Further studies in our lab have elucidated the mechanism for the negative regulation of Rap1GAP by $G\alpha_o$ [19]. The binding of $G\alpha_o$ to Rap1GAPII and RGS17 targets these proteins for degradation by the ubiquitin-dependent proteasome system. In rat hippocampal slices the induced degradation of Rap1GAPII could be stimulated by the addition of α_2 adrenergic agonist, which could be specifically blocked by inhibiting the proteasome. This novel mechanism for the regulation of a G-protein effector would allow for long-term modulation of signaling pathways. By selectively degrading negative regulators the intrinsic signaling properties

would be altered, thus changing the required input for signal activation as well as signal duration.

A study to elucidate direct interactors for the $G\alpha_z$ subunit conducted by Kozasa and colleagues led to the identification of a protein that directly binds $G\alpha_o$ [2]. The approach taken in this study was to screen a mouse embryo expression library by using GTP γ - $G\alpha_o$. The novel $G\alpha_o$ interacting protein identified by this method was termed GRIN [2]. Expression of $G\alpha_o$ and GRIN in Neuro2A (N2A) mouse neuroblastoma cells leads to their differentiation marked by outgrowth of neurite-like fine processes. There are two isoforms of GRIN—GRIN1 and GRIN2—and both bind directly to $G\alpha_o$. One of the main differences between the two isoforms is their expression in different tissues: whereas GRIN1 is widely expressed in neuronal tissue with highest levels in the spinal cord, GRIN2 is only expressed in the cerebellum.

In addition to these direct interactors of $G\alpha_o$, several laboratories have identified signaling molecules and pathways that are activated by $G\alpha_o$. The signaling pathways that are activated by $G\alpha_o$ include c-Src, MAPK1,2, Stat3, and PLC. These pathways are also cell-type specific and are not activated in all cell types. Activation of MAPK 1,2 via ligand activation of $G\alpha_o$ occurs in CHO cells but not in COS-7 cells [3]. Further, this pathway is dependent on PKC activation, as depletion of PKC inhibited $G\alpha_o$ -induced activation of MAPK 1,2. Experiments in chick DRG neurons show that the GABA-mediated inhibition of N-type calcium channels by $G\alpha_o$ occurs via activation of Src or a Src family kinase [4]. Src activation by $G\alpha_o$ has also been observed in NIH-3T3 mouse fibroblast cells [5]. Further characterization of the $G\alpha_o$ activation of Src showed that this leads to an increase in Stat3 tyrosine phosphorylation and activation [5].

Conclusions

It is still not clear how many signaling pathways are regulated by the $G\alpha_o$ subunit. However, what is increasingly

clear is that in contrast to the $G\alpha_s$ and $G\alpha_q$ pathways, which are ubiquitous, the $G\alpha_o$ and $G\alpha_i$ pathways are likely to be cell-type dependent. Defining which pathways operate in which cell type is an immediate goal in many laboratories.

Introduction

In normal cells, heterotrimeric G-protein subunits are known to undergo several forms of co-translational or post-translational modification. Lipid modifications, including *N*-myristoylation and palmitoylation of G α subunits and prenylation of G γ subunits, are required for plasma membrane targeting and contribute to the interaction of G α with G $\beta\gamma$ subunits, effectors, and regulators of G-protein signaling (RGS proteins) [1,2]. G α subunits, including members of each of the four major families of G α (G α_s , G α_i , G α_q , and G α_{12}), also undergo phosphorylation on serine or tyrosine residues. In addition, one G γ subunit is serine phosphorylated. Here we review what is known about G-protein phosphorylation and its subsequent effects on G-protein function. (See Table I).

Serine Phosphorylation

Several heterotrimeric G-protein subunits are phosphorylated on serine residues *in vivo* and *in vitro*. The kinases responsible include various protein kinase C (PKC) isoforms, the p21-activated protein kinase (PAK), and cGMP-dependent protein kinase. In most cases, serine phosphorylation of G α inhibits binding to G $\beta\gamma$ subunits and RGS proteins, which may lead either to prolonged G α -subunit activation or to feedback inhibition of G-protein signaling.

Protein Kinase C

PKC-mediated phosphorylation of G α_i family (G α_z , G α_i , G α_t), G α_q family (G α_{16}), and G α_{12} family (G α_{12} , G α_{13})

G α subunits, along with one G γ subunit (G γ_{12}), has been described. Of these, PKC phosphorylation of G α_z and G α_{12} are the most thoroughly studied. In human platelets, exposure to phorbol ester, which directly activates classical PKC isoforms, or thrombin, which stimulates a Gq/11-coupled heptahelical receptor, results in rapid and nearly stoichiometric phosphorylation of endogenous G α_z [3,4]. Ser 27 has been identified as the major site of PKC phosphorylation both *in vivo* and *in vitro*, while Ser 16 serves as a secondary site [5,6]. The preferred substrate for PKC is the monomeric G α subunit, since the addition of G $\beta\gamma$ *in vitro* strongly inhibits the phosphorylation [6–8]. The data are less clear as to whether the inactive GDP-bound or active GTP-bound form of G α_z is a preferred substrate. Since the G α N-terminus contains determinants for the binding of the G $\beta\gamma$ subunit heterodimer, PKC phosphorylation of G α_z blocks G $\beta\gamma$ subunit binding [6–8]. Similarly, phosphorylation inhibits G α_z interaction with the RGS proteins RGSZ1, RET-RGS1, and GAIP [9,10]. The effect of PKC phosphorylation on G α_z function is unclear, however. Inhibition of G $\beta\gamma$ subunit and RGS protein binding might be expected to prolong G α_z activation *in vivo*, but phosphorylation has no effect on the ability of G α_z -GTP γ S to inhibit adenylyl cyclase in a reconstituted system [8].

Conflicting data exist for the PKC-mediated phosphorylation of other G α_i family members. Some authors have reported PKC-mediated phosphorylation of G α_i or G α_t *in vitro* or phorbol ester-mediated phosphorylation *in vivo* [11–14]. Others, however, have failed to detect PKC-mediated phosphorylation of G α_i subunits [4,8]. In NG-108 cells, phorbol ester-induced phosphorylation of G α_{i2} correlates with a loss of the inhibitory effect of G α_i on adenylyl cyclase activation [14], suggesting that G α_i phosphorylation

Table I Phosphorylation of Heterotrimeric G protein Subunits.

G protein subunit	Kinase	Phosphorylation site(s)	Functional effect	References
<i>Serine phosphorylation</i>				
G α z	PKC	Ser27; Ser16	Inhibits G β γ subunit and RGS protein binding	[4–10]
	PAK	Ser16	Inhibits G β γ subunit and RGS protein binding	[6]
G α i1, G α i2, G α i3	PKC	N.D.	Inhibits regulation of adenylyl cyclase	[11–14]
	CGMP-dependent Protein kinase	N.D.	Inhibits IGF-1 and IGF-2 stimulated Ca ⁺⁺ influx	[20]
G α 16	PKC	N.D.	Inhibits TRH-stimulated PI hydrolysis	[15]
G α 12, 13	PKC	N-terminal 50 amino acids	Inhibits G β γ subunit binding	[8,16]
G γ 12	PKC	N-terminal SSK motif	Increases affinity for G α o; Inhibits activation of type II adenylyl cyclase; Increases binding to F-actin	[17–19]
<i>Tyrosine Phosphorylation</i>				
G α s	c-Src	Tyr37; Tyr377	Increases GTP binding/hydrolysis; Enhances β 2AR-stimulated cAMP production	[21–23]
	EGF receptor	N.D.	Enhances Gs activation	[29]
Gq/11	c-Src; c-Fyn; c-Yes; v-Src;	Tyr 356	Modulates R-G interaction; Enhances PI hydrolysis; Stimulates GLUT4 translocation	[24–26]
	Insulin Receptor	N.D.	Stimulates GLUT4 translocation	[28]
G α i, G α t	Insulin Receptor	N.D.	N.D.	[12,27]

might provide a mechanism for cross-talk between different G-protein pools.

When ectopically expressed in *Xenopus* oocytes, the G α q family protein, G α 16, can be phosphorylated in response to phorbol ester treatment or stimulation of thyrotropin-releasing hormone (TRH) receptors [15]. Phosphorylation correlates with a loss of TRH responsiveness, suggesting G α -subunit phosphorylation may represent part of a feedback inhibitory loop.

G α 12, like G α z, undergoes PKC-mediated phosphorylation in platelets in response to phorbol ester or thrombin [8]. The site of phosphorylation has been mapped to the N-terminal 50 amino acids but has not been explicitly determined. As with G α z, phosphorylation of G α 12 blocks G β γ -subunit binding. G α 13 is also phosphorylated in platelets in response to phorbol ester [16]. However, in contrast to G α 12, attempts to phosphorylate G α 13 *in vitro* using purified PKC α , δ , ϵ , or ζ have been unsuccessful [8], suggesting that the effect of PKC on G α 13 may be indirect.

G γ 12 contains a Ser-Ser-Lys motif at its N-terminus that is not present in other G γ subunits and that serves as a substrate for PKC *in vitro* [17,18]. Endogenous G γ 12 in Swiss 3T3 and aortic smooth muscle cells is phosphorylated in response to phorbol ester [17]. Phosphorylation of G γ 12 increases its affinity for G α o, presumably allowing for more stable heterotrimer formation and allowing phosphorylated G γ 12 to enhance high-affinity agonist binding to A1 adenosine receptors [18]. Phosphorylation selectively affects the interaction of G γ 12 with effectors, impairing G β γ subunit-dependent activation of type II adenylyl cyclase but having no effect on activation of phospholipase-C β . Phosphorylated

G γ 12 also affects its interaction with F-actin, possibly allowing G-protein phosphorylation to regulate cell motility [19].

p21-Activated Protein Kinase

G α z, but not G α s, G α i, G α o, or G α q, serves as a substrate for PAK1 *in vitro*, with a stoichiometry of phosphorylation of about 1:1 [6]. The preferred phosphorylation site is Ser 16, and the phosphorylation is independent of the activation state of G α z. In transfected HEK-293 cells, G α z is phosphorylated by coexpressed PAK1 to an extent similar to that observed with PKC. As with PKC phosphorylation of Ser27, PAK1 phosphorylation inhibits binding of G β γ subunits and RGS proteins *in vitro*. The effect of PAK1-mediated phosphorylation on G α z function *in vivo* remains to be determined but might be expected to resemble the effect of PKC phosphorylation.

cGMP-dependent Protein Kinase

In vitro, cGMP dependent protein kinase I α phosphorylates the G α subunits of heterotrimeric G α i1, G α i2, and G α i3 to a stoichiometry of about 0.4:1 [20]. The site of phosphorylation is not known, but a potential cGMP kinase site (Arg-Lys-Asp-Thr-Lys) is present in the C-terminal effector region of the protein. In CHO cells, expression of cGMP kinase modestly increases phosphorylation of endogenous G α i subunits and attenuates pertussis toxin-sensitive calcium influx following insulin-like growth factor stimulation, suggesting that phosphorylation of G α i may interrupt the coupling of G α i with effectors.

Tyrosine Phosphorylation

Tyrosine phosphorylation of $G\alpha$ subunits may account for the ability of tyrosine kinases to enhance certain G-protein-mediated signals. Phosphorylation of $G\alpha_s$, $G\alpha_i$, and $G\alpha_q/11$ by Src family nonreceptor tyrosine kinases, or in response to epidermal growth factor or insulin stimulation, has been reported. Specific phosphorylation sites have been determined only for Src-mediated phosphorylation of $G\alpha_s$.

Src Family Tyrosine Kinases

Expression of avian c-Src in murine fibroblasts leads to a significant enhancement of adrenergic receptor-stimulated cAMP production, both in isolated plasma membranes and in intact cells [21]. *In vitro*, c-Src phosphorylates purified $G\alpha_s$ and $G\alpha_i$ subunits to a stoichiometry of 0.3–0.9:1 [22]. The inactive monomeric form of the $G\alpha$ subunit appears to be the preferred substrate, since GTP γ S and $G\beta\gamma$ subunits both inhibit phosphorylation. Phosphorylation of $G\alpha_s$ involves two tyrosine residues, Tyr37 and Tyr377 [23], and increases the rate of GTP γ S binding and of β_2 adrenergic receptor-stimulated GTP hydrolysis.

Similarly, v-src transformation of fibroblasts causes enhanced endothelin-1 receptor-stimulated phosphatidylinositol hydrolysis [24]. The effect correlates with tyrosine phosphorylation of $G\alpha_q/11$ subunits. In a reconstituted system, $G\alpha_q/11$ from v-src transformed cells exhibits increased AlF_4^- -stimulated phospholipase C activity. Although the phosphorylation *in vivo* was sensitive to the tyrosine kinase inhibitor herbimycin A, the authors were unable to demonstrate phosphorylation of $G\alpha_q/11$ by v-Src *in vitro*. Tyrosine phosphorylation of $G\alpha_q/11$ may also be mediated by the Src family kinase, c-Yes. In a recent study, endothelin 1 receptor-stimulated tyrosine phosphorylation of $G\alpha_q/11$ in 3T3-L1 adipocytes was blocked by the Src inhibitor PP2 by microinjection of a dominant negative c-Src mutant and by microinjection of antibodies against c-Yes but not c-Src or c-Fyn [25]. Recruitment of a Src family kinase to the endothelin-1 receptor through the formation of β -arrestin-1-Src kinase complexes was proposed as the mechanism underlying endothelin-stimulated $G\alpha_q/11$ phosphorylation. The phosphorylation of $G\alpha_q/11$ appears to play a role in the regulation of glucose transport by endothelin receptors, since inhibition of endothelin-stimulated $G\alpha_q/11$ phosphorylation correlated with a marked decrease in of endothelin-stimulated translocation of the glucose transporter GLUT4.

Tyrosine phosphorylation of $G\alpha_q$ and $G\alpha_{11}$ in response to M1 muscarinic receptor stimulation has also been reported [26]. In this case, the phosphorylation appears to involve Tyr 356, located in the C-terminus in a position analogous to Tyr 377 of $G\alpha_s$. The responsible kinase has not been identified, but the effect can be mimicked by expression of c-Fyn, suggesting that it is mediated by a Src family kinase.

Insulin Receptor

Early work demonstrated that several $G\alpha$ subunits, including $G\alpha_t$, $G\alpha_i$, and $G\alpha_o$, can serve as substrates for the insulin receptor *in vitro* [12,27]. As is the case with Src kinases, the monomeric GDP-bound form of the $G\alpha$ subunit is the preferred substrate.

Tyrosine phosphorylation of $G\alpha_q/11$ subunits has been proposed to play a role in insulin-stimulated GLUT4 translocation [28]. Insulin stimulation is associated with a rapid and transient increase in tyrosine phosphorylation of $G\alpha_q/11$ subunits in 3T3-L1 adipocytes. In these cells, microinjection of RGS2 protein or antibodies against $G\alpha_q$ inhibited insulin-stimulated GLUT4 translocation, while expression of a constitutively active $G\alpha_q$ mutant stimulated GLUT4 translocation. Although the identity of the tyrosine kinase responsible for $G\alpha_q/11$ phosphorylation was not determined in these studies, the data suggest that tyrosine phosphorylation of $G\alpha_q$ may play a role in regulating the translocation of glucose transporters to the plasma membrane.

Epidermal Growth Factor Receptor

Purified EGF receptors catalyze the tyrosine phosphorylation of $G\alpha_s$ subunits *in vitro*, with a stoichiometry of phosphorylation of about 2:1 [29]. In this case, the heterotrimeric form of the $G\alpha$ subunit appears to be the preferred substrate. EGF receptor-phosphorylated $G\alpha_s$ exhibited increased GTP γ S binding and GTPase activity and enhanced activation of adenylyl cyclase, suggesting that the phosphorylation leads to activation of $G\alpha_s$.

Conclusions

There is convincing evidence that several heterotrimeric G-protein subunits are substrates for serine and/or tyrosine phosphorylation *in vitro* and in some cases, *in vivo*. The functional relevance of these phosphorylation events is less well established. Serine phosphorylation of $G\alpha$ subunits by second messenger-dependent protein kinases is a potential mechanism of feedback regulation of G-protein-coupled receptor signaling. Tyrosine phosphorylation of $G\alpha$ subunits may provide a mechanism for cross-talk between receptor and nonreceptor tyrosine kinases and G-protein-dependent signaling pathways.

Introduction

Heterotrimeric G proteins play a crucial role in determining the specificity of the cellular response to extracellular signals. Among the mechanisms controlling G-protein functions are a variety of covalent modifications, relevant in both normal and pathological conditions. The known post-translational modifications occurring on G protein α and $\beta\gamma$ subunits include lipid modifications, which are required for targeting to the plasma membrane of α and $\beta\gamma$ and for the interaction of α with either $\beta\gamma$ or effectors or RGS proteins [1]; phosphorylation, which affects the interactions between α and $\beta\gamma$, and between G proteins with either receptors or effectors [2]; and finally mono-ADP-ribosylation, whose function has not yet been fully defined. In the following, we will focus on the enzymatic mono-ADP-ribosylation of the G protein subunits, catalyzed by both bacterial toxins and eukaryotic enzymes, and discuss the mechanisms and potential role of this reaction in mammals.

The Mono-ADP-Ribosylation Reaction

The mono-ADP-ribosylation reaction is catalyzed by mono-ADP-ribosyltransferases (EC 2.4.2.31) that transfer an ADP-ribose residue from βNAD^+ to a specific amino acid of the acceptor proteins, via *N*- or *S*-glycosidic linkages, with the release of nicotinamide (Fig. 1). This reaction is easily distinguished from that catalyzed by poly(ADP-ribose)polymerases (PARPs), which are nuclear proteins involved in DNA repair, cell differentiation, and apoptosis

and are able to transfer multiple ADP-ribose residues, and even branched polymers of ADP-ribose linked by *O*-glycosidic linkage, onto target proteins [3]. The mono-ADP-ribosylation reaction is also different from the nonenzymatic binding of ADP-ribose to acceptor proteins that forms a thiazolidine, instead of thioglycoside (typical of the enzymatic reaction), bond [4]. ADP-ribose can be released from βNAD^+ by cellular NAD^+ -glycohydrolases (NADases), of particular interest among which is CD38, an ectoenzyme that catalyzes the formation and hydrolysis of cyclic ADP-ribose, a potent intracellular Ca^{2+} -mobilizing agent [5]. It is interesting that CD38 also catalyzes both auto-ADP-ribosylation on cysteine and ADP-ribosylation of unidentified proteins on the cell surface [6], thus displaying both ADP-ribosyltransferase and NADase activities [7], as seen with other enzymes such as cholera toxin (CT) [8].

ADP-ribosyltransferase activities have been reported in different organisms, including viruses and prokaryotic and eukaryotic cells. The pioneering studies by Rappuoli and colleagues [9] showed that ADP-ribosyltransferases fall into two groups: the first is characterized by a conserved histidine in the catalytic domain and includes diphtheria toxin, ART3, and PARPs; the second is characterized by a conserved arginine and includes pertussis toxin (PT), CT, heat-labile enterotoxins, and other ADP-ribosyltransferases.

The mono-ADP-ribosylation of proteins can be reverted by cellular ADP-ribosylhydrolases, which hydrolyze the protein-ADP-ribose linkage, thus releasing ADP-ribose [10,11]. So far three genes have been cloned from rat, mouse, and human, which encodes a soluble, intracellular protein that specifically hydrolyzes the ADP-ribose-arginine bond [12a].

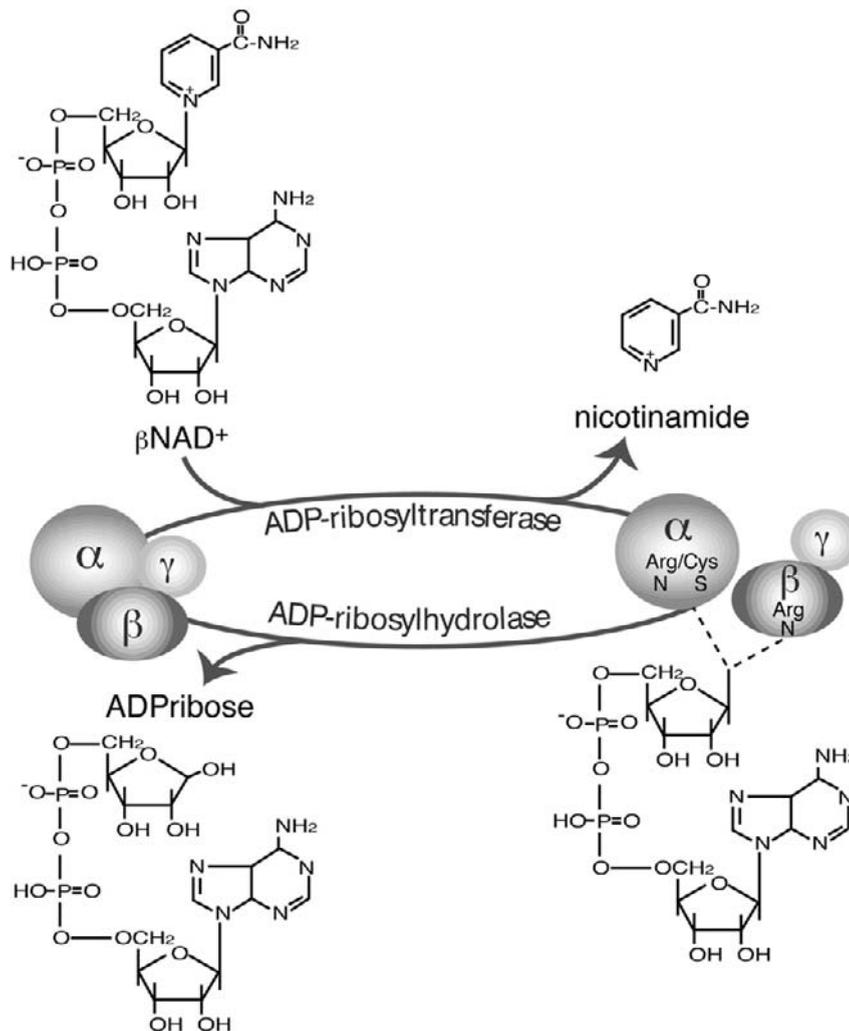

Figure 1 The mono-ADP-ribosylation cycle. The mono-ADP-ribosyltransferase transfers an ADP-ribose residue from β NAD⁺ to an arginine (α s and β) or to a cysteine (α i, α o, and α t) of the target G protein, via *N*- or *S*-glycosidic linkages, respectively, with the release of nicotinamide. Specific ADP-ribosylhydrolases hydrolyze the amino acid-ADP-ribose glycosidic linkage, thus regenerating free arginine or cysteine and releasing ADP-ribose.

The presence of ADP-ribosyltransferase and ADP-ribosylhydrolase activities in the cell is highly suggestive of a potential regulatory mechanism acting on the specific substrates of this reaction.

Bacterial Toxin-Induced ADP-Ribosylation

The mono-ADP-ribosylation of the G protein subunits was originally described as the mechanism of cell intoxication by bacteria, such as *Vibrio cholerae* (producing CT) and *Bordetella pertussis* (producing PT) [13,14]. These toxins, which specifically act on G proteins (see below), rapidly became important tools in the identification of these proteins and in investigations into their functional roles in cells (Table I). Other well-characterized bacterial ADP-ribosyltransferases are the diphtheria and clostridial toxins, which act by modifying

crucial host cell proteins, such as the monomeric GTPases of the Rho family, monomeric actin, and elongation factor-2, permanently inactivating the cellular functions modulated by these proteins (reviewed by [15]).

The CT and heat-labile enterotoxins LT-1 and LT-2 from *Escherichia coli* are arginine-specific ADP-ribosyltransferases that are able to modify the α subunit of the stimulatory G protein (G_s) and to irreversibly inhibit its GTPase activity; this results in the activation of adenylyl cyclase and in the increase in intracellular cyclic AMP [13]. CT is an 84 kDa oligomeric protein that consists of the monomeric A subunit, a 29 kDa polypeptide that exhibits the ADP-ribosyltransferase activity, and the homopentamer B subunit, a complex of five 11 kDa polypeptides, which itself binds stoichiometrically with high affinity and specificity to five GM1 molecules on the plasma membrane [16]. To cause disease, both CT and LT coopt molecular machineries of the

Table I ADP-ribosylating/deribosylating Enzymes Acting on Heterotrimeric G Proteins

Enzyme/Source	Subunit structure/ Localization	Target/s	Effects	Ref.
Toxin ADPRT				
Cholera toxin	AB ₅	G _s , G _t	Inhibition of G protein GTPase activity	13,18
<i>Escherichia coli</i> LT	AB ₅	G _s , G _t	Inhibition of G protein GTPase activity	13
Pertussis toxin	AB ₅	G _i , G _o , G _t	Uncoupling of G proteins from receptors	13,14
Cellular ADPRT				
Human erythrocytes	Membranes	G _i	Decrease in epinephrine-mediated AC inhibition	51,52
Human platelets	Membranes	G _i	Decrease in epinephrine-mediated AC inhibition	51,52
Rabbit ventricles	Membranes	G _s	Increase in AC activity	41
Human platelets	–	G _s	Increase in AC activity	42
Rat brain	Homogenate	G _s , G _o	–	43,44
Rabbit luteal	Membranes	G _s	Increase in AC activity	45
Chicken spleen	Membranes	G _s , actin	Increase in AC activity	46
NG108-15	Membranes	G _s	Increase in AC activity	47
CHO cells	Plasma Membranes	G _β	Inhibition of βγ-mediated function	55
Cellular Hydrolase				
Rat and human tissue	Cytosol	G _s	–	12
Human erythrocytes	Cytosol	G _i	–	11
CHO cells	Cytosol	G _β	–	55

This table lists the ADP-ribosylating activities (ADPRT) identified in different systems and related to G protein modification. The ADP-ribosylhydrolases (hydrolase) catalyzing the reverse reaction are also indicated. See the text for other enzymes for which the action on G proteins has not been proven directly, such as the mammalian ART family (including ART 1-5) and the mammalian Sirt family (including Sirtuin 1-7). AC, adenylyl cyclase; – not determined.

host cell; the toxin enters by endocytosis of the toxin-receptor complexes, follows retrograde transport to the Golgi cisternae or to the endoplasmic reticulum (ER), and finally translocates to its site of action on the inner surface of the plasma membrane [17]. The ADP-ribosyltransferase activity of the A subunit requires proteolysis for activation with the release of a smaller, carboxyl-terminus 7 kDa fragment (CTA2) and of a larger 22 kDa catalytically active fragment (CTA1) whose activity is promoted by a family of 20 kDa GTPases, the ADP-ribosylation factors (ARFs) [18].

PT, a cysteine-specific ADP-ribosyltransferase, ADP-ribosylates the α subunit of G_i, G_o, and G_t. Unlike CT, PT-catalyzed mono-ADP-ribosylation occurs when the α subunit is associated with $\beta\gamma$, thus generating a modified G protein unable to couple to activated receptors and to transduce signals [19]. PT is a 119 kDa toxin consisting of a 28 kDa monomeric A component, an S1 subunit expressing the ADP-ribosyltransferase activity, and a B component, a complex of five polypeptides (S2, S3, two S4s, S5) [20]. The function of the B component is to attach the native toxin to the cell-surface receptor, thus initiating toxin internalization by receptor-mediated endocytosis and its trafficking through early to late endosomes and the Golgi apparatus [21]. There is no evidence that the ADP-ribosyltransferase activity of the S1 subunit requires cofactors, such as the ARFs reported for CT.

Endogenous Mono-ADP-Ribosylation

Vertebrate ADP-ribosyltransferase activity was first detected in turkey erythrocytes [22,23], rat liver homogenates [24], and *Xenopus* tissues [25]. Specific enzymes have been cloned from different sources [26–31]. The family of mammalian ADP-ribosyltransferases includes five enzymes referred to as ART1 to 5 [32,33]. ART1, ART2, and most likely ART3 and ART4, are glycosylphosphatidylinositol (GPI)-anchored to the cell surface. ART5 possesses a hydrophobic N-terminal signal sequence and is likely to be a secretory protein but with an as yet unknown function [34]. ART1 and ART2 have roles in immune regulation: ART1 inhibits T-lymphocyte functions, such as their cytolytic activity and proliferation, by ADP-ribosylating arginines of cell surface molecules, such as the T-cell co-receptors [32,35]; ART2 is expressed on resting T cells and on natural killer cells, has not been found outside of the immune system, and exerts a regulatory role in rat models for autoimmune insulin-dependent diabetes mellitus, where its defective expression on T-cells has been associated with increased susceptibility to the disease [32,36]. ART3 is strongly expressed in human testis, and ART4 is preferentially expressed in human lymphatic tissue [31].

The catalytic domains of the mammalian ART enzymes are extracellular, and thus it is unlikely that members of this family are involved in mono-ADP-ribosylation of

intracellular targets, like heterotrimeric G proteins. In principle, ARTs could be internalized from the cell surface and transported to the site of action, as with the bacterial toxins. However, the sorting mechanism reported for GPI-anchored proteins, which involves endocytic vesicles, would result in a luminal localization of the catalytic domain, segregating it from cellular substrates such as the G proteins [37]. Thus, the possibility that a distinct family of intracellular enzymes that have ADP-ribosyltransferase activity should be considered. In support of this possibility, it has been suggested that the yeast silencing protein *syr2* possesses ADP-ribosyltransferase activity [38]; moreover, the cloning and characterization of seven human proteins (sirtuins 1 to 7) that are able to metabolize NAD⁺ and possess ADP-ribosyltransferase activity has recently been reported [39]. These *sir2*-like proteins do not share any obvious sequence homology with the well-characterized ART family, and represent good candidates for the intracellular ADP-ribosyltransferases.

Cellular ADP-ribosyltransferase activities able to catalyze the modification of G-protein arginine residues in a way similar to CT have been described in many cells and tissues (Table I) [40–49]. Although they present either the identification of the enzymatic activity or of the G-protein substrates, several of the initial reports do not fully demonstrate the mono-ADP-ribosylation reaction (no discrimination between the enzymatic and non-enzymatic ADP-ribose linkages, or use of α -NAD⁺ rather than β -NAD⁺, the preferred substrate of ADP-ribosyltransferases, in the ADP-ribosylation assays); moreover, the identification of the G-protein substrates remains elusive, since these reports were only based either on the determination of the molecular mass or on the comigration with the bacterial toxin substrates by polyacrylamide gel electrophoresis [40–46].

A series of more recent reports has led to a better understanding of the endogenous mono-ADP-ribosylation machinery. It has been shown that in highly purified canine cardiac sarcolemma, isoproterenol produces the selective ADP-ribosylation of a single 45 kDa protein, identified as G α s by immunoprecipitation. This effect was correlated with the ability of NAD⁺ to increase cyclic AMP production [48]. Similarly, a 52 kDa protein, identified as an α s isoform, is ADP-ribosylated in smooth muscle cells from bovine coronary arteries [49]. In this case, the G α s modification was related to the release of eicosanoids from the endothelium that stimulate the enzymatic reaction and thus activate K⁺ channels [50].

Endogenous ADP-ribosylation of cysteine residues of G proteins that are comparable to the PT effect has been reported in human erythrocytes and platelets [51], where it attenuates the inhibition of adenylyl cyclase induced by epinephrine (Table I) [52]. Thus, the picture emerging from these observations is that the pathological modification of G proteins produced by bacterial toxins has an endogenous, possibly physiologically relevant, counterpart that could be looked upon as an additional mechanism of regulation of G-protein-mediated functions. In addition, there are indications in *in vitro* assays that not only the α but also the

β subunit of G_i can be a substrate of an ADP-ribosyltransferase purified from the cytosol of turkey erythrocytes [53,54].

Recently, direct evidence of the functional, enzymatic modification of the G protein β subunit has been reported both in isolated plasma membranes and in intact cells [55]. The arginine-specific mono-ADP-ribosyltransferase that catalyzes this reaction is a plasma-membrane-associated, but not GPI-anchored, protein that acts intracellularly and specifically modifies residue 129 of the β subunit. It is interesting that the modified β subunit can be de-ADP-ribosylated by a cytosolic ADP-ribosylhydrolase, thus revealing a cellular ADP-ribosylation/de-ADP-ribosylation cycle that might parallel a functional activation-inactivation cycle of the $\beta\gamma$ dimer. It is worth mentioning that under resting conditions, the β subunit mono-ADP-ribosylation takes place also in intact cells, thus corroborating the potential physiological role of this reaction [55].

The modified β subunit loses its ability to modulate effector enzymes such as calmodulin-stimulated type 1 adenylyl cyclase and phospholipase C, indicating that the modification of arginine 129, a critical residue located in the β common-effector-binding surface [56], can indeed impair β subunit activities [55]. Mono-ADP-ribosylation can thus be considered to be a signal termination mechanism for $\beta\gamma$ -mediated functions. In principle, the ADP-ribosylation of the β subunit could also affect the function of the α subunits, since it can lead to a sustained activation of α -subunit-dependent functions by sequestering the $\beta\gamma$ subunit from the signal cascade and preventing the reassociation of the heterotrimer.

Among the substrates of mono-ADP-ribosylating enzymes, there are other cellular proteins involved in signaling and cell organization, such as GRP78/BIP, p33, integrin α 7, desmin, actin, and CtBP/BARS [57–64]. It is interesting, and in line with the data summarized above for the modification of the G-protein α and β subunits, that in all these cases ADP-ribosylation has been shown to cause protein inactivation.

Thus, although the regulation of mono-ADP-ribosylation in whole cells remains to be fully clarified, the information obtained to date indicates that this reaction has the characteristics of a fundamental regulatory process that is potentially relevant not only in G-protein-mediated signaling, but also in other cellular functions.

Receptor-G-Protein Chimeras: An Introduction

Direct measures of the levels of expression of the α subunits of heterotrimeric G proteins indicate that they are generally in considerable excess over the levels of any particular G-protein-coupled receptor (GPCR) that might activate them. Despite this, an emerging strategy that has been used to address both basic questions on the details of GPCR-G protein interactions and to allow screens to be designed for agonist ligands at GPCRs has been to generate chimeric GPCR-G protein constructs that define a 1:1 stoichiometry of the two partner polypeptides. Such constructs provide a convenient means to assess the effects of mutations and polymorphisms in GPCRs on signal transduction effectiveness without altering the ratio of expression of GPCR to G protein. They have also allowed effective means of developing direct assays of GPCR-mediated guanine nucleotide exchange on G proteins of the G_s and G_q families that historically has been difficult to monitor. Such assays have allowed direct analysis of the extent of constitutive activity of different GPCRs and the detection of inverse agonists.

Construction of a GPCR-G protein chimera involves linking the 5' end of a G protein α subunit cDNA to the 3' end of a GPCR cDNA or DNA from which the stop codon has been eliminated. This results in the production of a single open reading frame containing the sequences of both partner proteins. Despite the artificial nature of such constructs all available data indicate that the expressed polypeptides are properly folded and functional. The α subunit in such chimeras is clearly able to interact with G protein β/γ complexes and the basic pharmacology of the GPCR is preserved.

A number of recent reviews on the production and analysis of function of such chimeras are available [1–4] and should be consulted to expand on the information provided herein.

Defining the Signal

In the vast majority of cases analysis of GPCR-G protein chimeras takes place following expression in cell systems that also express endogenously the G protein of interest. A range of techniques has been developed to ensure that observed signals represent activation of the G protein within the chimera. For members of the G_i -family of pertussis toxin-sensitive G proteins, the cysteine residue that is the target for toxin catalyzed ADP-ribosylation is within a key receptor contact site but is not inherently required for function [5]. Amino acids with high hydrophobicity can substitute at least as effectively [5,6]. Thus, replacement of this cysteine in the GPCR-fused G protein ensures that the chimera is resistant to the actions of pertussis toxin. Prior treatment of cells with this toxin to modify the endogenously expressed G_i population thus prevents any possibility of agonist-induced signal deriving from interaction with these G proteins [7,8]. This idea has been adapted effectively to construct a ligand screen. The members of the edg family of GPCRs respond to lipid-derived products such as lysophosphatidic acid and sphingosine-1-phosphate [9]. However, at least eight GPCRs of this family are known and they display wide-ranging and complex patterns of expression. Virtually all cell lines respond to these ligands due to endogenously expressed edg family members, and such effects are generally transduced

via G_i family G proteins. A screening assay for ligands at the human *edg2* receptor was thus established by expressing a GPCR-G protein chimera in which a pertussis toxin-resistant mutant of $G_{i1}\alpha$ was linked to this receptor [10]. Following pertussis toxin treatment, guanine nucleotide exchange assays provided a specific and direct assay for ligand activation of *edg2* [10].

Because it has been well established that GPCRs within certain chimeras can also activate endogenously expressed G proteins [8], the functionality of GPCR-G protein chimeras has also been tested in cells that lack expression of certain G proteins. Elevation of intracellular $[Ca^{2+}]$ in cells derived from a mouse embryo in which the genes encoding both $G_q\alpha$ and $G_{i1}\alpha$ were inactivated requires co-expression of both a GPCR and an appropriate G protein [11]. A chimeric α_{1b} -adrenoceptor- $G_{i1}\alpha$ fusion protein is able to elevate $[Ca^{2+}]$ in response to agonist and thus must be functional [11]. This signal is in fact a monitor of release of β/γ complex from the chimeric protein and provides further confirmation that such GPCR-G protein chimeras function in the expected manner [11]. Introduction of mutations that block β/γ binding to the G protein α subunit or prevent α and β/γ dissociation also prevent agonist-induced elevation of $[Ca^{2+}]$ [12].

Guanine Nucleotide Exchange Assays

The initial steps in GPCR activation of a G protein are acceleration of GDP release from the G protein α subunit and its replacement with GTP. Deactivation requires hydrolysis of the terminal phosphate of the GTP. These processes provide conceptually easy assay endpoints. However, the low rates of basal guanine nucleotide exchange by G_s and G_q family G proteins has made this difficult to measure in membranes of mammalian cells because of the relatively high rates of exchange occurring on G_i family G proteins and on other non-signal transducing but GTP exchange-dependent polypeptides. Thus, in terms of assay screens for ligands, the signal-to-noise is generally too low to be acceptable. However, immunoprecipitation of such GPCR-G protein chimeras at the termination of a $[^{35}S]GTP\gamma S$ binding assay can produce data where signal-to-noise is between 20–40 to 1 [11–13]. This reflects that in the absence of agonist many GPCRs have a very low capacity to activate the G protein. Thus, when the chimeric protein is immunoprecipitated very little $[^{35}S]GTP\gamma S$ is associated with it. This is increased greatly by agonist occupation of the GPCR. Again, introduction of mutations that prevent guanine nucleotide exchange on the G protein can be used to confirm that the signal reflects activation of the G protein of the chimera [12,13]. Adaptation of this into a homogenous assay involving, for example, secondary antibody coated scintillation proximity assay beads offers an excellent opportunity to use this approach in ligand screening programs.

Although far less popular than $[^{35}S]GTP\gamma S$ binding assays, analysis of agonist-stimulated GTPase activity provides a

highly attractive assay point for activation of GPCR-G protein chimeras. This is particularly so in two regards. First, the defined 1:1 stoichiometry of the two components means that combinations of analysis of the effects of agonist at V_{max} and ligand binding studies means that direct measurement of GTP turnover and the catalytic efficiency of different ligands to activate the G protein can be obtained [7]. Second, the mechanisms of action of G protein interacting proteins can be deduced from their effects on enzyme kinetic parameters of GTP hydrolysis. These have been employed to examine the relative efficacy of different agonists and to demonstrate how regulators of G protein signaling (RGS) proteins function [14,15].

Constitutive Activity and Inverse Agonism

Many mutations have been described that introduce or enhance agonist-independent (also called constitutive) activity to GPCRs [16,17]. Such mutations may provide insights into the mechanisms of action of agonists and the conformational states of activated GPCRs. Such mutations have been introduced into GPCR-G protein chimeras. Using the $[^{35}S]GTP\gamma S$ binding assay in parallel with immunoprecipitation, direct measures of the extent of constitutive activity introduced by different mutations have been obtained for each of the α_{1b} -adrenoceptor when activating $G_{i1}\alpha$ [13] and for the β_1 -adrenoceptor to activate $G_s\alpha$ [18]. Equally, the very low levels of $[^{35}S]GTP\gamma S$ present in immunoprecipitates of the chimeras containing the wild-type forms of these GPCRs has allowed easy demonstration that a number of wild-type GPCRs display high levels of constitutive activity. For example when the melanocortin MC_4 receptor is fused to $G_s\alpha$ and a $[^{35}S]GTP\gamma S$ binding assay followed by immunoprecipitation, a large number of counts are present even in the absence of ligand. Addition of α MSH enhances this further but to a much smaller extent than produced by isoprenaline at an equivalent β_1 -adrenoceptor- $G_s\alpha$ fusion. This is not inherently surprising because the agouti-related peptide acts as an endogenously expressed inverse agonist at the MC_4 receptor [19] and this ligand does indeed greatly reduce the levels of $[^{35}S]GTP\gamma S$ binding to the melanocortin MC_4 receptor- $G_s\alpha$ fusion protein. This approach is thus likely to be valuable in assessment of the extent of inherent constitutive activity in many GPCRs and could clearly be applied effectively to GPCRs encoded by viral genomes, at least some of which are thought to display high levels of ligand-independent activity [20]. It also offers excellent potential for development for screens for ligands that have inverse agonist activity. A limitation in the development of screens for ligands at orphan GPCRs has been to decide the G-protein coupling specificity of the orphan [21], but combinations of the use of so-called “universal” [22] and “chimeric” [23,24] G proteins may overcome this.

A second useful approach to improving the sensitivity of detection of ligands at GPCR-G protein chimeras takes advantage of constitutive activity but now monitors GTPase activity.

RGS proteins act as GTPase activating proteins for heterotrimeric G proteins [25]. Addition of a recombinant RGS to a GTPase assay in membranes expressing a chimera of the 5HT-1A receptor and $G_{o1}\alpha$ greatly enhances the responses to agonist ligands [26]. More usefully, however, the RGS protein also acts as a GAP for GTP loaded by the constitutive activity of the GPCR. As this increases the basal activity markedly, it greatly increases the dynamic range available for detection of decreased spontaneous loading of GTP produced by addition of an inverse agonist [26]. Adaptations of this whereby a GPCR that couples traditionally to $G_s\alpha$ is incorporated into a fusion protein containing a chimeric G protein that has the receptor recognition elements of $G_s\alpha$ and the guanine nucleotide exchange and RGS interaction sites of a $G_i\alpha$ [27] will allow this enhanced sensitivity to be used in screens for inverse agonists at $G_s\alpha$ -coupled receptors.

Conclusions

Overall, GPCR-G protein chimeras display all the key properties of the two isolated polypeptides. However, due to the proximity produced by their fusion, they display enhanced effectiveness of interaction. Their defined stoichiometry also allows both detailed examination of basic research questions and the development of novel screens for GPCR ligands.

Introduction

The G protein $\beta\gamma$ dimer interacts with multiple partners to perform numerous functions in the signal transduction process (for reviews see [1–4]). First, the $\beta\gamma$ dimer interacts with the α subunit to form the G-protein heterotrimer. In this capacity, the $\beta\gamma$ dimer functions to target the α subunit to the membrane and acts as a guanine nucleotide dissociation inhibitor for the α subunit. Second, the $\beta\gamma$ dimer interacts with the receptor. In this capacity, the $\beta\gamma$ dimer may be required for the receptor to activate the G protein; and the $\beta\gamma$ dimer composition may contribute to recognition of the receptor. Third, the $\beta\gamma$ dimer interacts with the effector, such as adenylyl cyclases (AC), phospholipases (PLC), ion channels, and kinases. In this capacity, the $\beta\gamma$ dimer regulates the activity of the effector until re-association with the α subunit terminates the signal. Finally, the $\beta\gamma$ dimer interacts with accessory proteins, including the cytoskeleton, phosphatidylinositol 3-kinase, regulators of G protein signaling (RGS) proteins, and receptor kinases. In this capacity, the $\beta\gamma$ dimer influences the magnitude and duration of the signal transduction process.

In the foregoing, the functions of “the $\beta\gamma$ dimer” are discussed. In fact, there is the potential to generate a large number of different $\beta\gamma$ dimers given the known existence of

five β and twelve γ subtypes. However, their functional significance remains enigmatic. *In vitro* approaches have shown little specificity among the various $\beta\gamma$ dimers, whereas *in vivo* approaches indicate greater specificity. Thus, a major question revolves around to what extent the G-protein $\beta\gamma$ dimers are functionally interchangeable in the cell. The answer to this question has major implications for how these components are assembled into signaling pathways and how the fidelity of these signaling pathways are maintained. As discussed below, there is a growing recognition that the G-protein $\beta\gamma$ dimers have specific functions *in vivo*.

Diversity of the β and γ Gene Families

The β -subunit family is highly conserved. At the genomic level, five genes encoding β subunits (GNB) have been identified [5]. Since their specific functions are not known, they have been named in order of cloning. The GNB1–GNB4 genes share a common intron-exon structure within the coding region, whereas the GNB5 gene does not [5]. The structure of the human GNB3 gene has been described in detail [6]. At the protein level, the β subunits display substantial sequence homology that is conserved across species.

Notably, the β_1 through β_4 subtypes share 78 to 88 percent amino acid identity, whereas the β_5 subtype shows only 51 to 53 percent amino acid identity with the other β subunits.

By contrast, the γ subunit family is more divergent. At the genomic level, 12 genes encoding γ subunits (GNG) have been identified [5,7]. Again, since their functions are not

known, they have been named in order of cloning. As shown in Fig. 1, all GNG genes have two coding exons and share a common splice site in the coding region, with the exception of the GNG13 gene [8]. In addition, most GNG genes have one or more 5' noncoding exons, some of which are located more than 100 kb upstream of their coding regions.

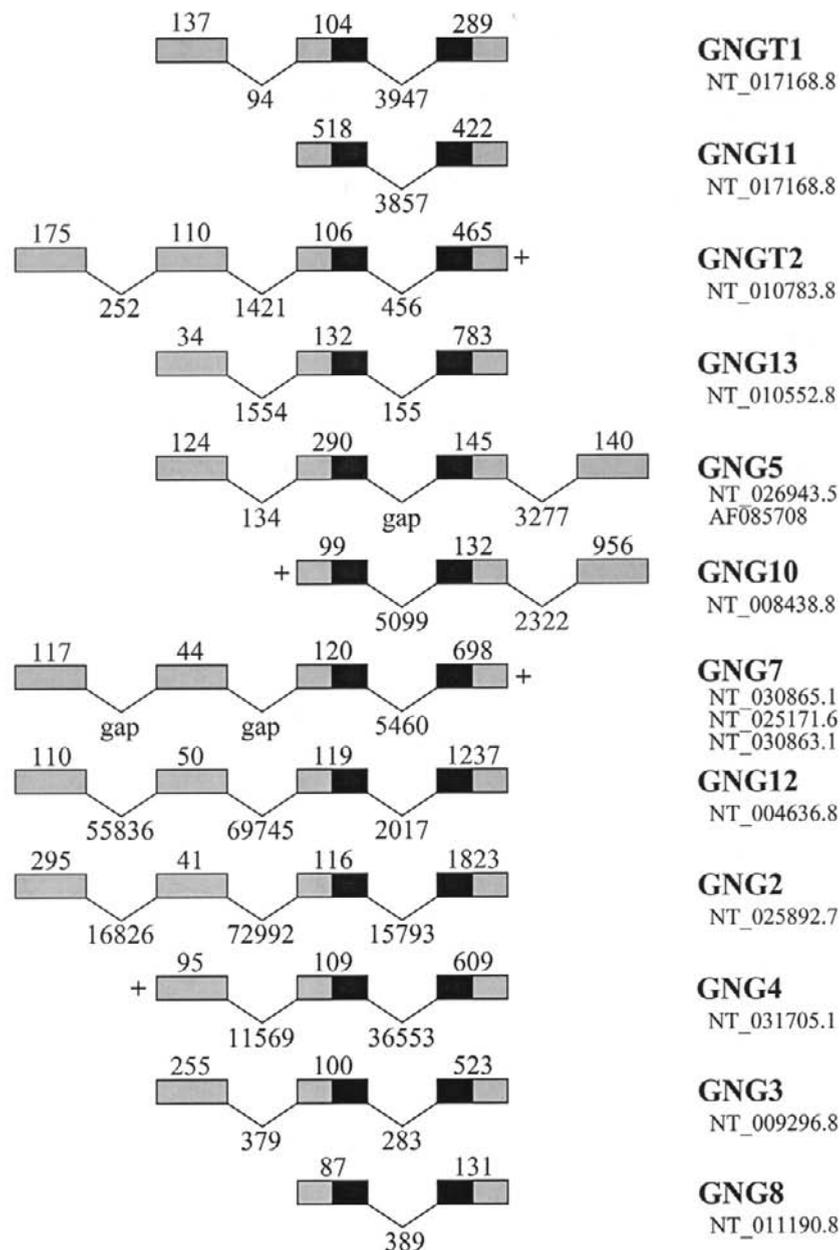

Figure 1 Structures of the genes encoding γ subunits, as predicted by comparing genomic sequences with mRNA and EST sequences via the data mining tools Evidence Viewer and Model Maker at the NCBI web site. Exons are diagrammed as shaded boxes, with size in bp indicated above each box. Dark shading indicates coding regions. Introns are diagrammed as V-shaped lines, with size in bp shown below each. The plus signs indicate the existence of ESTs with sequence beyond what is diagrammed, suggesting a possible additional exon or an extension of the indicated exon. At the right, the accession number for the working draft sequence containing each gene is shown below the gene name. Gaps were still present in the working draft sequences for the GNG5 gene and GNG7 genes. The coding portion of exon 2 of GNG5 was not identified in NT_026943.5 and was modeled based on AF085708. Two 5' noncoding exons of GNG7 were not identified in NT_030865.1, but were present in adjacent contigs.

Though the details remain to be worked out, these additional exons may allow for multiple promoters, coordinate regulation with other gene products, or alternate splicing of elements involved in regulation of translation. Finally, the GNG5 and GNG10 genes have one 3' noncoding exon, which may be involved in mRNA stability or subcellular localization. This diversity in GNG gene structure suggests variability in gene expression that may underlie specificity in function. At the protein level, the γ subunits display a sequence diversity that is conserved across species, suggesting the individual subtypes have specific and distinct functions. Based on amino acid diversity, they can be arranged into five classes [2], with each group showing less than 50 percent homology to the other classes: (1) γ_7 and γ_{12} (76 percent identity); (2) γ_1 , γ_{11} , and γ_{14} (62 to 73 percent identity); (3) γ_2 , γ_3 , γ_4 , and γ_8 (56 to 75 percent identity); (4) γ_5 and γ_{10} (53 percent identity); and (5) γ_{13} . Analogous to the G-protein α subtypes, this pattern of structural diversity suggests that the γ subtypes may fall into functional classes that have yet to be characterized.

The genomic analysis can be extended to identify genes that are adjacent to GNG genes. Except for GNGT1 and GNG11, the genes encoding the γ subunits are widely dispersed throughout the genome [5,7]. The GNG2 gene is arranged head-to-head with an SH3 domain protein, NESH. The GNG3 gene is located head-to-head with the BSCL2 gene (murine Gng3-linked gene), which is responsible for Berardinelli-Seip congenital lipodystrophy [9]. Because of these arrangements, the promoter elements of these genes may overlap, suggesting the possibility of coordinate regulation. The bovine γ_5 subtype and chitobiose protein are alternatively spliced products of the same gene [10]; the human GNG5 and CTBS genes appear to be similarly linked.

Assembly of the $\beta\gamma$ Dimer

Typically, the $\beta\gamma$ subunits exist as a tightly associated complex that functions as a single unit. The only known exception is the β_5 subtype that interacts with certain RGS proteins [11]. Hence, an important step in deciphering which $\beta\gamma$ subunit combinations can exist in intact cells is to understand the mechanics and determinants specifying their assembly. In this regard, there is some evidence suggesting that assembly of the $\beta\gamma$ dimer occurs in a specific order: beginning with synthesis of β and γ in the cytosol, progressing to formation of the $\beta\gamma$ dimer, to prenylation of the γ , to removal of the three terminal amino acids and carboxyl-methylation of the γ , and finally to translocation of the fully processed $\beta\gamma$ dimer to the plasma membrane, perhaps in association with the α subunit [12,13]. Moreover, there is increasing evidence suggesting that spatial and structural constraints can contribute to selective assembly of specific $\beta\gamma$ dimers.

Cellular Level

Just how β and γ subunits are brought together to form specific $\beta\gamma$ dimers remains unresolved. At one level, the

β and γ subtypes are expressed in cell-specific patterns [8,14–17], raising the possibility that each cell contains only a subset of all possible $\beta\gamma$ dimers to participate in the signal transduction process at a given time. The mechanisms governing their expression have not been defined but may include differences in promoter function, mRNA stability, mRNA localization, translation efficiency, protein stability, or protein localization. Does this mean that $\beta\gamma$ dimers assemble simply through random association in cells expressing multiple β and γ subtypes? *In vitro* studies indicate that structural constraints preclude a few $\beta\gamma$ subunit combinations [18–20], most notably those involving β_2 , β_3 , and γ_1 subtypes. Moreover, *in vivo* studies suggest that spatial considerations contribute to the assembly of specific $\beta\gamma$ subunit combinations [21–23]. For example, ribozyme-mediated suppression of the γ_7 subtype results in a coordinate reduction in the expression of the β_1 subtype but has no effect on the other three β subtypes expressed in human kidney cells [23]. Pulse-chase labeling studies show that there is a dramatic difference in the half-life of the β_1 monomer (20.8 min) compared to the $\beta_1\gamma_7$ dimer (14.2 hrs). Collectively, these results indicate that the β_1 protein is rapidly degraded when sufficient γ_7 protein is not available; and that other γ proteins are not able to randomly associate with the β_1 protein in these cells.

Subcellular Level

At another level, the γ subtypes exhibit distinct subcellular localizations [24,25], raising the possibility that they are involved in targeting the $\beta\gamma$ dimers to specific locations within the cell membrane. For example, we have shown that the γ_7 subtype is present in the membrane overlying the actin fibers in the leading edge of the cell, the γ_5 subtype is highly enriched in the membrane overlying focal adhesions, and the γ_3 subtype is localized in a membrane site distinct from caveolae (J.D.R., unpublished; [24]). Other reports suggest that the γ subunit is not only associated with the membrane but also with intracellular components. For example, the γ_{12} subtype is present in a detergent-insoluble fraction in Swiss 3T3 cells in association with F-actin [25], and the $\beta\gamma$ dimer associates with cytokeratin filaments in starfish oocytes [26]. These results suggest that differential subcellular localization of the γ subtypes may direct the specific assembly of $\beta\gamma$ dimers and predicts that β subtypes may be found to share these patterns of expression.

The region(s) of the γ subunit responsible for their targeting includes the C-terminal tail and posttranslational modifications thereof. This raises the possibility that heterogeneity in their processing may account for their distinctive subcellular localizations. In this regard, the type of prenyl group may be important. The γ_1 , γ_{11} , and γ_{14} subtypes are modified by the C15 farnesyl group, whereas the remaining subtypes are modified by the C20 geranylgeranyl group [17,19]. Though the prenyl group is important for targeting, the nature of this interaction is not clear. One possibility is that the prenyl group may interact as the result of a lipid-lipid interaction. In this case, the addition of the geranylgeranyl

rather than the farnesyl group may confer additional hydrophobicity to the protein [17,27]. This is consistent with the finding that the geranylgeranyl moiety is sufficient to target the $\beta\gamma$ dimer to the membrane, but farnesyl-dependent association of the $\beta\gamma$ dimer with the membrane requires additional modifications, including carboxyl-methylation [27]. Another possibility is that the prenyl group may associate as the result of protein-protein interactions. In this case, the presence of the geranylgeranyl or farnesyl group may act as part of a recognition target for specific “docking proteins.” This notion is consistent with recent results showing that the geranylgeranyl group of the γ subunit preferentially inserts into a hydrophobic binding pocket on PLC- β [28]. However, the type of prenyl group cannot explain the differences in subcellular localization among the γ_3 , γ_5 , and γ_7 subtypes noted above, since all three are modified with a geranylgeranyl group. This suggests that variable processing of the C-terminal tail and/or additional upstream regions may be important. In this regard, an alternatively processed form of the γ_5 subtype has been identified as the predominant species in brain [29]. Notably, this protein is prenylated but retains the three terminal amino acids. Whether this pattern of processing determines the unique localization of the γ_5 subtype in focal adhesions is the subject of ongoing studies. Also, there is some evidence that the N-terminal region of the γ protein could be important for subcellular localization based on its extensive sequence divergence [2] and the finding that phosphorylation within this region of the γ_{12} subtype alters the nature of its association with cytoskeleton [30]. Collectively, these results support a growing body of evidence that the G-protein-dependent signaling pathways may be segregated [31,32] and that this is a critical factor in maintaining the specificity of the $\beta\gamma$ signal, as discussed below.

Specificity of G Protein $\beta\gamma$ Dimer Signaling

Combinatorial association creates the potential to assemble 60 different $\beta\gamma$ dimers that can be utilized to direct the fidelity of signaling. However, specificity has been difficult to show in transfected and reconstituted settings where there is substantial overlap in terms of their functions. This is most likely due to the absence of critical factors that provide specificity only in the context of the intact cell setting. For this reason, investigators have begun to use reverse genetic approaches to ascribe specific functions to the β and γ subtypes. Such strategies clearly support the notion that the composition of the $\beta\gamma$ dimer, in particular the γ component, has important ramifications for the specificity of signaling that begins at the receptor level and continues to the effector level.

Structural Constraints on Specificity

Reconstitution studies of purified proteins show that the $\beta\gamma$ dimer interacts directly with the receptor and certain types of the effector. To identify the contact sites, chimeric

and mutagenesis approaches have been used to identify multiple sites on the $\beta\gamma$ dimer: some regions appear to stabilize the interaction, other sites appear to modulate the interaction, and a few regions appear to specify the interaction. These regions will be discussed in the context of the three-dimensional structure of the $\beta\gamma$ dimer [33,34]. In this structure, the β subunit is composed of two major domains—an N-terminal α helix and a seven-bladed β -propeller—whereas the γ subunit is composed of three major domains—an N-terminal α helix that forms a parallel coiled-coil structure with the corresponding region of the β subunit, a middle domain that forms extensive contacts along the bottom surface of the seven-bladed β -propeller, and a C-terminal domain, including the prenyl group.

$\beta\gamma$ DIMER-RECEPTOR

Recent evidence indicates that the $\beta\gamma$ dimer directly interacts with the receptor [35], where it may actively participate in receptor-catalyzed nucleotide exchange of the α subunit [36]. Cross-linking studies confirm a receptor contact site within the C-terminal region of the β subunit [37], and reconstitution studies comparing different $\beta\gamma$ subunit combinations reveal modest differences due to the β component [38–41]. Similar studies highlight even greater differences due to the γ component and point to the importance of the primary structure of the C-terminal domain and the type of prenyl group [38,41–45]. Collectively, these data indicate that the $\beta\gamma$ -subunit composition contributes to the selectivity of receptor interaction. In addition, other results suggest that the $\beta\gamma$ subunit composition may modulate the mechanism [46] and/or the duration [47] of receptor interaction. Nevertheless, the finding that the range of G protein $\beta\gamma$ -receptor interactions *in vitro* is far greater than that observed *in vivo* suggests the presence of additional mechanisms for conferring specificity of signaling beyond direct receptor recognition of $\beta\gamma$ subtypes.

$\beta\gamma$ DIMER-EFFECTOR

Once released from the G-protein α subunit, the $\beta\gamma$ dimer regulates a growing list of effectors. Multiple regions of the β subunit interact with the effector. One site lies within the N-terminal α -helix of the β subunit [48]. This region is exposed regardless of the activation state of the G-protein heterotrimer and hence may represent a region where the effector can remain bound to the $\beta\gamma$ dimer even in the presence of the α subunit. Another region lies along the top surface of the β propeller of the β subunit (49). This region is exposed only upon activation of the G-protein heterotrimer and hence may be critical for modulation of the effector. Other regions include the sides of the β propeller, with each effector having its own characteristic set of contact points [49]. Despite the large number of sites on β , there is little evidence that any of these regions is involved in specifying the interaction with the effector consistent with the high homology of these domains among the β_1 – β_4 subtypes. The apparent exception is the β_5 subtype [50,51].

Whereas the β subtypes are very similar, the γ subtypes are much more divergent, suggesting that functional specificity of

different $\beta\gamma$ subunit combinations is more likely due to the γ component. In this regard, comparison of $\beta\gamma$ dimers differing only in γ reveal moderate differences in their abilities to activate effectors. The differences are due to both the primary structure of the N-terminal domain and the nature of the prenyl group on the C-terminal tail. It is remarkable that the relative contribution of these two regions appears to vary depending on the identity of the effector. For example, the amino acid sequence and/or charge of the N-terminal region of γ appears to be the major determinant for the AC activation. In this regard, the γ_1 and γ_{11} subtypes, which are negatively charged, are poor activators [17,52]. Likewise, the γ_{12} subtype, which is negatively charged as a result of phosphorylation, is a poor activator [53]. By contrast, the C-terminal domain and the type of prenyl group appear to be the more critical factors for activation of PLC- β [27,28,52]. (In one model, the prenyl group inserts into the β subunit, thereby producing a more active $\beta\gamma$ dimer for regulation of PLC- β [54]. In the other model, the prenyl group inserts directly into PLC- β , thereby accounting for activation of PLC- β [28]. Supporting the latter model, fluorescence-based assays reveal that the prenylated γ peptide interacts directly with a site on PLC- β . Providing a possible basis for selectivity, this site prefers the geranylgeranylated to the farnesylated form of γ [28]. Finally, mutagenesis studies to alter the putative prenyl binding pocket of β [54] or the C-terminal tail of γ [28] reveal that all such mutants are less effective than wild type for activation of PLC- β . Thus, the position of the prenyl group on the $\beta\gamma$ dimer has a profound impact on its ability to interact with PLC- β regardless of the model. However, there are still many unresolved questions. For instance, if the prenyl group of γ inserts into PLC- β , how does this fit with the crystal structure of phosphoinositide-3-OH transferase dimer, which has the prenyl group of γ inserting into a hydrophobic pocket of the β subunit [55]? Also, how does this fit with the previous finding that the C-terminal tail and the prenyl group of γ bind directly to the receptor [45,46]?

Specific Functions of Individual β and γ Subtypes

The limited functional specificity that has been observed *in vitro* presents a conundrum. If all $\beta\gamma$ dimers display substantial overlap in their interactions *in vitro*, how is specificity of the $\beta\gamma$ signal maintained such that different classes of G-protein-coupled receptors have specific functions *in vivo*? For example, the β -adrenergic and muscarinic receptors activate G proteins to produce opposing effects on the rate and force of contraction of cardiac myocytes. This indicates that these two receptors cause release of $\beta\gamma$ dimers that are not functionally interchangeable, and implies the existence of critical factors for specificity that can only be provided in the context of the cell. Increasingly, reverse genetic approaches provide the most direct and compelling evidence for specific functions of the β and γ subtypes. Analogous to the α subunit, loss of the β or γ subunit is likely to have major functional consequences by compromising the assembly of a specific G-protein $\alpha\beta\gamma$ trimer required for upstream

interaction with the receptor and downstream regulation of effector(s).

RNA SUPPRESSION

Early studies relied on anti-sense oligonucleotides to suppress translation of the mRNAs encoding the β or γ subtypes. In rat pituitary cells, this approach was used to study regulation of voltage-dependent calcium channels following nuclear injection of anti-sense oligonucleotides against the various G-protein subunits. The intriguing results suggest a specific role for the $\beta_1\gamma_3$ dimer in the somatostatin receptor pathway, with a similarly selective requirement for the $\beta_3\gamma_4$ dimer in the muscarinic receptor pathway [56,57]. More recently, other studies in the same cells predict roles for the $\beta_2\gamma_2$ dimer in coupling the vasoactive intestinal peptide receptor to stimulation of AC, the $\beta_1\gamma_3$ dimer in linking the somatostatin receptor to inhibition of AC, and the $\beta_4\gamma_2$ dimer in coupling the thyroid-releasing hormone receptor to activation of PLC- β [58]. Finally, studies in mice suggest a role for the γ_2 subtype in antinociception by the opioid receptor [59]. Though intriguing, these studies do not show that such functional consequences are due to loss of the targeted protein(s). Compared to anti-sense RNA, ribozymes offer significant advantages by acting as site-specific nucleases [60]. In human kidney cells, we have used this approach for the first time to show a specific role for the $\beta_1\gamma_7$ dimer in coupling the β -adrenergic receptor to stimulation of AC [23,61]. Ongoing studies in mouse lung cells suggest a similarly selective requirement for γ_{11} subtype in control of cell growth. In both cases, these defects are linked to specific loss of the targeted protein(s).

GENE TARGETING

More recently, we have begun analysis of mice or ES cells carrying targeted knockouts of the γ subunit genes to identify specific functions. Of the known γ subtypes, the γ_3 and γ_7 subtypes are closely related with respect to their primary structures and high expression levels in brain. Nevertheless, the γ_3 and γ_7 knockout mice exhibit two distinctive phenotypes, indicating they perform nonredundant roles in separate signaling pathways in the context of the whole animal. Collectively, the results of these reverse genetic approaches support the notion that receptors associate with particular combinations of G protein α and $\beta\gamma$ subunits in the cell or whole animal setting; and that this provides a basis for the specificity of signaling through these pathways.

Conclusion

An intriguing, growing body of evidence suggests that polymorphisms in β_3 may be linked to disease [6]; and that sequestration of $\beta\gamma$ may alter the course of diseases, including tumor invasiveness [62], vascular re-stenosis [63], and cardiac hypertrophy [64]. Thus, knowledge of which distinct subsets of $\beta\gamma$ are involved in these processes will provide the rationale for more selective design of therapeutic strategies for these diseases.

Introduction

A large family of seven transmembrane-domain receptors for hormones, neurotransmitters, growth factors, chemoattractants, light, odorants, and other extracellular stimuli promote intracellular signaling responses by activation of heterotrimeric G proteins. Agonist-activated G protein-coupled receptors (GPCRs) selectively interact with one (or more) of approximately 20 different heterotrimeric G proteins, promoting exchange of GTP for bound GDP, dissociation of the G protein into GTP-bound G α and free G $\beta\gamma$ subunits, and ensuing activation of downstream effectors. Hydrolysis of GTP by GTPase activity intrinsic to each G α subunit returns the heterotrimer to its ground state of G α -GDP bound to G $\beta\gamma$. Thus, signal amplitude of G protein-mediated responses is governed by the prevailing balance of receptor-promoted guanine nucleotide exchange and GTP hydrolysis.

Whereas activation of heterotrimeric G proteins by GPCRs has been understood in kinetic terms for almost two decades, understanding of the regulation of the deactivation process has accrued much more slowly. Purified G proteins hydrolyze GTP at a rate much lower than the very rapid deactivation of these proteins observed under physiological conditions. This discrepancy between the rates of GTP hydrolysis measured *in vitro* and *in vivo* presaged the existence of other classes of proteins that accelerate the deactivation of GTP-bound G α -subunits. Observation of marked enhancement of the GTPase-activity of G α_q in the presence of its specific effector PLC- β 1 [1] provided the first evidence for GTPase-activating proteins (GAPs) for heterotrimeric G proteins. More recently, a family of approximately 30 proteins was identified that contain a signature domain that selectively binds to GTP-bound G α -subunits and stimulates

their intrinsic GTPase activity up to several thousand-fold [2–8]. These “regulator of G protein signaling” (RGS) proteins promote the deactivation step in the heterotrimeric G protein regulatory cycle, catalyzing GTPase rates *in vitro* that are consistent with the rates of deactivation of G-protein signaling *in vivo*. Interaction of RGS proteins with GTP-bound G α subunits confers to this large class of regulatory proteins the ability to modulate signaling response kinetics, amplitude, and specificity. The physiological functions of these proteins are currently under investigation and, in the case of many RGS proteins, include additional functionalities beyond their hallmark capacity to act as GAPs for G α subunits.

The Signature RGS-Box as a G α GAP

The defining feature of all RGS family proteins is an ~120 amino-acid region, the “RGS-box,” that directly binds G α -GTP subunits and markedly accelerates GTP hydrolysis. The RGS-box has a “modular” character like that of other recurrent protein functional modules such as PDZ (PSD-95/Dlg/ZO-1), PTB (phosphotyrosine-binding), and SH2 (Src homology-2) domains—that is, the minimal polypeptide sequence of the RGS-box is sufficient in isolation for full G α -binding and GAP activity [9,10]. Soon after discovery of the RGS-box, Tesmer and colleagues [11] solved the first crystal structure of an RGS-box/G α complex, namely RGS4 bound to the adenylyl cyclase-inhibitory G α subunit G α_i 1. The RGS-box of RGS4 folds as a compact bundle of nine-alpha helical segments [11]. Other structures of isolated RGS-boxes have since been solved by both NMR and X-ray diffraction methods [12–16], including a trimeric complex of RGS9 bound to both G α -transducin (G α_t) and the gamma subunit of cGMP-phosphodiesterase [17]. Each of these

RGS-boxes presents the same global fold comprising predominantly alpha-helical secondary structure.

The atomic-resolution structures of RGS-boxes in complex with $G\alpha$ partners [11,17] indicate that the RGS-box primarily interacts with the conformationally flexible “switch” regions in the GTP-binding domain of $G\alpha$ subunits. RGS-box residues do not directly take part in the chemistry of the GTP hydrolytic cycle. Rather, GTP hydrolysis traverses through a bipyramidal transition state, and the crystal structure of the RGS4/ $G\alpha$ i1 complex revealed $G\alpha$ i1 to exist in this transition state [11]. $G\alpha$ -GDP subunits bound with the planar ion aluminum tetrafluoride (AlF_4^-) mimic the transition state of GTP hydrolysis, and therefore most RGS proteins bind most avidly to GDP/ AlF_4^- complexed $G\alpha$ subunits over the GTP γ S- or GDP-bound states (for example Fig. 1A; [18]).

The multidomain structure of many RGS proteins confers a complexity to these proteins that makes it difficult to define unambiguously their biological activities *in situ* or *in vivo*. Nonetheless, their signature activity exists in a capacity to act as GAPs for heterotrimeric G proteins, and quantitation of the GTPase activities of $G\alpha$ subunits is directly possible *in vitro* and is also feasible by indirect means *in vivo*.

Single-Turnover Assays of GAP Activity

The GAP activity of RGS proteins can be quantitated reliably in single-turnover assays with most purified $G\alpha$ subunits and RGS proteins [19]. Such measurements require the binding of $[\gamma^{32}P]GTP$ to $G\alpha$ in sufficient stoichiometry and under conditions that minimize GTP hydrolysis. This is usually accomplished by incubation of purified $G\alpha$ with $[\gamma^{32}P]GTP$ in the absence of Mg^{2+} , followed by removal of free $[\gamma^{32}P]GTP$ by gel filtration. Since GTP hydrolysis is Mg^{2+} -dependent, addition of Mg^{2+} allows quantitation of a single cycle of GTP hydrolysis in the basal state of the $G\alpha$ subunit. Moreover, concomitant addition of an RGS protein with Mg^{2+} provides assessment of the extent of RGS protein-promoted increase in hydrolytic activity (for example, Fig. 1B). The monoexponential time courses for release of $[\gamma^{32}P]Pi$ under these conditions allow calculation of the first-order rate constant for catalysis (k_{cat}) of the intrinsic GTPase activity and the rate constant (k_{gap}) for GAP-promoted hydrolysis. Bimolecular Michaelis-Menten enzyme kinetics are followed under assay conditions in which $G\alpha$ -GTP concentration is in excess of RGS protein concentration.

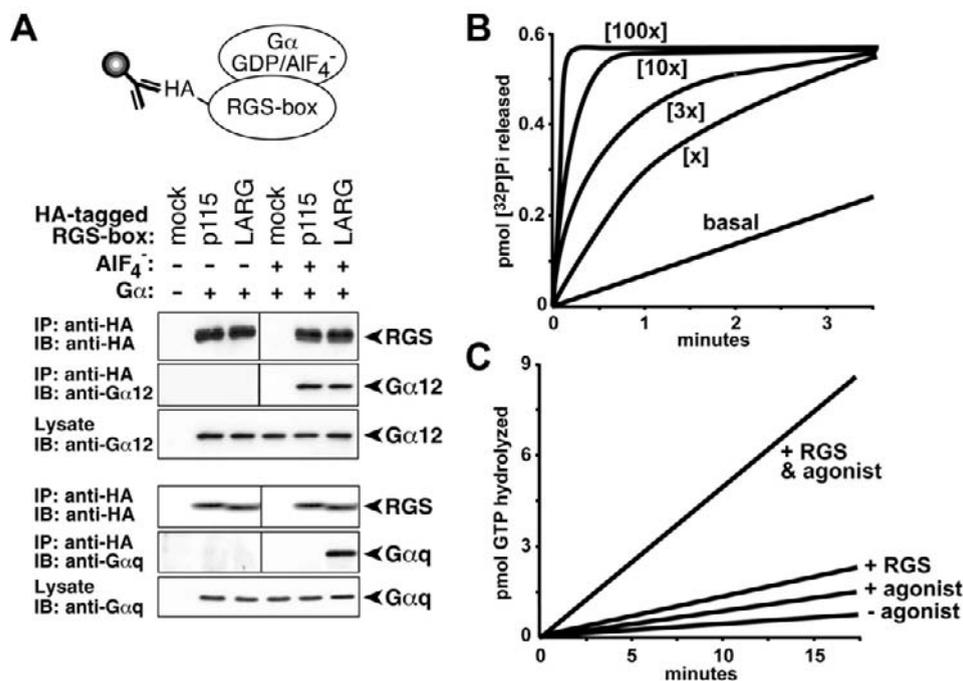

Figure 1 Representative functional data derived from assays of RGS-box activity. (A) Cellular co-transfection/co-immunoprecipitation assay to discern the $G\alpha$ -binding specificity of hemagglutinin (HA)-epitope tagged RGS proteins is illustrated schematically above the immunoblot results. Binding of $G\alpha$ subunits to the isolated RGS-boxes of p115-RhoGEF (“p115”) or leukemia-associated RhoGEF (“LARG”) is dependent on the addition to the cellular lysates of NaF and $AlCl_3$ (i.e., the components of aluminum tetrafluoride, AlF_4^-). IP, immunoprecipitation; IB, immunoblot. (B) Idealized results from a single-turnover assay measuring radioactive inorganic phosphate ($[\gamma^{32}P]Pi$) release (and, by inference, GTP hydrolysis) by $[\gamma^{32}P]GTP$ -loaded $G\alpha$ protein in the absence (“basal”) or presence of increasing concentrations ([x] to [100x]) of RGS protein. (C) Idealized results from a steady-state GTP hydrolysis assay employing proteoliposomes reconstituted with purified GPCR, heterotrimeric G-protein $G\alpha$ and $G\beta\gamma$ subunits, and incubated with $[\gamma^{32}P]GTP$ in the absence or presence of agonist and/or RGS protein. As in part B, GTP hydrolysis activity is quantitated as the production of $[\gamma^{32}P]Pi$.

Such single-turnover GTPase assays are straightforward with $G\alpha$ subunits that release GDP readily and therefore are readily labeled in solution by [$\gamma^{32}\text{P}$]GTP. Certain $G\alpha$ subunits bind GDP tightly and are more difficult to label with GTP. This is particularly true with $G\alpha_q$ and $G\alpha_{11}$. However, Ross and coworkers have experienced success in single-turnover assays with the $G\alpha_q$ mutant R183C [20], which exhibits reduced intrinsic GTPase activity and can thus be loaded (to relatively low stoichiometry) with [$\gamma^{32}\text{P}$]GTP by using prolonged incubations with [$\gamma^{32}\text{P}$]GTP.

A modification of the single-turnover assay takes advantage of the capacity of unlabeled $G\alpha$ subunits to act as competitive inhibitors of the activity of RGS proteins against [$\gamma^{32}\text{P}$]GTP-bound $G\alpha$. That is, RGS protein-promoted increases in the rate of hydrolysis of [$\gamma^{32}\text{P}$]GTP- $G\alpha$ are measured in the presence of AlF_4^- and a given GDP-bound $G\alpha$ -subunit (for example, [21]). Interaction of an RGS protein with the transition state $G\alpha$ (that is, GDP and AlF_4^- bound) will compete for the capacity of the RGS protein to act as a catalyst against the [$\gamma^{32}\text{P}$]GTP-bound $G\alpha$ substrate. Thus, the selectivity of interaction of an RGS protein with a series of $G\alpha$ subunits can be compared in measurements of their relative capacities to shift to the right the concentration effect curve for RGS protein-promoted release of [$\gamma^{32}\text{P}$]Pi.

Measurement of GTPase activity in single-turnover assays provides the most straightforward means of assessing RGS protein GAP activity. As discussed above, these assays are of limited use with $G\alpha$ subunits that bind GDP tightly and are thus difficult to label with radioactive GTP. Since single-turnover GAP assays are carried out in solution, these measurements also ignore any role played by the lipid bilayer in concentrating an RGS protein in the milieu of its site of action. This is an increasingly important concern given the growing evidence that membrane-binding domains and important sites of posttranslational modification exist in many RGS proteins.

Steady-State Measurements of GAP Activity

GTPase activity of $G\alpha$ subunits measured during multiple cycles of GTP hydrolysis depends on both GTP hydrolysis and guanine nucleotide exchange. Thus, steady-state GTPase activity can only be measured under assay conditions wherein GDP release and GTP binding are sufficiently rapid. In practice, it is the exchange rate that is usually rate-limiting, and increases in GTP catalysis by the presence of RGS proteins results in only small increases in measured GTPase activity (for example, Fig. 1C). Again, this also is particularly true for steady-state GTPase measurements with $G\alpha$ subunits such as $G\alpha_q$ that bind GDP tightly in the basal state. In contrast, if guanine nucleotide exchange is promoted by GPCR activation, GTP hydrolysis now becomes rate-limiting and remarkably large increases in GTPase activity are observed due to the catalytic activity of RGS proteins (Fig. 1C). Indeed, up to 2000-fold stimulation of steady-state GTPase activity of $G\alpha_q$ has been observed in a system in which guanine nucleotide exchange was promoted by carbachol-mediated

activation of the M1 muscarinic cholinergic receptor and GTP hydrolysis was accelerated by RGS4 [22].

Steady-state GTPase measurements have been effectively carried out with membrane preparations from various tissues [23]. Thus, activation of a native or heterologously expressed receptor with an appropriate agonist results in an increase in GTPase activity that may be enhanced by addition of a GAP for the involved G protein. Although such assays provide a readout for receptor activity, they are of limited value in assessing activities of RGS proteins per se. More elaborate assay systems have been developed that allow more quantitative analyses. For example, a useful test system is provided by heterologous expression of a GPCR in Sf9 insect cells (or a mammalian cell line) followed by membrane preparation and removal of endogenous G proteins by treatment with high concentrations of urea [24]. Purified G proteins then are reconstituted with the stripped membranes, and receptor-promoted G protein activation can be quantitated either by [^{35}S]GTP γS binding, which assesses guanine nucleotide exchange, or by steady-state GTPase assays. The activity of RGS proteins as GAPs for the reconstituted $G\alpha$ subunit also can be assessed. Similarly, purified GPCRs and G proteins can be reconstituted in phospholipid vesicles so that steady-state GTPase activity can be measured as a function of receptor agonist and RGS protein concentration [22,25,26].

Steady-state GTPase activity of a $G\alpha$ subunit under the concerted regulation by a GPCR and an RGS protein provides a complex signaling response that integrates many partial reactions. The work of Ross and coworkers in studying the GTPase activity of $G\alpha_q$ in proteolipomes reconstituted with the M1 muscarinic receptor, as a promoter of guanine nucleotide exchange, and PLC- β 1, as a GAP for $G\alpha_q$, provides an excellent example of the complexities that underlie such responses [27]. However, in its simplest application, such a system provides a reliable means to assess selectivity of RGS proteins (and other GAPs such as PLC- β isozymes) for $G\alpha$ subunits. Thus, the relative activities of RGS proteins can be compared in a more physiologically relevant milieu of a lipid bilayer than is the case in single-turnover GAP assays in solution.

Heterologous overexpression of RGS proteins utilizing mammalian expression vectors results in attenuation of GPCR-promoted activation of signaling pathways. Although RGS protein-promoted inhibition of signaling through heterotrimeric G proteins is predictably a consequence of enhancing the GTPase activity of cellular $G\alpha$ subunits, the physiological significance of such inhibition is often unclear. The $G\alpha$ subunit selectivity of most RGS proteins *in vivo* is unknown and, under conditions of RGS protein overexpression, promiscuity of GAP activity against many, if not all, $G\alpha$ subunits should be suspected. This may be a particular concern with overexpression of RGS protein constructs that include only the RGS-box. As discussed below, RGS proteins also exhibit many signaling modulatory activities, in addition to their $G\alpha$ -GAP activity, that may influence their cellular actions. Moreover, certain RGS proteins directly

inhibit heterotrimeric G-protein-mediated signal transduction by other means. For example, RGS2 acts both as a GAP for GTP-bound $G\alpha_q$ and as an “effector antagonist”—that is, by inhibiting GTP- $G\alpha_q$ promoted stimulation of PLC- β [28].

$G\alpha$ GAP and Other Signaling Regulatory Activities of RGS Family Members

The function of RGS proteins as multifaceted signaling regulators, rather than simply as $G\alpha$ GAPs, is reflected in the observed structures of these proteins—the RGS-box that embodies GAP activity is rarely found in the absence of other regulatory protein modules (Fig. 2). Even for those RGS proteins in subfamilies A (RZ) and B (R4) that lack defined modules beyond the RGS-box, recent work in the field has discerned roles for non-RGS-box components in their subcellular localization and/or receptor-selective GAP activity, as outlined below.

