resuscitation are also unresolved. As such, the goal of achieving hyperdynamic resuscitation remains controversial. While Aikawa⁷² was able to resuscitate 19/21 patients (90.5%) using the PAC to reach normal hemodynamic endpoints, Bernard⁷³ demonstrated that the ability to sustain a supranormal CI was associated with enhanced tissue perfusion and survival. This was supported by Schiller et al.⁷⁴ who demonstrated that an inadequate or unsustained response to hyperdynamic resuscitation was associated with nonsurvival. A follow-up study by these authors⁷⁵ also demonstrated significantly reduced mortality in those patients where PAC-guided resuscitation assisted in achieving hyperdynamic endpoints. The ability to achieve adequate oxygen delivery with hyperdynamic burn shock resuscitation has also been recently evaluated by Barton et al.⁷⁶ While patients achieved significant increases in VO_2I and DO_2I , they required 63% more fluid than predicted by the Parkland formula, a mean resuscitation volume of 9.07 mL/kg/% TBSA burn, and a mean of 50.4 hours to complete resuscitation.

More than 20 human studies in critically ill patients have demonstrated that blood lactate (BL) levels are highly accurate as a guide to the efficacy of resuscitation.^{71,77} Blood lactate levels directly reflect anaerobic metabolisms as a consequence of hypoperfusion, and normalizing levels have long been associated with improved survival from nonburn shock.⁷⁸ In other studies, BL has been demonstrated to distinguish survivors from nonsurvivors.^{79,80} In two prospective, goal-directed studies in critically ill patients, BL proved superior to not only MAP and urine output but also to DO_2 , VO_2 , and CI.^{81,82}

It is important to emphasize that all of the resuscitation formulas are only guidelines for burn shock resuscitation. The Parkland formula, for instance, decreases the volume administered by 50% at 8 hours postburn. The relationship between the fluid volume required and time postburn depicted by the smooth curve in Figure 9.1 represents the influence of temporal changes in microvascular permeability and edema volume on fluid needs. That curve is contrasted with the abrupt changes

Fig. 9.1 Physiological curve of fluid requirements compared to Parkland formula, emphasizing that formulas are only guidelines for fluid therapy during burn shock. (Reproduced with permission from Warden GD. Burn shock resuscitation. *World J Surg* 1992; 16:21–23. With Kind permission of Springer Science and Business Media.⁵¹).

in fluid infusion rate as prescribed by the formula. The formulas are utilized as starting points for volume replacement and to compare the individual patient with the ‘average’ burn patient. Investigators from the burn center at Harborview Medical Center have demonstrated an increase in fluid administration during the recent years. This has been called ‘fluid creep’ by Dr. Basil Pruitt. These authors demonstrated a doubling of fluid administered during burn shock resuscitation comparing 1975 to 2000.⁹² This increase in fluid resuscitation fluid volume is associated with abdominal compartment syndrome.^{93,94}

An interesting question is, ‘When has burn shock resuscitation been completed successfully?’ It is obvious that resuscitation is completed when there is no further accumulation of edema fluid, which generally occurs between 18 and 30 hours postburn. The resuscitation fluids are utilized until the volume of infused fluid needed to maintain adequate urine volume of 30–50 cc/h in adults and 1 cc/kg/h in children equals the maintenance fluid volume. The maintenance fluid requirements following burn shock resuscitation include the patient’s normal maintenance volume plus evaporative water loss.

Failure of burn shock resuscitation

In certain patients, failure of burn shock resuscitation still occurs despite administration of massive volumes of fluid. Such patients are characterized by either extreme age and exceptionally extensive tissue trauma or by major electrical injury, major inhalation injury, delay in initiating adequate fluid resuscitation, or underlying disease that limits metabolic and cardiovascular reserve.⁸³ In these patients, refractory burn shock and resuscitation failure remain major causes of early mortality despite advances in emergency care and transport, resuscitation regimens, and physiologic stabilization.

We have used plasma exchange in patients with major thermal injuries who failed to respond to conventional fluid volumes during resuscitation from burn shock.⁸⁴ The indica-

tions for plasma exchange are ongoing fluid requirements exceeding twice those predicted by the Parkland formula despite conversion to hypertonic lactated saline resuscitation fluid. During a 3-year period, 22 patients underwent plasma exchange during burn shock resuscitation. A therapeutic response was documented in 21 of the 22 patients, characterized by a sharp decrease in fluid requirements from a mean of 260% above the predicted hourly volume by the resuscitation formula to within calculated requirements at a mean time of 2.3 hours following plasma exchange. Only one patient, who had a 100% TBSA burn (88% full-thickness), failed to respond to plasma exchange and expired at 18 hours postburn. Slater and Goldfarb⁸⁵ have substantiated the beneficial effect of plasma exchange in sustaining patients during the immediate postburn period when patients fail to respond appropriately to conventional fluid resuscitation. This modality offers an alternative management technique for the treatment of refractory burn shock.

Fluid replacement following burn shock resuscitation

Although the heat-injured microvessels may continue to manifest increased vascular permeability for several days, the rate of loss is considerably less than that seen in the first 24 hours. Burn edema by this time is near maximal and the interstitial space may well be saturated with sodium. Additional fluid requirements will depend on the type of fluid used during the initial resuscitation. If hypertonic salt resuscitation has been utilized during the entire burn shock period, a hyperosmolar state is produced and the addition of free water will be required to restore the extracellular space to an isoosmolar state.

If colloid has not been utilized during burn shock and the serum oncotic pressure is low due to intravascular protein depletion, protein repletion is frequently needed. The amount of protein varies with the resuscitation utilized. Requirements of 0.3–0.5 cc/kg/TBSA burn of 5% albumin during the second 24 hours are utilized with the modified Brooke formula. The Parkland formula replaces the plasma volume deficit with colloid. This deficit varies from 20 to 60% of the circulating plasma volume. We have utilized colloid replacement based on a 20% plasma volume deficit during the second 24 hours (circulating plasma volume \times 20%).

In addition to colloid, the patients should receive maintenance fluids. In burn patients the maintenance fluids include an additional amount for evaporative water loss. The total daily maintenance fluid requirements in the adult patient following burn shock can be calculated by the following formula: basal (1500 cc/m²) + evaporative water loss [(25 + % burn) \times m² \times 24] = total maintenance fluid (m² = total body surface area in square meters). This fluid may be given via the intravenous route or with enteral feeding. The solution infused intravenously should be 50% normal saline with potassium supplements. With the loss of intracellular potassium during burn shock, the potassium requirements in adults are about 120 mEq/day. In the pediatric patient, increased fluids are required due to the differences in BSA to weight ratios compared to adults. In addition, children also require relatively larger volumes of urine for excretion of waste products. At the Cincinnati Shriners Unit, the maintenance fluid requirements

are calculated by the following formula: (35 + % burn) \times BSA \times 24 (evaporative water loss) + 1500 mL \times BSA per day (maintenance fluids). In Galveston, the recommended fluids needs are estimated as follows: 3750 mL/m² BSA per day (burn-related losses) + 1500 mL/m² BSA per day (maintenance fluids).

Following the initial 24–48 hours postburn period of resuscitation, urinary output is an unreliable guide to adequacy of hydration.⁸⁶ Respiratory water losses, osmotic diuresis secondary to accentuated glucose intolerance, osmotic diuresis secondary to high protein, high caloric feedings, and derangements in the ADH mechanisms all contribute to increased fluid losses despite an adequate urine output. In general, patients with major thermal injuries will require a urine output of 1500–2000 cc/24 hours in adults, and 3–4 mL/kg/h in children.

The measurement of serum sodium concentration is not only a means of diagnosing dehydration but also the best guide for planning and following successful fluid replacement. Other useful laboratory indices of the state of hydration and guides of therapy include body weight change, serum and urine nitrogen concentrations, serum and urine glucose concentrations, the intake and output record, and clinical examination.

Continuous colloid replacement may be required to maintain colloid oncotic pressure in very large burns and in the pediatric burn patient. Maintaining serum albumin levels above 2.0 g/dL is desirable.

The electrolytes calcium, magnesium, and phosphate must also be monitored. Although the replacement of these electrolytes has been studied in detail in burn patients, maintaining the values within normal limits is desirable and varies in each patient.

Summary

The volume necessary to resuscitate burn patients is dependent upon injury severity, age, physiological status, and associated injury. Consequently, the volume predicted by a resuscitation formula must commonly be modified according to the individual's response to therapy. In optimizing fluid resuscitation in severely burned patients, the amount of fluid should be just enough to maintain vital organ function without producing iatrogenic pathological changes. The composition of the resuscitation fluid, within limitations, in the first 24 hours postburn probably makes very little difference; however, it should be individualized to the particular patient. The utilization of the beneficial properties of hypertonic, crystalloid, and colloid solutions at various times postburn will minimize the amount of edema formation. The rate of administration of resuscitation fluids should maintain urine outputs of 30–50 cc in adults and 1–2 cc/kg in children. When a child weighs 30–50 kg, the urine output should be maintained at the adult level. Fluid resuscitation based on our current knowledge of the massive fluid shifts and vascular changes that occur following burn injury has markedly decreased mortality related to burn-induced volume loss. The failure rate for adequate resuscitation is <5% even for patients with burns >85% TBSA. These improved statistics, however, are derived from experience in burn centers where there is substantial knowledge of the pathophysiology of burn injury.

Inadequate volume replacement in major burns is, unfortunately, common when clinicians lack sufficient knowledge and experience in this area.

Areas of burn shock research that need further attention include:

- the definition of the postburn course of capillary permeability changes, and identification of humoral or cellular factors influencing these changes;
- the identification and evaluation of pharmacological agents that can significantly alter capillary leakage;
- elucidation of the relationships between resuscitation fluid composition and pulmonary function changes; and
- the effect of resuscitation on late organ dysfunction, such as post-resuscitation wound, renal, and pulmonary complications.⁸⁷

Pathophysiology of the burn wound	119
Assessment of burn depth	120
Mechanisms of thermal injury	121

Introduction

Advances in the resuscitation of burn patients have greatly improved survival, so that death from burn shock has become uncommon. In the 21st century, prompt recovery and good functional outcome for the burn patient hinges, in large part, on proper management of the burn wound.

Perhaps the greatest advance in burn care to date has been the institution of early surgical excision of the burn wound with immediate or delayed wound closure strategy individualized to each patient.¹⁻⁴ For many years, burns were treated by daily washing, removal of loose dead tissue, and application of some sort of topical nostrum until wounds healed by themselves or granulation tissue appeared in the wound bed. Superficial dermal burns healed within 2 weeks and deep dermal burns healed over many weeks if infection was prevented. Full-thickness burns lost their eschar in 2–6 weeks by enzyme production from bacteria and by daily bedside débridement. Split-thickness skin grafts were applied usually 3–8 weeks after injury. A 50% graft survival was considered acceptable and repeated grafting eventually closed the wound. The prolonged and intense inflammatory response made hypertrophic scars and contractures part of normal burn treatment.

Burns that heal within 3 weeks generally do so without hypertrophic scarring or functional impairment, although long-term pigment changes may occur. Burns needing longer than 3 weeks to heal produce unsightly hypertrophic scars, and may form contractures leading to functional impairment. With few exceptions, state-of-the-art burn care now involves early excision and grafting of all burns that do not heal within 3 weeks. The challenge is to determine which burns will heal within 3 weeks.

Burn wound assessment requires an understanding of skin biology and the pathophysiological changes caused by thermal

injury. The standard technique for determining burn depth in the 21st century still remains clinical assessment of the wound by an experienced burn specialist. Management decisions should take into account the mechanism of injury, as this invariably influences the healing potential of the wound, and therefore guides the timing of surgical intervention.

Pathophysiology of the burn wound

Skin biology

The skin is the largest organ in the human body and is composed of two layers: the epidermis and the dermis. The thickness of the epidermis varies among different parts of the body, from 0.05 mm on the eyelids to over 1 mm on the soles.⁵ Most of the skin thickness comes from the dermis, which varies with age, gender, and body location. The skin serves as protection against fluid and electrolyte loss, infection, radiation, and provides thermal regulation. Through skin contact, the individual obtains clues to the surrounding environment via touch, perception of temperature and pain. In addition, skin appearance is a major determinant of identity and affects interpersonal interactions.

The mostly cellular epidermis is derived from ectoderm and the principal cell is the keratinocyte. These cells begin their division and differentiation at the basal layer and move progressively outward over 2–4 weeks⁶ along the outer four layers of the epidermis: the stratum spinosum, the stratum granulosum, the stratum lucidum, and the stratum corneum. Keratinocytes lose their nuclei in the stratum lucidum and become flattened dead cells in the stratum corneum. Other important cells of the epidermis include melanocytes, which produce the melanin pigment essential for protection against ultraviolet radiation, and Langerhans cells, which perform phagocytosis and presentation of foreign antigens. The epidermis, because it is derived from ectoderm, is capable of regenerative healing. Thus, pure epidermal injuries heal by regeneration and without scarring. Keratinocytes proliferate from dermal appendages (hair follicles, sweat glands) and the edges of the wound to achieve reepithelialization. Depleted melanocytes after injury, however, regenerate more slowly and less predictably, which may lead to permanent pigment changes within the healed wound.^{7,8}

The basement membrane zone connects the epidermis to the dermis via epidermal projections (rete ridges) that interdigitate with dermal projections (papillae). The critical structures

that stabilize the epidermal–dermal junction are keratinocyte-derived collagen VII anchoring fibrils that extend into the dermis.^{9,10} These anchoring fibrils may take several weeks (and sometimes months) to mature during burn wound healing. Minor shearing forces may cause shearing, blistering and sometimes epidermal loss until the interdigitations mature.

The dermis with its abundant extracellular matrix component is derived from mesoderm and is divided into the more superficial papillary dermis and the deeper reticular dermis. Collagen fibers provide the bulk of the dermal structure. Their organized orientation allows for stretching and tensile strength of the skin.¹¹ Elastic fibers impart the elastic recoil properties of skin. Protein turnover (by degradation, production, and remodeling) increases with mechanical stress and during healing, accounting for the high plasticity of skin. Collagen and elastin are both synthesized by fibroblasts, the principal cell of the dermis. The non-fibrous component of the dermis is called the ground substance. It is composed of glycosaminoglycans and proteoglycans such as hyaluronic acid and chondroitin sulfate, whose function is to entrap fluid to maintain the semi-fluid matrix and to regulate cellular cross-talk by binding and releasing inflammatory mediators.¹² Adnexal structures (sweat glands, sebaceous glands, and hair follicles) originate in the dermis and extend through the epidermis. Since they are lined with epidermal keratinocytes, adnexal structures provide the epithelial cells necessary for reepithelialization after a partial dermal injury. The dermal plexus of capillary vessels delivers the necessary nutrients to cellular structures in both the dermis and epidermis. After wounding, however, the endothelial cells also mediate local and systemic inflammatory responses.¹³ Sensory nerves, which traverse the dermis into the epidermis, also play a significant role after injury, as they mediate pain and itching, modulate inflammation, and appear to influence the remodeling phase of wound healing.^{14,15} The dermis, like other structures derived from mesoderm, heals not by regeneration but by fibrosis and scarring.

Pathophysiological changes of thermal injury

Applied heat at the cellular level causes denaturation of proteins and loss of plasma membrane integrity. Temperature and duration of contact have a synergistic effect, such that cell necrosis occurs after 1 second of exposure at 156°F (69°C), or after 1 hour at 113°F (45°C).¹⁶ Following a burn, necrosis occurs at the center of the injury, and becomes progressively less severe at the periphery. Thus, Jackson's description in 1953 of the three zones of injury still remains our current conceptual understanding of the burn wound¹⁷ (Figure 10.1). The zone of coagulation is at the center of the wound where no viable cells remain. Surrounding it is the zone of stasis, characterized a mix of viable and non-viable cells, capillary vasoconstriction, and ischemia. This tenuous area represents the zone 'at-risk' and may convert to necrosis with hypoperfusion, desiccation, edema, and infection. With proper wound care management however, these changes may be reversed.¹⁸ Systemic factors such as advanced age, diabetes, and other chronic illnesses also put the zone of stasis at higher risk for 'conversion.' The outer periphery of the burn wound is the zone of hyperemia, with viable cells and vasodilation mediated by local inflammatory mediators. Tissue in this zone usually recovers completely unless complicated by infection or severe hypoperfusion.

Fig. 10.1 Jackson's three zones of injury on an ankle burn: (a) the zone of coagulation, (b) the zone of stasis, and (c) the zone of hyperemia.

Since medical care, for the most part, has little impact on the outcome of the zone of coagulation, efforts have focused on the prevention of necrosis in the zone of stasis. Systemically, protection of this sensitive area is achieved with adequate fluid resuscitation, avoidance of vasoconstrictors, and prevention of infection.^{19,20} Locally, optimal wound care consists of non-dessicating dressings, topical antimicrobials, and frequent monitoring of the wound.^{21–23} Interest in cooling of the wound to minimize the extent of injury can be traced to antiquity,²⁴ but to this day, firm evidence of its efficacy is lacking. To be effective, cooling must be performed immediately after injury, and should not supersede other priorities in the evaluation of the injured patient. The optimal temperature and duration of cooling is unknown;^{25–27} in fact, excessive or prolonged cooling may be harmful in that it promotes vasoconstriction and systemic hypothermia.^{28,29} Current guidelines of American Burn Association recommend limiting cooling to 30 minutes in the management of minor burns.³⁰ Modalities to improve dermal perfusion and block injury from released inflammatory mediators have also garnered much interest. Experimental benefits have been reported for many pharmacologic agents such as heparin, steroidal and non-steroidal anti-inflammatory agents, thromboxane inhibitors, and epidermal growth factor.^{31–39} Yet, all remain investigational since none has gained wide acceptance for clinical use.

Assessment of burn depth

Clinical observation

Burn injury may involve one or both layers of the skin, and may extend into the subcutaneous fat, muscle, and even bony structures.⁴⁰ Burns involving only the epidermis are erythematous and very painful but do not form blisters. Most sunburns fit this category of superficial, epidermal injury. Within 3–4 days, the dead epidermis sloughs and is replaced by regenerating keratinocytes.

Superficial dermal burns extend into the papillary dermis and characteristically form blisters. Blistering may not occur immediately following injury and burns thought to be superficial may subsequently be diagnosed as dermal burns by day.² Once the blister is removed from a superficial partial-thickness burn, the wound is pink, wet, and hypersensitive to touch. Wound care is often painful as uncovering the wound allows currents of air to pass over it. These wounds blanch with pressure, and the blood flow to the dermis is increased over that of normal skin due to vasodilation. With appropriate wound care, superficial dermal burns usually heal within 2–3 weeks without risk of scarring and therefore do not require operation.

Deep dermal burns extend into the reticular dermis and generally will take 3 or more weeks to heal. They also blister, but the wound surface appears mottled pink and white immediately following the injury (Figure 10.2). The patient complains of discomfort and pressure rather than pain. When pressure is applied to the burn, capillaries refill slowly or not at all. The wound is often less sensitive to pinprick than the surrounding normal skin. By the second day the wound may be white and is usually fairly dry. As a rule, partial-thickness burns that are predicted not to heal by 3 weeks should be excised and grafted.

Full-thickness burns involve the entire dermis and extend into subcutaneous tissue. Their appearance may be charred, leathery, firm, and depressed when compared to adjoining normal skin. These wounds are insensitive to light touch and pinprick. Non-charred full-thickness burns can be deceptive. Like deep dermal burns, they may be mottled in appearance. They rarely blanch on pressure, and may have a dry, white appearance. In some cases the burn may be translucent with clotted vessels visible in the depths. Some full-thickness burns, particularly immersion scalds or ‘bake’ injuries (caused by convective heat), may have a red appearance, and can be confused by the inexperienced observer as a superficial dermal burn. These burns, however, do not blanch with pressure. Full-thickness burns should be excised and grafted early to expedite the patient’s recovery process and prevent infection and hypertrophic scarring.

The most difficult management decision involves partial-thickness burns that are intermediate in depth. In this situa-

tion, the determining factor whether these burns heal in 3 weeks may only be a matter of a few tenths of a millimeter. These burns are more aptly called ‘indeterminate’ burns as their healing potential becomes evident with serial assessments over several days. As evidenced by histologic studies, burn injury is a dynamic process that peaks at about 3 days.^{41–43} Initial evaluation by an experienced surgeon as to whether an indeterminate dermal burn will heal in 3 weeks is only about 50–70% accurate.^{44–46}

Adjuncts to clinical evaluation

An intense search for a more precise diagnosis of burn depth has been mounted ever since it became recognized that many patients would benefit from early operation. A number of techniques have been trialed based on the physiology of the skin and alterations produced by burning. These techniques take advantage of the ability to detect: dead cells or denatured collagen (biopsy, ultrasound, vital dyes);^{17,47–50} the color of the wound (light reflectance);⁵¹ physical changes, such as edema (magnetic resonance imaging);⁵² and altered blood flow (fluorescein, laser Doppler imaging, and thermography).^{53–55} Unfortunately, none of these techniques has been proven superior to serial clinical assessments by an experienced burn provider. Several groups, however, have recently reported clinical benefits with the use of non-contact laser Doppler imaging in indeterminate-thickness burns.^{43,56} This technique provides a color perfusion map of the burn wound to add to the clinician’s assessment. Since the scanner is held at a distance from the wound, this test is well tolerated and perhaps more reliable as no pressure is exerted on the wound. Furthermore, this test can be repeated over the first several days post-burn to document dynamic changes in wound bed perfusion. Although a promising tool, non-contact laser Doppler imaging has, so far, not been widely adopted into clinical practice due to variable reproducibility.

Mechanisms of thermal injury

Flash and flame burns

Flash and flame burn injuries represent approximately half of the admissions to American regional burn centers. Explosions of natural gas, propane, gasoline, and other flammable liquids cause intense heat for a very brief time. In particular, gasoline has highly flammable vapors that are 3–4 times denser than air. At room temperature, gasoline vapors can diffuse above ground and may accumulate in enclosed spaces. Victims often describe an inappropriate use of gasoline as a fire accelerant (trash burning, outdoor fire). Clothing, unless it ignites, is protective in flash burns. Hence, flash burns generally have a distribution involving all exposed skin, with the deepest areas facing the source of ignition. For the most part, flash burns reach progressive layers of the dermis in proportion to the amount and kind of fuel that explodes. While such burns will generally heal without extensive skin grafting, they may cover large areas and may be associated with thermal damage to the upper airway.

In contrast to flash injuries, flame burns are invariably deep dermal if not full-thickness because of more prolonged exposure to intense heat. Although the incidence of injuries from house fires has decreased with the advent of smoke detectors,

Fig. 10.2 Lower extremity burn having components of a superficial dermal burn (a) with a wet, pink, and moist appearance, as well as a deeper dermal burn (b) with mottled pink and white areas.

careless smoking, improper use of flammable liquids, automobile accidents, and clothing ignited from stoves or space heaters still exact their toll. Patients whose bedding or clothes have been on fire rarely escape without some full-thickness burns. Many victims of house fires are also prone to deeper injuries because of intoxication or confusion caused by carbon monoxide poisoning. In one study of several burn centers, 28% of flame burns occurred in patients with high blood ethanol level, and 51% of victims in fires behaved inappropriately when trying to escape.⁵⁷ Loss of consciousness may also expose the victim to convective heat inside a burning room. This type of ‘bake’ injury may deceptively appear shallow with intact epithelium to the inexperienced observer, but is really a full-thickness burn.

Scalds

Hot water scalds are the next most common cause of burns in the United States. Despite educational programs, the epidemiology and incidence of scalds worldwide has changed very little. The depth of scald injury depends the water temperature, the skin thickness, and the duration of contact. Water at 140°F (60°C) creates a deep dermal burn in 3 seconds but will cause the same injury in 1 second at 156°F (69°C). Freshly brewed coffee from an automatic percolator is generally about 180°F (82°C). Once in the pot, coffee temperature approximates 160°F (70°C). Boiling water often causes a deep dermal burn, unless the duration of contact is very short. Soups and sauces, which are thicker in consistency, will remain in contact longer with the skin and invariably cause deep dermal burns. In general, exposed areas tend to be burned less deeply than clothed areas. Clothing retains the heat and keeps the liquid in contact with the skin longer. As a result, scalds are often a mosaic of superficial and indeterminate dermal burns. A common example is a toddler who reaches above head level and spills hot water on himself. His face bears a superficial burn, his trunk burn is of indeterminate thickness, and his skin under his diaper has a deep dermal burn.

Immersion scalds are often deep because of the prolonged skin exposure, although the water temperature may not be as high as in spill scalds.^{58,59} They occur in individuals who do not perceive the discomfort of prolonged immersion (i.e. a diabetic patient soaking his foot in hot water), or who are not able to escape from the hot water (i.e. young children, the elderly, or people with physical and cognitive disabilities). This latter group of vulnerable individuals is also susceptible to non-accidental scald burns.^{60,61} Children victims of non-accidental scalds represent about 2% of all children admitted to our burn center. Circumferential extremity injuries, symmetrical burns to a child’s buttocks and perineum are examples that should raise suspicion of abuse (Figure 10.3). A detailed description on the recognition and management of intentional burn injuries is available elsewhere in this text. The evaluating physician, therefore, must carefully consider whether the provided history matches the distribution and probable cause of the burn; this is best accomplished by an experienced burn surgeon who is familiar with burn distribution and etiologies.

Grease and hot oils will generally cause deep dermal or even full-thickness injuries. During cooking, grease and hot oils are

Fig. 10.3 Immersion scald burn on a child. Arrows denote sparing of bilateral popliteal fossae: the child by reflex bent his knees to avoid contact with the hot water.

heated to a level below their smoke point to avoid unpleasant odors from their decompositions. The smoke point for butter is 350°F (177°C), 400°F (204°C) for lard, and 450°F (232°C) for corn oil. Cooking oils reach their flash point at 600°F (316°C). Deep dermal burns commonly occur when a victim tries to carry the burning pan of grease outdoors and douses himself instead of putting the lid on the pan and extinguishing the fire. The extent of domestic grease injuries invariably follows a common pattern.⁶² A single wrist and forearm is first affected. The panicked victim lets go of the pan and splashes himself onto his feet and sometimes thighs and trunk. The now slippery floor from spilled grease causes the victim to fall and burn his back and buttocks. Approximately 30–40% of grease burns require excision and grafting.^{62,63}

Tar and asphalt are a special kind of scald. The ‘mother pot’ at the back of the roofing truck maintains tar at a temperature of 400–500°F (204–260°C). Burns caused by tar directly from the ‘mother pot’ are invariably full-thickness. By the time the tar is spread on the roof, its temperature has diminished to the point where most of the burns are deep dermal in nature. Initially evaluation consists of tar removal before injury depth can be assessed. Tar can be removed by application of petroleum-based ointment under a dressing. The dressing is changed and ointment reapplied every 2–4 hours until the tar has dissolved. Medi-Sol adhesive remover spray (Orange-Sol, Gilbert, AZ, USA) can be successfully used to remove the tar without injury to the burn wound.

Partial-thickness scald burns can be usually managed non-operatively for 10–14 days, unless they are obviously deep.

Burns should be excised and autografted as soon as it is clear that they will not heal by 3 weeks. Desai et al. confirmed the validity of this strategy in a randomized trial.⁶⁴ Children with large scald burns (approximately 25% TBSA) were either excised early (within 72 hours) or after 2 weeks post-injury. Children in the late group required excision of significantly smaller areas, while half achieved reepithelialization without surgery.

Contact burns

Contact burns result from hot metals, plastic, glass, or hot coals. Although generally small in size, contact burns are challenging in that the injury is often very deep (Figure 10.4). Burn depth can be predicted based on the temperature of the material and the duration of contact. Thus, molten materials in industrial accidents instantaneously cause a burn extending below the dermis. Likewise, an unconscious victim laying on top of a heating blanket all night will have a burn extending into fat and sometimes muscle. Industrial accidents involving presses or other hot, heavy objects may cause both contact burns and crush injuries. In these circumstances, the clinician must anticipate the possibility of extensive myonecrosis and myoglobinuria despite the relative small size of the wound. Contact burns with a hot muffler are usually full-thickness and require excision and grafting. Traffic accidents where the victim is trapped against a muffler or engine block may generate significant defects requiring flap coverage.⁶⁵

Domestic contact burns often involve palm and finger burns in toddlers. The unsuspecting child typically puts his hands on a wood-stove, fireplace insert, iron press or oven door.⁶⁶ With aggressive wound care and hand therapy, most intermediate-depth palm burns heal in about 2–3 weeks. On the other hand, unoperated deep palm burns heal from the edges with contracture of the palm leading to permanent disability. The decision to perform excision and grafting using thick split-thickness grafts or full-thickness grafts to deep palm burns^{67,68} should be tempered by the knowledge that sensory nerve endings unique to glabrous skin (Pacinian and Meissner's corpuscles) cannot be replaced by a skin graft. Therefore, an observation

Fig. 10.4 Deep contact burn in an elderly patient who was unconscious next to a space heater. Arrows denote the imprints of the space heater grill on his lateral thigh.

period of 2–3 weeks with splinting and aggressive exercise appears prudent.

Chemical burns

Chemical burns, usually caused by strong acids or alkalis, are most often the result of industrial accidents, drain cleaners, assaults, and the improper use of harsh solvents. Chemical burns cause progressive damage until the chemicals are inactivated by reaction with the tissue or dilution by flushing with water. Although individual circumstances vary, acid burns are usually more self-limiting than alkali burns. Acid tends to ‘tan’ the skin, creating an impermeable barrier that limits further penetration of the acid. Alkalis, on the other hand, combine with cutaneous lipids to create soap and thereby continue ‘dissolving’ the skin until they are neutralized.

Initial management consists of diluting the agent with copious water, preferably at the site of the accident. To this end, many industrial workplaces are now equipped with such showers and eye wash stations. The victim ought to have the contact site irrigated for 15–20 minutes at minimum. A paper pH test applied to the patient’s burn can verify that the agent has been neutralized. Attempts to neutralize alkalis with acids (and vice versa) are contraindicated because these maneuvers are dangerous and may induce an exothermic reaction leading to a thermal injury superimposed on the chemical burn. An exception to the irrigation rule is exposure to a chemical powder. In this instance, it is safer to brush the agent off. Examples of common dry chemicals include dry concrete, cement, and sodium hydroxide. A full-thickness chemical burn may appear deceptively superficial, clinically causing only a mild brownish discoloration of the skin. The skin may appear intact during the first few days post-burn, and only then begin to slough spontaneously. Unless the observer can be absolutely sure, chemical burns should be considered deep dermal or full-thickness until proven otherwise.

Burns caused by wet cement can be vexing. Workers often kneel in wet cement or spill cement inside boots or gloves and do not become symptomatic for hours.^{69–71} By the time they seek medical help, the wounds are often deep and most often need grafting.

Hydrofluoric acid (HF) burns are potentially very destructive. HF is widely used in the circuit board etching, cleaning solvents, and paint removers. HF coagulates the skin at site of exposure. Fluoride ions penetrate the skin and cause deep tissue destruction by combining with cellular calcium and magnesium.^{72,73} Fluoride is also a metabolic poison that inhibits key enzymes of cellular metabolism. A 10% TBSA HF burn may be life threatening due to systemic hypocalcemia;⁷⁴ this may be one instance where urgent surgical wound excision is indicated. As with cement, the worker may not become symptomatic for several hours after exposure, when severe pain develops in the involved fingers. Delayed or inadequate treatment can lead to amputation. Older recommendations of calcium-containing topical gels^{75,76} and direct injection of calcium gluconate into the involved tissue have now largely been replaced by intra-arterial infusion of calcium ions into vessels perfusing the injured area.^{77–80} Such treatment is almost magical, with immediate cessation of pain and minimal tissue

destruction. However, once acute symptoms resolve, it has no further role in preventing tissue damage.

Electrical burns

Electrical burns are in reality thermal burns from very high-intensity heat generated as the victim's body becomes an accidental resistor. Low-voltage injuries (less than 440 volts) rarely cause significant damage beyond a small deep thermal burn at contact points. An exception to this rule is the child who chews on an active electrical connection.⁸¹ The child's saliva completes the circuit between the positive and neutral leads. The short circuit may cause a severe burn inside the mouth and lip. Burns involving the oral commissure are at high risk for late contracture and warrant an aggressive splinting and exercise regimen.^{82,83} In addition, eschar separation at the corner of the mouth by day 7–10 after injury may be associated with brisk labial artery bleeding that requires surgical control.⁸⁴ High-voltage injuries (over 1000 volts) are more apt to cause deep tissue destruction. In fact, most electrical burns are work-related (i.e. construction workers, linemen, utility and electrical workers). In this setting, extensive deep tissue destruction may take place underneath a relatively small, innocuous-appearing wound (Figure 10.5).

High resistance at skin contact points is partially protective as a dry calloused hand may provide twice the resistance of normal skin, and five times the resistance of wet skin. High resistance within the victim's body, on the other hand, causes more harm. As electricity travels through the body, electrical energy is converted to heat in direct proportion to current and electrical resistance. Deep muscle necrosis may occur adjacent to bone, which has high resistance.^{85,86} A smaller body part conducting the electricity will generate more intense heat with less dissipation. Therefore, fingers, hands, forearms, feet, and lower legs are often totally destroyed, whereas the trunk usually dissipates enough current to prevent extensive damage to viscera (unless the entrance or exit wound is on the abdomen or chest).^{87–89} Arc electrical burns are also common as the current takes the most direct path, rather than a longer path of seeming less resistance. These injuries occur at joints in close apposition at the time of injury. Most common are burns of the volar aspect of the wrist, the antecubital fossa when the elbow is flexed, and the axilla if the shoulder is adducted.

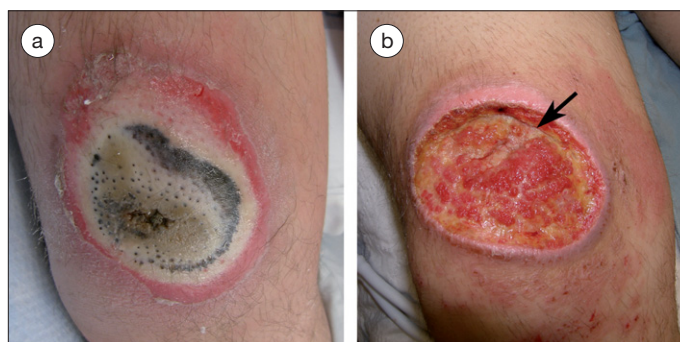

Fig. 10.5 High-voltage contact point on an electrician's knee: (a) prior to, (b) after débridement. Excision down to muscle tissue was required (arrow) to obtain a viable wound bed.

There are two reasons for early operation in the patient with electrical burns. Massive deep tissue necrosis may lead to acidosis or myoglobinuria that will not clear with standard resuscitation techniques. In this unusual circumstance, fasciotomies, major débridement, and amputation may be needed urgently. More commonly, tissue swelling raises the risk of compartment syndrome. Careful monitoring of the injured extremity is mandatory. Compartmental release is indicated with any sign of progressive peripheral neuropathy. Thus, worsening median or (less commonly) ulnar nerve deficit in the injured hand are indications for immediate median and ulnar nerve release at the wrist. The use of a technetium scan to help identify damaged and necrotic muscle has been advocated,⁹⁰ but has not achieved widespread use. This test is overly sensitive in detecting damage to deep, unexposed muscle groups that, left alone, will fibrose and not require excision.⁹¹

If immediate decompression or débridement is not required, definitive operations can be performed between days 3 and 5, before bacterial contamination occurs and after the tissue necrosis is delineated.^{91,92} Extraordinary measures, such as vascular grafts to replace clotted arteries, and urgent free flaps may sometimes be indicated,^{93,94} but the surgeon is cautioned that they may actually increase morbidity and prolong the patient's recovery. A well-fitting prosthesis might give better function than a hand or foot that is weak and has diminished sensation.

Author's Note

I had the privilege to collaborate with Dr William W. Monafa of St. Louis on the first versions of this chapter, which were included in the first two editions of *Total Burn Care*. Dr Monafa was a leader in the field at the end of the 20th century. He contributed widely to the understanding and techniques of burn resuscitation and wound care. He was a founding member and the ninth president of the American Burn Association, and he led an exemplary clinical burn program for most of his career. It is to his memory and in gratitude for his support and friendship that I dedicate this version of the chapter.

I dresst the wound . . . and God healed it.
Ambroise Paré, 1510–1590

Introduction

The over-riding objective of acute burn care is closure of the burn wound with the patient's own epidermis. Sometimes that happens spontaneously, and sometimes it requires an operation to excise the burned tissue and ultimately cover the wound with an autologous skin graft, or autograft. When it becomes clinically apparent that the burn is a full-thickness injury or third-degree burn, common, current practice is to proceed with operation as expeditiously as possible. The subject of this chapter is the care of the burn wound in the interval between its occurrence and closure, either by spontaneous generation of new epidermis or by surgical excision.

Cutaneous wound healing**Skin biology**

The skin is the largest organ of the body. It plays a major homeostatic role in maintaining body temperature and fluid balance and protecting the internal milieu from all variety of environmental dangers. It has a specialized epithelium, that is

made up of epidermis, hair follicles, sebaceous glands, and sweat glands, as well as a stroma. To sustain its biologic function it constantly renews itself, and it this renewal property that is exploited after a burn or other injury.

The outer mantle of the skin is a stratified squamous epithelium composed of keratinocytes which arise from a layer of basal cells. Cells in the basal layer of the epidermis give rise to transit amplifying cells, which function as progenitor cells for keratinocytes. They proliferate and become increasingly differentiated as they migrate outward to the skin surface elaborating proteins and lipids.^{1,2} As they approach the surface, they undergo a programmed cell death,³ and the flattened, enucleated cell skeletons (squames or corneocytes) become encased in a lipid and protein mortar to form the outer, cornified veneer. The entire process is relatively rapid. It is estimated that human epidermis — as much as 1¹/₂–2m² or more of it in adults — turns over every 2 weeks.

Hair follicles are distributed throughout the epidermis and the upper or outer portions of the follicles are also covered with epidermis. The sebaceous glands are located deep to the epidermis and empty into the upper follicle and thence out onto the epidermis (Figure 11.1). Sebocytes arise from a basaloïd layer of cells which are continuous with the follicular epithelium. As they differentiate and move outward they accumulate lipid and ultimately slough and are extruded onto the epidermis as sebum (holocrine secretion).^{4,5} The lower portion of the hair follicle consists of an outer root sheath, an inner root sheath, and the hair shaft. The lower hair follicle has cycles of growth and quiescence. The cells in the outer root sheath are continuous with the epidermal basal cell layer. Thus, the cells in the basal layer of each or the epithelial compartments serve as lineage-restricted stem cells that give rise to other cells which then proliferate and undergo terminal differentiation resulting in epidermis, sebum, or hair.

A region of the hair follicle just below the sebaceous gland is known as the bulge (Figure 11.1). It appears to be a protected niche,⁶ and the cells in it are multipotent stem cells that can give rise to the precursor cells of the epidermis, sebaceous gland, or outer root sheath.^{6–11} It is currently thought that the stem cells in the bulge play little role in maintenance of the skin but serve to repopulate the various epithelial precursor cell populations following injury.^{12–14}

Superficial or partial-thickness burns

The cells in the basal layer of the epidermis that give rise to the transit amplifying cells, that then proliferate and differentiate terminally into keratinocytes, qualify as epidermal

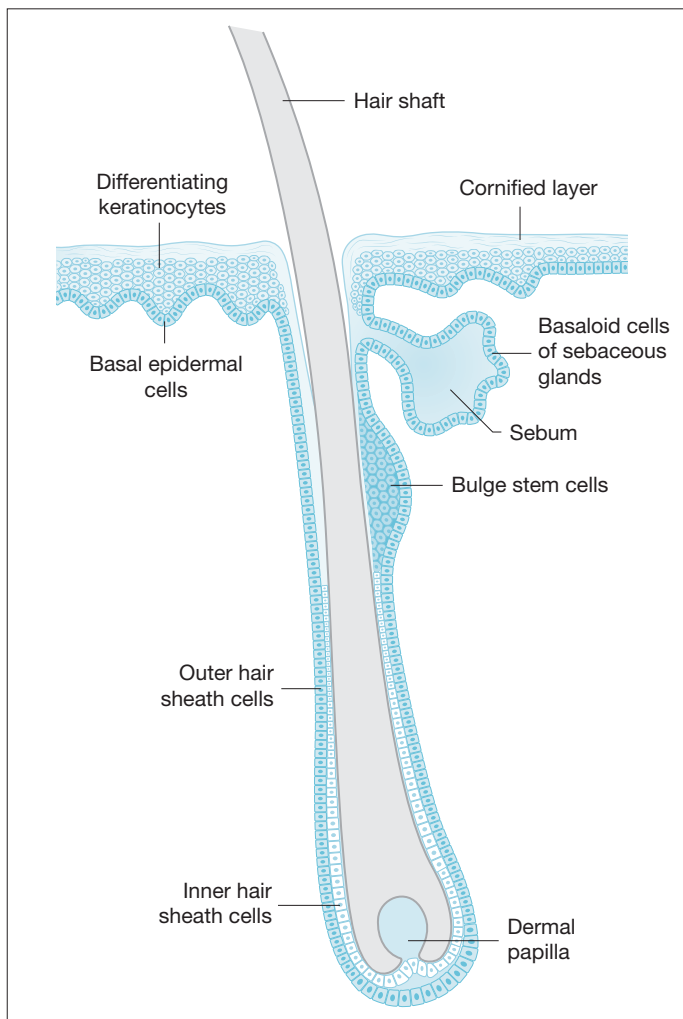

Fig. 11.1 A schematic diagram of a hair follicle. The basal cell layer of the epidermis, the basaloid cells of the sebaceous gland, and the cells of the outer hair sheath are all continuous. The cells in each compartment serve as stem cells and give rise to other cells that undergo terminal differentiation to form the cornified layer of the epidermis and sebum and also interact with the dermal papilla to form the hair shaft. Cells in the bulge region are multi-potent stem cells that can repopulate the basal cells in all compartments after injury.

stem cells. Burns involving only the epidermis, first-degree burns, thus heal readily with the rapid emergence of new keratinocytes.

Second-degree or partial-thickness burns destroy all of the epidermis as well as a portion of the dermis and the skin appendages. If the follicular bulge region is uninjured, its cells can repopulate the epidermal basal cell layer and also give rise to new sebaceous glands and hair follicles within the new epidermis (Figure 11.2). As burn depth extends into the deeper dermis, however, the remnants of hair follicles are sparser. Deep dermal burns heal slowly, if at all, and depend to a large degree on the migration of keratinocytes from surrounding uninjured skin. This is also the mechanism whereby the interstices of meshed split-thickness skin grafts are filled in by keratinocytes that migrate from the skin bridges.

The biology of epidermal renewal is currently an area of intense research. Understanding of the basic mechanisms

Fig. 11.2 This shows epidermal budding in a relatively deep second degree burn. Each bud of epidermis is arising from a single hair follicle. The source of the new keratinocytes is thought to be a collection of stem cells, known as ‘the bulge’.

involved is expanding rapidly. Translation into a useful technology that will improve clinical burn care and outcomes may soon be a reality.^{8,15}

Deep or full-thickness burns

Full-thickness burns involve the entire thickness of the dermis and extend into the subcutaneous fat. These do not heal spontaneously, unless they are of limited area and can reasonably be allowed to close by a combination of wound contraction and re-epithelialization by the surrounding intact epidermis. The layer of coagulated and necrotic soft tissue, eschar, varies in thickness depending on the duration and intensity of the heat exposure. Wound closure cannot occur while eschar remains *in situ*. Spontaneous eschar separation is due primarily to the action of proteases released by bacteria that proliferate beneath the eschar and do not occur in sterile full-thickness burns. For example, full-thickness burn eschar in gnotobiotic rodents may remain in place for 8 months or more.¹⁶ Separation of eschar may be delayed by ineffective wound cleansing measures.^{17,18} The thin layer of congealed necrotic debris and wound exudate that forms over deep dermal burns — referred to as a ‘pseudo-eschar’ — often separates spontaneously even in the absence of microorganisms as re-epithelialization proceeds beneath it.

The presence of necrotic tissue and debris and bacteria are all potent inflammatory stimuli. The burn wound soon becomes an inflammatory tissue mass containing a variety of cell types including at various times platelets, neutrophils, lymphocytes, macrophages, and fibroblasts, whose activity is regulated by a complex interplay of multiple cytokines as well as host neuro-endocrine mechanisms. The principal molecular regulators controlling the evolution of the burn wound include vascular endothelial growth factor (VEGF), platelet-derived growth factor (PDGF), and transforming growth factor- β (TGF- β). Wound cellular activities include cell recruitment and proliferation, proteolysis, bacterial killing, angiogenesis, and collagen synthesis, all of which exact a substantial metabolic price from the patient. Oxygen, energy substrate, and amino acids must be supplied to the wound to support its metabolic needs.¹⁹

Fig. 11.3 The influence of several factors on the rate of wound contraction. Infection, severe malnutrition, and other factors impede spontaneous decrease in wound surface area. Split-thickness grafts also impede but do not prevent subsequent wound contraction. Full-thickness grafts almost abolish it.

The magnitude of these requirements is proportional to the mass of inflammatory tissue, i.e. the extent or size of the wound. The presence of a wound is a constant drain on the patient's reserves. Only with closure of the wound will these processes abate.

Deep wounds that remain open for several weeks may progressively decrease in surface area. The primary mechanism is contraction of the wound as a result of forces generated in the wound bed by differentiated fibroblasts containing contractile protein, myofibroblasts. These develop in part due to transforming growth factor- β_1 and other inflammatory mediators.²⁰ Another mechanism for reduction in wound surface area is ingrowth of epidermis from the wound perimeter, but this accounts for only a small portion of shrinkage of the wound, perhaps 10% or less.

Contraction may be desirable in that it reduces both the risk of infection and the metabolic drain which results from the loss of water vapor and body fluids as well as from the inflammatory processes in an open, granulating wound.²¹ Wound contraction near joints, the eyelids, or the mouth is highly undesirable both functionally and cosmetically. Some factors that can alter the rate of wound contraction are schematically depicted in Figure 11.2. Successful split-thickness skin grafts slow contraction, while full-thickness ones often appear to abolish it. Split-thickness grafts have the advantage of resulting in a donor site that is akin to a superficial burn. It can heal readily by re-epithelialization in 10–14 days and does not require any surgical closure. Thick split-thickness grafts or full-thickness grafts leave deeper donor sites that do not heal readily without an additional surgical procedure. In extensive burns, it is advantageous to use thin split-thickness grafts so that the donor sites can be used for additional grafts after the initial wounds re-epithelialize in 10–14 days. Small full-thickness grafts are commonly used on the eyelids to reduce or correct severe ectropion and also for deep palmar burns in infants.²²

Full-thickness burns are the prototypical cause of hypertrophic scar.²³ Although other mammals also heal wounds by making scar, hypertrophic scars and keloids seem to be unique to humans. Lack of a simple animal experimental model slowed progress in the understanding of the biological mecha-

Fig. 11.4 Biobrane. The use of Biobrane has revolutionized care for second degree burns. Advantages of Biobrane include decreased pain and elimination of dressing changes.

nisms involved in the formation of hypertrophic scar, but recent studies of wound healing in fetuses have rekindled hope that it may soon be possible to control this tendency. Surgical incisions in fetuses (e.g. for prenatal correction of congenital defects) do not result in scar,²⁴ and that phenomenon is associated with differences in the amounts and timing of PDGF and various members of the TGF- β family.²⁵ In the fetal wound TGF- β_3 is elaborated in abundance, whereas TGF- β_1 is the predominant isoform in adults.

There is a tendency toward hypertrophic scar formation after any injury to the reticular dermis, but its severity is highly variable and unpredictable. Scar hypertrophy is common in deep dermal burns that are allowed to close spontaneously, at the perimeter of skin grafts, and in the interstices of meshed grafts. Unmeshed split-thickness skin grafts (sheet grafts) retard this process to some degree. Early closure of deep burns also seems to result in less hypertrophic scar than does delayed closure.

The surgical management of full-thickness wounds, the prevention and treatment of hypertrophic scar, and the physiologic support of the patient are all fully covered in other chapters in

this book. The wound is central to the total care of the burn patient, and its care prior to spontaneous healing or surgical closure has at least the potential to influence other aspects of the patient's care and the later, long-term outcome of the injury.

Wound care

Burns that obviously involve the full thickness of the skin are best treated with excision and grafting as soon as feasible.²⁶ Most burns, however, go on to heal spontaneously and do not require operation.²⁷ Some are obviously superficial on presentation and re-epithelialize quickly, and others are indeterminate or of mixed depth. Some of these may ultimately require skin grafting of a portion of the wound, but that is not obvious on presentation. In that context then, the goals of burn wound care are to assure an optimal environment for epidermal renewal, if it can occur; to avoid any further injury to the skin or deeper tissues; and to avoid secondary complications, such as infection. To achieve these goals, a two-pronged approach is needed, involving both care of the wound itself and care of the patient with a wound.

Care of the patient with a wound

The wound's need for oxygen, amino acids, and energy substrate requires effective perfusion of the wound. The environment of a wound is relatively hypoxic and that serves as an early inflammatory stimulus. The cellular activity that develops in the wound, however, requires increased consumption of oxygen and nutrients. Delivery of these substances to the site of repair requires both perfusion of the wound and surrounding tissues and also diffusion from the serum through the interstitial fluid to the wound. The driving force for diffusion is determined by the gradient between the concentration of a substance in the serum and that in the wound. If the gradient is not sufficiently great, it can limit the utilization of a given substance by the cells of the wound, even if perfusion is good. This is especially important for oxygen, which is poorly soluble in aqueous solution, so that a small gradient between the pO_2 in the serum and the pO_2 in the interstitial fluid may be rate limiting. In patients with elective surgical wounds, the level of interstitial pO_2 correlated with the risk of infection and delayed wound healing,²⁸ and in another series, supplemental perioperative oxygen increased the interstitial pO_2 , which reduced the incidence of wound infection by half.²⁹ Thus, a normal or somewhat elevated arterial pO_2 appears to be beneficial for wound healing.

Effective resuscitation and appropriate fluid management and measures to avoid vasoconstriction, such as maintaining a warm environment, controlling pain and anxiety, and avoidance of pressors, will help maintain perfusion. Maintenance of an arterial pO_2 near normal or slightly elevated should result in an oxygen gradient sufficient to meet the oxygen needs of the wound. In addition, provision of sufficient nutrients to meet the increased energy and protein needs of the patient and his or her wound will support wound repair and reduce the draft on the patient's metabolic reserves.

Assessing the wound

Some burns can be classified as partial- or full-thickness injuries with certainty on initial evaluation based on their appear-

ance and on the mechanism of injury, taking into account the source of the heat and the duration of skin exposure. There are many burns, however, about which there is less certainty at the outset. These will change in appearance over the first week, so that the initial clinical assessment may be inaccurate as much as 30% of the time. Some wounds may come to seem much deeper than they did originally. The initial heat exposure coagulates a portion of the thickness of the skin and may also result in an endothelial injury of the small vessels in the tissue immediately adjacent to this.³⁰ The apparent increase in the burn depth may be due to an inevitable, progressive occlusion of the circulation in this 'zone of stasis' at the wound periphery where endothelial injury has occurred, to potentially preventable inadequate resuscitation and perfusion, or to compression of the dermal vessels by the edema attending injury and/or resuscitation. This highlights the importance of adequate but not excessive resuscitation. The use of subatmospheric pressure may be helpful in this regard by reducing edema and promoting perfusion.³¹ Conversely, some dermal burns may appear to be quite deep early after burn and then go on to re-epithelialize well. This is often the case in burns on the palms of the hands and soles of the feet.

Clinical observation of the burn wound and its evolution remains the primary basis of wound depth assessment. Although the use of the laser Doppler may give a reasonably accurate measurement of burn depth, methodologic problems and details of standardization still need to be worked out before the potential benefits of this technique can be accurately assessed.³²

Once a burn has been determined to be a third-degree or full-thickness injury, excision of the burn and grafting are usually carried out as soon as the patient is clinically stable. Wound care for a full-thickness wound then consists of prevention of further tissue loss or invasive infection prior to excision. All other burns as well as donor sites and wounds with fresh split-thickness grafts must in addition be maintained in such a way as to facilitate or at least not impede re-epithelialization. This includes a warm and moist environment, removal of exudate and potentially contaminated or necrotic material, and control of bacterial proliferation.

The dressing

A burn dressing has three principal functions:

- *Comfort.* Superficial burns are initially extraordinarily sensitive to air currents; and deeper burns become progressively more tender with time. Open wounds also produce a substantial amount of drainage. The dressing shields the wound surface from air currents in the environment, absorbs and contains wound secretions, and if properly constructed may also provide splinting action to maintain a desirable position of function and limit movement.
- *Metabolic.* An occlusive dressing reduces evaporative heat loss and minimizes cold stress and shivering. Because the principal cutaneous water vapor barrier resides in the epidermis, even superficial burns result in substantial water vapor loss. Intact eschar provides only a partial impediment, while excised or granulating wounds lose water vapor maximally.¹¹ Evaporative loss from exposed burns may be much greater than the

'normal' 150 mL/24 hours, especially if air-fluidized beds are used. This loss of water from the wound also contributes to the loss of heat by 0.58 kcal/kg water lost.⁸ An occlusive dressing of reasonable thickness will impede water vapor loss appreciably, particularly if it is in turn kept covered with a dry blanket.

Biological dressings such as cadaver allograft and an ever-increasing number of commercially available synthetic dressings and bioengineered materials may also minimize the water loss, but their efficacy and cost-effectiveness are controversial, especially in major burns.

- *Protective.* When skin is thermally injured the physical barrier of the epidermis to microorganisms is lost, as well as its mild antiseptic property. The result is that the environmental flora proliferate readily on the wound surface. In small burns, an effective dressing can isolate the wound so that few if any organisms are ever recoverable. As the wound area increases, however, the efficacy of a dressing's barrier function decreases.

Wound hygiene

The French word débridement ('unbridle', i.e. as in escharotomy or fasciotomy) has, in North America at least, come to signify both the formal surgical excision of devitalized tissue (including, but not limited to burns) as well as the simple piecemeal removal of bits and fragments of separating eschar, ruptured bleb fragments, foreign material, and other debris during the routine dressing change. On initial evaluation, most burn wounds will be cleansed and debrided and a dressing will be applied. After that, there are a variety of ways to manage the wounds. The method that is selected will depend in part on the type and size of the burn, but equally or more important is local experience and other factors. The field does continue to progress, but differences between techniques of wound care are usually not so marked as to counter professional opinion. Thus, the management of acute burn wounds still relies to a large degree on uncontrolled clinical observations and anecdotal personal experience.

A common approach to burn wound care consists of wound cleansing and debridement daily or twice daily and reapplication of the dressing. Additional fragments of blebs or desquamated epidermis can then be removed. The thin pseudo-eschar that forms over deep dermal burns tends to separate piecemeal as re-epithelialization occurs beneath it. Although systematic, gentle wound cleansing with removals of bits of slough, exudate, and debris would seem eminently reasonable, evidence of benefit does not exist to our knowledge. It is, however, associated with not inconsiderable pain, apprehension, and expense.

Dressing materials

The typical burn wound dressing for wounds that are cleaned and debrided frequently consists of a relatively fine mesh material that contains or is placed over an antimicrobial cream or liquid and applied directly to the wound surface. This is then wrapped in several layers of gauze in pads or rolls. Use of non-adherent materials, such as Telfa[®], Exu-Dry[®], Xeroform[®], or Adaptic[®], directly on the wound may reduce both

the pain associated with removal of the dressing and the risk of pulling off migrating epidermal cells from the wound surface. The non-adherent sheet and the topical antimicrobial material together will serve as at least a partial barrier to the loss of water vapor from the wound and help provide a warm, moist environment for re-epithelialization. The dressings, however, become soaked with drainage from the wound and must be changed frequently.

Topical antimicrobial agents

General background

Burn injury not only damages the normal skin barrier but also impairs host immunological defenses. Because the eschar may be several centimeters or more distant from patent microvasculature, systemically administered antimicrobial agents may not achieve therapeutic levels by diffusion to the wound surface, where microbial numbers are usually greatest. Topically applied antimicrobials provide high concentrations of drug at the wound surface; they penetrate eschar variably, a property that should be considered in their selection. Normal skin harbors a sparse bacterial flora, consisting mainly of diphtheroids and *Staphylococcus epidermidis* and, occasionally, *S. aureus*.

Gram-negative bacteria are not usually present in normal skin. The burn wound flora changes in the post-injury interval, depending in part on the topical and/or systemic antimicrobial therapy being used and on the efficacy with which cross-contamination is prevented. After a variable initial period (days) when the wound is apparently sterile or contains only normal flora, Gram-positive organisms, mainly *S. aureus*, typically predominate. Subsequently, Gram-negative species appear. In the past, isolates of *Proteus*, *Klebsiella*, *Escherichia coli* and other enteric flora predominated, but *Pseudomonas*, *Enterobacter*, *Serratia*, and *Acinetobacter* are increasingly frequent today.³³⁻³⁵ Anaerobes are infrequent, but can be encountered when large volumes of necrotic muscle are present, as in high-voltage electrical injury.

The goal of prophylactic topical therapy is initially to delay and later to minimize wound colonization.³³ With effective topical agents and the prompt excision of full-thickness eschar, the incidence of invasive burn wound infections is low. Prophylactic agents do not need to penetrate the eschar deeply, as environmental fallout is the source of contamination. They should have activity against common wound pathogens as listed above, should not retard wound healing (although some of them do so, to some extent),³⁶ and they should have low toxicity, which implies that systemic absorption is low. None of the topical antimicrobials, either alone or in combination, will eliminate colonization of major burn wounds. Frequent clinical observation is necessary in order to ensure that basic wound hygienic measures are being satisfactorily carried out, that the frequency of dressing changes is appropriate, and that the clinical appearance of the wounds is satisfactory.

When an established burn wound infection is present, the spectrum of activity of a proposed agent must include the organisms responsible. Concerns about toxicity, patient comfort, cost, and other factors require careful assessment. In most instances, eradication of an invasive infection will require

the use of one or more topical agents, which penetrate eschar readily, as by definition microbial invasion of previously normal, unburned tissue exists. Systemic antibiotics of appropriate spectrum are also necessary; in relatively localized infections, sub-eschar antibiotic infusions are sometimes efficacious in reducing systemic septic toxicity, but excision of the eschar and infected eschar are required for cure. Invasive burn wound infections with *Staphylococcus* or *Pseudomonas* species have been frequently treated with topical mafenide acetate, which penetrates eschar readily.³⁴

Specific agents

As already noted, topical therapy in most instances is prophylactic. Frequent clinical inspection is the best method of noting the clinical response. Wound surveillance bacterial culture results require clinical correlation because the distinction between colonization, which is frequent, and invasive infection, which is now uncommon, is partly a clinical one. In general, quantitative wound biopsy cultures, which exceed 100 000 organisms per gram, are consistent with, although not diagnostic of, invasive infection. The microscopic visualization of organisms invading normal tissue in a wound biopsy specimen is diagnostic, but gives no information as to the extent of the infection.³⁴

0.5% Silver nitrate solution

One-half percent silver nitrate solution was introduced as an effective topical agent in the mid-1960s.³⁷ Together with the near-simultaneous introduction of topical mafenide, the modern era of topical burn wound therapy had begun. Shortly thereafter, silver sulfadiazine was synthesized and would become available. More recently, silver foil or mesh dressings (Acticoat® and Silverlon®) have been introduced. Silver nitrate is effective against most strains of *Staphylococcus* and *Pseudomonas*, and also has activity against many of the Gram-negative aerobes that commonly colonize burn wounds. Concentrations much above 5% are histotoxic. Most biologically important silver salts, especially the chloride and proteinate, are highly insoluble. The agent, or at least the silver moiety, does not therefore penetrate eschar significantly and silver absorption is minimal; although trace amounts have been detected in blood and tissue following protracted application, there is no significant direct toxicity.

The hypotonic solution (29.4 mmol Ag/L) leaches electrolyte, especially sodium from the wound surface. As much as 350 mmol of sodium/day/m² of body surface area treated may be lost. Continuous oral and/or intravenous (IV) electrolyte supplementation is therefore essential. Hyponatremia or hypokalemia may occur rapidly, especially in infants or children with large burns.

Another important but fortunately infrequent complication of this agent is methemoglobinemia, which occurs as a result of nitrate reduction by wound bacteria (usually Gram-negative species) with subsequent systemic absorption of the toxic nitrite. The diagnosis should be suspected if the skin or blood appears cyanotic or 'gray' but the arterial oxygen content is normal. Confirmation of the diagnosis by blood methemoglobin measurement should lead to prompt withdrawal of the agent. Additional specific treatment with reducing agents may also be required.

Silver nitrate is relatively painless on application. It is typically used to saturate gauze dressings similar to those described above. The dressings should be moistened with the silver nitrate at 2-hourly intervals to prevent silver concentrations reaching histotoxic levels. The agent stains everything it touches brown or black, including bed linens, floors, etc. Although silver nitrate is an effective prophylactic agent, it is presently not widely used routinely, principally because of its staining property. Its therapeutic effect is approximated by silver sulfadiazine, which is easier to use.

Silver sulfadiazine

Silver sulfadiazine is easily the most frequently used prophylactic agent in burn patients. It is a white, highly insoluble compound that is synthesized from silver nitrate and sodium sulfadiazine.^{33,38} It is available in 1% concentration in a water-soluble cream base. The cream is relatively painless to apply and does not stain bed linens or other objects, which it contacts. Silver sulfadiazine has *in vitro* activity against a wide range of organisms including *S. aureus*, *E. coli*, *Klebsiella* species, *Pseudomonas aeruginosa*, *Proteus* species and *Candida albicans*. The drug penetrates eschar poorly. Its precise mechanism of action is unclear.

The toxicity commonly associated with sulfonamides, such as crystalluria and methemoglobinemia, is rare after silver sulfadiazine treatment. Cutaneous sensitivity reactions, typically in the form of a maculopapular rash, occur in less than 5% of patients and rarely require discontinuing the drug. Acute hemolytic anemia has been reported in a burn patient treated with silver sulfadiazine who lacked the enzyme glucose-6 phosphatase.³⁹

The most frequently associated clinical finding is a transient leukopenia which occurs within several days of the initiation of therapy. This is associated with a disproportionate decrease in circulating neutrophils. The incidence is from 5 to 15% of patients treated,⁴⁰ and it has been proposed that there is a direct toxic effect of silver sulfadiazine on bone marrow.⁴¹ The leukopenia can reach alarmingly low levels — less than 1000/mm³ — and because of these observations, neutropenia is listed as a toxic effect of the agent.

Despite these observations, however, no increase in the incidence of infectious complications has been identified, and the leukopenia recovers spontaneously, whether or not the agent has been discontinued.⁴² An alternative hypothesis is that marked leukocyte margination in the wound occurs early after burn independent of any drug effect. Both leukocyte and platelet counts fall over the first 2–3 days following major burn and begin to recover by post-burn day 4. A recent prospective comparison between one burn center that used topical silver nitrate exclusively and another that used silver sulfadiazine invariably demonstrated equal proportions of patients with leukopenia and that in both cases the leukopenia improved spontaneously without change of topical agent.⁴³

Clinical trials have suggested that silver sulfadiazine reduces wound bacterial density and delays colonization with Gram-negative bacteria, but treatment failures occur with some frequency in large burns (>40–50% body surface area). The agent is usually applied on a daily or twice-daily basis. When it is used on superficial dermal burns, a yellow-gray pseudo-eschar typically forms after several days, which can

be confusing to inexperienced personnel. This film, several millimeters thick, results from interaction between the cream and the wound exudate and is harmless; it is easily lifted away, revealing a healthy, superficial wound bed beneath it.

Mafenide acetate

Mafenide was introduced as a topical burn treatment in the mid 1960s. It is available in a water-soluble cream base at 11.1% concentration, and also, more recently, as a 5% solution. It has excellent antibacterial activity against most Gram-positive species, including *Clostridium*, but limited activity against some staphylococci, particularly methicillin-resistant strains. It has a broad activity against most Gram-negative pathogens commonly isolated from burn wounds, but, importantly, has minimal antifungal activity.⁴⁴ Early enthusiasm for its prophylactic use was soon tempered because of its systemic toxicity and by the considerable pain that occurs on application. The drug is so rapidly absorbed through open wounds that local concentrations are sharply reduced, requiring usually twice-daily applications.

Mafenide is a potent carbonic anhydrase inhibitor. Thus, hyperchloremic metabolic acidosis is frequent when it is used continuously on extensive burns.⁴⁵ Moderate to severe hyperventilation as respiratory compensation for the acidosis is characteristic and the PaCO₂ is persistently subnormal. Minute ventilation may approach or exceed 50 L/min. Pulmonary complications are a hazard with its continuous use and toxicity increases in frequency to the wound area and treatment duration. A maculopapular rash occurs in about 5% of patients but can usually be controlled with antihistamines and may not require discontinuing the drug. Although the use of mafenide as a prophylactic agent has decreased for the reasons cited, its excellent eschar penetration makes it useful for the short-term control of invasive burn wound infections. In some centers, the drug is still used prophylactically but toxicity is minimized or avoided by alternating it with silver sulfadiazine, usually at 12-hour intervals.

Cerium nitrate–silver sulfadiazine

This agent was introduced by Fox and Monafo in the mid 1970s.⁴⁶ It is not now commercially available in the US, but a commercial preparation is available in several western European and South American countries.^{47–49} It can be easily prepared by combining commercially available silver sulfadiazine with a solution of cerium nitrate. Cerium, one of the lanthanide ‘rare earth’ series of elements, has antimicrobial activity *in vitro* and is relatively non-toxic. Wound bacteriostasis may be more efficient with its use in major burns compared to silver sulfadiazine alone.⁴⁸ The *in vitro* antimicrobial spectrum of this agent is qualitatively similar to that of silver nitrate or silver sulfadiazine. A highly favorable effect on mortality has been reported for burn patients who have been briefly immersed in a bath of cerium nitrate shortly after admittance to the hospital.⁵⁰ Methemoglobinemia due to nitrate reduction and absorption, as with silver nitrate, is rarely observed. The cerium moiety is absorbed to a limited extent. Electrolyte disturbances are not associated with the use of cerium nitrate–silver sulfadiazine.

Wassermann et al. reported excellent results in patients with massive burns treated with cerium nitrate–silver sulfadiazine

cream.⁵¹ That report parallels our own early experience using the cream in patients with very large, ostensible ‘lethal’ injuries.⁵² In the era of prompt burn excision, the addition cerium to silver sulfadiazine may be helpful for patients who are clinically unstable and not candidates for prompt excision.^{53,54} The cerium mixture appears to be beneficial because of its effect on eschar not because of an effect on wound infection.⁵⁵ The eschar that forms is harder and perhaps seals the wound more effectively than the eschar that forms with silver sulfadiazine alone. A randomized, prospective clinical trial in high-risk burn patients comparing the cerium nitrate–silver sulfadiazine combination to silver sulfadiazine alone is ongoing in the US.

Silver sheets/mesh

One product (Acticoat[®]) consists of a sheet of thin, flexible rayon/polyester to which is bonded polyethylene mesh that has been coated with a nanocrystalline film of pure silver.^{56–59} When exposed to body fluids or wound exudate, silver ions are released in an even, sustained manner over at least 24 hours and possibly 48 hours. Another product (Silverlon[®]) utilizes silver-coated gauze mesh. The antimicrobial spectrum of these products is broad, similar to that of silver nitrate. The silver that ionizes may have an atomic structure that differs from conventional silver ions as the result of the ‘sputtering’ process used and may be more bactericidal as a result. Several favorable clinical trials have been conducted.^{60–62} The material is relatively painless to apply and can be left in place for 48 hours, or possibly longer. To date there has been no significant toxicity or bacterial resistance reported.⁶³

Other agents

Since silver sulfadiazine may retard epithelialization,⁶⁴ other agents may be preferred on wounds that seem superficial or when initially indeterminate depth wounds begin to epithelialize. Such agents include the topical antibiotic ointments of bacitracin or polymyxin B. If methicillin-resistant staphylococci are suspected, the topical antibiotic mupirocin (Bactroban[®]) may be useful.⁶⁵

Enzymatic debridement

A variety of proteolytic enzymatic agents have been utilized to debride wounds, including proteases (sutilains) elaborated by *Bacillus subtilis*, collagenase, and papain-urea.⁶⁶ This approach has not gained wide acceptance in the treatment of extensive burns, because bacteremia may occur with its use in the presence of wound colonization. There is also the hypothetical disadvantage that proteolysis occurring in marginally viable tissue could increase burn depth unnecessarily. In partial-thickness burns, however, collagenase ointment mixed with polymyxin B/bacitracin powder was associated with a slight acceleration of the time to closure compared with silver sulfadiazine.⁶⁷

Occlusive dressings

Many fresh superficial wounds such as abrasions commonly form a protective scab which separates spontaneously as the wound epithelializes. Superficial burns and donor sites can also be dressed and allowed to form a scab after initial cleansing. Fine mesh gauze or petrolatum gauze (Xeroform[®]) can be

applied as a scaffold. Once the scab is formed, the wound is relatively impermeable and painless, but until then the pain is intense.

A number of synthetic silicone mesh products designed to adhere to the wound until re-epithelialization is complete have been developed. These are associated with much less pain than fine mesh gauze and include Biobrane[®], Aquacel Ag[®], and Transcyte[®]. These are most effective on superficial partial-thickness wounds (Figure 11.4). If the wound is deep, however, the material will not adhere and often needs to be removed at least in part to allow for effective drainage of wound exudate. Biobrane[®] has no inherent antimicrobial activity, but Aquacel Ag[®] contains silver.^{68,69} Transcyte[®] consists of a layer of neonatal fibroblasts incorporated onto Biobrane[®]. Several centers reported quite favorable experience with it in terms of shortened time to wound closure and apparent improvement in the quality of the resulting scar.⁷⁰ It has been recently withdrawn from the market, however, for economic reasons. It is mentioned here, because it was used fairly widely in burn centers and might be reintroduced.

Another type of occlusive dressings includes those that adhere to uninjured skin but not to the wound. These include

DuoDerm[®], OpSite[®], and Tegederm[®]. These essentially form a 'blister' in that the wound transudate collects under the material and bathes the wound. They often leak and may need to be replaced as the fluid extravasation subsides. They also must be removed if the fluid becomes colonized and purulent. They have also been associated with more rapid healing and less pain.⁷¹

Envoi

After a burne the scarre which remaineth is uncommonly rough, unequal and ill-favored.
Ambroise Paré, 1510–1590

Notwithstanding the numerous advances in supportive care that have made reasonably prompt surgical burn wound closure at a time of election a realistic option, the 'rough, unequal and ill-favored' scars that Paré lamented centuries ago unfortunately still occur and remain largely as unsightly as they were then. Although prompt excision and meticulous wound care may reduce its likelihood, hypertrophic scar remains the most important unresolved problem in burn care today.

Discussion	173

Introduction

Infection is a most undesirable partner in any operative procedure, and it is especially troublesome in burn injury. Burns become infected due to the environment at the site of the wound being ideal for the growth of the infecting organisms. The immunosuppressed status of the patient allows the microorganisms to freely multiply. A variety of factors contribute to this development of infection in the burn patient. Among these are the roles of wound management procedures, risk factors associated with infection, virulent factors of typically isolated pathogens, current problems with antibiotic resistance, as well as wound sampling.⁶

The purpose of this chapter is to describe the diagnosis and treatment of burn wound infections, as a means of providing the burn surgeon with a practical clinical guide to assist in clinical judgment. The chapter is divided into three main sections:

1. Clinical management strategies
2. The microbiology of burn wound infection
3. Pharmacology

The section on clinical management provides an overview of the clinician's thoughts on a given problem. A more in-depth discussion of the microbiology or pharmacology of a given subject can be found in their respective sections.

Clinical management strategies

The burn surgeon

It is evident that the human population is not germ-free. Health is not the absence of bacteria, but is characterized by a delicate balance between man and his microbes, to include those of the environment. Intact skin and mucous membranes are man's most significant defense. Any alterations of the integument disturb this defense, as well as the balance with the microbial flora. Infection occurs when the microbes gain access to the

underlying tissue and achieve a critical number. Invasive burn wound infection rarely occurs in partial-thickness injuries; they occur with the greatest frequency in young adults (15–40 years). Invasive burn wound is defined as the presence of bacteria in unburned tissue.¹ The major objective of the burn surgeon is to prevent this microbial invasion when and wherever possible, and, when contamination occurs, to reduce microbial levels so that wound healing can continue unretarded.²

Pathophysiology of the burn wound

Bacteria of normal endogenous skin flora are resistant to heat injury in practically the same degrees as are the skin cells. The bacteria on the surface are heat killed, as are the tissue cells of the surface, and initial swab cultures are usually sterile. The bacteria in the hair follicles and sebaceous glands may survive (dependent on the extent of the burn injury), and the quantitative counts of biopsied specimens may show the same numbers of bacteria per gram (10^3) as found in the tissue prior to burning.^{3–5}

The mean cell generation time in optimum conditions is approximately 20 minutes. Therefore, a single bacterial cell can increase in numbers within a 24-hour period to over 10 billion cells.⁶ As these bacteria increase in number following the thermal injury and reach levels of greater than 10^5 bacteria per gram of tissue, they will erupt from the hair follicles and sebaceous glands and begin transmigrating over the injury colonizing the dermal–subcutaneous boundary. Perivascular growth is accompanied by thrombosis of vessels and necrosis of any remaining dermal elements, transforming partial-thickness burns to full-thickness burn injuries. Levels of bacterial growth which exceed 10^5 bacteria per gram of tissue constitute localized burn wound infection, and levels greater than 10^8 – 10^9 bacteria per gram of tissue may be associated with lethal burns.^{3,4,7–9} As the levels of bacterial growth increase so does the incidence of invasion of viable tissue and septicemia.^{7,10} Histologically, invasive infection is seen with bacteria in unburned tissue. Other signs of invasion can be the presence of hemorrhage in unburned tissue, small-vessel thrombosis and ischemic necrosis of unburned tissue, dense bacterial growth in the subeschar space and intracellular viral inclusion bodies typical of HSV-1 infections.¹

Occasionally, unusual organisms that are related to the mechanism of injury will cause an invasive infection. By example a burn which is treated with water in an effort to minimize injury may be contaminated by waterborne organisms such as *Aeromonas* or *Flavobacterium*.¹¹

Maintaining wounds at low contamination levels diminishes the frequency and duration of septic episodes caused by wound

flora. This is accomplished by cleansing the wound two to three times per day by either showering or immersing the wound in cleansing solutions. Some burn facilities still immerse patients in a tub to remove the debris and exudate that has accumulated between dressing changes; however, most burn facilities no longer advocate this cleaning technique because of the potential seeding of surface bacteria to the open burn wound of other patients by an inadequately cleaned tub. We, along with other burn facilities, use the shower technique to wash down the debris from the patients. It is important to note that wound cleansing can be quite painful, cause cooling, and may be associated with hematogenous seeding causing a bacteremia. Therefore adequate monitoring and professional attention is critical with this procedure.

The natural progression of bacterial colonization as the days pass is from Gram positive to Gram negative. By the 21st day postburn 57% of burn wounds still open will be colonized with resistant Gram-negative bacteria, thus making the antibiotic choices increasingly limited.^{12,13}

Infection control best practice

Additional measures can be taken to diminish the incidence of burn wound colonization. The microorganisms initially populating the burned wound represent a mixture of endogenous resident flora and airborne contaminants seeded by contact with the environment and attending personnel. Burn patients are immunosuppressed and should be protected from exposure to environmental contaminants. (For a complete discussion of immunosuppression in the burn patient see Chapter 23.) The most elaborate methods of isolation have failed to effectively minimize the incidence of infection, although they have significantly reduced the incidence of cross-contamination.¹³⁻¹⁵ The most effective means of decreasing exposure of burned patients to exogenous bacteria is strict observation of appropriate hand washing among the healthcare providers. Face masks, waterproof gowns, and gloves should be worn whenever direct contact with body fluids and wound exudates are unavoidable, thus protecting both the patient and the healthcare provider from inadvertent contamination. All dressing materials should be maintained as patient specific. IV pumps and poles, blood pressure devices, monitoring equipment, bedside tables, and beds should be cleaned on at least a daily basis with antibacterial solutions. Terminal cleaning, following the discharge of the patient, should include the walls, ceiling, baseboards, and floors. Mattresses should be covered with vinyl or other impermeable surface that allows culturing and cleaning without soiling, and be frequently inspected for cracks in their surfaces. At our institution we use HEPA air filters with 99.99% efficiency on 0.3 μ m-sized particles. They are changed regularly, and cultured if clinically indicated by infection control monitoring.

Most units now house major burned patients within individual, self-contained positive pressure isolation rooms. However, common areas exist even within these units, predominantly the bathing or showering facilities. These areas should be conscientiously cleansed between patients with an effective bactericidal agent specifically directed at the bacteria, which are common to an individual unit. Disposable liners for cleaning surfaces are encouraged or sterilizable instruments should be used for débridements.

The smaller burn early presentation

The most common burns are less than 10%. These smaller burns when presented early for treatment are typically clean. The presence of fever alone does not indicate infection as burn is associated with an elevation in the body temperature set point. The routine use of systemic antibiotics is not advocated for early small burns. The presence of cellulitis calls for topical antimicrobials as well as systemic. For an uncomplicated burn, Gram positives are covered with vancomycin added for persistent cellulitis. Broader antibiotic coverage is added, as is clinically indicated, depending on the circumstance. Figures 12.1–12.4 demonstrate a small burn with early presentation through the stages of healing without complication.

Routine prophylaxis for tetanus (*Clostridium tetani*) is tetanus toxoid (0.5mL) if it has not been administered in the previous 3 years as part of the admission protocol to the burn center.^{16,17} In addition, if their last booster was more than 10 years ago, 250 units of tetanus antitoxin is also given. Local bacteriologic control is most frequently obtained through the use of a topical application of antimicrobials such as silver sulfadiazine (SSD). In our institution Mycostatin has been added to SSD. This decreases the incidence of *Candida* in the burn wound. (Chapter 11 offers a broad list of the antimicrobial topical dressing choices.)

Alternatively, the patient may have application of a synthetic or biologic adherent dressing. At our institution Biobrane is frequently used. Prior to application, proper cleansing is done. These patients are followed closely for the first week to assure that the dressing is adherent. The routine use of

Fig. 12.1 Superficial and deep second-degree scald burns to the head, face, and shoulder. Treatment is with silver sulfadiazine.

Fig. 12.2 Same patient as shown in Figure 12.1, 12 days after the injury. Note that most of the injury is healed.

Fig. 12.4 Same patient as shown in Figure 12.1, 2 months after injury. All wounds are healed.

Fig. 12.3 Same patient as shown in Figure 12.1, 26 days after injury. Deep second-degree burns are still healing. Note that all superficial second-degree burns are healed and maturing.

systemic antibiotics is not advocated for wounds treated this way. During the period of observation non-adherence, the presence of cloudy exudate, surrounding cellulitis, and/or fever should make the clinician suspicious of infection. Possibly infected areas should be opened, unroofed, and cultured. The clinical management of a patient with an infected occlusive dressing must be rapid and aggressive. Late in the course of the use of Biobrane we have seen pustular lesions develop away from the burn site. Oddly this occurs after the Biobrane is adherent and the patient does not appear ill. Culture of the pus has grown methicillin-resistant *Staphylococcus aureus* (MRSA).

In general, most of these small burns will be going home. Teach the family clean technique for wound care and dressings with written instructions. Emphasize the importance of hand washing before and after caring for the patient and most importantly when performing wound care. Instruct the family to clean the bathroom, especially the bathtub and shower before and after use with strong disinfectant like bleach. Teach the signs of sepsis: fever, redness, increased pain, changes in odor or drainage, and increased swelling.¹⁸ Our routine is to follow acutely until closed.

One area of special consideration when caring for the small burn is the small but serious complication of toxic shock syndrome (TSS). TSS is the result of a burn wound colonized with toxic shock syndrome toxin-1 producing *S. aureus*⁶ (see Figure 12.5). This disease is primarily of the young child, with a burn of less than 10% that would normally be thought to heal without problem. The incidence has been reported at approximately 2.6% at a mean age of 2 years. Clinically it is characterized by a prodromal period lasting 1–2 days with pyrexia, diarrhea, vomiting, and malaise. A rash is often present; at

Fig. 12.5 Gram stain of *Staphylococcus aureus* ($\times 1000$).

Fig. 12.6 Invasive burn wound infection with *Staphylococcus aureus*. The patient presented with extreme pain, intense inflammation to the forearm, functional impairment of forearm musculature, and high fever. Immediate excision showed purulent secretions collected in the reticular dermis and subcutaneous fat.

Fig. 12.7 Burn wound cellulitis caused by *Staphylococcus aureus*. Clinical findings include increased pain, local inflammatory signs, and fever. Treatment includes systemic intravenous antibiotics, excision, and autografting.

Fig. 12.8 Shown here is a child with extensive burns presenting very late. There is evidence of scar separation from the wound bed, a sign of late presentation.

this stage the burn appears clean. Shock then develops in untreated cases. This is the time of maximal illness and is usually 2–4 days after the burn injury. Once shock has developed, mortality can be as high as 50%. The main defense is knowledge and aggressive treatment.²⁰

Smaller burn with a later presentation

The early burn with surrounding blanching erythema likely has an area of surrounding first-degree burn. However, the burn wound presenting late with erythema, swelling, and/or pathologic colors and odors should alert the clinician to the strong likelihood of infection. Careful clinical exam can differentiate the action needed to begin treatment. Most commonly, the wound needs only thorough cleansing and application of topical antimicrobials. With late presentation and signs of cellulitis, systemic antimicrobials are indicated (see Figures 12.6 and 12.7). The offending organism is usually *Staphylococcus*. The circumstances, appearance or history may make consideration of Gram-negative pathogens realistic and expansion

of coverage is dictated by clinical judgment. Occasionally, the severely neglected wound can progress to full thickness and even have a contained area of pus beneath a true eschar. This area needs to be opened like any other abscess. Special care should be taken with evaluation of the burn wounds in the elderly and diabetics as the inflammatory response can be blunted and the wound severely underestimated.

The larger burn

Burns over 20–30% of the body have an immunosuppressive effect which involves both the humoral and cellular lines of host defense.⁶ Please see the chapter on immunosuppression in this text for a detailed discussion of the changes seen in the immune system after burn injury.

A large open wound is a favorable environment for bacterial colonization. The early management of burn must include aggressive efforts at removing the dead tissue and achieving wound closure with autograft, homograft or other biologic dressing (Figures 12.8 and 12.9). The very early burn wound,

Fig. 12.9 Seventy-five percent total body surface area full-thickness burns with burn wound sepsis by *Enterococcus faecalis* and *Enterobacter cloacae*. Prompt excision and homografting, hemodynamic support, and systemic antibiotics controlled the infection.

less than 48 hours, normally has low colony counts. Preoperatively the patients can be held in topical antimicrobial soaking dressings until early excision of the burn wound can be undertaken. Perioperative antibiotics should be broad to cover the Gram-positive and Gram-negative organisms that are encountered in the specific care center. The antibiotics are covering bacteria from the burn wound, as well as bacteria in the gut, which both have been shown to seed the bloodstream during burn excision. Wound cultures are taken at the time of surgery for microscopic and pathologic examination to determine if colonization is present with or without invasion. The term ‘colonization’ indicates only the presence of viable bacteria on the surface of the wound or in the burn eschar. Although potentially dangerous, wound colonization does not imply that locally destructive or systemic infection is present. If the microorganisms successfully invade into viable tissue, they will produce a locally destructive infection and may disseminate either viable bacteria or their toxic products systemically via blood or lymphatic vessels (burn wound sepsis).

Larger burn with a late presentation

Dead tissue has no resistance to infection. It is also excellent growth media for all manner of pathogenic organisms. Control of these wounds is by surgical excision often down to fascia as the delay has ensured that the zone of stasis has converted second-degree burns to full thickness. Large burns with delayed presentation have host immunosuppression, polymicrobial colonization, and possible invasive infection. The elimination of all dead tissue including aggressive removal of dead muscle is the basis of control. The antimicrobial choice for the first operation should be broad coverage for fungus, resistant Gram-positive and Gram-negative organisms. Complete removal of dead tissue and topical antimicrobials such as silver nitrate, Sulfamylon, and topical nystatin are common choices. Here the surgeon must be aggressive as in necrotizing fasciitis, if the wound is to come under control and support grafting. Further antimicrobial management follows the culture information obtained from biopsies with persistent efforts to cover the offending organisms with adequate well-timed doses of

Fig. 12.10 Gram stain of biopsy revealing Gram-positive cocci. Quantitative count 6.2×10^5 organisms per gram of tissue ($\times 1000$).

TABLE 12.1 BURN WOUND INFECTION: LOCAL SIGNS*

Black or dark brown focal areas of discoloration
Enhanced sloughing of burned tissue or eschar
Partial-thickness injury converted to full-thickness necrosis
Purplish discoloration or edema of skin around the margins of the wound
Presence of ecthyma gangrenosa
Pyocyanotic appearance of subeschar tissue
Subcutaneous tissue with hemorrhagic discoloration
Variable-sized abscess formation and focal subeschar inconsistency

cost-effective antibiotics chosen for their specific activity against the pathogen. This requires a coordinated effort of the clinician, microbiologist, and pharmacist.

Burn wound surveillance

Daily inspection of the burn wound by a burn surgeon is mandatory for decision making. Major burn wounds usually become colonized or infected within 3–5 days after admission; often infection arises from the patient’s own bacterial flora and not an exogenous source. Burn wound biopsies should be taken from any area of the wound which has changed in appearance, as described in Table 12.1. In Figures 12.10 and 12.11 we see the presence of bacteria on a wound culture Gram stain. Bacterial sepsis is often heralded by changes in the color, odor or amount of exudate from the wound, while fungal invasion is clinically suggested by a rapidly emerging and spreading dark discoloration. Consequently the burn wound must be closely assessed for these manifestations. Few histologically demonstrated fungal infections are initially determined by culture; therefore treatment should be predicated on the identification of hyphae by histological examination and which may be subsequently confirmed by culture.

Fig. 12.11 Gram stain of biopsy revealing Gram-negative rods. Quantitative count 7.5×10^5 organisms per gram of tissue ($\times 1000$).

Fig. 12.14 Fungal burn wound sepsis. Systemic antifungals, topical nystatin powder, and excision of all affected areas, which usually includes fascial excision and amputations, is the treatment of choice for such deadly infections.

Fig. 12.12 Burn wound sepsis caused by *Aspergillus* spp. Fungal infections should be suspected in wounds presenting with dark or black discoloration and hemorrhagic areas, in patients receiving prolonged systemic broad-spectrum antibiotics and/or who come from endemic areas. This patient died of fungal sepsis, fungal pneumonia, and respiratory distress syndrome.

Fig. 12.15 Lactophenol blue stain of a fungus from a burn wound biopsy identified as *Curvularia* spp. ($\times 400$).

Fig. 12.13 Lactophenol blue stain of *Aspergillus* sp. isolated from a burn wound biopsy ($\times 400$).

Figures 12.12–12.15 are examples of clinical and microscopic appearances of the fungal wound infection.

Many believe clinical sepsis with suspicion of the burn wound as source is a mandate for surgical control of the burn wound. Burn wound deterioration can be rapid; biopsy of changing lesions can be processed by frozen section in 1 hour or rapid prep in 24 hours. If bacteria are seen in viable tissue or in vessels, a diagnosis of burn wound sepsis is made, and wide excision of all involved areas should be completed. Surgical control can mean conversion of a tangential excision to the fascial level. The aggressive debridement of all remaining dead tissue is a minimal therapy. Dead muscle in particular can be problematic as compromised areas can be hidden from view. In the larger burn, any burden of dead tissue with loss of the skin barrier, combined with immunosuppression, makes a very aggressive surgical approach mandatory.

The major role of local burn wound infection in sepsis suggests that the diagnosis and treatment of infections should

focus primarily on the burn wound. Wound colonization will progress to infection only when the surface bacterial counts exceed some critical number. Accurate quantification of the burned patient's bacterial load is therefore the foundation of infection surveillance. This is achieved through routine cultures of sputum, urine, and wound. Quantitative cultures obtained at a goal of three times weekly will provide monitoring for the progress of bacterial colonization and guidance in the event that empiric antibiotic therapy becomes necessary. If a simultaneous sample is examined by a pathologist a diagnosis of burn wound invasion in need of emergent surgical treatment can be made. Quantitative swabs, smear cultures, and/or contact plates (Rodak®) provide information regarding the potential infectious agent; quantitative wound biopsies are a better determinant of bacterial loads. Quantitative cultures showing high bacterial counts correlate with histologic evidence of burn wound infection in approximately 80% of cases.^{2,3,7} If quantitative biopsies reveal greater than 10^3 organisms/g of tissue, a change in topical therapy is indicated. If bacterial counts exceed 10^5 organisms/g of tissue, localized burn wound infection should be considered and a histologic examination performed. If histologic evidence of invasion is present, systemic antibiotics should be given and the wound should be excised.^{3,20,21} In addition, routine cultures of the stool are obtained to identify colonization with pathogenic organisms. These results should guide preoperative antibiotic choice and treatment of infection. The burn wound must be recognized as the site of microbial colonization which may progress to invasion with systemic dissemination if not restrained.

Wound culture, topicals, and graft take

Robson found that when colony counts were less than 10^2 per gram of wound graft, survival was greater than 90%, but when colony counts were greater than 10^5 per gram of wound, only 60% graft survival was observed.²² We have routinely modified our topical antimicrobial therapy, alternating between silver nitrate solution and mafenide acetate when colony counts are greater than 10^5 . The only exception for this rule is infection with *Streptococcus*, which may appear with just 10^3 CFU.²³ Mafenide acetate is more successful at penetration of the necrotic dermis than is silver nitrate solution. Sodium hypochlorite (NaOCl) is very effective as a cleansing agent when a foul wound is identified. Studies by Heggens and his coworkers²⁴ clearly defined the efficacy of NaOCl at a concentration of 0.025 % which was found to be bactericidal and non-toxic to fibroblasts and did not inhibit wound healing, provided appropriate buffers are used. However, the NaOCl is only effective over a 24-hour time frame after the buffer (0.3 N NaH_2PO_4) is added to the NaOCl.²⁵ NaOCl soaks are most beneficial in reducing the bacterial numbers in a wound.

NaOCl is a broad-spectrum antiseptic and is bactericidal for *P. aeruginosa*, *S. aureus* as well as other Gram-negative and Gram-positive organisms.^{24,26} It is also effective against MRSA, MRSE, and the enterococci. NaOCl can be used separately but more commonly in concert with other longer-acting antibacterials to control colonization or infection. NaOCl 0.025% also enhances wound healing and increases wound breaking strength when compared to 5% mafenide acetate (Sulfamylon).²⁴

Sulfamylon is a very effective agent against bacterial wound contamination, with the added benefit of tissue penetration. It

can be used both as a cream or soak. Our topical sensitivity analysis routinely indicates it as the best choice for resistant *Pseudomonas* infection. Its use in large areas is limited by its ability as a carbonic anhydrase inhibitor to cause metabolic acidosis. The aqueous soak is commonly used on the open burn wound, while the ointment is chosen for auricular chondritis. Silver nitrate aqueous solution is our most frequent choice of a soaking agent for topical bacteriologic control. Although silver nitrate does not penetrate dead tissue well, it has a reliable broad-spectrum activity. Silver nitrate solution causes a characteristic staining of normal skin because of precipitation (Figure 12.16) The double antibiotic solution of neomycin and polymyxin is also considered as an antibiotic soak and is used clinically to control wound colonization. It also lacks the tissue penetration of Sulfamylon.

Sepsis in the burn patient

Rapid and complete closure of deep burns is the best defense against the development of sepsis in the burn patient. If a comparison is made between burn patients of equal size, those who have an occurrence of sepsis during their hospitalization will have decreased lean body mass and increased mortality. We attempt to control sources of bacteria by topical antibiotics, debridement, and early closure. In addition, the idea of the gastrointestinal tract as a source of bacteria has been the motivator behind trials at selective gut decontamination. Unfortunately, this effort thus far has failed to show benefit.²⁸

A major focus of rounds in the burn intensive care unit is on the identification of sepsis. There are several cardinal signs of sepsis which embody both Gram-negative as well as Gram-positive involvement (Table 12.2). Constant surveillance for these signs can provide adjunctive information concerning the etiologic agent of sepsis. A septic source can be documented as:

- burn wound biopsy with $>10^5$ organisms/g of tissue and/or histologic evidence of viable tissue invasion;
- positive blood culture;
- urinary tract infection with $>10^5$ organisms/mL of urine; or
- pulmonary infection.

Fig. 12.16 Silver nitrate treatment as precipitated on the normal skin.

TABLE 12.2 ADDITIONAL CARDINAL SIGNS OF BURN WOUND SEPSIS*

Gram-negative sepsis
Burn wound biopsy $>10^5$ organisms/g tissue and/or histologic evidence of viable tissue invasion
Rapid onset — well to ill in 8–12 hours
Increased temperature to 100–103°F (38–39°C) or may remain within normal limits (37°C)
WBC may be increased
Followed by hypothermia — 94°F (34–35°C) plus a decrease in WBC
Ileus/intolerance of tube feed
Decreased BP and urinary output
Wounds develop focal gangrene
Satellite lesions away from burn wound
Mental obtundation
Gram-positive sepsis
Burn wound biopsy $>10^5$ organisms/g tissue and/or histologic evidence of viable tissue invasion
Symptoms develop gradually
Increased temperature to 105°F or higher ($>40^\circ\text{C}$)
WBC 20000–50000
Decreased hematocrit
Wound macerated in appearance, ropy and tenacious exudate
Anorexic and irrational
Ileus/intolerance of tube feed
Decreased BP and urinary output
*Five or more signs or symptoms are definitive diagnostic parameters.

In addition to the identification of a septic source, at least five or more of the following criteria should be met: tachypnea (>40 breaths/min in adults), paralytic ileus, hyper- or hypothermia (temperature $<36.5^\circ > 38.5^\circ\text{C}$), altered mental status, thrombocytopenia (<50000 platelets/ mm^3), leukopenia or cytosis ($<3.5 > 15.0$ cells/ mm^3), acidosis or hyperglycemia. Local evidence of invasive wound infection includes black or brown patches of wound discoloration, rapid eschar separation, conversion of wounds to full thickness, spreading peri-wound erythema, punctate hemorrhagic subeschar lesions, and violaceous or black lesions in unburned tissue (ecthyma gangrenosum) (Table 12.1). When a patient exhibits signs and symptoms of sepsis, immediate institution of antibiotics is obligatory while awaiting confirmatory cultures. If a patient is already on antibiotics a broadening of coverage to include highly resistant bacteria is in order if possible. Specific antibiotic treatment should be administered if routine surveillance has identified the predominant organism. In addition to institution of antibiotic treatment, there should be a rapid aggressive attempt at surgical source control.

Tight glycemic control is increasingly showing promise as a way of decreasing infection rates in the intensive care unit. In a recent study in pediatric burn patients this finding has been

Fig. 12.17 Burn wound sepsis caused by *Pseudomonas aeruginosa*. Note the dark appearance of the burn eschar. Immediate excision after resuscitation and double antibiotic coverage against all organisms identified are mandatory.

Fig. 12.18 Ecthyma gangrenosum. Satellite lesions in Gram-negative sepsis are typical and diagnostic.

upheld and is now being recommended. This, however, remains an area of ongoing active research.²⁹

Extremely virulent pathogens

Years of clinical practice in the care of burn patients following the previously outlined principles have led to rewarding outcomes. However certain pathogens have come and defied the usual measures that control other organisms. The appearance of these organisms has often returned death rates to a time before the current era of massive early excision and grafting. The following discussion is born out of the clinical management of these difficult pathogens.

Ecthyma gangrenosum is a purple-bluish black spot in previously healthy tissues. Classically this is caused by invasive *Pseudomonas*. Histologically, this is characterized by thrombosis of vessels with perivascular hemorrhage. Unfortunately, multi-drug resistant *Pseudomonas* has become a common enemy. Figures 12.17–12.25 demonstrate the clinical and histologic appearance of invasive *Pseudomonas* infection.

Fig. 12.19 Satellite lesion to the left ear.

Fig. 12.20 Biopsy of ecthyma gangrenosum. The thrombolytic lesion in the center of the biopsy is characteristic of *Pseudomonas aeruginosa*.

Fig. 12.21 Transitional cut of biopsy showing thrombotic lesion.

Fig. 12.22 Thrombus present in blood vessel of the biopsy with bacilli in endothelium (hematoxylin and eosin, $\times 400$).

Fig. 12.23 Bacilli invading deep viable tissue. Invasion of viable tissue with histopathology confirmation is currently the only way to diagnose burn wound infection (hematoxylin and eosin, $\times 1000$).

Fig. 12.24 Pyocyanic discoloration on a grafted site treated with nitrofurazone ointment.

Fig. 12.25 Same patient as shown in Figure 12.24 after removal of the dressing. Cultures grew *Pseudomonas aeruginosa*. Note that all autografts have disappeared as a result of the action of the bacterial enzymes.

Fig. 12.26 *Candida* infection in a healing second-degree burn wound. Pain and itch is usually present in this kind of infection. Treatment with silver sulfadiazine mixed with Mycostatin has proved effective in controlling *Candida* infections in burn centers.

Invasive *Pseudomonas* in combination with vancomycin-resistant *Enterococcus* have clinically demonstrated a severe coagulopathy leading to death. The use of colistimethate has recently enabled control of multi-drug resistant *Pseudomonas*. Multi-drug resistant *Acinetobacter* has also been sensitive to colistimethate. The pharmacy section of this chapter has a complete discussion of colistimethate.

Fusarium with resistance to amphotericin has the ability to invade living tissue and create a wavefront of necrosis. This pattern is histologically recognizable by the presence of fungal hyphae extending like fingers to the border between necrotic and intact tissue, and does represent dangerous invasion of viable tissue. Very aggressive removal of all dead tissue, Voriconazole administered systemically as well as topical antifungals can be successful against this virulent organism. A similar virulent profile is possessed by *Aspergillus* spp. and *Mucor* spp. (see Figures 12.12 and 12.13).

Candida colonization will be present in 30% of burn patients with burns greater than 40% during their hospital stay. It is for this reason that nystatin was added to topical silver sulfadiazine. This change has resulted in a marked decrease in three organ involvement with *Candida* (see Figures 12.26 and 12.27). The isolation of *Candida* from three organs is usually required for the diagnosis of candidal sepsis.²⁹ Serum antibody titers to *Candida* have recently been advocated to assist in the early diagnosis.³¹ Premortem diagnosis, confirmed with sufficient time to implement appropriate treatment, occurs in less than 40% of infected patients.³² Because of their relatively large size, *Candida* are usually filtered out of blood at the capillary level; arterial blood cultures are recommended. Organisms are usually seen in the urine when sepsis from a distant site occurs. Candidal sepsis is considered when *C. albicans* can be isolated from any three of the following tissue sites: blood, wound, urine, bronchial washings, or by a positive retinal examination.

Candidal spores are omnipresent in the burned patient, appearing in stools, nasopharynx swabs, urine samples and cultures of intact integument. However, fewer than 20% of

Fig. 12.27 Gram stain of *Candida albicans* ($\times 1000$).

patients with candidal wound colonization develop widespread candidiasis.^{33,34} Only when the controlling bacterial populations are eradicated by systemic antibiotics or the host becomes immunosuppressed does candidal infection occur,³⁴ frequently following a bacterial sepsis. There is a 3–5% incidence of candidemia in the burned population^{30,33,36,37} and a comparable rate of burn wound invasion.³⁶ Candidal infections occur most commonly in patients with large burn injuries who are hospitalized for long periods of time and have received multiple courses of antibiotics. Prophylactic treatment with oropharyngeal and topical nystatin have therefore become recommended,³⁰ however, fluconazole may be more effective in some cases. Mortality associated with *Candida* is usually from amphotericin-associated renal failure.

Non-bacteriologic causes of infection

Viruses

Viral infections are being more frequently clinically recognized in burned patients. Prospective and retrospective assays

of sera have documented a large incidence of subclinical viral infection. Retrospectively, Linneman³⁸ assayed stored sera of burned children and found a four fold increase in antibodies to cytomegalovirus (CMV) in 22% of patients, 8% had increased herpes simplex titers and 5% demonstrated a rise in varicella zoster titers. The study continued in a prospective manner, with 33% of the children developing CMV infection, 25% developing herpetic infections and 17% developing adenovirus infection.

CMV infection typically occurs approximately 1 month post-burn and clinically presents as a fever of unknown origin and lymphocytosis.³⁹ Rarely are patients with less than 50% total body surface area burn infected. CMV infection frequently occurs concurrently with bacterial and fungal infections, but rarely alters the patient's clinical course. CMV inclusions may be identified in the cells of multiple organs, but have not been reported in the burn wound.⁴⁰ The burned patients who most commonly contract the infection are known to have received multiple blood transfusions, which represent a major source of contamination. In addition it has been shown in an animal model that cadaver skin has the ability to transmit CMV infection.

Most commonly, herpetic lesions appear in healing partial-thickness burns or split-thickness donor sites (see Figure 12.28), although other epithelial surfaces such as the oral or intestinal mucosa can be involved. In the latter case, herpetic lesions may lead to erosion and perforation. The clinical manifestations of lesions may be preceded by unexplained fever unresponsive to routine antibiotic coverage.⁴⁰ Partial-thickness burns and donor sites infected with herpes may 'convert' to full-thickness injuries requiring skin grafting for ultimate closure. Necrotizing hepatic and adrenal lesions may lead to multi-system organ failure. Mortality in patients with disseminated infection is about twice that expected for patients of similar age and burn size. Split-thickness grafts provide adequate coverage of previously infected herpetic wound.⁴¹

Chickenpox (varicella-zoster) infection is a frequent occurrence in school-aged children and is rapidly spread through inhalation of the virus. Varicella infections can be life-

threatening in an immunocompromised host and mini-epidemics have occurred within pediatric burn units.⁴² The characteristic fluid-filled lesions appear in healed or healing partial-thickness burn, as well as uninjured epithelium and mucous membranes. Due to the fragility of the newly healed or healing skin, the vesicles are much more destructive in the injured than in the uninjured skin, and may present as hemorrhagic, oozing pockmarks, which are prone to secondary infection and subsequent scarring. New, neovascularized skin grafts may be lost and further grafting procedures should be delayed until the lesions are quiescent. Herpes simplex and zoster are consistently treated with systemic acyclovir or Valtrex.

Parasites

In this age of world travel being common place, we must mention those organisms which are endemic to the patient's origin that could complicate the burn injury. Based on a study conducted by Barret et al. in 1999,⁴³ the authors concluded that patients being admitted from third-world countries where parasitism is endemic should be treated empirically with an antiparasite drug, preferably metronidazole or mebendazole.

Burn-associated infections

New open areas and 'ghosting' of grafts — the role of infection

New open areas in previously grafted burns, donor sites or areas that heal spontaneously can often be attributable to surface colonization (Figures 12.29 and 12.30). Typically the wounds form through blistering, which then ruptures, or through trauma from scratching. Care usually includes topical Bactroban ointment, and washing frequently with mild antibacterial soap. Swab culture is taken to identify the organism present and systemic antibiotics, if cellulitis is clinically identified. Large areas may come to re-grafting when they are clean. Folliculitis is a particular problem of the scalp and other hair-bearing areas. The same treatment algorithm applies with the addition of shaving (Figure 12.31).

Fig. 12.28 Herpes simplex virus type I infection in a patient with 35% partial-thickness and full-thickness burns. Extreme pain and itching are typical of this infection.

Fig. 12.29 *Staphylococcus aureus* infection in donor sites. Note the secretions and the geographic appearance of the wound, which is typical of this pathogen.

Fig. 12.30 Infection of the graft site with *Staphylococcus aureus*. Prompt topical treatment with antistaphylococcal ointment solutions stops the progression of the destruction of skin autografts.

Fig. 12.32 Wound with granulating tissue grafted with 3:1 meshed autografts.

Fig. 12.31 Chronic folliculitis to the scalp, also known as the concrete scalp deformity. Hairs from hair-bearing areas are embedded in the granulation tissue of converted second-degree burns and donor sites, and microorganisms are entrapped prolonging the process. Shaving of the affected area, topical treatment, and eventually skin autografting resolve the problem.

Fig. 12.33 The same wound as shown in Figure 12.32, 5 days after autografting. The mesh pattern is still visible, but the autograft is melting or vanishing. The melting graft syndrome or ghosting syndrome is probably related to the action of collagenases that are present in chronic wounds and wounds colonized by bacteria.

A frustrating problem for the burn surgeon is gradual loss of grafted areas that had taken through disappearance of the graft, which is commonly referred to as 'ghosting' (Figures 12.32 and 12.33). The exact etiology of this disappointing clinical phenomenon remains elusive. Enzymatic proteolysis in the presence of infection seems most likely. To combat this problem once noted, topical cultures are taken to identify the bacterial colonies present and topical soaking dressings of silver nitrate solution or equivalent are started. The series of Figures 12.34–12.37 outlines such a case. Once specific cultures are available, topical sensitivities can be obtained to more accurately treat the bacteria present. However, the causative role of bacteria in this process has not been completely established.

Fig. 12.34 Deep second-degree and third-degree flame burns to the lower extremities. The patient was treated with immediate excision and autografting.

Fig. 12.35 The same wound as shown in Figure 12.34, 5 days later. Same grafts are melting due to inadequate excision of small areas. Human collagenases dissolve the remaining burn eschar and part of the autografts.

Fig. 12.36 The same patient as shown in Figure 12.35, 1 week later after treatment with silver nitrate solution. The melting or ghosting syndrome can be treated with different dressings, such as silver nitrate, normal saline, Dakin's solution, and Bactroban ointment.

Chondritis

Burns to the ear represent a clinical management challenge. Full-thickness injuries can damage the cartilage of the ear, resulting in auto-amputation of a part or the entire external auricle. Because of the auricle's comparatively low blood supply, chondritis frequently follows the progression of tissue ischemia. Chondritis is usually seen 3–5 weeks following the injury, but may be seen earlier and may occur following partial- and full-thickness injuries. The introduction of mafenide acetate has become the topical agent of choice for burned cartilaginous surfaces and since its use, the incidence of suppurative chondritis has significantly decreased (Figures 12.38 and 12.39).

Characteristically, the patient will complain of dull pain. The ear will become warm, red, tender, and edematous.

Fig. 12.37 The same patient as shown in Figure 12.34, 5 months after the injury.

Fig. 12.38 Left ear with suppurative chondritis. Chondritis seen 3 weeks after flame burn to left ear. Note the erythema and drainage from the helical rim.

Fig. 12.39 Posterior view of the patient shown in Figure 12.38. Patients usually complain of dull pain, with warmth and tenderness to the touch. Topical mafenide acetate is the treatment of choice.

Appropriate antibiotics should be initiated immediately and if there is an identifiable site, immediate incision and drainage of the abscess should be undertaken with a culture and sensitivity obtained. Should induration and tenderness continue, a more extensive debridement is imperative. Generally the helix is bivalved at the posterior helical margin and all necrotic cartilage debrided. Difficulty may arise in distinguishing between viable and necrotic tissue and frequently normal cartilage is sacrificed in order to ensure debridement. However, infected cartilage is usually soft, while normal cartilage will feel granular on curettage. If appropriate adequate excision of the necrotic tissue is not performed, suppurative chondritis can proceed to invade the mastoid bone creating a potential for intracranial abscess formation.

Ophthalmic infections

The eyes in the burn unit are at great risk. They may have suffered an insult from the original trauma or from the time in the burn intensive care unit. The retraction of the lids from scar and the sedation that is at times necessary can interfere with the natural protective mechanism for the eye. The avascular corneal stroma is protected by one layer of epithelium. Once damaged, a perforation can mean loss of the eye. The cornerstone of treatment is prevention through treatment of abrasions with antimicrobial drops, early eyelid release, and vigilance to exposure trauma.

Pneumonia

Nosocomial pneumonia is the leading cause of death from hospital-acquired infections (Figures 12.40 and 12.41). The estimated prevalence of nosocomial pneumonia within the

Fig. 12.40 Left lower pneumonia. Burn patient with typical radiographic picture of lobar pneumonia. The diagnosis of pneumonia in patients with inhalation injury and respiratory distress syndrome is still very difficult.

Fig. 12.41 Lower lobe pneumonia superimposed on a severe respiratory distress syndrome.

intensive care setting ranges from 10% to 65%, with fatality rates greater than 25% reported in most studies. Ventilator-associated pneumonia (VAP) specifically refers to pneumonia that develops more than 48 hours after intubation (late-onset VAP) in mechanically ventilated patients who had no clinical evidence suggesting the presence or likely development of pneumonia at the time of intubation. VAP that occurs within 48 hours of intubation is frequently the result of aspiration and usually yields a better prognosis than late-onset VAP, which is more often caused by antibiotic-resistant bacteria.