A- or RZ-Subfamily (RGS17, RGS19, RGS20)

The founding member of the A- or RZ-subfamily, GAIP (G-alpha interacting protein, now known as RGS19), was the first mammalian RGS protein identified via the yeast

two-hybrid system, with $G\alpha_i3$ serving as the “bait” [2]. Additional family members, RGSZ1 (RGS20) and RGSZ2 (RGS17), were also isolated in yeast two-hybrid screens with $G\alpha_z$ and $G\alpha_o$ baits, respectively [29,30]; in addition, RGSZ1 was independently identified by purification and protein sequencing of a bovine brain $G\alpha_z$ -specific GAP activity [31]. It remains unclear whether the RGS-boxes of these RGS proteins exhibit strict selectivity toward $G\alpha_z$ or are indeed active *in vivo* as GAPs for other $G\alpha$ subunits. PKC-mediated phosphorylation of $G\alpha_z$ has been reported to block RGS-box interaction [29,31].

All three subfamily members share a cysteine-rich cluster or “cysteine string” that is N-terminal of the RGS-box (Fig. 2). This polypeptide is believed to be heavily palmitoylated, leading to tight membrane association [32]. Other RGS proteins outside the RZ-family, such as RGS4, RGS7, RGS10, and RGS16, are thought to be targeted to the membrane by palmitoylation of N-terminal cysteine residues, although they lack a formal cysteine string [33–35].

B- or R4-Subfamily (RGS1, RGS2, RGS3, RGS4, RGS5, RGS8, RGS13, RGS16, RGS18)

The largest group of RGS proteins, the B- or R4-subfamily, comprise some of the smallest proteins that possess

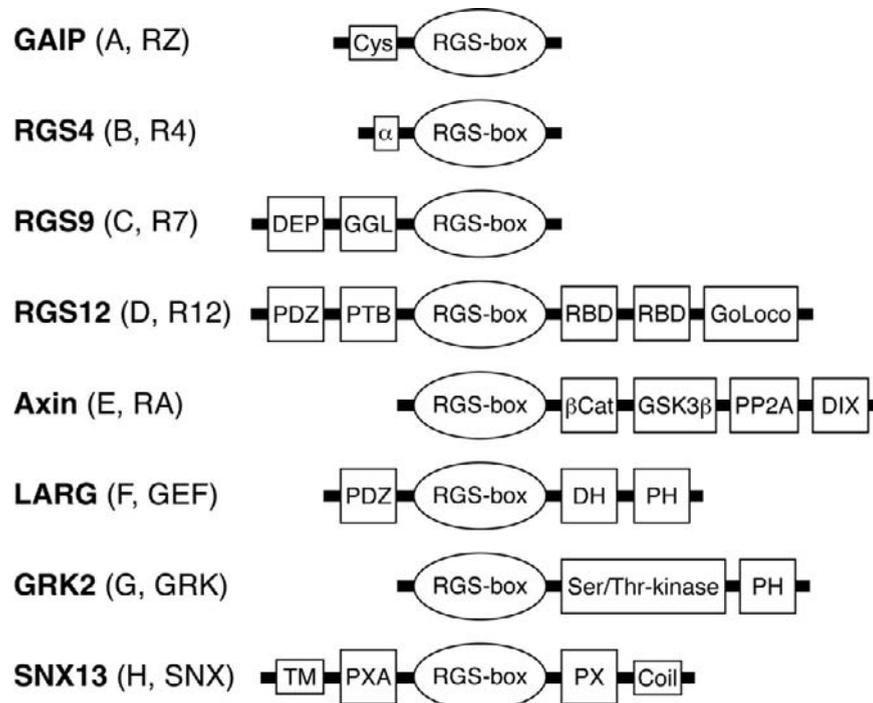

Figure 2 Protein domain architecture of representative members of the RGS protein subfamilies. Alternate nomenclatures for RGS protein subfamilies, as proposed independently by Zheng and Wilkie and coworkers [90,91], are denoted in brackets. Cys, cysteine-string motif; α , amphipathic alpha-helical region; DEP, dishevelled/Egl-10/pleckstrin domain; GGL, G-protein gamma subunit-like domain; PDZ, PSD-95/Dlg/ZO-1 domain; PTB, phosphotyrosine-binding domain; RBD, Ras-binding domain; GoLoco, $G\alpha_i/o$ -Loco interaction domain; β Cat, β -catenin binding region; GSK3 β , glycogen synthase kinase-3 β binding region; PP2A, phosphatase PP2A binding region; DIX, domain of unknown function shared between Dishevelled and Axin proteins; DH, Dbl-homology domain; PH, pleckstrin-homology domain; Ser/Thr-kinase, protein kinase catalytic domain specific for serine and threonine residues; TM, putative transmembrane domain; PXA, “PX-associated” domain of unknown function; PX, Phox-homology domain; Coil, putative coiled-coil region.

RGS-boxes, with little in the way of non-RGS-box sequence.¹ Nevertheless, specific members of this subfamily exert receptor-selective inhibitory activity. Rat vascular smooth muscle cells, for example, express at least three R4-subfamily members capable of G α q-directed GAP activity: RGS2, RGS3, and RGS5. However, ribozyme-mediated “knockdown” of the expression of each of these RGS proteins has a differential effect on cellular GPCR signaling coupled to G α q activation. Neubig and colleagues [36] have observed that RGS3-ribozyme treatment selectively potentiates carbachol signaling via the M3 muscarinic receptor, whereas RGS5-ribozyme treatment only potentiates angiotensin II signaling via the AT1a receptor; RGS2 ribozyme treatment was without effect on either receptor signaling pathway.

Thus, determinants outside the RGS-box appear to play a role in targetting the G α -GAP activity of these RGS proteins to particular receptors. In another example, RGS1, RGS4, and RGS16 exhibit large differences in their relative capacities to inhibit muscarinic-, bombesin-, or cholecystokinin-receptor-promoted Ca²⁺ signaling in permeabilized pancreatic acinar cells [37]. Since Ca²⁺ responses to all three GPCRs occur through Gq heterotrimers and all three RGS proteins exhibit similar activities *in vitro* as GAPs against G α q, it was concluded that receptor-selective action of these RGS proteins contributes to their differential inhibitory activity *in vivo* [37]. Mutational analyses confirmed that selectivity did not involve the RGS-box per se, but rather, was contributed by sequences in a 33 amino-acid span of the RGS4 N-terminus [38]. This work has been extended by Wilkie, Muallem, and colleagues to propose a mechanism whereby RGS proteins play a central role in the Ca²⁺ oscillations that often accompany GPCR-promoted activation of phospholipase C [39]. Activation of Gq heterotrimers results in formation of GTP-G α q, activation of phospholipase C- β , formation of Ins(1,4,5)P₃, and mobilization of intracellular Ca²⁺. G β γ also is released upon activation of Gq heterotrimers, which results in activation of phosphatidylinositol 3-kinase and formation of phosphatidylinositol-3,4,5-trisphosphate (PIP₃). PIP₃ binds to and inhibits the GAP activity of RGS4 [40]. Since Ca²⁺/calmodulin reverses this PIP₃-mediated inhibition, Wilkie and coworkers have proposed that competition between PIP₃ and Ca²⁺/calmodulin for inhibition and disinhibition of RGS4 may provide a feedback regulation that accounts for Ca²⁺ oscillations occurring in the constant presence of GPCR-activating agonists [39]. Kurachi and coworkers [41] recently proposed a similar role for PIP₃, Ca²⁺/calmodulin, and RGS4 in the voltage-dependent regulation of the activation state of cardiac G_i heterotrimers, which in turn regulates potassium channel activity in rat heart.

¹RGS3, while clearly a member of the R4-subfamily by virtue of its RGS-box sequence, is an outlier with respect to the overall length of its polypeptide sequence. RGS3 isoforms with considerable N-terminal extensions are known to exist; one extended RGS3 isoform contains an N-terminal PDZ domain that binds the ephrin-B cytoplasmic tail and mediates “reverse signaling” through these transmembrane-tethered ligands of Eph receptors (Schmucker, D., and Zipursky, S.L. (2001). Signaling downstream of Eph receptors and ephrin ligands. *Cell* **105**, 701–704.)

C- or R7-Subfamily (RGS6, RGS7, RGS9, RGS11)

The central structural features of the C- or R7-subfamily of RGS proteins are DEP and GGL domains N-terminal to the RGS-box (Fig. 2). The DEP domain [42] is a conserved ~80 amino-acid sequence found in Dishevelled (an intracellular component of Wnt/Frizzled signaling), EGL-10 (the first RGS protein discovered in *Caenorhabditis elegans* [3]), and Pleckstrin (a major PKC substrate in platelets). DEP domains are also found in an N-terminal tandem repeat within Sst2, the archetypal RGS protein of the yeast *Saccharomyces cerevisiae* [43]. The role of the DEP domain within RGS proteins is assumed to be membrane localization [3,44], but the intracellular target(s) of the DEP domain remain undefined. A recent report by Dohlgan and colleagues suggests that the N-terminal DEP domains of Sst2 modulate the yeast stress response pathway [45].

The discovery of the GGL or “G-protein gamma subunit-like” domain, present within all members of the R7-subfamily [21,46–48], has led to a radical departure from previous assumptions regarding the coupling of heptahelical receptors to heterotrimeric G-protein complexes [49]. In the standard model of heterotrimer assembly, conventional G γ subunits exist as short, isoprenylated, alpha-helical polypeptides that form obligate heterodimers with the conventional G β subunits G β 1 through G β 4 [50]. In contrast, the GGL domains of R7-RGS proteins serve as obligate binding partners for the more distantly-related G β subunit, G β 5 [21,46–48], thus supplanting the requirement for a conventional G γ subunit [49]. This novel GGL/G β 5 association implies a role for R7-RGS proteins in signaling functions akin to those well-characterized for conventional G β γ subunits—namely, functional coupling of G α subunits to GPCRs and modulation of downstream effectors [51]. With respect to the latter activity, screens of conventional G β γ effects (for example, modulation of phospholipase C- β and adenylyl cyclase activity) using recombinant G β 5/R7-RGS protein dimers have, to date, failed to identify any clear-cut effector activity by GGL/G β 5 dimers [21,52]. However, a role for GGL/G β 5 dimers in facilitating receptor/G α coupling is suggested by recent findings that the G β 5/RGS9 heterodimer can support agonist-stimulated guanine nucleotide exchange on G α by recombinant M2-muscarinic acetylcholine receptors (M2-mAChR) in proteoliposome reconstitution assays (Harden, T.K. *et al.*, unpublished observations). Such receptor-coupling activity could help to explain the accelerated, rather than attenuated, kinetics of GIRK channel activation by M2-mAChRs observed upon co-expression of G β 5 with RGS7 or RGS9 in a *Xenopus* oocyte reconstitution system [53].

The best-characterized R7-RGS protein is RGS9-1, the retinal-specific isoform of RGS9 that represents the long-sought GTPase-activating protein for G α t within the phototransduction cascade [54]. Inactivation of the mouse *Rgs9* gene leads to a greatly slowed inactivation of photon-induced signaling in both rod and cone photoreceptors [55,56]. RGS6, RGS7, and RGS11 all have been shown *in vitro* to accelerate GTP hydrolysis by G α o subunits [21,52,57],

but the physiological roles of these RGS/Gβ5 dimers remain to be elucidated.

D- or R12-Subfamily (RGS10, RGS12, RGS14)

All three of the D- or R12-subfamily RGS proteins, RGS10, RGS12, and RGS14, act as GAPs for Gαi-family Gα subunits *in vitro* [8, 58–60]. PKA-mediated phosphorylation of RGS10 at serine-168 attenuates its cellular function at the plasma membrane, not by reducing its intrinsic GAP activity, but by inducing its sequestration in the nucleus [61]. RGS10 belongs to the R12-subfamily given its RGS-box sequence similarity, but as a “small” RGS protein RGS10 is structurally similar to R4-subfamily members that lack discrete accessory modules.

In contrast, RGS12 and RGS14 share a multidomain organization C-terminal to the RGS-box that consists of tandem Ras-binding domains (RBDs) [62] and a GoLoco motif [63] (Fig. 2). Traver and colleagues [59] have identified the Ras-superfamily GTPases Rap1 and Rap2 as binding partners for the RBD region of RGS14; this interaction is dependent on the GTPases being in their GTP-bound or “activated” state, suggestive of a potential role for RGS14 as an effector for activated Rap proteins. The GoLoco motifs of RGS12 and RGS14 interact selectively with GDP-bound Gαi-family Gα subunits and prevent guanine nucleotide dissociation [60,64]. The X-ray crystal structure of the RGS14 GoLoco-motif region bound to Gαi1/GDP [65] indicates clear roles for both the Gα all-helical domain and polypeptide sequence C-terminal to the GoLoco motif in engendering binding specificity; guanine nucleotide dissociation inhibitor (GDI) activity is thought to result, in part, from direct contacts between a highly conserved arginine in the GoLoco motif and the phosphate groups of the bound GDP.

Unlike RGS14, RGS12 isoforms can also contain an N-terminal domain cassette consisting of a PDZ (PSD-95/Dlg/ZO-1) domain and a PTB (phosphotyrosine-binding) domain. The PDZ domain has a “group I” binding specificity (that is, C-terminal Ala/Ser-Thr-Xaa-Leu/Val motifs) and has been shown *in vitro* to interact with GPCR C-termini, including those of the interleukin-8 receptor CXCR2 [58] and the corticotrophin-releasing factor receptor CRF-R1 (D. P. Siderovski, *et al.*, unpublished observations). In chick dorsal root ganglia neurons, RGS12 controls desensitization of GABA_B-receptor coupling to calcium channel inhibition by virtue of its agonist-dependent recruitment to the phosphorylated N-type calcium channel via its PTB domain [66]. With the ability to bind phosphotyrosine-containing proteins, Gα subunits, and Ras superfamily GTPases, RGS12 appears to represent a signaling nexus that facilitates convergence and cross-regulation of receptor tyrosine-kinase, heterotrimeric G-protein, and Ras-superfamily GTPase signaling. Some as-yet undefined aspect of this cross-regulatory function must underlie the ability of RGS12 and RGS14 to inhibit G12/13-heterotrimer signaling; overexpression of either RGS12 or RGS14 is reported to block G12/13-dependent transcriptional readouts [67,68], yet neither

RGS protein acts as a GAP for Gα12/13 subunits in solution-based assays [58,68].

E- or RA-Subfamily (Axin, Axil)

Axin (“axis inhibition”) and Axil (“axin-like”) proteins, negative regulators of Wnt signaling through Frizzled receptors, constitute the E- or RA-subfamily of RGS proteins. Axin and Axil are scaffold proteins that coordinately bind β-catenin, glycogen synthase kinase-3β (GSK3β), and APC (the adenomatous polyposis coli tumor-suppressor protein), facilitating the effects of GSK3β and APC on β-catenin destruction, which is antagonistic to Wnt-dependent transcriptional upregulation [69]. The RGS-boxes of Axin and Axil have, as yet, not been found to associate with Gα subunits; rather, the RGS-box represents the binding site for APC [70,71]. The crystal structure of Axin in complex with APC indicates that this interaction occurs on the opposing face of the RGS-box, leaving the Gα-interaction face unhindered [14]. Thus, the possibility exists that a Gα partner may yet be discovered for the RGS-boxes of Axin and Axil. Additional circumstantial evidence for the involvement of Gα subunits in the Wnt/Frizzled signaling pathway includes several reports suggesting that Frizzled receptors act as canonical GPCRs (for example, [72,73]) and the recent finding that activated Gα12 and Gα13 subunits can release β-catenin from cadherins [74].

F- or GEF-Subfamily (p115-RhoGEF, PDZ-RhoGEF, LARG)

The three members of the F- or GEF-subfamily (p115-RhoGEF/Lsc, PDZ-RhoGEF/GTRAP48, and leukemia-associated RhoGEF [LARG]) represent the clearest examples of RGS proteins as *positive* regulators of GPCR signaling—that is, as effectors coupling the activation of Gαq, Gα12, and Gα13 subunits to the activation of the small GTPase RhoA. All three RhoGEF proteins share a common structure of an N-terminal RGS-box and C-terminal Dbl-homology (DH) and pleckstrin-homology (PH) domains that collectively encode RhoA-specific guanine nucleotide exchange factor (GEF) activity [75]; the latter two proteins (PDZ-RhoGEF and LARG) also possess an N-terminal PDZ domain (Fig. 2). Kozasa and colleagues first demonstrated that the p115-RhoGEF RGS-box can accelerate GTP hydrolysis by Gα12 and Gα13 subunits [76]. Moreover, binding of activated Gα13, but not Gα12, to the RGS-box was shown to derepress the RhoGEF activity of the C-terminal DH/PH tandem [77]. LARG acts as a Gα-responsive RhoGEF not only for Gα12 and Gα13 subunits [78], but also for Gαq [18]. In addition, LARG associates with the C-terminal tail of the insulin-like growth factor (IGF)-1 receptor tyrosine kinase via its PDZ domain [79] and its RhoGEF activity can be modulated by tyrosine phosphorylation [80]. These recent findings suggest that LARG, and potentially other members of this subfamily, can participate in cross-talk between tyrosine kinase, GPCR, and monomeric GTPase signaling pathways.

G- or GRK-Subfamily (GRK1, GRK2, GRK3, GRK4, GRK5, GRK6, GRK7)

Among the original set of papers [2–5] heralding the discovery of the RGS superfamily, one report identified the conserved RGS-box sequence within a known family of GPCR signaling regulators, the G-protein-coupled receptor kinases or GRKs [4]. These serine/threonine kinases phosphorylate activated GPCRs, thereby allowing the binding of arrestin proteins, functional uncoupling from G proteins, and endocytosis of the phosphorylated receptor [81,82]. Three groups [83–85] have since shown that, at least for GRK2, the N-terminal RGS-box can act to inhibit G α q signaling; this phosphorylation-independent inhibitory activity of GRK2 is thought not to result from RGS-mediated GAP activity (which is barely detectable *in vitro* [83]), but rather by sequestration of activated G α q by the N-terminal RGS-box.

H- or SNX-Subfamily (SNX13, SNX14, SNX25)

The RGS-box sequence is also present in at least three of the sorting nexins or SNXs, a growing family of proteins involved in vesicular trafficking between cellular compartments [86]. Sorting nexins invariably contain Phox-homology (PX) domains that generally bind phosphatidylinositol-3-phosphate (PtdIns(3)P); the SNX-subfamily of RGS proteins also contain a poorly-defined PX-associated (PXA) domain N-terminal to the RGS-box and C-terminal to a putative transmembrane region (Fig. 2). The RGS-box of SNX13 was purported to have G α s-directed GAP activity and inhibit G α s-dependent signaling pathways upon overexpression [87], but the G α specificities of the other two known subfamily members (SNX14 [88] and SNX25) have not been characterized to-date. SNX1, the founding member of the sorting nexins, is a binding partner of the epidermal growth factor receptor (EGF-R) and, upon overexpression, enhances EGF-R degradation [89]. Conversely, SNX13 overexpression delays EGF-R degradation [87]. A direct role for SNX13 or other SNX-subfamily RGS proteins in the trafficking of GPCRs and/or heterotrimeric G-protein subunits remains to be determined.

Acknowledgments

The authors thank M. Hains, R. Kimple, and F. Willard for critical appraisal of this manuscript. Work in the authors' laboratories is supported in part by P01 grant GM065533 from the National Institute of General Medical Sciences (NIH).

Mechanism of G $\beta\gamma$ Effector Interaction

Tohru Kozasa

*Department of Pharmacology,
University of Illinois at Chicago, Chicago, Illinois*

Introduction

The G $\beta\gamma$ subunit was initially recognized as an inactive subunit in G-protein-mediated signal transduction. Its main function was considered to form a high-affinity complex with GDP-bound G α to generate an inactive heterotrimer. Only GTP-bound G α subunits were thought to be responsible for the regulation of effectors. In 1987, Logothetis *et al.* presented the first clear evidence that $\beta\gamma$ subunit free from G α can activate K⁺ channels in cardiac atrial cells [1]. Activated G α subunit did not have an effect on K⁺ channel activity. The following year, Whiteway *et al.* showed that $\beta\gamma$, but not G α , is the responsible subunit to mediate mating-factor response in yeast [2]. Since then, various effectors or regulatory proteins have been identified as direct targets for the $\beta\gamma$ subunit. It is now clear that receptor activation of G proteins generate two active signal mediators, GTP-bound G α and free $\beta\gamma$ subunit (reviewed in [3–5]).

Structure of $\beta\gamma$ Subunits

cDNAs for five β subunits and 12 γ subunits have been isolated so far. Among five β subunits, β 1, β 2, β 3, and β 4 are highly homologous (about 80 percent identical to each other). β 5 is distantly related (about 50 percent identical with other β s) and is expressed only in brain [6]. γ subunits are divergent in amino acid sequences and tissue distributions. The carboxyl terminus of the γ subunit contains a CAAX motif that directs prenylation of the molecule. Most of γ subunits are geranyl-geranylated except for γ 1 and γ 11, which are farnesylated. β 1 to β 4 subunits form a tightly complex with γ s. They can only be separated under denaturing conditions.

The interaction of β 5 with γ s is weak and sensitive to detergent condition [7].

The G β subunit is made up of two structurally distinct regions, an amino terminal α -helical segment, followed by seven WD-repeat sequences. The role of the WD repeat (about 40 amino acids in length) in cell signaling is not clearly understood, but many WD repeat-containing proteins participate in large macromolecular assemblies [8]. The crystal structures of $\beta\gamma$ subunit, free or complexed with GDP-bound G α , were solved recently [9–11]. The core WD repeat provides a rigid scaffold of a seven-bladed β -propeller structure. Each blade is made up of four anti-parallel β strands. The amino terminal region of γ forms an α -helical coiled-coil structure with the amino terminus of β . The rest of γ subunit extends along the wider bottom surface of the propeller through multiple interaction sites. G α is mainly interacting with the opposite narrow surface of the propeller through its switch regions. The amino terminus of G α is interacting with the outer strand of blade 2. It is important to note that the $\beta\gamma$ subunit does not change its conformation when it dissociates from α subunit.

Effectors Interacting with $\beta\gamma$ Subunits

GIRK Channel

G-protein-gated inwardly rectifying potassium channels (GIRKs) play an important role in regulating membrane excitability through G-protein-coupled receptors, especially in heart and brain [12, 13]. To date five mammalian cDNAs for GIRKs (GIRK1–5) have been isolated. GIRK functions as the heterotetramer, such as GIRK1 and 2 in heart and brain or GIRK1 and 4 in brain [12]. $\beta\gamma$ subunits activate

hetero- or homotetramer of GIRKs. It was shown that $\beta\gamma$ subunits bind directly to the N- and C-terminal intracellular domains of GIRKs [14–16]. EC_{50} of $\beta 1\gamma 2$ for GIRK activation is about 30 nM [17,18]. $\beta\gamma$ subunits with $\beta 1$ – $\beta 4$ showed similar potency to activate GIRKs. It was shown recently that $\beta 5\gamma 2$ inhibited basal or agonist-induced GIRK1 and 4 activity by competing with $\beta 1\gamma 2$ [19]. The interaction of $G\alpha_o$ with N-terminal region of GIRK was reported, but the regulatory function of this interaction is unknown [15].

PLC β

Numerous G-protein-coupled receptors stimulate phosphoinositide phospholipase C β activity to induce intracellular Ca^{2+} release [20]. Both $G\alpha$ subunits of Gq subfamily and $\beta\gamma$ subunits can stimulate PLC β activity *in vitro* and *in vivo*. Four isozymes of PLC β are isolated, and all of them are activated by $G\alpha_q$. The stimulation by $\beta\gamma$ subunit was demonstrated for PLC $\beta 1$, $\beta 2$, and $\beta 3$ (with the potency of $\beta 3 > \beta 2 > \beta 1$) but not for PLC $\beta 4$ [21–23]. $G\alpha_q$ and $\beta\gamma$ directly bind to PLC β with separate binding regions. In PLC $\beta 2$, the binding site for $\beta\gamma$ has been mapped within the first half of the Y-domain of the catalytic region [24]. The stimulation of PLC activity by $G\alpha_q$ and $\beta\gamma$ is additive for PLC $\beta 3$ but not for PLC $\beta 2$ [23,25]. The potency of $\beta\gamma$ subunit to activate these PLC β s is much lower than $G\alpha_q$. EC_{50} of $\beta\gamma$ for PLC β activation is 30–300 nM; in contrast, EC_{50} of $G\alpha_q$ is in the sub to low nanomolar range [23,25]. $\beta\gamma$ -mediated PLC β activation mainly contributes to pertussis-toxin sensitive PLC activation that is mediated through G_i/o . Recently, *in vitro* reconstitution experiments showed that $\beta 5\gamma 2$ could stimulate PLC $\beta 1$ and $\beta 2$ but not PLC $\beta 3$ [26].

Adenylyl Cyclase

Isoforms of adenylyl cyclase (at least eight) are activated by $G\alpha_s$ and are differentially regulated by $\beta\gamma$ subunits, Ca^{2+} , and phosphorylation [27]. AC-I is inhibited by $\beta\gamma$ [28]. This inhibition by $\beta\gamma$ is independent of $G\alpha_s$ stimulation. However, $\beta\gamma$ activates AC-II and AC-IV synergistically with $G\alpha_s$ [28,29]. This activation of AC-II or AC-IV by $\beta\gamma$ requires the activation by $G\alpha_s$. Without $G\alpha_s$ stimulation, $\beta\gamma$ has no effect on these adenylyl cyclases. Thus, in cells that are expressing AC-II or AC-IV, receptors that normally do not regulate cAMP production, such as receptors that couple to G_i or G_q , can further potentiate cAMP production. The site of $\beta\gamma$ binding on adenylyl cyclase is not precisely known. For AC-I, the $\beta\gamma$ binding region is separated from the $G\alpha_s$ binding region. The amino terminal part of the first large cytosolic domain of AC-I appears to include a $\beta\gamma$ binding site [30]. For AC-II, a 14-amino acid peptide containing a QXXER motif derived from the second cytoplasmic domain blocks interaction with $\beta\gamma$ [31]. It is interesting to note that the same peptide can block interaction of $\beta\gamma$ with several other effectors, including PLC β and GIRK channels. In reconstitution experiments, $\beta 5\gamma 2$ was markedly less effective than $\beta 1\gamma 2$ to activate AC-II (EC_{50} of ~ 700 nM versus 25 nM) [7].

N- and P/Q-type Calcium Channels

It has been shown that several neurotransmitters inhibit N-type and P/Q type calcium channels through pertussis-toxin sensitive G proteins. This effect is mediated by the direct binding of $\beta\gamma$ subunit to calcium channels [32,33]. The $\beta\gamma$ binding site was mapped at the intracellular loop and the C terminus of $\alpha 1$ subunit [34,35]. QXXER motif in loop I was shown to be important for the modulation by $\beta\gamma$ subunit [35].

PI3K

Phosphoinositide 3-kinase (PI3K) catalyzes phosphorylation of phosphoinositide at the 3 position and plays a key role in a variety of cellular functions. It is stimulated by both G-protein-coupled receptors and receptor tyrosine kinases. PI3K γ is specifically activated through the direct interaction with $\beta\gamma$ subunit [36,37]. This activation involves the interaction of $\beta\gamma$ subunit with both p110 catalytic subunit and p101 regulatory subunit (EC_{50} about 20 nM). The presence of p101 enhances the sensitivity of PI3K γ to $\beta\gamma$ subunit [38]. $\beta 5\gamma 2$ does not activate PI3K γ but can bind to the molecule [26]. PI3K β is synergistically activated by $\beta\gamma$ subunit and phosphotyrosine-containing peptide [39]. PI3K α and δ are activated by tyrosine kinase pathway but not by G-protein-mediated pathway.

MAP Kinase Pathway

It has been shown that the yeast homologue of $\beta\gamma$ subunit (STE4 and STE18) is the active mediator for the pheromone-induced MAP kinase pathway to control cell cycle [2]. STE4 interacts with serine-threonine kinase STE20/PAK and scaffolding protein STE5 [40,41]. These interactions are critical to mediate pheromone-mediated MAP kinase activation. G-protein-linked pathways can also initiate MAP kinase pathways in mammalian cells [42]. Some of these pathways are pertussis toxin-sensitive and some are pertussis toxin-insensitive. $\beta\gamma$ subunit released from G_i or G_o appears to initiate Ras-dependent MAP kinase activation in pertussis toxin-sensitive pathways. It was shown that $\beta\gamma$ could activate several MAP kinase pathways, including the JNK/SAPK pathway and p38MAPK pathway [43,44]. Although the involvement of PI3K or nonreceptor tyrosine kinase has been suggested as a downstream component of $\beta\gamma$ to MAPK activation, the precise biochemical mechanism to link $\beta\gamma$ and MAP kinase activation has not been clearly understood. The complex of $\beta 5\gamma 2$ cannot activate either the MAPK or JNK pathway [45].

Other Effectors and Interacting Proteins

BTK FAMILY TYROSINE KINASES

Btk family tyrosine kinases are nonreceptor tyrosine kinases with a unique N-terminal extension that contain

PH and TH (Tec homology) domains. The regulation of these kinases in cell has not yet been well characterized. $\beta\gamma$ subunit binds to the PH-TH domain and catalytic domains of Btk to stimulate the catalytic activity of the kinase [46]. Tsk, another member of this family, was also activated by co-transfection with $\beta\gamma$ subunits [47].

PLC ϵ

PLC ϵ is a recently identified PI-PLC that is unique in that it contains a CDC25 domain and Ras-associating domains [48]. Involvement of G α 12 for the regulation of PLC ϵ activity has been demonstrated. In addition, co-expression of β 1 γ 2 but not β 5 γ 2 with PLC ϵ potently stimulated PLC activity [49]. Although an *in vitro* reconstitution experiment was unsuccessful, the $\beta\gamma$ stimulatory effect on PLC ϵ seems to be independent of Ras activation and PI3K activation, suggesting the direct stimulation by $\beta\gamma$.

GRK

$\beta\gamma$ binds directly to the C-terminal region of the pleckstrin homology domain of β adrenergic receptor kinases (GRK2 and GRK3) and enhances their kinase activity [50,51]. It is not clearly understood whether $\beta\gamma$ stimulates catalytic activity of GRKs or $\beta\gamma$ facilitates membrane translocation of GRKs for activation. The C-terminal region of GRK2 can sequester $\beta\gamma$ in cells without interacting with other α subunits. Thus, it is a useful tool to differentiate between $\beta\gamma$ -mediated effects and G α -mediated effects.

PHOSDUCIN

Phosducin is a phosphoprotein mainly expressed in retina or pineal gland. Phosducin regulates Gt-mediated phototransduction through high-affinity binding to $\beta\gamma$ subunit and prevents the reassociation of $\beta\gamma$ with G α t [52]. Phosducin-like molecule has also been found in brain [53]. The crystal structure of phosducin and $\beta\gamma$ complex revealed that phosducin interacts with the G α binding surface of the $\beta\gamma$ propeller and the outer surfaces of blades 1 and 7 [54]. The phosphorylation of phosducin inhibits its affinity to $\beta\gamma$. This phosphorylation site is not on the interacting surface on this structure, suggesting allosteric regulation of the interaction by phosphorylation.

In addition to these molecules, $\beta\gamma$ subunits can also interact with other regulatory proteins such as Dbl, Raf-1 kinase, RasGEF, Rho family GTPases, or ARF [55–59]. The functional significance of these interactions is not clearly understood yet.

Specificity of the Interaction between $\beta\gamma$ Subunit and Effectors

With multiple β and γ subunit cDNAs, various combinations of $\beta\gamma$ subunit were tested to examine the specificity of their interaction with effectors. Most of them could form functional dimers. However, the degree of specificity in reconstitution assays was minimal in general. Most of

$\beta\gamma$ pairs showed almost the same potency and efficacy for multiple effectors. β 1 γ 1, $\beta\gamma$ for retinal transducin, showed lower potency for several effectors compared with other combination of $\beta\gamma$ s, while showing better interaction with rhodopsin and phosducin. It was also shown recently that β 5, which is the most distantly related member of β subunits, differentially couples to several effectors; β 5 γ 2 activates PLC β 1 and β 2 but not β 3. β 5 γ 2 does not activate GIRK, PI3K γ , or MAP kinase pathways, although it can interact with GIRK or PI3K γ [26,45]. In addition, several groups suggested that the physiological binding partner of β 5 is not γ subunit but RGS proteins with a G-protein γ -subunit-like (GGL) domain (RGS6, 7, 9, and 11) [60,61]. Although the homologues of β 5-RGS have a regulatory function in the egg-laying signaling pathway in *C. elegans*, the biochemical function of the β 5-RGS complex in mammalian cells has not been understood yet [62].

$\beta\gamma$ -effector interaction requires C-terminus prenylation of the γ subunit. Although lipid modification does not affect $\beta\gamma$ subunit formation, it is essential for the interactions of $\beta\gamma$ s with effectors. It is likely that the difference of the lipid modification on γ 1 (farnesyl) versus other γ s (geranyl-geranyl) contributes to the difference of effector interaction mentioned above. Another common feature of $\beta\gamma$ -effector interaction is that $\beta\gamma$ has to dissociate from the heterotrimer in order to interact with effectors. This indicates that effectors share the top surface of $\beta\gamma$ with the G α subunit. This was confirmed by mutagenesis studies [63,64]. However, it also became evident that the different effectors overlap with the G α surface in different ways.

The effector-interacting region of the β subunit is not restricted to the G α interacting surface. The N-terminal α helical region of STE4 is involved in the interaction with STE20 to mediate phomone signaling [41]. It was also shown that the N-terminal 100 amino acid of β (including an α helical region and blade 1 and 2) interacts with GIRK1, AC-II, and PLC β 2 [65]. The importance of the C-terminal region of β for activation of PLC, AC-II, or MAP kinase pathways was also demonstrated [45,66,67]. The study with chimeras between β 1 and β 5 revealed that amino acids 52 to 143 of β 1, which spans blade 2 and 3, is critical for the activation of GIRK [68]. The outer surface of the β -propeller also contributes to the effector interaction. The crystal structure revealed that the C-terminal part of phosducin interacts with the outer surface of blades 1 and 7 [54]. And a mutational study demonstrated that outer strands of blade 2 and 3 are differentially involved in GIRK or PLC β 2 activation [18,69].

It is now evident that $\beta\gamma$ subunits of G protein play a variety of functions in cell signaling. In order to understand the physiological role of the $\beta\gamma$ subunit, including subunit specificity, further investigation will be required using methods such as antisense RNA, RNAi, or gene knockout mice. Also, the determination of the crystal structure of the complex of $\beta\gamma$ with different effectors will be critically important in understanding the effector activation mechanism by G $\beta\gamma$ subunits.

$\beta\gamma$ Signaling in Chemotaxis

Carol L. Manahan and Peter N. Devreotes

*Department of Cell Biology,
Johns Hopkins School of Medicine,
Baltimore, Maryland*

Introduction

Chemotaxis, the ability of a cell to sense and move up a chemical gradient, is important in various physiological processes and is involved in many disease states. Signal transduction during chemotaxis occurs through seven-transmembrane receptors that are coupled to heterotrimeric G proteins. The $\beta\gamma$ subunits transmit the signal downstream, and although the direct effectors are unclear, increases in phosphoinositide 3,4,5-trisphosphate and phosphatidylinositol 3,4-bisphosphate occur at the leading edge of the migrating cell. The formation of these lipids results in the recruitment of a variety of signaling proteins. Recent work has implicated phosphatidylinositol 3-kinase and the lipid phosphatases, PTEN and SHIP in chemotaxis. This review discusses the role of G proteins in chemotaxis of *Dictyostelium discoideum* and neutrophils, with an emphasis on the possible role of proteins involved in lipid production and degradation.

Directed movement of cells toward soluble attractants (chemotaxis) is critical in immunity, wound healing, embryogenesis, and neuron guidance. Also, abnormalities in chemotaxis have been implicated in disease states such as tumor metastasis, atherosclerosis, arthritis, asthma, and multiple sclerosis [1]. The cell biology of chemotaxis has primarily been studied in two cell types, the social amoeba *Dictyostelium discoideum* and mammalian leukocytes. Due to the genetic manipulations available, *D. discoideum* is an excellent model system in which to study chemotactic signaling. Many observations originally made in these simple eukaryotic cells have subsequently held true in mammalian cells such as neutrophils.

Chemotaxis in amoebae and leukocytes is mediated through a heterotrimeric G protein that couples to a seven-transmembrane receptor on the plasma membrane. $\beta\gamma$ dimers transduce the chemotactic signals downstream [2,3] to many known effectors ([reviewed in [4]). Recent work suggests that phosphatidylinositol-3-kinase (PI3K) is a critical effector involved in chemotaxis. $\beta\gamma$ -signaling results in the accumulation of the lipids phosphoinositide 3, 4, 5-trisphosphate [PtdIns(3,4,5)P₃] and phosphatidylinositol 3,4-bisphosphate [PtdIns(3,4)P₂] at the leading edge of the cell (see below). Other downstream events include increases in actin polymerization, changes in cell shape, Ca²⁺ mobilization, myosin phosphorylation, and activation of adenylyl and guanylyl cyclases (Table I).

Evidence That G Proteins Are Involved in Chemotaxis

G-protein subunits were first implicated in chemotaxis by the generation of mutants in *D. discoideum*. Amoebae have at least 11 G α subunits but only one β subunit and one γ subunit [5,6]. Mutation of the G α 2 or the G α 4 subunit [7–10] blocks chemotaxis to cAMP or folic acid, respectively. All chemotactic responses are defective in amoebae lacking the β subunit [11]. In mammalian systems, the scenario is more complicated, with many G protein subunits, receptors, and ligands involved (Table I). Early experiments showed that leukocyte chemotaxis was inhibited by pertussis toxin, indicating that many chemokine receptors couple to G α subunits from the G α i family. Studies using receptors that couple to G α i, G α q, or G α s transfected into HEK293 cells or a

Table I Proteins Involved in Chemotaxis of Amoebae and Neutrophils

	<i>D. discoideum</i>	Neutrophils
Ligands	cAMP [28] folic acid [29] other nutrients	<i>Classes*</i> chemokines [30] complement factors [31] N-formylated peptides [31] leukotrienes [32] lysophosphatidic acid [33] platelet-activating factor [34] prostaglandins [35]
Receptors (R)	cAR1 [36] cAR3 [37]	<i>Classes*</i> Chemokine receptors [39]
All are coupled to heterotrimeric G proteins	folic acid/pterin receptor [38]	Complement receptors N-formylated peptide R BLTR [40] Endothelial Differentiation Genes (Edg) [33] Platelet-Activating Factor R [40] Prostanoid R [35]
G proteins	G α 2, $\beta\gamma$ (cAMP, [6,7,11]) G α 4, $\beta\gamma$ (folic acid, [6,10,11])	G α i family, $\beta\gamma$ [2,3,12]
PI3Ks	PI3K1, PI3K2 [19,41,42]	PI3K γ [21,22,23]
Signaling proteins found at leading edge	CRAC [14] Akt/PKB [15] PhdA [19]	Akt/PKB [16] Rac1 [43,44] PAK1 [45]
Signaling proteins on lateral edges or back of cell	Myosin II [46] PAKa [47] PTEN [25]	Myosin II [48]
Cell responses	\uparrow PtdIns(3,4)P ₂ and PtdIns(3,4,5)P ₃ [14,42] \uparrow actin polymerization \uparrow Ca ⁺⁺ [49] Myosin phosphorylation [50,51] \uparrow cAMP [52] \uparrow cGMP [53]	\uparrow PtdIns(3,4)P ₂ and PtdIns(3,4,5)P ₃ [16] \uparrow actin polymerization \uparrow Ca ⁺⁺ Myosin phosphorylation \uparrow inositol phosphates [54] \uparrow cAMP [55]

*Due to space limitations the large number of ligands and receptors involved in neutrophil chemotaxis have been grouped into classes.

pre-B cell line have confirmed that G α i is involved in chemotaxis [2,3]. In these same studies, chemotaxis was blocked when the $\beta\gamma$ sequestering proteins (β ARK or G α t, transducin) were overexpressed, suggesting that the release of $\beta\gamma$ is necessary for chemotaxis [2,3]. By expressing a chimeric G α (which is activated by G α i-coupled receptors but cannot inhibit adenylyl cyclase), Neptune *et al.* definitively showed that release of $\beta\gamma$ subunits, not G α i activation, was important for mediating the chemotactic signal downstream [12]. G-protein signaling, specifically the release of $\beta\gamma$, is critical for chemotaxis in amoebae and neutrophils.

Recently, it has been demonstrated that the G-protein heterotrimer disassociates upon chemoattractant stimulation in living cells. Using amoebae expressing G α 2 fused to cyan (CFP) and β fused to yellow (YFP) fluorescent proteins, Janetopoulos *et al.* observed fluorescence resonance

energy transfer (FRET), which was lost when the cells were exposed to chemoattractant [13]. Upon removal of ligand, the heterotrimer quickly reassociated as indicated by the reappearance of the FRET signal. An important finding is that in the presence of continual stimulation, the FRET signal did not rebound, indicating that the heterotrimer remains disassociated in the presence of ligand and does not undergo desensitization [13]. Thus the key events that lead to desensitization are downstream or independent of G-protein activation.

PI3Ks—Role in Chemotaxis?

G-protein signaling activates the lipid kinase phosphatidylinositol-3-kinase (PI3K), which results in PtdIns(3,4,5)P₃

and PtdIns(3,4)P₂ being created at the leading edge. Studies on cytosolic regulator of adenylyl cyclase (CRAC), a pleckstrin-homology (PH) domain-containing protein in amoebae, provided the first clue to the involvement of phosphorylated lipids in the signaling pathway [14]. A class of PH-domains has been shown to associate with the lipids PtdIns(3,4)P₂ or PtdIns(3,4,5)P₃. CRAC (or just its PH domain) fused to green fluorescent protein (GFP) localized to the leading edge in chemotaxing amoebae [14], suggesting that these lipids are generated there. Subsequently, it has been shown that other PH-domain containing proteins, such as Akt/PKB, also localize to the leading edge in amoebae and neutrophils [15,16]. PI3K is undoubtedly involved in the formation of these lipids. However, studies using pharmacological inhibitors of PI3K, such as wortmannin and LY294002, have yielded conflicting results [17,18], with some studies showing effects on chemotaxis and others with no effect. *D. discoideum* have three genes encoding putative PI3Ks. Knockouts of these genes have been performed, and disruption of two of the PI3Ks result in impaired chemotaxis [19,20]. Disruption of all three PI3Ks in amoebae has not been completed. The conflicting genetic and pharmacological evidence indicates that the role of PI3K in chemotaxis is still unclear.

In mammalian systems, neutrophils from a PI3K γ null mouse line have been evaluated. These neutrophils did not create detectable PtdIns(3,4,5)P₃ when stimulated with specific chemoattractants, suggesting that PI3K γ is the sole PI3K that is coupled to chemoattractant receptors in these cells [21]. This phenotype could not be attributed to a global defect in G-protein signaling because other G-protein-mediated responses were functional. It is important that migration of the mutant neutrophils to chemokines *in vitro* (Boyden assay) and *in vivo* (infiltration assays) was reduced up to 50 percent [21–23], suggesting that PI3K γ activity is required for proper chemotaxis.

Lipid Phosphatases, PTEN and SHIP

Since PI3K is involved in chemotaxis, one would predict that lipid phosphatases also play an important role. Previous work has suggested that the lipid phosphatase PTEN plays a negative role in chemotaxis. PTEN is a phosphatidylinositol 3-phosphatase. Fibroblasts from *pten*^{-/-} mice exhibited faster motility and an increase in the number of pseudopods formed; however, directional sensing was not evaluated [24]. Recently, Iijima and Devreotes disrupted PTEN function in *D. discoideum* [25]. In the absence of chemoattractant, the mutant cells produced random pseudopods and some cells constitutively localized PH-GFP to the membrane [25]. This is consistent with PTEN playing a role in negatively regulating chemotaxis. However, the *pten*⁻ cells do not undergo constitutive development, indicating that loss of PTEN is not sufficient to result in chemotaxis. In the presence of chemoattractant, *pten*⁻ cells formed many pseudopods along the length of the cell, instead of only at the leading edge [25]. Therefore, the mutant cells took a slower, circuitous route up the gradient. Their hypothesis is that directional

sensing requires a regulated balance between the activities of PI3K and PTEN [25].

Another lipid phosphatase, SHIP, which hydrolyzes the 5'-phosphate from PtdIns(3,4,5)P₃ and inositol 1,3,4,5-tetrakisphosphate seems to be involved in negatively regulating chemotactic signaling. Various hematopoietic cells from SHIP-deficient mice exhibited enhanced chemotaxis toward SDF-1 and B-lymphocyte chemoattractant (BLC) [26], but not to another chemokine, CK β -II. SHIP's role in chemotaxis may be dependent upon the cell type or chemokine involved. The enhanced chemotaxis of cells toward SDF-1 and BLC is consistent with the hypothesis that SHIP negatively regulates chemotaxis by hydrolyzing the PtdIns(3,4,5)P₃ created by PI3K. Consistent with this, decreasing the level of this lipid in B cells inhibited PKB/Akt activation [27]. Both lipid phosphatases PTEN and SHIP appear to be involved in chemotaxis signaling pathways.

Cells can sense and move up chemoattractant gradients that vary by less than 2 percent across their length. Understanding how cells sense and respond to these shallow gradients is important to understanding the basic mechanism of chemotaxis. Chemotaxis is mediated by G-protein $\beta\gamma$ subunits and appears to be evolutionarily conserved from amoebae to mammalian neutrophils. Further study is necessary to determine the direct effector(s) of $\beta\gamma$ and establish whether the key to directional sensing is in the regulation of the PtdIns levels in the migrating cell.

Acknowledgments

The authors would like to thank Chris Janetopoulos for critically reading the manuscript. We apologize to the authors whose work we could not cite due to space limitations. This work was funded by NRSA fellowship GM65644 to C.L.M. and NIH grants GM28007 and GM34922 to P.N.D.

Reversible Palmitoylation in G-Protein Signaling

Philip Wedegaertner

*Department of Microbiology and Immunology, Kimmel Cancer Institute,
Thomas Jefferson University, Philadelphia, Pennsylvania*

Introduction

Numerous proteins involved in cellular signaling undergo reversible palmitoylation [1–3]. This review will focus on reversible palmitoylation of G-protein α subunits ($G\alpha$), briefly discuss some more general aspects of palmitoylation and depalmitoylation, and highlight recent evidence that many regulator of G protein signaling (RGS) proteins are palmitoylated.

Palmitoylation is a covalent lipid modification in which the saturated, 16-carbon fatty acid, palmitate, is linked through a thioester bond to a cysteine. Palmitoylation is often referred to as S-acylation or thioacylation to indicate that radiolabeled fatty acids of varying lengths can be incorporated into a protein. Very few studies have addressed the identity and stoichiometry of the endogenous fatty acid covalently attached to a particular cellular protein. In fact, it is mostly unknown if palmitoylated proteins exist as isoforms with different attached fatty acids, if specific cellular mechanisms exist to dictate a preference for palmitate, or if palmitate is primarily used merely because of its relatively high abundance in cells.

Much of the interest in palmitoylation stems from its dynamic nature and the resulting idea that this covalent modification is more than just a static membrane anchor. Numerous studies have demonstrated that palmitoylation is a reversible modification, i.e., attached palmitate often has a much shorter half-life than the protein it modifies. Such reversibility implies the potential for important regulatory roles for palmitoylation.

Sites of Palmitoylation in $G\alpha$ and RGS Proteins

Besides the modified cysteine(s) itself, no primary amino acid consensus sequence has been identified for palmitoylation.

The only consensus is that an additional hydrophobic modification or membrane-targeting motif is often a prerequisite for palmitoylation [1–4]. Table I lists identified sites of palmitoylation from representative $G\alpha$ and RGS proteins. Based on lipid modification, $G\alpha$ can be divided into two subfamilies (Table I)—ones that are palmitoylated only and ones that undergo both myristoylation and palmitoylation. Recently, it was demonstrated that the yeast *Saccharomyces cerevisiae* G-protein γ subunit is palmitoylated at a cysteine adjacent to the prenylated cysteine at the extreme C-terminus [5,6]. However, none of the 12 human $G\gamma$ subunits or the 2 $G\gamma$ of the model organism *Caenorhabditis elegans* contain a potential C-terminal palmitoylation site.

Palmitoylation has been identified in some members of the RGS family (Table I). Interestingly, palmitoylation of RGS proteins can occur at one or two cysteines within short N-terminal extensions [7,8], multiple cysteines in a cysteine string motif in the N-terminus [9], or at a cysteine within the RGS domain itself [10] (Table I). Additional palmitoylated proteins involved in G-protein signaling pathways include G-protein-coupled receptors (GPCR) [11], G-protein-coupled receptor kinases (GRK) [12], and small GTPases of the ras and rho superfamily [2,3].

Activation-Regulated Palmitoylation of $G\alpha$

If palmitoylation functions as a regulatory modification, then the expectation is that appropriate cellular stimuli will cause changes in the level of palmitoylation of a particular protein. Indeed, regulated changes in palmitoylation appear to be a general phenomenon for $G\alpha$ [1]. Regulated palmitoylation was first demonstrated for α_s . Palmitate attached to

^bMyristoylated glycines at position 2 are in bold. Myristoylation of G α has been well-reviewed [1–3].

^cPotential sites of palmitoylation have not been addressed for α_{14} and α_{16} .

^dSimilar N-terminal sequence found in RGS5.

^eCysteine-string motifs are found in other members of the RZ sub-family [63].

^fCysteine present at similar position in RGS box of most RGS proteins.

α_s turns over much more rapidly after activation by the β -adrenergic receptor (β -AR) agonist isoproterenol, activation by cholera toxin, or activation by a constitutively activating mutation in α_s [13–15]. Time courses of palmitate incorporation and pulse-chase analyses are consistent with a model [4,16] in which activation leads to both more rapid depalmitoylation and more rapid subsequent repalmitoylation of α_s . For G α other than α_s , a thorough recent study showed that agonist activation of stably transfected 5-HT_{1A} receptors in CHO cells resulted in increased palmitate turnover on endogenous α_i [17]. In addition, stimulation of gonadotropin-releasing hormone (GnRH) receptors in pituitary cells caused increased palmitate incorporation into α_s , α_i , and α_q [18,19], stimulation of m1-muscarinic receptors in transfected cells increases the rate of palmitate incorporation into α_q (author's unpublished observations), stimulation of GPCRs in isolated membranes has been shown to increase palmitoylation of α_i , α_o , α_s , and α_q [18,20,21], and agonist-regulated palmitoylation has been observed for α_s and α_q even when they are directly fused to GPCRs [22,23]. A similar model of regulated palmitoylation/depalmitoylation in response to agonist activation has been well described for GPCRs [11,24,25]. Regulated changes in palmitoylation have not yet been described for RGS proteins.

Mechanisms of Reversible Palmitoylation

Regulated palmitoylation implies that changes in a protein's palmitoylation state are carried out by regulation of the palmitoylation and/or depalmitoylation machinery in the cell or by changes in the accessibility of the palmitoylated protein substrate to constitutive palmitoylating and depalmitoylating activities. Although intensely studied by many investigators, surprisingly little is understood regarding relevant enzymes and cellular pathways that regulate reversible palmitoylation.

Palmitoyl Transferases

A major unresolved question is whether palmitoylation occurs enzymatically or nonenzymatically. This controversial topic has been well discussed in recent reviews [2,3]. Compelling arguments for nonenzymatic palmitoylation are based on observations of transfer of palmitate to specific and appropriate cysteines in an *in vitro* reaction containing only palmitoyl CoA and a purified protein substrate, such as G α [26]. On the other hand, others have argued that under physiological conditions, where most of a cell's palmitoyl CoA is bound to acyl-CoA binding proteins (ACBP), nonenzymatic palmitoylation would occur too slowly to be significant [27,28].

More importantly, the first convincing demonstrations of enzymatic palmitoylation have been described recently. Two different palmitoyl acyltransferases (PAT) were purified from yeast. One is composed of two proteins termed Erf2p and Erf4p and palmitoylates yeast Ras *in vitro* [29], while the other, Akr1p, was shown to palmitoylate the casein kinase Yck2p [30]. Both Erf2p and Akr1p contain a conserved Asp-His-His-Cys cysteine-rich domain (DHHC-CRD), and mutation of conserved residues in this domain abolishes PAT activity [29,30]. A large family of proteins exists that contains the DHHC-CRD domain, and clearly much research in the near future will be directed toward testing the possibility that the DHHC-CRD proteins are a family of PATs and identifying the relevant PAT(s) for heterotrimeric G-protein α subunits.

Palmitoyl Thioesterases

Recently, a candidate for a physiologically relevant palmitoyl thioesterase, termed an acyl-protein thioesterase (APT-I), was described [31]. Overexpression of APT in cultured cells increased the basal rate of depalmitoylation of co-expressed α_s . Further studies to substantiate a role for APT-I in depalmitoylation of signaling proteins are eagerly awaited.

Proteins and/or Pathways That Regulate Reversible Palmitoylation

G-protein $\beta\gamma$ subunits appear to regulate both palmitoylation and depalmitoylation of G α . $\beta\gamma$ promotes palmitoylation of G α *in vitro* [32] and allows palmitoylation of a non-myristoylated (G2A) mutant of α_i or α_z in transfected cells [33,34]. α_s or α_q containing mutations in N-terminal $\beta\gamma$ interaction sites display greatly decreased palmitoylation [35,36], while a mutant α_o that has an increased affinity for $\beta\gamma$ is

palmitoylated to a higher level than α_o wild type [37]. One way in which $\beta\gamma$ can enhance palmitoylation of $G\alpha$ is by promoting membrane targeting. Consistent with this, palmitoylation, and plasma membrane (PM) localization, of a $\beta\gamma$ -binding-deficient α_q is recovered when it is engineered to undergo myristoylation [35], and $\beta\gamma$ -binding mutations in α_o , a subunit that is normally myristoylated *and* palmitoylated (Table I), do not affect α_o palmitoylation [37]. Although myristoylation and binding to $\beta\gamma$ appear, in some cases, to function interchangeably as membrane-targeting signals for $G\alpha$, they may have additional, more specific roles in promoting palmitoylation [1,32,37].

$\beta\gamma$ can also inhibit depalmitoylation of α_s . A mutant α_s that binds tightly to $\beta\gamma$ is refractory to activation-induced rapid depalmitoylation in cultured cells [13,15], and purified $\beta\gamma$ inhibits depalmitoylation of α_s when assayed in cell extracts [15] or when using purified proteins [31,38]. These results suggest that activation-induced depalmitoylation of $G\alpha$ is mediated, at least in part, by its dissociation from $\beta\gamma$.

Although studies of palmitate turnover on $G\alpha$ and GPCRs suggest that palmitoylation and depalmitoylation are tightly coupled, a recent study utilizing a β -AR- α_s fusion protein was the first to separate these two activities [22]. The authors showed that palmitoylation occurred at appropriate sites in both the β -AR and α_s portions of the fusion protein, and isoproterenol induced rapid depalmitoylation, as seen with the separate proteins. However, isoproterenol-induced palmitoylation, likely re-palmitoylation, was blocked. This result suggests that, after rapid depalmitoylation, repalmitoylation requires dissociation of the G protein from the GPCR and/or later events that do not occur normally with this fusion protein, such as desensitization or internalization.

Tools for Studying Reversible Palmitoylation

As expected from our lack of knowledge of the proteins involved in palmitoylation and depalmitoylation, a dearth of tools exists for inhibiting these activities. Recently, the palmitate analog 2-bromopalmitate was used to inhibit palmitoylation of signaling proteins [39]. Another group synthesized analogs of cerulenin, a natural product inhibitor of fatty acid synthesis, and identified compounds that inhibited palmitoylation of H-ras without inhibiting a fatty acid synthase [40]. This interesting result suggests that not only might cerulenin analogs provide a powerful tool for studying palmitoylation of various proteins, but they might also provide a handle for identifying an elusive palmitoyl transferase [41].

Functions of Reversible Palmitoylation

Plasma Membrane Localization

An obvious role for palmitoylation is to tether a protein to cellular membranes, and thus regulation of this modification would allow changes in a protein's subcellular localization, either by dissociation off a cellular membrane or transfer to different membrane domains. Palmitoylation appears to

function, in a poorly understood manner, as a specific membrane-targeting device that specifies localization to PM, and in some cases specialized PM microdomains [1–3]. This role of palmitoylation has been well documented and discussed in terms of a two-signal model for PM localization of signaling proteins [1–4, 42–44].

Although the consensus is that palmitoylation plays a critical role in PM localization of many proteins, including the α_i subfamily [4,34,45,46] of $G\alpha$ (Table I), there is a surprising disagreement regarding a role for palmitoylation in the non-myristoylated $G\alpha$ (Table I). Due to the lack of tools for perturbing palmitoylation in cells, virtually all localization studies have relied on preventing palmitoylation by mutating the relevant cysteines to serines or alanines. Subcellular fractionation and immunofluorescence localization of cells transiently or stably expressing nonpalmitoylated cysteine mutants of α_s , α_q , α_{11} , or α_{13} have demonstrated that such mutants are cytoplasmic and soluble [47–50], and, recently, these analyses were extended by the demonstration that a GFP-tagged, nonpalmitoylated mutant of α_q is cytoplasmic in living cells [51]. Moreover, overexpression of $\beta\gamma$ with palmitoylation-defective α_s or α_q cannot restore their PM localization [36], providing further support for the critical importance of palmitoylation. On the other hand, some researchers have observed that nonpalmitoylated mutants of α_s , α_q , or α_{12} remain in a particulate fraction after subcellular fractionation of transiently transfected cells [14,52–55]. However, it is important to note that in the latter cases [14,52–55] immunofluorescence localization of the mutants has not been reported, and thus it is unknown whether these mutants arrive correctly at the PM or are mistargeted to intracellular locations. Lastly, mutation of the N terminally palmitoylated cysteines in RGS4 and RGS16 (Table I) had little effect on their localization [7,8,56]. Possibly, additional membrane-targeting signals may be favored in different cells or experimental conditions.

Can Reversible Palmitoylation

Regulate Changes in Subcellular Localization?

Although palmitoylation is reversible and plenty of evidence indicates that nonpalmitoylated mutants of various proteins are defective in PM localization and/or localization to PM microdomains, actually demonstrating a relationship between changes in a protein's palmitoylation and movement of that protein within a cell is a difficult problem. Nonetheless, α_s provides the best example of a correlation between reversible palmitoylation and reversible subcellular localization. As described above, activation of α_s induces rapid turnover of its attached palmitate. Similarly, activation of α_s , by GPCRs, cholera toxin, or a constitutively activating mutation, can promote its redistribution from PM to cytoplasm [48,57–61]. Significantly, β -AR-induced redistribution of α_s appears to follow a similar time course as β -AR-induced depalmitoylation of α_s [15,48,57]. In addition, replacement of the N-terminal single site of palmitoylation of α_s with other membrane-targeting motifs results in mutant α_s subunits that are unable to translocate from PM to

cytoplasm upon activation [62], consistent with depalmitoylation of a single palmitate playing a critical role in activation-induced subcellular redistribution of α_s . Others have speculated that regulated palmitoylation is more relevant for allowing reversible movement of $G\alpha$ within PM microdomains [2,16,54]. Possibly, reversible palmitoylation could help to regulate the availability of G proteins at diverse subcellular locations.

Palmitoylation Affects RGS- $G\alpha$ Interactions

One of the most interesting recent advances is evidence that palmitoylation of certain $G\alpha$ influences their interaction with RGS proteins, and, vice versa, palmitoylation of certain RGS proteins affects their interactions with $G\alpha$. *In vitro*, palmitoylation of α_z or α_{i1} greatly inhibited their sensitivity to the GTP-hydrolysis-stimulating activity of several RGS proteins [63]. This result implies that reversible palmitoylation of $G\alpha$ functions as a key switch to regulate the ability of RGS proteins to “turn-off” signaling.

Palmitoylation of RGS4 or RGS10 was shown to either inhibit or accelerate their ability to stimulate GTP hydrolysis of α_z or α_{i1} [10]. The positive or negative effect of palmitoylation differed depending upon the *in vitro* GAP assay used and whether palmitoylation occurred at N-terminal sites or cysteine sites in the conserved RGS box (Table I). Consistent with an important role for palmitoylation of RGS proteins, when nonpalmitoylated RGS16, containing N-terminal cysteine mutations (Table I), was expressed in cultured cells it failed to effectively inhibit signaling mediated by G_q or G_i [7]. It remains to be determined whether effects of palmitoylation on RGS- $G\alpha$ functional interactions are mediated through direct binding or via binding to membranes, although for RGS4 *in vitro* lipid vesicle binding experiments are consistent with the proposal that palmitoylation, in addition to an N-terminal amphipathic helix, is important for membrane binding and properly orienting the RGS protein for optimal activity [64].

Conclusion

Palmitoylation plays an important role in membrane binding and regulating interactions of signaling proteins. Future challenges include defining cellular pathways and enzymes that regulate reversible palmitoylation, and understanding how changes in a protein's palmitoylation are translated into functional changes inside the cell.

Introduction

The sense of taste in humans is comprised of five primary qualities: sweet, bitter, sour, salty, and *umami* (the taste of glutamate) (reviewed in [1,2]). Taste sensation is initiated in primary taste sensory cells located in papillae at the surface of the tongue and in the soft palate. The papillae contain one to several taste buds, each comprising approximately 100 cells, including taste receptor cells (TRCs), precursor, and support cells [3]. TRCs are specialized epithelial cells that typically respond to one or more tastants by undergoing depolarization, elevating intracellular calcium, releasing a neurotransmitter, and activating the afferent neurons that they synapse upon.

Based on electrophysiological, genetic, and biochemical studies, several mechanisms have been identified for signal transduction by taste cells. For salty and sour compounds, the main signaling pathway is initiated by passive diffusion of ions through apical ion channels, amiloride-sensitive sodium channels, and acid-sensing channels [4–10]. For bitter, sweet, and *umami* compounds, the main signaling mechanisms depend on seven transmembrane-helix receptors, their coupled G proteins, and downstream effector enzymes (reviewed in [1,2]).

Various molecular techniques (e.g. molecular cloning, ribonuclease protection, RT-PCR, *in situ* hybridization, and immunohistochemistry) have shown that α -gustducin, $G\alpha_{i-2}$, $G\alpha_{i-3}$, $G\alpha_s$, $G\alpha_{14}$, $G\alpha_{15}$, α -transducin, $G\alpha_q$, $G\beta_1$, $G\beta_3$, and $G\gamma_{13}$ are expressed in rodent TRCs [11–14].

α -Gustducin

α -Gustducin, a G-protein α subunit that shares 80 percent identity with rod α -transducin, is expressed in ~25 percent of TRCs [12] and has been implicated in responses of mice to bitter and sweet compounds [15]. Behavioral and nerve-recording studies showed that α -gustducin null mice have a marked reduction in their responses to the bitter compounds denatonium benzoate and quinine sulfate, and to the sweet compounds sucrose and SC45647, whereas their responses to salty and sour compounds were identical to those of their wild-type littermates [15].

Trypsin sensitivity and GTP γ S binding assays showed that α -gustducin can be activated by native bovine taste receptors in the presence of a variety of bitter compounds [16]. Molecularly cloned bitter-responsive taste receptors (the T_{2r}/T_{rb} receptors) have been shown to couple to and activate heterotrimeric gustducin in preference to heterotrimers containing $G\alpha_s$, $G\alpha_i$, $G\alpha_o$, or $G\alpha_q$ [17]. Recombinant α -gustducin has been shown capable of activating retinal phosphodiesterase (PDE) [18]. Specific PDE subtypes (PDE1a) have been identified in bovine taste tissue that can be activated by rod α -transducin ([11]; Bakre *et al.* 2003 submitted) and by α -gustducin or a peptide derived from the “effector-interaction” region of α -gustducin ([19]; Lupi and R.F.M., unpublished). Rapid quench-flow experiments have shown that anti- α -gustducin antibodies block a decrease in cAMP and cGMP levels in taste tissues elicited

by bitter compounds [20]. Based on the structural and biochemical similarity of α -gustducin and α -transducin, and the above observations, it appears that many bitter responses involve α -gustducin activation by heptahelical T2R/TRB taste receptors followed by α -gustducin activation of PDE1a in the taste cell.

α -Transducin

Rod α -transducin mRNA and protein has been shown to be expressed in rat taste tissue and TRCs [11,21]. The level of expression and the number of expressing cells were much lower than found with α -gustducin, suggesting a more limited role for α -transducin in taste signal transduction. The α subunit of cone transducin was also amplified by PCR from rat taste tissue RNA but was undetectable by ribonuclease protection, suggesting a very low level of expression and/or expression in only a small number of TRCs [11].

Rod α -transducin, like α -gustducin, can be activated *in vitro* by bitter-stimulated native bovine taste receptors [11,16]. A peptide that competitively inhibits activation of rod α -transducin by rhodopsin also inhibited activation of rod α -transducin by native taste receptors [11]. Taste PDE can be activated by aluminum fluoride-activated rod α -transducin or a peptide corresponding to the region of rod α -transducin that interacts with retinal PDE ([11]; Bakre *et al.* 2003 submitted). A small subset of frog taste cells respond to the sweeteners saccharin and NC-01 with the generation of an inward current [22]. Injection of a peptide derived from the effector-interaction region of rod α -transducin also induced this inward whole-cell current [22], suggesting that rod α -transducin, or the similar α -gustducin, might elicit this response *in vivo*.

To determine the role of rod α -transducin in taste signal transduction, behavioral tests with rod α -transducin single knockout mice and rod α -transducin/ α -gustducin double knockout mice were carried out [23]. No differences were found in the responses to denatonium benzoate, quinine sulfate, sucrose, and SC45647 between rod α -transducin knockout and wild-type mice or between rod α -transducin/ α -gustducin double knockout and α -gustducin single knockout mice. However, the preference responses to monosodium glutamate (MSG) of rod α -transducin/ α -gustducin double knockout mice were diminished compared to those of wild-type and α -gustducin single knockout mice [23]. At concentrations of MSG that are preferred strongly by wild-type mice, the double knockout mice were indifferent. These data show that rod α -transducin and α -gustducin are involved in *umami* signaling, but rod α -transducin, in contrast to α -gustducin, does not appear to contribute to sweet or bitter signaling.

Other G Protein α Subunits

The behavioral and gustatory nerve responses of α -gustducin knockout mice to bitter and sweet compounds

were reduced, but not totally abolished, indicating that other G proteins and/or pathways are involved. Transgenic expression in the α -gustducin lineage of TRCs of a dominant-negative α -gustducin mutant that can bind to taste receptors and G $\beta\gamma$ subunits, but cannot be activated by receptors, further reduced the residual responses to sweet and bitter compounds of α -gustducin knockout mice [24]. This dominant-negative transgene also reduced responses to bitter and sweet compounds when introduced into α -gustducin-positive mice, demonstrating its effectiveness as a dominant-negative competitor [24]. G α_{i-2} , G α_{i-3} , G α_s , G α_{14} , and G α_{15} are possible candidates to mediate the residual responses in α -gustducin knockout mice; clearly these residual responses are not mediated by rod α -transducin based on results from the double knockouts. The precise role in taste transduction of G protein α subunits other than α -transducin and α -gustducin remains to be clarified.

$\beta\gamma$ Subunits

A novel G γ subunit, G γ 13, was found by screening cDNA libraries from individual α -gustducin-expressing versus nonexpressing TRCs [25]. Immunohistochemistry showed co-expression of G γ 13 and α -gustducin. Southern blot analysis of RT-PCR products from individual TRCs showed co-expression of α -gustducin and G γ 13 with G β 3 (19/19 cells) and G β 1 (15/19 cells) [25]. It was subsequently determined that α -gustducin is expressed in most, but not all, TRCs that express G γ 13, and that the G γ 13-expressing TRCs also express phospholipase C β 2 and the type III inositol trisphosphate (IP $_3$) receptor [26–28]. The trypsin-sensitivity assay showed that G γ 13 can interact with α -gustducin and that α -gustducin/G β 1/G γ 13 complexes can be activated by native taste receptors in the presence of the bitter compound denatonium benzoate [25]. Many bitter compounds elicit an increase in taste tissue levels of IP $_3$ and diacyl glycerol (DAG); this response was entirely blocked by antibodies directed against G γ 13, G β 3 or PLC β 2 [14,25,29], implicating all three of these proteins in mediating this taste response. Control antibodies or antibodies directed against α -gustducin had no effect on IP $_3$ or DAG generation, while antibodies directed against G β 1 had a slight effect. G β 3G γ 13 appears to be the likely partner of α -gustducin and like α -gustducin is involved in TRC responses to bitter compounds.

G-Protein-Coupled Receptors

The T2r/TrB family of taste receptors contains approximately 25 members [30,31]. One member of this family, mT2r5, was shown *in vitro* to be activated by cycloheximide and to couple specifically to gustducin [17]; presumably the other T2r/TrB receptors are also bitter-responsive taste receptors. It was shown by *in situ* hybridization that multiple T2r/TrB receptors are co-expressed in a subset of the

α -gustducin-expressing TRCs in mice and rats, indicating that most if not all T2r/TrB receptors are expressed in the same subset of TRCs and that they most likely couple to gustducin.

The T1rs constitute a three-member family of taste receptors expressed in TRCs [32–37]. T1r1 is predominantly expressed in TRCs of the fungiform and foliate papillae and palate, whereas T1r2 is expressed in the circumvallate and foliate papillae and palate, but not in the fungiform papillae [32]. T1r3 is expressed in both anterior and posterior papillae of the tongue as well as in the palate [36]. Calcium-imaging

studies showed that HEK-293 cells expressing T1r3 and T1r2 responded to several sweeteners and D-amino-acids, whereas cells expressing T1r3 and T1r1 responded to L-amino-acids [36,38,39]. Transgenic expression of T1r3 from a highly sweet-preferring “taster” strain into the less sweet-preferring “nontaster” background converted the nontaster phenotype to that of the taster [36]. The G protein(s) that couple to these receptors are currently unknown, but probably include G_s for sugars based on biochemical and electrophysiological experiments, implicating adenylyl cyclase and cAMP in TRC responses to sugars.

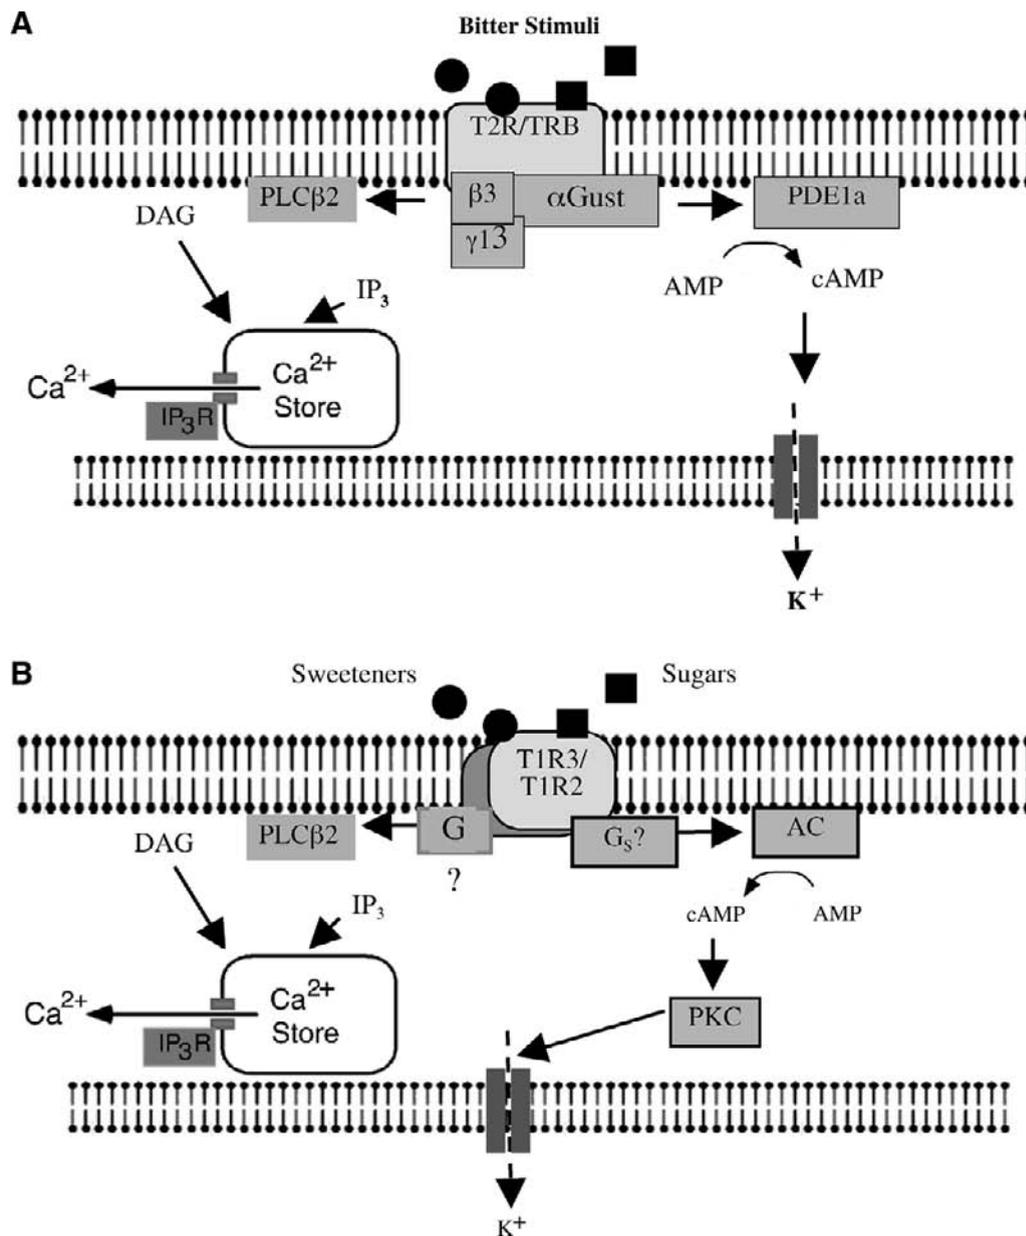

Figure 1 Schematic representation of the transduction pathways for bitter (A) and sweet (B) stimuli. One pathway, common to bitter compounds and artificial sweeteners, involves activation of PLC $\beta 2$, production of IP $_3$ and DAG, and release of Ca $^{2+}$ from the ER. This pathway is activated by the $\beta 3\gamma 13$ subunits of gustducin for bitters and by unidentified G protein α and/or $\beta\gamma$ subunits for sweeteners. The second main pathway for bitter compounds involves activation of PDE1a by the α subunit of gustducin and a drop in cAMP levels. For sugars the main pathway consists of activation of adenylyl cyclase (AC) by a G protein α -subunit, probably G_s , and a rise in cAMP.

Functional studies in heterologous cells, mRNA expression studies, and behavioral tests suggested that an mGluR4 variant, taste mGluR4, may function as an *umami* taste receptor [40,41]. It is currently not known whether taste mGluR4 couples to transducin and/or gustducin.

Second Messenger Pathways

The proposed main signaling pathways for bitter are

(1) T2r/TrB receptor → heterotrimeric gustducin → α -gustducin → activation of PDE1a → decrease in cAMP and cGMP → activation of a cyclic nucleotide suppressed cation channel → Ca^{2+} influx → neurotransmitter release;

(2) T2r/TrB receptor → heterotrimeric gustducin → $\beta\gamma$ -gustducin (G β 3/G γ 13) → PLC β 2 → IP₃ + DAG → Ca^{2+} release from internal stores → neurotransmitter release (Figure 1a).

The two main pathways for sweetener signal transduction are believed to be

(1) T1r heterodimeric receptor → heterotrimeric G-protein (G_s?) → adenylyl cyclase → rise in [cAMP] → protein kinase phosphorylation of K⁺ channels → depolarization → Ca^{2+} influx → neurotransmitter release;

(2) T1r heterodimeric receptor → heterotrimeric G protein → PLC β 2 → IP₃ + DAG → Ca^{2+} release from internal stores → neurotransmitter release. Experiments using rat TRCs showed that natural sweeteners use the cAMP/ Ca^{2+} influx pathway whereas artificial sweeteners use the IP₃ + DAG/ Ca^{2+} release pathway [42] (Figure 1b).

For *umami* signaling, biochemical experiments have implicated both a rise and a drop in [cAMP] and a rise in [IP₃] [43].

Conclusion

Heterotrimeric gustducin plays a central role in the signal transduction of bitter compounds by coupling to T2r/TrB receptors and activating PDE and PLC β 2. It also plays a central role in the signal transduction of sweeteners, although its coupling to specific taste receptors has not been experimentally demonstrated. The transduction of *umami* signals appears to use both gustducin and transducin. The role of the other G proteins expressed in taste tissue is still unclear. The expression of these G proteins in a wide range of tissues limits the usefulness of the conventional mouse knockout as a tool for elucidating their role in taste transduction. Many answers will probably come from taste tissue specific knockouts using the Cre/LoxP system.

Regulation of Synaptic Fusion by Heterotrimeric G Proteins

Simon Alford and Trillium Blackmer

Department of Biological Sciences, University of Illinois at Chicago, Chicago, Illinois

Introduction

Exocytotic release of a neurotransmitter is necessary for interneuronal communication. In neurons, exocytosis, or the fusion of a synaptic vesicle with a specialized area in the plasma membrane, is a tightly regulated process that must be activated with strict temporal control. Ca^{2+} entry to the terminal is the trigger for exocytosis and neurotransmitter release, but the release of neurotransmitter evoked by Ca^{2+} is modified by receptors located at the presynaptic terminal. These receptors include G-protein-coupled receptors (GPCRs).

The Vesicle Fusion Machinery

To understand how G proteins modulate the release of neurotransmitter we must understand some basic principles of exocytosis. The best-characterized proteins involved in exocytotic fusion are those that comprise the core complex, the formation of which is absolutely necessary for fusion to occur. The core complex, or SNARE (soluble NSF (N-ethylmaleimide-sensitive factor) attachment protein receptor), is a bundle of four α -helices, approximately 65 amino acids in length, which is thought to bridge the synaptic vesicle and plasma membranes [1]. These α -helices are donated by three different proteins; a family member from the syntaxin and SNAP-25 families, both located in the synaptic active zone, and a VAMP (vesicle associated membrane protein, also known as synaptobrevin) family member, located in the synaptic

vesicular membrane. The syntaxin family consists of integral membrane proteins around 300 amino acids in length, which have been shown to bind to many regulatory proteins [2]. Of these regulatory proteins, synaptotagmin is the most likely candidate for the Ca^{2+} sensor in synchronous release of neurotransmitter [3,4]. The core complex is sufficient to mediate fusion of lipid micelles *in vitro* [5], and fusion of the synaptic vesicle with the plasma membrane requires the interaction of syntaxin, SNAP-25, and VAMP.

Vesicles containing neurotransmitter must be able to fuse with the plasma membrane in microsecond time scales. Consequently, synaptic vesicles are located very near the point of fusion, the active zone, at the presynaptic terminal. This organization is termed *docking*. Vesicular recruitment and docking requires the actin assembly network and ATP [6]. Multistep fusion reactions are ruled out due to the speed of release. For this reason, it is believed that there is a pool of ready-to-fuse synaptic vesicles that have undergone a further maturation step referred to as *priming* [7]. Priming in large dense-core vesicle requires ATP, submicromolar Ca^{2+} concentrations, and alterations in membrane lipids by lipid transferases and kinases [8]. Furthermore, the possible role in priming of the N-ethylmaleimide-sensitive factor (NSF) in synaptic vesicles may indicate similar requirements [9]. Evoked synaptic fusion is thought to require high (hundreds of μM) local concentrations of Ca^{2+} [10] following action potential invasion of the nerve terminal, although more recent work suggests that low μM increases in Ca^{2+} concentrations ($\sim 10 \mu\text{M}$) may activate fusion in some neurons [11].

G Protein-Coupled Receptor Mediated Modulation at the Presynaptic Terminal

Regulation of neurotransmitter release at the presynaptic terminal plays an important part in the plasticity of the nervous system [12]. Various neurotransmitters modulate release from presynaptic terminals, and many of these interactions involve the activation of a GPCR [13]. Modulation of exocytotic release by GPCRs is an important mechanism by which neurons are able to respond and adapt to changes in secretory requirements. Some GPCRs may couple to more than one G protein, while others show a great deal of specificity. G $\beta\gamma$ binding to G α involves widespread contacts at two distinct interfaces. Following activation by a GPCR, the heterotrimeric G protein dissociates into an activated G α GTP subunit and a free G $\beta\gamma$ subunit [14]. Active G α -GTP and free G $\beta\gamma$ may then activate many different signaling pathways [15].

Uncertainty over the mechanisms by which G proteins alter neurotransmitter release in part reflects the variety of G-protein effector targets and the difficulties in gaining experimental access to these small structures. Thus, most molecular studies of the detailed mechanisms come from either transfection of the relevant proteins into cultured cell lines and *Xenopus* oocytes or from electrophysiological measurements from neuronal cell bodies.

Possible Mechanisms of Presynaptic Inhibition by G Proteins

GPCRs that inhibit neurotransmitter release have perhaps been the mostly widely studied modulators of synaptic transmission. A consensus mechanism by which these transmitters may modulate synaptic transmitter release has been hypothesized to involve an alteration in action potential evoked Ca²⁺ entry to the presynaptic terminal.

1. This reduction in Ca²⁺ entry could occur by a direct action of G protein $\beta\gamma$ subunit on the gating of voltage gated Ca²⁺ channels (VGCCs) [16,17]. If G $\beta\gamma$ inhibits VGCCs, less Ca²⁺ would enter the presynaptic terminal, and since neurotransmitter release is Ca²⁺ dependent, less neurotransmitter would be released. GPCR-mediated inhibition of release via a direct inhibition of VGCCs has been demonstrated at one presynaptic terminal [18] through multiple GPCRs [19,20]. Although, given the large number of neurotransmitters that inhibit release, many of which have very little effect on Ca²⁺ entry through VGCCs [20], it is unlikely that this is the only pathway involved in GPCR mediated inhibition at this terminal.

2. If G protein-coupled inwardly rectifying K⁺ channels (GIRKs) were located at presynaptic terminals, activation by G $\beta\gamma$ could modulate action potential amplitudes, allowing fewer Ca²⁺ channels to open. G $\beta\gamma$ activates GIRKs in neuronal cell bodiestransfected cell lines, and *Xenopus* oocytes [21,22]. Although GIRKs have been histochemically localized to presynaptic terminals [23], physiological evidence for their presynaptic action is lacking. These channels are

believed to be more important for postsynaptic modulation [24]. GPCR-mediated inhibition of voltage-gated K⁺ channels at an autaptic presynaptic terminal has also been shown [25] to occur through activation of dopamine receptors, although it is not clear what G protein subunit, G α or G $\beta\gamma$, is responsible. At the reticulospinal-motoneuron synapse of the lamprey, both glutamate and 5-HT activate GPCRs, which modulate a K⁺ current, although the channel subtype and G-protein subunit involved are unknown [26,27].

3. It has been suggested that G proteins may modulate voltage-gated Na⁺ channels at the presynaptic terminal; however, no direct evidence has yet been presented [28]. Modulation of Na⁺ channels could also indirectly affect the entry of Ca²⁺ into the presynaptic terminal.

These studies led to the idea that G $\beta\gamma$ -mediated inhibition of neurotransmission at the presynaptic terminal was through a direct or indirect effect on the amount of Ca²⁺ that enters the terminal during the action potential. However, there is growing evidence that G $\beta\gamma$ may also inhibit synaptic transmission by modulation distal to the point of Ca²⁺ entry. The ability of G proteins to inhibit neurotransmitter release by directly targeting the release apparatus was first demonstrated by Silinsky [29] in the neuromuscular junction. Spontaneous exocytotic events, where exocytosis occurs independently of Ca²⁺ entry, can be detected by recording miniature excitatory/inhibitory post-synaptic currents (mE/IPSCs). Measurements of mE/IPSCs allow the exocytotic modulatory processes that occur independently of Ca²⁺ entry to be isolated and studied, unlike evoked EPSCs. These mE/IPSCs have been shown to be regulated by many GPCRs [30].

In support of the hypothesis that G proteins inhibit vesicle fusion directly, G proteins can inhibit exocytosis after cell permeabilization, suggesting a role late in the exocytotic event [31]. In addition, exocytotic processes in pancreatic β cells, peritoneal mast cells, chromaffin cells, PC12 cells, and secretory granules are regulated independently of Ca²⁺ entry by G proteins [32]. G $\beta\gamma$ has been shown to interact directly with the fusion machinery in rat mast cells [33]. In the lamprey giant synapse 5-HT-mediated synaptic inhibition does not cause a reduction in Ca²⁺ entry to the synapse [27]. Furthermore, the actions of 5-HT at a GPCR are abolished by intracellular block of activated G $\beta\gamma$ [34]. A mechanism for a direct interaction between G $\beta\gamma$ and the core vesicle fusion machinery is suggested by the finding that G $\beta\gamma$ directly binds SNARE proteins syntaxin and SNAP-25 [34,35] as well as the cysteine string protein (CSP) [36].

Presynaptic Ca²⁺ Stores and Modulation of Neurotransmitter Release

Ca²⁺ release from internal stores located at the presynaptic terminal may lead to an enhancement of transmitter release. However, this Ca²⁺ may originate either from Ca²⁺ activated channels (that is, Ca²⁺-induced Ca²⁺ release; CICRs) [37] or

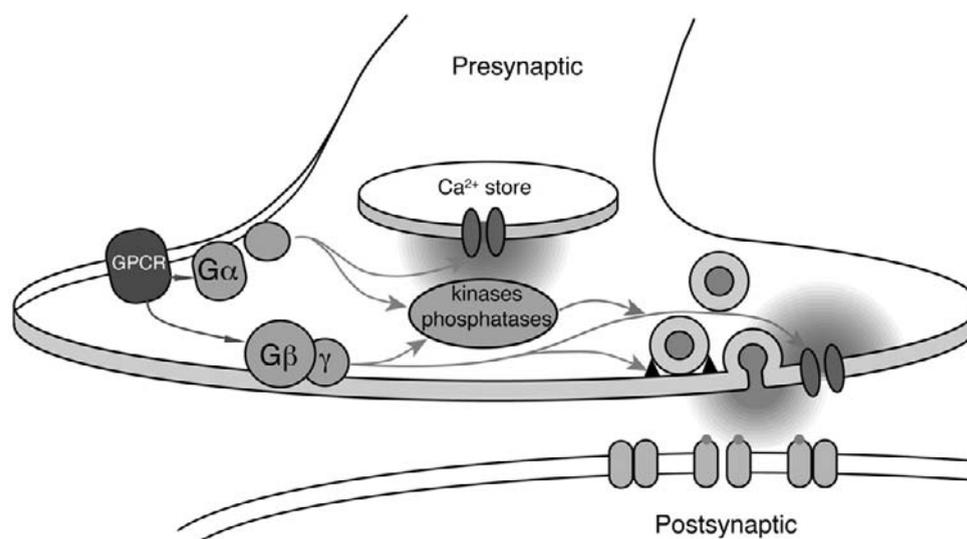

Figure 1 GPCRs at the presynaptic terminal (blue) may modulate transmission through either G α or G $\beta\gamma$. These pathways (green) may in turn alter the phosphorylation state of presynaptic proteins, cause the release of Ca²⁺ from presynaptic internal stores, or alter release through interactions with the release machinery or through actions at presynaptic ion channels.

following the activation of a presynaptic GPCR, leading to IP₃ production and activation of presynaptic IP₃ receptors [26,38]. It is also important to note that the activation of presynaptic receptors leading to IP₃ production will also produce diacylglycerol in the nerve terminal, leading to the possible activation of PKC or direct effects on proteins associated with the release machinery, for example UNC13 [39].

G Proteins and Phosphorylation

G proteins may alter the efficacy of synaptic transmission either through phosphorylation or dephosphorylation of presynaptic components. G $\beta\gamma$ has been suggested to activate the calcineurin phosphatase pathway to inhibit release independent of Ca²⁺ entry [40] in neuroendocrine cells. In addition, the activation of both PKA and PKC have been implicated in the enhancement of synaptic transmission in the central nervous system. Indeed, tonic activation of PKA may be necessary for vesicle fusion to occur [41,42] and PKA phosphorylates CSP to alter its binding to syntaxin [43]. Metabotropic glutamate receptors in the mammalian CNS may activate either of these latter pathways [44,45].

Although relatively difficult to study, the presynaptic terminal may contain as rich an array of receptor-mediated mechanisms that modify information flow as has been identified at the postsynaptic side of the synapse. Figure 1 demonstrates some of the possible mechanisms by which presynaptic receptors may alter neurotransmitter release.

G Protein Regulation of Channels

Ofer Wiser and Lily Yeh Jan

*Howard Hughes Medical Institute,
Departments of Physiology and Biochemistry,
University of California San Francisco,
San Francisco, California*

Stimulation of G-protein coupled receptor (GPCR) facilitates GTP exchange for GDP to $G\alpha$, leading to dissociation of $G\alpha^{GTP}$ from the $G\beta\gamma$ dimer and regulation of their effectors [1]. Ion channels as effectors allow neurotransmitters or hormones to elicit electric activity [2]. Measurements of ions that flow through the open channel pore by electrophysiological methods enable direct determination of the activity of a single channel protein at millisecond resolution *in vivo*. Different configurations of patch-clamp recording make it possible to control the composition of solutions on either side of the membrane.

There are numerous examples for modulation of channel activity by indirect means involving phosphorylation, second messengers (Ca^{2+} , cAMP), and regulators of G-protein activity such as RGS proteins [3]. In this chapter we will discuss modulation of channels due to their direct interaction with G proteins, and focus on the G-protein-gated inward rectifying potassium channels Kir3 (GIRK) [4], and the voltage-gated calcium channels [5,6]. This review is not comprehensive, as direct interaction of G proteins with other ion channels have been reported [7–10].

Interaction with K^+ Channels

The GIRK Channels

Opening of K channels allows outward flow of potassium ions down the concentration gradient, causing hyperpolarization. This way, the activation of GIRK channels by transmitter leads to calming of the heart rate and slowing of neuronal activity [4,11,12]. GIRK channels are tetramers of pore-lining subunits containing two transmembrane domains (TM1&2), and cytosolic N and C termini. The mammalian GIRK family has four members. They differ in the ability to form

homotetrameric channels [13] and the traffic signals they possess [14]. Whereas midbrain dopamine neurons express GIRK2 channels, the brain and cortex contain primarily heterotetramers of GIRK1 and GIRK2 and the heart contains primarily GIRK1 and GIRK4 [15].

GIRK channels have low basal activity, and are activated by GPCR, due to their direct binding to the $\beta\gamma$ subunit of the G protein [16,17]. Mutations in the transmembrane domain may rescue mutant GIRK channels constitutively active in the absence of $G\beta\gamma$, indicating that channel gating triggered by $G\beta\gamma$ binding is likely to involve conformational changes within the membrane [18,19].

The $G\beta\gamma$ Interacting Domain of GIRK

Almost all $G\beta\gamma$ combinations can activate GIRK [17]. Two-hybrid analysis showed interaction between the $G\beta 1$ and the N-terminal domain of GIRK1 [20], but only $G\beta\gamma$ dimers can activate GIRK channels [21]. A recent study compared $G\beta 1$ with $G\beta 5$, which does not activate GIRK, and identified $G\beta 1$ residues (S67, S98, and T128) important for basal activity [22]. Another study showed the importance of residues close or within the $G\alpha$ binding interface of $G\beta$ indicating a possible $G\alpha$ competition with GIRK [1].

Direct binding of $G\beta\gamma$ to both the N terminal (amino acid 34–86) and C terminal (amino acid 273–462) domains of GIRK1 shown by *in vitro* binding assay may be reduced by peptides from those GIRK1 domains, which also partially inhibit channel activation [23]. Peptides from GIRK4 C-terminal domain also affected $G\beta\gamma$ binding and channel activation [24]. A chimerical Kir2 channel gained sensitivity to $G\beta\gamma$ by introduction of the two GIRK1 termini [25]. Further experiments have localized $G\beta\gamma$ binding region in the

N- and C-terminal domains of GIRK1-4 [26]. Similar G $\beta\gamma$ activation has been shown for functional homotetramers of GIRK1 (F137S) and GIRK4 (S143T) [13]. Consistent with these findings, crucial GIRK1 (H57, L262) and GIRK4 (H64, L268) residues for G $\beta\gamma$ interaction have been identified at homologous sites [27].

Coupling of GIRK Activation to Specific Receptors

Remarkably, GIRK channels are activated specifically by Gi/o protein-coupled receptors *in vivo* and in mammalian HEK293 cells, even though GIRK channels are activated by G $\beta\gamma$ and in *Xenopus* oocytes, receptors coupled to different G proteins can all activate GIRK [28]. Chimeric G α containing primarily G α_i except for the C-terminal residues allow Gs-coupled receptors to activate GIRK [29], indicating a pivotal role for G α in G-protein/GIRK coupling. Conceivably, GIRK and Gi coupled receptors may be sequestered via scaffold proteins. If so, overexpression may saturate the scaffold protein that confers G-protein specificity *in vivo*. This may account for the observed GIRK activation by Gs coupled β_1 adrenergic receptors [30]. It is also of interest to note that the receptor kinase GRK2 [31], which has G $\beta\gamma$ binding domains, has been implicated in mediating receptor specificity.

The kinetics of GIRK channel activation in mammalian cells *in vivo* are very fast (<1 s) as opposed to the much slower activation when receptors and GIRK channels are expressed in *Xenopus* oocytes. One possible explanation for this is that in the native cell GIRK channels and Gi/o-coupled receptors are colocalized [23,32]. Indeed, expression in *Xenopus* oocytes of fused muscarinic receptor m2R with the PTX resistant G α_z resulted in acetylcholine (carbachol) stimulation of reduced currents with much faster activation kinetics [33]. The N-terminal domain of GIRK1 may also bind trimeric G $\alpha\beta\gamma$ [23,34,35]. The physical association of G α , though not needed for GIRK activation, may have a role in the coupling specificity to a certain GPCR, either by generating macro protein scaffold or by facilitating compartmentalization and hence rapid and specific channel activation by receptors. Interestingly, the N- and C-terminal domains of the GIRKs were found to interact with each other, including the N-terminal domain of GIRK1 to the C-terminal domain of GIRK4, and exhibited much enhanced binding of G $\beta\gamma$ [26]. Four G $\beta\gamma$ binding domains per GIRK tetramer have been implicated by cross-linking experiments [36], but any association between the channel and G α remain to be examined.

The GIRK basal activity is due to free G $\beta\gamma$ without receptor stimulation. However, qualitative differences have emerged between the basal activity and the receptor-induced GIRK currents. Studies of chimeras between the GIRK4 (S143T, used for expression of functional homotetramer) and IRK1 channels have identified a single site, namely GIRK4 (L339E), that when mutated reduced binding to G $\beta\gamma$ and impaired agonist-induced activity [37]. What might be different between the basal activity and the receptor-induced activity? One can speculate that at resting, G α is bound to

the receptors and both GIRK domains are free to exhibit high affinity to the low level of cytosolic-free G $\beta\gamma$ [1,37]. Upon receptor activation, both G α^{GTP} and G $\beta\gamma$ are separated from the receptors. G α is then bound to the GIRK N terminal, reducing its affinity to G $\beta\gamma$. Thus while the released G $\beta\gamma$ will bind GIRK and cause increase in GIRK currents above the basal activity, the reduction in GIRK affinity will result in a fast dissociation of G $\beta\gamma$ and hence the fast reduction in channel activity (the apparent fast desensitization or deactivation of GIRK currents). In another scenario, the G α^{GDP} alone or in a complex with $\beta\gamma$ is bound to the N terminal and actively inhibiting the channel [35]. This inhibition will be relieved upon agonist application only if the receptor itself is in a complex with the same G α^{GDP} and can facilitate the exchange to GTP. The mechanism of specificity of GIRK activation *in vivo* as well as the possible modulation of GIRK gating by G α required further study.

Calcium Channel Interaction with G Proteins

High-voltage-activated (HVA) Ca $^{2+}$ channels provide the coupling from the action potential to transmitter release in nerve terminals and endocrine cell, and of the excitation-contraction of muscle cells. The channel contains at least three subunits. The main subunit, α_1 has four homologous repeats (I–IV) of six transmembrane (TM) domains (S1–S6). Each repeat contains the voltage-sensitive S4 domain, and the S5–S6 pore-forming domain. There are two auxiliary subunits with regulatory roles: α_2/δ has extracellular domain and a single TM domain, and β is a cytosolic subunit [38]. There are three subfamilies of HVA Ca $^{2+}$ channels named Ca $_v$ 1–3. Ca $_v$ 1.1–1.4 mediate the L-type currents; Ca $_v$ 2.1–2.3 mediate the P/Q-, N-, and R-type currents, respectively; Ca $_v$ 3.1–3.3 mediate the T-type currents. HVA Ca $^{2+}$ channels are negatively regulated by G proteins in various neuronal preparations [2,39]. This response appears to be controlled by a membrane-delimited mechanism [40] via pertussis toxin (PTX)-sensitive G proteins [41].

G Protein Interacting Domains

Overexpression or injection of G-protein subunits in sympathetic neurons indicated that G $\beta\gamma$ mediates the Ca $^{2+}$ channel inhibition [42,43]. Alanine mutations of G β_1 residues 55 and 80, which reside at the N-terminal interface with G α , had enhanced ability to inhibit current through Ca $_v$ 2.2, while mutations within the switch interface eliminated current inhibition [1], indicating a G α role in regulating G $\beta\gamma$ interaction with Ca $^{2+}$ channels.

The G $\beta\gamma$ Interacting Domain of HVA Ca $^{2+}$ Channels

Gi/Go coupled receptors selectively inhibited N-, P/Q- and R-type calcium currents [44], due to G $\beta\gamma$ interaction with

the $\alpha 1$ subunit of $Ca_v2.1-2.3$, while the channel β subunit or strong depolarization (prepulse/voltage dependent facilitation), reduced this inhibition [45,46]. Multiple $G\beta\gamma$ interaction domains have been found, including the C-terminal region of $CaV2$ family [47–49], and the $\alpha 1$ cytoplasmic linker connecting S6 of the first repeat and S1 of the second repeat. Within this linker, $G\beta\gamma$ binding occurs both in the $\alpha 1$ interaction domain (AID), which also mediates the interaction with the channel β subunit, and in a second downstream sequence [49,50].

Modulation of $G\beta\gamma$ Inhibition

All channel β subunits antagonize $G\beta\gamma$ effect but not by direct displacement of $G\beta\gamma$ from the channel. The palmitoylation sites on subunit $\beta 2A$ are responsible for its unique modulation of the channel and the reduced competition with $G\beta\gamma$ [51]. Another putative modulator of $G\beta\gamma$ effect is the synaptic protein syntaxin 1A that may be involved in scaffolding $G\beta\gamma$ to the calcium channels [52]. RGS proteins interact with $G\alpha$ and facilitate its GTPase activity. Such interaction may reduce calcium current inhibition by $G\beta\gamma$ [53,54].

Voltage-Independent G-protein-Mediated Inhibition of Calcium Channels

Functional studies in calyx-type nerve terminal [55] and in sympathetic neurons [56] have identified a rapid, PTX- and voltage-insensitive (VI) inhibition of calcium currents. The N terminus of $G\alpha_{q/11}$ is necessary for its binding to the C termini of $Ca_v2.1-2.2$ [49] and for mediating the VI inhibition [57]. Consistently, *in vitro* binding assay identified direct interaction of $G\beta\gamma$ with the N and C termini of $Ca_v1.2$, which mediates the L-type current. The mechanism of voltage-independent channel inhibition thus differs from that of voltage-dependent channel inhibition in several ways: instead of channel β subunit it involves $G\alpha_{q/11}$ binding to the same channel region as $G\beta\gamma$, and it requires simultaneous interaction of calmodulin [58].

Ras and Cancer

San Francisco, California*

Introduction: Ras Activation in Cancer

It has been 20 years since H-ras mutations were identified in DNA from the bladder cancer cell line T-24. Since this seminal observation, rates of mutation in H-ras, N-ras, and K-ras have been measured in most types of human cancers [1]. The clonal nature of these mutations in tumors strongly suggests a causal role, a suggestion that has been amply verified by mouse models of Ras-induced cancer. A striking result of this comprehensive survey is the considerable variation in frequency in Ras mutation between different types of cancer. In pancreatic carcinoma, K-ras is activated by point mutation in almost every case, whereas Ras mutations are hardly ever detected in mammary carcinomas, to cite two extreme examples. The biological or molecular basis of these observations is not yet understood. One interpretation is that alternative mechanisms of activating the Ras pathway (receptor amplification, activation of downstream pathways) also occur at varying frequencies. Another interpretation is that different types of cancer vary in their dependence on the Ras pathway. Another unresolved issue is the predominance of K-ras mutations over N-ras and H-ras: this may reflect different levels of expression of these genes in different tissues and different levels of dependence on each type. Mouse knockout experiments show that K-ras is essential [2], whereas N-ras and H-ras are not, consistent with K-ras being the most important form and therefore the most likely to be directly involved in carcinogenesis. However, other models must be considered: for example, each type of Ras may signal through a different set of downstream effectors, and K-ras happens to provide a repertoire

of signals that is consistent with malignant progression. Although most evidence points toward shared effectors among all three types of Ras, evidence for discrimination among effectors also exists [3].

In addition to mutations in Ras genes, gains and losses of Ras genes have been reported in human tumors [4–9]. In mouse tumors double minute chromosomes encoding H-ras have been identified [10]. Also in mouse models, progress increase of copy numbers of H-ras mutants appears to drive malignant progression, along with selective loss of the wild-type allele [11].

Pathways Downstream of Ras

Figure 1 shows pathways regulated by Ras. In addition to the well-established pathways that Ras activates, the Raf-MAP kinase cascade and the PI 3' kinase pathway, Ras activates RalGDS and possibly other effector pathways that are not well characterized [12]. Raf and PI 3' kinase pathways act synergistically to mediate Ras transformation, suggesting that inhibitors of either pathway have profound effects on Ras transformation [13]. This is an important issue in the context of drug development based on Ras pathways.

The precise molecular basis of synergy between effector pathways is not fully understood. However, there are multiple elements of these pathways that intersect and could contribute to synergistic interaction. For example, the cyclin D1 gene is a transcriptional target of the Raf-MAP kinase pathway, and cyclin D1 protein is stabilized by the PI 3' kinase pathway [14].

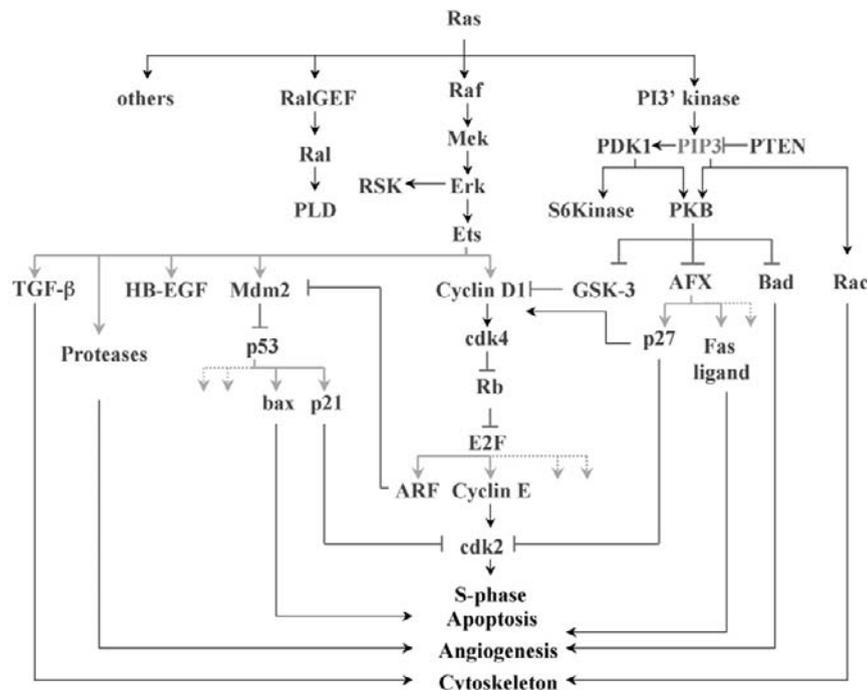

Figure 1

Until recently, there was little genetic evidence that the Raf-MAP kinase pathway is activated by mutation of gene copy number change in human cancer. However, the recent discovery that B-Raf is activated by mutation has changed this view dramatically. Two types of mutant have been described: one that renders B-ras independent of Ras and occurs in tumors in which Ras is wild type; another one that requires Ras interaction for full activity and occurs in tumors containing mutant Ras. It is conceivable that the high-throughput sequencing approach that identified these mutations may yet reveal other activating events in the Raf-MAP kinase pathway. Nonetheless, these new data imply that activation of the Raf effector pathway is the major selection for Ras mutation in these diseases.

In contrast, genetic changes activating the PI 3' kinase have been well documented and are considered of major importance in human cancer. Loss of PTEN is by far the most frequent event that activates this pathway, but increases in copy number of Akt/PKB have been documented and implicate this arm of the pathway in PTEN-deficient tumors. In endometrial and cutaneous melanoma cancers, loss of PTEN and Ras activation are mutually exclusive, suggesting that in these conditions, the major selection for Ras mutation is activation of the PI 3' kinase effector pathway [15,16].

Mouse Models of Cancer

Mouse models of cancer provide important clues relating to the role of Ras in cancer. Many have involved forced expression of mutant Ras proteins under tissue-specific promoters, revealing transforming power of the Ras oncogene

in different physiological settings. An interesting aspect of these models is the sustained requirement for Ras expression even in advanced cancers: withdrawal of Ras expression causes complete regression of such tumors [17]. Recently a model has been developed in which mutant K-ras is activated sporadically: this appears to be an excellent model for sporadic human lung cancer [18].

Other informative rodent models have used mutagens to initiate cancers, followed by analysis of Ras activation and progression. The classic studies of Sukumar and Barbacid and coworkers proved conclusively that Ras mutation can be the initiating event in cancer and showed that mutations caused by an early chemical insult can persist in latent forms before progressing to cancer [19]. The skin cancer models of Balmain and coworkers have revealed a step-wise activation of H-ras during initiation and progression: mutant H-ras alleles created by exposure to carcinogen are selectively amplified in a step-wise manner as the tumors evolve. In parallel to increased ras activity, levels of cyclin D1 increase during progression. A role of cyclin D1 in Ras transformation in this model was confirmed by demonstration that tumors' progression is strongly retarded in mice lacking the cyclin D1 gene. Even more striking effects of cyclin D1 were demonstrated recently in a model of mammary carcinogenesis driven by Ras, erbB, wnt, or myc: the former two oncogenes were completely dependent on cyclin D1, whereas the latter were not [20]. This clear role of cyclin D1 points toward the importance of the Raf/MAP kinase effector pathway in Ras transformation, since this pathway activates transcription of cyclin D1 directly. However, a role of the PI kinase pathway cannot be ruled out, as this pathway stabilizes cyclin D1 through inhibition of GSK-3-mediated degradation.

Prospects for Cancer Therapy Based on Ras

Attempts to block Ras signaling in human cancers by inhibiting posttranslational farnesylation have been stalled by the fact that K-ras, the major form of ras involved in human cancer, can also be modified by geranylgeranylation. Thus allows continued K-ras activity in the presence of farnesyl transferase inhibitors. Such inhibitors may have clinical value through their action on other cellular targets, however [21]. More recent approaches to blocking Ras activity have targeted enzymes downstream of Ras. A Raf kinase inhibitor entered clinical trials recently [22], and a MEK inhibitor followed soon afterwards [23]. Attempts to block other enzymes downstream of Ras are also under way [24].

Study of how cellular location influences the biological activity of signaling proteins is entering a second phase of important discoveries. Some of the very earliest studies on tyrosine kinases and Ras proteins recognized that these otherwise cytosolic proteins required membrane association in order to function. However, new work is providing a reminder that membrane structure is complicated and variable, and that the itineraries of Ras and other signaling proteins to and from membrane surfaces still contain mystery and controversy. The simple model of inactive cytosolic protein versus functional membrane-bound Ras has evolved into the greater challenge of mapping the topography of entire signaling pathways. As in the beginning, Ras proteins are teaching us many of these lessons.

Cytosolic Ras Is not Functional

The original work defining the membrane-binding domain of the vHRas protein discovered that if vHRas failed to achieve membrane binding it was completely and thoroughly transformation defective [1]. This crucial insight led to attempts to achieve similar potent interference with Ras function through pharmacological means, the results of which are described by A. D. Cox in another chapter of this volume. Further genetic and biochemical studies identified a farnesyl

transferase (FTase) that attaches a farnesyl isoprenoid to the Ras C-terminus (see Fig. 1, Step 1; [2]). Two (and in most cases, three) additional modifications must also occur to convert Ras into a fully active protein at the plasma membrane [3]. However, the cellular site for these modifications came as a bit of a surprise. Both a unique farnesyl-directed protease and a farnesyl-cysteine methyl transferase were unexpectedly found to be integral proteins of the endoplasmic reticulum (ER) (Fig. 1, Steps 2 and 3; [4,5]). The speed and efficiency of these processing enzymes had kept the discrete visits of all four mammalian Ras proteins [6] to the endomembrane system from being noticed.

After Modifications by Endomembrane Enzymes, Ras Proteins Move Toward the Cell Surface

The KRas4B protein requires no further modifications, although it must contain a basic domain adjacent to its farnesylated cysteine to strengthen its eventual interaction with the plasma membrane [7]. The route through which KRas4B accesses the cell surface does not appear to be the traditional secretory pathway [8], but remains uncharacterized (Fig. 1, Step 5b). However, both HRas and NRas take similar journeys along the Golgi and onward to the cell surface, astride

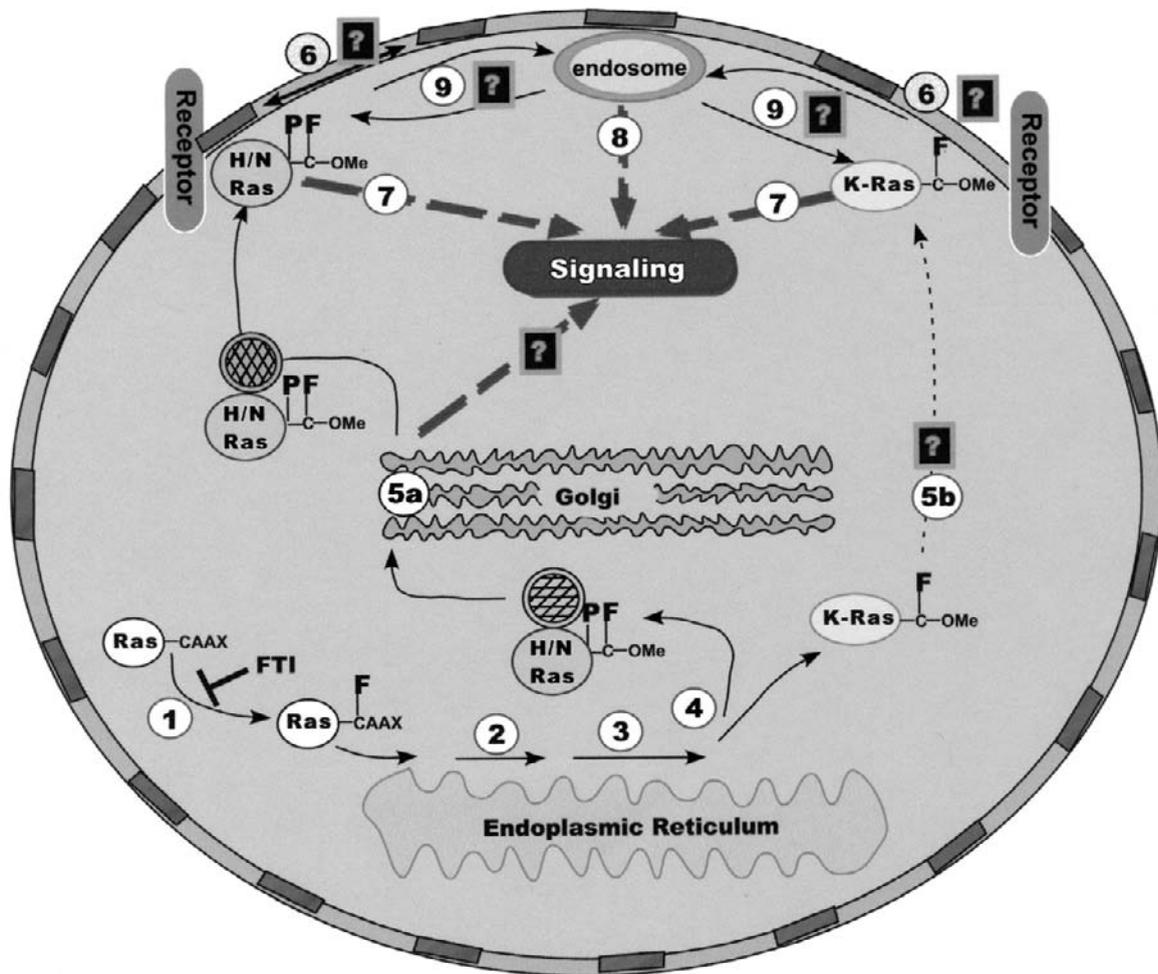

Figure 1 The life and times of Ras: a diagrammatic representation of Ras trafficking and localization. Newly synthesized Ras proteins are farnesylated in the cytoplasm (Step 1), then translocated to the cytoplasmic surface of the endoplasmic reticulum for further modification by a resident protease (Step 2) and carboxyl methyltransferase (Step 3). For H- and N-Ras, further modification occurs in the form of palmitoylation (Step 4). Processed Ras proteins then proceed to the plasma membrane and acquire functional activity. For H- and N-Ras, this occurs through vesicular transport through the endomembrane system (Step 5a). K-Ras4B is not palmitoylated and achieves plasma membrane localization via a separate, but undefined, mechanism (Step 5b). Once at the plasma membrane, H- and N-Ras (and perhaps K-Ras4B) partition into (and possibly out of) lipid rafts (shaded areas, Step 6). The primary events of Ras activation and signaling occur at the plasma membrane (Step 7). Endosomes (Step 8) may also be important sites for some Ras-mediated signaling events, but see text for questions on how Ras may be involved or recycled to the membrane (Step 9). Ras activity can be inhibited by preventing the first farnesylation step in this itinerary using farnesyl transferase inhibitors (FTI, Step 1). Steps where major unknowns remain in Ras trafficking and signaling are indicated with question marks.

intracellular vesicles [6]. Enroute both proteins claim a second modification—attachment of palmitoyl groups to C-terminal cysteines (Fig. 1, Step 4; [6,9]).

No enzyme for Ras palmitoylation has yet been identified. Two endomembrane proteins (ERF2 and ERF4/SHR5) that are required for palmitoylation of yeast Ras1 are known [10,11]. However, HRas palmitoylation also takes place, repeatedly, at the plasma membrane. A protein acyltransferase for G protein α subunits has been partially purified from plasma membranes, but it acylates HRas poorly [12]. This leaves no current candidate for an enzyme with the crucial function of maintaining Ras plasma membrane attachment. Enzymes for Ras palmitate removal also await discovery. An acyl-protein thioesterase (APT1) that depalmitoylates G protein α subunits has been cloned [13] and can depalmitoylate

HRas *in vitro*, but its activity toward HRas *in vivo* has not yet been confirmed.

Importantly, there are several studies showing that mutant HRas proteins that fail to be released from the ER or *cis*-Golgi [9,14] are almost completely transformation defective. A very new report suggests some intracellular HRas may be able to interact with Raf-1 even if endocytosis blocked [15]. Currently, there is almost nothing known about the fundamental processes or proteins that enable HRas and NRas to dock onto the surface of trafficking vesicles or move to the plasma membrane (Fig. 1, Step 5a). The first candidate is the PRA1 prenyl-dependent escort for Rab GTPases, which also interacts with Ras proteins in the Golgi [16]. Discovering these proteins will provide powerful new tools for controlling Ras activity.

Destination-Cell Surface: Ras Proteins Distribute Among Several Plasma Membrane Domains

A significant recent advance is the discovery that Ras proteins (and other signaling proteins as well) are not scattered evenly throughout the plasma membrane, but instead can reside in subdomains of the plasma membrane (Fig. 1, Step 6 [17]). These domains are popularly termed “rafts” and contain lipids that can coalesce into detergent-resistant, light density droplets within the more disordered phase of the general lipid bilayer [18,19]. Cells that express the protein caveolin have an additional raft subtype termed caveolae. It is notable that rafts are not a fixed entity. Microdomains can show dramatic variations in their lipid composition and size based on the lipids synthesized by a cell [20] and on rearrangements that occur during activation of the cell [21,22].

Because most immunofluorescence or gradient techniques utilize detergents or pH 11 carbonate buffers, it has proved difficult to study these dynamic, mobile microdomains without risking the release or intermixing of proteins that were separated in the native membrane. For proteins with a highly basic domain, such as KRas4B, pH 11 effectively neutralizes even the positive charge of lysines, and subsequent interactions may no longer reflect those initially present. For palmitoylated proteins, complete neutralization must occur rapidly to avoid hydrolysis of the delicate thioester-linked palmitates. The interaction of HRas with rafts appears to be tenuous, as the protein is easily dislodged by detergents [23,52], necessitating the use of nondetergent fractionation methods [24]. To complicate matters, although palmitates are readily accepted into the tightly packed core of a raft, farnesyl groups are poor inhabitants of raft-like domains [19,23,25]. HRas and NRas, which possess both palmitoyl and farnesyl modifications, therefore face a biophysical dilemma that is also a biological opportunity. The opposing effects of their lipids may poise these Ras proteins for easy transit into and out of raft domains. Such movement could then provide more than one location where regulatory interactions could occur. Given these caveats and speculations, optimism flavored with a good deal of skepticism should accompany current experimental conclusions.

Nevertheless, multiple techniques indicate that HRas proteins can reside graciously in raft domains [26,27]. Several reports indicate that some HRas is further localized within caveolae [28], where it may interact with caveolin-1 [29]. Whether this “some” represents a little or a lot of HRas is a matter of discussion. Discussions of how Ras proteins distribute among membrane domains are important, as HRas proteins with substitute membrane binding motifs can display aberrant signaling [30–32]. No consensus has yet been reached with the KRas4B protein. KRas4B has been reported to either avoid rafts [28,33], or to be concentrated in caveolin-rich (i.e., raft) domains [34]. Despite our poor understanding of the properties that control where or how tightly Ras proteins partition within the membrane, the underlying rationale that raft and nonraft membranes may

each present unique environments for regulatory and signaling interactions is compelling.

Ras Proteins Finally Become Active at the Plasma Membrane

Normal Ras proteins gain functional competency at the plasma membrane. This is due largely to the requirement that in order for a cellular Ras protein to become GTPbound it must interact with a guanine nucleotide exchange factor (GEF) [35]. GEFs are themselves placed along the plasma membrane through interactions initiated by receptor-generated calcium signals, phosphatidylinositols, and tyrosine phosphorylations. Thus coupling between Ras proteins and their GEFs may serve to (re)position *active* Ras at specific plasma membrane sites.

This possibility leads to two essential questions. Where are the active forms of each type of Ras located? Where do interactions of Ras-GTP with each of its effectors take place? A recent study suggests that HRas moves out of rafts when GTP-bound and that disrupting rafts diminishes the ability of HRas to activate Raf-1 [26,28]. In contrast, KRas4B is proposed to be in nonraft domains regardless of nucleotide state [28]. However, the question of whether Ras proteins are active when in raft domains (suggested by work in T and B cells and with EGF receptors in fibroblasts [21, 36–38]) or are inactive (especially if within caveolae) [27,39] remains an area of debate. One clear opportunity for discovery is to learn how GTP binding to HRas might be translated into lateral movement.

Although the mutations present in oncogenic Ras proteins cause constitutive elevations in GTP binding that occur prior to delivery to the cell surface, this does not seem to trigger premature signaling. In fact, in some situations, high levels of soluble oncogenic Ras proteins appear to dampen signaling [40]. An important unknown is whether membrane-bound oncogenic forms of Ras partition differently from the normal, cellular forms, or activate effectors in inappropriate locations.

Endocytosis—A New Stage for Ras Signaling

The plasma membrane has been considered the final destination for Ras, with the lipid-tethered protein undergoing repeated cycles of activation/inactivation and happily controlling signal passage through its territory. However, reports [41,42] that activation of the Raf-1/MEKK/ERK pathway may occur on early endosomes rather than the plasma membrane indicate that the tale of Ras location and signaling is not over [43,44]. During numerous signaling events, Raf-1 kinase is recruited to the plasma membrane where it interacts with GTP-bound Ras. However, this direct contact between Ras and Raf-1 does not seem to fully stimulate Raf-1 kinase activity [45]. Information from epidermal

growth factor (EGF)- or insulin-treated cells indicates that within minutes of its membrane recruitment [24], Raf-1 departs the plasma membrane aboard early endosomes (Fig. 1, Step 7), and it is there that the further steps of MEK and ERK phosphorylation may take place [42]. This finding immediately raises a plethora of questions. Do the endosomes form from rafts, caveolae, or more traditional coated pits [46]? Does Ras-GTP actually leave the plasma membrane and recycle immediately or simply break off the relationship before Raf-1 departs and remain available for interaction with additional effectors? If Ras enters the endosome, how does it reestablish its association with the plasma membrane (Fig. 1, Step 8)? At what location does a Ras protein interact with a GAP protein and return to the GDP state? This latter point is important as this site will then define when and where Ras signaling terminates. In neurons a complete and functionally competent signaling pathway, from the ligand NGF to Ras to ERK kinases, has been detected on clathrin-coated vesicles moving from the axon back to the cell body [47].

Drugs that Affect Ras Membrane Binding

For more than a decade it has been known that preventing Ras membrane binding can inhibit its oncogenicity. This has spurred the development of potent inhibitors of the farnesyltransferase enzyme (Fig. 1, Step 1) as novel cancer chemotherapeutics [48]. FTase inhibitors are not without their difficulties, however. Multiple other farnesylated proteins (e.g., lamins of the nuclear envelope, retinal transducin γ subunits, Rho GTPases [49]) are also targets of these compounds and may cause impairments in other important pathways. A significant frustration is that both NRas and KRas4B can be modified by a distinct prenyl transferase, GGTase I, that is not susceptible to FTase inhibitors [50]. An alternative strategy of dislodging already prenylated Ras proteins from membranes and accelerating their degradation, currently being explored with the prototype compound farnesylthiosalicylic acid, also appears to diminish Ras signaling [51]. As these studies demonstrate, manipulating the location of Ras proteins is not only possible, it is a tactic that can control Ras biological activity. The recent discoveries of Ras intracellular trafficking, partitioning in or out of rafts, and the link to endocytosis identify several new sites where novel approaches for controlling Ras location and its function can now be envisioned.

Introduction

Ras proteins (H-Ras, K-Ras4A and 4B, and N-Ras) are regulators of signal transduction, mutated in 30% of human cancers, and targets for novel approaches for cancer treatment. Ras proteins are the founding members of a superfamily of small GTP binding and hydrolyzing proteins (GTPases). The small GTPases that share the greatest amino acid identity with Ras, such as R-Ras, Rap, and Ral, constitute members of the Ras family of proteins (Fig. 1). Within this family, the R-Ras subfamily proteins (R-Ras, TC21/R-Ras2, and M-Ras/R-Ras3) exhibit the strongest structural and biological similarities with Ras (Fig. 1). While studies in experimental model systems have shown that R-Ras proteins can promote oncogenic transformation, there is only limited evidence for aberrant R-Ras function in human cancers. Thus, are R-Ras proteins simply inferior versions of Ras proteins, or do they play distinct roles in normal cell physiology? In this review, we first summarize the general features of R-Ras proteins that are shared with Ras proteins, and then we highlight unique features of each R-Ras protein.

General Properties of R-Ras Proteins: Variations on Ras

Structure

R-Ras proteins are GTPases of approximately 200 amino acids that share significant primary, secondary, and tertiary structural characteristics with the 21-kDa Ras GTPases (Fig. 2). In addition, R-Ras proteins possess extended amino (10–26 residues) or carboxyl-terminal residues not present in Ras proteins that account for their larger size

(approximately 25 kDa) and suggest functional differences with Ras proteins (Fig. 2). Therefore, the numbering of key R-Ras protein amino acid residues relative to Ras is by the addition of 26 (R-Ras), 11 (TC21), or 10 (M-Ras) to the Ras numbering system (Figs. 2 and 3).

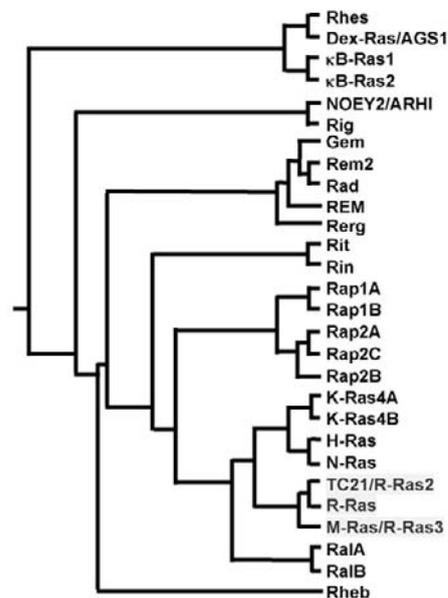

Figure 1 Ras family branch of the Ras superfamily. Small GTPases sharing strongest amino acid identity with Ras proteins are grouped together in the Ras branch. Among these, the three R-Ras proteins (highlighted) share the strongest overall amino acid identity with Ras. The dendrogram was generated by alignment of primary sequences of human proteins using ClustalW, a dynamic sequence alignment program. From the resulting multiple sequence alignment, a distance matrix was prepared and used to construct the dendrogram. Branch lengths are proportional to the estimated divergence along each branch.

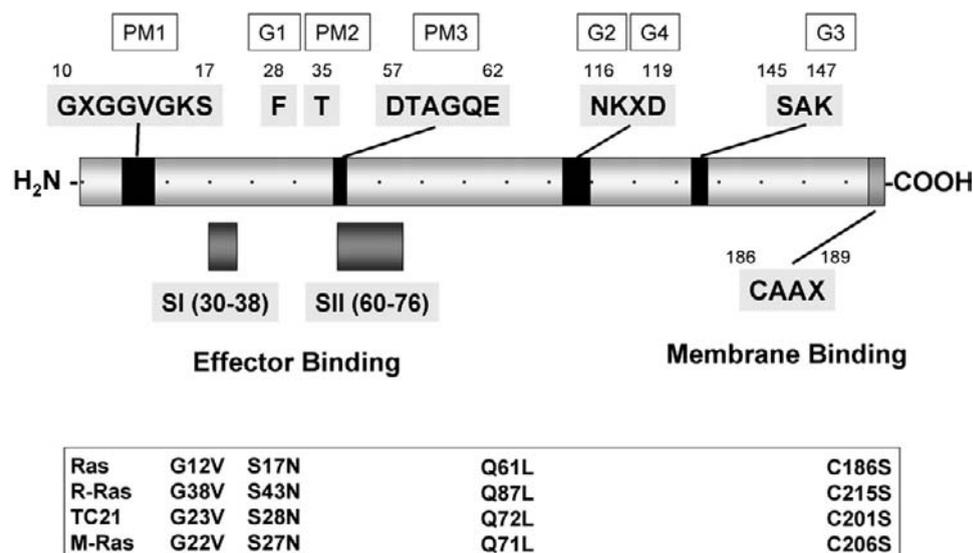

Figure 3 Functional amino acid sequence motifs of Ras and R-Ras proteins. R-Ras proteins possess a set of conserved sequence elements found in all small GTPases and are important for high-affinity binding of GDP and GTP guanine nucleotides, hydrolysis of GTP, or the conformational switch between the GDP- and GTP-bound states (numbers refer to positions in Ras proteins). These sequence elements are involved in binding to the phosphate and magnesium ions (PM) or to the guanine base (G) of the bound GDP or GTP nucleotide. By analogy to Ras proteins, the introduction of missense mutations in R-Ras proteins produces gain-of-function (e.g., Ras mutants G12V and Q61L), dominant-inhibitory (Ras mutant S17N), or loss-of-function cytosolic (Ras mutant C186S) mutants of R-Ras proteins that are useful reagents to study the signaling activities and biological functions of R-Ras proteins.

Table I Overlapping and Distinct Regulators and Effectors of R-Ras Proteins

GTPase	GAPs	GEFs ¹	Effectors ²	Putative effectors ³
Ras	P120 GAP, NF1-GAP, Gap1 ^m	Sos 1/2, RasGRF1/2, RasGRP1/2/3/4	Raf, PI3K, RalGEF, Rin1, PLC ϵ	AF-6, Nore1, RASSF1, Rin1, PLC ϵ
R-Ras	P120 GAP, NF1-GAP, Gap1 ^m , R-Ras GAP	RasGRF1, C3G, RasGRP1-3	PI3K	RalGEFs
TC21/R-Ras2	P120 GAP, NF1-GAP, Gap1 ^m , R-Ras GAP	Sos1, RasGRF1/2, RasGRP1-3, C3G	Raf*, PI3K, RalGEF*, PLC ϵ	AF-6, Rin1
M-Ras/R-Ras3	P120 GAP, NF1-GAP, Gap1 ^m	Sos1, RasGRF1, RasGRP1/3	Raf, PI3K	RalGDS, RGL3, Nore1, AF-6, Rin1, RapGEFs

¹RasGRP proteins are also called: Ca1DAG-GEFI (RasGRP2), Ca1DAG-GEFII (RasGRP), Ca1DAG-GEFIII (RasGRP3);

²Functional interactions

³Interactions determined, but functional activation not established

*conflicting reports

R-Ras proteins are modified by the more hydrophobic C20 geranylgeranyl isoprenoids [10]. Isoprenoid modification of Ras and R-Ras proteins is essential for biological function. Consequently, inhibitors (FTIs) of the enzyme farnesyltransferase which catalyzes the modification of Ras proteins, have been developed as inhibitors of oncogenic Ras function and are currently under clinical evaluation as anti-neoplastic drugs. Similarly, inhibitors (GGTIs) of the enzyme geranylgeranyltransferase I which catalyzes the modification of R-Ras proteins, have also been developed and have shown anti-tumor activity in preclinical studies [11].

Signal Transduction and Cell Biology

Like Ras, R-Ras proteins serve as relay switches that transmit signals initiated by diverse extracellular ligands to cytoplasmic signaling pathways. However, unlike Ras, the specific upstream signals which promote activation of endogenous R-Ras proteins are less well characterized, perhaps due in part to technical limitations and due in part to limited experimental analyses. Because Ras and R-Ras proteins share common GEFs, presumably many of the same signals that cause Ras activation also cause R-Ras protein family

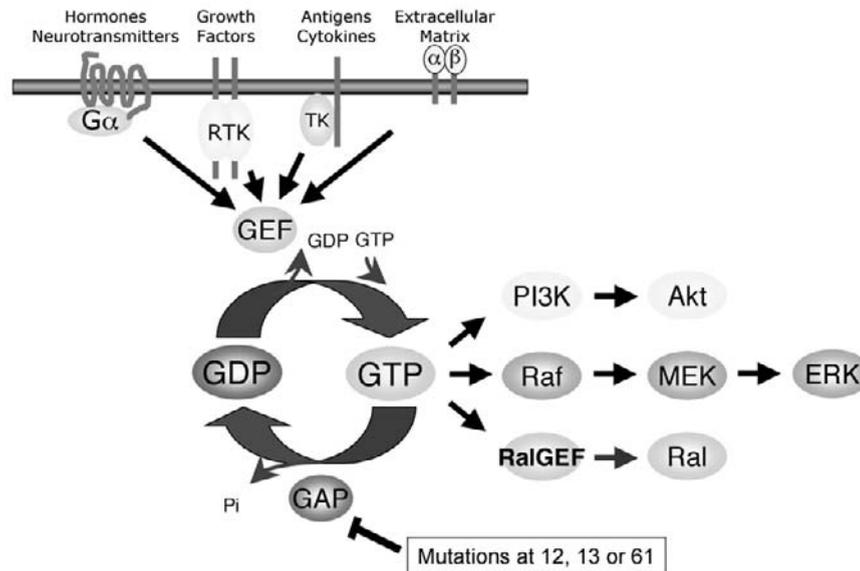

Figure 4 Ras family signaling pathways. Extracellular stimuli act on various cell surface receptors, including G-protein-coupled receptors, receptor tyrosine kinases (RTKs), tyrosine kinase (TK)-associated receptors, and integrins ($\alpha\beta$ subunits). The activated receptors typically cause Ras and R-Ras GTP-binding via the activation of guanine nucleotide exchange factors (GEFs) specific for one or more Ras and/or R-Ras proteins. GTPase activating proteins (GAPs) stimulate the intrinsic GTPase activity of Ras and R-Ras proteins to return the proteins to the inactive, GDP-bound state. Mutations analogous to those at Ras residues 12, 13, or 61 render R-Ras proteins insensitive to GAP stimulation, and constitutively GTP-bound and active in the absence of extracellular stimuli. The GTP-bound protein preferentially binds to downstream effectors, such as phosphatidylinositol 3-kinases (PI3Ks), Raf serine/threonine kinases, or GEFs specific for Ral small GTPases. The PI3K lipid kinases phosphorylate phosphoinositides and promote formation of phosphatidylinositol 3,4,5-phosphate (PIP3), which in turn facilitates the activation of other cytoplasmic signaling proteins, including the serine/threonine kinase Akt/PKB. Raf phosphorylates the MEK1/2 dual specificity protein kinases, which in turn phosphorylate the ERK1/2 serine/threonine kinases.

activation (Fig. 4). Once activated, Ras protein signaling is mediated by interaction with a multitude of downstream effector targets (Table I). Among these, the Raf serine/threonine protein kinases, the phosphatidylinositol 3-kinase lipid kinases (PI3Ks), and the Ral small GTPase guanine nucleotide exchange factors (RalGEFs) have been established as key mediators of Ras-mediated transformation [12]. The contribution of each of these major Ras effectors to R-Ras family-mediated transformation is distinct, and will be discussed in the following sections. The core effector domain of Ras (amino acids 32–40) is critical for interactions with downstream signaling molecules, and R-Ras proteins share complete identity with this core effector domain. However, flanking residues within the extended effector domain (Ras amino acids 25–45) of R-Ras proteins differ more significantly, suggesting that R-Ras subfamily members may regulate a distinct set of effectors and cytoplasmic signaling pathways.

R-Ras subfamily GTPases are implicated in regulating biological functions both similar to and distinct from those controlled by Ras proteins. For example, like Ras, constitutively activated forms of all three R-Ras members have been

shown to cause growth transformation of NIH 3T3 mouse fibroblasts. Similarly, both Ras and R-Ras family proteins regulate cell survival, actin cytoskeletal organization, and differentiation. However, R-Ras proteins also cause consequences opposing those of Ras, and the biological phenotypes of R-Ras function can be significantly different from those of TC21 and M-Ras. The following sections detail the distinct properties and roles of each R-Ras subfamily member in signal transduction and cell biology.

R-Ras

GDP/GTP Regulation

R-ras encodes a 218 amino acid protein that shares approximately 55% identity overall to Ras proteins (Fig. 2) [1]. While no GEFs have been shown to be specific for R-Ras, R-Ras GDP/GTP exchange is stimulated by GEFs for some Ras and/or Rap small GTPases (e.g., RasGRF, RasGRPs, C3G) (Table I) [13–19]. R-Ras interacts with some of the known Ras GAPs, and GTP hydrolysis is stimulated by p120GAP, GAP1^m and R-Ras GAP (Table I) [20–22].

Signal Transduction

R-Ras fails to activate the Raf>MEK>ERK mitogen-activated protein kinase (MAPK) cascade, which is the key effector pathway required for Ras-mediated transformation of rodent fibroblasts (Table I). However, R-Ras strongly activates the PI3K/Akt signaling pathway, perhaps the second most critical effector pathway for Ras-mediated transformation and survival [23–25]. This effector pathway has also been shown to be required for R-Ras-mediated cell survival and transformation [24,26,27]. R-Ras apparently does not utilize the RalGEF pathway [26], which contributes significantly to Ras-mediated transformation of human cells [28]. Nevertheless, the GTP-bound form of each R-Ras family member can bind to isolated Ras binding domains of Raf and RalGDS, which enables the selective detection of activated R-Ras proteins [29].

Cell Biology

Although mutated *R-ras* genes have not been identified in human tumors, introduction of point mutations analogous to those that cause mutational activation of Ras (38V, 87L) stimulate R-Ras transforming potential. Unlike Ras, in which mutations at positions 12 and 61 are similar in their transforming potency, in members of the R-Ras family, activating mutations analogous to Ras codon 61 (e.g., 87L, 72L, or 71L) are significantly more potent than those analogous to Ras codon 12 [8,26,30,31]. Although constitutively activated mutants of R-Ras cause tumorigenic transformation of NIH3T3 mouse fibroblasts, the strong morphological transformation observed in Ras-transformed rodent fibroblasts is not observed with activated mutants of R-Ras [30,32]. Further, constitutively activated R-Ras fails to rescue the block in growth caused by expression of dominant negative Ras [33], suggesting that R-Ras induces transformation by regulation of signaling pathways distinct from those utilized by Ras. Hence, the normal biological role of R-Ras may lie in processes distinct from those that contribute to cell transformation.

R-Ras has been shown to control and promote integrin-mediated cellular adhesion [34,35]. For example, expression of dominant negative R-Ras (S43N) in adherent cells reduced cell spreading and expression of activated R-Ras in suspension cells promoted spreading and fibronectin assembly, suggesting that R-Ras is required for integrin-mediated cell adhesion [34]. R-Ras also promoted retinal neural outgrowth on laminin, a process dependent on integrin function [36]. R-Ras induced integrin-mediated migration and invasion of breast epithelial cells on collagen, by signaling to $\alpha 2$, but not $\alpha 5$ integrin receptors, suggesting that R-Ras induces selective activation of integrins [37]. R-Ras-mediated control of adhesion may be linked to both Src- and Raf-mediated pathways [38,39]. R-Ras has also been shown to control apoptosis [33], although the effect on the apoptotic response varies depending on cell type. For example, R-Ras promoted myeloid cell apoptosis in response to growth factor withdrawal, an effect which is abrogated by overexpression of Bcl-2 [40].

In contrast, a greater pool of evidence from several model cell systems suggests that R-Ras blocks the apoptotic response. For example, constitutively activated R-Ras induced protection from cell death following withdrawal of anchorage or growth factors in RIE-1 rat intestinal epithelial cells, C2C12 skeletal myoblasts, and BaF3 cells, an IL-3-dependent mouse pro-B-cell line [24,27,41].

In summary, R-Ras is both similar to and distinct from Ras. R-Ras utilizes only some of the same effectors and signaling pathways, such as PI3K/Akt, and regulates only some of the same cellular functions, such as cell proliferation and survival, similar to Ras. Conversely, R-Ras also functions in opposing cellular regulatory roles, such as in cell adhesion. Thus, R-Ras effector utilization is expected to be distinct from that of Ras.

TC21/R-Ras-2

GDP/GTP Regulation

Human TC21/R-Ras-2 is a 204 amino acid protein that shares approximately 70% amino acid identity to R-Ras and approximately 60% amino acid identity to H-Ras (Fig. 2) [32,42]. TC21 is regulated by a set of GEFs and GAPs similar to those that regulate R-Ras GDP/GTP cycling, but responds to more Ras regulators than does R-Ras (Table I) [17]. TC21 intrinsic GTP/GDP cycling activity is activated by SOS, RasGRF1/2, C3G, and RasGRP [2,17,43]. Hydrolysis of TC21-bound GTP is enhanced by known Ras GAPs (p120 GAP, Gap1^m, neurofibromin) (Table I) [2,17]. Hence, extracellular signals that regulate Ras GDP/GTP cycling are also likely to cause concurrent regulation of TC21 activity.

Signal Transduction

Whether Raf is an important mediator of TC21-induced transformation remains unclear (Table I). One study found that TC21 failed to interact with and activate Raf kinases *in vivo* [2,44]. Consistent with this failure to activate Raf is the observation that, unlike Ras, TC21, as well as R-Ras, failed to induce senescence in primary fibroblasts [45]. Ras-mediated induction of senescence has been attributed to activation of the Raf/ERK pathway. However, other studies determined that TC21 interacts with and activates Raf kinases, and activates the Raf/MEK/ERK signaling pathway in transformation [43,46]. The basis for these different observations is currently not known. The recent observation that association of 14-3-3 proteins with Raf-1 prevented R-Ras- or TC21-, but not Ras-induced, activation of Raf-1 suggests that the presence of other Raf-1 interacting proteins may account for these different observations [47].

Using various screening approaches for protein-protein interactions, TC21 was found to interact with RalGDS and RalGDS-like proteins (RGL, RGL2) [48,49]. However, whether TC21 activates RalGEFs is unclear (Table I).

One study showed that although TC21 interacted with RalGDS proteins, in contrast to Ras, TC21 did not promote activation of RalA [49]. Thus, similar to observations with R-Ras [50,51], TC21 can bind but not activate RalGDS, suggesting that RalGDS may not be a key effector for mediating TC21-induced growth transformation. In contrast, another study [52] determined that activated TC21 stimulated activation of Ral. These differences may be attributed to experimental, cell type, or cell strain type differences [53] or to the utilization of different expression vectors for ectopic expression of TC21 proteins [54].

Aside from the conflicting observations regarding whether Raf or RalGDS are involved in TC21-mediated transformation, there is a strong consensus that TC21 binds the p110 catalytic subunit of PI3K and stimulates PI3K and PI3K-dependent Akt activities (Table I) [49,52,55]. Inhibition of PI3K function with pharmacological inhibitors or genetic manipulation reversed TC21-mediated transformation of rodent fibroblasts [49,52,55]. However, activated PI3K alone does not cause transformation of fibroblasts [56], suggesting that TC21 must also utilize other effectors to mediate transformation. Like Ras, TC21 also activates phospholipase C epsilon (PLC ϵ) (Table I) [49]. Further study is clearly necessary to determine whether PLC ϵ -mediated second messenger activation is important for TC21-mediated transformation.

Cell Biology

Of the R-Ras subfamily members, TC21 regulates biological functions most similarly to Ras. Unlike other R-Ras subfamily members, activating mutations in *tc21* or overexpression of wild-type TC21 protein have been observed in several human tumors and tumor-derived cell lines [32,43,46,57–59]. Similar to activated forms of Ras, activated TC21 causes strong morphologic growth and neoplastic transformation in several cell types, including rodent fibroblasts and human breast epithelial cells [31,43,57]. In addition, unlike R-Ras, activated TC21 can overcome the growth inhibitory actions of dominant negative Ras, indicating that TC21 and Ras share some common functions important for normal cell proliferation [33]. However, in contrast to Ras, neither TC21 nor R-Ras caused premature senescence of primary rodent fibroblasts [45]. In addition to regulating cell proliferation and transformation, TC21 promotes cell survival of matrix-deprived intestinal epithelial cells and chemotherapeutic drug-treated NIH3T3 cells [41,55]. Like Ras, TC21 also promoted PC12 pheochromocytoma cell differentiation and growth cessation and blocked serum deprivation-induced differentiation of C2 myoblasts [44]. In addition, like R-Ras, activated TC21 has been shown to induce migration and invasion of breast epithelial cells [37].

In summary, of the three R-Ras subfamily proteins, TC21 is regulated and functions most similarly to Ras to control processes such as cell proliferation and transformation. While controversy exists over the mechanism by which TC21 causes transformation, it is clear that chronically activated versions

are potent oncogenes, and contribute to various aspects of the transformation phenotype and to tumor formation in humans. Whether the three *ras* genes are functionally distinct or redundant remains an issue of considerable debate. Therefore, whether *tc21* is functionally distinct or redundant with *ras* genes is an issue that also remains to be elucidated.

M-Ras/R-Ras-3

GDP/GTP Regulation

Human M-Ras is a 209 amino acid protein that shares approximately 60% amino acid identity to R-Ras, TC21, and Ras. M-Ras GTP/GDP cycling is regulated more similarly to Ras than to R-Ras or TC21 (Table I). For example, while M-Ras is activated by RasGRF and RasGRP, unlike R-Ras and TC21, it is also stimulated by SOS [8,17]. In addition, like Ras but unlike TC21 and R-Ras, C3G failed to upregulate GTP-bound M-Ras [17]. Similarly, M-Ras GTPase activity is stimulated by the same set of GAPs, such as p120 Ras GAP that enhances GTP hydrolysis on Ras [8,17].

Signal Transduction

The effectors and pathways stimulated by M-Ras to cause transformation may involve both known Ras effectors and novel mechanisms, but are poorly characterized (Table I). Compared to Ras proteins, M-Ras interacts only weakly with Raf kinases [8], and activated M-Ras is only a weak stimulator of the Raf > MEK > ERK MAPK cascade [3,6,8,60]. However, inhibition of ERK activation by pharmacological inhibitors caused a reduction in M-Ras-mediated fibroblast transformation, and Raf-1 cooperated with M-Ras to induce transformation, suggesting that Raf is a key player in M-Ras-mediated transformation [8].

In addition to Raf, M-Ras associates, to varying extents, with other known Ras effectors, such as RalGEFs, PI3K, and Rin1 [8]. Like Ras and TC21, M-Ras was found to interact strongly with RGL3, a RalGDS-like protein [61]. In addition, M-Ras bound strongly to and activated PI3K in fibroblasts [60].

M-Ras-GTP also interacts with newly identified Rap GEFs, MR-GEF, and RA-GEF-2, which possess a Ras association (RA) domain [62,63]. Co-expression of constitutively activated M-Ras with RA-GEF-2 resulted in upregulation of GTP-bound, plasma membrane-bound Rap1 [63]. In contrast, activated M-Ras blocked MR-GEF-mediated GTP loading of Rap1A [62].

Cell Biology

Of the R-Ras subfamily proteins, the least is known regarding M-Ras biological function. Like R-Ras and TC21, M-Ras controls cell proliferation and survival and may also regulate actin cytoskeletal dynamics. M-Ras is only weakly transforming in NIH3T3 fibroblasts [6] and also induced transformation of melan-a immortalized mouse melanocytes [4].

Activated M-Ras also caused IL-3-independent proliferation of RX-6 mast cell/megakaryocyte or BaF3 mouse myeloid cells and blocked serum withdrawal induction of C2 myoblast differentiation [3,7,8]. Like Ras, R-Ras, and TC21, activated M-Ras also promoted cell survival in PC12 cells, by a mechanism that requires PI3K function [60]. It should be noted that these activities of M-Ras were revealed by overexpression of mutated M-Ras proteins, and hence, it is not clear whether they accurately reflect functions of endogenous M-Ras activated by extracellular stimuli.

Conclusions

In summary, the three R-Ras subfamily members, R-Ras, TC21/R-Ras2, and M-Ras/R-Ras3 mediate cell growth, division, differentiation, and death by utilizing both novel pathways and those regulated by Ras and other Ras-related proteins. Further, R-Ras subfamily members, especially R-Ras itself, clearly contribute to cellular processes such as integrin-mediated cell adhesion in a manner distinct from that of Ras. Deciphering the full contribution of R-Ras, TC21, and M-Ras to cellular growth control clearly awaits further study.

Molecular and Structural Organization of Rab GTPase Trafficking Networks

Christelle Alory and William E. Balch

Institute for Childhood and Neglected Disease,
The Scripps Research Institute, La Jolla, California*

Introduction

Rab proteins are small GTPbinding proteins (20 to 25 kDa) that belong to the Ras superfamily. Rab proteins specifically direct membrane traffic in eukaryotic cells. Having been first discovered early in the 1980s in the budding yeast *Saccharomyces cerevisiae* and referred to as Ypt proteins, the name “Rab” comes from “the *Ras* protein from *brain*” as the first Rab (Rab3/Smg25) in mammalian cells was identified in bovine and rat brain [1]. The Rab family of GTPases is now the largest family of GTPbinding proteins in the cell [2]. They have been found in all eukaryotes studied and new members have been recently identified through the genome sequencing projects: *S. cerevisiae* contains 11 members, *Caenorhabditis elegans* has 29 members, *Drosophila melanogaster* has 26 members, and *Arabidopsis thaliana* has 57 members. *Homo sapiens* tops the list with 63 members. The fact that the number of Rab proteins is correlated with the complexity of the organism underlines their biological importance in membrane traffic. Rab proteins play a crucial role in regulating the intracellular protein and lipid trafficking between the different specialized organelles of a eukaryotic cell [3,4]. They are important in a myriad of vesicle-mediated transport pathways where they are found to be crucial in recruiting molecular motors, tethering factors, and SNAREs (SNAP REceptors) that guide, dock, and fuse the transport vesicle with target membrane compartments [5,6].

Rab Proteins are Recycling GTPases

Like all other GTPases, Rab proteins cycle between inactive GDP-bound and active GTP-bound forms. Because Rab

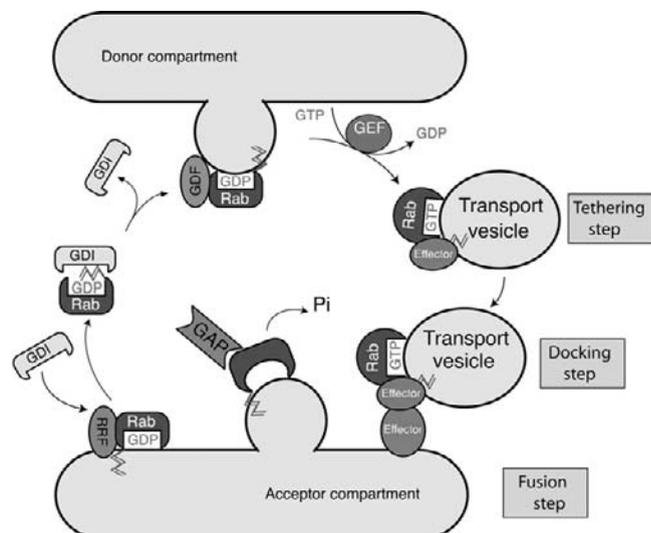

Figure 1 The general Rab GTPase cycle. Rab GTPases undergo a dynamic cycle of delivery and retrieval from the membrane. Delivery is initiated by the cytosolic form of Rab-GDP bound to GDI. Following recruitment, Rab is activated to the GTP-bound form by a Rab-specific GEF leading to recruitment of motors, tethers, and fusion factors. During or following fusion, Rab is converted back to the GDP-bound form and retrieved from the membrane by GDI through RRF.

proteins are prenylated and insoluble, they are maintained in the cytosol in their inactive GDP-bound state in a complex with a chaperone-like protein, the guanine-nucleotide dissociation inhibitor (GDI) (Fig. 1) [7,8]. During Rab recruitment to membranes, GDI is released and exchange of GDP for GTP is catalyzed by a guanine nucleotide exchange factor (GEF), activating the Rab protein. In the GTP-bound state, the Rab protein can recruit various effectors that direct the vesicle to the target membrane compartment and promote fusion [3–5,9]. Following hydrolysis by a GTPase-activating protein (GAP), the GDP-bound Rab protein is then extracted from the membrane and recycled back into the cytosol by GDI [7,8].

Rab Proteins: An Evolutionarily Conserved Family

Rab proteins define a diverse, but conserved functional family. They share ~20–95% overall amino acid identity within the mammalian family. Although more divergent between species, higher eukaryote homologs of several yeast proteins can complement function. For example, it has been shown that mammalian Rab1, involved in endoplasmic reticulum (ER) to Golgi transport, can replace the function of the yeast counterpart Ypt1p [10]. Sequence alignment of Rab proteins shows the presence of 8 conserved and 11 non-conserved regions (Fig. 2). Conserved domains include the universal 4 nucleotide binding regions (G1, G3, G4, G5) that are signature motifs found in nearly all Rasuperfamily

proteins, 3 phosphate/Mg²⁺ binding regions (PM1–PM3), and carboxyl-terminal cysteine motifs required for prenylation [11]. The variable regions are represented by the effector region G2 (also named switch I domain), the switch II domain, and the Rab family (RabF1–RabF5) and Rab subfamily (RabSF1–RabSF3) specific sequence motifs [2,12,13]. Based on the identification of these Rab-specific sequence motifs, Rab proteins have been clustered into 10 subfamilies (Rab1, 3–6, 8, 11, 22, 27, and 40). Based on the crystal structure of Rab proteins, Rab-specific motifs (RabF) are located in and around the switch domains and are thought to contribute to the binding of common regulatory molecules through such conserved regions. These have also been referred to as the complementarity determining regions (RabCDR) based on the structure of Rab3a bound to rabphilin3A (a Rab3A effector) [14]. Molecules that bind through RabF motifs may include GEFs, GAPs, GDIs, and Rab escort protein (REP) (also referred to as the choroideremia gene product; CHM [8]) involved in prenylation [8,15]. On the other hand, the RabSF regions, which show more variation, might allow specific binding of Rab proteins to a variety of divergent effector molecules involved in each of the different membrane trafficking pathways regulated by Rab [2,12].

Structural Organization of the Rab Proteins

Given their homology to other Ras superfamily GTPases, as early as the 1990s, the structural and biochemical information

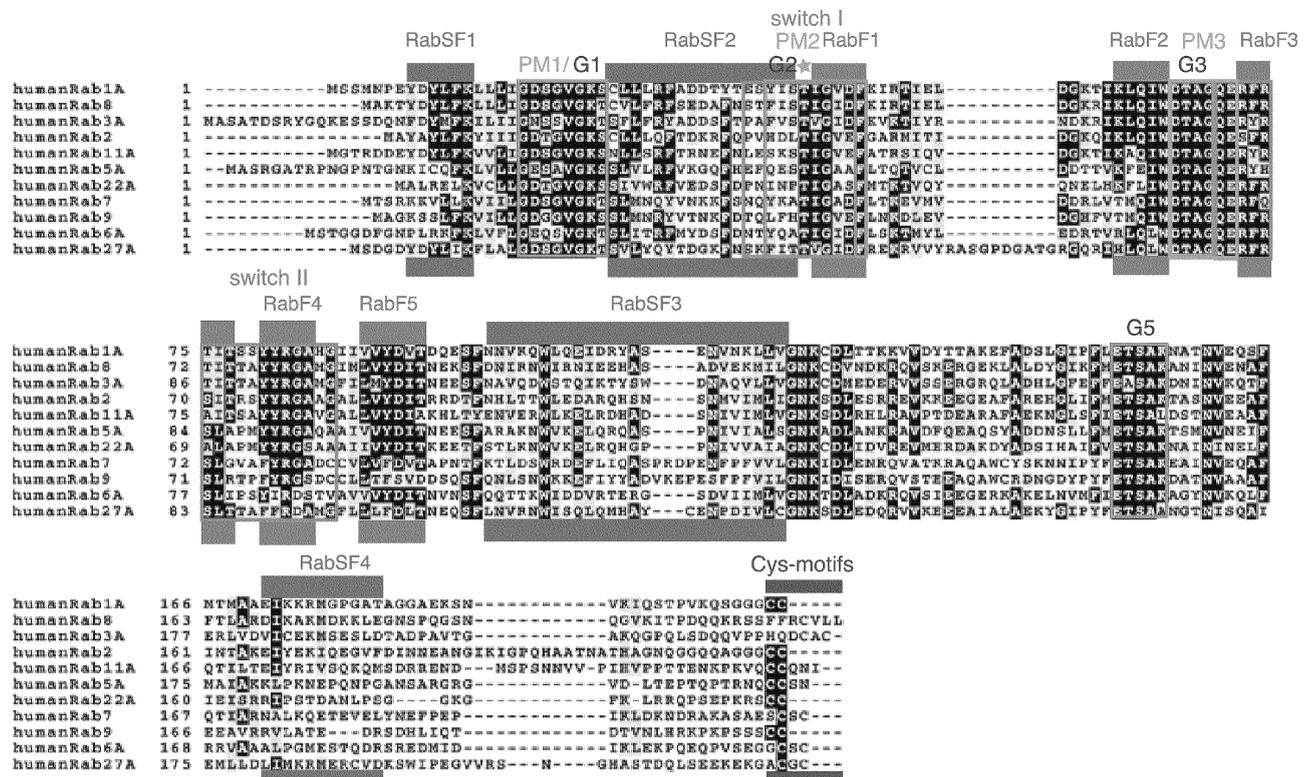

Figure 2 Rab-family and Rab subfamily domains direct Rab function. Illustrated are the location of the Rab family (RabF) and Rab subfamily (RabSF) domains in the context of nucleotide binding domains (G1–G5) and switch regions (switch I and II). These regions play an important role in defining the organization of the Rab gene family. (Adapted from Peirera-Leal and Seabra, *J. Mol. Biol.* 313, 889–901. With permission.)

available from the three-dimensional structure of the *ras* oncogene protein p21^{Ras} has been used to dissect Rab function [11]. This approach was confirmed by recent structures of Rab proteins. These now include Rab3A and Rab3A in complex with the effector Rabphilin-3A [13,14,16], Ypt51p (the Rab5 homolog) in its active GppNHp-bound conformation [17], and the yeast Sec4p (the Rab8 homolog) in both inactive GDP- and active GPPNHP-bound conformations [18]. Analysis of these structures reveals that the structure of Rab proteins is largely superimposable on the core structure *ras* oncogene despite its complete sequence divergence.

The structural core of the Rab proteins is comprised of six central β -strands in a relatively flat β -sheet that is sandwiched by three helices on either side, forming the guanine-nucleotide pocket. Comparison of the two Sec4 structures confirms that the protein undergoes a drastic conformational change in the regions called switch I and switch II which interact with effectors when Rab switches from the GDP- to the GTP-bound state [18]. Structurally, switch regions differ significantly from other Ras superfamily members. Consistent with this, mutagenesis studies have shown that the switch regions are crucial for the interaction of Rab proteins with regulatory proteins, such as GEF and GAP. Thus, Rab function recapitulates that classic *ras* oncogene GTPase paradigm.

Posttranslational Modification and Localization

To bind to membranes where they direct the assembly of protein complexes directing vesicle traffic, Rab GTPases need to be posttranslationally modified by the attachment of two 20-carbon geranylgeranyl moieties to cysteine residues located at their hypervariable carboxyl terminus [19,20]. Their consensus sequence for this posttranslational modification has been identified to be either -XXCC, -XCXC, or -CCXX where C is cysteine and X is any aliphatic amino acid [21]. The exceptions are Rab8 and Rab13, which contain only a single cysteine residue attached to a more traditional Ras-like -CAAX box. Deletion or mutation of the cysteine residues to serine eliminates the prenylation and inactivates all Rab species examined to date [22]. Prenylation requires the accessory component REP/CHM, and the enzyme complex geranylgeranyltransferase II (RabGGTase) composed of α and β subunits [23,24]. Unlike other members of the Ras superfamily that can be directly farnesylated by farnesyl transferase [19], newly synthesized Rab proteins are not recognized by the RabGGTase complex until they bind REP. Following prenylation, REP delivers the newly synthesized Rab proteins to the correct compartment through information found in their hypervariable 30–40 amino acid carboxyl terminus [25]. Indeed, each Rab protein has a very limited subcellular distribution diagnostic of its function [1,3,26]. For example, Rab1 is localized to the ER-Golgi interface in the exocytic pathway, Rab5 is found restricted to early endocytic compartments and clathrin-coated vesicles forming at the cell surface, Rab3A to synaptic vesicles, etc. The fact that 63 different Rab proteins have been identified to date suggests that there are at least this many different

specialized trafficking pathways found in the differentiated cells of higher eukaryotes. As expected, many Rabs are associated with only a single tissue type, suggesting that the limited number of Rabs found in yeast (11 Rabs total) may define the rudimentary trafficking comprising the basic functions of the exocytic and endocytic pathways. In this regard, it is interesting to note that only 2 Rabs in yeast are essential proteins. Ypt1 is required for ER to Golgi transport, and Sec4 is required for Golgi to cell surface transport. We have proposed the “homing hypothesis” whereby each Rab dictates the formation of an effector complex (the Rab interactome) that mediate a specific trafficking event in the cell, thereby ensuring high fidelity to membrane trafficking [6]. In addition, it was proposed that Rabs also control the mosaic organization of endocytic compartments by segregating cargo and transport factors into subdomains [27].

Effector Molecules: REP/CHM, GEF, Effectors (Motors/Tethers/Fusogens), GAP, and GDI

Rab proteins can interact with a diverse range of proteins [4,9]. GEFs are believed to play a critical role in the activation of Rab-GDP to Rab-GTP upon delivery to a specific membrane. Only a few exchange factors have been identified to date and they appear quite divergent indicating highly specialized function. However, it is likely that a conserved domain(s) promoting exchange will be a common feature of Rab GEFs. Once activated to the GTP-bound form and bound to membranes, Rab proteins recruit effector molecules [4,5,9]. While they are a highly heterogeneous group, they appear to fall into discrete categories in which they can be thought to function as (1) “tethers” that promote vesicle docking (such as p115, a Rab1 effector [28]; Rabphilin-3, RIM1 and 2, Rab3 effectors [29]; and EEA1, a Rab5 effector [5]), (2) SNAREs that direct vesicle fusion (SNAREs [30]), or molecular motors and their cognate receptor proteins that guide movement of membranes through the cell via the actin and microtubule cytoskeletons. A Rab6b effector is rabkinesin-6-involved microtubule binding during mitosis [31,32]. A Rab27a effector is the melanophilin/myosinVa complex involved in melanosome biogenesis and trafficking [33]. As many of the interactions between the Rab and various effector molecules could be indirect, this leads to the general principle that Rab GTPases serve as the focal point to regulate the assembly/disassembly of large macromolecular complexes to integrate the activity of these diverse components to move a vesicle from one cellular location to the next with speed and accuracy. While subfamily isoforms >80% homology (i.e., Rab3A–3D) may use evolutionarily related effectors; the high heterogeneity in effector function in more divergent Rabs emphasizes that they have become highly specialized in order to direct the specific function of a particular membrane transport step in the endocytic and exocytic pathways.