Pneumonia has two basic etiologies: direct contamination of the tracheobronchial tree via airborne or aspirated bacteria (having a better prognosis), and pneumonia spread hematogenously (Figure 12.42). Organisms cultured from pneumonia of burn patients often reflect the flora of the burn wound. In a

Fig. 12.42 This radiograph shows massive alveolar pneumonia. Although death by sepsis is declining in burn patients, respiratory infections are still a great concern, especially in patients with inhalation injury.

study by Ramzy et al., they attempted to establish the relationship of the burn wound flora to microbial pathogens in the tracheobronchial tree.⁴⁴ Management of hospital-acquired pneumonia is bolstered by surveillance quantitative wound cultures (QWC) and bronchial lavage fluid (BLF) cultures. In 30 (48%) of the 62 BLF cultures, there was a match between the organism identified in the BLF and the QWC. When strict quantitative criteria were applied, the match rate was only 9 (14%) of 62. Burn size and inhalation injury had no significant effect on match rate. Whereas the microbial pathogens were similar in the QWC and BLF, linear regression showed no value of QWC in predicting BLF culture results. The difference between qualitative and quantitative match rates suggests cross-colonization between the burn wound and tracheobronchial tree, but little to no cross-infection. The QWC and BLF cultures must be performed independently in determining antimicrobial specificity in the burned patient. This study supports the routine surveillance of the burn wound to help guide early thoughtful institution of antibiotics in a suspected pneumonia.

The diagnosis for pneumonia is often based upon clinical suspicion of infection coupled with the results of expectorated or aspirated sputum. Although these methods are readily available and often can be performed by a non-physician, the results can be misleading. If sputum expectoration is chosen, examination should include observation of the color, amount, consistency, and odor of the specimen. Mucopurulent sputum is most commonly found with bacterial pneumonia or bronchitis. Scant or watery sputum is more often noted in viral

Fig. 12.43 Class III sputum with predominant Gram-positive organisms. The number of epithelial cells and neutrophils should be quantified under low power ($\times 100$) in order to maximize the diagnostic yield. Samples with more than 25 neutrophils and fewer than 10 epithelial cells contain minimal oropharyngeal contamination (Gram stain $\times 1000$).

and other atypical pneumonias. ‘Rusty’ sputum suggests alveolar involvement and has been most commonly associated with pneumococcal pneumonia. Dark red, mucoid sputum suggests Friedländer’s pneumonia caused by encapsulated *Klebsiella pneumoniae*. Foul-smelling sputum is associated with mixed anaerobic infections most commonly seen with aspiration.⁴⁴

Gram stain of the sputum should be ordered. In order to maximize the diagnostic yield of the sputum examination, only samples free of oropharyngeal contamination should be reviewed. As a guide, the number of neutrophils and epithelial cells should be quantitated under low power ($\times 100$), with further examination reserved for samples containing >25 neutrophils and <10 epithelial cells. Such samples contain minimal oropharyngeal contamination. Samples with more epithelial cells and fewer neutrophils are nondiagnostic and should be disregarded. The sputum Gram stain is helpful to identify organisms other than the pneumococci. Small Gram-negative coccobacillary organisms are characteristics of *Haemophilus influenzae*. staphylococci appear as Gram-positive cocci in tetrads and grapelike clusters (Figure 12.43). Organisms of mixed morphology are characteristic of anaerobic infection. Few bacteria are seen with legionnaires’ disease, mycoplasma, pneumonia and viral pneumonia.

Often the diagnosis of pulmonary infection rests with the quantitative bronchoalveolar lavage (BAL) or protected specimen brush (PSB) with a threshold of $>10^4$ organisms as evidence of pneumonia. The most important clinical practice is to set a unit standard and use this as a guide to treatment. In particular, to know the common pathogens in the unit as well as the surveillance wound culture of the patient and start antibiotic treatment broadly and timely. Then discontinue or narrow coverage when all the information is in.

Recently, several groups of investigators have demonstrated that mortality was greater among patients with VAP who were judged retrospectively to be receiving inadequate antibiotic

therapy. These findings were based upon cultures of lower airway specimens obtained by either BAL, a PSB, or tracheal aspiration, than among patients receiving antibiotics to which the isolated bacteria were sensitive. More importantly, these studies also suggested that the increased risk or mortality persisted despite changes made to the initial antibiotic therapy after reviewing the findings from lower airway cultures.^{45,46} These studies demonstrated an increased hospital mortality rate for patients who received inadequate antibiotic regimen initiated before obtaining the results of cultures, even if adjusted to cover the culture results when available. The study by Luna et al. found that subsequent changes in antibiotic therapy, based on the results of BAL fluid cultures, did not reduce the risk of hospital mortality in patients for whom inadequate antibiotic therapy was initially prescribed.^{46,47}

The prevention of pneumonia can be minimized by meticulous aseptic tracheobronchial toiletry by use of effective gastric decompression to prevent emesis and aspiration during periods of ileus. Thus, it is important to limit endotracheal intubation to those patients with an absolute need for that intervention, as well as limit the duration as much as possible. Lung function should be monitored on a scheduled basis in all patients with extensive burns, particularly those with inhalation injury, with a low threshold for obtaining roentgenograms of the chest. When a pulmonary infiltrate characteristic of bronchopneumonia is identified on a chest roentgenogram, pulmonary physiotherapy and toilet should be intensified and antibiotic therapy begun with the agent showing greatest effectiveness against the predominant organism, as determined by the bacterial surveillance program if clinical infection is suspected.

Line infection

Infectious complications associated with intravenous and intra-arterial catheters represent a major problem irrespective of the constant attention to aseptic technique for insertion and appropriate maintenance.⁴⁸ The burned patient appears to be especially susceptible to this complication with catheter infection rates reported ranging from 8 to 57%.^{49,50} Suppurative thrombophlebitis may be confirmed in up to 5% of patients hospitalized for burns over 20% TBSA.⁵¹

A prospective study documented a 50% correlation between organism cultured from the catheter tips and hubs within 48 hours of insertion and the incidence of catheter infection was inversely proportional to the distance of the insertion site from the burn wound.⁵² It is interesting to note that the bacteria cultured from infected catheters could be traced to the skin in 96% of the cases. This data tend to support the hypothesis that catheter infections primarily arise from burn wound contaminants migrating down the catheter to the tip. Strict aseptic technique for insertion of intravascular catheters, the use of Teflon catheters, and rotation of the catheter site, tubing and apparatus every 72 hours have been related with a decrease in catheter infection rates.^{53,54} There is currently still a debate regarding the effectiveness of antibiotic-coated catheters to reduce the number of line infections and to allow longer safe retention of a venous access point in the burn ICU. Further study is needed to elucidate the impact this technology may have on the management of intravenous access in the burn patient. It is recommended that each burn center adopt a line

change protocol to standardize the management of access, and track the outcome.

Suppurative thrombophlebitis should be suspected in those patients who have persistent positive blood cultures without signs of local infection. Often suppuration can occur after the time of catheter removal so cultures at the time of removal may be an unreliable predictor of infection. Gross clinical signs of suppurative thrombophlebitis are frequently not present.⁵⁶ Careful records of previously cannulated sites can allow for sequential venotomy, examination for ultra luminal pus and histologic examination for intimal colonization. Upon confirmation of the diagnosis, immediate operative excision is essential to prevent progressive sepsis. Entire excision of a vein to the port of entry into the central circulation may be required because of the tendency of phlebitis to migrate to vein valves, leaving an apparently normal vein in between the infected foci. The subcutaneous tissue and skin should be packed open where a grossly purulent vein is removed and allowed to granulate and close by secondary intention (Figures 12.44 and 12.45).

Fig. 12.44 Close-up view of infected intravenous site at ankle with suppurative thrombophlebitis. This patient with lower extremity IV access developed fever, leukocytosis, and erythema at the intravenous site.

Fig. 12.45 In the same patient as shown in Figure 12.44, suppurative infection was noted along the length of vein. Proper treatment is total excision of vein from the site of infection to the point of entry into central circulation.

Urinary tract infections

Urinary tract infections are usually associated with prolonged and often unnecessary catheterization. Routine monitoring of urine from indwelling catheters should be done by needle aspirates through the rubber catheter with a 25-gauge needle on a regular basis two to three times a week. It is our practice not to use antimicrobial irrigations to prevent urinary tract infections, feeling that they are not particularly effective and may lead to infection by antibiotic-resistant organisms. When infection occurs, patients should be treated with appropriate systemic antibiotics. Candiduria is often insignificant but may reflect active infection or septicemia, especially when mycelia can be demonstrated. When present, an active infection with *Candida* species usually responds to low doses of amphotericin B, fluconazole or itraconazole.

Suppurative sinusitis

An infection of this type has become more obvious recently because of constant long-term transnasal intubation and the use of nasogastric or nasoduodenal tubes for enteral feeding. The diagnosis is usually delayed due to clinically inapparent symptoms and only after more frequent causes of fever are ruled out does it become evident. Diagnosis is confirmed based on X-rays or CT scans (Figure 12.46). Therapy with broad-spectrum antibiotics is initiated; however, surgical drainage of the involved sinuses may be necessary if the infection is unresponsive to the antibiotics. Oral intubation and nasogastric feeding may be utilized.

Fig. 12.46 Suppurative sinusitis after long-term intubation and tracheostomy. Note that the pneumatization of maxillary sinus has disappeared bilaterally.

Subacute bacterial endocarditis

Bacteremia associated with burn wound manipulations, as well as procedures such as tooth extraction, endotracheal intubation and sigmoidoscopy, can be transient.^{57,58} In healthy patients, transient bacterial showers are of little consequence. However, patients with a prior history of valvular heart disease are prone to the development of valvular vegetations. Burned patients, although usually young healthy adults prior to injury, develop a generalized immunosuppression and experience a significant number of invasive procedures which may increase the risk for endocarditis. The incidence of bacterial endocarditis appears to be increasing as we become more adept at treating major burn injuries. However, its development is usually occult and, like suppurative thrombophlebitis, frequently not noted until there are persistent positive blood cultures⁵¹ (Figure 12.47).

Patients whose risk factor is high for the development of bacterial endocarditis are those with repetitive bacteremias, which may occur after continual instrumentation or surgical intervention. These patients should be closely monitored for the development of heart murmurs, and if found, should undergo echocardiography to determine the presence of vegetations. Blood cultures should be randomly taken for 72 hours, and then appropriate broad spectrum antibiotics initiated and continued for the next six weeks.

The abdomen

The abdomen as an infectious source in the burn patient can be a clinical challenge. Often in larger burns the abdomen is involved, which can lead to a perceived limitation in the clinical exam as compared to other similarly complex ICU patients. The defects in the overlying skin should not be allowed to interfere with a proper physical exam. Burn patients like all patients can get appendicitis, intussusception, bowel obstruction, etc. In addition, in the severe burn, peritoneal dialysis may be necessary to aid compromised renal function and potentially introduce another possible source for infection.

Fig. 12.47 Subacute endocarditis to the tricuspid valve. Repetitive septic showers and the microtrauma of placement of central lines and Swan-Ganz catheters put the burn patient at risk for this kind of complication.

Larger burns have episodes of hypoperfusion at times, leading to sloughing of intestinal mucosa. Heme-positive mucoid or watery stools, abdominal distension, and diminished bowel sounds often characterize this condition. Stool for reducing substances is usually positive. A patient with a very severe burn, often combined with sepsis can have critical ischemia to the gut as a result of global hypoperfusion and have progression to necrosis.

Clostridium difficile (*C.diff*) is a well-known entity in critically ill patients, especially those with a history of antibiotic use. With the ubiquitous emergence of methicillin-resistant staphylococcus, the intravenous use of vancomycin has increased to such a great degree as this may decrease our observed clinical incidence of *C.diff* diarrhea.

Necrotizing enterocolitis occurs in patients who are severely granulocytopenic from any cause. Left upper quadrant abdominal pain is usual. Irritation of the adjacent diaphragm may result in pain referred to the left shoulder. Splenic enlargement and tenderness are often present with high, spiking temperatures. Radiographic examination may reveal an elevated left hemidiaphragm, basilar pulmonary infiltrates, atelectasis, or a left pleural effusion. Shift of the colon and stomach down and to the right and extraintestinal gas, either diffusely mottled or producing an air–fluid level in the left upper quadrant, may also be seen. Ultrasonography, computed tomography, and MRI are the preferred diagnostic techniques for the evaluation of suspected splenic abscess. Initial antibiotic therapy should have a broad spectrum of activity. A combination of antibiotics that has activity against streptococci and both aerobic and anaerobic Gram-negative bacilli would be appropriate initial antimicrobial therapy.

Musculoskeletal infection

The burn patient with a large percent injury is very complex. It is possible to miss a muscular compartment syndrome. This will lead to necrosis and may become complicated by bacterial contamination and develop into a source. Diagnosis requires a high index of suspicion and liberal surgical exploration. Treatment is surgical drainage and removal of all dead tissue.

HIV and the burn patient

The world incidence of HIV infection is very common in many parts of the world. In sub-Saharan Africa, some countries have rates of 35–39% in the adult population. In the US although much less, a practice of burn care in a large city will likely have patients who are HIV infected. The HIV seems to have an additive effect on the immunosuppression of the burn as reflected in the CD4/CD8 cell counts. Graft survival is compromised greatly and infections are increased.⁵⁹

The microbiology of burn wound infection

Selection, collection, and transport of specimens

There are several major benchmarks that must be adhered to in order to achieve reliable clinical microbiology results in its

association with the thermal injury. Most important to effective microbiologic diagnosis is the appropriate selection, collection, and transport of specimens sent to the laboratory (see Table 12.3). Appropriate specimen management affects patient care in several significant ways:

- it is the key to accurate laboratory diagnosis that directly affects patient care and patient outcome;
- it influences therapeutic decisions;
- it affects hospital infection control, patient length of stay, and overall hospital costs;
- it plays a major role in laboratory costs, and influences laboratory efficiency.⁶⁰

Before the specimen is collected for analysis, the specimen or the collection site must be selected and must represent a location of active disease. Even careful collection methods will produce a specimen of little clinical value if it is not obtained from a site where the infection is active. It must be noted that it is critical the specimen collectors know the appropriate device and collection of samples. (For specific details regarding specimen collection, it is suggested that the reader review the 8th edn. of the Manual of Clinical Microbiology, pages 55–66.⁶⁰).

With burn wounds, it is particularly important to obtain a culture which is free from contamination from the normal flora that may be present on the surface of the injured skin. In addition, the size or amount of the specimen plays an essential role in the appropriate identification of the etiologic agent. The use of prophylactic antimicrobials, both topical and systemic, should also be noted so that appropriate inhibitors and sufficient dilutions can be prepared, or reagents added to void any effects of drug interactions. The specimen should be collected and placed in a sterile container with appropriate media for transport to the laboratory. All specimens must be promptly transported to the laboratory. To obtain optimal results, specimens should be examined immediately upon receipt in the laboratory.

TABLE 12.3 SPECIMEN SELECTION, COLLECTION, AND TRANSPORTATION GUIDELINES*

Avoid contamination from normal flora to ensure sample is representative of the infectious process
Select correct anatomic site from which to obtain the specimen
Collect adequate volumes; insufficient specimen quantities may yield false-negative results
Specimens <i>must</i> be placed in a container designed to promote survival of suspected agents and eliminate leakage and potential safety hazards
Specimens <i>must</i> be properly labeled with patient's name, identification number, source, site, date, time of collection, and initials of collector
Specimens must be promptly transported to the laboratory, preferably within 2 hours

*The information in this table is from reference 60.

Processing and presumptive examination of burn wound specimens

The first step in processing virtually all clinical material is microscopic examination. Direct examination is a rapid, cost-effective diagnostic aid. Methods for direct examination are aimed at identifying microorganisms and enumerating cells. Visible microorganisms may denote the presumptive etiologic agent, guiding the laboratory in selecting appropriate isolation media and the physician in selecting empirical antibiotic therapy. The quality of the specimen and the measure of the inflammatory response can also be evaluated. Cellular material and organisms are usually transparent and are best distinguished by the use of dyes or biological stains. The most useful and cost-effective of these stains is the Gram stain. It is the differential stain most commonly used for direct microscopic examination of specimens and bacterial colonies due to the technique having a broad staining spectrum. Since the beginning of its use in the late 19th century, the Gram stain has remained basically the same procedure and serves in dividing bacteria into two main groups: Gram-positive organisms, which retain the primary crystal violet dye and are deep blue to purple in appearance; and Gram-negative organisms, which can be decolorized, thereby losing the primary stain and subsequently taking up the counterstain safranin and appearing pink to red. The staining spectrum includes almost all bacteria, many fungi, and some parasites. The Gram reaction is used to aid in distinguishing microbial cellular characteristics, such as shape (e.g. cocci or bacilli/rod-shaped) and arrangement of the organisms. This provides clues to the preliminary identification and significance of organisms.⁶⁰

The most reliable specimen for identification of infection in burn wounds is a tissue biopsy, which provides the best indicator of the potential pathogen in surgical sepsis. However, all specimens taken at the time of surgical intervention should be examined for the presence of potential pathogenic microorganisms. Tissue specimens should be homogenized or impression smears should be prepared, followed by microscopic examination as described above. Specimens should be inoculated to a variety of solid and liquid culture media. The liquid medium employed is generally an enriched thioglycolate medium (THIO) or brain heart infusion broth (BHIB), supplemented to facilitate the recovery of anaerobes as well as the aerobic pathogens.^{60,61} Aliquots of the serial-diluted specimens are subsequently inoculated to sheep blood agar (SBA) containing phenylethyl alcohol (PEA), and MacConkey's agar (MAC). SBA is an enriched medium that contains nutrient supplements, allowing a wide variety of organisms to reproduce. The SBA with PEA is an enriched and selective medium, in that it will permit the growth of fastidious and slow-growing aerobic and anaerobic organisms from specimens containing mixed flora. MAC is a differential medium that allows for the presumptive identification of microbes based on the organism's appearance on the medium.

Each inoculated plated media should be incubated in the suspected organism's appropriate atmospheric conditions. Tissue specimens should be inoculated onto plated media, utilizing quantitative culture methods.^{8,62} Quantitative cultures used in combination with histological examination provides for an indication of the predominant microorganism(s) in the burn wound, as well as the extent of the infectious process.⁶²

Etiologic agents of burn wound infections

Burn wound infections are most commonly caused by bacteria, fungi, or viruses. However, bacteria cause the majority of infections in most burn care centers. Almost all burn wound infections caused by bacteria are due to aerobic microorganisms.⁶³ Microorganisms are transmitted from the patient's surroundings at the time of injury due to implantation or can be acquired endogenously from the patient or exogenously from hands of medical personnel, as well as fomites.^{1,2} Table 12.4 describes the tissue associations of the microorganisms most often encountered in burn wound infections.

It is the design of the remaining portion of this section to describe some of the major distinguishing characteristics of the bacterial pathogens, as well as some of the fungi encountered in burn wound infection. A discussion of yeasts and viruses associated with burn injury can be found in the 'Clinical management strategies' section of this chapter.

Bacteria

Gram-positive organisms

Staphylococcus aureus is the most important cause of bacterial burn wound infections, and is well documented as a human opportunistic pathogen.^{1,2,60} As a nosocomial pathogen, *S. aureus* had been a major cause of morbidity and mortality.⁶⁰ Most common infections where the etiologic agent *Staphylococcus* spp. are encountered and are considered pathognomonic are septicemia; cellulitis; impetigo; scalded skin syndrome; and postoperative wound infections. However, the most serious staphylococcal infections are puerperal sepsis; pneumonia; osteomyelitis; endocarditis; and burn wound infections. Staphylococcal pseudomembranous enterocolitis will occur most frequently as a complication of antibiotic therapy. In burn injury, the staphylococci are responsible for graft loss when the colony count of the graft bed is $>10^5$ CFUs per gram of tissue.⁴

Strains of *S. aureus* as well as other *Staphylococcus* species produce a wide variety of metabolites. Some are pathognomonic and also toxigenic, while those with minimal toxicity or no toxic effects at all are of some diagnostic significance. An array of byproducts such as proteinases, collagenases, and hyaluronidase digest the extracellular matrix, which serves as the structural integrity essential in wound healing.¹ Most of the human pathogens produce α - and β -lysins. Some exotoxins, which are produced by the pathogenic strains of staphylococci, include a pyrogenic toxin, a dermonecrotizing toxin, a lethal toxin, and leukocidin. These organisms can also produce an exotoxin, TSST-1 and enterotoxins A, B, and C which are risk factors for TSS in susceptible patients.¹ TSS was first described as such in 1978.⁴⁵ As previously mentioned in this chapter, the disease is characterized by sudden onset of fever, vomiting, diarrhea, shock, and a diffuse macular erythematous rash, followed by desquamation of the skin on the hand and feet as well as hyperemia of various mucous membranes. It has been our experience that although TSS is very uncommon, it can be a devastating complication of minor burns. A clinical lack of vigilance in the care of a child with TSS can lead to shock, organ failure, and death.

Another member of the *Staphylococcus* genus, *Staphylococcus epidermidis*, is a resident of human skin and mucous

TABLE 12.4 TISSUE ASSOCIATION OF MICROORGANISMS MOST COMMONLY FOUND IN BURN WOUND INFECTION*

Organism	Soft tissue skin	Upper respiratory tissue	Lower respiratory tissue	Endocardial	Gastrointestinal tissue	Urogenital tract	Bone and joint
<i>Staphylococcus aureus</i>	NF, P	P, NF	P	P	P	NF, P	P
<i>Staphylococcus epidermidis</i>	NF, P	NF, P	P	P	P	NF, P	P
Other <i>Staphylococci</i> spp.	NF	NF, P	P	P	NF, P	NF, P	P
<i>Streptococcus pyogenes</i>	P, NF	P, NF	P	P	P	P	P
Other <i>Streptococci</i> spp.	NF	NF	P	P	NF	NF, P	P
<i>Enterococcus</i> spp.	P	P	P	P	NF, P	NF, P	P
<i>Escherichia coli</i>	NF, P	NF, P	P	P	NF, P	NF, P	P
<i>Klebsiella pneumoniae</i>	NF, P	NF, P	P	P	NF, P	NF, P	P
<i>Enterobacter cloacae</i>	NF, P	NF, P	P	P	NF, P	NF, P	P
<i>Enterobacter aerogenes</i>	NF, P	NF, P	P	P	NF, P	NF, P	P
<i>Proteus</i> spp.	NF, P	P	P	P	NF, P	NF, P	P
<i>Serratia marcescens</i>	NF, P	—	P	P	P	P	P
Other enterics	NF, P	NF, P	P	P	NF, P	P	P
<i>Pseudomonas aeruginosa</i>	P	NF, P	P	P	NF, P	P	P
<i>Acinetobacter</i> spp.	NF	NF	P	—	NF	NF	P
<i>Candida albicans</i>	NF	NF	P	P	NF	P, NF	P

*NF, normal flora; P, pathogens; — normally not found; however, these organisms should not be ignored when encountered.
Modified from Heggors J. Microbiology for surgeons. In: Kerstein MD, ed. Management of surgical infections. Mt Kisco, NY: Futura; 1980:27–55.

membranes and can also be associated with burn wound infection. *S. epidermidis* resembles *S. aureus* microscopically, and is tolerant of high NaCl concentrations as is *S. aureus*. However, it differs from *S. aureus* in that it is mannitol-, coagulase, and thermonuclease-negative. It is equally as pathogenic as *S. aureus*, and has been the principal etiologic agent in disease entities such as subacute bacterial endocarditis, infected surgical prosthesis, infections following bone marrow transplantation, or other states of immunosuppression such as in the thermal injury.

The streptococci are catalase-negative and produce a variety of hemolytic activity in the presence of blood. The types of hemolysis produced on SBA are frequently used as an initial means of identification for the streptococci. This hemolysis is considered a virulence factor, and quantitatively this group of organisms do not lend themselves to the standard rule of less than 10^5 for any tissue closure. The mere presence of a few β -hemolytic streptococci can cause a wound infection, failure of a primary closure, and loss of a skin graft. The major species that can be diagnosed with this particular type of hemolysis are *Streptococcus pyogenes*, β -hemolytic streptococci group

A and *S. agalactiae* β -hemolytic streptococci group B, just to mention a few. Presumptive identification of *S. pyogenes* can be made by sensitivity to bacitracin, since 90% of all *S. pyogenes* are sensitive to bacitracin.

The genus *Enterococcus* was established in 1984.⁶⁰ However, *Enterococcus faecalis* and *Enterococcus faecium* were the only two recognized species. Since that time, 12 additional species have been classified within the enterococci group.^{60,65} The enterococci have become one of the most important causes of burn wound infection. This is likely due to widespread use of third-generation cephalosporins over the last decade to which enterococci are resistant. In 1986, burn wound sepsis caused by enterococci was diagnosed by recovery of at least 10^5 colony-forming units (CFUs)/g of tissue on burn wound biopsy or by recovery from blood cultures. Therefore, enterococci appear to be not only common but also virulent burn wound pathogens. The majority of the enterococci are frequently nonhemolytic, termed γ -hemolysis. However, there are some strains that produce a α - or β -hemolysis on blood agar. All members of the enterococci group besides tolerating 6.5% NaCl and being bile esculin (BE)-positive are also

pyroglutonylaminidase (PYR)- and leucine aminopeptidase (LAP)-positive. The species are separated into three groups based on specific biochemical reactions. Group I does not hydrolyze arginine but forms acid in a manitol, sorbitol, and sorbose broth. The important species here is *Enterococcus avium*. Group II, on the other hand, hydrolyzes arginine and forms acid in mannitol and sorbitol broth only. The significant species in this group are *E. faecalis* and *E. faecium*. Group III, which includes *Enterococcus durans*, is negative for all tests described above.⁶⁰

Gram-negative organisms

This family of Gram-negative rods contains a distinctive group of etiologic agents of burn wound infections. Of this group, the *Pseudomonas* species are most repeatedly encountered and are chronic or acute. Since 1960, *Pseudomonas aeruginosa* has been recognized as a major burn pathogen.^{2,63,64} *Pseudomonas aeruginosa* is the second most common burn wound pathogen. *Pseudomonas* spp. have a worldwide distribution with a predilection for moist environments. Because of their ability to survive in aqueous environments, these organisms have become problematic in the hospital environment.⁶⁰ The spectrum of disease caused by this agent ranges from superficial skin infections to fulminant sepsis. *P. aeruginosa* is the leading cause of nosocomial respiratory tract infection. Patients receiving ventilatory assistance have a 20-fold higher likelihood of developing nosocomial pneumonia, with *P. aeruginosa* being the most frequently identified etiologic agent. Wound infections due to *P. aeruginosa* are particularly troublesome in burn patients. Although the incidence of such infections has declined in this patient population, the high rate of sepsis following these wound infections is responsible for significant mortality rates.⁶⁰

Acinetobacter spp. are part of the indigenous flora of the respiratory, skin, as well as the gastrointestinal and genitourinary tracts of man and animals. They have been isolated from a diversity of clinical sources, including upper and lower respiratory tracts, urinary tract, surgical and burn wounds, and in bacteremias secondary to IV catheterization. Also occasional cases of septicemia or pneumonia have occurred in attenuated patients. Many of these patients who develop infections with this microorganism have had various manipulations including the use of respiratory therapy equipment, tracheal intubation, or bladder or central venous line catheterization. While an agent of low virulence, it has a predilection for infecting patients with dysfunctional host defense mechanisms. It develops a high degree of antimicrobial resistance. This resistance may be a direct result of previous antimicrobial therapy.

The largest and most repeatedly encountered group of microorganisms populating any burn wound environment along with the *Staphylococcus* spp. are the enterics, and they are found in the family of Enterobacteriaceae. This family contains 12 individual genera. Many of these organisms were previously categorized as non-pathogens and among these were the *Klebsiella-Enterobacter* group, *Serratia marcescens*, *Providencia* species, and *Erwinia* species.^{3,6}

Escherichia coli, probably the most well-known enteric, has been responsible for a wide diversity of infectious processes. Among these are:

- frequently severe and sometimes fatal infections such as appendicitis, cystitis, pyelitis, peritonitis, septicemia, and gall bladder infections;
- surgical and burn wound sepsis, and epidemic diarrhea of children and adults; and
- ‘travelers’ diarrhea’.

E. coli can be identified from other members of Enterobacteriaceae by its response to the classical IMVIC (indole, methyl red, Voges-Proskauer and citrate) reaction.

The *Klebsiella-Enterobacter* group (*K-E*) are Gram-negative rods that are either motile or nonmotile. Fifty-one percent of moderately ill hospitalized patients had either *K. pneumoniae*, *Enterobacter aerogenes*, or *Enterobacter cloacae* isolated from their oropharyngeal space.^{60,61,66} *K. pneumoniae* and its family are fast becoming a regular pathogen in nosocomial infections.^{60,66} It is interesting that earlier isolation of the *K-E* group flora was thought to be part of the normal flora of the bronchial tree. The tribe *Klebsiella* is currently composed of the genera *Klebsiella*, *Enterobacter*, and *Serratia*.

The remaining enterics consist of three additional genera: *Proteus*, *Providencia*, and *Morganella*. The genus *Proteus* is composed of two species: *P. mirabilis* and *P. vulgaris*. Both species can be found in massive concentrations in the feces of individuals undergoing oral antibiotic therapy. This group of organisms are often accountable for surgical and burn wound infections, intra-abdominal infections, as well as bacteremias and urinary tract infections. The genus *Providencia* is composed of three species: *Providencia alcalifaciens*, *Providencia stuartii*, and *Providencia rettgeri*, which were formerly in the genus *Proteus*. *Providencia* species, like *S. marcescens*, have a broad range of pathologic involvement, from nosocomial infections to septicemias, postoperative incisional wounds, burn wounds, pneumonias, and urinary tract infections.^{60,61} *P. stuartii* has been incriminated in numerous infections of patients in a burn unit, to include urinary tract infections as well.

Morganella morganii is the only species in the genus *Morganella* and was considered earlier a member of the genus *Proteus*. *M. Morganii* has been co-joined with wound infections as well as urinary tract infections.

Like the Gram-positive clinical isolates, the Gram-negative isolates from the burn wound are equally selective. While man’s environment is overwhelmed with microbes, only a select smattering of Gram-negative rods predominate, which specifically includes the pseudomonads and enterics; with *P. aeruginosa* being the predominant isolate, followed by *E. coli* and the other enterics. In comparing the Gram-negative isolates for 1999 with those identified in a 1988–1989 study, we observed an increase in the number of *P. aeruginosa* isolates (53.4%) over 1988–1989 (33.6%), almost a 20% increase. Another interesting observation was the appearance of *Acinetobacter baumannii/haemolyticus*, accounting for 46.8% of the nonfermentors and, combined with *P. aeruginosa*, accounting for 53.4% of the total Gram-negative isolates. This appearance of *Acinetobacter* spp., in the ICU setting was experienced worldwide.

Anaerobes

The most repeatedly confronted organisms in this group, which may play a fearful role in surgical and burn wound

infections, are *Bacteroides* spp. and *Fusobacterium* spp. They are considered normal flora of the human body, beginning at the oropharyngeal cavity and ending at the gastrointestinal (GI) and urogenital tracts. Numerically they account for the major population in the oropharyngeal region in a 5:1 ratio over the aerobes and facultative anaerobes, while in the urogenital and GI tract the ratio is more dynamic at a 1000:1.^{60,61} Yet when one scrutinizes the current statistics of anaerobic infections related to locality, all but 2–5% of surgical wound infections occurring in the oropharyngeal area are caused by the anaerobic flora.^{66,67} Those occurring in the GI and urogenital tract are only responsible for about 10–15% of the wound infections.^{45,65} Prior surgery, malignant neoplasms, arteriosclerosis, diabetes mellitus, prior antibiotic therapy, alcoholism, improper debridement, and steroid and immunosuppressive therapy are commonly major contributors associated in these types of wound infections.^{45,66} Specimens collected for anaerobic organisms should be placed in appropriate transport tubes void of atmospheric O₂ or remain in syringes with attached needles containing suspect aspirates sealed off with a rubber stopper. However, with the advent of the early excision and grafting, the incidence of anaerobic infections in the thermal injury has been significantly reduced; therefore, anaerobic cultures are uneconomical. Culturing for these anaerobes would be futile, as they require vascular tissue for survival. Their presence would only be observed if such tissue were to remain.

Anaerobic infections in burned patients are usually associated with avascular muscle found in electrical injuries, frost bite, or cutaneous flame burns with concomitant crush-type injuries.⁶³

Fungi

Until the advent of topical antimicrobial agents, fungal infections were not common in burned patients. However, the incidence of mycotic invasion has doubled since the implementation of topical antimicrobial agents to control bacterial colonization.⁶⁹ The burn wound is the most commonly infected site, although local or disseminated fungal infections of the respiratory tract, urinary tract, GI tract, and vagina are increasingly common.^{68,69}

Fungi are generally isolated through the inoculation of both non-selective and selective culture media. The most commonly used non-selective media includes inhibitory mold agar and Sabouraud Dextrose Brain Heart Infusion (SABHI™) agar, which permit the enhanced growth of almost all fungi, including some of the more fastidious and slowly growing fungi. The most commonly utilized selective media include those containing antimicrobial agents such as penicillin (20 U/mL) plus streptomycin (40 U/mL) or gentamicin (5 µg/mL) plus chloramphenicol (16 µg/mL) to inhibit growth of bacteria. Media containing cycloheximide (0.5 µg/mL) may also be utilized to inhibit growth of rapidly growing molds that often overgrow slower-growing dimorphic fungi; however, a medium without cycloheximide should also be used, because this agent can inhibit the growth of some medically important fungi (e.g. *Cryptococcus neoformans* and *Aspergillus fumigatus*). Additionally, Sabouraud's dextrose or potato dextrose agar is used to allow for identification of fungi through their sporulation characteristics. Yeasts are identified on the basis

of specific biochemical tests, whereas identification of molds is based on growth rate, colony structure, microscopic appearance, dimorphism at different incubation temperatures, inhibition of growth by cycloheximide, and a few biochemical tests.⁶⁶

Candida spp. are the most common non-bacterial colonizers of the burn wound, although true fungi such as *Aspergillus*, *Penicillium*, *Rhizopus*, *Mucor*, *Rhizomucor*, *Fusarium*, and *Curvularia* are not uncommon and have a much greater invasive potential than the yeasts.^{67,69}

Early diagnosis of fungal infection is difficult as clinical symptoms frequently mimic low-grade bacterial infections. Routine culture techniques may require from 7 to 14 days to identify fungal contaminants, delaying the initiation of treatment as these pathogens are frequently not recovered in culture.⁶⁷ In contrast to bacterial sepsis, venous blood cultures may not reflect the causative organism.³⁶ Arterial blood cultures and retinal examination for characteristic candidal lesions can be useful.

Unlike candidal infections, true fungal infections occur early in the hospital course of patients with specific predisposing characteristics. Most frequently, burned patients infected with molds are exposed to spores in the environment by either rolling on the ground or jumping into surface water at the time of injury. Other environmental foci have been cited as the source of nosocomial fungal infection, including bandaging supplies left open to air, heating, and air conditioning ducts and floor drains.^{67,69} Once colonized, broad non-branching hyphae extend into subcutaneous tissue, stimulating an inflammatory response. This phenomenon is diagnostic of fungal wound infection. Vascular invasion is common and often accompanied by thrombosis and avascular necrosis, clinically observed as rapidly advancing dark discolorations of the wound margins or well-described lesions.³⁶ Systemic dissemination of the infection occurs with invasion of the vasculature.

Pharmacodynamics and kinetics in the burn patient

Pharmacotherapy in the control of infection in a burn patient presents many challenges for the clinician. The normal course of burn trauma effects pathophysiologic changes in the cardiovascular, renal, metabolic, hepatic, gastrointestinal, epidermal and immunological responses which changes the patient's pharmacodynamic and pharmacokinetic state.⁷¹

The acute or resuscitative phase

In the acute or resuscitative phase of the burn trauma which occurs within the first 48–72 hours post-burn, cardiovascular factors produce hypovolemia with decreased blood flow to organs and tissues.⁷¹ Intravenous drug treatments during this phase will result in a slower rate of distribution and elimination through the kidneys. The burn patient will also exhibit delayed absorption of enteral, subcutaneous, and intramuscular drugs. Pharmacotherapy regimens during this acute phase will result in delayed onset of action and peak concentrations.

The hypermetabolic phase

The hypermetabolic response phase mediated by greatly increased levels of catecholamines, prostaglandins, glucagons, and cortisol occurs after the acute phase and also produces pathophysiologic changes. The burn patient will exhibit increased blood flow to organs and tissues, an increased internal core temperature and hypoproteinemia and edema formation.⁷¹

Intravenous drugs will have an increased onset of action due to the increased rate of distribution.⁷¹ These drugs will also have a shorter half-life due to the enhanced glomerular filtration rate and elimination of renally excreted drugs. The antibiotic treatment of these patients requires higher doses for these drugs and perhaps a shorter dosing interval. The burn patient's antibiotic drug doses are similar to those higher doses used to treat cystic fibrosis patients. Renally excreted antibiotics such as vancomycin that are time-dependent in their ability to kill Gram-positive bacteria must be carefully monitored to ensure that they are meeting the minimum inhibitory concentration of the bacteria in the serum. Oral drugs will also exhibit an increased absorption from the GI tract and increased onset of action.⁷¹

The hypermetabolic phase will produce decreased levels of albumin and increased levels of acute-phase proteins.⁷¹ Albumin binds to acidic and neutral drugs such as aminoglycosides, vancomycin, aztreonam, and cefotetan. These drugs will be tightly bound and there will be less free drug in the blood and a decreased volume of distribution. Higher drug dosages may be necessary to produce a therapeutic effect.

The hepatic response in the hypermetabolic phase will present as a decrease in phase I metabolism such as oxidation, reduction, or hydroxylation of a drug by the cytochrome P-450 system. This will affect the metabolism of many antibiotics such as the quinolones and the macrolides. The decreased activity of these hepatic drug-metabolizing enzymes as well as the decreased hepatic clearance and prolonged half-life may produce systemic toxicity. Phase II metabolism in the liver such as conjugation reactions between the drug and endogenous substrate will not be impaired.

The gastrointestinal response during the hypermetabolic phase results in increased proton secretion. It is reported that erosion of the stomach lining and duodenum occurs in 86% of adult patients within 72 hours post-injury and 40% had GI bleeding.⁷¹ In children, the incidence of stress ulceration is twice that of adults.⁷¹ Erosion of the stomach lining and duodenum allows the transmigration of GI bacteria from the gut into the body's bloodstream. The use of antacids, H-2 antagonists, and proton-pump inhibitors may actually permit the proliferation of bacteria that is not normally present in the gut. Transmigration of these bacteria may be found in other parts of the body such as the lungs, heart, and intestinal tract.

Diffusion resistance to water movement through burn skin is less than 1/10 that of normal skin. The burn patient will experience increased drug loss and drug absorption. This is a factor that must be weighed in the appropriate use of topical antimicrobials. Fick's law of diffusion describes the decreased resistance in burn patients:⁷¹

$$F = DAK/t \times (C_2 - C_1)$$

F = flux

D = diffusion coefficient

A = area

K = oil-water partition coefficient

t = thickness of the stratum corneum

C_2 = drug concentration in the vehicle

C_1 = concentration across the stratum corneum.

Other factors that affect drug absorption are the degree of hydration of the stratum corneum, the temperature, the pH of the drug, and the molecular characteristics of the drug.

Finally, the immunological response will exhibit major changes in the hypermetabolic phase. The burn patient suffers damage to the epidermis of the skin. The depression in this, the first line of defense, allows systemic microbial invasion. However, there is also depression in the second line of defense with a burn size-related depression of both cellular and humoral aspects of the immune response and phagocytic activity of fixed and bloodborne macrophages and neutrophils. The patient suffers a release of chemical mediators, including prostaglandins, serotonin, thromboxanes, and leukotrienes which mount an inflammatory response. The patient will require a strong but specific pharmacotherapeutic regimen of antibiotics to protect the body against invasion.

Antimicrobial pharmacokinetic and pharmacodynamic parameters

The clinician should also understand key pharmacokinetic and pharmacodynamic parameters to most effectively use antibiotics in the treatment of infection. Pharmacokinetic parameters describe the action of the body on the drug. The drug is absorbed, distributed, metabolized, and eliminated by the body. Pharmacodynamic parameters describe the action of the drug on the body. They describe the relationship between drug concentration and the pharmacologic effect. They describe how an antibiotic produces its antimicrobial effects on the microbe as well as any other effects it may produce on the body. We want an antibiotic to approach the ideal pharmacokinetic parameters of 100% absorption, distribution to the site of infection, metabolism to inactive compounds, and elimination from the body. The drug should also achieve ideal pharmacodynamic parameters of a concentration in the body that is sufficient to effectively kill bacteria and maintain that effective killing concentration for a time period needed to keep the bacteria from regrowth. The pharmacodynamic parameter that describes the concentration that will effectively kill the microbe *in vitro* is the minimum inhibitory concentration or MIC while the minimum bacteriological concentration or MBC describes the concentration that will effectively kill the microbe *in vivo* and produce a clinical cure.

In order to optimize antimicrobial therapy, the clinician must also understand whether the antibiotic he has chosen produces its antimicrobial activity in a concentration dependent or independent manner, the tissue penetration of the antibiotic, whether the antibiotic is bactericidal or bacterio-

static, synergy between antibiotic agents, drug elimination dosing limitations, duration of therapy, and the use of IV versus oral therapy.

If an antimicrobial agent produces its activity in a concentration-dependent manner, it must reach the effective MBC in order to kill the microbe by producing a peak concentration that is generally about 8–10 times the MIC ($\text{Conc}_{\text{max}}/\text{MIC}$). Concentration-dependent antimicrobial agents include the aminoglycosides and metronidazole.

The relationship between an antibiotic's 24-hour area under the curve concentration divided by the MIC of a drug ($\text{AUC}_{24}/\text{MIC}$) describes the total exposure of the microbe to an antibiotic. This pharmacodynamic parameter best describes the efficacy of certain antibiotics such as fluoroquinolones (ciprofloxacin and levofloxacin), the ketolides and azithromycin to produce their antimicrobial effect. This parameter may be >100 for ciprofloxacin in the effective treatment of *P. aeruginosa* infections.¹⁰⁶

If an antimicrobial agent produces its activity in a concentration-independent or time-dependent manner, it must maintain a concentration at least 1–2 times the MIC for the entire period between dosing intervals in order to kill the microbe and prevent its regrowth ($T > \text{MIC}$). Time-dependent antimicrobial agents include the β -lactam antibiotics, erythromycin, clarithromycin, the oxazolidinones, vancomycin and clindamycin.

Time-dependent antibiotics are sometimes given as continuous IV infusions to ensure that the MIC is maintained in the serum. This tactic is sometimes used in immunocompromised patients to good effect.

Tissue penetration is necessary to produce antimicrobial effect. Antibiotics that are effective against a microorganism *in vitro* but unable to reach the site of infection are of little or no benefit to the host. Antibiotic tissue penetration depends on the chemical properties of the antibiotic (e.g. lipid solubility, molecular size) and tissue (e.g. adequate blood supply, presence of inflammation). However, antibiotic tissue penetration is rarely problematic in acute infections due to increased microvascular permeability from local release of chemical inflammatory mediators. In contrast chronic infections and infections caused by intracellular pathogens often rely on the aforementioned chemical properties of an antibiotic for adequate tissue penetration. Burn wound infections are especially problematic because of the localization of infection at a poorly perfused wound site. Antibiotics cannot be expected to eradicate organisms from areas that are difficult to penetrate or have impaired blood supply, such as necrotic burn tissue, which usually require surgical excision for cure.

Antibiotics may be bacteriostatic or bactericidal. For most infections, bacteriostatic and bactericidal antibiotics inhibit/kill organisms at the same rate, and should not be a factor in antibiotic selection. Bactericidal antibiotics have an advantage in certain infections such as endocarditis, meningitis, and febrile leukopenia but there are exceptions even in these cases.

Combination therapy may be useful for drug synergy or for extending the antimicrobial spectrum from what can be obtained with a single drug. However, since drug synergy is

difficult to assess and the possibility of antagonism always exists, antibiotics should be combined for synergy only if synergy is based on experience or actual testing. Synergy studies for bacterial isolates that are resistant to all or most antibiotics is especially necessary to ensure that these resistant bacterial organisms are treated appropriately.

Intravenous antibiotic therapy is preferred when a patient is first admitted to the hospital because IV therapy ensures 100% availability of the drug in the body. However, if an antibiotic is well absorbed orally then the advantages of such treatment include reduced cost, early hospital discharge, and virtual elimination of IV line infections. Drugs well suited for IV to PO switch or for treatment entirely by the oral route include doxycycline, minocycline, clindamycin, metronidazole, chloramphenicol, amoxicillin, trimethoprim/sulfamethoxazole, quinolones, and linezolid.¹⁰⁷

Usual antibiotic dosing assumes normal renal and hepatic function. Patients with significant renal insufficiency and/or hepatic dysfunction may require dosage reduction in antibiotics metabolized/eliminated by these organs.

Since most antibiotics eliminated by the kidneys have a wide 'toxic-to-therapeutic ratio', dosing strategies are frequently based on formula-derived estimates of creatinine clearance (CrCl), rather than precise quantization of glomerular filtration rates. Dosage adjustments are especially important for antibiotics with narrow 'toxic-to-therapeutic' ratios (e.g. aminoglycosides), and for patients who are receiving other nephrotoxic medications or have pre-existing renal disease. For patients with renal insufficiency receiving drugs eliminated by the kidneys, the loading dose (if required) is left unchanged, and the maintenance dose and dosing interval are modified in proportion to the degree of renal insufficiency. For moderate renal insufficiency ($\text{CrCl} \sim 40\text{--}60\text{ mL/min}$), the maintenance dose is usually cut in half and the dosing interval is left unchanged.¹⁰⁷ For severe renal insufficiency ($\text{CrCl} \sim 10\text{--}40\text{ mL/min}$) the maintenance dose is usually cut in half and the dosing interval is doubled.¹⁰⁷ Dosing adjustments in renal insufficiency can be circumvented by selecting an antibiotic with a similar spectrum that is eliminated by the hepatic route.

Antibiotic dosing for patients with hepatic dysfunction is problematic since there is no hepatic counterpart to the serum creatinine to accurately assess liver function. In practice, antibiotic dosing is based on clinical assessment of the severity of liver disease. For practical purposes, dosing adjustments are usually not required for mild to moderate hepatic insufficiency. For severe hepatic insufficiency, dosing adjustments are usually made for antibiotics with hepatotoxic potential.¹⁰⁷ Relatively few antibiotics depend solely on hepatic inactivation/elimination, and dosing adjustment problems can be circumvented by selecting an appropriate antibiotic eliminated by the renal route.

There are no good dosing adjustment guidelines for patients with hepatorenal insufficiency. If renal insufficiency is worse than hepatic insufficiency, antibiotics eliminated by the liver are often administered at half the total daily dose. If hepatic insufficiency is worse than renal insufficiency, antibiotics eliminated by the kidneys are usually administered and dosed in proportion to renal function.

Most bacterial infections in normal hosts are treated with antibiotics for 1–2 weeks. However, the duration of therapy may have to be extended in burn patients with impaired immunity and because these patients must undergo numerous surgical procedures to excise and graft burn wounds.

Pharmacological considerations in the treatment of burn infections

The major role of an antibiotic is to help the body eliminate an agent of infection in a burn patient. The treatment of an infection is often begun based on empiric knowledge of the most common types of microbial infections seen in the burn population and the antimicrobial agents that are most efficacious in their treatment. The appropriate choice of an antibiotic to treat an infection, however, should always be based on wound cultures and sensitivities that specifically identify the infecting organism, the colony counts, and the sensitivity of that organism to specific antibiotics. Pathology studies of wound biopsies give us information on how invasive the infecting organism is in the body. A pharmacotherapeutic regimen of antibiotics should follow known parameters about specific burn wound infections in order to potentiate each antibiotic agent's mechanism of action and pharmacokinetics while decreasing its side effects and systemic toxicities.

Gram-positive bacterial infections

The three most common Gram-positive organisms responsible for burn wound infections are the streptococci, staphylococci, and enterococci.

Streptococcal infections

β -hemolytic streptococci of group A or B (*S. pyogenes* or *S. agalactiae*) are most commonly seen in the first 72 hours post-burn. Cellulitis may develop due to streptococcal infections and usually responds to treatment with natural penicillins or first-generation cephalosporins.

The natural penicillins, which consist of penicillin G and penicillin V, and the first-generation cephalosporins are bactericidal in action. Like many other β -lactam antibiotics, the antibacterial action results from inhibition of mucopeptide synthesis in the bacterial cell wall. Resistance to these antibiotics is caused by the production of β -lactamases and/or intrinsic resistance.⁷² β -lactamase enzymes inactivate these antibiotics by hydrolyzing their β -lactam ring. Intrinsic resistance can result from the presence of a permeability barrier in the outer membrane of an infecting organism or alteration in the properties of target enzymes (penicillin-binding proteins).

Should resistance or tolerance to the natural penicillins or first-generation cephalosporins develop, then culture and sensitivity data should be utilized to appropriately treat the streptococcal infection. Please see Table 12.5 to review dosing and administration parameters.

Staphylococcal infections

Staphylococcus aureus and *Staphylococcus epidermidis* are natural pathogens found on skin and therefore are the most common cause of infections in burn populations. These microbes generally produce penicillinases which break the

penicillin β -lactam ring and make natural penicillins ineffective against these bacteria.

These types of infections were treated by penicillinase-resistant penicillins that were termed 'methicillin sensitive.' These antibiotics included the parenteral antibiotics, nafcillin, methicillin, and oxacillin, and the oral antibiotics, cloxacillin, dicloxacillin, nafcillin, and oxacillin. The penicillinase-resistant penicillins have a mechanism of action that is similar to other penicillins. They interfere with bacterial cell wall synthesis during active multiplication by binding to one or more of the penicillin-binding proteins. They inhibit the final transpeptidation step of peptidoglycan synthesis causing cell wall death and resultant bactericidal activity against susceptible bacteria. However, the staphylococcal bacteria resistance pattern has become such that these penicillinase-resistant penicillin are no longer very effective against these organisms. In 2005, only 31% of *S. aureus* burn wound isolates at the Shriners Burns Hospital, Galveston, Texas (SBH-G) were sensitive to oxacillin and none of the *S. epidermidis* and *S. haemolyticus* isolates were sensitive to oxacillin. The staphylococcal infections that are resistant to penicillinase-resistant penicillins are termed MRSA (methicillin-resistant *Staphylococcus aureus*) or MRSE (methicillin-resistant *Staphylococcus epidermidis*).

Vancomycin alone or in conjunction with other anti-infectives has generally been considered the treatment of choice for infections caused by methicillin-resistant staphylococci. In 2005, 100% of all staphylococcal isolates were susceptible to vancomycin at SBH-G. Vancomycin is bactericidal and appears to bind to the bacterial cell wall, causing blockage of glycopeptide polymerization. This effect, which occurs at a site different from that affected by the penicillins, produces immediate inhibition of cell wall synthesis and secondary damage to the cytoplasmic membrane.⁷² However, vancomycin is a time-dependent antimicrobial which requires that the serum level of this drug must remain at all times above the minimum inhibitory concentration (MIC) in order to provide adequate bactericidal activity.

The hypermetabolic burn patient exhibits an increased glomerular filtration rate and increased excretion of the renally cleared drug, vancomycin. Because of the wide interpatient variability of vancomycin elimination in a burn patient, the dosage must be individualized in order to provide an optimal time-dependent serum concentration. The effective peak and trough levels are derived from the MIC for a particular bacterial organism. The therapeutic peak level is approximately equivalent to 5–8 times the MIC and the trough concentration is equivalent to 1–2 times the MIC. The so-called therapeutic range most often quoted for vancomycin monitoring is peak levels of 30–40 $\mu\text{g}/\text{mL}$ and trough levels of 5–10 $\mu\text{g}/\text{mL}$. Because vancomycin is a concentration-independent, or time-dependent, antibiotic and because there are practical issues associated with determining a precise peak serum concentration with this multi-compartment antibiotic, most clinicians have abandoned the routine practice of determining peak serum concentrations.

The overall AUC/MIC value may be the pharmacodynamic parameter that best correlates with a successful outcome associated with the use of vancomycin. Prolonged exposure to serum levels close to the MIC are associated with the emer-

TABLE 12.5

Antibiotic (check references for neonatal dose)	Pediatric dose (do not exceed adult dose)	Adult dose	Frequency	Route	Rate of IV admin
Acyclovir PO	10mg/kg/dose	10mg/kg/dose	5 times a day	PO	
Acyclovir IV	10mg/kg/dose	10mg/kg/dose	Q8h	IVPB	60 minutes
Amikacin IV	7.5 mg/kg/dose	5 mg/kg/dose	Q8h	IVPB	30 minutes
Amoxicillin PO	8–16 mg/kg/dose	250–500 mg	Q8h	PO	
Ampicillin PO	25–50 mg/kg/dose	250–500 mg	Q6h	PO	
Ampicillin IV	25–33 mg/kg/dose	1–2 g	Q4h	IVPB	30 minutes
Amphotericin IV	0.5 mg/kg/dose	50 mg	Q24h	IVPB	4–6 hours
Augmentin (amoxicillin/clavulanate) PO	7–14 mg/kg/dose	250–500 mg	Q8–12 h	PO	
Aztreonam IV	50 mg/kg/dose	2 g	Q6h	IVPB	30 minutes
Caspofungin IV (Cancidas®)	70 mg/m ² /day × 1 day then 50 mg/m ² /day	70 mg × 1 day then 50 mg	Q24 h	IVPB	60 minutes
Cefazolin IV	16–33 mg/kg/dose	2 g	Q8h	IVPB	30 minutes
Cefepime IV	50 mg/kg/dose	2 g	Q8h	IVPB	30 minutes

gence of resistance; therefore it is important to maintain adequate serum concentrations in patients with fast or rapidly changing creatinine clearance such as burn patients. There are also certain body compartments in which penetration is poor, such as the lung and the CNS. It would, also, seem prudent to keep concentrations from being suboptimal in patients with pneumonia or meningitis, as well as in patients receiving dialysis for renal failure. The American Thoracic Society recently published guidelines for hospital-acquired, ventilator-associated, and healthcare-associated pneumonia. These guidelines recommend vancomycin trough concentrations of 15–20 µg/mL for the treatment of methicillin-resistant *Staphylococcus aureus* pneumonia.⁷⁴ These higher concentrations may be needed for sequestered infections or in situations where vancomycin penetration has been documented to be poor. Some clinicians recommend that these higher concentrations of vancomycin may be necessary in the treatment of staphylococcal infections as well. Recent testing has shown ‘vancomycin MIC creep’ that may necessitate higher vancomycin trough serum concentrations to eradicate these microorganisms in burn wound infections.⁷⁴

Vancomycin is derived from *Streptomyces orientalis* bacteria and used to be termed ‘Mississippi Mud’ because of the brown color of the unpurified product. These protein impurities are thought to have caused the ototoxicity and nephrotoxicity that was observed with the earlier products in the 1950s. However, when newer, purer preparations were retested in the 1970s, they produced no ototoxicity and little nephrotoxicity in the animal models, unless given in combination with ami-

noglycosides.⁷⁴ In one of the largest investigations to date, Pestotnik et al. reported that the incidence of nephrotoxicity among 1750 patients was 1.4%.⁷⁴ However, in the burn patient, vancomycin is often used not only in combination with other ototoxic and nephrotoxic agents such as aminoglycosides, the loop diuretic, furosemide and the antifungal drug, amphotericin. Nephrotoxicity is manifested by transient elevations in the serum blood urea nitrogen (BUN) or serum creatinine and decreases in the glomerular filtration rate and creatinine clearance. Hyaline and granular casts and albumin may also be found in the urine.

Vancomycin is administered only by slow intravenous infusion for at least 1 hour. Although, vancomycin injection is much purer it may still cause an anaphylactoid reaction known as ‘red man’s syndrome’ or ‘red neck syndrome.’ This reaction is characterized by a sudden decrease in blood pressure which can be severe and may be accompanied by flushing and/or a maculopapular or erythematous rash on the face, neck, chest, and upper extremities; the latter manifestation may also occur in the absence of hypotension. Since this is not a true ‘allergic reaction,’ the patient may be pretreated with acetaminophen and diphenhydramine before an extended infusion of vancomycin of at least 90–120 minutes.

The oral treatment of MRSA and MRSE may present a greater challenge to a burn clinician. Rifampin is a bactericidal antibiotic and has efficacy in the treatment of these organisms. In 2005, *S. aureus* was 64% susceptible, *S. epidermidis* was 74% and *S. haemolyticus* was 76% susceptible to rifampin at

SBH-G. Rifampin produces its action by inhibiting RNA synthesis in the bacteria, binding to the β subunit of the DNA-dependent RNA polymerase, and blocking RNA transcription.⁷² However, it must be used in combination with other anti-infectives in the treatment of MRSA and MRSE due to its high resistance pattern when used alone. Other anti-infectives with a different mechanism of action against MRSA and MRSE reduce the resistance of rifampin. Oral antibiotics such as Bactrim® (sulfamethoxazole and trimethoprim) or levofloxacin are often used in conjunction with rifampin. In 2005 at SBH-G, *S. aureus* was 64% susceptible, *S. epidermidis* was 71% susceptible, and *S. haemolyticus* was only 29% susceptible to the sulfamethoxazole/trimethoprim combination antibiotic.

Sulfamethoxazole works by interfering with bacterial folic acid synthesis and growth via inhibition of dihydrofolic acid formation from para-aminobenzoic acid; trimethoprim inhibits dihydrofolic acid reduction to tetrahydrofolate, resulting in sequential inhibition of enzymes of the folic acid pathway.⁷²

In 2005 at SBH-G, *S. aureus* showed 47% susceptibility, *S. epidermidis* showed 49% susceptibility, and *S. haemolyticus* showed 24% susceptibility to levofloxacin. Levofloxacin produces its antibacterial action by inhibiting DNA-gyrase in susceptible organisms. This action thereby inhibits relaxation of supercoiled DNA and promotes breakage of bacterial DNA strands.⁷²

Linezolid is a synthetic antibacterial agent of a new class of antibiotics, the oxazolidinones, which has joined the armamentarium against MRSA and MRSE. Linezolid inhibits bacterial protein synthesis by binding to a site on the bacterial 23S ribosomal RNA of the 50S subunit and prevents the formation of a functional 70S initiation complex, which is an essential component of the bacterial translation process.⁷² The results of time-kill studies have shown linezolid to be bacteriostatic against enterococci and staphylococci. For streptococci, linezolid was found to be bactericidal for the majority of the strains. *In vitro* studies, however, show that point mutations in the 23S ribosomal RNA are associated with linezolid resistance and have been reported with some strains of *Enterococcus faecium* and *Staphylococcus aureus*.⁷² In 2005 at SBH-G, *S. aureus* and *S. epidermidis* both showed 96% susceptibility and *S. haemolyticus* showed 99% susceptibility to linezolid.

Adverse drug effects to linezolid include myelosuppression (e.g. anemia leukopenia, pancytopenia, and thrombocytopenia) which is generally reversible upon discontinuation of the drug and *Clostridium difficile*-associated colitis. Linezolid is also a weak, nonselective, reversible inhibitor of monoamine oxidase (MAO) and may cause increased serotonin serum levels and serotonin syndrome in patients on various serotonin re-uptake inhibitors such as fluoxetine and sertraline.

Staphylococcal infections may also be treated with quinupristin/dalfopristin (Synercid®). Quinupristin/dalfopristin is bactericidal and inhibits bacterial protein synthesis by binding to different sites on the 50S ribosomal subunit, thereby inhibiting protein synthesis in the bacterial cell.⁷² In 2005 at SBH-G, *S. aureus* showed 97% susceptibility, *S. epidermidis* showed 99% susceptibility, and *S. haemolyticus* showed 100% susceptibility to this drug.

Major adverse cardiovascular effects are seen when quinupristin/dalfopristin is given concomitantly with cytochrome P-450 isoenzyme 3A4 substrates such as cyclosporine, midazolam, and nifedipine that may cause QT prolongation.⁷² The concomitant administration results in increased serum concentrations of those substrates and potentially prolonged/increased therapeutic or adverse effects. *Clostridium difficile*-associated diarrhea and colitis has also been reported with this drug ranging in severity from mild to life-threatening. Adverse venous effects (e.g. thrombophlebitis) may occur; therefore, flushing infusion lines with 5% dextrose injection following completion of peripheral infusions is recommended. Do not flush with sodium chloride injection or heparin because of possible incompatibilities. Arthralgia and myalgia, severe in some cases, of unknown etiology have been reported. Some patients improved with a reduction in dosing frequency to every 12 hours.⁷²

Enterococcal bacterial infections

The enterococcal microbial isolates most frequently isolated from burn wounds at the Shriners Burns Hospital are *E. faecalis* and *E. faecium*. Most enterococcal bacteria are susceptible to vancomycin. In 2005 at SBH-G, all *E. faecalis* and *E. faecium* isolates showed 100% susceptibility to vancomycin. Vancomycin-resistant enterococci, usually vancomycin-resistant *E. faecium*, or VRE, will require treatment with a combination of agents such as ampicillin and aminoglycosides. If this combination is not effective, the VRE may be treated with the quinupristin/dalfopristin (Synercid®) combination or linezolid. In 2005 at SBH-G, *E. faecalis* showed 94% susceptibility and *E. faecium* showed 96% susceptibility to quinupristin/dalfopristin. The literature also reports that the use of quinupristin/dalfopristin resulted in resistance in one study and a superinfection in another study during the treatment of VRE infection.⁷² In 2005 at SBH-G, *E. faecalis* showed 94% susceptibility and *E. faecium* showed 96% susceptibility to linezolid. Linezolid, however, is a bacteriostatic agent and resistance has been reported with some strains of *E. faecium*.

Gram-negative bacterial infections

The five most common Gram-negative microbial isolates found in the burn population at the Shriners Burns Hospital, Galveston are *Pseudomonas aeruginosa*, *Escherichia coli*, *Klebsiella pneumoniae*, *Enterobacter cloacae*, and *Acinetobacter baumannii/haemolyticus*. The efficacy of the antibiotic arsenal varies based on the individual susceptibility of the microbial isolate. Synergy between different classes of antibiotics is often tested to determine efficacy for a multiply drug-resistant organism (MDROs). The aminoglycosides and in particular, gentamicin, were historically the antibiotics of choice in the treatment of Gram-negative infections. The synergistic activity with penicillinase-resistant penicillins and vancomycin in the treatment of staphylococcal infections further standardized its premier status before the advent of newer extended-spectrum penicillins, the fourth-generation cephalosporins, the monobactams, the carbapenems, and the quinolones. However, some Gram-negative bacteria encountered in the burn unit are now resistant to all the aforementioned antibiotic

classes and must now be treated with an old drug class, the polymyxins. A discussion of each antibiotic group will elucidate the strengths and weaknesses of each group.

Aminoglycosides

Aminoglycosides are usually bactericidal in action. Although the exact mechanism has not been fully elucidated, these drugs appear to inhibit protein synthesis in susceptible bacteria by irreversibly binding to 30S ribosomal subunits. The aminoglycosides consist of amikacin, gentamicin, kanamycin, neomycin, netilmicin, paromycin, and tobramycin.

In 2005 at SBH-G, *A. baumannii/haemolyticus* showed 30% susceptibility, *E. cloacae* showed 89% susceptibility, *E. coli* showed 97% susceptibility, *K. pneumoniae* showed 92% susceptibility, and *P. aeruginosa* showed 48% susceptibility to amikacin.

Unlike some other antibiotics (e.g. β -lactams), aminoglycosides have concentration-dependent bactericidal effects against many pathogens; higher serum concentrations are associated with increased bactericidal effects. The drugs also exhibit a prolonged, concentration-dependent postantibiotic effect (PAE) against a variety of Gram-negative and Gram-positive pathogens.⁷² To effectively kill Gram-negative bacteria, these antibiotics must reach a peak level that is 5–8 times the MIC of the bacterial isolate.

These antibiotics have a narrow therapeutic blood serum range that must be closely monitored to achieve efficacy. However, toxic peak serum levels may result in ototoxicity and toxic trough levels may result in nephrotoxicity especially when used in conjunction with other ototoxic and nephrotoxic medications such as amphotericin, furosemide, and vancomycin.

Current evidence suggests that once-daily dosing of aminoglycosides is as effective as, and may be less toxic than, conventional dosage regimens employing multiple daily doses of the drug. Results of several analyses of pooled data from randomized, controlled studies in adults found that once-daily administration of aminoglycosides was associated with similar or greater efficacy (e.g. bacteriologic and/or clinical cure), less nephrotoxicity, and no greater risk of ototoxicity compared with administration of multiple daily dosing of these drugs.⁷² Less frequent (e.g. once-daily) dosing may minimize or prevent the occurrence of aminoglycoside-induced adaptive resistance (i.e. reversible refractoriness to the antimicrobial effects of subsequent aminoglycoside doses because of decreased uptake of the drug following the initial dose) and selection of aminoglycoside-resistant subpopulations in Gram-negative bacteria by allowing a recovery period during the dosing interval in which serum aminoglycoside concentrations are negligible.⁷² However, some clinicians have suggested that use of once-daily dosing of aminoglycosides may not be advisable in patients with serious infections and impaired host defenses (e.g. *P. aeruginosa* infections in patients with neutropenia) and/or clinical conditions associated with rapid clearance or unpredictable pharmacokinetics of aminoglycosides (e.g. extensive burns, cystic fibrosis, massive ascites) since these regimens could allow prolonged intervals of undetectable aminoglycoside concentrations that could outlast the PAE. Most clinicians, therefore, recommend monitoring of aminoglycoside serum concentrations and/or peak serum concentrations/

MIC ratio in burn patients with life-threatening infections, suspected toxicity or nonresponse to treatment, decreased or varying renal function, and increased aminoglycoside clearance.

Blood specimens for peak serum concentrations should be obtained approximately 1 hour following IM administration and 30 minutes after the completion of a 30-minute IV infusion or at the completion of a 1-hour IV infusion. Blood specimens for trough drug concentrations should be obtained immediately prior to the next IM or IV dose. For gentamicin and tobramycin, a commonly defined therapeutic range of serum concentrations is represented by peak serum aminoglycoside concentrations of approximately 4–12 $\mu\text{g}/\text{mL}$, and trough concentrations of less than 2 $\mu\text{g}/\text{mL}$; peak and trough serum concentrations of 15–40 and less than 5–10 $\mu\text{g}/\text{mL}$, respectively, have been suggested for amikacin and kanamycin. The ratio of the peak serum aminoglycoside to the MIC of the pathogen also has been evaluated as an indicator of aminoglycoside bactericidal efficacy by which to adjust the aminoglycoside dosage and serum concentrations. Limited data in patients receiving multiple daily doses of aminoglycosides have suggested an association between clinical response and a peak (i.e. 1-hour post-infusion) serum concentration/MIC ratio up to 12. When MIC data are unavailable for patients receiving once-daily aminoglycoside dosing regimens, some clinicians have used a high target peak serum concentration (e.g. 20 $\mu\text{g}/\text{mL}$ for gentamicin or tobramycin) to ensure optimal peak/MIC ratios.⁷²

Extended-spectrum penicillins

The advent of the extended-spectrum penicillins, and their reputed synergistic effect with aminoglycosides, brought a new era of antibiotic therapy in the treatment of burn infections. The extended-spectrum penicillins which consist of carbenicillin, mezlocillin, piperacillin and ticarcillin are a group of semi-synthetic penicillin antibiotics that, because of their chemical structure, have a wider spectra of activity than natural penicillins, penicillinase-resistant penicillins (e.g. nafcillin), and aminopenicillins (e.g. ampicillin). They are more active against Gram-negative bacteria because they are more resistant to inactivation by extended-spectrum β -lactamases (ESBLs) which are produced by Gram-negative bacteria and/or because they more readily penetrate the outer membranes of these Gram-negative organisms.

Extended-spectrum penicillins reportedly vary in their rates of bactericidal action and in the completeness of this effect. This appears to result partly from differences in drug-induced morphologic effects on susceptible bacteria and subsequent formation of bacterial variants with varying degrees of osmotic stability. For example, mezlocillin or piperacillin may be more effective in the treatment of some infections caused by Gram-negative bacteria, such as some strains of *Citrobacter*, *Enterobacter*, *Klebsiella*, *Serratia*, and *B. fragilis* that are resistant to carbenicillin and/or ticarcillin. Some clinicians suggest that α -carboxypenicillins (e.g. ticarcillin) are the preferred extended-spectrum penicillins for general use and that acylaminopenicillins (mezlocillin, piperacillin) should be reserved for the treatment of infections, especially, *P. aeruginosa* infections that are resistant to α -carboxypenicillins. Some clinicians further suggest that, when an extended-spectrum

penicillin is indicated, mezlocillin or piperacillin may be preferred for the treatment of infections caused by Enterobacteriaceae and that piperacillin may be preferred for the treatment of infections caused by *P. aeruginosa* because this drug is more active *in vitro* on a weight basis against these organisms than other commercially available extended-spectrum penicillins.⁷² Because resistant strains of some organisms, especially *P. aeruginosa*, have developed during therapy with these antibiotics, appropriate specimens should be obtained periodically during therapy with the drugs to monitor effectiveness and detect emergence of resistant organisms.

In certain severe infections (e.g. sepsis) when the causative organism is unknown or *P. aeruginosa* is suspected, some clinicians recommend that concomitant therapy with an aminoglycoside or third-generation cephalosporin be used pending results of *in vitro* susceptibility tests. Synergistic effects between extended-spectrum antibiotics and aminoglycosides or third-generation cephalosporins are generally unpredictable and should be confirmed with appropriate *in vitro* studies.

Whenever an aminoglycoside is administered in conjunction with extended-spectrum penicillins, *in vivo* mixing of the drugs in syringes or IV infusion containers should be avoided since *in vitro* studies indicate that β -lactam antibiotics, including extended-spectrum penicillins may inactivate aminoglycosides. In addition, because *in vivo* inactivation of aminoglycosides may also occur, some clinicians suggest that it may be advisable to monitor serum aminoglycoside concentrations more closely than usual in patients receiving concomitant therapy, especially when high doses of extended-spectrum penicillins are administered or when the patient has impaired renal function. In addition, because acylaminopenicillins contain less than half the sodium content of α -carboxypenicillins, piperacillin or mezlocillin may be preferred to ticarcillin in patients whose sodium intake is restricted.

The combination of ticarcillin with clavulanic acid, and piperacillin with tazobactam, two β -lactamase inhibitors, results in a synergistic bactericidal effect against many strains of β -lactamase-producing bacteria. Clavulanic acid and tazobactam have a high affinity for and irreversibly bind to certain lactamases which can inactivate the extended-spectrum penicillins, ticarcillin and piperacillin, respectively. In 2005 at SBH-G, *E. cloacae* showed 75% susceptibility, *E. coli* showed 90% susceptibility, *K. pneumoniae* showed 84% susceptibility and *P. aeruginosa* showed 69% susceptibility to piperacillin/tazobactam. During the same period at SBH-G, *A. baumannii/haemolyticus* showed 36% susceptibility, *E. cloacae* showed 62% susceptibility, *E. coli* showed 72% susceptibility, *K. pneumoniae* showed 84% susceptibility, and *P. aeruginosa* showed 39% susceptibility to ticarcillin/clavulanate.

The usage of extended-spectrum penicillin in the treatment of Gram-negative bacterial infections provide a burn population with a much less toxic antibiotic when compared to the aminoglycosides since the most frequent adverse reactions include hypersensitivity reactions, gastrointestinal effects, and local reactions.

Third- and fourth-generation cephalosporins

Cephalosporins are semisynthetic β -lactam antibiotics that are structurally and pharmacologically related to penicillins, carbacephem (e.g. loracarbef), and cephamycins (e.g. cefotetan,

cefoxitin). Cephalosporins are usually bactericidal in action. The antibacterial activity of the cephalosporins, like penicillins, carbacephems, and cephamycins, results from inhibition of mucopeptide synthesis in the bacterial cell wall. Although the exact mechanism of action of cephalosporins has not been fully elucidated, β -lactam antibiotics bind to several enzymes in the bacterial cytoplasmic membrane (e.g. carboxypeptidases, endopeptidases, transpeptidases) that are involved in cell-wall synthesis and cell division. It has been hypothesized that β -lactam antibiotics act as substrate analogs of acyl-D-alanyl-D-alanine, the usual substrate for these enzymes. This interferes with cell-wall synthesis and results in the formation of defective cell walls and osmotically unstable spheroblasts. Cell death following exposure to β -lactam antibiotics usually results in lyses, which appears to be mediated by bacterial autolysins such as peptidoglycan hydrolases.⁷²

The target enzymes of β -lactam antibiotics have been classified as penicillin-binding proteins (PBPs) and appear to vary substantially among bactericidal species. The affinities of various β -lactam antibiotics for different PBPs appear to explain the differences in morphology that occur in susceptible organisms following exposure to different β -lactam antibiotics and may also explain difference in the spectrum of activity of β -lactam antibiotics that are not caused by the presence or absence of ESBLs.

Cephalosporins generally are divided into four groups ('generations') based on their spectra of activity. In this section on the treatment of Gram-negative infections, we will discuss the third- and fourth-generation cephalosporins based on their expanded spectrum against Gram-negative bacteria as compared with the first- and second-generation drugs.

The third-generation cephalosporins include cefdinir, cefditoren, cefixime, cefoperazone, cefotaxime, cefpodoxime, ceftazidime, ceftibuten, ceftizoxime, and ceftriaxone. Third-generation cephalosporins generally are active *in vitro* against Gram-negative bacteria *Citrobacter*, *Enterobacter*, *E. coli*, *Klebsiella*, *Neisseria*, *Proteus*, *Morganella*, *Providencia*, and *Serratia* that may be resistant to first- and second-generation cephalosporins. Cefotaxime, ceftazidime, ceftizoxime, and ceftriaxone are reported to be the drugs of choice for the treatment of infections caused by susceptible Enterobacteriaceae, including susceptible strains of *E. coli*, *K. pneumoniae*, *P. rettgeri*, *M. morgani*, *P. vulgaris*, or *P. stuartii* and are alternatives for the treatment of susceptible *Serratia*. Ceftazidime (but not cefotaxime, ceftizoxime, or ceftriaxone) is reported to be a drug of choice for the treatment of infections caused by susceptible *P. aeruginosa*. Ceftazidime is more active *in vitro* on a weight basis against *P. aeruginosa* than most other currently available cephalosporins and is active against many strains resistant to many other cephalosporins. In 2005 at SBH-G, *A. baumannii/haemolyticus* showed 30% susceptibility, *E. cloacae* showed 58% susceptibility, *E. coli* showed 78% susceptibility, *K. pneumoniae* showed 78% susceptibility, and *P. aeruginosa* showed 51% susceptibility to ceftazidime.

However, ESBLs pose a particularly acute threat because they are found in common nosocomial pathogens such as *E. coli*, *K. pneumoniae*, and *Enterobacter* species. Before the advent of ESBLs, most of these infections could be confidently treated with third-generation cephalosporins. These enzymes are genetically derived from several progenitor enzymes,

particularly TEM and SHV β -lactamases. The use and overuse of third-generation cephalosporins have selected for ESBL-producing bacterial strains in hospitalized patients. This may have important therapeutic and epidemiological consequences. The detection of ESBLs has posed a problem for clinical microbiological laboratories; *in vitro* test results that indicate susceptibility to third-generation cephalosporins are sometimes inconsistent with clinical outcomes. New tests and new technology designed to increase the accuracy of ESBL detection have recently been introduced. These available tests are used to screen and confirm the presence of ESBL production and for distinguishing ESBLs from other β -lactamases, particularly the chromosome-mediated AmpC β -lactamases that have a phenotype similar to that of ESBLs.⁷⁵ Overall the clinical data indicate that treatment failures associated with the use of third-generation cephalosporins occur most frequently with ceftazidime. Because ESBL coding sequences are plasmid borne, they easily disseminate to other bacterial species. Effective measures to confine this highly transmissible trait promote the use of cefepime, a fourth-generation cephalosporin, β -lactam/ β -lactamase inhibitors and carbapenems, while concurrently restricting the use of third-generation cephalosporins.⁷⁵

Fourth-generation cephalosporins, which include cefepime, are active *in vitro* against some Gram-negative bacteria, including *Pseudomonas* and certain Enterobacteriaceae, that generally are resistant to third-generation cephalosporins. Cefepime has a spectrum of activity against aerobic Gram-positive and Gram-negative bacteria that is similar to that of cefotaxime, ceftriaxone, and ceftizoxime and has activity against *P. aeruginosa* that appears to approach that of ceftazidime. More importantly, cefepime is more active than third-generation cephalosporins against Enterobacteriaceae that produce inducible β -lactamases.⁷⁵ The extended spectrum of activity of cefepime is related to the fact that the drug penetrates the outer membrane of Gram-negative bacteria more rapidly and is more resistant to inactivation by chromosomally and plasmid-mediated β -lactamases than most other cephalosporins. In addition, inducible β -lactamases have a low affinity for cefepime and the drug is hydrolyzed by these enzymes at a slower rate than third-generation cephalosporins such as ceftazidime.⁷⁵ In 2005 at SBH-G, *A. baumannii/haemolyticus* showed 39% susceptibility, *E. cloacae* showed 86% susceptibility, *E. coli* showed 84% susceptibility, *K. pneumoniae* showed 80% susceptibility, and *P. aeruginosa* showed 36% susceptibility to cefepime.

Miscellaneous β -lactam antibiotics

Aztreonam is termed a synthetic monobactam antibiotic because unlike other β -lactam antibiotics which are bicyclic, it is a monocyclic β -lactam antibiotic. The antibacterial activity of aztreonam results not only from inhibition of mucopeptide synthesis in the bacterial cell wall, but in addition, aztreonam has a high affinity and preferentially binds to penicillin-binding protein 3 (PBP 3) of susceptible Gram-negative bacteria. The drug also has some affinity for PBP 1a of these bacteria, but little or no affinity for PBPs 1b, 2, 4, 5, or 6.⁷² Because PBP 3 is involved in septation, aztreonam causes the formation of abnormally elongated or filamentous forms in

susceptible Gram-negative bacteria. As a consequence cell division is inhibited and breakage of the cell wall occurs resulting in lyses and death.⁷² Studies using *S. aureus* indicate that aztreonam does not bind to the essential PBPs of Gram-positive bacteria. Aztreonam also has poor affinity for the PBPs of anaerobic bacteria. The drug, therefore, is generally inactive against these organisms.

Aztreonam usually is bactericidal in action. Since aztreonam has a poor affinity for PBPs 1a and 1b of susceptible Gram-negative bacteria, it is not as rapidly bactericidal as some other β -lactam antibiotics (e.g. imipenem, cefotaxime, ceftoxitin, ceftriaxone) against these organisms. For most susceptible Enterobacteriaceae, the minimum bactericidal concentration (MBC) of aztreonam is equal to or only 2–4 times higher than the minimum inhibitory concentration (MIC) of the drug.⁷² For *P. aeruginosa*, the MBC of aztreonam is usually only two times higher than the MIC, but may be up to 125 times higher than the MIC for some strains of the organism.⁷² In 2005 at SBH-G, *A. baumannii/haemolyticus* showed 21% susceptibility, *E. cloacae* showed 57% susceptibility, *E. coli* showed 80% susceptibility, *K. pneumoniae* showed 78% susceptibility, and *P. aeruginosa* showed 55% susceptibility to aztreonam.

Adverse effects reported with aztreonam are similar to those reported with other β -lactam antibiotics and the drug is generally well tolerated.

Imipenem/cilastatin sodium is a fixed combination of imipenem monohydrate (a semisynthetic carbapenem β -lactam antibiotic) and cilastatin sodium, which prevents renal metabolism of imipenem by a specific and reversible inhibitor of dehydropeptidase I which inactivates imipenem by hydrolyzing the β -lactam ring.

Imipenem usually is bactericidal in action. Imipenem has an affinity for and binds to most penicillin-binding proteins (PBPs) of susceptible organisms, including PBPs 1a, 1b, 2, 4, 5, and 6 of *Escherichia coli*; PBPs 1a, 1b, 2, 4, and 5 of *Pseudomonas aeruginosa*, and PBPs 1, 2, 3, and 4 of *Staphylococcus aureus*.⁷² In susceptible Gram-negative bacteria, imipenem has the highest affinity for PBP 2 and the lowest affinity of PBP 3.⁷² This results in the formation of spheroblasts or ellipsoidal cells without filament formation. Because imipenem also has a high affinity for PBPs 1a and 1b, for these organisms the spheroblasts lyse rapidly. Imipenem is able to penetrate the outer membrane of most Gram-negative bacteria and gain access to the PBPs more readily than many other currently available β -lactam antibiotics.⁷²

In vitro studies also indicate that imipenem may have a post-antibiotic inhibitory effect against some susceptible organisms, although the mechanism of this PAE has not been determined to date, *in vitro* studies using *S. aureus*, *E. coli*, and *P. aeruginosa* indicate that following exposure to bactericidal concentrations of imipenem these organisms do not immediately resume growth after the drug is removed.⁷² It is not known whether a PAE occurs *in vivo*. It has been suggested that this effect would be beneficial since imipenem may be able to prevent regrowth of susceptible organisms when drug concentrations at the site of infection fall below the MIC during a dosing interval. In 2005 at SBH-G, *A. baumannii/haemolyticus* showed 97% susceptibility, *E.*

cloacae showed 96% susceptibility, *E. coli* showed 98% susceptibility, *K. pneumoniae* showed 94% susceptibility, and *P. aeruginosa* showed 36% susceptibility to imipenem/cilastatin.

Meropenem is also a synthetic carbapenem antibiotic. Unlike imipenem, meropenem has a methyl group at position 1 of the 5-membered ring which confers stability against hydrolysis by dehydropeptidase I (DHP I) present on the brush border of proximal renal tubular cells and therefore does not require concomitant administration with a DHP I inhibitor such as cilastatin.⁷²

Meropenem has a broad spectrum of activity that resembles the microbiologic activity of imipenem; however, meropenem generally is more active *in vitro* against Enterobacteriaceae and less active against Gram-positive bacteria. Meropenem appears to be susceptible to hydrolysis by metallo- β -lactamases.⁷² The drug generally is inactive against methicillin-resistant staphylococci. Like imipenem, meropenem also is highly resistant to hydrolysis by a variety of β -lactamases.⁷²

In vitro studies indicate that imipenem may be a potent inducer of β -lactamases and can reversibly derepress inducible, chromosomally mediated β -lactamases in *P. aeruginosa* and Enterobacteriaceae.⁷²

Adverse effects with imipenem/cilastatin and meropenem are similar to those reported with other β -lactam antibiotics and the drugs are generally well tolerated although adverse nervous system effects, including seizures and myoclonus, have been reported with IV imipenem/cilastatin.

Quinolones

The quinolones class of antibiotics includes IV antibiotics ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, ofloxacin and alatrofloxacin and oral antibiotics ciprofloxacin, gatifloxacin, levofloxacin, lomefloxacin, moxifloxacin, nalidixic acid, ofloxacin, sparfloxacin, and trofloxacin. Quinolones are usually bactericidal in action and act by inhibiting DNA topoisomerase (ATP-hydrolyzing), a type II DNA topoisomerase commonly referred to as DNA-gyrase, in susceptible organisms. DNA gyrase is necessary for bacterial DNA replication and some aspects of transcription, repair, recombination, and transposition. Inhibition of DNA-gyrase in susceptible organisms results in inhibition of ATP-dependent negative supercoiling of DNA, inhibition or ATP-independent relaxation of supercoiled DNA, and promotion of double-stranded DNA breakage.⁷² Mammalian cells contain a type II topoisomerase similar to that contained in bacteria. At concentrations attained during therapy, quinolones do not appear to affect the mammalian enzyme, presumably because it functions differently than bacterial DNA-gyrase and does not cause supercoiling of DNA. Although the clinical importance has not been determined, ciprofloxacin appears to have a postantibiotic effect.⁷² In 2005 at SBH-G, *A. baumannii/haemolyticus* showed 27% and 27% susceptibility, *E. cloacae* showed 92% and 89% susceptibility, *E. coli* showed 70% and 70% susceptibility, *K. pneumoniae* showed 90% and 90% susceptibility, and *P. aeruginosa* showed 36% and 36% susceptibility to levofloxacin and ciprofloxacin, respectively.

Fluoroquinolones are well absorbed orally. IV therapy with these drugs is generally reserved for patients who do not toler-

ate or are unable to take the drug orally and for other patients in whom the IV route offers a clinical advantage.

Polymyxins

The polymyxins are amphipathic molecules that interact with the lipopolysaccharide (LPS) in the bacterial outer membrane. Entry into the cell is not necessary, since polymyxin B covalently attached to agarose beads retains the ability to alter membrane permeability and inhibit bacterial respiration. Initial binding to the outer membrane takes place when the polycationic portion of polymyxin B displaces Ca^{++} and Mg^{++} bridges that normally stabilize LPS molecules in the outer leaflet of the bacterial outer membrane.⁷⁷ Binding can be antagonized by high concentrations of divalent cations. Additional complexing with LPS is facilitated by hydrophobic interaction between the lipid A portion of LPS and the fatty acid of the antibiotic. Insertion of the antibiotic into the outer membrane disrupts the membrane and releases LPS into the surrounding milieu. They also have potent antiendotoxic properties and antibacterial activity against *P. aeruginosa* and many of the Enterobacteriaceae.

According to Storm et al., the polymyxins are bacteriostatic at low concentrations and bactericidal at high concentrations. Nord and Hoeprich reported that at a concentration of 0.01 $\mu\text{mol/mL}$, polymyxin B sulfate was bactericidal to 88% of the *P. aeruginosa* strains tested.⁷⁷ Bactericidal activity against *P. aeruginosa* is not seen with colistin until its concentration reaches 0.1 $\mu\text{mol/mL}$.⁷⁷ Polymyxin B and colistin (polymyxin E) are usually given at doses of 1.5–2.5 and 5 mg/kg/day, respectively, in two divided doses. Dosing must be altered in renal failure since the kidney is the primary route of elimination. Distribution into pleural fluid, joints, and cerebrospinal fluid is poor.

Polymyxins are recommended for serious systemic infections caused by Gram-negative bacteria that are resistant to other agents and have a definite role in therapy of multi-drug-resistant Gram-negative bacterial infections. The pediatric burn hospital, Shriners Burns Hospital in Galveston, Texas reviewed the use of colistimethate sodium from 2000–2004 in 109 patients, 72 males and 37 females (median and mean age of 9 years) with a TBSA from 21% to 99% (median 60% and mean 62%). The overall survival rate was 80% in all 109 patients. Colistimethate sodium provided an important salvage option for burn patients with otherwise incompletely treated and life-threatening Gram-negative infections. In 2005 at SBH-G, *A. baumannii/haemolyticus*, *E. cloacae*, *E. coli*, and *K. pneumoniae* all showed 100% susceptibility to colistin and polymyxin B while *P. aeruginosa* showed 96% and 99% susceptibility to colistin and polymyxin B, respectively.

However, monitoring the dose-dependent nephrotoxicity and CNS toxicity associated with its systemic use is necessary to achieve a therapeutic outcome. When polymyxin B is given to animals or humans, it binds, via its free amino acid groups, to negatively charged phospholipids in tissues. Kunin and Bugg showed that binding is greatest to kidney and brain tissues, followed by liver, muscle, and lung tissues.⁷⁷ After repeated doses, the drug accumulates in tissues to concentrations four to five times higher than peak serum concentrations and persists in tissues for at least 5–7 days.⁷⁷ Removal of the

drug by dialysis can be difficult due to extensive tissue binding. In our study, colistimethate sodium appears to proportionately increase the incidence of *C. difficile*-associated colitis, renal dysfunction, and neuropathies in relation to the length of its use.

Treatment of yeast and fungal infections

The five classes of systemic antifungal medications comprise the polyenes, the azoles, a nucleoside analog, an echinocandin, and an allylamine. Thus there are four potential target sites in the fungal cell for the antifungal drugs to act. The allylamine antifungal, terbinafine, which is used primarily for management of dermatophytosis and onychomycosis, and ketoconazole, which has been replaced by newer, less-toxic triazole drugs, will not be discussed.

Polyenes (amphotericin B)

Amphotericin B, an amphoteric polyene macrolide, is an antifungal antibiotic. Conventional IV amphotericin B is used for the treatment of potentially life-threatening fungal infections including aspergillosis, North American blastomycosis, systemic candidiasis, coccidioidomycosis, cryptococcosis, histoplasmosis, paracoccidioidomycosis, sporotrichosis, and zygomycosis.⁷²

Amphotericin B usually is fungistatic in action at concentrations obtained clinically, but may be fungicidal in high concentrations or against very susceptible organisms. Amphotericin B exerts its antifungal activity principally by binding to sterols (e.g. ergosterol) in the fungal cell membrane. As a result of this binding, the cell membrane is no longer able to function as a selective barrier and leakage of intracellular contents occurs. Cell death occurs in part as a result of permeability changes, but other mechanisms also may contribute to the *in vivo* antifungal effects of amphotericin B against some fungi.⁷² Amphotericin B is not active *in vitro* against organisms that do not contain sterols in their cell membranes (e.g. bacteria).

Binding to sterols in mammalian cells (such as certain kidney cells and erythrocytes) may account for some of the toxicities reported with conventional amphotericin B therapy. Nephrotoxicity is the major dose-limiting toxicity reported with conventional IV amphotericin B, and nephrotoxicity occurs to some degree in the majority of patients receiving the drug. Adverse renal effects include decreased renal function and renal function abnormalities such as azotemia, hypokalemia, hyposthenuria, renal tubular acidosis, and nephrocalcinosis.⁷² Increased BUN and serum creatinine concentrations and decreased creatinine clearance, glomerular filtration rate, and renal plasma flow occur in most patients receiving conventional IV amphotericin.

Increased BUN and/or serum creatinine, hypokalemia, hypomagnesemia, and hypocalcemia also have been reported in patients receiving the amphotericin B cholesteryl sulfate complex, amphotericin B lipid complex, or amphotericin liposomal. While these formulations appear to be associated with a lower risk of nephrotoxicity than conventional IV amphotericin B and have been used in patients with preexisting renal impairment (in most cases resulting from prior therapy with conventional IV amphotericin B), additional experience with these drugs is necessary to more accurately

determine the extent of nephrotoxicity that occurs with these formulations.⁷²

Acute infusion reactions consisting of fever, shaking, chills, hypotension, anorexia, nausea, vomiting, headache, dyspnea, and tachypnea may occur 1–3 hours after initiation of IV infusions of conventional IV amphotericin B or other formulations such as amphotericin B cholesteryl sulfate, amphotericin B lipid complex, and amphotericin B liposomal. Acetaminophen, meperidine, antihistamines (e.g. diphenhydramine), or corticosteroids have been used for the treatment or prevention of these acute infusion reactions.

Azole antifungals

The azole antifungals consist of the triazole antifungal oral and intravenous drugs, fluconazole, itraconazole, and voriconazole, and the imidazole oral drug ketoconazole. These antifungal agents act by interfering with cytochrome P450 activity, decreasing ergosterol synthesis (the principal sterol in the fungal cell membrane), and inhibiting cell membrane formation.⁷⁶

The three triazole antifungal drugs can be distinguished by differences in their spectrum of activity. Fluconazole is generally active *in vitro* against *Candida albicans*, many of the non-*albicans Candida* species, and *C. neoformans*. However it is not generally active against *Candida krusei* or *Aspergillus* species.⁷⁶ Itraconazole also has excellent anti-*Candida* activity, is more effective *in vitro* than fluconazole against the endemic fungi, *Histoplasma capsulatum*, *Sporothrix schenckii*, and *Blastomyces dermatitidis* and has fungistatic activity against *Aspergillus*.⁷⁶ Voriconazole has up to 60-fold lower MIC for *Candida* species (including resistant strains) than fluconazole, is fungicidal for *Aspergillus* and has some activity against *Fusarium* species and *Scedosporium apiospermum*.⁷⁶ None of the triazoles are active against the *Zygomycetes*.

A recently published study compared the *in vitro* activity of the three available triazoles against several thousand *Candida* isolates, most of which were obtained from blood or other normally sterile sites. Of note, fluconazole-resistant species were susceptible to voriconazole. Whereas only 5% of *C. krusei* were susceptible to fluconazole, 99% were susceptible to voriconazole.⁷⁶ *Candida glabrata*, which has emerged as one of the most common clinical isolates in patients with candidiasis, was susceptible to fluconazole in 60% of the cases and to voriconazole in 92%.⁷⁶ Voriconazole also had activity against fluconazole-resistant *C. albicans* isolates with the RS phenotype.⁷⁶ Thus voriconazole was a treatment option for infection with some *Candida* species that are resistant to fluconazole.

In general, the azole drugs are better tolerated than the amphotericin B formulations. Side effects of fluconazole, which are uncommon, include rash and elevations in liver function test results. In patients who receive prolonged courses of high-dose therapy, reversible alopecia and dry lips can occur. Potential side effects of itraconazole include peripheral edema, exacerbation of congestive heart failure (caused by a negative inotropic effect), hypokalemia, or rash.⁷⁶ Reported toxicities of voriconazole include elevations in liver function test results, rash, photosensitivity, and transient ocular toxicity, a unique phenomenon that has been studied extensively. The following visual disturbances have been described: blurred vision, pho-

tophobia, altered color vision, and perception of increased brightness of light. Up to one-third of patients treated with voriconazole have describes such visual disturbances, which typically occur early in the course of therapy, begin 15–30 minutes after a dose, and resolve within 30 minutes.⁷⁶ No histopathologic changes have been seen in the retinas of treated patients, and there have been no permanent sequelae of voriconazole-induced visual disturbances.⁷⁶

Because these azole drugs are metabolized by the hepatic cytochrome P450 system, a variety of interactions can occur between these agents and other medications. The azoles inhibit the metabolism of the sulfonyleureas, warfarin, digoxin, phenytoin, cyclosporine, sirolimus, tacrolimus, omeprazole, and cisapride, resulting in increased serum concentrations of these medications and the potential for drug toxicity. Conversely, serum concentrations of the triazoles are decreased by rifampin, isoniazid, phenytoin, and fosphenytoin, as well as carbamazepine.⁷³

Echinocandin antifungals

Caspofungin, an echinocandin antifungal, inhibits formation of β 1, 3 glucan of the fungal cell wall. Caspofungin is effective *in vitro* against *Candida* species, including azole-resistant isolates, and *Aspergillus* species.

Caspofungin therapy is usually well tolerated. Rash or GI toxicity occurs rarely. There are relatively few drug–drug interactions with caspofungin, which is neither an inducer nor an inhibitor of the cytochrome P450 system. Caspofungin does reduce the AUC and peak serum concentrations of tacrolimus by 20–25%, so tacrolimus serum concentrations should be monitored in patients taking caspofungin.⁷⁶ Cyclosporin increases the AUC of caspofungin by 35%.⁷⁶ It is suggested that caspofungin and cyclosporine not be coadministered.

Nucleoside analog antifungal (Flucytosine)

Flucytosine, the only available nucleoside analog, acts as an antifungal by disrupting pyrimidine metabolism in the fungal cell nucleus. Flucytosine is fungicidal *in vitro* against *Candida* species and *C. neoformans* but not against other commonly encountered fungi. Unfortunately, resistance emerges rapidly during flucytosine monotherapy, so use of this drug is limited to combination therapy.⁷⁶

Flucytosine can cause bone marrow suppression and GI toxicity, although these side effects are seen less frequently with the current recommended dosage (100mg/kg/day in 4 divided doses) than with the higher dosage that was used for many years (150mg/kg/day in 4 divided doses). Flucytosine does not have any significant drug interactions.

Treatment of systemic viral infections in burn patients

Burn centers are testing for and finding more viral infections in burn patients. Linneman³⁸ found that in the pediatric burn population that he was studying prospectively, 33% of the children developed cytomegalovirus infections, 25% developed herpetic infections, and 17% developed adenovirus infections. In this section, we will only deal with the treatment of systemic CMV infections and mucocutaneous HSV infections.

Treatment of cytomegalovirus (CMV) infections

IV ganciclovir (Cytovene®) and oral valganciclovir (Valcyte®) are the agents that are effective in the treatment of cytomegalovirus infections. Valganciclovir is the L-valine ester of ganciclovir that allows for oral systemic absorption of this drug. Ganciclovir and valganciclovir exert their antiviral effect on human cytomegalovirus and the other human herpesviruses by interfering with DNA synthesis via competition with deoxyguanosine for incorporation into viral DNA and by being incorporated into growing viral DNA chains.⁷² In addition to its activity against CMV, ganciclovir also has shown activity against herpes simplex virus types 1 and 2 (HSV-1 and HSV-2), human herpesvirus type 6 (the presumed causative agent of roseola), Epstein–Barr virus (EBV), and varicella-zoster virus (VZV).

The initial dose of ganciclovir is 10mg/kg/day divided every 12 hours for 14–21 days. The patient may be converted to the oral valganciclovir at a dose of 900mg orally twice daily to complete the recommended treatment regimen.⁷³

The most common adverse effects of ganciclovir are hematologic reactions that may be severe. Neutropenia (absolute neutrophil count less than 1000/mm³), which is potentially fatal, occurs in up to 25–50% of patients receiving ganciclovir and is the most common dose-limiting adverse effect of this drug.⁷² Adverse nervous system effects have been seen in 5–17% of patients and ranged in severity from headache to seizures or coma.⁷² Abnormal liver function test results (e.g. elevated aminotransferase and alkaline phosphatase concentrations) have been reported in 2–3% of patients receiving ganciclovir. Nausea and vomiting have been reported in up to 2% of patients receiving ganciclovir and diarrhea, anorexia, GI hemorrhage, and abdominal pain have been reported less frequently. Inflammation, phlebitis, and/or pain at the site of IV infusion occur commonly during ganciclovir therapy. Therefore it is recommended that veins with adequate blood flow be used to allow for rapid dilution and distribution of the drug.⁷²

Treatment of herpes infections

Acyclovir sodium IV (Zovirax®) is used for the treatment of initial and recurrent mucocutaneous herpes simplex virus (HSV-1 and HSV-2) infections and the treatment of varicella-zoster infections in immunocompromised adults and children. It is also used for the treatment of HSV encephalitis and neonatal HSV infections. Acyclovir is used orally for the treatment of initial and recurrent episodes of genital herpes. It is also used for the acute treatment of herpes zoster (shingles, zoster) and varicella (chickenpox) in immunocompetent individuals.

For the treatment of mucocutaneous HSV infections in immunocompromised adults and children 12 years of age or older with normal renal function, the recommended dose is 5 mg/kg/dose every 8 hours for 7–14 days; in children younger than 12 years of age, the manufacturer recommends a dosage of 10mg/kg every 8 hours for 7 days.⁷³

Adverse reactions generally have been minimal following oral or IV administration of acyclovir. However, potentially serious reactions (e.g. renal failure, thrombotic thrombocytopenic/hemolytic uremic syndrome) can occur and fatalities have been reported.⁷²

The use of topical antimicrobial compounds and agents

One of the most effective means to achieve a microbial balance in a colonized or infected wound is the proper use of prophylactic topical agents. Maintaining wounds at low colonization levels diminishes the frequency and duration of septic episodes caused by wound flora.²¹ The introduction of topical antimicrobial agents has resulted in a significant reduction in burn mortality to date.^{78,79} Recent studies have demonstrated that some agents used in the past are no longer effective in inhibiting bacterial growth *in vitro*.⁸⁰ Wounds in which the quantitative culture counts remain less than 10² organisms/gram tissue may remain dressed in the topical agent of choice. However, should the colony count show an increase beyond that point, a change in the topical agent is strongly recommended.

Sodium hypochlorite (NaOCl)

Currently the most effective topical antibacterial for cleansing a wound is sodium hypochlorite (NaOCl).⁸¹ It transcends the topical antimicrobial effects and tissue toxicity of such products such as povidone-iodine, acetic acid, and hydrogen peroxide.²⁹ While povidone-iodine is bactericidal at 1% and 0.5% concentrations, it is toxic to fibroblasts; acetic acid at a 0.25% concentration is not bactericidal and is toxic to fibroblasts; and hydrogen peroxide at 3% and 0.3% concentrations is toxic to fibroblasts but only the 3% concentration is bactericidal.^{8,81}

Studies by Heggers and his co-workers⁸² reported on the efficacy of NaOCl at a concentration of 0.025%. NaOCl 0.025% solution is one-tenth the concentration of 'Half-Strength Dakins,' the formulation that is used by many hospitals as a topical antimicrobial agent. Buffered NaOCl 0.25% was formulated to mimic normal human physiologic parameters. It is an excellent cleansing agent which was found to be bactericidal, nontoxic to fibroblasts, and did not inhibit wound healing. However, the NaOCl 0.025% solution is only effective over a 24-hour time frame after the buffer (0.3N NaH₂HPO₄) is added to the NaOCl.

Buffered NaOCl 0.025% solution soaks are most beneficial in reducing the bacterial numbers in a wound. NaOCl 0.025% solution is a broad-spectrum antiseptic and is bactericidal against *P. aeruginosa*, *S. aureus* microorganisms, as well as other Gram-negative and Gram-positive organisms.^{82,83} It is effective against MRSA, MRSE, and the enterococci. NaOCl 0.025% solution may be used separately or in concert with other antibacterial agents to control colonization or infection. NaOCl 0.025% solution also enhances wound healing and increases wound breaking strength when compared to mafenide acetate.⁸²

Silver nitrate (AgNO₃)

Silver nitrate was formerly used as a 10% solution but was found to be toxic at this concentration. It has now been reinstated as a 0.5% solution which is nontoxic, does not injure regenerating epithelium in the wound and is bacteriostatic against *S. aureus*, *E. coli*, and *P. aeruginosa* microorganisms. AgNO₃ is most effective when the wound is carefully cleansed

of all emollients and other debris, and debrided of all dead tissue. Multilayered coarse-mesh dressings should be placed over the wound and saturated with the AgNO₃ solution. Like silver sulfadiazine, AgNO₃ has limited penetration since the element silver is rapidly bound to the body's natural chemical substances, such as Cl⁻.^{25,78,79,84} Since it is hypotonic in nature, it can cause osmolar dilution, resulting in hyponatremia and hypochloremia. Serum electrolytes must be monitored very carefully.

AgNO₃ 0.5% solution is light-sensitive and turns black upon contact with tissues and other Cl⁻ containing compounds when it is allowed to dry out. Hyperpyrexia may also occur if AgNO₃ becomes dry and is covered with an impervious dressing.

Some institutions are combining silver nitrate with miconazole powder to produce a silver nitrate 0.5% and miconazole 2% aqueous solution that is effective in preventing fungal overgrowth in burn wounds treated with silver nitrate 0.5% solution alone.

Klebsiella species, the *Providencia* species, and other Enterobacteriaceae are not as susceptible to AgNO₃ 0.5% solution as other bacteria. The combination of AgNO₃ 0.5% solution with *E. cloacae* and other nitrate-positive organisms may cause methemoglobinemia by converting nitrate to nitrite in the body.^{25,78,79,84}

Silver sulfadiazine

Silver sulfadiazine (Silvadene®, Thermazene®, Flamazine®, SSD®), a 1% water-soluble cream, is a combination of sulfadiazine and silver. The silver ion binds with the DNA of the organism, consequently releasing the sulfonamide which interferes with the intermediary metabolic pathway of the microbe.^{5,85-87} It is most effective against *P. aeruginosa*, the enterics, and equally effective as any antifungal drug against *C. albicans* and *S. aureus*. However, some strains of the *Klebsiella* species have been less effectively controlled. Recently there have been reports of *P. aeruginosa* resistance to silver sulfadiazine.⁸⁸ Silver sulfadiazine can be applied with equal effectiveness using either the closed or open methods. Antimicrobial effectiveness has been observed to last for up to 24 hours. More frequent changes are required if a creamy exudate forms on the wound. Some of the benefits of this topical agent are its ease of use and its ability to reduce pain. It has some tissue-penetrating ability, but is limited to the surface epidermal layer.^{25,84} However, it is not associated with acid-base disturbances or pulmonary fluid overload, as is mafenide acetate.^{78,79} Silver sulfadiazine can be used separately or in combination with other antibacterials and with enzymatic escharotomy compounds. It can be combined with nystatin, which enhances the antifungal capability of this agent.

By itself, silver sulfadiazine has been shown to retard wound healing; however, in conjunction with nystatin or *Aloe vera*, the wound retardant effect is reversed. The breaking strength is not affected; in fact it may be enhanced when combinations are employed (unpublished data, 1994). An adverse drug reaction may be a reversible granulocyte reduction.^{25,78,79,84}

Mafenide acetate (Sulfamylon®)

Mafenide acetate is available both as an 8.5% water-soluble cream or a 5% aqueous solution. This agent has more

substantial bacteriological data to support its efficacy than any other topical antimicrobial. Mafenide acetate has been shown to be effective against a broad range of microorganisms, especially against all strains of *P. aeruginosa* and *Clostridium*.^{78,79,89}

After the wound has been cleansed of debris, mafenide acetate 8.5% cream is applied to the wound like 'butter' (Lindberg's butter). The treated burn surface is left exposed for maximal antimicrobial potency.^{78,79,89} The cream is applied a minimum of two times a day and reapplied between applications if rubbed off the wound. Advantages of the cream are its ability to control *P. aeruginosa* wound infections, ease of application, and the absence of the need for dressings. Additionally, it has the ability to penetrate burn eschar and circumvent the colonization of the burn.

The 5% solution is used to saturate an eight-ply gauze dressing and is applied to the burn wound area. The dressing should be kept saturated with the mafenide acetate 5% solution in order to produce maximal antimicrobial effects. The dressings may be changed every 8 hours. Mafenide acetate 5% solution is proclaimed to have effective tissue-penetrating ability and appears to be especially effective after the dead tissue is removed from the granulating bed.^{78,84,89,90}

However, there are several detrimental aspects to the use of mafenide acetate. Protracted use, with the low environmental pH, favors the growth of *C. albicans*. Mafenide acetate 5% solution is converted by monoamine oxidase to *p*-sulfamylvanzoic acid, a carbonic anhydrase inhibitor. Carbonic anhydrase inhibitors prevent the conversion of hydrogen ions in the body to carbonic acid, subsequently causing metabolic acidosis in the patient. If the patient has sustained an inhalation injury and developed a respiratory acidosis, the use of mafenide acetate over large areas of the body may produce a metabolic acidosis which can be fatal. This complication can also be seen when treatment with mafenide acetate occurs during septic episodes with metabolic acidosis or when applied over large areas of the body surface.^{78,79,89,91} Another detrimental problem encountered with mafenide acetate is that it is painful when applied to superficial partial-thickness burns with intact free nerve endings. The open application of mafenide acetate 8.5% cream to a burn wound site for increased antimicrobial activity may be considered a disadvantage if a burn wound dressing is necessary. However, it is quite effective in burn wound areas that are not well perfused such as the ear. The 5% aqueous solution of mafenide acetate can be used in a wet dressing covered by the splint.^{78,79,89,91}

Studies have reported that the use of mafenide acetate 5% solution in patients with major burns resulted in a 33% reduction of fatality.^{30,92} As with silver sulfadiazine, mafenide acetate can be used individually or in conjunction with other antimicrobials. However, mafenide acetate retards wound healing and reduces the breaking strength of healed wounds.²⁵

Povidone-iodine (Betadine®)

A 10% ointment of povidone-iodine was developed after the active agent demonstrated a broad spectrum of antimicrobial attributes in liquid form. Although its active antimicrobial component is iodine, there has been no documentation associ-

ated with intact skin hypersensitivity or toxic effects. It has a broad spectrum of antibacterial and antifungal activities.^{25,78,79,81,93,94} Povidone-iodine ointment can be employed effectively in both the closed and open techniques. Quantitative bacteriological assessments imply that iodine is most efficacious when it is administered every 6 hours. When it is used in this manner, it is effective in controlling and/or preventing bacterial colonization.

However, there are some adverse drug effects associated with the use of this topical antimicrobial at burn wound sites. The topical application of this agent is painful. Recent studies intimate that the iodine component of this topical agent may be absorbed more extensively in burn wound sites, resulting in iodine toxicity, renal failure, and acidosis. Concomitantly, it has been shown to be cytotoxic to fibroblasts as previously described.^{25,78,79,81,93,94} However, it remains a highly effective disinfectant when used on intact skin.