Following docking and fusion, conversion of Rab from the GTP- to the GDP-bound state is mediated by Rab-specific GAPs. Again, this appears to be a heterogeneous group,

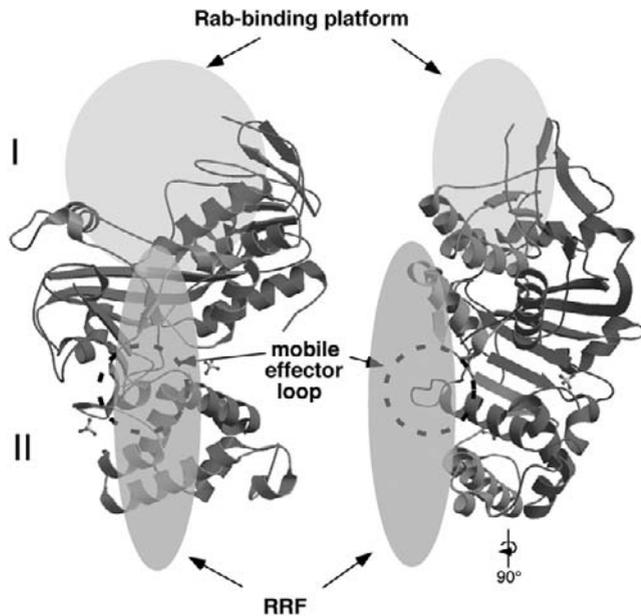

Figure 3 Structural organization of GDI, a Rab recycling factor. Shown is the two-domain organization of α GDI in which the upper domain (I) functions as a platform to bind Rab, whereas the lower domain (II) is involved in interaction with RRF, a membrane-associated recycling complex that assists GDI in removal of Rab from the membrane.

although only a few have been identified and their function in vesicle docking and fusion remains to be determined [9]. Following hydrolysis Rab-GDP must be recycled. This is the job of a common recycling protein, GDI, that interacts with all Rab GTPases studied to date [7,8]. The function of GDI has been extensively investigated using both structural and molecular approaches [34–38]. The structure of GDI shows that it is a two-domain protein—an upper domain I involved in Rab binding and a lower domain II involved in Rab extraction (Fig. 3). By binding of Rab through domain I in a reaction assisted by a membrane receptor (Rab recycling factor or RRF) which interacts with domain II [36], the prenyl groups of Rab are transferred from the lipid bilayer to the surface of GDI. Lipid binding triggers release of the Rab-GDI complex from the membrane. The cytosolic pool of the GDI-Rab complexes provides the principle source for re-recruitment of Rab to membrane. While the exact mechanism by which GDI releases Rab during delivery is unknown, it is believed to involve a guanine nucleotide dissociation factor (GDF) that displaces Rab from GDI in conjunction with interaction with the activity of Rab-specific GEFs found on the membrane [7,8].

Rab Dysfunction and Disease

Defects in intracellular trafficking can lead to a large variety of human diseases [39–41]. For example, mutation of the brain-specific guanine nucleotide dissociation inhibitor (α GDI), involved in Rab recycling, leads to X-linked mental retardation [42]. In contrast, mutation of

the REP1/CHM involved in Rab prenylation leads to choroideremia, an X-linked recessive eye degeneration disease [43]. To date, only one Rab protein, Rab27, has been directly implicated in hereditary disease. Mutation of Rab27a results in Griscelli syndrome (GS) in humans and the *ashen* phenotype in mice [15]. Rab27a has been shown to play a critical role in the transport of secretory granules, such as melanosomes in melanocytes, lytic granules in cytotoxic T lymphocytes and platelet-dense granules [15]. Moreover, Rab27a might also be the trigger for the retinal degeneration in CHM, since it is present at high levels in the retinal pigment epithelium and choriocapillaris of the eye, and it is not prenylated in CHM patients where REP1/CHM is missing [44]. Because Rab proteins are the key regulators of all the membrane trafficking activity and dictate the function of highly specialized cellular trafficking pathways, we anticipate that a variety of other hereditary disorders are likely to be discovered that directly involve Rab dysfunction.

Perspective

Rab GTPases comprise a large gene family that dictates the organization of the exocytic and endocytic pathways of eukaryotic cells. Without Rabs, the subcellular organization typically found in eukaryotes would not exist. Thus, they provide a critical foundation for cell development and differentiation through their ability to organize divergent membrane trafficking complexes that dictate specificity to membrane interactions.

Cellular Roles of the Ran GTPase

Jomon Joseph and Mary Dasso

*Laboratory of Gene Regulation, National Institute of Child Health and Human Development,
National Institutes of Health, Bethesda, Maryland*

Introduction

Ran is an abundant nuclear GTPase that has been extensively characterized for its role in nuclear transport. The Ran pathway is involved in spindle assembly and postmitotic nuclear assembly, independent of its role in nuclear transport. The distribution of Ran's nucleotide exchange factor (RCC1) and GTPase activating protein (RanGAP1) leads to the formation of gradients of Ran-GTP within the cell. These gradients provide spatial cues that direct Ran-dependent processes. These cues are monitored through a common set of Ran-GTP binding effector proteins that were originally characterized as nuclear transport receptors. The past year has seen a considerable deepening in our understanding of the molecular features of this pathway and of how gradients of Ran-GTP are built and utilized. In this chapter, we relate these new developments to Ran's role in cellular processes.

Introduction to the Ran Pathway

Ran's intrinsic rates of nucleotide hydrolysis and exchange are slow. These reactions are accelerated *in vivo* by RCC1, a guanine nucleotide exchange factor (GEF) [1], and by RanGAP, a GTPase activating protein [2]. A family of proteins that share homologous Ran-GTP-binding domains are also important *in vivo* regulators of Ran [3]. RanBP1 is the best-understood member of this family. RanBP1 does not have intrinsic GAP activity, but it increases the rate of RanGAP1-mediated nucleotide hydrolysis by roughly an order of magnitude *in vitro* [4]. Moreover, it is essential *in vivo* for RanGAP1-mediated hydrolysis of Ran-GTP bound to nuclear transport receptors [5].

There are four notable aspects of the Ran pathway that distinguish it from many other members of the Ras superfamily. First, Ran is not isoprenylated, and is thus freely soluble. Second, Ran is an extremely abundant protein (roughly 0.4% of total cellular protein [6]), as are many of

its interacting partners. Third, there is an asymmetric distribution of Ran's regulators throughout interphase [7]. RCC1 is chromatin bound and hence nuclear, whereas RanGAP1 and RanBP1 are predominantly cytoplasmic. This causes a steep gradient of RanGTP across the nuclear membrane [8,9]. Fourth, as mentioned above, Ran-GTP binds to a family of proteins that have a common structural motif (RanBD) first found in RanBP1. RanBP2, another Ran binding protein with four RanBD domains, is localized to the cytoplasmic side of the nuclear pore complex (NPC) [10]. The role of RanBP2 in promoting nucleotide hydrolysis has not been clearly demonstrated. A third member of this family, RanBP3, acts as a cofactor for the formation of complexes destined for nuclear export [11,12].

Structural Analysis of Ran Pathway Components

Several points emerging from structural studies on Ran and its regulators are notable. First, the structure of Ran itself is dramatically regulated by nucleotide binding, particularly in the switch I region [13]. The orientation of the switch I region precludes association between Ran-GDP and transport receptors [14], providing a molecular rationale for the specificity for transport receptors in binding to Ran-GTP only. Second, the Ran pathway shows an interesting divergence from other Ras-like GTPases with respect to its mechanism of GAP-mediated hydrolysis [15]. RanGAP consists of 11 leucine rich repeats of 28 to 37 residues each, forming a crescent [16]. While it was widely assumed that GAP-mediated hydrolysis of all ras family GTPases would require an arginine residue provided by the GAP protein, this is not the case for Ran [15]. Structures of a Ran-RanBP1-RanGAP ternary complex in the ground- and in the transition-state show that RanGAP does not provide a catalytic arginine. Rather, Ran alone provides the machinery for GTP hydrolysis, with tyrosine 39 of Ran replacing the arginine provided by other GAPs.

Third, RanBP1 is essential *in vivo* because it dissociates Ran-GTP from transport receptors to permit access of RanGAP [5]. Transport receptor binding to Ran-GTP blocks RanGAP-mediated hydrolysis, because the interaction sites for RanGAP and receptors overlap [14,15]. However, binding of Ran to transport receptors does not inhibit association between Ran-GTP and RanBP1 family members because they bind on different surfaces of Ran [14]. RanBD domains make extensive contacts that have been described as a “molecular embrace” of Ran [14], causing a shift in the Ran’s acidic C terminus, and promoting Ran’s release from bound transport receptors. Although RanBP1 can activate GAP-mediated hydrolysis *in vitro* about an order of magnitude [4], RanBP1 does not directly contact RanGAP within the RanGAP-Ran-GTP-RanBP1 ternary complex [15]. It appears that RanBP1 exerts a positive influence on GAP-mediated hydrolysis by shifting the C terminus of Ran, thereby facilitating interactions between Ran and RanGAP.

Fourth, RCC1 is a seven-bladed propeller protein [17], similar in structure to the WD40 propeller structure of the GEF for the G- β heterotrimeric GTPase. RCC1’s interaction interface with Ran resides in the loops between the propeller blades on one face of the protein [18]. RCC1 associates with chromatin through other proteins [19]. It has recently been demonstrated that the interaction of RCC1 with chromatin is mediated by histones [20]. RCC1 binds directly to mononucleosomes and to histones H2A and H2B [20], resulting in a modest stimulation of the catalytic activity of RCC1.

Ran’s Role in Nuclear Transport

The requirement for Ran in nuclear transport has been extensively studied (Fig. 1) (reviewed in reference [7]). Ran-dependent nuclear transport is mediated by a family of transport receptors that are able to freely pass through the NPC in an energy-independent manner. Importin β was the first member of this family to be described, and all members of this family (both import and export receptors) bind to Ran-GTP. Import receptors bind to their cargo in the cytoplasm, where Ran-GTP is absent, and permit cargo translocation through the NPC. In the nucleus, RCC1-generated Ran-GTP binds to the import receptors and releases the cargo. Conversely, export receptors and their cargo associate within the nucleus as complexes containing Ran-GTP. After these complexes translocate to the cytoplasm, RanGAP1 induces GTP hydrolysis thereby causing the dissociation of the complexes. A small Ran-GDP-binding protein, NTF2, re-imports Ran-GDP back into the nucleus after each round of transport, where regeneration of Ran-GTP is achieved by RCC1.

Within this model, Ran-GTP concentration regulates receptor loading and unloading in a manner that is appropriate to the nucleus or cytosol. A number of interesting variations have been reported recently upon the way in which different receptors utilize the Ran-GTP gradient. First, while it is essential in this model that each transport receptor can only

carry a particular cargo in one direction, there is no requirement that receptors cannot carry other cargos in the opposite direction. Indeed, bidirectional receptors have recently been reported in yeast [21] and mammals [22].

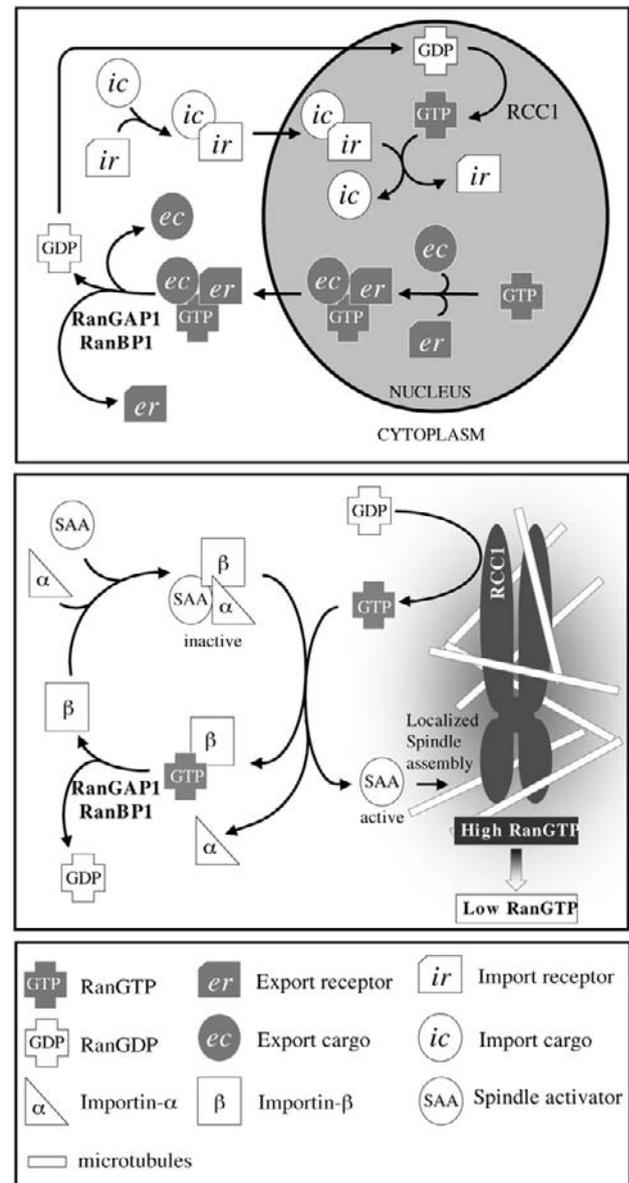

Figure 1 Ran regulates nuclear trafficking through the association and dissociation of transport complexes during interphase (upper panel). The compartmentalization of RanGAP1, RanBP1, and RCC1 cause an asymmetric distribution of Ran-GTP across the nuclear envelope. Import receptors and cargo form complexes in the cytosol and transit across the NPC. In the nucleus, Ran-GTP binds to the import receptors and causes cargo release. Import receptors return to the cytosol in association with Ran-GTP. RanGAP1, and RanBP1 hydrolyze Ran-GTP to Ran-GDP, promoting receptor recycling. Export receptors and Ran-GTP bind to export cargo in the nucleus. These complexes transit to the cytosol, where they dissociate after RanGAP1-mediated Ran-GTP hydrolysis. Elevated Ran-GTP levels near chromosomes promote mitotic spindle assembly (lower panel). Importin α and importin β inhibit spindle assembly activators (SAA) at low Ran-GTP concentrations in regions distant from chromosomes. Near chromosomes, Ran-GTP concentrations are higher. Ran-GTP binds to importin β , disrupting inhibitory complexes and allowing full SAA activity.

Second, many receptors interact with at least some of their cargo through adaptor proteins [7]. The best-characterized case of adaptor utilization is the import of substrates bearing classical nuclear localization signals (NLS) [7]. The Importin α adaptor protein binds to NLS sequences. Importin β associates with the importin α -NLS complex and promotes its transit through the NPC. Importin α is re-exported in association with Ran-GTP and CAS, an importin β -family export receptor. Two molecules of GTP are thus hydrolyzed during the import cycle of each NLS-bearing substrate, allowing substrates accumulation against a steeper nuclear-cytoplasmic concentration gradient through the expenditure of greater free energy.

Third, accessory proteins control the loading of cargo to receptors in many instances [7]. For example, the Crm1 export receptor binds RanBP3, a nuclear RanBD-containing protein [12,23]. RanBP3 does not directly bind to export substrates, but it increases the affinity of Crm1 for both Ran-GTP and export cargo. RanBP3 also associates with RCC1 in a manner that is stimulated by Ran, and activates RCC1s as Ran GEF [11]. Moreover, RanBP3 promotes the association of Crm1 and RCC1, perhaps acting as a scaffold to coordinate the loading of Ran-GTP onto Crm1. RanBP3 inhibits the association of unloaded Crm1 to the NPC in a manner that is relieved by Ran-GTP [12], suggesting that it permits Crm1 association to the NPC only after export complex assembly is complete.

Finally, import cargo unloading can be controlled by events in addition to Ran-GTP binding [24,25]. For example, DNA containing binding sites for the TBP transcription factor stimulates Ran-GTP-mediated dissociation of TBP from its import receptor (Kap114p) [24]. This stimulation suggests that TBP is released from Kap114p only when it finds its target DNA sequences within the nucleus. Import receptors may thus direct not only nuclear import but also intranuclear targeting or assembly of particular cargos into macromolecular complexes.

Ran's Function in Mitotic Progression

A number of observations have implicated Ran in regulating the onset of mitosis. When arrested in S phase and then shifted to the restrictive temperature, a mutant Hamster cell line with a temperature-sensitive allele of RCC1 (tsBN2 cells) progresses into mitosis prematurely, accompanied by nuclear envelope (NE) breakdown, precocious chromosome condensation, and activation of p34cdk1/cyclin B kinase [26]. These observations and others have shown that tsBN2 cells do not arrest appropriately in S phase in response to unreplicated DNA [27]. Moreover, mutant Ran proteins can block onset of mitosis in the presence or absence of nuclei in *Xenopus* cycling extracts, which would otherwise alternate between interphase and mitosis [28,29]. The molecular events whereby Ran regulates mitotic onset in metazoans remain unclear, and there is a lack of strong evidence from fission and budding yeast that Ran plays an analogous role for regulation of mitosis in either of those organisms [30].

Ran's Function in Spindle Assembly

Ran regulates spindle assembly in a manner that is independent of its nuclear transport function [31–35]. Spindle assembly is severely defective when Ran-GTP levels are lowered in *Xenopus* cytosolic factor (CSF) arrested egg extract, a mitotic system that is devoid of intact nuclei. Under these conditions, spindles are disorganized with low densities of microtubules (MTs) [33,35]. Conversely, increased levels of Ran-GTP in CSF extracts cause massive polymerization of MTs in a manner that does not require chromosomes or centrosomes [32,33,35]. It had been previously found that mitotic chromosomes can locally stabilize MTs, probably through the action of a diffusible MT-stabilizing factor produced by a chromatin-associated enzyme (reviewed in reference [36]). Since RCC1 binds to chromatin [37], it was natural to speculate from these results that Ran-GTP could play a role in the localized stabilization of mitotic MT by chromosomes. Consistent with this idea, it has recently been directly demonstrated through fluorescence resonance energy transfer (FRET) experiments that Ran-GTP concentrations are elevated in the vicinity of mitotic chromosomes [8].

The molecular mechanism by which Ran carries out its function in spindle assembly is closely related to its role in nuclear transport. Importin α/β bind and inhibit spindle assembly factors, such as the motor accessory proteins TPX2 and NuMA [38–40]. Ran-GTP near chromosomes destabilizes these inhibitory complexes, thereby allowing spindle assembly factors to function locally (Fig. 1). At a distance from chromosomes, Ran-GTP would presumably undergo nucleotide hydrolysis and inhibition would be restored. In reality, it is likely that the location of nucleotide hydrolysis may also be very important for spindle function, since vertebrate RanGAP1 is localized to the spindle in a highly regulated manner [41]. Another key aspect of this model is that importin α and β also promote the nuclear localization of spindle factors, ensuring that they are not inappropriately active on MT in interphase cytosol.

Since numerous other proteins involved in spindle assembly are nuclear during interphase, it is likely that additional targets are regulated in a similar manner. This notion is also supported by the fact that Ran regulates several different aspects of spindle assembly, such as the frequency of transition from shrinkage to growth of MTs (e.g., MT dynamics) [42,43], the capacity of centrosomes to nucleate MTs [42], and the behavior of other motor proteins or their accessory subunits [43,44]. Taken together, these data suggest that Ran may have acted in a multifaceted manner to coordinate assembly of spindles with respect to the mitotic chromosomes.

Ran's Role in Postmitotic Nuclear Assembly

Studies in *Xenopus* egg extracts have suggested that Ran is required for postmitotic NE assembly [45,46]. Nonhydrolyzable forms of Ran-GTP and loss of RCC1 activity or depletion of Ran all block early events of nuclear fusion

during NE assembly in egg extracts [45]. Addition of Ran-GTP reverses this inhibition, leading to the conclusion that Ran has an important role in re-formation of NE at the end of mitosis. Both nucleotide exchange and hydrolysis on Ran are required for this function to be fulfilled [45]. Remarkably, GST-Ran bound to beads can assemble structures resembling NE in egg extracts [46]. These structures contain NPC and are capable of nuclear transport. RCC1-bound beads do not assemble NE in this assay. Zhang and Clarke [46,47] have argued that Ran actually precedes RCC1 in binding to chromatin and can act as an RCC1-independent signal for NE assembly.

In an exciting set of new reports [48], it has been shown that importin β is required for NE assembly induced by Ran on beads. Concentration of importin β on beads is sufficient to induce NE assembly in *Xenopus* egg extracts in a manner similar to Ran-coated beads, while beads bound with other transport receptors did not have this property. Moreover, the function of importin β in NE assembly is disrupted by a mutation that decreases the affinity of importin β for nucleoporins, but not by a mutation that disrupts the interactions of importin β with importin α . In contrast to the mechanisms of nuclear transport and spindle assembly, it thus appears that importin β functions in NE assembly by recruiting NPC components rather than by importin α -dependent interactions with cargo protein.

Conclusions

Ran regulates nuclear transport, cell cycle progression, spindle assembly, and postmitotic NE assembly, suggesting a wide role for Ran in coordinating events during the cell cycle. These facets of Ran are mechanistically linked in two ways. First, in all cases where we have a rudimentary molecular understanding of Ran function, it appears that Ran-GTP gradients provide spatial cues that serve to indicate the localization of the chromatin. This notion is particularly well supported for nuclear transport and spindle assembly. Second, gradients of Ran are interpreted through a common set of Ran-GTP-binding effectors, with the importin β protein playing a particularly prominent role.

Introduction

Rho GTPases form a discrete family within the Ras superfamily of small GTPases, which currently comprises 23 members, in mammalian cells [1]. They play an important role in controlling many cellular activities including transcription, cell cycle progression, membrane traffic, transformation, and apoptosis, but they are best known for regulating the organization of the actin cytoskeleton [2,3]. The actin cytoskeleton is a highly dynamic network of actin polymers that controls many aspects of cell behavior, including morphology, adhesion, migration, and phagocytosis. This chapter summarizes our current knowledge on the control of the actin cytoskeleton by Rho GTPases.

Effects of Rho GTPases on the Actin Cytoskeleton

The role of Rho, Rac, and Cdc42 in controlling actin cytoskeleton organization was first discovered in quiescent Swiss3T3 fibroblasts, where it was found that the activation of each GTPase induces distinct filamentous actin structures in response to extracellular stimuli (Fig. 1). Activation of Rho by lysophosphatidic acid (LPA), for example, causes the formation of stress fibers (contractile bundles of actin:myosin filaments traversing the cell and ending in focal adhesions) [4], activation of Rac by platelet-derived growth factor (PDGF) or insulin results in the formation of lamellipodia (membrane protrusions driven by actin polymerization that can detach and fall backward onto the cell body creating membrane ruffles) [5], and activation of Cdc42

by bradykinin leads to the formation of filopodia (thin finger-like protrusions consisting of actin filament bundles) [6,7]. In addition, crosstalk can occur between the three GTPases: Cdc42 can activate Rac and stimulate membrane ruffling, and Rac can activate Rho to form stress fibers [5–7].

The effects of Rho, Rac, and Cdc42 on the actin cytoskeleton are not, however, restricted to fibroblasts, and over the last decade Rho GTPases have been implicated in many actin-dependent events in a wide variety of different cell types. Often, Rho GTPases function in a coordinated manner to promote complex changes to the actin cytoskeleton, while in other cases Rho GTPases can have opposing effects with Rac and Cdc42 causing membrane extension and Rho causing membrane retraction.

Rho, Rac, and Cdc42 also control the assembly of structures that are intimately associated with the actin cytoskeleton like cell-matrix and cell-cell contacts. Rho, for example, is required for the assembly of classical focal adhesions, while Rac and Cdc42 induce so-called focal contacts found at the leading edge of migrating cells [4,7,8]. Rho, Rac, and Cdc42 have also been reported to participate in the formation of cadherin-dependent cell-cell adhesion complexes [9], as well as tight junction complexes in epithelial cells [10]. Whether these effects on surface adhesion complexes are direct or mediated through the actin cytoskeleton is not entirely clear.

Cell Migration

Rho GTPases generate the protrusive forces needed for forward movement of migrating cells. Rac, in particular, is essential for the protrusion of lamellipodia at the leading

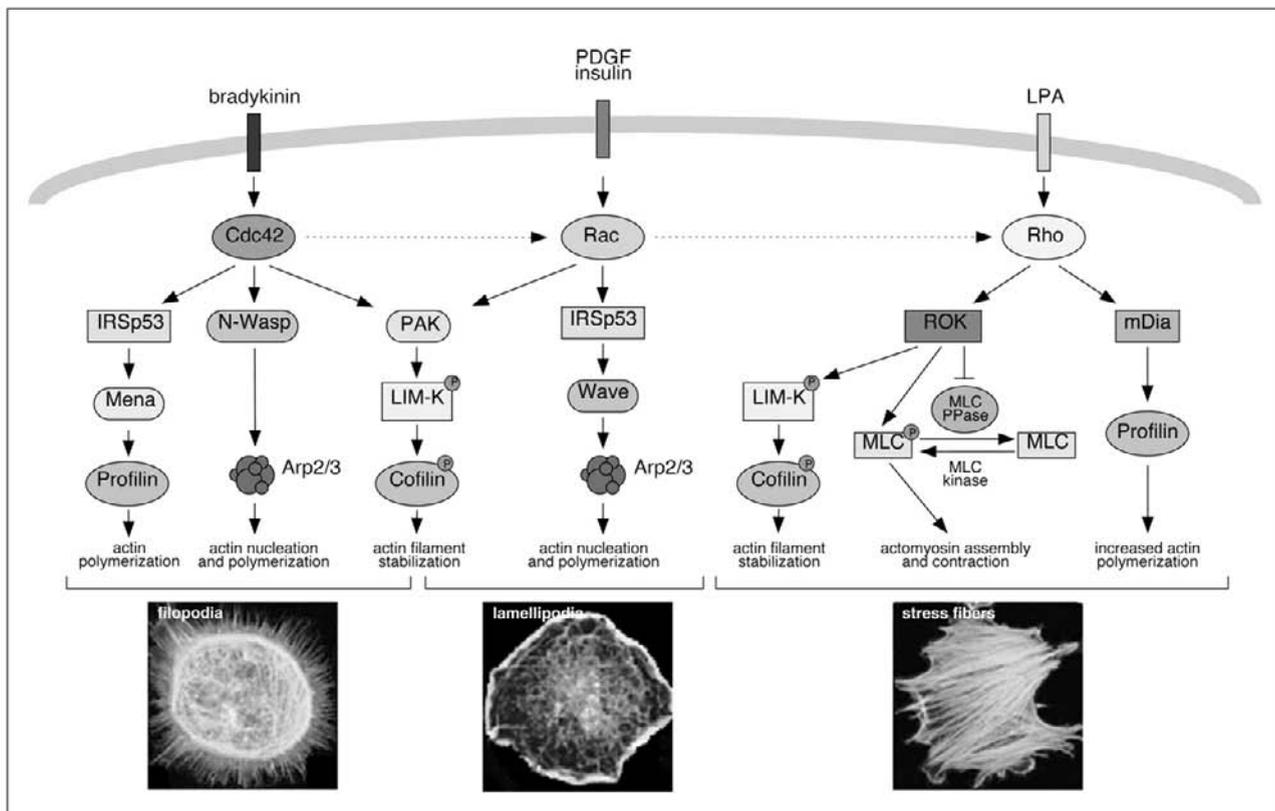

Figure 1 Schematic representation of Rho, Rac, and Cdc42 signaling pathways leading to organization of the actin cytoskeleton. Pictures of Swiss3T3 fibroblasts stained for filamentous actin structures are reprinted with permission from A. Hall (1998). *Science* 279, 509–514, Copyright 1998 American Association for the Advancement of Science.

edge of a moving cell, while Cdc42-stimulated filopodia have been implicated in the sensing of chemotactic gradients and may be important for polarized movement [11,12]. By regulating focal adhesion sites, Rho, Rac, and Cdc42 can also control the transient loss and reactivation of substrate attachment required for traction during cell movement.

Neuronal Morphology and Guidance

Rho GTPases are important regulators of neurite outgrowth, guidance, and plasticity [13]. Rac and Cdc42 have been shown to stimulate neurite outgrowth and extension, dendritic branching and spine formation, and growth cone guidance toward attractive extracellular guidance cues. In contrast, Rho induces neurite retraction, prevents spine formation, and mediates growth cone collapse in response to repulsive cues.

Phagocytosis

Rho, Rac, and Cdc42 also drive cytoskeletal remodeling required for particle internalization during phagocytosis [14], and Rac and Cdc42 are required for uptake of fluids and particles during pinocytosis [15]. Interestingly, during bacterial invasion, pathogens have found ways to modulate the activity of Rho, Rac, and Cdc42 thereby eliciting

changes in the actin cytoskeleton facilitating entry into the host cell [16].

Much less is known about the effects of other Rho GTPases on the actin cytoskeleton. The Cdc42-like protein TC10 induces filopodia [17], while two other Cdc42-like proteins, TCL and Chp, induce membrane ruffling [18,19]. Rnd1 and Rnd3 (RhoE), two apparently constitutively active Rho GTPases, cause disassembly of stress fibers and disruption of cortical actin filaments at least when overexpressed in cells [20]. RhoD stimulates the formation of actin-containing membrane protrusions and seems to antagonize Rho action by inducing stress fiber disassembly and blocking cytokinesis [21]. RhoG has been shown to induce Rac-dependent membrane ruffling and neurite outgrowth [22,23]. However, the physiological significance of these effects remains to be determined.

Signaling from Rho GTPases to the Actin Cytoskeleton

Signaling from Rho to the Actin Cytoskeleton

The pathways leading to Rho-induced actin:myosin filament assembly are relatively well understood and primarily involve two Rho-effectors, ROK and mDia (Fig. 1).

ROK α (Rho associated kinase, ROCKII) and its homolog ROK β (ROCKI) are Ser/Thr kinases that bind activated Rho and are required for stress fiber formation and cytoskeletal contraction [24]. Constitutively active ROK stimulates the formation of stellate stress-fiber-like structures, whereas kinase-dead ROK or pharmacological inhibitors of ROK inhibit Rho-induced stress fibers. Several targets of ROK have been identified which are likely to be involved in stress fiber formation and contraction. ROK phosphorylates and thereby inhibits myosin-light chain (MLC) phosphatase and can also phosphorylate MLC directly. Together, this leads to an increase in phosphorylated MLC, activation of myosin motor function, and subsequent actin-myosin-based contraction. ROK can also phosphorylate and activate LIM kinase (LIM-K) which in turn phosphorylates and inhibits the actin-severing protein cofilin, leading to stabilization of actin-filaments.

The Rho effectors mDia1 and 2 are members of the formin-related protein family and contain three formin homology domains through which they interact with the actin monomer-binding protein profilin and stimulate actin polymerization [25]. Dominant-active mDia induces weak stress fiber formation and dominant-negative mDia inhibits Rho-induced stress fiber formation. Co-expression of active ROK and mDia induces stress fibers very reminiscent of those induced by activated Rho suggesting that the cooperative activity of these two target proteins is crucial for actin:myosin filament assembly [26].

Signaling Downstream of Cdc42 and Rac

Recently, considerable progress has been made in identifying downstream effectors of Cdc42 and Rac which may mediate filopodia and lamellipodia formation (Fig. 1). The Wiscott-Aldrich-syndrome protein (WASP) and its neuronal isoform N-Wasp have been implicated in filopodia formation downstream of Cdc42 [27]. Overexpression of N-WASP leads to the enhanced formation of filopodia, and Cdc42-induced filopodia can be blocked by anti-N-WASP antibodies or WASP-deletion mutants. Activated Cdc42 binds to WASP and synergizes with PI4,5P₂ to unfold the protein allowing it to interact with and activate the Arp2/3 complex. WASP also interacts with monomeric actin and profilin acting as a scaffold protein to bring together the machinery required for actin polymerization. The Arp2/3 complex is known to initiate actin nucleation and stimulate the formation of branched networks of actin as seen in lamellipodia [28]. However, it is not clear how Arp2/3 controls the formation and organization of the straight actin bundles seen in filopodia.

Another member of the WASP family, Wave/Scar, has been reported to mediate Rac-induced membrane ruffling by stimulating the Arp2/3 complex [27]. Rac activates Wave via the insulin receptor substrate p53 (IRSp53) which interacts both with GTP-bound Rac and Wave [29]. Interestingly, IRSp53 and its brain-enriched isoform IRSp58 also bind to activated Cdc42 and participate in filopodia formation and

neurite outgrowth [30,31]. In this case, actin polymerization is mediated by binding of IRSp53 to Mena, a member of the Vasp/Ena family that interacts with profilin. Co-expression of Mena and IRSp53 strongly enhanced filopodia formation, though whether the interaction of Mena with profilin is needed in the formation of filopodia is unknown.

The PAK family of Ser/Thr kinases (PAK1, 2, and 3) also appears to promote actin assembly [32]. PAK binds to both Cdc42 and Rac and activated mutants of PAK1 have been reported to stimulate filopodia formation and membrane ruffling in fibroblasts, and induce neurite outgrowth in neuronal cells. Like ROK, PAK phosphorylates LIM-K leading to stabilization of actin filaments. PAK also phosphorylates and inactivates MLC kinase thereby reducing MLC phosphorylation and subsequent actomyosin assembly.

Conclusions

In the last decade it has emerged that Rho GTPases play a pivotal role in controlling actin filament assembly/disassembly during actin-based processes in all eukaryotic cells. A surprisingly large number of downstream effectors of Rho GTPases have been identified and some have been shown specifically to mediate signaling to the actin cytoskeleton. However, the detailed biochemical mechanisms by which this occurs are still unclear. The central role of Rho GTPases in regulating cell migration and bacterial invasion underscores their potential importance in the development of therapeutic agents to treat metastatic cancer or bacterial infections.

Regulation of the NADPH Oxidase by Rac GTPase

Becky A. Diebold and Gary M. Bokoch

Department of Immunology, The Scripps Research Institute, La Jolla, California

Phagocytic leukocytes play critical roles in the innate immune response to pathogens. An important component of this response is the ability of leukocytes to generate reactive oxygen species (ROS) via a membrane-associated NADPH oxidase [1,2]. This multicomponent enzyme utilizes electrons derived from intracellular NADPH to generate superoxide anion, which subsequently dismutates to H_2O_2 and other ROS that are used for host defense. The NADPH oxidase of phagocytic leukocytes was the first identified, and remains one of the best-characterized, Rho GTPase-regulated systems. Historically, the involvement of a GTP binding protein in the NADPH oxidase regulation was suspected when guanine nucleotide analogs such as GTP γ S and Gpp(NH)p were found to enhance superoxide production in cell-free assays [3–5]. A requirement for a prenylated cytosolic component suggested the involvement of a small GTPase [6]. Subsequently, it was simultaneously shown that either Rac1 or Rac2 GTPase was required for oxidase activity in the cell-free system [7,8], with Rac2 being the predominantly active isoform in human neutrophils [9]. Several additional lines of evidence have established that Rac is an integral and required component of the NADPH oxidase. Rac antisense oligonucleotide inhibited superoxide production in Epstein-Barr virus (EBV)-transformed B lymphocytes [10]. In neutrophils of bcr-null transgenic mice, Rac activity was increased due to the loss of a GTPase-activating protein, Bcr, and superoxide production was concomitantly increased, suggesting that not only is Rac activation required, but that it may be rate-limiting for oxidase activity [11]. Finally, the generation of Rac2-null mice led to the demonstration that *rac2* $-/-$ neutrophils had significantly reduced or absent superoxide production in response to various stimuli [12].

Components and Regulation of the NADPH Oxidase

The NADPH oxidase system of stimulated neutrophils catalyzes the one-electron reduction of oxygen to produce superoxide anion using NADPH as substrate (Fig. 1). In the unstimulated neutrophil, Rac exists as a complex with GDP dissociation inhibitor (GDI) in the cytosol [13]. When the phagocyte is activated through the action of soluble chemoattractants, chemokines, or phagocytic particles, Rac dissociates from GDI by an as yet undetermined mechanism. GDP is exchanged for GTP through the action of membrane-localized guanine nucleotide exchange factors (GEFs) [14] and Rac, now in its GTP-bound active form, becomes membrane associated [15]. Activation of the neutrophil also results in phosphorylation on multiple sites of cytosolic p47^{phox}, which exists in a complex with a third cytosolic component, p67^{phox}, followed by translocation of the p47^{phox}/p67^{phox} complex to the membrane [16,17]. Phosphorylation of p47^{phox} is thought to lead to the disruption of an inhibitory, intramolecular interaction within p47^{phox}, allowing exposed SH3 domains in p47^{phox} to interact with proline-rich regions of other NADPH oxidase components [reviewed in references 1, 2, and 18]. The translocation of the p47^{phox}/p67^{phox} complex occurs simultaneously and independently from the translocation of Rac GTPase [9,19]. p47^{phox} is now known to be dispensable for NADPH oxidase activity under cell-free conditions, and appears to serve primarily as an adapter to facilitate membrane binding of p67^{phox} [20]. The translocation of p47^{phox}, p67^{phox}, and Rac to the plasma membrane culminates in the formation of an active complex with integral flavocytochrome *b*₅₅₈ (cyt *b*). Cyt *b* possesses an NADPH binding site, FAD, 2 hemes, and 2 subunits, gp91^{phox} and p22^{phox} [21]. The formation of this minimal

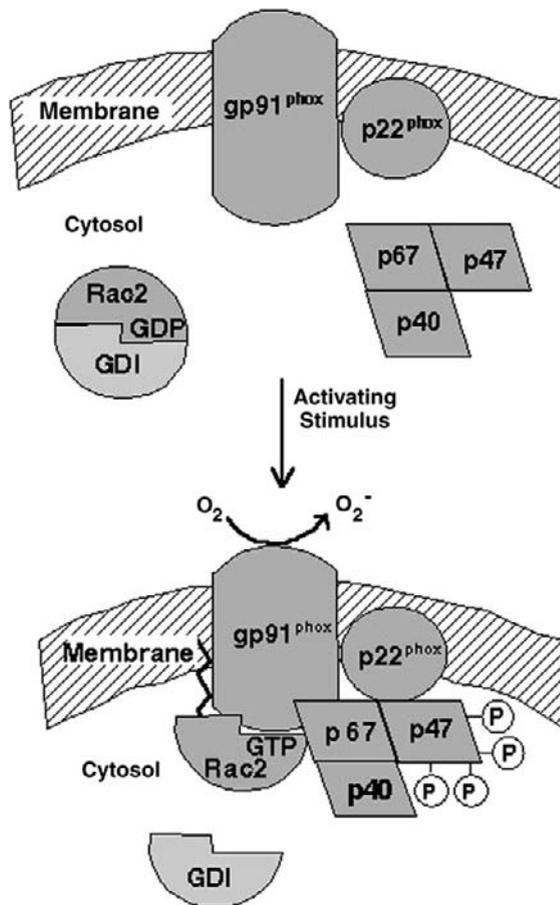

Figure 1 Formation of the NADPH oxidase complex. In the unstimulated neutrophil, cytosolic p47^{phox}, p67^{phox}, and p40^{phox} are believed to exist as a complex in the cytosol. The other cytosolic component, Rac1/2 GTPase in its GDP-bound form exists in a separate complex with Rho GDP dissociation inhibitor (RhoGDI). Upon activation of the neutrophil, Rac is released from GDI and nucleotide exchange occurs. Rac in its GTP-bound form translocates to the membrane. Also during activation, p47^{phox} is phosphorylated on multiple serines leading to the translocation of the p47/p67/(p40?) complex to the membrane; this event is separate from the translocation of Rac GTPase. At the membrane, the cytosolic components interact with cytochrome *b*₅₅₈, which is composed of two subunits, gp91^{phox} and p22^{phox}. gp91^{phox} contains the binding site for NADPH, FAD, and two heme groups. The interaction of the cytosolic components with cytochrome *b*₅₅₈ allows electrons to flow from NADPH to FAD and finally to the heme-bound oxygen to form superoxide anion.

complex allows electrons to flow from NADPH to FAD and from FAD to the heme of cyt *b*, and finally to the heme-bound oxygen whose reduction leads to the formation of superoxide anion. An additional cytosolic component, termed p40^{phox} [22], may play a role in regulating the response of the system to phosphatidylinositol-3-phosphate *in vivo* [23], but is not required for NADPH oxidase activity in the cell-free system.

The Role of Rac in NADPH Oxidase Regulation

Understanding the precise nature of the role of Rac in the oxidase regulation is facilitated by an examination of the

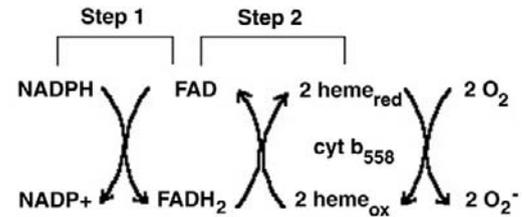

Figure 2 Electron transfer steps of the NADPH oxidase. Step 1 of electron transfer in the NADPH oxidase is defined as the pathway from the cytoplasmic electron donor NADPH to cytochrome *b*₅₅₈-bound FAD. Step 2 is defined as the pathway from FAD to the cytochrome *b*₅₅₈-associated heme groups.

specific domains of this GTPase. Most studies report that Rac is able to support oxidase activity only in its GTP-bound active form [24]. (There may be an exception to this—see reference [25]). This indicates that the switch I domain is important for Rac action on the oxidase (the switch II domain only undergoes minimal conformational changes upon GTP binding). Consistent with this, point mutations within the switch I or effector domain of Rac, including RacD38A, Y40K, A27K, and G30S, were unable to support oxidase activity [26–29]. The finding that Rac binds directly to p67^{phox} (but not p47^{phox}) via the switch I domain provided important insight into Rac function in the oxidase [26,30]. It was shown that the tetratricopeptide repeat (TPR) in the N terminus of p67^{phox} was the site of Rac binding [31], and this was confirmed upon determination of the crystal structure of the Rac-p67(TPR) complex [32]. The structure revealed specific stabilizing interactions between amino acids A27 and G30 of Rac and the TPR domain of p67^{phox}. At the same time, this structure revealed the availability of other Rac surface domains, particularly the insert domain present in members of the Rho GTPase subfamily, for possible protein interactions. Several prior investigations had suggested a requirement for the Rac insert domain in the activation of the NADPH oxidase. Peptide walking experiments indicated that blocking the insert domain of Rac abrogated NADPH oxidase activation [33]. Studies using insert domain deletion mutants of Rac have yielded conflicting results, however, concluding either that the insert domain was absolutely required [34,35] or unnecessary [36,37] for Rac oxidase activity.

The role of Rac in NADPH oxidase regulation had been generally supposed to be that of a docking protein, in which the prenylated C terminus of Rac bound to membrane phospholipids, while the switch I domain facilitated the binding of the p67^{phox}/p47^{phox} complex to cyt *b*. Our laboratory recently investigated the role of Rac in the electron transfer reactions of the NADPH oxidase using a purified cell-free system [34]. We determined that Rac2 was required for both electron transfer steps (from NADPH to FAD and from FAD to cyt *b*) (Fig. 2). In order to assess whether Rac2 had a functional role that was distinct from its interaction with p67^{phox}, we used Rac2 and p67 constructs that were mutated in domains involved in Rac/p67^{phox} interactions. We observed

that the non-Rac-binding mutant, p67 Δ 178-184, could still support electron transfer from NADPH to FAD (step 1), but not from FAD to cyt *b* (step 2). In a reciprocal experiment, we observed that a Rac2 mutant (Rac2 D38A) that is not able to bind p67^{phox} supported step 1, but not step 2 activity. These data suggested that Rac2 and p67^{phox} did not have to functionally interact for electrons to be transferred from NADPH to FAD, but that a Rac/p67^{phox} interaction was required for completion of electron transfer from FADH₂ to cyt *b*. Furthermore, since Rac2 was operative in the absence of p47^{phox}, this indicated that Rac2 must interact directly with cyt *b* to support the step 1 reaction. Based upon these observations, we proposed a two-step model for regulation of the NADPH oxidase by Rac2 GTPase (Fig. 3).

We hypothesized that the insert domain of Rac2 may play a role in binding to cyt *b* and regulation of electron transfer. Using an insert domain deletion mutant of Rac2 in our electron transfer assays, we found that the insert domain was critical for the step 1, and consequently, step 2 reactions. We furthermore demonstrated that the intensity of a fluorescent analog of mant-GppNHP bound to Rac2 increased in the presence of cyt *b*, indicating direct interaction between Rac2 and cyt *b*. In addition, using the insert domain deletion mutant of Rac2 in place of wild-type Rac2 eliminated this interaction, indicating that the insert domain of Rac2 is necessary for both the functional and physical interaction of

Rac2 with cyt *b*. In support of the fluorescence data, we have recently demonstrated that glutathione-S-transferase (GST)-Rac2 can specifically bind cyt *b* purified from neutrophils in pull-down assays (Diebold and Bokoch, unpublished observations).

Current Models of Rac Function in NADPH Oxidase Regulation

Overall these data suggest a novel paradigm for NADPH oxidase regulation by Rac2 GTPase, showing that Rac2 can interact directly with cyt *b* and that Rac2 has a separate and required function in regulating catalytic activity of the NADPH oxidase (Fig. 4C). These two points differ from other models. The model of Lambeth *et al.* [2] (Fig. 4A) agrees with the first point that the insert domain of Rac may bind to cyt *b*. However, the only role of the insert domain of Rac according to this model is to facilitate binding of p67^{phox}. p67^{phox}, which has an activation domain and also binds cyt *b*, is proposed in the model of Lambeth *et al.* to be the only protein influencing the rate-limiting electron transfer step (step 1) of the NADPH oxidase (reviewed in [2]). Their model is based on the observation that a nonprenylated Rac1 mutant, which lacks the insert domain, decreased the affinity (EC₅₀) of Rac for the oxidase, but had no effect

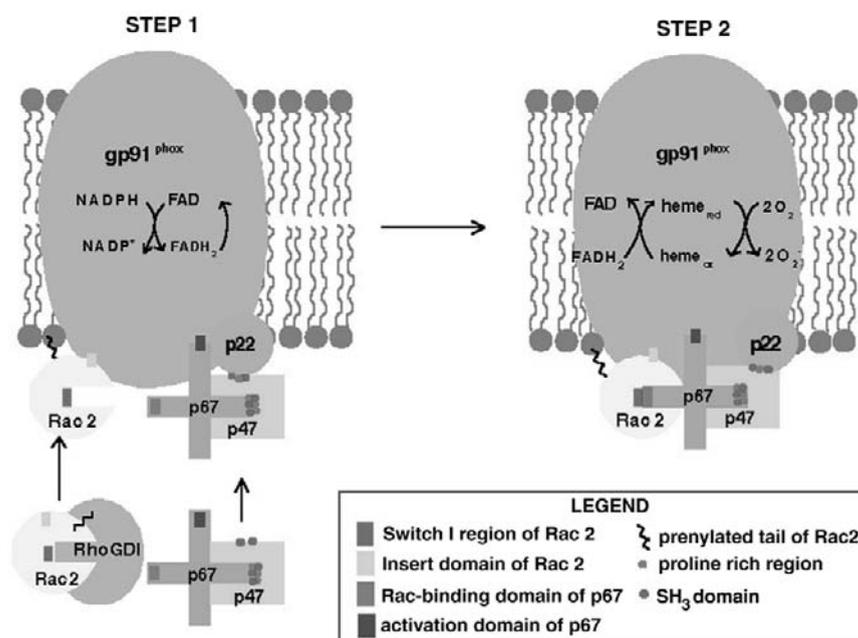

Figure 3 Two-step model for the regulation of the NADPH oxidase by Rac GTPase. Diebold and Bokoch [34] proposed a two-step model for the regulation of NADPH oxidase by Rac. In step 1, Rac translocates to the membrane and interacts with the phospholipid bilayer via its prenylated C terminus. In addition, Rac, via its insert domain, interacts with cytochrome *b*₅₅₈ and contributes to the regulation of electron flow from NADPH to FAD without interacting with p67^{phox}. p67^{phox} is still required for electron flow to occur in step 1 and regulates electron flow via its activation domain. The interaction of the insert domain of Rac with cytochrome *b*₅₅₈ may induce a conformational change in cytochrome *b*₅₅₈ that improves the interaction of p67^{phox} and cytochrome *b*₅₅₈. In step 2, the interaction between the switch I domain of Rac and the Rac-binding domain of p67^{phox} is required for electrons to continue to flow from FAD to the heme groups of cytochrome *b*₅₅₈.

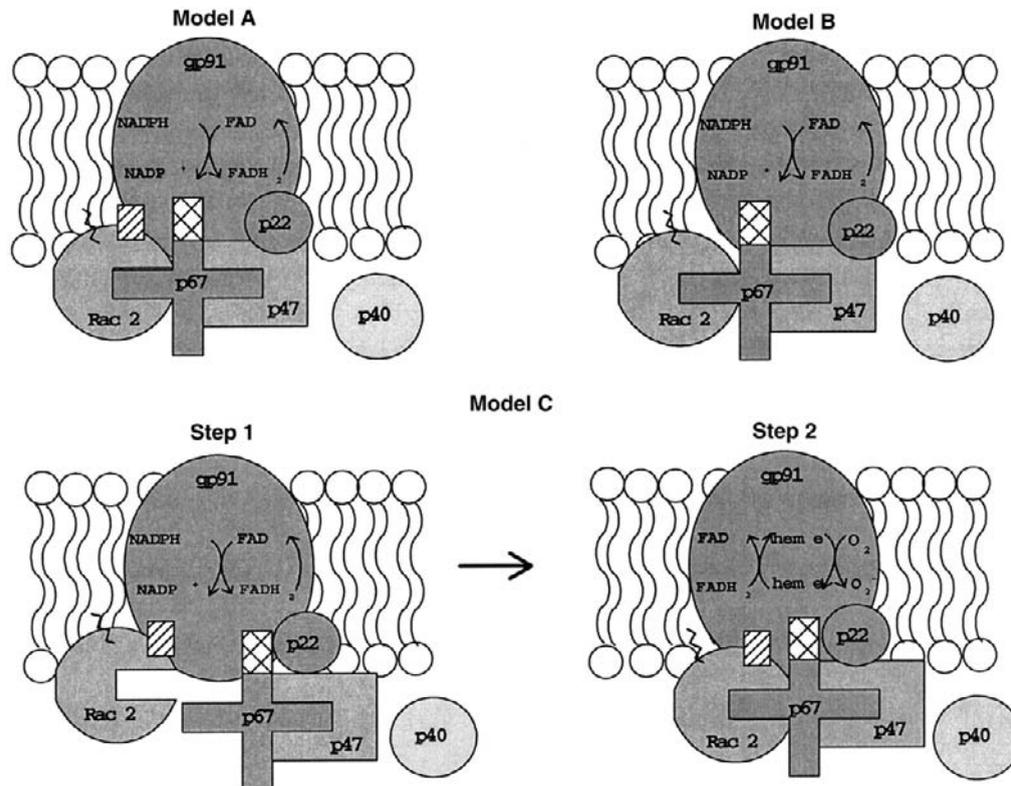

Figure 4 Comparison of proposed models of NADPH oxidase regulation by Rac. In each of the existing models, the switch I region of Rac (not indicated) interacts with p67^{phox}, the prenylated tail of Rac (shown as a zigzag line) interacts with the membrane, and the activation domain of p67^{phox} (a crosshatched section) interacts with cytochrome b_{558} . In the model of Diebold and Bokoch (C) [34] and that of Lambeth *et al.* (A) [2], the insert domain of Rac (hatched section) has direct protein interactions with cytochrome b_{558} . The Diebold and Bokoch model differs in that Rac contributes to the regulation of electron flow from NADPH to FAD, while Lambeth proposes that only the activation domain of p67^{phox} regulates this electron transfer step. In the latter model, Rac and p47^{phox} serve as adapters aiding in the interaction of p67^{phox} with cytochrome b_{558} . In model B proposed by Pick *et al.* [38], Rac interacts only with the phospholipids of the membrane via its prenylated C terminus and does not interact with cytochrome b_{558} . In this model, the insert domain is not involved in protein interactions or regulation of the NADPH oxidase. As in the model of Lambeth *et al.*, p67^{phox} is the only regulatory protein, while Rac and p47^{phox} serve as adapters for p67^{phox}.

on the maximal rate, V_{\max} , of superoxide production [35]. Our laboratory, on the other hand, has observed a decrease in V_{\max} when using a prenylated Rac2 version of this mutant [34].

The model of Pick *et al.* [38] (Fig. 4B) opposes the view that Rac interacts with *cyt b*. Instead, they propose that Rac interacts only with the phospholipids within the plasma membrane via its prenylated C terminus. This model is based upon observations that prenylated Rac can bind to phospholipid vesicles devoid of *cyt b*. (Phospholipids are used to re-lipidate cytochrome b_{558} purified from neutrophil membranes before it is used in cell-free assays). Like the previous model, this model portrays Rac and p47^{phox} only as adapter molecules that aid p67^{phox} in binding to *cyt b*. Interestingly, this group of investigators initially observed in a peptide walking study that peptides overlapping the insert domain of Rac inhibited superoxide production in the cell-free system [33]. Recently, however, this group used non-prenylated Rac1-p67^{phox} chimeras in the cell-free system

and showed that deletion of the insert domain of Rac1 did not affect the ability of this chimera to support superoxide production [37]. Consequently, based on these observations and observations by Lambeth's group that deletion of the insert domain does not affect V_{\max} [35], the model of Pick *et al.* [38] does not support an interaction of the Rac insert domain with *cyt b* (Fig. 4B). At least part of the discrepancy between these models may be due to the use of prenylated Rac (Bokoch model) versus nonprenylated Rac (Lambeth and Pick models) in the cell-free system. The concentration of prenylated Rac required in the cell-free assay is at least 100-fold less than nonprenylated Rac. The use of such high concentrations of unprocessed GTPase may obscure relevant protein-protein interactions that normally occur at physiological concentration of reactants. Ultimately, a consensus model for the role of Rac in the oxidase will depend upon *in vivo* studies using neutrophils or cell lines bearing resemblance to neutrophils.

Rac GTPase—A More General Role in Regulating Oxidant-Based Signaling?

The finding that Rac can bind to cyt *b* and regulate electron transfer in the NADPH oxidase of neutrophils is relevant to other ROS-generating signaling pathways used by nonphagocytic cells. Recently, homologs of cyt *b*, called Nox, have been found in several tissues (reviewed in [39]). These new NADPH oxidases produce low levels of superoxide anion that appear to be used as signals for the control of cell growth and transformation. It has been known for some time that Ras and Rac contribute to the control of signaling pathways that are critical for mitogenesis and oncogenesis. In stimulated NIH3T3 cells, transient expression of a constitutively activated form of Ras leads to a significant increase in intracellular ROS, and expression of a dominant negative allele of Ras or Rac1 inhibited this rise in ROS production [40,41]. ROS production in NIH3T3 cells was suppressed by treatment with a diphenylene iodonium (DPI), a flavoprotein inhibitor of NADPH oxidase of phagocytes, indicating that a Nox protein may be involved [41]. Interestingly, it has been shown that the insert region of Rac1 was essential for mitogenesis and superoxide production in fibroblasts [42]. Rac1 also appears to be involved in the signaling pathway leading to reperfusion injury caused by ROS production during reoxygenation of vascular smooth muscle [43,44]. Recombinant adenoviral expression of a dominant negative Rac1 suppressed the reperfusion-induced injury in an *in vivo* model of mouse hepatic ischemia/reperfusion injury. This was also observed in mice deficient for the gp91^{phox} of phagocytic NADPH oxidase, suggesting that the Rac mutant inhibited ROS production by a Nox system rather than by one employing gp91^{phox} [44]. Thus, it appears that ROS production in nonphagocytic cells involves both a Nox protein and Rac GTPase. The possibility exists that Rac may directly regulate superoxide production by Nox proteins in nonphagocytic cells by a mechanism similar to its binding to cyt *b* and regulating oxidant production by phagocytes. Determining if Rac has a function in superoxide production by Nox may lead to a better understanding of redox signaling pathways in other cell types and potentially provide a means to therapeutically intervene in ROS-related pathological disease states.

The Role of Rac and Rho in Cell Cycle Progression

Laura J. Taylor and Dafna Bar-Sagi

*Department of Molecular Genetics and Microbiology,
State University of New York at Stony Brook, Stony Brook, New York*

Introduction

The ability of cells to progress through the cell cycle depends on the concerted action of mitogen- and anchorage-stimulated signal transduction pathways. The regulation of the cell cycle machinery is often disrupted in tumor cells, with the most common targets being proteins involved in G1 progression. Identifying the signaling pathways responsible for G1 progression is therefore important for increasing the understanding of control mechanisms that operate during normal cell proliferation and their subversion in tumor cells. One class of signaling proteins that has recently been recognized to play a significant role in G1 phase progression is the small GTP binding proteins of the Rho GTPase family. This chapter will focus on the role of two members of the Rho GTPase family, Rac and Rho, in G1 progression.

Regulation of G1 Progression

Cell cycle progression through G1 is a complex and tightly controlled process. It is regulated by stimulatory and inhibitory signals, both of which are targets of the Rho GTPases. Three activities are recognized to be important for progression through the G1 phase of the cell cycle: early-G1 transcriptional activation of immediate early genes, mid-G1 activation of cyclin D/cdk4/6, and late-G1 activation of cyclin E/cdk2 [1,2]. Mitogenic stimulation results in the induction of many immediate early genes containing the serum response element (SRE) in their promoter [1]. The SRE is activated by binding to a ternary complex containing the transcription factors, serum response factor (SRF) and

ternary complex factor (TCF) [1]. Although activation of immediate early genes is necessary for early G1 progression, it is not sufficient for progression to S phase, and progression through later phases of G1 requires the activity of cyclin-dependent kinases (cdks).

Cdks are a group of serine/threonine kinases that are activated by binding to their respective cyclin partners and by phosphorylation [2]. Two main cdk activities play a role in G1, cyclin D/cdk4/6 functions in mid G1 and cyclin E/cdk2 functions in late G1. The major substrate of the G1 kinase complexes is the retinoblastoma protein (Rb). In its unphosphorylated form, Rb functions as an inhibitor of E2F, a transcription factor that controls the expression of genes required for G1 progression [3]. The inhibitory effect of Rb on E2F transcriptional activity is exerted by two mechanisms, one involving the direct binding to E2F and the other involving the recruitment of histone deacetylase (HDAC) [4]. Both inhibitory effects are antagonized by the coordinated and sequential phosphorylation of Rb by cyclin D/cdk4/6 and cyclin E/cdk2 which in turn allows the ordered expression of E2F-dependent genes [4,5]. Phosphorylation of Rb by cyclin D/cdk4/6 initially releases HDAC thereby alleviating transcriptional repression, and phosphorylation of Rb by cyclin E/cdk2 dissociates the Rb-E2F complex [6,7].

An important mechanism for regulation of cyclin/cdk activity involves inhibition by cyclin-dependent kinase inhibitors. The main inhibitors of cyclin D/cdk4/6 complexes are p16^{ink4a} and p21^{Cip1}, whereas inhibition of cyclin E/cdk2 occurs by p21^{Cip1} and p27^{Kip1} [2]. The levels of these inhibitors are regulated by multiple mechanisms. p21^{Cip1} is regulated predominantly at the level of transcription [8] and mRNA stability [9]. p27^{Kip1} can be regulated at multiple

levels including transcriptional [10], translational [11,12], and posttranslational [13,14] mechanisms dependent on the cell type and the extracellular signal. However, the predominant mechanism by which p27^{Kip1} levels are controlled is through cyclin E/cdk2-dependent phosphorylation [15,16], which targets p27^{Kip1} for ubiquitination and proteolytic degradation [13].

The Function of Rac and Rho in Cell Cycle Progression and Transformation

The Rho family of GTPases functions as molecular switches by oscillating between an active GTP-bound form and inactive GDP-bound form. Activation of the Rho GTPases can be induced by soluble growth factor stimulation and cell adhesion to the extracellular matrix (ECM). Their biological effects are exerted through the activation of multiple effector pathways that control transcription, cytoskeleton organization, and changes in the redox state [17].

The importance of the Rho GTPases in cell cycle progression was initially illustrated through studies demonstrating their involvement in both growth-factor-induced proliferation and oncogenic transformation. Rac1 and RhoA are each required for transformation by Ras and co-expression of a constitutively active form of Raf, a Ras effector, with either constitutively active RhoA or Rac1 synergistically enhances focus-forming activity [18,19].

Rac and Rho have been shown to be necessary and sufficient for cell cycle progression. In Swiss 3T3 cells, introduction of dominant interfering forms of Rac1 and RhoA inhibits progression of growth-factor-induced cell cycle progression, while a dominant active form of each is sufficient to induce cell cycle progression [20]. However, the capacity of Rac1 and RhoA to promote cell cycle progression is cell-type specific. For example, in rat embryo fibroblasts,

G1 to S transition requires the synergistic activities of Rac and Raf [21]. Using partial loss of function mutants of Rac it has been shown that the contribution of Rac to cell cycle progression is dependent on two distinct effector functions, cytoskeleton rearrangements and superoxide production [21,22]. Rac-induced cytoskeleton rearrangements are mediated by the effector binding loop [21], a region spanning amino acids 26 to 40 that interacts with multiple downstream effector molecules. Rac-dependent superoxide generation is controlled by the insert region, a sequence of 11 amino acids common to all of the RhoGTPase family members, but not found in the Ras GTPase family members [23]. Significantly, superoxide generation has been shown to be essential for Ras-induced proliferation [24] indicating that Rac-mediated superoxide production might be functionally relevant to Ras-induced proliferation. It is noteworthy that the insert region of Rho also plays an important role with regard to cell cycle progression through the activation of the Rho effector, Rho kinase, which cooperates with activated Raf to promote transformation [25,26].

Cell Cycle Targets of Rac and Rho

Increasing evidence indicates that Rac and Rho influence cell cycle progression by targeting multiple regulatory steps throughout G1. A well-documented mechanism by which Rac and Rho affects early-G1 involves the activation of genes controlled by the SRE. Rac, through its effector PAK, promotes the phosphorylation of both Raf and MEK, two components of the signaling cascade leading to ERK activation [27,28]. Both PAK-mediated phosphorylation events act synergistically with the Ras pathway to promote full activation of ERK [27,29]. Subsequently, activated ERK phosphorylates and activates TCF thereby stimulating SRE-dependent transcription (Fig. 1). Rac activity has also been demonstrated

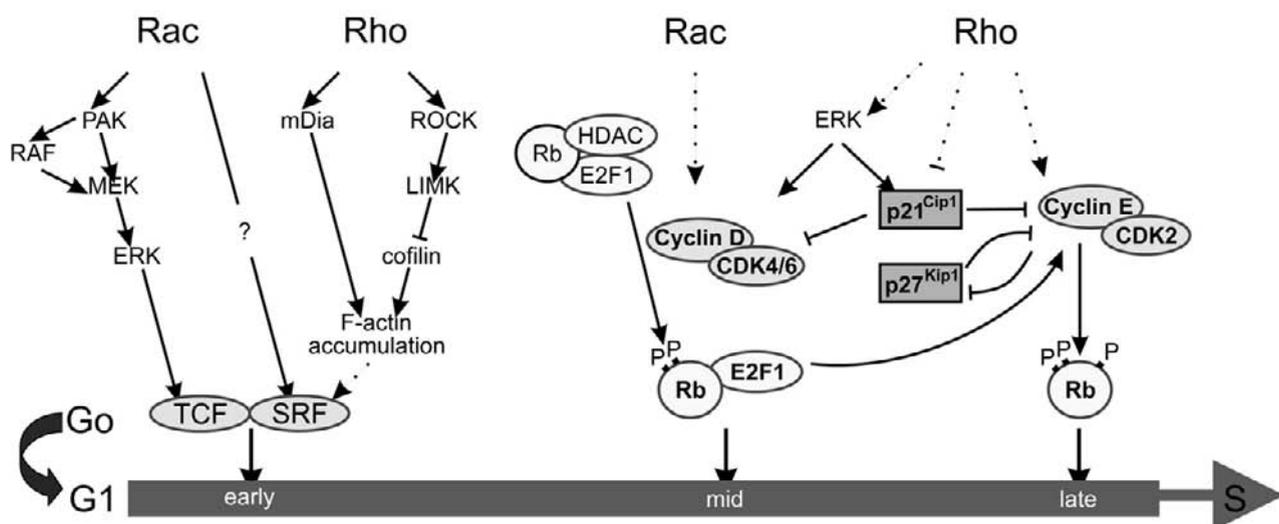

Figure 1 Integration of Rac and Rho signaling pathways with the cell cycle. Rac and Rho target multiple regulatory events during the G1 stage of the cell cycle. The contribution of Rac and Rho to TCF/SRF and cyclin/cdk complexes promotes G1-phase progression.

to potentiate SRF activity, but the signaling pathways regulating this response have not been identified [30,31].

RhoA activity is essential for mitogen-induced activation of SRF [30]. The ability of Rho to activate SRF is linked to its effect on actin cytoskeleton dynamics. This is indicated by studies showing that the Rho effectors LIMK and mDia potentiate SRF activity independently of extracellular signals [32–34]. Although the relative contribution of the Rho-dependent pathways to SRF activity seems to be cell-type dependent, both LIMK and mDia pathways contribute to F-actin accumulation, suggesting a causal role for F-actin levels in the activation of SRF (Fig. 1).

Progression through mid G1 of the cell cycle is dependent upon upregulation of cyclin D and formation of the cyclin D/cdk4/6 complex. Both Rac and Rho have been shown to contribute to the upregulation of cyclin D1 through ERK-dependent and -independent pathways (Fig. 1). Rac-mediated induction of cyclin D1 occurs in part through the Rac effector PAK [31], and is also dependent on NF- κ B activation as evident from the findings that an intact NF- κ B binding site in the cyclin D1 promoter is required for Rac-dependent cyclin D1 transcription [35].

Recent evidence by Welsh *et al.* demonstrates that Rho plays a central role in controlling adhesion- and mitogen-dependent cyclin D1 expression [36]. First, in early G1, Rho inhibits Rac-induced expression of cyclin D1 by antagonizing Rac through an unknown mechanism [36]. Second, in mid-G1 phase of the cell cycle, Rho promotes cyclin D1 induction by maintaining a sustained activation of ERK [36]. The mechanisms by which Rho might contribute to ERK activity are not well defined, but the Rho kinase pathway seems to be necessary for this effect [36]. Thus, Rho appears to have an important role in setting up the correct timing of cyclin D1 expression during cell cycle progression.

In addition to its role in the regulation of cyclin D1 expression, Rho regulates cyclin D/cdk4/6 activity by inhibiting the accumulation of the cdk inhibitor p21^{Cip1} [37]. For example, in some cell types, high levels of Ras or Raf activities induce p21^{Cip1} expression and cell cycle arrest [38–40], and this effect can be rescued by ectopic expression of activated Rho [37]. Furthermore, mouse embryo fibroblasts lacking p21^{Cip1} do not require Rho for Ras-induced S-phase entry [37]. Rho can also be involved in the regulation of late-G1 progression by activating the cyclin E/cdk2 complex, which in turn promotes the degradation of the cdk inhibitor p27^{Kip1} (Fig. 1) [41]. Together, the effects of Rho on the levels of cdk inhibitors are likely to contribute to the ability of cells to undergo G1 to S progression in response to proliferative signals.

Future Perspectives

Although, as outlined in this chapter, the involvement of Rac and Rho in regulating cell cycle progression is supported by many lines of evidence, the biochemical mechanisms that couple the signaling activities of these GTPases and the cell

cycle machinery remain to be established. By virtue of their effects on the actin cytoskeleton, Rac and Rho play a key role in the regulation of cell shape changes that accompany adhesion and motility. It is well recognized that cell shape is an important determinant for the proliferative capacity of normal anchorage-dependent cells and loss of cell-shape-dependent growth control is a hallmark of oncogenically transformed cells. Thus, understanding the molecular basis for the involvement of Rac and Rho in cell cycle regulation should provide insights into the mechanisms by which alterations in cellular morphology can be sensed and converted to a growth response.

Cdc42 and Its Cellular Functions

Wannian Yang and Richard A. Cerione

Department of Molecular Medicine, Cornell University, Ithaca, New York

Cdc42 is a member of the Rho subfamily of small GTP-binding (G) proteins. A variety of biochemical and cellular studies have shown that Cdc42 plays important roles in the regulation of cell growth, differentiation, programmed cell death, and in the establishment of cell polarity. The molecular mechanisms underlying these biological activities have emerged from recent breakthrough studies of the interactions of Cdc42 with its various downstream targets including Wiscott-Aldrich Syndrome Protein (WASP), γ -coatomer (γ -COP), and the p21-activated kinase (PAK), activated Cdc42-associated kinase (ACK) and partitioning-defective (PAR) proteins. Through these interactions, Cdc42 impacts two major cellular activities: F-actin polymerization and membrane vesicle trafficking. These findings now lead to the suggestion that Cdc42 serves as a convergence point for pathways that influence actin cytoskeletal architecture and intracellular trafficking.

Introduction

Cdc42 is a member of the Rho subfamily of Ras-related (small) GTP-binding proteins. The CDC42 gene was initially identified in *Saccharomyces cerevisiae* as being essential for polarized growth and assembly of the bud-site [1]. The human homolog, originally designated Cdc42Hs, was independently cloned following its identification as a potential participant in epidermal growth factor (EGF) receptor-coupled signaling [2,3]. Early microinjection studies in Swiss3T3 cells indicated that Cdc42 caused filopodium or microspike formation, thus linking it to actin cytoskeletal organization [4,5]. Now after a decade of studies, a variety of upstream signaling activators, which catalyze the guanine nucleotide exchange activity of Cdc42 (thus designated guanine nucleotide exchange factors or GEFs) have been identified including the prototype GEF, Dbl (diffuse B-cell

lymphoma, as well as Cdc24, Fgd1 (facial genital dysplasia, intersectin-1/Ese1 (EH domain and SH3 domain regulator of endocytosis), hPEM (human homolog of ascidian protein posterior end mark-2), Brx (breast cancer nuclear hormone receptor auxiliary factor), and Clg (common-site lymphoma/leukemia GEF) [1, 6–8]. It is now felt that a variety of receptor-coupled signaling pathways feed into these GEFs, including those mediated by receptor tyrosine kinases, trimeric G-protein-coupled receptors, neurotrophic receptors, integrins, and cytokine receptors [12–18]. A number of targets or effectors suspected to function downstream of Cdc42 have also been discovered and characterized, including PAK, ACK, myotonic related Cdc42-associated kinase (MRCK), WASP, IQGAP, γ -COP, partitioning-defective protein 6 (PAR6) and binder of Rho GTPases (BORG) [1,9,10]. These discoveries seem to position Cdc42 in signaling pathways that regulate a vast array of cellular activities, ranging from cell growth and differentiation to apoptosis, as well as a number of fundamentally important molecular events including gene transcription, actin cytoskeletal organization, membrane vesicle endocytosis and trafficking, cell adhesion and migration, and RNA processing and transport [11]. In this review, we will focus on the molecular mechanisms underlying the ability of Cdc42 to mediate its cellular functions.

Biological Effects of Cdc42

Cell Growth Regulation

Cdc42 is essential for cell growth. Early genetic studies in *S. cerevisiae* showed that yeast cells containing function-defective mutants of Cdc42 were not viable [1], and more recently, it was shown that Cdc42-knockout mice were embryonic-lethal [19]. Overexpression of a GTPase-defective Cdc42 mutant, Cdc42(G12V), as well as a mutant capable of constitutive GTP-GDP exchange, Cdc42(F28L), induced

the transformation of fibroblasts [20,21]. The dominant-negative mutant, Cdc42(T17N) blocked transformation by the oncogenic Ras protein, Ras(G12V), indicating that the activation of Cdc42 is somehow required for transforming signals of Ras. Mutations or truncations of various GEFs for Cdc42, including Dbl, Vav, Brx, and Clg, have been shown to give rise to transformation [8,22,23], further suggesting a connection between the activation of Cdc42 and cell growth regulation.

Differentiation and Development

Cdc42 has been shown to serve important functions in cellular differentiation and embryonic development, through roles in myogenesis, neurite outgrowth, monocyte differentiation, and embryogenesis [24–27]. For example, overexpression of the GTPase-defective Cdc42(G12V) mutant in L6 rat myoblasts blocked myotube formation [24]. Ectopic expression of Cdc42(G12V) in chick spinal cord neurons stimulated neurite outgrowth and enhanced the size of the growth cones and their number of filopodia [25]. In *Drosophila*, Cdc42 negatively regulates notch signaling during wing development [28].

Apoptosis

Cdc42 has been shown to regulate the apoptosis of neuronal cells and the survival of epithelial cells [29,30]. Mixed lineage kinase 3 (MLK3), a downstream effector of Cdc42, was shown to induce the apoptosis of neuronal cells through the activation of the c-Jun kinase (JNK [31]). However, it has also been suggested that Cdc42 provides a survival (antiapoptotic) signal through its activation of PAK [32], which in turn phosphorylates Bad [33]. Recent studies have shown that Cdc42 contains a caspase-substrate motif and is sensitive to caspases 3 and 7 [34]. Caspase-insensitive mutants of activated Cdc42 exhibit protective effects against Fas-induced apoptosis [34]. These data led to the suggestion that Cdc42 may somehow influence the timing of apoptotic signals, protecting against a full-scale apoptotic response, until a caspase-catalyzed degradation of Cdc42 occurs.

Cell Adhesion and Migration

Cell adhesion and migration require active cytoskeletal organization and rearrangements. Many lines of evidence indicate that Cdc42 participates in cell adhesion signaling pathways and promotes cell migration through its effects on actin cytoskeletal organization [35–37]. However, the mechanism of activation of Cdc42 by cell adhesion is still not clear.

Cell Polarity

Cell polarity encompasses asymmetrical properties of cells that are manifested during cell division, differentiation,

morphogenesis, and embryogenesis. To generate or sustain cell polarity, many processes, including actin cytoskeletal organization and membrane vesicle trafficking, are required. Cdc42 has been shown to play a key role in cell polarity [1,38]. Two such polarity-dependent processes that are controlled by Cdc42 and its downstream effectors are bud-site assembly in *S. cerevisiae* and apical/basolateral protein transport in epithelial cells [1,39].

Molecular Mechanisms Underlying the Biological Activities of Cdc42

The recent identification and biochemical characterization of the downstream effectors of Cdc42 have provided important insights into the molecular mechanisms that underlie its many biological effects. Below, we describe the molecular mechanisms that are thought to be responsible for the effects of Cdc42 on actin cytoskeletal organization, membrane vesicle trafficking, and the establishment of cell polarity.

Cdc42/WASP/Arp2/3 Complexes in F-Actin Polymerization

Although a complete understanding of how Cdc42 influences actin cytoskeletal organization has not yet been achieved, it is becoming clear how Cdc42 stimulates F-actin polymerization. WASP is a specific downstream effector for Cdc42. The carboxyl terminus of WASP contains a VCA (verprolin-homology, cofilin-homology, and acidic) domain that serves as a binding site for the Arp2/3 complex to organize the actin nucleation core and initiate F-actin polymerization [40,41]. In its inactive conformation, the VCA domain is masked through an intramolecular interaction with its Cdc42/Rac-interactive binding (CRIB) domain. When activated Cdc42 binds to the CRIB domain on WASP, the VCA region is released and interacts with the Arp2/3 complex to form an actin nucleation core and initiate F-actin polymerization [41]. Cdc42-induced filopodia formation appears to be mediated through its interaction with WASP, as the overexpression or microinjection of an Arp2/3-binding defective mutant of WASP inhibits the ability of EGF or bradykinin to stimulate filopodia [41].

Cdc42/ γ -COP Complexes in Cdc42-Induced Cellular Transformation and Intracellular Transport

Cdc42 is required for cell-cycle progression and DNA synthesis. It appears that the ability of Cdc42 to stimulate actin polymerization or produce actin filopodia is not required for its effects on cell growth [42]. A Cdc42 mutant, Cdc42 (Y40C), which excludes the binding of all CRIB-domain-containing effectors, only interfered with Cdc42-mediated cytoskeletal organization and JNK activation, but did not influence cell-cycle progression or DNA synthesis [42]. This implied that the effector responsible for mediating

the effects of Cdc42 on cell-cycle progression is a non-CRIB-domain-containing protein. The γ subunit of the γ -COP, which lacks a CRIB domain, was found to be an essential effector for Cdc42-induced cellular transformation [10]. Because γ -COP is part of the COP1 complex, which is involved in vesicular trafficking, the interaction between Cdc42 and γ -COP suggests a direct link between Cdc42-mediated cell growth regulation and some type of a trafficking function.

Cdc42/WASP/Intersectin and Cdc42/ACK/Intersectin Complexes: Possible Roles in Receptor Endocytosis

Intersectin or Esei is a prototype for a family of endocytic proteins whose members contain two EH domains and five SH3 domains [43,44]. The long-form of Intersectin, designated Intersectin-1, contains a DH/PH domain and is a specific GEF for Cdc42 [6]. WASP interacts with the SH3 domains of Intersectin-1, activates its GEF activity, and influences receptor endocytosis [6,45]. It has been proposed that Cdc42/WASP/Intersectin complexes may play an important role in the regulation of endocytic vesicle transport by connecting endocytic vesicles to the actin cytoskeleton.

ACK is a nonreceptor tyrosine kinase that specifically interacts with activated forms of Cdc42 [46,47]. There are two isoforms of ACK that have very similar functional domains [46]. It has been shown that ACK contains a clathrin-binding motif and directly interacts with clathrin, an endocytic vesicle-coating protein [48,49]. Overexpression of ACK2 inhibits transferrin-receptor endocytosis via a competition with AP-2 for binding to clathrin [48]. Interestingly, both ACK2 and Intersectin-1 are enriched in neuronal tissues and ACK2 interacts with the SH3 domains of Intersectin-1 (Esei) via its proline-rich domain 2 (PRD2) (Smith, W. *et al.*, unpublished data). This raises the interesting possibility that a ternary Cdc42/ACK/Intersectin-1 may form in neuronal tissues, containing both a specific upstream activator and downstream target for Cdc42. Recently, it has been reported that ACK2 phosphorylates SH3PX1 (sorting nexin 9) in both *Drosophila* and mammalian cells [50,51] and facilitates the degradation of the EGF receptor [51], suggesting that the Cdc42/ACK/Intersectin-1 complex may form a functional unit that directly influences receptor degradation.

Cdc42/PAR6/PKC ζ Complexes in Cell Polarity

The PAR protein family has 6 members (PAR1–6) and were originally identified in *Caenorhabditis elegans* embryos as being essential for the establishment of polarity [52]. The PAR6 protein directly interacts with activated Cdc42, thus serving as a putative target/effector [53–55]. It has been shown that PAR6 binds to PAR3 through its PDZ domain [53] and that this heterodimer recruits both activated Cdc42 and PKC ζ . The resultant tetrameric complex appears to function as a determinant for cell polarity as well as regulates tight junction structures in mammalian epithelial cells [54]. The Cdc42/PAR6 complex also stimulates PKC ζ kinase

activity and this activation has been reported to induce cellular transformation [55].

The Cdc42/PAR6/PKC ζ complex apparently is not the only functional unit involved in Cdc42-mediated cell polarity. The Cdc42/ γ -COP complex may also play an important role in cell polarity through the regulation of vesicular trafficking. Moreover, a ternary complex consisting of activated Cdc42, the putative Cdc42-effector IQGAP, and β -catenin has been reported to regulate cell-cell contact adhesion and cortical F-actin polymerization and to play an important role in embryogenesis and the establishment of epithelial cell polarity [56]. Recent studies have shown that Cdc42 regulates polarized exocytosis by directly interacting with Sec3p, a component of the exocyst complex [57].

Cdc42/PAK/Cool(Pix)

Complexes in Cell Growth, Adhesion, and Arf6-Mediated Membrane Vesicle Trafficking

The PAK family has been studied extensively and its members have been reported to exhibit very broad effects on cell growth, differentiation, apoptosis, and actin cytoskeletal organization. However, the specific role of PAK in cells is not clear. It has been reported that PAK can mediate the Cdc42/Rac-stimulated activation of JNK, which leads to increased gene expression [58,59]. PAK activity has also been shown to be crucial for Ras-induced transformation, and PAK-catalyzed phosphorylation of Raf has been reported to be required for Raf activation [60]. PAK also phosphorylates the BAD protein to prevent cellular apoptosis [33]. There is a subfamily of Dbl-related proteins named Pix (PAK-interactive exchange factor) and Cool (cloned-out of library), whose members specifically interact with PAK [61,62]. In cells, Cdc42, PAK, and Cool(Pix), together with a Cool(Pix)-binding partner called Cat (Cool-associated tyrosine phosphosubstrate; also very similar if not identical to the G-protein-coupled receptor kinase interactor or GIT, and the Paxillin-kinase linker or PKL), form a stable complex [63]. The Cat protein has an Arf-GAP domain and specifically stimulates Arf6 GTPase activity, thus connecting Cdc42/Rac signaling to Arf6 signaling [64]. The Cat protein also directly interacts with Paxillin, an important component in focal adhesion complexes, thereby providing a possible link between Cdc42/Rac signaling and cell adhesion [65].

Conclusions

Cdc42 influences a broad range of biological and cellular activities that are mediated by multiple downstream effectors. How Cdc42 is able to discriminately interact with its many upstream activators, GEFs, and downstream targets to give rise to specific signals will be an important issue for further understanding how this GTP-binding protein mediates its multiple functions. One intriguing possibility is that specific signaling complexes are constructed that contain both a specific GEF and a specific target/effector for Cdc42.

Two such examples are the Cdc42/PAK/Cool(Pix) complex and the Cdc42/WASP/Intersectin-1 complex. At present, there appear to be two major cellular activities that are regulated by Cdc42: actin cytoskeletal organization and membrane vesicle trafficking. Whether these two functions are often intimately linked or more typically represent distinct activities under the control of Cdc42 remains to be established. There are some data implicating Cdc42 in the organization of F-actin cytoskeletal structures in vacuole membranes, as well as in T-cell receptor endocytic vesicles and in Golgi vesicles [66,67]. It is thus intriguing to hypothesize that Cdc42 organizes actin cytoskeleton-based vesicle “motors” that power and guide vesicle transport. Hopefully, in the not-too-distant future we will be able to determine the validity of this hypothesis.

Tissue Transglutaminase: A Unique GTP-Binding/GTPase

Richard A. Cerione

*Department of Molecular Medicine and
Department of Chemistry and Chemical Biology,
Cornell University, Ithaca, New York*

Tissue transglutaminase (TGase) is capable of GTP-binding/GTPase activities like members of the large and small families of G proteins, as well as exhibiting an enzymatic activity that catalyzes the crosslinking of glutamine residues to primary amino groups or to the epsilon amino groups of protein lysine residues (transamidation). The binding of GTP to the TGase has a negative regulatory effect on transamidation, whereas Ca^{2+} , which is essential for transamidation activity, weakens the binding of guanine nucleotides. The recent determination of the three-dimensional structure for the guanosine diphosphate (GDP)-bound form of TGase sheds light on the molecular basis of the interplay between guanine binding and transamidation activity. Recent studies also point to an unexpected role for the GTP-binding activity, as well as transamidation activity, in the protection of cells against apoptosis.

Introduction

Tissue transglutaminase (TGase) is capable of multiple types of catalytic activity. Namely, it undergoes a GTP-binding/GTP hydrolytic cycle like members of the families of large heterotrimeric G proteins and small Ras-related G proteins [1–3], as well as it exhibits an ATP hydrolytic activity which appears to be noncompetitive with GTPase activity [4], and an acyl transferase activity [5,6] that results in the crosslinking of proteins (transamidation). Recent breakthroughs on the three-dimensional structure of TGase [7–10], and new insights into how TGase influences whether cells undergo differentiation versus apoptosis [11–13], provide interesting

perspectives regarding the relationship between the GTP-binding/GTPase activities and the transamidation capability that resides on this single chain polypeptide. It is the relationship between these activities and how they might fit into new biological roles for the TGase that is the subject of this chapter.

General Overview

Transglutaminases are Ca^{2+} -dependent acyl transferases that catalyze the formation of an amide bond between the γ -carboxamide groups of peptide-bound glutamine residues (which serve as acceptor residues in the reaction) and the primary amino groups in various (donor) compounds, and in particular, the ϵ -amino group of lysine residues in proteins [5,6]. These enzymes contain an active site thiol group (6) within a Cys-His-Asp catalytic triad [7,10]. Six classes of transglutaminases have been identified and characterized in mammals. These are factor XIII-A and the keratinocyte (type I), tissue (type II or TGase), epidermal (type III), and prostate (type IV) transglutaminases, as well as TGX [6,14]. The erythrocyte membrane proteins Band 4.2 are also typically classified as a noncatalytic transglutaminase homologs [15]. It has been suggested that the different members of the transglutaminase family participate in diverse biological activities.

Tissue transglutaminase (TGase) is particularly interesting because of its ability to bind and hydrolyze GTP like traditional G proteins. There have been a number of suggestions that TGase functions as a signal transducer by mediating the stimulation of phospholipase C activity by $\alpha 1$ -adrenergic

receptors [16–21]. An important breakthrough came when it was appreciated that a GTP-binding protein, designated Gh, which was being studied for its ability to couple α adrenergic receptors to phosphoinositide lipid metabolism, was identical to TGase [18]. Other studies have shown that TGase binds most effectively to certain α adrenergic receptor subtypes (α 1B and α 1D but not α 1A) [21,22], and that the target/effector for TGase is not phospholipase C- β , which is regulated by the heterotrimeric Gq protein [23], but rather phospholipase C- δ [16,24]. It remains to be established just how analogous a role TGase plays in α adrenergic-coupled phospholipase C activity compared to the well-characterized role of the Gq protein. The expectation is that some insight will come from comparisons of the structures of the GDP- and GTP-bound forms of TGase (see the following section), and whether there are specific conformationally sensitive regions on the TGase that are analogous to the switch I and II regions of large and small G proteins.

Recent Implications

Tissue transglutaminase appears to be ubiquitously distributed in mammalian tissues and exists in a variety of cellular locations. It has been generally found in cytosol, although TGase has also been purified from the nucleus [3], and appears in the plasma membrane upon stimulating the cells with certain factors (e.g., retinoic acid [25]). It has been suggested that TGase participates in a variety of biological activities including wound healing [26]), cell-matrix interactions [27], differentiation [25,28–30], neuronal degeneration [14,31], and programmed cell death [32–34]. In particular, possible roles for TGase in both the induction of and protection against apoptosis have received a good deal of attention over the past few years. A number of correlative observations have been made regarding TGase expression and transamidation activity and cellular apoptosis, among the most interesting being the TGase-catalyzed crosslinking of the retinoblastoma protein (Rb) [34]. Given the potential for transamidation to disrupt protein function, conditions that generate hyperactive forms of TGase could well have deleterious effects on cells and likely account for the tight regulatory control over TGase expression and activation that has been observed [25]. However, it is becoming increasingly attractive to consider that TGase is expressed and/or activated in response to factors that would normally cause some insult or stress to cells, and that even in some cases, TGase-catalyzed transamidation is directed toward protecting against these perturbations rather than exacerbating them (see the following sections). There are now reasons to believe that the GTP-binding activity and potential signaling function of the TGase, as well as its enzymatic transamidation activity, contribute to its protective (anti-apoptotic) effects. This then makes it important to understand the molecular basis for the GTP-binding/GTP hydrolytic activity and the transamidation activity and their functional interplay.

TGase as a GTP-Binding/GTPase

Biochemical Characterizations

It has been realized for some time, starting with the initial characterizations of purified preparations of TGase, that there is a negative relationship between guanine-nucleotide-binding and transamidation activity [1–3]. In some studies, it has been shown that GTP is a much more potent inhibitor of transamidation activity, compared to GDP [1,2], thereby raising the provocative possibility of a direct coupling between the protein crosslinking activity of the TGase and its GTP-binding/GTPase cycle. However, in other studies, the differences in the abilities of GTP versus GDP to inhibit transamidation activity were minimal [4]. If true, this would then raise questions regarding the cellular conditions necessary for transamidation to occur, and in particular, whether those physiologically relevant transamidation substrates, upon binding to the TGase, weaken guanine nucleotide binding and stabilize a guanine-nucleotide-depleted state of the protein. Unlike the large and small G proteins, which show a high degree of preference for guanine nucleotides relative to adenine nucleotides, the TGase is able to bind and hydrolyze ATP. It is interesting that ATP binding and hydrolysis are not competitive with GTP binding and hydrolysis, suggesting that distinct binding sites exist on the TGase for these two nucleotides. At the present time, there is little known regarding the role of the ATP hydrolytic activity and further insight awaits the generation of TGase mutations that are highly specific for blocking ATP binding and hydrolysis without perturbing guanine nucleotide binding or GTP hydrolysis. There also have been questions regarding the affinity of guanine nucleotides for the TGase, as compared to guanine nucleotide binding to G proteins, as well as how rapidly GTP is hydrolyzed by the TGase. Some estimates have suggested that guanine nucleotides bind to the TGase with relatively weak affinity (dissociation constants in the micromolar range) and that GTP is hydrolyzed relatively slowly [4]. However, the turnover number for GTP hydrolysis catalyzed by the TGase purified from rabbit liver nuclei [3] was measured to be ~ 1 mol $^{32}\text{P}_i$ released per minute per mol protein, which is on the order of the intrinsic GTP hydrolytic activity for heterotrimeric G proteins. Moreover, the TGase has recently been crystallized with bound GDP (see the following sections), suggesting a high-affinity interaction similar to what has been demonstrated for members of both the large and small G-protein families.

Three-Dimensional Structure for the GDP-Bound TGase

The three-dimensional structure for the GDP-bound form of the human TGase has recently been determined to 2.8 Å resolution by x-ray crystallography [10]. The TGase organizes as three dimers within the unit cell. Each monomer contains a bound GDP molecule and is made up of four

distinct domains, an amino terminal β -sandwich domain (Met1 to Phe139), a transamidation catalytic core (Ala147 to Asn460), and two carboxyl-terminal β -barrel domains (Gly472 to Tyr583 and Ile591 to Ala687, respectively). Cysteine 277 lies within the middle of a groove within the transamidation active site [thus the TGase(C277A) mutant is transamidation-defective] and is part of a catalytic triad, Cys277-His-335-Asp358. The transamidation active site and the general domain structure of TGase are similar to those reported for factor XIIIa and for TGase III [7,8].

The guanine-nucleotide-binding site lies in a cleft formed by the catalytic core domain and the first β -barrel domain [10]. Most of the residues contacting GDP come from the end of the first β -strand of the first β -barrel domain and the loop that connects it to the second β -strand. There are also two residues contributed by the catalytic core domain that are involved in binding the guanine ring moiety. In this regard, the overall architecture for the guanine-nucleotide-binding site on TGase differs significantly from the guanine-nucleotide-binding domains of the α subunits of heterotrimeric (large) G proteins or the Ras-related (small) G proteins. For both the large and small G proteins, the guanine-nucleotide-binding site consists of five helices surrounding a six-stranded β -sheet [35]. The α subunits of the large G proteins also contain a helical domain that is adjacent to (and in effect closes over) the guanine-nucleotide-binding site and enables the α subunits to bind GDP with high affinity. Ras and other small G proteins lack this helical domain and bind GDP with high affinity through the coordination of Mg^{2+} . Both large and small G proteins require Mg^{2+} for the GTP hydrolytic reaction and thus share conserved serine and threonine residues that bind to the β - and γ -phosphates of the guanine nucleotide. The TGase also requires Mg^{2+} for its GTP hydrolytic activity, however, the location of the Mg^{2+} -binding site is not obvious as the TGase lacks amino acids with either hydroxyl or carboxyl side chains in the immediate vicinity of the nucleotide phosphate groups. Mutation of serine 171 does inhibit the GTP-binding activity of the TGase, however, the position of this serine is closer to the guanine ring rather than to the nucleotide phosphate groups and thus would seem to be an unlikely participant in the GTP hydrolytic reaction.

The importance or location of the normally essential arginine (i.e., arginine finger) for the GTP hydrolytic reaction of the TGase is also not known at the present time. There are various positively charged groups that surround the phosphate moieties of the bound GDP on the TGase and could conceivably play a similar role as the essential arginine residues provided by the helical domains of the large G protein and by the GTPase-activating proteins (GAPs) of small G proteins. These include Arg 580 from the last β -strand of the first β -barrel domain of the TGase, which forms two ion-pairs with the α - and β -phosphate groups of the guanine nucleotide, and Arg 478 from the first β -strand, which is located close to the β -phosphate of GDP. Both Arg 478 and Arg 580 are conserved in all TGases (i.e., from different species) but are

missing in other members of the transglutaminase family that are incapable of binding GTP. Because the β -phosphate is pointed toward Arg 478, the γ -phosphate of GTP would likely need to rotate to avoid clashing with the side chain of Arg 478 and its hydrogen-bonding partner Val 479. This would bring the γ -phosphate into the vicinity of the positively charged side chains of Lys 173 and Arg 476. Because the TGase lacks the conserved glutamine residue found in all large and small GTP-binding proteins, which functions to position water for nucleophilic attack during GTP hydrolysis, a plausible mechanism for the GTP hydrolytic activity of the TGase would be that a water molecule hydrogen bonded to either the side chain of Lys 173 or Arg 476 would serve as the attacking group. Consistent with this idea, mutation of Lys 173 yields a GTPase-impaired TGase molecule [36].

Another notable difference between the guanine-nucleotide-binding pockets of large and small G proteins and that of the TGase is the absence of the NKXD motif that is conserved in virtually every large and small G protein. The asparagine residue within this motif always forms a hydrogen bond with the N7 atom of the guanine moiety, and the aspartic acid residue hydrogen bonds with the N1 and N2 atoms. In the TGase, a main chain oxygen from Tyr 583 from the last β -strand of the first β -barrel domain forms hydrogen bonds with the N1 and N2 atoms of the guanine ring, and Ser 482 from the first β -strand forms an additional hydrogen bond with N2.

There is one interesting similarity regarding the guanine-nucleotide-binding site in the TGase, compared to that for Ras or other small G proteins like Cdc42. In the TGase, the guanine ring lies in a hydrophobic pocket that includes a phenylalanine residue (Phe 174), which appears to be positioned to stack with the guanine moiety. The α subunits of heterotrimeric G proteins lack such a phenylalanine residue, however, in Ras and other small GTP-binding proteins, a conserved phenylalanine approaches one side of the guanine ring at an $\sim 90^\circ$ angle and participates in π - π stacking interactions. This stabilization has been noteworthy, as mutation of the phenylalanine (Phe 28) to leucine in Ras and Cdc42 yields proteins that show an accelerated dissociation of tightly bound GDP and are capable of constitutive GTP-GDP exchange in cells, thereby giving rise to malignant transformation [37,38]. It will be interesting to see if the corresponding mutation in TGase yields a molecule capable of constitutive GDP-GTP exchange activity.

An examination of the TGase structure also provides some possible insight into the nature of the interplay between guanine nucleotide binding and transamidation activity. In the GDP-bound form of TGase, it appears that access to the enzymatic (transamidation) active site is restricted by a loop that connects the third and fourth β -strands, and a loop that connects the fifth and sixth β -strands of the first β -barrel domain. Tyrosine 516, a residue conserved in different members of the transglutaminase family, is located within the first loop and hydrogen bonds with the essential cysteine residue (Cys 277). It is expected that Tyr 516 needs to move

to make the essential cysteine accessible to participate in catalysis, and it is easy to imagine how guanine nucleotide binding might stabilize the tyrosine residue and hinder the accessibility to the catalytic cysteine. The binding of GTP could further stabilize this catalytically compromised conformation thereby accounting for the enhanced inhibitory effects exhibited by GTP toward transamidation activity.

Based on comparisons of the structures of TGase, factor XIIIa, and type III transglutaminase [7–10], a major Ca^{2+} -binding site on the TGase is formed by the side chains of Asn 436, Asp 438, Glu 485, and Glu 490, as well as by the main chain oxygen from Ala 457. These are located near the end of the loop that connects the transamidation active site to the first β -barrel domain. In the TGase, Ile 416 and Ser 419 form a β -strand (anti-parallel) with Leu 577 and Glu 579 in a manner that maintains the first β -barrel domain and stabilizes the guanine-nucleotide-binding site [10]. It seems reasonable to expect that the binding of Ca^{2+} alters the position of Ile 416 and Ser 419 thus eliminating their stabilizing effects and weakening guanine nucleotide binding. Increasing Ca^{2+} would then potentially have a dual effect on transamidation activity by inducing a conformational change that is both essential for catalysis and weakens guanine nucleotide binding, which in turn reverses a negative regulatory effect normally imparted by bound guanine nucleotide.

New Links to Biological Function

It has been well documented that TGase activity is under the control of retinoic acid (RA) in a variety of cell types [11,25]. In some cases (e.g., the human leukemia cell line HL60), both the expression and activation of TGase are stimulated by RA treatment, whereas in HeLa cells, we have found that RA promotes the activation of TGase without having a significant effect on its expression. Because of its ability to trigger cell cycle arrest and cellular differentiation, RA has been examined as a possible therapeutic agent against human cancers. Whereas the natural retinoids have shown somewhat limited activity, the synthetic analog all-*trans*-*N*-(4-hydroxyphenyl) retinamide (HPR) has shown some promise in the treatment of breast and prostate cancers [39–041]. Interestingly, HPR has been consistently linked to apoptosis, while RA has been reported to give rise to cellular differentiation as well as apoptosis [42,43]. We have found that only HPR, and not RA, induces an apoptotic response in both NIH3T3 cells and HL60 cells. A major difference that has been detected in response to treatment with RA versus HPR is that RA stimulates the expression and/or activation of TGase, whereas HPR appears to inhibit its expression. It is interesting that pretreatment of cells with RA, prior to addition of HPR, induces TGase expression and activation and completely protects against HPR-induced apoptosis. The RA-mediated protection effect can be mimicked by the expression of wild-type TGase in NIH3T3 cells or by a TGase (C277S) mutant where the active site cysteine residue has been changed to serine. However, TGase mutants

that are unable to bind GTP [e.g., TGase (S171E)] do not provide protection against HPR.

These results have led us to propose that the TGase may be functioning as a protection-factor that is activated by differentiation agents in order to ensure that cells remain viable and not susceptible to cell death programs during cellular differentiation. Apparently, the GTP-bound TGase can activate a signaling pathway that is essential for this protection effect. It will be interesting in the future to delineate this survival pathway and to identify the target that binds to GTP-bound TGase and mediates these effects. It should be noted that addition of the TGase competitive inhibitor, monodansylcadaverine (MDA), to RA-treated cells results in converting the RA response to one that mimics HPR treatment (i.e., apoptosis). This is interesting in light of our finding that mutation of the active site cysteine on the TGase did not abrogate its protection capability or give rise to apoptosis. Thus, the effects of MDA may be directed at altering the ability of TGase to bind GTP or preventing GTP-bound TGase from initiating signaling activities that can protect against apoptosis. However, recently, we have found that in Rb knock-out cells, which are sensitive to HPR, co-expression of wild-type TGase and Rb can overcome the apoptotic effects of HPR, whereas expression of TGase (C277A) together with Rb cannot [13]. Thus, there may be cell types where both the GTP-binding activity of the TGase and its transamidation activity are critical to trigger pathways that protect against programmed cell death.

Future Directions

A number of questions regarding the role of TGase, and in particular its GTP-binding/GTPase cycle, in various cellular functions await future studies. It will be important to know whether in fact the TGase undergoes significant conformational changes as an outcome of GDP-GTP exchange, analogous to large and small G proteins, and where those changes occur. How are such changes translated into the binding of target/effector proteins and what are the identities of these proteins? At the present time, phospholipase C appears to be a leading candidate, however, similar to the cases for other G proteins, there are likely to be additional cellular targets for the TGase. We also know very little regarding how the GDP-GTP exchange reaction for the TGase is regulated, and it will be important to determine whether guanine nucleotide exchange factors (GEFs) exist with functions analogous to the serpentine receptors (which stimulate the activation of heterotrimeric G proteins) and the GEFs for small G proteins. Likewise, nothing is known regarding the regulation of the GTP hydrolytic activity of the TGase. Are there specific GTPase-activating proteins? If so, how are they regulated, as GTP hydrolysis may be necessary to promote optimal transamidation activity? Can the TGase bind aluminum fluoride and will this induce a conformation that mimics the transition state for GTP hydrolysis similar to what has been observed in large and small G proteins?

Finally, what other binding partners exist for the TGase and how do these interactions give rise to survival or anti-apoptotic effects? We are at a much earlier stage in appreciating the functional importance of the GTP-binding/GTPase cycle of the TGase, compared to what we know about other more traditional G proteins, but there is every reason to believe that the TGase will prove to be an important, albeit somewhat unusual, type of G-protein switch.

The Role of ARF in Vesicular Membrane Traffic

Melissa M. McKay and Richard A. Kahn

*Department of Biochemistry,
Emory University School of Medicine,
Atlanta, Georgia*

The ARF Family of Regulatory GTPases

ADP-ribosylation factors (ARFs) are a family of highly conserved, ~20-kDa GTPases with a number of cellular activities; most notably the regulation of vesicular membrane traffic. ARFs are ubiquitous in eukaryotes with as many as 23 members of the ARF family expressed in mammalian cells. The ARF family includes both ARF and ARF-like (ARL) proteins, based upon the extent of sequence and functional identities; e.g., the 6 mammalian ARFs share > 60% identity to one another, while most ARLs share 40–60% identity to each other or to any ARF [1]. With this high level of structural conservation we expect that ARLs perform mechanistically and functionally homologous roles to those of ARFs, but these are much less well defined and will not be covered here. The ARF subfamily can be further divided into three classes. In mammals, class I includes ARF1–3, class II includes ARF4 and ARF5, and class III is ARF6 [2]. In contrast, *Caenorhabditis elegans* and *Drosophila melanogaster* each have single representatives of each ARF class. The results discussed in the following sections were obtained primarily from studies of ARF1. The extent to which ARF4 and ARF5 act as described below is unknown, while ARF6 clearly has some differences in location and presumed actions [3,4].

Like other regulatory GTPases, ARFs cycle between GDP- and GTP-bound conformations in a cycle whose rate is determined by binding to guanine nucleotide exchange factors (GEFs), GTPase-activating proteins (GAPs), and effectors. In addition to these functionally critical protein interactions, ARFs are unique among regulatory GTPases in

that their affinity for biological membranes is affected by the nucleotide bound [5]. Specifically, ARFs are co-translationally modified by the addition of myristic acid to the N terminal glycine [6]. This hydrophobic N-terminal anchor functions coordinately with the amphipathic N terminus to orient the protein on the surface of the membrane when GTP is bound. ARFs are predominantly soluble when GDP is bound. Thus, activation of ARF (GTP binding) alters both its location and its affinity for effectors.

All of the currently identified actions of ARFs take place on membrane surfaces. These different functions can be divided into four different groups, (1) regulation of lipid metabolism, (2) regulation of vesicle transport, (3) cofactor for bacterial toxins [7,8], and (4) GTP-dependent binding to other miscellaneous proteins [9–11] with less well understood functions. Because of the likelihood of functional interplay, the rest of this review will focus only on the first two.

ARF as a Regulator of Membrane Traffic

The primary cellular roles for ARFs are the regulation of membrane traffic and lipid metabolism. Whether these represent one integrated or two distinct aspects of ARF biology is controversial. Most likely, ARF-dependent changes in lipid metabolism occur both during vesicle biogenesis and at other times. The observations that (1) activation of ARF is sensitive to its lipid environment, (2) specific lipids serve as cofactors in some ARF-dependent activities, (3) ARF can alter lipid metabolism, and (4) ARF is required for the biogenesis of a broad array of vesicles in cells (see Fig. 1),

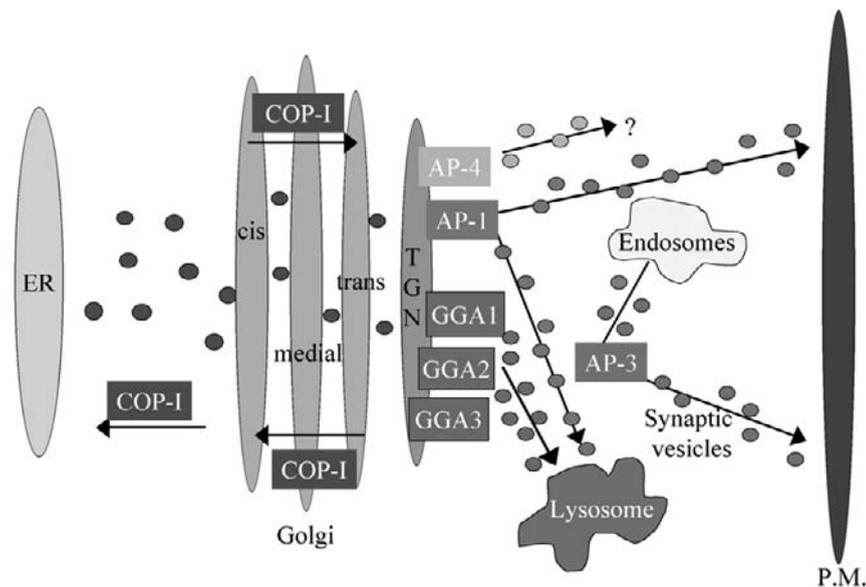

Figure 1 ARFs act to regulate the recruitment of coat proteins to a wide variety of intracellular membranes. The different compartments implicated as a source or destination of vesicles regulated by ARF proteins are shown. Coat/adaptor proteins or complexes are represented by shaded rectangles at the membranes at which they are thought to initiate vesicle budding. The direction and destination of the vesicles are indicated by arrows. Arrows emanating from AP-1 and GGA2 are intended only to indicate traffic from TGN to endosomes/lysosomes, and P.M. routing between different endosomal compartments is not shown. Note that the destination and possibly directionality of transport of each of the coated vesicles are still under investigation (particularly, e.g., AP-4). P.M. = Plasma Membrane.

implicate ARFs as both sensors and modulators of different lipids and membranes. The role of ARF as regulator of membrane traffic is very likely to be intimately linked to roles in lipid metabolism and signaling.

ARF is Activated on Membranes

The dependence on a hydrophobic environment for GTP binding was first described when ARF was purified and shown to bind guanine nucleotides [12]. The ability of a broad list of different lipids and detergents to satisfy this requirement reveals a nonspecific requirement for lipids in the activation process. This is likely an *in vitro* correlate of the GTP-stimulated translocation of ARF to membranes. ARFs are sufficiently hydrophobic to interact weakly with membranes in the GDP-bound state [13]. Once at the membrane they encounter ARF GEFs, which promote GTP binding and a more stable association with the membrane. In this way, specificity in membrane binding is likely tied to the localization of ARF GEFs, though we cannot exclude the lipid composition of the membrane from playing a role.

Specific Lipids are Cofactors for ARF-Stimulated Activities

The search for an ARF GEF led to the observation that acid phospholipids can stimulate the release of GDP from ARFs, and can stabilize the protein in the nucleotide-free state [14].

Phosphoinositides, specifically phosphatidylinositol 4,5-bisphosphate (PI(4,5)P₂), were the most active lipids in these studies. At about the same time, ARF was found to be a potent, direct, GTP-dependent activator of phospholipase D (PLD), which catalyzes the conversion of phosphatidylcholine to phosphatidic acid and choline [15,16]. Surprisingly, ARF-stimulated PLD activity was dependent on the addition of PI(4,5)P₂ [15]. Similarly, some ARF GAPs were found to be potently stimulated by PI(4,5)P₂ [17,18]. The product of PLD, phosphatidic acid, can also increase ARF GAP activity and alter affinity of ARF GAP for PI(4,5)P₂ [18]. Thus, there exist both nonspecific effects of lipids to stabilize GTP binding and specific effects of lipids to bind and modulate ARF, ARF effectors (PLD), or ARF GAPs. As seen in the following section, the interplay between ARF actions and PI(4,5)P₂ gets even more complicated.

ARF as Modifier of Lipid Metabolism

A role for ARF in lipid metabolism was first revealed by its role as co-activator of PLD [16,19]. This led to speculation that effects of ARF on vesicle traffic may result from changes in membrane lipid composition. This theory was supported by the observation that PLD was localized to Golgi membranes [20], a major site of ARF actions, and that a persistently active form of PLD can mimic many of the actions of activated ARF on coated vesicle formation *in vitro* [21]. More recently, ARF has been shown to recruit both PI 4-kinase and PI(4)P 5-kinase to membranes, [22] and is a

direct activator of the latter [23]. The sequential actions of these two enzymes produce PI(4,5)P₂, the allosteric activator of PLD and some ARF GAPs and a molecule with widespread effects on cell signaling and morphology. Thus, ARF can increase PLD activity and PA levels both through direct activation of PLD and indirectly, through increased production of PI(4,5)P₂ via activation of PIP kinases. ARF activity can produce changes in local and perhaps cellular levels of phosphatidylcholine, phosphatidic acid, PI, PI(4)P, and PI(4,5)P₂.

Together these data reveal extensive interplay between ARF and phospholipids that may have profound effects on signal transduction, through the activation of specific enzyme effectors and generation of PI(4,5)P₂ and on changes in the lipid composition in microdomains that could impact the rate or ability to form transport vesicles.

The Role of ARF in Vesicle Biogenesis

Cell biological, genetic, and pharmacological data all pointed to intracellular membranes, and particularly the Golgi and *trans*-Golgi network (TGN), as important sites of ARF action. For example, electron microscopy and indirect immunofluorescence of cultured mammalian cells localized ARF to cis-Golgi [24] and TGN membranes [25]. Further, deletion of yeast *ARF1* resulted in defects in the processing of secreted proteins as they pass through the Golgi and genetic interactions with other Golgi proteins [24]. Later, brefeldin A was shown to progressively cause the release of proteins from the cytosolic surface of Golgi and TGN membranes [26], loss of Golgi integrity with fusion of Golgi elements with the endoplasmic reticulum (ER) [27,28], inhibition of protein secretion [29], and death of some cells [30]. All the cellular actions of brefeldin A result from inhibition of ARF GEFs [31], suggesting a role (though perhaps an indirect one) for ARFs in each.

A breakthrough occurred with the observation that the inhibition of intra-Golgi transport by GTPγS led to the accumulation of vesicles of uniform size and possessing an electron-dense coat. Purification of these vesicles allowed the identification of the coat proteins; consisting of the heptameric COP-I complex and ARF [32]. The brefeldin A sensitivity of both ARF and COP-I localization at Golgi membranes led to the proposal that binding to activated ARF is required for COP-I to bind Golgi membranes and promote the budding process [33]. Since that time the number of different coat proteins recruited by ARF has increased markedly, leading to the need for mechanistic details that can explain specificity in recruitment of cargo and coats into the nascent vesicle.

Thus far, seven coat complexes have been identified whose binding to ARF is GTP-dependent and to membranes is brefeldin A-sensitive. These include COP-I, the tetrameric adaptin complexes AP-1 [34], AP-3 [35], and AP-4 [36], and the three monomeric GGAs, GGA1-3 [37–39]. COP-I is required for retrograde transport from the Golgi to the ER

and for transport between the Golgi stacks (see Fig. 1). The adaptin complexes are involved in vesicle traffic from the TGN (AP-1 and AP-4) and from endosomes and synaptic vesicles (AP-3). GGAs regulate vesicle traffic from the TGN to endosomes/lysosomes. Thus, ARF regulates the recruitment of coat complexes from a variety of membranes within a cell, including multiple coats at a single membrane, the TGN.

The initiation of vesicle budding requires a minimum of three components: ARF, the coat/adaptor¹ protein or complex, and a transmembrane anchor protein (see Fig. 2). For COP-I, these roles are filled by ARF, COP-I, and the p24 family of transmembrane proteins (Fig. 2A) [40]. The transmembrane proteins have cytosolic “tails” that carry sorting motifs, such as the acidic dileucine motif that bind GGAs (Fig. 2B) [41,42] or the tyrosine-based signals that bind adaptins (Fig. 2C) [43]. Once the initial three components are in place, the adaptor proteins recruit other components necessary for vesicle formation, transport, uncoating, and fusion. In only some cases does this include clathrin. It is not clear when ARF dissociates from the bud or vesicle but it is likely to be soon after initiation of the coating process. Thus, activation of ARF promotes vesicle budding through the recruitment of vesicle coat proteins which can act as scaffolding in the assembly of the components necessary for vesicular transport.

The correct matching of cargo with adaptor is required for appropriate targeting of the vesicle. An attractive model for how the three components act to “proofread” the coating process was provided by Goldberg [44] and was based on the observation that ARF GAP activity was increased by COP-I. When cargo with an incorrect sorting signal is present, GAP activity is stimulated by COP-I; leading to GTP hydrolysis on ARF, release of COP-I, and prevention of coat assembly and bud maturation. If the sorting motif on the cargo is appropriate to the adaptor, GTP hydrolysis is not stimulated, and vesicle coating proceeds. Though data supporting this model have been generated only with COP-I, we present a more general model for ARF-dependent vesicle biogenesis, showing the different sorting motifs and adaptors that result in the production of different coated vesicles (Fig. 2). Further experimentation is needed to support this three-component model for ARF action. An even more challenging goal is the integration of this protein-based model with the changes in membrane lipids that are known to occur in response to ARF activity. Such a holistic model will be required before detailed understanding of membrane traffic and signal transduction by ARFs is achieved.

¹The terms coat protein and adaptor are used interchangeably here. The former name originates from the electron-dense coat first seen on the non-clathrin coated, COP-I vesicles. Such a coat can be seen in AP-1 bearing clathrin-coated vesicles but has not been described for other ARF coats. The term adaptor is more generic and intended to refer to the fact that whether monomeric or oligomeric, a key component in their biological functions is the ability to bind multiple proteins, including ARFs, transmembrane cargo, clathrin, and accessory proteins.

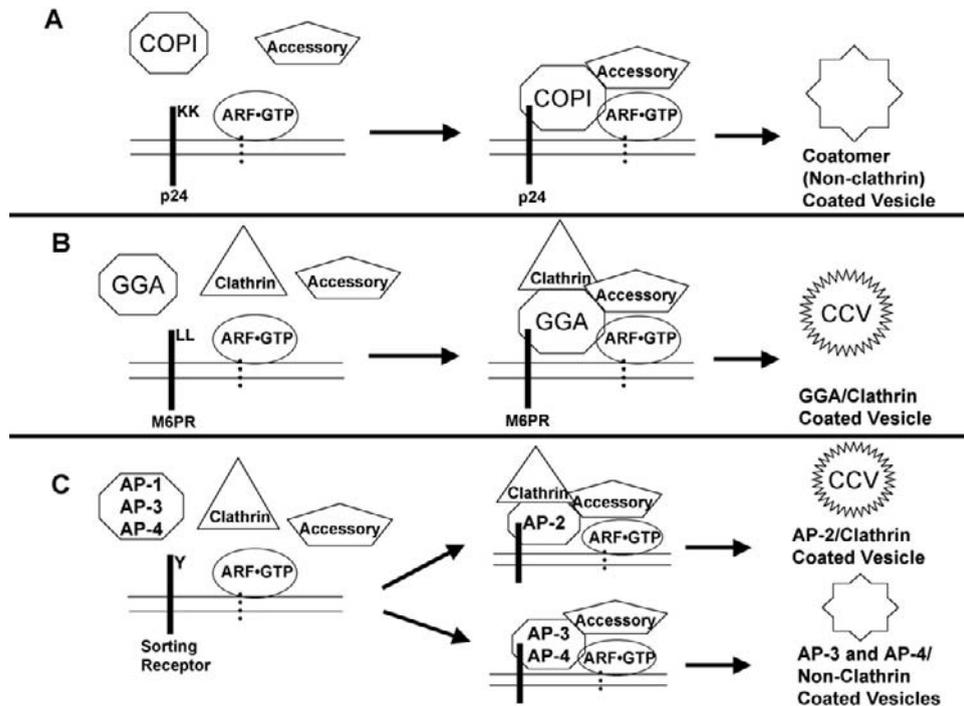

Figure 2 Three-component model for the initiation of ARF-mediated coated vesicle assembly. A minimum of three components are proposed as being critical to the assembly of coat proteins and initiation of vesicle budding; ARF-GTP, a coat/adaptor protein or complex, and a transmembrane anchor or sorting receptor. The latter carries sorting motifs which help match cargo and coat. The p24 family has a dilysine (KK) sorting motif, the mannose 6-phosphate receptors (M6PR) carry an acidic dileucine motif, and sorting receptors have a tyrosine-based signal. Once assembled the adaptor proteins are proposed to act as scaffolds to recruit clathrin (in some cases) and (poorly defined) accessory proteins. The minimal components required for coating of COP-I (panel A), GGA (panel B), and adaptin (panel C) vesicles are shown. Note that GGAs and AP-1 form clathrin-coated vesicles (CCV), while clathrin is not found on vesicles carrying COP-I, AP-3, or AP-4.

Introduction

Cell polarity is critical for the function of the many cell types involved in vectored processes such as nutrient transport, neuronal signaling, and motility. Development of a polarized cell, regardless of cell type, follows a common plan [1]. First, a spatial cue (landmark) marks the site of polarized growth. Signal transduction molecules then interpret the identity of the landmark and signal the establishment of polarity by an asymmetric organization of the cytoskeleton. Polarity is then reinforced with the secretory transport and deposition of molecules needed for growth at the site chosen for polarized growth.

The budding yeast *Saccharomyces cerevisiae* is an outstanding experimental organism with which to decipher the molecular mechanisms of polarity development by small G proteins (hereafter GTPases). GTPases make numerous molecular interactions with effectors and regulators and can be involved in multiple distinct signaling pathways in response to the internal and external cues. The facile experimental genetics of yeast affords the opportunity to study GTPases in individual signaling pathways under different physiological conditions [2]. Herein, the role of GTPases in linking spatial landmarks on the cell cortex to the reorganization of the cytoskeleton will be presented in the context of yeast budding.

The Rsr1/Bud1 Ras-Like GTPase Module Interprets Spatial Landmarks

Yeast cells undergo oriented cell division by selecting a specific site for polarized growth, the bud site, on their cell cortex. Haploid **a** and α cells bud in an axial pattern in which both mother and daughter cells select a bud site immediately adjacent to their previous division site. Diploid **a**/ α cells bud in a bipolar pattern: mother cells select a bud site adjacent to their daughter or on the opposite end of the cell, whereas daughter cells always choose a bud site directed away from their mother [3–5] (Fig. 1). Thus, the choice of a bud site determines the axis for cell polarity and ultimately the cell division plane.

A GTPase module consisting of the Ras-like GTPase Rsr1/Bud1, its GDP-GTP exchange factor (GEF) Bud5, and its GTPase activating protein (GAP) Bud2, is essential for selecting the proper site for polarized growth in both haploid and diploid yeast cells [6–10]. Deletion of *RSR1/BUD1*, *BUD2*, or *BUD5* leads to random budding [6,7,10] as does the expression of *rsr1*^{G12V} (predicted to be constitutively GTP-bound) or *rsr1*^{K16N} (predicted to be constitutively GDP-bound or nucleotide-empty) [11], suggesting that Rsr1/Bud1 needs to be cycled between GTP- and GDP-bound states for proper bud-site selection. Rsr1/Bud1 localizes to the plasma membrane and then becomes

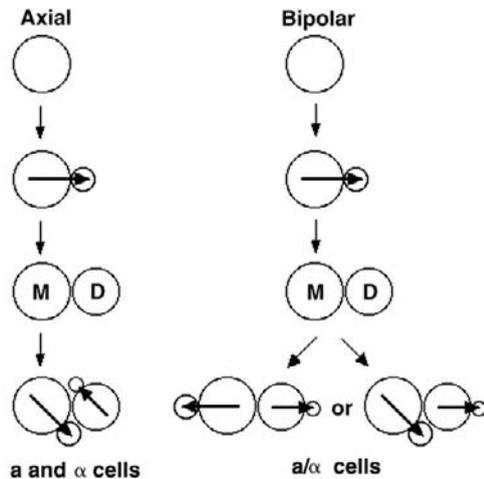

Figure 1 Wild-type patterns of bud site selection in yeast. In the axial pattern (exhibited by an *a* or α cell), the mother cell (M) buds immediately adjacent to its last daughter; the daughter cell (D) buds toward its mother. In the bipolar pattern (exhibited by an *a/α* cell), the mother cell can bud at or near either of its poles; the daughter cell buds away from its mother. The arrows within the cells indicate the axis of polarity. (Reprinted, with permission, from Chant, J. and Herskowitz, I. *Cell*, **65**, 1203–1212, 1991. Copyright Cell Press).

concentrated at the presumptive bud site in G1 of the cell cycle [11a]. Bud2 and Bud5 proteins are also found at the presumptive bud site in unbudded cells [12,13]. Although each protein of the Rsr1/Bud1 GTPase module can localize to the presumptive bud site independently of each other, localization of each protein to the proper bud site cannot be maintained in the absence of any other protein in the module. Thus the localized action of the Rsr1/Bud1 GTPase module is required for proper bud site selection [12,13].

Isolation of cell-type specific alleles of *BUD2* and *BUD5* suggests that each of the proteins encoded by these genes localizes to the presumptive bud site through interactions with cortical landmarks unique to haploid or diploid cells [13,14]. Recent studies on Bud5 have established that Bud5 interacts physically with a transmembrane protein, Ax12/Bud10 [15,16], a potential landmark for axial budding in haploid cells [13]. Bud5 mislocalizes in cells lacking Ax12/Bud10 [13,17]. Thus, the interpretation of a cortical landmark by a GTPase module occurs by the interaction of the landmark protein with the GEF of the module, which may result in the localized activation of module at the site of polarized growth. It is not known whether Bud5 interacts with potential bipolar landmarks such as Bud8 or Bud9 [14,18] to establish the bipolar budding pattern in diploid cells (Fig. 2).

The Rsr1/Bud1 module does not complete the link between cortical landmarks and polarity establishment; rather, it links the spatial signals from both axial and bipolar landmarks to the Cdc42 GTPase module (discussed in the following section), which is essential for the establishment of cell polarity.

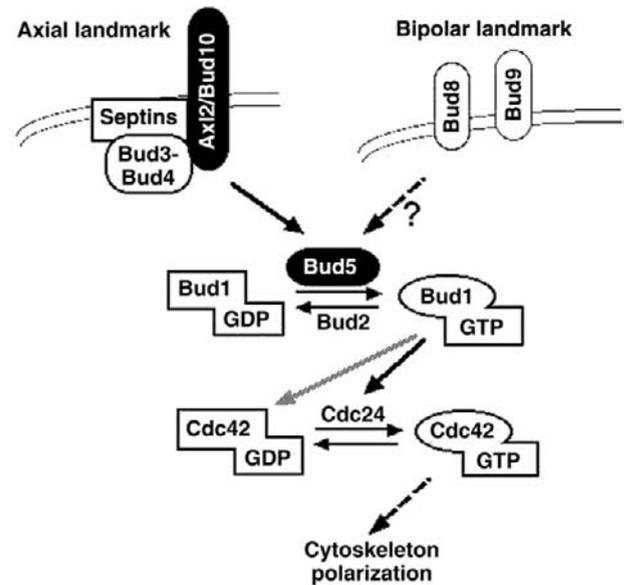

Figure 2 A model for spatial control of cell polarity during yeast budding. Bud5 is likely to be localized to the presumptive bud site in haploid *a* and α cells through the interaction with Ax12, a component of the axial landmark. Bud5 locally activates Bud1 to the GTP-bound state, which then associates with proteins necessary for bud-site assembly, such as Cdc24 and Cdc42. Bud5 may interact with Bud8 or Bud9, putative landmarks of diploid *a/α* cells, thus directing polarity establishment for bipolar budding pattern. (Adapted from Kang, P. J., Sanson, A., Lee, B., and Park, H.-O., *Science*, **292**, 1376–1378, 2001. With permission.)

The Cdc42p Rho-Like GTPase Module Regulates the Establishment of Cell Polarity

A GTPase module consisting of the Rho-like GTPase Cdc42, its GDP-GTP exchange factor (GEF) Cdc24, its GTPase-activating proteins (GAPs) Bem3, Rga1, and Rga2, and guanine nucleotide dissociation inhibitor (GDI) Rdi1, is essential for the establishment of cell polarity prior to budding (reviewed in [19]). Mutation of *CDC42* or *CDC24* prevents an asymmetric organization of the actin cytoskeleton at the bud site as well as bud formation [20,21]. Association of Cdc42 with the plasma membrane via posttranslational geranylgeranylation of its C terminus is essential for Cdc42 function [22]. Deletion of each of the GAP-encoding genes does not result in a *cdc42* phenotype, due perhaps to a redundancy of function among this class of proteins [23,24]. How the Cdc42 module effects the establishment of cell polarity at the site chosen for polarized growth is a question of expanding complexity because the proteins of the Cdc42 module make numerous physical and genetic interactions [19,25,26] that result not just in the polarization of the actin cytoskeleton (see the following section), but of other proteins involved in polarized growth as well (e.g., Sec3 of the exocyst complex) [27].

Coupling the Rsr1/Bud1 GTPase Module to the Cdc42 GTPase Module

A web of genetic interactions among the *BUD* genes and *CDC24* hinted at a linkage between the Rsr1/Bud1 and

Cdc42 GTPase modules (reviewed in [28]). Subsequent studies showed that Rsr1/Bud1 interacts with Cdc24 (as well as Cdc42 and the scaffold Bem1) in a guanine nucleotide-dependent manner [29,30] (Fig. 2). The scaffold protein Far1 sequesters Cdc24 in the nucleus [31–33]. In late G1, Cdc24 is exported into the cytoplasm upon cyclin activation of Cdc28 kinase [32,33]. In the absence of Rsr1/Bud1, Cdc24 localizes in a patch randomly located on the plasma membrane [11a], consistent with the proposed role of Rsr1/Bud1 GTPase module guiding bud-site assembly proteins to the proper bud site.

The Cdc42 GTPase Module Spatially Restricts Actin Assembly to the Site of Polarized Growth

Localized activation of Cdc42 at the bud site by Cdc24 leads to an asymmetric distribution of filamentous actin structures within the cell. In late G1, actin cables align along the cortex of the cell and cortical actin patches concentrate at the bud site (reviewed in [34]). Recent studies suggest that new Cdc42-dependent actin assembly and stabilization at the bud rather than the movement of existing actin structures to the bud causes the asymmetric distribution of these cytoskeletal structures within the cell [35–38].

A permeabilized cell assay provided the first evidence for Cdc42-dependent actin assembly at the site of polarized growth. Permeabilized cells with impaired Cdc42 function did not assemble exogenously added actin at the site of polarized growth, except with the prior addition of recombinant Cdc42 or an activated form of the Cdc42 effector Ste20, a PAK family kinase [39,40]. This latter result is consistent with the ability of GTP-bound Cdc42 to relieve PAK autoinhibition (reviewed in [41]), although a role for Ste20 in actin assembly remains undefined. Cla4, a PAK kinase that is partially redundant with Ste20, may, however, have a bona fide role in cortical actin assembly. Phosphorylation of class I myosins by Cla4 may activate the actin nucleating complex, Arp2/3, directly or indirectly through interaction with the Arp2/3 activator Las17/Beel [38]. To what extent this activity depends upon the kinase activity of Cla4 is unclear [42]. Interestingly, overexpression of *CLA4*, but not *STE20*, is lethal [2]. Phosphorylation of Cdc24 by Cla4 may release Cdc24 from a Bem1 scaffold that also contains Cdc42, ending polarized bud growth [43, 43a]. Thus, activation of Cla4 by Cdc42 may initiate actin assembly at the site of polarized growth and may result in the negative regulation of Cdc42 by acting on its GEF Cdc24.

Polarization of the actin cytoskeleton also depends upon two other Cdc42 effectors, the redundant formin family proteins Bni1 and Bnr1. Bni1 localization at the site of polarized growth depends upon Cdc42 activity and is enhanced by interactions with proteins of the polarisome and the Cdc42 effectors Gic1 and Gic2 [44–46]. In the absence of formin function, the actin cytoskeleton becomes depolarized. Upon recovery from formin inactivation, actin cables assemble from the site of polarized growth in an Arp2/3-independent manner [36,37]. Formins are also required for

maintaining a polarized distribution of Las17 [38]. It is unclear whether recruitment of this activator of Arp2/3-dependent actin assembly depends upon Cdc42.

Furcation of Cdc42-dependent actin assembly pathways may allow for greater regulation of polarized actin assembly among growth conditions and cell types. For example, the Cdc42 effectors Gic1 and Gic2 may be more important in haploids and at higher temperatures in contrast to the putative Cdc42 effectors Msb3 and Msb4, which are suggested to be more important in diploids and at low temperatures [47].

Conclusion

Substantial progress has been made in deciphering the molecular basis of cell polarity in yeast. One important aspect, but still poorly understood, is the regulation of each component, in particular GEFs and GAPs, involved in polarity development. Some of the machinery is specific to yeast, but the general principles underlying cell polarity and the components in the signaling pathways appear highly conserved throughout evolution. Thus understanding the spatial and temporal control of the GTPases and their regulators in yeast is undoubtedly relevant to other eukaryotes. This article aimed to be a brief guide to the field. For in-depth discussion, we recommend recent reviews [25,34,48–51]. A guide to yeast genes can also be found in the *Saccharomyces* Genome Database (SGD) [52].

Introduction

Cell signaling requires proper localization of all the players involved. Many proteins are targeted to the appropriate subcellular location, and are directed to interact with their regulators and effectors, by lipid modification. Prenylation, the modification by a C15 farnesyl isoprenoid or a C20 geranylgeranyl isoprenoid, is required for the biological activity of small GTPases and other proteins containing specific C-terminal CAAX motifs. Inhibitors of farnesyltransferase (FTase), FTIs, have been designed for use as anti-Ras and anti-cancer drugs, but in fact they are selective for FTase, not for Ras. This distinction has important implications for their use as pharmacological tools to dissect signaling pathways. For example, FTIs can completely suppress the prenylation of H-Ras but not of the other Ras isoforms, so grouping all the Ras proteins together as FTI targets is an oversimplification that adversely affects the interpretation of results using FTIs to block Ras-mediated signaling events. Efforts are underway to identify the biological consequences of disrupting the farnesylation and geranylgeranylation of specific prenylated proteins, and it now seems clear that multiple proteins are involved in cellular responses to FTIs. For example, genetic evidence indicates that RhoB is required for the apoptotic response to FTIs, but not for the suppression of anchorage-independent growth. Understanding the contribution of specific targets to distinct consequences of FTI disruption will be important in identifying the roles of prenylated proteins in specific aspects of cell signaling.

Farnesylation and Protein Function

Like many other things in life, successful cell signaling requires accurate and specific localization of all the players.

For many proteins, the correct subcellular localization and biological activity requires the attachment of specific lipids that mediate both positioning within the appropriate cellular compartment and interaction with upstream regulators and downstream effectors. It has become apparent in the last decade or so that the modification of proteins by prenylation, that is, the attachment of isoprenoid lipids, plays a critical role in the signaling activity of G proteins both large and small. In particular, the finding that farnesylation, the attachment of a 15-carbon farnesyl isoprenoid group, to the small GTPase Ras is required for its biological activity, provoked massive efforts to develop inhibitors of (FTase), the enzyme responsible for this attachment. The resulting (FTI) compounds have helped to shed considerable light on the role of such modifications in cell signaling events, but have also introduced a few mysteries of their own.

Ras—the Prototype of Farnesylated Proteins

Ras is an important hub in the complex network of intracellular signaling pathways. Ras proteins receive signals from a wide range of cell surface receptors including receptor tyrosine kinases, G-protein-coupled receptors, and integrins [1]. In turn Ras transmits these signals through an ever-increasing list of effector proteins, the most well characterized of which are the serine/threonine kinase Raf, phosphatidylinositol-3-kinase (PI3-K) and Ral-guanine nucleotide dissociation stimulator (Ral-GDS). Ras signaling ultimately influences gene transcription to alter properties including cell survival, proliferation, differentiation, adhesion, motility, and morphology. Normally GDP-bound and inactive, Ras proteins are converted to the active, GTP-bound conformation by guanine nucleotide exchange factors (GEFs), and back again to the resting state by GTPase-activating proteins (GAPs) that stimulate the

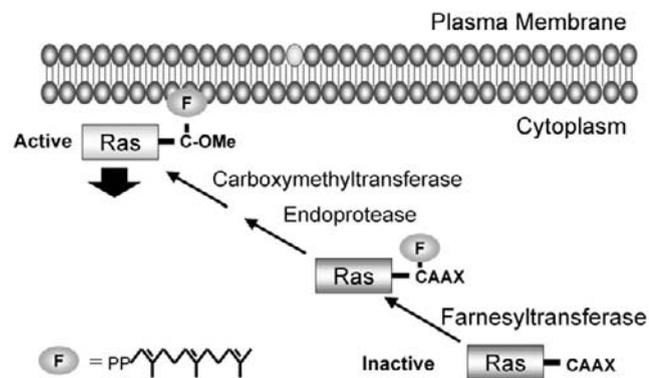

Figure 1 Posttranslational modifications are required for membrane localization and biological activity of prenylated proteins.

intrinsic GTPase activity of Ras. When Ras is rendered constitutively GTP-bound and active by oncogenic mutations (typically at positions 12, 13, or 61), the resulting uncontrolled signaling leads to increased cell proliferation, survival in the absence of substratum, loss of contact inhibition, changes in adhesion, motility, and morphology, and the development of other aspects of the transformed phenotype. Alternative splicing results in the three *ras* genes encoding four Ras proteins, H-Ras, N-Ras, K-Ras4A, and K-Ras4B. Recent work suggests that these proteins, while highly similar, are not completely functionally equivalent. In keeping with this possibility, although activating Ras mutations in general are associated with approximately 30% of human cancers, the distribution of mutations of each Ras isoform differs among tumor types [2]. The high prevalence of mutated Ras in cancers has led to many attempts to develop compounds that block Ras signaling for cancer treatment.

Localization of Ras to the inner leaflet of the plasma membrane is an absolute requirement for both its normal and oncogenic functions, and is accomplished through a series of posttranslational modifications (Fig. 1) (reviewed in reference [3]). The first is the addition of a 15-carbon farnesyl isoprenoid to the cysteine of the C terminal four amino acid sequence called the “CAAX motif,” where C = cysteine, A = aliphatic, and X = any amino acid. This prenylation step is then followed by proteolysis of the -AAX sequence, carboxymethylation of the resulting farnesylated C-terminal cysteine, and (in H-, N- and K-Ras4A) palmitoylation of either one or two cysteines upstream of the CAAX motif. The first and obligate step of all these posttranslational modifications is catalyzed by FTase. Mutants of Ras that lack a farnesylatable cysteine neither localize to membranes nor signal to downstream effectors. Thus, FTase has been an attractive target for anti-cancer drug development efforts directed toward inhibiting aspects of cellular transformation influenced by Ras. Farnesyl isoprenoids are obligate intermediates in the cholesterol biosynthetic pathway, but blocking FTase is far more selective than disrupting the entire pathway via statins, which are inhibitors of the mevalonic acid precursor (Fig.2). However, although FTIs were originally

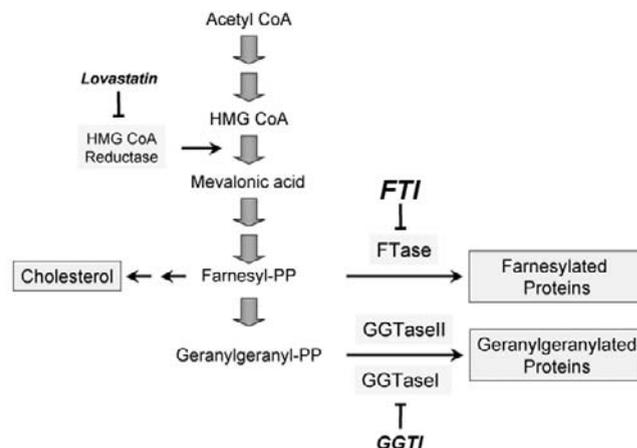

Figure 2 Farnesyl isoprenoids, obligate intermediates in cholesterol biosynthesis, are key elements of the mevalonate pathway.

developed as anti-Ras drugs, the consequences of inhibiting FTase are more complicated than simply inhibiting the farnesylation of Ras. In this chapter we will describe the activities of FTIs, the current confusion surrounding the identity of the biologically relevant downstream targets of FTase, and the use of FTIs as pharmacological tools to disrupt cellular signaling events.

Identification and Development of FTIs

The first FTI was a simple synthetic tetrapeptide corresponding to the CAAX motif of K-Ras4B (CVIM), which was designed to act as a competitive inhibitor of full-length Ras for binding to FTase [4]. However, the instability and poor membrane permeability of simple peptides demanded that different chemical entities be developed. Thus, in rationally designed peptidomimetic FTIs, labile peptide bonds were replaced with more stable chemical moieties [5–7] to increase biological half-life, and modification of the negatively charged carboxyl terminus greatly improved cell permeability. Current FTIs are generally nonpeptidomimetics that have been identified by screening small molecule libraries generated by combinatorial chemistry [8]. Naturally occurring FTIs have also been discovered in screens of natural products from bacteria [9], fungi [10], and plants [11], although only the fungal FTI manumycin has been used extensively for research purposes. The mechanism and kinetics of Ras prenylation by the zinc-containing metalloenzyme FTase, and its inhibition by FTIs, have been studied extensively (reviewed in reference [12]). These studies have been facilitated by the determination of the crystal structure of FTase alone or in complex with Ras and/or farnesylpyrophosphate [13,14], and by the use of NMR to define the interactions between FTase and FTIs in solution. This work has further contributed to refining the structures of subsequent FTIs. Most FTIs developed to date have been competitive for the protein substrate of FTase, but prenyl-competitive [15,16]

and dual-competitive [17] FTIs have also been developed successfully. Peptide-competitive FTIs with IC₅₀s in the micromolar to nanomolar range are commercially available for research purposes. Two of the best of these compounds for use in cell-based assays are FTI-277 [18] (Calbiochem, San Diego, CA) and L744,832 [19] (BioMol, Plymouth Meeting, PA). Other peptide-competitive FTIs with favorable pharmacokinetic and pharmacodynamic properties are currently in clinical trials. These include R115777 (Zarnestra, Johnson & Johnson), SCH66336 (Sarosar, Schering-Plough), BMS-214662 (Bristol Myers-Squibb), and CP-609754 (Pfizer). The status of clinical trials using FTIs is the subject of recent reviews [20,21].

FTI Activity in Cell Culture and Animal Models

Early FTIs showed great promise *in vitro* against purified FTase, with many FTIs inhibiting H-Ras farnesylation in the low nanomolar range [5,22], and demonstrating excellent specificity for FTase compared to the highly related enzyme geranylgeranyltransferase I (GGTase I) [23]. Further, FTIs inhibited the prenylation of H-Ras and other farnesylated proteins in a variety of cell culture systems, as demonstrated most often by gel shift analysis wherein the unprenylated protein migrates slower than the prenylated form. FTIs selectively inhibited transcriptional transactivation of reporters driven by Ras compared to Raf, and also caused reversion of many aspects of the transformed cell phenotype (reviewed in references [3,24,25]). FTIs inhibited the proliferation of H-Ras-transformed cell lines and human tumor-derived cell lines, reverted Ras-transformed morphology, re-established actin stress fibers lost upon Ras transformation, inhibited Ras-dependent anchorage-independent cell growth and migration, inhibited DNA synthesis, and affected the transcription of a variety of genes downstream of Ras-responsive promoters. Oddly, FTIs showed remarkably little toxicity toward normal cells, which is a highly desirable feature for potential drugs, but a surprise at the time given the inability of cells to cope with dominant negative Ras. Except for the relative lack of toxicity, these studies suggested that Ras was an important target of FTIs, and encouraged further studies in animal models.

In both mouse tumor xenograft models and transgenic mouse models, FTIs also produced impressive effects with little overt toxicity (reviewed in reference [26]). In nude mice, FTIs inhibited the growth of a wide variety of human tumor-derived cell lines and human tumor explants from the pancreas, lung, colon, blood, brain, prostate, and bladder. Inhibition of the growth of tumors derived from rodent epithelial and fibroblast cell lines transformed with specific oncogenes including Ras was also observed. Regression of tumors was rare in nude mouse models, consistent with a cytostatic mode of action. Transgenic mice told a different story. In transgenic animals harboring mutations in H-Ras [27], N-Ras [28], or K-Ras [29] giving rise to stochastic mammary, salivary, or lymphoid tumors, FTI treatment

inhibited the growth of existing tumors and prevented the growth of new ones. But in H-Ras-driven transgenic tumors, rapid regression of existing tumors was also observed [27]. The basis for the different responses of xenografted and transgenic tumors to FTIs is still not understood.

Although FTIs were originally intended to be used against solid tumors harboring Ras mutations, there is increasing preclinical and clinical evidence that they are actually more effective against various forms of leukemia (reviewed in reference [30]), as well as gliomas and breast cancer (reviewed in reference [31]). These tumors are not typically associated with Ras mutations, but instead may have upregulated Ras signaling due to elevations in epidermal growth factor receptor (EGFR) family activity via overexpression or mutation [1]. Thus, inhibition of endogenous Ras function may play a role in this sensitivity. Whether such inhibition is direct or indirect is a matter of debate.

Studies in human tumor cell lines have also shown that FTIs are additive or synergistic in combination with a wide variety of other anti-cancer agents including [32], taxanes [33,34], aminobisphosphonates [35], cyclophosphamide [36], inhibitors of the MEK pathway [37], and ionizing radiation [38]. It is not clear why FTIs work particularly well with taxanes, but interactions with farnesylated microtubule binding proteins including CENP-E and K-Ras have been proposed. Clearly, many questions regarding the consequences of FTI inhibition still exist.

Alternative Prenylation in the Presence of FTIs

Early in the development of FTIs it was observed that, while prenylation of H-Ras was effectively blocked by FTIs, prenylation of N- and K-Ras was not [39,40]. Instead, when FTase is inhibited, N- and K-Ras were shown to be alternatively prenylated by GGTase I [41,42]. Sharing a common α subunit with FTase, GGTase I catalyzes the addition of a 20-carbon geranylgeranyl isoprenoid to proteins terminating in appropriate CAAX motifs. The canonical CAAX motif specifying geranylgeranylation terminates in leucine (L) [23]. However, in the absence of FTase activity, the C-terminal methionine (M) of N-Ras (CVVM) and K-Ras (CVIM) permits alternative prenylation while the serine (S) of H-Ras (CVLS) does not. Because of this, N- and K-Ras, but not H-Ras, were shown to bypass functional FTI inhibition. Unless farnesylated and geranylgeranylated N- and K-Ras proteins were functionally distinct, which does not appear to be the case, this end-run around FTI suggested that functional compensation by N- and K-Ras for FTI-inhibited H-Ras might explain the lack of toxic side effects of FTIs [40]. However, it also suggested that FTIs might not be effective against the majority of human tumors that harbor N- or K-Ras mutations, an assertion that is inconsistent with the observation that such tumors were sensitive to FTIs in mouse models. Alternative prenylation of N- and K-Ras, as well as of other farnesylated proteins with a C-terminal methionine, further complicates attempts to define clearly the appropriate

downstream targets and mechanism of FTI action. Importantly, a critical role for non-Ras FTI targets is implied by these observations.

FTIs as Pharmacological Tools to Study Signaling and Biology

FTIs have been used to implicate Ras in numerous cellular processes including cell transformation, mitogenesis, neurite outgrowth, motility/migration, response to oxidative stress, transcriptional regulation, and protein secretion. Further, contributions of specific downstream Ras effectors, such as Raf/MEK/Erk, PI3-K/Akt, and upstream Ras activators such as receptor tyrosine kinases have also been implicated by using FTIs. However, the interpretation of such data can also be problematic. Despite their differing responses to FTI, H-, N-, and K-Ras proteins are often wrongly lumped together, and "Ras" is often wrongly presumed to be implicated in any process that is affected by FTI treatment. Thus, FTIs have been used as putative Ras inhibitors in ways analogous to inhibitors of other signaling intermediates such as the MEK inhibitors U0126 and PD98059, the PI3-K inhibitors LY294002 and wortmannin, and the p38 MAPK inhibitor SB203580. This is potentially problematic for two reasons. First, as was discussed in the above section, not all Ras proteins respond equally to FTIs (N- and K-Ras are resistant), and second, Ras proteins are neither the only farnesylated proteins affected by FTIs, nor necessarily the most sensitive. The mechanism of FTI action is still poorly understood because there are many farnesylated proteins other than Ras whose functions are affected by FTIs, making it difficult to conclude that a particular FTI-induced phenotype is Ras dependent. Other possible FTI targets will be discussed in the section about inhibition of signaling by FTIs.

In short, FTIs are literally FTase inhibitors, not Ras inhibitors. As will become apparent, only when the phenotype of interest is known to be H-Ras-dependent, is it really safe to use FTIs as Ras inhibitors. Instead, FTIs should be used as inhibitors of farnesylation, with the understanding that the processing, localization, and function of multiple farnesylated proteins are inhibited upon FTI treatment.

Targets of FTIs

During the early years of FTI research initial success was tempered by the increasing realization that the efficacy of FTIs was not simply the result of functional Ras inhibition, and that the original straightforward model of FTI-as-Ras-inhibitor was not the full story. FTI sensitivity does not correlate with the presence of activating Ras mutations in a series of human tumor cell lines [19], and FTIs inhibit N- and K-Ras-induced transformation, even though these isoforms are alternatively prenylated and therefore not rendered unprocessed and inactive by FTI. Together these observations support the notion that farnesylated proteins

other than Ras proteins, whose prenylation and activity are also affected by FTIs, are also important targets of FTI action (reviewed in references [43] and [44]).

Our own search of the SwissProt database revealed approximately 250 human proteins containing a C terminus that resembles a CAAX motif. Some of these are shown in Table I. *In vitro* studies using synthetic or mutant CAAX sequences [4,45,46] demonstrated that many of these proteins are poor substrates for FTase and are not likely normally to be farnesylated. Of those that are potential FTase substrates, many, including numerous members of the Ras superfamily, are known to be farnesylated while others have not yet been evaluated. At present, several CAAX-containing, farnesylated human proteins are currently under investigation as mediators of FTI action.

The most intensively studied putative FTI target is RhoB [47], an immediate-early, inducible small GTPase that is highly related to RhoA and RhoC. Uniquely, RhoB exists in both a farnesylated (F) and a geranylgeranylated (GG) form [48]. The geranylgeranylated form of RhoB is growth inhibitory in both rodent fibroblasts and human carcinomas [49,50], and an increase in RhoB-GG is proposed to mediate the antineoplastic effects of FTIs [51]. It remains to be demonstrated whether a shift of RhoB-F to RhoB-GG or an induction of RhoB-GG correlates with FTI sensitivity in human tumor cells. Interestingly, RhoB may be upregulated as a consequence of FTI treatment, in keeping with its role as a stress detector. Genetic evidence from RhoB null MEFs shows that loss of RhoB impairs the apoptotic response to FTIs [51], suggesting that RhoB is required for apoptosis. By contrast, loss of RhoB does not impair the inhibition of anchorage-independent growth by FTIs [51], suggesting that RhoB is not the mediator of that response.

Other potentially critical FTI targets include the centromere binding protein CENP-E [52,53] which is involved in spindle formation and chromosome alignment during mitosis, the phosphatases PRL-1, -2, and -3, nuclear lamins, inositol 3,5-diphosphate phosphatases I and IV, kinases such as S/T kinase 11, and numerous small GTPases of the Ras (Rheb, Rap2) and Rho (RhoD, RhoE, Rho6, RhoN, and TC-10) families (reviewed in reference [43]). Proteins that have specialized expression patterns, such as the α and β subunits of skeletal muscle phosphorylase B kinase, may play important roles in specialized circumstances. CAAX-containing proteins whose prenylation status has not yet been explicitly determined, but whose CAAX sequences and homology to other farnesylated proteins imply that they too will be farnesylated, include the small GTPases RhoI, Ras-related protein 22 (RRP22), Rab28, and the putative tumor suppressor NOEY2/ARHI, as well as AGS1, a GEF for heterotrimeric G proteins. In addition, there are approximately 40 other human proteins unrelated to GTPases that contain CAAX motifs that could support farnesylation. Further complicating the issue is the observation that several potentially farnesylated proteins have a methionine-containing CAAX motif similar to N- and K-Ras, suggesting that they also might be resistant to FTI inhibition via alternative prenylation.

Table I CAAX-Containing Proteins as Potential FTI Targets

FTI targets	Accession no.	CAAX	Prenyl group
H-Ras	RASH_HUMAN	CVLS	F
hPRL-3	NP_116000	CCVM	F(=>GG?)
Lamin A/C	LAMA_HUMAN	CSIM	F(=>GG?)

RRP22	RR22_HUMAN	CSLM	F(=>GG?)
Rab28	RB28_HUMAN	CAVQ	F?
Serine/threonine kinase 11	ST11_HUMAN	CKQQ	F?

Also, the fact that RhoB (CKVL) is both farnesylated and geranylgeranylated, even though it ends with a leucine (L) that normally signals exclusively for geranylgeranylation, suggests that other proteins might be exceptions to the basic rules governing prenylation. Given the current confusion surrounding the identity of relevant FTI targets, it will be important to determine which of these proteins is farnesylated, affected by FTIs, and can account for the observed biological effects of FTIs. In any case, it is likely that FTIs

will affect numerous farnesylated proteins to produce complex, cell-type-specific effects.

Inhibition of Signaling by FTIs

Why must farnesylated proteins be farnesylated? First, this lipid modification has been shown to be necessary for membrane localization. Both pharmacological inhibition with

lovastatin and similar compounds and with FTIs prevent farnesylation and cause normally membrane-localized farnesylated proteins to remain cytosolic. Mutagenesis of the CAAX motif to a SAAX motif, which cannot be prenylated, also renders normally farnesylated proteins cytosolic. These results imply the existence of specific protein:lipid interaction sites at membranes, whether simply to increase hydrophobicity or for specific docking interactions. Second, farnesylation is important for protein:protein interactions. Farnesylated Ras proteins have long been known to be better substrates for GEFs such as SOS, to interact better with downstream effectors such as PI3-K p110 δ and adenylyl cyclase [54] and to stimulate downstream signaling to kinases such as ERK2 as compared to their nonfarnesylated counterparts, even in cell-free systems [55]. The assembly of β/γ dimers of heterotrimeric G proteins depends upon appropriate prenylation of the γ subunit [56,57], as does cell-free activation of downstream effectors including PLC- β and adenylyl cyclase [57]. The enhancement of protein:protein interactions by lipid modification even in cell-free systems suggests that this is not simply a secondary consequence of necessary subcellular localization conferred by the isoprenoid.

If the critical consequences of FTI activity are due to cellular stress responses, then the most critical FTI targets may not necessarily even be farnesylated (viz. RhoB). But if the consequences of FTI activity are primarily due to blocking FTase-mediated farnesylation of target proteins, then the challenge is to determine the identities and relative affinity for FTase of all farnesylated proteins. FTIs can demonstrate the existence of farnesylated proteins in a particular pathway. Growth inhibition by FTIs is associated primarily with their induction of cell cycle arrest in either G0/G1 or G2/M, depending on p53 status. FTIs do not generally kill transformed cells except in conjunction with a second apoptotic signal such as serum starvation [58] or the absence of substratum [59], but exceptions have been observed. In some human tumor cell lines, sensitivity to FTI-induced apoptosis is dependent on the inhibition of the PI3-K/Akt/BAD pathway and a concomitant reduction in the level of phospho-Akt in those cells [60]. What farnesylated protein is critical to regulate this pathway is unknown at present, although it could be endogenous H-Ras; it has also been suggested that FTI does not inhibit Akt via blocking the processing and activity of a farnesylated protein, but rather by upregulating the expression of RhoB [61]. However, even the correlation between FTI-induced apoptosis and phospho-Akt suppression is not universal across all cell types, so additional mechanisms are likely. FTIs may also have an indirect effect on tumor growth by inhibiting angiogenesis [62,63], and this is known to be the consequence of a decrease in vascular endothelial growth factor (VEGF). However, it is unclear whether the farnesylated protein controlling VEGF that is inhibited by FTI to produce the anti-angiogenic effect is a Ras protein, which is known to regulate VEGF in a PI3-K-dependent manner, or is another protein altogether. Therefore, at this stage it is not possible to draw definitive causal connections between most of the observed cellular

effects of FTIs and particular biochemical pathways that may mediate those effects. Making such connections is now a major goal for understanding what FTIs are doing in the context of both whole cells and animals.

Summary and Prospects

The development of FTIs during the past ten years constitutes a convoluted story. Originally designed to treat Ras-related cancers by inhibiting oncogenic Ras function, FTIs are now thought to be ineffective against N- and K-Ras due to alternative prenylation, and to exert their effects primarily through inhibition of the farnesylation of other substrate proteins or the induction of proteins such as RhoB. With so many potential FTI targets, each with a different cellular function and sensitivity to FTIs, the task of unraveling the mechanism of FTI action is complex. But even in the absence of an understanding of which specific substrates mediate which specific consequences, it is clear that FTIs do have utility as anti-cancer agents, and can be useful tools to demonstrate the contribution of farnesylated proteins to the control of a particular signaling pathway.

Structure of Rho Family Targets

Helen R. Mott and Darerca Owen

*Department of Biochemistry, University of Cambridge,
Cambridge, United Kingdom*

The variety of cellular processes controlled by the Rho family proteins, of which Cdc42, Rac, and Rho are the most widely studied members, are mediated through a number of downstream effector proteins, many of which are still being characterized. The members of the Rho subfamily have a far greater number of effector proteins than other G-protein subfamilies. The effectors can be loosely divided into those that bind to Cdc42 and Rac and those that bind to Rho. The effectors are both functionally and structurally diverse, as is the nature of their interactions with the small G proteins.

Structurally, the Rho family proteins are distinguished from the Ras family by the presence of an extra pair of helices (the insert region) [1]. It has been reported that removal of this insert region in Rac expressed *in vivo* prevented both the formation of membrane ruffles [2] and transformation [3]. Thus it is expected that at least one target protein of the Rho family will interact with this region. The structures of six Rho family effectors and their complexes have been studied so far and will be described here.

CRIB Proteins

Many of the downstream effectors for the Rho family proteins Cdc42 and Rac contain a small (16 amino acid) consensus sequence known as the CRIB (Cdc42/Rac interactive binding), which is essential for mediating interactions with the G proteins [4]. In several studies it has been shown that additional residues, C terminal to the CRIB, are also necessary for tight binding, making the full G protein binding domain (GBD) 40–45 amino acids. All the CRIB proteins bind to Cdc42-GTP and some of them bind to Rac-GTP. Structural studies of the CRIB family proteins have addressed two fundamental questions: How do some CRIB proteins discriminate between the closely related Cdc42 and Rac, and how does binding a Rho family protein activate downstream events?

The solution structures of three different Cdc42/CRIB complexes have been solved: activated Cdc42 kinase (ACK), a tyrosine kinase, which has been implicated in integrin signaling and endocytosis [5]; Wiscott-Aldrich syndrome protein (WASP), which is thought to mediate interactions with the cytoskeleton [6], and p21 activated kinase (PAK), a serine/threonine kinase involved in JNK signaling and cytoskeletal rearrangements [7]. Comparison of these structures reveals interesting differences in the way that the effectors contact the G proteins (Fig. 1). In addition, since ACK and WASP are specific for Cdc42 while PAK binds to both Rac and Cdc42, the structures shed light on how the CRIB proteins may discriminate between two such similar molecules. In each structure, the CRIB consensus region binds in a similar manner, forming an intermolecular β -sheet with the β 2-strand of Cdc42 and then interacting with switch I. This is reminiscent of the structure of Ras with its effectors Raf-1 [8] and Ral-GEF [9], both of which form a similar intermolecular β -sheet, although all the other features of these structures differ. The regions outside the CRIB consensus all interact with the same regions of Cdc42, helix α 5, and switch II, although the details of the interactions are all different. ACK does not form any more secondary structure but wraps around the G protein, forming an irregular hairpin at the top of switch I. WASP and PAK both form a regular β -hairpin that interacts with switch I and switch II, followed by a short piece of α -helix which interacts with switch II. In WASP and PAK the relative orientation of this hairpin and α -helix are different, as is their orientation with respect to the switch II helix.

NMR studies on the free GBDs of these three proteins revealed no significant tertiary structure. In both PAK and WASP there was some evidence for the formation of the short section of α -helix that is seen in the complex with Cdc42 [7,10]. In ACK, where there is no secondary structure in the complex, none could be discerned in the free GBD [5].

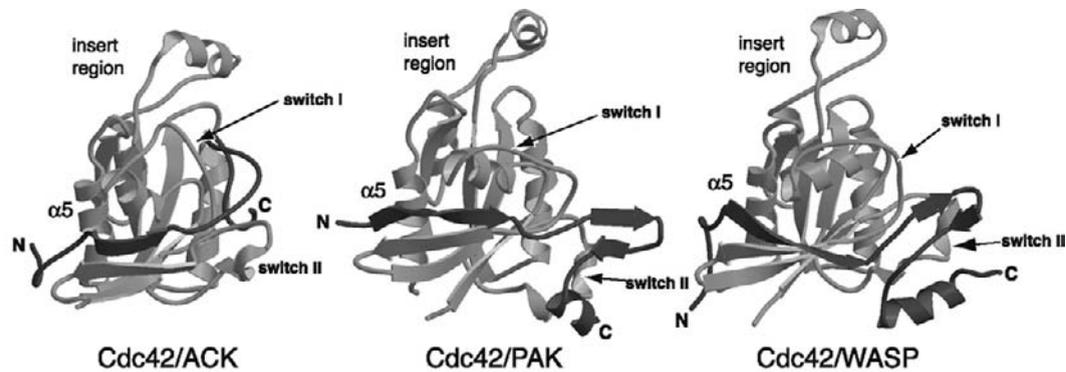

Figure 1 Comparison of CRIB/Cdc42 structures. In each case the G protein is shown in pale gray and the CRIB fragment in dark gray. The insert region that defines the Rho family is marked. The positions of the two switch regions that become fixed on effector binding are also shown, as is the position of the $\alpha 5$ -helix, which interacts with the CRIB effector in all three cases and is the location of the mutation that specifically disrupts Cdc42/ACK and Cdc42/WASP binding.

Sequence alignments of Cdc42 and Rac reveal that switches I and II are almost completely conserved, the only difference being a single (conservative) substitution. It was therefore clear that the basis of the selectivity of CRIB effector proteins such as ACK and WASP for Cdc42 would lie outside these switches. Mutagenesis studies combined with measurements of K_d suggested that interactions with Leu-174 in helix $\alpha 5$ of Cdc42 contribute to binding of WASP and ACK to Cdc42 but do not contribute to PAK binding [11]. Position 174 is an Arg residue in Rac and thus it may represent one of the points of discrimination between G proteins. Analysis of single residue mutations may not lead us to a complete understanding of the discrimination between Cdc42 and Rac, because in all the Cdc42/effector complexes solved the buried surface area is large (2500–4000 Å²). Also, since there is no Rac/CRIB fragment complex solved so far, the details of Rac/CRIB interactions are still unknown.

Insight into the activation mechanisms of the CRIB proteins came when the structures of both PAK and WASP in autoinhibited forms were solved [12,13]. WASP has no enzyme activity but it has a region at the C terminus that binds both the Arp2/3 complex and actin. It was found that a small region of the C terminus that is homologous to cofilin (CHR) interacts with residues within and C terminal to the GBD. The structure of a molecule comprising the CHR tethered by a flexible linker to the GBD extended at the C terminus by approximately 20 residues has been solved (Fig. 2). This structure showed that the β -hairpin and α -helix seen in the Cdc42 complex are still present but that they now interact with three extra α -helices C terminal to the GBD, mainly through hydrophobic contacts. These four helices form a hydrophobic surface, against which a helix from the CHR is packed. It is clear that in this form the protein cannot bind either to the Arp2/3 complex (via the CHR) or to Cdc42 (via the GBD). To bind Cdc42 the protein would have to undergo a conformational change that results in release of the CHR, allowing it to bind to other partners. The thermodynamic cost of this conformational change would be paid for by a lower binding affinity between the autoinhibited form of the protein and Cdc42 than between GBD fragments

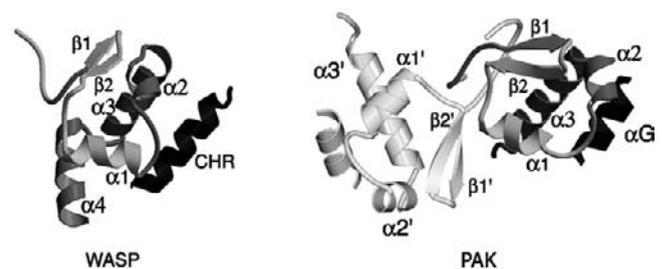

Figure 2 Structure of autoinhibited WASP and PAK fragments. The layers of the structures are shown in different shades. In both cases the $\beta 1/\beta 2$ and $\alpha 1$ elements are part of the GBD and are involved in the interaction with Cdc42; $\alpha 2$ and $\alpha 3$ are in the region immediately C terminal to the GBD that is involved in negative regulation of the C terminus of the molecule. In WASP, helix $\alpha 4$ follows $\alpha 3$; this helix has no counterpart in PAK. The CHR and αG are the cofilin homology region (WASP) and helix G from the kinase domain (PAK), respectively. The second PAK monomer is shown in pale gray and labeled $\beta 1'$, $\alpha 1'$ etc.

and Cdc42 as is seen, with K_d s approximately 100-fold higher for the tethered construct [13].

It had been shown by yeast-two hybrid experiments with PAK that a region C terminal to the GBD, known as the kinase inhibitory (KI) domain could bind directly to its kinase domain, thus inhibiting its catalytic activity. An x-ray-derived structure has been solved of the GBD/KI bound to the kinase domain and reveals that the GBD/KI domain is strikingly similar to the equivalent region of WASP, although in PAK there are only three helices to WASP's four (Fig. 2). One of the helices from the kinase domain packs against the three helices of the KI domain in a manner closely resembling the CHR helix of WASP packing against its autoinhibitory domain. There is one striking difference in the PAK structure: it is a dimer that is held together by an interaction between the CRIB/KI regions. Given this structure it would seem to be impossible to form a Cdc42/PAK complex without breaking the dimer. This was shown in a later paper by the same authors [14]. However others have shown that PAK forms a stable dimer, even in the presence of Cdc42 [15].

The activation mechanism of ACK is not known at present but it is likely to involve a similar, intramolecular inhibition.

This is implied by the discovery that mutation of Leu-543 of ACK causes constitutive activation of the kinase [16]. This Leu interacts with switch II in the Cdc42/ACK complex [5] and mutation of the equivalent Leu residue in PAK (Leu-107) or WASP (Leu-270) also disrupts their autoinhibitory interactions [17,18]. The activation of ACK may, however, be more complicated since it appears that Cdc42 also disrupts an intramolecular interaction between the SH3 domain and a Pro-rich region [19]. An intramolecular SH3/Pro interaction is also thought to exist in another CRIB-containing protein, mixed lineage kinase 3 (MLK3) [20]. In both ACK and MLK3 the role of Cdc42 binding in activation is still unclear.