Gentamicin sulfate (Garamycin®)

Gentamicin sulfate is available as a 0.1% water-soluble cream and is chemically similar to other aminoglycosides, such as kanamycin and neomycin. It has a broad spectrum of antimicrobial activity. Its popular use in wounds was based on its antimicrobicidal efficacy against *P. aeruginosa*. However, gentamicin resistance has rapidly developed due to its widespread use as a topical antimicrobial agent.^{25,78,79,81,93,94}

Bacitracin/polymyxin (Polysporin®)

The topical antibiotics ointment bacitracin/polymyxin is used to 'butter' bolsters to prevent mechanical shearing of newly grafted tissue. However, this topical ointment barrier used after a grafting procedure has not been shown to be effective in controlling infection. Many surgeons rely on this topical agent for skin graft coverage because it is nontoxic and is similar to petrolatum gauze dressings, which were previously considered as a dressing for grafts. These two combined antibiotics have little or no effect on localized burn wound infections⁹⁵ (Table 12.6).

Nitrofurazone (Furacin®)

The topical antimicrobial nitrofurantoin was used in the past but had questionable value therapeutically. Recent research, however, has shown that nitrofurantoin is effective in the treatment of MRSA and other methicillin-resistant staphylococci. Nitrofurantoin has also proved to be 75% effective against Gram-negative bacterial isolates other than *P. aeruginosa* while bacitracin/polymyxin was only 21% effective^{10,95} (Table 12.7).

Mupirocin (Bactroban®)

Mupirocin is one of several antibiotics derived from the fermentation of *P. fluorescens* and is also known as pseudomonic acid A. While the antimicrobial activity derived from cultures of *P. fluorescens* was first reported over a century and a half ago, this agent could not be used as an antimicrobial agent until Fuller et al.⁹⁶ executed a more complete isolation and purification of pseudomonic acid A. Further research described

Summary of results.

the antimicrobial activity of mupirocin as an inhibition of microbial isoleucyl t-RNA synthetase that causes inhibition of protein synthesis in the bacterial cell.^{96,97}

In vitro studies have subsequently established that mupirocin has omnipotent inhibitory activity against the Gram-positive microbes, specifically *S. aureus* and *S. epidermidis*. Mupirocin's efficiency in the treatment of infection or colonization due to *S. aureus*, whether methicillin-sensitive or not,

has been shown in various clinical settings.⁹⁶⁻⁹⁸ Rode and co-workers⁹⁹ have provided additional data regarding the efficacy of mupirocin in the treatment of established wound infections with *S. aureus* that were resistant to systemic methicillin, topical mafenide acetate, and povidone-iodine.

Recent *in vitro* and *in vivo* endeavors have shown mupirocin to be as efficacious in methicillin-resistant burn wound infections.⁹⁵ Mupirocin, while not sanctioned for Gram-negative

organisms, has been shown to be 75% effective against most enteric organisms and is significantly more effective against these microorganisms than bacitracin/polymyxin⁹⁵ (Table 12.6).

Mupirocin inhibits wound healing when compared to controls by a half-life of 2 days, while the breaking strength is significantly enhanced over the control ($p < 0.05$) (unpublished data 1994).

Acticoat® A.B.

Acticoat® A.B. Dressing consists of two sheets of high-density polyethylene mesh coated with ionic silver with a rayon/polyester core. Acticoat® A.B. Dressing provides broad-spectrum antimicrobial, bactericidal coverage against VRE, MRSA, *P. aeruginosa*, *Candida* sp. and approximately 150 other organisms. It can remain intact for several days on the wound, if there is minimal exudation.¹⁰⁰

Nystatin (Mycostatin®, Nilstat®)

Nystatin is an antifungal antibiotic produced by *Streptomyces noursei*. Nystatin exerts its antifungal activity by binding to sterols in the fungal cell membrane. The drug is not active against bacterial and mammalian cells because they do not contain sterols in their cell membrane. As a result of this binding, the membrane is no longer able to function as a selective barrier to prevent the loss of potassium and other cellular constituents from the fungal cell. Nystatin has fungistatic or fungicidal activity against a variety of pathogenic and non-pathogenic strains of yeasts and fungi. *In vitro*, nystatin concentrations of approximately 3 µg/mL inhibit *C. albicans* and *C. guilliermondii*. Concentrations of 6.25 µg/mL are required to inhibit *C. krusei* and *Geotrichum lactis*. In general, there is little difference between minimum inhibitory and fungicidal concentrations for a particular organism. Nystatin is not active against bacteria, protozoa, or viruses.

Nystatin is not absorbed systemically and is used orally for the treatment of intestinal candidiasis. In our burn population, nystatin 'swish and swallow' is used prophylactically to prevent the oral or perineal overgrowth of yeast and fungi in patients receiving two or three systemic antibiotics. In patients with coexisting intestinal candidiasis and vulvovaginal candidiasis, nystatin may be administered orally, in conjunction with the intravaginal application of an antifungal agent. Most evidence suggests that combined therapy does not substantially reduce the risk of recurrence of vulvovaginal candidiasis, compared with intravaginal therapy alone. However, limited evidence suggests that the reduction of intestinal candidal colonization in combination with intravaginal antifungal therapy may provide some improvement in mycologic response and reduction in recurrence rate of vulvovaginal candidiasis.

For the treatment of cutaneous or mucocutaneous candidal infections, nystatin 100 000 units/gram may be applied topically as a cream, lotion, or ointment to affected areas 2–4 times daily. The cream or lotion formulations are preferred to the ointment for use in moist, intertriginous areas. The use of occlusive dressings and ointment formulations should be avoided in the treatment of candidiasis because they favor the growth of yeast and release of its irritating endotoxin. Concomitant therapy should include attention to proper hygiene

and skin care to prevent spread of infection and reinfection. In addition, the affected areas should be kept dry and exposed to air whenever possible.

Burn patients are affected by an immunocompromised system and are thus more susceptible to opportunistic infections. Depletion of the number of neutrophils, defects in neutrophil function, and T-cell defects all predispose the host to fungal infections. Aspergillosis and hyalohyphomycosis (specifically *Fusarium*) are the most common angioinvasive fungal infections in burn patients. Barret et al. examined the curative effects of direct application of nystatin powder on severely burned children affected by angioinvasive fungal infection.¹⁰¹ The topical treatment of burn wounds with nystatin powder at a concentration of 6 000 000 units/gram proved to be effective in eradicating the invasive fungal infections. This new regimen of topical treatment not only is effective superficially but also eradicates invasive clusters of fungi in deep wound tissues, as documented by pathological examination. The application of the powder is easy and did not produce pain or discomfort. It did not impair wound healing and all previously autografted areas healed uneventfully.¹⁰¹

Nystatin powder may be combined with silver sulfadiazine 1% cream and mafenide acetate 5% aqueous solution to prevent the overgrowth of yeast and fungi at the wound site with continuous application of these potent topical antimicrobial agents.

Discussion

Though topical antimicrobial therapy has significantly diminished the occurrence of invasive burn wound sepsis, we must search for other methods to prevent burn wound infection. Bacterial control is imperfect at best. Burn wound biopsies, blood, and bodily fluid cultures must be coupled with early excision and grafting to prevent, diagnose, and treat the infection in a timely manner.^{7,78,85,102–105}

In a recent *in vitro* study conducted at the Shriners' Children's Hospital to assess the efficacy of eight of the aforementioned topical agents against multiresistant Gram-positive and Gram-negative isolates, silver sulfadiazine 1% cream and mafenide acetate 5% aqueous solution still remained extremely effective against both groups of organisms as determined by a modified NAWD. Among 126 Gram-positive isolates, silver sulfadiazine 1% cream was 100% effective, nitrofurazone was 98.4% effective, mafenide 5% aqueous solution was 97.6% effective, silver nitrate 0.5% aqueous solution was 96.8% effective, and silver sulfadiazine 1% cream with nystatin 100 000 units/gram in a 1:1 combination was 94.4% effective. Mupirocin's susceptibility has been markedly reduced (88.9%) since Strocks et al.'s study in 1990⁸² (Table 12.6). Of the 79 Gram-negative isolates tested, which included 25 clinical isolates of *P. aeruginosa*, mafenide acetate 5% aqueous solution was 97.5% effective, silver sulfadiazine was 92.4% effective, mupirocin was 91.1% effective (an increase of 16% over the Strocks et al. study).⁸² The only other two topicals showing an antimicrobial effect were the silver sulfadiazine 1% cream and nystatin 100 000 units/gram in a 1:1 combination, which showed 84.8% susceptibility, and silver nitrate 0.5% aqueous solution, which showed an 83.5% susceptibility (Table 12.7).

Operative management of burns in special areas	188
Conclusion	193

Removing dead or partially devitalized tissue saves lives and improves form and function. Skin grafting of granulation tissue (the precursor of ugly scar) following eschar separation has been replaced with operative intervention within hours of injury. Skin substitutes, dermal replacements, skin culture, and bioengineering are exciting and rapidly expanding technologies that are already offering simply amazing results. This chapter deals with the pathophysiology of the burn wound, the scientific basis of wound excision, and the techniques and technologies now available to burn surgeons.

The burn wound

Dead burned tissue promotes an inflammatory response at the junction of the eschar and the underlying viable tissue. At this interface, bacterial proliferation in the eschar attracts polymorphonuclear leukocytes (neutrophils) that release large quantities of proteolytic enzymes and inflammatory mediators. Subsequent enzymatic action results in consumption or separation of the eschar leaving granulation tissue. If the burn is large, the inflammatory response at the burned site becomes generalized. This effect is described fully elsewhere. Briefly, mediators such as prostanooids, thromboxane, histamine, cytokines, and tumor necrosis factor are all produced and released from the burned site. The serum levels of these mediators become measurable and increase in proportion to the area of the burn. The hypermetabolic response with protein catabolism, increased metabolic rate, increased susceptibility to infection, marked weight loss, and poor wound healing

continue until the outpouring of mediators abates. While topical antimicrobial agents such as mafenide acetate and silver sulfadiazine have decreased the frequency and severity of systemic sepsis, these agents prolong eschar separation and therefore the hypermetabolic response.

Treatment of full-thickness burns by awaiting spontaneous eschar separation and subsequent skin grafting is a prolonged process associated with much pain and suffering, severe metabolic derangements, multiple septic episodes, and lengthy hospitalization. In the modern era, this technique should be limited to those who are so infirm that any other method cannot be contemplated.

Beneficial effects of operative wound management

Prompt wound closure has been shown repeatedly to improve survival, decrease length of hospital stay, and curb expenditure in burned patients of all ages. Children particularly have benefited from more timely and extensive surgical intervention.^{1,2} There has been a remarkable increase in the burn size associated with a 50% mortality risk over recent decades such that it is now unusual for a child to succumb to burn injury of any size, even if it is associated with a smoke inhalation injury (Tables 13.1 and 13.2). Improving nutritional support and control of sepsis have also played a part in this achievement. Early surgery, however, has contributed most toward this major advance. Burke³ reported on results of total excision of full-thickness burns in 1974. He applied homografts (cadaver skin) to seal the wound, controlled rejection by adding immunosuppressives, and cared for his patients in laminar flow chambers. Children with massive burns began surviving their injuries where they had never previously done so. Improved mortality, shorter hospital stay, and fewer metabolic complications were noted by others when early excision was retrospectively compared with late excision.⁴ When 32 children, average age 7 years and mean burn size 65% total body surface area (TBSA) who underwent either total excision to fascia or serial debridement were studied: mortality, overall blood loss, and cumulative operating time were equivalent.⁵ The early excision group, however, had their length of hospital stay almost halved (97 ± 8 days vs. 57 ± 5 days). Since that time, hundreds of children with burns >30% TBSA treated with early excision have exhibited a length of hospital stay less than 1 day/% TBSA burned.⁶

Mortality of adult burn patients at Massachusetts General Hospital declined from 24% in 1974 to 7% for 1979–1984

after prompt eschar excision and immediate wound closure was instituted as standard therapy in 1976.⁷ Logistical regression analysis showed that this treatment significantly improved survival ($p < 0.001$). Thirty adult patients admitted to the Galveston Burn Unit with very large burns were randomized to receive either early total or staged excision. In patients with no inhalation injury, mortality was decreased with early excision. Total blood requirements were similar between groups, negating an often-used argument against excisional therapy. This study was expanded to include 85 patients, aged 17–55 years.⁸ Those patients aged 17–30 years without inhalation injury showed significantly reduced mortality if treated by early excision (9%), than if treated conservatively (45%). Patients with a concomitant inhalation injury or age greater than 30 years, however, derived no survival benefit from early excision. More recently, Herndon's group have shown that delayed excision of severely burned children leads to increased hypermetabolism and all the detrimental effects that follow.⁹

Munster and colleagues¹⁰ demonstrated a statistically significant decrease in length of hospital stay that significantly correlated with a decrease in the interval between surgical interventions over a 14-year period at his institution. Other variables such as burn size, inhalation injury, and age remained static during this time; they found that mortality rate decreased significantly while burn indices remained constant. The average annual increase of hospital charges for burn care grew at 9.6%, which was substantially lower than the hospital as a

whole (10.8%). Active surgical intervention in burn care can be associated with cost containment and fewer lives lost.

Older burn patients have been shown to benefit from an early surgical approach. Deitch¹¹ operated upon 114 consecutive patients with an average age of 68 years, and showed a reduction of 40% in mean length of hospital stay when compared to national averages, and mortality was less than predicted. Many studies^{12–16} show that early excision can be safely performed in the elderly, with clear benefit of reductions in duration of hospitalization and the number of septic episodes. Saffle¹⁵ showed that the number of preexisting medical conditions in the elderly had no effect on survival, a salient point when planning treatment. The elderly also benefit from aggressive surgical treatment of their donor site wounds. They very commonly have loose and mobile skin. If donor sites or burns are situated on the lower abdomen, the flank, or thigh, they are amenable to excision and repair in the same manner as a reduction abdominoplasty.¹⁷ This has the effect of reducing the area of open wound and decreasing the metabolic demand placed on their physiology.

Hypertrophic scar formation is common, with dark-skinned people and children being more prone to its development. However, the most important determinant of hypertrophic scarring is delayed wound healing. Deitch¹⁸ has clearly shown that if wounds take more than 10 days to heal then the risk is significant and it rises to 80% if healing is delayed beyond 21 days. Surgery is therefore indicated for those whose wounds fail to heal promptly. Operative treatment is also an effective means of limiting the duration of pain that burn patients must endure. The ghastly experience of wound debridement in the tub by picking at the eschar, sometimes for many weeks, has been recounted by many as the worst part of their burn experience. Excisional therapy of the burn wound is humane, life-saving, offers improved cosmetic and functional results, is cost-effective, and more swiftly returns the patient to their normal environment.

Techniques of burn wound excision

Excising a small, deep burn

Once a burn wound is determined to be 'deep', operative intervention is indicated without further delay. 'Deep' burns are those which are clearly full-thickness or are deep dermal

TABLE 13.1 MORTALITY FOLLOWING BURN OVER TIME FOR DIFFERENT AGE GROUPS SHOWN AS THE BURN SIZE AT WHICH 50% LIVE OR DIE—LETHAL AREA 50 (LA50)

Age [years]	LA50 (% TBSA)		
	1942–1952	1980–1991	1992–2004
0–14	49	98	99
15–44	46	70	88
45–64	27	46	75
>65	10	19	33

TBSA = percentage of total body surface area burned.
LA50 = lethal burn area for a 50% mortality.
1992–2004: Branski LK, Barrow RE, Herndon DN, unpublished data.

TABLE 13.2 PEDIATRIC SPECIFIC MORTALITY RATES OVER TIME. NEAR-TOTAL EARLY EXCISION IS THE BASIS OF THESE EXCELLENT RESULTS. MORTALITY AND PEDIATRIC BURN PATIENTS, SHRINERS BURN INSTITUTE, GALVESTON

Years	Mortality sorted by burn size (% TBSA)							
	<20%	<i>n</i>	21–40%	<i>n</i>	41–60%	<i>n</i>	61–100%	<i>n</i>
1980–1985	<0.1%	889	1%	230	8%	105	33%	95
1986–1990	<0.1%	571	1%	224	4%	117	19%	88
1991–1995	<0.1%	522	2%	192	8%	94	20%	78
1996–2000	<0.1%	635	1%	222	3%	133	19%	114
2001–2004			2%	83	2%	121	26%	91

n = total number of patients admitted with respective burn size in given time period.

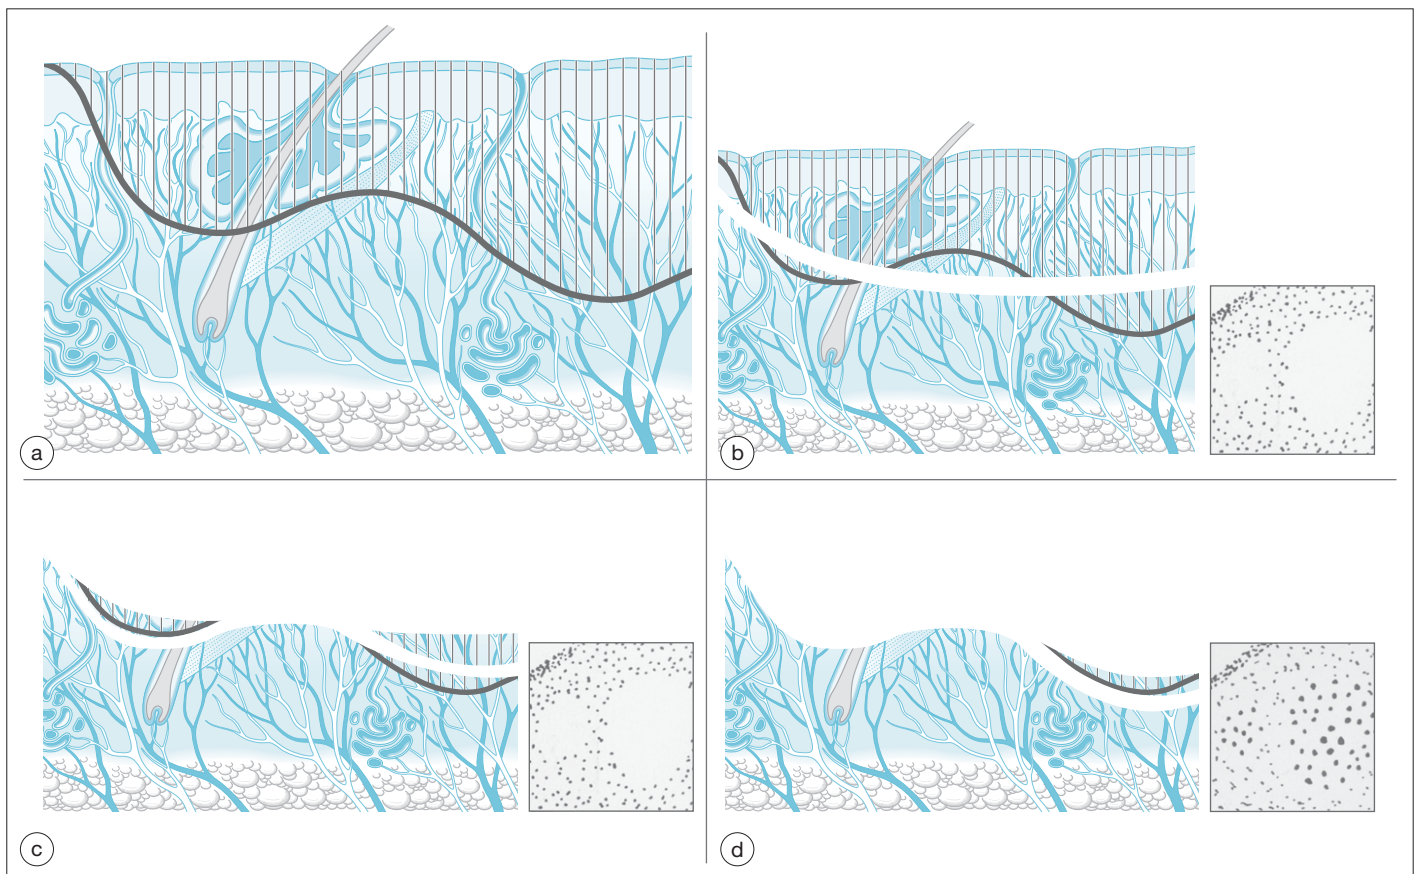

Fig. 13.1a–d Schematic representation of tangential excision; sequential slices are taken until punctate hemorrhage is evident. (Adapted from Janzekovic Z. A new concept in the early excision and immediate grafting of burns. *J Trauma* 1970; 10:1103–1108 with permission.)²²

burns unlikely to heal within 14–21 days. They are typically flame and contact burns and are commonly situated on the extremities. Heimbach¹⁹ observed that deep partial-thickness burns did not convert to full-thickness when topical antimicrobials were used to control infection. Although these wounds did eventually heal after many weeks, they showed persistent blistering, pruritus, hypertrophic scar formation, and poor functional results. These observations prompted a prospective trial of early excision and grafting versus non-operative treatment of burns of indeterminate depth of less than 20% TBSA.^{20,21} Shorter hospitalization, lower cost, less time away from work, but greater use of blood products were seen in those treated operatively. Those patients treated nonoperatively required more late grafts for closure and developed more hypertrophic scarring. There was no difference in need for reconstructive procedures, range of motion, or contour irregularities.

Tangential excision

Tangential excision removes necrotic tissue while preserving as much of the underlying viable tissue as possible. Body contours are better preserved than with fascial level excision and therefore this is the usual method for small burns. The technique of tangential excision was originally described by Janzekovic,²² who observed that deep donor sites could be overgrafted with thinner split-thickness skin harvested from

another area. She then extended this concept to dermal burns by excising thin layers of burn until living tissue was reached (Figure 13.1a–d). Split skin grafts were immediately applied. This technique of tangential excision and autografting of dermal burns was a major advance. Prior to this time only full-thickness burns were excised and usually as a formal integumentectomy, taking subcutaneous fat and accompanying lymphatics down to the underlying layer of investing fascia (fascial excision) (Figure 13.2). Janzekovic analyzed the results of the use of tangential technique of excision in over 2000 patients. She found that hospital stay, pain, and reconstructive procedures were all decreased compared to fascial excision.²³

A number of different instruments can be used to perform tangential excision. The Rosenberg knife, Goulian knife, Watson knife, and Versajet water dissector²⁴ are all used around the world (Figure 13.3). The Watson knife is probably the most popular instrument for tangential excision. The technique is aided by traction and counter-traction to place the area under tension. To ensure adequate depth is obtained, the excised tissue can be grasped as it appears from the top of the instrument and traction applied. Partial-thickness injuries are debrided to a white, shiny dermal surface with punctate bleeding that is fine and copious if the burn depth is superficial and less frequent from larger vessels for deep partial-thickness burns. Healthy fat has a yellow glistening appearance and it

Fig. 13.2 Fascial level excision using cutting diathermy and incorporated smoke evacuator.

Fig. 13.3 A selection of hand-cutting dermatomes available for use for tangential excision. Most have the ability to have the aperture set to the desired depth while the Goulian has a large series of blades that are changed.

is imperative excision continues, layer by layer, until this appearance is obtained. Dullness, punctate hemorrhages, purple discoloration, or thrombosed vessels indicate nonviable tissue upon which grafts will fail and deeper excision is mandatory (Figure 13.4). When excision is performed on limbs following exsanguination with a rubber bandage and control of arterial inflow with a pneumatic tourniquet, these features are especially important. In particular, staining of the dermis with hemoglobin from lysed red cells indicates a need for deeper excision.

Controlling blood loss

Tangential excision can lead to copious blood loss unless measures are taken to limit potential hemorrhage. The simplest

Fig. 13.4 A deep flame burn on the left thigh that is in the process of being debrided. The wound has been tumesced with 1:1 000 000 epinephrine in normal saline and shows minimal bleeding. The lower part of the wound demonstrates residual dead dermis with dull appearance and staining from lysed cells. The area just above demonstrates shiny yellow living fat and (mostly) surviving shiny white dermis with a few patches needing another slice.

measure is to operate within 24 hours of injury. Vasoactive metabolites, particularly the potent vasoconstrictor thromboxane, are in abundance during this time and do much to limit blood loss.²⁵ This proposition is supported by a prospective trial of 318 children and adolescents with burns >30% TBSA. The average blood loss per surface area excised (mL/cm^2) was compared at various postburn periods of excision. The entire full-thickness burn, with the exception of the face and perineum, was tangentially excised with a hand knife with contiguous partial-thickness burn removed to punctate bleeding with serial passes of an electric dermatome. Patients whose blood pressure was greater or less than 40% of baseline, urine output less $0.75 \text{ mL}/\text{kg}/\text{h}$, or developed pulmonary edema intraoperatively, or whose hematocrit was >48 or $<24\%$ were not included in the analysis. Overall mortality was 5% for an average size burn of 60% TBSA. Notably, early excision had no adverse effect on mortality and no intraoperative deaths were recorded. Very early excision led to a halving of blood loss for both large and small burns^{26,27} (Figure 13.5).

Further adjunctive measures to limit blood loss include tourniquets for the extremities, pre-debridement tumescence with weak epinephrine (adrenaline) solution, topical application of epinephrine 1:10 000–1:20 000 via either spray or cannula, topical application of thrombin, fibrin sealant, autologous platelet gel, calcium-enriched alginate sheets, epinephrine-soaked ($\sim 1:400\,000$) lap-pads (sponges), and immediate bandaging with delayed grafting. Reconstituted whole blood (packed cells plus fresh frozen plasma) helps to allow extensive debridements with up to 2–3 blood volume replacement by controlling consumptive coagulopathy.²⁸

All the above is predicated on normothermia being maintained.

Fig. 13.5 Blood loss is almost halved by operating within 24 hours of injury. (Adapted from Desai et al. Early burn wound excision significantly reduces blood loss. *Ann Surg* 1990; 221:753-762. with permission.)²⁶

Use of a sterilizable, silicone tourniquet protected by a plastic sleeve allows for bloodless, unhurried debridement. This is a boon for the hand and fingers. The technique requires close attention to detail and some practice to recognize adequacy of debridement using the appearance of the wound bed as described above. The tourniquet can be released briefly to check adequacy of debridement and then quickly reinflated. The larger vessels are controlled by electrocautery or ligation and the wound is then flooded with a strong epinephrine solution, and covered with sheets of calcium alginate which are also soaked in a 1:100 000 epinephrine solution. The tourniquet is released after 5-8 minutes. The limb should then be held elevated for about 10 minutes. Pre-excisional tumescence with epinephrine saline can be used almost everywhere except the digits. This technique is particularly useful for the trunk, scalp, and face. An infuser device speeds the process and certainly saves operator thumb strain (Figure 13.6). Pressure-bags, 'pitkin' syringes, and liposuction infusers can all be used. Delayed grafting is used in some centers to limit blood loss. If delayed grafting is undertaken, the wound bed needs to be kept moist and clean. A number of means are available: the wounds can be covered with bulky cotton dressings with tubing through the dressing to the wound surface used for continuous or intermittent irrigation with antibiotic or sulfamylon solution. Acticoat, kept moist with water via cannulae, also works. The patient returns to the operating room within 72 hours and undergoes a second procedure of harvest and application of skin grafts.

Techniques of wound closure

If the burn is small and donor sites are plentiful, skin grafts can be applied as 'sheet' or unmeshed skin. This technique requires experienced personnel to attend to the graft every few hours for a number of days to ensure that seromas and hematomas are controlled and expressed. Another less labor-intensive technique is to mesh the graft at a ratio of 1:1 or 1.5:1, but not to expand or stretch the mesh. If performed carefully, blood and seroma will drain away from the wound and a good cosmetic appearance is left. These grafts are best

Fig. 13.6 An infuser device.

laid perpendicular to the long axis of limbs, particularly across joint flexural creases, which is in line with the general rule of placing potential scars perpendicular to the dominant muscle contraction in the area. This will decrease the degree of contracture if it occurs. Possible exceptions are the dorsum of the hand and forearm where some clinicians argue that longitudinally placed grafts are cosmetically superior.

If burns are huge and donor sites scarce, then areas such as the scalp, scrotum, and axillas may need to be harvested. These are meshed and widely expanded. The wound is then sealed by an overlay of unexpanded, 1.5:1 meshed, fresh or frozen partial-thickness allografts. These are applied at 90° to the autograft in a sandwich pattern as described by Alexander et al²⁹ (Figure 13.7a,b). The cellular immune depression associated with massive burns makes rejection phenomena to the allograft uncommon. Fresh allografts, stored at 2-4°C in nutrient media, achieve an adherence rate of 95%. Even in large burns the face, neck, and hands are sheet grafted with thick (say 15 000th inch or more) split-skin if at all possible.

Advances in wound closure

When the burn has reached the fat layer, dermal replacement material such as IntegraTM/Terudermis are indicated. Contracture is decreased (but not eliminated) and results pleasing. Engraftment is aided by the use of negative pressure (VAC) dressings³⁰ (Figure 13.8a-e).

Cultured skin has a definite place in modern burn care. Munster has shown that use of cultured epithelial autografts (CEA) in the massively burned decreased mortality.³¹ Herndon³² compared the use of CEA with wide mesh autograft and allograft overlay in a group of children with enormous burns, >90% TBSA. Use of CEA was associated with a much better cosmetic result at the expense of a longer length of hospital stay and more reconstructive procedures. Successful use of CEA in the massively burned, critically ill (usually) ventilated patient is difficult. CEA is most often supplied as sheets measuring 10 cm × 15 cm. Unfortunately, it is very thin with 10-15 cell layers being the norm. This has all the strength

Fig. 13.7 (a) Schematic representation of 'sandwich' technique of allograft overlay. (Adapted from Alexander JW, MacMillan BG, Law E et al. Treatment of severe burns with widely meshed skin autograft and meshed skin allograft overlay. *J Trauma* 1981; 21(6):433–438. with permission.)²⁹ (b) Sandwich technique on the chest of a boy with massive deep burn having a return surgery a week after sandwich grafting. Most of the (fresh) allograft has vascularized with one piece obviously whiter than the rest. The mesh pattern of the underlying widely meshed autograft is visible.

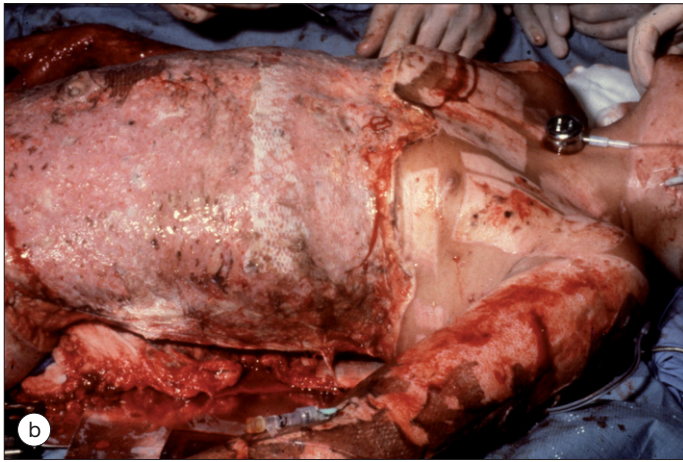

Fig. 13.8a–e Deep flame burn on a boy's chest treated with early excision and Integra with VAC.

Fig. 13.8a–e – cont'd (d) The silicone layer being removed on day 12 ready for thin grafting with well-vascularized dermal template underneath. (e) The pleasing final result.

of wet tissue paper and is very prone to shearing. As CEA in this patient group is most usually applied to a wound bed devoid of dermis, anchoring of the epithelial layer is delayed and consequently shearing and blistering is common for many months. Long-term survival of CEA is therefore particularly problematic on the posterior surfaces of these massively burned patients and goes some way towards explaining the 5–50% long-term CEA engraftment rates reported in the literature. CEA does have a definite place in wound management of the massively burned and biopsies should be procured on admission and sent immediately to commence the process of culture. Areas that are less prone to shearing such as the anterior surfaces of the torso and thighs are particularly appropriate for its use. Wound excision should not be delayed whilst waiting delivery of the CEA. The wound should be temporarily closed with allograft until the CEA arrives.

Tissue engineering technology is advancing rapidly. Fetal skin constructs having been recently successfully trialled³³

and the bilaminar skin substitute of Boyce³⁴ is now in routine clinical use and delivering truly spectacular results. We await stem cell culture technology to deliver full cosmetic restoration for our patients.

Donor site

Selecting the best donor site region and depth is a matter of careful judgment and much controversy; even more so is the method of donor-site management. There is general agreement that, if at all possible, the face and neck should be resurfaced by grafts harvested from the 'blush' area above the line of the nipple for the best color match. Small burns in other areas allow the donor site to be hidden on the upper thigh or buttock. In children, some favor the scalp for all applications as re-growth of hair hides the area. Unfortunately, for some, this does not come with a lifelong guarantee. If a small graft is required, the mons pubis area should be considered as a

potentially hidden site. The upper lateral thigh is a good compromise. The area is usually hidden from view and effective pressure garment therapy can be applied against the underlying bony structure if hypertrophic scar eventuates. The buttock donor site is easier to hide but effective pressure therapy is less assured. Good-quality grafts of consistent depth are obtained by use of a powered dermatome and certainly avoid the saw-tooth pattern often seen following use of a hand knife to harvest split-skin grafts. When the burn size is huge, some unusual donor sites need to be used. The axilla and scrotum, in males, can provide useful amounts of skin graft after tumescence to produce a tight surface for harvest. The soles of the feet can also be used. It is best to shave and discard a first layer of keratin and then harvest the grafts for definitive use.

Selection of depth of split-skin grafts is influenced by a number of factors. The overall burn size may predicate a need for re-cropping and wide expansion of meshed grafts. Thinner grafts of $\frac{6}{1000}$ inch in adults should then be harvested. Massively burned patients can sometimes have such limited available donor site area that re-cropping may have to be performed repeatedly to achieve wound closure. Even if harvesting is performed at as shallow a depth as possible, there is a point at which any subsequent re-cropping is of largely nonviable skin.³⁵ This loss of the donor sites' regenerative capabilities has drastic implications, not only for the closure of the original burn but also for the ability to perform reconstructive procedures at some later time. Overgrafting of the donor wound with CEA sheets in patients with massive burns can allow re-cropping in a week rather than the usual 3 weeks (M Rudd, personal communication).

Donor-site management

There are as many ways of managing donor wounds as there are burn units. We present a small representative selection. The Galveston Unit favors donor sites covered by scarlet red gauze, followed by dry gauze and compression bandages if anatomically possible. Bandages are removed 6 hours later and donor sites exposed. If donor sites fail to dry or develop excess moisture, a 40 watt heat lamp is positioned 18 inches away. Heat is applied for 20 minutes each hour until dry. Smaller donor sites can be treated with occlusive or adherent dressings such as Opsite™ or Biobrane™. These dressings can be applied to larger areas with innovation and effort but they carry the risk of promoting infection if fluid accumulates beneath the occlusive layer. This can lead to conversion to full-thickness wounds. Another technique is to use alginate sheets or hydrocolloid fiber dressings. They have the advantage of promoting moist wound healing and may diminish donor-site wound pain. The trapped moisture does lend itself to Gram-negative infection, however, and this should be carefully monitored. Silver-impregnated dressings such as Acticoat™ or Acticoat Absorbent™ or Aquacel Ag™ seem to diminish bacterial overgrowth and can be used directly on the donor wound or as an intermediate layer. The slightest hint of green exudate mandates immediate removal and treatment with topical antimicrobials. Split-thickness skin graft donor sites heal primarily by epithelialization from the remaining epithelial elements. Healing is rapid with thin split-skin grafts as the residual hair follicles, sweat glands, and sebaceous glands are close together but with thicker skin grafts healing is slowed. The time to healing depends on

depth of harvest, vascularity of the donor site, wound management, and general patient factors such as age, sepsis and vaso-pressors. There is no regeneration of harvested dermis. This has implications particularly for patients who require harvesting of healed donor sites. There is also a greater risk of hypertrophic scarring after harvesting of deeper grafts.

Management of specific burns

Scald burns

Hot water scald burns of small or moderate size have been shown to be the exception to the general rule of early excision. Young children who had scald burns up to 20% TBSA required less area to be excised and had smaller blood transfusion requirements if operated upon in the second and third week postburn.³⁶ Earlier operation resulted in greater blood transfused and later operation led to much increased hospital stay. A subsequent prospective trial randomized 24 children to early or late excision if their hot water scald injury had caused burns of clinically indeterminate depth.³⁷ No patient experienced a significant wound infection or systemic sepsis. Only half of the delayed excision group ultimately required surgical intervention and a significantly smaller area of excision was necessary for the remainder.

In light of the foregoing evidence, children with hot water scald burns <20% TBSA can be appropriately treated with a topical antimicrobial such as silver sulfadiazine or Acticoat™ for about 2 weeks in the reasonable expectation of healing for the majority. This approach needs to be balanced by the knowledge that the longer a wound remains exposed to the environment, the greater the inflammatory response and subsequent scarring. Trauma, desiccation, and microorganisms almost certainly play a part in this process. A number of techniques are now available to cover the partial-thickness wound. When successful, they have the added advantage of eliminating a great deal of the pain associated with dressing changes. These techniques are based on adherent wound dressings in the form of skin substitutes such as Biobrane™ and Transcyte™. Glycerol or cryopreserved allograft has also been used. More superficial wounds can be covered by a polyurethane membrane such as Omiderm™. These techniques can be used on patients with burns up to about 30% TBSA. The authors favor Biobrane™ for smaller and more superficial wounds that are pink, moist, and blanch readily.³⁸ Biobrane™ is a nylon/silicone bilaminated composite skin substitute. At the time of the first wound dressing, all loose skin and creams are removed to leave a clean, moist surface. The skin substitute is applied under some tension (like cling wrap on a bowl) and either stapled to itself on the extremities or taped to nonburned skin. A dry, nonadherent dressing should be applied and, where possible, firmly bandaged. The material works by becoming densely adherent to the exposed dermis, thus acting as a neo-epidermis. Herndon's group report no increase in infection rates using Biobrane™ in this way.³⁹ If problems do occur, it follows accumulation of fluid and non-adherence which needs to be dealt with promptly or an abscess-like state can develop with pus trapped between the skin and the material. A few days of inactivity by the patient helps the development of adherence. The material needs to be applied in the first few

postburn days and the normal amount of vigilance is required to watch for invasive Gram-positive infection. A toxic patient with increasing, throbbing wound pain and surrounding cellulitis are signs of this serious condition. Removal of the material, application of topical antimicrobial and appropriate systemic therapies are immediately indicated. Some centers have taken a middle ground and use Acticoat™ with great success. It has the advantage of having antimicrobial activity and only needs to be changed each 3–7 days. A series of catheters are inserted through the overlying dressing (often a retention dressing such as Hypafix/Fixomull) through which carers instill 5–10 mL of water each 4–6 hours. Another variation is to have the (adult) patient spray or immerse the material

whenever they feel it becoming dried out and adhering painfully to the wound.

Slightly deeper partial-thickness scald burns up to 40% TBSA can be treated by thin tangential excision or dermabrasion and application of Transcyte™. Transcyte™ is Biobrane™ that has been placed in a culture medium of fibroblasts derived from fetal foreskin for a week. They adhere to the material and produce ground substances, collagen, and growth factors. These substances, it is said, have a modulating effect on the inflammatory response in the wound bed. It is then frozen and so has to be defrosted prior to use. Transcyte™ achieves better adherence rates than Biobrane™ and is useful in more mobile and concave areas⁴⁰ (Figure 13.9a–d).

Fig. 13.9a–d Scald burn to face, chest, and arm of a young boy. The wounds were scrubbed under anesthetic within hours of injury with Transcyte™ applied to the face, neck, and chest and Biobrane™ to the arm. Tape was used extensively.

The postoperative care of either material needs to be attentive with regular examination and preemptive trimming as required. It is important that creams, gels, and ointments are not allowed in contact with the material as this prevents or loosens adherence and leads to failure. This is particularly important if the standard wound dressing is tullegras or similar. Transcyte™ and Biobrane™ can also be used as temporary wound cover for excised full-thickness wounds and in place of allograft as the overlay for widely meshed autograft. Adherence is more likely to occur and continue if the level of excision is fascia rather than subcutaneous fat — especially in very large burns.

Patients with very large scald burns, >40% TBSA, require total excision and immediate wound coverage. This may be with a combination of autograft, skin substitute, allograft, and dermal replacement (see later). Those with massive scald injury, >60% TBSA, require the same approach as the massive flame burn with selective fascial excision, widely meshed autograft and allograft overlay, dermal replacement material, and perhaps CEA.

The very large burn

Patients with deep (flame) burns between 50 and 70% TBSA pose unique challenges with many conflicting demands for available donor sites. This is even more so when the patient has suffered a concomitant smoke inhalation and is likely to require ventilation for some weeks. In general, a fascial excision is indicated unless very healthy deep dermis can be left. This may be possible in areas of thick dermis such as the back. Near total excision should be completed in the first few days after injury and certainly by the fifth day postburn. The back, buttocks, and posterior thighs are covered with autograft taken at 6/1000 in adults, thinner in children, which is meshed at an expansion ration of 4 or 6:1. This is left on the carrier, if a Zimmer™ system is used, and applied to the wound bed and then painstakingly spread. A bulb syringe is a useful tool to ‘float’ the spaghetti-like graft into appropriate position. ‘Fresh’ allograft is the best option as an overlay. The central intravenous sites — subclavian and femoral — are covered with at least a 10 cm diameter patch of narrowly meshed, 1.5:1 autograft as is the tracheostomy site.

Consideration needs to be given to the use and extent of dermal replacement such as Integra™. Dermal replacement is an expensive option, but one that leaves an excellent result — when it works. Integra™ is, to date, the material with which most units have experience. It is a bilaminar composite that has a neodermis of bovine collagen held in a matrix pattern with shark cartilage chondroitin-6-sulfate. A layer of rubberized silicone is press sealed onto this and acts as a neoepidermis. The silicone layer does not drape and bend very well and is prone to delamination by movement over joints or by external shearing forces such as rough hands. For these reasons, Integra™ lends itself to application on flat, anterior surfaces. Many centers have moved to meshing Integra™ and our experience is very positive. A cutting 1:1 (Brennan) mesher works but requires close attention or the material is mashed not meshed! The abdomen, anterior thigh, forearm, leg, and male chest are such sites (Figure 13.10a,b).

Meticulous operative technique is essential with every point of excessive electrocautery that results in tissue necrosis

Fig.13.10 a,b High-voltage electrical flash burn treated by fascial excision and Integra™. Flat anterior surfaces are particularly amenable to use of Integra™.

leading to an area that fails. Topical epinephrine, and pinpoint accuracy with monopolar and selective use of bipolar electrocautery are the hemostatic methods of choice. Integra™ is best held in place by either a VAC or by attaching an elastic netting material (Surginet™) over it. A layer of Acticoat™ is frequently added in many centers. Further protection is then afforded with layers of netting (wedding veil, Conformant 2™, Exudry™). The neodermis is then revascularized from the underlying wound. This process takes 2–3 weeks to complete but is usually underway by 3–5 days. The neodermis often becomes a plum color due to suffusion through the matrix of

red cells from minor hemorrhage. This is normal and should be left alone. Actual hematomas are recognized by lifting of the material associated with a very dark red color. The area overlying the hematoma is best excised and the edges stapled down. The Integra™ can be replaced or the area treated with Acticoat™. It must be remembered that the neodermis is inert and nonviable with no resistance to infection until neovascularization has occurred. This window of extreme vulnerability lasts about 5 days but the risk of delamination and shearing continues until the silicone neoeplidermis has been replaced by epidermis.

The neodermis is 'ready' when it becomes a 'straw' color. Close inspection with magnification will reveal telangiectatic vessels dotted about. The second-stage operation involves gentle removal of the silicone layer and application of 6/1000 inch autograft which can be meshed up to an expansion of 3:1. If shortage of donor sites necessitates expansion then the harvest needs to include as little dermis as possible otherwise a mesh pattern will permanently remain. It is said that CEA can be used for epidermal cover of Integra™ neodermis.⁴¹ It is probably best to delay this procedure to ensure adequate vascularization and enhance CEA engraftment. The author's experience with this technique in very large and massive burns with multiresistant organisms resident upon them has not been gratifying. There is benefit in performing staged, sequential replacement of the silicone layer with thin, 1:1.5 meshed autograft in sick patients with very large burns. Engraftment and graft survival seems to be more reliable in the long term and the cosmetic result enhanced; less haste but more progress. Debate continues regarding the role of Integra™ in wound coverage of patients with burns >70% TBSA. The incidence of failure due to infection rises dramatically as the burn size tops 75% TBSA. Decisions regarding its use will be influenced by the availability, or otherwise, of allograft. It cannot be stated too strongly that Integra™ cannot be left abutting unexcised wound. It all has to be removed or infection will spread relentlessly from the edge and lead to failure. Selective use of dermal replacement in areas of increased likelihood of success leaves autograft available for use on important structures such as the hand. The hands are then managed at a separate operating session on day 4 or 5 when burn edema has detumesced and the operator is fresh. While unmeshed grafts are preferable, especially for the fingers, an expansion ratio of 1.5:1 (unstretched) leaves an acceptable result and allows blood and serous exudate egress through the interstices without hindrance.

Massive burns

The operating room

The safe management of a patient undergoing a massive burn debridement requires commitment and cooperation from a large group of individuals. The procedures are long, intense, and performed under conditions that are physically and emotionally stressful. The room becomes crowded as the surgical team alone can number 6–8.

A very important perioperative issue for safe management of a patient undergoing a massive burn excision is the maintenance of body temperature. The patient is usually completely exposed and has little intact skin, especially after

donor skin harvest. These areas are moist and evaporation leads to rapid heat loss. Convective heat loss also occurs at a great rate. To combat these sources of heat loss, a number of strategies can be used. The operating room should be warmed to 32°C. The latent heat of evaporation of water is 31.5°C. Above this temperature, the energy source for evaporation will come from the environment rather than the patient. This temperature, or higher, is definitely required during the process of patient preparation when the patient is being washed. Radiant heaters are also very helpful for perioperative thermoregulation. An indwelling bladder catheter temperature probe is essential to accurately monitor the patient's core temperature. Other adjunctive measures include the use of 'space blankets' — aluminum foil coverings on areas not being accessed — plastic sheeting over the head and face, and all intravenous fluids being given at 38°C through a warming coil. Repeated applications of warm blankets are also useful as are warm air blowers. Once these adjunctive measures have been put in place, the ambient temperature can often be decreased to a more comfortable (sic) 28–32°C! The operating room staff should be reminded to take fluids themselves each 30 minutes. Failure to do so leads to severe dehydration and a sickening headache.

The patient

Good vascular access is required and subclavian central and femoral arterial lines are favored. These lines need to be sutured securely to prevent dislodgment during positioning of the patient. Special attention to prevention of pressure areas is needed. The patients are often operated upon for many hours and so are at great risk of pressure necrosis. Gel pads under the heels, elbows, and occiput and an 'egg-crate' dimpled foam mattress or a Dacron-filled mattress are essential. A customized, stainless steel surgical table with a channel at the periphery, which drains fluids towards an outlet, is very useful. The ability to obtain Trendelenburg and reverse Trendelenburg positions, along with the ability to raise and lower the whole table, is essential. Scales for weighing the patient incorporated into the table are very helpful. Clipping and shaving of body hair in and around the wound and in donor sites is followed in many units with a total body wash with povidone-iodine detergent solution. The patient is then laid upon sterile drapes. This is more easily accomplished with children than with enormous adults.

The operation

During this process, loose skin and blisters are removed and cloudy burn blister fluid sent for microbiological examination. Two electrocautery dispersive devices are needed. A Megadyne mattress is a great advance. Donor skin harvest is performed early in the procedure and is often preceded by instillation of 0.9% or 0.45% saline solution, preferably with added epinephrine, to assist in the process.

Excision commences with the patient in the prone position. Tangential or fascial excision, as appropriate, of the shoulders, back, buttocks, and upper thighs is performed. Wide-meshed autograft with allograft or Biobrane™ overlay is applied. If insufficient autograft is available, the excised wound is

covered with unexpanded, 1:1.5 meshed fresh allograft. Other alternatives include skin substitutes, such as Biobrane™ or Transcyte™, or cryopreserved allograft. Dermal replacement material is prone to failure due to infection in massive burns particularly on posterior surfaces, but can be used selectively on anterior flat surfaces. Multiple layers of bulky gauze dressings are applied over the antibiotic-impregnated gauze, in the case of allografts, or Exudry™ dressings if Biobrane™ was used. Thick silk sutures are inserted in a row along the flanks and tied in a loop. Tapes are then tied to the loops and tied over the bulky gauze dressing as a bolster. Another alternative is to apply multiple layers of chlorhexidine-impregnated, Vaseline gauze (Bactigras™), held with multiple staples. The patient is then placed in the supine position. Sterilizable, silicone tourniquets are often used on the limbs to decrease blood loss. Weak epinephrine clisis, topical 1:10 000 epinephrine irrigation, topical 5–20% thrombin solution spray, epinephrine-soaked lap pads/sponges, and compression bandaging are all techniques used to limit blood loss during debridement. Electrocautery is used after a period of compression bandaging to control the residual, larger bleeding points.

Fascial level excision is required for those areas where fat has been burned and often in those with massive burns. This involves surgical removal of the full-thickness of integument, including all the subcutaneous fat, down to the layer of investing fascia. The advantages of this technique are that grafts take very well on fascia and blood loss is reduced. Episodes of sepsis lead to ischemic necrosis of subcutaneous fat subsequent to poor peripheral perfusion and microvascular stasis. This becomes problematic in patients with very large burns and leads to late graft loss and these ischemic areas become portals for invasive wound sepsis. The disadvantages of fascial excision are lymphedema and contour deformities. All lymphatics are excised, so lymphedema of dependent parts is often troublesome. The excised fat never regenerates and can give a spindly appearance to the areas excised while any increase in body fat is deposited in the remaining beds of adipose tissue. Moon faces and thick necks can result. Fascial excision is also indicated for life-threatening invasive wound sepsis particularly with fungi and yeast such as *Aspergillus* and *Candida* and also for large areas with failed graft take in a critically ill patient with massive burns.

Patients return to the operating room as soon as donor sites are healed for further autografting and replacement of nonadherent allograft or infected skin substitute. Massively burned children, when treated with recombinant human growth hormone (GH), showed donor-site wound healing accelerated by 25% even if the patients presented infected and malnourished. There is a transient hyperglycemia in a third of patients that require insulin. The GH-treated patients require less infused albumin to maintain normal serum levels and this is an indication of the net positive protein balance induced.⁴² The usual hospital stay for a 30 kg patient with a 60% TBSA burn of 42 days was reduced to 32 days. This tremendous decrease in length of hospital stay realized a net saving of 15% in total costs. Salutory effects have also been documented in a group of patients treated nonoperatively. Mortality dropped from 45 to 8%.⁴³ Whilst it must be acknowledged that two European studies in critically ill adults of mixed etiology showed increased mortality among the GH-treated groups,

this experience has not been repeated in the massively burned, pediatric population in North America.⁴⁴ Hypertrophic scar formation has been shown to not be made worse by GH treatment.⁴⁵

Other anabolic agents have shown promise as a means of speeding wound healing in severely injured, catabolic burn patients.⁴⁶ Oxandrolone in a dose of 20 mg/day (0.1 mg/kg in 2 divided doses) has demonstrated a positive effect on protein kinetics and wound healing in both animal models and clinical trials. Emaciated, massively burned children whose presentation was delayed by, on average, 30 days were also greatly aided by oxandrolone 0.2 mg/kg/day. Protein kinetics were normalized, further weight loss prevented, and wound healing was enhanced. Donor-site wound healing was accelerated by 20% in oxandrolone-treated severely burned adults compared to nontreated. While these pharmacological agents provide great support to the massively burned, they are only an adjunct to early, near-total excision and prompt wound coverage.

Operative management of burns in special areas

The hand

Full-thickness burns should be excised and grafted as soon as practicable after diagnosis. However, the role of early operation for partial-thickness hand burns is contentious.^{47–50} If donor skin is available, and the depth of the burn indicates that wound healing will not be complete in 10–14 days, then excision and grafting is reasonable and advantageous. Thick split-thickness skin grafts have been widely used to resurface hands. However, a prospective trial by Heimbach et al. demonstrated no difference between 15/1000 inch and 25/1000 inch skin graft, on assessment by blinded observers (unpublished data). The thinner graft will obviously induce less donor-site morbidity and obviate the need for overgrafting. Heimbach's group have promoted the use of Integra™ and a VAC dressing for deeply burned fingers. They report fewer amputations with this technique. Indeed, some units advocate Integra™ for all deep hand burns.⁵¹

Deep hand burns (section author Dr Dilip Gahankari)

An alternative to Integra™ reconstruction for deep hand burns is local, pedicle, and free flap reconstruction. While microsurgical expertise is not freely available and septic burns patients not ideal candidates for microvascular anastomosis, consideration should be given to pedicle flap reconstruction for selected cases involving a devastatingly burned hand. Pedicle flaps can be performed by most surgeons and should be considered for salvage of a dominant or only remaining hand, especially when resources are meager.

Operative approach

Severe acute hand burn injury, especially from electrical injury, may cause subcutaneous tissue destruction. If, after debridement, extensor tendons or the metacarpophalangeal or interphalangeal joints are exposed and involved, skin grafts alone are inadequate for resurfacing. Small areas, usually less than 1 cm can be managed non-operatively with an emphasis

on active physical rehabilitation. These small defects can be allowed to granulate and be later covered with skin grafts if necessary. As previously mentioned, Integra™ resurfacing combined with VAC suction dressings have a role and if resources are available this approach can certainly be tried in the first instance. If the areas of exposed and burnt tendon are large, we have found the technique to not always be successful. Therefore, we actively consider skin flaps during decision making for these patients.

The ideal flap for dorsal hand defects needs to be thin and supple. It needs to be well vascularized and reliable. Although a detailed account of reconstructive surgery is beyond the scope of this chapter, we would like to briefly describe some of the available options. These include, microsurgical and non-microsurgical procedures. Microsurgical reconstruction often provides well-vascularized and swift reconstruction. Although microvascular free flaps generally provide best reconstruction for hand defects, by virtue of their great versatility, they may not always be possible in severe burns for various reasons. Not uncommonly, a severely burnt upper extremity precludes the use of radial and ulnar arteries and superficial and/or deep venous systems essential for anastomosing the free flap veins. In the same context, local flap options may not be available or suitable.

In such situations, delayed pedicle flaps, like the groin flap or the abdominal flap, may be the only reliable alternatives. We frequently use these pedicle flaps with multiple delays when microvascular reconstruction options are not available. In our experience, multiple delays give an opportunity to not only make these flaps more predictable and reliable in relatively sick patients, but also to make them thin and pliable. However, the obvious disadvantage of multiple delays is inability to mobilize the hand joints adequately and expeditiously. The resultant stiff hand after the complete division of the flap requires vigorous mobilization. The key is to start early limited mobilization of the hand while it is still attached by the pedicle. The judicious use of Kirschner wires also helps to maintain the joints in functional position without being detrimental to the pedicle.

When available, a groin flap is always our first choice as it provides a much more versatile coverage and mobility of the pedicle and therefore opportunity for mobilizing the hand while still being attached by the pedicle (Figure 13.11a–e).

For both groin and abdominal flaps, preoperative planning is the key to a successful reconstruction. Bedside planning in reverse with cloth pattern (in consultation with the patient if possible), helps tremendously in getting a good functional result with minimal stages. We pay particular attention to the following aspects in pedicled flap planning.

Comfortable position of the hand at rest with pedicle attached: we always plan as long a pedicle as possible with groin flap. In most instances, the groin flap donor site can be primarily closed (up to 11cm wide in our experience). With abdominal flap, the pedicle could be planned inferiorly, superiorly, medially or in composites of above directions depending on the resting position of the hand at the donor site and the coverage requirement (Figure 13.12a–d). It is also important to make allowance for the thickness of the flap and skin retraction. As a general rule, we add at least 0.5cm on either side of the ‘finger’ extensions in case of multiple fingers

Fig. 13.11a–e Deep burn to dominant hand of a 9-year-old male with juvenile diabetes. Tendons were exposed. A 10cm wide groin flap was used with the donor being closed primarily.

Fig. 13.11a–e – cont'd (e) The result at 6 months. He was back at work as a sale assistant.

Fig. 13.12a–d Deep burns to dorsum dominant hand with all tendons and capsules exposed in a 25-year-old whose other hand was amputated and extensive deep burns (45%) elsewhere. The hand was placed in the abdomen, not far from a left-sided colostomy seen top right (a). The palmar surface partial-thickness burn was tangentially debrided and split skin grafted. Division was in three stages over a month.

coverage and at least 1cm on either side of the dorsal or palmar margin of the defect. Both the groin flap and abdominal flaps are designed while respecting the principle of the random pattern vascularity. (Although groin flap is axial pattern flap, the useful area of groin flap used for hand coverage is the random pattern extension of the flap.) Bedside pre-operative planning also permits the assessment of mobility of shoulder and elbow joints in terms of patient comfort during the period of attachment of the pedicle. This can be up to 4 weeks. We also pay specific attention to the axillary and antecubital areas if they are burnt. In such instances, we prefer to use flap coverage for axillary and antecubital areas rather than skin graft resurfacing to prevent possible contracture. These flaps are performed prior to coverage of the hand. If fingers and thumb are involved, we make an attempt to incorporate the coverage of the first web in the original planning. This prevents first web contracture and expedites the mobilization of hand after flap detachment. We exercise utmost conservatism in debridement of the tendons and the joint capsules even if they have been exposed. It is our experience that the vascularized flap coverage does normally salvage exposed extensor tendons and joints, even though they appeared clinically non-viable. Coverage of infected joints and finger tips is however a difficult problem. Joint infections and osteomyelitis in exposed joints or bones is a real risk in severely burnt patients, especially if the flap coverage is delayed for any reason. We manage this problem by addressing the specific areas by localized lavages and judicious debridement. We also attempt to preoperatively identify the risk areas and make allowance in planning of the flap so that the total period of the flap attachment is not prolonged by occurrence of the localized infection.

Finger tip coverage is a difficult area. Flap skin is usually a poor substitute for reconstruction of the nail fold or subungual skin. It is also our experience that most patients needing significant hand coverage by flap reconstruction, have poor outcome in salvage of finger tips. Hence most such hands end up in delayed amputation of finger tips. Most commonly this

amputation is performed just proximal to the nail fold or at the DIP joint level. Another useful hint in finger tip flap coverage is to allow a slight extra skin coverage for the finger tips. This is keeping in line with the principle of designing these flaps on the random-pattern vascularized pedicle. The vascular status of the finger tip, especially on the dorsal aspect is often poorer in burnt hands compared to more proximal aspect of the fingers.

Abdominal and groin pedicle flaps for hand coverage: planning

For palmar coverage: whenever possible, groin flap is preferred as it allows judicious twisting of the tubed or semi-tubed pedicle. If groin flap is not available, abdominal flap is carefully planned. Both inferior pedicle as well as superior design is possible when available, but we prefer the former as it tends to have a more robust blood supply in the form of superficial inferior epigastric artery. This permits at least 1:1/2 or 1:2 length-to-breadth ratio and extensive thinning of the flap. For dorsal coverage, above considerations do apply; however, our preference is towards superior pedicle design of abdominal flap, if groin flap is not available. Superiorly based abdominal flap allows more deliberate mobilization of hand while still being attached by the pedicle. Uncommonly, coverage is needed on both dorsal and volar aspects and, in this situation, we prefer to use a combination of groin (superficial external pudendal artery-based) and abdominal (superficial inferior epigastric artery-based) flaps. These flaps are then raised on a common pedicle and wrapped on dorsal and volar aspects. The pedicle tubes itself well and is hence protected from kinking and twisting. If both these flaps are used jointly, donor site needs the split skin graft. For isolated fingers involvement, which quite commonly is the case for their dorsal coverage, the step-ladder pre-thinned abdominal flaps are ideal choice. Since these flaps are broad pedicle based, we divide their pedicles between 2 and 3 weeks but do not make any attempt for inseting of the flaps. This is done 1 week later when the vascularity of flaps is more stable (Figure 13.13a–d). Mobilization of the fingers and

Fig. 13.13a–d Exposed tendons to the dorsum of left hand were residual defect following grafting. Thin abdominal step-ladder pedicle flaps were used to good effect.

Fig. 13.13a-d – cont'd

mild compressive bandaging is, however, started immediately after the separation of the fingers.

The face

Facial burns that are obviously full-thickness and obviously require operative management are less problematic than those that are deep dermal with small patches of full-thickness injury. The face that definitely needs grafting can be scheduled for operation as soon as swelling has subsided. Some centers use face masks to exert pressure so that the grafts can be applied to a surface that more closely resembles the norm. This is a very labor-intensive exercise as the mask needs to be remolded each day to keep up with detumescence.

Selection of site and depth of donor skin harvest needs careful consideration. If at all possible, the donor skin should come from the ‘blush’ area above the line of the nipples for the best color match. While most favor the scalp, the potential problems of alopecia and hair growth from transplanted hair follicles are real concerns.⁵² If the scalp is not available, an alternative is to harvest across the upper part of the back with subsequent overgrafting with a thin graft. Epinephrine clisis is a sensible pre-emptive measure to decrease blood loss especially if delivered in a large volume of saline.^{53,54} This will make the harvesting process easier. If the skin over the upper back and shoulders is sun-damaged or freckled in fair-skinned individuals then other alternatives may need to be sought. It is best to remember also that the skin of the scalp of a bald man is usually quite thin and therefore not suitable as a donor site. If the upper back/shoulder region is selected, the donor site is best overgrafted with thin split-skin graft of, say, 6/1000 inch to prevent hypertrophic scar formation. Grafts should be taken as widely as possible so as to decrease the number of seams required.

Excising the face can be very bloody and loss of more than a total blood volume is not unknown — be prepared! Epinephrine clisis is essential to limit the exsanguinating hemorrhage. If the burn is obviously full-thickness, excision with needle-point electrocautery works well. If there is any doubt as to the depth, tangential excision with a Goulian knife is more

Fig. 13.14 Tangential excision being applied with a Goulian knife to the chin. Previous grafting had been largely successful. The instrument is useful for small and tricky areas.

appropriate as preservation of any viable dermal elements is essential for optimum results (Figure 13.14). Magnification with loupes aids accurate excision and graft placement. Some centers delay the reconstructive phase of the procedure to decrease graft loss from hematoma formation. Temporary wound closure with allograft is a good option if this course is chosen.⁵⁵ IMF screws can be placed into the maxilla to secure the endotracheal tube and rid the face of the tapes that inevitably rub on the grafts.

Grafts should be placed in such a fashion as to mimic the esthetic units as much as possible. Glue is useful to ‘spot-weld’ around the edge of the grafts and is certainly an excellent adjunct to suturing. Fibrin glue, e.g. Tisseal™, is also used routinely in some centers to increase graft adherence and limit hematoma formation.

Deep dermal facial burns were shown by Tredget⁵⁶ to be more prone to hypertrophic scarring if they took longer than

18 days to heal. This being the case, surgery can be planned for the third postburn week. At operation, the first question to be answered is what to do with unhealed/unburned areas that do not completely cover a cosmetic unit. Folklore has it that excision of a whole cosmetic unit is essential for optimum results. It is difficult to find anyone who actually uses this approach and it is one that has no appeal. The second question is what to do with the hair-bearing beard area in the adult male. If healing of this area is prolonged, folliculitis, which incites development of hypertrophic scar, is a common sequela. Excision requires removing all hair follicles as grafting a partial-thickness excision results in hair erupting through the graft, with much infection and inflammation leading to hypertrophic scarring. The answer to this conundrum remains elusive. Skin substitutes can be used for the burned face in the same fashion as described for scald burns. Transcyte™, in particular, seems to offer benefit in this situation.⁵⁷ Exposure, desiccation, trauma to fragile tissues, and presence of microorganisms are all decreased.

Eyelids

Deep burns to the eyelids should be excised and grafted early. Delay inevitably leads to cicatricial ectropion, corneal exposure, and a threat to sight.⁵⁸ Postburn cicatricial ectropion is a dangerous condition, with unconscious, ventilated patients at particular risk. Release and full-thickness grafts to the lower lid and thick, split-thickness grafts to the upper lids should be undertaken as soon as the condition is diagnosed.⁵⁹ Unconscious patients can have their corneas protected by a combination of ophthalmic lubricants and cling-film stretched over the eye socket. This creates a moisture trap and prevents exposure keratitis (unpublished data).

Genital burns

Hot water scald burns to the genitalia of both sexes, such as those in children, are best treated expectantly with spontaneous healing the usual result. Small, patchy full-thickness burns to the scrotum can be excised and closed to good effect. Most partial-thickness burns will heal spontaneously as scrotal skin is quite thick and contains multiple hair follicles. The very deep burn from flammable liquid or high-voltage electricity is often associated with full-thickness loss. Excision with electrocautery is recommended. If the tunica requires excision, temporary allografting of the testes, followed by delayed autografting, is recommended. Circumcision of full-thickness burns to the foreskin works well and is appropriate as phimosis is a common sequela. A deep burn to the glans may be best allowed to proceed to eschar separation and grafting of resultant granulation tissue as severe hemorrhage accompanies surgical

debridement. Full-thickness burns to the labia majora should be excised and grafted as a delayed procedure. This will decrease the degree of contracture that would certainly develop.

Perianal burns are seen in association with extensive burns in adults and in scalded children. Early excision is required for obvious full-thickness burns. Some centers recommend diversion of the fecal stream, preferably achieved laparoscopically, to aid healing and graft take.⁶⁰ An alternative is to keep the stool liquid and maintain a rectal tube *in situ*. Another technique is to administer a bowel prep and follow surgery with an elemental diet and stool thickeners such as codeine. Bowel actions can thus be delayed for 5–7 days. If graft failure occurs, it is important to keep trying to achieve engraftment as the perianal, circular contracture that results from healing by secondary intention is difficult to fix.

The breast

The nipple-areola complex, especially in females, is another area that requires extra attention. In general, it is best left unexcised as healing can occur from the deep glandular structures that are usually preserved. Sensation is also usually preserved and this is much appreciated by patients. Absence of a nipple is very noticeable and is often the one thing remarked upon by patients of both sexes even though they have other areas of more extensive scarring. It needs to be made clear that excision of the breast mound in postpubertal, or the breast bud in prepubertal, females should be avoided if possible. Dermal replacement, such as Integra™, when applied in juxtaposition to the unexcised areola, requires close attention. Acticoat™, Lodoflex granules™, or silver nitrate 0.5% soaked gauze can be used to attempt to control infection in this situation. The relatively avascular nature of the fat and connective tissue matrix that constitutes the majority of the nonlactating breast makes careful excision of all nonviable tissue even more important than usual. Tie-over bolsters, retention and VAC dressings are useful for the isolated burn to decrease movement and increase graft take.

Conclusion

Modern burn care is based on operative wound management. The evidence is clear that prompt excision and closure is life-saving for patients with large burns. Skin substitutes and dermal replacement have made operative wound care even more appealing and offer an attractive alternative to topical antimicrobial therapy for partial-thickness wounds. Bioengineered composite skin replacement will soon make surgical management of burn wounds the norm.

Introduction

Continuous improvement in burn care since World War II has resulted in a steady increase in the rate of survival after large burn injury.¹ These improvements have been attributed to aggressive fluid resuscitation, early excision and grafting of burn wounds, more effective antimicrobials, advances in nutritional support, and development of burn centers. Today, most patients with more than 80% total body surface area (TBSA) burned will survive if promptly treated in a modern burn unit with adequate resources. In their study of risk factors for death following burn injuries Ryan et al. identified three variables that can be used to estimate the probability of death: age greater than 60 years, burns over more than 40% of the total body surface area, and the presence of inhalation injury.² Mortality increased in proportion to the number of risk factors present: 0.3%, 3%, 33%, or approximately 90% mortality depending on whether zero, one, two, or three risk factors were present, respectively. The incidence of mortality is also influenced by significant coexisting disease or delays in resuscitation. O'Keefe et al. observed an approximately two-fold higher risk of death in women aged 30–59 years compared with men with similar burns and age.³ Although it has been assumed that very young children are also at increased risk of death from burn injuries, Sheridan et al. found very low rates of mortality in children younger than 48 months who had suffered large burns.⁴ Some burn patients develop refractory burn shock soon after injury and cannot be resuscitated.⁹

Major burn injury results in pathophysiological changes in virtually all organ systems. Table 14.1 lists and Figure 14.1 illustrates some of the challenges presented by the acutely burned patient during the perioperative period. In addition to the predictable challenges relating to airway management, monitoring, and vascular access, patient positioning requires close communication and teamwork. Burns involving posterior areas may require turning the patient to the prone position for optimal access (Figure 14.1). Vascular catheters and the endotracheal tube must be secured with confidence and due care given these life lines during patient turning. Several highly informative reviews of anesthetic management for burn surgery have been written during the past decade, each with its own special areas of concentration.^{5–7}

Patients suffering burn injuries often require surgical treatment for years after the initial injury in order to correct functional and cosmetic sequelae. Anesthetic management for reconstructive burn surgery presents many special problems⁸ but this chapter will concentrate on the care of acute burn patients. The acute phase of burn injury is defined as the period from injury until the wounds have been excised, grafted, and healed.

Modern burn care depends on coordination of a multi-disciplinary team including surgeons, intensivists, nurse clinicians, nutritionists, rehabilitation therapists, pulmonary care therapists, and anesthesia providers. Rational and effective anesthetic management of acute burn patients requires an understanding of this multi-disciplinary approach so that perioperative care is compatible with the overall treatment goals for the patient. The current standard of surgical treatment calls for early excision and grafting of nonviable burn wounds, which may harbor pathogens and produce inflammatory mediators with systemic effects resulting in cardiopulmonary compromise. After an extensive burn injury, the systemic effects of inflammatory mediators on metabolism and cardiopulmonary function reduce physiological reserve and the patient's tolerance to the stress of surgery deteriorates with time. Assuming adequate resuscitation, extensive surgery is best tolerated soon after injury when the patient is most fit. However, it must be recognized that the initial resuscitation of patients with large burns results in large fluid shifts and may be associated with hemodynamic instability and respiratory insufficiency. Reynolds et al. reported that more than half of deaths after burn injuries occur due to failed resuscitation.⁹ Effective anesthetic management of patients with extensive burn injuries requires an understanding of the pathophysiological changes associated with large burns and careful pre-

TABLE 14.1 PERIOPERATIVE CHALLENGES IN THE ACUTE BURN PATIENT

- Compromised airway
- Pulmonary insufficiency
- Altered mental status
- Associated injuries
- Limited vascular access
- Rapid blood loss
- Impaired tissue perfusion due to:
 - Hypovolemia
 - Decreased myocardial contractility
 - Anemia
- Decreased colloid osmotic pressure
- Edema
- Dysrhythmia
- Impaired temperature regulation
- Altered drug response
- Renal insufficiency
- Immunosuppression
- Infection/sepsis

Fig. 14.1 As illustrated in this photograph anesthetic management of the acute burn patient for excision and grafting of wounds presents numerous challenges regarding monitoring, vascular access, temperature regulation, and rapid blood loss.

operative evaluation to assure that resuscitation has been optimized and an appropriate anesthetic plan has been formulated.

Preoperative evaluation

The preoperative evaluation of burn patients requires knowledge of the continuum of pathophysiological changes that occur in these patients from the initial period after injury through the time that all wounds have healed. The dramatic changes that occur in all organ systems following burn injury

TABLE 14.2 MAJOR PREOPERATIVE CONCERNS IN ACUTELY BURNED PATIENTS

- Age of patient
- Extent of burn injuries (total body surface area)
- Burn depth and distribution (superficial or full thickness)
- Mechanism of injury (flame, electrical, scald, or chemical)
- Airway patency
- Presence or absence of inhalation injury
- Elapsed time from injury
- Adequacy of resuscitation
- Associated injuries
- Coexisting diseases
- Surgical plan

TABLE 14.3 FUNCTIONS OF SKIN

1. Protection from environmental elements (e.g. radiation, mechanical irritation or trauma)
2. Immunological — antigen presentation, antibacterial products (sebum), barrier to entry of pathological organisms
3. Fluid and electrolyte homeostasis — helps maintain protein and electrolyte concentrations by limiting evaporation
4. Thermoregulation — helps control heat loss through sweating and vasomotor regulation of superficial blood flow
5. Sensory — extensive and varied sensory organs in skin provide information about environment
6. Metabolic — vitamin D synthesis and excretion of certain substances
7. Social — appearance of skin has strong influence on image and social interactions

Adapted from Williams WG, Phillips LG. Pathophysiology of the burn wound. In: Herndon DN, ed. Total burn care, 1st edn. London: WB Saunders; 1996:64.

directly affect anesthetic management. The following discussion will describe the pathophysiological changes that occur in the acutely burned patient as they relate to the preoperative evaluation. In addition to the routine features of the preoperative evaluation, evaluation of acute burn patients requires special attention to airway management and pulmonary support, vascular access, adequacy of resuscitation, and associated injuries. The severely burned patient presents with numerous preoperative concerns (Table 14.2).

The preoperative evaluation must be performed within the context of the planned operative procedure, which will depend on the location, extent, and depth of burn wounds, time after injury, presence of infection, and existence of suitable donor sites for autografting.

Initial evaluation of burn injury

Destruction of skin by thermal injury disrupts the vital functions of the largest organ in the body. The skin provides several essential protective and homeostatic functions (Table 14.3). Treatment of patients with burn injuries must compen-

sate for loss of these functions, until the wounds are covered and healed. As a barrier to evaporation of water, the skin helps maintain fluid and electrolyte balance. Heat loss through evaporation and impairment of vasomotor regulation in burned skin diminishes effective temperature regulation. The skin's barrier function also protects against infection by invading organisms. Wound exudate rich in protein depletes plasma proteins when large body surface areas are injured.

In addition to loss of important functions of the skin, extensive burns result in an inflammatory response with systemic effects that alter function in virtually all organ systems. Preoperative evaluation of the burn patient is guided largely by a knowledge of these pathophysiological changes.

Much of the morbidity and mortality associated with burn injuries are related to the size of the injury. The extent of the burn injury is expressed as the TBSA burned. Estimates of TBSA burned are used to guide fluid and electrolyte therapy and to estimate surgical blood loss. Percentage of the skin's surface that has been burned can be estimated by the so-called rule of nines (see Figure 14.2). Estimates are modified for pediatric patients because of age-related differences in body proportions. A knowledge of the burn depth is also critical to anticipating physiological insult, as well as planned surgical treatment. First-degree or superficial second-degree burns may heal without scarring or deformity and do not require surgical excision. Deeper second-degree and third-degree burns require surgical debridement and grafting with associated surgical blood loss.

Accurate estimates of blood loss are crucial in planning preoperative management of burn patients. With extensive wound excision or debridement, large amounts of blood can be lost rapidly. Adequate preparation in terms of monitors, vascular access, and availability of blood products is essential. Surgical blood loss depends on area to be excised (cm^2), time since injury, surgical plan (tangential vs. fascial excision), and presence of infection.¹⁰ Blood loss from skin graft donor sites will also vary depending on whether it is an initial or repeat harvest. These variables are valuable predictors of surgical blood loss, which is a critical factor in planning anesthetic management (Table 14.4).

Airway and pulmonary function

Special attention must be paid to the airway and pulmonary function during preoperative evaluation. Burn injuries to the face and neck can distort anatomy and reduce range of mobility in ways that make direct laryngoscopy difficult or impossible. Specific alterations include impaired mouth opening, edema of the tongue, oropharynx, and larynx, as well as decreased range of motion of the neck. The tissue injury and sloughing present after severe facial burns may make mask ventilation difficult. Inhalation injury may impair pulmonary gas exchange and lead to respiratory insufficiency or failure.

The level of respiratory support must also be assessed. The level of required support may range from supplemental blow-by or mask oxygen to intubation and ventilation with high positive end-expiratory pressure (PEEP) and FIO_2 . Acute lung injury can occur from inhalation of chemical irritants, systemic inflammation from burn wounds or difficulties with resuscitation, or ventilator-induced injury. Common pathologies include upper thermal airway injury with stridor,

pulmonary parenchyma damage from chemical irritants or inflammation, lower airway obstruction from mucus plugs and epithelial casts, as well as pulmonary edema due to acute lung injury or volume overload. With very high levels of PEEP or peak inspiratory pressure it must be determined if the anesthesia ventilator is adequate or if an ICU ventilator will need to be brought to the operating room. If the patient is intubated at the time of the preoperative evaluation it is essential to know what the indications for intubation were so that an appropriate plan for postoperative support can be made.

There is general recognition that smoke inhalation injury increases morbidity and mortality for burn patients.¹¹ The presence of an inhalation injury in combination with a cutaneous burn increases the volume of fluid required for resuscitation as much as 44%.¹² Numerous studies have also shown an increased incidence of pulmonary complications (pneumonia, respiratory failure, or ARDS) in patients with burns and inhalation injury when compared with burns alone.¹³ Sequelae of inhalation injury include upper airway distortion and obstruction from direct thermal injury as well as impaired pulmonary gas exchange due to effects of irritant gases on lower airways and pulmonary parenchyma. These two components of the inhalation injury have separate time courses and pathophysiological consequences.

Foley described findings of 335 autopsies performed on patients who died from extensive burns.¹⁴ Intraoral, palatal, and laryngeal burns were not uncommon among patients with inhalation injuries. The most common sites of laryngeal injury were the epiglottis and vocal folds where their edges were exposed. In contrast, thermal necrosis below the glottis and upper trachea was not observed in any of these patients. The lower airways are nearly always protected from direct thermal injury by the efficiency of heat exchange in the oro- and nasopharynx unless the injury involves steam or an explosive blast. This has been demonstrated in an experimental model.¹⁵ Inhalation injury to the lower airways and pulmonary parenchyma is due to the effect of toxic or irritant gases.

Clinical suspicion of inhalation injury is aroused by the presence of certain risk factors such as history of exposure to fire and smoke in an enclosed space or a period of unconsciousness at the accident scene, burns including the face and neck, singed facial or nasal hair, altered voice, dysphagia, oral and/or nasal soot deposits, or carbonaceous sputum. The most immediate threat from inhalation injury is upper airway obstruction due to edema. Early or prophylactic intubation is recommended when this complication threatens. However, exposure to smoke does not always lead to severe injury and in the absence of overt evidence of respiratory distress or failure it may be difficult to identify patients who will experience progressive inflammation and ultimately require intubation of the trachea. In a retrospective study, Clark et al. reported that 51% of their patients exposed to smoke inhalation did not require intubation.¹⁶ Unnecessary intubation in the presence of an inflamed laryngeal mucosa risks further damage to the larynx and subglottic area.^{17,18}

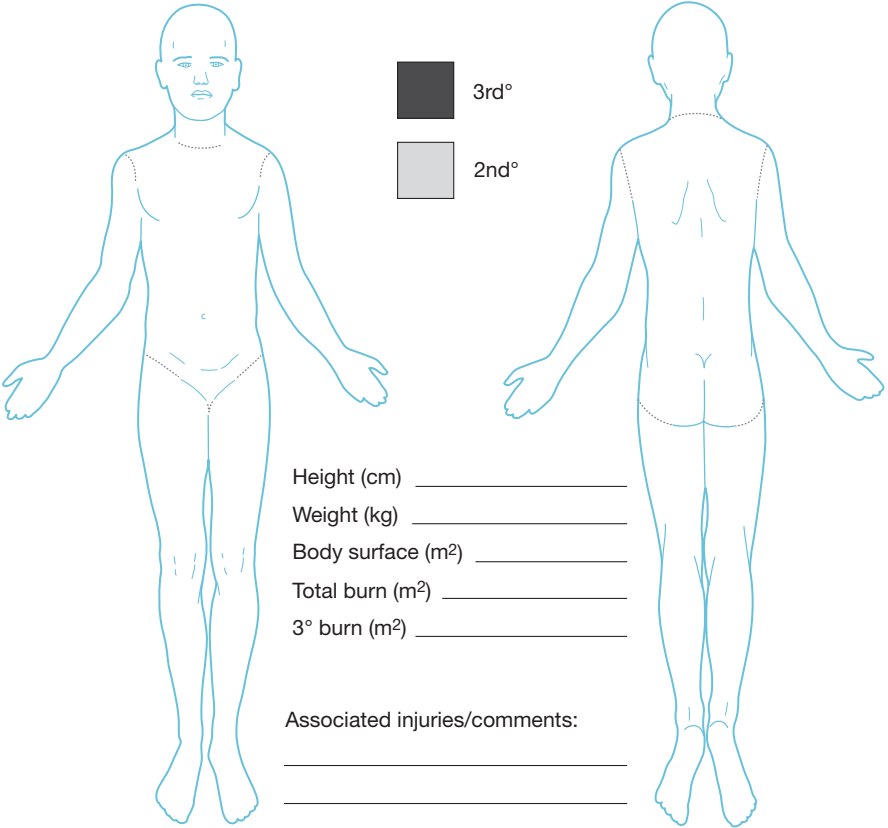

Traditional clinical predictors of airway obstruction have been found to be relatively insensitive and inadequate for identifying early severe airway inflammation and often underestimate the severity of the injury.^{19,20} More objective criteria for evaluation of the risk of airway obstruction are often

needed. Hunt et al. found fiberoptic bronchoscopy to be a safe and accurate method for diagnosis of acute inhalation injury.²¹ They described observations of severe supraglottic injuries associated with mucosal edema obliterating the piriform sinuses and causing massive enlargement of the epiglottis and arytenoid eminence. Haponic et al. made serial observations by nasopharyngoscopy in patients at risk for inhalation injury and found distortions of the upper airway described as compliant, edematous mucosa of the aryepiglottic folds, and arytenoid eminences that prolapsed to occlude the airway on inspiration.²² Progressive upper airway edema in these patients was correlated with body surface area burned, resuscitative volume administered, and rate of infusion of resuscitative fluids. For patients who are at risk for inhalation injury but lack definitive indications for intubation, fiberoptic nasopharyngoscopy is effective in identifying laryngeal edema. Serial exams may help avoid unnecessary intubations and at the same time identify progressive inflammatory changes and allow intubation before severe airway obstruction and emergent conditions develop.

Lower airway and parenchymal injuries develop more slowly than upper airway obstruction. Prior to resuscitation, clinical signs and symptoms, chest X-ray, and blood gas analysis may be within normal limits despite significant injury that eventually progresses to respiratory failure requiring intubation and mechanical ventilation.²³

Linares et al. studied the sequence of morphological changes following smoke inhalation in an experimental sheep model.²⁴ They observed four discrete but overlapping phases of injury described as exudative, degenerative, proliferative, and reparative. During the first 48 hours the *exudative phase* was characterized by polymorphonuclear (PMN) infiltration, interstitial edema, loss of Type I pneumocytes, and damage to the tracheobronchial epithelium in the form of focal necrosis, hemorrhage, and submucosal edema. The *degenerative phase* occurred between 12 and 72 hours and was characterized by progressive epithelial damage with shedding of necrotic tissue and formation of pseudomembranes and casts. Hyaline membranes developed over alveolar surfaces. Macrophages began to accumulate to begin absorption of necrotic debris. A *proliferative phase* was described between days 2 and 7 during which Type II pneumocytes and macrophages proliferated. After the fourth day *reparative* changes were observed with regeneration of epithelium from spared epithelium from the orifices of glands.

Demling and Chen have provided a lucid description of the pathophysiological changes following inhalation injury.²⁵ Decreased dynamic compliance increases the work of breathing. Increased closing volume and decreased functional residual capacity lead to atelectasis and shunt resulting in hypoxia. Airways become plugged by sloughed epithelium, casts, and mucus. Impaired ciliary action exacerbates the airway obstruction by decreasing the clearance of airway debris. These changes lead to further shunt and allow colonization and pneumonia. Treatment for inhalation injury is empiric and supportive with tracheal intubation and mechanical ventilation. The application of aggressive pulmonary toilet, high-frequency percussive ventilation, and respiratory therapy protocols designed to mobilize obstructing debris are also highly beneficial. The importance of strategies to limit ventilator-induced lung injury has been recognized.^{26–30}

Carbon monoxide (CO) and cyanide are two major toxic components of smoke. The burn patient with evidence of inhalation injury should be evaluated for the presence of toxicity resulting from these compounds. CO binds hemoglobin 200 times more avidly than oxygen.³¹ Therefore, CO markedly impairs the association of oxygen with hemoglobin and decreases oxygen-carrying capacity. CO also shifts the oxyhemoglobin dissociation curve to the left, thus decreasing the release of oxygen into tissues. These factors result in decreased oxygen delivery to tissues and, at critical levels, lead to anaerobic metabolism and metabolic acidosis. Signs and symptoms of CO poisoning include headache, mental status changes, dyspnea, nausea, weakness, and tachycardia. Patients suffering CO poisoning have a normal PaO₂ and oxygen saturation by routine pulse oximetry. They are not cyanotic. Carboxyhemoglobin must be detected by co-oximetry. Carboxyhemoglobin levels above 15% are toxic and those above 50% are often lethal. The major treatment approach is administration of 100% oxygen and, in severe cases, hyperbaric treatment to increase the partial pressure of oxygen in blood.³²

Cyanide is also a component of smoke, resulting from the burning of certain plastic products.³³ Cyanide directly impairs the oxidative apparatus in mitochondria and decreases the ability of cells to utilize oxygen in metabolism. These alterations result in conversion to anaerobic metabolism and the development of metabolic acidosis. Signs and symptoms include headache, mental status changes, nausea, lethargy, and weakness. Hydrogen cyanide levels above 100 ppm are generally fatal.^{34,35}

Treatment of cyanide toxicity begins with a high inspired oxygen concentration, which may increase intracellular oxygen tension enough to cause non-enzymatic oxidation of reduced cytochromes, or displace cytochrome oxidase and potentiate the effects of administered antidotes. Pharmacological intervention includes methemoglobin generators such as the nitrates (amyl nitrite inhalation 0.2 mLs, or sodium nitrite intravenous 10 mL of 3% solution for adults and 0.13–0.33 mL/kg of 3% solution for pediatrics) and dimethylaminophenol (3.25 mg/kg) to increase methemoglobin levels. Methemoglobin competes with cytochrome oxidase for cyanide. However, excessive levels of methemoglobin lead to decreased oxygen-carrying capacity and may be toxic. Direct binding agents have a high affinity for cyanide. Di-cobalt edetate (20 mL of 15% solution for adults or 0.3–0.5 mL/kg of 15% solution for pediatrics) is

extremely rapid in action but has significant toxicity, whereas hydroxocobalamin (adults 5–10g or pediatrics 70mg/kg), the precursor of vitamin B₁₂, has been shown to be safe with few systemic side effects; it is actively metabolized by the liver and avoids renal absorption. Sulfur donors such as sodium thiosulfate (adults 25 mL of 50% solution or pediatrics 1.65 mL/kg of 25 % solution) accentuate the bodies' enzymatic conversion of cyanide to thiocyanate in the presence of the mitochondrial enzyme rhodanese, decreasing its toxicity and increasing elimination.^{34,35}

Effect of burn injury on circulation

Thermal injury has profound effects on the systemic circulation, and hemodynamic management is a major component of perioperative care. It is critical for the anesthesiologist to assess the adequacy of postburn fluid resuscitation and the hemodynamic status of the patient. Important variables include blood pressure, heart rate, urine output, central venous pressure, base deficit, and blood lactate levels. In patients with pulmonary artery catheters, cardiac output, mixed venous oxygen saturation, cardiac and pulmonary filling pressures, and oxygen delivery parameters provide important information regarding the hemodynamic status of the burn patient. In addition, determination of blood hemoglobin level, fluid requirements, and the need for pressors or inotropes are important for developing an effective anesthetic plan.

After massive thermal injury, a state of burn shock develops due to intravascular hypovolemia and, in some cases, myocardial depression. This state of burn shock is characterized by decreased cardiac output, increased systemic vascular resistance, and tissue hypoperfusion.^{36,37} Intravascular hypovolemia results from alterations in the microcirculation in both burned and unburned tissues, leading to the development of massive interstitial fluid accumulation. Cutaneous lymph flow increases dramatically in the immediate postburn period and remains elevated for approximately 48 hours.³⁸ The forces responsible for this massive fluid shift involve all components of the Starling equilibrium:³⁹

$$J_v = K_f [(P_c - P_{if}) - \sigma(\pi_p - \pi_i)]$$

where: K_f is the capillary filtration coefficient, P_c is the capillary pressure, P_{if} is the interstitial hydrostatic pressure, σ is the reflection coefficient for protein, π_p is the plasma colloid osmotic pressure, and π_i the interstitial colloid osmotic pressure.

The specific alterations include:

- an increased microvascular permeability coefficient (k_f and s) due primarily to the release of local and systemic inflammatory mediators;
- an increase in intravascular hydrostatic pressure (P_c) due to microvascular dilatation;
- decreased interstitial hydrostatic pressure (P_{if});
- decreased intravascular oncotic pressure (π_c) due to leakage of protein from the intravascular space; and
- a relative increase in interstitial oncotic pressure due to a smaller decrease in interstitial oncotic pressure (π_i) compared to π_c .

The leakage of protein and fluid into the interstitial space often results in a washout of the interstitium and markedly increased lymph flow. The net effect of these changes is the development

of massive edema during the first 24–48 hours after thermal injury with a concomitant loss of intravascular volume. The hypotension associated with burn injury is also due, in part, to myocardial depression.^{40–44} The inflammatory response to thermal injury results in the release of large amounts of inflammatory mediators such as tumor necrosis factor α (TNF α), interleukin-1 (IL-1), and prostaglandins. TNF α and IL-1 are known to have myocardial suppressant effects.^{45,46} These factors, and other possibly unrecognized factors, are responsible for the depression in myocardial function that often results from burn injury.

If the patient survives the initial burn shock and is adequately resuscitated, a state of hyperdynamic circulation develops that is mediated by a variety of inflammatory mediators. This state of massive inflammation has been termed the systemic inflammatory response syndrome (SIRS) and is characterized by hypotension, tachycardia, a marked decrease in systemic vascular resistance, and increased cardiac output. SIRS has a continuum of severity ranging from the presence of tachycardia, tachypnea, fever, and leukocytosis to refractory hypotension and, in its most severe form, shock and multiple organ system dysfunction. In thermally injured patients, the most common cause of SIRS is the burn itself; however, sepsis, SIRS with the presence of infection or bacteremia, is also a common occurrence.

Burn patients require large-volume fluid resuscitation in the immediate postburn period. This is due to a state of burn shock that develops in the immediate postburn period as described earlier. Several resuscitation protocols that utilize various combinations of crystalloids, colloids, and hypertonic fluids have been developed (Table 14.5). Isotonic crystalloid resuscitation is the most commonly used fluid for initial resuscitation in US burn centers. The most popular fluid resuscitation regimen, the Parkland Formula, uses isotonic crystalloid solutions and estimates the fluid requirements in the first 24 hours to be 4 mL/kg/% TBSA, although, many burn centers are administering 50% more fluid than the Parkland formula would predict.⁴⁷ Crystalloid solutions generally provide adequate volume resuscitation; however, the large volumes that are needed result in substantial tissue edema and hypoproteinemia. Therefore, interest has developed in analyzing colloid and hypertonic resuscitation regimens. Overall, colloid resuscitation within the first 24 hours of burn injury has not improved outcome compared to crystalloid resuscitation.^{48,49} Furthermore, a recent meta-analysis indicated that mortality is higher in burned patients receiving albumin as part of the initial resuscitation protocol with a 2.4 relative risk of mortality compared to patients receiving crystalloid alone.⁵⁰ Because of the added cost with little established benefit, colloid solutions have not been used routinely in the United States for initial volume resuscitation in burned patients. Recently, however, in a prospective, randomized study, use of plasma for volume resuscitation has been found to limit volume infused along with intra-abdominal pressure and abdominal compartment syndrome (see below).⁵¹ These outcome variables have not been used for comparing crystalloid and colloid resuscitation in the past. With the trend toward larger volumes for initial resuscitation it may be that the use of colloid may be beneficial for larger injuries requiring more volume.

TABLE 14.5 FORMULAS FOR ESTIMATING ADULT BURN PATIENT RESUSCITATION FLUID NEEDS

Colloid formulas	Electrolyte	Colloid	D5W
Evans	Normal saline 1.0 mL/kg/% burn	1.0 mL/kg/% burn	2000 mL/24 h
Brooke	Lactated Ringer's 1.5 mL/kg/% burn	0.5 mL/kg	2000 mL/24 h
Slater	Lactated Ringer's 2 liters/24 h	Fresh frozen plasma	75 mL/kg/24 h
Crystalloid formulas			
Parkland	Lactated Ringer's	4 mL/kg/% burn	
Modified Brooke	Lactated Ringer's	2 mL/kg/% burn	
Hypertonic saline formulas			
Hypertonic saline solution (Monafo)	Volume to maintain urine output at 30 mL/h Fluid contains 250 mEq Na/liter		
Modified hypertonic (Warden)	Lactated Ringer's +50 mEq NaHCO ₃ (180 mEq Na/liter) for 8 hours to maintain urine output at 30–50 mL/h Lactated Ringer's to maintain urine output at 30–50 mL/h beginning 8 hours postburn		
Dextran formula (Demling)	Dextran 40 in saline — 2 mL/kg/h for 8 hours Lactated Ringer's — volume to maintain urine output at 30 mL/h Fresh frozen plasma — 0.5 mL/kg/h for 18 hours beginning 8 hours postburn		

The use of hypertonic saline, either alone or in conjunction with colloids, has also been advocated by some in the initial resuscitation of burned patients. Among the potential benefits are reduced volume requirements to attain similar levels of intravascular resuscitation and tissue perfusion compared to isotonic fluids.⁵² Theoretically, the reduced volume requirements would decrease the incidence of pulmonary and peripheral edema, thus reducing the incidence of pulmonary complications and the need for escharotomy. Hypertonic saline dextran solutions have been shown to expand intravascular volume by mobilizing fluids from intracellular and interstitial fluid compartments. Although hypertonic saline dextran solutions will transiently decrease fluid requirements, there is a potential for a rebound in fluid resuscitation needs.^{53,54} Therefore, most burn centers continue to employ isotonic crystalloid fluids for initial resuscitation of patients in burn shock.

Several parameters have been used to assess the adequacy of volume resuscitation in burned patients (Table 14.6). Unfortunately there is no single physiological variable that is always reliable as an endpoint to guide resuscitation in acute burn patients. The overall goal is early volume resuscitation and establishment of tissue perfusion. Traditionally, urine output (0.5–1 mL/kg/h) and normalization of blood pressure (mean arterial blood pressure of greater than 70 mmHg) have been used as endpoints. However, recent studies indicate that these parameters may be poor predictors of adequate tissue perfusion. Jeng and colleagues showed that attaining urine outputs of greater than 30 mL/h and mean blood pressures of greater than 70 mmHg correlated poorly with other global indicators of tissue perfusion such as base deficit and blood lactate levels.⁵⁵ In order to maintain perfusion of vital organs such as heart and brain, blood flow is often redistributed away from splanchnic organs. Persistent hypoperfusion of these organs ultimately results in tissue injury and may be a contributing factor to multisystem organ dysfunction. Several studies have shown that normalization of blood pressure, heart rate, and

TABLE 14.6 CRITERIA FOR ADEQUATE FLUID RESUSCITATION

• Normalization of blood pressure
• Urine output (1–2 mL/kg/h)
• Blood lactate (<2 mmol/liter)
• Base deficit (<-5)
• Gastric intramucosal pH (>7.32)
• Central venous pressure
• Cardiac index (CI) (4.5 liters/min/m ²)
• Oxygen delivery index (DO ₂ I) (600 mL/min/m ²)

urine output do not correlate with improved outcome.^{56,57} Therefore, in the preoperative assessment of the burn patient, the anesthesiologist should not base the cardiovascular assessment strictly on these parameters.

Invasive cardiovascular monitors are not used routinely in burned patients to guide volume resuscitation. Most patients can be adequately resuscitated without their use. However, a small subset of patients, such as those with underlying cardiovascular disease or those who do not respond normally to volume resuscitation, may benefit from invasive monitoring. Some investigations have focused on the use of cardiac index and oxygen delivery as useful endpoints to guide volume resuscitation.^{58,59} One way in which shock can be defined is oxygen debt. Therefore, maintaining an adequate cardiac index and oxygen delivery capacity such that oxygen delivery meets oxygen consumption provide useful criteria in guiding volume resuscitation. Bernard and colleagues have shown that patients surviving large burn injuries had higher cardiac indices and more effective oxygen delivery than nonsurvivors.⁶⁰ Some investigators have proposed the use of supranormal oxygen delivery as a means of assuring adequate tissue

perfusion.^{61,62} The preselected goals were a cardiac index of 4.5 l/min/m² and an oxygen delivery index of 600 mL/min/m². These values represent approximately 150% of normal cardiac index and oxygen delivery values. Attaining supraphysiological cardiac output and oxygen delivery has been shown to improve outcome in some studies. Schiller and colleagues demonstrated that maintaining a hyperdynamic hemodynamic state using fluids and inotropes improved survival in burn patients.⁶³ However, other investigations, including a meta-analysis, have shown that achieving supra-physiological levels of cardiac output and oxygen delivery did not improve mortality or decrease the incidence of organ failure in trauma and burn patients.^{64–66} The use of inotropes to attain supra-physiological oxygen transport could be detrimental in some cases. One study that employed dobutamine to increase cardiac output and increase oxygen delivery demonstrated increased mortality.⁶⁷

Estimating preload in the acutely burned patient is quite challenging. Filling pressures (central venous pressure and pulmonary artery occlusion pressure) correlate poorly with circulating blood volume especially during positive pressure ventilation.⁶⁸ A single indicator transcatheter pulmonary thermodilution technique has been used to estimate the volume of blood in the thorax (intrathoracic blood volume or ITBV).⁶⁹ This technique has been used in burn patients during resuscitation. Holm and colleagues observed that where neither central venous pressure nor pulmonary capillary wedge pressures correlated with changes in cardiac index or oxygen delivery during fluid resuscitation of burn patients, there was a moderate correlation of these variables with ITBV.⁷⁰ This monitor was used successfully to resuscitate 24 severely burned patients. Volumes administered were significantly larger than predicted by the Parkland formula.⁷⁰ This technology is available commercially as the PiCCO system (Pulsion Medical Systems, Munich, Germany). In addition to ITBV this system also provides an estimate of extravascular lung water and continuous estimate of cardiac output and systemic vascular resistance.

Blood lactate and base deficit provide indirect metabolic global indices of tissue perfusion. Lactic acid is a byproduct of anaerobic metabolism and is an indicator of either inadequate oxygen delivery or impaired oxygen utilization. In the absence of conditions such as cyanide poisoning or sepsis that alter oxygen utilization at the cellular level, lactate production serves as a useful marker of oxygen availability. Serum lactate levels have served as a useful marker of fluid resuscitation and tissue perfusion in burn patients.⁷¹ A recent study showed serum lactate to be the most predictive index of adequate tissue perfusion and a lactate level of less than 2 mmol/L in the first 24–72 hours after burn injury correlated with increased survival.⁵⁷ Base deficit is another indirect indicator of global tissue perfusion. The base deficit is calculated from the arterial blood gas using the Astrup and Siggard-Anderson nomograms. Although it is not directly measured, base deficit provides a readily obtained and widely available indicator of tissue acidosis and shock. Base deficit has been shown to correlate closely with blood lactate and provides a useful indicator of inadequate oxygen delivery. A retrospective study by Kaups et al. showed that base deficit was an accurate predictor of fluid requirements, burn size, and mortality rate.⁷³

Lactate and base deficit serve as global markers of tissue perfusion and oxygen delivery. However, in burn patients, tissue perfusion is not uniform. Perfusion of the splanchnic beds is often sacrificed in order to maintain the perfusion of heart, brain, and kidneys. The use of gastric intramucosal pH (pH_i) has been advocated as a measure of splanchnic perfusion. Several studies have shown that measurement of pH_i is useful in guiding resuscitation and that low pH_i is a predictor of organ failure and death.⁷⁴ pH_i is measured by gastric tonometry and can provide useful information regarding tissue perfusion.

Formulae for resuscitation of burns provide an approximation of fluid needs but volumes actually administered need to be individualized for each patient. Although two patients may each have 50% TBSA burns, it is not likely that their wounds will be equivalent otherwise. Several factors can increase fluid requirements (Table 14.7). Deep full-thickness burns require larger volume than partial-thickness injuries. Likewise, extensive soft tissue damage from electrical burns or crush injuries increases fluid needs. Inhalation injury can also increase fluid requirements as much as 50% as noted above.¹² These differences in wounds and fluid requirements among patients make it very difficult at times to optimize fluid administration. None of the physiological endpoints is always reliable. All available clinical information must be examined and each variable evaluated within the context of all the other variables.

It has been observed over the past several years that increased volumes of crystalloid solutions are being used for resuscitation of burn patients.⁷⁵ In many cases as much as twice the volume recommended by the Parkland formula is used. As a consequence, patients experience increased edema. During the preoperative evaluation, attention must be paid to the degree to which edema produces physiologic derangements. The edema can lead to compartment syndrome of extremities or abdomen (Figure 14.3). Blindness due to ischemic optic neuropathy has been reported as a complication of burn resuscitation.⁷⁶ Increased intra-abdominal pressure is a complication of vigorous fluid resuscitation, which may be more common than generally appreciated and may often explain difficulties with resuscitation. Greenhalgh and Warden first described the association of increased abdominal pressures and compartment syndrome with burn resuscitation.⁷⁷ Ivy and colleagues prospectively studied 10 adult patients presenting with greater than 20% TBSA burns and found that 70% of these patients had at least transient intra-abdominal hypertension.⁷⁸ Two of their patients with more than 80% TBSA burns developed

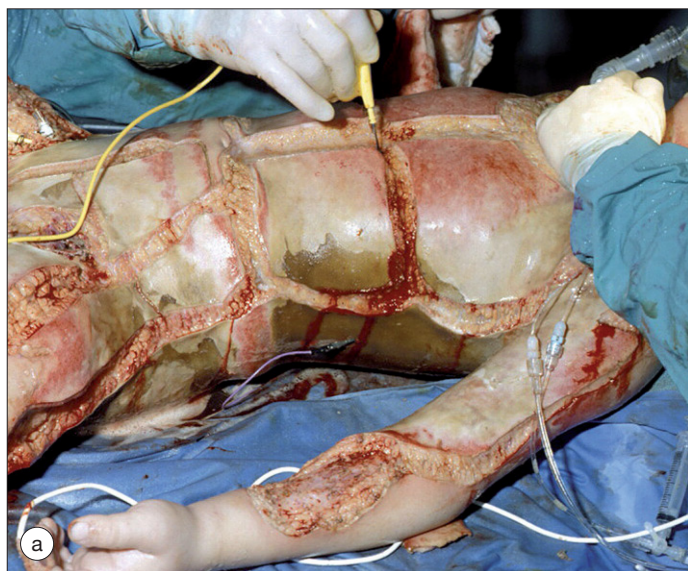

Fig. 14.3 Large volumes of crystalloid solution required for resuscitation of patients with acute burns can be associated with compartment syndrome of extremities and abdomen. (a) Escharotomies can decompress these compartments but (b) laparotomy may be required for abdominal compartment syndrome when escharotomies do not adequately decompress the abdomen.

abdominal compartment syndrome requiring surgical decompression. Several studies since then have described the common occurrence of increased intra-abdominal pressure with large-volume burn resuscitation. Increased intra-abdominal hypertension is termed abdominal compartment syndrome when it is associated with impaired respiration, circulation, and urine output. Mechanical ventilation is impaired by pressure on the diaphragm, circulation is impaired by restricted venous return due to caval compression, and urine output is impaired by compression of renal vessels. When this pattern presents the patient should be examined for elevated intra-abdominal pressure. This can be accomplished by measuring bladder pressure: 50 mL of saline is instilled into the bladder through the Foley catheter and the height of the saline column above the symphysis pubis is measured ($1.36 \text{ cm H}_2\text{O} = 1 \text{ mmHg}$).⁷⁹

Conservative treatment of elevated intra-abdominal pressure includes attempts to limit the volume of intravenous fluid needed for resuscitation. The inclusion of plasma with infused fluids has been found to reduce volume required and was associated with significantly lower intra-abdominal pressures.⁵¹ In addition adequate analgesia and sedation should be achieved. Diuresis with furosemide and muscle relaxants to reduce muscle tone have been used to reduce intra-abdominal pressure. More invasive measures include escharotomies,⁸⁰ percutaneous peritoneal dialysis catheter drainage,⁸¹ and laparotomy.⁷⁷

Recently several clinicians have reported a specific type of burn injury that has been associated with difficulties with resuscitation.^{82–84} There has been a dramatic increase in burn injuries from explosions and fires related to methamphetamine production in illicit labs. Victims of these accidents present unique challenges for a variety of reasons. Substances used in methamphetamine production include chemicals that are corrosive and toxic (e.g. anhydrous ammonia, hydrochloric acid, red phosphorus, and ephedrine). Other ingredients are flammable (acetone, alcohol, and gasoline) and explosions can coat the victims with all these chemicals. As a result, in addition to the victim's toxic exposure, contacting incompletely decontaminated victims of these accidents has injured first responders and hospital workers.^{85,86}

In addition to exposures described above, these patients are usually intoxicated with methamphetamine, as demonstrated by positive urine screen, and may have inhaled toxic fumes such as phosphine gas. Santos et al. found the incidence of inhalation injury twice as great in victims of methamphetamine-related burns as in age and burn-matched controls.⁸² Among their patients requiring intubation for inhalation injury methamphetamine users also required roughly twice as many ventilator days.

Clinical studies have consistently observed increased fluid requirements for resuscitation of methamphetamine patients.^{82,85} For example, Santos et al. found that resuscitation volumes were 1.8 times greater for methamphetamine users with burns than controls.⁸²

Methamphetamine users with burns experienced more behavioral problems also. These patients are more often agitated and require restraints. Santos et al. reported that all their methamphetamine patients required greater than normal doses of sedatives and displayed what they referred to as 'withdrawal type syndrome.'⁸² This behavior may be due to withdrawal of methamphetamine from chronic users.

Effect of burn injury on renal function

Acute renal failure (ARF) is a relatively common complication following major burn injuries. The incidence of ARF following burn injury has been reported to range from 0.5 to 30% and is most dependent on the severity of the burn and the presence of inhalation injury.^{87–89} The development of ARF is a poor prognostic indicator with mortality rates as high as 100% reported by some investigators.⁹⁰ However, Jeschke and colleagues have shown a decrease in mortality in pediatric burn patients with ARF to 56% since 1984.⁹¹ Holm and colleagues observed that ARF could be divided into early and late categories. Early ARF was defined as occurring within 5 days of burn

injury.⁹² The most common apparent causes were hypotension and myoglobinuria. ARF occurring after 5 days of injury was defined as late. Here, sepsis was the most common cause, with a small number of cases resulting from the administration of nephrotoxic drugs. Factors that will decrease the incidence of ARF and, if it occurs, associated mortality, include adequate fluid resuscitation, early wound excision, and prevention of infection.⁹³ Regardless of the cause, it is critical to assess renal function in burn patients in order to develop a comprehensive anesthetic plan. Important areas of analysis include urine output, dialysis dependence, volume status, and electrolytes; also diuretic therapy should be noted. Scheduled doses of diuretics may need to be continued during the perioperative period to maintain urine output.

Metabolic changes associated with burn injury

Increased metabolic rate is the hallmark of the metabolic alteration that takes place after thermal injury. The magnitude of the hypermetabolism is influenced by the size of the burn wound, how the burn patient is treated, and the ambient temperature of the patient.^{94,95} Within the range of 30–70% TBSA burn injury the hypermetabolism tends to be proportionate to the size of the burn wound. With burns beyond this range the hypermetabolism appears to plateau and only increases in smaller increments.⁹⁶ Septic complication is an important factor that can increase the metabolic response and so does the physiologic stress of pain. It has been observed that modern day treatment of burn injuries with early excision and closed wound treatment ameliorates the hypermetabolism.⁹⁷ As mentioned earlier, burn patients increase their metabolic rate in an effort to generate heat according to a new threshold set point for the body temperature that is influenced by the size of the burn (see below: Thermoregulation in burn patients). The recognition of this fact has led to an increased awareness of the importance of the ambient temperature in modulating the hypermetabolism of the burn patient. Using indirect calorimetry in acute patients with major burn injuries that are treated according to current standards, resting energy expenditures that are 110–150% above predicted values are frequently measured.⁹⁸

As a result of the hypermetabolic response the burned patient has an increased O₂ consumption along with an increased CO₂ production that collectively demands a higher respiratory effort. The anesthetic care of the acute burned patient has to accommodate these changes and frequently this has to be done in patients with compromised pulmonary function due to burn injury.

According to the hypermetabolism the caloric needs of the burn patient are also increased. Furthermore, numerous studies have shown that optimized nutritional care not only can ameliorate the burn-associated state of catabolism and immune suppression but also improves wound healing.⁹⁴ Oral or enteral feeding is recognized as the optimal feeding route of the burned patient. Frequently the acute burn patient has to be fed continuously over extended time periods. This is not only because of the increased caloric needs but also because of compromised gastric emptying and decreased intestinal motility that necessitates a slower feeding rate of critically ill

patients. If standard guidelines for perioperative fasting are implemented recurrent operative procedures can significantly impinge on the nutritional needs of the patient and ultimately cause a caloric deficit. To accommodate the nutritional needs of the patient a continuation of duodenal nutrition perioperatively has been advocated. Studies indicate that not only is this procedure safe but it might also provide for a favorable gut oxygen balance.⁹⁹

At the time of the withdrawal of ventilator support and extubation the metabolic state of the burn patient should be considered. The characteristic catabolic state of major burn injury spares no muscles¹⁰⁰ and the respiratory muscles are affected. Along with decreased muscle strength there is frequently decreased pulmonary compliance not only due to the formation of scar tissue and pulmonary interstitial changes but also due to increased intra-abdominal content. Burn-associated hepatomegaly along with gastrointestinal retention can significantly impinge on respiratory reserves.¹⁰¹

Severe insulin resistance with hyperglycemia and concurrent hyperinsulinemia is a key feature of the metabolic alterations of burn injury.⁹⁵ It is well recognized that critically ill patients with insulin resistance benefit from tight glycemic control in the ICU¹⁰² and these findings have been expanded to the burn patient population.¹⁰³ During the intraoperative period the question is less studied. Although the benefit of tight intraoperative glycemic control has been documented in other patient populations,¹⁰⁴ the risk versus benefit during anesthesia has not been studied specifically in burn patients.

Thermoregulation in burn patients

Maintenance of proper body temperature is an important factor in the care of severely burned patients. The thermoregulatory system is controlled by three major components. These are the afferent system that senses changes in core body temperature and transmits this information to the brain, the central regulatory mechanisms located primarily in the hypothalamus that process afferent input and initiate responses, and the efferent limb that mediates specific biological and behavioral responses to changes in core body temperature (Figure 14.4). Temperature is sensed by A δ and C fibers present in peripheral tissues such as skin and muscle as well as core tissues such as brain, deep abdominal tissues, and thoracic viscera.¹⁰⁵ The vast majority of afferent input arises from the core tissues. Because the skin is in direct contact with the environment, it senses immediate changes in environmental temperature. However, the overall afferent input of the skin and other peripheral tissues is estimated to be only 5–20% of total afferent thermoregulatory input.¹⁰⁵ Therefore, loss of skin following a burn injury is not likely to markedly alter overall afferent input. Wallace and colleagues have shown that burn patients perceive changes in ambient temperature as effectively as normal controls.¹⁰⁶ This is likely due to the retained ability of burn patients to sense changes in core temperature and transmit this information to the central nervous system. Central control of temperature is a complicated system that is not well understood. The hypothalamus plays an important role in temperature regulation, but the complete mechanism of temperature control is likely to be multifaceted and is an area of intense research. Regard-

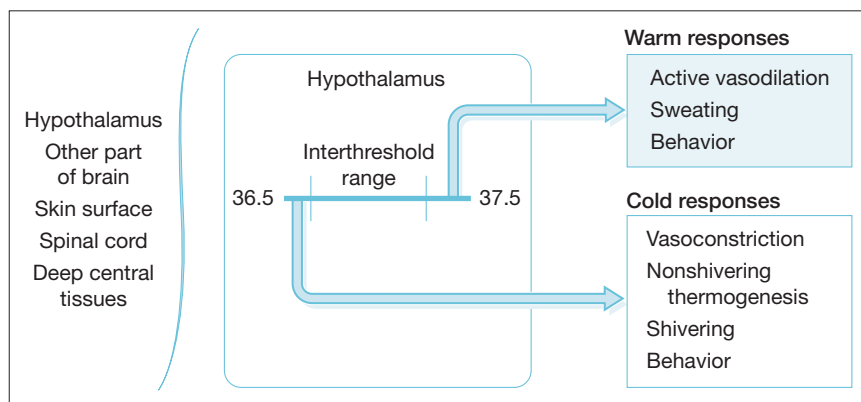

Fig. 14.4 Thermoregulatory control mechanisms. Afferent input from a variety of sites, most notably skin, central tissues, and brain, are processed in the central nervous system. Based on input, a variety of efferent thermoregulatory responses are initiated. (From: Sessler DI. Temperature monitoring. In: Miller R, ed. Anesthesia, 3rd edn. New York: Churchill Livingstone; 1990.)

less of the ultimate control mechanisms, temperature control can be divided into three main functions: threshold, gain, and maximum response intensity.

Threshold encompasses a set point at which responses to temperature change are initiated. In normal individuals the threshold range is generally near 36.5–37.5°C. In burn patients, the threshold set point is higher and the increase is proportional to the size of the burn. The work of Caldwell and colleagues predicts that the temperature set point will increase by 0.03°C/% TBSA burn.¹⁰⁷ This increase in temperature threshold appears to be due to the hypermetabolic state and the presence of pyrogenic inflammatory mediators such as TNF, IL-1, and IL-6 that are present after thermal injury. The elevated temperature set point can be decreased by administration of indomethacin, which suggests prostaglandins act as final common mediators of this response.^{108,109}

Gain describes the intensity of response to alterations in temperature. In most cases the gain of thermoregulatory responses is very high with response intensity increasing from 10 to 90% with only a few tenths of a degree change in core temperature. This response is maintained in most burn patients, resulting in a further increase in metabolic rate.¹⁰⁶ Burn patients respond with a brisk increase in heat generation and metabolic rate in response to changes in core body temperature.¹⁰⁶ However, work by Shiozaki and colleagues has shown that burn patients who are slow to respond to postoperative hypothermia are at increased risk of mortality.¹¹⁰ The decreased responsiveness may be due, in part, to tissue catabolism, poor nutrition, or sepsis. In addition, the response to relative hypothermia is characterized by increased catecholamine release, tissue catabolism, and hypermetabolism. These responses further stress burn patients, and decrease their ability to respond to their primary injury.¹¹¹

The most important efferent responses to hypothermia are behavioral responses such as gaining shelter, covering up, and seeking a more desirable ambient temperature. In the acute postburn setting, most of these behaviors are impeded by positioning, sedation, and inability to seek a more favorable environment. Therefore, caregivers must be attentive to the patient's temperature and perception of cold so that measures can be undertaken to optimize the patient's temperature. Cutaneous vasoconstriction is another important mechanism for preserving heat and core body temperature. In unburned persons, a temperature gradient of 2–4°C exists between skin and core tissues. This gradient is maintained by cutaneous vasoconstriction. Without cutaneous vasoconstriction, heat is

Fig. 14.5 Effects of anesthesia on thermoregulatory mechanisms. (From: Sessler DI. Temperature monitoring. In: Miller R, ed. Anesthesia, 3rd edn. New York: Churchill Livingstone; 1990.)

redistributed from the core compartment to the periphery. This heat is ultimately lost to the environment. Peripheral vasoconstriction minimizes temperature redistribution and acts to maintain core body temperature. This mechanism of heat preservation is lost with the loss of large areas of skin, particularly if cutaneous tissues are excised down to the fascial level. The loss of skin facilitates the loss of core body heat into the environment and places the burn patient at risk for core hypothermia. Another mechanism of heat loss in burn patients is evaporation. Burn patients can lose as much as 4000 mL/m² burned/day of fluids through evaporative losses.¹¹² Mechanisms of nonshivering heat production, and shivering remain intact in burn patients. However, shivering increases metabolic requirements and is likely deleterious.

The induction of anesthesia results in relative ablation of thermoregulatory mechanisms and puts the patient at further risk for developing hypothermia. Patients under general anesthesia exhibit a markedly decreased threshold for responding to hypothermia (Figure 14.5). This is particularly important in burn patients given their high temperature set point and the deleterious effects of further stress responses and hypermetabolism in this patient population. Most anesthetics decrease nonbehavioral responses to hypothermia such as vasoconstriction, nonshivering thermogenesis, and shivering. Of course, behavioral responses are ablated during general anesthesia. Therefore, it is the responsibility of the intraoperative caregivers to monitor and maintain patient temperature.

Actions such as maintaining higher ambient air temperature, covering extremities and head, applying warm blankets, utiliz-

ing radiant heaters and forced air warming devices, warming fluids and blood, and warming gases are usually effective in maintaining core temperature if applied aggressively. Ideally, hypothermia should be corrected prior to transport to the operating room.¹¹³ Hypothermia revealed in the preoperative evaluation may be due to inadequate resuscitation or metabolic instability. Either situation may predispose burn patients to intolerance of anesthetic drugs or the stress of surgery.

Pharmacological considerations

General considerations

Burn injury and its treatment result in physiological changes that may profoundly alter response to drugs. These changes alter both pharmacokinetic and pharmacodynamic determinants of drug response. Altered drug response in burned patients may require deviation from usual dosages to avoid toxicity or decreased efficacy.¹¹⁴ The complex nature of the pathophysiological changes, interpatient variation in the nature and extent of burn injuries, as well as the dynamic nature of these changes during healing and recovery make it difficult to formulate precise dosage guidelines for burn patients. However, an understanding of the systemic response to large burn injuries can help predict when altered drug response can be expected and how to compensate.

The two distinct phases of cardiovascular response to thermal injury can affect pharmacokinetic parameters in different ways. During the acute or resuscitation phase the rapid loss of fluid from the vascular space due to edema formation results in decreased cardiac output and tissue perfusion. Volume resuscitation during this phase dilutes plasma proteins and expands the extracellular fluid space especially, but not exclusively, around the burn injury itself. Decreased renal and hepatic blood flow during the resuscitation phase reduces drug elimination by these organs. Also, decreased cardiac output will accelerate the rate of alveolar accumulation of inhalation agents, which may result in an exaggerated hypotensive response during induction of general anesthesia.

After approximately 48 hours, the hypermetabolic and hyperdynamic circulatory phase is established with increased cardiac output, oxygen consumption, and core temperature. During this phase, increased blood flow to the kidneys and liver may increase clearance of some drugs to the point where increased doses are required.¹¹⁵

Many drugs are highly protein bound. Drug effects and elimination are often related to the unbound fraction of the drug which is available for receptor interaction, glomerular filtration, or enzymatic metabolism. The two major drug-binding proteins have disparate response to burn injury. Albumin binds mostly acidic and neutral drugs (diazepam or thiopental) and is decreased in burn patients. Basic drugs (pKa >8, propranolol, lidocaine, or imipramine) bind to α -acid glycoprotein (AAG). AAG is considered an acute phase protein and its concentration may double after burns. Since these drug-binding proteins respond in opposite ways to thermal injury it can be expected that changes in drug binding and function will depend on which of these proteins has the highest affinity for the drug in question. Martyn et al. observed decreased plasma albumin concentration and increased plasma

AAG concentration in burn patients.¹¹⁶ These observations were associated with an increased unbound fraction for diazepam (bound by albumin) and a decreased unbound fraction for imipramine (bound by AAG).

Volume of distribution (V_d) can be changed by alterations of either extracellular fluid volume or protein binding. Large changes in both of these variables occur with thermal injuries. Drugs with high protein binding and/or a V_d in the range of the extracellular fluid volume may be associated with clinically significant alterations of V_d in burned patients. V_d is the most important determinant of drug response following a rapid loading dose. However, adjustments in dose to compensate for altered V_d are indicated only when V_d for the drug is small (<30 liters) because with larger V_d only a small fraction of the drug is present in the plasma.¹¹⁴

Clearance is the most important factor determining the maintenance dose of drugs and can influence the response to drugs given by infusion or repeated bolus during anesthesia. Drug clearance is influenced by four factors:

- metabolism;
- protein binding;
- renal excretion; and
- novel excretion pathways.

The characteristic hepatic extraction of a particular drug influences changes in its clearance that occur after thermal injury. Drugs vary greatly in their extraction by the liver. Hepatic clearance of drugs highly extracted by the liver depends primarily on hepatic blood flow and is insensitive to alterations in protein binding. Clearance of these drugs may increase during the hyperdynamic phase when hepatic blood flow is increased. In contrast, clearance of drugs that have a low hepatic extraction coefficient is not affected by changes in hepatic blood flow but is sensitive to alterations in plasma protein levels.¹¹⁴ For these drugs it is the unbound fraction of the drug that is metabolized. As above, changes in unbound fraction depend on whether the drug is bound by albumin or AAG. Changes in protein levels produce clinically significant pharmacokinetic changes only for drugs that are highly bound (>80%).¹¹⁷

During resuscitation, renal blood flow may be reduced and renal excretion of drugs may be impaired. Later, during the hypermetabolic phase, renal blood flow is increased as a result of the elevated cardiac output. During this period excretion of certain drugs can be increased to the point that the dose may need to be increased. Loirat et al. reported increased glomerular filtration rates and reduced half-life of tobramycin in burn patients.¹¹⁸ However, this was age-dependent and patients over 30 years of age did not have increased glomerular filtration or reduced half-life.

Burn patients may also experience altered drug clearance due to novel excretion pathways. Glew et al. found that 20% of a daily gentamicin dose was eliminated in the exudates lost to wound dressings.¹¹⁹ In addition, rapid blood loss during surgery may speed elimination of drugs when blood loss and transfusion amount, essentially, to an exchange transfusion.

Hepatic clearance of drugs with low extraction coefficients is also sensitive to alterations of hepatic capacity (enzyme activity). There is evidence of impairment of hepatic enzyme activity in burn patients.¹¹⁴ Phase I reactions (oxidation, reduction, or hydroxylation by the cytochrome P-450 system) are impaired in burn patients while phase II reactions (conjugation

tion) seem to be relatively preserved.¹¹⁵ However, these generalizations do not always produce predictable alterations in pharmacokinetic parameters. For example, contradictory observations of morphine clearance in burn patients have been reported. Morphine metabolism is by glucuronidation. This is a phase II reaction which is normally retained in thermally injured patients. Consequently, morphine clearance has been reported unchanged as predicted or decreased.^{120,121} With so many variables involved, such as hepatic blood flow, V_d , plasma proteins, multiple drug exposure, and variation in burn injury, this inconsistency is not surprising. The key to effective drug therapy in burn patients is to monitor drug effects and carefully titrate the dose to the desired effect.

Muscle relaxants

In terms of anesthetic management, the most profound and clinically significant effect of burn injuries on drug response relates to muscle relaxants. Burn injuries of more than 25% total body surface area influence responses to both succinylcholine and the nondepolarizing muscle relaxants. In burned patients, sensitization to the muscle relaxant effects of succinylcholine can produce exaggerated hyperkalemic responses severe enough to induce cardiac arrest.^{122–124} In contrast, burned patients are resistant to the effects of nondepolarizing muscle relaxants.^{125–127} These changes are explained by up-regulation of skeletal muscle acetylcholine receptors.^{128–130}

Martyn and Richtsfeld¹³⁰ have recently reviewed the mechanisms of exaggerated hyperkalemic responses to succinylcholine. There are several disease states, including burns, denervation, and immobilization, that are associated with potentially lethal hyperkalemic responses to succinylcholine. The molecular mechanism appears to be both quantitative and qualitative changes in skeletal muscle postsynaptic nicotinic acetylcholine receptors. Animal and human studies consistently demonstrate an association of increased numbers of skeletal muscle acetylcholine receptors with resistance to nondepolarizing muscle relaxants and increased sensitivity to succinylcholine. In addition, the distribution of the new receptors is altered. Nicotinic receptors are normally restricted to the neuromuscular synaptic cleft but in these disease states new receptors are distributed across the surface of the skeletal muscle membrane. The new receptors are also a distinctly different isoform ($\alpha 7$ AChR) that has been referred to as an immature, extrajunctional, or fetal receptor. The immature receptors are more easily depolarized by succinylcholine and their ion channel stays open longer. The immature receptors are also strongly and persistently depolarized by the metabolite of acetylcholine and succinylcholine, choline. It has been suggested that the hyperkalemic response to succinylcholine after burn or denervation injury results when potassium is released from receptor-associated ion channels across the entire muscle cell membrane rather than just the junctional receptors. Depolarization persists because the channels stay open longer and the breakdown product of succinylcholine, choline, is also a strong agonist for the immature receptors.

Cardiac arrest in burned patients after succinylcholine administration was first reported in 1958.¹²² It was not until 1967, however, that an exaggerated hyperkalemic effect was identified as the cause of this phenomenon.^{123,124} Several clinical studies have documented exaggerated increases in potas-

sium concentrations after succinylcholine administration in burned patients. However, considerable individual variability exists; only a few patients in these series developed dangerously high potassium levels. The size of the increase was greatest about 3–4 weeks after injury. The earliest exaggerated hyperkalemic response described occurred 9 days after injury and normal responses were observed in the remaining patients in this series for up to 14–20 days.¹³¹ The shortest post-burn interval associated with succinylcholine-induced cardiac arrest was 21 days.¹³² Controversy surrounds recommendations regarding the safe use of succinylcholine after burn injury. Various authors recommend avoidance of succinylcholine at intervals ranging from 24 hours to 21 days after burn injury.^{5,133} A series of letters to the editor of *Anesthesiology* from experts in this area illustrates the controversy surrounding this question.^{134–136} It was pointed out by Martyn¹³⁶ that at the time when the mechanism of the cardiac arrest after succinylcholine was elucidated surgical treatment of burns was delayed for approximately 2 weeks until the eschar spontaneously separated. As a result there are few clinical data regarding potassium changes during this early period. On the basis of indirect evidence from experimental data, Martyn¹³⁶ recommended avoidance of succinylcholine, starting 48 hours after injury. This seems rational and prudent. Brown and Bell¹³⁷ described supersensitivity of burned pediatric patients to the relaxant effect of succinylcholine. They observed more than 90% depression of muscle activity with 0.2 mg/kg succinylcholine without dangerous hyperkalemia. Despite these observations, Brown and Bell state that it is generally advisable not to use succinylcholine in patients with large burns. The question remains: in the presence of life-threatening laryngospasm in a burn patient, is it acceptable to give a small dose of succinylcholine (e.g. 0.1 mg/kg) and accept a theoretical risk of hyperkalemia to treat a real and immediate risk of asphyxia? There is not enough clinical evidence to answer this question conclusively and it remains a matter of clinical judgment.

When rapid sequence induction and quick onset of paralysis in burn patients is desired rocuronium is the drug of choice. A dose of 1.2 mg/kg of this drug provided good intubation conditions in 86 + 20 seconds in burned patients.¹³⁸ The problem with this choice is that muscle relaxation will persist for some time and precludes extubation after short cases and difficulty with intubation and ventilation may require emergent surgical airway access. A cyclodextrin (Org 25969) has recently been tested in man as a reversal agent with a novel mechanism of action for rocuronium.^{138b} Org 25969 has been specifically designed to encapsulate rocuronium. This agent has been found to rapidly terminate neuromuscular blockade by rocuronium theoretically by sequestering it from nicotinic neuromuscular receptors. If this agent becomes approved for clinical use it may provide a way to rapidly reverse muscle relaxation with rocuronium and provide a more attractive choice for burn patients when rapid sequence induction is indicated.

Responses to nondepolarizing relaxants are also altered by burn injury. Three-to-fivefold greater doses are required to achieve adequate relaxation.¹²⁵ Resistance is apparent by 7 days after injury and peaks by approximately 40 days. Sensitivity returns to normal after approximately 70 days. Two reports described slight but measurable resistance to nondepolarizing relaxants persisting for more than a year after

complete healing of the wounds. The mechanism of the altered response appears to involve pharmacodynamic rather than pharmacokinetic changes. Up-regulated immature receptors are less sensitive to nondepolarizing relaxants. Burns greater than 25% total body surface area require higher total dose and greater plasma concentrations of nondepolarizing blockers to achieve a given level of twitch depression.¹²⁶

Proliferation of acetylcholine receptors across the muscle membrane has been used to explain both resistance to nondepolarizing muscle relaxants and the exaggerated hyperkalemic response to succinylcholine.³⁰ The observation of resistance of a patient to metocurine for up to 463 days after burn has been used to suggest that hyperkalemic responses to succinylcholine also could persist for more than a year.¹²⁷ However, no pathologic hyperkalemic responses to succinylcholine in burned patients have been reported more than 66 days after burns.¹³³

In contrast to other nondepolarizing neuromuscular blockers, mivacurium dosage requirements in pediatric patients appear to be unchanged by burn injury. The time to onset of drug action, degree of paralysis achieved by a specific dose, and rate of infusion required to maintain a given level of relaxation were all the same in burn patients as values reported for non-burned control patients.^{134,135} Plasma cholinesterase activity is reduced in burn patients.¹³⁶ In a study by Martyn, the observation of an inverse relationship between plasma cholinesterase activity and recovery time from 25 to 75% twitch tension suggests that reduction of metabolic degradation of mivacurium may compensate for other factors that induce resistance to relaxants.^{134,140} This observation suggests that mivacurium can be administered to burn patients in normal doses that would avoid cardiovascular perturbations associated with required larger doses of other relaxants in burn patients.

Anesthetic management

Airway management

If injuries do not preclude conventional airway management (i.e. mask fit, jaw lift, and mouth opening), standard induction and intubation procedures are appropriate. Hu et al. reported that gastric emptying was not delayed in patients with severe burns so that a rapid sequence induction is not necessary.¹⁴¹ However, attention should be given to gastric residuals during enteric feeding. Development of sepsis can slow gastric emptying which can result in retained fluids in the stomach and risk of aspiration.

When burns include face and neck, swelling and distortion may make direct laryngoscopy difficult or impossible. In addition, loss of mandibular mobility may impair airway manipulation and make mask ventilation difficult. Fiberoptic intubation while maintaining spontaneous ventilation is a safe and reliable technique under these conditions. Fiberoptic intubation can be performed in awake adults but pediatric patients are unable to cooperate and must be sedated. Since most anesthetics cause collapse of pharyngeal tissues and airway obstruction they are unsuitable for fiberoptic intubation in patients whose airway would be difficult to manage with a mask.¹⁴² Ketamine, however, is unique among anesthetic drugs because it maintains spontaneous ventilation and airway patency (Figure 14.6).^{143,144}

Fig. 14.6 Magnetic resonance images of a healthy volunteer during inspiration while conscious (a), or anesthetized with propofol (b) or ketamine (c). Anterior-posterior diameter of the pharynx at the level of the soft palate is marked by decreased during propofol anesthesia (b) but maintained during ketamine anesthesia (c).

Ketamine anesthesia has been found safe and effective for airway management in infants with difficult airways caused by congenital airway anomalies. Reports of successful nasotracheal intubation in infants with congenital airway malformations have been made both by manipulations guided by fiberoptic nasopharyngoscopy and the conventional technique of fiberoptic intubation with the endotracheal tube mounted on the fiberscope.^{145,146} In the latter case an ultra-thin bronchoscope (2.7 mm) was required because a larger fiberscope would not fit through the appropriate-sized endotracheal tube. To facilitate intubation under ketamine anesthesia, topical anesthesia of the larynx with lidocaine prior to instrumentation of the larynx is advised. Since the ultra-thin bronchoscope lacks a working channel for administration of topical lidocaine, fiberoptic intubation with the 2.7 mm bronchoscope was preceded by nasopharyngoscopy with a 3.5 mm fiberscope for administration of topical lidocaine. At SBH Galveston we have also found this technique, utilizing two fiberscopes, effective in infants with burn injuries. Wrigley et al. evaluated the use of a 2.2 mm intubating fiberscope during halothane anesthesia in ASA 1 or 2 children aged 6 months to 7 years.¹⁴⁷ In this series of 40 patients a number of complications were experi-

enced including laryngospasm and failure to achieve intubation with the fiberscope. This experience is in contrast to numerous reports of safe and effective airway management with ketamine.

Securing an endotracheal tube in a patient with facial burns presents a variety of problems and numerous techniques have been described.¹⁴⁸ Tape or ties crossing over burned areas will irritate the wound or dislodge grafts. A useful technique to avoid these problems involves the use of a nasal septal tie with one-eighth inch umbilical tape (Figure 14.7). The umbilical tape is placed around the nasal septum using 8 or 10 French red rubber catheters that are passed through each naris and retrieved from the pharynx by direct laryngoscopy and McGill forceps. A length of umbilical tape is tied to each of the catheters; and when the catheters are pulled back through the nose, each end of the umbilical tape is pulled out its respective naris, producing a loop around the nasal septum. Before securing with a knot, care should be taken to assure that the uvula is not captured in the loop. A knot in the nasal septal tie should be snug enough to prevent excessive movement of the endotracheal tube but loose enough to prevent ischemic necrosis of the underlying tissues.

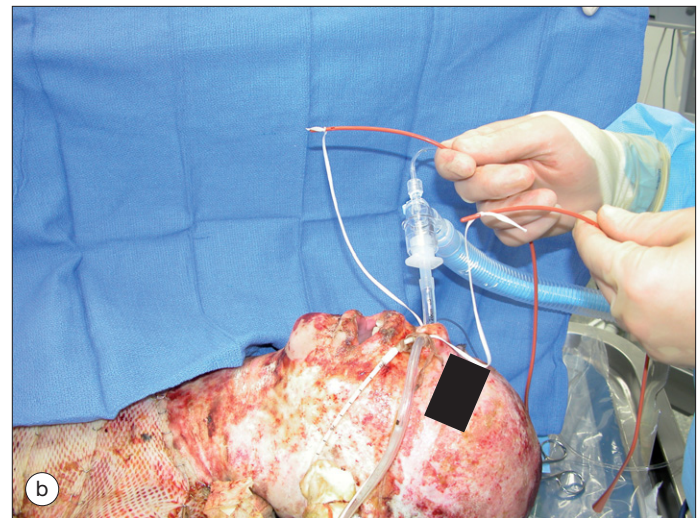

Fig. 14.7 Nasotracheal tubes can be secured with confidence by tying to umbilical tape tied in a loop around the nasal septum. (a) Red rubber catheters (8 or 10Fr) are passed through each naris, retrieved with McGill forceps from the oropharynx, and each end of a piece of umbilical tape is tied to the catheters. (b) When the catheters are pulled out of the nares, the umbilical tape follows and, after laryngoscopy to assure the uvula has not been entrapped, a loop can be tied around the bony nasal septum. (c) Umbilical tape can be used to secure the endotracheal tube to this loop. This technique is very secure, avoids irritating facial burn wounds or grafts, and leaves the surgical field free of tape or ties.

Airway management using a laryngeal mask airway (LMA) has also been used successfully during burn surgery for children. McCall et al. reported their experience with 141 general anesthetics administered to 88 pediatric burn patients.¹⁴⁹ Nineteen (14.5%) of the procedures were complicated by respiratory events such as unseating, desaturation, and partial laryngospasm that required intervention. Two of these events required intraoperative intubation without sequelae, while all other events resolved with therapy. Interestingly, the presence of preoperative respiratory problems or face/neck burns did not predict intraoperative respiratory problems. These authors suggest that, in patients with upper airway mucosal injury, LMA airway management may help avoid further laryngeal injury that might occur with intubation of the trachea.

Hagberg et al. published a case report describing the successful use of an esophageal tracheal Combitube™ in a patient undergoing elective surgery for burn scars involving the mouth.¹⁵⁰ The patient had a Class IV oral airway by Samsoon and Young's modification of the Mallampati airway classification and limited mouth opening. A translaryngeal endotracheal tube was undesirable because tracheostomy had resulted in subglottic stenosis which could have been exacerbated by an endotracheal tube. After induction with fentanyl and propofol the Combitube™ was placed and the patient was relaxed with rocuronium and mechanically ventilated during the 60 minute procedure.

Monitors

As with any critically ill patient suffering from multiorgan system involvement, the choice of monitors in a burned patient will depend on the extent of the patient's injuries, physiological state, and planned surgery. In addition to the preoperative pathophysiology associated with thermal injuries, perioperative monitoring must be adequate to assess rapid changes in blood pressure and tissue perfusion associated with the massive blood loss that can accompany excision of burn wounds. The minimum standards of the American Society of Anesthesiologists require monitoring of circulation, ventilation, and oxygenation. Standard monitors include electrocardiography (EKG), measurement of systemic blood pressure, pulse oximetry, capnography, and inspired oxygen concentration. The ability to measure body temperature should be readily available and is highly recommended for the burn patient.

Standard EKG gel electrodes usually will not adhere to burn patients because the skin is injured or covered with antibiotic ointment. For acute burn surgery, surgical staples and alligator clips are useful. Respiratory rate can be quantitated using bioimpedance from the EKG signal or from the capnogram. Pulse oximetry in burn patients can be difficult when transmission pulse oximetry sites are either burned or within the operative field. Reflectance pulse oximetry has been suggested as an alternative in these circumstances.¹⁵¹ However, an effective commercially available instrument has been slow in development.

If direct arterial pressure monitoring is not necessary, a blood pressure cuff can provide accurate measurements even if placed over bulky dressings applied to an extremity.¹⁵² Systolic blood pressures obtained from the pressure at which the pulse oximetry signal returns during cuff deflation has also been found accurate.¹⁵³

When blood loss is expected to be rapid and extensive, blood pressure may change more rapidly than the interval between cycles of noninvasive blood pressure measurement. In this case an arterial catheter can provide direct and continuous measurement of blood pressure. This monitor can provide much more information regarding the patient's circulatory status than just systolic and diastolic blood pressure. The arterial pressure waveform is influenced by preload, contractility, and vascular tone. Perioperative variation in the rate of rise of arterial pressure, the area under the pressure wave, position of the dicrotic notch, and beat-to-beat alterations in systolic pressure related to respiration all reflect clinically significant hemodynamic changes.¹⁵⁴ With experience, trends in these variables can help guide volume and vasoactive therapy. Display of the beat-to-beat arterial pressure allows measurement of systolic pressure variation (SPV). SPV is the difference between maximum and minimum systolic blood pressure during a single cycle of positive pressure mechanical ventilation. Several studies have correlated SPV with cardiac output response to volume infusion. Tavernier et al. reported that in septic patients on mechanical ventilation, SPV is a better predictor of left ventricular ejection volume response to volume loading than either pulmonary artery occlusion pressure or echocardiographic measurement of left ventricular end diastolic area.¹⁵⁵ Measurements are not as simple as merely 'eyeballing' the blood pressure trace because several variables influence SPV, including arrhythmias, tidal volume, and mechanical versus spontaneous ventilation. SPV provides a dynamic assessment of the interaction of preload and cardiac output.¹⁵⁶

Arterial blood sampling for blood gas analysis also provides valuable information regarding pulmonary function and acid-base balance. Inadequate tissue perfusion may manifest as metabolic acidosis despite apparently adequate arterial and central venous blood pressures.

In patients with large burns a central venous catheter serves several functions. Central venous pressure can be useful for titrating blood and fluid administration. Blood samples from a central vein are not truly mixed venous but trends in central venous oxygen tension can help identify inadequate tissue perfusion. A central venous catheter sutured into place also provides very secure intravenous access and is an ideal route for administration of vasoactive infusions. A pulmonary artery catheter is usually not required for burn surgery. In some cases, however, the ability to more closely monitor ventricular function and oxygen supply/demand relationships may be helpful as when large doses of inotropes or high PEEP is required. As described above, a newer transpulmonary thermodilution catheter system is also capable of estimating thoracic and end diastolic cardiac blood volumes. These measures of preload have been reported to correlate better than filling pressures (central venous pressure or pulmonary artery occlusion pressure) with changes in cardiac index or oxygen delivery with fluid volume administration.

Urine output is the most useful perioperative monitor of renal function. Urine output of 0.5–1.0 mL/kg/h is often recommended as an endpoint for fluid management in acute burn patients. Adequate urine output is one measure of both renal and global perfusion. When intraoperative transfusion is planned, examination of the urine may be the only reliable

indicator of a transfusion reaction since signs and symptoms other than hematuria are masked by general anesthesia or hemodynamic changes associated with burn surgery. Myoglobinuria may also occur after burn injury and in this case a Foley catheter is necessary to monitor response to therapy. Diuretic therapy for myoglobinuria or any other indication will negate the usefulness of urine output as an index of perfusion.

Vascular access

Securing adequate vascular access in the acutely burned patient is one of the more technically challenging procedures facing the anesthesia care team. In the pediatric age group the task can be even more difficult. Skin sites for insertion of vascular access catheters may be involved in the burn, and regional anatomy is often distorted by burn, edema, or scarring. Early in the course of an acute burn, shock leads to vasoconstriction, making cannulation of peripheral vessels nearly impossible. Later, once the patient has had several operative procedures, scarring in the area of access sites makes their placement difficult as well. Since burn patients undergo multiple debridement procedures it is necessary to attain vascular access many times in each patient. The need for frequent catheter changes between procedures to minimize catheter-related sepsis compounds the problem. The anesthesia care team is frequently involved in the maintenance of adequate vascular access during the period of acute care and therefore must be facile in their placement. When a large portion of the surface area is burned, it becomes necessary to insert catheters through burned skin. Sutures are typically necessary to secure these catheters. If the burn is deep, it may have to be debrided prior to line placement so that the catheter can be sutured to viable tissue.

For the operative excision of a large burn wound, an arterial catheter allows continuous blood pressure monitoring in the face of sudden and sometimes massive blood loss as well as during the titration of vasoactive drugs. It also allows easy access to blood samples for arterial blood gases, chemistries, and serial hematocrit determinations. For pediatric patients with large burns, arterial monitoring is essential. Achieving arterial access is often complicated by overlying burn, skin graft, or scarring. In the latter case palpation of pulses can be difficult and the use of a Doppler probe is often very helpful.

The radial artery is the most frequently used site for monitoring nonburned patients, with large numbers of patients cannulated without complications.¹⁵⁷ There is a relatively high rate of arterial occlusion: 8% with 20-gauge catheters and 34% with 18-gauge, but almost all completely recanalize.¹⁵⁸ Clearly, however, the catheter must be removed if distal hand or digit ischemia develops. In patients with severe hypotension the radial artery is not always easy to cannulate and blood pressure readings from the vessel can be inaccurate. Additionally, it is often difficult to maintain a radial arterial catheter in burn patients for more than 48 hours, particularly in pediatric patients, and, unfortunately, the hands and forearms are typically involved in a large burn wound.

Accessing the femoral artery is easier in most patients, particularly those in low perfusion states because it is a larger and more central vessel.^{159,160} The groin is often spared from injury, even in a large burn, and placement of a catheter in the femoral

artery is not affected greatly by the presence of edema.¹⁶¹ The duration of patency is longer than that of a radial artery catheter, and the incidence of infection in a femoral artery catheter is similar to that of any other location, about 1%.¹⁵⁹ The risk of mechanical complications is smaller than that of more peripheral arteries because the arterial/catheter diameter ratio is larger. Still some recommend avoiding the femoral site unless no other site is available since loss of limb, or limb length discrepancy in children, is a devastating, if rare, complication.¹⁶²

Other sites for arterial access include the dorsalis pedis, posterior tibial, and temporal arteries, none used with great frequency, and all distal enough to give inaccurate blood pressure readings, particularly in hypotensive patients. Use of the axillary artery has the disadvantages of a relatively higher rate of infection and difficulty in maintaining correct arm positioning for proper catheter function.¹⁶³

The incidence of complications from arterial catheters has been cited as anywhere from 0.4 to 11%, with the higher rate seen most often in pediatric patients, particularly those under 1 year of age.^{164–166} Early complications include bleeding, which is usually easily controlled, and hematoma formation, which is more common if the artery is transected during cannulation and is avoided by an adequate period of pressure applied to the site if bleeding occurs. Damping of the arterial waveform or clotting of the catheter is more common with small catheters or small arteries; this can be lessened somewhat by continuous heparin flushing systems.¹⁶⁷

The incidence of catheter-related infections with arterial catheters is generally low, quoted at anywhere from 0.4 to 2.5% until 4 days duration. The incidence of infection gradually increases to 10% by 7 days, but stays constant thereafter. This relatively low rate of infection in comparison to central venous catheters confirms the clinical impression that catheter-related infections are less commonly seen in the high-flow arterial system.^{162,168}

Vascular insufficiency of the distal extremity occurs in 3–4% of patients in whom arterial catheters are placed.¹⁶³ Fortunately, most cases of ischemia resulting from vascular obstruction are evident immediately and resolve when the catheter is removed. The risk of ischemia can be minimized by selecting the smallest possible catheter that will give an accurate arterial waveform.¹⁶¹ There is a marked increase in the incidence of arterial vasospasm when over 50% of the vessel lumen is occluded by the catheter.¹⁶⁹ This is certainly more of a problem in pediatric patients than adults. Predisposing factors to ischemia from arterial obstruction include hypotension, the use of vasoconstrictors, prolonged catheterization, age under 5 years, and insertion by cutdown.¹⁷⁰ Indeed, most reports of chronic sequelae have come in patients less than 1 year of age who were hypotensive at the time of catheter insertion. Other less commonly reported complications from arterial catheters include cutaneous damage, pseudoaneurysm formation, and septic arthritis of the hip.^{171–173}

Central venous catheters are very useful for large-volume resuscitation in patients with burns over 30% or more of their TBSA. As with arterial catheters, burn wound, edema, and scarring all hamper the placement of central venous catheters. Normal anatomic landmarks can be totally obliterated. The problem is compounded by the need for long-term access in

patients with large burns who are also at high risk for central venous catheter infections and so will require frequent line changes. Ultrasound guidance has been used successfully to guide correct placement of appropriate-size catheters into central veins but is less helpful for the subclavian approach and extensive scarring from burn wounds can degrade the ultrasound image.

Catheters placed in the subclavian vein have a lower risk of infection than those placed in the internal jugular or femoral vein, but carry a higher risk of mechanical complications during their placement.¹⁷⁴ The internal jugular vein is typically more difficult to access in burn patients with facial and neck burns or edema and is associated with a higher infection risk. Additionally it is a difficult position in terms of patient comfort, particularly for pediatric patients. The femoral vein is a large central vein that is usually easy to cannulate. It has several advantages, including no risk of pneumothorax, easier control of bleeding, less anatomic distortion due to edema, and the inguinal region is often spared even in a large burn. The risk of catheter-related infection is higher in the femoral vein than at other vascular access sites in some studies, and the risk of venous thrombosis is also quoted by some authors as being greater.^{175–177}

Early complications with the placement of venous catheters include trauma, hematoma, bleeding, air embolus, pleural effusion, pneumothorax, or pericardial tamponade. Delayed complications include infection and thrombosis, which have been studied by many authors with often conflicting results. In one trial, 45 patients were randomized to either an upper extremity catheter group in which catheters were placed in the internal jugular or subclavian vein, or to a lower extremity catheter group in which catheters were placed in the femoral vein. No patients in the upper extremity group developed thrombosis, while six patients (25%) in the lower extremity group developed deep vein thrombosis. Additionally, another seven patients (29%) in the lower extremity group had non-diagnostic ultrasound findings.¹⁷⁷ In another trial involving pediatric patients, mechanical complications occurred in 9.5% of femoral venous catheters but only 1.8% of nonfemoral catheters.¹⁷⁸ A third study involved 162 femoral venous catheters and 233 nonfemoral venous catheters; mechanical complications were equal in the two groups, 2.5% versus 2.1%. However, three of four patients who developed thrombosis were in the femoral group, as was the one patient who developed an embolus.¹⁷⁶ Conversely, 1449 femoral venous catheters were maintained in 313 burn patients with no pulmonary emboli. These catheters were changed every 3 days and the authors maintain that the femoral site can successfully be used as part of a site rotation for central venous access in burn patients.¹⁷⁹ Another 224 pediatric burn patients with femoral venous catheters had only a 3.5% incidence of mechanical complications, including only one thrombus.¹⁸⁰ Finally, there has been a 20–46% incidence of femoral venous thrombosis found at autopsy in patients with femoral venous catheters left in place for a week or longer. A 67% incidence of thrombotic complications has been reported with internal jugular catheters and 61% with umbilical venous catheters when studied at autopsy.¹⁸¹ It would seem safe to say that the femoral vein can be used for catheterization for short intervals with frequent line changes and diligent monitoring for thrombotic complications.¹⁸²

When looking at the incidence of catheter-related infection from central venous catheters in burn patients, the answer is even less clear. There is an inherent difficulty when talking about the incidence of catheter-related infection in burn patients for several reasons. First, the patients with central venous catheters are the sickest patients. Secondly, the burn wound is a constant source of infection and pneumonia, and urinary tract infections are also fairly common in critically ill burn patients; in many patients catheter-related infection is a diagnosis of exclusion but burn patients always have at least one other obvious source of infection. Finally, since most catheter-related infections develop when bacteria migrate down the catheter tract from the skin, there is a higher risk of catheter infection when the insertion site is through or very near a burn wound.^{183,184} To further cloud the picture, differing definitions of catheter-related infection make comparing different studies of the problem more difficult. Catheter-related infection in burn patients has been reported to have an incidence as low as 2.5% and as high as 22.4%.¹⁸³ One large study of 1183 burn patients and 1346 central venous catheters showed that the incidence of catheter-related infection was 19.5% with a mortality of 14.1%. These authors cite catheter-related infection as the second most common cause of sepsis in the burn patient after the burn wound.¹⁸⁵

Many older studies recommend frequent catheter changes to decrease the incidence of infection, but several studies show no increase in infection out to as many as 7–10 days. Three large randomized trials demonstrated no difference in the incidence of catheter-related infections among groups who had lines placed at a new site every 7 days and groups who had their lines changed over a guidewire every 7 days.^{175,186,187} The incidence of mechanical complications is clearly lower with guidewire exchange rather than changing to a new site. Several other trials have also indicated no advantage to routine changing of catheters before 7–10 days.^{180,188,189} There are conflicting data in relation to incidence of infection and the site of the central venous catheter, although almost all studies agree that the incidence of infection is lowest if the subclavian approach is used.^{175,178,189,190} Also, all studies that compared single-lumen and multilumen catheters found a lower rate of infection with single-lumen catheters.^{174,189,190} Those that compared percutaneous catheter placement with placement via cutdown technique found a higher incidence of infection with cutdowns.^{189–191}

Advances in vascular catheters that incorporate an antibiotic have improved the efficacy of these devices in reducing the incidence of catheter-related bloodstream infections. A recent prospective, randomized trial examined the efficacy of two types of central venous catheters that incorporate antibiotics: one catheter releases silver ions continuously and the other is impregnated with two antibiotics with different mechanisms of action, rifampin and minocycline. Both catheters were associated with low rates of catheter-related bloodstream infections.¹⁹² Improvements in this technology would provide two significant clinical advantages. Reduced colonization of central venous catheters will reduce bloodborne infections and reduced need for changes in vascular access sites for infection control will reduce the incidence of mechanical complications of catheter insertion.

Additional measures recognized by the CDC for reducing catheter-related bloodstream infections include maximum

sterile barrier technique (cap, mask, sterile gown, sterile gloves, and large sterile drape with a small opening).¹⁹³ A meta-analysis concluded that chlorhexidine gluconate is superior to providone-iodine for insertion-site disinfection.¹⁹⁴

The operative debridement of a large burn wound is accompanied by rapid and sometimes considerable blood loss. Critical hypoperfusion of vital organs begins to occur when 20–30% of the blood volume is lost.¹⁹⁵ Irreversible shock and cellular damage can begin to occur within minutes, depending on the continuing rate of loss. The achievement of a very rapid fluid infusion rate is critical in the resuscitation of the patient undergoing operative excision of the burn wound. Clearly, adequate venous access to achieve rapid infusion rates is imperative.

The laminar nonpulsatile flow of fluid through a tube was described by Poiseuille and is expressed by the formula:

$$Q = \Delta P \pi r^4 / 8 \eta L$$

where Q is flow, ΔP is the pressure differential in the tube, r is the radius of the tube, η is viscosity of the fluid, and L is the length of the tube. From this formula, several relationships are established (Table 14.7). Flow through a tube can be increased by high-pressure gradients, tubes of large diameter and short length, and the use of low-viscosity fluids. The most significant variable is the radius of the tube, where changes result in exponential changes in flow: doubling the diameter of the tube increases flow 16 times. There have been a number of studies comparing flow rates of various catheters under different conditions. It is difficult to compare these studies directly since methods are not standardized. However, it is possible to gain from them valuable insight about the factors affecting flow. Large-diameter, short catheters maximize flow, as does a central venous location: flow is 20–40% less in a peripheral vein than in a central vein for the equivalent diameter and length catheter. Peripheral veins add resistance to flow before fluid is delivered to the central compartment.¹⁹⁶ Flow rates, however, are equal in hypovolemia and normovolemia for the same catheter size and length.

The high viscosity of blood diminishes flow rates considerably. Diluting one unit of packed red blood cells with 250 mL of normal saline can increase the flow of the blood by tenfold.¹⁹⁷ The application of a 300 mmHg pressure device to the blood unit can increase the flow rate another seven times. The diameter and length of the intravenous tubing system delivering fluid from the bag to the patient has profound effects on the rate of fluid delivery. Large-bore trauma tubing with an internal diameter of 5.0 mm allows fluid to flow three times as fast as standard blood infusion set tubing with an internal diameter of 4.4 mm, which is twice as fast as standard intravenous tubing with an internal diameter of 3.2 mm. The large-bore trauma tubing allows fluid flow rates of 1200–1400 mL/min.¹⁹⁸ Also, infusing blood or fluid through a ‘piggyback’ system into another access line can decrease flow by up to 90%

Several large studies have shown introducer catheters to be superior to all other devices for the rapid infusion of blood and intravenous (IV) fluid (Tables 14.8 and 14.9). These catheters are typically of large diameter, with thin walls and no tapering so that for any given catheter size the inner diameter is largest.^{195,199,200} This finding holds especially true for pediatric patients where vessel size is limited. The flow rate of a 4-French introducer catheter is greater than a 16-gauge IV cath-

TABLE 14.8 INTRODUCER CATHETER SIZES AND FLOW RATES (FLOW RATES FOR NORMAL SALINE UNDER GRAVITY)

Catheter size	Patient size	Flow rate
4 French	5–10 kg	285 mL/min
5 French	10–15 kg	380 mL/min
6 French	15–20 kg	480 mL/min
7 French	>20 kg	585 mL/min
8.5 French	>40 kg	805 mL/min

TABLE 14.9 INTRAVENOUS CATHETER SIZES AND FLOW RATES (FLOW RATES FOR NORMAL SALINE UNDER GRAVITY)

Intravenous catheter	Flow rate
24 gauge	14 mL/min
22 gauge	24 mL/min
20 gauge	38 mL/min
18 gauge	55 mL/min
16 gauge	75 mL/min
14 gauge	93 mL/min

eter. However, the 4-French introducer, placed by the Seldinger technique, requires only a 21-gauge needle to be inserted into the vein for its placement.

When planning vascular access for perioperative anesthetic management it is important to be aware of and take into account the patient’s hospital course. Choice of access site should avoid vessels previously involved in complications such as thrombosis or vascular injury. Note must be taken of when existing catheters were placed and what the local convention is with regard to timing of regular changes of access sites for infection control. The patient’s hospital course must also be considered when choosing a catheter. Although introducers offer the greatest flow and may provide the anesthesiologist a sense of assurance, the patient may require continuous vascular access for months of hospitalization and may return for surgery weekly. Large vascular introducers placed weekly will not be tolerated without complications that may result in morbidity and will limit access sites for future surgery. The catheter should be large enough to transfuse appropriately for the case but catheters much larger will increase risk without benefit.

Patient transport

The safe transport of a critically ill burn patient to and from the operating room can be a formidable task. A methodical approach will help to insure patient safety and the seamless maintenance of respiratory, hemodynamic, and general support. Hemodynamic status should be optimized prior to patient transport; pharmacological support may be required. The American Society of Anesthesiologists standards mandate evaluation, treatment, monitoring, and equipment appropriate to the patient’s medical condition for any transport. Depending on the patient’s condition, simple observation may be

appropriate. Patients requiring supplemental oxygen should be monitored by pulse oximetry. Hemodynamic monitoring is guided by the patient's hemodynamic status. Sufficient battery power must be available for uninterrupted monitor and infusion pump function during transport.

Airway supplies should be readily available, including a full oxygen cylinder, a self-inflating Ambu bag with mask, and intubation equipment. The patient's airway and ventilation as well as overall condition must be continually observed by the anesthesia care team. Drugs for resuscitation should accompany the patient on any transport. As discussed below, hypothermia is poorly tolerated by patients with an acute burn injury. It is imperative that patients be kept warm during transport in order to avoid increasing oxygen consumption and taxing limited metabolic reserve.

Selection of anesthetic agents

Many anesthetic agents have been used effectively for the induction and maintenance of anesthesia in burn patients. Intravenous agents (Table 14.10) can be used for both induction and maintenance and the specific agent used will depend primarily on the patient's hemodynamic and pulmonary status as well as the potential difficulty in securing the patient's airway. Ketamine has many advantages for use in the burn patient for induction and maintenance of anesthesia. As an induction agent, ketamine can be administered at a dose of 0.5–2.0 mg/kg. Except in patients that are catecholamine-depleted, ketamine generally preserves hemodynamic stability (Figure 14.8). In addition, ketamine preserves hypoxic and hypercapnic ventilatory responses and reduces airway resistance.²⁰¹ Compared to other IV anesthetics, airway reflexes remain more intact after ketamine administration. However, some risk of aspiration remains. Patients who do not require ventilatory support can be allowed to breathe spontaneously, which provides an additional margin of safety should inadvertent extubation occur. In fact, some clinicians have reported the use of ketamine anesthesia without instrumentation of the

airway.^{202,203} Patients were allowed to breath spontaneously and the airway complication rate was comparable to that of intubated patients. The use of intramuscular ketamine can be beneficial in securing the airway in pediatric burn patients or uncooperative adults who do not have vascular access. Because ketamine preserves spontaneous ventilation and induces dissociative anesthesia, it provides good conditions for securing the airway by fiberoptic bronchoscopy. Addition of other anesthetic agents, particularly potent volatile agents or opioids, should be avoided until the airway is secured because these anesthetics depress respiratory drive and relax pharyngeal muscles, thus increasing the risk of apnea, upper airway obstruction, or laryngospasm. Ketamine can also be utilized, either alone or in combination with other anesthetics, for maintenance of anesthesia either by infusion or intermittent bolus. Ketamine has potent analgesic properties and is used extensively in the operating room as well as for painful dressing changes and patient manipulations. A drying agent such as glycopyrrolate (2–5 µg/kg) is commonly given in combination with ketamine to reduce ketamine-induced secretions. In addition, benzodiazepines are often recommended in older children and adults to reduce the incidence of dysphoria sometimes associated with ketamine administration. Induction agents such as thiopental or propofol are more commonly used in patients returning for reconstructive procedures rather than in the acute phase of injury but are also sometimes chosen in patients with small burns and no evidence of airway or facial involvement when direct laryngoscopy is planned.

TABLE 14.10 DOSAGE GUIDELINES FOR THE MOST COMMONLY USED INTRAVENOUS ANESTHETIC INFUSIONS			
Infusion rate			
Anesthetic	Loading dose (mg/kg)	Maintenance of anesthesia* (mg/min)	Sedation (mg/min)
Thiopental	2.0–4.0	10–20	1.0–5.0
Methohexital	1.5–3.0	5.0–8.0	0.5–2.5
Midazolam†	0.2–0.4	0.1–1.0	0.035–0.7
Etomidate	0.2–0.4	1.0–2.0	0.5–1.0
Propofol	1.5–2.0	4.0–12.0	2.0–5.0
Ketamine‡	0.5–1.0	0.7–5.4	1.0–2.0

*Adjuvant to other agents (i.e. nitrous oxide, opioids).
†Infusion rate for midazolam is highly variable. Values in the table represent more commonly used doses.
‡Ketamine is contraindicated in head-injured patients. Its inclusion in this table pertains to use in other injuries.

Fig. 14.8 Heart rate, mean arterial pressure, and cardiac index changes during a 15-minute period of ketamine administration to critically ill patients. (From: Nolan JP. Intravenous agents. In Grande CM, et al., eds. Textbook of trauma anesthesia and critical care. St. Louis: Mosby Yearbook; 1993.)

Volatile anesthetics may be used for both induction and maintenance of anesthesia in burn patients. In pediatric patients, mask induction with either halothane or sevoflurane is commonly used if the patient does not have injuries that may make airway manipulation difficult. In the acute setting, an anesthetic technique involving nasotracheal intubation after mask induction with halothane, nitrous oxide, and oxygen has been described.²⁰⁴ The proponents particularly emphasize avoiding the potential problems associated with the ketamine-based technique. However, volatile agents produce dose-dependent cardiac depression and vasodilation (Table 14.11). In addition, hypoxic ventilatory drive is ablated by volatile anesthetics at low concentrations and a dose-dependent depression of hypercapnic drive also occurs. However, as maintenance agents, volatile anesthetics have predictable washin and washout kinetics (Figure 14.9) and provide a useful adjunct to other agents when titrated to hemodynamic and ventilatory parameters. Of the volatile agents, nitrous oxide has the least impact on cardiovascular and respiratory function and can serve as a useful component of a balanced anesthetic if the patient's oxygen requirements permit (Table 14.11).

Opioids are important agents for providing analgesia for burn patients throughout the acute phase of injury and for

providing postoperative analgesia in patients undergoing reconstructive procedures. The spectrum of opioids currently available provides a wide range of potencies, durations of action, and effects on the cardiopulmonary system (Table 14.12). Burn patients experience intense pain even in the absence of movement or procedures, and opioids are the mainstay for providing analgesia in the acute phase of burn management. However, acute burn patients usually become tolerant to opioids because they receive continuous and prolonged administration of these drugs. Therefore, opioids should be titrated to effect in the acute burn patient. Most opioids have little effect on cardiovascular function but they are potent respiratory depressants. Therefore, the ventilatory status of patients receiving opioids, particularly those with challenging airways, should be monitored closely.

Regional anesthesia can be used effectively in patients with small burns or those having reconstructive procedures. In pediatric or adult patients having procedures confined to the lower extremities, lumbar epidural or caudal anesthesia can provide a useful adjunct for control of postoperative pain. In cooperative adult patients with injuries confined to lower extremities, epidural or intrathecal anesthesia may be used if no contraindications exist. For upper extremity procedures,

brachial plexus block may be considered as the primary anesthetic or as an adjunct for postoperative pain control.

Scalp donor sites are particularly painful. Sensory nerves to the scalp are superficial and easily blocked with injections of local anesthetic and this technique has been used for awake craniotomy.²⁰⁵ Scalp blocks have been used with success at our institution for donor sites in acute patients (unpublished observation) and for scalp procedures in reconstructive patients.²⁰⁶

Fluid management

Fluid management and blood transfusion for burn wound excision can be quite challenging. Fluid administration should be guided not only by intraoperative events but previous hospital course and ICU treatment goals. If early excision is performed during the first 24 hours, perioperative fluid management may involve the acute resuscitation and fluid needs will exceed replacement of shed blood. Even after this period insensible fluid requirements are increased by large open surfaces from excised wounds, hypermetabolic state, and hyperthermia. However, early in the patients' hospital course, patients are edematous from the large amounts of crystalloid solutions administered during resuscitation. At this time additional crystalloid administered during the perioperative period may be poorly tolerated and may result in complications of compartment syndrome in extremities or the abdomen. After the initial period of resuscitation, ICU therapy may include vigorous attempts to reduce edema including the use of diuretics. If the ICU staff have been administering diuretics to the patients all week in order to reduce interstitial edema it is not helpful when the patient receives several liters of fluid in the operating room. Perioperative fluid management must also take into account hypotonic clysis fluids that the surgeons may inject to facilitate donor skin harvest with the dermatome. In

small children the volume of this fluid can be in excess of 50 mL/kg. State of hydration and electrolyte balance must be monitored carefully in order to maintain proper fluid balance.

Replacement of surgical blood loss during burn wound excision and grafting can be just as challenging. Unlike most general surgical procedures, during burn surgery it is impossible to accurately estimate the amount of shed blood. Shed blood is not collected in suction canisters where it can be measured. During burn surgery shed blood is concealed beneath the patient, in drapes, in sponges, or may be washed down a drain on the operating table. As discussed above regarding the initial resuscitation, there is no one physiological endpoint to titrate volume replacement. Arterial pressure may be maintained by vasoconstriction despite significant hypovolemia, central venous pressure is not a reliable index of preload, changes in urine output and hematocrit lag behind rapid reductions in blood volume, and metabolic acidosis may indicate deficient perfusion but does not identify the specific problem. All of these variables are useful, however, when evaluated together. Although, systolic blood pressure may be within the normal range, alterations in the arterial waveform and changes with the respiratory cycle may indicate hypovolemia. Even though central venous pressure correlates poorly with hemodynamic function, this variable is useful in determining if volume administration will be tolerated by the patient. If perfusion appears inadequate and central venous pressure is low or normal it is safe to give volume. If central venous pressure is elevated, volume administration may cause pulmonary edema.

The concept of transfusion trigger with regard to burn care is discussed below. It must be remembered, however, that during rapid blood loss the hematocrit may change much

slower than the blood loss and often blood must be administered before the hematocrit falls below a specific trigger.

Blood transfusion

The need for blood transfusion is usually not a major concern during the immediate resuscitation phase in acutely burned patients unless other coexisting trauma exists. Nevertheless, a fall in plasma hemoglobin concentration can occur during the acute resuscitative phase due to hemodilution and blood loss from escharotomies and other invasive procedures.²⁰⁷ However, major blood loss is common when patients are taken to the operating room for excision and grafting of burn wounds. Desai and colleagues reported that the amount of blood loss during burn wound excision is determined by the age of the burn, the body surface area involved, and whether infection is present (see Table 14.4).¹⁰ In general, more blood loss was observed as the time from initial injury increased and if wounds were infected. Transfusion requirements ranging from 0.45 to 1.25 mL of packed red blood cells (PRBCs) per cm² burn area were reported. In another study, Criswell and Gamelli²¹² reported an average transfusion rate of 0.89 mL PRBC/cm² burn area in a cohort of adult burn patients. A study by O'Mara and colleagues showed an average transfusion rate of 0.65 mL PRBC/cm² in a heterogeneous group of burn patients.²⁰⁸

Controversy exists regarding transfusion triggers and targets. Some authors advocate allowing hematocrit to drop to 15–20% prior to transfusion in otherwise healthy patients undergoing limited excision and transfusing at a hematocrit of 25% in patients with preexisting cardiovascular disease.²⁰⁹ The same group proposed maintaining hematocrit near 25% in patients with more extensive burns, and near 30% if the patients have preexisting cardiovascular disease. A small study by Sittig and Deitch showed fewer transfused units and no increase in adverse hemodynamic or metabolic effects in patients transfused at a hemoglobin of 6–6.5 g/dL compared to patients maintained at a hemoglobin near 10 g/dL.²¹⁰ However, in general, little outcome data exist regarding the optimum transfusion trigger for blood transfusion during burn wound excision. Assessment of blood transfusion needs is best determined by evaluating the clinical status of the patient. Specifically, assessment of ongoing blood losses, preoperative hemoglobin levels, vital signs, and evidence of inadequate oxygen delivery such as hypotension, tachycardia, acidosis, and decreasing mixed venous oxygen tension provide important information regarding the oxygen balance in the patient. In addition, determinations of the patient's oxygen content needs are important in determining the transfusion trigger for an individual patient. Patients with coexisting cardiac and pulmonary disease generally require higher oxygen-carrying capacity. Oxygen requirements will be determined by the type and severity of coexisting conditions. Overall, American Society of Anesthesiologists guidelines indicate that blood transfusion is rarely required at a hemoglobin of 10 g/dL or above and is almost always indicated at a hemoglobin of less than 6 g/dL.²¹¹ For each patient, therefore, acceptable blood loss can be determined based on preexisting diseases, preoperative hematocrit (Hct), and the patients estimated blood volume (EBV). Estimated blood volumes for different patient populations are indicated in Table 14.13.

TABLE 14.13 AVERAGE BLOOD VOLUMES

Age	Blood volume (mL/kg)
Neonate	
Premature	95
Full-term	85
Infants	80
Adults	
Men	75
Women	65

During excision of large burn wounds, patients will often require one or more blood volumes of transfused blood to replace intraoperative blood losses. Massive blood transfusion can be associated with a variety of complications and the use of blood products is associated with significant financial costs.²¹²

Several means of decreasing surgical blood loss during burn wound excision may be employed such as the use of tourniquets on limbs and compression dressings at sites of burn wound excision or skin graft harvesting.²¹³ Tourniquets have been shown to be an effective strategy for decreasing blood loss during burn wound excision.²⁰⁸ The drawbacks of tourniquet use are that their effectiveness is limited to surgery on the extremities and tourniquets may interfere with the surgical field. Pharmacological interventions that may decrease blood loss include the use of epinephrine-soaked dressings, or topical epinephrine spray to induce local vasoconstriction. Alternatively, subcutaneous tissues may be infiltrated with epinephrine-containing fluids. The use of epinephrine may be associated with tachycardia and hypertension if significant amounts are absorbed into the systemic circulation. However, some studies have reported that the use of topical or subcutaneous epinephrine in burn patients is not associated with an increased incidence of side-effects or complications.²¹⁴ However, the effectiveness of this approach is unclear. A recent study showed that the use of topical epinephrine spray or subcutaneous epinephrine infiltration did not result in decreased blood loss during burn wound excision.²¹⁵ However, the data were quite variable and the patients also received topical thrombin. A larger study examining the effects of subcutaneous epinephrine and topical thrombin might clarify this issue. In a more recent study, Mzezewa and colleagues reported that treatment with systemic terlipressin, a vasopressin analog, decreased blood loss and transfusion requirements in a cohort of pediatric and adult burn patients.²¹⁶ The authors did not report significant complications associated with this approach.

Blood components

Several blood components are available for replacement of losses incurred during burn wound excision.

Whole blood

Whole blood consists of unfractionated blood and contains all of the components of blood, including red blood cells, plasma,

platelets, and white blood cells; however, whole blood stored for more than 24 hours does not contain functional white blood cells or platelets (Table 14.14). One unit of whole blood contains approximately 200 mL of red blood cells and 250 mL of plasma. Whole blood is available in some hospitals for large-volume blood transfusions (trauma, liver transplantation, burns) and treatment of hypovolemic shock. However, because of the scarcity of blood products in most communities, whole blood is not readily available. Fractionation of whole blood into its individual components is a much more efficient and cost-effective means of maximizing blood usage. When available, however, whole blood provides an excellent means of volume expansion and providing oxygen-carrying capacity in patients requiring large volume blood transfusion.

Packed red blood cells

PRBCs are the most common means of replacing RBC loss during surgical procedures. Most of the plasma and platelets are removed during processing so that PRBCs provide few plasma components, clotting factors, or platelets. A unit of PRBCs contains approximately 200 mL of red cells and 50 mL of residual plasma. A comparison of PRBC composition with whole blood is shown in Table 14.15. PRBCs provide oxygen-carrying capacity and, when reconstituted with crystalloid or plasma, volume resuscitation.

Fresh frozen plasma

In the setting of burn injury, fresh frozen plasma (FFP) is most commonly used to replace clotting factors during massive blood transfusion. FFP will replace clotting factors as well as protein S and protein C by a factor of 2–3% per unit. The initial recommended volume is 10–15 mL/kg. The use of FFP varies among different burn centers. Plasma is frozen within 6 hours of collection and each unit provides approximately 250 mL of plasma containing normal levels of all coagulation factors. A National Institutes of Health consensus conference has recommended usage guidelines for FFP (Table 14.16).

In the setting of massive blood transfusion, FFP administration is indicated if active bleeding exists and laboratory evidence of coagulation factor depletion is shown. A volume of 2–6 units is generally used depending on the severity of the coagulopathy. In some burn centers, PRBCs are reconstituted with FFP on a one-to-one basis. Although this practice has not been shown to be deleterious compared to use of PRBCs

reconstituted with crystalloid, there is no evidence that it decreases bleeding complications.²¹⁷ However, some practitioners argue that the use of FFP rather than crystalloid to reconstitute PRBCs results in less interstitial edema during the postoperative period and may enhance skin graft survival.

Platelets

Platelets are stored at room temperature to maximize viability. The incidence of bacterial contamination increases exponentially after 4 days. However, refrigerated platelets remain viable for only 24–48 hours. Platelets are obtained from either units of whole blood or by apheresis from a single donor. ABO-compatible platelets, particularly if from a single donor, should be used when possible because post-transfusion viability is improved. One unit of whole blood platelets contains approximately 5×10^{10} platelets in 50 mL of plasma. Most commonly, 6 units of platelets are combined into a single bag and transfused. A unit of single-donor platelets contains about 30×10^{10} platelets suspended in 200–400 mL of plasma. Therefore, 1 unit of single-donor platelets is equal to about 6 units of whole blood platelets. One unit of whole blood platelets will increase the platelet count by 5000–10 000/ μ L.

TABLE 14.15 COMPARISON OF WHOLE BLOOD AND PACKED RED BLOOD CELLS

Value	Whole blood	Packed red blood cells
Volume (mL)	517	300
Erythrocyte mass (mL)	200	200
Hematocrit (%)	40	70
Albumin (g)	12.5	4
Globulin (g)	6.25	2
Total protein (g)	48.8	36
Plasma sodium (mEq)	45	15
Plasma potassium (mEq)	15	4
Plasma acid (citric/lactic) (mEq)	80	25
Donor/recipient ratio	1 unit per patient	1 unit every 4–6 patients

TABLE 14.14 CHANGES THAT OCCUR DURING STORAGE OF WHOLE BLOOD IN CITRATE–PHOSPHATE–DEXTRASE

	Days of storage at 4°C			
	1	7	14	21
pH	7.1	7.0	7.0	6.9
PCO ₂ (mmHg)	48	80	110	140
Potassium (mEq/L)	3.9	12	17	21
2,3-Diphosphoglycerate (μ mol/mL)	4.8	1.2	1	1
Viable platelets (%)	10	0	0	0
Factors V and VII (%)	70	50	40	20

TABLE 14.16 INDICATIONS FOR FFP ACCORDING TO NATIONAL INSTITUTES OF HEALTH GUIDELINES

A. Replacement of isolated factor deficiencies (as documented by laboratory evidence)
B. Reversal of warfarin effect
C. In antithrombin III deficiency
D. Treatment of immunodeficiencies
E. Treatment of thrombotic thrombocytopenia purpura
F. Massive blood transfusion (only when factors V and VIII are 25% of normal)
G. Requirements for indications A and F would be a prothrombin and partial thromboplastin time of 1.5 times normal

Cryoprecipitate

Cryoprecipitate is prepared by thawing FFP at 4°C and collecting the precipitate. Cryoprecipitate is rich in factors VIII and XIII, fibrinogen, and von Willebrand's factor. In the setting of massive blood transfusion, it is used primarily to treat hypofibrinogenemia. Generally, cryoprecipitate is administered when plasma fibrinogen levels fall below 100 mg/dL. One unit of cryoprecipitate will increase plasma fibrinogen levels by 5–7 mg/dL.

Complications of massive blood transfusion

Coagulopathy

Coagulopathy associated with massive blood transfusion is due to thrombocytopenia or depletion of coagulation factors. PRBCs are essentially devoid of platelets, and whole blood stored for more than 24 hours does not possess significant numbers of viable platelets. Whole blood contains essentially normal levels of coagulation factors with the exception of the volatile factors V and VIII. Because most plasma is removed from PRBCs, they provide a poor source of coagulation factors. Massive blood loss and transfusion with PRBCs or whole blood results in dilutional losses of both platelets and factors V and VIII.

Thrombocytopenia is the most common cause of nonsurgical bleeding after massive blood transfusion. In general, 15–20 units, or 2–4 blood volumes of blood or PRBCs, must be transfused before bleeding due to thrombocytopenia will develop (Figure 14.10). Observed platelet counts usually remain higher than calculated values due to release of platelets from sites of sequestration. Bleeding due to thrombocytopenia usually develops when the platelet count drops below 50–100 000

Fig. 14.10 Calculated versus observed mean platelet counts in two studies of platelet count after massive blood transfusion. (Reproduced with permission from Reed RL, et al. Prophylactic platelet administration during massive transfusion. *Ann Surg* 1986; 203:46.)

platelets/µL. Replacement of platelets usually requires transfusion of 6 units of whole blood platelets or 1 unit of single-donor platelets as described earlier in this chapter.

Development of coagulopathy due to depletion of coagulation factors is also possible during massive blood transfusion. Significant prolongation of the prothrombin (PT) and partial thromboplastin time (PTT) can result after transfusion of 10–12 units of PRBCs. Generally, FFP should be given to correct dilutional coagulopathy if the PT and PTT exceed 1.5 times normal levels. It is also important to know the fibrinogen level in massively transfused patients since hypofibrinogenemia can also result in prolongation of the PT and PTT. Fibrinogen may be replaced using cryoprecipitate.

Citrate toxicity

Citrate is universally used as an anticoagulant in the storage of blood because of its ability to bind calcium that is required for activation of the coagulation cascade. Citrate is metabolized by the liver and excreted by the kidneys. Patients with normal liver and kidney function are able to respond to a large citrate load much better than patients with hepatic or renal insufficiency. During massive blood transfusion, citrate can accumulate in the circulation, resulting in a fall in ionized calcium.²¹⁸ Hypocalcemia can result in hypotension, reduced cardiac function, and cardiac arrhythmias. Severe hypocalcemia can also result in clotting abnormalities. However, the level of calcium required for adequate coagulation is much lower than that necessary to maintain cardiovascular stability. Therefore, hypotension and decreased cardiac contractility occur long before coagulation abnormalities are seen. During massive blood transfusion it is generally prudent to monitor ionized calcium, especially if hemodynamic instability is present in the hypocalcemic patient.

Potassium abnormalities

During the storage of whole blood or packed red cells, potassium leaks from erythrocytes into the extracellular fluid and can accumulate at concentrations of 40–80 mEq/L. Once the RBCs are returned to the *in vivo* environment, the potassium quickly reenters RBCs. However, during rapid blood transfusion, transient hyperkalemia may result, particularly in patients with renal insufficiency. The transient hyperkalemia, particularly in the presence of hypocalcemia, can lead to cardiac dysfunction and arrhythmias. In patients with renal insufficiency, potassium load can be minimized by the use of either freshly obtained blood or washed packed RBCs. Hypokalemia can also result from massive blood transfusion due to reentry of potassium into RBCs and other cells during stress, alkalosis, or massive catecholamine release associated with large volume blood loss. Therefore, potassium levels should be monitored routinely during large-volume blood transfusions.

Acid–base abnormalities

During the storage of whole blood, an acidic environment develops due to the accumulation of lactate and citrate with a pH in the range of 6.5–6.7. Rapid transfusion of this acidic fluid can contribute to the metabolic acidosis observed during massive blood transfusion. However, metabolic acidosis in this setting is more commonly due to relative tissue hypoxia and anaerobic metabolism due to an imbalance of oxygen con-

sumption and delivery. The anaerobic metabolism that occurs during states of hypovolemia and poor tissue perfusion results in lactic acidosis. Generally, administration of sodium bicarbonate is not indicated. The re-establishment of tissue perfusion and homeostasis is a much more important factor in re-establishing acid–base balance. In contrast, many patients receiving massive blood transfusion will develop a metabolic alkalosis during the post-transfusion phase. This is due to the conversion of citrate to sodium bicarbonate by the liver and is an additional reason to avoid sodium bicarbonate administration during massive blood transfusion except in cases of severe metabolic acidosis (base deficit >12).

Altered oxygen transport

During the storage of blood, red blood cell 2,3-diphosphoglycerate (DPG) levels decline. This results in a shift in the oxyhemoglobin dissociation curve to the left. Under these conditions, oxygen has a higher affinity for hemoglobin, and oxygen release at the tissue level is theoretically diminished. In clinical practice, this alteration in oxygen affinity has not been shown to be functionally significant.

Hypothermia

Rapid infusion of large volumes of cold (4°C) blood can result in significant hypothermia. When added to the already impaired thermoregulatory mechanisms in burn patients this can result in significant hypothermia. Potential complications of hypothermia include altered citrate metabolism, coagulopathy, and cardiac dysfunction. During large-volume blood transfusion in burn patients, fluids should be actively warmed with systems designed to effectively warm large volumes of rapidly transfused blood. In addition, the room temperature should be elevated and the patient's extremities and head covered to minimize heat loss. Body temperature should be maintained at or above 37°C in burn patients.

Pulmonary complications

Pulmonary edema is a potential complication of massive blood transfusion. This may result from volume overload and/or pulmonary capillary leak due to inflammation and microaggregates present in transfused blood. Some studies have indicated that the incidence of pulmonary edema is more related to the patient's underlying injury than to blood transfusion *per se*. However, volume status should be monitored closely during large-volume blood transfusion so that volume overload may be avoided.

Transfusion reactions

Hemolytic transfusion reactions are a relatively rare but devastating complication of blood transfusion. The incidence of transfusion reactions is approximately 1:5000 units transfused and fatal transfusion reactions occur at a rate of 1:100000 units transfused. Most severe reactions result from ABO incompatibility. The most common cause of transfusing ABO-incompatible blood is clerical error. Therefore, most hospitals have developed policies that require multiple checks of the blood prior to transfusion. A list of blood types and associated circulating antibodies is shown in Table 14.17. Massive hemolytic transfusion reactions result from destruction of transfused erythrocytes by circulating antibodies and complement. Many of the common signs and symptoms of transfusion reactions (Table 14.18), such as chills, chest pain, and nausea, cannot be detected in the patient under anesthesia. The most commonly recognized signs of transfusion reaction in the anesthetized patient are fever, hypotension, hemoglobinuria, and coagulopathy. The steps involved in the treatment of hemolytic transfusion reaction are outlined in Table 14.19. The cornerstones of treatment are to stop the transfusion, protect the kidneys with aggressive hydration and alkalization of urine, and treat existing coagulopathy.

Delayed hemolytic transfusion reactions can occur in patients that have received prior blood transfusions and result from a secondary immune response with production of antibodies to blood antigens. This reaction can occur from 2 to 21 days after transfusion and should be suspected in patients with unexplained decreases in hematocrit during the postoperative

TABLE 14.18 FREQUENCY AND SIGNS AND SYMPTOMS FROM HEMOLYTIC TRANSFUSION REACTIONS IN 40 PATIENTS

Sign or symptom	No. of patients
Fever	19
Fever and chills	16
Chest pain	6

O	None	Anti-A Anti-B	45	49
Rh	Rh		42	17

TABLE 14.19 STEPS FOR THE TREATMENT OF A HEMOLYTIC TRANSFUSION REACTION

1. STOP THE TRANSFUSION
2. Maintain the urine output at a minimum of 75–100 mL/h by the following methods:
a. Generously administer fluids intravenously and possibly mannitol, 12.5–50 g, given over a 5- to 15-minute period
b. If intravenously administered fluids and mannitol are ineffective, then administer furosemide, 20–40 mg IV
3. Alkalinize the urine; since bicarbonate is preferentially excreted in the urine, only 40–70 mEq/70 kg of sodium bicarbonate is usually required to raise the urine pH to 8, whereupon repeat urine pH determinations indicate the need for additional bicarbonate
4. Assay urine and plasma hemoglobin concentrations
5. Determine platelet count, partial thromboplastin time, and serum fibrinogen level
6. Return unused blood to blood bank for re-cross-match
7. Send patient blood sample to blood bank for antibody screen and direct antiglobulin test
8. Prevent hypotension to ensure adequate renal blood flow

period. Renal injury is less common than in acute hemolytic reactions but adequate hydration and alkalinization of urine are usually indicated. Febrile reactions are common following blood transfusion and are generally due to contaminating leukocytes and leukocyte antigens present in transfused blood. Pure febrile reactions usually do not require termination of the transfusion but the patient should be monitored closely to assure that a more severe transfusion reaction is not developing.

Infection

Infection is a major problem in burn patients due to disruption of the cutaneous barrier and immunosuppression. Blood transfusion adds to the infection risk. Graves and colleagues showed a significant correlation between the number of blood transfusions and infectious complications in burn patients.²¹⁹ The most common source of major infection from blood products is hepatitis. Hepatitis C is the most common offender, followed by hepatitis B. The incidence of hepatitis C is approximately 3 in 10 000 units transfused. The development of rigorous screening mechanisms has markedly decreased the incidence of HIV infection to 1 in 200 000–500 000 units transfused. Cytomegalovirus (CMV) has been identified in blood products and could cause clinically significant problems in immunocompromised burn patients. However, the incidence of clinically important CMV infection is low in burn patients.

Postoperative care

Decisions regarding postoperative airway management and support of ventilation depend on several factors. Extubation is desirable as soon as it is indicated but in burn patients, for a number of reasons, it often may be even more important not to extubate when it is not indicated. If the patient came to the operating room intubated, the indication for intubation must

Fig. 14.11 Inflammation of the larynx caused by thermal, mechanical, or chemical irritation may result in swelling of the mucosa over the arytenoid eminences and this redundant tissue can fold into the glottic inlet and cause obstruction.

be determined. If the initial indication has resolved, the decision to extubate depends on perioperative events. Some patients with neck and facial burns are intubated to protect the airway from obstruction by edema. The airway must be examined to be sure edematous tissues will not cause obstruction when the endotracheal tube is removed. Air leaking around a deflated endotracheal tube cuff during positive pressure ventilation is an encouraging sign that the airway may remain patent after extubation. The upper airway can also be examined by direct laryngoscopy or with an endoscope. In marginal cases the endotracheal tube can be removed while an exchanger is left in the trachea. Another technique is to extubate under direct vision with a bronchoscope with an endotracheal tube already loaded on the bronchoscope. Especially in small pediatric patients a common reason for post-extubation stridor and failed extubation is edematous and redundant mucosa over the arytenoid eminences that obstruct the glottic inlet during inspiration (Figure 14.11). This condition can be exacerbated by an endotracheal tube that is too large, excessive patient motion due to inadequate sedation and analgesia, reflux of acidic gastric contents, and mechanical irritation due to compression of the posterior laryngeal structures between the endotracheal tube and gastric tubes. These irritants can also cause laryngomalacia in pediatric patients (Figure 14.12). If laryngeal obstruction persists despite attention to all these details, a short course of steroids is often effective as long as concerns regarding burn wound infection do not preclude the use of steroids (unpublished observations). Heliox has also been used successfully in this situation.²²⁰

After transfer of monitors and ventilatory support in the intensive care unit, a full report of the intraoperative anesthetic course is given, along with information about the patient's current condition and therapy. A chest radiograph

Fig. 14.12 Laryngomalacia due to local irritation and inflammation can cause dynamic inspiratory airway obstruction. (a) During exhalation the glottic opening is patent but (b) during inhalation the larynx collapses and obstructs air flow.

may be needed for vascular catheters placed in the OR or to check position of an endotracheal tube if the patient will be ventilated postoperatively. Laboratory studies including arterial blood gas, blood chemistries, renal function tests, hematocrit, platelet count, and coagulation studies are sent soon after patient arrival to the intensive care unit. These studies are particularly important if massive transfusion was required in the operating room.

One of the most important issues in the immediate postoperative period for burn patients is adequate analgesia and sedation, particularly for the intubated and mechanically ven-

tilated patient. Debridement of burned tissue and the harvesting of skin grafts are painful procedures that merit ample analgesic doses in order to insure patient comfort. It is not uncommon for burn patients to be quite tolerant to narcotic analgesics, especially after they have had several operative procedures, and in this case larger doses than normal are required.

Ongoing blood loss is unfortunately a common problem after the excision and grafting of a large burn wound, even when strict attention is placed on intraoperative hemostasis by surgical personnel. The burn wounds are necessarily excised down to bleeding tissue before skin grafts are applied. Massive intraoperative transfusion adds to the problem with dilutional thrombocytopenia and coagulopathy. Diligent postoperative care is needed to continually assess ongoing blood loss and transfuse additional blood products as they are indicated by clinical course and laboratory studies. Ongoing bleeding may manifest as hypovolemia and hypotension even in the brief period of transport from the operating room to the intensive care unit. Monitoring of central venous pressure and urine output also help in guiding postoperative blood and fluid therapy.

Adequate ventilation is essential in the postoperative period in order to minimize hypoxemia and hypercarbia. Blood gases and oxygen saturation can be used as guides to ventilator management. Patients with inhalation injury benefit not only from rational ventilator management but also from a program of inhaled bronchodilators and mucolytics combined with judicious airway suctioning. Extubated patients require supplemental oxygen for at least the first few hours postoperatively in order to maintain adequate oxygen saturation. Airway support may also be necessary initially in these patients until they are more alert and responsive.

Finally, burn patients must be recovered in a warm environment. Postoperative hypothermia can result in vasoconstriction, hypoperfusion, and metabolic acidosis. Radiant heaters, blood and fluid warmers, warm blankets, heated humidifiers for gas delivery, and high room temperature are all useful in the postoperative period to provide warmth to the recovering patient.

Summary

Anesthetic management of the burn patient presents numerous challenges. Anatomical distortions make airway management and vascular access difficult. Pathophysiological changes in cardiovascular function range from initial hypovolemia and impaired perfusion to a hyperdynamic and hypermetabolic state that develops after the resuscitative stage. These and other changes profoundly alter response to anesthetic drugs. Effective anesthetic management will depend on knowledge of the continuum of pathophysiological changes, technical skills, proper planning, and availability of proper resources. A team approach is necessary, keeping in mind that perioperative management should be compatible with ICU management and goals. This requires close communication with other members of the burn care team and is one of the most important principles of effective anesthetic management of these challenging patients.

History

The first skin autograft was described by Reverdin¹ in 1871 and the use of allograft skin as a clinical method for wound coverage soon followed.² In 1874, Thiersch published a report about a small series of patients on whom he had used partial-thickness skin grafts.³ This led to extensive trials of harvesting extremely thin grafts, leaving some of the surface epithelium behind to aid in donor site healing. Results from the use of these small thin grafts, known as ‘Thiersch grafts,’ ‘pinch grafts,’ ‘epidermis grafts,’ or ‘razor grafts’ were generally so unsatisfactory for resurfacing large areas that they were typically limited to the treatment of small ulcerated wounds. The first successful use of allogeneic skin for burn wound coverage was reported by Girdner⁴ in 1881. Five years later, Thiersch described the histologic anatomy of skin engraftment which popularized the clinical use of split-thickness skin grafts.³

Radical advances in the treatment of burn wounds brought about three developments in skin graft recovery techniques. First, it was noted that the dermal layer was the most important part of a skin graft in producing a new, tough, resilient surface. Secondly, it was demonstrated that after removing a partial-thickness graft, the donor-site epithelium was regenerated from deep epithelial islands within the hair follicles and sebaceous glands; therefore, thicker grafts could be harvested and transferring the upper dermis would not interfere with donor-site healing. Finally, by allowing for the recovery of thicker grafts, the design instruments for their harvesting became more feasible. These thicker grafts were termed ‘split-thickness grafts,’ and resulted in the coverage of large areas of the body surface. These major advances in skin graft

recovery techniques permitted increased flexibility in the treatment of burn wounds so that the Thiersch, or pinch-graft, method and the use of pedicle flaps were rarely necessary for the treatment of cutaneous scar contractures. The use of split-thickness grafts permitted skin grafting to become a routine procedure.

Storage of human skin did not begin until the early 1900s, when Wentscher⁵ reported his experience with the transplantation of human skin that had been refrigerated for 3–14 days; however, it wasn’t until the 1930s that blood and tissue banking took their place in the clinical practice of medicine. The clinical utility of allograft skin in burn wound coverage was first described in 1938 when Bettman⁶ reported his success in the treatment of children with extensive full-thickness burn injuries. Webster⁷ and Matthews⁸ later described the successful healing of skin autografts stored for 3 weeks at 4–7°C; however, it wasn’t until 1949, following the establishment of the United States Navy tissue bank, that modern day skin banking began.

The establishment of skin banking signaled the beginning of significant research related to the processing, preservation, and storage of human tissues. Baxter⁹ explored the histologic effects of freezing on human skin and discovered that the formation of ice crystals caused the destruction of skin architecture. This was followed in 1952 by the pioneering research of Billingham and Medawar¹⁰ who demonstrated that skin could be effectively cryopreserved using glycerol. Soon afterwards, Taylor¹¹ was able to demonstrate that the addition of glycerol to storage solutions decreased ice crystal formation in frozen tissues. These advancements permitted Brown¹² and Jackson¹³ to popularize the use of allogeneic human skin grafts as biologic dressings for extensive burns and denuded tissue. By 1966, Zaroff¹⁴ had reported the 10-year experience using allograft skin in the treatment of thermally injured patients at the Brooke Army Medical Center. In this report, he described the mechanical and physiologic advantages of allograft skin as a biologic dressing. In 1966, Cochrane¹⁵ reported the first successful use of frozen autologous skin grafts following controlled-rate freezing in 15% glycerol and rapid rewarming prior to implantation. This was followed by Morris¹⁶ report demonstrating the beneficial effects of using allogeneic skin in the treatment of infected ulcers and other contaminated wounds and Shuck et al.’s¹⁷ report suggesting the potential use of allogeneic skin in the treatment of traumatic wounds based upon their Vietnam War experience. These increased uses of allograft skin led to further research into the beneficial effects of allograft skin on wound healing, including its association

with a reduced incidence of bacterial infections^{18,19} and the stimulation of wound bed neovascularization.²⁰

Bondoc and Burke²¹ are credited with the establishment of the first functional skin bank in 1971. Their experience with allograft skin led to a report of successful burn wound excision and allografting with temporary immunosuppression in children with extensive injuries.²² Today, allograft skin remains an ideal temporary cover for extensive or excised cutaneous or soft tissue wounds, particularly when sufficient autograft skin is not available or when temporary wound coverage is desired.

Clinical uses of allograft skin

Coverage of extensive full-thickness wounds

The increasing use of allograft skin in specialized burn care centers has been one of the driving forces behind the growth and development of skin banks in the United States. The general indications for its use in wound management are listed in Box 15.1. Allograft skin possesses many of the ideal properties of biologic dressings and plays a major role in the surgical management of extensive wounds when autologous tissue may not be immediately available (Box 15.2). It reduces evaporative water loss and the exudation of protein-rich fluids, prevents wound desiccation, and suppresses microbial proliferation. Wound pain is lessened and is associated with better patient compliance with occupational and physical therapy. By restoring the physiologic barrier at the wound surface, the allografts reduce heat loss through the wound and mitigate the hypermetabolic response to burn injury. The frequent and unpredictable demand for allograft skin in specialized burn care centers has prompted the growth and development of local and regional skin banks throughout the world.

BOX 15.1 Indications for allograft skin use in wound management

- Coverage of extensive wounds where autologous tissue is not available
- Coverage of widely meshed skin autografts
- Extensive partial-thickness burns
- Extensive epidermal slough.
 - Stevens–Johnson syndrome
 - Toxic epidermal necrolysis
 - Staphylococcal scalded skin syndrome
- Testing the wound bed's ability to accept autograft
- Template for the delayed application of keratinocytes

BOX 15.2 Advantages of human allograft skin use

- Reduce water, electrolyte, and protein loss
- Prevent desiccation of tissue
- Suppress bacterial proliferation
- Reduce wound pain
- Reduce energy requirements
- Promote epithelialization
- Prepare wounds for definitive closure
- Provide dermal template for epidermal grafts

Fresh allograft skin represents the gold standard for all biologic dressings employed for temporary wound closure based upon a number of its distinctive properties compared to cryopreserved skin (Box 15.3). Its availability is critically important for the surgeon faced with the need to provide immediate coverage of large excised burn wounds. Allogeneic grafts are best applied unmeshed (or minimally expanded) in order to maximize their ability to temporarily close the wound. Fresh allografts become well vascularized, stimulate neovascularization in the underlying wound bed, and prepare the recipient sites for permanent coverage with autologous skin. In addition, fresh allografts tolerate modest wound contamination and adhere better to the freshly excised subcutaneous fat than do cryopreserved grafts. The allogeneic skin is usually removed once the patient's donor sites have healed sufficiently for reharvesting or once autologous cultured skin is available for permanent wound closure. Figure 15.1 depicts the quantitative use of allograft skin and, in particular, the increased use of fresh refrigerated allograft skin, in thermally-injured children treated at the Shriners Hospital for Children in Cincinnati, Ohio since 1998.

When fresh allograft is not available, cryopreserved skin is an excellent alternative for temporary wound coverage. Although frozen cryopreserved skin generally has less measurable viability than fresh skin, it is currently difficult to maintain continuous and ample stores of fresh skin beyond 14 days. It has therefore been standard skin banking practice to cryopreserve allograft skin within 7–10 days of recovery if it is not going to be utilized within the time period that viability can be maintained. Regardless of whether the allografts are fresh or cryopreserved, wide (mesh) expansion of allograft skin is rarely performed because reepithelialization of the interstices by allogeneic epidermis is uncommon. Figure 15.2 demonstrates the difference in appearance

BOX 15.3 Advantages of fresh allograft skin

- Rapidity and strength of adherence to the wound
- Control of microbial growth
- Rapidity of revascularization
- Reproducible clinical results

Fig. 15.1 Fresh allograft skin usage at the Shriners Burns Hospital, Cincinnati, Ohio.

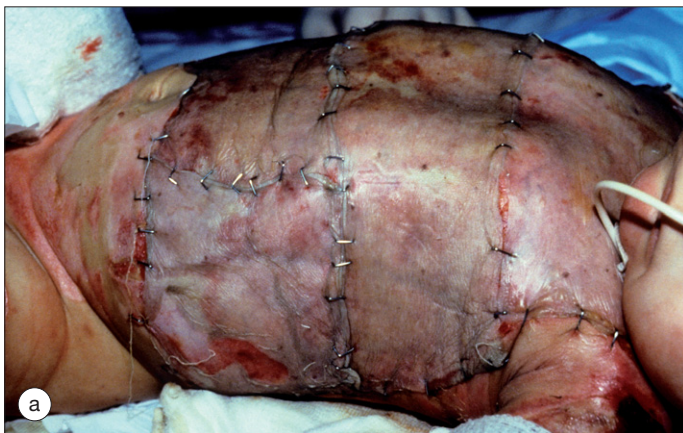

Fig. 15.2 Appearance of cryopreserved and fresh, refrigerated allograft skin on postoperative day 5. Note poor vascularization and epidermolysis in the cryopreserved skin (a) compared to the pink revascularized refrigerated allograft (b).

and vascularization of cryopreserved and fresh, refrigerated skin.

The emergence of Integra® dermal regeneration template for the treatment of excised burn wounds has been significant and in some burn centers has replaced or decreased the use of allograft skin in patients with extensive full-thickness burn injuries. Heimbach et al. reported the results of a randomized multicenter clinical trial comparing Integra® and other grafting materials.²³ When the artificial dermis was compared to allograft, there was no difference in the ‘take’ rates; however, ‘take’ was not defined in the manuscript and it is unclear whether there were equivalent rates of adherence and/or vascularization. Furthermore, it is unclear if the allografts applied were fresh or cryopreserved, although it is most likely that the allografts were frozen as the refrigeration of allograft skin was not common skin banking practice at the time of the study. A subsequent retrospective study performed at our burn center and skin bank 10 years later indicated that fresh, refrigerated allograft had a better rate of engraftment than the dermal regeneration template.²⁴

Coverage of widely meshed skin autografts

Another use of allograft skin has been its application as an overlay on top of widely expanded, meshed autologous skin grafts (Figure 15.3). This technique was originally described utilizing meshed allograft²⁵ and provides immediate, as well as both temporary and permanent wound closure. For this reason, most burn surgeons who currently perform overlay allografting utilize nonmeshed or nonexpanded mesh allografts. This affords better protection of the underlying wound bed from desiccation and microbial contamination as this tissue is potentially exposed by the interstices of the widely meshed autograft until autologous epithelialization is complete. While this technique may play a role in the

Fig. 15.3 Diagrammatic illustration of meshed allograft overlay technique as described by Alexander et al. The allograft is generally meshed 1.5:1 or 2:1 while the underlying autograft may be meshed 3:1 or greater. Reproduced with permission from Alexander JW, MacMillan BG, Law E, et al. Treatment of severe burns with widely meshed skin autograft and widely meshed skin allograft overlay. *J Trauma* 1981; 21:433–438.²⁵

management of massive excised full-thickness injuries, it should be used with discretion since many surgeons have expressed concern that the overlying allograft may induce an inflammatory rejection response that can retard the rate of reepithelialization of the underlying autografts. Some have therefore advocated the use of lyophilized allograft for this purpose as it is less viable and less antigenic.²⁶

Healing of partial-thickness wounds

Frozen allograft skin is an excellent wound cover when vascularization is not desired. Because it is usually less viable than fresh skin, it functions more as a biologic dressing than as a temporary skin replacement. Its adherence to the underlying wound bed results in the relief of pain and the limitation of exudative and water losses, and reduces the need for frequent dressing changes. As the partial-thickness wound reepithelializes, the allograft slowly separates without disturbing the delicate underlying epithelium. Although this application is probably not cost-effective in the management of small second-degree burns or skin graft donor sites, it is often beneficial in the treatment of extensive partial-thickness burns where its ability to prevent desiccation and promote epithelialization may reduce hospital stay and/or the need for autografting. In addition, cryopreserved allograft is an excellent biologic dressing for the management of patients with extensive cutaneous wounds resulting from drug reactions or superficial skin disorders (i.e. toxic epidermal necrolysis, Stevens–Johnson syndrome, staphylococcal scalded skin syndrome). When used for the coverage of these superficial wounds, allograft skin should be applied prior to exposing the wound to topical antibiotics since the application of these agents results in decreased allograft adherence to the wound surface.

Testing for later acceptance of autograft

Both cryopreserved and fresh allografts have been used for the care of a variety of cutaneous and soft tissue wounds. In these instances, allograft is used to provide a temporary biologic cover and to help predict the likelihood of autologous graft take later in the course of treatment. Allograft usage for this indication has been quite common in the management of deep electrical burns and purpura fulminans while the viability of the deep soft tissues is in doubt. Allograft has also been used to cover the soft tissues exposed by escharotomies and fasciotomies as well as extensive open abdominal and soft tissue wounds. Adherence or vascularization of the allograft is a reliable indication that the wound bed has sufficient blood supply to accept an autologous graft or flap.

Template for delayed application of keratinocytes

The clinical use of cultured epidermal autografts (CEA) in the care of burn patients was first described by O'Connor²⁷ in 1981. Since that time, there have been numerous reports supporting its use as a permanent skin replacement for patients with extensive full-thickness burn injuries. This methodology has not been without problems, however, with many authors describing variable take rates and instability of the grafts. Cuono first advocated the use of allogeneic skin with CEA, allowing the allograft skin to vascularize before removing the antigenic epidermal layer by dermabrasion.²⁸ Hickerson

reported his results on five burn patients demonstrating over 90% CEA take on the allogeneic dermis and supple, durable grafts up to 4 years postoperatively.²⁹

The past decade has also witnessed the development of an acellular allogeneic dermal matrix (AlloDerm[®]) as a template for the simultaneous application of thin split-thickness autografts.³⁰ The potential advantage of the dermal template is reasoned to be the use of a thinner autologous skin graft resulting in more rapid donor site healing and reduced morbidity. A recently completed multicenter clinical trial demonstrated equivalence of this technique with a standard split-thickness meshed autograft; however, autograft take rates were somewhat lower than that for controls and varied from center to center.³¹ In addition, the allogeneic dermal grafts measured only 36 to 116 cm² and were only evaluated up to 180 days post-grafting. AlloDerm[®] has also been used as a template for CEA; however, there have been only a few anecdotal reports related to this potential application.

Micrografting techniques

Chinese surgeons have proposed the use of micrografts using both autologous and allogeneic skin.³² This technique involves the mincing of autologous skin into pieces less than 1 mm in diameter. These micrografts are then used to seed the dermal surface of large sheets of allogeneic skin prior to transplantation onto the excised burn wound. As the autologous epidermal cells propagate on the wound surface, the allograft skin gradually separates in a manner similar to that observed with the overlay technique. This method, while resulting in an effective skin expansion ratio approaching 1:18, has been shown to be associated with severe wound contraction that is often worse than that noted following the application of meshed skin autografts.

Potential disadvantages of allograft use

Infection

Allograft skin has been reported to cause bacterial infection.³³ It is therefore imperative that skin banks perform microbial cultures prior to releasing the tissue for transplantation. Although White has suggested that cadaver allograft containing <10³ organisms/gram of tissue can be safely used for wound coverage,³⁴ current American Association of Tissue Banks (AATB) Standards^{35,36} require that skin be discarded if pathogenic bacteria or fungi are present. This is particularly important given the immunocompromised status of the potential recipient and the potential for developing wound sepsis following such contamination.

There have also been reports of viral disease transmission by skin allografts. In 1987, Clarke reported what was thought to be the transmission of HIV-1 to a burn patient from an HIV-positive donor;³⁷ however, the results of donor testing were not known prior to skin use. Moreover, the recipient, who had a number of risk factors for HIV, had not been tested prior to receiving the allograft. To date, there have been no other reported cases of HIV or hepatitis transmission from skin allografts.

Kealey et al. recently reported the transmission of cytomegalovirus (CMV) from cadaver skin allografts.³⁸ Because nearly 23% of the CMV-negative patients seroconverted, they recommended the use of CMV-negative allograft skin for

seronegative burn patients. Plessinger et al. reviewed 479 consecutive skin donors and found 63% of this predominantly adult donor pool to be CMV-positive.³⁹ They reasoned that while tissue from seronegative donors would be ideal for use in seronegative patients, such a practice would significantly limit the availability of fresh allograft skin for most thermally-injured patients. In addition, while there is good evidence to support the transmission of CMV by allograft in burn patients, there is little evidence that CMV seroconversion is clinically significant or affects outcome in thermally-injured patients.^{40,41} Furthermore, Herndon and Rose⁴⁰ reiterated that the benefits of using cadaver allograft skin for the treatment of burn patients clearly outweigh the small risks associated with CMV seroconversion. At present, most burn surgeons and skin banks recommend that the decision regarding the use of allograft skin from CMV-positive donors should be made by the burn/transplanting surgeon.

Rejection

While demonstrating many characteristics of an ideal wound covering, allograft skin contains Langerhans cells which express class II antigens on their surface. These cells reside in the epidermis of the skin and are ultimately rejected as the result of an immunologic rejection response. This typically results in an acute inflammatory reaction and can lead to wound infection. Vascularized allogeneic skin grafts typically remain intact on the wound of a burn patient for 2–3 weeks although there have been reports of allograft skin survival for up to 67 days due to the inherent immunosuppression of extensive burn injury.⁴² Recent improvements in immunonutrition, critical care management, and a more aggressive surgical approach to definitive wound closure, however, have made the persistence of allografts less predictable.

Efforts to prevent rejection have included methods that might reduce antigen expression by controlling the activity of the Langerhans cells in the allograft skin. Treatment of the allografts with ultraviolet light irradiation and incubation of the skin in glucocorticoids has been reported to result in a modest prolongation of allograft survival compared to non-treated skin; however, the utility of this methodology has not been substantiated. Other investigators have studied the effects of pharmacologic agents to induce immunosuppression in patients with major burn injuries. Initial clinical trials reported an improvement in both allograft and patient survival when children were treated with azathioprine and anti-thymocyte globulin;⁴³ however, this regimen was associated with azathioprine-induced neutropenia and the clinical outcomes have not been corroborated by others. More recently, the use of cyclosporin A has been demonstrated to prolong skin allograft survival in patients with extensive full-thickness burns.^{44,45} In these studies, allograft rejection was generally observed within a few days of discontinuing treatment; however, there were instances where engraftment persisted after the completion of therapy. Further studies of these and newer immunosuppressive agents may be warranted.

The growth of skin banking

The widespread use of allograft skin in the management of patients with extensive burn, traumatic and soft tissue injuries

has had a major impact on the number of skin banking facilities over the past two decades. Consequently, the majority of skin banks have been founded in close proximity to regional burn centers or within the burn center hospitals themselves. Skin banks must therefore maintain a close working relationship with regional burn centers not only to meet the specific needs of the burn surgeon but also to help generate community support for skin donation through combined educational outreach programs.

From 1969 to 1988, there was a steady growth in the number of skin banks; however, this number declined, reaching its nadir in 2002. Since that time, however, there has been a steady increase in the number of skin banking facilities to its current total of 52 AATB-accredited tissue banks that recover, process, store, and/or distribute skin for transplantation (Figure 15.4). In 1983, DeClement and May estimated that as much as 32 000 square feet of skin might be needed in burn and wound care centers.⁴⁶ This figure, however, was only a crude estimate and, over the past 6 years, there has recently been a substantial increase in the amount of skin recovered and distributed for transplantation within North America (Figure 15.5), as indicated in the AATB's

Fig. 15.4 Growth in the number of skin banks in the United States and Canada. (Data collected from AATB sources (various) with permission).

Fig. 15.5 Allograft skin donation and distribution from 1990–2003. (Data collected from AATB sources (various) with permission).

2003 Survey of accredited tissue banks. In that calendar year, skin was recovered from over 11000 donors with nearly 19000 square feet of skin distributed for human transplantation.

Role of the American Association of Tissue Banks

As skin banking facilities grew in number, it became apparent that policies and procedures required standardization. This was quite difficult initially as there was insufficient data to develop a consensus regarding standards of practice. As early as 1976, the AATB had begun to address this issue by the formation of a Skin Council. This provided a forum for the discussion of skin banking practices and was complimented by the activities of the American Burn Association's Skin Banking Special Interest Group. The Standards and Procedures Committees were created in 1977 and produced the first 'Guidelines' for tissue banking in 1979. The first Standards for Tissue Banking was published in 1984 and tissue-specific technical manuals (including skin) were developed in 1987. Since that time, the Standards have been modified and refined based upon consensus and, where available, supportive scientific research. In addition, shortly after the development and promulgation of its Standards for Tissue Banking, the AATB created an inspection and accreditation committee in 1982 and began conducting voluntary inspections in 1986. This program continues today and is important in ensuring that tissue banks adhere not only to AATB Standards but also the Food and Drug Administration (FDA) regulations governing all aspects of human tissue banking.

Technical aspects of skin banking

Donor screening

It is vitally important that complete and accurate medical information about the potential donor be obtained to ensure the safety of the tissue for transplantation. The AATB and the FDA require a comprehensive medical and social history of the donor. In this regard, the AATB developed a Donor Medical History and Behavioral Risk Assessment Questionnaire with the cooperation and assistance of other organ and tissue procurement organizations and the FDA. A thorough physical examination is also necessary to determine if the donor should be deferred for other medical reasons as well as to determine the quality of the skin and the technical feasibility of skin retrieval by evaluating the donor's size and skin condition. Box 15.4 lists disease states which are commonly associated with deferral of a potential skin donor.

While it is also necessary for the tissue bank medical director to review the results of an autopsy (if one was performed), a review of over 2200 consecutive donors recovered by our tissue bank from January 1994 through May 1998 indicated that only 11 donors (0.5%) required discard as a result of the autopsy findings.⁴⁷ Furthermore, a 10-month follow-up study of 264 donors recovered following the 1998 changes in the AATB Standards revealed that none of the donors required deferral based upon the autopsy findings alone.⁴⁷

BOX 15.4 Disease states commonly associated with potential skin donor deferral

- Extensive dermatitis
- Acute burn injuries
- Cutaneous malignancy
- Poor skin quality
- Extensive tattoos
- Collagen vascular disease
- Toxic chemical exposure
- Skin infections
- Extensive skin lesions
- Extensive skin or soft tissue trauma

A panel of serologic screening tests for transmissible viral diseases (HIV-1/2 antibody, hepatitis B surface antigen and B core antibody, and hepatitis C and HTLV-1 antibodies) is also required. Recently, skin/tissue banks have been obtaining HIV-1/2 and HCV nucleic acid tests (NAT) to add to the safety of the tissue grafts being transplanted. Ideally, the test kits should be approved for cadaveric specimens. Barnett et al. reported their 2-year experience with cadaveric skin donor discards due to positive serologic tests. In that report, they noted that 61 of 813 donors (7.5%) required tissue discard due to positive serologic tests. A positive hepatitis B core antibody test accounted for 52.3% of the serology-based discards while hepatitis B surface antigen testing accounted for 18.1%, and hepatitis C, HIV-1/2, HTLV-1, and syphilis tests accounted for 14.3%, 4.9%, 4.9%, and 5.5%, respectively.⁴⁸ This finding was substantiated by our tissue bank's 5-year review of 1235 donors, of whom 93 (7.5%) were deferred based upon positive serologic tests.⁴⁷

Skin recovery

Once donor screening is complete and proper consents have been obtained, the recovery team must arrange the time and location for skin removal in an appropriate facility (i.e. hospital morgue or operating room, medical examiner's office, or the tissue bank). It is extremely important that the time of death and body storage conditions be accurately documented as these have a significant bearing upon skin viability and microbial contamination. Current AATB Standards require that skin retrieval begin within 24 hours of death if the donor was refrigerated within 12 hours of asystole or within 15 hours if refrigeration did not occur within the prescribed time limits.

In brief, the skin is removed under aseptic conditions. The areas from which the skin is taken are shaved of hair and cleansed with detergent solutions approved for use in operative procedures (i.e. povidone-iodine, chlorhexidine). The retrieval technician puts on a cap and mask, performs a surgical scrub, and dons a sterile gown and gloves while the circulating technician prepares tissue and transport containers. This is usually followed by a chlorhexidine prep and rinsing with 70% isopropyl alcohol, and allowing the skin surface to dry. The donor is then draped with sterile sheets and a blood sample is obtained by either a central venous or intraventricular puncture. Following this, a thin layer of sterile mineral oil (or other sterile lubricant) is applied to the surfaces from which

skin is to be removed. Split-thickness skin grafts are then removed using a dermatome at a thickness of 0.012–0.018 inches. The width of the grafts generally should range from 3 to 4 inches but ideally should be determined by the preference of the transplanting surgeon(s). Skin retrieval sites are usually limited to the torso, hips, thighs, and upper calves. The amount of skin obtained may vary depending on body habitus, skin defects or lesions, and body geometry; however, an average of 4–6 square feet per donor is not unusual. After tissue is obtained from the posterior surfaces, the donor is turned to expose the anterior surface, repped, and draped prior to completing the retrieval process. The skin is then placed in tissue medium and maintained at 1–10°C during transport to the skin bank for processing.⁴⁹

Skin processing

Processing environment

Skin should be processed under aseptic conditions. While current AATB Standards mandate the processing of cardiovascular tissues in a class 100 laminar flow environment, no such requirement exists for human skin banking. In fact, a study performed at our skin bank failed to demonstrate any statistically significant quantitative or qualitative difference in microbial growth whether the skin was processed and packaged in a class 100 laminar flow hood or a class 100000 clean room.⁵⁰

Microbiologic testing

After returning to the skin bank, the procurement team should obtain cultures for aerobic and anaerobic bacteria, yeast, and fungi. Incubation of allograft skin in antibiotics remains somewhat controversial since many of these antimicrobial agents are unable to effectively kill microorganisms at 4°C and there is the potential for exposing the recipient to resistant organisms. In addition, there has been little research to determine which antibiotics are effective against most skin contaminants yet nontoxic to the cellular components of the skin. It is therefore recommended that samples should be obtained prior to exposure of the skin to antibiotics³⁵ using a 1 cm² biopsy sample for each 10% of the body surface area from which the skin has been recovered.^{49,51} Testing should be conducted in accordance with the National Committee on Clinical Laboratory Standards and the skin should not be used for transplantation if it contains any of the following microorganisms:

- coagulase-positive staphylococci,
- group A, beta-hemolytic streptococci,
- enterococci,
- Gram-negative organisms,
- *Clostridium* sp., or
- yeast or fungi.

When fresh, non-cryopreserved allograft skin is to be released for transplantation within days of tissue recovery, the results of the microbial cultures are frequently unavailable; however, AATB Standards require that microbiology culture results not be reported before 7 days of incubation before releasing the tissues for transplantation. Since our tissue bank frequently provides allograft skin to our regional burn centers under the exceptional release provision, we reviewed the results of the

microbiologic skin cultures from 219 consecutive skin donors whose tissues were released for transplantation prior to the availability of culture results. While 14.3% of the cultures were positive for microbial growth, only 1.8% of the cultures identified organisms that required subsequent notification of the transplanting surgeon. In each of these instances, there were no adverse outcomes in any of the burn patients who received the skin transplants.⁵² This issue was also addressed by Lynch et al. in their review of 939 allograft skin donors whose skin was authorized for exceptional release after only 3 days of incubation. They reported that three cases resulted in tissue recall due to positive microbiological cultures. The authors concluded that 3-day culture results do not result in significant microbiologic contamination of allograft skin.⁵³ Despite the results of these studies, it is strongly recommended that the tissue bank communicate all available information regarding donor and tissue suitability to the transplanting surgeon so that he/she can adequately assess the potential risks and benefits for the recipient.

Maintenance of viability

Maintenance of cell viability and structural integrity are vital for the engraftment and neovascularization of allograft skin, yet there have been no studies that have quantified the degree of viability necessary to ensure allograft ‘take.’ Postmortem time lapse appears to have the single greatest effect on skin viability as May demonstrated that the functional metabolic activity of the skin rapidly declined if the donor was not refrigerated within 18 hours of death.^{54,55} The ideal nutrient tissue culture medium has also not yet been identified. Eagle’s MEM and RPMI-1640 continue to be generally accepted; however, Cuono has demonstrated the potential benefits of University of Wisconsin (UW) solution.⁵⁶ Lastly, it remains unclear which cryoprotectants offer the greatest preservation of cell viability and structural integrity. Glycerol (10–20%) and dimethylsulfoxide (10–15%) have been reported to maintain skin viability following incubation times ranging from 30 minutes to 2 hours; however, the optimal concentrations of these cryoprotectants have not been identified nor have these agents been compared for efficacy. Factors such as age and gender do not appear to influence skin viability.