Non-CRIB Rac Effectors

p67^{phox}

p67^{phox} is one component of the multiprotein enzyme complex, NADPH oxidase. This complex, found in phagocytes, forms the principal defense mechanism against microbial infection in humans. Binding of Rac to p67^{phox} is a critical step in the activation of the latent NADPH oxidase complex. The Rac binding region of p67^{phox} had been localized to the N terminal 200 amino acids, which contains four copies of the tetratricopeptide repeat (TPR) motif. Structures of other TPR-containing proteins had shown that each TPR motif is composed of a pair of anti-parallel α -helices (A and B), and that these repeated units pack together to form an extended structure with an amphipathic groove on the A helix face of the domain (the TPR groove), which mediates interactions with other proteins [21,22]. The structure of Rac-GTP complexed with the N terminal 200 amino acids of p67^{phox} revealed both an effector GBD distinct from the CRIB family of effectors and also a different use of the TPR repeats as a binding motif [23]. The N terminus of p67^{phox} contains 9 α -helices: the first eight of these form four TPR motifs, while the ninth helix packs against the B helix of TPR4 (Fig. 3). The TPR groove is filled by a stretch of residues C terminal to the ninth helix, which binds in an extended conformation and thus it is not available for intermolecular interactions. Rather, contacts are made between Rac and one face of the TPR domain, which consist of a β -hairpin insertion between TPR3 and 4 and the loops connecting TPR1 with TRP2 and TPR2 with TPR3. Contacts on the G-protein side are also unusual and include residues from helix α 1 and the following loop, residues from the N terminal end of switch I, and the loop between strand β 5 and helix α 5. The TPR domain does not contact all of switch I and no contacts are seen with switch II or the insert region. This is in contrast to the complexes between Cdc42 and the CRIB effectors, where extensive contacts are made with both switch I and II. The TPR/Rac complex also differs from the CRIB effector complexes in that no intramolecular β -sheet is formed. Still, 1170 Å² is buried in the TPR/Rac complex, less than that in the CRIB/Cdc42 complexes, possibly resulting in the lower affinity observed.

p67^{phox} binds specifically to Rac rather than Cdc42. Analysis of the residues involved in the interface showed that all were conserved between Rac and Cdc42, except Gly-30. Ala-27 and Gly-30 have been defined as critical residues for the specificity of the interaction between Rac and p67^{phox}: Mutation of these residues in Cdc42 to the corresponding residues in Rac results in a Cdc42 protein that binds p67^{phox} with a relatively high affinity [23]. Ala-27 does not directly contact the TPR domain but in Cdc42 this residue is a Lys, which would cause a steric clash, preventing binding.

Arfaptin

Arfaptin (or POR, partner of Rac) was identified independently as an effector for both the Rac and Arf small G proteins and, consequently, has been proposed to be a facilitator of crosstalk between signaling pathways. Arfaptin (residues 118–341) has been crystallized alone and in complex with both Rac-GDP and Rac-GMPPNP [24]. The Arfaptin domain consists of 3 α -helices (A–C) that form an anti-parallel α -helical bundle; 2 of these self-associate to give an elongated crescent-shaped dimer, with an overall length of 140Å, which binds to one Rac molecule. Rac sits on the concave surface of the Arfaptin crescent close to the dimer interface, and contacts are seen predominantly between switch I and II of Rac and monomer A of Arfaptin (Fig. 3). Switch I packs against helix α A while switch II interacts with helix α B. A single contact is seen to monomer B, at His 57 in helix α A'. This interaction is sufficient to preclude the binding of another Rac molecule to Arfaptin, thus accounting for the observed stoichiometry of 1 Rac:1 Arfaptin dimer. 1600Å² of solvent-accessible surface area is buried in the complex. Similar of Arfaptin affinities for both the GDP- and GTP-bound forms of Rac argues against its being a conventional effector for the G protein. In contrast, Arfaptin binds to both Arf1 and Arf6 in a GTP dependent manner. Examination of the Rac-GDP and Rac-GMPPNP molecules reveals crucial similarities between the two in complex with Arfaptin. Critically, Thr-35, which coordinates to the Mg²⁺ in G protein-GTP forms is instead in contact with Arfaptin, giving rise to a more GDP-like structure. It is predicted that a canonical Rac-GTP conformation could not be accommodated by Arfaptin [24]. Presumably, in the Arf/Arfaptin complex the G protein can take up its usual GTP-like conformation, thus allowing discrimination in that case. It is possible that Arfaptin's ability to bind both forms of Rac allows it to sequester Rac until Arf is activated, whereupon Arf displaces Rac freeing it to signal appropriately. In this model, the function of Arf is to allow coordinated activation of Rac and Arf.

Rho Effectors

Effectors for Rho include at least eleven proteins: DAG Kinase, PLD, PIP5-kinase, Kinectin, Rhotekin, Rhophilin, p140 Diaphanous, MBS, Citron, ROK and PRK. Within this

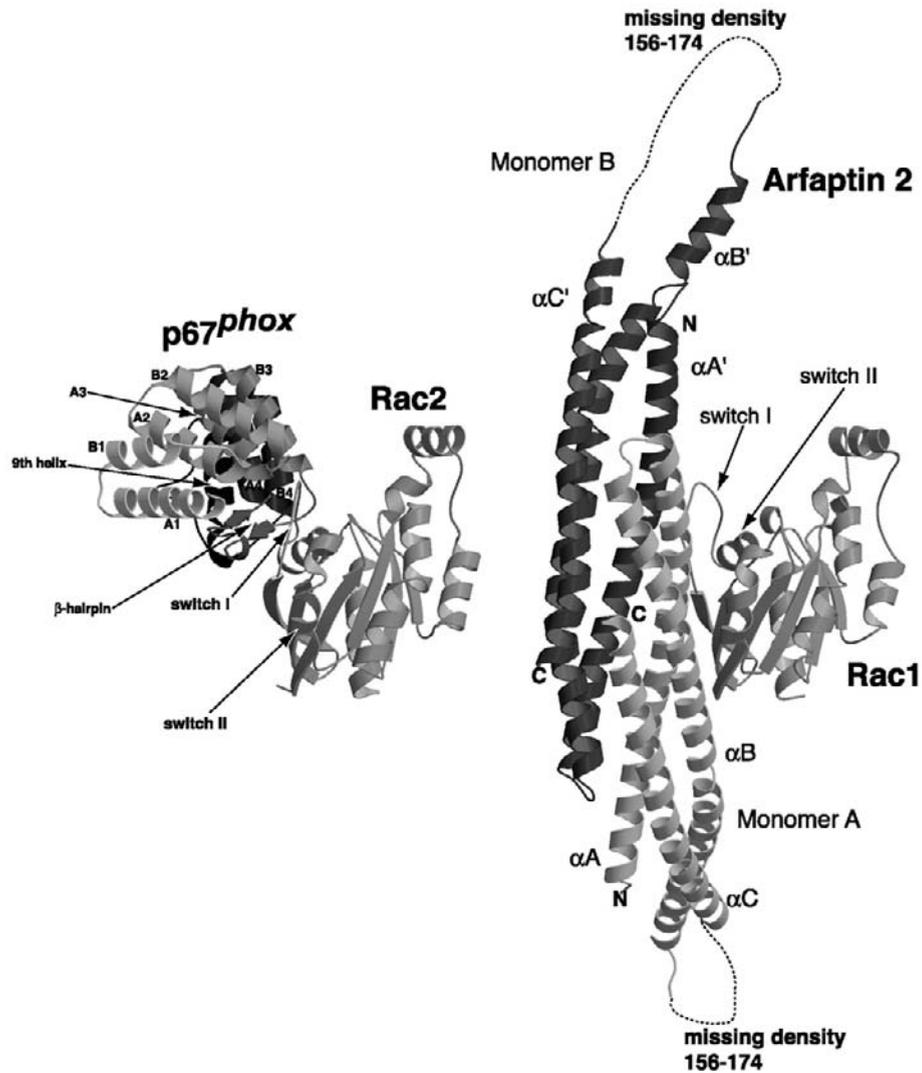

Figure 3 The structures of Rac2/p67^{phox} and Rac1/Arfaptin 2. The layers of the TPR repeats of the p67^{phox} become darker going from the N to the C terminus. The switch regions of Rac are shown in both structures. The two monomers in the Arfaptin 2 dimer are shown in different shades. In the Arfaptin structure the two regions where no electron density was observed are shown as dotted lines.

group of effector proteins there are at least two Rho binding motifs defined by sequence homology: REM proteins (or Class 1 Rho binding motif) include the PRKs, Rhophilin and Rhotekin, while RKH proteins (REM2 or Class 2 Rho binding motif) include the ROKs and Kinectin (reviewed in [25]). Structural information is limited at present to one of the REM proteins, PRK1, in complex with RhoA.

Protein Kinase C Related Kinases

PRK1 (PKN) and 2 are highly related serine/threonine kinases with a catalytic domain homologous to that of the protein kinase C family in their C termini and a unique regulatory domain in their N termini [26,27]. The N terminus of the PRK1 contains three HR1 repeats, one of which, HR1a, incorporates an inhibitory pseudosubstrate site [28]. Kinase activity is enhanced by binding of GTP-bound Rho or Rac [29–32].

The x-ray structure of RhoA in complex with the HR1a repeat of PRK1 describes the fold of the HR1a domain as an anti-parallel coiled-coil (ACC) finger domain [33] (Fig. 4). The ACC finger domain is quite distinct from other G protein binding domains and known Rho family effectors. It does show limited similarity with the Rab binding domain of Rabphilin and the Rac/Arf effector Arfaptin, but the contacts that these effectors make with their G proteins are quite different [24,34]. The structure of the complex between HR1a and RhoA indicated two possible contacts sites on RhoA for HR1a. The major site, contact 1, has a buried surface area of 2080Å² and mainly involves hydrophilic interactions. This contact involves residues in the β2- and β3-strands of RhoA, the N-terminal part of helix α5 and residues at the ends of switch I. Contact 2, which involves more hydrophobic residues, buries a total surface area of 1640Å² and involves residues in switch I (Val38–Asn41),

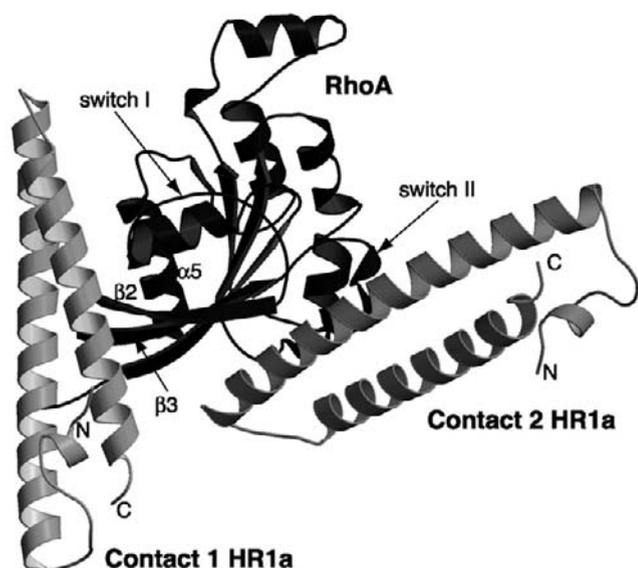

Figure 4 The structure of the RhoA/PRK1 HR1a complex. The two potential HR1a binding sites are shown as contact 1 and contact 2. Contact 1 was defined as the primary contact site on the basis of the buried surface area, although the HR1a in contact 2 makes more interactions with the switches.

strand $\beta 3$, and switch II (Trp58 and Asp65–Asp76). The size of contact 2 means that it is unlikely to be an artifact of crystal packing. It is also noteworthy that it involves more residues in the switch regions of RhoA, which are likely to be involved in effector binding.

Concluding Remarks

We have attempted to summarize here the pertinent details of all the Rho family/effector structures determined. Several points emerge from this discussion. First, it is clear that the structural diversity in the Rho effectors is extensive. It is likely, for example, that the CRIB proteins, although they will all have some similarities in the way that they interact, will also differ in their details, particularly outside the short CRIB consensus sequence. The other three effector structures are also completely different both to each other and to the CRIBs, although it is likely that families will emerge whose members interact with the G proteins in a similar, but not identical manner. There are also, however, several other effector proteins with no sequence homology to Arfapatin, PRK, TPR domains, or CRIBs. It is likely that these proteins will adopt different structures and will interact with the Rho family proteins in novel ways.

The manner in which the effectors contact the Rho family G proteins is multifarious. They utilize β -strands (the CRIBs), β -hairpins (the CRIBs), α -helices (Arfapatin, PRK1, and the CRIBs), interhelical loops (p67^{phox}), and even a dimer interface (Arfapatin) to interact with the G protein. In some cases, such as the CRIB proteins, the effectors make an extensive set of contacts with the Rho family proteins, burying a large surface area (2500–4000 Å²) while in others,

such as p67^{phox}, which binds with a lower affinity, the buried surface is only ~ 1200 Å².

The region of the G proteins that interact with the downstream targets is also not conserved. In most cases, switch I is involved in the interactions, which is perhaps not a surprise given that effectors bind preferentially to the GTP-bound form of the G protein. It is usually the case that other regions of the G protein are also involved in binding to effectors; this may be in part to bring about specificity. The switches are relatively well conserved within the family while the diversity in the other regions is higher. In most of the structures discussed here switch II is also involved in the interaction; the exceptions being p67^{phox} and PRK1, contact I. The other regions of the Rho family that are involved in effector binding are helix $\alpha 1$, the $\beta 2$ - and $\beta 3$ -strands, the $\beta 5$ - $\alpha 5$ loop, and the C-terminal helix, $\alpha 5$. In no case so far is the insert region involved in effector binding.

Structural information on the Rho family targets has moved at an exciting pace over the last three years. The next stage must be to determine how the binding of the Rho family protein then causes the downstream effects that are seen. This point has begun to be addressed with the elegant work on PAK and WASP activation. We can look forward to many more such breakthroughs in the future, where a combination of structural and mechanistic studies will help us to understand fully these complex systems.

Introduction

Effective cellular signaling relies upon the tight control of the various proteins within a signal transduction pathway. For GTPases (guanosine triphosphatases), common mechanisms of regulating the activation and attenuation of these critical molecules have sustained throughout evolution. All GTPases cycle between two discrete states, an inactive guanosine diphosphate (GDP)-bound form, and an active guanosine triphosphate (GTP)-bound form. The removal of GDP nucleotide from an inactive GTPase allows subsequent loading of GTP, thereby triggering these “binary switches” to recognize downstream effectors. This critical process of GTPase activation is rigidly controlled by guanine nucleotide exchange factors (GEFs).

Dbl family proteins are the major recognized class of GEFs for the Rho family of small GTPases [1–3]. Rho GTPases have risen to prominence since a large body of work over the last ten years has implicated these ~25-kDa members of the Ras superfamily in controlling vital cellular functions, including organization of the actin cytoskeleton, progression through the cell cycle, and regulation of transcriptional activities [4–9]. Given that Rho GTPases manage various critical cellular processes, it is not surprising that these small GTPases, as well as their activators (RhoGEFs), promote oncogenesis when constitutively activated [10–16]. Membership within the Dbl family of RhoGEFs is solely dependent upon the possession of an ~300 amino acid segment containing a Dbl homology (DH) domain directly adjacent to a pleckstrin homology (PH) domain [17]. While PH domains exist in a multitude of signaling proteins, the DH domain is unique to these RhoGEFs, and accordingly constitutes the primary

catalytic portion of a Dbl protein by supporting nucleotide exchange activity within a substrate Rho GTPase *in vitro* and *in vivo* [18,19].

Recent biophysical investigations into the function of Dbl-family proteins have revealed substantial insight into the means by which these RhoGEFs catalyze the removal of bound nucleotide from Rho proteins. Specifically, an understanding at atomic resolution of the roles of the conserved DH and PH domains found within all Dbl-related proteins is now available. Here we survey the structural features of RhoGEFs and highlight the key determinants responsible for dictating the activation of Rho GTPases.

Structural Accomplishments

The founding member of the Dbl family, Dbl, was first identified as a transforming factor from a human *diffuse B-cell lymphoma* [20,21]. Further analysis delimited the DH/PH domain segment as the minimal transforming portion of Dbl-related RhoGEFs [22]. While most Dbl proteins possess a plethora of protein modules, which most likely regulate GEF activity, including Src homology 2 (SH2) domains, Src homology 3 (SH3) domains, Ras-binding domains (RBD), and regulator of G-protein signaling (RGS) domains, the conserved tandem DH and PH domains have been clearly characterized as the region possessing biochemical guanine nucleotide exchange activity for Rho GTPase targets. This combined information has set the stage for an in-depth structural examination of the catalytic mechanism of Dbl proteins.

NMR structures of the isolated DH domains from the exchange factors Trio [23], β PIX [24], and Vav [25], as well

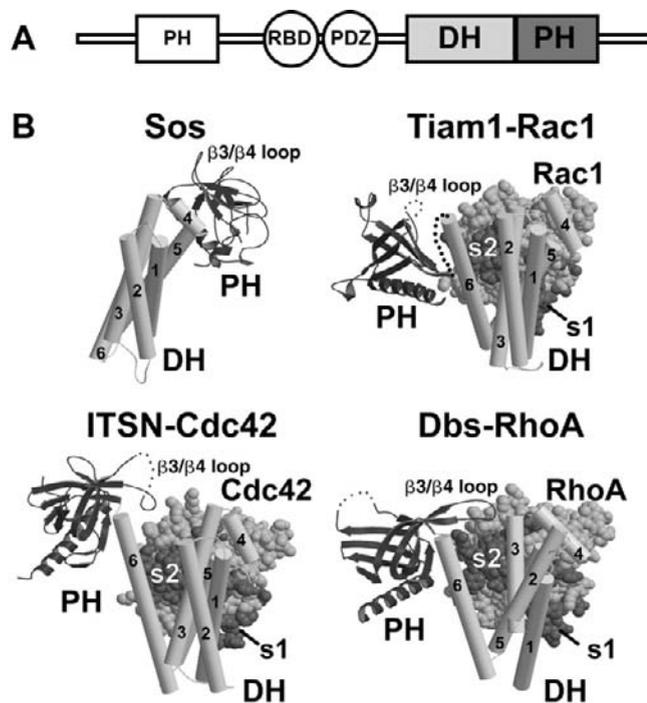

Figure 1 Structural comparison of the DH/PH portion of several Dbl exchange factors. (A) Domain architecture of Tiam1, a representative Dbl family protein, highlighting the conserved DH/PH domain cassette. Tiam1 also possesses an N-terminal PH domain, a Ras binding domain (RBD), and a PDZ domain. (B) The crystal structures of Sos DH/PH (PDB accession code #1DBH), Tiam1-Rac1 (PDB accession code #1FOE), ITSN-Cdc42 (PDB accession code #1KI1), and Dbs-RhoA (PDB accession code #1LB1) were aligned using the CR1 and CR3 regions of the DH domains. The identified helical segments of the DH domains (yellow) are depicted as cylinders, while the PH domains (blue) are presented as ribbon representations. Bound Rho GTPase substrates are portrayed as green CPK spheres, with the exception of the noted switch regions (s1, s2), highlighted in red. Black circles depict the linker region between the DH and PH domains of Tiam1, while blue circles illustrate PH domain loops that are disordered in the crystal structures. (A color representation of this figure is available on the CD version of the *Handbook of Cell Signaling*.)

as the crystal structure of the DH/PH portion of son of sevenless (Sos) [26], first presented the three-dimensional architecture of a DH domain (Fig. 1). In addition, significant insight has been gained by crystal structures of the DH/PH fragments of several RhoGEFs in complex with their cognate Rho GTPase substrates. Specifically, the initial structure of the DH/PH segment of Tiam1 bound to Rac1 (Tiam1-Rac1) [27], followed by subsequent similar structures, (Dbs-Cdc42, Dbs-RhoA, intersectin (ITSN)-Cdc42) [28,29] have explained several facets of the conserved mechanism of Dbl protein catalyzed nucleotide exchange.

DH Domain Features

DH domains form an elongated α -helical bundle composed of six major helical segments, with a unique fold unrelated to other nucleotide exchange factors (RCC1, Sec7 domain, EF-Ts, and the Cdc25 domain of Sos) for different G-protein families [30,31]. DH domains possess three evolutionarily conserved regions: CRs 1–3. Together CR1

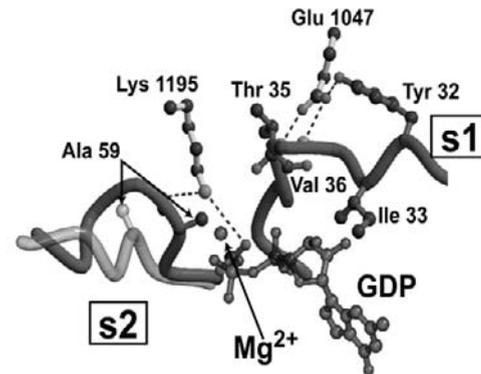

Figure 2 Mechanism of RhoGEF-induced release of GDP from a Rho GTPase. Close-up view of the switch regions of Rac1 (red) binding important Tiam1 residues (yellow) in the Tiam1-Rac1 complex. (Adapted from WorthyLake, D. *et al.*, *Nature*, **408**, 682–688. With permission). GEF-GTPase interactions are depicted with dotted blue lines. GDP and magnesium ion (in semi-transparent blue) have been superimposed in their natural binding sites of a Rho GTPase based on the Cdc42-GDP structure (PDB accession code #1AN0). A portion of switch II is shown both before (pink), and after (red) engaging Tiam1, to highlight the dramatic rearrangement of Ala 59, which occludes magnesium binding, and therefore promotes removal of nucleotide. (A color representation of this figure is available on the CD version of the *Handbook of Cell Signaling*.)

(within helix 1), and CR3 (within helix 5), along with a small region of helix 6, create the primary binding surface for a substrate Rho protein (Fig. 1). In sharp contrast, CR2 (within helix 2), maps to the opposite face from the active site, and most likely functions to stabilize the helical bundle.

The Tiam1-Rac1 structure first revealed the critical DH domain positions that engage the nucleotide-binding “switch” regions of a Rho GTPase [27]. Specifically, well-conserved, solvent-exposed DH domain residues equivalent to Glu 1047 and Lys 1195 in Tiam1 make important contacts with Thr 35 and Ala 59 of Rac1, respectively (Fig. 2). Subsequent RhoGEF/Rho GTPase structures [28,29], and mutagenesis within the DH domains of Trio [23], and Dbl [32] support the fundamental importance of these positions in catalyzing the removal of bound GDP from a Rho GTPase. In all four RhoGEF/Rho GTPase structures [27–29], the DH domains bury significant solvent exposed surface area to stabilize the GTPase in a nucleotide-free transition between the inactive and active states.

DH-Associated PH Domains

Extensively characterized as lipid-binding membrane tethers, PH domains from many different proteins display a wide assortment of affinities and specificities for phosphoinositide components of the cell membrane [33–35]. The invariant organization of the DH and PH domains in RhoGEFs suggests a vital role of the PH domain in Dbl-catalyzed nucleotide exchange. Specifically, the PH domain has been implicated in anchoring a Dbl protein to the cellular membrane [36], allosterically regulating GEF activity via phosphoinositide interactions [37,38], and directly engaging the substrate GTPase [28].

Structurally, within Sos, the PH domain is connected to the DH domain by a flexible interdomain linker, while for Tiam1, Dbs and ITSN, the PH domain begins immediately after the terminal helix ($\alpha 6$) of the DH domain. Overall, Dbl PH domains resemble the classical ~ 100 residue anti-parallel β -sandwich PH domain fold, composed of seven strands capped by a terminal α -helix. However, unlike PH domains from other proteins, DH-associated PH domains usually possess an additional short β -strand and a 3_{10} helix at the N terminus of the fold, that pack against the $\alpha 6$ helix of the DH domain using extensive hydrophobic interactions.

PH Domain Configurations

Comparison of the DH/PH structure of Sos with the Tiam1-Rac1, Dbs-Cdc42, Dbs-RhoA, and ITSN-Cdc42 structures provides significant insight into the dramatic conformational heterogeneity of the PH domain. Where the PH domain of Sos partially occludes the GTPase binding site of the DH domain, within the RhoGEF/Rho GTPase complexes, the PH domains are positioned to allow the Rho proteins access to the CR1/CR3 surface of the DH domain (Fig. 1). In addition, where the PH domains of Tiam1 and ITSN reside distant from Rac1 and Cdc42, respectively, the PH domain of Dbs is rotated about the $\alpha 6$ helix of the DH domain such that the $\beta 3/\beta 4$ loop of the PH domain now contacts the substrate GTPases, (Cdc42 and RhoA), with interactions shown to be functionally important for exchange activity [28]. Together, this structural data potentially reflect several of the configurations that DH and PH domains sample when engaging their target Rho GTPases. However, complicating this model is the fact that, *in vitro*, Dbs requires its PH domain for full catalytic activity when comparing DH to DH/PH elements [28], while the PH domain of ITSN is dispensable for robust exchange activity (our unpublished observations). Thus, it is quite possible that these structural snapshots depict two distinct classes of RhoGEFs, where Dbs and closely related family members can utilize their PH domains to assist in activating a Rho GTPase, while others cannot.

With regard to the functional role of the conserved PH domain, several reports document allosteric modulation of RhoGEF activity in response to specific phosphoinositides binding the PH domain [37–39]. In contrast, other studies find conflicting or no modulation of DH domain-catalyzed nucleotide exchange activity in response to phosphoinositides [40,41]. A large body of structural studies has revealed how PH domains specifically engage the head groups (inositol phosphates) of phosphoinositides, using a positively charged patch composed of variable length loops [33]. It is quite possible that at a cellular membrane, specific phosphoinositide-PH domain interactions could restrict the conformation of the PH domain leading to novel PH domain/GTPase, or PH domain/DH domain contacts that modulate exchange activity. However, studies involving prenylated Rho proteins, and using lipid bilayers will be necessary to dissect the complete

functional roles of the DH-associated PH domain in activating Rho GTPases.

Mechanism of Nucleotide Exchange

An important feature revealed by the RhoGEF/Rho GTPase structures is the mechanism of release of bound GDP from the GTPase. As mentioned, all GTPases possess flexible switch regions that adopt distinct conformations depending upon the state of bound nucleotide [42]. Similar to other characterized GEFs [43], DH domains engage switches I and II of the Rho protein, and induce these regions to physically impede upon both magnesium and GDP binding sites. For example, significant rearrangement of switch II (residues 57–75) of Rac1 occurs in the Tiam1-Rac1 structure relative to the architecture of an inactive GTPase [27]. Importantly, Ala 59 of Rac1, stabilized by Lys 1195 of Tiam1 dramatically swings into the binding site of the Mg^{2+} ion normally associated with bound nucleotides (Fig. 2). The crystal structure of the Mg^{2+} -free form of RhoA-GDP documents the paramount consequence of the removal of magnesium in encouraging an open conformation of the switch regions of a Rho GTPase [44].

Additionally, other RhoGEF-induced rearrangements within the switch regions of a Rho GTPase help stabilize the nucleotide-free state of the protein. For instance, Glu 1047 in CR1 of Tiam1 binds several Rac1 residues of switch I (Tyr 32, Thr 35, Val 36) to effectively shift Ile 33 of Rac1 into the binding site of the bound GDP (Fig. 2). This reorientation of switch I destroys the positive interaction that Cys 18 of Rac1 normally makes with bound nucleotide in the Rho GTPase. Moreover, binding of the DH domain of Tiam1 is further secured by Tyr 64 of Rac1, which contacts a set of conserved Tiam1 residues [27]. In addition, Tiam1 binding prevents Phe 28 of Rac1 from making a positive contact with bound nucleotide. This observation is consistent with the finding that Rac1(F28L) exhibits a “fast-cycling” phenotype, showing an increased spontaneous nucleotide exchange rate, thereby mimicking a Dbl-induced Rho GTPase [16]. The combined network of DH domain-Rho GTPase interactions encourages release of nucleotide, and thus traps a Rho GTPase in a nucleotide-free state, where the large excess of GTP *in vivo* begets GTP loading and concomitant downstream effector activation. While the Tiam1-Rac1 structure, as well as the other RhoGEF/Rho GTPase complexes, serve as models to interpret the determinants responsible for nucleotide exchange in Rho proteins, a mechanistic study of the effect of these proposed critical residues is sorely lacking.

Molecular Recognition of Rho GTPase Substrates

The combined structural wealth of data has allowed a framework to interpret the determinants within RhoGEFs and Rho GTPases that dictate the proper pairing between

these oncoproteins. To date, the Rho GTPase family possesses 21 members [45], while greater than 70 distinct mammalian Dbl proteins exist. Discrimination by RhoGEFs for the highly similar Rho GTPase substrates remains a paramount issue, given that individual Rho proteins stimulate diverse cellular events. For example, three well-studied Rho GTPases provoke dramatically different cytoskeletal morphologies, where Cdc42 stimulates filopodia production, Rac1 induces lamellipodia formation, and RhoA initiates actin-myosin filament assembly [5].

DH domains selectively recognize a nonconserved patch of positions between the switch regions of Rho GTPases, and utilize these residues for selecting the appropriate target. Structure-based mutagenesis of complementary residues within DH domains and Rho GTPases has demonstrated the basis for this superb specificity. For instance, mutation of Trp 56 in Rac1 to mimic the equivalent Cdc42 side chain (Phe 56) prohibits exchange activity catalyzed by the Rac1-specific GEF Tiam1, while simultaneously removing steric constraint to allow the Cdc42-specific GEF ITSN, to engage and exchange nucleotides within W56F Rac1 [46,47]. In addition, recent work using subtle point mutations within DH domains has remodeled the exchange profiles of ITSN and Dbs to alter their specificity for Rho GTPase substrates [29]. These studies have focused entirely upon Cdc42, Rac1, and RhoA, and must be extended to the entire Rho family to truly appreciate the basis for this selective molecular recognition.

External Regulation of the DH and PH Domains

While the tandem DH and PH domains effectively activate members of the Rho family, outside portions of Dbl proteins surely contribute to the regulation of nucleotide exchange activity. For example, several RhoGEFs (LARG, p115, and PDZ-RhoGEF) possess an N-terminal RGS domain, which binds and hydrolyzes GTP within G α subunits. Accordingly, emerging studies suggest that modulation of RhoGEF activity is induced by G α subunit binding to the RGS domain of a Dbl protein [48–50], however, further investigation must decipher this complex mode of regulation. In addition, the upregulation of ITSN-catalyzed exchange activity within Cdc42 by N-WASP binding to an SH3 domain of ITSN has been reported [51].

An exceptional example of external regulation of RhoGEF exchange activity was presented by Rosen and colleagues [25]. Using NMR spectroscopy, the authors determined the structure of the DH domain of Vav along with an N-terminal helical extension that folds back and occludes the conserved DH domain residue (equivalent to the previously mentioned Glu 1047 of Tiam1) at the GTPase binding surface. Interestingly, this amino terminal sequence adjacent to the DH domain contains an Src phosphorylation site (Tyr 174), and accordingly, phosphorylation of Tyr 174 disrupts the inhibitory contacts made on the catalytic surface of the DH domain. These structural data coincide well with

previous findings reporting that phosphorylation stimulates the exchange activity of Vav homologs [52]. Thus, outside of the conserved DH/PH cassette, external autoregulation of exchange activity may prove a common theme in all Dbl proteins. Although, given the diverse protein modules present in these RhoGEFs, numerous means of regulating the capacity of the DH and PH domains are anticipated.

Structural Considerations of Small GTP-Binding Proteins

Alfred Wittinghofer

*Max-Planck-Institut für molekulare Physiologie,
Dortmund, Germany*

Introduction

The basic switching apparatus of small GTP-binding proteins is the G domain. The G domain itself is a conserved structural unit with a canonical switch mechanism, with minor modifications in different members of the family. Their regulators and effectors show a large diversity in their structures and modes of interaction. Here we will try to define some underlying principles.

The G Domain Functional Unit

The basic structural unit of small GTP-binding proteins consists of about 160–170 residues. It is α,β fold typical for nucleotide binding proteins and is called the G domain (for earlier reviews and references, see references [1–3]). This G domain consists of a mixed six-stranded β -sheet and five helices on both sides. It contains four to five conserved sequence elements, which are lined up along the nucleotide binding site and mediate binding, GTP hydrolysis, and the switching apparatus (Fig. 1). The most important contributions to binding are first due to the interactions of the nucleotide base with the N/TKxD motif and an invariant Ala and second of the phosphates with the conserved P-loop GxxxGKS/T motif [4]. Specificity is due to an Asp side chain forming a bifurcated H bond with the guanine ring, but also due to the Ala main chain interaction with the guanine oxygen, which for steric reasons does not allow replacement by the adenine amino group [5]. Other conserved sequence elements are a conserved Thr and a DxxG motif, both of which are involved in the conformational change.

Structures of several Ras-related proteins like Ras/Rap/Ral, Rac/Rho/Cdc42, Arf/Arl, Ran, and Rab have been solved. The easiest way to compare these structures is to consider the 166–171 residue long G domain of the Ras protein as the minimal switch unit, and to describe the others as variations of this canonical structure. In addition to the G domain, small GTP-binding proteins contain a C- and N-terminal extension of varying length and various insertions. Rho proteins Rho/Rac/Cdc42 contain a α -helical insertion of approximately 13 amino acids, Ran has an elongated C-terminal element very crucial for its function in nuclear transport, whereas Arf/Sar1 proteins contain a myristoylated N-terminal extension that is important for nucleotide-dependent insertion into the plasma membrane. The G domain with its conserved features is also found in multidomain GTP-binding proteins such as the heterotrimeric G proteins and the protein biosynthesis factors eIF5B, EF-Tu, and EF-G.

Whereas the small G proteins are structurally highly homologous, and the structural features of the switch mechanism are conserved, the regulators actually show a variety of shapes and the effectors have, in addition, a variety of function. Here we will concentrate on the major regulators GEF and GAP and the effectors.

The Conformational Switch

Requirements of the molecular switch can be defined from comparing GDP- and GTP-bound structures. Structural differences are mostly subtle and are primarily confined to two regions, which have first been observed in Ras and are called the switch regions [6]. These regions usually show an increased flexibility in X-ray structures and in magnetic

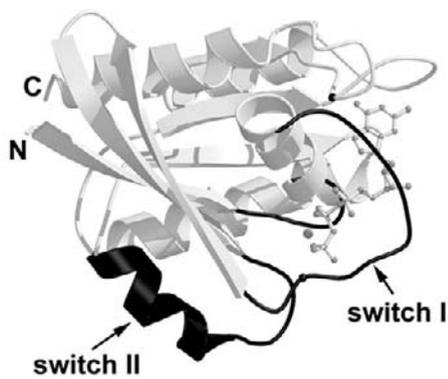

Figure 1 Structure of the G domain. Ribbon plot of the minimal G domain in gray, containing six β -strands and five α -helices, with the conserved sequence elements and the switch regions in black. GTP and Mg^{2+} ion are shown in ball and stick representation.

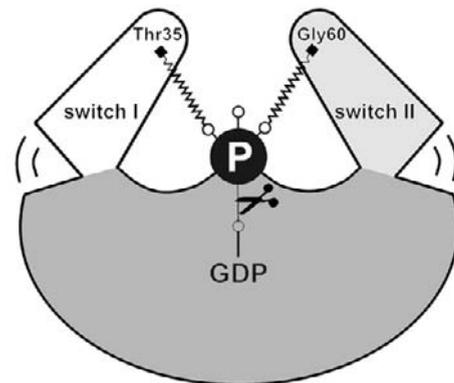

Figure 2 Schematic diagram of the universal switch mechanism where the switch I and II domains are bound to the γ -phosphate via the main chain NH groups of the invariant Thr and Gly residues, in what might be called a loaded spring mechanism. Release of the γ -phosphate after GTP hydrolysis allows the switch regions to relax into a different conformation.

resonance studies using NMR and electron paramagnetic resonance (EPR) [7,8]. Furthermore, whereas the GDP-bound proteins show a large variation of structural details, the GTP-bound forms of the G domain are remarkably similar [3]. Most important, the trigger for the conformational change is rather universal.

In the triphosphate form there are two hydrogen bonds from γ -phosphate oxygens to the main chain NH groups of the invariant Thr and Gly residues (Thr35/Gly60 in Ras) in switch I and II, respectively. The conformational change can best be described as a loaded-spring mechanism where release of the γ -phosphate after GTP hydrolysis allows the two switch regions to relax into the GDP-specific conformation (Fig. 2). The extent of the conformational change is different between the different proteins. In Ras the switch regions involve residues 32–38 for switch I and 59–57 for switch II.

The canonical switch mechanism is modified in many ways. Whereas Ras/Rap/Rho/Rac/Rab show minor changes involving only switch I and II, Ran experiences a large conformational change in switch I with an unfolding of an extra β -strand which in turn induces the long C-terminal extension, the so-called C-terminal switch, to drastically alter its location [9–11]. An even more dramatic change in switch I of Arf and Arl involves the change in register of two β -strands relative to the rest of the sheet and the detachment and subsequent membrane insertion of the N-terminal helix. This has been called the N-terminal switch [12,13].

Guanine Nucleotide Exchange Factors

Guanine nucleotide release from small GTP-binding proteins is slow and is stimulated by several orders of magnitude by guanine nucleotide exchange factors (GEFs). The mechanism of GEF action involves a series of fast kinetic steps, which lead from a binary protein-nucleotide complex via a trimeric complex to a binary nucleotide-free complex, which is stable in the absence of nucleotide. This series of reactions is reversed by rebinding of nucleotide, which is predominantly

GTP due to its higher concentration in the cell. In principle, these reactions are fast and fully reversible such that GEF merely acts as a catalyst, which increases the rates at which equilibrium between the GDP- and GTP-bound form of the protein is reached.

Structures of GEFs are conserved within a given subfamily. GEFs for the Ras subfamily have a Cdc25 catalytic domain, whereas the GEFs for Rho-type proteins contain a DH (dibble-homology) domain (see chapter by John Sondek). Structures for the Ran-GEF RCC1, for the Ras-GEF Sos, for the Arf-GEFs Arno/Ge α 2p, the Rho-GEFs Sos, Trio, Pix, and Tiam and Dbs have been solved. To better understand the mechanism of nucleotide exchange structures of the nucleotide-free binary complexes Ras-Sos [14] Arf-Ge α 2 [12], of the Ran-RCC1 [15], Rac-Tiam [16], and Dbs-Cdc42 [17] complexes with a polyanion in the phosphate binding (P) loop have been solved. Although the details of the interactions are all different, arguing for a variety of kick-out mechanisms, the complexes have structural features in common suggesting mechanistic similarities. The GEFs do not act allosterically but directly interfere with nucleotide binding by inserting residues close to or into the P loop, the Mg^{2+} and/or guanine base binding area which create structural changes that are inhibitory for tight binding of nucleotide. This agrees with binding studies which show that the β -phosphate-P-loop interaction and the Mg^{2+} phosphate interaction are the most important elements for tight binding [5].

Effector B Via Switches and Others

Effectors for GTP-binding proteins are operationally defined as molecules interacting more tightly with the GTP- than with the GDP-bound form. This implies that effector binding involves the switch regions of G proteins, which is borne out by the structures. The Ras-binding domain (RBD) or Ras association domain (RA) has been identified in many

different proteins [18], which may or may not be true effectors [19]. In any case many of the bona fide Ras effectors also bind to proteins of the Ras subfamily such as Rap, R-Ras, and TC21. The structures of several Ras effectors such as Raf, RalGDS, PI3kinase, and recently byr2 [20] either alone or in complex with Ras, Rap, and their mutants have shown that the RBD is a small, well-defined domain with a ubiquitin fold, which binds to Rap/Ras by forming a GTP-binding dependent interprotein β -sheet between both molecules [21]. In the case of the complex with the phosphatidylinositol-specific lipid kinase PI(3)K γ , the contacts produce structural changes in PI3K γ which are believed to allosterically influence the catalytic activity [22–24].

Binding of Rac/Cdc42 to its effectors, some of which contain a so-called CRIB (Cdc42/Rac interactive binding) region [25,26] induces major structural changes and has been shown to directly activate the protein kinases PAK (p21-activated kinase), activated Cdc42-associated kinase (ACK), and the scaffold protein WASP (Wiskott-Aldrich syndrome protein). Fragments containing the CRIB domain show no apparent three-dimensional structure, but are structured in complex with C-terminal fragments from the same protein in an autoinhibitory conformation [27,28] or with Cdc42 (see chapter by Mike Rosen) [29,30].

Other structures of effector complexes show a variety of interaction patterns (Fig. 3) the only common feature of which is to include the switch region(s) for the interaction, the exception being the complex between RhoA and an anti-parallel coiled-coil fragment from the regulatory region of the protein kinase PKN, where it is not clear why the interaction should be GTP-specific [31]. The complex between Rab3A and its effector Rabphilin-3A involves two modes of binding [32], where one end of Rabphilin-3A contacts the switch region of Rab3A and thus senses its nucleotide status. A second site interacts with the complementarity-determining region (CDR), a site on the surface whose sequence varies among members of the Rab subfamily, and is thus responsible for specificity.

Small GTP-binding proteins such as Arf, Rab, or Ran are involved in a variety of transport processes. Ran-GTP binding to nuclear import factors-cargo complexes is necessary to release cargo on the nuclear side of the nuclear pore. Structures of the Ran complexes with importin- β and transportin show the switch I- and II-mediated interaction with the helical repeat motif of the factors [9,11]. Additional structural studies of a complex of importin with cargo [33] or with components from the nuclear pore [34] have suggested that the cargo-loaded transport factors can bind simultaneously to the nuclear pore but that interaction with Ran-GTP in the nucleus sterically interferes with binding of both, suggesting how Ran terminates the import reaction. The structure of the Arf-related protein Arl2 in complex with its effector PDE δ showed the latter to have a RhoGDI fold with an empty hydrophobic pocket [13], which together with biochemical studies suggested it to be involved in the transport of farnesylated proteins.

The only unifying principle that we find in the structures of effector complexes is that they involve the switch regions.

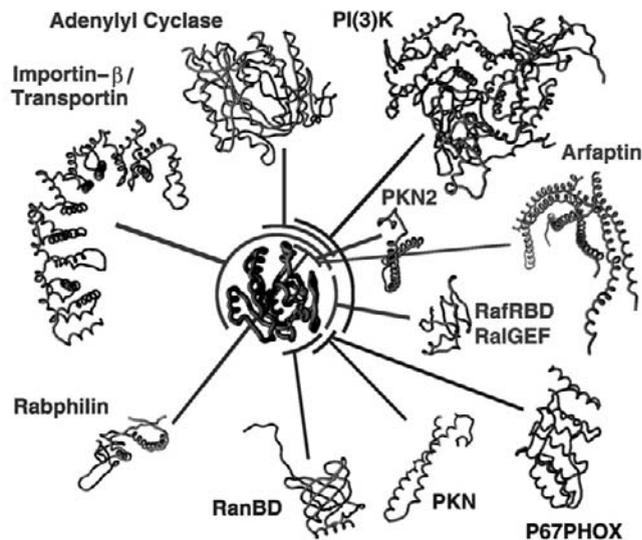

Figure 3 Interaction with effectors is mediated via different surface regions of GTP-binding proteins (see reference [3]). The structures were aligned on the G domain in the middle, and the effectors are removed from the interface in the direction indicated by the line. Involvement of the switch I and/or switch II region in the interface is the only common feature of these complexes. For PKN, the two variations found in the crystal structure are shown.

Other than that they show that the effectors have a variety of shapes of folds and interact in many different ways such that the different effectors cover almost the complete surface of the G domain (Fig. 3). We can distinguish between effectors, which contain a preformed binding domain and show no major structural change on binding, and those involving a large conformational change on binding to the GTP-binding protein. In the former case experimental evidence points toward (only) a recruiting function as the major signal transduction mechanism [24], whereas the other clearly involves (additional) allosteric regulation of the effector.

GAP Proteins and the GTPase Reaction

The GTPase reaction for most Ras-like proteins is slow and would not be suitable for most biological signal transduction processes where inactivation is complete within minutes after GTP loading. It is not surprising then that GTPase activating proteins (GAPs) have been discovered for all major forms of these proteins [35,36]. They increase GTP hydrolysis by several orders of magnitude. As with GEFs, the structures of GAPs for various (sub)family Ras proteins are different, although an evolutionary relationship between Ras- and RhoGAP has been suggested [37,38].

Biochemical experiments showed that the active site arginine of heterotrimeric G α is supplied in “trans” by RasGAP [39]. Structures of G α -GDP in the presence of aluminum fluoride had shown that the latter is in a planar conformation and thus seems to mimic the transferred phosphate of the reaction [40,41]. In those structures both the arginine and a conserved glutamine stabilize the conformation of the transition state mimic. The structures of RasGAP and RhoGAP in complex with their respective G proteins in the presence

of AlF_x showed an intrinsic Gln and a so-called arginine finger supplied by GAP into the active site [42–44]. The structures also give an explanation for the inability of oncogenic mutants of Ras to hydrolyze GTP. The mechanism of inserting an arginine finger into the active site of Rho proteins is also used by some bacteria that insert these toxins into eukaryotic cells [45,46].

It has been discussed whether the mechanism of GAP-assisted GTP hydrolysis applies to all G-domain proteins [35]. This is clearly not the case. Rap proteins have a Thr, and protein synthesis factors have a histidine in place of the catalytic glutamine. For Arf, the presence or absence of an arginine of ArfGAP participating in catalysis is disputed [47,48]. Furthermore, in a recent structure of the trimeric complex between Ran, RanGAP, and a Ran-binding protein, no arginine was found to be participating in catalysis [49].

Conclusions

A large number of structural studies on small G proteins showed that there is a conserved module with a canonical structure and switch mechanism that can be considered as a *tema con variazioni*. The variations are derived from insertions into and additions to the canonical G domain and from a variety of regulators and effectors that are different for different types of G-binding proteins. The mechanisms by which GEFs and GAPs stimulate the otherwise slow intrinsic nucleotide dissociation and GTP hydrolysis have been worked out in some cases and suggest some underlying common principles in spite of the multitude of differences in detail. Interactions with effectors show a similar multitude of interactions. How these interactions generate the biological response of the particular system remains to be established in most cases with more structural studies on complexes of small GTP-binding proteins.

Conventional and Unconventional Aspects of Dynamin GTPases

Sandra L. Schmid

Department of Cell Biology,
The Scripps Research Institute, La Jolla, California

Introduction

Dynamin is unique among GTPases for its large size (~96 kDa), its multidomain structure, its low affinity for GTP, its relatively high intrinsic rate of GTP hydrolysis and most strikingly, its ability to self-assemble into rings and helical stacks of rings and its very robust ($\geq 100 \text{ min}^{-1}$) assembly-stimulated rates of GTP hydrolysis. These unique properties have led to the suggestion that dynamin functions, unlike any other GTPase superfamily member, as a mechanochemical enzyme that encircles the necks of deeply invaginated coated pits and generates the force necessary to drive scission. Recent structural data show that the GTPase domain of dynamin is, however, quite conventional. Moreover, dynamin overexpression affects many cellular processes, in addition to its effects on endocytosis, including actin dynamics, MAP kinase activation, transcriptional activation, and changes in cell morphology. Re-evaluation of the current data, from a new perspective, may suggest a broader role for the dynamin subfamily more akin to other regulatory GTPases.

Dynamin is one of the youngest members of the GTPase superfamily, having been discovered in the late 1980s. As a young upstart, it has proven to be unconventional and textbooks have rushed to include models for dynamin function as a fission GTPase—the first example of a GTPase functioning as a mechanochemical enzyme. However, more recent evidence suggests that, like signaling or regulatory GTPases, dynamin overexpression can effect many aspects of cell physiology, including actin dynamics, cell morphology, transcription, and even cell death. Dynamin's function in endocytosis has been extensively reviewed in references [1–3].

Here, with special emphasis on often overlooked aspects, I will review some of the features that set dynamin apart from its GTPase cousins, place it in the context of its siblings in the dynamin subfamily of GTPases, and describe dynamin effects that are not easily reconciled with its “text-book” function as a fission GTPase.

Common and Unique Features of Dynamin as a GTPase

Dynamin is a Multidomain Protein with a Conventional GTPase Domain

Atypically for GTPase family members, dynamin is large (~96 kDa) and has a modular domain structure (Fig. 1) consisting of an N-terminal GTPase domain, a middle domain

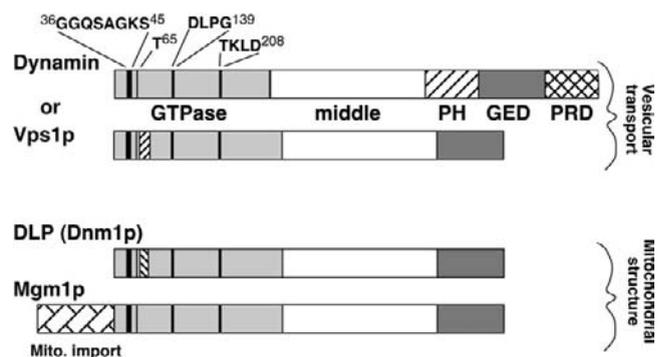

Figure 1 Domain structure of the only three evolutionarily conserved dynamin family members. The conserved elements of the GTPase binding site are indicated for dynamin-1.

of unknown function, a PH domain that binds PI4,5P₂, a GTPase effector domain (GED) that functions in dynamin self-assembly and assembly-stimulated GTPase activity, and a C-terminal proline and arginine-rich domain (PRD) that interacts with numerous SH3 domain-containing partners [4]. The recently solved three-dimensional structure of the 316 amino acid GTPase domain of *Dictyostelium* dynamin A [5], which is 60% identical to the GTPase domain of human dynamin-1, reveals it to have a typical, ras-like core GTPase domain fold (Fig. 2) with several distinguishing features. The first is an insertion, which is quite divergent among dynamin family members (see Fig. 1), that adds two additional strands to the core 6-stranded β -sheet and a variable length extended loop (Fig. 2). It is positioned immediately distal to T65 (in dynamin-1) which coordinates with γ -phosphate on bound GTP, at a region equivalent to switch I of other GTPases. Its position, its variability, and the high content of charged residues suggest that this loop could be involved in interactions with downstream partners, like other GTPases. The loop between β 3 and α 2 that constitutes the switch II region of the GTPase (element 3 of the GTP binding site), also undergoes GTP-dependent conformational changes and is considerably longer in dynamin than in ras. A third insert is located

near the C terminus of the GTPase domain and constitutes two α -helices which extend out from and run perpendicular to the core β -sheet. The fourth distinguishing feature is that the N and C terminus of the GTPase domain come in close contact with each other through an additional N-terminal α -helix and an extended C-terminal α -helix. Interestingly, together these two terminal helices form a hydrophobic groove, which was occupied in the solved structure by hydrophobic residues from the N-terminal fusion partner used in the dynamin construct, the catalytic domain of *Dictyostelium* myosin II [5]. The author's speculation, that this groove might normally be a docking site for the GED domain of dynamin is consistent with results from the dynamin-related mx proteins which identified a hydrophobic residue within GED that is essential for self-assembly and assembly-stimulated GTPase activity [6], and results from two-hybrid analysis mapping the GED-GTPase interaction site in dynamin to the C-terminal regions of the GTPase domain [7]. Importantly, this model for GED-GTPase interaction is inconsistent with that based on the structure of GBP-1, another interferon-inducible GTPase [8]. However, comparison of the GTPase domain structures of GBP1 and dynamin A, together with their lack of sequence similarity would strongly

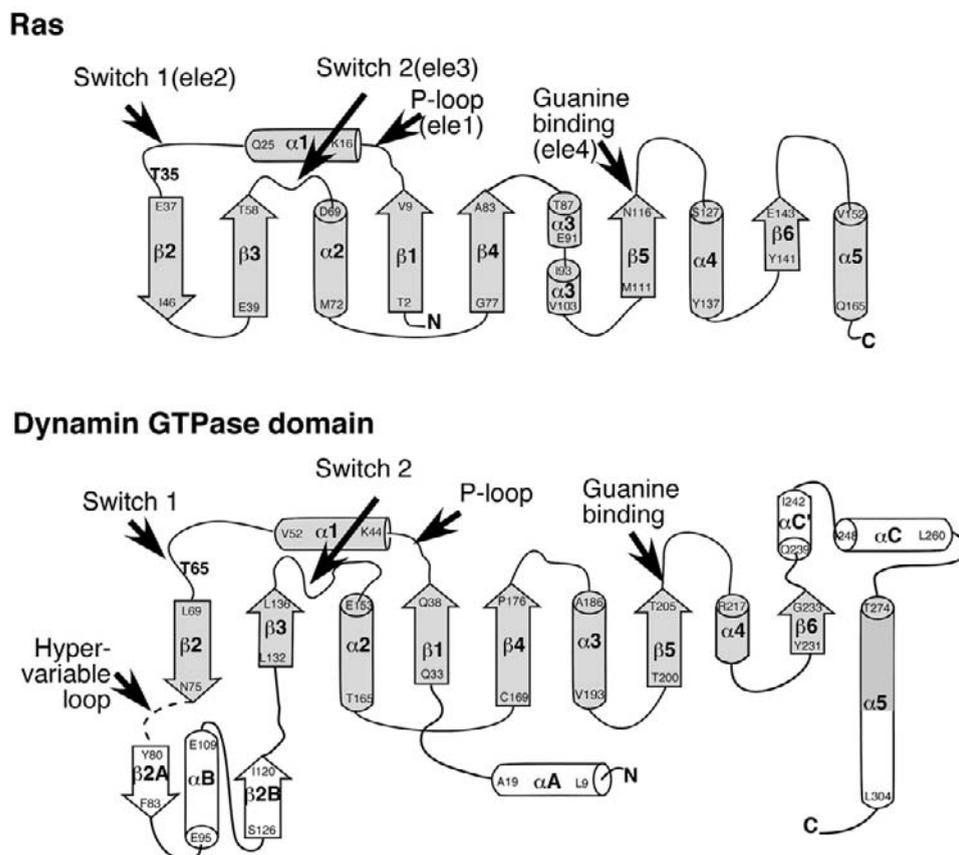

Figure 2 Topology of dynamin GTPase domain compared to Ras. The models for ras and dynamin are redrawn and modified from Wittinghofer, A., *GTPases*, Vol. 24, 244–310, Oxford University Press, New York, with permission and Niemann, H.H. *et al.*, *EMBO J.*, 20, 5813–5821, 2001, with permission, respectively. The location of the four GTPase binding site elements are indicated.

argue that they represent distinct GTPase subfamilies and, therefore, that the structure of distal domains of GBP-1 may not reflect those of dynamin-family members.

Dynamin's Unconventional GTPase Activity

Although dynamin's GTPase domain is structurally quite conventional, there are several important distinguishing features of its GTPase activity that set it apart from most GTPase family members. The first is dynamin's relatively low affinity for guanine nucleotides (2.5 μM for GTP and \sim 40-fold weaker for GDP) and the very rapid dissociation rates for both GTP (2.1 s^{-1}) and for GDP (93 s^{-1}) [9]. Thus, unlike most other GTPases, nucleotide exchange is not rate-limiting for dynamin's GTPase activity. The second is dynamin's relatively fast intrinsic rate of GTP hydrolysis. Reported measurements of this rate have varied considerably probably due to variable amounts of dynamin aggregation or self-assembly under different assay conditions. However, when assayed in high salt to inhibit self-assembly, more consistent rates (0.01–0.03 s^{-1}) are reported [10,11]. This rapid intrinsic rate is comparable to that measured for trimeric G proteins; however, the steady-state GTPase activity of trimeric proteins is greatly limited by the very slow dissociation rates of GDP. Together, these unusual properties of dynamin's GTPase activity would suggest that *in vivo*, in the absence of as yet unidentified regulatory factors, dynamin would rapidly cycle between the GTP-bound and unoccupied state, occasionally hydrolyzing bound GTP.

Dynamin has an Intrinsic GAP Domain

As alluded to above, perhaps the most unusual property of dynamin is its ability to self-assemble into rings and helical stacks of rings. Depending on the template provided, self-assembly stimulates dynamin's GTPase activity >100-fold [9,12–14]. This assembly-stimulated GTPase activity is mediated by GED, which functions as an assembly-dependent GAP domain [15]. Thus, dynamin, unlike other GTPase family members, encodes its own GAP; however, like other GTPases, GED appears not to function intramolecularly, but is only activated by intermolecular interactions that occur between dynamin molecules upon self-assembly.

The mechanism of GED-stimulated GTPase activity is unknown. Mutagenesis studies had identified an arginine residue in GED (R725), which when mutated to alanine, appeared to specifically inhibit assembly-stimulated GTPase activity while not affecting dynamin's ability to self-assemble upon dilution into low-salt buffers or on a microtubule template [15]. These findings led to the suggestion that R725 might function as a catalytic residue akin to the Arg-finger in rasGAP. However, a more recent study has shown that dyn(R725A) is capable of near wild-type stimulated GTPase activity when assayed on lipid tubule assembly templates, and instead revealed an assembly defect in the R725 mutant [16]. Consistent with this result, we have found that dyn(R725K) exhibits wild-type self-assembly and GTPase

activity (S. Sholly and S.L. Schmid., unpublished results), a finding inconsistent with a role for R725 in catalysis. Given that dynamin's intrinsic rate of GTP hydrolysis parallels that of trimeric G protein α subunits, it is possible that GED functions more in analogy to RGS-type GTP-activating proteins (GAPs) that stabilize and position catalytic residues already in place in the GTPase domain (reviewed in reference [17]).

Dynamin's Function in Endocytic Vesicle Formation

The rapid temperature-sensitive inhibition of endocytosis seen in *Drosophila* bearing mutations in *shibire*, the ortholog of dynamin, remains the strongest and most compelling evidence for dynamin's essential role in endocytosis [18]. In mammalian cells, endocytic clathrin-coated vesicle formation is inhibited by overexpression of dominant-negative mutants of dynamin. One striking example is the finding that HeLa cells overexpressing human dyn(G273D), corresponding to the *shibire-ts1* allele, exhibit rapid and reversible temperature-sensitive inhibition of receptor-mediated endocytosis [19]. Several mutations have been made at conserved residues in the nucleotide-binding site within dynamin's GTPase domain (see Fig. 1), which by analogy to other GTPases are predicted to disrupt dynamin's ability to bind GTP. Overexpression of these "dominant-negative" mutants [e.g., dyn(K44A) or dyn(S45N)] potently inhibits receptor-mediated endocytosis and leads to the accumulation of invaginated clathrin-coated pits on the cell surface [16,20–22]. Other endocytic events, such as internalization of caveolae [23,24] and phagocytosis [25] are also inhibited, but the internalization of bulk fluid or membrane markers mediated by a constitutive, but poorly understood, clathrin-independent endocytic process is unaffected [20,26]. In stable HeLa cells induced to express dyn(K44A), the mutant also blocks the retrograde transport of the plant toxin ricin from late endosomes to the trans-Golgi network (TGN) [26]. Other membrane transport events, such as trafficking from the TGN to the cell surface, transport from the TGN to late endosomes or delivery of endocytic tracers to lysosomes are unaffected in these cells [20,27].

Two Models for Dynamin Function in Endocytic Vesicle Formation

While there exists considerable evidence establishing a critical role for dynamin in endocytic clathrin-coated vesicle formation, its exact function remains a matter of dispute [3]. One prevailing model (Fig. 3, model 1) suggests that after self-assembly around the necks of invaginating coated pits, dynamin functions as a mechanochemical enzyme to generate the force—either by constriction (model 1A [28]) or expansion (model 1B [14]) of the assembled ring driven by rapid GTP hydrolysis—that mediates membrane fission and vesicle detachment. This model, which is consistent with its unique enzymatic properties, places dynamin in a class of its

Dynamin as a mechanochemical GTPase

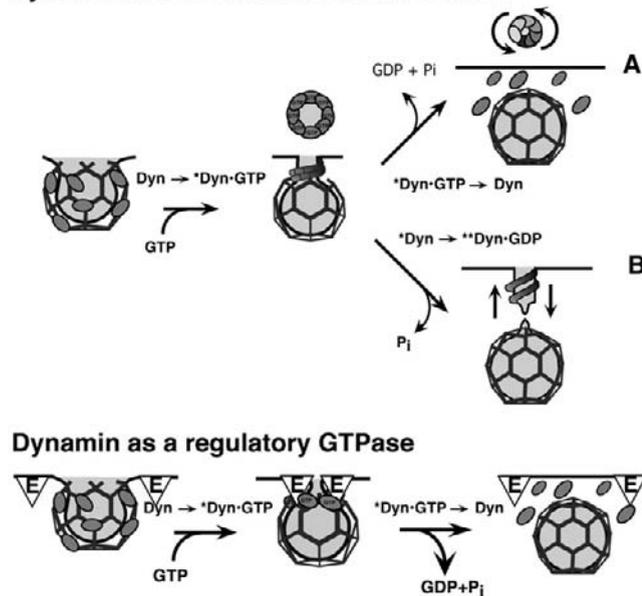

Figure 3 Two prevailing models for dynamin's function in endocytosis. Model 1 asserts that dynamin functions in a mechanochemical manner as either a "pinchase" or a "spring" to sever the necks of invaginated coated pits. Model 2 asserts that in its GTP-bound form dynamin recruits downstream effector molecules that mediated vesicle formation. In both models dynamin must bind and hydrolyze GTP (at least at its basal rate) and undergo GTP-dependent conformational changes (indicated by asterisks).

own as the first example of a mechanochemical GTPase. The second, more recently espoused model (Fig. 3, model 2), is more in keeping with dynamin's membership in the GTPase superfamily, and suggests that dynamin functions, in its GTP-bound form, to recruit downstream effectors, which themselves constitute the vesicle fission/detachment machinery [15]. In this model the collar functions as a geometric sensor and dynamin's GAP, when activated by self-assembly, functions by analogy with all other GTPase superfamily members, as a timer to turn off and recycle the activated GTPase. Naturally, these two models are not mutually exclusive and other models are possible that incorporate features of both extremes.

Testing Models for Dynamin Function *in vivo*: GTPase Domain Mutants

Good faith efforts have been made to test models for dynamin function *in vivo*, but as yet none of the experiments have unambiguously supported one model over the other. One approach is to ask whether GTP hydrolysis by dynamin is required for endocytosis. If dynamin functions like a regulatory GTPase one would predict that an "activating mutant" of dynamin locked in its GTP-bound form would support and perhaps stimulate endocytosis. In contrast, if dynamin functions as a mechanochemical enzyme, its high rates of GTP hydrolysis would be required for endocytosis. Based on analogy to other GTPases, Thr65 of dynamin, which is located in the switch I region of GTPases and is required to

coordinate the Mg^{2+} ion essential for GTP hydrolysis, was mutated in an effort to generate such an activating mutant. Overexpression of dyn(T65A) inhibits receptor-mediated endocytosis, suggesting that GTP hydrolysis by dynamin is essential [16].

However, the results are not conclusive, as mutation of this conserved Thr in ras or trimeric G proteins reduces their affinity for GTP by >100-fold [17]. However, ras and G α GTPases are still able to bind GTP with relatively high affinity and binding is not significantly impaired under *in vivo* conditions. By contrast, given dynamin's already low affinity for GTP, this mutation is more likely to perturb its ability to bind GTP *in vivo*. Moreover, the coordination of this conserved Thr to Mg^{2+} and the γ -phosphate in other GTPases is essential for the GTP-dependent conformational change in the effector loop necessary for interaction with downstream partners. Thus, it is unclear whether GTPases with this mutation are able to efficiently adopt the "active" conformation. Consistent with this interpretation, dyn(T65A) is unable to adopt the GTP-dependent conformation on lipid tubules [16].

Thus the issue of whether GTP hydrolysis by dynamin is essential for endocytosis remains unresolved. Ideally, one needs to mutate an essential catalytic residue, equivalent to Q61 in ras, that does not affect GTP binding or the GTP-dependent conformational change in order to test whether GTP hydrolysis was required for dynamin function. Unfortunately, candidate residues based on other GTPases are not conserved in dynamin. However, the recently solved structures of the GTPase domain of dynamin A in the unoccupied and GDP-bound state [5] may suggest candidate residues for further mutagenesis.

Testing Models for Dynamin Function *in vivo*: GED Mutants

Given that dynamin encodes its own GAP, another approach to making activating mutants is to identify residues in GED that affect the assembly-dependent GAP activity. Two such mutations, dyn(K694A) and dyn(R725A), were shown to specifically perturb the assembly-stimulated GTPase activity of dynamin *in vitro* [15]. Importantly, these GED mutations do not alter the basal rate of GTP hydrolysis, nor do they effect GTP binding affinities. In contrast to the GTPase mutants of dynamin, overexpression of these GED mutants accelerated the rate-limiting step in clathrin-mediated endocytosis [15]. Dyn(K694A) and dyn(R725A) were overexpressed under the control of a tetracycline-regulatable promoter in stably-transfected HeLa cells and studied using stage-specific endocytosis assays that distinguish the formation of constricted coated pits, an intermediate in endocytosis, from subsequent membrane fission and coated vesicle release [29]. Dyn(K694A) overexpression increased the rate of formation of both constricted coated pits and coated vesicles. Consistent with these findings, expression in yeast of an analogous mutation (K705A) in Dnm1p, a dynamin family member, results in increased mitochondrial fission [30].

Given that the dyn(K694A) mutant was specifically defective in self-assembly, this result is difficult to reconcile with models for dynamin function as strictly a mechanochemical enzyme. Instead, these findings are most consistent with the interpretation that by impairing GAP activity and prolonging dynamin in its GTP-bound form, as yet unidentified, downstream effectors(s) are activated and in turn accelerate the rate of endocytosis. Importantly, dyn(K694A) was impaired but not incapable of self-assembly, and so these results do not rule out a requirement for dynamin self-assembly in vesicle formation. Moreover, results with dyn(R725A) were more difficult to interpret, because, unexpectedly, although overexpression of dyn(R72A) enhanced the rate of formation of constricted coated pits, it had no effect on or was slightly inhibitory for vesicle formation [29]. These results suggested that the dyn(R725A) mutant reduces the rate of membrane fission, while increasing the rate of constricted coated pit formation. Thus, dynamin assembly and assembly-stimulated GTPase activity may be required for the final stages in vesicle detachment. New mutants with more pronounced defects in assembly and assembly-stimulated GTPase activity will be needed to rigorously test models for dynamin function *in vivo*. Interestingly, mutations in mx protein that have abolished self-assembly and assembly-stimulated GTPase activity do not alter the protein's ability to confer viral resistance [6], suggesting that for this dynamin family member, self-assembly is not essential for function.

Dynamin's Siblings: The Dynamin Subfamily of GTPases

Although not the founding member, dynamin was born into a subfamily of GTPases that now bears its name. Members of the dynamin family of GTPases are functionally diverse, and not numerous. That is, unlike other components of the vesicle transport machinery (i.e., arfs, coats, SNAREs, rabs, etc.), there does not appear to be a dynamin analog functioning in every vesicle formation event within the cells. In the yeast, *Saccharomyces cerevisiae* there are only three dynamin family members. These include Vps1p, which is the only dynamin family member involved in vesicular transport in yeast and plays an as yet undefined role in protein trafficking between the *trans*-Golgi network (TGN) and the vacuole; Dnm1p, a cytosolic protein that binds to the outer mitochondrial membrane and plays a role in regulating the size and number of mitochondria; and, Mgm1p, an inner mitochondrial protein also involved in controlling mitochondrial division. These dynamin-related GTPases share high degrees of homology with dynamin's GTPase, middle and GED domains, but they lack the pleckstrin homology (PH) domain and the PRD of true dynamins (Fig. 1).

The *Drosophila* and *Caenorhabditis elegans* genomes also encode only three dynamin family members. These include Dnm1p and Mgm1p homologs, which appear to function like their *S. cerevisiae* counterparts in regulating mitochondrial membrane dynamics [31]. Surprisingly, there are no

Vps1p homologs in either organism, instead they both encode a single gene for dynamin. Thus, Vps1p may be the yeast homolog of dynamin, given that both proteins function in vesicular trafficking, albeit at distinct sites. Vps1 mutations have no effect on endocytosis in yeast, whereas dynamin mutations in *C. elegans* and *Drosophila* specifically disrupt endocytosis, without affecting other trafficking pathways.

The issue is more complicated, however, in mammals, which in addition to a Dnm1p homolog (called DLP1 and also known as dymple, DRP1 or DVLP) and a Mgm1p homolog, both of which are associated with mitochondrial membrane dynamics, express three dynamin genes in a tissue-specific manner [31]. Dynamin-1 is exclusively expressed in neurons, dynamin-2 is ubiquitously expressed, and dynamin-3 is expressed primarily in testes, brain, and lung. There are also numerous splice variants of each gene product [2]. Gene duplication in mammals is not uncommon and the simplest interpretation is that the newly evolved isoforms perform specialized functions in specialized cells (e.g., rapid and regulated synaptic vesicle recycling at the synapse). In HeLa cells and MDCK cells, overexpression of dyn2(K44A) functions indistinguishably from dyn1(K44A) in membrane trafficking to specifically and potently inhibit receptor-mediated endocytosis without affecting other vesicular trafficking events [27]. There are conflicting data as to whether specific splice variants of dynamin-2 do [32] or do not [33] localize to the TGN and effect vesicle formation from this compartment. These discrepancies may reflect cell-type differences and/or they may reflect nonspecific effects or incomplete inhibition due to too much or too little overexpression. Knock-out experiments will be needed to unambiguously resolve this issue; however, given that a function for dynamin in the Golgi does not appear to be conserved in *C. elegans* or *Drosophila*, it seems unlikely that it is essential for vesicle formation at these sites.

Mammals also express a fourth, and original member of the dynamin subfamily, the α -interferon inducible mx proteins [34]. The mx proteins are localized in either the cytoplasm or the nucleus and confer cellular resistance to RNA viruses. Recent evidence suggests that one mx family member (mxA) does so by binding to and sequestering the viral nucleocapsid in large aggregates in the cytosol [35]. Thus, of the four dynamin family members in mammals, all of which self-assemble into rings and helical stacks of rings and all of which exhibit assembly-stimulated GTPase activity, only one is involved in vesicular trafficking. This latter point is important when considering dynamin's proposed function as a fission GTPase or vesicle "pinchase" that is integral to the fundamental mechanism of vesicle formation. One might expect such an elegant fission apparatus to be a ubiquitous component of the vesicle formation machinery

Dynamin as a Signaling Molecule

While the mechanisms remain to be established, a growing body of evidence suggests that dynamin (and dynamin

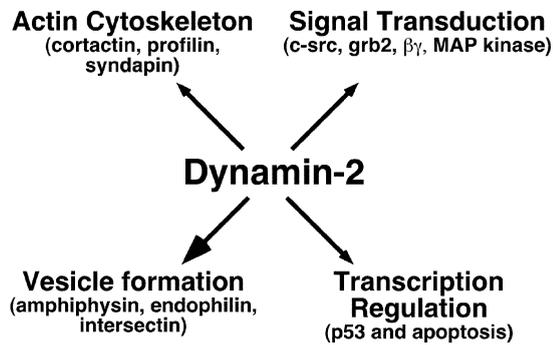

Figure 4 Dynamin as a signaling GTPase. There is now considerable evidence that dynamin can signal to multiple, functionally diverse downstream cellular processes. Some of these signaling pathways are specific for dynamin-2 versus dynamin-1.

family members) may instead, or in addition, function as signaling molecules to control multiple aspects of cell physiology (Fig. 4). For example, dynamin is known to interact with several actin regulatory proteins, including profilin, cortactin, syndapins, and Abp1 [36] and has recently been shown to be associated with sites of active actin assembly/disassembly, including membrane ruffles [37], podosomes [38], and actin comet tails [39,40]. Actin dynamics at these sites are disrupted or altered by overexpression of dyn2 (K44A) mutants suggesting a role for GTP binding and/or hydrolysis in regulating these events. Overexpression of dyn2(Δ PRD) in clone 9 cells causes dramatic changes in overall cell shape [37], again suggesting a more pleiotropic effect than one would expect from a defect in vesicle formation alone.

Dynamin can also effect other signaling pathways, directly or indirectly. Three studies have shown that dyn(K44A) overexpression perturbs G-protein-coupled receptor (GPCR) signaling to MAP kinase family members, independent of its effects on endocytosis [41–43]. Dyn(K44A) overexpression also inhibits high-affinity binding to epidermal growth factor (EGF) receptors [44] and causes reduced acidification of endosomes [45]. While the mechanisms underlying these effects are unknown, these observations are not easily reconciled with a model for dynamin as simply a vesicle pinchase.

Finally, low levels of overexpression of dynamin-2 induces p53-dependent apoptosis in several cell types including HeLa cells, rat-1 fibroblasts, and mouse embryo fibroblasts [46]. Several lines of evidence support the specificity of this effect: (1) <5-fold overexpression of dyn2 induces apoptosis, whereas >250-fold overexpression of the 80% identical dynamin-1 isoform has no cytotoxic effect; (2) dyn2-induced apoptosis requires GTP binding because dyn2(K44A), which inhibits endocytosis, does not induce apoptosis; (3) dyn2 at high levels of overexpression does not induce apoptosis in nondividing cells (e.g., contact inhibited MDCK cells or primary macrophages) or in p53-deficient mouse embryo fibroblasts. Interestingly, a recent report established that dominant-negative DRP1, a mitochondria-associated dynamin family member, can protect cells from staurosporine-induced apoptosis [47]. Together these data suggest that dynamin family members might play a more general role in

monitoring membrane dynamics at critical cellular locations—the plasma membrane and the mitochondria—to control cellular homeostasis.

Conclusion and Perspectives

Consider the following re-ordering of the discoveries surrounding dynamin function: (1) dynamin-2 is cloned and found to be a GTPase superfamily member; (2) analysis of the complete genomes of *Drosophila* and *C. elegans* reveal that the only two other dynamin-related GTPases are mitochondrial—there is no “true” dynamin in yeast; (3) in mammals, a fourth dynamin related GTPase is identified as the α -interferon-inducible mx protein, which confers viral resistance; (4) overexpression of dyn2(wt) activates p53 and induces apoptosis, mutants unable to bind GTP do not; (5) overexpression of dyn2(K44A) inhibits MAP kinase activation and alters actin cytoskeleton dynamics; (6) all dynamin-related proteins, even those not involved in vesicular transport, are shown to self-assemble and to have assembly-stimulated GTPase activity; (7) mutants of mx incapable of either self-assembly or assembly-stimulated GTPase activity are fully functional in conferring viral resistance, although GTPase domain mutants are not; (8) dyn(K44A) mutants inhibit endocytosis and assembled dynamin accumulates in GTP γ S-treated membranes. Given this set of facts, presented in this order, one might have reached a different conclusion regarding dynamin’s cellular function, perhaps one in which dynamin functions more broadly and more in line with rho family regulatory GTPases. While images of “collared” pits are compelling, the function of dynamin GTPase’s may turn out to be more than meets the eye.

Mx Proteins: High Molecular Weight GTPases with Antiviral Activity

Georg Kochs, Othmar G. Engelhardt, and Otto Haller

*Abteilung Virologie,
Institut für Medizinische Mikrobiologie und Hygiene,
Universität Freiburg, Freiburg, Germany*

Mx proteins belong to a family of interferon-induced GTPases within the superfamily of high molecular weight GTPases. A unique property of some Mx GTPases is their antiviral activity against RNA viruses. Much progress has been made in better understanding the molecular mechanisms of Mx action over the years. Here we review recent insights into the workings of this fascinating class of large GTPases.

Antiviral Activity of Mx GTPases

Mx, for Myxovirus resistance, has first been described in mice, as an interferon-induced resistance phenomenon against influenza A virus (FLUAV) infection [1]. Subsequently, a variety of Mx proteins from different species were found to have antiviral activity, as shown by transfection experiments with Mx cDNA expression constructs [1,2]. Rodents express nuclear as well as cytoplasmic Mx proteins, whereas most other vertebrates express Mx proteins that accumulate exclusively in the cytoplasm. Interestingly, the antiviral specificity of rodent Mx proteins correlates with their subcellular localization. The nuclear forms (Mx1 in mouse and rat) confer resistance to orthomyxoviruses, FLUAV, and Thogoto virus (THOV), known to replicate in the cell nucleus. In contrast, cytoplasmic proteins (Mx2 in mouse and rat) inhibit multiplication

of viruses that replicate in the cytoplasm, such as rhabdoviruses (e.g., vesicular stomatitis virus; VSV) and bunyaviruses (e.g., LaCrosse virus ;LACV) [1]. This suggests that rodents have evolved two distinct types of Mx GTPases to allow control of viruses with different intracellular replication sites.

Humans express a single antiviral Mx GTPase, called MxA. The cytoplasmic MxA has a rather wide antiviral spectrum against different classes of viruses, irrespective of their intracellular site of replication. MxA interferes with the multiplication of members of the bunyaviruses, orthomyxoviruses, paramyxoviruses, and rhabdoviruses [1]. Initially, Mx proteins were assumed to be active against negative-strand RNA viruses only, but recent studies showed inhibitory activity of MxA also against Semliki Forest virus and coxsackievirus B4, two plus-strand RNA viruses, as well as hepatitis B virus, a DNA virus with a genomic RNA intermediate [3–5]. The power of MxA as an intrinsic host defense mechanism is best illustrated in experiments with *MxA*-transgenic mice lacking interferon- α/β receptors. These animals survived an otherwise lethal infection with MxA-sensitive viruses, despite their interferon-nonresponsiveness [6]. Interestingly, Mx proteins without antiviral function also exist, such as human MxB or rat Mx3. It is presently not known whether these Mx GTPases are directed against a different set of microbial pathogens or serve other functions.

Mouse Mx1 Protein Blocks Primary Transcription of Orthomyxoviruses by Interfering with the Viral Polymerase Activity

The nuclear mouse Mx1 protein inhibits FLUAV and THOV multiplication at the level of primary transcription of the viral genome. It is noteworthy that primary transcription of these viruses occurs in the nucleus of infected cells and is catalyzed by the viral polymerase. The FLUAV polymerase consists of three subunits, PB1, PB2, and PA. Overexpression of the PB2 subunit abolished the antiviral effect of Mx1, suggesting that the PB2 subunit of FLUAV is an Mx1 target [7]. The subcellular localization of Mx GTPases is important for their antiviral activity, as demonstrated by artificial translocation of cytoplasmic Mx proteins into the nuclear compartment. When MxA or rat Mx2 was translocated into the nucleus with the help of a foreign nuclear translocation signal, both proteins gained an Mx1-like phenotype and blocked primary transcription of FLUAV and THOV [8,9].

Human MxA Interferes with Virus Multiplication by Missorting Viral Components

Studies in cell culture showed that cytoplasmic MxA inhibits primary transcription of VSV and measles virus, all of which are known to transcribe their genome in the cytoplasm [1]. Surprisingly, MxA also inhibited primary transcription of THOV which takes place in the nucleus [10]. In addition, MxA inhibits the multiplication of FLUAV, human parainfluenza virus type 3, and bunyaviruses, at later steps in the viral replication cycle [1]. In the case of THOV, we could demonstrate that MxA binds to the nucleocapsids and prevents their transport into the nucleus (Fig. 1A). As a consequence, THOV primary transcription is inhibited [10]. In the case of LACV, we could show that MxA binds to the viral nucleocapsid protein [11]. This interaction leads to the formation of MxA/nucleocapsid protein copolymers. A redistribution of the viral nucleocapsid protein takes place in MxA-expressing cells leading to the disappearance of nucleocapsid proteins from the putative viral replication sites near the Golgi apparatus and to accumulation in the perinuclear area (Fig. 1B). This indicates that the antiviral action of MxA against bunyaviruses is based on missorting of an essential virus component which thus becomes unavailable for the generation of new virus particles. In summary, our analysis of THOV and LACV, representing two viruses with different replication strategies, suggests that MxA acts by interfering with proper transport of critical viral components to their ultimate target compartments within the infected cell.

Mx Proteins Belong to the Superfamily of High Molecular Weight GTPases

Mx proteins are large GTPases that differ from small GTPases and heterotrimeric G proteins in their molecular weight of about 70,000 to 80,000, a relatively low affinity

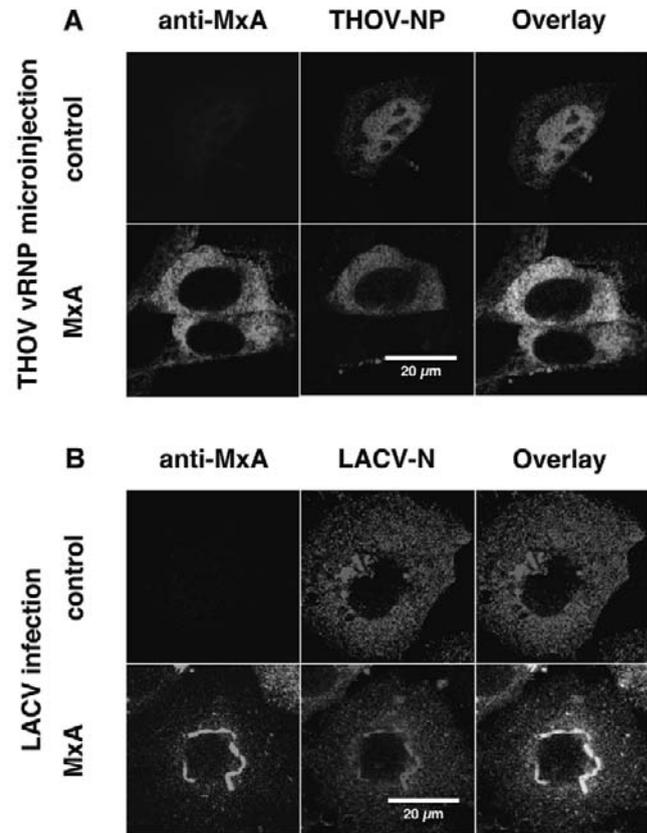

Figure 1 Inhibition of LACV and THOV multiplication by human MxA protein. (A) MxA-expressing or control cells were microinjected with purified viral nucleocapsids and incubated for 2 h. (B) Monolayers of the cells were infected with LACV for 12 h. Cells were fixed and analyzed for MxA and the viral nucleoproteins by double-immunofluorescence as described in references [10] and [11]. The right panels show the superimposition of the two images.

to GTP, and a high intrinsic rate of GTP hydrolysis [7]. Accordingly, Mx proteins belong to the superfamily of high molecular weight GTPases known to have mechanochemical properties. The prototype of this superfamily is the mammalian dynamin that is involved in endocytosis at the plasma membrane and other intracellular vesicle trafficking events (see previous chapter and reference [12]). Large GTPases share similarities in their overall domain structure. They contain a conserved tripartite GTP-binding motif within their N-terminal G domain and a less conserved C-terminal part that serves effector functions (Fig. 2A). GTP-binding and/or hydrolysis are necessary for large GTPases to display their force-generating functions [13]. Likewise, GTP binding and/or hydrolysis are required for the antiviral activity of Mx proteins [14].