Refrigeration

‘Fresh’ allograft skin is the preferred biologic dressing for the temporary coverage of excised extensive full-thickness burn wounds due to its more rapid adherence and rapid vascularization. The skin is typically stored at 4°C in tissue culture medium with or without antibiotics. Refrigeration slows the metabolic rate of the viable cells and nutrient tissue culture medium supports cellular metabolic activity. The skin should be free-floating in an aseptic container with approximately 300 mL of medium per square foot of skin. Recent studies suggest that skin viability can be maintained for up to 2 weeks at 4°C if the nutrient medium is changed every 3 days.^{57,58} The major shortcoming of this storage method is the limited time that viability can be maintained.

It has been common practice to cryopreserve the skin within 5–7 days of refrigeration. This has been based on the work of May et al., who demonstrated that glucose metabolism declines at a rate of 10–15% each day during refrigerated storage.⁵⁵

Recently, we have demonstrated the benefit of a two-layer storage method utilizing 95% oxygen-enriched perfluorocarbon (O₂PFC) combined with changing the nutrient media every 3 days in an effort to prolong the viability of refrigerated skin. This method results in maintenance of skin viability for up to 41–63 days as well as maintenance of normal skin anatomy.⁵⁹ Further research in allograft skin cryopreservation techniques will be essential in order to maintain an ample supply of viable fresh tissue for clinical use.

Cryopreservation

When skin is frozen for long-term storage, it is important that the methods utilized maintain cell viability and structural integrity. If the skin is not to be used ‘fresh,’ it should be cryopreserved within 10 days of procurement if the nutrient media is changed every 3 days. If the media is not changed in this manner, AATB Standards dictate that the skin must be frozen within 96 hours of recovery. The skin is generally incubated in cryoprotectant solution for 30 minutes at 4°C. Skin that is to be frozen should be folded with fine mesh gauze or bridal veil covering the dermal surface prior to placement in a flat packet to ensure uniformity of the cooling process.⁶⁰ This is followed by slow-rate cooling at a rate of approximately –1°C per minute. Although computer-assisted, control-rate freezing is thought to be optimal, studies have demonstrated that cooling in a heat sink box at less than –2°C per minute is equally effective and does not compromise the metabolic activity of the skin.⁶¹ The skin is frozen to a temperature of –70° to –100°C prior to placement in either a mechanical freezer or liquid nitrogen. Skin stored in a mechanical freezer (–70 to –100°C) can be maintained for 3–6 months, whereas storage in liquid nitrogen (–150 to –196°C) has been shown to maintain viability for up to 10 years. Although this methodology has been reported to result in 85% retention of viability, there remains a need for research to determine the optimal technology for skin preservation.⁶²

Lyophilization

Skin can also be lyophilized by freeze drying or incubation in glycerol.⁶³ This process has been reported to decrease biologic degradation and antigenicity; however, this also results in epidermal cell destruction and the loss of barrier function. Moreover, lyophilized allograft skin has poor adherence to the excised wound bed and is far less effective than ‘fresh’ skin or cryopreserved skin in controlling microbial growth. Its clinical use has been further limited by its high cost of production compared to conventional allograft.

Transport

Refrigerated skin should be transported in tissue culture medium at wet ice temperatures (1–10°C) in an insulated container. Frozen allograft skin is transported on dry ice in an insulated container to prevent the skin temperature from rising to greater than –50°C. If the frozen skin is thawed at the tissue bank, it should be transported at wet ice temperatures.

Rewarming

Rewarming of frozen cryopreserved allograft skin must be performed in such a manner as to minimize cryodamage and

preserve the structural integrity and viability of the skin. Early studies demonstrated that warming rates of 50–70°C/min resulted in 80–95% graft survival. Subsequent research⁶⁰ has revealed that warming should be performed in 2–4 minutes or less at a temperature of 10–37°C (127–470°C/min). Rewarming in a microwave is not recommended due to uneven heating and excessive intracellular temperatures.

The future of skin banking

Skin banking must continue to evolve as engineered skin substitutes enter the clinical arena for the temporary and permanent coverage of partial- and full-thickness wounds. A number of skin substitutes have recently received FDA approval for use in the United States and have become part of the surgeon’s armamentarium. Although they are generally more costly than allograft skin, some of these products have been demonstrated to possess a number of attributes, including:

- nonantigenicity,
- ready availability,
- sterility, and
- the ability to provide a dermal equivalent as a template for the later application of ultrathin (0.006 inch) skin autografts.

Allograft skin has the potential to play a major role in permanent skin reconstruction after extensive thermal injury; however, this will require interactive research with the burn centers caring for these patients. This point is well illustrated by the studies of Rose⁶⁴ and Naoum⁶⁵ who demonstrated more rapid healing times and shorter hospital stays for children with extensive indeterminate depth scald burns when treated with early wound debridement and allografting compared to conventional topical antimicrobial therapy. Homografts acted as the best protection for damaged dermis, thus providing an environment for spontaneous epithelialization.

Skin banks must also identify ways of increasing cadaveric skin donation, ensuring recipient safety from potential disease transmission, and reducing procurement and processing costs while optimizing allograft viability. This will become increasingly difficult as it becomes necessary to perform additional and newer microbiological testing procedures to ensure recipient safety. To accomplish these goals, it may become necessary for skin banking operations to become regionalized. Such an undertaking could enhance tissue supplies and availability and result in increased clinical use by surgeons.

Allograft-based skin products

There is tremendous potential for human allograft-based skin products to be developed in the upcoming years; however, it will become increasingly important for skin banks to perform basic science and clinical research (in conjunction with burn and wound healing centers) to demonstrate the clinical indications and efficacy of allograft skin products in various clinical applications. Technological advances may include modifications to reduce immunogenicity and/or the potential for disease transmission. Newer processing techniques could sterilize the skin without injuring the viable cellular elements or the structural integrity of the tissue. In addition, with continued research, deepidermized allograft dermis could become:

- a source of growth factors and antimicrobial agents,
- a permanent full-thickness wound cover seeded with the patient's autologous keratinocytes and fibroblasts,
- a bilayer membrane system for epidermal autografting, and/or
- a readily-available permanent wound cover preseeded with non-antigenic allogeneic keratinocytes, fibroblasts, and melanocytes.

Allogeneic skin provides a source of skin cells, including keratinocytes, fibroblasts, melanocytes, and endothelial cells. These cells may be grown into large populations (greater than 1×10^{12} cells), cryopreserved in liquid nitrogen, recovered into culture, and combined with degradable biopolymers to form cultured skin substitutes.⁶⁶ Preclinical studies have shown organization of the epidermal keratinocytes to form a skin

barrier,^{67,68} expression of pigment by melanocytes,⁶⁹ and organization of endothelial cells into vascular analogs.⁷⁰ Clinical studies have demonstrated improved healing of chronic wounds with allogeneic skin substitutes,⁷¹ and permanent closure of excised burns with cultured autologous grafts;⁷² however, cryopreservation of multilayered grafts with keratinized epithelium remains an unachieved goal in tissue transplantation. It therefore appears likely that the principles and practices of skin banking may contribute to eventual availability of unlimited supplies of skin grown in laboratories for the treatment of a wide variety of skin-loss conditions. Collaborative research efforts will be necessary to achieve these goals in a timely and cost-effective manner as skin banks find themselves competing and/or collaborating with the tissue bioengineering industry.

The future of alternative wound coverings	243

Introduction

The skin envelope consists of two basic layers. The epidermis, consisting of keratinocytes attached to an underlying basement membrane, provides most barrier functions. The dermal layer provides the durable and pliable characteristics of skin, which are so vital to proper function and cosmesis. When available, the replacement material of choice is the patient's own (autologous) skin as shown in an algorithm describing the decision process to treat acute burns. In smaller injuries, this can be accomplished by split-thickness sheet autograft (Figure 16.1). However in larger injuries, meshed autologous skin grafts or skin substitutes are required.

Physiologic considerations

Skin is a truly amazing organ, rarely properly appreciated until it is missing. To date, all attempts to replace it, either temporarily or permanently, have been highly imperfect. As those with serious burns survive in greater numbers, the absence of effective skin replacements is increasingly a hindrance to progress in burn care.

Structure and function of the skin

Skin, the body's largest organ, is incredibly complex. Functionally there are two layers with a highly specialized and effective bonding mechanism. Numerous appendages traverse the skin and a rich and reactive capillary network provides nutrient flow while controlling temperature. The epidermis, consisting of the strata basale, spinosum, granulosum, and corneum, provides a vapor and bacterial barrier. The dermis provides strength and elasticity. The thin epidermal layer is constantly refreshing itself from its basal layer, with new keratinocytes undergoing terminal differentiation over approximately 4 weeks to anuclear keratin-filled cells that make up

the stratum corneum, which provides much of the barrier function of the epidermis. The basal layer of the epidermis is firmly attached to the dermis by a complex bonding mechanism containing collagen types IV and VII. When this bond fails, serious morbidity results, as demonstrated by the disease processes of toxic epidermal necrolysis¹ and epidermolysis bullosa² (Figure 16.2).

Consequences of loss of barrier function

Loss of the epidermal barrier has serious adverse physiologic effects. Direct and evaporative fluid losses are immediately seen. If wounds are large, this quickly leads to dehydration and shock. Protein losses are also substantial, leading to loss of colloid oncotic pressure and secondary edema. Microorganisms have unimpeded access to the microcirculation with resulting systemic infection. Deep tissues become desiccated with secondary cell death and progression of wound depth. Dry wounds will not epithelialize as readily. It is clearly important for the burn surgeon to have prompt biologic closure of wounds as an important early objective.

Although it is an imperfect replacement, autologous split-thickness skin is closest to being the ideal skin substitute (Box 16.1). Because of the paucity of autologous donor skin available in patients with massive burn injuries, both the short-term and long-term problems of skin loss must be solved by alternative wound closure materials. Alternative materials can be used for either wound coverage which will be temporary or for permanent wound closure. Allogenic (cadaver) skin has been the most widely used alternative wound closure material. However, there are other choices. This is an exciting and fast-moving area which may profoundly change the care of patients with serious burns. The objective of this chapter is to review the currently available alternative skin closure materials, both temporary and permanent.

Temporary skin substitutes

Temporary skin substitutes provide transient physiologic wound closure, thereby helping to control pain, absorb wound exudate, and prevent wound desiccation. They are clinically useful in several settings in burn care:

- as a dressing on donor sites to facilitate pain control and epithelialization from skin appendages;
- as a dressing on clean superficial wounds for the same reasons;
- to provide temporary physiologic closure of deep dermal and full-thickness wounds after excision while

Fig. 16.1 The replacement material of choice remains the patient's own (autologous) skin.

Fig. 16.2 The basal layer of the epidermis is firmly attached to the dermis by a complex bonding mechanism containing collagen types IV and VII. When this bond fails, serious morbidity results, as demonstrated here by the disease processes of dystrophic epidermolysis bullosa.

BOX 16.1 The perfect skin substitute — autologous split-thickness skin

- Prevents water loss
- Barrier to bacteria
- Inexpensive
- Long shelf life
- Can be applied in one operation
- Does not become hypertrophic
- Flexible
- Conforms to irregular wound surfaces
- Can be used 'off the shelf'
- Does not require refrigeration
- Cannot transmit viral diseases
- Does not incite inflammatory response
- Durable
- Easy to secure
- Grows with a child

awaiting autografting or healing of underlying widely meshed autografts; and

- as a 'test' graft in questionable wound beds.

Their principal utility is provision of temporary physiologic closure of wounds, which implies protection from mechanical trauma, vapor transmission characteristics similar to skin, and a physical barrier to bacteria. These membranes create a moist wound environment with a low bacterial density.

Human allograft

Human allograft is generally used as a split-thickness graft after being procured from organ donors. When used in a viable fresh or cryopreserved state, it vascularizes and remains the 'gold standard' of temporary wound closures.³⁻⁵ It can be refrigerated for up to 7 days, but can be stored for extended periods when cryopreserved. It is also used in a nonviable state after preservation in glycerol or after lyophilization; however, most existing data describe results when it is used in a viable state. Viable split-thickness allograft provides durable biologic cover until it is rejected by the host, usually within 3 or 4 weeks. Prolongation of allograft survival, through the use of antirejection drugs, has been advocated,⁶ but is not generally practiced for fear that antirejection drugs will increase the risk of infection.⁷

Human skin allografts are generally placed into frozen storage awaiting the return of numerous laboratory tests allowing one to safely exclude the possibility of viral disease transmission. When modern screening techniques are followed, the risk of viral disease transmission is exceedingly small. Allograft is also effectively used in combination with meshed autograft in patients with large burns, the interstices of the meshed graft being immediately closed by the overlying unexpanded allograft, possibly reducing metabolic stress and local wound inflammation (Figure 16.3).

Human amnion

Human amniotic membrane is used in many parts of the world as a temporary dressing for clean superficial wounds such as

Fig. 16.3 Allograft is also effectively used in combination with meshed autograft in patients with large burns, the interstices of the meshed graft being immediately closed by the overlying unexpanded allograft, possibly reducing metabolic stress and local wound inflammation.

partial-thickness burns, donor sites, and freshly excised burns awaiting donor site availability.^{8,9} Amniotic membrane is generally procured fresh and used after brief refrigerated storage.^{10,11} It can also be used in a nonviable state after preservation with glycerol. It has been treated with silver to facilitate control of bacterial overgrowth.¹² Amnion does not vascularize but still can provide effective temporary wound closure.¹³ The principal concern with amnion is the difficulty in screening the material for viral diseases unless preservation methods can eliminate potential viral contamination. Without the ability to screen the material in this way, the risks of disease transmission must be balanced against the clinical need and the known characteristics of the donor.

Allogenic epithelial sheets

In many centers, particularly in Europe, sheets of allogenic and autogenous epithelium are used to dress partial-thickness wounds or to cover the interstices of meshed split-thickness autografts.^{14,15} These are generally applied as thin sheets placed on a gauze carrier for ease of handling. Cell suspensions in fibrin sealant have also been trailed. The concept is that the sheets will both prevent desiccation of underlying wounds and that the release of unknown growth-stimulating substances by the cells as they die will stimulate native wound healing.¹⁶ The concept is attractive, but controlled data are not available, particularly as regards any impact on long-term outcomes.

Xenografts

Although various animal skins have been used for many years to provide temporary coverage of wounds,¹⁷ only porcine xenograft is widely used today (Figure 16.4).¹⁸ Porcine xeno-

Fig. 16.4 Although various animal skins have been used for many years to provide temporary coverage of wounds, only porcine xenograft is widely used today.

graft is commonly distributed as a reconstituted product consisting of homogenized porcine dermis which is fashioned into sheets and meshed.¹⁹ Split-thickness porcine skin is also used fresh, after brief refrigeration, after cryopreservation, or after glycerol preservation. It effectively provides temporary coverage of clean wounds such as superficial second-degree burns and donor sites²⁰ and has been used in patients with toxic epidermal necrolysis.^{1,21} Porcine xenograft has been combined with silver to suppress wound colonization.^{22,23} Porcine xenograft does not vascularize, but it will adhere to a clean superficial wound and can provide excellent pain control while the underlying wound heals.

Synthetic membranes

A number of semipermeable membrane dressings can provide a vapor and bacterial barrier and control pain while the underlying superficial wound or donor sites heal. These typically consist of a single semipermeable layer that provides a mechanical barrier to bacteria and has physiologic vapor transmission characteristics.^{24,25} Biobrane™ (Dow-Hickham, Sugarland, TX) is a two-layer membrane constructed of an inner layer of nylon mesh that allows fibrovascular ingrowth and an outer layer of silastic that serves as a vapor and bacterial barrier.²⁶ It is widely used to provide temporary closure of superficial burns and donor sites. All synthetic membranes are occlusive and can foster infection if placed over contaminated wounds, especially in the presence of necrotic tissue.²⁷ Appropriate monitoring is essential to their proper use.

Hydrocolloid dressings are generally designed with a three-layer structure: a porous, gently adherent inner layer; a methyl cellulose absorbent middle layer; and a semipermeable outer layer. They foster a moist wound environment while absorbing exudate. A moist wound environment has been found to favor wound healing.²⁸ A variety of pastes and powders made from hydrocolloid materials are also widely available. These can be applied to superficial or deeper chronic wounds to absorb wound exudate while maintaining a moist wound environment.

Hydrofiber matts absorb wound exudate and have been used as temporary wound membranes. When combined with ionic silver (Aquacel-Ag, ConvaTec, Chester, UK), additional antimicrobial activity is seen. This membrane has been used successfully in some burn programs as an adjunct in the management of partial-thickness burns and donor sites.²⁹

Combined allogenic and synthetic membranes

Epidermal growth factor, transforming growth factor- β , insulin-like growth factor (IGF), platelet-derived growth factors (PDGF), fibroblast growth factors, and other mediators play an important role in wound healing.³⁰ To provide some of these substances topically to wounds, investigators have placed both viable and nonviable allogenic cell types into temporary wound dressings.³¹ These cells persist for no more than 14 days, but it is hoped that factors secreted by the allogenic cells, or released upon their death and dissolution, will enhance wound healing. These membranes are generally regulated as both devices and biologics.

An allogenic dermal-epidermal device that used a collagen lattice to culture both cell types was shown effective in an athymic mouse model³²⁻³⁴ and then went into clinical trials.

Although it has not been demonstrated to have a clinical role in burn patients, the device is being explored for utility in chronic ulcers of the lower extremity.^{35–39} Dow-Hickam's Biobrane™ has been used as a scaffold to support the growth of allogenic fibroblasts. This device is now marketed as Transcyte® (Smith and Nephew, La Jolla, CA) and has been successful in some burn programs as an adjunct to the management of dermal burns.^{40–44} Viral transfection can be employed to modify keratinocytes so that they overexpress PDGF, human growth hormone, IGF-1, and other growth factors,⁴⁵ and it is possible that such cells might be employed as components of wound membranes over the next few years.⁴⁶ Although stimulation of wound healing by topical application of mixed growth factors in this fashion is an intriguing concept, convincing evidence of the concept's general validity is awaited.

Permanent skin substitutes

Realization of a practical permanent skin substitute will revolutionize the care of patients with burns and other difficult wounds. The perfect substitute is described in Box 16.1, but has yet to be approached by any currently available device. However, there are a number of imperfect or partial-skin substitutes available at the present time that are valuable in particular clinical settings and may be the forerunners of this hypothetical ideal.

Epidermal cells

For over 20 years it has been possible to culture vast numbers of epithelial cells from a small skin biopsy,^{47,48} and this has led to the widespread clinical use of cultured epithelial grafts to cover burn wounds. Epithelial cells are procured from a full-thickness skin biopsy, the cells being separated with trypsin. The resulting epithelial cell suspension is cultured in medium containing fetal calf serum, insulin, transferrin, hydrocortisone, epidermal growth factor, and cholera toxin, overlying a layer of murine fibroblasts that have been treated with a non-lethal dose of radiation that prevents them from multiplying. Colonies of epithelial cells expand into broad sheets of undifferentiated epithelial cells. These cells are separated from the culture vessel with trypsin and taken to secondary culture using the same techniques until confluent thin sheets of undifferentiated cells are obtained. The resulting sheets are removed from the dishes after treatment with dispase, which digests the proteins attaching the epithelial cells to the dish. The sheets of epithelial cells are attached to a petrolatum gauze carrier to ease handling.

When epithelial cultures were first used in patients with large burns it was hoped that they would provide the definitive answer to the clinical problem of the massive wound.^{49–51} With more frequent use of epithelial grafts, specific liabilities have become apparent including suboptimal engraftment rates and long-term durability.^{52,53} However, when faced with a very large wound and minimal donor sites, epithelial cell wound closure is a useful adjunct to split-thickness autograft, their liabilities and expense becoming more acceptable as wound size increases.

Many of the imperfections associated with epithelial cell wound closure may be attributed to the absence of a dermal

element. Epithelial grafts are now commercially available. Application is generally most successful in wounds from which vascularized allograft has been removed. Despite scattered cases, application of cultured epithelial grafts onto synthetic dermal analogs has not been shown effective.

Dermal analogs

Virtually all of the characteristics of normal skin that are not related to barrier function are provided by the dermis. These characteristics include flexibility, strength, heat dissipation and conservation, lubrication, and sensation. The first dermal substitute used clinically was 'artificial skin', also called Integra™ (Integra LifeSciences Corporation, Plainsboro, NJ, USA); it has been recently approved by the US Food and Drug Administration for use in life-threatening burns. This material was developed in the early 1980s by a biomaterials research team from the Massachusetts General Hospital and Massachusetts Institute of Technology.⁵⁴ The research team, led by surgeon John Burke from the Massachusetts General Hospital and materials scientist Ionnas Yannas from the Massachusetts Institute of Technology, had the goal of developing a wound covering that would both provide a temporary vapor and bacterial while providing a scaffold for later dermal regeneration. The material was intended to be placed on excised burn wounds and is now approved for clinical use. Its use for other indications is being explored. The inner layer of this material is a 2 mm thick combination of fibers of collagen isolated from bovine tissue and the glycosaminoglycan chondroitin-6-sulfate. This 2 mm thick inner layer has a 70–200 μm pore size that allows fibrovascular ingrowth, after which it is designed to slowly biodegrade.^{55,56} To manufacture the device, glycosaminoglycan and collagen fibers are precipitated and then freeze-dried and cross-linked by glutaraldehyde. The outer layer of the membrane is 0.009-inch (0.23 mm) thick polysiloxane polymer with vapor transmission characteristics similar to normal epithelium. This membrane is intended to be placed on freshly excised full-thickness burns and the outer silicone membrane replaced with an ultra-thin epithelial autograft 2–3 weeks later (Figure 16.5).⁵⁷ Clinical reports in patients with large burns have been

Fig. 16.5 Integra™ is intended to be placed on freshly excised full-thickness burns and the outer silicone membrane replaced with an ultra-thin epithelial autograft 2–3 weeks later.

generally favorable,^{58,59} although submembrane infection must be watched for. Integra™ has also been found to be useful in selected burn reconstruction operations.⁶⁰

Another currently available device designed as a dermal replacement is cryopreserved allogenic dermis. This material is intended to be combined with a thin epithelial autograft at the time of initial wound closure. It is marketed as AlloDerm® (LifeCell Corporation, The Woodlands, TX, USA).^{61,62} Split-thickness allograft skin is obtained from cadaver donors through tissue banks after proper screening for transmissible diseases. Using hypertonic saline, the epithelial elements of the grafts are removed and the remaining dermis is treated in a detergent to inactivate any viruses and the device is freeze-dried. The process is intended to provide a nonantigenic dermal scaffold, leaving basement membrane proteins (particularly laminin and type IV and VII collagen) intact. The material is rehydrated immediately prior to placement on wounds with overlying ultra-thin epithelial autograft (Figure 16.6). Clinical experience with this material in burn surgery is limited, but early experiences have been favorable.^{63,64}

Generating a dermal replacement through the prior use of human split-thickness allograft is another strategy with significant clinical support. This has been done on occasion for many years by surgeons who ‘leave behind’ remnants of vascularized allograft dermis when replacing allograft with thin split-thickness autografts in patients with large injuries. This has been modified for use with cultured epithelial grafts, such that the cultured epithelial cells are placed on wounds closed initially with vascularized allograft. Once allograft has vascularized, the allogeneic epithelial cells are removed by dermabrasion or tangential excision, purposefully leaving behind a vascularized but theoretically nonantigenic allogenic dermal layer.^{65–67} The method has been favorably reported,^{68,69} but has not been

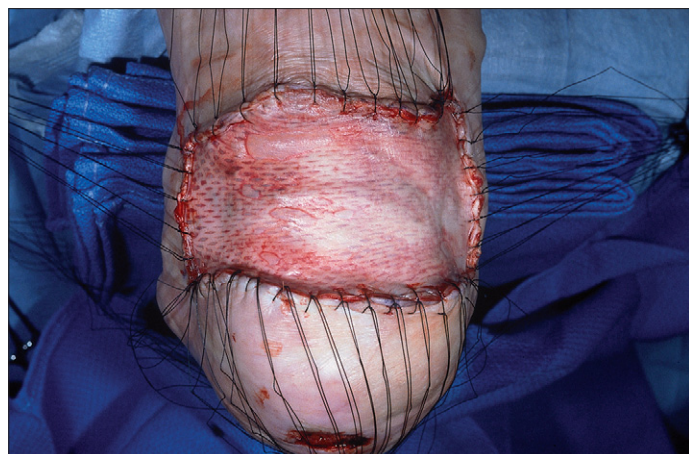

Fig. 16.6 AlloDerm® is rehydrated immediately prior to placement on wounds with overlying ultra-thin epithelial autograft.

universally adopted. Perhaps the epithelial excision either leaves behind nests of antigenic epithelial cells if too superficial or removes the epidermal–dermal attachment structures if too deep.

Composite substitutes

Ideally, a skin replacement technique would provide immediate replacement of both dermal and epidermal layers. Combining epithelial cells with a dermal analog in the laboratory seems logical. A completely biologic composite skin substitute, culturing human fibroblasts in a collagen–glycosaminoglycan membrane, and then growing keratinocytes upon this, has been under development for some years.^{70,71} This composite membrane has been successful in both a nude mouse model and in initial clinical series.^{72,73} There is even potential to control pigment expression.⁷⁴ This exciting technology continues to be refined in laboratory and clinical investigations and may have a major impact on the field. A similar project, in which autogenic epithelial cells are cultured onto allogenic dermis, shows some promise as well.⁷⁵ It remains to be seen if either technique will lead to a reliable and durable permanent skin replacement.

The future of alternative wound coverings

We are likely to see significant improvements in skin substitute technologies, both temporary and permanent, over the next few years. In temporary wound coverings, not only are improved synthetics and improved skin banking techniques probable but we may see temporary dressings containing growth factor-secreting allogenic tissues that stimulate native wound healing. Genetic modification of keratinocytes is now possible. These cells have been engineered to overexpress PDGF, human growth hormone, IGF-1, and other growth factors.⁴⁵ It is likely that they will be trialed in animal models and human wounds over the next few years.⁴⁶ If they prove efficacious, their application to healing burns and donor sites, through incorporation in temporary dressings, may become possible. It might be further possible to combine autogenous cells with modified allogenic cells such that the resulting chimeric graft benefits from transient overexpression of critical growth factors during the early stages of engraftment.

As we become increasingly successful at salvaging the lives of those with large burns, our need for a durable and reliable permanent skin substitute becomes increasingly acute. This material is needed both to truncate the acute illness through earlier wound closure and to facilitate timely and effective burn reconstruction. Just what form that substitute will take is not clear. Most likely, it would seem to be an *in vitro* combination of autologous keratinocytes and possibly fibroblasts and/or endothelial cells with a dermal analog. Whatever form the successful replacement takes, it is certain to profoundly impact the field of burn care.

Burn scar resurfacing with AlloDerm application	246
Preparation of the burn wound	246
Usage of AlloDerm	247
Dressings and postoperative instructions	247

AlloDerm (Life Cell Corporation, Branchburg, NJ) is an acellular dermal matrix derived from donated human skin tissue. Scientific production of this dermal-derived skin template started with research with porcine skin. The basis of the process that allowed AlloDerm production was developed in the pig model, which demonstrated that tissue rejection does not develop in an acellular allodermis.¹ Donated skin is supplied by US AATB-compliant tissue banks utilizing the standards of the American Association of Tissue Banks (AATB) and Food and Drug Administration (FDA) guidelines. It is classified as banked human tissue by the FDA since it is minimally processed and not significantly changed in structure. Human donor tissue undergoes a multistep proprietary process that removes both the epidermis and the cells that can lead to tissue rejection and graft failure, without damaging the matrix and framework of biochemical and structural components of the dermis, thus allowing the wound to regenerate and replace. Once the dermal tissue has been decellularized, the final step is preservation. The matrix is preserved with a patented freeze-drying process that prevents damaging ice crystals from forming. During this process, all cells responsible for immune response are removed, leaving a matrix ready to enable the wound to mount its own tissue regeneration process. AlloDerm allows the repair cascade to follow a more determined and guided regenerative process, restoring similar original structural, functional, and physiological conditions and minimizing scar formation. During the regeneration process, the AlloDerm matrix becomes part of the existing tissue structure by migration of stem cells in the matrix, differentiation into tissue-specific cell types, and elaboration of new matrix. Applications of AlloDerm include abdominal wall reconstruction, breast reconstruction, tissue filling, and wound coverage. The product comes in different thickness (0.17–1.8mm and over) and sizes, some of them custom made, besides being available mesh and unmeshed. Thickness appropriate for burn wound coverage ranges from 0.18mm to 0.34mm.

Burn scar resurfacing with AlloDerm application

The philosophy behind the application of AlloDerm in burn scar resurfacing is the same of that with Integra dermal regeneration template; however, important differences of the technical application exist. The purpose of the technique is to remove all damage and scarred tissue, and to replace it with an even, flat, surface that will accommodate a laminar thin split-thickness skin autograft. The objective being an outcome with an exchange of hypertrophic non-pliable scar by a smooth, pliable, soft skin-like tissue. Two main points differentiate the Integra technique from the AlloDerm technique: AlloDerm resurfacing is a one-step operation (instead of the two-step Integra technique), and the nature of AlloDerm prevents it from being applicable to large wound areas. Indeed, AlloDerm is used together with a thin skin graft, which makes it appealing as a one-step operation, but the fact that all areas of AlloDerm require autograft coverage limits its use to an area of wound resurfacing that matches donor site availability. The experience with AlloDerm, although it has been on the market for many years, is still limited, with few references in acute burn surgery,^{2,3} which showed good engraftment of autograft and outcomes and a decrease of length of hospital stay and donor site healing time. The applications in reconstructive surgery are most commonly retrieved as dermal or tissue filling, with few usages as reconstruction or resurfacing.⁴

Preparation of the burn wound

During the preoperative burn reconstructive visit, all areas amenable for burn scar resurfacing are outlined and discussed with the patient. An inventory of potential donor sites is developed and a decision is made on whether Integra or AlloDerm will be used. Generally speaking, indications for AlloDerm will include small areas requiring burn scar resurfacing and patients that will benefit from a one-step operation (i.e. zones of limited range of motion that require intensive and aggressive postoperative physiotherapy and occupational therapy to maintain function). A complete informed consent of the treatment proposed, which includes alternatives to the technique and the potential hazards of the product, should be obtained.

The burn scars should be completely excised to provide a clean, viable, vascularized wound bed. Hemostasis should

proceed very carefully to avoid active bleeders. The area must be completely released and all joints and tendons treated with capsulotomies, ligament releases, and tenolyses when appropriate to return the area to normal anatomy. The area is kept in warm saline compresses until AlloDerm is ready for application. A thin ($6/1000$ – $8/1000$ of an inch) split-thickness skin autograft is harvested from an available donor site. It should match the wound requirements, allowing for an excess to account for graft shrinkage after harvest.

Usage of AlloDerm

Prior to use, AlloDerm must be rehydrated. The rehydration procedure should begin at least half an hour ahead of intended use. Liberal amounts of warmed saline should be used in a two-step bath with light agitation. Normal rehydration is usually accomplished in 20–40 minutes depending on thickness. The first step starts by tearing and opening the outer foil bag. AlloDerm is aseptically removed from the packaging, leaving the backing on, and it is placed in the first bath of saline solution warmed at 37°C (50 mL–100 mL, depending on the total surface of AlloDerm). AlloDerm is soaked and kept submerged for a minimum of 5 minutes or until the backing separates. The backing is discarded and AlloDerm is transported to a second bath, leaving the piece submerged until it is fully rehydrated. When it is fully rehydrated, it is soft and pliable and it is ready for application to the surgical site.

AlloDerm has two distinct sides. The basement membrane is the upper side (it looks rough and dull) and the dermal surface is the lower side (it looks smooth and shiny). They can be distinguished by appearance and by the blood test. A drop of blood will infiltrate the vascular channels within the matrix after rinsing with saline, and the dermal side will look bright red, whereas the basement membrane side will look pink. The dermal side must be applied on the wound surface (placement on the wrong side will prevent engraftment), and AlloDerm is secured with absorbable sutures. Following this, the skin graft is applied on top of the basement membrane side of AlloDerm and it is secured in the usual fashion (absorbable sutures, running suture, staples, etc.) (Figure 17.1).

Dressings and postoperative instructions

Petrolatum-based fine mesh gauze is applied on top of the graft, and is secured with bacitracin ointment. No special

dressings are required. Tie-over dressings may be used, depending on location and surgeon preferences, but they are not necessary. Conversely, the vacuum assisted system may be used as well.

Grafts are inspected at day 7. Autografts will look white yellow and at this time the patient may be sent to rehabilitation services to be measured for silicone inserts, placement of interim pressure garments, and start physiotherapy and occupational therapy. Bathing and moisturizing may proceed from day 10 after surgery, when a complete stratum corneum is present. In the case of small open wounds, they are treated with gentle care and baseline or any other wound care protocol. It is seldom necessary to regraft AlloDerm; small raw areas heal spontaneously by proliferation of keratinocytes of the skin graft that seed the areas despite disintegration of the architecture of the skin graft.

Fig. 17.1 Burn scar incision and resurfacing with AlloDerm. The dermal template integrates in the wound and behaves as true dermal tissue. The use of AlloDerm allows for the harvest of super-thin skin autografts, with rapid healing of the donor site. (Reproduced with permission from Barret JP, Herndon DN, eds. Color atlas of burn care. London: WB Saunders; 2001.)

Introduction and epidemiology	248
The fire environment	248
Pathophysiology	253

Introduction and epidemiology

It has been over two decades since the authors published their first manuscript on inhalation injury.¹ In the review article published the following year it was reported that inhalation injury was a main, if not *the* main, factor responsible for mortality in thermally injured patients.² Smoke inhalation causes 5000–10000 deaths annually in the United States and more than 23000 injuries, including approximately 5000 firefighter injuries.³ In fact the United States has one of the highest fire death rates among industrialized countries. Inhalation injury is a serious medical problem. In the case of smoke, more than 30% of thermally injured patients admitted to burn centers in the United States have a concomitant smoke inhalation injury.⁴ Similar percentages of fire victims who have sustained smoke inhalation appear in several other countries.^{5–8} Despite effective management of fluid resuscitation, early surgical excision of burned tissue, and improved ventilation techniques, the mortality rate of patients who have combined burn and smoke inhalation injury is still high.^{4,9–11} In patients with combined injury, the lung is a critical organ and the progressive respiratory failure associated with pulmonary edema is a pivotal determinant of mortality.^{12–14} Though not as lethal, smoke inhalation alone is a serious problem. It is estimated by the World Health Organization that there are over one billion people who develop airway and pulmonary inflammation as a result of inhaling smoke from indoor cooking fires, forest fires, and burning of crops (Figure 18.1).^{15,16}

The inhalation of toxic materials has been of interest for a number of years especially as the result of their use in gas warfare. In the 1940s there were two very large fires that focused interest in on the inhalation of smoke in fire victims. The first was a fire at a nightclub in Boston called ‘The Coconut Grove’ where a large number of people were trapped in a burning building and consequently sustained severe inhalation injury.^{17,18} The second disaster occurred in Texas City across the bay from Galveston, Texas.¹⁹ Here a ship exploded

in a harbor and set off a chain of explosions and fires among some 50 refineries and chemical plants resulting in over 2000 hospital admissions of patients with burn injury many of whom had simultaneously inhaled smoke as well as victims with smoke inhalation alone. In many ways the burn victims of the 9/11 disaster at the Pentagon were similar to these individuals since the burns and inhalation involved combustion of petroleum products. Among the 790 injured survivors of the terrorist attack on the World Trade Center in NY on September 11, 2001, 49% suffered from inhalation injury. The situation was the same as the attack on the Pentagon. In both situations inhalation injury was also seen in some patients who were not burned.^{20–23} Disasters like those in Boston and Galveston led to the establishment of centers for the care of burn victims and to research into the pathophysiology of burn injury.

The fire environment

Toxic smoke compounds

Smoke toxicity is an increasing concern because industrial products used today are changing from woods and natural materials towards lighter construction materials, synthetics, and petrochemical-based materials, which ignite and burn two to three times hotter and faster than conventional materials and, when heated, emit a gas or smoke that will also ignite two or three times faster and burn hotter than natural biological materials. Consequently, firefighters have less time to gain control of a fire, and victims are more likely to be incapacitated by breathing toxic gases and are more likely to sustain smoke inhalation because they have less time to escape from the burning area.³ Inhalation injury is caused by steam or toxic inhalants such as fumes, gases, and mists. Fumes consist of small particles or droplets dispersed in air with various irritants or cytotoxic chemicals adherent to the particles. Mists consist of aerosolized irritant or cytotoxic liquids. Smoke consists of a combination of fumes, gases, mists, and hot air. Heat, toxic gases, and low oxygen levels are the most common causes of death at a fire scene. A large variety of toxic gases and chemicals can be generated, depending on the fire environment (Table 18.1).

Many of these compounds may act together to increase mortality, especially carbon monoxide and hydrogen cyanide,^{24,25} where a synergism has been found to increase tissue hypoxia and acidosis²⁵ and may also decrease cerebral oxygen consumption and metabolism.^{26,27} Hydrogen sulfide would also be predicted to synergize with carbon monoxide,

since both cyanide and hydrogen sulfide are inhibitors of mitochondrial cytochrome oxidase. Victims may be incapacitated by the blinding and irritating effects of smoke, as well the decreasing oxygen concentration that occurs with combustion and results in progressive hypoxia.

Fig. 18.1 An example of direct exposure to smoke as a result of an open fire using various materials as a fuel.

Inhalation injury can be classified into:

- upper airway injury;
- lower airways injury;
- pulmonary parenchyma injury; and
- systemic toxicity.

The extent of inhalation damage depends on fire environment: the ignition source, temperature, concentration, and solubility of the toxic gases generated. For instance, thermal and chemical compounds usually cause upper airway injury. The water-soluble materials such as acrolein and the other aldehydes damage the proximal airways and set off reactions, which are inflammatory to the bronchi and parenchyma, whereas agents with lower water solubility such as chlorine, phosgene, and nitrogen oxide, nitrogen dioxide or N_2O_3 or even N_2O_4 are more likely to cause insidious injury.²⁷ Toxic gases such as carbon monoxide and cyanide rarely damage the airway but affect gas exchange, producing more systemic effect. It is thus important to obtain information relative to the source of the fire and the combustion products generated when treating a fire victim (see Table 18.1). It is also important to know the duration of exposure and the extent to which the fire victim was in an enclosed area since this relates to the dose of toxic materials presented them.

TABLE 18.1 ORIGIN OF SELECTED TOXIC COMPOUNDS ²⁴		
Gases and chemicals	Material	Source
Carbon monoxide	Polyvinyl chloride Cellulose	Upholstery, wire/pipe coating, wall, floor, furniture coverings Clothing, fabric Wood, paper, cotton
Cyanide	Wool, silk, cotton, paper, plastic, polymers Polyurethane Polyacrylonitrile Polyamide Melamine resins	Clothing, fabric, blankets, furniture Insulation, upholstery material Appliances, engineering, plastics Carpeting, clothing Household and kitchen goods
Hydrogen chloride	Polyvinyl chloride Polyester	Upholstery, wire/pipe coating, wall, floor, furniture coverings Clothing, fabric
Phosgene	Polyvinyl chloride	Upholstery, wire/pipe coating, wall, floor, furniture coverings
Ammonia	Wool, silk Polyurethane Polyamide Melamine resins	Clothing, fabric, blankets, furniture Insulation, upholstery material Carpeting, clothing Household and kitchen goods
Sulfur dioxide	Rubber	Tires
Hydrogen sulfide	Wool, silk	Clothing, fabric, blankets, furniture
Acrolein	Cellulose Polypropylene Acrylics	Wood, paper, cotton, jute Upholstery, carpeting Aircraft windows, textiles, wall coverings
Formaldehyde	Melamine resins	Household and kitchen goods
Isocyanates	Polyurethane	Insulation, upholstery material
Acrylonitriles	Polyurethane	Insulation, upholstery material

Carbon monoxide

Carbon monoxide (CO) is an odorless, colorless gas that is produced by incomplete combustion of many fuels, especially cellulolytic (cellulose products) such as wood, paper, and cotton.²⁸ Carbon monoxide toxicity remains one of the most frequent immediate causes of death following smoke-induced inhalation injury. The predominant toxic effect of CO is its binding to hemoglobin to form carboxyhemoglobin (COHb). The affinity of CO for hemoglobin is ~200 to 250 times higher than that of oxygen.²⁹ Inhalation of a 0.1% carbon monoxide mixture may result in generation of a carboxyhemoglobin level as high as 50% of the total hemoglobin. The competitive binding of CO to hemoglobin reduces delivery of oxygen to tissues, leading to severe hypoxia, especially of most vulnerable organs such as brain and heart where oxygen extraction is considerably higher than most other organs. The oxygen-hemoglobin dissociation curve loses its sigmoid shape and is shifted to the left, thus further impairing tissue oxygen availability.^{24,30} In addition, the ability of CO to bind to intracellular cytochromes and to other metalloproteins contributes to CO toxicity. This competitive inhibition with cytochrome oxidase enzyme systems (most notably cytochromes *a* and P-450) results in an inability of cellular systems to use oxygen.^{30,31} Shimazu and his colleagues have shown that extravascular binding of CO to cytochromes and other structures accounts for 10–15% of total body CO stores. This intracellular binding of CO explains the two-compartment elimination of CO from the circulation.³² Miro and colleagues reported that CO inhibits cytochrome-c oxidase activity in lymphocytes.³³ The electron chain dysfunction by CO may cause electron leakage, leading to superoxide production and mitochondrial oxidative stress.³⁴

Symptoms and diagnosis of carbon monoxide poisoning

The symptoms of CO poisoning may predominantly manifest in organ and systems with high oxygen utilization. The severity of clinical manifestations is varied depending on the concentration of CO. For instance, the central nervous system symptoms such as headache, confusion, and collapse may occur when the blood COHb level is 40–50%. Symptoms such as unconsciousness, intermittent convulsions, and respiratory failure may occur if the COHb level exceeds 60% eventually leading to death if exposure continues. The cardiovascular manifestations may result in tachycardia, increase in cardiac output, dysrhythmias, myocardial ischemia, and hypotension, depending on severity of poisoning. The correlation of clinical manifestation and severity of CO poisoning is summarized in Table 18.2.

Diagnosis should be based on direct measurement of COHb levels in arterial or venous blood by co-oximetry; it has to be taken into account that venous blood underestimates the arterial COHb content.³⁷ Diagnosis may be facilitated by use of on-site portable breath analyzers. The inability to differentiate oxyhemoglobin from COHb limits the use of a pulse oximeter. The use of blood gas analyzers that estimate SO₂ based on measurement of dissolved PO₂ should also be avoided. The measurements of acid-base balance, plasma lactate levels, and bicarbonate are helpful in management of CO poisoning with accompanying lactic or metabolic acidosis. It is important to note that high oxygen concentrations are usually administered

TABLE 18.2 SYMPTOMS AND SIGNS AT VARIOUS CONCENTRATIONS OF CARBOXYHEMOGLOBIN^{35,36}

COHb%	Symptoms
0–10	None
10–20	Tightness over forehead, slight headache, dilation of cutaneous blood vessels
20–30	Headache and throbbing in the temples
30–40	Severe headache, weakness, dizziness, dimness of vision, nausea, vomiting, collapse
40–50	As above; greater possibility of collapse, syncope, increased pulse and respiratory rate
50–60	Syncope, increased pulse and respiratory rate, coma, intermittent convulsions, Cheyne–Stokes respirations
60–70	Coma, intermittent convulsions, depressed cardiac and respiratory function, possible death
70–80	Weak pulse, slow respirations, death within hours
80–90	Death in less than 1 hour
90–100	Death within minutes

Reproduced from Einhorn IN³⁵ National Institute of Environmental Health Sciences, and Schulte JH³⁶ Heldref publications.

to the victim in transit to hospital and some delay from cessation of exposure to measurement of CO may limit evaluation of true extent of exposure.³⁸ A nomogram has been developed which can relate the carboxyhemoglobin levels of a patient to the values that may have been present at the time of smoke inhalation and this can be used to estimate the true degree of inhalation injury.³⁹

Treatment for CO poisoning

The half-life of carboxyhemoglobin is 250 minutes (adult male) in room air and 40–60 minutes in a person breathing 100% oxygen at 1 atmosphere.⁴⁰ Those values are 30% shorter in females.⁴¹ Therefore all fire victims should be isolated from fire site and given 100% oxygen on route to hospital. This allows delivery of an inspired oxygen concentration of 50–60%, which is usually adequate. To adequately treat a CO poisoning it is important also to establish COHb level as early as possible. If it is necessary (loss of consciousness, cyanosis or an inability to maintain the airway), 100% oxygen should be delivered via mechanical ventilation through endotracheal tube until COHb levels drop below 10–15%. The alternative method to rapidly decrease COHb is hyperbaric oxygenation therapy (HBOT): 100% oxygen at pressure greater than 1 atmosphere in a pressure vessel. This technology has been used to treat a variety of disease states. HBOT may be necessary and beneficial for patients with smoke inhalation. If the carboxyhemoglobin level exceeds 25% or if significant clinical toxicity is present, administration of three atmospheres of pressure will reduce the carboxyhemoglobin half-life to 30 minutes. HBOT allows CO to dissociate from cytochrome *a*, *a*₃ and to increase PO₂ despite impaired hemoglobin function.^{42,43} Carbon monoxide may cause xanthine dehydrogenase to convert to xanthine oxidase; the latter is associated with the formation of oxygen free radicals and tissue damage. Treatment with hyperbaric oxygen will convert the

xanthine oxidase back to its less toxic dehydrogenase. If neurological impairment persists, this treatment may be repeated.^{42,44,45} Finally, as many as 10% of survivors may demonstrate a neurological or mental deterioration delayed some months after an initial recovery. Early hyperbaric oxygen may reduce these neurological problems.⁴⁶ However, the use of HBOT in burn patients is controversial despite the benefit of this treatment for patients with smoke inhalation alone.⁴⁷ Burn patients are difficult to monitor in small chambers and are at high risk for unstable hemodynamic conditions and complications such as seizures or aspiration. A recent systematic study review has not found sufficient evidence to support or refute the effectiveness of HBOT for the management of thermal burns. Evidence from controlled trials is insufficient to provide clear guidelines for practice. Further research is needed to better define the role of HBOT in the treatment of thermal burns.⁴⁸

Hydrogen cyanide

Hydrogen cyanide (CN), the gaseous form of cyanide, is generated by the combustion of nitrogen- and carbon-containing substances, such as wool, silk, cotton, and paper as well as synthetic substances like plastic and other polymers. Combustion of these materials may produce a rapid and lethal incapacitation of a victim at the fire source.⁴⁹ CN is a colorless gas with the odor of bitter almonds; however, it is difficult to detect at the site of a fire. The cytotoxicity of cyanide is produced by inhibition of cellular oxygenation with resultant tissue anoxia which is caused by reversible inhibition of cytochrome *c* oxidase.³⁸ CN is toxic to a number of enzyme systems. The exact chemical mechanism by which cyanide induces its toxicity includes combination with essential metal ions, formation of cyanohydrins with carbonyl compounds, and the sequestration with sulfur as a thiocyanate. However, the principal target enzyme of CN is cytochrome *c* oxidase, the terminal oxidase of the respiratory chain, and involves interaction with the ferric ion of cytochrome *a*₃. The importance of cyanide in smoke inhalation injuries is reflected by a study performed in Paris, France which shows that mean blood cyanide concentrations in both fire victims who survived (21.6 mol/L), and in those who died (116.4 mol/L) were significantly higher than those in control subjects (5.0 mol/L) and levels in fire victims who died were significantly higher than those in victims who survived.⁵⁰ A report of 144 fire victims in Dallas County, Texas, showed consistent results with the Paris study.⁵¹ Elevated cyanide concentrations showed a direct relationship to the probability of death. Cyanide also played a greater role in mortality in the aircraft fire at Manchester International Airport, Manchester, UK in 1985. These patients were not severely burned. The majority (87%) of the 54 individuals who died had potentially lethal levels of cyanide in their blood, whereas only 21% of these fire victims had COHb levels exceeding 50%. This indicates the high possibility that, under certain conditions, cyanide can be a more important determinant of morbidity and mortality following smoke inhalation than CO, which is usually regarded as the primary toxic threat.³ Smoke is also an often overlooked source of CN exposure in terrorist bombings. Following the World Trade Center bombing in 1993, traces of cyanide were found in the vans where the explosion originated. The Center of Disease Control

and the Department of Homeland Security consider CN among the most likely agents of chemical terrorism.⁵² Cyanide possesses all the attributes of an ideal terrorist weapon: it is plentiful, readily available, and easily obtainable because of its widespread use in industry and laboratories. In addition, the use of cyanide does not require any special knowledge. Cyanide is capable of causing mass incapacitation and casualties, and can cause mass confusion, panic, and social disruption.⁵³

Symptoms and diagnosis of cyanide poisoning

Diagnosis at the fire scene may be difficult. Poisoning may result in central nervous, respiratory, and cardiovascular dysfunction due to inhibition of oxidative phosphorylation, depending on the concentration of cyanide inhalation (Table 18.3).

Electrocardiographic changes, such as S-T segment elevation, that mimic an acute myocardial infarction⁵⁴ may be suggestive. Laboratory findings of anion gap metabolic acidosis and lacticacidemia aid in confirming the diagnosis.⁵⁵ The lactic acidosis that is not rapidly responsive to oxygen therapy may be good indicator for cyanide poisoning.^{39,50} Also, an elevated mixed venous saturation is suggestive for cyanide toxicity. Cyanide increases ventilation through carotid body and peripheral chemoreceptor stimulation. Low levels of hydrogen cyanide are routinely found in the blood of healthy individuals at levels of 0.02 µg/mL in nonsmokers and 0.04 µg/mL in smokers. Toxicity occurs at a level of 0.1 µg/mL and at 1.0 µg/mL death is likely.⁵⁶ The correlation of severity of clinical symptoms and HCN concentration is summarized in Table 18.4.

Treatment

Successful intervention for cyanide poisoning depends primarily on the concentration of exposure and the time between exposure and treatment; clearly it is critical that treatment is administered as quickly as possible after exposure. Therefore, presumptive diagnosis and empiric treatment may prove necessary. Fire victims suspected with cyanide poisoning should be removed from exposure and fully decontaminated, while

TABLE 18.3 SYMPTOMS OF CYANIDE TOXICITY

Symptoms in low or moderate inhaled cyanide concentrations	Symptoms in moderate or high inhaled cyanide concentrations
Faintness	Prostration
Flushing	Hypotension
Anxiety	Tremors
Excitement	Cardiac arrhythmia
Perspiration	Convulsions
Vertigo	Stupor
Headache	Paralysis
Drowsiness	Coma
Tachypnea	Respiratory depression
Dyspnea	Respiratory arrest
Tachycardia	Cardiovascular collapse

TABLE 18.4 HYDROGEN CYANIDE CONCENTRATIONS IN AIR AND ASSOCIATED SYMPTOMS IN HUMANS^{35,57}

HCN concentration (ppm)	Symptoms
0.2–5.0	Threshold of odor
10	(TLV-MAC)
18–36	Slight symptoms (headache) after several hours
45–54	Tolerated for 1/2–1 hour without difficulty
100	Death in 1 hour
110–135	Fatal in 1/2–1 hour
181	Fatal in 10 minutes
280	Immediately fatal

Einhorn IN³⁵ National Institute of Environmental Health Sciences, and Kimmerle G⁵⁷ University of Utah.

maintaining appropriate provider respiratory protection, restoring or maintaining airway patency, administering 100% oxygen via non-rebreathing mask or a bag valve mask. All victims should be given intravenous access and aggressive fluid resuscitation (4 mL/kg/m² body surface area when patients have burn injuries). When clinically indicated, anticonvulsants (benzodiazepines) should be given for seizures, epinephrine and antiarrhythmics to support cardiopulmonary function, and sodium bicarbonate to correct metabolic acidosis.³ Oxygen therapy appears to have strong positive effect; however, hyperbaric oxygen therapy is not recommended for the reasons previously discussed.^{54,56} Cyanide is metabolized by hepatic rhodanase, which catalyzes the donation of sulfur from the sulfane pool to cyanide to form nontoxic thiocyanate. The half-life of cyanide is ~1–3 hours in humans.^{50,58} Although there is still controversy surrounding the treatment of cyanide poisoning, there are few antidotes available that can be used by first responders. Kelocyanor (dicobalt edentate) may be useful, but is dangerous in itself and requires experts to administer it.⁵⁹ A cyanide antidote appropriate for the use in smoke inhalation victims is available in Europe, but not yet in the US, where the cyanide antidote kit (Lilly-, Taylor-, or Pasadena-kit) is the only currently available antidote. The kit contains amyl nitrite, thiosulfate, and sodium nitrite. These agents may be considered in an intensive care setting, but not preclinically, since they are *methemoglobin generators*. The therapeutic goal is to convert the ferrous ion of hemoglobin to ferric ion. The resultant methemoglobin chelates cyanide to form cyanmethemoglobin. The drugs of choice in this group are sodium nitrite (IV) and amyl nitrite (inhaled). These drugs reduce oxygen-carrying capacity; therefore they should be used with caution, especially in patients with concomitant CO poisoning which induces COHb that may further compromise oxygen transport. These drugs should be also used with precautions in patients with burn shock because they are also vasodilators and can cause hypotension. In addition, there is little evidence to suggest these are effective measures, and cardiac toxicity in people with heart disease may be problematic.⁶⁰ The therapeutic goal of *sulfur donors* is to convert cyanide to thiocyanate. The drug of choice in this group is

sodium thiosulfate (IV). Toxicity is minimal other than acting as an osmotic diuretic action that in itself may be beneficial. The onset of action, however, is quite slow.²⁴ *Direct binding agents* are based on cobalt chemistry and chelate the cyanide ion directly. Hydroxycobalamin is the precursor of vitamin B₁₂ and has very little toxicity.^{24,56} Hydroxycobalamin detoxifies cyanide by binding with it to form B₁₂, and is in excess excreted in the urine.⁶¹ However, this drug is being investigated for possible introduction in the US. Hydroxycobalamin (Cyanokit) has been available in Europe for nearly a decade. Accumulating data from an ongoing study on the prehospital use of hydroxycobalamin for cyanide poisoning suggest that it has a favorable risk benefit ratio and a reasonable safety profile. Hydroxycobalamin at a dose of 5g appears to be effective and safe in smoke inhalation victims, as an empiric prehospital treatment.⁶²

Other toxic chemicals

These may also contribute substantially to the morbidity and mortality in a burn victim. Hydrogen chloride is produced by polyvinyl chloride degradation and causes severe respiratory tract damage and pulmonary edema. Nitrogen oxides may also cause pulmonary edema and a chemical pneumonitis and may contribute to cardiovascular depression and acidosis. Aldehydes such as acrolein and acetaldehyde, which are found in wood and kerosene, may further contribute towards pulmonary edema and respiratory irritability. Toxic industrial chemicals such as, chlorine, phosgene, hydrogen sulfide, and ammonia, are of central importance. Because of their widespread availability and high toxicity, there is certain concern that these chemicals may be used as a weapon by terrorists.^{63,64}

Phosgene is a colorless, non-flammable, heavier-than-air gas at room temperature with an odor of newly mown hay. Under 8°C phosgene is an odorless and fuming liquid. Phosgene's inadequate warning properties and delayed symptoms make it a potential terrorist weapon.^{65,66} Phosgene is only slightly soluble in water; hence its deeper penetration in the pulmonary system. On contact with water it hydrolyzes into carbon dioxide and hydrochloric acid, resulting in direct caustic damage. It also undergoes acylation reactions with amino-, hydroxyl-, and sulfhydryl- groups of cellular macromolecules, resulting in cell damage and apoptosis.^{65,67} As mentioned, phosgene has delayed effects from 20 minutes up to 48 hours depending on the intensity of exposure. Phosgene inhalation produces severe pulmonary edema. Initially victims develop upper airway irritant symptoms (eye irritation, rhinorrhea, cough) and then will develop lower respiratory symptoms such as shortness of breath, substernal burning, and chest tightness. The development of overt pulmonary edema within 4 hours of exposure portends a poor prognosis.

Chlorine is a greenish yellow gas, an oxidizing agent, and very reactive with water. It has a pungent odor. Upon contact with water, chlorine liberates hypochlorous acid, hydrochloric acid, and oxygen free radicals. It causes irritant effects throughout the respiratory tree but mostly nasal mucosa and upper airways. Cell damage is caused by its strong oxidizing capability.⁶⁸ Phosgene and chlorine were extensively used during World War I.

Ammonia is a colorless gas at room temperature with a very pungent odor. Ammonia readily dissolves in water to form

ammonium hydroxide, a very caustic alkaline solution. It causes cutaneous, ocular, and pulmonary injuries. Inhaled ammonia can rapidly produce laryngeal injury and obstruction. It causes upper tracheobronchial mucosal necrosis with sloughing and severe pulmonary edema.⁶⁸ There are no specific antidotes against irritant gases (phosgene, chlorine, and ammonia) toxicity. Depending on the severity of exposure, supportive therapy such as airway management and ventilation should be provided. Early intubation is required if any significant upper airway symptoms such as stridor are present.

Pathophysiology

Injury to the oropharynx

Much of the pathophysiology that occurs with inhalation injury is related to edema formation in the oropharynx, bronchial areas, and parenchyma, and results from an increased transvascular fluid flux from these respective vascular beds. Before a discussion of the changes that occur in these structures following inhalation injury, a review of the forces responsible for the variables of the Starling–Landis equation should be given:^{69,70}

$$J_v = K_f[(P_c - P_{if}) - \sigma(COP_p - COP_{if})]$$

This equation describes the physical forces and physiologic mechanisms that govern fluid transfer between vascular and extravascular compartments. J_v , the transvascular fluid flux, is equal to lymph flow during equilibrium states. As transvascular fluid flux increases, interstitial volume also increases (edema formation) until a new equilibrium with lymph flow occurs. K_f is the filtration coefficient, an index of the total number of pores that are filtering. The number of pores could increase if a larger area of the microcirculation were perfused or if there were more pores per given area of the microcirculation. These pores are the same size as water and electrolytes, as opposed to the larger pores associated with permeability to protein. P_c and P_{if} are the hydrostatic pressures in the microcirculation and interstitial space, respectively. The reflection coefficient, σ , is an index of microvascular permeability to protein. If σ is 1, the membrane is impermeable to protein; when σ is 0, the membrane is completely permeable to protein. COP_p and COP_{if} are the oncotic or colloid osmotic pressures in the plasma and interstitial spaces, respectively.

The major pathophysiology seen in the oropharynx following inhalation injury induces microvascular changes similar to those seen with thermal injury in other areas of the body. The heat denatures protein that, in turn, activates complement. Complement activation causes the release of histamine.^{71,72} Histamine then causes the formation of xanthine oxidase, an enzyme involved in the breakdown of purines to uric acid.⁷³ During this conversion, reactive oxygen species are released.^{74,75} Reactive oxygen species combine with NO, constitutively formed in the endothelium, to form reactive nitrogen species. The latter produce edema in the burned area by increasing the microvascular pressure and permeability to protein.⁷⁶ Eicosanoids are also released,^{77,78} that, along with oxygen free radicals and IL-8, attract polymorphonuclear cells to the area.⁷⁹ These neutrophils then amplify the release of oxygen

radicals, proteases, and other materials into burned areas (Figure 18.2).

The massive edema occurring in the soft tissue of the oropharynx following burns involves most of the variables in the Starling equation. There is a large increase in microvascular hydrostatic pressure,⁸⁰ a decrease in interstitial hydrostatic pressure,⁸¹ a fall in the reflection coefficient,⁸⁰ and an increase in interstitial oncotic pressure.^{81,82} The usual treatment for burn resuscitation calls for the administration of large amounts of crystalloid solutions, which has the effect of reducing the plasma oncotic pressure.^{83,84} This reduction not only affects the oncotic pressure gradient in the microcirculation but also has been reported to increase the filtration coefficient.^{85,86} The result of this almost complete breakdown in control of the microvascular function and the insult of fluid administration is massive edema. This is probably nowhere more apparent than in soft tissues of the face and oropharynx. The danger to the patient is extreme. The edema may obstruct the airway, not only making it laborious or impossible to breathe but also making it difficult for the physician to intubate the patient. To avoid this problem, many practitioners prophylactically intubate patients who have evidence of thermal injury to the upper airway on admission. However, intubation in itself may present problems. The tube may further damage injured areas, especially the larynx.⁸⁷ It may be time to reconsider some of these practices. Perhaps some consideration should be given to types of fluid resuscitation, which can prevent some of this soft tissue edema and reduce the volume of fluids required for resuscitation.^{88,89}

Tracheobronchial area

With rare exceptions such as inhalation of steam, the injury to the airway is usually from the chemicals in smoke. The heat capacity of air is low and the upper airway circulation very

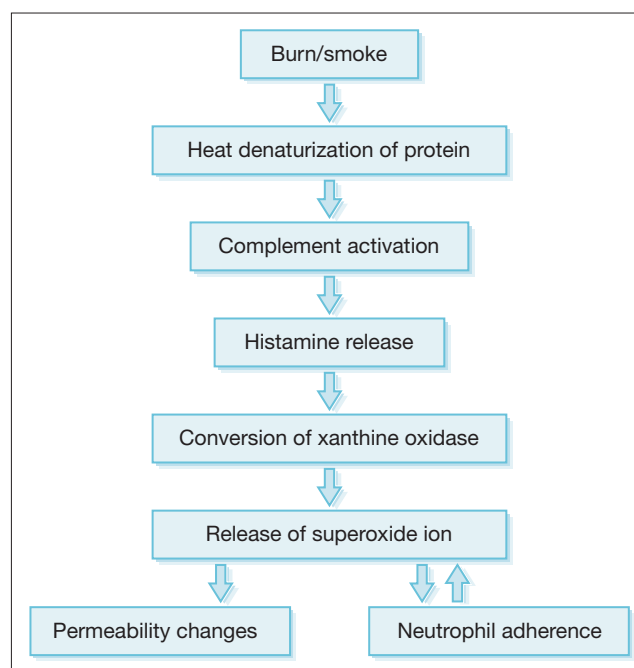

Fig. 18.2 Mechanism for edema formation in the oropharynx.

efficient in warming or cooling the airway gases so that most gasses are at body temperature as they pass the glottis.⁹⁰ Flames must almost be in direct contact with the airway to induce thermal injury.⁹¹ The chemicals in smoke are dependent on the materials that are being burned; however, for the most part, the host response is similar. In most instances biological materials such as cotton fabric, wood, or grass contain caustic materials such as reactive oxygen and nitrogen species (ROS and RNS), organic acids, and aldehydes.⁹² These chemicals interact with the airway to induce an initial response to trigger an inflammatory response.

Many of the studies that have been reported relative to the bronchial circulation following smoke inhalation injury have been performed in sheep because these animals have a single bronchial artery⁹³ and have a single lymphatic draining the lung that allows the measure of pulmonary transvascular fluid flux.⁹⁴ There was a 10-fold increase in bronchial blood flow within 20 minutes of smoke inhalation.⁹⁵ These same animals demonstrate a six-fold increase in pulmonary transvascular fluid flux and a fall in $\text{PaO}_2/\text{FiO}_2 = 300$, but these were delayed to 24 hours post-injury. Similar findings have been reported in patients with smoke inhalation alone or the combination of a large cutaneous thermal injury and smoke inhalation.⁹⁶

Hyperemia (Figure 18.3a) of the airway is such a consistent finding in smoke inhalation that it is used to diagnose the injury.^{97,98} Other variables that are used include injury in an enclosed space, singed nasal hair, and soot in sputum. However these latter findings may be present but the subject may still not develop the signs of low Pa and pulmonary edema characteristic of inhalation injury. Airway inflammation plays a major role in the overall response to inhalation injury.

As we have noted, there is a large sustained increase in blood flow in the airway following smoke inhalation.⁹⁹ These changes in blood flow were associated with increased bronchial microvascular permeability to protein and small particles¹⁰⁰ and pressure.¹⁰¹ Simultaneous with the changes in the function of the bronchial microvasculature, there is a loss or shedding of the bronchial columnar epithelium.^{102,103} These changes result in a profuse transudate with a protein content similar to an ultrafiltrate of the plasma.¹⁰⁴ There is also a copious secretion from the goblet cells.¹⁰⁵ Early in the response these secretions are fluid and form a foam material in the airway many have mistaken for severe pulmonary edema in patients.¹⁰⁶ After several hours this transudate/exudate solidifies or clots, forming obstructive materials in the airways.¹⁰⁷ These obstructive materials formed in the upper airway may appear (Figure 18.3b) in the lower airway and alveoli.¹⁰⁵ This obstructive material is problematic from several standpoints. In some rare instances of severe airway injury these materials can induce total obstruction (Figure 18.4). Table 18.5 illustrates the degree of airway obstruction in sheep subjected to burn, smoke, or combined burn and smoke inhalation injury. Occlusion of some of the bronchi or bronchioles in the setting of high production of NO (Figure 18.5) can lead to a loss of hypoxic pulmonary vasoconstriction and thus increased shunt fraction. Loss of hypoxic pulmonary vasoconstriction with inhalation injury has been reported. Furthermore, if single bronchi are occluded while the patient is on a volume-limited ventilated ventilator, there could be overstretch and barotrauma to the alveoli of the non-occluded portion of the lung.

Fig. 18.3 Smoke inhalation injury in patients after burn and smoke inhalation. (a) Hyperemia of airway epithelium. (b) Formation of airway obstructive cast.

The airway is richly innervated with vasomotor and sensory nerve endings.¹⁰⁸ It is also known that these fibers release neuropeptides in response to caustic materials.¹⁰⁹ Neuropeptides release can cause activation of nitric oxide synthase, have chemokine activity, and change microvascular permeability.¹¹⁰ The resultant activities lead to the formation of reactive oxygen and nitrogen species. Some of the latter are very potent oxidants that can damage DNA. Damage to DNA causes the activation of a repair enzyme poly (ADP-ribose) polymerase (PARP). This enzyme depletes the cell of high-energy phosphates and causes the activation of nuclear factor- κB (NF- κB). Activation of the nuclear factor causes the up-regulation of iNOS and IL-8, thus creating accelerated production of reactive oxygen and nitrogen species.¹¹¹ NO and 3-nitrotyrosine, an index of reactive nitrogen species, iNOS mRNA, and protein have been reported to be in the airway after smoke inhalation.¹¹² Poly (ADP-ribose) [PAR], the product of the constitutive enzyme PARP, was identified in the airway tissues following smoke inhalation. Inhibition of PARP prevented the formation of PAR, the up-regulation of

Fig. 18.4 Airway obstructive cast. (a) Macroscopic pictures of airway obstructive cast in sheep 48 hours after burn and smoke inhalation injury. (b) Macroscopic picture of airway cast taken from patient with burn and smoke inhalation injury by bronchoscope.¹⁵⁵ (c and d) Microscopic pictures of totally blocked by obstructive cast bronchi in sheep and bronchiole in patient after burn and smoke inhalation injury.

TABLE 18.5 MEAN LEVELS OF AIRWAY OBSTRUCTION IN UNINJURED SHEEP AND 48 HOURS AFTER BURN, SMOKE INHALATION, AND COMBINED SMOKE INHALATION AND BURN INJURY
AIRWAY LEVEL

Injury	Bronchi	Bronchiole	Terminal bronchioles
Uninjured ($n = 5$)	$2.7 \pm 2.4\%$	$1.6 \pm 0.9\%$	$0.0 \pm 0.0\%$
Burn alone ($n = 6$)	$4.4 \pm 3.5\%$	$2.5 \pm 1.5\%$	$0.04 \pm 0.1\%$
Smoke alone ($n = 5$)	$18.1 \pm 10.1\% *†$	$8.1 \pm 3.0\% *†$	$0.3 \pm 0.4\%*$
Smoke + burn ($n = 7$)	$29.3 \pm 15.1\%*†$	$11.5 \pm 6.7\%*†$	$1.2 \pm 1.9\%*$

Data are presented as mean percent \pm SD (n = number of animals in each group).

*Significantly different from uninjured animals means, Wilcoxon rank sum test, $p < 0.05$.

†Significantly different from burn injury, Wilcoxon rank sum test, $p < 0.05$.¹⁰⁵

Fig. 18.5 Time changes in plasma concentration of NOx (nitrite/nitrate), a stable metabolite of nitric oxide in sheep subjected to combined burn and smoke inhalation injury. Sham, non-injured, non-treated. Control, injured (flame burn, 40% total body surface area, third degree, non-treated). **p* < 0.05 vs. Sham.

NF-κB, and the formation of 3-nitrotyrosine.¹¹³ It is interesting to note that in the presence of a PARP inhibitor or in mice lacking the PARP gene, airway inflammation is not seen in a typical asthma model.¹¹⁴ The pathophysiology of burn and smoke inhalation-related acute lung injury is shown in Figure 18.6.

Lung parenchyma

The lung parenchyma changes, as reflected by reduced PaO₂/FiO₂ and reduced compliance, increased edema formation, are delayed. The delay is dependent on the severity of the airway injury. Lung injury is associated with an increased pulmonary transvascular fluid flux.¹¹⁵ The degree of transvascular fluid is proportional to the duration of smoke exposure⁹² and is independent of the levels of CO in the inhalant gas.¹¹⁶ The factors responsible for fluid leak are codified in the Starling–Landis equation.^{69,70} The variables of this equation relate fluid movement to pressure and permeability variations. With inhalation of smoke there is a reduction in reflection coefficient (permeability to protein), an increase in filtration coefficient

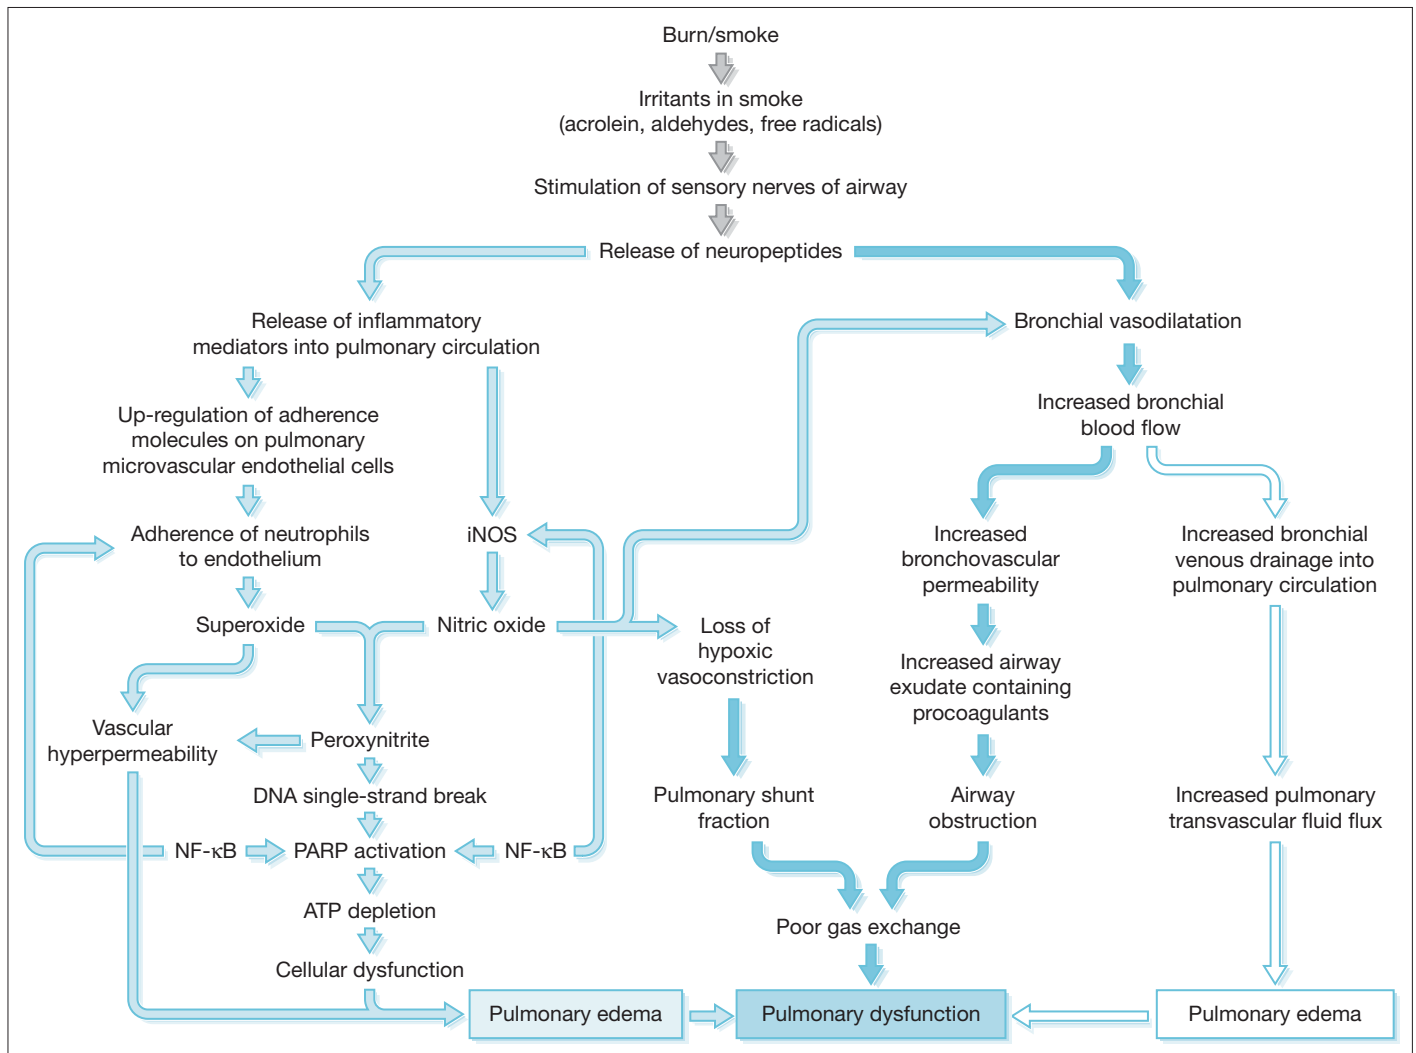

Fig. 18.6 Pathophysiology of burn and smoke inhalation-induced acute lung injury. iNOS, inducible nitric oxide synthase; PARP, poly(ADP-ribose) polymerase.

(permeability to small particles), and an increase in pulmonary microvascular pressure.^{117,118}

Animals that had been exposed to smoke inhalation injury were also noted to have reduced PaO₂/FiO₂. The change in this variable showed a good relationship to the histology injury scores and the changes in transvascular fluid flux.¹¹³ In addition, there was a loss of hypoxic pulmonary vasoconstriction in the injured animals that would help to explain the loss of oxygenation.¹¹⁹ As in the airway, the injury is associated with the reduction of poly (ADP-ribose) and 3-nitrotyrosine and is markedly reduced by the administration of an iNOS or PARP inhibitors.^{112,120,121}

The venous outflow of the bronchial circulation drains into the pulmonary microcirculation at the pre-capillary level.¹²² Considering the fact that initial damage to the airway appeared to drive the pathophysiology of the parenchyma, led investigators to hypothesize that the bronchial blood might deliver cytotoxic materials or cells into the pulmonary microcirculation. To test this hypothesis, several investigators have tied off the bronchial artery of sheep and then exposed the animals to smoke.^{100,123,124} In these studies the hypothesis was affirmed: the lung parenchymal changes were reduced.

What could be the linkage between the airway, the bronchial venous drainage, and parenchymal injury to the lung? Neutrophils activated in the bronchial circulation flow out into the bronchial venous drainage. Activated polymorphonuclear cells (PMNs), especially neutrophils, are stiff. The diameter of neutrophils that have been fixed are approximately 7µm.¹²⁵ Since these cells have been dehydrated in alcohol as part of the fixation process, unfixed cells are much larger, on the order of 12µm. The pulmonary capillary is small, with an average diameter of 6µm.¹²⁵ Normally, the large neutrophil can traverse the pulmonary capillary by changing shape. However many of the neutrophils have been activated in the bronchial areas, their F-actin is activated and the cells are stiff and cannot deform. These stiff cells are carried to the pulmonary microvasculature where they are impaled by the narrow pulmonary capillaries. The activated neutrophils release reactive oxygen species and proteases that damage the parenchyma. The following evidence supports this concept of neutrophil cytotoxicity. Oxidative processes are well known following inhalation injury. There is lipid peroxidation and release of proteolytic enzymes following injury.¹²⁶⁻¹²⁸ Administration of protease inhibitors or scavengers of reactive oxygen species will reduce the response to smoke inhalation,^{127,129-131} when activated PMNs lose the L-selectin on their surface. This L-selectin shedding is prevented by the treatment with an L-selectin antibody.¹³² Treatment of the cells with an antibody to L-selectin will prevent the changes in transvascular fluid flux and other aspects of parenchymal damage.¹³³ The final proof of this hypothesis was to deplete the animals of their neutrophils and determine how this affected the response to inhalation injury. In these studies of sheep depleted of their leukocytes, a high percentage of the response to smoke inhalation was blocked.¹³⁴

In addition to the depletion of antioxidants discussed above, it has also been reported that burned patients are depleted of arginine.¹³⁵ When arginine levels are low, the nitric oxide synthase produces superoxide rather than nitric oxide.¹³⁶

Administration of arginine may assist in reducing the oxidation that occurs with inhalation injury. However, the necessity of administering the arginine as arginine hydrochloride (because of solubility) limits the amount that may be given intravenously without producing acidosis.

Treatment

Some pretreatment for smoke inhalation can be accomplished. People who are chronically exposed to smoke include farmers who burn crops, individuals with fires in their huts, and firefighters. There are reports that individuals who are chronically exposed to smoke are depleted of antioxidants.^{137,138} Consequently supplementation of antioxidants should be considered.¹³⁷

In the post-inhalation period a major concern will be the airway. In the case of combined inhalation and burn injuries this is very difficult. In the burn includes the soft tissues of the face, oral pharynx, and neck, intubation is very difficult. Burn injury to these soft tissues results in an almost immediate and severe edema and swelling.⁸¹ Intubation in such an individual requires great skill. Securing the tube is difficult. Accidental removal of the endotracheal tube is easy and may be lethal. Often, burns and/or the chemicals in smoke can damage the larynx and placement of the tube can cause damage and delay healing of such a wound. Tracheostomy is sometimes performed but can also be difficult if it has to be placed through burned skin on the neck. For information in this area, the reader is referred to two excellent chapters in a text on burn care.^{139,140}

To counter obstruction, vigorous toilet should be performed. Cast material contains fibrin. Experimentally, the use of heparin has been reported to be effective in reducing airway obstruction.¹⁴¹ However heparin requires the presence of antithrombin to be effective and this factor has been reported to be deficient following burn injury;¹⁴² consequently, antithrombin has been reported to be effective in animal studies.¹⁴³ Antithrombin and may also act as anti-inflammatory agents.¹⁴⁴ Once obstructive materials have formed in the airway, heparin and antithrombin are ineffective in removing them. Animal studies have demonstrated that tissue plasminogen activator could be effective in removing these materials.¹⁴⁵ Aerosolized tissue plasminogen activator has also been reported to be effective in removing bronchial obstructive material in patients who have had Fontan procedures.^{146,147} Many burn units nebulize heparin into the airway of their patients with inhalation injury.¹⁴⁸

Many drugs have proven effective in reducing the injury to the lung parenchyma of in animals models of inhalation injury including cyclooxygenase inhibitors,¹⁴⁹ iNOS inhibitors,¹²⁰ PARP inhibitors,¹¹³ and oxygen scavengers,¹²⁹ as well as the anticoagulant factors mentioned above. However, only the latter are in clinical use and/or clinical trial.

In many instances conventional methods of ventilation can no longer sustain the pulmonary function of burned patients. Extracorporeal membrane oxygenation has been used in these patients with some success.¹⁵⁰ Techniques have now been developed in animal models of inhalation injury that involve a unique form of CO₂ removal called arterial venous CO₂ removal (AVCO₂R). Off-the-shelf CO₂

removal devices, used in extracorporeal bypass and cardiopulmonary bypass, have been modified to be driven by the subject's own arterial pressure.¹⁵¹ These were tested in animal models and shown to be very successful in reducing patho-

physiology, morbidity, mortality, and days of ventilatory support of inhalation injury models.¹⁵²⁻¹⁵⁴ AVCO₂R is now in clinical trials for the treatment of severe ARDS associated with inhalation injury.

Summary	270

Introduction

Inhalation injury remains one of the most critical injuries following thermal insult. It may occur in conjunction with cutaneous burns or in isolation. The severity of injury varies, depending on the chemical composition of the agent(s) inhaled, the duration of exposure, temperatures reached during combustion and pre-existing comorbidities.^{1,2} For the most part, treatment consists of supportive respiratory and critical care measures.^{3–6}

Many studies over the years have shown inhalation injury to be strongly associated with increased morbidity^{6,7} and mortality in the thermally-injured patient. In one study by Shirani et al, the presence of an inhalation injury increased mortality by up to 20%, and pneumonia by up to 40%.⁷ Most prediction models for mortality in burns include age extremes, burn size and presence of an inhalation injury as risk factors for increasing probability of death.^{8,9} When inhalation injury and another risk factor, such as an elderly patient or an extensive burn, are both present, the influence on mortality rises.^{8,10} Improvements in survival of patients with inhalation injury have been attributed to better overall burn outcomes, improved ventilatory management and improved management of pneumonias.¹¹

Inhalation injuries are present in approximately one-third of major burn patients.^{3,7,12,13} Early diagnosis and treatment of this injury, and the resulting complications associated with it, are required to reduce the consequent impact of this injury on morbidity and mortality rates. Clinicians involved in burn care should have a high index of suspicion for inhalation injury when assessing the burn victim, as missing or underestimating the extent of respiratory compromise can have devastating effects on the patient.

Pathophysiology of inhalation injury

Inhalation injury can occur from either the inspiration of superheated gases or steam, or the toxic, often incomplete products of combustion.⁴ The respiratory tract can be injured in one or more of three zones; supraglottic, tracheobronchial and parenchymal. The supraglottic area can be injured by direct heat or chemicals. Severe edema can occur quickly, causing upper airway obstruction. Direct thermal injury to the lower airway is less common than injury due to inhalation of noxious gases, and is usually associated with steam inhalation injuries. Steam has been shown to have a heat-carrying capacity 4000 times greater than hot dry air, and also gives up heat more slowly. As a result steam-related lung injuries can be more severe.^{14–16}

The toxic contents of fire smoke vary according to the source of combustion and the amount of oxygen in the environment. Carbon monoxide (CO) and several organic chemicals such as aldehydes are usually present.^{3,17} Nitrogen- or halogen-containing polymers in building materials can cause release of hydrogen cyanide and inorganic acids.¹⁷ Sulphur- and nitrogen-containing oxides are also often present.¹

The clinical course of the patient with an inhalation injury can usually be broken into three stages. During the first phase (0–36 hours), carbon monoxide poisoning, hypoxia and thermal injury occur. Upper airway obstruction and bronchospasm can also occur here. This can result in acute pulmonary insufficiency.^{1,6,18} The second phase (24–72 hours) encompasses pulmonary edema, atelectasis and tracheobronchitis.^{3,4,6,18,19} There is damage to the airway and alveolar epithelium, with sloughing of mucosa and formation of mucous plugs and casts, which can cause obstruction and air trapping (Figure 19.1). This can result in areas of atelectasis and ventilation/perfusion (V/Q) mismatching. The normal ciliary action of the mucosa is disrupted, impairing the patient's ability to clear foreign particles from the airway. There is also an increase in capillary permeability, thus increasing lung water, causing pulmonary edema and reducing lung compliance. Surfactant can also become impaired by the noxious chemicals inhaled.^{3,6,18,19} As a result of these assaults on respiratory function, gas exchange can become compromised at this time. Inflammatory mediators are released at this stage from damaged cells and inflammatory cells, such as alveolar macrophages and neutrophils. Alveolar macrophages appear to have increased production of superoxide radicals and tumor necrosis factor- α (TNF α), as well as impaired phagocytosis of bacteria.^{18–20} The third phase is bronchopneumonia typically

Fig. 19.1 Tracheal cast taken from the carina of a child. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

occurring 3 to 10 days post injury, and as a result of impaired lung defenses such as the mucociliary system and alveolar macrophages, and abnormal lung function and ventilation.^{5,6,18} Respiratory failure and acute respiratory distress syndrome (ARDS) can develop from the initial inhalation injury.

Diagnosis

When a burn victim is being assessed, the clinician should always be alert to the possibility of the presence of an inhalation injury. Patients with inhalation injuries may present with or without cutaneous burns. Important details in the history include if the patient was exposed to smoke in an enclosed space such as often happens in house fires or industrial accidents,² and also the duration of exposure to smoke. Time from injury to arrival at hospital or treatment at scene, and use of oxygen should be noted. If possible, the source of combustion should be determined, as some chemicals are more irritating than others to the airway. Carbon monoxide is usually present,^{17,21} however, hydrogen cyanide and hydrochloric acid can be released from synthetic polymers used in the modern building industry such as polyvinyl chloride.¹⁷ Zinc chloride is present in smoke bombs, and although rare, can lead to chemical pneumonitis and ARDS with a high mortality rate.²²

During the initial assessment, the first priority is to establish if there is an immediate threat to airway patency. When a patient has hoarseness and stridor, partial airway obstruction is present, usually due to edema of the upper airway. These patients should be intubated as there is a significant risk of progression to complete airway obstruction.^{3,4} Head and neck cutaneous burns may contribute to this airway problem as well as inhalation injury (Figure 19.2). This is particularly important in small children, where, due to the small diameter of the airway, even moderate edema can result in severe or complete airway obstruction. Edema can be progressive, as the body responds to injury and as resuscitation fluid is given.⁴ Signs and symptoms that should evoke suspicion of an inhalation injury include dyspnea, hoarse voice, cough, anxiety or agitation, stridor, wheezing, facial burns, singed nasal hairs, production of carbonaceous sputum or presence of carbonaceous

Fig. 19.2 Severe head and neck burns with marked edema. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

material in the oral cavity.⁴ These patients may also be disoriented or obtunded or in a coma. While the altered mental status may be as a result of CO or cyanide poisoning,^{23,24} confounding factors such as intoxication with alcohol or other substances, or head trauma need to be outruled. When CO poisoning is present, cutaneous burn wounds may take on a cherry red appearance.

A carboxyhemoglobin blood level should be drawn on arrival at hospital, and the result correlated with the time from insult to treatment/use of oxygen. As CO binds to the oxygen-binding sites of hemoglobin with a greater affinity than oxygen, it reduces the oxygen-carrying capacity of blood and thus, oxygen delivery to the tissues. Systemic hypoxia develops as a result.^{5,25} During this time, arterial oxygen partial pressure and oxygen saturations are often normal.⁴ While an arterial blood gas should be drawn from the patient, normal oxygen values cannot be relied upon during the initial stages, and cannot be used to outrule an inhalation injury. Later as the response to injury evolves, arterial blood gas values can deteriorate, and can be used to monitor the patient's course. Blood cyanide levels may also be measured to assess exposure to hydrogen cyanide.^{17,26}

Signs and symptoms indicating inhalation injury, or a history suggesting the possibility of an inhalation injury, are usually present. However, these can sometimes be unreliable, and other methods may be used to confirm the diagnosis. Chest radiography is an insensitive measure of inhalation injury. The initial radiograph is often normal,^{4,27} but can be useful as baseline study. When atelectasis or pulmonary edema develop, this can show up on X-ray, as can later pneumonia and ARDS changes. Computed tomography is generally not used for the diagnosis of smoke inhalation, although atelectasis and infiltrations can show up on this scan.²⁸

One of the most useful tools for the assessment of inhalation injury is the fiberoptic bronchoscope^{4,29-31} (Figure 19.3). Direct visualization of the supraglottic airway as well as the tracheo-bronchial tree can be achieved. This allows assessment of edema of the airway mucosa and patency of the supraglottic airway, thus identifying patients at risk for airway occlusion (Figure 19.4). If deemed necessary, an endotracheal tube of

Fig. 19.3 Bronchoscope and bronchoscopy equipment. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

Fig. 19.5 Nasotracheal intubation under direct vision using a bronchoscope. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

Fig. 19.4 Edematous larynx with decrease in opening but normal movement. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

appropriate size can be placed over the bronchoscope, prior to commencement of the procedure. Then if there is a need for intubation, the tube can be slid down over the bronchoscope, and secured in place (Figure 19.5). The presence or absence of soot or carbonaceous material in the supraglottic and the tracheobronchial tree can also be seen, as can early inflammatory changes in the tracheal mucosa, such as edema, hyperemia and mucosal sloughing and breakdown (Figures 19.6–19.8). If required, biopsies can also be taken of the mucosa.³⁰ Bronchoscopy can be performed without sedation, as local anesthesia of the airway is adequate for most patients to tolerate the procedure. Lidocaine sprays can be used for the supraglottic area, and lidocaine can be administered to the lower airways through the appropriate channel in the bronchoscope. When photographic and video equipment are available, this becomes a useful teaching tool. In experienced hands, the complication rate of these bronchoscopies is low.³⁰ Complications include hemoptysis, pneumothorax, pneumonia and cardiac arrhythmias.

Pulmonary function tests are more useful for follow-up assessments of patients with inhalation injuries than for diagnosis in the acute setting, as they are effort-dependant and it can be difficult to obtain reliable values initially. They have a useful role in evaluating patients for residual impairment in lung function following inhalation injury.³²

Less commonly utilized, is xenon-133 ventilation-perfusion scanning. Intravenous injection of the radioisotope is performed, and then serial scintiphotograms of the chest are taken. Areas demonstrating delayed excretion of the xenon isotope by the lung indicate regions of small airway partial or total obstruction.^{4,5,31,33} Patients with pre-existing respiratory disease such as chronic obstructive pulmonary disease or a pneumonia prior to thermal injury, may have unreliable results with this technique. It is useful as a confirmatory test if inhalation injury is suspected but not confirmed by other investigations.

Treatment

The management of patients with inhalation injury mostly consists of supportive treatment of the respiratory system until the patient is able to maintain adequate ventilation and gas exchange independently. For some inhaled toxins, there are additional therapeutic agents that can be used to alleviate the harm caused by their inspiration. Treatment should begin at the scene of injury. The victim must be removed from the unsafe area in a manner that does not cause further harm to them or to the rescuer. In the victim with cutaneous burns, the burning process must be halted. Next the airway needs to be assessed and if necessary secured, with protection of the cervical spine, if appropriate. Usually obstruction has not yet developed at this stage, but if the airway appears compromised, it must be protected. Oropharyngeal sweeps can clear any intraoral debris, and artificial airways such as nasopharyngeal or oropharyngeal airways can help. Sometimes, it is necessary to intubate using an endotracheal tube or in emergency situations, cricothyroidotomies. Once an adequate airway is in place, victims should receive 100% oxygen until assessed at a healthcare facility. Next, ventilation and circula-

Fig. 19.9 Chest escharotomies in full-thickness burns. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

tion need to be assessed. Appropriate intravenous access should be obtained, and fluid administration should begin at this stage.

A focused history and physical examination need to be obtained, including a neurological assessment, bearing in mind that the patient with an inhalation injury may have other, sometimes more serious and imminently life-threatening injuries. Cutaneous burns are often but not always present. The signs and symptoms of an inhalation injury need to be looked for. A blood carboxyhemoglobin level and an arterial blood gas should be obtained, along with a baseline chest radiograph. Fiberoptic bronchoscopy is useful at this stage, both to confirm the diagnosis, and to intubate the patient if this is necessary.^{14,29-31} Intubation should be performed if any signs of upper airway obstruction, such as stridor, are present, if the airway appears at risk from progressive edema, or if the patient is failing to maintain adequate oxygenation. If at potential risk of airway obstruction, but no significant edema is present, the patient may be kept under close observation for a period of time, until the time of maximal risk has passed 24–36 hours post injury. If circumferential chest wall cutaneous burn eschar is present and limiting ventilation, escharotomies should be performed⁴ (Figure 19.9). The incisions should adequately release both sides of the chest wall and connect transversely at the sternal notch, or costal margin. Fluid resuscitation must be commenced if significant cutaneous burns are present, to prevent hypovolemia and its associated problems. There are several resuscitation formulae that can be used to determine the fluid requirements of the patient; however, the infusion rate should be titrated to maintain an adequate urine output. Generally 0.5–1 mL urine/kg/hour is acceptable in adults, and 1–2 mL urine/kg/hour in children. Several studies have shown, that in the presence of an inhalation injury, the patient's fluid requirement is increased.^{12,34,35}

Patients with inhalation injury commonly have CO and cyanide exposure. If the initial carboxyhemoglobin level is high, patients should receive 100% oxygen, until a level under 10% is reached. However, low or normal levels do not outrule inhalation injury. CO binds to iron-containing compounds such as hemoglobin and cytochromes. It has a much higher

affinity for the oxygen-binding site on the hemoglobin than oxygen, and causes a leftward shift of the oxygen–hemoglobin dissociation curve, thus diminishing the amount of oxygen transported to the tissues. It also disrupts the action of cytochromes and intracellular utilization of oxygen, causing a hypoxic environment.³⁶ Using 100% oxygen decreases the elimination half-life ($t_{1/2}$) of CO, which is dependant on oxygen tension. On room air (FiO_2 0.21), the $t_{1/2}$ is approximately 320 minutes, while on 100% normobaric oxygen, it is reduced to 80 minutes, lower in some studies.³⁷ When hyperbaric oxygen therapy (2–3 atmospheres) is used, this decreases to 23 minutes.^{38,39} Hyperbaric oxygen therapy is usually delivered in a monoplace hyperbaric chamber. A typical regimen consists of 90 minute sessions at 2–3 atmospheres, with 10 minute airbreaks to lower the incidence of seizures due to oxygen toxicity. Patient access can be difficult in small chambers, so caution should be used in placing unstable patients under this treatment. Larger chambers expose staff to the risks of treatment.⁴ Some studies have shown improvement in neurological complications of CO poisoning by using hyperbaric oxygen therapy;⁴⁰ however, a review of seven randomized trials of hyperbaric compared to normobaric oxygen therapy, published in 2005 by Juurlink et al., found mixed results for the reduction of neurological sequelae. They concluded that further research was needed to establish this effect of hyperbaric oxygen treatment.³⁹ For those suspected of having cyanide toxicity as a component of their inhalation injury, blood cyanide levels can be measured.^{26,41,42} This assay may not be readily available in many hospitals, and by the time a result is obtained, it may not be clinically useful. The half-life of cyanide is approximately 3 hours.⁴³ The clinical significance of cyanide levels is controversial, with no clear correlation with mortality. Cyanide can cause hypoxia and otherwise unexplained metabolic acidosis. Therapy is also controversial, with some advocating aggressive supportive treatment, and others, the use of cyanide antidotes. The rationale behind treatment is to oxidize hemoglobin to methemoglobin, which preferentially binds cyanide to form cyanmethemoglobin. This dissociates to form free cyanide, which is metabolized by the liver mitochondria, using thiosulfate as a substrate, to thiocyanate, which is excreted in the urine.⁴⁴ Amyl nitrite or sodium nitrite and sodium thiosulfate are used to achieve this effect. However the nitrites can cause significant hypotension and cardiovascular instability, and should be used with caution in the burn patient, who is often hypovolemic. Because of this, thiosulfate is sometimes given alone, as this is safer, although its effect is much slower.⁴⁴ Chelating agents, such as hydroxycobalamin (B_{12}) or dicobalt edentate, have also been used as cyanide antidotes.^{44,45} The use of agents to treat cyanide toxicity should be reserved for those with a confirmed or highly suspected exposure, and who are adequately resuscitated, as the therapeutic agents have significant side effects. Thiosulfate and hydroxycobalamin have fewer side effects than the other agents used. Other antidotes can be used in specific situations: for example, atropine for organophosphate exposure, or heavy metal chelators.²³

Supplemental humidified oxygen should be used for patients suspected of having inhalation injury, the humidification helping to prevent inspissation of the airway secretions, and the head of the bed placed at a 30–45° angle. This helps reduce

upper airway edema, and decreases the effect of pressure from abdominal contents on the diaphragm. Meticulous pulmonary hygiene is a vital component of the management of inhalation injury. Frequent airway suctioning, chest physiotherapy including percussive and coughing techniques, and early mobilization all help prevent build-up of secretions, which can cause airway obstruction, atelectasis and predispose to the development of pneumonias.^{3,5,21} Care should be taken when suctioning to avoid hypoxia and bradycardia. Preoxygenation and suctioning for short periods of 10–15 seconds can reduce the incidence of these problems. Postural drainage can be useful, although sometimes skin graft location and fragility impede use of this technique.⁴⁶ Percussive and vibratory techniques such as high-frequency chest wall oscillation also help expectorate mucoid secretions.^{46,47} It is also important to maintain good nutritional status in these patients.⁶

As a result of inhaled irritants, patients can suffer from severe bronchospasm. This can usually be managed by using inhaled beta agonists, such as albuterol or salbuterol. Sometimes intravenous bronchodilators are necessary.^{4,48} Aminophylline or terbutaline can be used. Aerosolized heparin can be used as a mucolytic to help prevent inspissation of secretions and bronchial cast formation by affecting the fibrin component of the cast.^{48–50} It does not appear to cause systemic anticoagulation in the doses used clinically. Aerosolized and intravenous acetylcysteine has also been used as a mucolytic and was shown to improve pulmonary antioxidant capacity in one study.⁵¹ In a pediatric study, a combination of aerosolized heparin and acetylcysteine was used, and resulted in a significant reduction in reintubations, the incidence of atelectasis and in mortality following smoke inhalation injury.⁵⁰ When physical therapy and pharmacological agents still fail to expectorate secretions or ameliorate cast formation, fiberoptic bronchoscopy can be effective to remove secretions, and also to obtain microbiological specimens through bronchoalveolar lavage in suspected cases of pneumonia. Attempts to replace surfactant have also been studied, but are not in widespread clinical use. Antibiotics are indicated for suspected or proven pulmonary infection.^{4,5} Corticosteroids are not generally used in burn patients, but may be useful in severe bronchospasm inadequately controlled by beta agonists or other bronchodilators.⁴

Mechanical ventilation is indicated when either the signs of respiratory failure are present or are imminent. These include tachypnea, use of accessory muscles of respiration, sternal retractions in children and the presence of upper airway edema. Parameters indicating inadequate ventilation or oxygenation include the following: respiratory rate >30 breaths/minute, $\text{PaO}_2 < 65$ mmHg, $\text{PaCO}_2 > 50$ mmHg and a $\text{PaO}_2/\text{FiO}_2 < 200$. As mentioned previously, when using a fiberoptic bronchoscope to assess the airway for inhalation injury, an endotracheal tube can be passed over the scope to secure the airway, if necessary. A nasotracheal tube may be preferable for patient comfort, oral hygiene and stability. The patient should be preoxygenated. Muscle relaxants should not be given during intubation, as if the intubation proves difficult, it may not be possible to adequately ventilate the paralyzed patient.⁴⁸

Several different modes of ventilation can be used for the patient with an inhalation injury. The aim is to provide

adequate ventilation to maintain airway and alveolar patency without causing overdilation of alveoli and barotrauma. In this patient population, airways may be narrowed by edema, and this increases airway resistance and thus, airway pressures. High airway pressures can damage already damaged airway mucosa. One technique to reduce airway pressures is to allow mild respiratory acidosis or permissive hypercapnia.^{4,52} This allows lower airway pressures and smaller tidal volumes to be used when ventilating the patient, and is well tolerated when of gradual onset and the pH is kept above 7.2–7.25.^{4,48} The optimal positive end-expiratory pressure (PEEP) should be determined using a pressure–volume curve. This helps maintain alveolar patency, which is important as reopening the alveoli requires higher airway pressures. The lower inflection point of the pressure–volume curve of a mechanical breath is where the slope of the lower curve begins to increase, and is the airway pressure below which the alveoli collapse. The PEEP value should be set just above this. FiO₂ should be weaned down as tolerated to reduce oxygen-related complications. The PaO₂ can be maintained between 80 and 100 mmHg, although values over 65–70 mmHg can support adequate tissue oxygenation. The ventilation rate should maximize ventilation initially, and may need to be set slightly higher than usual if lower tidal volumes or pressures are being used. Thereafter, it should be weaned to allow spontaneous ventilation.⁴⁸

Conventional mechanical ventilation can either be volume controlled or pressure controlled. Volume-controlled ventilation delivers a consistent tidal volume and minute volume to the lungs, but this can result in variable airway pressures depending on the compliance of the lungs. Pressure-controlled ventilation limits the inflating pressure used, and thus the tidal volume varies depending on compliance and inspiratory time.⁴⁸ High-frequency percussive ventilation (HFPV) is a ventilatory mode that delivers sub-tidal breaths at a high frequency. These are superimposed on pressure-controlled ventilatory cycles. Studies of this technique have shown it to have advantages over conventional mechanical ventilation. It appears to be associated with decreased work of breathing, improved oxygenation (higher PaO₂/FiO₂ ratios) and lower peak pressures.^{53–56} A pediatric study group also had a significant reduction in the incidence of pneumonia, when compared to a conventionally ventilated control group.⁵³ Airway pressure release ventilation (APRV) is a more recently developed pressure-controlled, time-cycled mode of ventilation, that can allow spontaneous breathing during the ventilatory cycle, without changing the preset pressure settings. It has a high-pressure and a low-pressure setting. Recruitment of alveoli and oxygenation occur at the high-pressure setting, and ventilation occurs by controlled releases to the lower pressure. The mechanical inspiratory phase can be prolonged to achieve high mean airway pressures, without high peak airway pressures. It has so far shown promising results in trauma patients and pediatric patients with mild to moderate lung disease. They achieved comparable or superior oxygenation values, while using lower peak airway pressures.^{57,58} This mode may be useful in the burn population as a means to ventilate while reducing barotrauma. Extracorporeal membrane oxygenation (ECMO) is a technique, which can be used in patients with severe respiratory failure, in which the patient's blood is cir-

culated through an extracorporeal cardiopulmonary bypass circuit, that facilitates gas exchange through a semipermeable membrane. While this is taking place, low ventilatory pressures and a low FiO₂ can be used to ventilate the damaged lung. This allows the lung to heal without additional complications of mechanical ventilation such as barotrauma or oxygen toxicity. Anticoagulation is necessary during treatment. While numbers in burn patient studies are small, it may offer a salvage therapy for patients with severe respiratory disease on conventional ventilation.^{59–61}

Tracheostomy may be necessary in a small number of patients. The most common indications are prolonged dependence on mechanical ventilation due to respiratory failure or pulmonary sepsis, emergent airway access, severe facial/neck burns or edema and following complications of endotracheal intubation.^{62,63} In the past, high reported complication rates following tracheostomy led to controversy over its use in the burn population. However, more recent studies have shown that tracheostomy can be performed safely, without increased risk of infectious complications.^{62,64} Advantages of tracheostomy include a shorter tube with reduction of dead space and airway resistance, greater ease to maintain pulmonary hygiene and a reduction in development of subglottic stenosis. Long-term endotracheal intubation is also uncomfortable for the patient. Both endotracheal intubation and tracheostomy have long-term complications associated with their use, and neither should be used unnecessarily. The decision to convert to a tracheostomy should not be taken lightly, and should take into account the characteristics of the individual patient and their injury.

Mechanical ventilation should be weaned as the patient's condition improves, and discontinued as soon as it is no longer necessary. During the weaning process, the FiO₂, PEEP and rate should be reduced as tolerated, until the patient is capable of supporting their own respiratory requirements. Parameters used as indicators for extubation include the presence of the following: an alert patient, resolution of upper airway edema with an audible air leak around the endotracheal tube with the cuff deflated, PaO₂/FiO₂ ratio greater than 200, an adequate tidal volume (6–10 mL/kg) and negative inspiratory pressure <–20 cm H₂O.⁴ The patient should also not be acidotic and should be hemodynamically stable. Once extubated, supplemental, humidified oxygen should be provided, and the patient should be carefully observed for any signs of respiratory compromise that might necessitate reintubation.

Complications

Complications in patients with inhalation injuries occur secondary to the original injury and due to the mechanical ventilation used to support the injured lung. Barotrauma can occur as a result of mechanical ventilation, particularly in patients that have required high peak and mean airway pressures to maintain adequate ventilation and oxygenation.⁶⁵ Sustained high airway pressures can lead to tracheal mucosal ischemia. Barotrauma can manifest itself as a pneumothorax, pneumomediastinum, pneumoperitoneum, pneumopericardium or subcutaneous emphysema.⁵² Thoracostomy tubes may be required for treatment of pneumothoraces (Figure 19.10). Ventilatory strategies to reduce airway pressures, such as per-

Fig. 19.10 Child with right-sided pneumothorax, treated with a chest tube. A tracheostomy is also in place. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

Fig. 19.11 Autopsy specimen of necrohemorrhagic tracheobronchitis. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

missive hypercapnia, HFPV and APRV, aim to prevent these complications.

Infectious complications, such as tracheobronchitis or pneumonia, increase morbidity and mortality significantly (Figure 19.11). In one study, the presence of pneumonia, in thermally-injured patients with inhalation injury, substantially increased mortality up to 60%.⁷ Infectious complications typically occur after the first 3–10 days post injury,^{5,6} and in patients with inhalation injury, the incidence of pneumonia has varied from 38% to 60%.^{52,56,66} The source of infection is generally from bacteria colonizing the oropharyngeal tract and the burn wound. Intubated patients also do not have the same capacity for self-clearing of secretions and debris from their respiratory tract as do extubated patients. The mucociliary mechanism may be damaged by the inhalation injury, alveolar macrophage function is altered, and ventilation of the lung may be impaired, due to atelectasis and small airway obstruction by secretions and casts.^{5,6,18} The endotracheal tube also bypasses some of these mechanisms for self-defense, and can become colonized too. All these impairments contribute to predisposing the patient to develop pneumonia.

Fig. 19.12 Left lower lobe pneumonia on chest radiograph. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

Fig. 19.13 Bilateral pneumonia on chest radiograph of a patient with inhalation injury. (Courtesy of Jaclyn Jones.) (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

The diagnosis of pneumonia is based the presence of clinical signs such as fever, increased sputum or airway secretion production, laboratory values such as leukocytosis, and the presence of organisms on Gram stain and culture of sputum or bronchoalveolar lavage specimens. The chest radiograph should also show a new or altered parenchymal infiltrate⁶⁶ (Figures 19.12 and 19.13). There may also be a deterioration in the patient's oxygenation, or an increase in ventilatory requirements. Organisms colonizing the upper airway can sometimes confuse the diagnosis, as they will be commonly present and not necessarily causing pulmonary infection.⁶² Treatment consists of intravenous antibiotic therapy, initially based on Gram stain from the airway specimen or previous cultures, and this is then adjusted according to the sensitivities

Fig. 19.14 Glottic stenosis 1-year post thermal injury. (From Barret JP, Herndon DN. Color atlas of burn care. Philadelphia: WB Saunders; 2001.)

of the organisms cultured. Ventilatory support is administered as necessary to maintain adequate ventilation and oxygenation, and meticulous pulmonary hygiene is essential. Some studies have shown a reduced incidence of pneumonia in patients receiving HFPV ventilation compared to conventional mechanical ventilation.^{53,66}

Mechanical problems from endotracheal or tracheostomy tubes can also occur, and may not present acutely. As a result of injury to the upper airway epithelium, upper airway stenoses can occur. These can be supraglottic or subglottic, subglottic being more common (Figure 19.14). This is usually associated with prolonged endotracheal intubation, and theoretically should not happen with tracheostomy tubes. No treatment is necessary in mild cases; more severe cases may need dilatations or even laryngoplasties. Erosion of the tracheal cartilage can occur from cuff pressure, and lead to tracheomalacia, a weakening of the tracheal wall that can allow the airway to collapse inwards during inspiration.^{62,63} Granulomatous and fibrous tissue can grow around tracheostomy sites, and this can lead to airway or tube obstruction, necessitating removal of the obstructing tissue. Tracheoesophageal fistulae and erosion into the innominate artery can occur. This can cause mediastinitis and/or exsanguinating hemorrhage.⁶³

Long-term pulmonary function

Post-inhalation injury, patients can have hyper-reactive airways. This has been shown to persist for at least 6 months in one study, along with inflammatory changes in the bronchial mucosa, and elevated inflammatory cytokine (TNF α , interferon (IFN γ), and interleukin-2 (IL-2)) levels in serum and bronchoalveolar lavage fluid. The majority of subjects, however, had normal pulmonary function tests.⁶⁷ Longer-term studies have, in some cases shown, development of obstructive and restrictive patterns on pulmonary function testing, indicating that normal lung function may not always be regained following recovery from inhalation injury.^{32,68,69} In a pediatric burn cohort, no difference in exercise tolerance was noted between children who had sustained an inhalation injury and

those who had not; however, the children who had had an inhalation injury achieved their goal with a significantly higher respiratory rate, and had a higher incidence of abnormal lung function.⁶⁹ Conversely, an adult study did not find any evidence of altered respiratory function post-inhalation injury, or in those tested, any significant exercise intolerance.⁷⁰

Damage to the larynx by inhaled toxins and thermal injury, and also by intubation as a treatment for inhalation injury or upper airway edema, can result in persistent hoarseness or dysphonia. Injury to the laryngeal mucosa can cause scarring that can affect the flexibility and vibratory capacity of the vocal cords, and also their ability to open and close properly. As a result, voice production may be affected, and this may not resolve without treatment. Some of the phonation problems can be helped by voice therapy, and some of the laryngeal scarring may be amenable to surgical or laser excision.⁷¹

Future/investigational therapies

While the treatment of inhalation injury is currently mostly supportive, research is continuing in an effort to improve care. Attempts to improve present ventilatory and supportive strategies, as well as research into the local and systemic response to thermal and inhalation injury, are ongoing. With further understanding of the pathophysiology, it may be possible to modulate the body's response to injury, and minimize the impact of this insult to the respiratory system.

At present, the emphasis in ventilatory strategies is to adequately ventilate the lungs, while trying to reduce the airway pressures necessary to achieve this to levels that will not cause or minimize barotrauma to the patient. Methods such as HFPV and APRV appear to recruit alveoli and allow efficient gas exchange, while at the same time using lower peak airway pressures when compared to conventional mechanical ventilation.⁵⁵⁻⁵⁸ ECMO has been used in cases of severe respiratory failure following smoke inhalation with some success in both the adult and pediatric populations.⁵⁹⁻⁶¹ Arteriovenous carbon dioxide removal (AVCO₂R), a technique utilizing an extracorporeal membrane gas exchanger to remove CO₂, while O₂ diffuses across the native alveoli by low-frequency positive pressure ventilation, has undergone animal and clinical trials, and appears to be capable of efficient CO₂ removal. This can significantly reduce ventilatory requirements, and improve arterial blood pH levels in severe respiratory failure.^{72,73}

The pathophysiology of inhalation injury and the systemic response are also being explored, in conjunction with the effects of various mediators along the pathways involved. Therapies attempting to decrease airway inflammation by reducing the release of inflammatory mediators or by utilizing free radical scavengers are being investigated with varying results. Dimethylsulfoxide, a free radical scavenger, has been used alone and in conjunction with heparin. In one study, this combination, in an ovine model of smoke inhalation, improved survival and PaO₂/FiO₂ ratios. Cast formation was also reduced, and the usual increase in pulmonary lymph flow was less apparent, probably due to a reduction in free radical-induced microvascular permeability.⁷⁴ Manganese superoxide dismutase has also been evaluated for its action on free radicals. While it appears to reduce loss of protein, it does not

appear to improve gas exchange or lung permeability problems.⁷⁵ Pentoxifylline⁷⁶ and lisofylline⁷⁷ (which is metabolized to pentoxifylline in the liver) have been studied for their effects on inhibition of inflammatory mediators and down-regulation of leukocytes. They seem to improve ventilation-perfusion mismatching in animals and reduce ventilatory requirements. This is attributed to reduced edema formation and decreased airway damage. The use of heparin in combination with other agents such as lisofylline and dimethylsulfoxide appears to attenuate the results.

More selective inhibitors are also being evaluated, such as endothelin-1 receptor antagonists,⁷⁸ neurokinin-1 receptor antagonists (blocking the proinflammatory effect of substance P)⁷⁹ and thromboxane A₂.⁸⁰ These agents have shown potential in reducing the inflammation and pulmonary edema associated with inhalation injuries. Recombinant antithrombin⁸¹ and tissue plasminogen activator⁸² have shown beneficial effects in animals in reducing fibrin cast formation and reducing pulmonary transvascular fluid shifts and lung water. The decrease in airway obstruction as a result of less cast formation can help prevent further ventilation-perfusion mismatching and trauma

to alveoli. Many other agents are also undergoing evaluation for potential benefit in treating smoke inhalation injury.

Summary

Inhalation injury is one of the leading causes of morbidity and mortality in burns. It is present in approximately one-third of burn victims, and can be present alone or in conjunction with cutaneous thermal injury. Early diagnosis and treatment are crucial to prevent complications. Diagnosis is based initially on history and physical exam. Fiberoptic bronchoscopy is a very useful diagnostic tool, and can also be utilized for an intubation aid if necessary. Treatment is mostly supportive, and must start with assessing the airway and obtaining a secure airway if needed. The patient should be removed from the source of injury and supplemental oxygen provided. Meticulous pulmonary hygiene is essential. Mechanical ventilation may need to be commenced if the patient cannot adequately support their ventilatory needs independently. Complications of inhalation injury include infectious complications such as pneumonia, and those as a result of mechanical ventilation and barotrauma.

Introduction	273
Barotrauma	273
Other management techniques	275
Prevention	278

Introduction

Occasionally, the thoracic surgeon is called on to assist in the management of patients with complex pulmonary problems in the burn unit. One of the more common examples is barotrauma. To adequately manage this condition, it is important to understand the underlying mechanisms of injury. Support and specific therapies then can be administered properly. Frequently these patients are suffering from acute respiratory distress syndrome (ARDS) and are at the limits of conventional management. In this chapter we will review the etiology, incidence and management of patients with barotrauma. We will also explore adjuncts to mechanical ventilation that may act to limit injurious ventilator strategies while at the same time augmenting gas exchange. The pathophysiology of mechanical ventilation in the burn patient is complex and multifactorial, but to avoid duplication we will focus on barotrauma caused by pulmonary and non-pulmonary ARDS.

Barotrauma

In a study that included 5183 patients across 361 centers, Anzueto et al.¹ noted a 2.9% incidence of barotrauma in patients on mechanical ventilation in the intensive care unit, with highest incidence in patients with chronic interstitial lung disease (10.0%) or acute respiratory distress syndrome (ARDS) (6.5%). They also demonstrated, in a case-control analysis, an independently increased risk of mortality in patients with barotrauma (51.4 vs. 39.2%). Macklin and Macklin² first described the most common mechanism of injury: a small airway or alveolus ruptures and the air dissects through the bronchovascular connective tissue proximally into the mediastinum, ultimately rupturing in the pleural space.

Etiology

Although it is obvious that an air sack must rupture to produce a pneumothorax, the mechanism of that rupture is a subject

of debate (Box 20.1). Most theories are based on overdistention or pressurization of the alveolus. Historically, supportive management for severe respiratory failure involved mechanical ventilation with tidal volumes of 10–15 mL/kg because Bendixen et al.³ noted that high lung volumes minimize atelectasis and prevent deterioration in oxygenation in patients undergoing anesthesia. This strategy often requires high airway pressures (>35 cmH₂O) to deliver these volumes and maintain normocapnia in patients with severe lung injury. In fact, the original description of ARDS by Ashbaugh et al.⁴ included high inspiratory ventilator pressures as part of the definition.

Webb and Tierney⁵ first recognized ventilator-induced parenchymal lung injury as separate from the previously recognized forms of barotrauma. Rats ventilated at high airway pressures (45 cmH₂O) developed alveolar edema, hypoxemia, and decreased lung compliance, with death occurring within 1 hour. They proposed that interstitial edema may be caused by pulmonary interdependence and that the alveolar edema may be from depletion or inactivation of surfactant. Dreyfuss et al.⁶ demonstrated increases in capillary permeability, edema and inactivation of surfactant during intermittent positive-pressure hyperventilation with high inflation pressures.

Controversy surrounds peak inspiratory pressure (PIP) as a potential cause of barotrauma. Diakun⁷ reasoned that PIP requirements remain the single best predictor of barotrauma because of the higher pressures necessary to deliver an adequate minute volume when the lungs sustain a severe injury that decreases pulmonary compliance. PIP of less than 50 cmH₂O had initially been considered safe due to work by Peterson and Baier.⁸ In comparing three groups of patients with PIP exceeding 70 cmH₂O, between 50 and 70 cmH₂O and below 50 cmH₂O, Peterson and Baier⁸ found an incidence of barotrauma of 43%, 8% and 0%, respectively, but even this level may be too high if an underlying pulmonary pathologic condition exists that predisposes the patient to barotrauma.

More recent studies have found conflicting evidence as to what extent reducing PIP can affect mortality in patients with ARDS. Stewart et al.⁹ found that in patients with ARDS, there is no mortality benefit to limiting ventilation pressures and there may be greater morbidity. In this study, 120 patients were randomly assigned to one of two groups: a limited ventilation group with PIP restricted to 30 cmH₂O and tidal volume no more than 8 mL/kg, or a conventional ventilation group with PIP as high as 50 cmH₂O and tidal volume of 10–15 mL/kg. They found no significant difference in mortality between the two groups. Additionally, patients in the limited-

BOX 20.1 Potential causes of barotraumas

High peak airway pressures
 High mean airway pressures
 Alveolar overdistention, increased volume
 Positive end-expiratory pressure

ventilation group required dialysis for renal failure more frequently and required more paralytic drugs. Weg et al.¹⁰ analyzed 725 patients with sepsis-induced ARDS, 77 of whom had pneumothorax or other air leaks. In comparing the PIP, airway pressure and tidal volume of patients who had pneumothorax or other air leak to those who had no air leak, they also found no correlation between high ventilatory pressures or volumes and the development of pneumothorax. Bousarsar et al.¹¹ conducted a two-part study, using a randomized prospective trial of two ventilation strategies as well as a literature analysis of risk factors for barotrauma in ARDS patients. The randomized trial, which maintained plateau pressures (the pressure applied to the alveoli and small airways in positive pressure ventilation) below 35 cmH₂O, produced no relationship between high ventilatory pressures or volumes and barotrauma in patients with early ARDS. However, the literature analysis found a significantly higher incidence of barotrauma in patients with plateau pressure greater than 35 cmH₂O and in patients with lung compliance (a static measure of lung and chest recoil) of less than 30 mL/cmH₂O.

Alveolar distensibility, a measure of alveolar energetics, is a precursor to barotrauma. Tsuno et al.¹² studied regional pressure-related overdistention of healthy alveoli, termed *barotrauma* or *volutrauma*, that can result in a pattern of diffuse alveolar damage that is histologically indistinguishable from other causes of ARDS. Overdistention of alveoli and distal airways, regardless of the pressure involved, has also been proposed by Hillman and Barber,¹³ Hurd et al.¹⁴ and Alpan et al.¹⁵ as a cause of barotrauma. It occurs either through selection of a tidal volume that is too large or as a result of non-uniform lung disease. Non-uniform lung disease causes preferential ventilation of the normal alveoli, which leads to overdistention of these alveoli as they try to accommodate most of the tidal volume.

Animal studies have suggested that alveolar overdistention, whether produced by positive or negative pressure, is responsible for the initiation and/or propagation of the lung injury. Tsuno et al.¹² analyzed the histopathologic changes in lungs of baby pigs after mechanical ventilation at a PIP of 40 cmH₂O for 22 ± 11 hours. Alveolar hemorrhage, alveolar neutrophil infiltration, alveolar macrophage and type II pneumocyte proliferation, interstitial congestion and thickening, interstitial lymphocyte infiltration, emphysematous change, and hyaline membrane formation were all consistent with the early stages of ARDS. Animals ventilated with conventional ventilatory parameters (tidal volume 15 mL/kg, PCO₂ at 44 mmHg) for an additional 3–6 days showed the aforementioned findings coupled with prominent organized alveolar exudates, which resemble the changes seen in the late stages of ARDS. A

control group ventilated at a PIP of 18 cmH₂O showed no histopathologic changes in the lung. Dreyfuss et al.⁶ likewise showed that application of high inflation pressure ventilation in rats resulted in pulmonary edema after only 20 minutes, with histologic findings similar to those seen in human ARDS.

In 2000, the landmark ARDSNet trial¹⁶ compared traditional tidal volume (10–15 mL/kg) and maximum plateau pressure of 50 cmH₂O with low tidal volume (6 mL/kg) and plateau pressure of ≤30 cmH₂O in patients with acute lung injury and ARDS. The study was stopped after enrolling 861 of an anticipated 1000 patients because it demonstrated that the lower tidal volume group had lower mortality (31.0 vs. 38.9%, $p = 0.007$) and a greater number of ventilator-free days (mean ± SD, 12 ± 11 vs. 10 ± 11, $p = 0.007$). The lower tidal volume reduces injury related to lung overdistention and inflammatory mediator release at the expense of a greater incidence of respiratory acidosis and decreased arterial oxygenation. While the trial demonstrated decreased mortality and increased number of ventilator-free days in comparing the low tidal volume group to the high tidal volume group, they found no difference in the incidence of barotrauma between the groups. Several studies have reached findings different from that of the ARDSNet. Stewart et al.⁹, as noted above, found no mortality difference when comparing 120 ARDS patients receiving limited ventilation (PIP = 30 cmH₂O, tidal volume of 8 mL/kg) and conventional ventilation (PIP = 50 cmH₂O, tidal volume of 10–15 mL/kg). Brower et al.¹⁷ examined 52 patients with ARDS and could find no benefit to mortality, medication requirement or any other clinical outcome measure, to a lower tidal volume (5–8 mL/kg) when compared with traditional tidal volume (10–12 mL/kg). Brochard et al.¹⁸ reached similar findings when comparing 116 patients with ARDS randomized to receive reduced tidal volume (7.1 ± 1.3 mL/kg) or traditional tidal volume (10.3 ± 1.7 mL/kg). They found no difference between the two groups in mortality, duration of mechanical ventilation or incidence of pneumothorax.

Ranieri et al.¹⁹ studied the effects of positive end-expiratory pressure (PEEP) on alveolar recruitment in patients with respiratory distress syndrome. Observing the pressure–volume loops on zero end-expiratory pressure and PEEP, they found two populations of patients. Some patients showed evidence of alveolar recruitment as evidenced by an upward concavity of the pressure–volume curve during zero end-expiratory pressure ventilation, which increased with PEEP. Other patients demonstrated an upward convexity, noting volume displacement without alveolar recruitment. This was aggravated with PEEP. They believed that this subpopulation of patients would be susceptible to barotrauma. In the recent ARDSNet ALVEOLI trial, Brower et al.¹⁷ randomized 549 patients with acute lung injury and ARDS to receive 6 mL/kg tidal volume and either high (13.2 ± 3.5 cmH₂O) or low (8.3 ± 3.2 cmH₂O) PEEP. They found no difference in clinical outcomes between the high and low PEEP groups. They hypothesized that while higher PEEP levels could improve oxygenation and decrease ventilator-associated lung injury, they could also cause lung injury from overdistention.

Patients at risk for barotrauma range from infants receiving physiologic continuous positive airway pressure (5 cmH₂O), as reported by Alpan et al.,¹⁵ to adults requiring controlled

mechanical ventilation and high levels of PEEP, as reported by Mathru et al.²⁰ and Kohn and Bellamy.²¹ Mathru et al.²⁰ and Reines²² noted that patients who are treated with volume-cycled or controlled mechanical ventilation have a higher incidence of barotrauma when compared to patients who are treated with pressure-limited or intermittent mandatory ventilations. As pointed out by Carlon et al.²³ and Parker et al.,²⁴ this is due to the higher airway pressures that are generated by volume-cycled ventilators compared with pressure-limited ventilators.

Gattinoni et al.²⁵ observed that ARDS is a heterogeneous, not diffuse, lung injury, with areas of relatively normal lung interspersed with areas of alveolar and interstitial edema. The term 'baby lungs' has been used to describe the smaller physiologic lung volume. Exposure of relatively normal alveoli with near normal compliance characteristics to high distending pressures results in a larger delivered volume per lung unit, marked overdistention, and the possible increased risk of further lung injury. This scenario occurs regardless of which mode of ventilation generates the high inspiratory pressures.

Another potential method of pulmonary injury involves the increased production of inflammatory mediators and cytokines secondary to mechanical ventilations, dubbed 'biotrauma' by some. A study by Chiumello et al.²⁶ demonstrated an association between high-volume ventilation and increased levels of TNF- α and MIP-2 in the lungs and in the serum. The authors hypothesized that the increased cytokines may contribute to multiple organ dysfunction, the leading cause of death in patients with ARDS. Tremblay et al.²⁷ found similar results when they exposed rats to varying degrees of ventilation. They discovered increased levels of TNF- α , MIP-2, IL-1 β , IL-6, IL-10 and IFN- δ associated with high-volume ventilation. These cytokines serve to initiate and propagate inflammation, stimulating the recruitment and differentiation of macrophages to the lung parenchyma and facilitating neutrophil adherence. Ranieri et al.²⁸ compared inflammatory cytokines in 44 patients who were randomized to either a control ventilatory strategy or a lung-protective strategy. The two strategies were significantly different (mean (SD)) in terms of tidal volume (11.1 (1.3) vs. 7.6 (1.1) mL/kg), plateau pressures (31.0 (4.5) vs. 24.6 (2.4) cmH₂O) and PEEP (6.5 (1.7) vs. 14.8 (2.7) cmH₂O). The study demonstrated significantly higher levels of TNF- α , IL-1 β and IL-6 in the control ventilation group.

The role that inflammation plays in ventilator-associated lung injury is not entirely clear. Kawano et al.²⁹ used a saline lung lavage followed by mechanical ventilation (tidal volume of 12 mL/kg) on three groups of rabbits: a control group, a neutropenic group secondary to pretreatment with nitrogen mustard, and a nitrogen mustard group that was retransfused with granulocytes before the study was begun. The first and third groups developed a high permeability pulmonary edema with hyaline membrane formation, whereas the neutropenic group showed none of these changes. Karzai et al.³⁰ examined rats that were assigned to be pretreated with fucoidin (a neutrophil adhesion inhibitor), granulocyte colony-stimulating factor (G-CSF) or a placebo prior to 4 hours of low (10 mL/kg) or high (40 mL/kg) tidal volume mechanical ventilation. In the G-CSF group that received high tidal volume ventilation, 18 of 22 rats died, a significantly higher number than the 3 of 20

rats that died in the placebo high tidal volume group, while the fucoidin high tidal volume group showed no significant difference from placebo. All of the low-volume animals survived. These experimental findings suggest a prominent role for inflammatory cells and mediators in the development of lung injury and argue against an injury that is entirely mechanical.

Presentation

One of the earliest radiographic signs of barotraumas is mediastinal air. Although this finding is often a precursor of pneumothorax, not all patients with pneumomediastinum develop a pneumothorax. In addition, pneumomediastinum usually does not give a clue as to the site of origin. Once pneumomediastinum develops, vigilance is important to discover early signs of pneumothorax.

Often, the first sign of barotrauma is not seen on routine chest radiography but presents as an acute change in hemodynamics or oxygenation. Any patient with poor compliance on positive-pressure ventilation and PEEP who becomes acutely hypotensive or hypoxemic may have a pneumothorax. In patients who have severe respiratory distress syndrome, the pneumothorax may not be large. The loss of even a small amount of lung volume may be sufficient to alter the steady state. Auscultation of the chest in pneumothorax may demonstrate disparate breath sounds, which may be confirmed by chest radiography.

Management

In a patient who has acutely developed barotrauma and is hemodynamically unstable, a needle catheter thoracostomy may be diagnostic as well as lifesaving. A sterile needle placed through the second or third intercostal space lateral to the midclavicular line allows the air to escape and should stabilize the patient until a more definitive catheter or tube can be placed. A large tube, preferably 28 Fr or 32 Fr, should be placed in the fifth or sixth intercostals space at the anterior axillary line. The large tube is used to remove any high-volume leak produced. Because many of these severely ill patients also have associated effusions, the tube should be directed posteriorly.

Sometimes the surgeon is notified of a critically ill ventilated patient when the patient develops a pneumomediastinum. Because the side of origin cannot be determined in such a case, the choice is observation or bilateral tube thoracostomy. Our preference is to assemble in a room the equipment necessary for both a needle and a tube thoracostomy but to await the development of a pneumothorax and treat only that side.

Because of the underlying disease, the lungs are stiff and may not completely re-expand. However, positive-pressure ventilation is being used on these patients. Because of these two facts, negative suction on the drainage system is unnecessary. Air from the air leak escapes through the water seal. Tubes should be left in place until the compliance significantly improves and the PEEP levels are consistently below 10 cmH₂O.

Other management techniques

In addition to conventional ventilators, other investigators have utilized alternate ventilatory modes in attempts to

improve survival. Substantial interest in high-frequency ventilation (HFV) in burn patients has existed for a number of years.^{31,32} Driven by some success of high-frequency oscillatory ventilation (HFOV) in the neonatal and pediatric populations, application of various high-frequency techniques to select groups of burn patients yielded encouraging results in small case series or non-randomized trials; most reports of success have been in its use as salvage therapy for patients failing conventional ventilatory modes.³³ Recently a randomized study in adults failed to demonstrate any superiority in outcome comparing HFOV and standard therapy although a post-hoc analysis demonstrated a slight treatment benefit with HFOV in patients with higher oxygen index (OI).³⁴ However, Carman et al.³⁵ reported a decrease in the incidence of barotrauma in a randomized comparison of the Volume Diffusive Respirator® compared to conventional ventilation. More scientific study will be required prior to the recommendation of high-frequency modalities for the prevention of barotrauma can be made. HFV requires specific ventilators with trained staff. With the lack of efficacy noted, its complexity and increased costs, it cannot be recommended at this time. Airway pressure release ventilation, proportional assist ventilation and bilevel positive pressure ventilation are other alternative modes that are currently under investigation but have not been demonstrated to be superior to current LTV strategy.

For the last 15 years, our group has studied ARDS in order to develop viable alternative treatments. We have exploited mechanical ventilation to its limits, including pressure-limited ventilation (permissive hypercapnia), inverse ratio ventilation, high-frequency jet ventilation, high-frequency oscillatory ventilation, intratracheal pulmonary ventilation, and prone position ventilation. In addition, we have participated in clinical trials on partial liquid ventilation, inhaled nitric oxide and surfactant therapy. All of these therapies have shown promise toward improving arterial blood gases and limiting lung injury in the short term, but none have demonstrated significant survival benefit. Work in our animal laboratory first demonstrated a role for extracorporeal gas exchange devices in our ovine model of smoke/burn inhalation-induced ARDS.³⁶

We found that avoiding high ventilation pressures ameliorated the amount of barotrauma and biotrauma induced,³⁷ however, this is not always possible in the acutely ill patient. Some patients would require such large reductions in ventilation to achieve a 'safe' level that the resulting hypoxia or acidosis would not be tolerated. In these patients, adjunctive measures to achieve gas exchange can be employed. Treatment modalities such as extracorporeal membrane oxygenation (ECMO) and arteriovenous carbon dioxide removal (AVCO₂R) allow for a more gentle ventilation strategy by providing partial or total gas exchange.

ECMO exists as an adaptation of cardiopulmonary bypass in the operating room. Early investigators reasoned if the heart and lungs could be bypassed for a few hours to facilitate repair of a congenital defect or bypass a coronary artery, this same technology could facilitate the recovery of lungs that have temporarily lost the ability to exchange gas. This theory was first tested 30 years ago by Hill et al.³⁸ who successfully supported an adult ARDS patient for 3 days. Although ECMO is now associated most commonly with diseases of the neonatal population, its earliest use was as a supportive therapy for

adults with severe respiratory failure. The use of ECMO in neonates has resulted in a collective experience of 23080 patients with an 82% survival rate.³⁹ The experience with ECMO in children and adults with burns has been limited.

ECMO involves the placement of large catheters into the central veins or arteries of the patient, draining the blood from the body, facilitating oxygenation, removing carbon dioxide and placing it back into the circulation. In venoarterial (VA) ECMO, blood is drained from either an internal jugular vein or a femoral vein, pumped through a gas exchanger and then returned to either a carotid or femoral artery, bypassing the native lungs (Figure 20.1). This form of ECMO allows for both pulmonary and cardiac support. In venovenous (VV) ECMO, the blood is returned to a large central vein rather than an artery (Figure 20.2). Venovenous ECMO is primarily indicated in isolated pulmonary failure. Both VV and VA ECMO require patients to be fully anticoagulated with heparin.

The need for full anticoagulation would seem to exclude patients with large burns from this therapy; however, our center has had a limited experience and some degree of success in supporting this population. Recently we reported our experience with pediatric burn patients supported with ECMO at the Extracorporeal Life Support Organization annual meeting (ELSO 2005, Houston Texas). Our center has no formal inclusion criteria for ECMO; each patient is evaluated on a case-by-case basis (Box 20.2). In general, patients were placed on ECMO after maximum medical management had failed. To date, we have supported 12 pediatric patients with burns including four scald burns (3/4 survivors), seven flame burns (4/7 survivors) and a single successful case of isolated inhalational injury.

Data presented at 2005 ELSO Conference, Houston, Texas.

thermore, initial excision and allografting prior to heparinization appears beneficial. In a follow-up study, Kane et al.⁴¹ reiterated Goretsky's findings, adding that the onset of sepsis, the requirement of blood transfusion that exceeded the patients total blood volume for 2 consecutive days, or the need for >7 days of support favored a poor outcome. Interestingly, 6 of the 8 survivors at our institution required >7 days of support and no patients required removal from ECMO for excessive bleeding. While our experience is limited to a single center, it does reiterate the need for further study in this patient population. Based on the ECMO burn experience, we will continue to offer ECMO to burned children at our institution.

The use of ECMO in burn patients has been limited for several reasons. The equipment required is expensive and requires one-on-one nursing care as well as an ECMO specialist nurse and/or a specially trained respiratory therapist. Without evidence from a randomized, controlled trial demonstrating survival benefit, some hospitals are unwilling to incur the expense associated with an ECMO program. The use of ECMO is likely to continue in specialized centers but unlikely to become a widespread treatment option for patients with burns until level I evidence-based studies show efficacy in populations other than neonates.

Occasionally, the full gas exchange support of ECMO is not needed. An adjunct to facilitate less injurious ventilator settings may be sufficient to support a patient without the need for the invasive cannulation involved with ECMO. This need can arise from the gentle ventilation techniques described by the ARDSNet trial,¹⁶ which can result in severe respiratory acidosis. Arteriovenous carbon dioxide removal (AVCO₂R) is a technique that allows for CO₂ homeostasis without employing damaging ventilator settings. Utilizing a simple arterial-to-venous shunt with a low-resistance gas exchange device interposed, this system allows for removal of almost all metabolically produced CO₂ with less than a 25% shunt.⁴²⁻⁴⁴

Utilizing 'off-the-shelf' components, this form of simplified extracorporeal support provides some of the benefits of ECMO but does not require a pump, a dedicated specialist or complex equipment. A relatively small (10 Fr) cannula is placed percutaneously in the femoral artery and a slightly larger (12 Fr) cannula is placed in the femoral vein. Our early animal work

BOX 20.2 ECMO burn patient selection criteria

GUIDELINES RATHER THAN CRITERIA

- Patient without PIP >50 cmH₂O for >24 hours
- Patient without PaO₂ <40 mmHg for >12 hours
- All burn wounds covered
- Has been mechanically ventilated <7 days
- Failed maximum medical management

CONTRAINDICATIONS

- CPR in progress pH <6.9 for >4 hours

*All cases evaluated on a case-by-case basis.

The most difficult aspect of utilizing ECMO to support a burn patient utilizing ECMO is deciding which patients will be successful and which will not. In a review of our experience, we found no predictive value of pre-ECMO arterial blood gases, ventilator settings, or days on mechanical ventilation (Table 20.1). As with previous studies, degree and extent of burn did not seem to affect survival ((survivors 46% (32–85), non-survivors 64% (48–60)).

Once the patient is on ECMO, the focus becomes which ones are likely to benefit from the therapy and which will not. Goretsky et al.⁴⁰ have described their experience with burns patients on ECMO and indicators that may predict a good outcome. These predictors of survival included younger age, shorter duration of ECMO support needed (<7 days) and fewer complications while on ECMO. This group also found that the extent and degree of burn had no effect on the outcome. Fur-

Fig. 20.3 $\text{PaO}_2/\text{FiO}_2$ ratio (P/F) following smoke inhalation and cutaneous flame burn injury and following placement of AVCO₂R. Entry criteria ($\text{P/F} < 200$) were met at 48 hours (194.8 ± 25.9). At the time AVCO₂R was initiated P/F was 151.5 ± 40.0 . After 36 hours P/F had improved to >200 and after 72 hours P/F was >300 (320.0 ± 17.8).

demonstrated that this technique was both safe and efficacious in our smoke/burn model of ARDS (Figure 20.3). Animal model studies have demonstrated that AVCO₂R has allowed for increased survival time⁴⁵ and a significant decrease in ventilatory parameters (minute ventilation, tidal volume and PIP)⁴⁶ (Figures 20.4 and 20.5). Early phase I human testing showed the ability of AVCO₂R to provide complete CO₂ removal during acute respiratory failure.⁴⁷ Our experience has shown that the device is safe for use in patients with severe respiratory failure, and that CO₂ removal rates of approximately 70% can be achieved.⁴⁸ As phase II clinical trials continue in this country and have struggled to meet anticipated accrual numbers, the European experience with pumpless CO₂ removal (termed pumpless extracorporeal lung assist (pECLA)) has grown significantly. Reports by Liebold et al.⁴⁹ of the first 70 patients show promise. To date over 700 patients have been supported with the pECLA system.

The gas exchanger currently used in the pECLA system has not been approved in the United States by the FDA. This hollow-fiber gas exchanger with polymethylpentane fibers allows days to weeks of support before failure and is ultra-low resistance ($<10\text{mmHg}$ @ 2L/min blood flow) (Figure 20.6). Gas exchange devices used clinically in early phase I studies in the United States require change-out predictably before 72 hours of support due to ‘fiber wetting,’ a phenomenon attributable to the polypropylene composition of these devices. The polypropylene has hydrophilic properties which cause condensation to accumulate outside the device, thereby reducing its capacity for diffusion and gas exchange. While AVCO₂R has shown success in both laboratory settings and in early trials in humans, its use is likely to remain limited. Both AVCO₂R and pECLA require the patient to be anticoagulated and require the placement of a catheter in the femoral artery. This will likely limit the use of these therapies to tertiary care centers.

Fig. 20.4 Reduction in MV, tidal volume, and peak inspiratory pressure during arteriovenous CO₂ removal. MV reduced from $10.3 \pm 1.4\text{L/min}$ to $0.5 \pm 0.0\text{L/min}$ at 6 hours on arteriovenous CO₂ removal while maintaining normocapnia; similarly, tidal volume significantly reduced from $467 \pm 53\text{mL/min}$ at baseline to $102 \pm 52\text{mL/min}$. With reductions in MV and tidal volume, peak inspiratory pressure significantly reduced from $40.8 \pm 2.1\text{cmH}_2\text{O}$ at baseline to $19.7 \pm 7.5\text{cmH}_2\text{O}$ at 6 hours on arteriovenous CO₂ removal (* $p < 0.05$ and ? $p < 0.01$ vs. baseline).

Prevention

Techniques to prevent barotrauma are as varied as the theories concerning its etiology. Because the major pulmonary mechanical changes in respiratory distress syndrome are decreased compliance and defect in diffusion, ventilation must be adjusted to optimize these values. Both pressure and volume determine alveolar distention and compliance. Some have theorized that peak airway pressure and PEEP are the major contributors to barotrauma. ARDSNet¹⁶ established that tidal volumes of 6mL/kg resulted in a lower mortality and increased number of ventilator-free days. However, Young et al.⁵⁰ surveyed three tertiary care hospitals and found that the findings from the ARDSNet trial are not being widely applied by physicians. While the tidal volumes administered by physicians after the publication of the ARDSNet trial were significantly lower compared to before publication (10.6 vs. 12.3mL/kg of predicted body weight), they were still well above the 6mL/kg level recommended by the study.

Fig. 20.5 Kaplan–Meier curve depicting the number of sheep surviving the 7-day (168 hours) study. All the sheep in the 24 breath/40% TBSA III° cutaneous flame burn group survived to 7 days: 5/7 sheep in the 36 breath/40% TBSA III° cutaneous flame burn group survived to 7 days (LD_{30}). None of the sheep in the 48 breath/40% TBSA III° cutaneous flame burn group survived to 7 days. Only 1 sheep receiving 48 breaths of cotton smoke survived to day 4.

The causes and treatments of barotrauma represent dynamic subjects. As our understanding of the pathophysiology of lung injury has progressed, so has our ability to manage and prevent these injuries. In the past, physicians had employed peak inspiratory pressures as high as 75–100 mmHg to achieve physiologically ‘normal’ arterial blood gas values; today, the emphasis is placed on low-volume ventilation in order to minimize alveolar overdistention at the expense of marginal arterial blood gas values. As our understanding of the molecular markers of lung injury improves, so may our ability to predict which patients are at greater risk and our knowledge of how they should best be managed.

With the body of knowledge frequently changing, it is important to bear in mind the observation by Marini and Gattinoni:⁵¹ precise numerical guidelines for selecting PEEP, tidal volume, and ventilatory position that are applicable to any

Fig. 20.6 The symmetrical lung assist device is shown with two low-resistance cannulae attached. The system’s low-pressure gradient allows use without a mechanical blood pump in an arteriovenous shunt created between femoral artery and vein. given individual patient should not be expected from the results of studies conducted in a diverse sample population. While this advice holds true, clinicians should avoid using potentially injurious ventilatory settings in an attempt to normalize blood gases. Instead more focus should be on the minimum amount of support required to provide the patient with acceptable blood gas values without inflicting further damage on their fragile lungs.

Late complications of inhalation injury	289
Conclusion	290

Introduction

The multitude of respiratory complications caused by smoke inhalation, thermal burns, and their treatment epitomize the clinical challenges which confront respiratory care practitioners. Smoke inhalation injury and its sequelae impose demands upon the respiratory care practitioners who play a central role in its clinical management. These demands may range from intubation and resuscitation of victims in the emergency room to assistance with diagnostic bronchoscopies, to performance of pulmonary function studies, monitoring of arterial blood gases, airway maintenance, chest physiotherapy, and mechanical ventilator management.¹ Additional demands are placed upon the respiratory care practitioner in the rehabilitation phase in determining disability or limitations diagnosed by pulmonary function studies or cardiopulmonary stress testing. In some countries outside the United States, the duties of the respiratory care practitioner are augmented by a combination of physicians, nurses, and physiotherapists. It is imperative that a well-organized, protocol-driven approach to respiratory care of the burn patient be utilized so that improvements can be made, and the morbidity and mortality associated with inhalation injury can be reduced (Box 21.1). This chapter provides an overview of the common hands-on approaches to the treatment of inhalation injury, with emphasis on mucociliary clearance techniques, pharmacologic adjuncts, mechanical ventilation, infection control, and the late complications associated with inhalation injury.

Bronchial hygiene therapy

Airway clearance techniques are an essential component of respiratory management of patients with smoke inhalation. Bronchial hygiene therapy is a term used to describe several of the modalities intended to accomplish this goal. Therapeutic coughing, chest physiotherapy, early ambulation, airway suc-

tioning, therapeutic bronchoscopy, and pharmacologic agents have been effective in the removal of retained secretions.

Therapeutic coughing

Therapeutic coughing functions to promote airway clearance of excess mucus and fibrin cast in the tracheal bronchial tree. The impairment of the cough mechanism will result in retained secretions, bronchial obstruction, atelectasis, and/or pneumonia. A cough may be either a reflex or a voluntary action. The mechanisms of a cough include:

- a deep inspiration;
- the closure of the glottis;
- contraction of the muscles of the chest wall, abdomen, and pelvic floor;
- opening of the glottis; and
- a rapid expulsive exhalation phase.

During a cough, alveolar, pleural, and subglottic pressures may rise as much as 200 cmH₂O. A failure of the cough mechanism may be due to an impairment of any step in the sequences described. When this occurs, it is necessary to perform techniques which are used to improve the cough.

Series of three coughs

The patient is asked to start a small breath and small cough, then a bigger breath and harder cough, and finally a really deep breath and hard cough. This technique is especially effective for postoperative patients who tend to splint from pain.²

Tracheal tickle

The therapist places the index and middle finger flat in the sternal notch and gently massages inward in a circular fashion over the trachea. This is most effective in obtunded patients or in patients coming out of anesthesia.²

Cough stimulation

Patients with artificial airways cannot cough normally since a tube is either between the vocal cords (endotracheal) or below the cords (tracheostomy). Adequate pressure cannot be built up without approximation of the cords. These patients may have a cough stimulated by inflating the cuff on the tube, giving a large, rapid inspiration by a manual resuscitation bag, holding the breath for 1–2 seconds, and rapidly allowing the bag to release and exhalation to ensue. This technique is normally performed by two persons and is made more effective by one therapist performing vibration and chest compressions from the time of the inspiratory hold, all during exhalation.² Cough and deep breathing exercises are encouraged every 2 hours to aid in removing retained secretions.

BOX 21.1 Inhalation injury treatment protocol

- Titrate humidified oxygen to maintain $\text{SaO}_2 > 90\%$
- Cough, deep breath exercises every 2 hours
- Turn patient side to side every 2 hours
- Chest physiotherapy every 4 hours
- Aerosolize 3 cc of 20% N-acetylcysteine every 4 hours with a bronchodilator
- Alternate aerosolizing 5000 units of heparin with 3 cc of normal saline every 4 hours
- Nasotracheal suctioning as needed
- Early ambulation on postoperative day 5
- Sputum cultures for intubated patients every M-W-F
- Pulmonary function studies prior to discharge and at outpatient visits
- Patient/family education regarding inhalation injury

The protocol is continued for 7 days.

Chest physiotherapy

Chest physiotherapy has come to mean gravity-assisted bronchial drainage with chest percussion and vibrations. Studies have shown that a combination of techniques are effective in secretion removal.³⁻⁶

Bronchial drainage/positioning

Bronchial drainage/positioning is a therapeutic modality that uses gravity-assisted positioning designed to improve pulmonary hygiene in patients with inhalation injury or retained secretions. There are 12 basic positions in which patients can be placed for postural drainage. Due to skin grafts, donor sites, and the use of air fluid beds, clinical judgment dictates that most of these positions are not practical. In fact, positioning in the Trendelenburg and various other positions may acutely worsen hypoxemia. Evidence has shown that a patient's arterial oxygenation may fall during positioning.⁷ To accomplish the same goal it is common practice, in intensive care units, to turn patients side to side every 2 hours so as to aid in mobilizing secretions (Figure 21.1).

Percussion

Percussion aids in the removal of secretions from the tracheal bronchial tree. Percussion is done by cupping the hand so as to allow a cushion of air to come between the percussor's hand and the patient. If this is done properly, a popping sound will be heard when the patient is percussed. There should be a towel between the patient and the percussor's hand in order to prevent irritation of the skin.⁸ Percussion is applied over the surface landmarks of the bronchial segments that are being drained. The hands rhythmically and alternately strike the chest wall. Incisions, skin grafts, and bony prominences should be avoided during percussion (Figure 21.2).

Vibration/shaking

Vibration/shaking is a shaking movement used to move loosened secretions to larger airways so that they can be coughed up or removed by suctioning. Vibration involves rapid shaking of the chest wall during exhalation. The percussor vibrates the thoracic cage by placing both hands over the percussed areas

Fig. 21.1 Patient positioning for secretion mobilization.

Fig. 21.2 Chest physiotherapy techniques.

Fig. 21.3 Gentle mechanical chest vibrations.

and vibrating into the patient, isometrically contracting or tensing the muscles of their arms and shoulders. Mechanical vibrations have been reported to produce good clinical results. Gentle mechanical vibration may be indicated for patients who cannot tolerate manual percussion (Figure 21.3). Chest phys-

iotherapy techniques should be used every 2–4 hours for patients with retained secretions. Therapy should continue until breath sounds improve.

Early ambulation

Early ambulation is another effective means of preventing respiratory complications. Patients routinely should be helped out of bed on postoperative day 5 and encouraged to ambulate and sit in a chair. With appropriate use of analgesics, even patients on continuous ventilatory support can be helped out of bed and into a chair (Figure 21.4). The rocking chair (Figure 21.5) has several beneficial effects:

- the patient can breathe with regions of the lungs which are normally hyperventilated;

Fig. 21.4 Early ambulation.

Fig. 21.5 Patient up out of bed, secretions being mobilized by rocking, and chest physiotherapy techniques.

- muscular strength and tone are preserved;
- contractions are prevented and exercise tolerance is maintained.⁹

Airway suctioning

Airway suctioning is another method of clearing an airway. Normal bronchial hygiene is usually accomplished by the mucociliary escalator process. When these methods are not effective in maintaining a clear airway, tracheobronchial suctioning is indicated.^{10–13} Nasotracheal suctioning is intended to remove from the trachea accumulated secretions and other foreign material which cannot be removed by the patient's spontaneous cough or less-invasive procedures. Nasotracheal suctioning has been used to avoid intubation which was solely intended for the removal of secretions. Nasotracheal suctioning refers to the insertion of a suction catheter through the nasal passages and pharynx into the trachea in order to aspirate secretions or foreign material. The first step in this process is to hyperoxygenate the patient with 100% oxygen. The patient should be positioned in the Fowler's position and the catheter slowly advanced through the nares to a point just above the larynx. The therapist or nurse then listens for air sounds at the proximal end of the catheter. When airflow is felt to be strongest and respiratory sounds are loudest, the tip of the catheter is immediately above the epiglottis. On inspiration, the catheter is advanced into the trachea. After the vocal cords have been passed, a few deep breaths are allowed and the patient is reoxygenated. Suction is begun while the catheter is slowly withdrawn from the trachea. The patient should not be suctioned for more than 15 seconds without being reoxygenated. Suctioning is not without potential hazards.^{14,15} Complications include irritation of the nasotracheal mucosa with bleeding, abrupt drops in PO_2 , vagal stimulation, and bradycardia. Preoxygenating and limiting suction time have been shown to decrease or eliminate the fall in the PO_2 .^{12–14} Sputum cultures should be performed for microbiological identification when they are clinically indicated. Patients on mechanical ventilation should have sputum cultures performed once per week.

Therapeutic bronchoscopy

When all other techniques fail to remove secretions, the use of the fiberoptic bronchoscope has proven to be of benefit. In addition to its diagnostic functions, bronchoscopy retains important therapeutic applications. Copious secretions encountered in patients with inhalation injury may require repeated bronchoscopic procedures when more conservative methods are unsuccessful. The modern fiberoptic bronchoscope is small in diameter, flexible, and has a steerable tip that can be maneuvered into the fourth- or fifth-order bronchi for examination or specimen removal.

Pharmacologic adjuncts

Bronchodilators

Bronchodilators can be helpful in some cases. Inhalation injury to the lower airways results in a chemical tracheobronchitis which can produce wheezing and bronchospasms. This is especially true for patients with preexisting reactive airway diseases. Most drugs used in the management of bronchospasms are believed to act on the biochemical mechanism which con-

trols bronchial muscle tone. Aerosolized sympathomimetics are effective in two ways: they result in bronchial muscle relaxation and they stimulate mucociliary clearance. The newer bronchodilators are more effective and have fewer side-effects than the older generation drugs. Some of the newer compounds used in the United States are worthy of note. First, metaproterenol is available in cartridge inhalers, as a liquid to be aerosolized, as an oral medication in tablets, or as a syrup. The recommended oral dose is 10–20 mg every 6–8 hours; as an inhaled bronchodilator, 1–2 puffs every 3–4 hours. Its duration of action as an inhaled bronchodilator is 1–5 hours.¹⁶

Albuterol can also be administered orally, parenterally, and by aerosol. Albuterol is available in a metered cartridge inhaler and its standard dose is 1–2 puffs three to four times daily. Aerosolized albuterol has a duration of action of approximately 4–6 hours.¹⁷

Racemic epinephrine is used as an aerosolized topical vasoconstrictor, bronchodilator, and secretion bond breaker. The vasoconstrictive action of racemic epinephrine is useful in reducing mucosal and submucosal edema within the walls of the pulmonary airways. A secondary bronchodilator action serves to reduce potential spasm of the smooth muscles of the terminal bronchioles. Water, employed as a diluent for racemic epinephrine, serves to lower both adhesive and cohesive forces of the retained endobronchial secretions, thus serving as a bond-breaking vehicle. Racemic epinephrine has also been used for the treatment of post-extubation stridor.¹⁸ Its mode of action is thought to be related to the vasoconstrictive activity, with the resultant decrease in mucosal edema. Aerosolized treatments may be given every 2 hours as long as the heart rate is not increased.

Hypertonic saline offers a theoretically more effective form of mucokinetic therapy. The deposition of hypertonic droplets on the respiratory mucosa results in the osmotic attraction of fluids from the mucosal blood vessels and tissues into the airway. Thus a ‘bronchorrhea’ is induced, and the watery solution helps to dilute down the respiratory tract secretions and to increase their bulk, thereby augmenting expectoration. Furthermore, there is evidence that hypertonic saline has a direct effect on the mucoprotein DNA complexes, and by reducing the cohesive intramolecular forces, the salt helps reduce the viscous properties of the mucoid fluid.¹⁹ Excessive use of hypertonic saline is not recommended because irritation can occur in the respiratory tract, absorption can occur, and burn patients who cannot tolerate the sodium load may develop edema.

Finally, aerosolized acetylcysteine is a powerful mucolytic agent in use in respiratory care. Acetylcysteine contains a thiol group; the free sulfhydryl radical of this group is a strong reducing agent which ruptures the disulfide bonds that serve to give stability to the mucoprotein network of molecules in mucus. Agents that break down these disulfide bonds produce the most effective mucolysis.²⁰ Acetylcysteine is an irritant to the respiratory tract. It can cause mucosal changes, and it may induce bronchospasm. For this reason, patients are evaluated for signs of bronchospasm, and a bronchodilator may be added if necessary. Acetylcysteine has proven to be effective in combination with aerosolized heparin for the treatment of inhalation injury in animal studies.²¹

Heparin/acetylcysteine combinations have been used as scavengers for the oxygen free radicals produced when alveolar macrophages are activated either directly by chemicals in smoke or by one or more of the compounds in the arachidonic cascade.²² Animal studies have shown an increased *P/F* ratio, decreased peak inspiratory pressures, and a decreased amount of fibrin cast formation with heparin/acetylcysteine combinations.²³ In a retrospective review, Desai et al. have shown that the use of heparin/N-acetylcysteine is effective in pediatric patients with inhalation injury.²⁴ Results indicate a significant decrease in the reintubation rates, incidence of atelectasis, and improved mortality for patients treated with heparin/N-acetylcysteine therapy. Therefore a standard treatment for patients with inhalation injury might include 5000–10000 units of heparin and 3 mL normal saline nebulized every 4 hours, alternating with 3–5 mL of 20% acetylcysteine for 7 days. This insures that the patient receives an aerosolized treatment every 2 hours. Baseline and daily clotting studies are recommended for the entire length of the aerosolized treatments.

A prospective randomized study on the use of nebulized heparin for the treatment of inhalation injury is necessary to validate the continued use of this mode of therapy. A multicenter study is being developed that will evaluate the effectiveness of therapy and answer some of the questions regarding the mechanism of action, safety, and effects on lung function.

Patient/family education

Burn care involves utilizing a family-centered care approach. Therefore the patient and family should be informed about the extent of the lung injury and the various treatment options available based upon evidence-based medicine or best practice.

Mechanical ventilation

Over the past 30 years, and especially over the past decade, there has been an increase in new ventilatory techniques which present alternatives for the treatment of patients with smoke inhalation. Unfortunately, although the number of options available to the clinician has appeared to increase exponentially, well-controlled clinical trials defining the specific role for each of the modes of ventilation and comparing them to other modes of ventilation have not been forthcoming. Based upon current available data, the recommendations from the American College of Chest Physicians consensus conference on mechanical ventilation generally serve as guidelines.²⁵ The general consensus concludes:

- The clinician should choose a ventilator mode that has been shown to be capable of supporting oxygenation and ventilation and that the clinician has experience in using.
- An acceptable oxygen saturation should be targeted.
- Based primarily on animal data, a plateau pressure of greater than 35 cmH₂O is cause for concern. With clinical conditions that are associated with a decreased chest wall compliance, plateau pressures greater than 35 cmH₂O may be acceptable.
- To accomplish the goal of limiting plateau pressures, PCO₂ values should be permitted to rise (permissive

hypercapnia) unless other contraindications exist that demand a more normal PCO_2 or pH.

- Positive end-expiratory pressure (PEEP) is useful in supporting oxygenation. An appropriate level of PEEP may be helpful in preventing lung damage. The level of PEEP required should be established by empirical trials and reevaluated on a regular basis.
- Large tidal volumes (8–10 mL/kg) with PEEP may be needed to improve oxygenation if the use of protective ventilatory strategies becomes ineffective. Peak flow rates should be adjusted as needed to satisfy patient inspiratory needs.²⁵ Care must be taken to avoid the consequences of utilizing high ventilator pressures if large tidal volumes are required.

A new multicenter study by the Acute Respiratory Distress Syndrome Network of the National Heart, Lung, and Blood Institute is the first large randomized study comparing high versus low tidal volumes for patients with ARDS.⁴⁷ The trial compared traditional ventilation treatment, which involved an initial tidal volume of 12 mL/kg of predicted body weight, and an airway pressure measured of 50 cmH₂O or less, to ventilation with a lower tidal volume, which involved an initial tidal volume of 6 mL/kg of predicted body weight and a plateau pressure of 30 cmH₂O or less. The volume-assist-control mode was used for the ventilation study. The trial was stopped after the enrollment of 861 patients because mortality was lower in the group treated with lower tidal volumes than in the group treated with traditional tidal volumes, and the number of days without ventilator use during the first 28 days after randomization was greater in this group.⁴⁷

This study was the first large randomized investigation documenting a decrease in mortality with the use of lower tidal volumes for the treatment of patients with ARDS. In light of this new evidence, the tidal volumes used when initiating mechanical ventilation should be 6–8 mL/kg of predicted body weight. If the patient becomes obstructed with fibrin cast and presents with an acute increase in PCO_2 and decrease in PaO_2 , the clinician should first provide aggressive pulmonary toilet, then consider changing over to volume ventilation with higher tidal volumes. If ventilation continues to worsen, tidal volumes of 8–10 mL/kg may be needed to provide adequate mechanical ventilation.

Modes of ventilation

Control mode

In the control mode of ventilation, the ventilator cycles automatically at a rate selected by the operator. The adjustment is usually made by a knob calibrated in breaths/min. The ventilator will cycle regardless of the patient need or desire for a breath, but guarantees a minimum level of minute ventilation in the apneic, sedated, or paralyzed patient. The control mode of ventilation is often utilized in patients with ARDS because of the high peak pressures needed to achieve adequate chest expansion. The major disadvantage with this mode is that the patient cannot cycle the ventilator and thus the minute ventilation must be set appropriately.

Assist-control mode

In the assist-control mode of ventilation, in which every breath is supported by the ventilator, a back-up control rate is set;

however, the patient may choose any rate above the set rate. Using this mode of ventilation, the tidal volume, inspiratory flow rate, flow waveform, sensitivity, and control rate are set.^{26–28} Advantages are that assist-control ventilation combines the security of controlled ventilation with the possibility of synchronizing the breathing pattern of the patient and ventilator, and it ensures ventilatory support during each breath. Disadvantages are as follows:

- Excessive patient work occurs in case of inadequate peak flow or sensitivity settings, especially if the ventilator drive of the patient is increased.^{26–28}
- It is sometimes poorly tolerated in awake, nonsedated subjects and can require sedation to insure synchrony of patient and machine.
- It can cause respiratory alkalosis.
- It may worsen air trapping with patients with chronic obstructed lung disease.²⁴

Synchronized intermittent mandatory ventilation

Synchronized intermittent mandatory ventilation (SIMV) combines a preset number of ventilator-delivered mandatory breaths of present tidal volume with the facility for intermittent patient-generated spontaneous breaths.^{29,30}

Advantages are as follows:

- The patient is able to perform a variable amount of respiratory work and yet there is the security of a preset mandatory level of ventilation.
- SIMV allows for a variation in level of partial ventilatory support from near total ventilatory support to spontaneous breathing.
- It can be used as a weaning tool.

Disadvantages are:

- Hyperventilation with respiratory alkalosis.
- Excessive work of breathing due to the presence of a poorly responsive demand valve, suboptimal ventilatory circuits, or inappropriate flow delivery could occur.
- In each case, extra work is imposed on the patient during spontaneous breaths.

Pressure control mode

In pressure-controlled ventilation all breaths are time- or patient-triggered, pressure-limited, and time-cycled. The ventilator provides a constant pressure of air to the patient during inspiration. The length of inspiration, the pressure level, and the back-up rate are set by the operator. Tidal volume is based upon the compliance and resistance of the patient's lungs, the ventilator system, as well as on the preset pressure. Pressure control ventilation has become a frequently used mode of ventilation for the treatment of ARDS.

Pressure support ventilation

Pressure support ventilation (PSV) is a pressure-targeted, flow-cycled, mode of ventilation in which each breath must be patient-triggered. It is used both as a mode of ventilation during stable ventilatory support periods and as a weaning method.^{30–34} It is primarily designed to assist spontaneous breathing and therefore the patient must have an intact respiratory drive.

Advantages are:

- It is generally regarded as a comfortable mode of ventilation for most patients.
- Pressure support reduces the work of breathing.
- It can be used to overcome the airway resistance caused by the endotracheal tube.
- Pressure support may be useful in patients who are difficult to wean.

Disadvantages are:

- The tidal volume is not controlled and is dependent on respiratory mechanics, cycling frequency, and synchrony between the patient and ventilator.
- Pressure support may be poorly tolerated in some patients with high airway resistances because of the preset high initial flow rates.

Alternate modes of ventilation

During the last decade, a new concept has emerged regarding acute lung injury. In severe cases of ARDS, only a small part of the lung parenchyma remains accessible to gas delivered by mechanical ventilation.^{35,36} As a consequence, tidal volumes of 10 mL/kg or more may overexpand and injure the remaining normally aerated lung parenchyma and could worsen the prognosis of severe acute respiratory failure by extending nonspecific alveolar damage. High airway pressures may result in overdistension and local hyperventilation of more compliant parts of the diseased lung. Overdistension of lungs in animals has produced diffuse alveolar damage.^{37–39} This is the reason why alternative modes of ventilation, all based on a reduction of end-inspiratory airway pressures and/or tidal volumes delivered to the patient, have been developed and are used by many clinicians caring for patients with severe forms of acute or chronic respiratory failure. Four alternative modes of ventilation — high-frequency ventilation (HFV), high-frequency percussive ventilation (HFPV), pressure control inverse ratio ventilation (PCIRV), and airway pressure release ventilation (APRV) — will be discussed.

High-frequency ventilation

High-frequency ventilation (HFV) is the administration of small tidal volumes of 1–3 mL/kg at high frequencies of 100–3000 cpm.⁴⁰ Because it is a mode of ventilation based on a marked reduction in tidal volumes and airway pressures, it has the greatest potential for reducing pulmonary barotrauma. There are a number of different types of high-frequency ventilation techniques. The two most common are high-frequency jet ventilation (HFJV) and high-frequency percussive ventilation (HFPV).

High-frequency jet ventilation is the only high-frequency mode routinely used to ventilate patients with ARDS, mainly in Europe.²⁵ Comparative data concerning the advantages of HFJV over conventional ventilation are limited. There is no agreement, however, that HFJV is better than conventional mechanical ventilation in ARDS.⁴¹

High-frequency percussive ventilation is a new technique that has shown some promise in the ventilation of patients with inhalation injury.^{42–44} Clinical studies indicate that this mode of ventilation may aid in reducing pulmonary barotrauma.^{42,43} In a retrospective study, Cortiella et al. have shown a decreased incidence of pneumonia, peak inspiratory pressure, and an improved *P/F* ratio in children ventilated with the use of HFPV as compared to controls.⁴⁵

In the first prospective randomized study on HFPV, Mlcaik et al. have shown a significant decrease in the peak inspiratory pressures needed to ventilate pediatric patients with inhalation injury.⁴⁶ No significant differences were found for incidence of pneumonia, *P/F* ratios, or mortality.

Based upon clinical experience, the following guidelines are given for initial set-up of the HFPV in children (Table 21.1). The pulsatile flow (PIP) rate should be set at 20 cmH₂O. The pulse frequency (high rate) should be set between 500 and 600. The low respiratory rate should be set at about 15–20. Oscillatory PEEP levels should be initially set at about 3 cmH₂O, and demand PEEP set on 2 cmH₂O. Ventilator settings are adjusted based upon the patient's clinical condition and blood gas values. To improve oxygenation, the ventilator can be set up in a more diffusive mode (increased pulse frequency) and, to eliminate carbon dioxide, the ventilator can be set up in a more convective mode (decreased pulse frequency). With this mode of ventilation, subtidal volumes are delivered in a progressive stepwise fashion until a preset oscillatory equilibrium is reached and exhalation is passive.

Clinicians must be familiar with the technique used and its possible limitations. There must be adequate humidification of the respiratory gases or severe necrotizing tracheobronchitis can occur. Special delivery devices for providing adequate humidification during HFV are required.

Pressure control inverse ratio ventilation

Pressure control inverse ratio ventilation (PCIRV) is the use of pressure ventilation with an inspiratory/expiratory (I:E) ratio greater than 1:1. The rationale behind this is to maintain a high mean airway pressure and to hold peak alveolar pressure within a safe range. The second theoretical concept underlying PCIRV is the prolongation of inspiration to allow for recruitment of lung units with a long time constant. Deep sedation and/or paralysis is nearly always required with this mode of ventilation. At this time there is no conclusive scientific data comparing PCIRV to conventional mechanical ventilation in patients with inhalation injury.

Airway pressure release ventilation

Airway pressure release ventilation (APRV) is a pressure-regulated mode of ventilatory support that allows for time-cycled decreases in pressure to facilitate CO₂ elimination. This mode allows spontaneous breathing while limiting airway pressures and may therefore limit the amount of sedatives or

TABLE 21.1 HIGH-FREQUENCY PERCUSSIVE VENTILATION SET-UP GUIDELINES

Variable	Settings
Pulsatile flow rate (PIP)	20 cmH ₂ O
Pulse frequency (high rate)	500–600
Low respiratory rate	15–20
I:E ratio	1:1 or 2:1
Oscillatory PEEP	3 cmH ₂ O
Demand PEEP	2 cmH ₂ O

neuromuscular blocking agents needed. APRV is a protective ventilator strategy that uses inverse ratio ventilation at two levels of PEEP. Several limited studies have suggested that APRV may be beneficial for the treatment of burn patients who develop ARDS. Evidence-based recommendations to use this mode of ventilation await outcome studies.

Typical ventilator settings required

A large multicentered study by the NHLBI evaluated the use of volume ventilation with low versus high tidal volume on ARDS. This study documented a decreased incidence of mortality in patients with ARDS who were ventilated with small tidal volumes.⁴⁷ Based upon this study, it has become clinically accepted practice to use small tidal volumes when initially setting up mechanical ventilation (Table 21.2).

Tidal volumes

In volume-cycled ventilation, a machine-delivered tidal volume is set to be consistent with adequate gas exchange and patient comfort. The tidal volume selected for burned patients normally varies between 6 and 8 mL/kg of predicted body weight. Numerous factors, such as lung/thorax compliance, system resistance, compressible volume loss, oxygenation, ventilation, and barotrauma, are considered when volumes are selected.⁴⁶ Of critical importance is the avoidance of overdistension. This can generally be accomplished by insuring that peak airway and alveolar pressures do not exceed a maximum target. Many would agree that a peak alveolar pressure greater than 35 cmH₂O in adults raises concern regarding the development of barotrauma and ventilator-induced lung injury increases.^{49,50} The clinician must always look at the patient to insure adequate chest expansion with the setting of the tidal volume. Expired tidal volumes should be measured for accuracy at the connection between the patient's wye and the artificial airway. This insures that the volume selected reaches the patient and is not lost in the compressible volume of the ventilator tubing.

The range of tidal volumes will vary depending on the disease process, with some diseases requiring maximum tidal volumes and others needing less. Severe interstitial diseases such as pneumonia and ARDS may require a tidal volume of 8–10 mL/kg to adequately inflate the lungs and improve gas exchange if protective ventilatory strategies become inadequate. However, the acceptable range of 6–8 mL/kg allows the clinician to make more precise adjustments in volume, as needed by the patient.

TABLE 21.2 TRADITIONAL MECHANICAL VENTILATION GUIDELINES IN CHILDREN

Variable	Settings
Tidal volumes	6–8 mL/kg
Respiratory rate	12–45 breaths/min
Plateau pressures	<30 cmH ₂ O
I:E ratio	1:1–1:3
Flow rate	40–100 L/min
PEEP	7.5 cmH ₂ O

Respiratory rate

Setting of the mandatory ventilator respiratory rate is dependent on the mode of ventilation selected, the delivered tidal volume, dead space to tidal volume ratio, metabolic rate, targeted *PCO*₂ levels, and level of spontaneous ventilation. With adults, set mandatory rate normally varies between 4 and 20 breaths/min, with most clinically stable patients requiring mandatory rates in the 8–12 range.⁴⁸ In patients with inhalation injury, mandatory rates exceeding 20 per minute may be necessary, depending on the desired expired volume and targeted *PCO*₂. It is important to have targeted arterial blood gas values set to aid the clinical team in proper management (Table 21.3) Along with the *PCO*₂, pH, and patient comfort, the primary variable controlling the selection of the respiratory rate is the development of air trapping and auto PEEP.⁵¹

The respiratory rates of children and infants all need to be set substantially higher than those of adults. For pediatrics, the respiratory rate can be set at from 12 to 45, depending on the disease state and the level of targeted *PCO*₂ one wishes to achieve. Slower respiratory rates are useful in the patient with obstructed airways because slower rates allow more time for exhalation and emptying of hyperinflated areas.

Arterial blood gases should be checked after the patient has been on the ventilator for approximately 20 minutes and the respiratory rate adjusted accordingly.

Flow rates

The selection of peak inspiratory flow rate during volume ventilation is primarily determined by the level of spontaneous inspiratory effort. In patients triggering volume breaths, patient effort, work of breathing, and patient ventilator synchrony depend on the selection of peak inspiratory flow.²⁷ Peak inspiratory flows should ideally match patient peak inspiratory demands. This normally requires peak flows to be set at 40–100 L/min, depending on expired volume and the inspiratory demand.²⁵

Inspiratory/expiratory (I:E) ratio

The time allowed for the inspiratory and expiratory phases of mechanical ventilation is commonly referred to as the inspiratory/expiratory (I:E) ratio. The inspiratory part of the ratio includes the time to deliver the tidal volume before the exhalation valve opens and exhalation begins. The expiratory part of the ratio includes the time necessary for the tidal volume to exit through the exhalation valve before the next inspiration begins. The inspiratory time should be long enough to

TABLE 21.3 ARTERIAL BLOOD GAS GOALS

Variable	Goal
pH	7.25–7.45
<i>PO</i> ₂	55–80 mmHg or SaO ₂ of 88–95%
<i>PCO</i> ₂	35–55 mmHg (permissive hypercapnia can be used as long as pH >7.25)

deliver the tidal volume at flow rates that will not result in turbulence and high peak airway pressures. The usual I:E ratio is 1:1–1:3.⁵²

In severe lung disease, it is acceptable to prolong the inspiratory time to allow for better distribution of gas and enhance oxygen diffusion. When a longer inspiratory time is required, careful attention should be given to sufficient expiration to avoid stacking of breaths and impeding venous return. Prolonged inspiratory time creates a more laminar flow, which helps to keep the peak pressures lower. Fast inspiratory times are tolerated in patients with severe airway obstruction. The fast inspiratory time allows for a longer expiratory phase, which may help to decrease the amount of overinflation.

Inspired oxygen concentration

As a starting point, and until the level of hypoxemia is determined, a patient placed on a ventilator should receive an oxygen concentration of 100%. The concentration should be systematically lowered as soon as arterial blood gases dictate. In general, as a result of the concerns regarding the effects of high oxygen concentration on lung injury, the lowest acceptable oxygen level should be selected as soon as possible. In patients who are difficult to oxygenate, oxygen concentrations can be minimized by optimizing PEEP and mean airway pressures and selecting a minimally acceptable oxygen saturation.⁵³

Positive end-expiratory pressure

Positive end-expiratory pressure (PEEP) is applied to recruit lung volumes, elevate mean airway pressure, and improve oxygenation.⁵⁴ The level of PEEP used varies with the disease process. PEEP levels should start at 8–10 cmH₂O and be increased in 2.5-cm increments. Increasing levels of PEEP, in conjunction with a prolonged inspiratory time, aids in oxygenation and allows for the safe level of oxygen to be used. The use of pressure–volume curves to determine the best PEEP level has been recommended to aid in overstretching the alveoli. This technique has certain limitations and is difficult to perform in the clinical setting. The use of PEEP trials can determine the best PEEP without causing a decrease in cardiac output.

Usually a minimum of 8 cmH₂O of PEEP will be indicated for use during mechanical ventilation since tracheal intubation holds the larynx constantly open, which leads to alveolar collapse and a reduction in the functional residual capacity.

Optimal PEEP is the level of end-expiratory pressure that results in the lowering of intrapulmonary shunting, significant improvement in arterial oxygenation, and only a small change in cardiac output, arteriovenous oxygen content differences, or mixed venous oxygen tension.

Extubation criteria

Standard extubation criteria include a wide variety of physiologic indices that have been proposed to guide the process of discontinuing ventilatory support. Traditional indices include:

- PaO₂/FiO₂ ratio of greater than 250.
- Maximum inspiratory pressure of greater than 60 cmH₂O.
- Vital capacity of at least 15–20 mL/kg.

- Tidal volume of at least 5–7 mL/kg.
- Maximum voluntary ventilation of at least twice the minute volume.^{55–58}
- An audible leak around the endotracheal tube must be present.

In general, these indices evaluate a patient's ability to sustain spontaneous ventilation. They do not assess a patient's ability to protect the upper airway. For this reason, traditional indices often fail to reflect the true clinical picture of a patient with an inhalation injury. For a complete evaluation prior to extubation, bronchoscopic examination will aid in determining if the airway edema has decreased enough to attempt extubation. Prior to a scheduled extubation it is recommended that reintubation equipment be set up and that the person doing the extubation be experienced in emergency intubations.

If the patient demonstrates signs of inspiratory stridor, the use of racemic epinephrine by aerosol has been effective in reducing the mucosal edema and may prevent the patient from being reintubated.

Infection control of respiratory equipment

Infections are the leading cause of mortality in burned patients. Pneumonia has become one of the most frequent life-threatening infections and is an important determinant of survival.⁵⁷ The majority of pneumonias are nosocomial, occurring in the burned patient after 72 hours of hospitalization, and are often associated with either an inhalation injury or endotracheal intubation with exposure to respiratory care equipment, or both.^{62–64} One of the most important risk factors predisposing to pneumonia in burned patients is endotracheal intubation.^{65,66} The incidence of pneumonia developing is estimated to be five times higher for intubated than nonintubated patients, and tracheostomy increases this risk even higher.⁶⁷ Exposure to respiratory care equipment adds an increased risk of pneumonia above and beyond the risk associated with endotracheal intubation.^{68,69} After the use of nebulization equipment in respiratory care became popular, several epidemics of nosocomial pneumonia were reported.⁷⁰ The risk of pneumonia from mechanical ventilators was significant but decreased with a better understanding of the necessity to decontaminate respiratory equipment.^{71,72} Intubated patients receiving respiratory care may be at an increased risk of pneumonia because of coincidental exposure to other procedures such as suctioning and bronchoscopy. Respiratory care equipment, if not properly cared for, may provide a source of extraneous organisms that can contaminate the patient's respiratory tract.

The potential role of respiratory care equipment in providing reservoirs for organisms that are capable of infecting the lungs is well established. This problem, particularly pertaining to reservoir devices and medications, has been recognized for a number of years, and effective control strategies have been developed. Most hospitals maintain a bacteriological monitoring system, and significant contamination by this route is not likely.⁷³ Contamination of the compressed gases used to operate respiratory care devices is uncommon, principally because of the desiccation of gases and the inability of most bacterial species to survive such harsh treatment. Nebulization equipment delivers a fine-particle aerosol and, if contaminated, the aerosol droplets may contain bacteria. Humidification

equipment provides water vapor but does not deliver a large quantity of water in particulate form. In fact, humidifiers generally remove bacteria from airstreams, because the bacteria are physically trapped in the fluid phase and are not vaporized.

Bag-mask units have been shown to allow the persistence of infectious organisms and the subsequent infection of other patients on whom the equipment has been later used.⁷⁴

Ventilator circuits are inevitably contaminated by the patient's own respiratory tract flora during exhalation and coughing, and the fluid that collects in this tubing is thereby contaminated. However, the American Association for Respiratory Care evidence-based clinical practice guidelines suggest that ventilator circuits should not be changed routinely for infection control purposes.⁷⁵ The exact length of time that circuits can be used safely is unknown.

Handwashing

Handwashing is generally considered the single most important procedure for preventing nosocomial infections. Regardless of whatever benefits are accrued by cleaning or sterilization, they are negated if the simple process of handwashing is overlooked. The recommended handwashing procedures depend on the purpose of washing. In most situations, a vigorous brief washing with soap under a strong running water is adequate to remove transient flora. Generally, simple handwashing with soap is performed before and after contact with patients and whenever the hands are soiled.

Antimicrobial handwashing procedures are indicated before all invasive procedures, during the care of patients in strict, respiratory, or enteric isolation and before entering intensive care units. The most commonly used agents are 70% isopropyl alcohol, iodophors, and chlorhexidine. Scrub regimens such as the povidone-iodine surgical scrub are appropriate for these areas.⁷⁶

Chemical agents for sterilization/disinfection

Disinfectants act to kill microorganisms by several methods:

- oxidating microbial cells;
- hydrolyzing;
- combining with microbial proteins to form salts;
- coagulating the proteins of microbial cells;
- denaturing enzymes; or
- modifying cell wall permeability.⁷⁷

Aldehydes

Aldehydes contain some of the most commonly used antimicrobials in respiratory care practice. These agents achieve their antimicrobial action through the alkylation of enzymes.

The cidal action of glutaraldehyde is accomplished by disruption of the lipoproteins in the cell membrane and cytoplasm of vegetative bacterial forms. This reaction between the chemical glutaraldehyde and cell proteins is dependent on both time and contact. Items to be disinfected must be free of material that would inhibit contact, and adequate contact time is needed for the chemical reaction to be complete.

Alkaline glutaraldehyde, buffered by a 0.3% bicarbonate agent, is used as a 2% solution. Once activated with the buffering agent, it is fully potent for approximately 14 days. This

solution is bactericidal, virucidal, and tuberculocidal within 10 minutes and produces sterilization when applied for 10–20 hours. Equipment disinfected or sterilized with glutaraldehyde should be thoroughly rinsed and dried prior to use, because any residue would be irritating to mucous membranes.

Glutaraldehyde solutions are commonly used for the cold disinfection or sterilization of respiratory care equipment and have a large degree of safety. These solutions can be used to disinfect bronchoscopes as well as many of the current respiratory supplies.

Alcohols

Alcohols, especially ethylene and isopropyl alcohol, are perhaps the most commonly used disinfectants. Alcohols, as a chemical family, have many desirable characteristics needed in disinfectants. They are generally bactericidal and accomplish their bactericidal activity by damaging the cell wall membrane. They also have the ability to denature proteins, particularly enzymes called dehydrogenases. For alcohol to coagulate microbial proteins, water must be present. For this reason, 70% has been considered the critical dilution for alcohol, with a rapid loss of bactericidal activity with dilutions less than 50%. Both ethyl and isopropyl alcohols are rapidly effective against vegetative bacteria and tubercle bacilli but are not sporicidal.

To be sure that the current infection control practice is effective in each institution, use of random microbiological cultures should be done whenever a problem is suspected or to test the reliability of the disinfection or sterilization techniques.

Late complications of inhalation injury

Tracheal stenosis

Tracheal complications are commonly seen and consist of tracheitis, tracheal ulcerations, and granuloma formation. The location of the stenosis is almost invariably subglottic and occurs at the site of the cuff of the endotracheal or tracheostomy tube.⁷⁸ Several problems arising after extubation represent sequelae of laryngeal or tracheal injury incurred during the period of incubation. While tracheal stenosis or tracheomalacia are usually mild and asymptomatic, in some patients they can present as severe fixed or dynamic upper airway obstructions. These conditions can require surgical correction. In the management of intubated patients, such complications should be mostly preventable by meticulous attention to the tracheostomy or endotracheal tube cuff. Inflation of the cuff should be to the minimal pressure level consistent with preventing a leak in the ventilator at end inspiration.

Obstructive/restrictive disease

Chronic airway disease is a relatively rare reported sequel of inhalation injury and its supportive treatment. Spirometry is a useful screening tool for airway obstruction. Reports in the literature for adults indicate that lung function returns to normal after inhalation injury.^{79,80} However, Mlcak et al. reported pulmonary function changes following inhalation injury for up to 10 years post-injury in a group of severely burned children.⁸¹ Fortunately, most pulmonary function abnormalities will persist for only months following lung

parenchymal injury. In the great majority of cases, eventual resolution of both symptoms and physiologic abnormalities will occur. During the resolution phase, serial measurement of airflow obstruction should be obtained.⁸² Desai et al. demonstrated that physiologic insults that occur as a result of thermal injury may limit exercise endurance in children.⁸³ Data from exercise stress testing showed evidence of a respiratory limitation to exercise. This was confirmed by a decrease in the maximal heart rate, decrease in the maximal oxygen consumption, and increased respiratory rate. In the cases of persistent severe respiratory symptoms, the severity of the impairment should be documented and the patient evaluated for a pulmonary rehabilitation program.

Conclusion

Inhalation injury and associated major burns provide a challenge for healthcare workers who provide direct hands-on

care. The technical and physiologic problems which complicate the respiratory management of these patients require a practical knowledge of the possible sources of nosocomial infections. Patients with inhalation injury frequently require the use of respiratory care equipment that, if not properly cared for, can aid in the spread of infections. Important priorities for reducing the risk of infections include: an aggressive bronchial hygiene therapy program, the adherence to established infection control practices, the use of universal precautions during procedures, meticulous cleaning of respiratory care equipment, as well as routine epidemiologic surveillance of the established infection control practices within each institution.

It is imperative that a well-organized protocol-driven approach to respiratory care of the burn patient be utilized so that further improvements can be made, and the morbidity and mortality associated with inhalation injury be reduced.

Changes in permeability	303
Summary	305

Introduction

Burn patients, with or without inhalation injuries, commonly exhibit a clinical picture that is largely produced by systemic inflammation. The phrase ‘systemic inflammatory response syndrome (SIRS)’ has been introduced to designate the signs and symptoms of this condition. SIRS has a continuum of severity ranging from the presence of tachycardia, tachypnea, fever, and leukocytosis, to refractory hypotension and, in its most severe form, shock and multiple organ system dysfunction. In thermally injured patients, the most common cause of SIRS is the burn itself. Sepsis, defined as SIRS in the presence of infection, is also common in burn patients and is a significant cause of morbidity and mortality. Starting from a local infection at the burn wound or an infected catheter tip, the spread of microbes and their toxins can further potentiate the already activated immune system. Pathological alterations of metabolic, cardiovascular, gastrointestinal, and coagulation systems occur as a result of the hyperactive immune system. This chapter will review current understanding of SIRS and the associated immunological, cardiovascular, and pulmonary dysfunction that occurs following trauma and thermal injury.

Definition of SIRS

The phrase ‘systemic inflammatory response syndrome (SIRS)’ was recommended by the American College of Chest Physicians/Society for Critical Care Medicine (ACCP/SCCM) consensus conference in 1992 to describe a systemic inflammatory process, independent of its cause.¹ The proposal was based on

clinical and experimental results indicating that a variety of conditions, both infectious and noninfectious (i.e. burns, ischemia-reperfusion injury, multiple trauma, pancreatitis), induce a similar host response. Two or more of the following conditions must be fulfilled for the diagnosis of SIRS to be made:

- body temperature $>38^{\circ}\text{C}$ or $<36^{\circ}\text{C}$;
- heart rate >90 beats/min;
- respiratory rate >20 /min or $P_{\text{aCO}_2} <32$ mmHg;
- leukocyte count $>12\,000/\mu\text{L}$, $<4\,000/\mu\text{L}$, or $>10\%$ immature (band) forms.

All of these pathophysiologic changes must occur as an acute alteration from baseline in the absence of other known causes. This definition is very sensitive and non-specific and most of the SIRS criteria are also addressed in other scoring systems of injury-induced physiologic derangement such as the Acute Physiology and Chronic Health Evaluation (APACHE), Mortality Probability Model (MPM), and Simplified Acute Physiology Severity (SAPS) systems. Several investigators have criticized the definition of SIRS as being too sensitive and encompassing the majority of ICU patients and certainly the vast majority of patients suffering extensive thermal injury.^{2,3} The initial definition of SIRS also did not address the continuum of disease severity as was defined for sepsis. Specifically, sepsis was defined by the same criteria as SIRS in patients with demonstrable infection. Criteria for the diagnosis of severe sepsis included the additional derangements of organ dysfunction, hypotension, and hypoperfusion. Evidence of hypoperfusion included, but was not limited to, the presence of lactic acidosis, oliguria, and altered mental status. Septic shock was characterized by hypotension and hypoperfusion in patients who were adequately volume resuscitated or required treatment with catecholamines or other vasoactive drugs to support cardiovascular function. Muckart and Bhagwangee,² in an effort to define a continuum of severity for SIRS, later proposed the categories of severe SIRS and sterile shock. These conditions were defined by the same criteria as severe sepsis and septic shock in the absence of demonstrable infection. In its most severe form, SIRS can induce organ injury and subsequent multiple organ dysfunction syndrome (MODS).

Despite the limitations in the definitions of SIRS and sepsis, most clinicians and investigators generally adopted the SIRS concept. However, it is difficult to define a specific pattern of host response. To address these issues, a second consensus conference was assembled in 2001.^{4,5} The goal of the conference was to revisit the previously defined criteria for SIRS and sepsis as well as determine if revision of these criteria was indicated. The consensus was that the concepts of sepsis and

SIRS are useful but the diagnostic criteria are overly sensitive and non-specific. The participants added additional criteria that defined metabolic, biochemical and functional alterations associated with SIRS and sepsis. Among these were hyperglycemia, edema, elevated plasma C reactive protein concentration, coagulation abnormalities, thrombocytopenia, ileus and hyperbilirubinemia. This group further proposed a staging system for sepsis and SIRS that could be used to stratify patients for prediction of outcome and potential response to therapy. This staging system, termed PIRO, defined several criteria including the predisposition of patients toward poor outcome as determined by pre-morbid conditions and possible genetic factors. Other factors include the severity and type of insult, the host response to injury and the presence of organ dysfunction. The participants proposed that this model could be used to generate more specific criteria for defining the SIRS phenomenon. The validity of this approach remains to be established.

Another pitfall in the designation of SIRS is the difficulty in applying the initial criteria to children. Some of the criteria, particularly those for heart rate and respiratory rate, fall within the normal physiologic range for young children. In 2002, a consensus conference was assembled to define criteria for sepsis and SIRS in children.⁶ The participants defined six age groups based on clinical and physiological characteristics (Table 22.1). SIRS was defined as the presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

- temperature $>38.5^{\circ}\text{C}$ or $<36^{\circ}\text{C}$;
- tachycardia, defined as mean heart rate $>2\text{SD}$ above normal for age or for children <1 year, bradycardia, defined as heart rate $<10\%$ of normal for age;
- mean respiratory rate $>2\text{SD}$ above normal for age or requirement for mechanical ventilation;
- leukocyte count elevated or depressed for age.

The conference participants defined severe sepsis as sepsis plus one of the following: cardiovascular dysfunction, acute respiratory distress syndrome or two or more organ dysfunctions (respiratory, renal, neurologic, hematologic or hepatic). The definition of septic shock is problematic in children because children can maintain blood pressure until they become severely ill. Therefore, hypotension is not a useful criteria for diagnosing shock in children. This group proposed criteria for septic shock that included the presence of tachycardia in conjunction with signs of decreased peripheral perfusion such as decreased capillary refill, decreased peripheral pulses, decreased urine output, altered mental status and cold/mottled extremities.⁶

TABLE 22.1 PEDIATRIC AGE GROUPS FOR SIRS CRITERIA

Newborn	0 day to 1 week
Neonate	1 week to 1 month
Infant	1 month to 1 year
Toddler and preschool	2 to 5 years
School age	6 to 12 years
Adolescent	13 to 18 years

Several studies have been conducted with the goal of determining the prognostic value of the SIRS designation. In the acute setting, SIRS has been demonstrated in the majority of critically injured patients and the intensity of the response correlates directly with the severity of injury.^{3,7} The presence of SIRS within the first 24 hours after severe injury has not served as a predictor of mortality in trauma or burn patients in some studies.^{3,7} However, the presence of sterile or septic shock is an important predictor of poor outcome, particularly when associated with MODS.² In addition, the presence of more than two of the SIRS criteria in the setting of acute injury has correlated with increased morbidity and mortality.^{8,9} A study by Rangel-Frausto et al.⁹ showed that trauma patients who did not meet SIRS criteria had a mortality rate of 3% compared with 6% mortality in those with two SIRS markers. Patients with three or four SIRS criteria had mortality rates of 10 and 17%, respectively, while those with culture-negative shock had a 46% death rate. Haga et al.¹⁰ have shown that the persistence of SIRS for more than 3 days in surgical patients is a harbinger of complications and is associated with increased morbidity. Talmor et al.⁷ reported that persistence of SIRS to the second postoperative day in high-risk surgical patients correlated with an increased incidence of MODS. Additional studies have shown that persistence of SIRS criteria for more than 3 days in trauma and burn patients is associated with worse outcome.¹⁰⁻¹³ Therefore, three important factors appear to determine the effect of SIRS on the host. The first factor is the severity of the initial inflammatory response. This response is proportional to the severity of injury. Specifically, the presence of shock or MODS within the first 24 hours after injury bears a poor prognosis. The second determinant is the persistence of SIRS beyond the first days of injury. Specifically, prolongation of SIRS beyond the second day after severe trauma or thermal injury is associated with an increased complication rate. Factors that appear to be important in decreasing the incidence of a prolonged inflammatory state include adequate fluid resuscitation within the first 24 hours of injury, aggressive excision of necrotic tissue and enteral feeding.¹¹⁻¹⁴ A further factor is the adaptive capacity of the host. Results of several studies have shown that extremes of age, either old or young, and the presence of coexisting disease will diminish the adaptive capacity of the host and predict a worse prognosis for any given severity of injury.^{14,15}

The initiating event

The crucial pathophysiologic event that precipitates systemic inflammation is tissue damage. This can occur both as a result of the direct injury to tissues from mechanical or thermal trauma as well as cellular injury induced by mediators of ischemia-reperfusion injury such as oxygen free radicals. Injury results in the acute release of pro-inflammatory cytokines such as tumor necrosis factor- α (TNF α) and interleukins IL-1 and IL-6. If injury is severe, such as in extensive thermal injury, a profound release of cytokines occurs, resulting in the induction of a systemic inflammatory reaction (Figure 22.1). The ability of the host to adapt to this systemic inflammatory response is dependent on the magnitude and duration of the response as well as the adaptive capacity of the host. If the insult and host response to the insult are beyond the adaptive

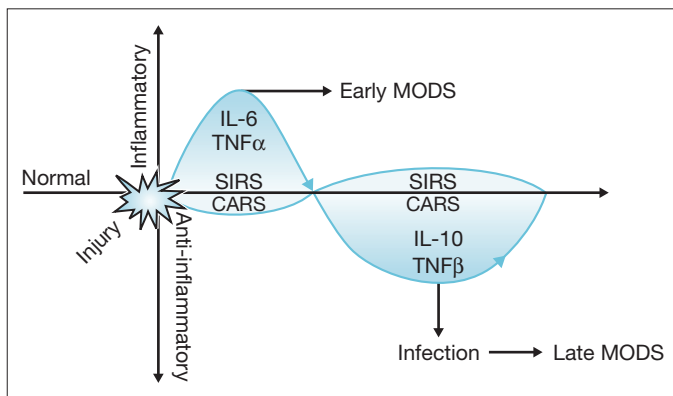

Fig. 22.1 Pathogenesis of the systemic inflammatory response syndrome (SIRS) and counter anti-inflammatory response syndrome (CARS). Tissue injury induces production of pro-inflammatory mediators such as $\text{TNF}\alpha$ and IL-6 resulting in SIRS. A compensatory anti-inflammatory response (CARS) may also be mounted through production of anti-inflammatory mediators such as IL-10 and $\text{TGF}\beta$. In many cases SIRS and CARS may coexist. (From Cotran R, Kumar V, Collins T, eds. Robbins pathologic basis of disease, 6th edn. Philadelphia: WB Saunders; 1999: 75.)

capacity of the host, organ injury may ensue during the early post-injury period. Factors that have been implicated in the worsening or prolongation of SIRS include inadequate resuscitation during the acute phase following thermal injury, persistent or intermittent infection, ongoing tissue necrosis, and translocation of endotoxin across the bowel.^{15,16} In many cases, SIRS may precipitate a state of immunosuppression known as the counter anti-inflammatory response syndrome (CARS). Frequently, SIRS and CARS may actually coexist (Figure 22.1). Current research indicates that the injured host responds to severe inflammation by activating anti-inflammatory pathways that are aimed at protecting the host from further inflammatory injury. Among these pathways are increased production of anti-inflammatory cytokines such as IL-10 and transforming growth factor- β ($\text{TGF}\beta$).^{17,18} However, this anti-inflammatory state may lead to immunosuppression that predisposes the host to opportunistic infections. If uncontrolled, local infections may escalate to severe systemic infections and sepsis. Sepsis can cause further inflammatory injury and serve as an additional source of organ injury in severely burned patients. The pathogenesis of injury-induced immunosuppression is discussed in detail in Chapter 23 of this text.

The two-hit hypothesis

Many investigators have described a phenomenon in which the injured host manifests an exaggerated inflammatory response if confronted with a secondary inflammatory stimulus during the post-injury period. This phenomenon has been termed the ‘two-hit hypothesis.’ Although the pathobiology of the two-hit hypothesis is not completely understood, monocytes and macrophages appear to play a central role in mediating the process. For example, the lymphokine α -interferon ($\text{IFN-}\alpha$), produced during the initial injury, might act as the first signal and prime macrophages for a heightened inflammatory response if a second stimulus is encountered. Several changes in macrophage function, including an increase in the transcription rate of mRNA for $\text{TNF}\alpha$, can be induced by exposure to $\text{IFN-}\alpha$.

However, $\text{TNF}\alpha$ protein is not produced in large amounts in response to the first inflammatory insult. If a second stimulus, such as endotoxin, is provided in even a small dose, macrophages are triggered to become fully activated and to secrete large amounts of $\text{TNF}\alpha$. Studies by Paterson et al.¹⁹ show that macrophages have increased responsiveness to ligands for toll-like receptor 2 (TLR2) and TLR4 following burn injury. TLR2 and TLR4 are proteins that play integral roles as components of receptor complexes for various microbial products such as peptidoglycans, lipoproteins and lipopolysaccharide. Enhancement of TLR2 and TLR4 responses during the post-injury period may be one mechanism contributing to the two-hit phenomenon. T lymphocytes may also become hyper-responsive during the post-injury period. Zang et al.²⁰ showed an exaggerated response to bacterial superantigens at 1 day after burn injury in mice. Superantigens, such as staphylococcal enterotoxins, induce polyclonal activation of T cells and cause a shock syndrome that is similar to endotoxin shock. This mechanism may also contribute to the hyper-inflammatory response seen in many patients during the post-burn period.

The exaggerated response to a secondary stimulus seen in severely injured patients appears to have functional consequences. Several studies that focused on organ injury caused by systemic inflammatory processes indicate that a phenomenon comparable to the cellular events described above can occur in severely injured patients.²¹ Dehring et al. found more persistent pulmonary hypertension and an exaggerated hyperdynamic response to bacteremia in sheep when a week-old thermal injury preceded systemic bacterial challenge.²² In a rat model of intestinal ischemia-reperfusion injury and endotoxemia, lung albumin leak and mortality rate increased only if both injuries occurred.²³ Combined administration of low doses of endotoxin and $\text{TNF}\alpha$ to rats caused hypotension and metabolic effects that are commonly seen after giving a highly lethal dose of either compound alone.²⁴ These findings are in keeping with the fact that multiple organ damage usually develops over a prolonged period of time during which several insults might occur. It also emphasizes why it is so important to prevent any subsequent ischemia or other insult that can initiate a systemic inflammatory response, particularly in patients in whom systemic inflammation is already present.

Cytokine and non-cytokine mediators of SIRS

Several proinflammatory cytokines, chemokines, and non-cytokine inflammatory mediators play a role in the pathogenesis of SIRS. Cytokines comprise a broad group of polypeptides with varied functions within the immune response (Table 22.2). The classical mediator of systemic inflammation is $\text{TNF}\alpha$. $\text{TNF}\alpha$ is released primarily by macrophages within minutes of local or systemic injury and modulates a variety of immunologic and metabolic events.²⁵ At sites of local infection or inflammation, $\text{TNF}\alpha$ initiates an immune response that activates antimicrobial defense mechanisms and, once the infection is eradicated, tissue repair. It is a potent activator of neutrophils and mononuclear phagocytes, and also serves as a growth factor for fibroblasts and as an angiogenesis factor. However, systemic release of $\text{TNF}\alpha$ can precipitate a destructive cascade of events that can result in tissue injury, organ

TABLE 22.2 CYTOKINE MEDIATORS OF SYSTEMIC INFLAMMATION

Cytokine	Polypeptide size	Cell source	Cell target	Primary effects
Tumor necrosis factor- α (TNF α)	17kDa	Monocytes, macrophages, T lymphocytes	(a) Neutrophil (b) Endothelial cell (c) Hypothalamus (d) Liver (e) Muscle, fat (f) Heart (g) Macrophages (h) T lymphocytes (i) Various tissues	Activation (inflammation) Activation (inflammation/ coagulation) Release of vasodilators (NO) Fever Acute phase response Catabolism Myocardial suppression Release of cytokines, inflammation Inflammation Apoptosis?

Interleukin-12 (IL-12)	70 kDa	Macrophages	T cells, B cells, NK cells	Activation, differentiation
Interleukin-18 (IL-18)		Macrophages	T cells, NK cells	Activation, differentiation

dysfunction and, potentially, death. Among the systemic effects of TNF α are the induction of fever, stimulation of acute phase protein secretion by the liver, activation of the coagulation cascade, myocardial suppression, induction of systemic vasodilators with resultant hypotension, catabolism, and hypoglycemia.^{25,26} Numerous studies have shown that administration of TNF α to experimental animals will mimic the systemic inflammatory response observed in sepsis and after severe injury. Another important effect of TNF α is its ability to induce apoptosis of a variety of cell types.²⁷ TNF-induced apoptosis may be one mechanism by which it induces tissue injury at high systemic concentrations.

TNF α is also a potent stimulus for the release of other inflammatory mediators, particularly IL-1 and IL-6. IL-1 is released primarily by mononuclear phagocytes and its physiologic effects are essentially identical to those of TNF α .²⁸ However, important differences between the functions of IL-1 and TNF α exist. Most notably, IL-1 does not induce tissue injury or apoptotic cell death by itself but can potentiate the injurious effects of TNF α . The IL-1 family of proteins, including IL-18, are the only group of cytokines for which known natural antagonists have been identified. The IL-1 receptor antagonists (IL-1ra) bind to the IL-1 receptor but do not induce receptor activation.²⁸ These proteins appear to function as competitive inhibitors of IL-1 action.

IL-6 is another protein that is commonly increased in the circulation of patients with SIRS.²⁸ Macrophages, endothelial cells, and fibroblasts secrete this protein. Interleukin-6 itself does not induce tissue injury but its presence in the circulation has been associated with poor outcome in trauma patients, probably because it is a marker of ongoing inflammation. The primary effect of IL-6 is to induce secretion of acute phase proteins from the liver as well as serve as a growth and differentiation factor for B lymphocytes.

Interferon γ (IFN- γ) is a cytokine involved in the amplification of the acute inflammatory response, particularly the stimulation of cytokine secretion, phagocytosis, and respiratory burst activity by macrophages. IFN- γ is secreted primarily by T lymphocytes and natural killer (NK) cells in response to antigen presentation as well as macrophage-derived cytokines such as IL-12 and IL-18. The primary effect of IFN- γ is to amplify the inflammatory response of macrophages. In response to IFN- γ , the phagocytic and respiratory burst activity of macrophages are increased, secretion of inflammatory mediators such as TNF α and IL-1 are enhanced, and antigen presentation is potentiated by upregulation of class II major histocompatibility complex. Blockade of IFN- γ production or function has been shown to markedly decrease the deleterious inflammatory effects induced by bacterial endotoxin.²⁹ Therefore, IFN- γ is believed to be an important factor in the amplification of SIRS.

Chemokines are a family of proteins that function primarily as chemotactic factors for leukocytes (Table 22.3). Interleukin-8 is the most widely studied chemokine in the setting of sepsis and SIRS; it is a potent chemoattractant for neutrophils and is a major factor in recruiting neutrophils to inflammatory foci. Several studies have shown that IL-8 plays a role, particularly in the lung, in mediating tissue injury in the setting of trauma and burn injury.³⁰ It is likely that that other chemokines also

play a role in inflammatory injury. A recent study demonstrated increased circulating levels of macrophage inflammatory protein-1 α (MIP-1 α) in patients with SIRS.³¹

Upregulation of most soluble mediators of inflammation is regulated at the transcriptional level. Some of the key transcription factors that control pro-inflammatory gene expression include nuclear factor- κ B (NF- κ B), AP-1 and STAT1 (Figure 22.2). During the last 20 years, NF- κ B has emerged

TABLE 22.3 CLASSIFICATION OF CHEMOKINES

Chemokine type	Target cell	Chemokine type	Target cell
α Chemokines			
IL-8	Neutrophils	GCP-2	Neutrophils
GRO α (mouse equivalent is GRO/KC)	Neutrophils	PF4	Fibroblasts
GRO β (mouse equivalent is GRO/KC)	Neutrophils	Mig	T lymphocytes
GRO γ (mouse equivalent is GRO/KC)	Neutrophils	IP-10	T lymphocytes
ENA-78	Neutrophils	I-TAC	T lymphocytes
LDGF-PBP	Neutrophils, fibroblasts	SDF-1 α/β	T lymphocytes
β Chemokines			
MIP-1 α	Monocyte/macrophages, T lymphocytes, B cells, NK cells, basophils	DC-CK-1	T lymphocytes
MIP-1 β	Same as above	MIP-3 α	T lymphocytes
MDC	Monocyte, T lymphocytes	MIP-3 β	T lymphocytes
TECK	Macrophages, T lymphocytes	MCP-1	T lymphocytes, monocytes
TARC	T lymphocytes	MCP-2	Same
RANTES	Monocyte/macrophages, T lymphocytes, NK cells, basophils	MCP-3	Same
HCC-1	Monocytes	MCP-4	Same
HCC-4	Monocytes, lymphocytes	Eotaxin	Eosinophils
Other chemokines			
Lymphotactin	T lymphocytes, NK cells	Fractalkine	T lymphocytes, monocytes

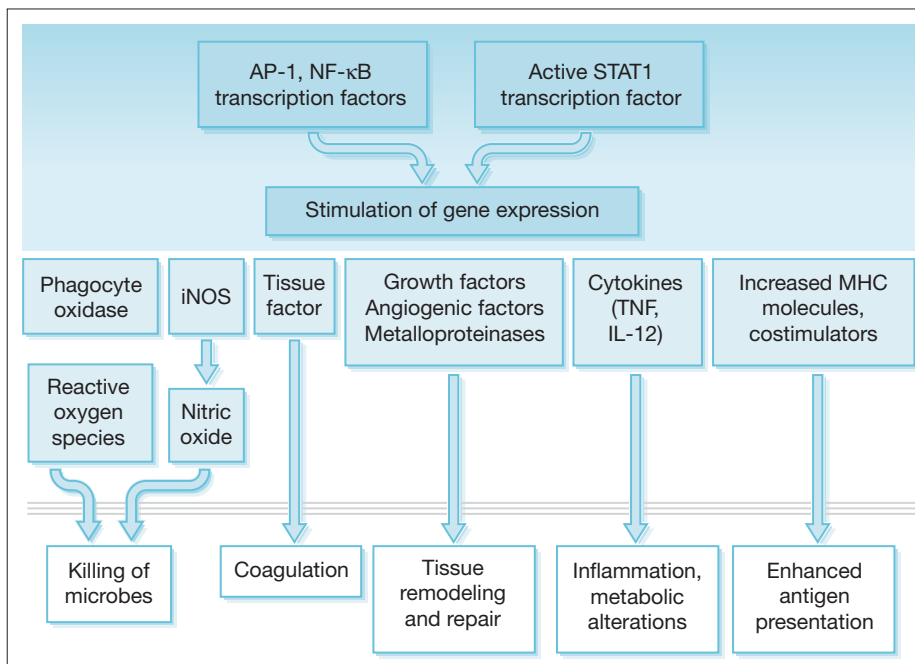

Fig. 22.2 Regulation of pro-inflammatory gene expression. Inflammatory stimuli induce activation of transcriptional pathways mediated by NF- κ B, AP-1 and STAT1 that result in production of pro-inflammatory mediators. (From Cotran R, Kumar V, Collins T, eds. Robbins Pathologic basis of disease, 6th edn. Philadelphia: WB Saunders; 1999: 75.)

as a central regulator of the inflammatory process.³² NF- κ B is composed of a family of proteins including p50 (NF- κ B1), p65 (RelA), C-Rel, and p52 (NF- κ B2) that combine to form homo- or heterodimers and ultimately function to regulate the transcription of a variety of cytokine, chemokine, adhesion molecule, and enzyme genes involved in SIRS. Increased activation of NF- κ B has been associated with poor outcome in some studies. Activation of NF- κ B in peripheral blood monocytes correlates with increased mortality in septic patients, and alveolar macrophages from patients with adult respiratory distress syndrome (ARDS) exhibited greater nuclear NF- κ B levels than critically ill patients without ARDS.^{33,34} The AP-1 complex is activated through activation of the protein kinase JNK by stimuli that are similar to those required for NF- κ B mobilization. The STAT1 pathway is induced by activation of the IFN- α receptor on phagocytes.

Several non-cytokine factors have been implicated in the pathogenesis of SIRS. Platelet activating factor (PAF) is a phospholipid autocoid released by endothelial cells that regulates the release of cytokines and amplifies the pro-inflammatory response. It appears to be an important factor in the adhesion of neutrophils to endothelial cells. The prolonged presence of PAF in the serum of patients with SIRS has correlated with poor outcome.³⁵ Eicosanoids are arachadonic acid metabolites that regulate many aspects of the immune response. Leukotrienes (LTC₄-LTE₄) induce contraction of endothelial cells and encourage capillary leakage.³⁶ Thromboxane A₂, a macrophage and platelet-derived factor, promotes platelet aggregation, vasoconstriction and, potentially, tissue thrombosis.³⁷

The complement cascade is composed of more than 30 proteins that interact in a complex fashion to mediate inflammation and direct lysis of microbes and other cells (Figure 22.3). However, in SIRS, excessive complement activation appears to cause significant cellular injury in the host. Products of the complement cascade, most notably C3a and C5a, are potent activators of inflammation and leukocyte chemotaxis.³⁸ C3a

and C5a also directly activate neutrophils and promote release of reactive oxygen intermediates and proteases. Excessive release of these factors can result in significant tissue injury. The membrane attack complex (MAC) is the terminal component of the complement cascade. MAC results from the aggregation of the complement components C5–C9 on biological membranes. The accumulation of MAC on cell surfaces can result in significant tissue and cellular injury and may be a major factor in the pathogenesis of MODS.

Circulating cytokines as markers of SIRS and predictors of outcome

Numerous studies have been undertaken with the goal of using plasma cytokine levels as diagnostic and prognostic markers in patients with SIRS. This approach seems logical based on the observation that circulating cytokines have been observed in several clinical studies of trauma, sepsis, and thermal injury. Given its central role in the activation and regulation of the pro-inflammatory response, TNF α has been studied extensively as a plasma marker of SIRS. The results have been inconsistent. Martin et al.³⁹ showed that TNF α levels were markedly elevated in patients with septic shock and correlated with fatal outcome. However, their results also showed that trauma patients did not exhibit the same marked elevations in circulating TNF α nor did circulating TNF α concentrations correlate with increased mortality in trauma patients. In some published studies, measurement of circulating TNF α levels in burn patients has not provided a useful marker of outcome.^{40,41} Overall, plasma TNF α levels have been variable and inconsistent and have not correlated with mortality or the development of MODS. However, a study by Zhang et al.⁴² in 25 patients with greater than 30% total body surface area (TBSA) burns demonstrated marked increases in plasma TNF α levels in burned patients and a significant correlation between TNF α concentration and shock, MODS, and death. These findings support the results of Marano et al.,⁴³ who showed a significant correlation between circulating TNF α concentration and mortality in burned patients. Therefore, taken together, these results show that the value of TNF α as a marker of ongoing inflammation as well as an indicator of morbidity and mortality in the setting of burn injury remains to be established.

TNF α interacts with two known cell surface receptors designated tumor necrosis factor receptor (TNFR)-I and TNFR-II. TNFR-I, also known as TNF-R55 or p55, is expressed on a variety of cells and its activation mediates most of the activities of TNF α , including induction of apoptosis. Activation of TNFR-II (TNF-R75 or p75) results in cellular proliferation and activation. During inflammatory states, TNFR are released from cells and may serve as antagonists of TNF α . Several investigators have characterized surface-bound and soluble TNFR (sTNFR) in sepsis and trauma.^{42,44,45} Hubl et al.⁴⁴ showed that surface TNFR-I were upregulated while TNFR-II were downregulated in patients with SIRS. Increased TNFR-I correlated with increased body temperature but not with survival. SIRS patients with decreased surface TNFR-II had a trend toward increased mortality. A study by Zhang et al.⁴² showed a higher incidence of shock, MODS, and mortality in burn patients with increased plasma sTNFR-I and sTNFR-II levels. Presterl et al.⁴⁵ showed a correlation between sTNFR and

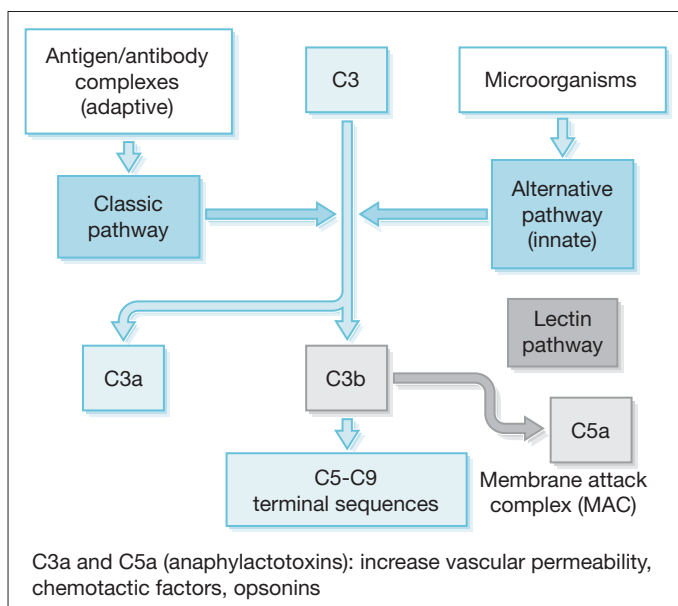

Fig. 22.3 The complement cascade. The complement cascade can be activated through three distinct mechanisms and plays an important role in innate and acquired inflammatory responses.

APACHE III scores, as well as the incidence of shock and mortality in septic patients. Overall, in the studies published to date, the presence of high levels of circulating sTNFR is a poor prognostic indicator.

Another family of proteins that has been extensively analyzed as markers of SIRS is IL-1 and IL-1 receptor antagonist (IL-1ra). In burn patients, low IL-1ra levels have correlated with mortality in two independent studies.^{41,42} Plasma IL-1ra levels have been shown to correlate with body surface area burned, extent of third-degree burn, and the presence of inhalational injury.^{41,46}

Of the cytokine markers studied to date, elevated levels of IL-6 appear to be one of the more consistent markers of poor outcome in burn, trauma, and septic patients. One of the primary known functions of IL-6 is induction of acute phase proteins such as C-reactive protein (CRP) by the liver. In some studies, CRP has been shown to parallel IL-6 as a marker of increased mortality.⁴⁷ Although IL-6 itself does not have any known direct injurious effects, it apparently serves as a consistent marker of ongoing inflammation. Elevated plasma IL-6 levels have correlated with increased mortality in experimental and clinical studies of thermal injury, sepsis, trauma, and hemorrhagic shock.^{45,48,49} A study by Taniguchi et al.⁴⁹ showed that an increased ratio of IL-6 to the anti-inflammatory cytokine IL-10 was a predictor of poor outcome in patients with SIRS.

In trauma and burn patients it is often difficult to differentiate whether SIRS is a result of the injury itself or due to superimposed infection. Most of the clinical signs of infection, such as fever and leukocytosis, are, by definition, present in SIRS. Considerable attention has been placed on identifying indirect markers of systemic infection. The identification of circulating markers of infection that can be rapidly assessed and serve as reliable markers of the presence of infection has important implications. First, it is important clinically to identify patients with systemic infection in order to initiate antibiotic therapy in a timely fashion. Secondly, blood cultures are the gold standard for diagnosis of systemic infections. Although blood cultures provide important information regarding the presence of infection and the identity of the infecting organism, it can often take several days to obtain reliable results, and the presence of negative cultures does not assure the absence of infection. Therefore, efforts have been made to identify other markers of systemic infection. The two markers that have been most consistently elevated in patients with infection are procalcitonin and CRP. Studies have shown that increased plasma levels of procalcitonin are a sensitive marker of systemic infection.⁵⁰ Likewise, increased circulating CRP has been shown to be a sensitive marker of infection.^{51,52} Both of these markers have been shown to be more reliable than clinical signs in the diagnosis of infection in high-risk surgical and trauma patients.

Overall, several markers of inflammation and infection have been identified in burn and trauma patients. Some of these markers have been shown to be consistent indicators of high-risk patients. However, cytokine and non-cytokine markers of inflammation are not used routinely in the laboratory evaluation of burned patients. With further research and demonstration of the reliability of these markers, they may become an accepted part of clinical practice. In addition, technology is evolving to measure these markers in a rapid and cost-

effective manner. The combination of these factors may allow blood cytokine markers to become a component of patient management in the future.

Anti-inflammatory therapy for SIRS

Despite our increased understanding of the role of inflammatory mediators in the pathogenesis of SIRS, most anti-inflammatory drug regimens have had little success in the treatment of this problem. Neutralizing approaches to several inflammatory mediators have been studied. All of these studies have demonstrated, at best, marginal improvement in septic morbidity and mortality. One of the most widely studied approaches for the treatment of SIRS is the use of monoclonal antibodies to TNF α . Several multicenter, prospective, clinical trials have been undertaken in septic patients using several different antibodies to TNF α .^{53,54} These studies did not demonstrate improved outcome in patients receiving anti-TNF α compared to placebo. One recent study evaluated the efficacy of a chimeric antibody to TNF in patients with severe sepsis.⁵⁴ Circulating levels of TNF α as well as a variety of other inflammatory mediators were assessed. Although circulating levels of TNF α were transiently decreased, anti-TNF α therapy did not result in reduction of circulating levels of other inflammatory mediators such as IL-1 β , IL-1ra, sTNFR, or IL-6. In addition, evidence of systemic inflammation was not decreased and overall mortality was not improved in anti-TNF α -treated patients. Similarly, the use of sTNFR as a strategy to neutralize the systemic effects of TNF α and decrease sepsis-associated morbidity and mortality has been unsuccessful.^{55,56} Other anti-inflammatory approaches that have been studied and found to be largely ineffective include the use of IL-1ra,^{57,58} anti-bradykinin,⁵⁹ PAFra,^{60,61} and ibuprofen.^{62,63}

Because of the relative ineffectiveness of anti-inflammatory therapy aimed at neutralizing single mediators, more broad-based strategies were developed with the goal of neutralizing, removing, or inhibiting the production of several inflammatory mediators. Hemofiltration was one approach that received considerable attention. Several studies have shown that hemofiltration will increase the clearance of inflammatory mediators, particularly IL-6, from blood in patients with sepsis.^{64,65} However, none of these studies has demonstrated a significant reduction in IL-6 plasma levels. A study by Kellum et al.⁶⁵ showed that continuous venovenous hemofiltration (CVVH) reduced plasma TNF α concentrations by 13%, while the use of continuous venovenous hemodialysis (CVVHD) resulted in a 32% increase in circulating TNF α levels. Overall, the use of hemofiltration has been largely ineffective in removing significant amounts of inflammatory mediators from the blood of patients with sepsis and there is currently no evidence that this approach will decrease morbidity and mortality.