The crystal structure of human guanylate-binding protein 1 (GBP-1) has been solved [15] and presently represents best the putative three-dimensional structure of high molecular weight GTPases. GBP-1 monomers consist of a globular G domain, a compact central core that is composed of two helix bundles and a long C-terminal helix, which interacts with the central core and the G domain. Figure 2B depicts a

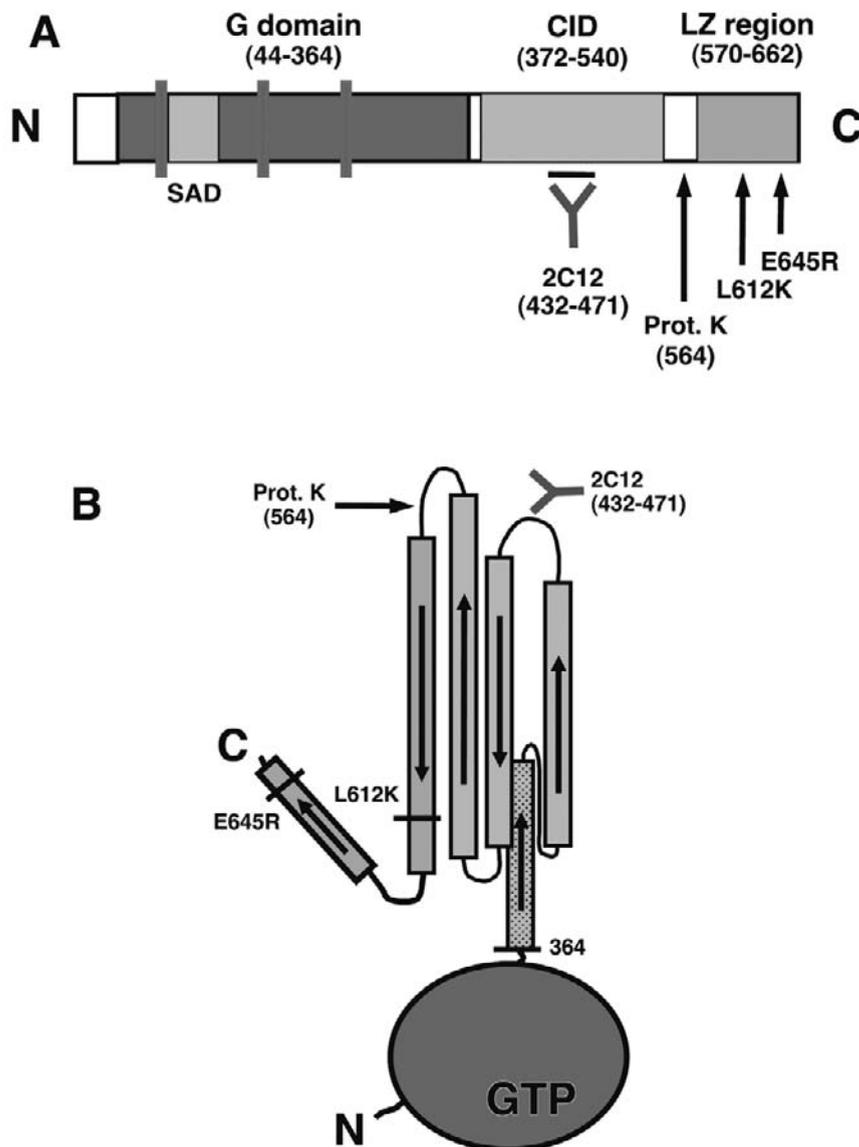

Figure 2 Functional domains of human MxA protein. (A) Schematic diagram of MxA domains and (B) a model of the putative structure according to the three-dimensional structure determined for GBP-1 [15]. The N-terminal globular G domain contains the tripartite GTP-binding element (red bars) and the “self-assembly domain,” SAD (light blue box). The C-terminal effector domain contains the “central interactive domain,” CID (yellow box), and the leucine zipper (LZ) region (green). The positions of the 2C12 antibody-binding site, the proteinase K cleavage site, and the critical amino acid substitutions L612K and E645R are indicated.

hypothetical model of the structure of human MxA, based on the structure of GBP-1. In this model, MxA consists of a large globular G domain and an extended helical C-terminal domain that controls self-assembly and association with other molecules, such as viral target structures or cellular binding partners.

Three different regions have been identified to be involved in molecular interactions of Mx proteins (Fig. 2A) [16]: (1) an N-terminal “self-assembly” sequence between GTP-binding elements 1 and 2 [17], (2) a “central interactive domain” (CID) [16], and (3) a leucine zipper motif (LZ) [18]. In our model, the central core containing the CID is composed

of four helices which interact with the long C-terminal helix formed by the LZ region. This interaction was confirmed by biochemical studies and studies using cellular systems [19]. The CID and LZ region are connected by a putative hinge region that was identified by its accessibility to proteinase K cleavage [20]. The backfolding of the LZ region on CID results in increased GTPase activity, indicating that the C-terminal part acts as a “GTPase effector domain” [20]. Further biochemical studies with the C-terminal half indicated that the effector domain containing the CID and the LZ region is also crucial for binding to the viral target. Likewise, point mutations in the LZ region of MxA, like

MxA(E645R), and rat Mx2 identified the C-terminal effector domain as an important determinant for viral target recognition [8,11,21]. Other members of the superfamily of large GTPases have a comparable molecular structure which is also in agreement with recent reconstructions of electron microscopic pictures of human dynamin-1 [22] and dynamin A of *Dictyostelium discoideum* [23] (see also the previous chapter on dynamin).

What Is the Function of Mx Oligomerization?

Self-assembly of Mx proteins seems to be critical for GTPase activity, protein stability, and recognition of viral target structures. In cells, Mx proteins aggregate into punctate granula [24,25]. *In vitro*, purified Mx proteins form high molecular weight homo-oligomers and self-assemble into ring-like and helical structures [17,18,26]. Homo-oligomerization is essential for the biological function of other dynamin-like GTPases [13]. Dynamin, for example, self-assembles into ring-like and helical structures around membrane invaginations. Hydrolysis of guanosine triphosphate (GTP) to guanosine diphosphate (GDP) then induces conformational changes in these complexes, which generate the mechanochemical force necessary for membrane vesiculation.

A characteristic feature of Mx proteins and other large GTPases is their ability to hydrolyze GTP to GDP in the absence of additional factors like GTPase-activating proteins or nucleotide exchange factors [7]. Mutational analysis and proteolytic digestion of MxA showed that the association of the C-terminal LZ region with the CID is necessary for GTP binding and hydrolysis [20]. Accordingly, it has been demonstrated that oligomerization stimulates GTPase activity of MxA [27]. Homo-oligomerization most likely results from binding of the LZ region of one molecule to the CID of a second neighboring molecule [19]. Mutant MxA(L612K) carries an amino acid exchange from leucine to lysine at position 612 in the proximal part of the LZ region (Fig. 2A). MxA(L612K) has lost both its ability to self-assemble and its ability to hydrolyze GTP [28], indicating that oligomerization is the major regulator of GTPase activity.

Studies in cell culture showed that the monomeric MxA(L612K) is rapidly degraded [28]. In contrast, wild-type MxA is stable, with a half-life of over 24 h. Therefore, we propose that aggregation of Mx proteins prevents their rapid degradation and provides a storage form from which active molecules can be recruited for prolonged periods of time.

As already mentioned, biochemical studies demonstrated complex formation of MxA with the ribonucleoprotein complex of THOV and with the nucleocapsid protein of LACV [10,11]. This interaction only occurred when MxA was in the GTP-bound form, indicating that GTP-MxA is in a conformation able to recognize viral target structures. With LACV we demonstrated that binding of MxA to the viral nucleocapsid protein leads to the formation of protein complexes, most likely by copolymerization of MxA with the viral nucleocapsid protein [11]. We envisage that oligomerization

of MxA occurs as a consequence of viral target recognition and is important in mediating the antiviral effect.

Cellular Interaction Partners of Mx GTPases

The antiviral activity of MxA against certain viruses was found to be cell-type specific. In the case of measles virus, MxA inhibited viral transcription in human glioblastoma cells, but not in a human monocytic cell line in which a later step, namely viral glycoprotein synthesis, was affected [29]. Also, the antiviral activity of MxA against Semliki Forest virus was detectable in human cells, but not in MxA-expressing mouse cells [3]. These findings suggested that unknown cellular factors are modulating the antiviral activity of MxA and influence its antiviral specificity for some viruses. Early work by Horisberger revealed an association of MxA with actin and tubulin [30], but the significance of this interaction remained unresolved. It is conceivable that the cytoskeleton plays a role in MxA-mediated relocalization of viral components as observed in infected cells [10,11]. Furthermore, nuclear factors may contribute to the antiviral activity of mouse Mx1 protein against influenza viruses [31]. Interestingly, rodent Mx1 proteins accumulate in distinct dots within the interchromatin nucleoplasm [24]. These dots are in close proximity to subnuclear structures, called promyelocytic leukemia protein nuclear bodies (PML NBs) (Fig. 3) [32,33]. Using a yeast-two-hybrid screen, we found that mouse Mx1 interacts with components of PML NBs, such as Sp100 and Daxx. Moreover, Mx1 interacted with components of the SUMO-1 protein modification system [33]. This is interesting because protein constituents of PML NBs are targets for SUMO-1 modification and SUMOylation of PML has been demonstrated to be crucial for PML NB assembly [34]. Again, the C-terminal effector domain of Mx seems to be responsible for at least some of these interactions (Trost, Kochs, Haller, unpublished results). PML NBs are involved in transcriptional regulation, cell cycle control,

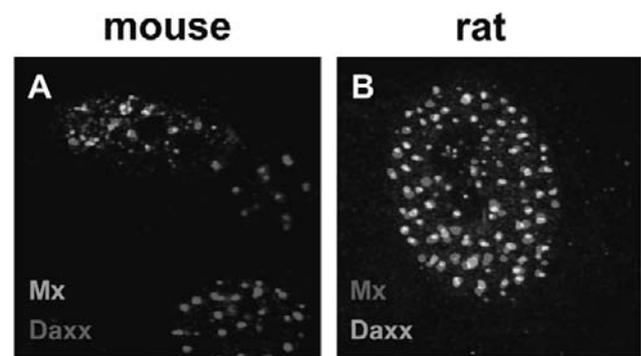

Figure 3 Mouse and rat Mx1 proteins form nuclear dots that are associated with PML NBs. Mouse embryo fibroblasts were transfected with cDNA expression constructs coding for mouse Mx1 (A) or rat Mx1 (B). The cells were fixed 24 h later and analyzed for the accumulation of Mx1 and endogenous Daxx by double-immunofluorescence. The pictures show the superimposition of the separately recorded images for Mx1 and Daxx.

apoptosis, and antiviral defense [34]. Whether these structures play a role for the antiviral activity of Mx1 is presently being investigated. It will be of interest to see whether the nuclear Mx1 dots are simply storage sites of Mx1, as discussed for MxA, or whether they represent, in fact, specialized nuclear compartments in which the inhibition of the viral polymerase takes place.

Toll-Dorsal Signaling in Dorsal-Ventral Patterning and Innate Immunity

Ananya Bhattacharya and Ruth Steward

*Waksman Institute, Department of Molecular Biology and Biochemistry, and
Cancer Institute of New Jersey, Rutgers University,
Piscataway, New Jersey*

The Toll-Dorsal Pathway

The Toll-Dorsal pathway functions in *Drosophila* in the establishment of dorsal-ventral polarity in the early embryo. The same pathway also controls the innate humoral and cellular immune response in larvae and adults and, besides Dorsal, involves an additional NF- κ B/Rel protein, Dif. The NF- κ B/Rel pathway is conserved in flies and vertebrates. In mammals it functions in the immune and inflammatory responses, and it is critical for cell growth and survival. Moreover a large number of mammalian tumors are associated with misregulation of the NF- κ B/Rel proteins. Dorsal, like all Rel proteins, is retained in an inactive state in the cytoplasm through direct interaction with a I κ B protein, Cactus. The ventral signal, transmitted through the transmembrane receptor Toll, destabilizes Cactus and controls the formation of a ventral-to-dorsal nuclear Dorsal gradient that, through the specific activation of zygotic genes, results in the formation of the dorsal-ventral axis.

Maturation of the Toll Ligand

Dorsal-ventral asymmetry is set-up in the egg chamber midway through oogenesis and is controlled mainly by EGF signaling [1]. This asymmetry is transmitted to the embryo through the interaction of two groups of genes. One group is expressed specifically on the ventral side of the follicle cells

that surround the oocyte and secrete the egg-membranes. The other group is expressed in the oocyte and their products are secreted into the perivitelline space, between the egg or early embryo and the egg membranes. The interaction of the proteins encoded by the two groups of genes culminates in the maturation and cleavage of the ligand, Spätzle, which activates the Toll-Dorsal signaling pathway.

Spätzle is thought to diffuse and form a gradient in the perivitelline fluid. The extent of the Spätzle gradient is controlled by the upstream genes expressed in the ventral follicle cells and is refined by Spätzle autoregulation [2]. The Toll trans-membrane receptor is uniformly distributed in the plasma membrane of the early embryo and is asymmetrically activated by Spätzle.

Toll Signaling Establishes the Embryonic Dorsal Gradient

In early embryos Dorsal is uniformly retained in the cytoplasm bound to its inhibitor I κ B protein, Cactus. The graded activation of the Toll receptor induces the nuclear translocation of the NF- κ B-Rel homolog Dorsal in a gradient in the early embryo (Fig. 1A). The highest level of protein is present in the ventral nuclei and the concentration decreases laterally until on the dorsal side no Dorsal protein is present in the nuclei. The Dorsal gradient represents the first step in setting up the ultimate fate of each cell along the axis.

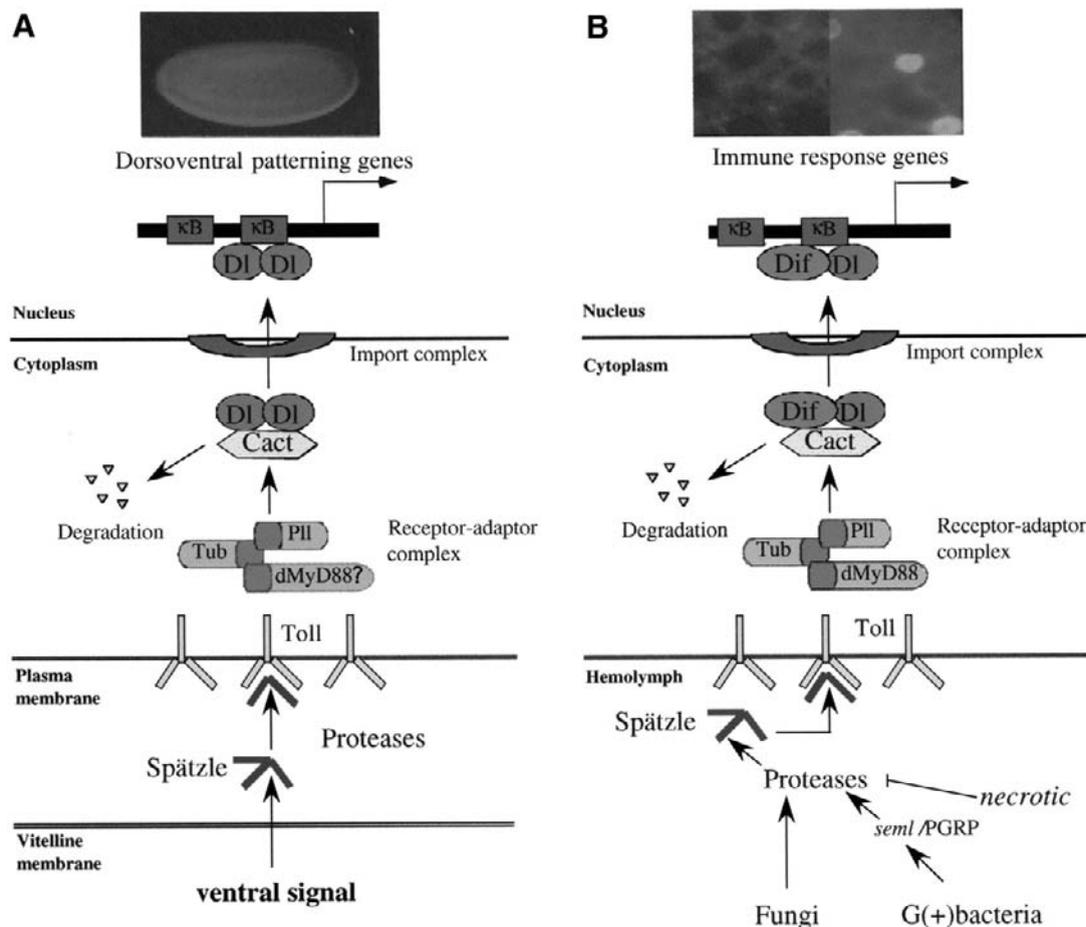

Figure 1 The Toll-Rel pathway in the early embryo and in immune response. (A) The top panel shows a blastoderm stage embryo, anterior to the left and dorsal side up, exhibiting a Dorsal-GFP gradient. Next, the steps in the Toll-Dorsal pathway occurring in the early embryo are depicted. Tub = Tube, PII = Pelle, Cact = Cactus, DI = Dorsal, KB = κ B binding sites in DNA. (B) The top panel shows Dorsal-GFP in unchallenged (left) and bacterially challenged (right) larval fat body. Next, the steps in the Toll-Rel pathway occurring in the immune response are depicted. Dif = Dorsal-related immunity actor.

Cells with high levels of Dorsal protein will become mesoderm, while cells with no Dorsal protein will form the dorsal hypoderm, with ventral and lateral fates in-between.

The products of the *tube* and *pelle* genes relay the signal from Toll to the cytoplasmic Dorsal-Cactus complex. The Tube encodes a novel adaptor protein while Pelle functions as a serine-threonine kinase. Genetic and biochemical experiments suggest that the transmission of the Toll signal to the Dorsal-Cactus complex is mediated through the formation of a multimeric complex involving Tube, Pelle, Dorsal, Cactus, and possibly additional proteins [3]. Toll signaling results in the phosphorylation of Cactus and targets it for degradation. The same signal also controls Dorsal phosphorylation, essential for the high levels of nuclear protein and the establishment of the gradient [4]. The kinases involved in these phosphorylation events are not known.

In addition to the Toll-mediated degradation of Cactus, there is a signal-independent mechanism for degrading Cactus that also influences the Dorsal nuclear gradient. This degradation is probably controlled by an additional signaling pathway involving the maternally supplied TGF β protein, Dpp [5]).

Dorsal Regulates the Function of Zygotic Genes

The Dorsal gradient subdivides the embryonic axis into distinct domains by setting the expression limits of key zygotic genes that are responsible for initiating the differentiation of various tissues. Dorsal interacts directly with κ B binding sites and activates promoters of different genes. In the same cells it also functions as a repressor by recruiting co-repressors. The control of expression of genes in specific domains along the dorsal-ventral axis is controlled by the levels of Dorsal protein and the number and affinity of Dorsal binding sites in the target promoters [6].

The Intracellular Pathway Is Conserved in the *Drosophila* Immune Response

Fungal or gram-positive bacterial infections elicit a specific response in both adults and larvae that involves Spätzle, Toll, and the intracellular components of the pathway (Fig. 1B) [7].

Gram-positive and gram-negative bacterial infections are sensed by distinct pattern recognition proteins called peptidoglycan recognition proteins (PGRPs). PGRPs are highly conserved in organisms from insects to mammals. In the Toll-mediated immune response pathway Spätzle activation is under the control of a different set of genes than in the early embryo. The interaction between the microorganism and the PGRP is likely to occur in the circulating hemolymph and triggers a serine protease inhibitor (serpin)-controlled proteolytic cascade to activate Spätzle. Once activated, Toll interacts with death domain proteins: DmMyd88 and Tube, two adaptor proteins, and the kinase Pelle. This receptor adaptor complex relays the signal to the Cactus-Rel protein (Dif and/or Dorsal) complex. Dif is the predominant transactivator in the antifungal and anti-gram-positive bacterial infection. Dorsal acts redundantly with Dif in larvae but has no function in the adult immune response. Dif and Dorsal control the transcription of the antimicrobial peptide genes Drosomycin and Metchnikowin. In addition, a compound Rel protein, Relish, with an N-terminal Rel homology domain and a C-terminal I κ B-like domain, is crucial for the response to gram-negative bacterial infection. While it is also inactive in the cytoplasm and translocated to the nucleus upon signaling, this signal is not transmitted through Toll.

Nuclear Import of Rel Proteins

Although the nuclear import of Rel proteins is a key step in the formation of the nuclear gradient and in the immune response, little is known about the factors involved. Proteins destined for nuclear import containing a nuclear localization sequence (NLS) are transported through nuclear pore complexes (NPCs) in a multistep process [8]. The NLS of Dorsal is essential and sufficient for nuclear import [9] and in conjunction with the signal-dependent phosphorylation of Dorsal it could provide a substrate for a specific import in α/β , which has not been identified thus far. Some of the nuclear pore proteins (Nups) forming the NPC have been shown to interact with importins. Mutant analysis has shown that both Nup88 or *mbo* and nuclear transport factor-2 (NTF-2) are involved in the import of the Rel proteins.

NTF-2 is an essential gene in yeast, *Caenorhabditis elegans*, and *Drosophila*. Dorsal, NTF-2, and Nup88 form a complex necessary for nuclear import [10,11]. The NLS in the NF- κ B/Rel proteins and the proteins identified thus far as important for nuclear import in *Drosophila* are all highly conserved. It is therefore likely that the same mechanisms are functioning in vertebrates.

The NF- κ B/Rel pathways are some of the best known signaling processes and play central roles in development, immune response, and cancer. Because of their high level of conservation from flies to humans, further study of the Toll-Dorsal (Rel) pathways in flies will continue to complement our understanding of events in vertebrates.

Developmental Signaling: JNK Pathway in *Drosophila* Morphogenesis

Beth E. Stronach¹ and Norbert Perrimon²

¹Department of Biological Sciences, University of Pittsburgh, Pittsburgh, Pennsylvania

²Department of Genetics, Harvard Medical School, Howard Hughes Medical Institute, Boston, Massachusetts

Introduction

For a cell to be able to distinguish and respond appropriately to extracellular signals, intracellular information transfer must be precise and reliable yet versatile. One key mode of signal transduction is the use of sequential phosphorylation events mediated by modules of protein kinases. The mitogen-activated protein kinase (MAPK) cascade is a highly conserved linear module that threads information from the cell surface to the nucleus to modulate transcription factor activity and thus gene expression [1]. Several related but functionally distinct MAPK modules have evolved that transduce a variety of extracellular signals. Genetic and molecular studies in *Drosophila melanogaster* over the last several years have revealed that components of stress signaling MAPK pathways, namely the Jun NH2-terminal kinase (JNK) and p38 kinase signaling modules, are functionally conserved and participate in numerous processes during normal development [2].

Loss-of-function genetic studies using *Drosophila* have identified the JNK signal transduction cascade as one of the key modulators of morphogenetic events. The *Drosophila* model system is providing a number of new insights into the general organization of the JNK pathway, the identification of new components and their epistatic relationships, and the various biological roles of the signaling activity. In the context of normal development, JNK signaling has been linked to the movement and fusion of epidermal cell sheets during

dorsal and thorax closure, and to the formation of epithelial tubes during oogenesis [3]. Besides the use of JNK signaling for developmental events, accumulating evidence suggests that activation of the JNK pathway can be induced by stress and injury, as it is in mammalian systems.

The Paradigm of JNK Signaling: Dorsal Closure

In a process that has been compared to mammalian wound healing, dorsal closure of the fly embryo occurs when hundreds of ectodermal cells undergo coordinated cell elongation and movement to close over the dorsal side of the embryo. [4]. The opening is covered initially by a squamous epithelial tissue called the amnioserosa. Coverage of the area occupied by the amnioserosa is achieved by contraction of amnioserosa cells concomitant with dramatic cell elongation within the ectoderm [5,6]. Upon completion of dorsal closure, the opposing ectodermal epithelia meet and fuse at the dorsal midline; this fusion serves to internalize the amnioserosa and to surround the embryo in a continuous protective epidermis [7].

JNK signaling is precisely regulated throughout dorsal closure. Prior to initiation of closure, JNK signaling is transiently active in a broad dorsal domain; this activity requires the product of the *u-shaped* (*ush*) gene, a protein related to mammalian FOG (friend of GATA), which appears to be permissive for JNK activation [8–10]. JNK signaling then

becomes restricted to the ectoderm by the negative action of *hnt*, which downregulates JNK signaling specifically in the amnioserosa [8,9]. Thus, although the nature of the signal that activates the JNK pathway is still unknown, expression of transcriptional targets of the pathway reveal a spatial refinement of activation, by the start of dorsal closure, to the leading row of migrating cells at the epithelial front. There, JNK pathway activation mediates changes in gene expression, accumulation of a contractile band of actin and myosin, and movement of the epidermis toward the dorsal midline [5,11–13]. Loss of or failure to activate JNK signaling results in defective cell shape changes, failed closure, and lethality [14].

Figure 1 shows a current model of JNK signaling in dorsal closure. One of the molecules that is thought to be activated early in the JNK pathway is the small GTPase, Rac1 [15]. Genetic epistasis studies in the fly are consistent with the proposed biochemical mechanism: Rac1, together with a JNKKKK, *msn*, activates the JNKKK *slpr*, a mixed lineage kinase, through direct interaction with the Rac-binding CRIB domain [16–19]. MLK catalytic activity is stimulated, which by analogy, leads to phosphorylation of Hep (JNKK) and then Bsk (JNK) [19–22]. JNK substrates include, but are not limited to, dJun, a component of the jun/fos AP-1 transcription factor [23]. As a result of AP-1 activation, transcriptional targets of JNK signaling are expressed.

Among those targets are Dpp, a secreted morphogen related to the BMP/TGF β family of signaling molecules, and Puc, a dual specificity phosphatase that provides crucial negative feedback regulation of JNK signaling via dephosphorylation of the JNK, Bsk [12,13,15,24,25]. The precise role of *dpp* expressed in leading cells is not well understood; however, Dpp signaling may control the speed and direction of leading edge cell motility through the GTPase, Cdc42 [3,26].

Given that loss-of-function mutations in any of the component kinases leads to a loss of target gene expression and a failure of dorsal closure, it has been suggested that JNK signaling regulates differentiation and function of the leading cells in which it is activated [9,27]. The special properties of these leading cells, where JNK signaling is highest, are essential for the cell biological mechanics that underlie the morphogenetic movements of dorsal closure. These properties include: (1) the assembly of a contractile actomyosin cable that provides tension for the epithelial front as it moves forward, (2) assembly of focal complexes presumed to regulate adhesion and possibly signal transduction, and (3) protrusion of actin-rich filopodia that may sense the correct segmental position of the approaching contralateral epithelium [5–8].

Until recently, it was not clear if the cytoskeletal changes observed in the leading ectoderm were controlled by JNK signaling directly or through a transcriptional mechanism.

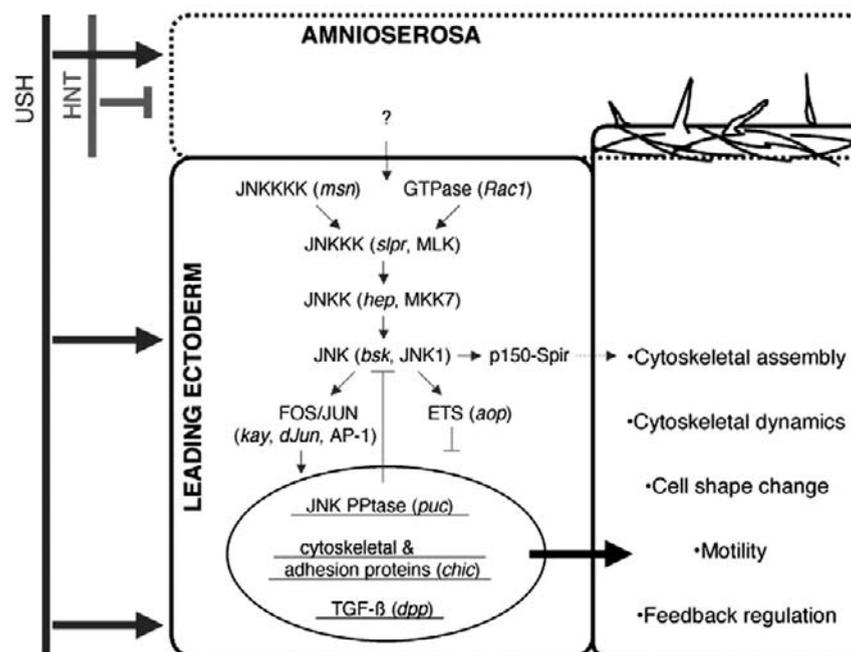

Figure 1 A model of JNK signaling during tissue morphogenesis in *Drosophila*. Prior to dorsal closure, JNK signaling is active in both the amnioserosa and the dorsal ectoderm, requiring the function of U-shaped (Ush), related to mammalian Friend of GATA (FOG) proteins. Hindsight (Hnt), a nuclear Zn-finger protein, participates in restricting JNK signaling to the leading cells of the ectoderm by repressing signaling specifically in the amnioserosa. In the leading ectoderm, JNK signaling is mediated by a kinase cascade, which results in activation of the FOS/JUN (AP-1) transcription factor and regulation of gene expression. The effectors of JNK signaling (both direct and via transcription) execute functions critical for tissue morphogenesis including cytoskeletal deployment and modulation, i.e., assembly of a contractile actomyosin network and extension of cell protrusions.

The expression of the Dpp morphogen in leading cells led to the speculation that Dpp signaling could mediate the majority of the downstream cellular events [13]. Transcript analysis by the serial analysis of gene expression (SAGE) method in embryos with either constitutive-active or blocked JNK signaling has provided compelling evidence that coordinated regulation of many genes encoding actin-binding proteins and cell adhesion molecules is essential for the execution of dorsal closure [28]. These data show that cytoskeletal reorganization driving morphogenetic movements can be mediated through JNK-dependent changes in gene expression. In addition though, biochemical methodology revealed a direct interaction between activated JNK and p150-Spir, a protein that contains an actin-binding motif with similarity to known cytoskeletal regulators of the WASP/WAVE family [29]. Thus, in some cases, the ability of JNK signaling to regulate cell shape change and motility may be direct, without a requirement for changes in transcription.

Thorax Closure

Adult tissues of the fly are generated from precursor cells (called imaginal cells or imaginal discs) that are set aside during embryogenesis and undergo proliferation and eventual large-scale morphogenetic movements during metamorphosis. Genetic analysis of semilethal *hep* (JNKK) and *kay* (dFos) zygotic mutant animals revealed an important role for JNK signaling in the spreading and fusion of sets of matched, laterally-positioned disks as they come together to meet dorsally [30,31]. In a scenario that parallels embryonic dorsal closure, Hep and dFos regulate Puc phosphatase expression in cells that adopt a position at the leading margin of the spreading discs. Ectopic *puc* expression, induced under conditions where imaginal cells are programmed to express an activated form of the Cdc42 GTPase, is also *hep*-dependent, suggesting that in this system Cdc42 may be the relevant upstream activator during disc morphogenesis [30]. In contrast to dorsal closure, *dpp* is not under transcriptional control by the JNK pathway, even though *dpp* and *puc* are co-expressed in a subset of disc cells, notably those at the leading margin [30,31].

Follicle Cell Morphogenesis

The somatic follicle cells that surround the germline consist of several distinct populations that, over the course of oogenesis, take on characteristic morphologies and migration patterns. The JNK signaling pathway has been implicated, through genetic mosaic analysis, in regulating a late-stage morphogenetic process whereby the respiratory appendages of the eggshell are built up from two populations of dorsal anterior follicle cells [32–34]. Dorsal appendage morphogenesis is impaired when mutant cell clones of *slpr*, *hep*, or *bsk* are induced prior to the convergence of the appendage primordia [34] (B. E. Stronach, unpublished). Short, thin

appendages result from a failure of the clustered pre-appendage cells to fully elongate. Overexpression of the negative JNK regulator, Puc phosphatase, phenocopies the JNK loss-of-function effect on dorsal appendage outgrowth [34]. Together, these data suggest a model similar to that for the role of JNK signaling in dorsal closure; in both processes maintenance of the levels of JNK activity are critical to achieve and maintain proper epithelial cell shape change and migration [33]. Like thorax closure, but in contrast to dorsal closure, *dpp* is not under transcriptional control by Jun in follicle cells. During oogenesis Dpp does not appear to mediate the late morphogenetic events of dorsal appendage formation; in fact, Dpp acts before JNK signaling to regulate the A/P position of the appendage primordia [34].

A New Paradigm: Planar Cell Polarity

Epithelial planar polarity refers to the uniform orientation of cells or cell groups within the plane of an epithelium, observable in the adult fly as oriented bristles on the thorax, hairs on the wings, and facets of the compound eye [35]. Mutations in genes required for the development of planar polarity, such as the *frizzled* (*fz*) receptor, result in random orientation of bristles, hairs, or ommatidia [36]. Genetic mosaics and dominant interaction studies have uncovered the backbone of a signaling pathway required for establishment of planar polarity; this pathway shares several components with, yet is distinct from, the canonical Wg/Wnt pathway [37,38]. The emerging model places the JNK cascade downstream of Fz1 receptor activation. JNK activity is thought to be stimulated through a pathway that includes Disheveled (Dsh), a PDZ-containing adaptor molecule, Misshapen (Msn), related to the yeast Ste20 kinase, and the RhoA GTPase [3,35]. This linkage of Fz/Dsh signaling to JNK activation is also being investigated as a general mechanism underlying convergent extension in vertebrate embryos [39,40].

Cellular Stress Response and Wound Healing

To date, genetic analysis of the JNK pathway in *Drosophila* has revealed developmental requirements throughout the life cycle of the fly from embryogenesis to metamorphosis. Given the widespread use of the JNK signaling pathway in mammals in response to environmental and systemic stresses, such as an inflammatory response, it is important to ask if the *Drosophila* JNK pathway is similarly inducible by stress or injury. It has been suggested that the mechanics of dorsal closure movements resemble, to a large extent, the process of tissue repair during mammalian wound healing [30,41,42]. Recent investigations have probed the requirement for JNK pathway proteins during the response of flies to wounding or the response of fly cells to toxic stresses [43–45]. These studies reveal that *puc*, a transcriptional marker for activation of the JNK pathway, becomes upregulated at the site of tissue injury in the adult

fly in a *Dfos*-dependent manner [44]. Moreover, the temporal pattern of *puc* expression is correlated with cell shape changes and movement of the wound margins to close the injury. In contrast to the noted requirement for Dpp in many of the processes that require JNK, adult tissue wounds do not appear to induce *dpp* marker expression, suggesting a Dpp-independent mechanism of healing. Whether one of the other TGF β -related ligands is upregulated upon injury remains an open question. The JNK-activating signal resulting from injury also remains elusive. Although the molecular identities of JNK-activating signals for numerous JNK-dependent processes are largely unknown, there must be a variety of developmental, inducible, and environmental signals, since markers of JNK signaling activity can be observed under various conditions, e.g., tissue closure, injury, infection, and chemical stress. Future work aims at identifying the relevant signals.

Perspectives

Most of what we have learned from studying JNK signaling in *Drosophila* comes from the dorsal closure paradigm. Further studies on the function of the pathway in other processes (polarity, stress signaling, immunity) are likely to reveal different routes of JNK activation and insights on signaling. Characterization of JNK signaling in various morphogenetic processes throughout development reveals several common themes. Cumulative evidence supports the notion that JNK signaling can modulate cytoskeletal organization and cell adhesion [46]. This would provide a basis to explain the observation that JNK signaling promotes the differentiation of margin cells to establish a boundary between columnar and squamous epithelia or to define the properties of a “free” motile edge [30]. Cooperation between the JNK pathway and the Dpp pathway is a predominant, but not obligate, theme in various morphogenetic events of *Drosophila* epithelia. The role of Dpp, whether or not its expression is transcriptionally coupled with JNK activity, seems to be involved in modulating the dynamic nature of cytoskeletal assemblages beneath the cell surface and in cell projections [46]. The uncoupling of JNK signaling and *dpp* expression in several instances, however, raises the interesting possibility that there may be tissue-specific regulators that act in combination with JNK-inducible factors to specify unique morphogenetic outcomes in a tissue- or context-dependent manner.

Wnt Signaling in Development

Christian Wehrle, Heiko Lickert, and Rolf Kemler

*Department of Molecular Embryology,
Max-Planck Institute of Immunobiology,
Freiburg, Germany*

Introduction

Development is controlled by an interplay of many signaling molecules. Among these, Wnt proteins comprise a large family of secreted proteins with key roles in intercellular signaling throughout the animal kingdom. This chapter is dedicated to reviewing present knowledge about Wnt signaling in invertebrate and vertebrate development, beginning with a brief overview of the components of the Wnt signaling pathway. More details about this signaling cascade can be obtained from the Wnt homepage (www.stanford.edu/~rnusse/) and the references therein. Wnt genes were discovered from two different areas of research. In 1982, Nusse and Varmus [1] identified a proto-oncogene, called *Int-1*, by mouse mammary tumor virus integration into it in mammary tumors. The molecular cloning of the *Drosophila* segment polarity gene *wingless* (*wg*) revealed that *Int-1* and *wg* are orthologs [2], and both terms (W+nt) were combined in a common nomenclature of Wnt genes. By now, roughly 100 Wnt genes have been isolated in different species ranging from hydra to man. Information collected from genetic analysis in *Drosophila* and *Caenorhabditis elegans*, cell and molecular studies in mammalian cells, and functional overexpression experiments in *Xenopus*, as well as loss-of-function analysis in mice, has provided a detailed picture about the molecular components which transduce Wnt signals. In general, there is a high complexity of positive and negative regulation of Wnt signal transduction in each cellular compartment. At the cell membrane, binding of Wnts to their cognate receptors, Frizzled (Fz) proteins, is modulated by co-receptors or inhibitors. In the cytoplasm, Wnt signals can diverge into different molecular cascades, e.g., the best known canonical Wnt/ β -catenin pathway, the planar polarity pathway, and the

Wnt/ Ca^{2+} pathway. The canonical Wnt/ β -catenin signaling pathway provides by far the most comprehensive picture of Wnt signaling. Here the central component is β -catenin, which upon Wnt signaling enters the nucleus and functions as a transcriptional co-activator with members of the TCF/LEF-1 family of transcription factors. Wnt signaling results in the activation of specific target genes, which again involves an interplay of repressors (groucho, Sox) and activators (p300, TBP) and the coordinated action of other signaling pathways, e.g., TGF β signaling (regulation of *Twin* in *Xenopus*), or retinoic acid receptor stimulation (regulation of *cdx1* in mouse). The activation of Wnt/ β -catenin target genes controls cell proliferation and cell fate decisions and regulates various morphogenetic events during the development of various organisms.

Wnt Signaling in Invertebrate Development

The *Drosophila* *wg* gene was discovered in the classical genetic screen for zygotic lethal mutations affecting the larval cuticle pattern [3]. Genome sequencing revealed a total of seven *wg* genes in the genome. The *wg* gene belongs to the class of segment polarity genes, which mediate intercellular interactions regulating parasegmental periodicity and cell fates in the larval cuticle [4]. Additionally, the adult appendages—legs and wings—are formed from sheets of epithelial cells in imaginal discs in which the dorsal-ventral (DV) and anterior-posterior (AP) axes are defined as the disc grows during larval development [5,6]. The AP and DV patterning of the imaginal discs is directed through organizing centers and morphogen gradients of the secreted signaling proteins Wingless, Hedgehog, and Decapentaplegic (reviewed in [7]).

Studies in *C. elegans* have shown that Wnt signaling acts very early in nematode development (at the four-cell stage) to induce endoderm formation. This is brought about by relieving transcriptional repression and partially by aligning the mitotic spindle in a responding cell along the AP body axis [reviewed in 8]. The outcome is the polarization of the bipotential precursor cell (EMS) producing one daughter that makes endoderm and one for mesoderm [9,10]. In the absence of the polarizing Wnt signal both daughters form mesoderm, a phenotype represented by seven different mutants, *mom-1-5* (for more mesoderm), *lit-1* (for loss of intestine), and *pop-1* (for posterior pharynx-defective). Cloning and sequencing of these genes revealed that they code for components of the Wnt signaling cascade [reviewed in 8]. There are 5 Wnt genes in *Caenorhabditis elegans*. In the invertebrate phylogenetic tree components of the Wnt pathway have been described in the diploblastic Cnidaria (e.g., Hydra) [11], and even in the slime mold *Dictyostelium* homologs to β -catenin (Aardvark) and GSK3 β have been found (reviewed in [12]).

Wnt Signaling in Vertebrate Development

Our knowledge about the Wnt signaling cascade in vertebrate development began with pioneer work in *Xenopus laevis*. Injection of Wnt1 mRNA into ventral blastomeres of early *Xenopus* embryos led to duplication of the body axis, and this was subsequently used as a read-out to explore the details of this signaling cascade [13]. The siamese twin tadpoles obtained after ventral injection of mRNA for Wnt/ β -catenin pathway members were strongly reminiscent of the experimental animals Hans Spemann and Hilde Mangold [14] had produced by transplanting the dorsal blastopore lip to the ventral side of a host newt embryo. It became apparent that the Spemann-Mangold organizer, which when transplanted had this remarkable ability to induce a secondary body axis, is induced by target genes of the Wnt/ β -catenin signaling cascade (reviewed in [15]). This underlines the importance of the Wnt/ β -catenin signaling cascade in the induction of the primary body axis. The endogenous Wnt molecule inducing the primary body axis is still not identified, but at least 16 Wnt genes have been described in *Xenopus*. Also in chicken and zebra fish the Wnt genes apparently have similar activities during early development, with 11 and 12 identified genes, respectively.

Conventional and conditional gene knockouts in the mouse have demonstrated the important function of the Wnt/ β -catenin signaling cascade in higher vertebrate development in inducing the primary body axis and directing cell fate. Both Wnt3 and β -catenin have been functionally inactivated, leading to the arrest of the mutant embryos in gastrulation due to the inability to form a primitive streak and hence mesoderm and endoderm. Evidence that the Wnt/ β -catenin signaling pathway is directly involved in Spemann-Mangold organizer formation in the mouse, here called the node, came from both gain- and loss-of-function

experiments [16,17]. More recently, conditional gene inactivation of β -catenin supported the existence of a bipotential mesendodermal precursor cell in the mouse embryo similar to the EMS cell in *C. elegans* embryos [18]. In addition to these Wnt functions in early development, knock-out studies of different Wnt family members have revealed their involvement in organ formation, mid- and hindbrain patterning, and limb development [19–23]. Genome sequences from mouse and human revealed a total of 19 Wnt genes in each species.

Wnt/ β -Catenin Target Genes

Based on the mechanisms that lead to gene activation, one can distinguish between direct and indirect target genes. Direct target genes are defined as genes with TCF/LEF-1 binding motifs in the gene regulatory regions, where the functional importance of these motifs in β -catenin-mediated gene activation has been demonstrated. The transcriptional activation of such direct target genes does not require *de novo* protein synthesis. In contrast, indirect target genes are not regulated by TCF/ β -catenin complexes, and their activation depends on other factors and requires *de novo* protein synthesis.

Because the unphysiological activation of the Wnt/ β -catenin pathway leads to tumor formation, much effort has been made to identify target genes of this pathway in tumorigenesis (reviewed in [24]). Expression profile analysis of cells with an activated Wnt/ β -catenin pathway led to identifying direct target genes involved in cell cycle control, e.g., c-Myc [25], Cyclin D1 [26,27], transcription factors including Tcf-1 [28], c-jun and fra-1 [29], or cell surface components such as claudin-1 [30] and MMP-7 [31,32].

The first Wnt/ β -catenin developmental target genes were identified via a candidate gene approach correlating gene expression temporally spatially with the known action of Wnt/ β -catenin in morphogenetic processes. The *Xenopus* genes *siamois* and *Xnr3*, originally cloned in expression screens for dorsalizing genes, turned out to be direct target genes of the Wnt/ β -catenin pathway [33–36]. Direct transcriptional regulation was also reported for *X. fibronectin* [37], *connexin43* [38], *twin* [39], and *engrailed-2* [40]. Developmental mutants proved very helpful in identifying direct Wnt/ β -catenin target genes, e.g., *nacre* [41] and *bozozok* [42], in zebra fish or *Dpp* [43] and *Ubx* [44] in *Drosophila*. Although valuable, this candidate gene approach has obvious limitations, making a broader search for developmentally regulated target genes desirable.

In this respect the use of ES cells represents an interesting alternative [45]. It was shown that mouse ES cells express all the necessary components to respond to a Wnt signal. Hence, by seeding ES cells on a feeder layer of NIH3T3 fibroblasts expressing different Wnts, it was possible to screen for expression of Wnt/ β -catenin target genes (Fig. 1). *T-brachyury* [45] and *Cdx1* [46] are examples of genes found to be directly regulated by the Wnt/ β -catenin signaling

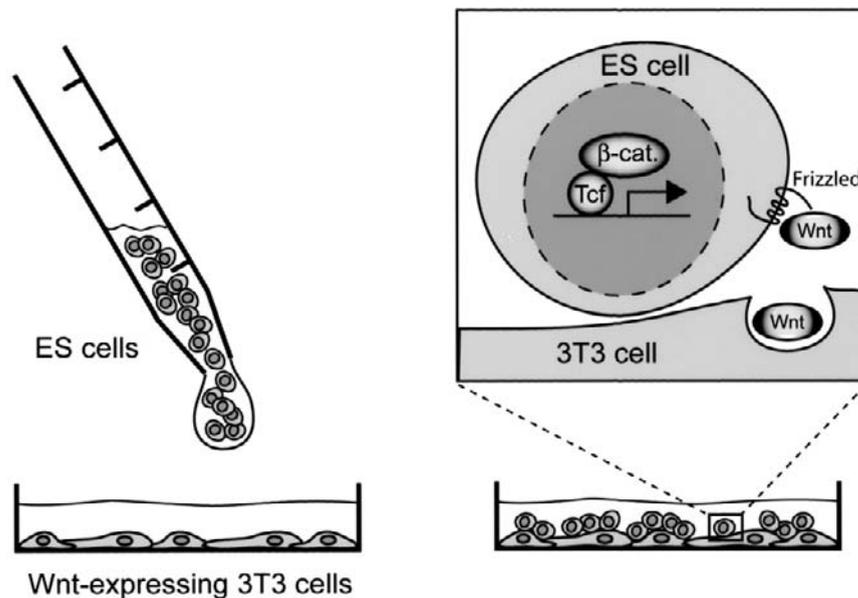

Figure 1 Scheme of the ES cell co-culture system suitable to search for Wnt/ β -catenin target genes. (Adapted from Arnold, S. J. *et al.*, *Mech. Dev.*, **91**, 249–258, (2000). With permission.) ES cells expressing a Wnt/ β -catenin reporter gene (gfp driven by TCF-binding motifs) are seeded on 3T3 cells expressing various Wnts. ES cells receiving a Wnt signal as monitored by gfp expression can be separated and analyzed for Wnt/ β -catenin target gene expression.

pathway, using this ES cell co-culture system. The T-box gene *T-brachyury* codes for a transcription factor involved in mesoderm formation [47–49]. *Cdx1* is a homeodomain-containing transcription factor with important roles in anterior-posterior patterning [50] and likely in intestinal development [46,51]. The ES cell co-culture system in combination with microarray analysis should allow screening systematically for a large number of potential Wnt/ β -catenin target gene candidates.

In conclusion, the Wnt/ β -catenin signaling pathway is evolutionarily highly conserved on a biochemical level and regulates many morphogenetic processes during development. From the direct target genes found thus far, it is apparent that this pathway regulates gene expression of a large variety of cellular components, i.e., transcription factors, cytoplasmic and cell surface molecules, and growth factors.

South San Francisco, California

The Hedgehog Proteins: Generation and Distribution

The hedgehog mutation was originally identified in a *Drosophila* genetic screen as one of the segment-polarity genes important in fly development [1]. Cloning of the hedgehog gene (*hh*) revealed a secreted peptide whose expression is confined to Engrailed expressing cells and is dependent upon Wingless expression. It is now clear that Hh plays a vital role in the development of multiple organ systems in the fly and vertebrates [2]. In mammals there are three Hh proteins named Sonic Hh (Shh), Desert Hh (Dhh), and Indian Hh (Ihh). Dhh appears to be most closely related to *Drosophila* Hh, while Shh and Ihh are more closely related to one another. Production and diffusion of these factors in different tissues determines proper development of multiple organ systems.

Hh proteins are synthesized as precursor proteins of about 45 kDa. The C-terminal portion of the Hh precursor has autoproteolytic activity and cleaves Hh into a C-terminal peptide of about 25 kDa with no known function and an N-terminal fragment (Hh-N), which constitutes the biologically active portion of Hh [3]. During autoprocessing, a cholesterol moiety is coupled to the C-terminus of Hh-N, a form which is further denoted Hh-Np [4]. It is thought that the addition of cholesterol helps to retain Hh-Np to cell membranes, thus limiting the range of action of Hh activity. However, in mice engineered to express a form of Shh lacking cholesterol modification (N-Shh), short-range Hh signaling was maintained while long-range signaling was defective, resulting in loss of digits and proper patterning in the developing limb and suggesting differential requirements for cholesterol in Hh signaling [5]. Additional proteins involved in

the secretion and diffusion of cholesterol-modified forms of Hh have been identified, such as Dispatched (Disp), which is required for release of Hh-Np from Hh-producing cells, and Tout velu (TTV), which is involved in the biosynthesis of a putative Hh-interacting proteoglycan [6–8].

Hh proteins are further modified by palmitoylation on a highly conserved N-terminal cysteine residue [9]. Mutation of the *sightless/skinny Hh (sig/ski)* gene, encoding a transmembrane (TM) acyl transferase, abrogates palmitoylation of Hh-N and results in an Hh-like phenotype, indicating that palmitoylation of Hh is required for some aspect of Hh function [10,11]. In some systems both modified and unmodified forms of Hh show equivalence, indicating that the importance of fatty acid modification may be context dependent [9,12]. Together these data indicate that the biological activity of the Hh proteins is finely tuned through posttranslational modification, affecting its activity and capacity to diffuse.

Transmitting the Hh Signal

Both *Drosophila* and mouse genetics indicate that the transmembrane protein, Smoothed (Smo), is required to transmit the Hh signal [13–15], and another TM protein, Patched (Ptc), negatively regulates Smo in the absence of Hh [16,17]. While it is widely accepted that Hh binds to Ptc [18,19], it is not clear how Hh binding results in downstream Smo activation and signal transduction.

In the conventional model, Ptc binds directly to Smo and represses its activity (Fig. 1A). Upon Hh binding the normal inhibition by Ptc is released and Smo initiates signaling (Fig. 1B). However, recent studies in *Drosophila* have

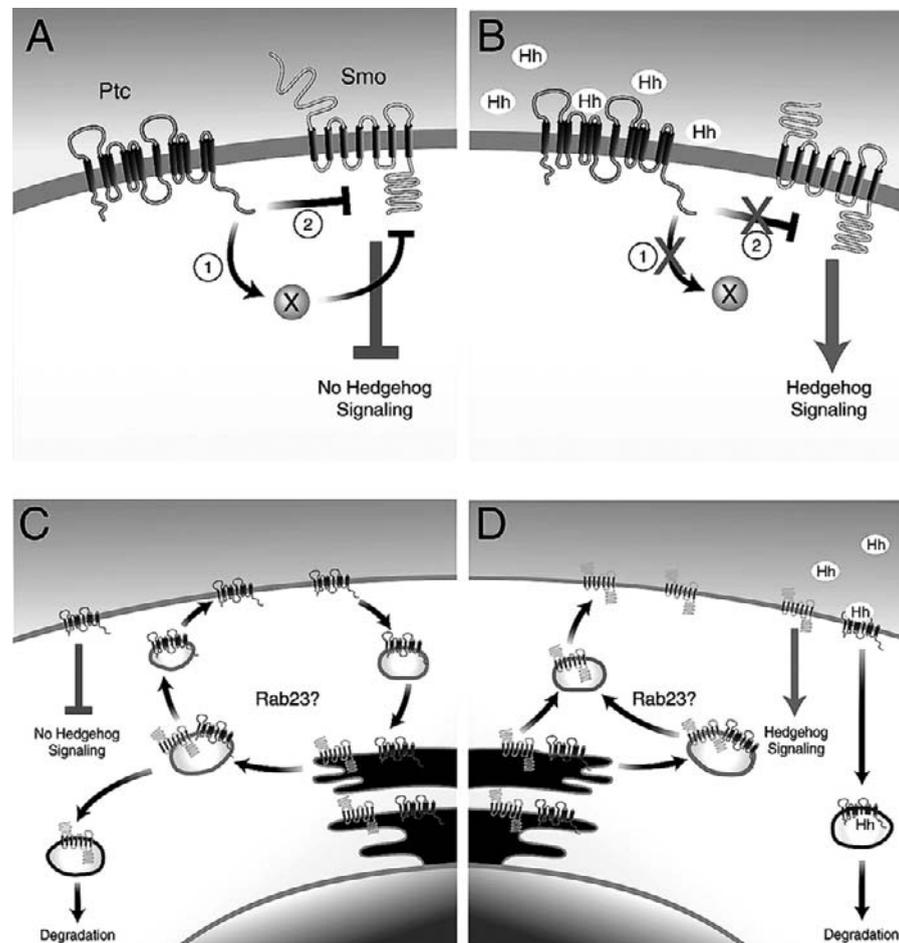

Figure 1 Two models for transmitting the Hh signal through Patched and Smoothed. (A) In the conventional model Patched (Ptc; red) inhibits Smoothed (Smo; green) function through (1) direct inhibition of Smo function or (2) an indirect effect, where Ptc acts upon an unknown factor (X) that subsequently inhibits Smo activity. (B) Upon Hedgehog (Hh; yellow) stimulation, the repressive function of Ptc is abrogated allowing for activation of Smo and transmission of the Hh signal to downstream targets. (C) In a more unconventional model, Ptc (red) acts to repress Smo vesicular trafficking. In the absence of Hh, Ptc and Smo are generated in the endoplasmic reticulum (ER) and are processed through the Golgi. Ptc traffics to and from the cell surface, while Smo may traffic to an unknown subcellular compartment, possibly resulting in Smo degradation, ultimately resulting in a lack of Hh signaling. Rab23 may act to coordinate some aspect of Ptc or Smo trafficking. (D) Upon Hh signaling, Ptc binds to Hh stimulation, the Ptc-Hh complex is internalized via endocytosis resulting in the degradation of Ptc. This allows for the transportation of Smo to the cell surface where it can mediate Hh signaling.

suggested that Ptc may not repress Smo activity through a direct interaction, but rather that Ptc inhibits Smo activity from a distance [20–24]. For example, regulation of Smo activity may occur through control of vesicular trafficking by Ptc. SCAP, a protein involved in cholesterol metabolism and trafficking, regulates the activity of SREBP by controlling its movement between the endoplasmic reticulum (ER) and Golgi via a mechanism involving use of a SSD in SCAP [25,26]. Ptc may regulate the activity of its cargo, Smo, in a similar fashion (Fig. 1C and D). Mutation within the Ptc SSD results in the abrogation of Ptc-mediated inhibition of Smo activity [27,28]. Further support for the regulation of Smo transport has come from the *open brain* (*opb*) mutation in the mouse, recently identified as the *Rab23* gene [29], a GTP-activating

protein involved in vesiculotubular transport. A model involving the negative regulation of Smo movement to the cell surface by Rab23 has been hypothesized, however, it is also possible that Rab23 aids in the proper localization and function of Ptc.

The main target of Hh activity is a family of zinc finger transcription factors known as cubitus interruptus (Ci) in the fly and Gli in vertebrates. Gli activity is regulated at multiple levels, including nuclear export, proteasome-mediated degradation, and subcellular localization. In vertebrates there are three Ci orthologs; Gli1, Gli2, and Gli3, which may have retained aspects of Ci-155 and Ci-75 function (reviewed in references [2] and [30]). Knockout or transgenic mice of each Gli isoform have been generated and the

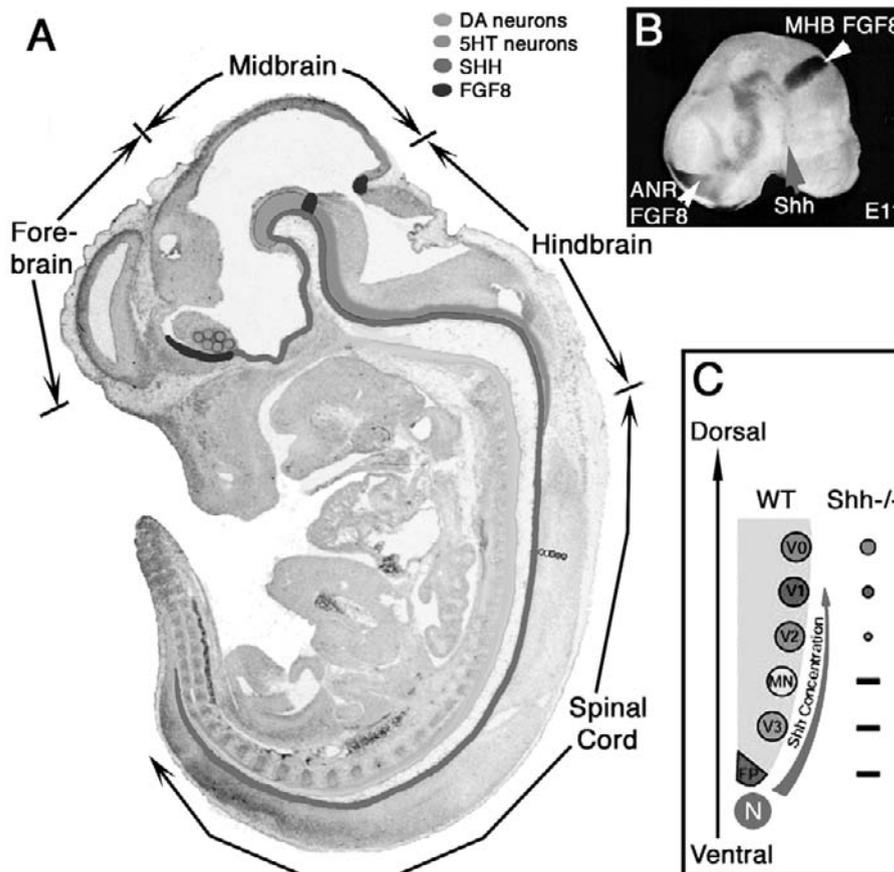

Figure 2 Shh in the developing nervous system and the cell types controlled by SHH. (A) Shh (red), FGF8 (dark blue), dopaminergic (DA) neurons (light blue), serotonergic (5HT) neurons (green), and six ventral spinal cord neurons (colored dots with black circles) are diagramed on a sagittal section of a 12-day-old mouse embryo. Shh in the notocord and floor plate is represented by a single line. (B) Whole mount *in situ* hybridization of Shh (red) and FGF8 (dark blue) in the brain of an 11-day-old embryo. Shh is expressed in the ventral midline (red arrow), FGF8 is expressed in two organizers—the mid-hindbrain junction (MHB) and the anterior neural ridge (ANR) (white arrow heads). (C) The position of six Shh-dependent cell types (color-filled circles) in the ventral spinal cord of wild-type (WT) and Shh mutant embryos (Shh^{-/-}), and their relationship to SHH concentration (red arrow). Different cell types are induced by different threshold concentrations of SHH. Higher concentration of SHH induces cells in progressively more ventral locations. FP = floor plate, N = notochord, MN = motor neuron, and V0, V1, V2, and V3 are four classes of interneurons.

phenotypes observed support the idea that Gli2 and Gli3 are critical for normal development, while Gli1 may be redundant for Gli2 and Gli3 function. The interplay between the activities of these isoforms increases the complexity of vertebrate systems dramatically making it difficult to conclusively delineate all of the functions for the different Gli proteins during normal development (reviewed in reference [2] and in Section III of this book).

Hh in Development and Disease

Studies of the normal functions for the Hhs in animal models have helped in our understanding of Hh-related diseases. Many studies have shown that Shh acts as a morphogen in the nervous system, where it is secreted from the

notochord and later from the floor plate, patterning neurons along the dorsal-ventral axis of the neural tube in a dose-dependent manner [2] (Fig. 2). In the spinal cord and part of the hindbrain, a fine gradient of SHH with two- to three-fold incremental changes from the source (floor plate and notochord) delineates the ventral neural tube into six distinct domains along the dorsal-ventral axis. The expression of a set of homeodomain and bHLH transcription factors is tightly controlled by different SHH protein concentrations, thus generating six intricate combinatorial transcription factor codes in these domains [31,32]. These codes specify the identities of neural progenitors, which ultimately give rise to six cell types, including the floor plate (FP) cells, motor neurons (MN), and four classes of interneurons, V0, V1, V2, V3[33] (Fig. 2A and C). In the Shh^{-/-} mouse embryos, FP cells, MNs, and V3 neurons are missing, and

the numbers of V0, V1, and V2 neurons are greatly reduced [34,35] (Fig. 2C). In the brains of mouse embryos, SHH acts in concert with another organizer molecule FGF8 to create information grids, which serve as spatial cues for the specification of ventral cell types. Ventral neurons such as dopaminergic (DA) neurons and serotonergic (5HT) neurons are specified in locations where Shh and FGF8 intersect (Fig. 2A and B) [36,37]. Earlier patterning events dictate how neural stem cells respond to these organizer signals, so that DA neurons are induced by SHH and FGF8 in the fore- and mid-brain, whereas 5HT neurons are induced by the same set of signals in the hindbrain, because the hindbrain progenitors have been prepatterned by another signal(s) from the posterior [36]. Shh controls cell fates not only by induction, but also by repression. It is found that SHH in the forebrain is required to repress Pax6 expression, thus resulting in the separation of a single eyefield into two retinal primordia [38,39]. This explains the cyclopic phenotype in the Shh-deficient embryos [34]. Late in development, Shh elicits other cellular responses than cell fate specification. For example, in the fetal cerebella, SHH induces proliferation of granule cells while inhibiting their differentiation [40–42].

Shh also acts to determine anterior-posterior (AP) patterning in the developing skeleton, limb bud, and gut tube [2,30]. Shh has recently been shown to act as an angiogenic factor leading to neovascularization and the proliferation of blood cells [43]. In some tissue types, such as the pancreas, Shh acts both as a positive and negative regulator, as its activity is needed for inhibition of pancreatic anlagen formation, but is also needed for specification of the pancreatic β cells [44,45]. Shh is also involved in the morphology of branching structures such as the lung [46]. The importance of Shh is highlighted by the phenotype of Shh knockout mice, which die at birth due to multiple defects, including cyclopia and holoprosencephaly (HPE), as well as other defects in limbs, brain, spinal cord, axial skeleton, and midline structures [34]. Overlapping roles of Shh and Ihh have been identified in heart development as well as specification of left/right (L/R) asymmetry, as observed in Shh/Ihh double knockout mice and Smo knockout mice [47]. The major impact of Ihh is in radial patterning of the gut as well as bone morphogenesis [48,49]. Loss of Ihh function results in a lack of chondrocyte proliferation and differentiation [49]. Dhh is predominantly involved in peripheral nerve sheath and germ cell development, particularly in the development of the male germline and maturation of the testes [50,51].

The patterning functions of Hh are also highlighted in humans where mutations have clearly been linked to developmental disorders, including spina bifida, neural tube defects, and skeletal deformations. For example, mutations in human Shh result in cyclopia and HPE [52]. Downstream of Hh, mutations within Gli3 are found in Grieg's cephalopolysyndactyly [53] and Pallister-Hall syndrome (PHS) [30,54], disorders associated with various abnormalities including polydactyly.

The first indication that the Hh pathway might be involved in tumor formation stemmed from the observation

that human Ptc (PTCH) gene was mutated in individuals with Gorlin's syndrome (also known as basal-cell nevus syndrome; BCNS) [55], a familial inherited predisposition to the development of basal cell carcinomas (BCCs), medulloblastomas, and rhabdomyosarcomas [56,57]. Many sporadic BCCs have been associated with mutation within Ptc [58]. In all cases loss of Ptc function leads to constitutive Smo signaling and Hh pathway activation. In addition, point mutations in Smo, which result in constitutively active Ptc-insensitive forms of Smo, have been identified in sporadic BCC [59]. However, most of these tumors show upregulation of the Hh target genes, suggesting that other components of the Hh pathway may be mutated. One such example was identified in Smo where a point mutation, known as the Smo-M2 mutation (Smo-M2), results in a constitutively active form of Smo [59].

Interestingly, treatment of Hh-responsive cells with the teratogenic steroidal alkaloid cyclopamine blocks Hh signaling and Smo activation in cell lines and induces HPE in animal models [60,61]. Treatment of some glioma and medulloblastoma cell lines *in vitro* with cyclopamine has resulted in successful inhibition of cell growth, indicating that cyclopamine or other drugs that specifically block the Hh pathway may be effective in the treatment of Hh-associated tumors [62,63].

Acknowledgments

The authors would like to thank J. Peña and A. Bruce for their help in generating figures. The authors also apologize to the many authors whose work was not referenced in this chapter due to space constraints.

Control of Left-Right (L/R) Determination in Vertebrates by the Hedgehog Signaling Pathway

Javier Capdevila and Juan Carlos Izpisúa Belmonte

*The Salk Institute for Biological Studies,
Gene Expression Laboratory, La Jolla, California*

Introduction

Although the bodies of most vertebrate animals appear to be almost perfectly symmetrical, profound left-right (L/R) asymmetries exist that are clearly demonstrated by the specific disposition of internal organs (such as the heart to the left side of the chest cavity, or the liver to the right side of the abdomen, just to mention two examples). At another level, there is also asymmetry in the activity of the brain, with specific functions performed by each individual brain hemisphere, resulting in asymmetries in locomotor functions (among which being right- or left-handed is only one well-known manifestation). The normal disposition of organs is called *situs solitus*, and *situs inversus* refers to a complete or near-complete mirror-image reversal of organ disposition. Right or left isomerism usually refers to situations where individual organs are bilaterally symmetric.

Interestingly, this normal (that is, asymmetric) disposition of organs develops in embryos that are initially perfectly symmetrical, at least as far as we can tell from their morphological examination at very early stages of development. Therefore, the problem is to explain how asymmetric animals develop from (apparently) symmetric embryos, and to define the molecular mechanisms that control this process. That L/R development is under genetic control is clear from the existence (in humans as well as in other vertebrates) of congenital syndromes that result in a variety of laterality defects that can severely impair the function of the heart, lungs, liver, and other vital organs.

The problem of L/R specification has enticed biologists for many years, but until very recently a solid molecular entry point that could be used to successfully attack the problem had been missing. The situation changed in 1995, when the first molecular asymmetries were discovered in chick embryos (and later in other vertebrates). This discovery revealed that certain genes were expressed in asymmetric patterns in the developing embryo, and that these asymmetric patterns were somehow translated into asymmetric development of internal organs. Alterations in some of these genes have already been shown to be linked to some of the human syndromes that display laterality defects, further adding to our knowledge of the etiology of L/R defects in humans. Several comprehensive reviews published recently deal with multiple aspects of L/R development from a broader perspective [1–3].

One of the first genes shown to be involved in L/R determination in vertebrate embryos was *Sonic hedgehog* (*Shh*), a member of the *hedgehog* (*hh*) family of genes, which encode secreted factors that play key roles in multiple aspects of embryonic development in both vertebrate and invertebrate embryos. Since general aspects of HH signaling during embryonic development are reviewed by F. de Sauvage elsewhere in this volume, we will focus here only on the aspects of HH signaling relevant to the development of the embryonic L/R axis, especially in chick and mouse embryos. Further discussion on possible species-specific mechanisms can be found in the reviews mentioned above.

The Discovery of the First Molecular Asymmetries in Vertebrate Embryos and the Role of SHH

In 1995, a team of researchers led by Cliff Tabin and Claudio Stern published a seminal paper that brought into focus key aspects of the molecular basis of L/R determination [4]. The paper demonstrated that asymmetric gene expression did indeed exist in the early embryo, and that it played a key instructive role in the development of the L/R axis in vertebrates. Specifically, it was shown that the *Shh* gene was initially expressed in Hensen's node (the organizer of the chick embryo) without any apparent bias, but that shortly after, *Shh* expression became restricted to the left side of the node by an inferred Activin-like activity (most likely Activin β B) coming from the right side of the node. Activins belong to the transforming growth factor β (TGF β) superfamily of secreted factors, another group of signaling factors that play fundamental roles in the development of vertebrate and invertebrate embryos and during tumorigenesis [5,6]. It was shown that application of purified Activin protein to the left side of the node resulted in repression of *Shh* expression, and that application of purified SHH protein (this time to the right side of the node) repressed transcription of the gene encoding the Activin receptor (*ActRIIa*), which depends on the Activin β B ligand. Therefore, a mutually exclusive regulatory interaction between two secreted proteins with complementary patterns of expression resulted in the "specification" of a right side of the node (producing Activin β B protein) and a left side (producing SHH protein; Fig. 1A).

Another gene encoding a TGF β factor, *Nodal*, was shown to be expressed on the left side of the chick node under the control of SHH. *Nodal* also has a second domain of expression in the left lateral plate mesoderm (LPM) of the embryo, including cells that eventually will give rise to the organ primordia (Fig. 1A). Importantly, left-specific expression of *Nodal* has been observed in all types of vertebrates examined thus far, correlating absolutely with the development of normal organ *situs*. For example, when *Nodal* is either completely absent or present on both sides, organ *situs* is randomized. When *Nodal* is present exclusively on the right side (which occurs naturally in the *inv* mutant mouse and in some human patients that suffer from specific ciliary dysfunctions), there is *situs inversus*. Therefore, left-specific expression of the SHH target *Nodal* appears to play an instructive role in determining organ *situs* and constitutes a key feature of L/R development that has been absolutely conserved during the evolution of vertebrates. It is important to point out that the correct (that is, left-specific) expression of *Nodal* is not required for the development of the organs, but only for the establishment of their correct L/R asymmetry. When *Nodal* expression is altered, organs still form, but with an altered L/R axis that can result in malformations incompatible with life.

Further work identified additional factors that interact with SHH during L/R determination (Fig. 1A). On the right side of the node, Activin β B controls expression of another

TGF β factor, bone morphogenetic protein-4 (BMP-4), which in turn induces fibroblast growth factor-4 and -8 (FGF-4, -8). Mutual antagonism between BMP-4 and SHH appears to be necessary and sufficient to maintain asymmetric *Shh* expression in the node [7]. Moreover, SHH was shown to induce *Nodal* expression in the left LPM through the control of Caronte (Car), a secreted factor that binds to BMPs and antagonizes their repressive effect on *Nodal* transcription in the left LPM. On the right side of the embryo, FGFs turn off expression of Car, and thus BMPs are free to signal, which keeps the *Nodal* gene repressed on the right [8–10]. *Nodal* expression on the left side of the embryo controls the expression of genes such as *Pitx2*, which direct asymmetric organogenesis by mechanisms that are still poorly understood (see the reviews mentioned before in references [1–3]).

The control of *Nodal* by the HH signal on the left side of the node is likely to involve the activity of the HH reception complex, composed of the transmembrane proteins Patched1 and Smoothed (see F. de Sauvage's review in Chapter 253). Recent results indicate that additional components of the HH signaling pathway also play key roles in L/R determination. For example, protein kinase A (PKA) had been previously shown to act as an antagonist of HH signaling in vertebrates, most likely by phosphorylating GLI proteins, which are key nuclear effectors of the pathway. However, PKA has been recently described to act as a positive regulator of the SHH target *Nodal* during L/R determination in the chick embryo [11]. Consistent with this, the endogenous PKA inhibitor, PKI is more strongly expressed on the right side of Hensen's node, where it inhibits PKA, thus restricting its *Nodal*-inducing effects to the left side of the node [11,12]. Interestingly, the induction of *Nodal* expression by PKA does not require Car activity, and thus PKA appears to control *Nodal* through a pathway which acts in parallel to that operated by SHH and Car. Other components of HH signaling pathways are also likely to operate during L/R determination, but their exact roles have not yet been determined.

Finally, it is important to point out that the exact nature of the event that breaks the initial symmetry of the chick embryo remains unknown, although an intriguing hypothesis has been proposed that stresses the role of gap junction communication in this process [13].

The Role of a Composite HH Signal during L/R Determination in the Mouse

In the context of L/R development in the chick embryo, the role of SHH could be defined as that of a "left determinant." That is, SHH becomes restricted to the left side of Hensen's node, it controls expression of *Nodal* in and around the left side of the node, and (through Car) it also controls the *Nodal/Pitx2* domains in the left LPM. Inhibition of SHH activity (achieved, for instance, by exposing the chick embryo to an anti-SHH blocking antibody), inhibits

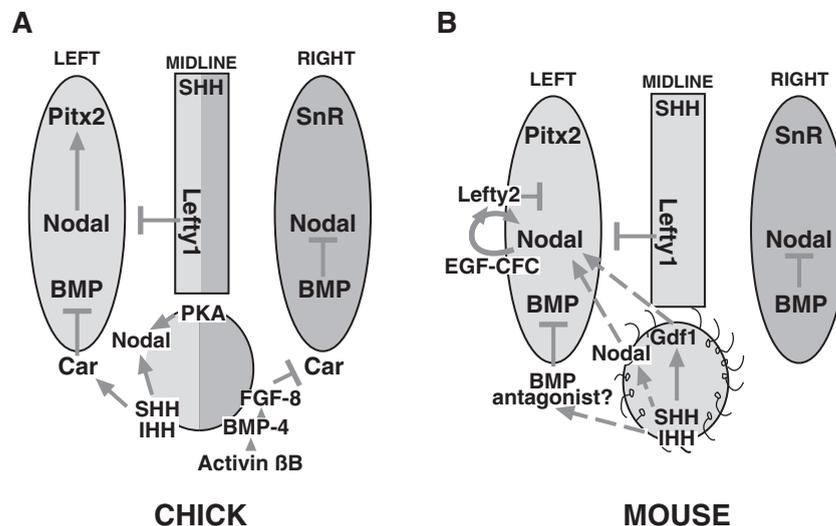

Figure 1 Comparison of the role of HH signaling during L/R determination in chick (A) and mouse embryos (B). At early stages of development of the chick embryo, breaking of the initial embryonic symmetry by mechanisms that are still unknown results in restriction of transcription of *Shh* (and most likely also of *Ihh*) to the left side of Hensen's node (the node is depicted as a circle, and the left side is shown in light gray), Activin β B triggers a cascade that activates expression of the *Bmp-4* and *Fgf-8* genes (and also of *Fgf-4*). HH signals display an antagonistic regulatory interaction with both Activin β B and BMP-4, which contributes to stabilize these side-specific patterns of transcription in the node. In and around the left side of the node, HH signaling mediated by the reception complex formed by the membrane proteins Patched1 (the receptor component) and Smoothed (the transducing component, not shown) results in activation of *Nodal* expression. PKA and other factors may act in parallel to ensure correct *Nodal* expression in the node area. HH signals also operate on the paraxial mesoderm cells adjacent to the node to maintain expression of the *Caronte* (*Car*) gene, which encodes an extracellular antagonist of BMP signaling. The presence of Car protein in the left side of the embryo antagonizes a repressive effect of the BMPs on transcription of the *Nodal* gene in the left LPM (the LPM is depicted as an ellipse), so that Nodal protein is produced and activates its target *Pitx2*. This gene encodes a bicoid-type homeoprotein that plays a key role in the transference of L/R positional information to the organ primordia. In contrast, on the right side of the embryo *Car* expression cannot be maintained, due to the absence of HH signaling and the presence of FGF-4 and/or -8, and thus BMP signals keep the *Nodal* gene repressed in the right LPM. This results in expression of *SnR*, a gene encoding a Snail-related zinc-finger transcription factor that also plays an important role in the determination of organ *situs*, in this case as a "right determinant" [19].

SHH (but not IHH) is also present in the midline (depicted as a rectangle), where it is required for the development of the floor plate, a structure in which the *Lefty1* gene is expressed. *Lefty1* encodes yet another TGF β member that has been proposed to function as a "midline barrier" to the diffusion of left-specific inducing signals from the left to the right side of the embryo (probably through direct interaction with Car and/or Nodal proteins). In cases where development of midline structures is compromised (such as in *Shh*-deficient embryos, for instance), bilateral expression of left-specific genes occurs, most likely due to secondary loss of *Lefty1* expression.

In the early mouse embryo, transcription of the *Shh*, *Ihh*, *Activin β B*, and *Fgf-8* genes in the node is not restricted to the left side, and a leftward nodal cilia flow (which has been proposed to carry some still unidentified extracellular inducers) results in the transient asymmetrical expression of *Nodal* in the left side of the node. Despite the lack of left-specific restriction of HH signals, deficiency in both SHH and IHH proteins (or, alternatively, deficiency in *Smo*), completely abolishes *Nodal* and *Pitx2* expression in the left LPM, indicating that HH signaling also acts in the mouse as a left determinant. Interestingly, *Nodal* expression in the node is not abolished, but is nevertheless altered, suggesting that HH signaling does not control *Nodal* directly in the node, but is somehow involved in the specification of its normal domain. Both Gdf1 and Nodal itself play important roles downstream of HH signaling in controlling *Nodal* expression in the left LPM. Indeed, the Nodal protein, in the presence of extracellular cofactors of the EGF-CFC superfamily, has been shown to activate transcription from its own promoter. Exactly as in the chick embryo, Nodal expression in the left LPM activates *Pitx2* expression.

Thus far, no *Car* gene has been identified in vertebrates other than the chick, but it seems likely that a BMP antagonist (or an alternative mechanism of attenuation of BMP signaling) may also exist in the mouse embryo, as illustrated by the fact that mouse mutants deficient in BMP signaling display bilateral expression of *Nodal*. The nature of this putative BMP antagonist remains unknown, as is the chain of events that operate on the right side of the mouse embryo and its possible interactions with HH signaling in the node.

the expression of all these left-specific genes. Moreover, when SHH protein is applied ectopically to the right side of the embryo, it can ectopically trigger the whole program of “left expression.”

In the mouse embryo, however, *Shh*, *Activin β B*, *ActRIIA*, and *Fgf-8* are all expressed in the node, but without any detectable asymmetry (Fig. 1B). *Nodal*, in contrast, displays a (transient) stronger expression on the left side of the node, besides its domain in the left LPM, further confirming it as a bona fide evolutionarily conserved left determinant. But does SHH act as a left determinant in the mouse embryo? Interestingly, recent studies in mouse embryos demonstrate that a second member of the HH family, named Indian Hedgehog (IHH), plays a role in L/R development that is partially redundant to that of SHH [14]. Indeed, the SHH and IHH proteins have been previously shown to display similar activities (and bind to the same receptor) in a variety of assays. Both SHH and IHH are expressed in the mouse node without apparent L/R bias, and *Shh*-null embryos still express IHH, which can perform part of the activities of SHH, thus obscuring the consequences of completely removing all HH signals from the node [15,16]. In fact, in *Shh/Ihh* double mutant embryos, *Pitx2* is completely absent from the LPM, which indicates that a compound HH signaling is absolutely required for the establishment of left-specific gene expression in the mouse embryo. Importantly, this phenotype is comparable to that of *Smo*-deficient embryos. The *Smoothed* (*Smo*) gene encodes the essential transducer of both SHH and IHH signals, and in the *Smo*-deficient embryos, *Nodal* (as well as other left-specific genes) is absent from the LPM. *Nodal* expression is, however, retained in the node, although with variable levels and patterns of expression, and the significance of this observation is still unclear.

These results demonstrate that HH signaling from the mouse node is absolutely required for the activation of left-specific genes in the LPM, exactly as in the chick embryo, even though expression is not restricted to the left side of the node. In contrast with the situation in the chick, however, ectopic HH signaling in the mouse fails to induce ectopic expression of *Nodal*, which suggests that the regulation of *Nodal* by HH is indirect. In this regard, the TGF β family member *Gdf1* and the EGF-CFC extracellular factor *Cryptic* (a cofactor for the *Nodal* protein) both appear to be targets of HH signaling, and may mediate the effects of HH proteins on the node and the LPM (Fig. 1B). In the mouse, there is also some evidence that the domain of *Nodal* expression in the node is required for expression of *Nodal* in the left LPM, where a positive autoregulatory loop is established. It is important to point out that the same situation of redundancy between SHH and IHH in the node is likely to occur in the chick (Fig. 1A), where the anti-SHH blocking antibody presumably blocks both SHH and IHH proteins.

Why isn't there left-specific expression of *Shh*, *Activin β B*, or *Fgfs* in the mouse node? It has been postulated that a leftward “nodal flow” driven by nodal cilia (possibly carrying some extracellular inducing factor), is the event that breaks the initial symmetry in the mouse embryo (and most

likely also in other mammals), resulting in asymmetric expression of *Nodal* in and around the node [17]. The existence of this putative inducing factor carried by the nodal flow has not been demonstrated yet, but it is clear from the results indicated above that HH signaling in the node is required for the correct regionalization of *Nodal* expression in the mouse node. The reason why *Nodal* is transiently upregulated specifically on the left side of the mouse node is still unknown, and it is also important to point out that it is still unclear whether nodal cilia control the L/R axis in the chick embryo [18].