The use of glucocorticoids in the treatment of sepsis has been proposed for more than 30 years. A meta-analysis⁶⁶ of studies using high-dose glucocorticoids in the treatment of sepsis was published in 1995 and later summarized by Zeni et al.⁶⁷ Overall, the use of high-dose glucocorticoids to treat sepsis and septic shock has not been beneficial. In many studies, the use of glucocorticoids in septic patients was associated with increased mortality. In burned patients, there is no evidence that administration of glucocorticoids provides effective

treatment for systemic inflammation. More recent studies show that replacement dose steroids will improve survival in septic patients that have adrenal suppression.³⁹ Some practitioners now advocate the use of replacement dose glucocorticoids in septic patients that are refractory to conventional management.⁶⁸

Reasons for the lack of efficacy of these anti-inflammatory strategies are likely to be multifactorial. First, the inflammatory response to injury and sepsis is mediated by a complex array of mediators that are largely interrelated. Therefore, blocking or neutralization of a single mediator is not likely to have a marked effect on the overall response. Secondly, the same mediators that are important in inducing tissue injury also play an important role in antimicrobial immunity. Blockade of these mediators may leave the host more susceptible to subsequent infection. Thirdly, many of the mediators, particularly TNF α and IL-1 β , are released within minutes of injury and mobilize the inflammatory cascade shortly thereafter. Therefore, by the time that signs of SIRS or sepsis are apparent, many of the injurious effects of the inflammatory response have already been set into motion, making therapy ineffective. A recent emphasis has been placed on the identification of late mediators of inflammatory injury. This search has been prompted by the observation that SIRS and sepsis-associated death occur days after the peak effect of inflammatory cytokines. One potential late mediator that has recently been identified is high-mobility group protein-1 (HMG-1).⁶⁹ HMG-1 is released by macrophages up to 8 hours after LPS challenge and persists in the circulation for days. Administration of anti-HMG-1 in mice has been shown to improve survival. Conversely, systemic administration of HMG-1 to mice is lethal.

Whether HMG-1 plays an important role in inflammatory injury in humans remains to be determined. However, the concept of late mediators of inflammatory tissue injury may improve our understanding of the pathophysiology of SIRS.

As discussed earlier in this chapter, factors that appear to be important in limiting the extent of SIRS and, in many cases, decreasing the incidence of shock and MODS, are aggressive fluid resuscitation, excision of necrotic tissue, and adequate nutritional support.⁷⁰ There is controversy regarding the ideal fluid for volume resuscitation in trauma and burn patients. However, recent studies show that hypertonic saline has beneficial effects in modulating the SIRS-associated immunological cascade as well as restoring hemodynamic parameters and microcirculatory flow. The effect of hypertonic saline on immune function has largely centered on attenuation of post-injury immunosuppression. Recent studies have shown that resuscitation with hypertonic saline will improve macrophage and T cell function as well as increase resistance to infection in experimental models or trauma and hemorrhage.⁷¹ Proper nutritional support is also an important factor in the treatment of severely injured patients. Enteral feeding formulas supplemented with glutamine, arginine, omega-3 fatty acids, and nucleotides have been shown to improve outcome in trauma patients.^{72,73} Overall, trauma patients receiving immune-enhancing diets have been shown to have fewer infectious complications.

More recently, Metz and Tracey have described a cholinergic anti-inflammatory pathway that may be important in the regulation of inflammation and could be exploited for therapeutic benefit.^{74,75} As described, local inflammation activates afferent fibers of the vagus nerve that signal the brain to elicit an anti-

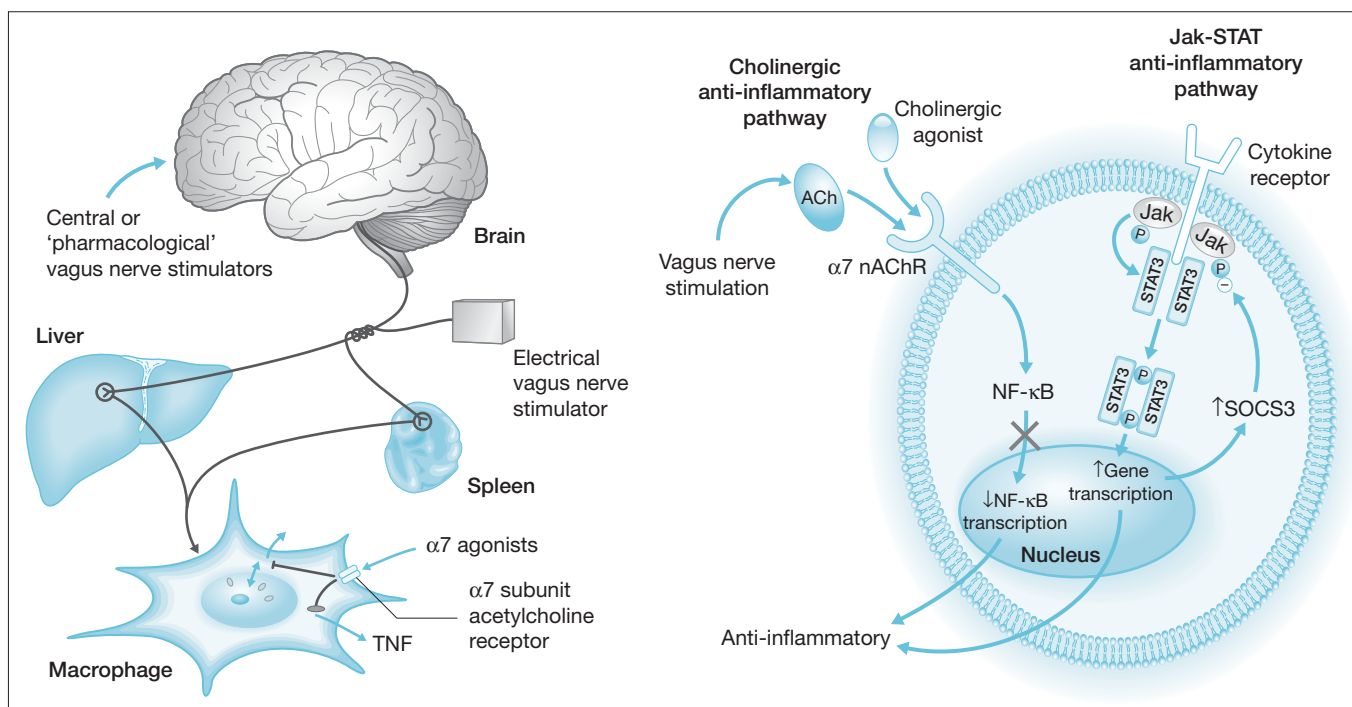

Fig. 22.4 The cholinergic anti-inflammatory pathway. Tissue inflammation sends afferent signals to the central nervous system resulting in activation of the cholinergic anti-inflammatory pathway. Release of acetylcholine by the vagus nerve induces anti-inflammatory effects by binding to nicotinic receptors on the surface of leukocytes. (Adapted from Czura CJ, Tracey KJ. Autonomic neural regulation of immunity J. *Int Med* 2005; 257:156–166; Metz CN and Tracey KJ. It takes nerve to dampen inflammation. *Nat Immunol* 2005; 6:756–757. Reprinted by permission from Macmillan Publishers Ltd.)

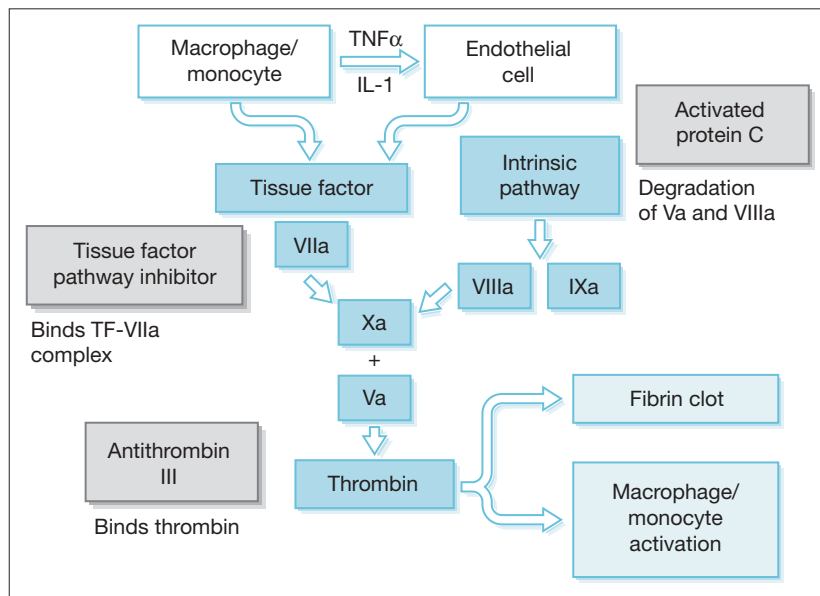

Fig. 22.5 Regulation of the coagulation cascade during inflammation. Inflammation primarily causes activation of the extrinsic coagulation pathway.

inflammatory response through efferent vagal fibers (Figure 22.4). Acetylcholine released by the vagus interacts with $\alpha 7$ nicotinic acetylcholine receptors ($\alpha 7$ nAChR) on macrophages and suppresses the production of pro-inflammatory mediators. These investigators have shown that electrical stimulation of the vagus nerve will attenuate the pro-inflammatory response induced by cecal ligation and puncture or endotoxin challenge. Acetylcholine has also been shown to inhibit the release of pro-inflammatory cytokines by cultured macrophages following endotoxin challenge.^{74,75} More specific $\alpha 7$ nAChR agonists are under investigation for the treatment of hyperinflammatory states.

Activation of the coagulation cascade during inflammation

Inflammation and coagulation are intimately intertwined. The coagulation cascade is activated during tissue injury and during infection. It is divided into two pathways that converge and ultimately cause the activation of thrombin with subsequent cleavage of fibrinogen into fibrin (Figure 22.5). The intrinsic pathway is a series of plasma proteins that are activated by Hageman factor (factor XII), a protein synthesized in the liver that is activated by binding to collagen, basement membrane or activated platelets.⁷⁶ Activated Hageman factor triggers a cascade of proteins to become activated, resulting in the formation of thrombin. The intrinsic pathway is most commonly activated by direct tissue trauma. In contrast, the extrinsic pathway is initiated by the production of tissue factor. Recent studies indicate that the extrinsic pathway is the primary coagulation pathway activated during infection and systemic inflammation, particularly during sepsis and the SIRS.⁷⁶ Tissue factor is expressed on tissue surfaces that are not normally exposed to the vascular compartment such as subcutaneous tissues and the adventitial layer of blood vessels. In addition, endothelial cells and activated monocytes produce tissue factor during periods of inflammation in response to

TNF α , IL-1, IL-6 and CRP.¹⁷ The presence of tissue factor causes activation of factor VII, which then forms a complex with tissue factor and ultimately causes the formation of thrombin by the activation of a series of coagulation factors (Figure 22.5). Activation of the coagulation cascade is not only important in the formation of fibrin clots but also has important effects on the pro-inflammatory response. Factor Xa, thrombin and the tissue factor–VIIa complex have been shown to elicit pro-inflammatory activity. Specifically, thrombin and the tissue factor–VIIa complex can induce production of pro-inflammatory cytokines such as TNF α by mononuclear and endothelial cells.⁷⁷ This effect appears to be mediated by the binding of these factors to protease-activated receptors on the surface of target cells. Therefore, acute inflammation causes activation of the coagulation cascade, which can then further potentiate the inflammatory response.

Activation of the clotting cascade during inflammation is limited by several factors. This is important because it prevents uncontrolled induction of procoagulant mechanisms. The most well-defined factors are antithrombin, the protein C system and the tissue factor pathway inhibitor. Antithrombin is produced in the liver and directly binds and inactivates thrombin.⁷⁸ The binding of antithrombin to thrombin is greatly potentiated by heparin and by glycosaminoglycans present on the endothelial cell surface. In rodents, interaction of antithrombin with the endothelial cell surface promotes the release of PGI₂, which inhibits TNF α production by monocytes through inhibition of transcription factor NF- κ B activation.⁷⁹ Thus, antithrombin may have anti-inflammatory properties in addition to its function in regulating coagulation.

Protein C is a circulating protein that is activated by the thrombin–thrombomodulin complex on the surface of endothelial cells (Figure 22.6). Activation of protein C decelerates the clotting cascade by inactivating factors Va and VIIIa.⁸⁰ Activated protein C also inhibits thrombin-induced production of TNF α by monocytes by inhibiting the activation of transcription factors NF- κ B and AP-1 (to be discussed).⁸¹ There-

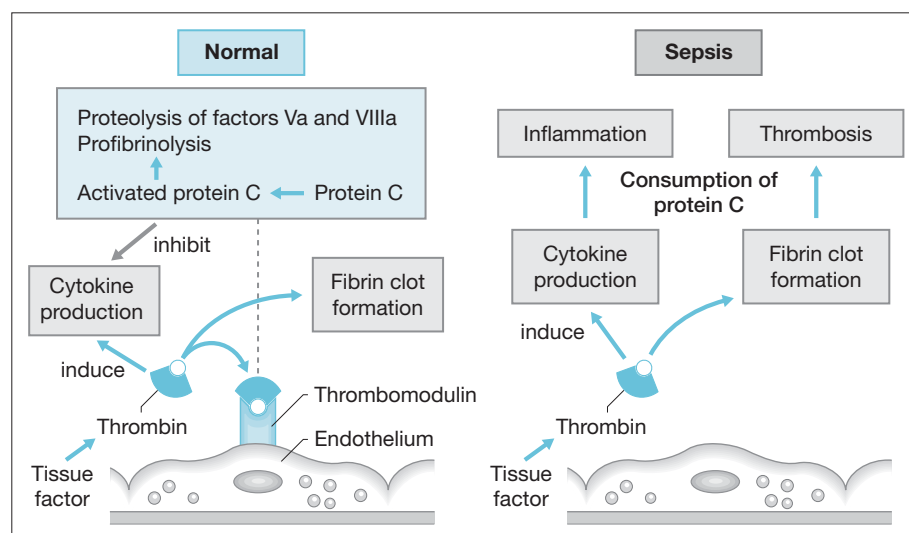

Fig. 22.6 Biology of protein C during inflammation. Activated protein C can become consumed during severe inflammation, resulting in hypercoagulability and amplification of the inflammatory response.

fore, activated protein C has both anticoagulant and anti-inflammatory properties. During sepsis, activated protein C levels can become depleted due to consumption and inflammation-induced downregulation of thrombomodulin. This results in unchecked formation of thrombin, causing accelerated coagulation and increased pro-inflammatory activity. The importance of protein C in regulating thrombin formation during sepsis is demonstrated by increased mortality in septic patients that have low activated protein C levels.⁸²

A third important factor in the regulation of thrombin formation is the tissue factor pathway inhibitor (TFPI). TFPI is present on the surface of endothelial cells and bound to lipoproteins in plasma. TFPI inactivates tissue factor by forming a quaternary complex with tissue factor and factor VIIa. Factor Xa is the fourth component of the complex.⁸³ Inhibition of tissue factor function inhibits activation of the extrinsic clotting pathway during inflammation. Infusion of TFPI has also been shown to decrease pro-inflammatory cytokine production during endotoxin infusion in baboons, but not in humans.

The hemodynamic response

The full clinical picture of systemic inflammation after thermal injury, multiple trauma, or sepsis includes a hyperdynamic circulation. It is characterized by a low systemic vascular resistance, which requires a high cardiac output to maintain mean arterial pressure. This fall in resistance is not the result of an increase in metabolic rate. The oxygen extraction of the tissues remains the same. Blood is thus flowing to tissues that are not metabolically active. Patients who are not well resuscitated or whose heart function is compromised may not be able to increase their cardiac output to the extent needed to maintain arterial pressure during states of extensive vasodilatation and, thus, might go into shock. A reduced vascular responsiveness to vasoconstrictors finally prevents successful pharmacologic intervention and patients might die in irreversible shock. The time period from insult until the hyperdynamic response develops can vary between hours after a septic insult

or days after multiple trauma. It has been hypothesized that the development of the hyperdynamic state might be dependent on the presence of endotoxin or bacteria in the blood. An intravenous bolus injection of 4ng/kg endotoxin into healthy volunteers mimics some aspects of the hemodynamic response seen in patients.^{84,85} The low systemic vascular resistance and the elevated cardiac output can also be induced in animal models by continuous infusion of low-dose endotoxin⁸⁶ or bacteria.⁸⁷ Studies in conscious sheep revealed that the hemodynamic response to continuous low-dose endotoxin can be divided into three parts.⁸⁸ The first two phases might be missed under clinical conditions most of the time due to their short duration (<3 hours).

Phase 1

Systemic vascular resistance and pulmonary vascular resistance increase markedly both upon intermittent administration of endotoxin⁸⁹ or during its continuous infusion into conscious sheep.⁹⁰ This reaction occurred within 30 minutes to 1 hour of the endotoxin administration and was attributed to the release of the potent vasoconstrictor thromboxane (TX) A₂. Lymph and plasma levels of TXB₂, the stable metabolite of the eicosanoid TXA₂, were found elevated 1 and 4 hours after challenge of sheep with 1μg/kg endotoxin.⁹¹ Cyclooxygenase⁹² and thromboxane synthetase inhibition diminished the hypertensive response.⁹¹ Thromboxane synthetase inhibition was equally effective in preventing the marked pulmonary vasoconstriction after burn injury in pigs.⁹³ The high pulmonary vascular resistance during phase 1 of endotoxemia has been demonstrated to compromise myocardial function of the right heart in terms of a low ejection fraction and an increase in end-systolic diameter.^{91,94} Administration of the thromboxane synthetase inhibitor OKY046 blocked these early changes in right heart function.⁹⁴

The early systemic vasoconstriction did not occur equally throughout the vasculature. Blood flow through the superior mesenteric artery was particularly reduced.⁹⁵ Vasoconstriction of the splanchnic vessels has been associated with the release of so-called myocardial depressant factors⁹⁶ and with bacterial

translocation.⁹⁵ The coincidence of markedly decreased mesenteric blood flow and bacterial translocation has also been demonstrated after burn injury⁹⁷ and multiple trauma associated with a state of circulatory shock.⁹⁸ Moreover, hypoperfusion, particularly of the ileal mucosa, was still noted during the hyperdynamic phase in a murine sepsis model, when blood flow to most of the splanchnic area was not decreased.⁹⁹ Bacterial translocation has been hypothesized to be one of the major factors maintaining systemic inflammation.

Phase 2

This portion of the response, between 3 and 4 hours after the endotoxin infusion has been started, is characterized more by pulmonary permeability changes (see below) than by hemodynamic alterations. In the hyperdynamic sheep model, the pulmonary artery pressure is mildly elevated and cardiac output demonstrates the lowest values throughout the experiment. The underlying mechanisms of this response are not yet clear. Many mediators of the immune system have been released by that time, including TNF α , IL-6, PAF, and peptidoleukotrienes.¹⁰⁰ This might indicate that these mediators are proximal elements of the mediator cascades. Although investigations into the release of many of these cytokines are few as a result of the limitations of respective assays, TNF α has been shown to be increased in both phase 1 and 2 of the response in sheep^{100,101} and volunteers.^{102,103} Moreover, the vasoconstrictor endothelin is elevated in the chronic sheep model of endotoxemia at that time,¹⁰⁴ as well as the vasodilator atrial natriuretic peptide.^{105,106} Endothelin has also been correlated with reductions in cardiac output in septic humans.¹⁰⁷ The hemodynamic changes in phase 2 are most likely the result of the action of the mediator cocktail.

Phase 3

Continuous infusion of endotoxin into sheep and pigs resulted in a hyperdynamic circulation.^{90,108,109} Beside a low systemic vascular resistance and a high cardiac output with a slightly decreased mean arterial pressure, the hyperdynamic response is further characterized by hyporesponsiveness of isolated vessels to vasoconstrictors¹¹⁰ and an increased pulmonary shunt fraction in the presence of a reduced pulmonary hypoxic vasoconstriction.^{90,111,112} The high cardiac output is due to an increase in heart rate in the presence of depressed myocardial contractility.^{113,114}

Nitric oxide

The endothelium-derived relaxing factor, recently identified as nitric oxide (NO), has been implicated as a mediator in this reaction. NO can be synthesized from its precursor L-arginine by two different enzymes. The calcium-dependent constitutive nitric oxide synthase (NOS) is responsible for the basal release of NO, which seems to play an important role for the regulation of vascular tone under physiologic conditions (Figure 22.7). *In vitro* data suggest that this enzyme might become inactivated early after administration of endotoxin, thus accounting for some of the vasoconstrictive phenomena seen in phases 1 and 2.¹¹⁵ Dependent on the species, cells producing the inducible NOS include macrophages, vascular smooth muscle cells, and vascular endothelium upon stimulation by endotoxin, TNF α , IL-1, or IFN- α .¹¹⁶

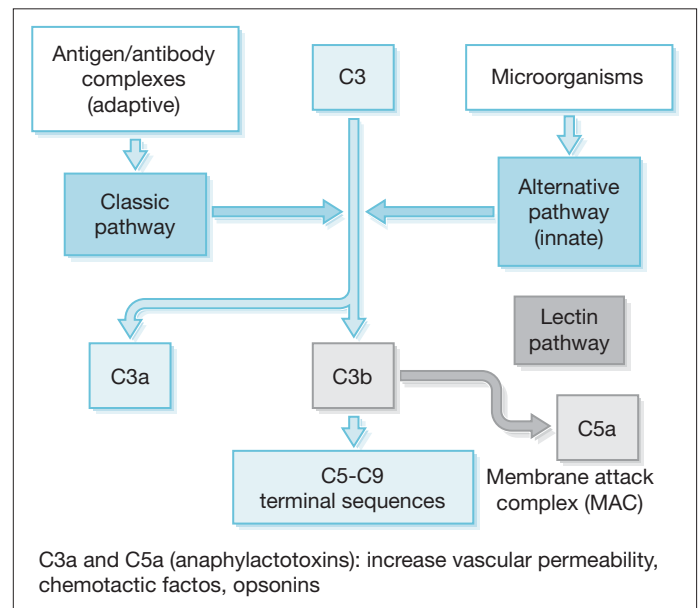

Fig. 22.7 Nitric oxide during SIRS. Activation of nitric oxide synthase isoforms, particularly eNOS and iNOS, causes vascular smooth muscle relaxation during severe inflammation.

On the other hand, it has recently been reported that the human macrophage cannot form NO under these circumstances.^{117,118}

NO is a lipophilic gas which can easily enter vascular smooth muscle cells where it stimulates the soluble guanylate cyclase^{119,120} to synthesize cyclic guanosine monophosphate (cGMP). High levels of cGMP stimulate cells to lower their intracellular Ca²⁺ concentration. This leads to vascular dilatation and hyporesponsiveness to vasoconstrictors. Administration of an NOS inhibitor to septic humans^{121,122} and to endotoxemic sheep^{90,123} increases their vascular resistance and restores their responsiveness to vasoconstrictors. It was assumed that the hemodynamic abnormalities mediated by NO formed via the inducible NOS. However, plasma concentrations of nitrite/nitrate and nitrosylated proteins were not elevated during *ovine* endotoxemia. Species specificity was also indicated by the finding that human macrophages do not produce the inducible form of NOS. However, the inducible form of the enzyme seems to be present in human hepatocytes. Elevated nitrite levels were reported in one study evaluating septic newborns.¹²⁴ There are currently no convincing data available with regard to high nitrite levels in adult humans with SIRS. Ochoa found somewhat elevated nitrite concentrations in some septic patients, but failed to demonstrate them in septic trauma patients.¹²⁵ At this point it can neither be concluded nor can it be excluded that NO mediates the hyperdynamic response during systemic inflammation.

Guanylate cyclase

The second messenger cGMP appears to play an important role in the vasodilation seen with sepsis. There have been reports of cGMP elevations in plasma of septic patients¹²⁶ and endotoxic rats.¹²⁷ cGMP was elevated in tissues removed from our animals following a continuous infusion of endotoxin.¹²⁸ The guanylate cyclase occurs in a soluble and in a particulate

form.¹²⁹ The particulate form is activated by atrial natriuretic peptide (ANP).^{130,131} The soluble form has a heme group that is activated by NO. This reaction is inhibited by methylene blue and hemoglobin.¹³² There is a high probability that ANP is the source of the stimulation of guanylate cyclase during sepsis and endotoxemia, because the cGMP formed in some of the experiments was not inhibited by methylene blue or L-arginine analogs.

Atrial natriuretic peptide

We have reported a marked elevation in ANP after the injection of endotoxin into sheep.^{105,106} We have also examined our chronic sheep models and found that the increase in plasma levels of ANP was sustained with the continuous infusion of endotoxin or bacteria. ANP has also been shown to be elevated in septic humans.^{126,130} In the rat study reported above, in which the plasma levels of cGMP remained elevated despite administration of an NOS inhibitor, a marked increase in plasma levels of ANP was found.¹²⁷ ANP elevates smooth muscle cGMP^{133,134} through stimulation of particulate or membrane guanylate cyclase, which is not affected by methylene blue,^{129,130} and thereby produces vasodilation. ANP is released from the right atrium and might be the material responsible for the cGMP elevation that was seen in animal models of sepsis and humans with septicemia. Brigham's group has shown that cGMP levels were higher in the lung lymph than in the plasma, and higher in plasma from arterial than mixed venous blood, suggesting a thoracic origin for the second messenger.¹³⁵

The kallikrein–kinin system

The kallikrein–kinin system, which includes several vasoactive substances, has been shown to be activated during endotoxemia in humans¹³⁶ and in sheep.¹³⁷ However, administration of a bradykinin antagonist did not change the cardiovascular or microvascular response to endotoxin in chronically instrumented sheep.¹³⁷ Therefore, activation of this mediator cascade seems rather to be an epiphenomenon of endotoxemia.

Changes in permeability

Endothelial permeability

Endotoxemia increases microvascular permeability both in the systemic¹³⁸ and in the pulmonary circulation.¹³⁹ The lung is the organ most commonly compromised during processes that lead to systemic inflammation. Edema formation due to an increase in microvascular permeability is a hallmark of the acute lung injury. The factors that determine the transvascular fluid flux are summarized in the Starling–Landis equation:^{140,141}

$$J_v = K_f [(P_{mv} - P_i) - \alpha(\pi_{mv} - \pi_i)]$$

where: J_v is the transvascular fluid flux, K_f is the filtration coefficient (measure of the endothelial permeability to small solutes and water as well as of the permeability surface area), P_{mv} is the microvascular hydrostatic pressure, P_i is the interstitial hydrostatic pressure, α is the osmotic reflection coefficient to protein, π_{mv} is the microvascular oncotic pressure, and π_i is the interstitial oncotic pressure.

A model has been developed in sheep that allows the determination of the variables included in the Starling equation. The lymph flow draining from the efferent vessel of the caudal mediastinal lymph node has been used as a measure of the transvascular fluid flux. Using this model, changes in lymph flow and lymph protein flux were evaluated during sepsis and endotoxemia. Again, the changes in pulmonary endothelial permeability can be divided into three phases.

Phase 1

Several investigators studied lymph flow and lymph protein flux after administration of bacteria or short-time infusion of 1–2 µg/kg of endotoxin in sheep. Two phases of permeability change could be distinguished in these models.¹⁴² During phase 1 there was a high microvascular hydrostatic pressure as defined by the Gaar equation.¹⁴³ It was associated with an increase in lung lymph flow, while the lymph protein concentration was low. It was concluded that the high microvascular hydrostatic pressure was responsible for the early increase in transvascular fluid flux. As mentioned above, TXA₂ had been found to be responsible for the vasoconstriction occurring during phase 1 of the response to endotoxin. Therefore, it is not surprising that administration of the thromboxane synthetase inhibitor OKY046 prevented the rise in lymph flow during phase 1.⁹¹ This effect was also noted after blockage of the cyclooxygenase by ibuprofen.⁹² Early edema formation after burns at the site of the injury might be due to a different mechanism. Recent data suggest that a marked fall in interstitial hydrostatic pressure might occur in the injured tissue, which can explain the immediate onset of edema formation after thermal injury.^{144,145} These changes might be the result of an inhibition of the fibroblast β_1 -integrin attachment to collagen.

Phase 2

During phase 2, lymph flow continues to be high. However, the lymph protein concentration rises considerably¹⁴² and the pulmonary artery pressure is only mildly elevated. The oncotic pressure gradient between microvasculature and interstitial space is reduced during that period.¹⁴⁶ Together these data suggest that the permeability of the pulmonary endothelium to protein increases in phase 2. In fact, the reflection coefficient for total protein fell from 0.73 to 0.58, with respective changes of the reflection coefficients for albumin (0.66 to 0.5), IgG (0.76 to 0.64), and IgM (0.91 to 0.83) after 4 hours of *Escherichia coli* sepsis in sheep.¹⁴⁷ Confirmation of this hypothesis is still pending in models of endotoxemia, but it has been generally accepted that the changes in pulmonary transvascular fluid flux in phase 2 represent changes in microvascular permeability. The mechanisms of the increased microvascular permeability are still under discussion.

Endothelial cells play an important role in the development of vascular permeability. It has been hypothesized that endothelial cells can contract upon stimulation.¹⁴⁸ As a result, the intercellular gaps might increase in number and/or size, establishing the so-called capillary leak syndrome. The development of the protein-rich high-permeability edema can be ameliorated if substances are administered that raise the endothelial cell content of cyclic adenosine or guanosine monophosphate.^{149,150} Endothelial cells do not merely serve as targets

during systemic inflammation. They actively contribute to the ongoing inflammatory process. Their role in the inflammatory reaction has been estimated so highly that even the term 'endothelial inflammation' has been used to describe it. The endothelial cell can be stimulated by endotoxin, TNF α , or IL-1 to express E-selectin, an adhesion molecule.¹⁵¹ E-selection on the surface of endothelial cells interacts with the corresponding L-selection complex on PMNs to facilitate rolling of these cells along the endothelium.¹⁵² Moreover, endothelial cells secrete the pro-inflammatory cytokine IL-1,¹⁵³ which activates PMNs.

Conflicting data exist regarding the role of PMNs in SIRS. PMNs are usually found at the site of tissue injury, to which they migrate following a concentration gradient of chemotactic stimuli. Upon stimulation, PMNs roll along endothelial cells, and in a further step, after interaction of the PMN CD11/18 integrin with its ligand, the intercellular adhesion molecule (ICAM-1), the PMN can emigrate from the vessel into the interstitial space. Antibodies against the common CD18 β chain showed beneficial effects in an animal model of sepsis-induced lung injury.¹⁵⁴ On the other hand, patients who are deficient in CD18 have abundant PMNs in their alveolar spaces. In addition, the monoclonal antibody 60.3 was ineffective in completely blocking the migration of PMNs into the lung in a number of conditions.¹⁵⁵ We have recently reported that in chronic endotoxemia there were few PMNs in the lung but numerous macrophages.¹⁵⁶ Activated PMNs and macrophages secrete oxygen free radicals and proteases, which is part of their defense mechanism against bacteria. Administration of oxygen free radical scavengers and antiproteases proved to be useful in diminishing edema accumulation after endotoxin.^{157,158} However, proteases and oxygen radicals are also released by macrophages, which are already present in the tissue and by monocytes that can migrate. Animals were depleted of their granulocytes by anti-PMN antiserum¹⁵⁹ or by treatment with nitrogen mustard.¹⁶⁰ This did not prevent the changes in microvascular permeability following the administration of endotoxin. Moreover, patients deficient in PMNs would still develop the adult respiratory distress syndrome associated with sepsis.^{161,162} On the other hand, treatment of sheep or goats with hydroxyurea, which is another compound used to deplete granulocytes, was effective and diminished the fluid accumulation in the lung.¹⁶³ However, urea scavenges free radicals, which might explain its efficacy.¹⁶⁴ As the inflammatory response becomes chronic, many mediators have been released and more than one mechanism might be assumed to be responsible for the capillary leak.

Many studies were performed to evaluate the role of metabolites of the arachidonic acid for the increase in permeability. Administration of the thromboxane synthetase inhibitor OKY046 did not only reduce transvascular fluid flux in phase 1, but it was also effective in phase 2 after a bolus of endotoxin.⁹¹ Nevertheless, this does not mean that TXA₂ itself had induced the increase in permeability. Indication has been reported that TXB₂, previously assumed to be an inactive metabolite of TXA₂, might cause lung damage.¹⁶⁵ Moreover, thromboxane synthetase blockage by OKY046 reduced the plasma-conjugated dienes, which are peroxidation products of oxygen free radicals.⁹¹ Granulocyte chemiluminescence was elevated 4 hours after administration of 1.5 μ g/kg of endotoxin

to chronically instrumented sheep, indicating the production of oxygen free radicals.¹⁶⁶ Oxygen free radicals can increase microvascular permeability both by activation of endothelial cell contraction¹⁶⁷ and by damaging the endothelial cell membrane. OKY046 has been demonstrated to reverse other forms of oxygen free radical-induced lung injury.^{168,169} On the other hand, inhibition of the cyclooxygenase did not affect transvascular fluid flux during phase 2, even if TXA₂ is a cyclooxygenase metabolite.⁹² This discrepancy is still unexplained; however, prostacyclin is elevated after endotoxin administration and this material has many actions that counter the actions of thromboxane. Administration of a cyclooxygenase inhibitor will prevent the release of this salutary eicosanoid.

Microvascular damage during systemic inflammation might also be regarded as an ischemia/reperfusion injury, particularly when it was preceded by a period of intestinal hypoperfusion. Xanthine oxidase-generated oxygen free radicals have been reported to mediate changes in microvascular and epithelial permeability.¹⁷⁰ Endotoxin-induced ileal and cecal permeability was associated with an increased xanthine oxidase activity and inhibition of xanthine oxidase by allopurinol has been shown to reduce intestinal mucosal damage.^{171,172} Circulating xanthine oxidase after ischemia/reperfusion injury in rats was associated with pulmonary retention of PMNs and pulmonary capillary leak, which was diminished by pretreatment with allopurinol.¹⁷² Intravenous injection of purified xanthine oxidase, however, induced pulmonary retention of PMNs without increasing microvascular permeability. Therefore, a final evaluation of the role of xanthine oxidase in ischemia/reperfusion-induced permeability changes is not yet possible.

TNF α is one of the early mediators in systemic inflammation. It has been reported to be elevated during sepsis and endotoxemia, after hemorrhagic shock or thermal injury. It is considered as one of the most important mediators in the cascade because it has the potential to stimulate or enhance most of the steps in the inflammatory response. Moreover, administration of human recombinant TNF α reproduced most of the effects of endotoxemia, including the alterations in pulmonary microvascular permeability in the chronic sheep model.^{173,174} However, it has been questioned whether the *ovine* response to human TNF α was only related to the cytokine,⁸⁸ because contamination of the recombinant material with endotoxin is not uncommon.

TNF α also induces the secretion of PAF, which is a further early mediator of the systemic inflammation. PAF causes an increase in lung lymph flow and permeability to protein when it is infused into conscious sheep.¹⁷⁵ Administration of a PAF antagonist abolished the cardiopulmonary response that occurs during phase 1 and attenuated it during phase 2.¹⁷⁶ However, PAF had no direct effect on endothelial cells.¹⁷⁵ This suggests that it probably increased microvascular permeability through other mechanisms such as its priming effect on PMNs.¹⁷⁷

Phase 3

The hyperdynamic cardiovascular response is associated with profound changes in pulmonary transvascular fluid flux in the *ovine* model of continuous endotoxemia.^{109,139} The lymph protein concentration gradually decreased after phase 2 and after 24 hours of endotoxemia the reflection coefficient to protein was at baseline level, while the lymph flow was still

high. Microvascular hydrostatic pressure, evaluated by Holloway's technique, was not significantly different from baseline.¹⁷⁸ The elevated transvascular fluid flux was attributed to a high filtration coefficient. An increase both in perfused surface area and in pore numbers might have contributed to the change in filtration. Repeated injections of endotoxin also decreased subsequent lung lymph production in response to endotoxin.¹⁷³ These changes in lung lymph flow were associated with elevations in endothelin^{104,178} and atrial natriuretic peptide. However, further studies must determine if these factors affect the pulmonary microvascular changes during the late phases of sepsis and multiple organ failure.

Increased epithelial permeability

Permeability changes during systemic inflammation are not restricted to the endothelium. Loss of epithelial barrier function has been noted both in the lung and in the intestine. Administration of 2–4 ng/kg endotoxin to healthy human volunteers increased their alveolar epithelial permeability to the inhaled 492 Da molecule [^{99m}Tc] diethylenetriamine pentaacetate (DTPA) 3 hours after endotoxin had been given.⁸⁵ Human volunteers demonstrated a higher intestinal epithelial permeability to mannitol/lactulose.¹⁷⁹ Bacterial translocation occurred both during endotoxemia,⁹⁵ thermal injury,⁹³ and multiple trauma with hemorrhagic shock.¹⁸⁰ This might well be interpreted as a loss of intestinal barrier function. Nevertheless, one must bear in mind that epithelial permeability to molecules like lactulose/mannitol and bacterial translocation do not necessarily relate to each other. The epithelium could also be injured by ischemia/reperfusion that occurs in all of these situations.¹⁸¹

Summary

Burn injury, associated ischemia/reperfusion injury, the presence of necrotic tissue, or a septic episode might function as the initiating event of SIRS. The host response to this insult might be a localized inflammation or, if the stimulus surpasses

a certain threshold, a systemic inflammatory response might occur. After a limited injury, the local tissue perfusion will increase and mediators released by macrophages and endothelial cells attract monocytes and polymorphonuclear neutrophils to the area. These cells, as well as the vascular endothelium, are stimulated to express adhesion molecules and their interaction enables the inflammatory cells to leave the vascular lumen and to enter the interstitial space. Once there, activated cells of the immune system will secrete proteolytic enzymes and oxygen radicals, phagocytize and digest bacteria and necrotic tissue, and thereby defend the organism. A side effect of this reaction is that healthy tissue will be affected by the immune attack and will be damaged. As long as the inflammatory response is localized and feedback mechanisms are effective, tissue repair will follow tissue injury as recovery ensues. When the immune system becomes extensively activated and the inflammatory mechanisms escape local control, the whole body can seriously become involved in a systemic inflammatory response. A vicious circle might evolve in which the cytotoxicity of the immune cells might contribute to early organ dysfunction. Widespread increase in microvascular permeability will lead to interstitial edema and thereby impair oxygen diffusion to the tissue. Blood flow also becomes maldistributed due to a loss of vaso-regulative function and as a result of widespread microthrombosis. Oxygenated blood does not reach the capillary bed. Moreover, oxygen utilization is impaired. The resultant hypoxic cell damage further promotes organ dysfunction. One important difference between localized and systemic inflammation is that the early dysfunction of the intestine might itself sustain the inflammatory reaction. Extensive studies have provided evidence that during a state of systemic inflammation the barrier properties of the intestine seem to fail. Similar changes might also occur in the airway barrier to bacteria. Subsequently, enteral bacteria traverse these barriers in a process called bacterial translocation. These bacteria can be cultured from the blood where they might act as potent stimuli for both the immune system and endothelial cells.

Introduction

Improvements in the management of burn injury have resulted in a decreased incidence of sepsis and improved survival in patients with large burn wounds. Early excision of the burn eschar coupled with wound coverage has greatly diminished the incidence of burn wound infection, and burn mortality, in the last 2 decades.¹⁻³ These advances in burn care have paralleled the development of broad-spectrum antibiotics, which has further decreased the incidence of life-threatening infections in burn victims. However, infections still remain a major cause of morbidity and mortality in burn patients.⁴⁻⁶ Post-burn immunosuppression is thought to be a predisposing factor for the development of severe infections. Many infections in burn patients are associated with organisms considered opportunistic in nature and occur at sites other than in the burn wound, which supports the concept that immune function may be impaired in these patients. One paradigm of burn-induced immune dysfunction asserts that the initial burn injury induces an inflammatory response that is characterized by systemic release of pro-inflammatory cytokines and chemokines (Figure 23.1). This initial inflammatory response could lead to significant tissue injury and organ dysfunction. However, most burn victims survive the initial injury and enter a phase that is characterized by immune dysfunction. This state of dysfunction appears to place the burned host at increased risk of infection and further injury. Immunosuppression may be associated with the anti-inflammatory response initiated by the burned host in an effort to minimize inflammation-induced tissue injury during the acute post-burn period. Accumulation of inflammatory insults during the early post-burn period may potentiate injury-induced immunosuppression. Normalization, or enhancement, of immune function is becoming increasingly

attractive because of the emergence of antibiotic-resistant microorganisms. However, few effective immunomodulatory approaches have been developed for clinical application in burn patients.

Predisposing factors

There are approximately 45 000 hospitalizations per year for burn injury in the United States (www.ameriburn.org). More than half of the hospital admissions are for burns of less than 10% total body surface area (TBSA) while 4% (~1800 admissions per year) are for burns of 60% TBSA or greater (www.ameriburn.org). Depth and size of the burn wound are well-known risk factors for burn wound infection and ultimately sepsis. The overall incidence of bacteremia in burn patients is approximately 19%⁷ but rarely occurs in patients with less than 40% TBSA burns⁸. Concomitant inhalation injury is associated with an increased risk of infection, particularly pneumonia. This predisposition to infection may be due to impairment of alveolar macrophage function and the need for intubation and ventilation in many of these patients.

While studies have reported a gender effect on post-burn mortality, with females having a lower chance of survival,⁹⁻¹² there have not been any consistent data demonstrating any gender effect on the incidence of sepsis in post-burn patients. A similar study of children did not show a relationship between gender and the incidence of sepsis.¹³ However, age appears to be a predisposing factor for the development of septicemia after burn injury. Not surprisingly, young children and elderly patients have the highest incidence of sepsis.^{10,14}

Physical barriers are an important part of host resistance to infection. The epidermal barrier is compromised in burn patients due to the burn itself as well as the frequent insertion of intravascular catheters. Vascular access devices are significant sources of nosocomial infections in burn patients. Typical organisms associated with line sepsis include *Staphylococcus* spp. (either *S. epidermidis* or *S. aureus*) although infections with Gram-negative bacteria or yeast can also occur, especially in immunocompromised patients. Central venous catheters, relative to other catheters, are particularly prone to bacterial contamination. Approximately 25% of central venous catheters become colonized with bacteria. Lesseva et al. reported an incidence of catheter-related bacteremia of 6.6%, accounting for approximately 20% of sepsis in post-burn patients.¹⁵ Peripheral catheters are much less likely to be associated with infection although this may be due to their shorter duration of use. Suppurative peripheral vein thrombophlebitis

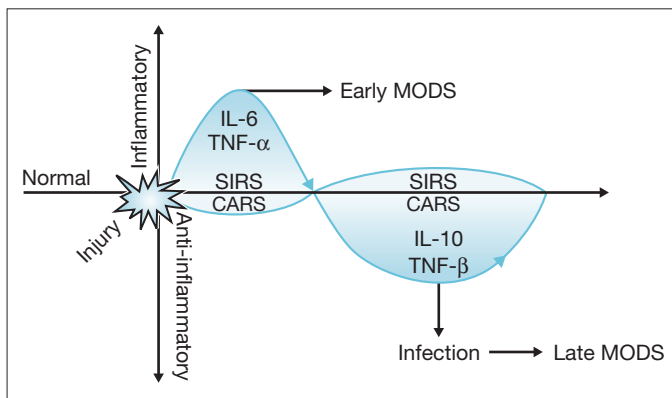

Fig. 23.1 Major injury is followed by induction of a short-lived pro-inflammatory cytokine response. During hospitalization, episodic rises in pro-inflammatory cytokines may occur in response to treatments or adverse events. However, the predominant cytokine profile in the days to weeks after a major injury is typically characterized as an immunocompromised.

was a common cause of systemic sepsis prior to the wide use of central venous catheters in critically ill patients. The risk of catheter-related infection is greatly increased if devices are inserted through infected or contaminated skin, such as burn wounds. Femoral vein catheters are more likely to become infected than subclavian or internal jugular vein catheters and catheter replacement via guidewire exchange has a higher infection rate than catheterization at a separate site.¹⁶

One of the most common causes of Gram-negative bacterial sepsis in hospitalized patients is urinary tract infection, especially in the presence of Foley catheters.¹⁷ Nearly all patients with large TBSA burns require bladder catheterization. The incidence of urinary tract infection in burn patients ranges from 10% to approximately 18%.^{7,18}

The incidence of respiratory infections in burn patients ranges from 20% to 40%.^{7,19} Nosocomial pneumonia is frequently associated with prolonged intubation and mechanical ventilation. Gram-negative bacteria such as *Pseudomonas aeruginosa* are commonly isolated, but Gram-positive bacteria and yeast such as *Candida* spp. should also be considered.

Medications administered to burn patients may, in some instances, also be a contributing factor to post-burn immunosuppression. Prophylactic administration of systemic antibiotics has not been associated with a reduction of infections in burn patients in a number of clinical reports and, in fact, may be a predisposing factor for the development of fungal infections.^{20–22} Recent experimental work suggests that administration of opiate analgesics may contribute to post-burn immunosuppression by adversely affecting T cell proliferation and altering the predominant T helper phenotype.²³ Transfusion of blood products has been reported to predispose burn victims²⁴ and other critically ill patients²⁵ to nosocomial infections. Although the exact mechanism of immunosuppression is unknown, blood transfusions have been associated with a decrease in the T-helper lymphocyte ratio, as well as adverse effects on natural killer cell activity and antigen presentation.^{26,27} Finally, victims of large total body surface area burns usually require numerous operative procedures for

debridement and grafting of burn wounds. Intravenous and inhalation anesthetics have demonstrated variable and inconsistent effects on neutrophil functions including alterations in chemotaxis, endothelial adherence and transmigration, phagocytosis, and respiratory burst²⁸ and could contribute to post-injury immunosuppression.

Microbiology

Normal intact skin has a bacterial count of 10^5 colony-forming units (cfu)/gram without any evidence of clinical infection.²⁹ Loss of the epidermal barrier provides a favorable environment for bacterial growth and 10^5 microbial cfu/gram of tissue is often associated with infection³⁰ although some bacteria such as β -hemolytic streptococci can cause infection at significantly lower concentrations. Furthermore, polymicrobial interactions may also be a significant factor in wound infections because it has been shown that the presence of four or more bacterial species within burn wounds correlates with non-healing.³¹

Initially, wounds are colonized with commensal skin organisms. Gram-positive organisms tend to predominate in wounds during the early post-burn period. Gram-negative aerobic rods such as *Pseudomonas* spp. are typically detected later. Resident microbes of the skin that have pathogenic potential include *Staphylococcus aureus*, *Staphylococcus epidermidis*, and non-enterococcal streptococci. Bacterial flora in locations below the diaphragm are also more likely to include Gram-negative enteric organisms such as *E. coli*, as well as *Streptococcus faecalis*. Resident microbes of the oropharynx that are potentially pathogenic include *Fusobacterium*, *Haemophilus*, *Peptostreptococcus*, and *Bacteroides*, as well as *S. aureus*, *S. epidermidis* and non-enterococcal streptococcus. Fungal infections are not uncommon and can occur concurrently with bacterial infections. The most prevalent fungal organisms are *Candida* or *Aspergillus*.

Innate immune function after burn injury

After a large burn injury with extensive tissue necrosis, the immune system is activated systemically and may become ineffective or even self-destructive. Loss of some components of innate immune function after thermal injury may lead to infections in burn patients. Study of immune function in burn patients is limited by feasible tissue access and generally consists of measuring circulating soluble factors and immune cells. Not surprisingly, this provides only a limited view of the entire immune response as suggested by animal studies in which alternate tissues such as spleen and liver are available.³² This review will highlight observational data from clinical studies and try to use results from experimental research to provide some context for these observations.

Healthy individuals resist many infectious challenges without preexisting specific (acquired) immunity because of the effectiveness of the innate immune response. Innate immunity is a protective set of rapid and primitive non-specific responses to infection including epithelial barrier defenses, cytokine elaboration, complement activation, and phagocytosis of microorganisms. These mechanisms may eradicate the infection or contain the infection during the time needed for

the development of an adaptive immune response specific to the offending microbe.

Physical barriers

A mechanical barrier against invasion of microbial pathogens is provided by the epithelium of skin and mucosal tissue. This protective barrier is lost after serious burn injury, and burn wounds often have poor vascularization. The presence of necrotic tissue provides a favorable environment for microbial growth. Cellular damage may cause the release of molecules that predispose the host to bacterial infections. Syndecans are expressed by all adherent cells and their release after cellular damage may be a signal for the need of tissue repair processes including vascular permeability, angiogenesis, wound repair, and modulation of chemokine activity.³³ However, recent studies in burned mice suggest that syndecan shedding may potentiate systemic dissemination of *P. aeruginosa* from burn wound infections.³⁴

Besides the loss of epidermal integrity in areas of burns, barrier function may also be compromised at other remote anatomic locations. Endothelial barrier function in the gastrointestinal tract can be compromised after burn injury^{35,36} and may be due to decreased mesenteric blood flow in the early post-burn period.³⁷ This may lead to systemic translocation of bacterial toxins or enteric bacteria. Increased intestinal permeability after burn injury has been associated with systemic infection in a number of studies,^{37–40} and forms the basis for the therapeutic strategy of selective decontamination of the digestive tract as well as interventions aimed at improving gut barrier function such as early enteral feeding.⁴¹ In the respiratory tract, defense mechanisms include mucus secretion and ciliary movement, which serve to trap microbes and sweep them into the upper airways and oropharynx where expulsion by coughing may occur. These defenses can be diminished after inhalation injury, or compromised by endotracheal intubation, resulting in microbial proliferation and expansion into the distal branches of the respiratory tract causing bronchitis or pneumonia.¹⁶ Pneumonia is one of the most common infections encountered in burn patients and is associated with a higher risk of mortality.^{5,19}

Epithelial cells further contribute protection by manufacturing antimicrobial peptides, including defensins, lysozymes, and cathelicidins. Defensins exert antimicrobial activity against a broad range of bacteria and fungi⁴² and appear to function through disruption of the bacterial cell wall.^{42,43} Although epithelial cells display some constitutive production of defensins, production is increased after microbial activation of toll-like receptors (TLRs) on the epithelial cells.^{44,45} However, burn injury has been associated with a downregulation of defensin mRNA expression⁴⁶ and it is not clear that microbial stimulation would invoke an appropriate level of activation in affected areas.

Phagocytes

Beyond the physical barriers, the key cellular components of the innate immune response are the professional phagocytes, including macrophages, dendritic cells and neutrophils, that are not only important in removing microbes and debris from sites of inflammation but also are key regulators of the innate immune response (Figure 23.2). Macrophages are capable of

Fig. 23.2 The cellular component of innate immunity. (1) The innate immune response is initiated by recognition of microbial organisms. Toll receptors, CD14, NOD1, and NOD2 are among the specialized receptors found on immune cells to recognize molecules that are consistently found on microbes, including LPS, lipoprotein, flagellin, peptidoglycan, zymosan, and others. (2) Intracellular pathogen killing mechanisms include a variety of antimicrobial peptides, proteases, glycosidases, hydroxyl radicals, peroxy-nitrite, and others. (3) Intercellular communication and coordination of the cellular immune response occurs via cytokine and chemokine elaboration. (4) Macrophages and dendritic cells present microbial-derived antigen to T cells to initiate the adaptive immune response.

engulfing and killing microbes, but probably function most importantly as supervisors of the immune response to infection. They elaborate chemotactic factors for the recruitment of other cells, particularly neutrophils, to the site of infection. Macrophages also function, along with dendritic cells, to initiate the adaptive immune response by presenting antigen from the pathogen to CD4⁺ T cells. Neutrophils are effective at killing microbes through an arsenal of specialized antimicrobial weapons (discussed below). Because the innate immune system must react immediately in response to potential pathogens before they proliferate and disseminate, detection is dependent upon recognition of a limited number of microbial molecules that are consistently found among a vast assortment of microorganisms.

Toll-like receptors, found on mononuclear phagocytes, provide a primitive, non-specific mechanism of pathogen recognition based upon binding to conserved pathogen-associated molecular patterns rather than to specific microbial antigens.^{47,48} Humans have at least 10 TLRs which recognize microbial ligands such as Gram-negative bacterial lipopolysaccharide, bacterial lipoproteins, lipoteichoic acids from Gram-positive bacteria, cell-wall components of yeast and mycobacteria, unmethylated bacterial CpG DNA, and viral RNA^{48,49} as well as endogenous ligands such as heat shock proteins (Table 23.1). Signaling through TLRs results in nuclear translocation of NF- κ B and AP-1, which are important transcription factors that activate the promoters for a number of genes encoding inflammatory end products such as cytokines and chemokines. Interestingly, macrophages seem primed for innate immune activity after burn injury. Experimental induction of burn injury in mice causes upregulation of mRNA expression of TLR4 and increased reactivity to LPS chal-

TABLE 23.1 KNOWN HUMAN TOLL-LIKE RECEPTORS (TLRS) AND CORRESPONDING LIGANDS

TLR	Associated proteins	Described ligands
TLR1	Only signaling as a dimer with TLR2	Exogenous: Tri-acylated lipopeptides (LP), phenol-soluble modulin, LP from <i>Mycobacterium tuberculosis</i> , Osp A LP from <i>Borrelia burgdorferi</i>
TLR2	CD11a/CD18, CD11b/CD18, CD14, TLR1, TLR6, dectin-1, possibly MD-2, peptidoglycan recognition proteins (PGRPs)?	Exogenous: LP are probably principal group activating TLR2 from wide range of species, in association with TLR1 or TLR6, inc. <i>M. tuberculosis</i> , <i>B. burgdorferi</i> , <i>T. pallidum</i> ; peptidoglycans (PG) from species inc. <i>Staphylococcus aureus</i> ; lipoteichoic acids, mannuronic acids, <i>Neisseria</i> porins, some rare LPS species (e.g. <i>P. gingivalis</i>), bacterial fimbriae, <i>Yersinia</i> virulence factors, CMV virions, measles hemagglutinin Exogenous: HSP60 with TLR4 Other: May have role in responses to oxidative stress
TLR3		Exogenous: Double-stranded RNA
TLR4	Lipopolysaccharide (LBP) binding protein (presents LPS to cell surface), CD14, MD-2, CD11b/CD18	Exogenous: LPS from a wide range of Gram-negative bacteria. Also bacterial HSP60, mannuronic acid polymers, flavolipins, teichuronic acids, <i>S. pneumoniae</i> pneumolysin, bacterial fimbriae, respiratory syncytial virus coat protein Endogenous: HSP60, HSP70? (LPS contamination in some preps), surfactant protein A, hyaluronan oligosaccharides, heparan sulfate fragments, fibrinogen peptides, β -defensin-2 Drugs: Taxol (mouse TLR4 only)
TLR5		Exogenous: Flagellin
TLR6	As dimer with TLR2	Exogenous: Di-acylated LP, ?PG, phenol-soluble modulin
TLR7		Drugs: Responds to imidazoquinoline antivirals. Exogenous or endogenous activators unknown
TLR8		Drugs: Responds to an imidazoquinoline
TLR9		Exogenous: Bacterial DNA as CpG motifs
TLR10		Unknown

lenge.^{50,51} The importance of toll receptors in the innate immune response is illustrated by one clinical study which has suggested that post-burn patients who are at high risk for development of severe sepsis can be identified by a mutation in the TLR4 gene.⁵²

Monocytes, macrophages, and neutrophils respond to bacterial invasion by migrating to the site of infection; recognizing and ingesting the microorganism; and killing and digesting the microorganism (Figure 23.3). Chemotactic gradients are provided by chemoattractants such as the complement protein C5a, endothelium-derived IL-8, and leukotrienes.^{53–56} Chemoattractants and other stimuli also cause upregulation of surface phagocytic receptors.⁵⁷ Bonding between phagocyte receptors and opsonins on microbial surfaces activates cytoskeletal contractile elements resulting in invagination of the cell membrane and extension of pseudopods around the microbe. Clinical studies of neutrophils from post-burn patients demonstrate reduction in phagocytic activity.^{58,59} Smoke inhalation injury may predispose to a higher incidence of bacterial pneumonia, in part, because phagocytic function of alveolar macrophages is impaired.^{60,61}

Neutrophil microbicidal function

Massive neutrophil infiltration is characteristically seen in burn wounds. While this is probably an advantageous response to protect against potential pathogens, it may also be associated with some undesirable biologic effects. Oxidants and hydrolytic enzymes released from activated neutrophils can contribute to proteolysis within the wound and aid in the

Fig. 23.3 Mechanisms of neutrophil migration during infection. Infection induces local neutrophil infiltration by causing inflammation and inducing upregulation of adherence factors on neutrophils and endothelial cells. Neutrophil surface lectins bind loosely to endothelial cell selectins to facilitate rolling of neutrophils along the blood vessel wall. Tighter neutrophil–endothelial cell bonds are formed through interaction of β integrins and intercellular adhesion molecule-1 (ICAM-1) to cause neutrophil adherence. Neutrophils then move into the interstitium by transendothelial migration, a process that is facilitated by platelet endothelial cell adhesion molecule (PECAM) and chemoattractants such as chemokines, bacterial products and leukotrienes (LTB₄). After phagocytosis and killing of microbes, neutrophils undergo apoptosis and are removed from the site of infection. (From: Seeley AJ, Pasqual JL, Christon NV. Science review: cell membrane expression (connectivity) regulates neutrophil delivery, function and clearance. *Crit Care* 2003; 7:291–307. Permission Biomed Central, Ltd.)

spread and dissemination of bacteria.^{62,63} Abnormal neutrophil function has been associated with bacteremia in patients with burns and other major injuries.⁶⁴ Neutrophil microbicidal mechanisms are generally classified as either oxygen dependent or oxygen independent. Oxygen-independent microbicidal activity of neutrophils involves several peptides and proteins stored within the primary (azurophilic) granules, including lysozyme, bactericidal/permeability-increasing protein, β -defensins, and cathelicidin.⁶⁵ In the oxygen-dependent mechanism, NADPH oxidase within the phagosome of neutrophils (and macrophages) converts molecular oxygen into superoxide anion (O_2^-) and a series of reactions creates further oxidant products with microbicidal activity, including H_2O_2 , OCl^- (hypochlorite) and NH_3Cl and RNH_2Cl (chloramines).⁶⁵ A reduction in neutrophil-mediated oxygen-dependent bacterial killing has been reported in several studies of burn patients.^{58,66–68} Poor tissue perfusion and low oxygen tension in wound sites are additional factors likely to contribute to impaired oxidative killing in burn patients.

Innate lymphocytes — natural killer (NK), natural killer T (NKT), and $\gamma\delta$ T cells

Natural killer (NK) cells are lymphoid cells that do not express clonally-expanded receptors for specific antigens.⁶⁹ NKT cells express both NK cell markers and T cell receptors (TCRs), and $\gamma\delta$ T cells express $\gamma\delta$ TCRs instead of the $\alpha\beta$ TCRs found on classical T cells. All 3 innate lymphocytes are able to induce DC maturation through a combination of cell contact-dependent mechanisms and cytokine signaling. In turn, matured DCs can stimulate NK, NKT, and $\gamma\delta$ T cells to sustain the innate immune response during the development of adaptive immunity.⁷⁰ $\gamma\delta$ T cells, which are found in high numbers in intestine, may play a role in recruitment of neutrophils to that site after burn injury.⁷¹

NK cells have been well described for their role in containing viral infections prior to the adaptive immune response, as well as assisting in the control of malignant tumors. Activated NK cells are an important source of $IFN\gamma$, which promotes the development of specific protective immune responses.^{69,72} NK cells kill infected cells through the release of perforin and granzymes and through the binding of the death receptors Fas and TRAIL-R on target cells.^{69,73} NK cells also interact with other cells of the immune system, including dendritic cells, by providing signals for maturation or apoptosis.^{69,72} Studies of patients after burn injury have revealed a decline in NK cell activity. Most significantly, the decline in NK cell activity is most apparent more than 1 week after the occurrence of the burn injury^{74,75} and corresponds with the period during which sepsis is more likely to be identified. One of these studies also noted that sera from burned patients had an inhibitory action upon NK cell activity on cells from healthy individuals.⁷⁴

Complement

Other than toll receptors, the innate immune system has additional mechanisms for recognizing and neutralizing microbial pathogens, including the complement system, scavenger receptors, and specialized receptors on NK cells. Activation of the complement system results in production of a cascade of proteins that function to opsonize microbes and recruit phagocytes. Three distinct pathways constitute the complement

system: the classical pathway; the mannan-binding lectin pathway; and the alternative pathway (Figure 23.4). Binding of IgG or IgM to antigens on microbial surfaces activates the classical pathway. The remaining two pathways can be activated in the absence of specific antibodies. The mannan-binding lectin pathway is similar to the classical pathway but is initiated after mannan-binding lectin protein binds to mannose-containing carbohydrates on microbial surfaces.⁷⁶ The alternative pathway is dependent upon low constitutive expression of complement activity. All three of the activation pathways act on microbial surfaces to assemble a convertase that cleaves C3 to form C3b, which either binds to the surface as an opsonin, or helps activate C5 and the remainder of the complement cascade.^{76–78} Opsonization facilitates the removal of microbes by macrophages and neutrophils.⁷⁷ C3a and C5a are potent chemoattractants for monocytes and neutrophils. Cleavage of C5 also leads to assembly of the membrane attack complex that causes disruption of the microbial membrane. After burn injury, neutrophil surface expression of receptors for complement are increased⁷⁹ but the complement cascade itself is diminished and may serve as a prognostic indicator. In a clinical study of severely burned patients (>60% TBSA, third-degree), serum concentrations of complement proteins were measured sequentially. All patients had decreased concentrations of C3 initially; however, serum concentrations of C3 rebounded fully in surviving patients while remaining depressed in non-survivors.⁸⁰ Diminished complement, in combination with decreased concentrations of fibronectin and serum immunoglobulins, contributed to the depression of opsonic activity in both serum and blister fluid from burn patients,⁸¹ and likely predisposes to the development of burn wound sepsis.

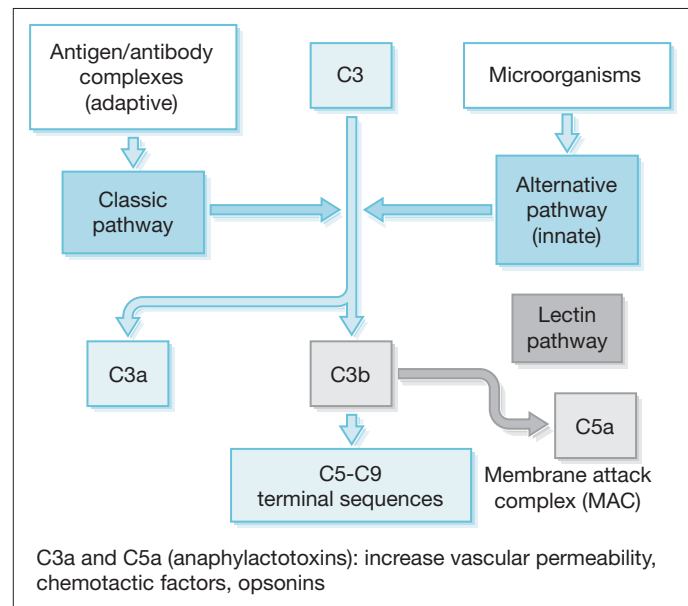

Fig. 23.4 The complement cascade (condensed). Antigen–antibody complexes or molecules on the surface of bacteria activate the complement cascade. This results in production of the anaphylatoxins C3a and C5a as well as the membrane attack complex. (From: Sherwood ER, Toliver-Kinsky T. Mechanisms of the inflammatory response. *Best Pract Res Clin Anesthesiol* 2004; 18:385–405.

Cytokine/chemokine

Cytokines are a heterogeneous group of small polypeptide soluble mediators that are important for the regulation of antimicrobial immunity. In conjunction with hormones and neurotransmitters, cytokines regulate tissue repair and immune responses. Most cells of the immune system either release cytokines and/or respond to cytokines through specific receptors. The cytokine response evoked by microorganisms controls both innate and adaptive immune responses, including inflammation, defense against viruses, and proliferation of specific T- and B-cell clones while regulating the function and interaction of a variety of immune cells. It is interesting that cytokines do not appear to have any direct effect on microorganisms.

The description of the cytokine response after burn injury has varied widely in several clinical studies. It is likely, based upon accumulated evidence and results from well-controlled animal experiments, that burn injury by itself evokes only a modest increase in circulating cytokines. This limited cytokine response may be related to burn-induced upregulation of suppressor of cytokine signaling-3 (SOCS 3) within hours of burn injury.⁸² Cytokines may be elevated within the circulation of post-burn patients, in part, because patients are subjected to a number of stresses during treatment including intubation and ventilation, surgery, transfusions, and exposure to microorganisms. In fact, there is some evidence to suggest that the cytokine response to a secondary insult may be greater after burn injury. Burn injury appears to 'prime' immune and inflammatory cells for an exaggerated response to endotoxin.^{83,84} Post-burn 'hyperreactivity' in terms of cytokine production has been well described in macrophages.⁸⁵ Similar priming for an exaggerated response to LPS stimulation has been described in alveolar macrophages harvested from bronchoalveolar lavage of smoke inhalation patients or from rabbits after experimental smoke inhalation injury.^{61,86} Interestingly, while surgery may potentially invoke an inflammatory response, burn wound excision has been associated with a reduction in circulating concentrations of endotoxin and cytokines⁸⁷⁻⁸⁹ perhaps resulting from the removal of inflammatory stimuli such as necrotic tissue and bacteria.

IL-6 is one of the most consistently elevated cytokines within the circulation of post-burn patients^{90,91} and in experimental animals.⁹² It is unclear what function IL-6 has in the burn-induced immune response but a study in mice showed a decrease in macrophage-derived IFN γ when IL-6 was blocked in *ex vivo* experiments.⁹² In another study, the pro-inflammatory response and mortality were attenuated in post-burn mice subjected to endotoxin when IL-6 was blocked.⁹³

Perhaps of more importance than the burn-induced cytokine response is the secondary cytokine response to potential pathogens in the post-burn period. In this regard, burn injury may be followed by a period of attenuated expression of some cytokines that are important in the immune response to microbial organisms, and increased expression of cytokines that may hinder the immune response. For example, expression of IFN γ and a number of IFN γ -inducing cytokines including IL-2, IL-12, and IL-15 is decreased in response to a secondary immune stimulus after burn injury.⁹⁴⁻⁹⁶ IFN γ is a cytokine with a number of beneficial effects on the immune response to microbial organisms including upregulation of class II major

histocompatibility complex (MHCII) proteins on many cell types. Phagocytes utilize the MHCII as a mechanism for presenting microbial antigens to CD4+ T cells at sites of inflammation.⁹⁷ Decreased monocyte expression of the MHCII is a consistent finding in septic patients. IFN γ activity also contributes to phagocytosis and microbial killing through several mechanisms. IFN γ induces IgG2a (in mice), which opsonizes bacteria, and promotes the expression of Fc γ R1 receptors on phagocytes.⁹⁸ IFN γ also potentiates the availability of NO, hydrogen peroxide, and superoxide in phagocytic cells⁹⁹ and promotes expression of chemotactic factors and adhesion molecules for mononuclear cell recruitment to areas of infection.^{99,100} In experimental burn models, lack of IFN γ activity has been associated with diminished ability to clear bacteria.^{101,102} Impaired production of IL-12 in response to endotoxin has also been described in mice after burn injury.¹⁰³ IL-12, an important product of dendritic cells and monocytes, serves to stimulate NK cell activation and production of IFN γ as well as playing a role in determining the ultimate class of T-helper lymphocyte response.

IL-10 is an anti-inflammatory cytokine that functions to attenuate the pro-inflammatory response and prevent excessive inflammation. Increased production of IL-10 may contribute to immunosuppression in the post-burn period. Immune cells from burn patients demonstrated an exaggerated IL-10 response to secondary stimulation with endotoxin or other microbial products,¹⁰⁴ and this finding correlated with septic episodes. Experimental studies confirm an increased IL-10 response to microbial stimuli in animals that had previously been subjected to thermal injury.^{96,105} Concentrations of IL-10 have been reported to reach a peak in the plasma of patients approximately 1 week after burn injury,¹⁰⁶ which correlates with the time when septic episodes in post-burn patients begin to occur with increased frequency. In another clinical study, serum concentrations of IL-10 appeared to be highest in non-surviving patients with sepsis.¹⁰⁷

Chemokines are a group of specialized polypeptides that play a complex role in the innate immune response by directing cell migration of immune and inflammatory cells.^{53,108-110} The leukocytes and endothelial cells of most inflamed tissues can release a variety of chemokines that recruit specific sets of leukocytes to a site of infection based upon the nature of the inciting pathogen.^{110,111} Chemokines also recruit leukocytes to sites of tissue injury such as the burn wound. IL-8, a neutrophil-specific chemoattractant, is one of the most widely studied chemokines. IL-8 has been reported to be significantly elevated in the circulation of post-burn patients⁹¹ and the highest concentrations are detected in non-survivors.^{106,112} Conversely, PBMC elaboration of macrophage inflammatory protein-1 alpha (MIP-1 α) was diminished in post-burn patients when compared to healthy volunteers.¹¹³ Monocyte chemoattractant protein-1 (CCL2) is upregulated in mice after thermal injury.¹¹⁴

Severe burn injury is often associated with a period of neutropenia, perhaps as a function of neutrophil activation and exit from circulation. Besides the burn wound, the lung is a preferred site for neutrophil sequestration in burn patients, even in the absence of inhalation injury. Experimentally, neutrophils can appear in lung tissue within hours of burn injury and this phenomenon can be attenuated by neutralization of

complement C5a or of the chemokines keratinocyte-derived cytokine (KC) or macrophage inflammatory protein-2 (MIP-2).^{115,116} MIP-2 is an IL-8 homolog in the mouse. After thermal injury, IL-8 is a major bioactive chemoattractant for neutrophils in both blister and graft donor sites of patients.^{117,118} Several studies have demonstrated diminished neutrophil chemotaxis in post-burn patients which may, in part, be due to a combination of suppressive circulating soluble factors and a reduced ability to upregulate the MAC-1 (CD11b/CD18) adherence receptors on the cell surface.^{119–121} A recent clinical study of burn patients demonstrated an association between the development of bacteremia and a decrease in neutrophil expression of CD11b, an adhesion molecule that functions in endothelial binding and migration from the circulation.⁵⁸

Acquired immune function after burn injury

Whereas innate immunity provides non-specific responses that limit the growth and spread of infection, adaptive immunity provides potent, antigen-specific responses that are designed to eliminate infection and establish immunologic memory. Cytokines that are produced as a part of the innate immune response to infection can directly influence adaptive immunity. For example, production of IL-12 by antigen-presenting cells and IFN γ by natural killer cells during the innate response can influence the subsequent differentiation of CD4+ T helper cells towards a type 1 T helper (Th1) phenotype,^{122,123} whereas production of IL-4, and perhaps the absence of IL-12, during innate responses can promote differentiation towards a type 2 (Th2) phenotype.^{124,125} Consequently, the burn-associated alterations in innate immunity undoubtedly have an impact on subsequent adaptive immune responses both by influencing the nature of the response and also by increasing the burden that is placed on adaptive responses to eliminate infection. Indeed, there have been numerous reports of altered adaptive immune functions in burned patients. As is the case with all clinical studies, patient care precludes extensive experimental investigation, so investigators have relied on experimental models of burn injury for determining mechanisms of the immunological response to burn trauma. The current knowledge of burn-induced alterations in adaptive immune function will be reviewed, as well as information obtained from experimental models of burn injury.

Antigen presentation

Adaptive immunity is initiated upon recognition of antigen on antigen-presenting cells by antigen-specific T cell receptors. Antigenic peptides must be associated with an MHCII molecule for T cell recognition. HLA-DR is an MHCII molecule that is critical for antigen presentation in humans. A significant decrease in expression of HLA-DR has been detected in monocytes isolated from burn patients. Additionally, HLA-DR expression was further suppressed in burn patients that became septic compared to burn patients that did not develop sepsis.^{126,127} In murine models of burn injury, antigen presentation is significantly impaired early after burn injury.¹²⁸ This has been associated with decreased expression of class II MHC and may be a result of diminished IFN γ ,^{129–131} a known inducer of class II MHC gene expression.¹³²

T cell activation

The majority of observations of immune function in burn patients have come from analysis of T cells and their responses to *ex vivo* stimulation. The effects of burn injury on specific T cell subsets is not clear, and may vary depending on the time from injury, patient care, and exposure to microorganisms. One study found that the proportion of CD4+ T helper cells was significantly lower 7 days post-burn in patients that developed septicemia whereas the CD8+ cytotoxic T cell numbers were increased, and suggested that inverted CD4/CD8 ratios may be of prognostic value for septic complications.¹³³ However, this does not appear to be a reliable prognostic indicator since other studies have reported a decrease in CD8+ T cell numbers in burn patients.^{127,134} A consistent finding among these studies was that CD4+ T helper cell numbers were decreased in burn patients, and were even further depleted in burn patients with sepsis.¹³⁵ This depletion of CD4+ T cells may be due to activation-induced apoptosis, as a significant proportion of burn patient's circulating lymphocytes were undergoing apoptosis upon analysis, and apoptosis could be further increased by mitogenic stimulation *in vitro*.¹³⁶ Additionally, expression of the T cell activation marker CD25 was reported to be increased both spontaneously, suggesting *in vivo* activation, and after mitogenic stimulation *in vitro*.¹³⁷ Perhaps related to these alterations are burn-associated effects on T cell phospholipid and fatty acid composition and defective transmembrane signaling.^{134,138} Mouse models of burn injury have confirmed burn-induced apoptosis in T cells from various lymphoid and non-lymphoid organs, and have suggested that glucocorticoids are responsible for increased caspase-3 activity and subsequent apoptosis.^{139,140} Murine burn models have also demonstrated suppressed expression of c-fos and relA, and altered activities of the AP-1 and NF- κ B transcription factors that regulate genes involved in maintenance of cell survival and inflammation.^{141–143}

It has been proposed that an early, 'non-specific' activation of immune cells after severe burn injury results in a subsequent impairment of their specific effector functions.¹⁴⁴ There appears to be at least a correlation between these early activation markers and T cell dysfunction after burn injury. T cell proliferation after mitogenic stimulation and alloreactivity in mixed leukocyte reactions have been consistently reported as being impaired in samples from burn patients.^{127,137,144,145}

Significant alterations in elicited cytokine production have also been reported to occur after major burns, with a decrease in the production of Th1-associated cytokines relative to Th2 cytokines. IFN γ production by mitogen-stimulated burn patient PBMCs was significantly attenuated, whereas IL-4 production was significantly augmented.⁹⁶ Another study reported that IL-2 and IFN γ production by stimulated T cells was significantly lower in non-survivors than in survivors of severe burn injury.¹⁴⁶ Zedler et al.¹⁴⁷ found that the number of IL-4-producing CD8+ T cells was significantly higher and the number of IFN γ -producing memory T cells significantly lower in non-survivors, than in patients that survived after burn injury. Additionally, IL-10 production is reported to be higher after burn injury, and elevated plasma levels in burn patients correlated with poor prognosis.^{104,126} Experimental studies in a mouse model of burn injury have demonstrated a significant increase in the activity of regulatory T cells (CD4+/CD25+)

in lymph nodes draining the burn wound. Specifically, regulatory T cells isolated from burned mice were potent suppressors of T cell proliferation and IL-2 and IFN γ production, due in part to elevated surface expression of transforming growth factor- β 1 (TGF- β 1). Depletion of these cells prior to burn injury ameliorated the burn-induced suppression of antigen-specific Th1-type immune responses.^{148,149} While the exact significance of each of these functional impairments remains to be determined, there does appear to be a correlation between T cell dysfunction and susceptibility to infection and subsequent mortality after severe burns. In a clinical study of trauma and burn patients, those that had depressed cell proliferation of isolated T cells were at high risk for the development of multiple organ failure and mortality.¹⁵⁰ Teodorczyk-Injeyan et al. reported that burn patients that were unable to recover IL-2 production and T cell IL-2 receptor expression over time developed fatal sepsis.¹⁴⁵

B cell-mediated immunity

Hansbrough et al. noted a defect in the ability of burn patient sera to opsonize bacteria, which subsequently affected *in vitro* phagocytosis.¹⁵¹ Schluter et al. reported a decrease in expression of the B cell activation marker CD25 both before and after cytokine stimulation of burn patient samples.¹³⁷ In a clinical study, mitogen-induced immunoglobulin production was increased initially but suppressed at 3–4 weeks after burn injury. In survivors, immunoglobulin production returned to baseline, or higher, levels whereas production remained suppressed in burn patients that developed fatal septicemia.¹⁵²

Analysis of immunoglobulin production in murine burn models has indicated that injury has a significant suppressive effect on antigen-specific antibody production. The reported effects on specific immunoglobulin subtypes vary, perhaps due

to the use of different eliciting antigens, or other experimental conditions. Production of tetanus toxoid-specific IgG, specifically IgG2a, was impaired after burn injury in mice, and could be restored by exogenous IL-12, suggesting that impaired IgG2a production after burn injury is related to impairments in Th1-associated cytokine production.^{153,154} Other studies have reported that numerous B cell functions are impaired after burn injury. Specifically, antigen-specific IgM, total IgM, and total IgG production, and B cell proliferation were impaired 8 days after burn injury in mice. LPS-specific IgM could be restored to normal by cyclo-oxygenase inhibition, suggesting a role of PGE₂ in impaired B cell responses to antigen.^{155,156} Others have reported a role of TGF- β in impairment of B cell clonal expansion, and inhibition of IgM synthesis and antigen-specific antibody production after burn injury.^{148,157,158}

Hematopoiesis after burn injury

In addition to the numerous injury-associated alterations in innate and acquired immune cell functions, there are also effects of burn injury on immune cell production from bone marrow-derived progenitor cells (Figure 23.5). Analysis of burn patient peripheral blood leukocytes has revealed fluctuations in immune cell composition, with periods of neutropenia, monocytopenia, and at other times monocytosis.¹⁵⁹ Analysis of hematopoiesis in murine models has suggested that burn injury increases myelopoiesis in both the spleen and bone marrow, with alterations occurring at the level of the myeloid cell phenotype.¹⁶⁰ Burns appear to shift the hematopoietic potential of myeloid progenitor cells towards monocytopenia at the expense of neutrophil production.¹⁶¹ These alterations may be potentiated by high norepinephrine levels seen in burned and septic patients.¹⁶²

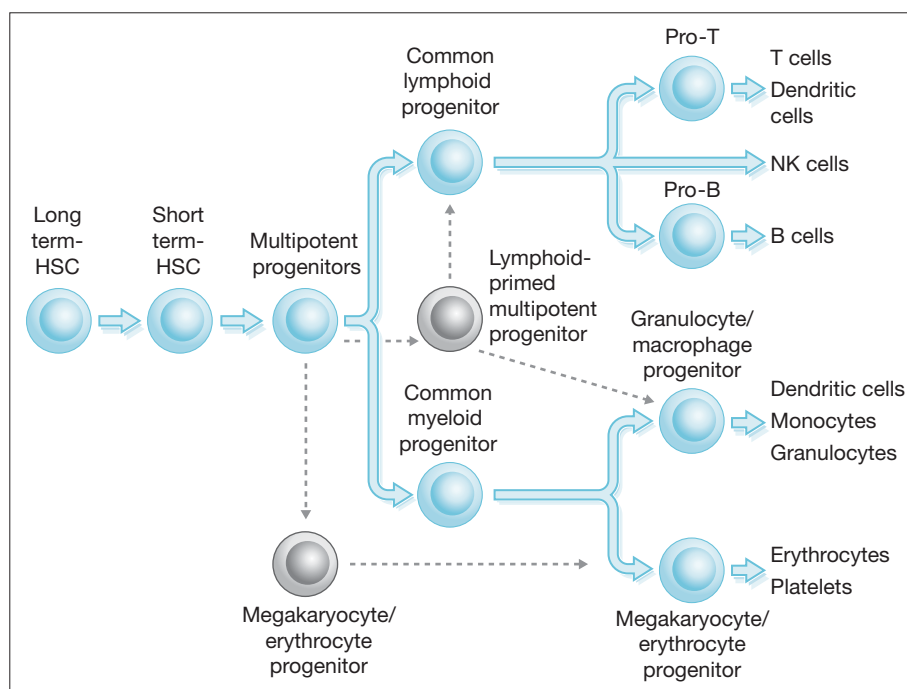

Fig. 23.5 Differentiation of hematopoietic stem cells (HSC). The conventional model of HSC differentiation (shown in bold with solid arrows) suggests that multipotent progenitor cells differentiate into strictly committed common lymphoid progenitor or common myeloid progenitor cells. The common lymphoid progenitor gives rise to T cells, dendritic cells, natural killer cells, and B cells. The common myeloid progenitor further differentiates into either a granulocyte/macrophage progenitor, which gives rise to monocytes, dendritic cells, and granulocytes, or a megakaryocyte/erythrocyte progenitor that can differentiate into erythrocytes and platelets. A recent alternative model (shown in gray with dotted lines) suggests that the megakaryocyte/erythrocyte progenitor is distinct from a 'lymphoid-primed multipotent progenitor' that further differentiates into the common lymphoid progenitor or granulocyte/macrophage progenitor.

Immunomodulation

Immunonutrition

To date, the most consistently successful intervention for enhancing immune function in burn patients is nutritional supplementation. It has been reported that early enteral feeding may decrease intestinal permeability and reduce enterogenic infection.¹⁶³ Berger et al. reported that trace element (Cu, Zn, Se) supplementation, given early, decreased the incidence of bronchopneumonia infections and decreased length of hospital stay.¹⁶⁴ Garrel et al. found that enteral supplementation with glutamine after burn injury significantly reduced the incidence of infections and decreased mortality.¹⁶⁵ Interestingly, there was no effect on PMN phagocytosis, indicating that glutamine supplementation works by some other mechanism. Arginine supplementation in burned mice was found to enhance humoral immunity (production of *P. aeruginosa*-specific antibodies) and decrease oxidative stress, but a benefit on survival was not observed in this model.¹⁶⁶

Selective decontamination of digestive tract

Whether or not bacterial translocation due to changes in gut permeability is a source of infections in burned patients is controversial. In 1997 Yao et al. reported that selective decontamination of the digestive tract (SDD) in burned rats decreased bacterial translocation and endotoxemia and prevented burn-associated suppression of mitogenic responses and IL-2 production.¹⁶⁷ Clinically, SDD by enteral administration of antibiotics to burned children did not decrease the incidence of infections.¹⁶⁸ However, a recent study by De la Cal et al. reported that SDD, which included the administration of parenteral cefotaxime in addition to enteral antibiotics, significantly reduced mortality and the incidence of pneumonia in burned adults.¹⁶⁹

Vaccination

A technique that may be highly effective for prevention of *P. aeruginosa* infections is vaccination with *P. aeruginosa* outer membrane proteins after burn injury. In 1970 this approach was investigated in a rat burn model,¹⁷⁰ and it was later demonstrated that vaccination of burned mice decreased systemic bacterial load and increased survival upon lethal infection with *P. aeruginosa*.¹⁷¹ In 1983 it was reported that both active and passive vaccinations for *Pseudomonas* were effective in inducing antibodies to *Pseudomonas* and reducing mortality in both burned adults and children.¹⁷² Since then, numerous studies have reported that vaccination of burn patients with *P. aeruginosa* outer membrane proteins is safe, significantly increases *P. aeruginosa*-specific titers, and is associated with a decrease in detection of *P. aeruginosa* by nested PCR in blood of vaccinated patients.¹⁷³⁻¹⁷⁶ While this approach may be effective for decreasing *P. aeruginosa* infections, the limitation of this strategy is that it will be restricted to single bacterial species unless vaccinations against widely conserved pathogenic motifs can be developed.

Cytokine modulation

Due to the profound effects that severe burns have on pathogen-elicited cytokine production, coupled with the observed correlation between these alterations and a negative outcome

in burn patients and in experimental animal models of burn injury, many attempts to modulate immune function after burns have been directed towards restoration of normal cytokine balance. One approach has been the administration of exogenous Th1 or Th1-promoting cytokines. IFN γ has been administered to burn and trauma patients in clinical studies but unfortunately has shown no benefit with respect to the incidence of infections or mortality.^{177,178} Experimentally, administration of IL-12 and IL-18 has shown some benefit in animal models, but these cytokines have not been tested in the clinical scenario.^{94,179,180} Adverse reactions to IL-12 in other clinical trials may preclude its introduction as an immunomodulator in burn patients.^{181,182}

Another attempt at cytokine modulation has been the neutralization of cytokines believed to contribute to post-burn immunosuppression. Treatment of mice with antibodies specific for IL-10 was shown to increase resistance to infection, but only if given immediately after burn injury.¹⁸³ In a murine model of burn and sepsis, the utility of antibodies against TNF- α was found to be limited in that TNF- α neutralization was only effective during a narrow time frame after burns, and may have worsened outcome when high doses of antibodies were used.¹⁸⁴ Given the interactive and dynamic nature of the cytokine network, therapies targeted to modulate the levels of a single cytokine may not be sufficient to restore immunological homeostasis after severe burn injury.

Hematopoietic factors

Another approach to improving immune function in burn patients is to stimulate hematopoiesis to generate new immune cells from bone marrow-derived stem and progenitor cells. The supposition underlying this approach is that accelerated and amplified production of new effector cells may be more effective than therapies that are designed to compensate for specific burn-induced impairments in immune function. Given the propensity of burn patients to mount excessive and hazardous pro-inflammatory responses, it is imperative to consider factors that can enhance immune cell production and effector function without activation of a pronounced inflammatory response. Stimulation of macrophage and neutrophil production after burns has been investigated using granulocyte-colony stimulating factor (G-CSF), a neutrophil growth factor, and granulocyte macrophage colony-stimulating factor (GM-CSF), a growth factor for neutrophils and macrophages. Both G-CSF and GM-CSF improved immune function in animal models of burn-associated sepsis.^{185,186} Treatment of burn patients with GM-CSF was shown to increase white cell counts and improve neutrophil activities, but the effect of GM-CSF on infection rate and patient outcome has not been evaluated.¹⁸⁷

Another hematopoietic factor that has been examined in a mouse burn model is fms-like tyrosine kinase-3 ligand, or Flt3L, a hematopoietic cytokine and dendritic cell growth factor (Figure 23.6). Treatment of burned mice with Flt3L has been shown to stimulate the production of dendritic cells, restore pathogen-elicited Th1-associated cytokine production, and increase survival after an otherwise lethal burn wound infection. Resistance to burn wound infection could be conferred by the adoptive transfer of dendritic cells that were isolated from Flt3L-treated mice,¹⁸⁸ indicating that modulation of dendritic cell production and function may have future

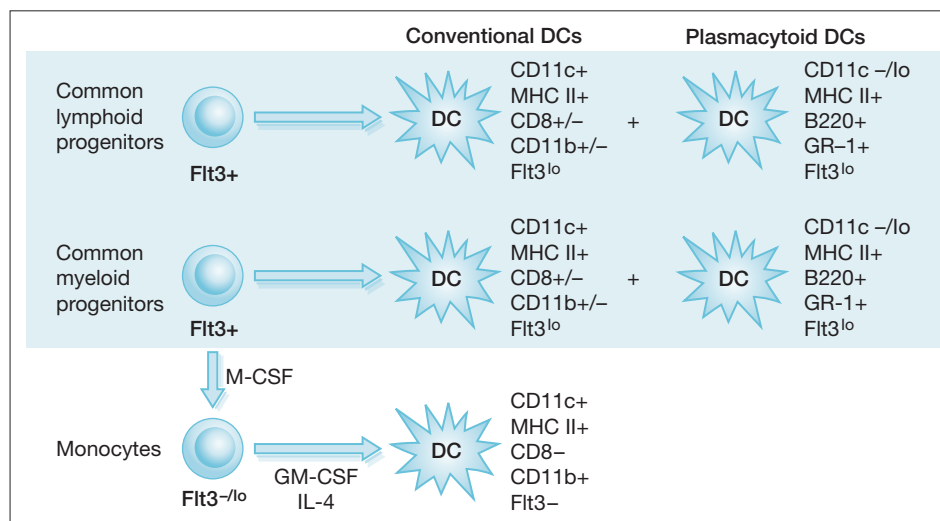

Fig. 23.6 Dendritic cell development from murine hematopoietic progenitor cells. Dendritic cells can be derived from both common lymphoid progenitor cells and common myeloid progenitor cells. The Flt3 tyrosine kinase receptor is expressed at high levels on common lymphoid and myeloid progenitors. Differentiation in response to Flt3 ligand generates both plasmacytoid (IFN α -producing cells) and 'conventional' dendritic cells (both CD8+ CD11b- and CD8- CD11b+ subtypes), all of which maintain a low level of Flt3 receptor expression. Cells that are potentially responsive to Flt3 ligand treatments are highlighted in blue. Dendritic cells can also be derived from monocytic precursors in the presence of GM-CSF and IL-4, but dendritic cells derived along this pathway do not retain Flt3 receptor expression.²⁰⁸⁻²¹⁰ M-CSF, macrophage colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; DC, dendritic cells.

potential for prevention of infections after major burn injury. This approach is supported by several clinical findings that suggest that decreases in dendritic cell numbers and function, due to increased apoptosis and/or decreased dendritic cell differentiation, contribute to immune dysfunction after major trauma. In one study of trauma and burn patients, decreased T cell activation in patients that eventually developed sepsis was attributed to deficient activation by dendritic cells subsequent to impaired dendritic cell differentiation from monocyte precursors.¹⁸⁹ Another study reported that the number of dendritic cells in spleens of patients that died from sepsis-associated complications was significantly reduced.¹⁹⁰ The direct relevance of these findings to burn-associated immunosuppression remains to be determined. However, in combination with the experimental studies in which dendritic cell enhancement by Flt3L was highly effective for increasing resistance to burn wound infection, these clinical observations justify further investigations of dendritic cell modulation after burn injury. It should be noted that clinical studies in healthy individuals and cancer patients have indicated that Flt3L significantly increases dendritic cell numbers in peripheral blood, with no overt toxicity.¹⁹¹⁻¹⁹³

Other approaches

There are numerous ongoing attempts to develop prophylactic treatments to prevent infections after major burn injury. Other potential treatments have been described in clinical studies in trauma patients, since there are similarities in the immunological alterations that occur after major burns and other types of trauma. One treatment that shows promise is glucan, a β -1,3-linked glucose polymer derived from the cell wall of *Saccharomyces cerevisiae*. Glucans have been shown experimentally to decrease sepsis-induced inflammation while enhancing

microbial clearance.^{194,195} Clinical studies with trauma and high-risk surgical patients have shown that glucans can decrease infectious complications and mortality in these patient populations.^{196,197} Although these compounds have not yet been tested in burn patients, they have been effective in decreasing susceptibility to burn wound infection and mortality in a mouse model of burn injury.¹³¹

Another approach that is under investigation is the use of resuscitation fluids as immunomodulators. Junger and others have found that hypertonic saline has the ability to attenuate inflammation, decrease neutrophil-mediated lung damage, and rescue T cells from experimental trauma-associated suppression. It was reported that IL-2 production by phytohemagglutinin-stimulated human PBMCS was completely suppressed by sera from trauma patients, but that costimulation with hypertonic saline could restore IL-2 production.¹⁹⁸ Additionally, it was found that resuscitation of mice with hypertonic saline (compared to lactated Ringer's solution) after hemorrhagic shock decreased bacteremia and increased survival upon a subsequent cecal ligation and puncture.¹⁹⁹ They have proposed that leukocytes respond to hyperosmotic stress through an osmosensory system that signals a phosphorylation cascade resulting in p38 MAP kinase activation.^{200,201} Clinical studies have examined resuscitation of burn patients with hypertonic saline and have reported that it is safe, provides adequate resuscitation, and may decrease severity and incidence of pulmonary dysfunction,²⁰²⁻²⁰⁴ but the effects of hypertonic saline on inflammation and immune function have not yet been addressed in the clinical scenario.

Host defense peptides are another potential mechanism for immunomodulation after burn injury. Defense peptides are naturally occurring antimicrobial effector molecules of the

innate immune system. Human β -defensins are produced in the skin by keratinocytes, and expression of one of these peptides, human beta-defensin 2, is significantly decreased in burn wounds.²⁰⁵ Human cathelicidin hCAP-18/LL-37 is another class of defense peptide that is expressed in the skin. Using a rat model of burn wound infection, Jacobsen et al. showed that transient cutaneous adenoviral delivery of hCAP-18/LL-37 to infected burn wounds induced hCAP-18/LL-37 and significantly inhibited bacterial growth.²⁰⁶ Future studies appear warranted to evaluate the efficacy of host defense peptides for the treatment and/or prevention of infections after burn injury.

Summary

Improvements in burn care have decreased the incidence of serious infections in burn patients. However, infectious complications remain common in severely burned patients and are

one of the most common causes of mortality in patients that survive the initial burn trauma. The relatively high incidence of infections in this setting appears to be due, in part, to alterations in innate and acquired immunity. Clearly, loss of the skin barrier and the presence of invasive instrumentation contribute to the susceptibility to infection in these patients. Numerous studies suggest that alterations in cellular immunity, both innate and acquired, may also predispose burn patients to infection. Several immunomodulatory approaches have been studied in experimental models and have been shown to improve resistance to infection. This benefit may be due to reversal of immunosuppression or may simply result from augmentation of antimicrobial immune function. In either case, immunomodulatory interventions appear attractive as a means of improving host resistance to infection during the acute post-burn period, especially considering the increased prevalence of antibiotic-resistant microorganisms.

Hematologic, hematopoietic, and acute phase responses

Jason W. Smith, Richard L. Gamelli, and Ravi Shankar

Chapter contents

Introduction	325
Red blood cells and erythropoiesis	325
Platelets and coagulation cascade in burns	326
Acute phase proteins	327
Leukocytes and burn injury	328
Hematopoiesis and burns	330
Putative role for hematopoietic transcription factors in thermal injury	333
Hematologic and acute phase response: treatment strategies	336
Conclusion	337

Introduction

Although our ability to care for major burns has improved over the last two decades, mortality due to septic complications still remains a major threat to the survival of severely injured patients. General physiological and cellular changes that occur immediately following a burn injury are not only important for the initial survival of the injured patients but also act as triggers for initiating the inflammatory response. Much of our understanding of the pathophysiology of burn injury has come from advances in the biology of inflammation. Well-regulated inflammation to any given insult including burn trauma is an essential part of the healing process. The inflammatory reaction allows the recruitment of leukocytes, antibodies, and other serum proteins to the site of injury which initiates the wound healing process^{1,2} and serves to localize and eradicate microbial infection.³ While controlled inflammation is an essential part of the ‘healing process’, uncontrolled systemic inflammatory responses, often seen during prolonged hospitalization of severely injured burn patients, represents a generalized response to trauma and can result in derangements in immune function.^{4,5}

Fundamental alterations and derangements in the function and production of leukocytes and erythrocytes occur after burn injury. The primary focus of this chapter is to highlight current understanding of how severe thermal injury precipitates these hematologic and hematopoietic changes. Within this framework, we discuss recent advances in the cellular and molecular biology that have helped shed new insights into burn biology. In particular, we outline the cellular and molecu-

lar mechanisms that are responsible for the dysregulated inflammatory changes that occur following severe burn injury. Lastly, we will describe how hematopoietic transcription factors can potentially play a role in the hematopoietic changes observed following severe thermal injury.

Red blood cells and erythropoiesis

Almost all hematologic parameters are significantly affected by severe burns in a characteristic biphasic manner. Following burns that are greater than 10% total body surface area (TBSA), anemia is frequently present.^{6,7} The extent of anemia due to erythrocyte loss is directly proportional to the extent of the initial injury. It is estimated that patients with 15–40% full-thickness burn lose approximately 12% of their red cells within 6 hours of the injury, and as much as 18% in 24 hours.⁷ Patients with severe burns continue to lose red blood cells at the rate of 1–2% per day until the burn wound is healed, primarily as a result of blood loss through multiple surgical procedures and repeated blood draws for various hematologic and biochemical tests.^{6,8–10}

Several factors could explain the early onset of anemia in burn patients. First, acute red blood cell destruction occurs as a direct result of thermal injury. Secondly, extensive burns induce the formation of thrombi within the capillaries, arterioles, and venules due to the activation of complement and coagulation cascades.¹¹ The amount of small vessel thrombosis that results is directly proportional to the size of the burn; thus for burns of similar depth, larger burns produce a greater prothrombogenic effect. Additionally, loss of red blood cell mass can arise from burn-induced intrinsic and extrinsic alterations to the erythrocytes. Previous studies have shown that thermal energy damages the normal morphology of red blood cells not only at the site of burn wound but also within the peripheral circulation.^{12,13} Systemically released oxygen free radicals and proteases from the inflammatory cells can also damage the integrity of red blood cell membrane.¹³ It is hypothesized that the burn wound triggers the release of these biological mediators that compromise the integrity of red blood cell membranes to induce osmotic fragility and loss of membrane deformability. These changes in red blood cell membrane property manifest themselves as increased spherocytosis, membrane disruption, and vesiculation of erythrocytes and are apparent within a short time following severe thermal injury.^{14,15} Animal studies have shown that removal of female sex hormones worsens the severity of the changes in the RBC membranes, but that the addition or subtraction of

male sex hormones has no effect on membrane fragility.^{16,17} If these cell membrane defects continue it may lead to red cell lysis and an increase in acute hemoglobinuria.^{14,18}

Paradoxically, despite the initial and continued loss of red blood cells following burns, erythrocytosis and an increase in hematocrit are often observed in the acute phase of burn injury.^{18,19} The loss of plasma volume into the extracellular space, or hemoconcentration, is the primary reason for this observed effect following thermal injury.^{20,21} Nevertheless, the long-term postburn period is characterized by diminished red cell production. Under normal conditions, blood loss would stimulate the bone marrow to produce more erythrocytes. A major factor in the induction of bone marrow erythropoiesis or red blood cell production is the availability of the growth factor erythropoietin. Interestingly, despite the high circulating levels of erythropoietin, burn patients remain anemic. The defect appears to be in the ability of erythroid progenitor cells in the bone marrow to respond adequately to erythropoietin.^{10,22–25} The use of exogenous erythropoietin to try and stimulate increased RBC production in these patients has not been shown to improve outcomes or change hemoglobin, hematocrit or reticulocyte counts, except in small surface area burns.²⁶ A possible explanation for this hyporesponsiveness is the high circulating levels of cytokines such as tumor necrosis factor- α (TNF α) and interleukin-1 (IL-1), which are often seen in severe burns. These cytokines can retard erythropoiesis by disrupting the physiologic regulation between erythropoietin and hemoglobin levels in erythroid progenitor cells.²⁷ Evidence from the cardiac surgery literature supports the relationship between an elevation in these cytokines and persistent anemia, which is associated with delayed RBC maturation and decreased responsiveness to erythropoietin.²⁸

Burn patients may have reduced serum iron levels due to substantial loss of blood and repeated surgical procedures for purposes of skin grafting and debridement of the burn wound.^{8,10,22} This reduction in serum iron levels may act as an impediment to hemoglobin synthesis and hence erythropoiesis. However, serum iron levels are unlikely to be the sole cause of burn-induced anemia, particularly among patients receiving blood transfusions during their course of burn care. Other potential explanations exist for burn-induced anemia. For example, the bone marrow's unresponsiveness to erythropoietin can stem from a yet unidentified serum factor, termed erythropoietin inhibitory factor, that inhibits erythropoietin's action on erythroid progenitor cells.^{10,22,24,29} Glucocorticoids have been shown to play an important role in stress-induced erythropoiesis.³⁰ In burn patients and in animal models of thermal injury, high circulating levels of glucocorticoids occur simultaneously with anemia, which suggests the potential for signaling defects in erythroid differentiation in severe thermal injury. In non-burn trauma patients there is a similar failure of hematopoiesis and late, persistent anemia associated with bone marrow failure.³¹ There is rodent and primate model evidence to suggest that preventing exposure to mesenteric lymph, by diverting the thoracic duct lymph flow, after severe injury, may prevent bone marrow failure and protect against injury-induced lung dysfunction.^{32,33} Hence, the anemia that is observed following burns results from several factors that cause increased red blood cell destruction in the periphery and decreased production of mature red blood cells from the bone marrow.

Platelets and coagulation cascade in burns

Advances in burn and trauma care have allowed for increased success in areas of resuscitation and control of hemorrhage. It is now becoming clear that there are also elements of deranged coagulation that lead to hypercoagulability and the accumulation of thrombi in the microcirculation which contribute to the development of end-organ failure and death.^{34,35} Dysregulated coagulation occurs through altered platelet maturation and function, changes in the proteins of the coagulation cascade and imbalances in the deposition and dissolution of peripheral clots.

Thermal injury causes marked reduction in circulating platelet levels during the acute phase of burn resuscitation, primarily due to the consumption of platelets during the formation of systemic microthrombi.^{36,37} Although local microthrombi formation at the site of injury helps maintain the integrity of the microvasculature surrounding the burn wound, generalized systemic microthrombi formation leads to reduced end-organ perfusion and finally multiple organ failure.^{35,36} In addition, dilutional effects of extensive fluid resuscitation may also contribute to a reduction in platelet counts. After the initial resuscitation, thrombocytopenia that is observed during the first week following the thermal injury is believed to be due to the diminished half-lives of platelets in circulation.³⁷ The thrombocytopenic phase is subsequently followed by a period of increased platelet production or bone marrow megakaryocytopoiesis during the 2–3 weeks following the initial injury that results in either a return to normal levels or to overt thrombocytosis.³⁸ However, in some burn patients, thrombocytopenia persists and is often considered a poor prognostic indicator.³⁹ Among patients with critical burn injuries who develop intravascular hemolysis an apparent thrombocytosis may be observed, which could be due to inadvertent counting of fragmented red cells and red cell microvesicles as platelets in an automated counter.³⁸ Therefore, in severe burns, the clinician should be aware of the possibility of spurious platelet counts in the presence of intravascular hemolysis.

In addition to the observed changes in the platelet numbers, there are significant alterations in the concentrations of coagulation proteins following thermal injury. The interplay amongst antithrombotic, prothrombotic cellular interactions, and fibrinolytic processes within the vasculature intricately control the homeostatic regulation of coagulation. Under normal physiologic conditions, the fluidity of the blood is maintained by morphological integrity of erythrocytes and the endothelial cells lining the blood vessels.¹⁵ Normal levels of prothrombotic and antithrombotic factors, which are well regulated and remain for the most part in their quiescent state, also help maintain the homeostatic balance. In burn patients, however, both the thrombotic and fibrinolytic pathways are triggered in direct proportion to the extent of the injury.^{40–42} During the early resuscitation phase of a burn injury there is a general reduction in the levels of coagulation proteins.⁴⁰ Dilutional effects of volume administration during this period and the loss of plasma proteins to the interstitium could partially explain the decrease in plasma concentrations of many coagulation proteins. This phase, however, appears to be transient in most patients as clotting factors return to normal levels 1 week post-burn.³⁶ Many patients suffering from major burn injuries develop a hypercoagulable state later in the postburn

course, with an increase in thrombotic complications.⁴⁰ Clinical studies indicate that, in addition to elevated coagulation factors, levels of antithrombotic proteins such as antithrombin III, protein S, and protein C are decreased in burn patients.^{36,40,43} These alterations prevent the normal checks on intravascular coagulation and tip the balance toward a hypercoagulable state. A significant number of studies have looked at different treatments aimed at offsetting this hypercoagulable state or replacing depleted elements of the natural anticoagulant proteins. Heparin, an extracellular matrix glycosaminoglycan, has been widely studied for anticoagulant, as well as anti-inflammatory, properties. The evidence suggests that there is a role for therapeutic doses of heparin in the care of serious burn injuries when other contraindications are not present. The benefits seem to be primarily as an anti-inflammatory agent, preventing the ongoing activation inflammation at the burn site and systemically.^{43,44} Antithrombin III (ATIII) is a serine protease inhibitor that regulates hemostasis and has been shown to have anti-inflammatory properties.⁴⁵ ATIII is depleted after burn injuries as both coagulation and fibrinolysis are activated simultaneously.⁴⁶ Administration of exogenous antithrombin III to burn patients has been shown to be beneficial in reversing thrombogenicity and decreasing mortality, while animal models have suggested a role for this agent in attenuating pulmonary inflammation.^{41,42,45,46}

Fibrinolytic pathways are activated in burn injuries due to the increased levels of tissue plasminogen activator protein.⁴⁰ Consumption of antithrombotic proteins by activation of fibrinolytic activities predisposes burn patients to thrombosis. Contributing to the thrombotic state in severely injured burn patients are the release of tissue phospholipids and tissue factor, activation of complement cascade, tissue ischemia, and the presence of sepsis.^{36,39,40,47} As a result, patients are at increased risk for developing disseminated intravascular coagulation (DIC), which is characterized by activation of coagulation, intravascular fibrin formation and vascular thrombosis resulting in organ hypoperfusion and failure. The consumption of coagulation and anticoagulation factors leads to small vessel thrombosis and simultaneous uncontrolled bleeding.³⁵ It has been reported from postmortem studies that 30% of severely burned patients exhibit pathological findings of DIC with extensive microthrombi accumulation in all major organ systems. The clinical scenarios in which the autopsy evidence of DIC was present were patients with massive burns, delayed presentation, hypotension, acidosis, and/or hypothermia.⁴⁸ Retrospective clinical studies, however, report the incidence of clinically significant DIC in burns over 20% TBSA to be less than 1%.⁴⁹ Due to the high morbidity and mortality associated with episodes of DIC, a high index of suspicion needs to be maintained in this patient population when sepsis complicates the clinical course. Signs of impending DIC may include refractory shock out of proportion to apparent blood loss, bleeding from venipuncture and catheter sites and urinary and gastrointestinal bleeding. Standard laboratory values in patients with suspected DIC include prolonged prothrombin time (PT) and activated partial thromboplastin time (APTT), increased levels of fibrinogen degradation products, decreased levels of antithrombin III, and decreased platelet counts and fibrinogen levels. Vigilance must be maintained for other thromboembolic complications in this population such as deep

vein thrombosis and pulmonary embolism. The use of D-dimer levels has been shown to have a high negative predictive value in selecting populations for more thorough investigation.⁵⁰ The treatment modalities recommended for patients that develop DIC are primarily supportive and geared toward maintaining hemostatic parameters with replacement therapy. Future efforts in the treatment of this disease process will focus on re-establishing the balance of coagulation and fibrinolysis.³⁵

Acute phase proteins

The body's reaction to injury involves the initiation of host defenses including the synthesis and release of acute phase proteins.⁵¹ The clinical manifestations of the acute phase response include leukocytosis, fever, increased vascular permeability, increases in metabolic responses and stimulation of nonspecific host defense.^{52,53} The acute phase proteins mediate these effects and therefore play a key role in protecting cells and tissues from progressive cellular injury and in restoring homeostasis (Table 24.1).⁵² Acute phase proteins serve as mediators of the inflammatory process, function as transport proteins, and participate in burn wound healing.^{54,55} In response to burn injury, an acute phase response also results in the activation of coagulation and complement cascades, activation of granulocytes and monocyte/macrophages, platelets, endothelial cells and fibroblasts.^{36,37,56–59} The orchestration of coordinated activation is the production of proinflammatory cytokines from the burn wound and from leukocytes recruited to the wound.^{51,60,61} The acute phase response stimulates the hypothalamus, which leads to pyrexia and activates the pituitary–adrenal axis to release steroid hormones.^{52,62} More importantly, it induces the liver to synthesize and release acute phase proteins capable of exerting pleiotropic effects on many tissues.⁵² During an acute illness or a significant injury, such as a burn injury, enhanced production of acute phase proteins serves to stimulate the healing process and is sustained by proinflammatory cytokines.⁵⁵ However, prolongation of the acute phase response and the unabated production of acute phase proteins are detrimental and can lead to a hypermetabolic state, multiple organ failure, and death.^{61,63–65} The scenario is complicated by the fact that increase in acute phase proteins is sustained at the expense of constitutive hepatic proteins, propagating a vicious cycle of detrimental effects.^{65–67}

Specific acute phase proteins that have been shown to be elevated in thermal injury include C-reactive protein, serum amyloid A, α_1 -acid glycoprotein, α_1 -antitrypsin, fibrinogen, haptoglobin, ceruloplasmin, α_1 -chymotrypsin, and α_2 -macroglobin.^{55,68–74} Levels of constitutive proteins such as albumin, transferrin, and α_1 -lipoprotein have been shown to decrease after thermal injury.^{52,74–77} Generally, the greater the size of the burn, the greater is the change in acute phase proteins; however, even minor thermal burns can lead to alterations in acute phase protein.^{58,78,79} The induction of acute phase proteins is driven by the proinflammatory cytokines IL-1, IL-6, and TNF α levels, with IL-6 having the most direct and significant effect.⁷⁶ IL-6 directly stimulates the production of C-reactive proteins, ceruloplasmin, haptoglobins, fibrinogen α_1 -antitrypsin, and α_1 -acid glycoprotein on the one hand and depresses the synthesis of hepatic constitutive proteins such as albumin, fibronectin, and

TABLE 24.1 STATUS OF ACUTE PHASE PROTEIN RESPONSE FOLLOWING THERMAL INJURY

Acute phase protein	Levels	Functions
C-reactive protein	Increased	Opsonin, complement activation, and immune modulation
Serum amyloid A	Increased	Leukocyte chemotaxis and phagocytosis
α_1 -antitrypsin	Increased	Protease inhibitor of elastase and trypsin
α_1 -antichymotrypsin	Increased	Inhibits chymotrypsin
α_1 -acid glycoprotein	Increased	Immunomodulator, potential wound healing properties, decreases albumin clearance from circulation, transport protein, steroid binding
α_1 -antiplasmin	Increased	Protease inhibitor of fibrinolysis
Ceruloplasmin	Increased	Copper transport protein, potential antioxidant properties
Haptoglobin	Increased	Hemoglobin scavenger
Fibrinogen	Increased	Mediate coagulation
C ₁ inhibitor	Increased	Complement inactivation opsonization
Complement-C ₃	Increased	Complement activation
α_2 -macroglobulin	Decreased	Transports zinc, panprotease inhibitor, binds growth factors and cytokines and targets them toward particular cells
α_1 -lipoprotein	Decreased	Transport protein
Transferrin	Decreased	Iron transport

Reproduced from Kushner I. The phenomenon of the acute phase response. *Ann N Y Acad Sci* 1982; 389:39–48.⁵²

transferrin on the other.^{52,75} While IL-6 is the prime mediator of the acute phase response, TNF α and IL-1 play a subsidiary role through their ability to stimulate IL-6 production.^{75,77} Acute phase proteins are essential in the wound healing and host defense processes, but when production becomes unregulated to the point that systemic changes in inflammatory cell function take place, the unchecked immune cell activation can have deleterious effects on the host.

Aside from its role as a regulator of acute phase protein production, IL-6 is also considered a prognostic indicator in burn patients.^{79,80} Clinical studies have demonstrated that non-survivors of major burn injuries have higher levels of IL-6 than do survivors of similar burn injuries. It is hypothesized that in non-survivors acute phase protein production becomes unresponsive to IL-6 and the cytokine continues to be up-regulated because of the lack of negative feedback.^{80–82} Additionally, prostaglandins, activated complement factors, cortisol, neuroendocrine, and other hormones have been implicated in the activation of acute phase proteins.⁸³ Future studies on the role of cytokines in the regulation and functions of acute phase proteins will add insights into their role as physiological mediators and points in the activation sequence that may allow therapeutic intervention.

Since the overproduction of proinflammatory cytokines may lead to unchecked systemic inflammation and poor outcomes, several clinical trials have been undertaken to investigate methods to attenuate the rise in these cytokines and acute phase proteins.^{59,63,67,84,85} Failures of these trials clearly indicate that such anti-cytokine antibody monotherapies are not likely to be useful in modifying and controlling the prolonged acute phase response. Broader therapeutic modalities aimed at simultaneously enhancing the constitutive production of hepatic proteins (e.g. albumin, fibronectin) while inhibiting acute phase protein expression have been shown to be benefi-

cial both in animal models of thermal injury and in burn patients.^{55,67–69,72,86,87} Administration of growth hormone to thermally injured rats with 40% TBSA burns decreases α_1 -acid glycoprotein mRNA expression and protein levels while reversing the decline in albumin production.⁶⁹ In severely burned pediatric patients, administration of recombinant human growth hormone (GH) was able to decrease the production of acute phase protein and serum TNF α and IL-1 β levels without any effect on IL-6.⁵⁵ This protocol, however, did not influence the mortality rate in these studies. Since recombinant GH exerts some of its effects through its ability to stimulate insulinlike growth factor 1 (IGF-1), administration of a combination of IGF-1 and IGF-binding protein 3 (IGFBP3) was attempted as a therapeutic modality to control acute phase response in severely burned children. Similar to rGH administration, infusion of IGF-1/IGFBP3 decreased IL-1 β and TNF α levels as well as type I acute phase protein production in burn patients, while increasing constitutive hepatic protein production. Interestingly, administration of cholesterol containing cationic liposomes used in gene delivery systems have been shown to attenuate the acute phase response in thermally injured rats.⁸⁸ Given the deleterious effect of unabated and prolonged acute phase response following severe burns, continued improvements in therapeutic modalities aimed at regulating this response may develop into additional tools in the care of burn and critically injured patients.

Leukocytes and burn injury

The primary effectors of host defense are the main populations of leukocytes, lymphocytes, NK cells, polymorphonuclear cells (PMN), and monocytes/macrophages. A balanced activation of these cells is important for robust host defense. Inappropriate activation of these leukocytes, especially the PMN

and macrophages, can lead to tissue destruction and systemic inflammation with dire consequences to the burn patient. Over-activation of PMN and macrophages has been implicated in the development of adult respiratory distress syndrome (ARDS) and multiple organ failure.^{59,89–95}

In the first 24–48 hours following burns, a leukocytosis, and more specifically a granulocytosis, is generally observed that is dependent on the size of the burn wound, with the larger burns giving rise to a greater degree of leukocytosis.⁹⁶ The initial increase in the white blood cell count (WBC) is attributable to three major factors: the acute plasma volume loss due to the burns, demargination of mature neutrophils from peripheral blood vessels, and the rapid release of bone marrow reserves. Following this initial period of leukocytosis, burn patients frequently develop leukopenia which is related to a trauma-induced failure bone marrow hematopoiesis.³¹ Leukopenia is also frequently seen in burn patients whose wounds are treated with silver sulfadiazine, a common topical antimicrobial agent.⁹⁷ The severity of the leukopenia that develops from drug toxicity is directly proportional to the amount of agent that is applied to the wound and thus indirectly to the size of the burn wounds themselves. The mechanism underlying this drug-induced leukopenia is yet to be elucidated although direct bone marrow and cellular toxicity may play a role. In general, leukopenia is self-limiting and does not require discontinuation of silver sulfadiazine treatment.

Leukopenia and granulocytopenia often persist in patients when severe bacterial infection is superimposed on burn injuries, especially those with Gram-negative sepsis.^{57,98,99} In the early 1970s, Newsome and Eurenus demonstrated that the initial granulocytosis was due to demargination of PMN from the blood vessels and through accelerated release of bone marrow stores in their rat model of thermal injury.¹⁰⁰ This granulocytosis, however, is transient and is followed by a robust bone marrow response to replenish granulocyte stores.^{101–103} If the burn injury is complicated by sepsis, granulocytopenia persists.^{104,105} Granulocytopenia under these conditions appears to be due to bone marrow failure.^{103,104,106,107} McEuen demonstrated a significant inhibition of granulocyte colony-forming units in the bone marrow of burn septic rats.¹⁰⁶ In addition, serum from septic burn-injured animals retarded the granulocyte colony formation when added to bone marrow cells from normal non-septic animals.¹⁰² In septic animals and in burn patients with sepsis, the observed granulocytopenia is not likely due to lack of available colony-stimulating factor. Granulocyte colony-stimulating factor (G-CSF) is the primary growth factor responsible for the proliferation and differentiation of bone marrow granulocyte progenitors into mature granulocytes.^{108,109} In thermal injury and sepsis, the activation of macrophages, endothelial cells, and fibroblast by bacterial products and cytokines such as TNF α and IL-1 leads to increased production of G-CSF. This scenario is very similar to that seen with erythropoietin levels following thermal injury. Administration of recombinant G-CSF to burn septic animals prior to the initiation of septic insult has been shown to improve the survival rate of the burn septic mice.^{110–112} However, administration of G-CSF 24 hours after the onset of septic insult had little effect on their survival.^{113,114} G-CSF has been employed in cases of severely burned patients with refractory neutropenia, in particular with active HIV disease.

In addition to alterations in the kinetics of production and maturation, PMN exhibit qualitative functional changes after burn injury in animals and humans.^{115–118} Some of the documented functional changes include depressed chemotaxis, phagocytosis and intracellular killing.^{119–127} For example, isolated neutrophils of burn patients were shown to be defective in intracellular killing of *Pseudomonas aeruginosa* and the impairment in phagocytosis and intracellular killing are further exacerbated with sepsis.^{128,129} These alterations in the production and function of PMN provide for a framework for understanding the contributing factors in the depressed immune status of severely burned patients.

Monocyte/macrophage function is also altered following severe burns, but unlike PMN where neutropenia is common, in severe burns and sepsis, monocyte counts tend to increase in both animals and humans.^{24,98,130} Studies demonstrate marked monocytosis with a dramatic increase (3–5-fold) associated with sepsis.^{130,131} The importance of the burn-induced monocytosis is underscored by the observation that attenuation of monocytosis as well as blunted macrophage activation results in improved survival.¹³² Miller-Grazziano and Faist demonstrated that after trauma, including burns, monocyte/macrophages could be broken down into subsets that were either hypereactive or hyporeactive.^{133,134} These cells may develop their phenotypic differences as a result of an altered monocytopoietic program within the bone marrow itself or as a result of local cytokine environments in the peripheral tissues. Ogle et al. have demonstrated that bone marrow-derived macrophages from thermal injured animals produce increased amounts of TNF α , IL-1, and PGE₂ compared to macrophages from non-injured animals, suggesting that thermal injury can stimulate the development of functionally different monocytes within the bone marrow.^{135,136}

Patients with severe burns often suffer from suppressed cell-mediated immunity due to impairment in T cell functions.^{137,138} Impairment in cell-mediated immunity has been implied by observations of delay in skin allograft rejection, suppression of the graft versus host response, and skin hypersensitivity reactions in burn patients.^{139–141} The various alterations that have been reported include an overall suppression of circulating T lymphocytes, decreased mitogenesis in response to mitogens, reduced response to antigenic stimulation or activation, and redistribution of T lymphocytes within peripheral blood and tissue compartments.^{138,142–144} T lymphocytes are divided into T_{helper} and T_{suppressor} populations based on expression of lymphokine profiles, cell surface receptors, and ability to affect functions of NK cells, T_{cytotoxic} and B lymphocytes. In recent years strong evidence has emerged to support the hypothesis that burn injury-induced immune suppression is in part mediated by a shift in lymphocyte subpopulations from T_{helper} to T_{suppressor} subtypes.^{137,139,140} Part of the initial response to a significant burn is the activation of T_{helper} cells as assayed by IL-2R, HLA-2R, and transferrin receptor markers.^{145,146} *In vitro* functional assays reveal that despite the initial activation of T cells, they were unable to respond to mitogenic and/or antigenic stimulation. The addition of IL-2 fails to reverse T cell anergy and fails to relieve the suppression of IL-2R.¹⁴⁷ In addition, thermal injury triggers the apoptotic pathway in T cells.^{148,149} The exact mechanisms that initiate T lymphocyte apoptosis are still unclear. However, Fas ligand, TNF α , and

IL-2 mediated pathways have been implicated in T lymphocyte cell death.^{150,151} Lastly, macrophage activation products such as PGE₂ and tumor transforming growth factor- β (TGF β) can also contribute T cell suppression.

B lymphocytes also undergo functional changes with a profound reduction in immunoglobulin levels following thermal injury. All classes of immunoglobulins are reduced; however, IgG levels display the greatest reduction, with concentrations reaching as low as 300–400 mg/dL.^{152–155} This drop in immunoglobulin is rapid and early, and is attributed to plasma leakage, increased protein turnover, and decreased IgG synthesis by the B cells. The initial deficit in immunoglobulins is slowly replenished to near-normal levels within 2 weeks.¹⁴⁰ Major histocompatibility complex (MHC) glycoproteins are reduced after thermal injury. Nonspecific B cell activation by burn toxins and antigen-dependent mechanisms, activation by phagocytosis of non-specific antigen, may inhibit their ability to form antigen-MHC complexes.¹⁵⁶ Additionally, the display of self-antigens by the B lymphocytes could contribute to antigen-dependent cell death of T lymphocytes and T cell anergy.^{138,140} Previous work has shown that CD23 expression on activated B cells is abrogated in response to thermal injury.¹⁵⁷ IL-7 levels rise during the 1-week postburn and could account for the decreased proliferative capacity of mature B lymphocytes. Taken together, these data indicate that the functional alterations in B cells induced by thermal injury could further exacerbate the immune suppression in these high-risk patients.

Hematopoiesis and burns

Pressure is placed on the hematologic system in severely burned patients as a result of extensive tissue necrosis, fluid balance alterations, infections and repeated surgical interventions. Bone marrow hematopoiesis responds to this demand by replacing or providing additional blood cells to the circulation. A robust hematopoietic response with a balanced production of the different blood elements is required for adequate immune response, host defense and hemostasis in burn patients. In order to understand the dynamic response of the bone marrow to burn injury, a basic understanding of hematopoiesis is essential. Hematopoiesis is a dynamic orchestration of cellular events that follows a series of tightly coupled proliferation and differentiation signals. In this paradigm, the pluripotent hematopoietic stem cells (HSCs) give rise to erythrocytes, megakaryocytes, mature T cells and B cells, and cells of myeloid lineage such as neutrophils, basophils, eosinophils, and monocyte/macrophages (Figure 24.1). The process of hematopoiesis requires interactions between the pluripotent hematopoietic stem or committed progenitor cells and the stromal microenvironment.¹⁵⁸ The stromal environment is a source of cytokines for regulated hematopoiesis, and the proliferation and differentiation of HSCs/progenitor cells into specific terminally differentiated blood cells is dependent on the actions of both the lineage-specific early-acting and late-acting cytokines.¹⁵⁹ Stem cell factor and IL-3 act on bone marrow cells early in development, while erythropoietin, granulocyte-macrophage colony-stimulating factor (GM-CSF), G-CSF, macrophage colony-stimulating factor (M-CSF or CSF-1), and thrombopoietin act later in the process.^{109,160}

The hematopoietic stem cell has the ability for self-renewal that insures abundant numbers of cells are present for commitment towards lineage-specific cells in response to different challenges. For example, it has been shown that during acute bacterial infection, expansion of granulocytes predominates and is attributed to increases within the stem cell compartment.^{161,162} Additionally, a small percentage of the total stem cell pool that circulates in peripheral blood is activated in response to the local cytokine environment. The current consensus is that HSCs give rise to the multipotent CFU-GEMM cell, granulocyte-erythrocyte-monocyte-megakaryocyte and the lymphoid stem cell. Although the actual existence of the lymphoid stem cell has not been definitively shown, it is hypothesized that this stem cell gives rise to mature T and B cells.¹⁶³ The CFU-GEMM cell in the presence of steel factor or stem cell factor, IL-3, and GM-CSF, can develop into the myeloid-restricted bipotential cell CFU-GM, which can form either granulocytes or monocyte/macrophages depending upon the presence of G-CSF or M-CSF.¹⁶⁴ The terminally differentiated granulocytes in the bone marrow reserves are recruited into the circulation during periods of bacterial infection, stress, and thermal injury. Additionally, monocytes can either circulate in the peripheral blood or migrate into sites of inflammation and infection and become tissue macrophages in response to the local cytokine milieu.

Much of the knowledge of how hematopoiesis is modulated by thermal injury and sepsis has been gained through the use of animal models. Work on the cells of burn patients has demonstrated a reduction in the circulating stem cells in severely burned patients.¹⁶⁵ Animal models of thermal injury, however, continue to provide significant information on the status of bone marrow hematopoiesis after burns, and have allowed us to probe the overall pathophysiology of thermal injury and sepsis. For example, animal experiments have demonstrated that the initial granulocytosis observed is due to peripheral demargination and release of nondividing granulocytes from bone marrow reserves, stimulating an increase in the bone marrow CFU-G growth.¹⁰⁰ In the same model, burns superimposed with *P. aeruginosa* infection led to significant decreases in CFU-G colonies.¹⁶⁶ The serum from burn-infected animals inhibited the formation of CFU-G colonies from normal bone marrow cells.¹⁰⁵ These observations pointed to a primary defect in bone marrow granulocyte production, or myelopoiesis.

Although Eurenus and McEuen demonstrated that the granulocytopenia observed in their rat model of thermal injury and sepsis was due to the failure of bone marrow hematopoiesis. Gamelli et al. compared the size of burn wound, and superimposed localized *P. aeruginosa* infection, to inflammatory mediators.^{104,167} Using these criteria, they demonstrated that mice exhibited peripheral leukopenia and lymphopenia on day 1 postburn and returned to normal values in 8 and 12 days.¹⁰⁴ Mice also exhibited diminished bone marrow and splenic cellularity following thermal injury that increased in a time-dependent manner. In addition, *in vitro* clonogenic assays showed that burn injury led to an initial depression of bone marrow and splenic cellularity. This initial decrease was followed by a consistent bone marrow and splenic hypercellularity. The bone marrow and splenic mitotic index positively correlated with the cellularity. In addition, the number of bone

(From Sandoz Pharmaceuticals Corporation.)

marrow and splenic CFU-GM cells was consistently elevated beginning days 4–12 postburn. The increased CFU-GM production within the bone marrow and splenic compartment were threefold and 100-fold, respectively.

In direct contrast to thermal injury alone, concomitant sepsis dramatically altered the bone marrow myelopoietic responses. When mice were subjected to scald injury followed by a septic challenge with *P. aeruginosa* inoculation at the burn wound site, a marked reduction (~50%) in CFU-GM growth was observed 3 days after the initial injury.¹⁶⁷ Interestingly, the introduction of endotoxin into normal or burned mice led to a similar decrease in CFU-GM proliferation as observed in infected burn mice. Under these conditions, the total colony-stimulating activity (CSA) was also reduced in burn-infected animals, suggesting either the levels of CSFs were low or the serum contained a potent inhibitor of colony growth.

In severe thermal injury and sepsis, however, the circulating levels of the myelopoietic growth factors such as G-CSF and M-CSF are elevated. Therefore the logical hypothesis was that the burn sera contained a potent inhibitor for clonal growth of bone marrow cells. Based on the literature evidence, PGE₂ appeared to be a logical choice for this clonal growth inhibitory substance. Prostaglandins of the E-series (PGE₁ and PGE₂) but not the prostaglandins of the F-series (PGF₁α and PGF₂α) have been shown to inhibit CFC proliferation *in vitro*.¹⁶⁸ In addition, Pelus and his co-workers have demonstrated that administration of PGE₂ to cyclophosphamide-treated or intact mice resulted in significant suppression of myelopoiesis.¹⁶⁹ Pelus went on to show that inhibition of prostaglandin biosynthesis through administration of indomethacin, a cyclooxygenase inhibitor, reversed the clonal inhibitory effect of IL-1β administration.¹⁷⁰ Extending these observations to their murine model of thermal injury and sepsis, Gamelli et al. were able to show that administration of indomethacin could reverse burn sepsis or burn endotoxin-induced suppression in CFU-GM growth and improve survival of the septic animals.¹⁶⁷ While these studies directly implicated prostaglandin metabolites in burn sepsis-induced bone marrow myeloid suppression, further studies confirmed that PGE₂ is the primary mediator of this myelosuppression. Thermal injury and sepsis activate macrophages to produce PGE₂ through the induction of the enzyme cyclooxygenase-2 (COX-2).¹⁷¹ Administration of a specific COX-2 inhibitor, NS-398, has been shown to both inhibit PGE₂ production of endotoxin-treated macrophages to improve the survival rate of burn septic animals compared to controls, and to restore absolute neutrophil counts and CFU-GM's proliferative capacity.¹⁷² Similar results were also reported with the treatment of burn septic mice with a PGE₂ receptor antagonist SC-19220.¹⁷³ These results have helped establish a significant role for PGE₂ in burn-induced myelosuppression and suggest new treatment modalities for burn injury and sepsis.

Although PGE₂ has been established as a mediator of bone marrow myelosuppression in thermal injury and sepsis, until recently, no attempt has been made to explain the cellular mechanism for this myelosuppression (Figure 24.2). Using the same murine model of scald burn injury, Shoup et al. characterized the specific stages in granulopoiesis that are altered in burn sepsis.¹⁷² The specific granulocytic cell surface marker, GR-1 was employed to document the stage of bone marrow

Fig. 24.2 Reprioritization of myeloid commitment following thermal injury and sepsis. PGE₂, prostaglandin E₂; TNFα, tumor necrosis factor-α; LPS, lipopolysaccharide/endotoxin; CFU-GM colony forming unit-granulocyte, monocyte; CFU-G, colony forming unit-granulocyte; G-CSFr, G-CSF receptor; M-CSFr, M-CSF receptor (*c-fms*). (From Shoup et al. Cyclooxygenase-2 inhibitor NS-398 improves survival and restores leukocyte count in burn infection. *J Trauma* 1998; 45:215–220; discussion 220–221. with permission.)¹⁷²

myeloid maturation arrest in the injured animals. The expression of GR-1, also designated as Ly-6C, progressively increases with granulocytic maturation. The lowest levels of GR-1 expression are found in myeloblasts and the highest levels in neutrophils, with promyelocytes and myelocytes expressing intermediate levels of the antigen.^{174,175} The strength of GR-1 expression allowed these investigators to follow the developmental stages of granulopoiesis in sham, burn, and burn septic mice. Their results revealed that burn infection gives rise to an increased number of cells in the compartment comprising immature granulopoietic cells compared to sham or burn mice, and there was a concomitant decrease in the compartment comprising the mature granulocyte population. Using another granulocyte marker, myeloperoxidase, whose mRNA is not expressed after the promyelocyte stage in granulocyte development, they demonstrated that burn sepsis resulted in an accumulation of promyelocytes. This suggests the possibility of myeloid maturation arrest at this stage of granulopoietic development. They could further demonstrate that myelosuppression was accompanied by an attenuation of G-CSF receptor mRNA expression and G-CSF-stimulated proliferation of bone marrow cells, thereby providing a mechanistic explanation for the observed myelosuppression in thermal injury and sepsis.

Despite these data on the mechanisms regulating granulopoietic development during thermal injury and sepsis, very little information is available on the development of monocytes or monocytopoiesis in the bone marrow under the same

conditions. Myelopoiesis is a development paradigm responsible for the production of granulocytes and monocytes within the bone marrow. The common myeloid committed progenitor for these lineages is the bipotential progenitor CFU-GM.¹⁷⁶ The CFU-GM cells under the influence of GM-CSF and M-CSF give rise to committed CFU-M progenitors and progressively differentiate into mature monocytes. The mature monocytes are released into peripheral circulation and can differentiate into tissue macrophages upon entry into tissue.^{177,178} Although monocyte/macrophage activation and the resultant dysregulated cytokine milieu are considered central players in the development of systemic inflammation in severe burns and sepsis, the status of monocyte production by the bone marrow has been largely neglected. In fact, thermal injury has been shown to be associated with increased CFU-GM levels.^{101,104} Patients suffering from acute peritonitis and various acute infections have also been shown to possess elevated circulating levels of CFU-GM in their blood.⁷¹ Furthermore, increased monocytopoiesis has been documented in animal models with bacterial infections.^{24,98} Recently, Santangelo et al. have specifically addressed this issue of the status of monocytopoiesis during thermal injury and sepsis.¹⁶⁶ These investigators took advantage of the recent development of monoclonal antibodies against monocyte developmental antigens ERMP-12 and ERMP-20.^{179,180} While ERMP-12 antigen is predominantly expressed in CFU-M cells, ERMP-20 antigen is expressed primarily in monoblasts and promonocytes.¹⁸⁰ Through flow cytometric analysis (FACS) of ERMP-12 and ERMP-20 antigen expression, a significant increase was shown in the early monocyte progenitors expressing both ERMP-12 and ERMP-20 antigens in burn and burn septic animals compared to sham-treated animals. The burn sepsis group also showed a significant increase in the late monocyte progenitors compared to the sham and burn group. These increases in monocytopoiesis were also reflected in the peripheral blood counts. Thermal injury and sepsis stimulated absolute monocytopoiesis and a concomitant reduction in absolute neutrophil counts in circulation. Interestingly, the creation of a localized infection without systemic involvement did not result in any changes in absolute monocyte or granulocyte counts.

This study also demonstrated that M-CSF-responsive colony growth of the total bone marrow cells, as well as ERMP-12-enriched bone marrow cells, was significantly increased in thermal injury and sepsis compared to the sham group. Similar increases were also seen with GM-CSF. Of interest, G-CSF-responsive colony growth was severely depressed in thermal injury and sepsis. More importantly, they were able to provide a mechanistic explanation for the enhanced monocytopoiesis in thermal injury and sepsis through the documentation of increased M-CSF receptor expression on ERMP12+/RMP-20+ enriched bone marrow cells. These studies provided a novel observation that the acute expansion of the CFU-GM compartment caused a shift in the production of the myeloid lineage toward monocytopoiesis and away from granulocytopoiesis. The observed shift led to overproduction of monocytes with concurrent underproduction of granulocytes that could be due to increased M-CSF receptor expression on monocytic lineage cells and a downregulation of G-CSF receptor expression on the cells of the granulocytic lineage. Both the increased susceptibility to infections and the maintenance of systemic

inflammatory response syndrome (SIRS) can be explained in part by the shift in myelopoiesis during severe burn injury and sepsis. Thus, these studies highlight the importance of understanding the pathophysiology of burn injury through concerted regulation of related cellular events and pave the way to new, rational therapies.

This thought process is supported by the observation that blocking PGE₂'s actions can reverse the preferential shift in myelopoiesis observed during the course of experimental thermal injury.^{172,173} Administration of a PGE₂ receptor antagonist, SC-19220, that specifically blocks cellular interactions of PGE₂ without affecting synthesis or activation of other prostaglandins to burn septic animals restored the balance between monocytopoiesis and granulocytopoiesis toward near-normal levels. Measurement of circulating neutrophil and monocyte counts also mirrored the bone marrow myelopoietic changes. More importantly, the administration of SC-19220 improved overall survival of burn septic mice.

Aside from the hematopoietic colony-stimulating factors, other pro- and anti-inflammatory cytokines that are often elevated in burn patients can also modulate hematopoiesis. Interleukin-6, which plays a central role in the acute phase response of burn injury is also a potent stimulator of early progenitor cell proliferation without inducing differentiation.¹⁸¹ Furthermore, IL-6 is a powerful mitogen for megakaryocytes and committed myeloid cells.¹⁸²⁻¹⁸⁴ It also synergizes with IL-3 and GM-CSF to modulate multiple lineages within the hematopoietic hierarchy.^{109,159,160} Increased IL-6 production in severely burned patients could serve to stimulate hematopoiesis so that adequate numbers of leukocytes and platelets can be produced to meet the increased demands. Similarly, TNF α can modulate myelopoiesis through its capacity to downregulate G-CSF receptor expression on granulocytic cells.^{185,186} TGF β is another cytokine that can influence hematopoiesis through its ability to suppress early hematopoietic precursor growth.¹⁸⁷⁻¹⁸⁹ Depending on the severity of the burn injury and the presence or absence of other complicating factors such as sepsis, these and other pleiotropic cytokines in the burn milieu can significantly influence the hematopoietic commitment patterns.

In addition to thermal injury and infection, the stress response to the burn injury can also profoundly influence myelopoiesis. It has been established that the immune and hematopoietic systems are under physiologic regulation by neuroendocrine modulation. Conversely, the cytokine and hematopoietic products can alter functions of nervous system and endocrine organs. The ability of sympathetic activation to influence not only the cardiovascular and metabolic functions of the body following severe thermal injury but also its effects on the regulation of myelopoiesis are discussed elsewhere in this book.

Putative role for hematopoietic transcription factors in thermal injury

Recent advances in molecular and cellular biology have begun to describe the importance of the multitier control of pathophysiological changes that occur as a response to any injury state. The initial injury and the resultant changes in metabolic and cardiovascular responses trigger alterations in hemato-

logic parameters, which in turn initiate the appropriate hematopoietic commitment programs. Ultimately, specific sequential and temporal gene expression patterns dictate the hematopoietic commitment. Inherent in this concept of physiological regulation is the hierarchy of genes that control proliferation, developmental fate, and functions of hematopoietic progenitor cells. These genetic processes are governed through modulations in the rate of gene transcription which are accomplished through the binding of DNA-binding proteins or transcription factors to specific regions on a gene.¹⁹⁰

Transcription factors are nuclear proteins that act as control points in the conversion of a gene to a functional protein.¹⁹⁰ Since many key proteins are turned over rapidly to meet the changing needs of the tissues, a complex system of cell signaling architecture, with the final common pathway of gene transcription, must exist to produce bioactive proteins on demand. To exquisitely regulate the rate of protein synthesis, genes need to be quickly transcribed into RNA within the nucleus, transported to the cytoplasm, and proteins synthesized from RNA templates. Since cells respond to several signals simultaneously, and many ligand–cell interactions stimulate similar proximal signals, tight control of transcriptional initiation must exist for the proper orchestration of cellular responses.

The lineage-restricted proliferation and differentiation program in hematopoiesis is achieved through switching on and off the specific sets of genes in response to cell signals. Since thermal injury and sepsis are accompanied by hematologic and hematopoietic changes that determine the overall pathophysiological response of burn patients, it is reasonable to assume that transcriptional regulation of hematopoietic developmental genes play a significant role. Although, at present, there is little direct evidence for the role of hematopoietic transcription factors in the pathophysiology of burn injury, considerable evidence does exist to support their pivotal role in hematopoietic commitment.^{191–193} Therefore a brief review of the relevant transcription factors is essential to research endeavors in burn biology. Much of our current knowledge of hematopoietic transcription factors has come from diverse fields such as hematology-oncology, immunology, mammalian virology, and signal transduction. Many concepts have been found by studying the molecular controls of leukemias, *in vitro* cell clonal assays, and various hematopoietic cell lines. The gene knockout technology has also aided in ascertaining the functional roles of characterized genes in hematopoiesis. Biological processes in cells involve changes in gene expression that manifest as altered function or cellular response. Basically, alterations in expression of a certain gene can arise from modulating its level (transcription) or changes in mRNA stability and translation (post-transcriptional mechanisms). In this section, we will review a set of transcription factors that have been shown to be essential for the normal development of many elements of hematopoietic lineage.

tal-1/SCL

The *tal-1/SCL* gene encodes a bHLH (basic helix-loop-helix) protein that was originally identified at the chromosomal breakpoint in a human acute T cell leukemia.^{194,195} *tal-1/SCL* is a master gene required for development of hematopoietic

stem cells that eventually differentiate into lineage-specific blood cells.¹⁹⁶ Previous studies have revealed that the early hematopoietic stem cells (CD34+/c-kit+/Sca+ cells) express the *tal-1/SCL* gene.^{196–198} T cell leukemia, which consists of a clonal cell line with the potential to differentiate into myeloid and lymphoid lineages, was shown to express *tal-1/SCL* protein.^{195,196} In addition, mature erythrocytes, megakaryocytes, mast cells, and endothelial cells also express *tal-1/SCL*. These data indicate that the *tal-1/SCL* gene may play a required role in a later stage of maturation of committed progenitors. Homozygous *tal-1/SCL* gene knockout mice provided definitive evidence for its role in hematopoiesis. The homozygous *tal-1/SCL* gene deletion was lethal *in utero*.^{196,199} These mice exhibited a failure in blood formation and their yolk sac contained no detectable blood elements and lacked *in vitro* clonogenic potential. These results were further confirmed by the inability of the *tal-1/SCL* knockout embryonic stem (ES) cells to develop into any hematopoietic lineages in culture.

GATA family

Another set of transcription factors that are essential in hematopoiesis belong to the GATA family of proteins. The GATA transcription factors are related zinc-finger DNA-binding proteins. These transcription activators bind to the canonical GATA sequence motif found in the cis-regulatory regions of many hematopoietic genes. The proteins have differential expression patterns and activate a unique set of target genes in their restricted cells. GATA-1, GATA-2, and GATA-3 proteins play pivotal roles in hematopoiesis. It was reported that GATA-2 is involved in proliferation and self-renewal of early hematopoietic stem cells. Mice engineered with a homozygous deletion of *GATA-2* gene display severe hematopoietic defects. The *GATA-2* knockout mice survive to embryonic day 10–11, harbor a small number of red blood cells at that stage, undergo anemic crisis, and eventually die.²⁰⁰ *In vitro* clonogenic assays revealed a drastic reduction in the number of erythroid progenitors and a substantial loss of mature erythroid and mast cell precursors. GATA-1, the other important member of this family, is expressed in erythroid, eosinophil, megakaryocyte, and mast cell progenitors.^{201,202} GATA-1 appears to be critical for survival and differentiation of erythroid progenitors. Mice lacking *GATA-1* protein display normal hematopoiesis, except for the erythroid lineage.⁹⁴ *In vitro* differentiation assay with the *GATA-1*-deficient ES cells demonstrated differentiation up to the proerythroblast stage of erythropoiesis with eventual apoptosis of the arrested cells.^{94,196} Interestingly, there seems to be interrelated complex regulation among the GATA family of transcription factors. During erythroid differentiation, *GATA-1* levels increase and *GATA-2* expression is downregulated. Moreover, this interplay is absent in *GATA-1*-deficient ES cells that display high levels of *GATA-2* during *in vitro* erythroid differentiation assays.^{196,201,203} Aside from its role on erythroid differentiation, *GATA-1* appears to have a negative regulatory role in myeloid differentiation. Increased expression of *GATA-1* has been shown to negatively modulate *PU.1* expression and thus suppress myeloid commitment.^{193,204} Since burn injury is commonly associated with a downregulation of erythropoiesis despite increased levels of endogenous erythropoietin, studies specifically designed to correlate the strength of *GATA-1* expression in progenitor cells to the status of eryth-

ropoiesis will provide novel and mechanistic information on the pathophysiology of anemia in burn injury. Lastly, mice lacking GATA-3 fail to develop normal fetal liver hematopoiesis, lack all hematopoietic lineages, except the megakaryocytic cells, and succumb to embryonic hemorrhage.¹⁹⁶

PU.1

The PU.1 proto-oncogene encodes a member of the ets family of DNA-binding proteins. It was originally cloned as a sequence-specific DNA-binding protein that was found to be homologous to the *spi-1* oncogene.²⁰⁵ The *spi-1* oncogene was isolated from erythroblastic leukemia cells transformed by spleen focus forming virus (SFFV). The PU.1 transcription factor contains an amino-terminal glutamine/aspartic acid-rich region (TAD) followed by PEST domain and a carboxy-terminal ets DNA-binding domain.²⁰⁶ PU.1 possesses transcriptional activation potential that requires other co-activators for full potency.²⁰⁷ PU.1 expression is found in monocytic, granulocytic, and B lymphoid cells.²⁰⁸ Two different PU.1 knockout mice reveal the absence of monocytes, B cells, and greatly reduced neutrophil production.^{209,210} Moreover, these neutrophils are unable to express some markers of fully differentiated neutrophils.^{210,211} Embryonic stem cells from PU.1-deficient mice can differentiate into immature myeloid progenitors in the presence of IL-3 and G-CSF cytokines. Additionally, these PU.1 hematopoietic progenitors express low levels of mRNA for the GM-CSF, G-CSF, and M-CSF receptors.²¹² The primitive hematopoietic progenitors are unable to differentiate into M-CSF and G-CSF responsive progenitors after introduction of M-CSF-R or G-CSF-R genes. Nevertheless, exogenous PU.1 expression in the PU.1-deficient hematopoietic progenitors restores myeloid differentiation. Therefore, multiple lines of evidence implicate PU.1's central role in commitment to myeloid lineage and terminal differentiation of monocytes, granulocytes, and B cells.

c-Myb

c-Myb proto-oncogene belongs to the basic helix-turn-helix (bHTH) family of DNA-binding proteins.²¹³ *c-Myb* contains an LZ motif that mediates homotypic and heterotypic protein interactions.²¹⁴ Multiple serine residues are located within the amino-terminal and carboxy-terminal regions of *c-Myb* that affect its DNA-binding activity and negative regulatory domain.^{215–217} Studies have shown that *c-myb* expression is restricted to myeloid, erythroid, and immature lymphoid cells.^{218–220} Collaborative data from *c-myb* knockout mice reveal the absence of all hematopoietic lineages, except within the megakaryocytic compartment. *c-myb* knockout mice exhibited normal yolk sac hematopoiesis, while liver hematopoiesis was greatly compromised and these mice die *in utero* at E14–15.²²¹ Detailed analysis of hematopoietic lineages revealed that functional granulocytes and monocytes were present, but they harbored 10–20-fold reduction in mature cells compared to normal mice. It is hypothesized that *c-Myb* functions to control quantitative effects rather than differentiation *per se* during hematopoiesis. It was also noted that *c-Myb* levels decrease during differentiation of hematopoietic progenitors and enforced *c-Myb* expression promotes proliferation and blocks hematopoietic differentiation. Hence, *c-Myb* plays a critical role in controlling proliferation of imma-

ture hematopoietic progenitors and its physiological downregulation is required for commitment towards lineage-specific differentiation.

C/EBPs

CCAAT/enhancer binding proteins (C/EBPs) are transcription factors that bind to core cis-regulatory sequence of CCAAT found in many regulated genes. *C/EBP α* was the original transcription factor described as a basic leucine zipper (bLZ) DNA-binding protein in hepatocytes and adipocytes.²²² Interestingly, C-EBP family of transcription factors, including *C-EBP α* have been shown to be elevated following thermal injury.²²³ Although their expression is implicated in the acute phase response, the role of C-EBPs in the regulation of hematopoiesis during thermal injury and sepsis is yet to be delineated. Other members of this family include *C/EBP β* , *C/EBP δ* , *C/EBP ϵ* , and GADD153/CHOP proteins. These C/EBPs are able to homodimerize and heterodimerize with each other via the leucine zipper regions.²²⁴ Expression studies showed that *C/EBP α* is present in monocytes, eosinophils, and neutrophils.^{225,226} Moreover, human myeloid precursors and immature myeloid cell line, 32 DC13, express high levels of *C/EBP α* that decreased upon G-CSF-induced differentiation.^{227,228} *C/EBP α* was shown to possess a transcriptional activation domain involved in the upregulation of mRNA from certain neutrophil genes such as G-CSF-R, lactoferrin, and collagenase. *C/EBP α* gene knockout mice are deficient in neutrophils and eosinophils, but harbor functional lymphocytes and monocytes.²²⁹ Fetal liver cells formed M-CSF- and GM-CSF-responsive colonies, but G-CSF-induced colonies were not obtained. Hence, these studies determine that *C/EBP α* is essential for neutrophil differentiation, but not essential for monocytic differentiation. Conversely, during neutrophil differentiation of myeloid cell line, 32 DC13, *C/EBP β* levels increase. Recently, data from the *C/EBP β* -deficient mice revealed that hematopoiesis proceeds normally, but defects in macrophage activation and decreased B lymphocytes are observed.^{230–232} Additionally, *C/EBP ϵ* gene knockout mice exhibited abnormal neutrophilic function and deficiencies in certain key enzymes.²³³ Otherwise, the mice appeared to have intact hematopoietic tissues. The preceding studies demonstrate the important regulatory function of the C/EBPs transcription factors in myelopoiesis.

c-Myc/MAD/Mxi-1

c-myc proto-oncogene is part of the bHLHLZ (basic helix-loop-helix leucine zipper) family of transcription factors.²³⁴ *c-Myc* binds to canonical CANNTG DNA motifs located in many proliferative or cell cycle-regulated genes.²³⁵ *c-Myc* has three transcriptional activation domains in the amino terminus and a carboxy-terminal with sequence-specific basic region and helix-loop-helix leucine zipper domains that mediate protein-protein interactions. *c-Myc* is required for cellular proliferation and its downregulation is essential for differentiation of many cell types.^{219,234,236,237} Max is another bHLHLZ protein partner of *c-Myc* and this heterodimeric complex is essential for cognate DNA binding and transactivation of target genes.^{238,239} Another set of genes that belong to *c-myc* family are *MAD*, *Mxi-1*, *Mxi-3*, and *Mxi-4* genes. The most important ones in hematopoiesis are *MAD* and *Mxi-1*.^{240,241} *MAD* and

Mxi-1 proteins can heterodimerize with Max to form heterodimers that unlike Myc-Max can repress transcription at the same cognate DNA sites bound by c-Myc-Max heterodimers. Hence, within a given cell, there is a dynamic equilibrium of c-Myc-Max and MAD-Max complexes that compete for the same binding sites and the predominant complex determines whether proliferation or differentiation ensues.^{239,242} During *in vitro* and *in vivo* hematopoietic differentiation, MAD/Mxi-1 levels increase, while *c-myc* expression is downregulated.^{240,243,244} Recently, it was reported that *MAD* null mice have defects in myelopoiesis as demonstrated by delayed cell cycle exit during granulocytic differentiation.²⁴⁵ In summary, c-Myc/MAD's roles in regulating the onset of proliferation versus differentiation are crucial for hematopoietic development.

Hox genes

The *Hox* genes encode homeobox containing transcription factors that are involved in neural development, organogenesis, and segmental development of branchial and mesoderm layers.²⁴⁶ The homeodomain common to these proteins is a sequence-specific helix-turn-helix DNA-binding motif. The role of the various *Hox* genes has been examined in hematopoietic development.²⁴⁷ The *Hox* genes identified in this process are *HoxA9*, *HoxA5*, *HoxA10*, *HoxB4*, and *HoxB7*.^{247,248} In myeloid development, *HoxA9* and *HoxA10* are expressed at the highest levels in immature progenitors, and then are downregulated during differentiation.²⁴⁹ *HoxA10* null mice exhibit increased levels of peripheral monocytes and neutrophils with no other apparent abnormality. Conversely, *HoxA9* knockout mice had decreased numbers of granulocytes and attenuation in G-CSF responsiveness. A recent study on *HoxA5* gene expression using antisense oligos demonstrated inhibition of neutrophil and monocytic differentiation.²⁵⁰ It was hypothesized that *HoxA5* functions in early myeloid progenitors before commitment. Lastly, it was reported that *HoxB7* and *Hlx* genes might be involved in terminal differentiation or maturation of granulocytic cells.^{251,252} The overall importance of the *Hox* gene family is well established in that they seem to control progression of immature myeloid precursors into mature granulocytes.

Hematologic and acute phase response: treatment strategies

Patients suffering 15% or greater body surface area burns undergo significant alterations in their circulatory status. The blood and its constituent elements must be supported, with the primary goal in the initial management phase being support of intravascular volume. A patient suffering 40% surface area burn would be subjected to a 40–50% reduction in circulating volume if not resuscitated. If the volume of resuscitation fluid is insufficient to meet the patient's needs then the patient will suffer inadequate tissue perfusion and shock, but hemoconcentration will also develop. With progressive increases in hemoglobin concentration, there is a disproportionate change in the blood's viscosity and resistance to flow through the circulatory bed. By maintaining plasma volume, perfusion will be enhanced with restoration of the rheological properties of the blood.

Patients suffering significant burns will experience some progressive decreases in their hemoglobin and hematocrit values over the first several days of hospitalization.^{10,22,29,253} This is related to the reduction in red cell mass, due to the changes in red cell characteristics and erythropoietic response. Additionally, with expansion in plasma volume following successful resuscitation, there may be an element of dilution. Further reductions in hemoglobin and hematocrit concentrations are also the consequences of repeated blood sampling and blood loss related to wound manipulation. The performance of escharotomies can be associated with significant blood loss from thrombosed vessels that bleed once tissue turgor is reduced following eschar release. The characteristics of the burn wound can also contribute to ongoing hematologic loss. Patients with deep partial-thickness wounds with their associated damaged capillary bed can serve as sites for ongoing blood loss.

The optimum hematocrit for patients suffering extensive burn injuries is a matter of opinion. Many experts suggest maintaining hematocrit values of 25% or greater. In doing so, a considerable number of transfusions are likely to be required as attempts at replacement with iron and erythropoietin are typically not successful in patients with major body surface area injuries. Many patients can tolerate a hematocrit of less than 25%, and young healthy individuals whose wounds are closed will tolerate a hematocrit in the 18–22% range with a mild tachycardia and no impairment in wound healing or physiologic response. The optimum hematocrit for the individual burn patient should be adjusted to their clinical status and their co-morbid conditions. Elderly patients with significant underlying cardiac disease should be supported more aggressively with maintenance of their hemoglobin and hematocrit values above the 30%. Strategies should be invoked throughout the patient's care and surgical interventions to limit blood loss. The use of tourniquets, vasoconstrictive agents, tumescence with burn eschar excision, and fibrin sealants provide opportunities to limit operative blood loss. Additionally, the use of hemo-dilution with auto-transfusion represents another approach that can be used to limit the need for transfusions, particularly in patients who will not accept random donor transfusions.²⁵⁴ Blood loss must be closely followed during the course of surgery to avoid hypotensive episodes and the development of systemic acidosis which will further compromise the patient's hemostatic capacity and exacerbate bleeding. Attention to the patient's coagulation parameters and platelet counts are important to avoid the development of coagulopathic complications due to dilutional coagulopathy. Patients receiving intensive broad-spectrum antibiotic therapy must be carefully monitored for the development of vitamin K-dependent coagulopathy. This must be corrected with the replacement of vitamin K as well as coagulation factor component therapy.

The goal of nutritional support in patients with burn injuries is to replete lean body mass and to facilitate restoration of visceral proteins. Hypo-albuminemia is a near universal response to significant burn injury. The benefit of albumin replacement therapy and how it impacts outcomes is a matter of opinion. In today's environment of cost containment, the challenge to the clinician is to provide care that is evidence based. A recent analysis by the Cochrane Injuries Group has suggested that

there is no indication for the use of albumin in the management of critically ill patients.²⁵⁵ Whether burn patients fall outside this recommendation remains controversial.

The response of the formed elements of the blood following burn injuries has been reviewed in great detail previously in this chapter. The impact of various interventions may also compound the pathologic response induced by the burn injury. Patients receiving heparin for the maintenance of various vascular devices may experience heparin-induced thrombocytopenia. It has been our practice for the last decade to not use heparin flushes to maintain intravascular catheters. With this approach we have had no increase in complications related to line occlusion or embolic events and no incidences of heparin-induced thrombocytopenia. Changes in leukocyte numbers occur as part of the response to injury and can be further compounded by responses to drug therapy and/or septic events. Rapid diagnosis and effective therapy for infections should be undertaken. In patients who develop profound neutropenia, current clinical experience suggests that exogenous administration of recombinant human G-CSFs is effective in supporting increases in circulating neutrophil numbers.

Following burn injury there are dilutional reductions and depletion of coagulation factors. However, after the early burn phase, the tendency for burn patients is to be hypercoagulable. A reduction in antithrombin III levels is associated with an increased propensity for microvascular thrombosis. Limited clinical trials have been performed in which there appears to be a therapeutic effect for the administration of antithrombin III in the early postburn phases.^{41,42,46} The studies that have been reported suggest that there is a relative preservation of burn wound vascularity and an enhancement in the healing

process. There is also some suggestion that there may be a benefit to other microvascular beds such as in the lung with preservation of pulmonary function. These studies are preliminary and provide intriguing observations that need to be confirmed in larger multicenter trials. Burn patients with intravascular devices are at risk for the development of thrombotic complications with limb ischemia as can occur with femoral arterial lines. Also, the presence of large-bore femoral venous catheters has been associated with up to a 30% incidence of deep vein thrombosis. The risk of pulmonary emboli is a recognized risk in burn patients. Preservation of circulatory volume and aggressive and early ambulation are important strategies to limit deep vein thrombotic complications and pulmonary emboli. The risk of thromboembolic complications can extend into the rehabilitation phase in patients with large burns.

Conclusion

Burn-induced changes in hematopoiesis and the induction of the acute phase response are components of the body's reaction to injury. With an extensive degree of injury, or when complications develop, the physiologic limits of this system can be exceeded. The blood and its constituent elements must provide tissue nutrition, and maintain host defenses and hemostasis. Modern day burn care allows the clinician to limit the impact of injury and provide access to various components in the form of replacement therapy. Pursuing a better understanding of the basic pathobiology of thermal injury will provide additional opportunities to intervene in the response to injury and improve patient outcome.

Significance of the adrenal and sympathetic response to burn injury

Stephen B. Jones, Kuzhali Muthu, Ravi Shankar, and Richard L. Gamelli

Chapter contents

Introduction	343
Part I — Sympathetic activation and release of catecholamines following burn trauma.	344
Part II — Adrenal cortical steroids following burn trauma	350

Introduction

The physiological importance of the adrenal gland is most often associated with the release of epinephrine and glucocorticoids in response to cognitive stress widely recognized as the ‘fight or flight’ response. Such responses involving the hypothalamic–pituitary–adrenal axis begin with the hypothalamic release of corticotropin-releasing hormone (CRH) that mediates the release of adrenocorticotropic hormone (ACTH) from the pituitary that in turn stimulates cortisol synthesis and release from the adrenal cortex. Hypothalamic stimulation also initiates epinephrine and norepinephrine release from the adrenal medulla as well as the release of sympathetic neurotransmitter norepinephrine from adrenergic nerve terminals throughout the body. The action of these hormones and neurotransmitters is traditionally thought to serve in a compensatory manner facilitating heightened mental awareness along with metabolic and cardiovascular activity that supports rapid increases in muscular work.

Thermal injury, like other forms of trauma as well as infectious challenge, is a non-cognitive stimulus but also results in an elevated hormone/neurotransmitter milieu similar in magnitude to that of the cognitive ‘fight or flight’ responses.^{1,2} However, there are important characteristics of the injury response that contrast with the fight or flight response. These include prolonged hormone/neurotransmitter elevation, the absence of increased muscle work limiting metabolic demand and the presence of massive tissue injury. Additional hormone/neurotransmitter responses may also be evoked by surgical debridement of burn wounds and skin grafting procedures. The second surge of stress hormones complicates the severe metabolic derangements and compromised immune capacity that is characteristic of the burn course during the initial 7–10 days following injury.

Regardless of the cognitive or non-cognitive nature of stress hormone stimulation, events that increase corticosteroids and catecholamines represent a stress response but may or may not

involve pathology. Traumatic injury, however, clearly initiates an initial stress response with a magnitude that is proportional to the severity of injury. Under these conditions, hormone/neurotransmitter release seems to promote survival. Although such a benefit may be difficult to see in human injury, experimental animal models have provided some insights. Animals that lack stress hormones or suffer from impaired release or where hormone action is pharmacologically blocked often die of an otherwise survivable event. Similarly, overwhelming traumatic injury in man may result in stress hormone release that is detrimental to survival. Whereas this may also be difficult to document in burn patients, animal studies have demonstrated that exogenous administration of high amounts of stress hormones is detrimental.

Two historical perspectives are important to consider regarding stress and the trauma of burn injury. First is the concept described by Cuthbertson,³ where the initial response to thermal injury is considered an ‘ebb’ phase characterized by reduced metabolism and tissue perfusion. Within days there is a transition to a ‘flow’ phase typified by increased resting energy expenditure and hypermetabolism with supportive cardiovascular function. Changes in endocrine hormone levels are important for these acute catabolic alterations. The concepts of ‘stress’ and release of ‘stress hormones’ widely used today, were clarified by the classic work of Selye.⁴ His notion of stress responses include an initial ‘alarm reaction’ of fairly short duration with high levels of stress hormones followed by a ‘resistance phase’ described as a prolonged period during which there is compensation to maintain homeostasis during continued stress. Selye’s final stage of ‘exhaustion’ is where compensation could not be maintained and death rapidly follows. The acute initial period of high-stress hormone release encompasses both Cuthbertson’s ebb phase and Selye’s alarm reaction and the flow phase³ has similar features to the resistance phase.⁴ These compensatory changes promote increased energy expenditure and support cardiovascular function; however, in patients with severe injury the same compensatory changes result in depletion of energy reserves, extensive muscle wasting and immune suppression; all of which are hallmarks of post-burn sequelae. This compensatory pattern is described as a hypermetabolic state with patients displaying elevated resting metabolic rates for several weeks to months following injury.^{5–7} The extent of the hypermetabolic response is dependent upon the extent and depth of burn injury, septic complications and surgical interventions. Although the well-conceived concepts of ebb and flow and generalized phases of stress help to conceptualize what is happening during recovery

from uncomplicated thermal injury, questions related to the magnitude of stress hormone responses and beneficial versus detrimental actions in the recovery from severe thermal injury remain unanswered.

During the last 50 years great strides have been made in the care of burn patients and with various treatment modalities attempting to exploit some of the concepts described above. Examples include:

- rapid fluid resuscitation to stabilize cardiovascular function and reduce the stimulus for continued sympathetic drive;
- nutritional support to meet metabolic demands and to support homeostasis during healing;
- elevated environmental temperatures and occlusive dressings to lessen the metabolic demands, reduce metabolic rate and cardiac output and to optimize wound healing.

Aside from the regulation of metabolic and cardiovascular function, neuro-immune interactions may be important in mediating the marked alterations in immune function that often follow severe injury. In the present chapter we have chosen to present the adrenomedullary–neurotransmitter activation and actions as separate from the adrenocortical activation and actions to clarify specific responses as we currently understand them. To this end the current chapter will review the magnitude and time course of the stress hormone/neurotransmitter responses to thermal injury as well as how the action of these substances may be integrated. How these responses may be beneficial or detrimental during the course of recovery will also be addressed. Given the cadre of pharmacologic antagonists and agonists available to the clinician, taking a mechanistic approach to understanding adrenal hormones and neurotransmitter involvement in the pathophysiology of severe thermal injury is critical to further advance the successful treatment of these patients.

Part I — Sympathetic activation and release of catecholamines following burn trauma

Although clinical observations suggested the activation of sympathetic nerves in response to thermal injury^{8–10} direct evidence for such activation was not fully appreciated until the simultaneous publication of papers by both American and Swedish groups that documented these responses.^{11,12} These landmark studies described marked elevations in 24-hour urinary levels of norepinephrine and epinephrine in burn patients using a bioassay system. Despite considerable variation both within individuals and between patients, the increases in urinary norepinephrine and epinephrine were proportional to the severity (size) of the injury, were highest within the first 3 days post burn and in many cases remained elevated for several weeks. Furthermore, these studies also suggested that subsequent surgical interventions and the onset of sepsis and septic shock such as hypotension or serious infections caused catecholamine secretion to increase again. Since these early reports of urinary catecholamines as measured by bioassay techniques, many studies have confirmed the initial sympathetic responses in burn patients using fluorometric, HPLC/electrochemical or radioenzymatic techniques in plasma and urine samples.^{13–17} However, documenta-

tion of the striking prolongation of sympathetic activation extending from 5 to 35 weeks following thermal injury¹² has not been repeated using newer analytical techniques. With improvements in critical care medicine and the management of burn patients during the last 40 years, prolonged sympathetic activity may not occur during extended recovery. In contrast, elevations in catecholamines may still occur in transient response to surgical procedures but cardiovascular, nutritional and immune-related interventions, as part of the treatment regimen, may ameliorate the extent or impact of the hormone response (Table 25.1). Nonetheless, in the light of the strong evidence for sympathetic activation consequent to thermal injury, the compensatory or possible decompensatory consequences are important to consider.

In response to thermal injury there are acute responses in what Cuthbertson³ described as an ebb phase and long-term responses that support a flow phase. Cardiovascular adjustments to thermal injury appear to be critical for survival following burn trauma and with initial reductions in cardiac output sympathetic responses are rapidly brought into play as reviewed by Carleton.¹⁸ Initial sympathetic activation contributes to the dramatic increases in peripheral vascular resistance that preserves mean arterial pressure but typically limits perfusion to the kidney and splanchnic beds. Although the mechanisms for the reduction in cardiac output are not completely understood, they are in part related to the sudden loss of vascular volume as a result of fluid transudation of plasma from the wound and from non-wound vascular sites.^{19,20} Movement of fluids from the vascular to interstitial spaces are compounded by the loss of plasma proteins through the incompetent capillary beds that normally act to retain ions by Donnan equilibrium.²¹ Such apparent hypovolemia would initially decrease blood pressure and baroreceptor afferent nerve activity with resultant increases in efferent sympathetic nerve activity. The resultant increase in peripheral vasoconstriction and consequent increase in peripheral vascular resistance are mediated in part by nerve-stimulated release of norepinephrine but also to a significant degree by both angiotensin II (AII) and arginine vasopressin.^{15,22} Since arginine vasopressin (AVP) has been shown to directly depress myocardial function in the isolated heart and this depression can be reversed pharmacologically, AVP may contribute to myocardial depression following burn injury.²³

Myocardial depression following thermal injury can be manifest as decreased cardiac output due to decreases in vascular volume, reductions in diastolic compliance as well as decreases in myocardial contractility. Various myocardial depressant factors have also been described for many years without specific detailed identification of the actual substances. Such deficits in contractility are compounded by the increases in aortic pressure afterload that is the consequence of increased peripheral vascular resistance and, in total, contribute to the observed reductions in cardiac output. Although diastolic dysfunction has been demonstrated in patients following thermal injury, evidence for decreases in contractility are largely based on animal studies with little evidence that this occurs in patients. Consequent to decreased ventricular performance and potential intrinsic myocardial dysfunction, sympathetic drive would be important to maintain ventricular function of the non-compromised muscle upon recovery from thermal injury.

TABLE 25.1 INFLUENCE OF CATECHOLAMINES ON CARDIOVASCULAR, METABOLIC, AND IMMUNE RESPONSE TO THERMAL INJURY

Physiologic variable	Sympathetic-mediated change following burn injury
Resting metabolic rate	Increase ³⁷ Increase ³⁸ Increase ¹⁷ Increase (<i>in vitro</i>) ²⁶⁶
Proteolysis	No change (urea production) ³⁹ No change (protein oxidation) ³⁷ Decrease ⁴⁸
Glucose production and oxidation	Decrease secondary to increase in lipid catabolism ^{38,267} No change ³⁷
Glycogenolysis	Increase (indirect evidence via cAMP) ³⁶
Gluconeogenesis	Increase (indirect evidence via cAMP) ³⁶
Lipolysis	Increase ³⁹ Increase ³⁷ Increase ³⁸ Increase ⁴¹
Cardiac output	Increase ³⁸ Increase ³⁹
Peripheral vascular resistance	Unknown
Heart rate	Increase ⁴⁸ Increase ³⁹
T-cell number and function	Unknown
B-cell number and function	Unknown
Neutrophil number and function	Unknown
Monocyte number and function	Increase (indirect — clonogenic potential) ¹⁴⁴ Increase (indirect — clonogenic potential) ¹⁵⁶
Citation of studies from the current literature suggesting that sympathetic activation is involved in changing the above physiologic variables following thermal injury.	

Cardiovascular disturbances might be predicted to be the dominant signal initiating a generalized sympathetic response but the persistence of such sympathetic activation after hemodynamic stabilization suggests that afferent stimulation from other sources may initiate as well as maintain this response. Hemodynamic stabilization in burn patients typically requires 1–2 days after fluid resuscitation and is followed by the flow phase of recovery characterized by low peripheral vascular resistance, elevated cardiac output, increased peripheral blood flow and increased metabolism.^{24,25} The marked decrease in peripheral vascular resistance most likely drives this hyperdynamic phase by decreasing cardiac afterload, increasing cardiac preload and thus increasing cardiac output. There is abundant evidence that mediators of neural, humoral and metabolic origin are involved in driving the decrease in vascular resistance following thermal injury but which ones are dominant and details of the time sequence of release are not well defined. Specific adrenergic agonists such as epinephrine may be involved through actions on vascular β -adrenergic receptors that mediate vasodilation²⁶ and the specific importance of β_2 -adrenergic receptors in vasodilation has recently been demonstrated using knockout mice.²⁷ The situation is complicated in

the burn patient by the increase in nerve-stimulated release of norepinephrine which has the potential to mediate vasoconstriction. However, there is evidence that the local distribution of adrenergic receptors mediating either vasodilation or vasoconstriction will determine the effect of circulating epinephrine and nerve-stimulated norepinephrine release on peripheral vascular resistance.²⁸ In addition, increased tissue metabolism has been recognized for many years to produce metabolites that mediate increased blood flow by decreasing vascular resistance.²⁹ With markedly increased metabolism in major burns, these metabolites along with catecholamines, nitric oxide,³⁰ and atrial natriuretic peptide¹⁵ may contribute to the observed decreased vascular resistance.

Typically, decreases in tissue perfusion leading to compromised organ function only occur in patients with complications related to septic events or severe metabolic acidosis. Most often in thermally injured patients there is a modest decrease in mean arterial blood pressure that is not indicative of hypoperfusion and is left untreated. Where decreases in peripheral vascular resistance become dominant with marked decreases in mean arterial pressure, pressor agents may be required to maintain adequate tissue perfusion and norepinephrine is the

drug of choice providing both vasoconstrictor and inotropic effects. Clinical use of vasoconstrictor and inotropic agents are essential to counter low tissue perfusion during periods of altered hemodynamic function often seen with the onset of sepsis in burn patients.

In this regard it is interesting to note the recent work by Macarthur et al.³¹ suggesting that the inactivation of catecholamines by superoxide anions contributes to the observed hypotension of septic shock. Treatment of rats with superoxide dismutase not only abrogated endotoxin-induced hypotension in anesthetized rats but also elevated circulating levels of catecholamines. These findings suggest that compensatory sympathetic activation that counteracts hypotension during conditions of sepsis may be blunted by inactivation of catecholamines by superoxides in the extracellular milieu. More recently these studies have been extended³² to a conscious rat model with infusion of live bacteria to simulate conditions of sepsis. Furthermore, these investigators modified the activity of the superoxide dismutase mimetic agent used in their initial study by 100-fold and demonstrated its effectiveness to enhance plasma levels of catecholamines, enhance blood pressure and improve survival. In their most recent work³³ these investigators demonstrated that nitric oxide, widely recognized as a mediator of hypotension during systemic inflammation as occurs in sepsis, decreases the biological activity of norepinephrine. Furthermore, increasing NO levels in an isolated perfused mesenteric circulation was shown to decrease vascular responses to endogenously released norepinephrine (NE) without altering nerve-stimulated release. These findings may provide some insight into the clinical observations involving critically ill trauma patients where exogenous norepinephrine administration is ineffective in correcting hypotension.

Following the initial insult of thermal injury the ebb or immediate phase of recovery is characterized by decreased body temperature and decreased oxygen consumption that is accompanied with progressively elevated lactate levels and developing hyperglycemia.^{34,35} The same period of recovery involves intense sympathetic stimulation suggesting the involvement of adrenergic mechanisms mediated by adenylyl cyclase and cAMP in the mobilization of liver glycogen to glucose.³⁶ Developing hypermetabolism that follows 1–2 days later in the flow phase can also be attributed to adrenergic influences^{17,37} but does not involve increased glucose mobilization and utilization since adrenergic blockade increased glucose production and clearance under these hypermetabolic conditions.³⁸ The experimental studies of Wolfe and Durkot³⁸ suggest that adrenergic drive following thermal injury facilitates lipolysis driving increased fatty acid oxidation. These results are based on changes observed following adrenergic blockade with propranolol and further clarify that the observed increase in glucose production and clearance under such conditions reflect a shift to carbohydrate utilization in the absence of mobilized lipid. Examination of the importance of adrenergic drive on lipid metabolism following thermal injury was extended to human patients through the use of stable isotopic studies as well as adrenergic antagonists.^{39–41} These results not only indicate that lipolysis following thermal injury is mediated by β_2 -adrenergic receptors, but suggest increased triglyceride-fatty acid cycling with resultant heat production.

The initial description of the sustained hypermetabolic response to thermal injury⁴² prompted studies to examine the role of thyroid function and catecholamines in mediating this response. Although abnormal thyroid function was not involved in the response,^{42,43} Wilmore developed experimental paradigms suggesting the role of catecholamines in mediating the hypermetabolic response to thermal injury.¹⁷ Evidence for the positive correlation of increased plasma catecholamines and whole-body oxygen consumption following thermal injury,¹⁷ as well as the demonstration that adrenergic blockade lowers the thermal injury-induced increase in metabolic rate and cardiac output to control levels in animal models directly support this contention.^{17,38} However, experimental findings using the rat suggested that the adrenal medulla is essential for high rates of heat production following thermal injury but is not responsible for the primary drive of the hypermetabolic response.^{44,45} These conclusions are further supported by experiments examining hypothalamic temperature regulation that suggest an upward shift in the set or operating temperature following thermal injury. The net result of this shift is increased metabolism at room temperature. Animals with hypothalamic lesions did not increase metabolism following thermal injury and were chronically hypothermic⁴⁶ not unlike experiments where the adrenal medulla was removed prior to thermal injury.⁴⁴ These results are consistent with clinical observations in burn patients in whom reductions in heat loss were achieved with occlusive dressings; and elevated environmental temperatures have decreased metabolic rate and catecholamine secretion.^{14,47}

Building on these findings that catecholamines drive post-burn hypermetabolism, Herndon et al.⁴⁸ demonstrated that pediatric patients could be treated with the β -adrenergic blocker propranolol to successfully reduce metabolic rate without compromising cardiovascular function. In a more recent study by this group,⁴⁹ β -adrenergic blockade in pediatric patients for 4 weeks during recovery from severe burns decreased the elevation in resting energy expenditure and reversed the reduction in net muscle–protein balance by 82%. Such treatment also prevented the loss in fat-free whole body mass and provided for a more efficacious recovery in these children.

An important and all too frequent complication of severe thermal injury is infection that frequently leads to sepsis, septic shock, multiple organ failure and death. The development of septic complications can decrease predicted survivability by up to 50%.⁵⁰ As with thermal injury, infection results in marked sympathetic responses that are well characterized in both experimental and clinical settings. Whereas experimental paradigms of sepsis have used plasma catecholamines, nerve recordings and norepinephrine turnover to assess sympathetic activation,^{51–56} human studies have primarily focused on changes in plasma catecholamines.¹ Similar to thermal injury, sympathetic responses also appear to be proportional to the degree of insult, based on experiments using incremental doses of bacterial endotoxin.⁵² Furthermore, animal models of septic peritonitis suggest that initial sympathetic activation, as measured by elevated levels of plasma norepinephrine and norepinephrine turnover, persist for many hours.^{51,54} Burn patients are most susceptible to infection during the second week of their hospitalization when the sym-

pathetic response, as reflected by urinary and plasma catecholamines, has moderated but is still elevated.^{13–15} Although the onset of bacterial infection and developing sepsis would be expected to cause marked increases in plasma catecholamines above that due to burn alone, longitudinal studies charting the course of plasma catecholamines following thermal injury leading to infection and progressing into septic shock are not available. While the consequences of secondary insults following the initial injury are important to consider, unfortunately no information is available comparing plasma catecholamine changes with burn and burn plus sepsis.

Sympathetic influences on immune function

Over the last 20 years experimental evidence describing the interactions between neural and immune cell systems has expanded greatly. This has important implications in our understanding of the pathobiology of thermal injury since *in vivo* sympathetic activation as well as compromised immune function both occur following thermal injury. In addition to endogenous release of catecholamines, burn patients are often treated with adrenergic pressor agents; they may be on a therapeutic regimen of β -adrenergic antagonist prior to injury or hypermetabolism may be controlled in pediatric burn patients with β -adrenergic antagonists. Thus, adrenergic modulation following thermal injury may involve therapeutic as well as endogenous mediators and may have an important impact on immune system function.

For the activation of sympathetic nerves to influence immune responses, evidence of sympathetic innervation in peripheral immune structures, namely the lymphoid organs, is important to consider. Existing anatomical evidence is based on immunohistochemical techniques to visualize tyrosine hydroxylase (the rate-limiting step in the biosynthesis of norepinephrine). These studies clearly indicate a substantial innervation of all primary (thymus and bone marrow) and secondary (spleen and lymph nodes) lymphoid organs.^{57–61} Furthermore, they also show sympathetic innervation in the immune cell compartment of the spleen (the white pulp), the periarterial lymphoid sheath, marginal zone and marginal sinus areas as well as in the splenic capsule and trabeculae.^{62–66} Sympathetic nerve terminals have been described in direct apposition to T cells, interdigitating dendritic cells and B cells using electron microscopic techniques.⁶³ The proximity of nerve terminals to immune cells may be critical in achieving the necessary local concentrations of neurotransmitters at the neural-immune junctions to modulate immune functions. In fact, that neuro-immune junction is estimated at 6 nm⁶⁵ in comparison to 20 nm in typical CNS junctions. Therefore a high enough neurotransmitter concentration could be realized across these small junctions to impact on resident immune cells.

Anatomical evidence of sympathetic innervation of the immune system is complemented by evidence for nerve-stimulated release of norepinephrine neurotransmitter in both spleen and bone marrow.⁶⁷ Whereas evidence in spleen has been recognized for many years and has been assessed in a variety of ways, norepinephrine release in bone marrow has only been recently described using norepinephrine turnover techniques based on radiotracer methods involving *in vivo* experimental paradigms.⁶⁷ In contrast, exocytosis of norepinephrine from lymph nodes has not been demonstrated. To

complete the criteria for the physiologic importance of functional innervation, nerve-stimulated release of norepinephrine within lymphoid organs must increase at the appropriate time to influence the immune response and norepinephrine modulation of immune responses must be demonstrated.

β -adrenergic receptors, particularly β_2 subtypes, are known to be expressed on a number of different immune cells including activated and resting B cells, naïve CD4+ T cells, T-helper (Th1) cell clones and newly generated Th1 cells but they are not expressed in newly generated Th2 cells.^{68–71} Furthermore, there is significant evidence that norepinephrine can modulate the function of CD4+ T cells, which in turn can modulate antibody production of B cells.⁷² In addition, norepinephrine can directly influence B cell antibody production depending upon the time of exposure following activation.^{73,74} The physiologic importance of these *in vitro* findings are supported by a series of *in vivo* experiments involving severe combined immune-deficient (*scid*) mice depleted of norepinephrine prior to reconstitution with antigen-specific Th2 and B cells. These experiments demonstrate that norepinephrine is necessary for maintaining a normal level of antibody production *in vivo*.⁶⁸ Furthermore, other recent whole animal experiments, also involving *scid* mice, provide evidence that the immune response itself stimulates the release of norepinephrine from adrenergic nerve terminals in bone marrow and spleen, that in turn can influence antibody production by B cells.⁷⁵ Although these findings fall far short of direct application to immune cell function following thermal injury they suggest the important potential of sympathetic activation in mediating immune responses.

In addition to neural influences on T and B cell function, there are direct effects on myeloid cell function particularly with respect to lipopolysaccharide (LPS)-stimulated cytokine production. The most striking examples of neural influences on macrophage function were demonstrated by the work of Spengler et al.,⁷⁶ who concluded that α -adrenergic stimulation increases tumor necrosis factor- α (TNF- α) release whereas β -adrenergic stimulation decreases such release in response to LPS. They provided further evidence to suggest that extracellular stores of catecholamines in macrophages are capable of modulating TNF- α release. Furthermore, sympathetic inhibition of TNF- α release initiated by LPS has been suggested to occur in whole animal preparations although adrenergic actions on macrophages were indirect.^{32,77–82} More direct evidence of adrenergic inhibition of LPS-stimulated TNF- α production has involved whole blood.^{82–87} Apart from adrenergic inhibition of LPS-stimulated TNF- α release in isolated macrophages,^{88–91} similar inhibition of LPS-stimulated TNF- α production has also been demonstrated in human mast cells,⁹² microglial cells,⁹³ astrocytes⁹⁴ and cytotoxic T lymphocytes.⁹⁵ In contrast to adrenergic stimulation of TNF- α release, experiments with isolated atria,^{96,97} myenteric plexus⁹⁸ and brain tissue⁹⁹ have demonstrated that TNF- α can negatively impact on the release of norepinephrine.

Adrenergic influences on the expression and release of interleukin-6 (IL-6) has been suggested by a number of studies demonstrating increases in plasma IL-6 in response to direct or indirect stimulation.^{100–102} Adrenergic enhancement of IL-6 responses to LPS has also been demonstrated *in vivo*^{78,80} as well as in *ex vivo* paradigms using isolated liver.⁹¹ In isolated

cell systems, adrenergic stimulation enhances LPS-induced IL-6 response.^{103,104} Catecholamines in combination with IL-1 β stimulate IL-6 release from rat C6 glioma cells and vasoactive intestinal polypeptide (VIP) has been reported to synergize with norepinephrine to induce IL-6 release in astrocytes.^{105,106} In addition, adrenergic agonists have been shown to mediate IL-6 release in brown adipocytes, pituicytes, hepatocytes, astrocytes and thymic epithelial cells.^{105–111}

In contrast, Nakamura et al.⁹⁴ reported that catecholamines decreased the IL-6 response to LPS and van der Poll et al.⁸⁶ demonstrated that norepinephrine inhibits the LPS-induced IL-6 response in whole blood. Other evidence for adrenergic suppression of IL-6 responses has been suggested by the work of Straub.^{112–114} Using isolated splenic tissue preparation, electrically stimulated release of norepinephrine appears to inhibit IL-6 production induced by LPS or bacteria. These authors suggest that adrenergic inhibition of IL-6 is reduced under conditions simulating infection where cytokine mediation of the inflammatory response is compensatory in eradicating the bacterial load. It is apparent from these studies that catecholamines can exert a negative or a positive influence on proinflammatory cytokines, especially IL-6. However, when these different modulatory functions come into play and what role(s) they play in the pathophysiology of burn injury are unexplored.

Although the exact mechanisms of the negative modulation of proinflammatory cytokines by catecholamines are poorly understood, it may be achieved through the ability of catecholamines to induce the anti-inflammatory cytokine interleukin-10 (IL-10).^{80,83,115,116} Whole animal studies involving assessment of circulating levels of IL-10,⁸⁰ as well as studies of human whole blood and mononuclear cells stimulated with LPS in the presence of adrenergic agonists,^{82,83,116} support this premise. In addition, experimental neurotrauma results in increased IL-10 consequent to endogenous adrenergic stimulation in the absence of LPS or other evidence of infectious challenge.¹¹⁷ The only experimental evidence suggesting an attenuation of IL-10 with adrenergic stimulation involved a macrophage cell line (RAW 264.7).¹¹⁸

Evidence that elevations of IL-10 can be blocked with inhibition of protein kinase A^{116,119} is consistent with adrenergic mediation of changes in TNF and IL-6 and suggests that activation of protein kinase A is important in effecting these adrenergic modulations of cytokine release. More specifically, the recent work of Platzer et al.,¹¹⁵ suggests that catecholamines in monocytic cells directly stimulate the IL-10 promoter/enhancer and provide evidence that a cAMP response element was the major target of the cAMP/protein kinase A pathway. In contrast, two recent studies from our laboratory report evidence that although adrenergic stimulation increases IL-10 release from macrophages, release of cytokines TNF- α and IL-6 are inhibited by direct adrenergic stimulation not secondary to IL-10.^{120,121} These studies involved both peritoneal elicited- and bone marrow progenitor derived-macrophages under normal conditions as well as following cecal ligation and puncture injury. Macrophages from both preparations were incubated overnight with LPS both in the presence and absence of epinephrine and cytokines were determined in the conditioned media. Epinephrine attenuated TNF- α in the conditioned media but increased IL-10; however, addition of anti-IL-10

antibody did not prevent epinephrine's ability to block TNF- α reductions. Further experiments demonstrated the action of epinephrine to inhibit LPS-stimulated release of proinflammatory cytokines to be mediated by β_2 -adrenergic receptors. The dominance of direct adrenergic inhibition of LPS-mediated proinflammatory cytokine was maintained during conditions of sepsis although such conditions elevated endogenous levels of IL-10.

Adrenergic stimulation of bacterial growth

Since the identification of mammalian hormone and neurotransmitter receptors in bacterial cells there has been considerable interest in defining a role for such signaling molecules in bacterial cells. As a consequence during the last 15 years support has emerged for the concept that release of norepinephrine within intestinal tissue promotes the growth of bacteria within the gut.^{122–124} Initial experiments demonstrated the growth-promoting action of catecholamines *in vitro* using several different bacterial species and provided evidence that these compounds were not acting as nutritional substrates. Since growth-stimulating effects of norepinephrine were not blocked by adrenergic blocking agents, adrenergic receptors do not appear to be involved.^{125,126} Further observations suggest that norepinephrine may act within an 8-hour period to induce bacterial growth, during which time stimulation of growth factors can promote bacterial growth.^{127,128} Norepinephrine-stimulated bacterial growth has also been shown to produce Shiga-like enterotoxins from enterohemorrhagic strains of *E. coli*. Furthermore, norepinephrine promotes the expression of K99⁺ pilus adhesin, a virulence factor known to play a critical role in the attachment of these bacteria to the intestinal wall which initiates the infective process.^{129,130} Although these studies utilize very high concentrations of norepinephrine compared to the observed plasma concentrations following thermal injury, bacteria *in vivo* may be exposed to high norepinephrine concentrations if such bacteria are in close proximity to the nerve terminal synapse. A related concern is the lack of information regarding the actual norepinephrine concentration within the culture media throughout the incubation period. Whereas rapidly growing bacterial cultures may generate an acid environment in which catecholamines are quite stable, initial growth conditions containing low bacterial counts and minimal nutrients may promote rapid deterioration of norepinephrine. However, high initial norepinephrine concentrations in cultures may counteract such unfavorable conditions but in turn would provide misleading dose-response information.

The extensive sympathetic innervation of the gut and associated structures has been recognized for many years with well-defined nerve terminals located primarily along blood vessels but without evidence of neurotransmitter release into the intestinal lumen. Furthermore, there is considerable evidence that once released from nerve terminals, most norepinephrine is taken back into the same terminals by uptake 1 (active) or 2 (passive) mechanisms, metabolized into a non-active form or diffuses through tissues to reach blood vessels to become part of the circulation.¹³¹ Thus, even though intestinal bacterial growth has the potential to be enhanced by the neurotransmitter norepinephrine, transport of the norepinephrine into the intestinal lumen would seem problematic. However,

since massive catecholamine release is such a consistent component of burn patients, especially those with superimposed sepsis, the hypothesis that bacterial growth can be enhanced by norepinephrine is very appealing.

Important *in vivo* findings strengthen this concept by demonstrating that cecal bacterial growth increases dramatically following massive *in vivo* release of norepinephrine and that passage of bacteria through the gut enhance their growth response to norepinephrine. In the first case¹²⁴ mice were treated with 6-hydroxydopamine, a neurotoxin that displaces norepinephrine from adrenergic nerve terminals causing a transient but massive sympathetic reaction. At 24 hours post treatment cecal bacterial growth was elevated 3–4 degrees of magnitude compared to vehicle-treated controls but bacterial growth returned to control levels by 14 days. In the second study¹²⁹ an attenuated strain of *Salmonella typhimurium* was administered to rhesus monkeys whereupon isolated fecal bacterial cultures from these animals displayed increased *in vitro* growth response to norepinephrine. To elucidate whether this hypothesis has a role in the pathophysiology of thermal injury with sepsis, future studies must build on experimental paradigms of thermal injury to demonstrate that endogenous norepinephrine enhances bacterial growth leading to sepsis.

Evidence for norepinephrine regulation of myelopoiesis in experimental thermal injury with sepsis

Patients with severe burn trauma often display significant impairment in cell-mediated immunity involving defective neutrophil chemotaxis, phagocytosis and superoxide production.^{132–135} Patients with sepsis and systemic inflammatory response may also present with monocytosis and neutropenia.^{136,137} While neutropenia and defective neutrophil functions may compromise host defense, monocytosis has the potential to fuel excessive cytokine production through increased availability of circulating and tissue monocyte/macrophages. For the past 15 years our laboratory has been investigating bone marrow following thermal injury with sepsis to understand mechanisms that govern leukocyte production and how they might contribute to the observed defects in leukocyte functions. The potential for sympathetic activation to modulate myelopoiesis following thermal injury and sepsis is supported by previous studies where adrenergic stimulation has been shown to participate in the regulation and control of hematopoiesis.^{138,139} Maestroni¹³⁹ has not only provided evidence for the presence of adrenergic receptors on bone marrow immune cells but also that adrenergic agonists stimulate lymphopoiesis while attenuating myelopoiesis under normal non-injury conditions. These findings are further strengthened by animal experiments where adrenergic agents have been shown to modulate both lympho- and myelopoiesis.^{140–143} Another important factor supporting the possible adrenergic regulation of myelopoiesis following thermal injury is that sympathetic activation can occur directly within the bone marrow compartment with nerve-stimulated release of norepinephrine in close proximity to developing immune cells. We have documented a significant increase in murine bone marrow norepinephrine release in response to either cold exposure or bacteria through the use of traditional pulse-chase experiments.⁶⁷ Furthermore, we have extended these measurements to our

murine model of thermal injury with sepsis and demonstrate increased bone marrow norepinephrine release in response to thermal injury with sepsis.¹⁴⁴

These findings suggest that sympathetic activation has the capacity to drive events within the bone marrow and adrenergic-mediated expansion of leukocyte production could conceivably contribute to heightened inflammatory responses with immune challenge following thermal injury with sepsis. Experimental evidence suggesting that adrenergic stimulation inhibits myelopoiesis under normal conditions¹³⁹ but is shifted following injury to enhanced monocyte development¹⁴⁴ is a most interesting phenomenon. Whether adrenergic stimulation within the bone marrow functions in a compensatory or a decompensatory way toward the host following thermal injury is also interesting to consider. Is adrenergic stimulation involved in the immunosuppression of patients with severe burns through functional alterations in circulating and tissue leukocytes?^{145–151} These and other important questions are likely to involve events that occur within the bone marrow as it serves as a major source of new leukocytes both in the circulation and in tissues following thermal injury with sepsis.

Alterations in bone marrow hematopoietic progenitor cells have been the focus of our work and have involved our murine model of thermal injury (15% TBSA) using *Pseudomonas aeruginosa* applied directly to the wound site to establish sepsis. Following the demonstration of a shift in bone marrow myeloid commitment toward monocytopoiesis and away from granulocytopoiesis in thermal injury and sepsis,^{152,153} we began to focus on the potential significance of the increased nerve-stimulated release of norepinephrine within the bone marrow under these same experimental conditions. We tested the premise that neural stimulation was modulating myeloid lineage function by manipulating the peripheral stores of norepinephrine prior to injury. Peripheral norepinephrine levels were reduced by using 6-hydroxydopamine (6-OHDA) and then animals were subjected to thermal injury with sepsis. Following thermal injury and sepsis, femoral bone marrow cells from mice with reduced norepinephrine content demonstrated a significant decrease in monocytopoietic potential compared to mice with intact bone marrow norepinephrine stores.¹⁴⁴ In addition, reduction of peripheral norepinephrine content prior to the injury protocol resulted in a significant survival benefit compared to animals with intact norepinephrine content.

The influence of norepinephrine on bone marrow monocyte progenitor differentiation following thermal injury with sepsis was assessed by cell surface expression patterns of ER-MP12 and ER-MP20. While ER-MP12 is a surface antigen expressed in early monocyte progenitors and represents predominantly CFU-M, progressively more ER-MP20 antigen is expressed from the CFU-M stage onwards but disappears after the monocytic stage.¹⁵⁴ By following the distribution pattern of the expression of these two antigens on bone marrow cells the phenotypic separation and identification of bone marrow monocyte precursors have been demonstrated.¹⁵⁵ Results of ER-MP12 and ER-MP20 expression patterns in animals with intact norepinephrine stores suggests that there is a significant decrease in immature monocyte progenitors following thermal injury with sepsis compared to sham. Furthermore, there is a significant population of cells in the intermediate stage of

development under normal conditions and this population increases significantly following thermal injury with sepsis. In contrast, norepinephrine-depleted animals present an entirely different distribution pattern of monocyte progenitors using these markers. The norepinephrine-depleted sham group has very few cells in the immature and intermediate compartments with most cells staining for the mature monocyte progenitor cells. Thermal injury in norepinephrine-depleted animals resulted in further increases in mature monocyte progenitors. Taken together these results suggest that monocyte maturation pathways may be greatly influenced by the presence of norepinephrine and that stimulation of such pathways may be involved in the pathobiology of thermal injury with sepsis.

The potential site of adrenergic action within the hierarchy of bone marrow macrophage progenitor cells has been addressed in more recent work.¹⁵⁶ Whereas initial work examined the monocytoid potential of total bone marrow cells, Cohen et al. examined very early progenitors not committed to the myeloid lineage that express the CD117 marker.¹⁵⁶ In addition they also examined cells expressing ER-MP12 antigen which are early myeloid committed progenitors that differentiate either into neutrophils or monocytes. The monocytoid potential of both progenitor types were enhanced above control values following thermal injury and thermal injury with sepsis; however, this enhancement was greatly reduced by depletion of norepinephrine prior to the injury protocol. These findings suggest that myeloid bone marrow progenitors as well as early progenitors that are not committed to the myeloid lineage can be stimulated by endogenous norepinephrine release following thermal injury and sepsis to enhance proliferation.

Another important aspect of Cohen et al.,¹⁵⁶ is the demonstration that progenitor-derived macrophages express enhanced cytokine release following thermal injury and sepsis. Both CD117- and ER-MP12-enriched progenitors were taken from mice 72 hours after burn injury protocol and they were then differentiated into macrophages *in vitro* during a 7-day incubation with GM- and M-CSF. These progenitor-derived macrophages were then stimulated with bacterial endotoxin (LPS) and both TNF- α and IL-6 determined in the conditioned media. Expression of both TNF- α and IL-6 were significantly reduced in progenitor-derived macrophages from animals with depleted norepinephrine prior to the injury protocol. These results suggest that endogenous norepinephrine released during conditions of burn and sepsis impact the phenotype of differentiated macrophages and enhanced amounts of proinflammatory cytokines released could contribute to systemic inflammation. Collectively, the work of Cohen et al.¹⁵⁶ suggest that adrenergic stimulation during experimental thermal injury and sepsis contributes to enhanced numbers of macrophages as well as the expression of proinflammatory cytokines in bone marrow progenitor-derived macrophages.

In order for norepinephrine to act on bone marrow progenitor cells such cells should express functional adrenergic receptors. In fact specific β -adrenergic receptors on bone marrow hematopoietic progenitor cells enriched for ER-MP20 antigen have been characterized using conventional pharmacologic binding techniques, and values of total receptors (B_{MAX}) and

affinity (K_D) were determined. Furthermore, the effect of thermal injury and sepsis on these receptors was determined at 72 hours following thermal injury and sepsis.¹⁵⁷ Thermal injury and sepsis resulted in significant reductions in cell surface β -adrenergic receptors (B_{MAX}) but binding affinity was increased (decreased K_D values). This paradoxical change was resolved by agonist stimulation of intracellular cAMP, which showed that agonist coupling was increased in burn sepsis. Increased cAMP production under conditions of decreased receptor number but increased affinity suggests the dominant effect of changes in affinity in the bone marrow monocyte progenitor cells. Although these findings do not provide evidence that β -adrenergic-cAMP coupling alters the phenotype of these progenitors *in vivo*, additional *in vitro* experiments demonstrate that adrenergic stimulation during differentiation of ER-MP20 progenitors significantly alters the phenotype of mature macrophages. These changes in phenotype expression with adrenergic stimulation could be reversed with the selective β_2 -adrenergic blocker.¹⁵⁷

Although the murine animal model reflects important clinical features of thermal injury with infection, there may be important limitations. Whereas the murine animal model involves immediate infection following thermal injury, burn patients typically develop septic complications in the second week of their hospitalization. This does not, however, change the interpretation of these experimental findings that increased sympathetic activation in the bone marrow may result in both increased myelopoietic potential and altered cellular phenotype following thermal injury with sepsis. This frame of reference suggests that immune responses following injury should be considered in the context of potential action of sympathetic neurotransmitters on cellular events that occur during cellular differentiation in the bone marrow compartment.

Part II — Adrenal cortical steroids following burn trauma

Release of glucocorticoids

Whereas the acute ebb phase of recovery from thermal injury is mainly dependent upon re-establishment of cardiovascular function following circulatory disruption, the flow phase is considered to be dependent upon an adequate metabolic response. These responses are mediated in part by adrenal cortical steroids, of which cortisol is the dominant glucocorticoid hormone (Table 25.2). Elevation of glucocorticoids occurs in response to most forms of trauma,¹⁵⁸ including burn injury, with rapid increases in blood and urine levels.^{8,159} During the first 2 weeks following burn injury, the extent of elevation of total plasma cortisol concentration is proportional to the severity of the injury. Early studies observed that glucocorticoid levels were excessively high in severely burned patients and remained high in non-surviving patients.¹⁶⁰ In burn patients where recovery is likely, plasma glucocorticoid levels are moderately elevated or are in the upper normal range and can persist for up to 36 days^{161,162} and return to normal as healing progresses.¹⁵⁹ In contrast, patients with severe injury (90% TBSA) have markedly lower levels of glucocorticoid concentration, suggesting that they are unable to mount an adequate response.¹⁶²

TABLE 25.2 INFLUENCE OF GLUCOCORTICOIDS ON METABOLIC AND IMMUNE RESPONSE TO THERMAL INJURY

Physiologic variable	Glucocorticoid-mediated change following burn injury
Resting energy expenditure	Increased ⁵⁻⁷
Oxygen consumption	Increased ^{268,269}
Primary fuel	Lipids, glucose ²¹⁶
Proteolysis	Increased in skeletal muscle ^{190,191,193,194,270}
Acute phase protein synthesis	Increased ^{170,271,272}
Nitrogen excretion	Increased ²⁶⁹
Glycogenolysis	Increased via effect on glucagons ^{186,188}
Gluconeogenesis	Increased ^{182,183,271}
Lipolysis	Increased ²¹⁷
Ketone body formation	Normal ²¹⁹
Triglyceride level	Increased ^{219,271}
Thymic changes T-cell population T-cell proliferation B-cell population	Involution ²³⁸ Decreased ^{237,273} Inhibited ^{239,240,272} Not conclusive from current data
Neutrophil population Chemotaxis Demargination Bactericidal activity	Increased ^{242,273,274} Suppressed ²⁴² Increased ^{242,245} Suppressed ²⁴⁶
Monocyte population Chemotaxis Bactericidal activity	Increased transiently with corticosteroids but decreased in burn patients ^{137,274,275} Suppressed ²⁴³ Suppressed ^{243,276}
Bone formation	Decreased ²²⁵
Citation of studies from the current literature suggesting that glucocorticoid release is involved in changing the above physiologic variables following thermal injury.	

Glucocorticoids circulate in the body bound to cortisol binding protein (CBG) or transcortin, as an inactive complex. Only 1–10% of total plasma cortisol circulates unbound and it is this free fraction that is responsible for the biological activity of glucocorticoids. Burn injury results in a shift in the equilibrium between unbound cortisol and total cortisol towards an elevation in the unbound fraction.¹⁶² Serum CBG as well as CBG binding capacity are low in burn injury, severe infection and septic shock.^{162–164} In burn patients, CBG levels have been shown to decrease markedly with lowest values occurring 48 hours after injury.¹⁶⁵ Even a minor burn such as 3% TBSA results in the reduction of serum CBG levels by 30%,¹⁶⁶ which return to normal levels 1–2 weeks later. The net effect of the decrease in CBG levels following thermal injury may not only result in increased free levels of cortisol but also in the amount of excreted cortisol, which is reflected in high urinary corticosteroid levels in burn patients. Additional

explanations for the increased levels of corticosteroids in burn patients may be due to the direct inhibitory effect of corticosteroids on the biosynthesis of CBG.^{167–169} Furthermore, the proinflammatory cytokine IL-6 which is known to be elevated following massive burns has also been implicated in reducing CBG synthesis. Human hepatoma-derived cells (HepG2) respond to IL-6 by decreasing CBG protein and mRNA.¹⁷⁰

The hypothalamic–pituitary–adrenal axis displays a biphasic pattern during the course of critical illness. In the initial phase, excessive cortisol levels are associated with elevated levels of ACTH. In the second phase, which occurs 3–5 days after the initial injury, ACTH levels decline while cortisol remains elevated.^{2,171} There is some evidence to suggest that cortisol elevation with decreased ACTH may be driven by endothelin or atrial natriuretic peptide/hormone (ANP/H). Vermes et al.¹⁷¹ demonstrated that both plasma endothelin and ANP levels were significantly elevated for 8 days following hospitalization in severely ill patients with sepsis or trauma. In addition, infusion of ANP in humans has been shown to block CRH-stimulated secretion of ACTH and cortisol¹⁷² while endothelin-1 and endothelin-3 enhance secretion of steroid hormones from the adrenal cortex.¹⁷³ Furthermore, endothelin-3 has been reported to elevate ACTH and corticosterone levels in rats¹⁷⁴ while endothelin-1 results in elevated ACTH in humans.¹⁷⁵ Based on this information, Vermes et al.¹⁷¹ suggest that endothelin may be responsible for stimulating steroid secretion while ANP's action on the hypothalamic–pituitary axis may suppress ACTH secretion, thus explaining the paradoxical increase in cortisol with concomitant low ACTH levels in severely stressed patients.

Release of C₁₉ steroids

Dehydroepiandrosterone sulfate (DHEAS), a weak androgen, is the major secretory product of the human adrenal cortex. Despite the increase in cortisol secretion by the adrenals in burn patients, there is a distinct decrease in serum DHEAS levels.¹⁷⁶ This is due to a reduction in the synthesis and secretion rather than an effect of enhanced metabolism or excretion.¹⁷⁷ While serum DHEAS levels decrease gradually, testosterone and androstenedione levels decrease abruptly. In some burn patients, subnormal testosterone levels persist for 3–18 months following the burn injury whereas cortisol levels return to normal earlier.¹⁷⁷ The decrease in testosterone secretion may be due to a direct effect of excessive cortisol levels on the testis.^{178,179}

It appears that synthesis of C₁₉ steroids by the adrenals and testes is compromised as a result of enhanced production of the C₂₁ steroids such as cortisol. Aldosterone levels are also subnormal despite elevated plasma renin activity. This suggests a shift of pregnenolone metabolism away from mineralocorticoid and adrenal androgen pathways towards the glucocorticoid pathway.¹⁷⁶ The low level of DHEAS may also contribute to the suppressed state of the immune system in burn patients and will be discussed later.

Influence on metabolic pathways

High energy expenditure and hyperglycemia are hallmarks of thermal injury. The heavy demand for energy is due to the increase in essential functions such as the synthesis of proteins

required for wound healing, the synthesis of acute phase proteins and inflammatory mediators. In addition, severe burns exert a burden on the metabolism to generate heat which in part compensates for the loss through the wound site. Part of the elevation in resting energy expenditure in burn patients is due to the increase in substrate cycling. This occurs when enzymes catalyzing opposing reactions of the same pathway are active simultaneously: for example, the conversion of glucose to glucose-6-phosphate and back to glucose. The demand for energy is increased in order to resynthesize ATP used in this and similar reactions. In burn patients the rate of glucose production and glycolysis as well as lipolysis and reesterification of triglycerides are elevated.⁴⁰ This cycling of substrates generates heat due to the hydrolysis of high-energy phosphate bonds in ATP, thus contributing to thermogenesis as well as increased energy requirement in burn patients. Keeping burn patients thermally comfortable lowers the metabolic rate and thus the demand for energy can also be lowered.¹⁸⁰ Increased glucocorticoid levels during severe burns can orchestrate multiple metabolic pathways to meet this energy demand. In order to understand how glucocorticoids may influence major metabolic pathways following thermal injury to facilitate the hypermetabolic state, in this section we will review the effects of glucocorticoids on glucose, protein and fatty acid metabolism as they pertain to thermal injury.

Glucocorticoids and glucose metabolism

Glucocorticoids can contribute to hyperglycemia, which persists for several days, by enhancing endogenous production of glucose in the liver.^{6,181–183} In burn injury, elevated glucose levels are predominantly sustained through gluconeogenesis and impaired glucose utilization. Increased levels of plasma lactate produced by peripheral tissues following thermal injury, as documented by Wolfe et al.,¹⁸⁴ is an essential substrate for gluconeogenesis by the liver. Recent evidence further confirms that thermal injury causes metabolic adaptations to enhance gluconeogenesis. Burn injury causes intrinsic alterations in the liver, which increases the flow of pyruvate to oxaloacetate at the expense of non-tricarboxylic acid cycle sources.¹⁸⁵ Mobilization of glucose stored as glycogen and skeletal muscle amino acids as substrates for gluconeogenesis requires glucagon secretion,^{186,187} which is stimulated by glucocorticoids.^{186–188} In addition to gluconeogenesis, insulin resistance can also play a role in sustaining high circulating levels of glucose in burn patients. For example, glucose utilization is impaired in burn patients who do not respond to insulin infusion.⁶

Glucocorticoids and protein metabolism

In severe burn injury, protein catabolism is a part of the hypermetabolic state resulting in negative nitrogen balance. Cuthbertson's landmark studies¹⁸⁹ were the first to suggest the important concept that nitrogen loss is a whole-body response rather than a local burn-wound response. The increase in proteolysis seen in burn injury is, at least partly, mediated by glucocorticoids. In humans,¹⁹⁰ and in animal models,¹⁹¹ administration of glucocorticoids enhances muscle proteolysis. Further, burn injury-induced muscle proteolysis can be inhibited by a glucocorticoid receptor antagonist.¹⁹² Amino acids mobilized from peripheral tissues are transported to the liver,

where unlike in other tissues, cortisol stimulates protein synthesis. The increased hepatic protein synthesis in response to cortisol can drive the new synthesis of gluconeogenic enzymes and acute phase proteins in response to injury.

Specific mechanisms involved in burn-mediated alterations in protein metabolism following thermal injury are not known. However, some information could be gleaned from studies on other states of excessive catabolism. In conditions such as metabolic acidosis, adrenalectomy halts muscle proteolysis and does not increase expression of components of the ubiquitin-proteasome pathway.^{193,194} These effects can be reversed by dexamethasone administration. Further support for this premise is provided by *in vitro* studies, which show that dexamethasone-induced increases in proteolytic degradation in myocytes can be abolished by the glucocorticoid receptor inhibitor RU486.¹⁹⁵ Ding et al.¹⁹⁶ suggest that partial inhibition of the ubiquitin-proteasome pathway may be beneficial in enhanced catabolic states. Taken together these data suggest that interaction of glucocorticoids and the ATP requiring ubiquitin-proteasome system may play an important role in burn-induced proteolysis.^{196–201}

Another important aspect of protein catabolism following thermal injury is the generation of gluconeogenic amino acids. In fact, following thermal injury plasma levels of alanine are increased.²⁰² Nitrogen produced as a result of transaminating alanine to the gluconeogenic intermediate pyruvate is converted into glutamine and then to urea for excretion by the liver. Glutamine is one of the major participants in the translocation of amino acids from peripheral tissues to the liver for nitrogen excretion. Expression of the enzyme responsible for synthesis of this amino acid, glutamine synthase, is increased to compensate for the glutamine depletion in peripheral tissues. Following burn injury, glutamine synthase mRNA is increased first in the lung and later in muscle.²⁰³ This is further supported by the observation that adrenalectomy partially decreases burn injury-induced glutamine synthase mRNA.²⁰¹ This is a tissue-specific response as no such effect is seen in the kidney or liver. There is evidence to suggest that glucocorticoids may augment glutamine synthesis. In lung and muscle tissues glucocorticoid administration increases glutamine production.²⁰⁴ Mobilization of protein from peripheral tissues is also indicated by the increase in phenylalanine in the blood of burn patients.²⁰² Phenylalanine is the only amino acid that is not degraded by peripheral tissue and hence accumulates in the circulation when uptake by the liver is compromised.

The hypermetabolic and catabolic states seen in thermal injury remain long after the burn wound is completely healed.^{5–7,205,206} In a recent study by Hart et al.,²⁰⁵ stable isotopic methodology and gas chromatography-mass spectrometry analysis were used to measure muscle kinetics in burned children. Reduction in protein catabolism and enhancement of lean body mass were only seen 9–12 months after the initial injury.²⁰⁵ This suggests that treatment to alter growth deficiency must be prolonged long after early wound healing is complete.

Other more indirect effects of glucocorticoids on glucose levels in thermal injury include modulation of insulin-like growth factor-1 (IGF-1), an important mediator of growth hormone (GH) action.^{207,208} Marked depression of all compo-

nents of the IGF-1 complex are seen in burn injury.^{209–213} Elevated glucocorticoid levels in burn patients may contribute to the suppression of the acid labile subunit (ALS) of the IGF-1 complex. Treatment of rats with dexamethasone results in low levels of serum ALS as well as liver ALS mRNA.^{214,215}

In addition to the use of amino acids released from peripheral tissue to increase endogenous glucose production, body fat is the major source of energy in traumatic situations.²¹⁶ Free fatty acids are released from adipose tissue to be used as an alternate source of fuel during times of crisis, as is the case in thermal injury. Cortisol stimulates lipolysis²¹⁷ enabling the release of free fatty acids. In burned children and adults increased lipolysis is reflected in the elevated plasma levels of palmitic and oleic acid.^{41,218,219}

Influence on bone metabolism

Aside from combating the increased demand for energy, glucocorticoids also affect bone development, which has profound effects in children. Abnormal bone metabolism in burn injury has been demonstrated in animals and humans.^{220,221} In children, the reduction in bone mineral density persists for at least 5 years after severe burn injury (>40% TBSA) and results in permanent retardation of linear growth.^{222,223} The reasons for loss of bone mineral density include increased production of endogenous glucocorticoids, the inflammatory response, immobilization, aluminium loading and production of cytokines such as IL-1 and IL-6 that facilitate bone resorption.²²⁴

Glucocorticoids have potent effects on bone formation and resorption resulting in loss of bone mass. Weinstein et al.²²⁵ investigated the long-term (equivalent to 3–4 human years) effects of glucocorticoids on bone metabolism in an animal model and reported a reduction in osteoclastogenesis causing reduced bone turnover and a reduction in osteoblastogenesis resulting in reduced bone formation. Enhanced osteoclast and osteoblast apoptosis was observed in mice subjected to long-term glucocorticoid administration as well as in patients with glucocorticoid-induced osteoporosis.²²⁵ This depletion in the bone cell population limits the number of cells that can synthesize matrix proteins. In addition, glucocorticoids directly downregulate expression of type I collagen and upregulate expression of collagenase-3 in chondrocytes.²²⁶ On the other hand, IGF-1 enhances expression of type I collagen and suppresses the expression of collagenase-3.²²⁷ Thus the massive increase in glucocorticoids and the corresponding decrease in IGF-1 in burn injury has the ability to profoundly alter bone and cartilage formation.

The mechanisms by which glucocorticoids mediate bone resorption are not clear. One possible mechanism is that glucocorticoids increase osteoclast apoptosis.²²⁸ Glucocorticoids may also mediate bone resorption by its dual capacity to initially inhibit osteoclast synthesis but later stimulate osteoclast synthesis coupled with an increase in bone resorption.²²⁹ Yet another mechanism by which cortisol may influence bone resorption is by suppression of IGF-1 or GH-induced chondrocyte proliferation.²³⁰ The antiproliferative effect of glucocorticoids may be mediated through downregulation of the GH receptor and binding affinity as well as suppression of the local production of IGF-1 by these cells. These effects illustrate probable mechanisms by which glucocorticoids may impair the growth stimulatory effects of GH.

Influence on immune suppression

Severely burned patients are susceptible to opportunistic infections and sepsis is a major cause of death associated with burn injury. Immune suppression occurs soon after burn injury, perhaps to prevent over-responsiveness. This, however, leaves the patient extremely vulnerable to bacterial infection through a number of routes. Patients can be infected through the wound site and by translocation of gut bacteria.²³¹ Surgery and other life-supporting procedures such as nutritional supplementation and ventilation are also fertile sources of infection. The glucocorticoid response to thermal injury appears to play an important role in immune dysfunction with impairment of both specific and non-specific defences. Corticosteroids reduce lymphocyte, eosinophil and basophil numbers, alter lymphocyte subpopulations, depress immunoglobulin production by B cells and suppress neutrophil and monocyte/macrophage activity.

Acute thymic involution^{232,233} and a reduction of the total T-cell population occurs soon after burn injury.^{232–235} During initial thymic involution in an animal model there is marked depression of CD4⁺CD8⁺ lymphocytes. CD4⁺CD8⁺ cell numbers are also reduced with recovery in the ensuing thymic regeneration phase during the next 2 weeks. Thymic involution is a common response to various types of stress and trauma.²³⁶ In humans, the depression of T lymphocytes is reflected by reduction of both CD4⁺ as well as CD8⁺ cell numbers.²³⁴ In an animal model²³² CD4⁺CD8⁺ cells are reported to be more sensitive to the effects of thermal injury than CD4⁺CD8⁺ cells. CD4⁺CD8⁺ cell numbers remain constantly depressed during a 2-week period following burn injury, whereas CD4⁺CD8⁺ cell numbers are variable and can even be increased in comparison to control animals not subjected to thermal injury.

Thymic changes following exogenous administration of glucocorticoids are similar to that seen in burn injury^{237,238} in that exogenous hypercortisolism in non-injury states or that following burn injury is associated with decreasing CD4⁺CD8⁺ and elevating CD4⁺CD8⁺ thymocytes.²³³ The reduction of CD4⁺CD8⁺ cell numbers during the first 24 hours after thermal injury is due to glucocorticoid-mediated apoptosis since burn injury-induced thymocyte apoptosis is suppressed by adrenalectomy or administration of a glucocorticoid receptor antagonist (RU486).²³³ Other factors contributing to lymphocyte dysfunction and immunosuppression resulting from elevated corticosteroid levels may include the ability to directly inhibit T-cell proliferation, IL-2 production^{239,240} as well as the ability to alter lymphocyte membrane fluidity.²⁴¹

Apart from these effects on lymphocytes, glucocorticoids also enhance susceptibility to infections by altering monocyte and neutrophil functions at several stages. Movement of circulating inflammatory cells to the site of infection is suppressed by the ability of glucocorticoids to reduce the cellular response to chemotactic stimuli,^{242–244} diminish neutrophil adherence²⁴⁵ and induce a shift from marginal to circulating cells.²⁴² Glucocorticoids also suppress bactericidal activity of monocytes²⁴³ and neutrophils,²⁴⁶ perhaps through impairment of lysosomal function.²⁴⁷

Although severe burns are associated with alterations in B-cell production and function, there is considerable inconsistency in the status of literature concerning B-cell biology.^{248–253}

For example, in rats subjected to 30% burn injury, splenic lymphocytes respond poorly to LPS and immunoglobulin synthesis is reduced in comparison to control animals.²⁵⁴ Others have found an increase in circulating B cells early after burn injury.^{250,255} Interestingly, administration of methylprednisolone to normal volunteers for 2–4 weeks also reduces serum immunoglobulin levels.²⁵⁶ Changes in the B-cell population parallel changes in urine 17-hydroxysterol levels and increase in stress hormones in the early stages of burn injury may result in the release of B cells from lymphoid organs.

Aside from glucocorticoids, adrenal androgens such as DHEAS, also have profound influence on the immune responses. In fact, a role for DHEAS as a potent modulator of the immune response is now well established.^{257–260} DHEAS which has immunosuppressive properties on Th1 helper cells, are low during severe illness.¹⁷⁶ *In vitro* treatment of human T cells with DHEAS increases IL-2 production (which is required for clonal expansion) and IL-2 mRNA synthesis.²⁶⁰ It is interesting to note that this effect was seen only in CD4⁺CD8⁻ and not in CD4⁺CD8⁺ cells. DHEAS-treated cells were also able to mediate a more potent cytotoxic effect than cells without DHEAS treatment.

Yet another factor that profoundly influences the immune status and adrenal steroid secretion in burn patients is the neurotransmitter dopamine. Dopamine is often used in the treatment of critically ill patients because of its vasopressor, renal vasodilating, and cardiac inotropic properties. However several studies indicate that dopamine treatment may undermine an already depressed immune system. This effect appears

to act via the suppression of prolactin release from the anterior pituitary. Dopamine suppresses serum prolactin and DHEAS levels but not cortisol concentration.^{261,262} *In vitro*, prolactin has a synergistic effect on ACTH-induced DHEAS secretion by human adrenal cells.²⁶³ Thus it is possible that the dopamine-induced suppression of prolactin is responsible for lowering DHEAS levels and therefore suppression of the T-cell proliferative response. The *in vitro* proliferative response of T cells from patients on dopamine therapy is diminished²⁶¹ and cells treated with DHEAS mediate a more potent T cell cytotoxic effect.²⁶⁰ Dopamine levels are elevated under conditions of severe physical stress and chronic illness.^{264,265} This may be partly responsible for the anergic state of the immune system during severe stress.

The present review affirms that catecholamines and adrenal steroid hormones are integral parts of the physiologic response to thermal injury that are thought to support recovery through compensatory cardiovascular, metabolic and immunologic changes. Although adrenergic mechanisms are important for their ability to influence intracellular signaling pathways, their role as modulators of gene expression is still being explored. On the other hand, while much is known about the modulation of gene expression by glucocorticoids, very little is known about their modulation of gene expression consequent to severe thermal injury or other forms of trauma. Future studies hold great promise of providing important new information in these areas as to how these bioactive compounds may influence responses to thermal injury and how such information can lead to the development of new treatment modalities.