In conclusion, although the mechanisms that break the initial symmetry may be very different in chick and mouse embryos, the basic role of HH signaling as a left determinant appears to be conserved during evolution, as is the left-specific expression of the *Nodal* gene. Without a doubt, the characterization of additional components of HH signaling pathways and of their roles in the early vertebrate embryo will still provide very valuable information about the mechanisms that control L/R determination during early embryogenesis.

EGF-Receptor Signaling in *Caenorhabditis elegans* Vulval Development

Nadeem Moghal and Paul W. Sternberg

HHMI and Division of Biology, California Institute of Technology, Pasadena, California

A crucial aspect of *Caenorhabditis elegans* vulval development is induction of the vulval precursor cells by the anchor cell of the developing uterus. Precisely three of the six vulval precursor cells are induced by the anchor cell to generate vulval cells. As we shall discuss, this induction uses an epidermal growth factor (EGF)-receptor signaling pathway involving the *C. elegans* EGF-receptor homolog LET-23. There are a number of other cell-signaling events during vulval development including at least three uses of WNT [17,19,48,61], and the LIN-12 (Notch-type receptor) pathway. The LET-23 pathway is also used for a reciprocal induction by which a subset of the vulval cells signal back to the developing uterus [9]. Because vulval induction is relatively easy to observe, it can be used to study EGF-receptor signaling *in vivo*.

The Core LET-23 Signaling Pathway

Proteins necessary for LET-23 signaling during vulval induction were found by analyzing mutants with defective (vulvaless) or excessive (multivulva) vulval induction, or by suppressor mutations altering other pathway components. The order of action of these proteins was inferred from analysis of double mutant combinations, in the presence or absence of the inducing cell. The double mutant experiments relied on use of overexpressed EGF, activated EGF-receptor LET-23, or activated RAS. For example, a gain-of-function mutant version of LET-23 causes vulval development in the absence of the anchor cell. *lin-3* encodes multiple products sharing an EGF domain and a transmembrane domain, but differing in their amino termini and spacing of the EGF and transmembrane domain [27,40]. *let-23* encodes the *C. elegans*

EGF receptor subfamily ortholog [1]. *sem-5* encodes a GRB2 ortholog with an SH2 domain and two SH3 domains [14]. *let-341* encodes an SOS ortholog, a Ras guanine nucleotide exchange factor [10,15]. *let-60* encodes RAS [23]. *lin-45* encodes RAF [24]. *mek-2* encodes MAP kinase [35,36] and *mpk-1/sur-1* encodes MAP kinase [37,63]. The genetic data are consistent with a linear pathway from LET-23 to MAP kinase: LET-23 acts downstream or in parallel to LIN-3; SEM-5 acts downstream or in parallel to LET-23; LET-60 acts downstream or in parallel to SEM-5; LIN-45 acts downstream or in parallel to LET-60, etc. Downstream of MAP kinase the pathway is more complicated, with a number of positive- and negative-acting nuclear factors. The LIN-1 ETS-domain protein and the winged helix protein LIN-31 primarily act to inhibit vulval development, but direct targets are not yet known [2,46,58]. LIN-1 and LIN-31 can dimerize and affect each other's activity. Positive-acting transcription factors include LIN-25 and SUR-2 [54,60], which appear to act together. SUR-2 is homologous to a component of a human mediator complex [4], which in mammals and yeast links site-specific DNA binding proteins to RNA polymerase. The hox gene *lin-39* is a positive-acting nuclear factor, while the hox gene *mab-5* acts negatively on the two posterior vulval precursor cells [12,43].

Tissue Specificity

Analysis of the tyrosines in the carboxyl terminal, cytoplasmic domain of LET-23 revealed distinct positive functions in activation of the RAS pathway activity involved in cell fate specification and an inositol 1,4,5 trisphosphate (IP₃)

pathway involved in ovulation [6,13,39]. The three tyrosines sufficient for RAS pathway have the YXN consensus for GRB2 (SEM-5) binding, and a single tyrosine site can act via SEM-5 in the absence of the other two. By contrast, yet another tyrosine site stimulates the ovulation pathway not via RAS. The coupling of LET-23 to IP₃ is predicted to involve a phospholipase.

A number of cell fate choices during *C. elegans* development also depend on LET-23. For several of these choices, the outcome may depend on the particular hox gene the cells express. The vulval cells express *lin-39*, the male hook precursor cells express *mab-5*, and the P12 cell expresses *egl-5* [32,44,49].

Positive and Negative Regulators

Besides the core signaling components, additional positive and negative regulators of vulva development have been identified. Elimination of LIN-2, LIN-7, or LIN-10 results in a partial vulvaless phenotype identical to elimination of the carboxyl six amino acids of LET-23. The inferred signaling defect correlates with a shift in LET-23 localization from the basolateral to apical surface of vulval precursor cells, which is the side furthest away from the anchor cell [35,53]. Overexpression of LET-23 rescues the vulvaless phenotypes indicating that these genes facilitate signaling by concentrating LET-23 close to LIN-3 [53]. LIN-2, LIN-7, and LIN-10 all contain PDZ domains [29,53,62]. *In vitro* experiments indicate that the PDZ domain of LIN-7 binds the cytoplasmic tail of LET-23 [53], and that LIN-2 promotes ternary complex formation with LIN-7 and LIN-10 [34]. A truncated form of LIN-10 that lacks both PDZ domains has a relatively weak vulval phenotype indicating that at least for LET-23 signaling, LIN-10 PDZ domains are not crucial [62].

Genetic screens for mutations that suppress the multivulva phenotype conferred by a gain-of-function *let-60* allele (*n1046gf*) identified a number of modulators of vulval development. On their own, mutations in *ksr-1* [36,57], *sur-8/soc-2* [49,51], and *sur-6* [52] result in no obvious vulval phenotype. However, they cause *let-60(n1046gf)* animals to become wild-type, and produce highly penetrant vulvaless phenotypes in the presence of weak reduction of function mutations in core components such as *mpk-1* and *lin-45*. *ksr-1* encodes a predicted Ser/Thr kinase related to RAF, but lacks the CR1 and CR2 domains. *ksr-1* likely functions upstream of *lin-1*, and *in vitro* studies suggest that it may interact directly with MPK-1/SUR-1 through an FXFP site during vulval development [31]. Although some *ksr-1* alleles harbor missense mutations in the kinase domain, transgenes mutant in the ATP binding site or the catalytic aspartate have the same rescuing activity as wild-type DNA, indicating kinase activity is not crucial for its function [56]. *sur-8* encodes a protein consisting of 18 tandem Leu-rich repeats similar to yeast adenylate cyclases. *sur-8* mutations do not reduce the penetrance of the multivulva phenotype conferred by a gain-of-function LIN-45 RAF transgene, suggesting it works upstream of RAF activation. SUR-8 interacts with a

different part of the LET-60 effector domain than LIN-45 RAF, and not all *sur-8* mutations affect this interaction [51]. *sur-6* encodes a regulatory β subunit of protein phosphatase 2A (PP2A). *sur-6* mutations do not suppress the multivulva phenotype conferred by a gain-of-function LIN-45 RAF transgene, suggesting it also works upstream of RAF activation. *sur-6* mutations produce a strong synthetic vulvaless phenotype with *sur-8*, but not with *ksr-1*, raising the possibility that SUR-6 function is intimately connected with KSR-1. dsRNA interference experiments against the A and C PP2A catalytic core components, also inhibit the multivulva phenotype of *let-60(n1046gf)* [51], suggesting that SUR-6 is a positive regulator of PP2A, and that the phosphatase activity of the complex promotes RAS-dependent vulva development.

Deletion of the SH2-domain containing protein tyrosine phosphatase, *ptp-2*, which is most closely related to SHP-2/corkscrew [21] does not perturb vulval development on its own, but reduces the multivulva phenotypes conferred by mutations in *lin-15* and activated alleles of *let-23* and *let-60*. In addition, a *ptp-2* mutation results in a synthetic vulvaless phenotype in the presence of a weak *sem-5* mutation.

Loci involved in negative regulation of vulva induction have been elucidated through three different approaches. Genetic screens for mutations, which suppress reduction-of-function mutations in the *let-23* pathway, led to the identification of *unc-101* [38], *sli-1* [33,65] *gap-1* [20], and *sur-5* [22]. UNC-101 is a functional homolog of the AP47 medium chain of the trans-Golgi clathrin-associated AP-1 complex. dsRNAi experiments indicate it works redundantly with a second AP47 homolog, *apm-1* [50]. An *sli-1* mutation suppresses a severe non-null allele of *let-23*, but not severe non-null alleles of *let-60*, suggesting it works upstream of RAS [66]. SLI-1 is related to the CBL family of adaptors/E3 ubiquitin ligases. Although both the PTB and RING finger domains are required for full inhibitory activity, SLI-1 displays some activity in the absence of the RING finger, indicating it may have some function independent of E3 ubiquitin ligase activity [66]. Recently, a tyrosine in the C-terminal tail of LET-23, in the sequence NSSRYKETP, was shown to be required for the genetic inhibition of *sli-1* on *sem-5*-dependent vulval induction [66], similar to a ZAP-70 binding site for the CBL PTB domain [42,45], and consistent with a model of direct binding of SLI-1 to LET-23. *gap-1* mutations suppress reduction-of-function mutations in *let-60*, but not *lin-45*, and its encoded protein is most similar to the Gap-1 and Gap-1m RAS GTPase activating proteins in *Drosophila* and vertebrates, respectively, strongly suggesting that it is a direct regulator of LET-60. *sur-5* was isolated as a suppressor of a dominant negative *let-60* allele. Unlike the previously described negative regulators, it has the unusual property of not being able to suppress any of the standard reduction-of-function mutations in the core components, including a weak allele of *let-23*. Moreover, it only suppresses a subset of dominant negative *let-60* alleles. SUR-5 has some identity to acetyl-CoA synthetases, but its mechanism of action is a mystery. The *cdf-1* gene also was identified as a suppressor of activated RAS [5]. Zinc ions inhibit RAS signaling in *C. elegans*, and the cation

diffusion facilitator CDF-1, which lowers cytoplasmic zinc concentration, is thus a positive modulator of the pathway [5].

Genetic screens in sensitized, but phenotypically wild-type backgrounds have identified other negative regulators of vulva induction. Ferguson and Horvitz [18] first defined this approach by isolating mutations in two classes of loci, A and B, wherein any class A mutation caused a synthetic multivulva (synmv) phenotype in combination with any class B mutation. Using class A or B sensitized backgrounds, a number of additional class A and B mutations have been isolated. *lin-15A* [16,30], *lin-15B* [16,30], and *lin-36* [59] encode novel proteins. LIN-35 is related to the retinoblastoma family of proteins [41], *lin-53* encodes the Rb-binding protein, RbAp48 [41], and DPL-1 is related to the DP family of transcription factors [8]. Reverse genetics indicate that *eft-1/2*, which are E2F-like genes, also have synmv properties [8]. Genetic [8,30,41,59] and cell ablation [30,55] experiments indicate that the synmv phenotype is strongly dependent on LET-23 and its downstream signaling components, but not LIN-3. Expression, transgenic, and mosaic analyses suggest that both the vulval precursor cells and the surrounding epidermal syncytium might be a source for an inhibitory signal by these genes [8,25,26,41,59].

Similar to the synmv screens, *ark-1* was recovered as a mutation that caused a synthetic multivulva phenotype in the presence of a *sl-1* mutation [28]. An *ark-1* mutation also suppresses non-null mutations in the *let-23* pathway. *ark-1* encodes a putative tyrosine kinase most similar to Ack, and yeast two hybrid studies indicate that a C-terminal, proline-rich domain can bind to SEM-5, suggesting its function may be intimately connected to SEM-5. In addition, both SEM-5 and ARK-1 have an inhibitory effect on LET-23 signaling during ovulation, suggesting that SEM-5 might recruit ARK-1 to inhibit LET-23.

A loss-of-function mutation in *lip-1*, a gene predicted to encode a MAPK phosphatase, was generated based on its genomic sequence [3]. This mutation suppresses vulvaless defects conferred by loss-of-function mutations in the *let-23* pathway. LIP-1 transcription is induced by LIN-12 (Notch) signaling [3], and thus might be one way in which Notch signaling is antagonistic to LET-23 signaling [55].

Prospects

One key issue includes the identification of direct targets for the transcriptional response to the MAP kinase pathway. The *egl-17* gene, which encodes a fibroblast growth factor necessary for muscle precursor positioning, is induced by the LET-23 pathway [7], and is one candidate for an immediate target. The hox gene *lin-39* is upregulated by LET-23 signaling [43], and is another candidate. A long list of other candidates has been generated by DNA expression microarray experiments [47]. With the continued discovery of regulators and modulators of this core LET-23 pathway, studies in *C. elegans* will help place these many proteins into their physiological context, including other extracellular signals, tissue-specific effects, and environmental modulation.

Induction and Lateral Specification Mediated by LIN-12/Notch Proteins

Sophie Jarriault and Iva Greenwald

Howard Hughes Medical Institute, Department of Biochemistry and Molecular Biophysics, Columbia University, New York, New York

In this chapter, we describe general and conserved features of the LIN-12/Notch signal transduction pathway. We also describe features of two different binary cell fate decisions mediated by this pathway in *Caenorhabditis elegans*. Finally, we discuss whether the primary role of Notch is to mediate binary decisions between alternative cell fates or to block differentiation.

The LIN-12/Notch Pathway

Receptors of the LIN-12/Notch family are evolutionarily conserved single pass transmembrane proteins. A single *Notch* gene exists in *Drosophila*, whereas two, *lin-12* and *glp-1*, have been described in *C. elegans* and four, *Notch-1* to *Notch-4*, in vertebrates (Table I). The ligands for LIN-12/Notch are single pass transmembrane proteins of the DSL family, after canonical proteins from *Drosophila* (Delta, Serrate) and *C. elegans* (Lag-2).

Genetic and biochemical experiments on invertebrates, mainly *C. elegans* and *Drosophila melanogaster*, and more recently on vertebrates, have defined members of the LIN-12/Notch signal transduction pathway (Table I), as well as an original model for signal transduction (Fig. 1). LIN-12/Notch proteins in vertebrates appear to be cleaved during their transit to the cell surface by the protease furin at site 1 (see Fig. 1). Upon activation of LIN-12/Notch by a DSL ligand, the receptor is cleaved both in its extracellular domain (site 2) and within its transmembrane domain (site 3), to produce an active intracellular fragment which translocates to the nucleus. The site 2 cleavage is likely to be mediated by a transmembrane metalloprotease of the ADAM family (see Table I).

The site 3 cleavage requires a complex that contains the membrane proteins Presenilin, APH-1, Nicastrin and PEN-2 (reviewed in references [1,2]).

In the nucleus, the intracellular part of LIN-12/Notch associates with a sequence-specific DNA binding protein (known as LAG-1 in *C. elegans*, Su(H) in *Drosophila*, and RBP-J or CBF1 in mammals [3]), with a glutamine-rich protein (SEL-8, for example, see Table I [4,5]), and with another protein called SKIP [6]. This complex, which is likely to include other proteins as well, binds to promoters of target genes, activating their transcription. In addition, the activation complex is believed to contribute to target gene activation by displacing a co-repressor complex previously associated with CBF1 [7].

A number of negative modulators of LIN-12/Notch signaling have been described, which influence the ability of a ligand to signal (Fringe, [8]), the ability of the receptor to transmit the signal (Numb, [9]), or the stability of the receptor (Sel-10, [10]). Crosstalk between the LIN-12/Notch signaling pathway and others, such as the frizzled pathway in *Drosophila* [11] or the Ras pathway in worms [12], has also been described.

Cell-Cell Interactions Mediated by the LIN-12/Notch Pathway

When equivalent cells interact with each other, that process has classically been termed “lateral inhibition,” or more recently, “lateral specification” (see the following section). When the signal comes from a different cell type, that process

Table I Members of the LIN-12/Notch Pathway in *C. elegans*, *Drosophila*, and Mammals

Role	<i>C. elegans</i>	<i>Drosophila</i>	Mammals
Ligands (DSL family)	LAG-2, APX-1, others	Delta Serrate	Delta 1–4 Jagged 1–2
Receptors	LIN-12, GLP-1	Notch	Notch 1–4
Site 1 cleavage	(Furin)	(Furin)	Furin
Site 2 cleavage	SUP-17	Kuzbanian	TACE/ADAM-17
Site 3 cleavage	SEL-12, HOP-1 APH-1 APH-2 PEN-2	Presenilin Aph-1 Nicastrin PEN-2	Presenilin Aph-1 Nicastrin PEN-2
Modulators	(NUMB) – SEL-10	Numb Fringe (Sel-10)	(Numb) Fringe Sel-10
Nuclear complex	LAG-1 SEL-8 (SKIP)	Su(H) Mastermind (Skip)	RBP-J/CBF1 Mastermind SKIP
Selected targets	– <i>lip-1</i> <i>lin-12</i>	<i>E(spl)</i> complex – (<i>Notch</i>)	<i>HES-1,5</i> – <i>Notch-1</i>

Proteins drawn on the same line are equivalents in the three groups shown. Proteins shown in parentheses, e.g. (furin), exist in the organism, but have not been proven to function in that step. Fringe and genes of the *E(spl)* complex do not have clear orthologs in *C. elegans*; it is not known whether *lip-1* orthologs exist or are targets of the LIN-12/Notch pathway in other organisms. Note that SUP-17, Kuzbanian and TACE are metalloproteases belonging to the ADAM family.

has classically been termed “induction.” LIN-12/Notch signaling has been shown to underlie both kinds of interactions in many different systems. The outcome is a binary decision, so that bipotential cells choose between one of two alternative fates depending on whether LIN-12/Notch activity is high or low. We will illustrate the basic principles here using two simple cell fate decisions from *C. elegans*.

Lateral Specification in the AC/VU Decision: A Decision between Two Equivalent Cells

During formation of the somatic gonad of the hermaphrodite, two cells, named Z1.ppp and Z4.aaa, have an equal probability to become either the anchor cell (AC) or a ventral uterine precursor cell (VU; Fig. 2A). In wild-type hermaphrodites, Z1.ppp and Z4.aaa interact with each other, so that only one of the two cells becomes the AC while the other becomes a VU [13,14]. Cell contact appears to be necessary for the interaction to occur correctly, because in mutants that disrupt contact between Z1.ppp and Z4.aaa, both cells become ACs [15].

Genetic studies of mutations in *lin-12* and other members of the LIN-12/Notch pathway have established that in Z1.ppp or Z4.aaa, a low level of *lin-12* activity results in the AC fate, whereas a high level results in the VU fate. Manipulation of the relative level of *lin-12* activity in genetic mosaics [14] and the detailed analysis of *lin-12* and its ligand *lag-2*

transcriptional reporter gene expression during the course of the AC/VU decision [16] has revealed that *lin-12* and *lag-2* are initially expressed at comparable levels in Z1.ppp and Z4.aaa. A stochastic initial difference in *lin-12* or *lag-2* activity is further amplified by a feedback mechanism involving positive and negative autoregulatory loops. As a result, there is an increase of *lin-12* expression and a decrease in *lag-2* expression in one cell, and the reciprocal situation (decrease in *lin-12*, increase in *lag-2*) in the other. The cell in which *lin-12* activity is high becomes a VU and the other, in which *lin-12* activity is low, becomes an AC [14,16].

Lateral specification that includes transcription-based feedback loops also appears to operate in cell fate decisions in *Drosophila* and probably in vertebrates [17,18]. We prefer the term lateral specification to lateral inhibition to emphasize the bidirectional nature of the communication (see also reference [19]). Such simple circuits can also be modified by either intrinsic factors or external signaling events so that the element of randomness seen in the AC/VU decision is reduced or eliminated (see, for example, references [9] and [11]).

Inductive Signaling: Germline Proliferation and Meiotic Differentiation in *C. elegans*

The *C. elegans* gonad is organized as two symmetrical U-shaped arms extending distally from a common uterus (Fig. 2B). The distal-most germ cells divide mitotically, and

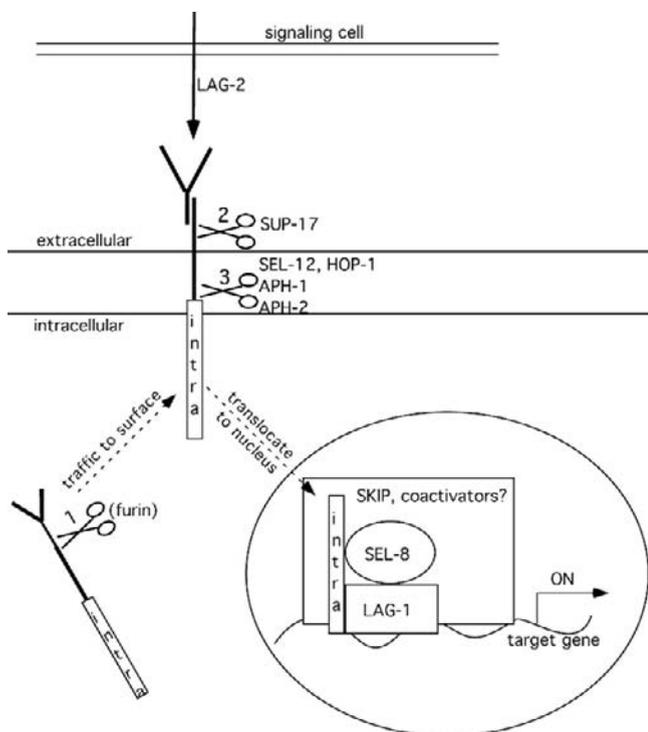

Figure 1 Simplified model of LIN-12/Notch signal transduction. The *C. elegans* names for components are used; see Table I for *Drosophila* and mammalian equivalents. A DSL ligand, such as LAG-2, on the surface of a neighboring cell activates LIN-12/Notch, triggering cleavage in the extracellular domain (site 2) and within its transmembrane domain (site 3). The released intracellular domain translocates to the nucleus, where in a complex with LAG-1, and probably SEL-8, SKIP, and other co-activators, it participates in the transcriptional activation of target genes. The protease furin has been shown to cleave LIN-12/Notch at site 1 during its transit to the surface in mammals [30]; however, this cleavage has not been addressed experimentally in *C. elegans* nor in *Drosophila*.

progress down the arm; at the bend, they enter a transition zone and proceed to meiosis. At the extremity of each arm, there is a somatic distal tip cell (DTC) that regulates the decision of the germ cells between mitosis and meiosis: If the DTC is ablated, the distal germ cell nuclei in that gonad arm enter meiosis precociously [20].

Genetic studies of *glp-1* have established that a low level of *glp-1* activity is required for germ cells to undergo meiosis, whereas high levels of *glp-1* activity promote mitosis [21–23]. The DTCs express the DSL gene *lag-2*, and the distal germ cells express the LIN-12/Notch protein GLP-1 [24,25]. Activation of GLP-1 in the germ cells that lie near the DTC causes them to remain proliferative.

The Role of LIN-12/Notch Proteins: Suppression of Differentiation versus Specification of Binary Cell Fate Decisions

Truncated forms of LIN-12/Notch proteins, such as the intracellular domain, mimic the natural cleavage product and behave like constitutively active receptors [26]. This approach

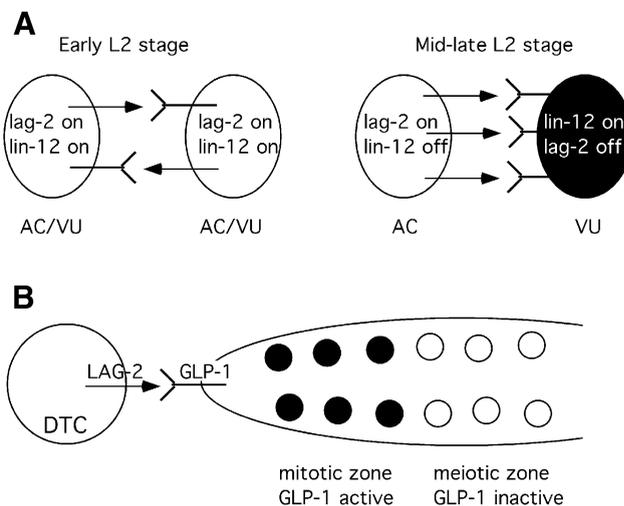

Figure 2 Lateral specification and inductive signaling events mediated by LIN-12/Notch. (A) Lateral specification, the AC/VU decision: Two equivalent cells each have the potential to adopt the AC or VU fates (AC/VU) in the early L2 stage. As the L2 stage progresses, a small variation in ligand or receptor activity is amplified by transcription-based feedback loops, so that activation of LIN-12 in one cell promotes *lin-12* expression and represses (or fails to maintain) *lag-2* expression. Failure to activate LIN-12 has the opposite effect. The presumptive AC is the cell that continues to express *lag-2*, and the presumptive VU is the cell that continues to express *lin-12*. (B) Induction, the mitosis/meiosis decision: The distal tip cell (DTC) of the somatic gonad expresses LAG-2, which activates GLP-1 in the distal portion of the germline syncytium. Distal germline nuclei therefore undergo mitosis, although as they move more proximally, they enter a zone in which GLP-1 is inactive and they begin to enter meiosis.

has been important for studying the role and the molecular mechanism of the Notch pathway in vertebrates.

The idea that the role of Notch is to block differentiation was first proposed when activated Notch was thought to inhibit photoreceptor differentiation in *Drosophila* [27]. Furthermore, this view was reinforced by studies of proneural clusters in *Drosophila*, which showed that expression of the achaete-scute neural competence factors are lost in cells in which Notch has been activated [28]. The view that Notch activation inhibits differentiation in *Drosophila* strongly influenced the interpretation of phenotypes caused by expressing the Notch intracellular domain in vertebrates. However, recent work has established that Notch does not block differentiation of photoreceptors, and indeed, plays a direct role in photoreceptor differentiation (for example, see reference [29]). Thus, photoreceptor differentiation in the *Drosophila* eye, like the *C. elegans* examples illustrated above, suggest that activated Notch promotes a fate that is a normal outcome of a binary decision.

These considerations suggest that, while it may be that in some cases the effect of activated Notch is to “block differentiation” there may perhaps be an underlying binary cell fate decision; to differentiate or to remain a stem cell. Indeed, the continued mitotic proliferation of the germline when GLP-1 is constitutively activated in *C. elegans* may be considered a model for this kind of binary decision.

Notch Signaling in Vertebrate Development

Chris Kintner

*The Salk Institute for Biological Studies,
La Jolla, California*

Introduction

The Notch signaling pathway was discovered in *Caenorhabditis elegans* and *Drosophila* by studying gene mutations that cause equivalent embryonic phenotypes, many of which entail alterations in cell fate [1]. Subsequently, homology cDNA cloning identified the vertebrate counterparts of these genes, paving the way for the discovery that Notch also plays a prominent role in the development of just about every organ system in the vertebrate embryo [2]. The first part of this chapter will describe the structural features of the receptors, ligands, and accessory proteins that mediate Notch signaling in vertebrates. The second part will describe how Notch signaling is used, in many cases in a similar manner, to regulate various aspects of cell fate determination and tissue patterning during vertebrate development.

Components Mediating Vertebrate Notch Signaling

Vertebrate Notch Receptors

The Notch receptors comprise a relatively small family of type I transmembrane proteins with just one member in *Drosophila*, two in *C. elegans*, and four in vertebrates [1]. As illustrated in Fig. 1A, the extracellular domains (ECN) of these receptors share a number of structural similarities, including multiple, tandem copies of an epidermal growth factor (EGF)-like motif that comprises most of the ectodomain as well as tandem copies of a second motif called the Notch/lin-12 repeat. The intracellular domain (NICD) contains a conserved juxtamembrane region called

RAM23, six tandem ankyrin repeats (ANK), and a PEST (P) domain located at the carboxy terminus. The different receptors presumably arose during vertebrate evolution by several gene duplications starting from a receptor very similar to *Drosophila* Notch. Thus, mouse Notch1 and 2 contain the same number of EGF repeats as *Drosophila* (36) while Notch3 and Notch4 contain 34 and 29 repeats, respectively. The NICD of both Notch 3 and 4 is also shorter than that of Notch1 and 2. In addition, as expected for genes recently duplicated, the four Notch homologs show some degree of genetic redundancy based on the phenotypes produced by targeted mutations [3]. Nonetheless, the “knockout” phenotype of mouse Notch1 is more severe than that of the other Notch homologs, suggesting that the latter receptors have evolved to serve more specialized functions [4–6]. These specialized functions may have arisen by changes in their developmental expression pattern (for example, see [7,8]), in their preference for activation by the different ligands [9], or in the way that they signal. An example of the latter is Notch3, which may activate downstream targets differently than the other Notch receptors under at least some assay conditions [10].

The vertebrate Notch receptors were also identified as genes linked with several disease states. In certain forms of T-cell leukemia, a chromosomal translocation fuses the intracellular domain of the human Notch1 receptor to the extracellular domain of the β chain of the T-cell receptor [11]. Similarly, in MMTV-induced mammary tumors in the mouse, one of the viral integration sites (INT3) leads to expression of just the Notch4 intracellular domain [12]. Based on the known Notch signaling pathway (see the following section), these observations suggest that constitutive

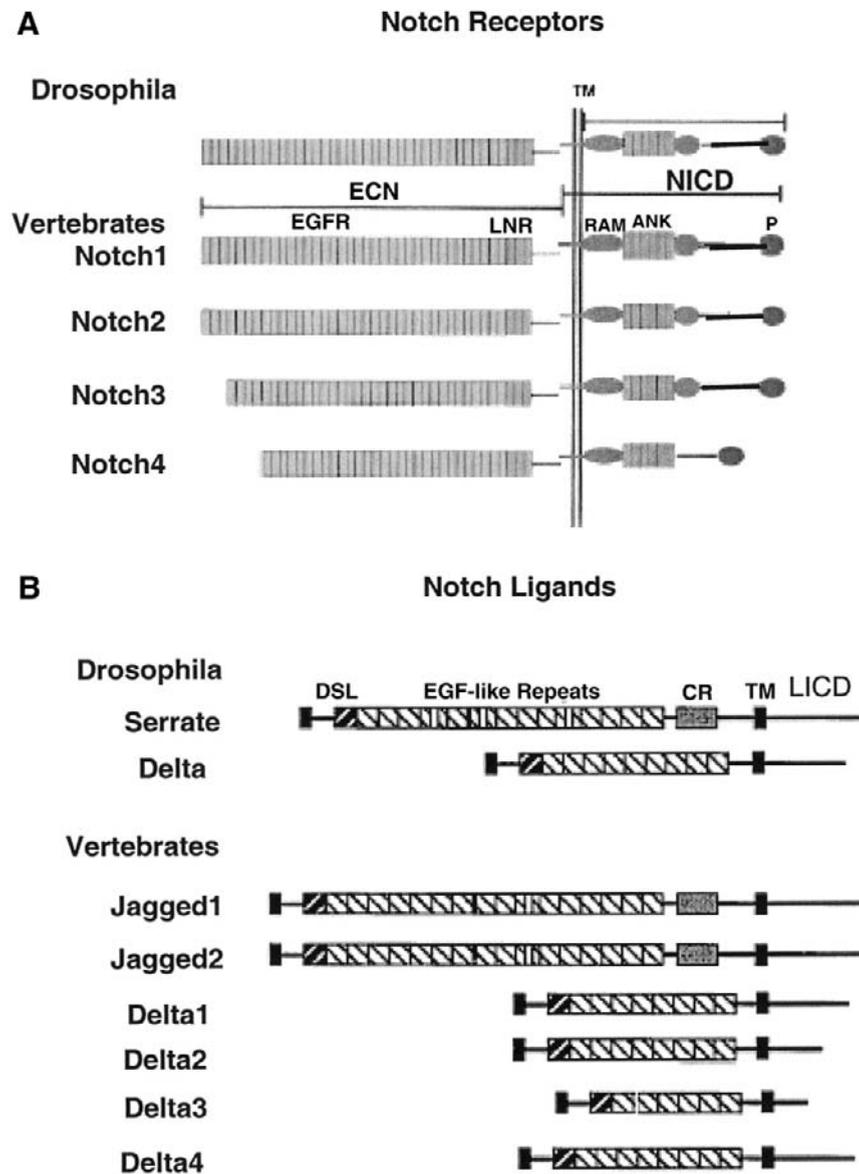

Figure 1 Diagram illustrating the structure of the Notch receptors (A) and ligands (B) in vertebrates relative to their *Drosophila* counterparts. See text for details.

Notch signaling contributes to tumor progression. Finally, an autosomal dominant disease resulting in stroke and dementia, called CADASIL, is associated with missense mutations in the human Notch3 receptor [13], although the consequences of these mutations on receptor activity are not fully known.

Vertebrate Notch Ligands

Ligands for the vertebrate Notch receptors are type I transmembrane proteins that are closely related in structure and sequence to the two ligands, Delta and Serrate, which bind and activate *Drosophila* Notch (Fig. 1B) [14]. The extracellular domains of these ligands are primarily made up of EGF-like repeats like the receptors but are distinguished by a signature divergent EGF-like repeat located at the

amino terminus called the DSL domain (Delta, Serrate, and Lag-1). While the Delta-like ligands contain from 6–9 EGF-like repeats, the Serrate-like ligands (referred to mainly as the Jagged ligands) have 16 repeats, as well as a unique cysteine-rich (CR) domain located between the EGF repeats and the transmembrane domain. All vertebrate species have a Delta-like ligand, called Delta1, which seems to be the most closely related to *Drosophila* Delta in terms of structure and function. The other Delta-like ligands in vertebrates, such as Delta3 [15] and Delta4 [16] in the mouse or Delta2 in *Xenopus* [17], are either much more divergent in structure (Delta3), or more restricted in their expression pattern during development (Delta2 and 4). Vertebrates have at least two Serrate-like ligands (Jagged1 and Jagged2) [18,19] that contribute to the development of a number of tissues based on knockout phenotypes in the mouse [20,21]. Like the

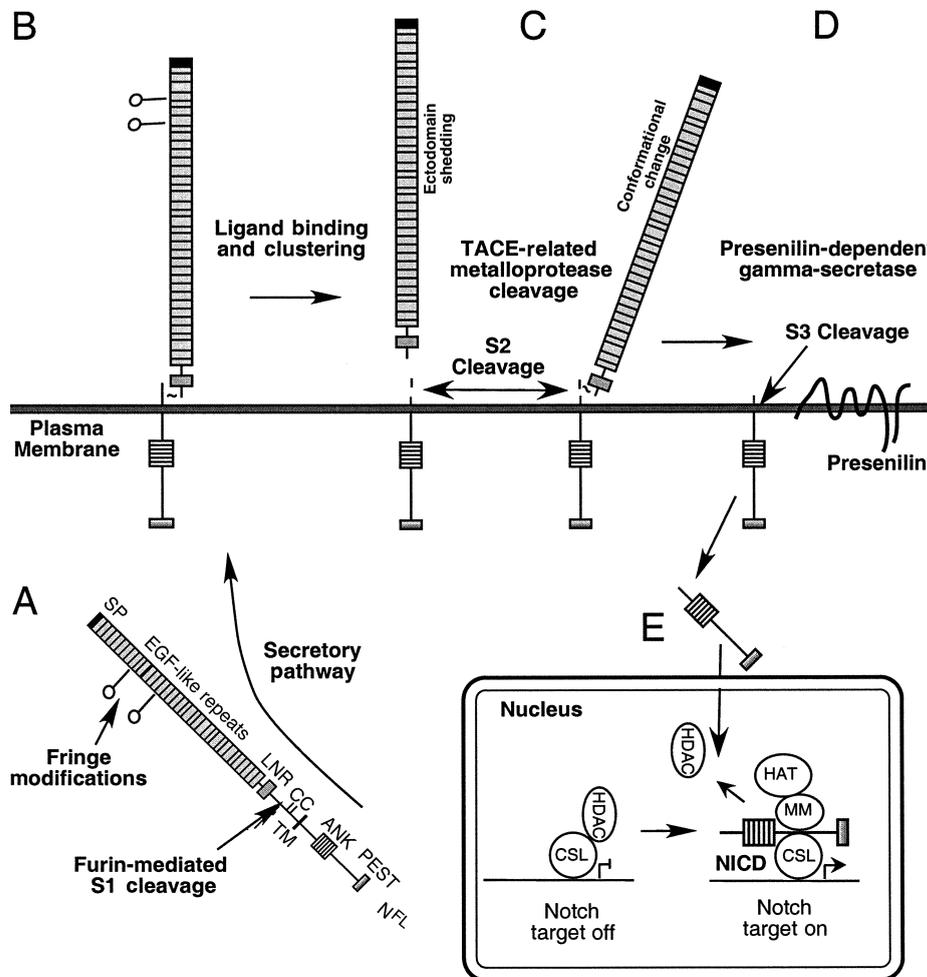

Figure 2 Signal transduction in the Notch pathway. (A) Receptors are modified during secretion by addition of sugar residues by the Fringe proteins as well as by a Furin cleavage that produces a heterodimeric receptor linked by metal bridge. (B) Ligand binding leads to receptor clustering which exposes an S2 cleavage site either by ectodomain shedding or a conformational change (C). Following S2 cleavage, the remaining receptor in the membrane is cleaved at S3 by a presenilin-dependent protease activity. (E) This cleavage releases the intracellular domain that then moves to the nucleus and associates with the CSL proteins to modulate transcription. In the absence of NICD, the CSL proteins repress transcription by associating with co-repressors with histone deacetylase (HDAC) activity. Binding of NICD to the CSL proteins displaces the co-repressor complexes and recruits co-activators including the mastermind (MM) proteins, which in turn recruit proteins such as p300 and CREB binding protein (CBP) with histone acetyltransferase (HAT) activity.

receptors, mutations in the ligands are associated with several disease states. Haploinsufficiency in the *Jagged1* gene is tightly associated with Alagille’s syndrome; a human autosomal dominant, developmental disorder characterized by liver, heart, eye, skeletal, craniofacial, and kidney abnormalities [13]. A mutant *Delta3* gene is tightly linked with a skeletal abnormality spondylocostal dysplasia in humans, [22] and is responsible for the skeletal defects seen in the pudgy mouse [23].

Vertebrate Notch Signal Transduction

The mechanism used in vertebrates to transduce a Notch signal is largely the same as that used in *Drosophila* and *C. elegans*, and is one where the NICD is released from the

plasma membrane, moves to the nucleus, and serves as a dedicated transcriptional co-activator for the CSL proteins (Fig. 2) [24–28]. CSL is the name given to essentially the same DNA binding protein found in different species (CBF1, vertebrates; SuH, *Drosophila*; Lag 2, *C. elegans*), and this particular form of Notch signaling is termed the CSL-dependent pathway. Evidence for a CSL-independent form of Notch signaling exists in vertebrates [29], but the nature of this pathway remains poorly understood. In *Drosophila*, several examples of CSL-independent signaling by Notch have been described including one that is transduced by a cytoplasmic RING domain protein, called Deltex, [30,31], a second involving the abl tyrosine kinase during axon guidance [32], and a third involving the c-Jun N-terminal kinase (JNK) during dorsal closure [33].

Although the components involved in these pathways are found in vertebrates, including vertebrate homologs of Deltex [34–36], their contribution to Notch signaling during vertebrate development remains largely unexplored. These alternative pathways may gain further prominence as Notch signaling is studied in cases other than those involving cell fate choices, such as the reported effects of Notch signaling on the remodeling of neuronal dendrites [37,38].

The idea that NICD moves between the membrane and the nucleus was at first controversial [39] but became more generally accepted with the discovery of other dual-address transcription factors such as SREBP, which are activated by regulated intramembranous proteolysis (RIP) [40]. In the case of Notch, a key step in RIP (Fig. 2D) is carried out by a presenilin-dependent gamma-secretase activity that is also known for its role in processing the beta amyloid protein precursor (β APP) into soluble peptides that potentially contribute to Alzheimer's disease [41,42]. Mutations in the presenilin homologs in *Drosophila* and *C elegans* disrupt Notch signaling, and subsequent biochemical experiments indicated that this activity cleaves the Notch receptor within the transmembrane domain at a site referred to as S3 [43]. By analogy with β APP, the S3 cleavage of Notch is thought to occur constitutively upon the formation of a suitable substrate generated by other proteolytic processing events [44]. In the case of Notch, the substrate for S3 cleavage can be generated by cleaving the receptor by a TACE-related metalloprotease at a second site (S2), which lies extracellularly between the transmembrane domain and the conserved paired-cysteines (Fig. 2C) [45–47]. Thus the current model suggests that activation of the receptor induces changes that permit cleavage at S2, resulting in a substrate that is constitutively processed at S3, thereby releasing NICD from the membrane.

How ligand activation regulates cleavage of the receptor at S2 is not fully known, but one insight into this issue comes from the observation that forms of the receptor lacking an extracellular domain are constitutively processed at both S2 and S3 [45]. In the absence of ligand, the S2 cleavage site of the full-length receptor may be masked by interactions with another region in the extracellular domain, most likely the conserved Lin12/Notch repeats. The S2 cleavage site might be exposed during ligand binding through conformational changes that disrupt this inhibitory domain (Fig. 2B). Alternatively, for reasons discussed next, ligand binding might expose the S2 cleavage site by promoting the shedding of the receptor ectodomain (Fig. 2B). The Notch receptors could easily undergo ectodomain shedding because they reach the cell surface as heterodimers that are produced during secretion by cleavage with a Furin-like protease at a site called S1 (Fig. 2A) [48]. Disrupting the metal bridge that holds this heterodimer together exposes the S2 cleavage site [49], but whether or not this is ligand regulated is unknown. Regardless of whether the S2 cleavage is promoted by a conformational change or by ectodomain shedding, the proteolytic processing of the receptor is apparently inefficient, producing only small amounts of NICD that are

difficult to detect biochemically, even though they are effective physiologically [50].

Upon release from the membrane, NICD associates with the CSL proteins, thereby converting these DNA binding proteins from transcriptional repressors into transcriptional activators (Fig. 2E) [27]. A prominent group of genes that are upregulated directly by Notch signaling encode basic helix-loop-helix (bHLH) transcriptional repressors [51], such as the HES and HRT genes in mouse [5,24,52], the HER/HRT genes in zebra fish [53,54], and the ESR genes in *Xenopus* [55]. Activation of these genes is dependent on tissue type and developmental context, indicating that Notch transcription in most cases acts in combination with additional transcriptional cofactors [56]. Additional complexity is likely to come from various proteins that are recruited by the Notch transcription complex that both positively and negatively regulate its activity. Further description of the mechanisms by which Notch regulates transcription of these genes via the CSL proteins are reviewed in more detail in Chapter 294.

Regulation of the Notch Ligands

One important feature of the Notch signaling pathway is that all of the known ligands presumably activate receptors on neighboring cells as membrane-bound proteins. Indeed, when secreted forms of the Notch ligands are engineered and expressed *in vivo*, they inhibit Notch signaling [57,58], suggesting that they bind but do not activate the Notch receptors. In cultured cell experiments, soluble ectodomains of the vertebrate ligands are much less effective at activating Notch signaling than membrane-bound ligands expressed on cells and used in co-cultivation assays [19]. Significantly, among the effective soluble Notch ligands are those engineered by fusing the ligand extracellular domain to the FC portion of antibodies, known as ligand-bodies. Ligand bodies activate Notch signaling but are the most effective when crosslinked extensively using FC antibodies or immobilized on plastic surfaces [59,60]. As a practical matter, these reagents have proved to be important tools for activating Notch signaling in many experimental systems [61]. Moreover their properties suggest that a simple monomeric interaction between the Notch ligands and receptors is not sufficient for receptor activation, but that clustering of the normally membrane-bound ligands may be required for signaling [62].

Even though the intracellular domains of the vertebrate Notch ligands (LICD) are not highly conserved in primary sequence, ligands lacking this domain are also potent dominant-negative inhibitors of Notch signaling [63,64]. Recent evidence suggests that one function of the LICD is to facilitate interactions between the ligands and the intracellular machinery that promote endocytosis into endosomes and perhaps other intracellular events that traffic ligands back to the cell surface or to destruction [65]. These trafficking events are regulated by ubiquitination and at least one E3 ubiquitin ligase, called neuralized, has been shown to promote the endocytosis of Notch ligands [66–68]. The function of ligand trafficking, and thus the LICD, in Notch signaling

may be threefold. First, ligand endocytosis may be one means of promoting ligand clustering on the cell surface and thus receptor activation as described above [62]. Second, ligand trafficking could be used to produce asymmetric levels of ligand among populations of cells in cases where Notch signaling regulates cell fate by the process of lateral inhibition (see the following section). Finally, ligands lacking an intracellular domain may accumulate on the cell surface, resulting in a block of Notch signaling, presumably because ligand, at high levels, sequesters the Notch receptor into nonproductive cis-complexes [69]. Thus, ligand trafficking may be needed for the ligand to function in signal-emitting cells, as well as to keep ligand levels in a range that permits the Notch receptor to be activated in signal-receiving cells.

The ability of the ligands to bind and activate the Notch receptors is also regulated by a mechanism first found in *Drosophila* through the analysis of the *fringe* gene [70]. *Fringe* encodes a 1,3 *N*-acetylglucosamine transferase [71,72] that modifies an *O*-fucose linkage on a subset of the EGF-like repeats of Notch, thus enhancing activation of the receptor by Delta but inhibiting activation by Serrate [73]. The vertebrate genome contains three fringe homologs [74] that clearly interact at least in some cases with the Notch pathway [75–77]. Experiments in cultured cells have shown that mammalian lunatic fringe potentiates the ability of mammalian Notch1 to respond to signaling by Delta1 but inhibits the response to Jagged1 [9,78]. Significantly the change in ligand activation produced by lunatic fringe is not at the level of ligand binding, but rather at the level of receptor activation. One area where the fringes regulate Notch activity in vertebrates is during segmentation where they modulate signaling in a periodic fashion (see the following section).

Notch Signaling in Vertebrate Development

A large body of work has implicated the Notch pathway in the development of a variety of tissues in the vertebrate embryo. The ubiquitous contribution of Notch signaling to vertebrate development makes generalization difficult, particularly when, in many cases, the exact function of Notch signaling in a given developing tissue is still poorly understood. Nonetheless a few common themes are clear. First, the Notch pathway is commonly used to control the fate of progenitor cells, often through genetic interactions with the bHLH transcription factors. These interactions can take on many different forms, and examples are discussed in the following section where the dynamic output of Notch signaling is used to produce salt-and-pepper patterns of cell differentiation (neurogenesis) or sharp boundaries of differentiation between two groups of cells (segmentation). Second, during many developmental processes, rapid changes occur in the expression and/or activity of the Notch ligands or in the ability of cells to respond to Notch activation. Examples of this regulation are discussed in the context of lateral inhibition. Finally, Notch signaling is not likely to be limited to the regulation of cell fate, but may also have

roles in cell proliferation, death, and morphology. A challenge for the future is to explore these other roles as the Notch pathway is examined in the context of developmental processes as hematopoiesis, vascularization, and limb development.

Notch Function during Neurogenesis

One function of Notch during vertebrate development is to regulate the activity of bHLH proteins that promote the differentiation of neural precursors into neurons. This regulation mirrors almost identically one that was first uncovered by genetic studies in *Drosophila*, where Notch signaling restricts the formation of neuroblasts or sensory organ precursors by regulating the activity of the proneural bHLH proteins [79]. In vertebrates, this interaction has been studied extensively in fish and frog embryos during primary neurogenesis where an early-born population of neurons is generated from neural progenitors located within discrete domains of the neural plate [63,80–82]. Within these domains, expression of bHLH proteins such as the neurogenins initially occurs in a relatively uniform pattern, thus establishing progenitor cells that can give rise to neurons [83,84]. While the neural bHLH proteins promote neuronal differentiation cell-autonomously, they inhibit neuronal differentiation non-cell-autonomously by promoting the expression of the Delta ligands [82,83], which activates Notch signaling in neighboring cells (Fig. 3A). Activation of Notch leads to the upregulation of genes encoding bHLH repressors, such as the ESR genes in *Xenopus* and the HER genes in zebra fish [53,55], which then act to antagonize the expression/activity of the neural bHLH proteins, both in terms of their ability to promote neuronal differentiation and to activate the expression of Notch ligands [51]. Blocking Notch signaling during primary neurogenesis results in a marked increase in the expression of the neural bHLH proteins within each proneural domain, with a corresponding increase in the number and density of neurons that subsequently differentiate. Conversely, increased Notch signaling in gain-of-function experiments represses the expression of the neural bHLH proteins and blocks neuronal differentiation.

Significantly, by restricting the number of progenitors that form neurons, Notch signaling keeps progenitor cells uncommitted, making them available for alternative neural fates, such as the neural crest [84]. Indeed, it is hard to argue that the *raison d'être* of Notch signaling is to regulate neuron number since neurons are usually overproduced in many regions of the developing nervous system during neurogenesis and then eliminated later on by cell death. It is also not likely that Notch exists to ensure that neurons differentiate in a precise spatial pattern since neurons undergo extensive migration to reach their final destination. Rather, Notch seems to be required to maintain a population of uncommitted precursors, which can contribute to later-born cell types that are generated over the protracted course of neural cell differentiation [85].

Studies of Notch function during secondary neurogenesis suggest that Notch signaling is used widely to maintain cells

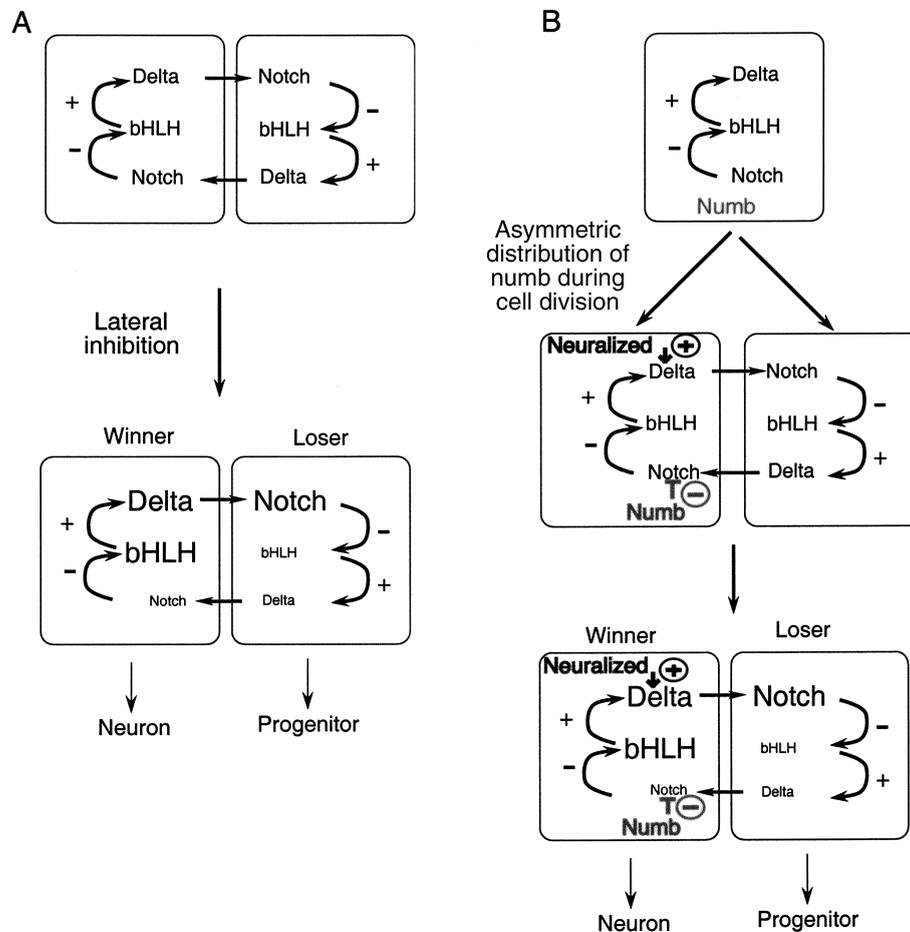

Figure 3 Lateral inhibition. (A) Genetic interactions between the Notch pathway genes and the differentiation bHLH proteins result in winners and losers during lateral inhibition. In this model, bHLH proteins promote neuronal differentiation cell autonomously but also inhibit neuronal differentiation in neighboring cells by activating the expression of ligand activating Notch, which inhibits the activity of the bHLH proteins. As a result, an unstable situation ensues in which some cells will tend to increase both bHLH activity and their ability to inhibit their neighbor (winner) while other cells will do the opposite (loser). (B) Example of mechanisms that preordain the outcome of lateral inhibition. In one case, the cytoplasmic determinate numb is asymmetrically localized to one daughter cell during division. Notch signaling is disabled in the cell that inherits numb, ensuring that this cell wins lateral inhibition while its sister loses. In another case, the protein neuralized is asymmetrically activated in one cell, and promotes Delta signaling by promoting its endocytosis in one cell, thus ensuring that it wins lateral inhibition.

in a progenitor state by preventing their differentiation en masse into neurons [86]. In the retina, loss of Notch function results in an excess production of early-born neuronal cell types at the expense of cell types that would be generated at later stages, while expression of activated forms of Notch activity in the retina represses neuronal differentiation [87–89]. Similarly, functional studies of Notch in neural precursors in the developing forebrain, the cerebellum, or in neural stem cells isolated from either the central or peripheral nervous system also point to a role for Notch in inhibiting neuronal differentiation [61,90–95]. Finally, Notch signaling negatively regulates the differentiation of hair cells in the inner ear as well as the differentiation of a mechanosensory neuron, the neuromast, in the developing lateral line of fish [20,96–98].

In cases where Notch inhibits neuronal differentiation, it seems to act by inducing the expression of the bHLH repressors that inhibit the activity/expression of the proneural bHLH proteins [5,99,100]. As a result, the role of Notch as a regulator of cell fate during neurogenesis has been viewed as permissive rather than instructive in nature. However, in some cases, expression of activated Notch in progenitor cells not only represses neuronal differentiation, but also promotes the differentiation of glial cells. For example, activated Notch promotes the differentiation of a later-born glial cell type, the Müller cell, in the retina [101], radial glial cells in the forebrain [90], myelin-producing glia in cultures of neural crest stem cells [61], or astrocytic glia in CNS neural stem cell cultures [95]. Nonetheless, it remains unclear whether Notch acts instructively in these cases since

the targets of Notch required for glial differentiation are unknown [90].

Lateral Inhibition

During primary neurogenesis, the levels of RNA encoding the Notch ligand and to some extent the receptor change rapidly among progenitor cells. These changes have been attributed in part to the fact that the bHLH proteins not only promote neuronal differentiation but also promote the expression of the Delta-like ligands [82]. Activation of Notch therefore not only inhibits neuronal differentiation but also the ability of that cell to produce ligand and inhibit its neighbors (Fig. 3A). In principle, these interactions produce a dynamic negative feedback loop, called lateral inhibition, which amplifies differences in ligand expression between neighboring neural progenitor cells and generates winners that go on to form neurons (Fig. 3A)[102,103]. At one extreme, lateral inhibition has been proposed to act as a self-organizing selection process that uses the negative feedback loop to generate a salt-and-pepper pattern of ligand expression and differentiation from an initially equivalent population of neural progenitors (Fig. 3A). However, at the other extreme, lateral inhibition has been proposed to reinforce a bias that arose by another mechanism. An example of the latter has been described in *Drosophila*, whereby an asymmetrically localized, cytoplasmic determinant encoded by *Numb* has been shown to determine the fate of two daughter cells by regulating Notch signaling (Fig. 3B) [104,105]. In a similar manner, the vertebrate homologs of *Numb*, *numb*, and *numb-like*, may also determine cell fate by regulating Notch activity in the nervous system [106–109]. Another example is the protein *neuralized* which potentially promotes Delta activity, thus ensuring that certain cells consistently win lateral inhibition (Fig. 3B).

Notch and bHLH Factors

The role of Notch in regulating the differentiation of progenitor cells by targeting the activity of bHLH proteins is not restricted to the developing nervous system. Activated forms of Notch inhibit myogenesis in cultured myoblasts and this phenomenon has served as a model system for exploring potential inhibitory interactions between Notch and both myogenic bHLH proteins and associated transcription factors such as MEF2 [29,110–113]. Upregulation of MyoD and subsequent myogenic differentiation can also be blocked in chick embryos by Notch in gain-of-function experiments [114], but whether or not this regulation normally plays a physiological role *in vivo* is still unexplored. In the developing pancreas, there is strong genetic evidence showing that endodermal cells differentiate into an endocrine cell fate in response to a bHLH protein, neurogenin 3, and this differentiation step is inhibited by Notch signaling [115–117]. In a manner similar to that observed during neurogenesis, disabling Notch signaling, or the putative Notch target gene *HES1*, greatly increases the expression of neurogenin 3,

resulting in a premature production of endocrine cells. Thus, the pancreas is another case where cell differentiation is promoted by a bHLH protein but inhibited by the Notch pathway [118].

Notch Function during Vertebrate Segmentation

During lateral inhibition, Notch signaling is used on a cell-by-cell basis to control cell fate. However, the study of Notch signaling in invertebrate embryos has also emphasized its role in patterning larger tissue domains such as when it is used to regulate the size of veins [119] or used to specify the margin in the developing *Drosophila* wing disc [120]. In an analogous manner, Notch signaling is also used in vertebrate embryos to pattern larger tissue domains, a particularly striking example of which occurs during segmentation of the mesoderm into somites.

Somites are the repeating, metameric building blocks of the vertebrate body plan that arise in early development from two bilateral sheets of cells, called the paraxial, or presomitic, mesoderm (PSM), which lie on both sides of the notochord [121]. Somites do not form en masse, but in an anterior to posterior progression, one unit arising at a regular interval every 30–90 minutes depending on the species. Because the process is progressive, a “differentiation wavefront” has been proposed that determines the point along the anterior-posterior (A/P) axis where paraxial cells mature and form a somite (Fig. 4A). However, to divide this differentiation process into a periodic pattern a segmental clock has been proposed which oscillates on and off during each segmental cycle, thus specifying the boundary between one somite and the next [121].

A role for the Notch pathway in somitogenesis was first evident from defects in somite morphology observed in mice with targeted mutations in the *Notch1* gene or in the CSL protein, RBPjk [6,122]. Subsequently, the expression pattern of Notch pathway genes within the PSM revealed the formation of a segmental pattern of gene expression that prefigures the formation of somites. Indeed, based on this pattern, one could identify 1–3 segments, depending on the species, within the presomitic mesoderm (S0 to S-3 in Fig. 4A) [17]. Moreover, further analysis has produced a wealth of evidence indicating that Notch signaling is required for generating this segmental patterning, and that it contributes to this process somewhat as a component of the segmental clock [123]. First, the pioneering work of Pourquie and colleagues showed that genes encoding bHLH repressors oscillate in expression within the undifferentiated paraxial mesoderm with a periodicity corresponding to one segmental cycle (Fig. 4A) [124–127]. While it is not yet clear in all cases whether these genes are direct targets of Notch-mediated transcription, evidence from mouse and zebra fish indicate that their oscillatory expression is dependent on Notch signaling [127–129]. Secondly, Notch signaling seems to be activated synchronously within the paraxial cells during each segmental cycle. In fish and frog, the expression of RNA encoding the Notch ligand cycles off and on during

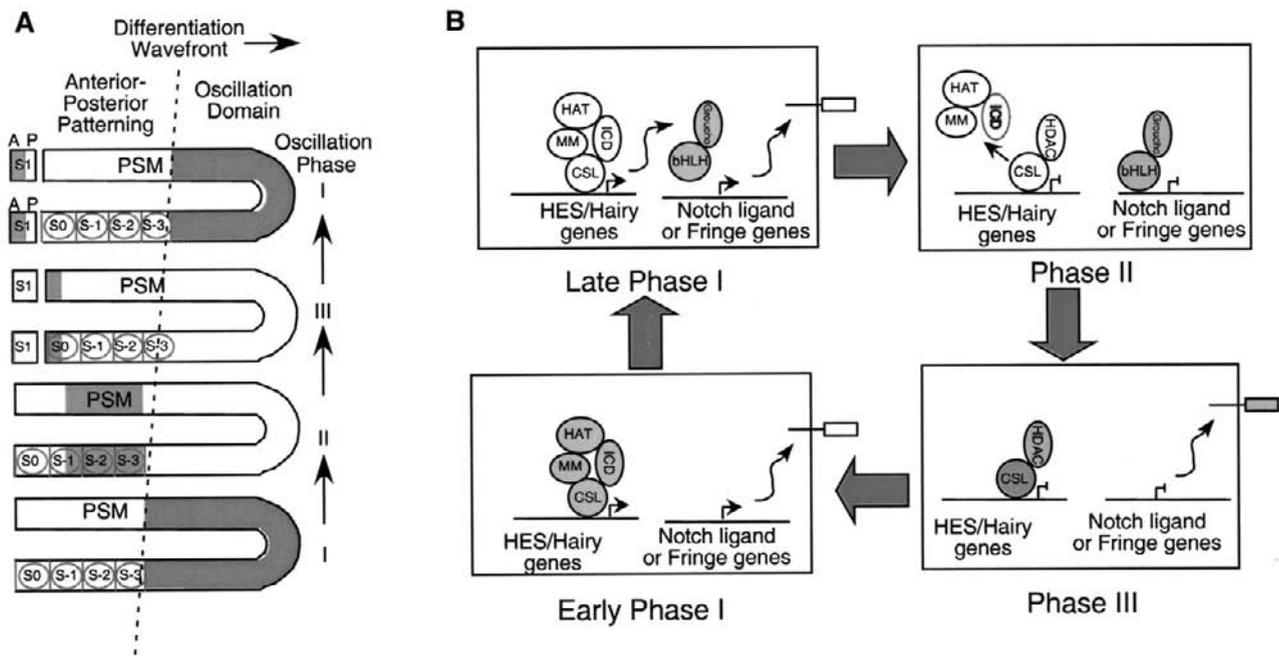

Figure 4 Model for Notch signaling during segmentation. (A) Somites form from the presomitic mesoderm (PSM) at regular intervals, with the most recently formed somite called S1. Each somite is divided into an anterior (A) and posterior (P) half (green shading). Notch signaling potentially plays two roles when segments (S0–S3) are generated within the PSM. In the more caudal region of the PSM (oscillatory domain), Notch signaling oscillates on and off during each segmental cycle (blue shading). This oscillation has been proposed to be part of the segmental clock that establishes segmental boundaries (purple lines). In the more rostral portion of the PSM (anterior-posterior patterning), Notch signaling may also act to subdivide segments into two halves by undergoing a dynamic refinement from a broad domain to a narrow half-segmental domain (red shading). (B) Model for the oscillation in Notch signaling that underlies the segmental clock. In this model, the bHLH repressors form a negative feedback loop that generates an oscillation much the same way the transcriptional repressors underlie oscillation in gene expression during circadian rhythms. A key element in the model shown is that the expression of a bHLH repressor (bHLH-groucho) is activated during each segmental cycle via Notch signaling, which then turns off the expression of genes required for Notch signaling, such as the Notch ligands or the fringe genes.

each segmental cycle within the undifferentiated paraxial mesoderm [130]. In contrast, ligand RNA expression is relatively uniform in the paraxial mesoderm of mouse and chick, but cycling is observed instead in the expression of RNA encoding the Notch modifier lunatic fringe [77,131]. Finally, mutations in these various components of the Notch pathway produce defects in somitic boundaries, indicating that the oscillating expression of these genes is critical for proper segmentation [76,77,126,129,132]. The exact role of Notch signaling in the segmental clock is still a matter of debate. One possibility is that the Notch pathway is the clock itself in which oscillations in gene expression are generated by Notch activation of the repressor bHLH proteins which then negatively feed back to shut down their own transcription by repressing the expression of the ligands or the fringe genes (Fig. 4B) [128]. Alternatively, Notch signaling may be downstream the target of a master clock, which drives the cyclic expression of components in the Notch pathway, perhaps as a means of synchronizing the phase of the clock among paraxial cells [130].

Establishment of boundaries during somitogenesis is tightly associated with the division of each somite into an anterior and posterior half, which is marked by the restricted expression of Notch ligands [121]. This A/P somite polarity has important functional consequences since it imposes

segmental organization on the spinal cord and peripheral nervous system [133]. Loss of somite A/P polarity occurs in many cases where Notch signaling is disrupted during somitogenesis, indicating that Notch may also have a secondary role in polarizing somites along the A/P axis [121]. Significantly, the Notch pathway may contribute to A/P polarity by regulating the expression of the Mesp-like bHLH proteins [134,135]. Thus, the output of Notch signaling seems to specify domains of bHLH gene expression and thus patterns of differentiation during segmentation, in a manner that is similar to that seen during neurogenesis.

Notch Signaling in the Limb

The limb is another prominent example in vertebrate development where the contribution of Notch signaling to tissue patterning has been examined in some detail. In this case, Notch signaling contributes to the formation of a structure, called the apical epidermal ridge (AER), which forms at the boundary between the dorsal and ventral limb epidermis [120]. In chick limbs, Notch signaling may be modified during this process by a vertebrate homolog of *Drosophila* fringe, called *radical fringe*, which is expressed in the dorsal but not ventral limb epidermis [136–138]. When ectopically expressed ventrally using retrovirus vectors,

radical fringe induces ectopic AER cells as does an activated form of Notch, while a dominant-negative form of the CSL proteins inhibits AER formation. It remains uncertain, however, whether these findings extend to the mouse where targeted mutations in *radical fringe* have no effect on limb development, although the situation is further complicated by potential genetic redundancy with the two other mammalian fringe genes, *lunatic* and *manic* [139]. Expression of the Notch ligand *Jagged2* is localized to the AER, and mice with targeted or naturally occurring mutations in this gene develop with syndactyly in both fore- and hindlimbs [140,141]. Additional work is needed to determine whether Notch signaling is a necessary factor in generating the AER, or whether it only has a secondary role in its maintenance and/or function.

Notch Signaling and Lymphoid Development

The hematopoietic system is an impressive example of cell diversification, and thus it is not surprising that the Notch pathway may have multiple roles in regulating cell fate as hematopoietic progenitors become progressively restricted in their developmental potential. The best evidence in this respect is for a role in Notch signaling in directing the differentiation of lymphoid-restricted progenitors into a T-cell versus a B-cell fate as these cells pass through the thymus and bone marrow, respectively. In mice where Notch1 is conditionally ablated in lymphocytic progenitors using the CRE-LOX system, T-cell development is inhibited [142] with a corresponding increase in intrathymic B cells [143]. Conversely, expressing activated Notch in bone marrow progenitors promotes extrathymic development of T cells and represses the development of early B cells [144]. A major unresolved issue is why Notch signaling is preferentially promoted in the thymus where T-cell development occurs [145] but repressed in the bone marrow during B-cell development. One likely target of Notch signaling within the T-cell lineage is the gene encoding one chain of the pre-TCR receptor whose expression then reinforces a T-cell fate [146], but the targets of Notch signaling that repress B-cell development are unknown.

Several lines of evidence indicate that Notch signaling influences the subsequent diversification within the T-cell lineage where progenitors are restricted further between a $\gamma\delta$ or $\alpha\beta$ fate or between the CD4 versus CD8 T-cell fate [147,148]. While most attention has been given to the role of Notch in the CD4/CD8 choice, how Notch affects this T-cell subdivision remains controversial [149–152]. The phenotypes reported for alterations in Notch signaling in this context may differ due to experimental differences in the forms of activated Notch used and how these forms were expressed in developing thymocytes. Nonetheless, one idea with far-reaching implications produced by this work is that Notch signaling may not be acting in the CD4/CD8 switch to influence cell fate per se, but rather to regulate such processes as lineage-specific cell death or differentiation. If this is indeed the case, then the targets of Notch signaling may be more

extensive than previously appreciated, and inappropriate expression of such targets may potentially contribute to oncogenic transformation when the Notch pathway goes awry [153].

Notch Signaling during Vascular Development

Another venue where Notch signaling may control developmental processes other than simple cell fate choices is vascularization [154]. Indeed, one of the major reasons why mutations in the Notch pathway lead to embryonic lethality is defects in vascularization. These defects are likely to be due, in part, to a misspecification of angioblasts along an arterial or venous fate, thus producing profound defects in the how the vascular network is established. In zebra fish, loss of Notch signaling in fish embryos leads to a loss of artery-specific markers and a corresponding ectopic increase in cells that express venous markers [155]. Conversely, activated Notch signaling suppresses the expression of markers of venous differentiation. A potential direct target of Notch signaling during this process is a bHLH repressor encoded by the gene *gridlock*, which is also required genetically for establishing an arterial over a venous fate [54]. Further evidence for a role in vascular development comes from targeted mutations in various components of the Notch pathway in the mouse. Severe vascular defects associated with angiogenesis occur in mice that are double-mutant for both Notch1 and Notch4 [3]. Misexpressing the Notch4 intracellular domain specifically within the endothelial lineages produces a striking disorganization of the vascular network, indicating that Notch signaling acts in part by regulating some aspect of angioblast differentiation [156]. Both the *Jagged1* and *Delta1* knockout mice die at early embryonic stages with defects in vascular morphology [21,157] and a fourth ligand, *Delta4*, is expressed even earlier in the developing arterial system [3,16]. Thus, Notch signaling is likely to be required within the endothelial cells during the processes that elaborate the vascular network. Whether Notch functions simply as a regulator of cell differentiation or whether it has multiple roles during vascularization remains to be determined. Given that several Notch ligands and receptors are expressed with varying degrees of genetic overlap during vascular development, the role of Notch signaling during this process is likely to be quite complex.

Aspects of Notch Signaling in Other Organ Systems

The discussion thus far has focused mainly on the prominent examples of where Notch signaling has been shown to act during vertebrate development. However, this list is incomplete given the variety of tissue defects that have been described in various mouse mutants or combination of mutants in components in the Notch pathway. For example, mice with a hypomorphic mutation in Notch2 die from kidney defects that are most apparent within the developing glomeruli, and also show defects in various aspects of heart and eye development [158]. Various combinations of mutant

forms of Notch2 and Jagged1 result in liver defects and other abnormalities that mimic those found in Alagille's syndrome [159]. In addition, the early lethality of the mouse mutants in many components of the Notch pathway has precluded the analysis of the pathway in tissues that develop at later stages, a problem that can be overcome by generating conditional knockouts. Based on both gene expression and functional studies, there is already a clear indication that Notch signaling has additional diverse roles in vertebrate development, including the patterning of the forebrain [160], the differentiation of oligodendrocytes into myelinating cells [161], the differentiation of epidermal stem cells into keratinocytes [162], and the formation of the lung [163].

Summary

Over the last ten years, the Notch pathway has emerged as one of the key signaling pathways operating during vertebrate development. In many cases, Notch signaling is used widely in vertebrate development to regulate cell fate often by activating the expression of bHLH repressors which in turn regulate the expression and/or activity of bHLH activators. These interactions can determine patterns of differentiation that range from salt-and-pepper to segmental. The role of Notch is not likely to be exclusive to cell fate decisions, but emerging evidence suggests that it might regulate a variety of cellular events ranging from differentiation, morphogenesis, and cell death to proliferation. A key goal of future studies is to identify the various gene targets of the CSL-dependent pathway that mediate these events, or to elucidate parallel pathways in which Notch signals by a CSL-independent mechanism if they exist. In addition, the diversity of Notch signaling is likely to depend in part on functional diversity of ligands and receptors, about which we still know very little. Finally, the Notch signaling pathway is likely to contribute to various human diseases, but more needs to be done to identify the nature of these lesions and how they alter cell physiology.

Reiterative and Concurrent Use of EGFR and Notch Signaling during *Drosophila* Eye Development

Raghavendra Nagaraj and Utpal Banerjee

*Departments of Molecular Cell and Developmental Biology,
Biological Chemistry, and Human Genetics,
Molecular Biology Institute, University of California at
Los Angeles, Los Angeles California*

Notch and epidermal growth factor receptor (EGFR) pathways are conserved throughout evolution and function together in many different developmental contexts. During the specification of the *Drosophila* eye, these two pathways either function in synergy or in opposition to achieve different outcomes. Similarly, in some instances, EGFR activation causes a serial activation of the Notch pathway through the control of the Notch ligand Delta, while in others, the two pathways act together on the same enhancer element in parallel to control target gene expression. We propose that the combinatorial effects of these two pathways have evolved as a network that generates a significant diversity in output with a small number of components used in a reiterative fashion.

Introduction

Intercellular signaling plays a critical role in the establishment of the body plan and cell fate during the development of multicellular organisms. The variation in the cell fates adopted is quite extensive; yet the number of conserved signaling pathways that mediate a majority of cell-cell interactions is extremely limited [1]. These few signaling pathways are used reiteratively and evoke specific responses depending upon the context in which they function. Understanding how this context is created within an equipotent group of

cells is fundamental to our understanding of the role of cell-signaling in fate specification during development.

The *Drosophila* compound eye consists of a large number of ommatidia (facets), each containing a fixed number of cells: eight photoreceptor cells (R cells), four non-neuronal cone cells, three classes of pigment cells, and a bristle complex [2]. The fate of these cells is not derived by clonal mechanisms but through cell-cell communication [3]. The *Drosophila* eye develops from a sheet of epithelial tissue called the eye imaginal disc. In the third larval instar an indentation called the morphogenetic furrow (MF) initiates at the posterior tip and sweeps anteriorly across the disc. As cells emerge out of the furrow they attain the competence to respond to signaling pathways and initiate differentiation in a precise order (Fig. 1). The photoreceptors are the first cells to differentiate, followed by the cone cells and the pigment cells. This led to the hypothesis that unique signals from differentiated cells will sequentially induce the precursors of later developing cell types [4]. The molecular basis for such a combinatorial model is now becoming clear. The biggest surprise is that the signals involved are not very specific and that a small number of common signaling pathways and transcription factors can combine in different ways to generate a tremendous diversity of readouts [5–8]. The EGFR and Notch signaling pathways are prominently involved in this process. All components of these pathways, except the ligands, are ubiquitously expressed. The spatiotemporal

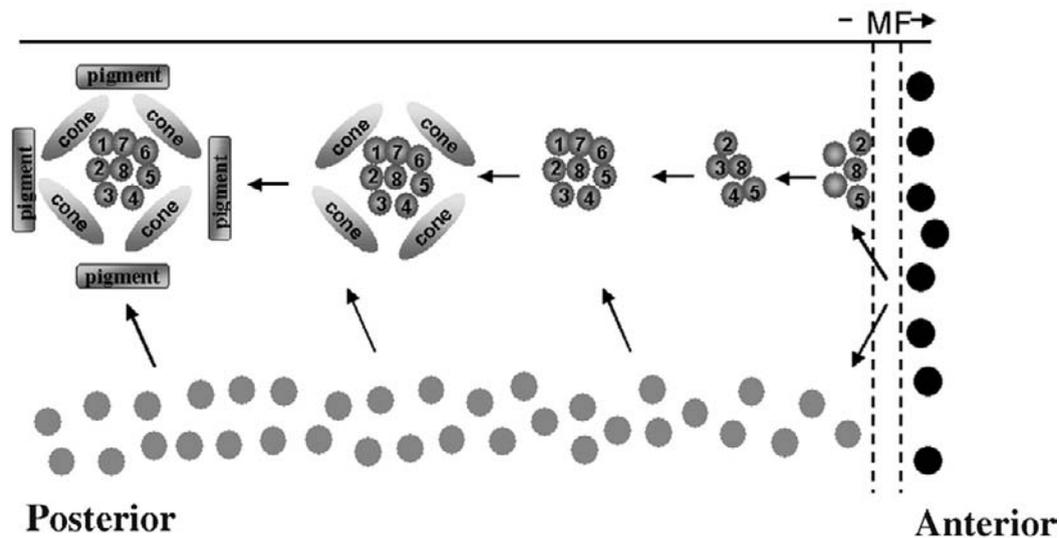

Figure 1 A schematic representation of cell fate specification during eye development. Cells ahead of (anterior to) the morphogenetic furrow (MF) are pluripotent and undergo extensive proliferation. The MF marks the onset of cell fate specification. The precluster cells (R2–R5, R8) differentiate first from cells ahead of the furrow. Cells that do not join the precluster undergo a single round of mitosis and become precursors to the rest of the cells in the ommatidial cluster (R1, R6, R7, Cone, and Pigment cells).

control of the ligand determines the cells in which a mosaic pattern of activated transcription factors is generated. In this chapter we briefly discuss steps in *Drosophila* eye development in which the Notch and EGFR pathways combine in different ways to generate unique outputs.

Establishment of the Eye Primordium

The *Drosophila* eye and antenna both arise from a single primordium at stages 14–15 of embryonic development [9], and only later the posterior region of this common primordium differentiates into the eye disc while the anterior region gives rise to the antenna. Expression of either a dominant-negative version of Notch or an activated version of EGFR in the common primordium converts the eye tissue into antenna [10]. This interplay of signals is important for the expression of Eyeless (DPax-6) in the aspect of the tissue that will give rise to the eye. Eyeless encodes a conserved transcription factor containing a Paired and a homeodomain and functions as a pivotal control point for a network of genes that establish eye fate [11]. Although the directness of the signaling control is not yet clear, it seems that Notch signaling is required for the expression of Eyeless, while EGFR antagonizes Notch-mediated Eyeless expression [10,12]. A balance between these two pathways is crucial for the specification of the eye primordium. It seems that such a balance is invoked repeatedly to create unique cell fates.

Proliferation and D/V Patterning

The eye disc primordium undergoes extensive proliferation during the later embryonic stages, as well as in the first and second larval instars. During late stages of the second

larval instar, the eye disc primordium is patterned along the dorso-ventral (D/V) axis [13]. The segregation between the dorsal and ventral regions is not along traditional compartmental boundaries. Rather, the dorsal and ventral halves of the eye disc express distinct ligands for Notch. Cells in the ventral region express Serrate while those in the dorsal region express Delta (Dl) [14]. These ligands function differentially with the Fringe protein such that they activate Notch only at the boundary. This promotes the specification of a D/V organizer, which initiates cell proliferation and patterning along its edges [14]. Loss of EGFR at this stage will also cause a block in cell proliferation; however, its possible role in the specification of cell fate at this early stage remains to be established. In a comparable situation in the wing disc, EGFR functions with Notch during D/V boundary specification to control both proliferation and cell fate specification [15].

Morphogenetic Furrow and R8 Specification

Cells ahead of the morphogenetic furrow are undifferentiated and undergo several rounds of mitosis. These cells express all the genes that specify them as eye tissue and can adopt one of many possible differentiated fates upon the reception of an appropriate signal. Ectopic activation of EGFR and Notch in clones of cells ahead of the furrow causes them to differentiate as R cells, suggesting a readiness and capacity of these undifferentiated cells to respond to these signals [16,17].

The signaling pathways most closely linked to the initiation and progression of the morphogenetic furrow are Hh and Dpp (TGF β) [18]. As the furrow progresses along the largely oval shaped disc it needs to be continuously reinitiated at the lateral edges so that it extends across the increasing width of the disc. This reinitiation requires Wingless (Wnt)

signaling, and also the function of EGFR and the Notch pathways [19–21]. Loss of EGFR or Notch causes loss of furrow initiation at lateral edges and activation of EGFR and Notch at the lateral edges ahead of the furrow causes ectopic furrow initiation [21]. This is therefore an example of the EGFR and Notch pathways working cooperatively. In contrast, during the differentiation of the founder cell, R8, at the morphogenetic furrow, EGFR and Notch signals function in an antagonistic manner. EGFR has been proposed to be required for the establishment [22] and maintenance [23] of R8 cell fate, and these cells are lost in mutations that abolish the signal. In contrast, loss of Notch at the morphogenetic furrow causes overspecification of R8 cell types [24]. This is because Notch functions in a lateral inhibitory process at the furrow that helps restrict the number of R8 cells and generate regular spacing between the clusters. This lateral inhibition by Notch is mediated by the activation of repressor proteins of the E(spl) complex, which block the expression of the proneural gene *atonal* and the specification to an R8 cell type [25].

R-Cell Specification

Cells within the morphogenetic furrow are arrested in the G1 phase of the cell cycle. As they exit out of the morphogenetic furrow they follow one of two possible paths. A subset of these cells form “preclusters” consisting of the first five R cells (R2–R5, R8), and those that do not join the precluster undergo a terminal round of mitosis and continue to be pluripotent undifferentiated cells [26]. These cells express a distinct set of transcription factors (e.g., Lozenge) not found in the undifferentiated cells ahead of the furrow from which they are derived [27]. The remaining cell types within an ommatidium (R1, R6, R7, Cone, and Pigment cells) arise from the undifferentiated cells behind the morphogenetic furrow. This second round of recruitment completes the ommatidial cluster and is referred to as the second wave of morphogenesis in the eye [3]. The EGFR pathway is required for the G2/M transition during mitosis that gives rise to the precursors for the second wave [28]. Additionally, EGFR function is also required for maintaining viability and differentiation of all R cells. In contrast, during this later step of R-cell differentiation the function of Notch seems to be more specific. The Notch signal specifies the R4 cell and distinguishes it from R3, a process that is essential for the proper rotation of the ommatidial cluster with respect to the midline (equator) of the eye disc [29,30]. Furthermore, the Notch signal is required for the specification of the R7 cell fate as in its absence R7 cells are converted to an R1/6 type [31].

Sequential Linkage between Notch and EGFR Pathways

Although the Notch signal is required in only a subset of R cells for their proper specification, the Notch ligand *Dl* is

expressed at high levels in all R cells [32]. The *Dl* protein functions in R cells to induce the later arising cone cells [8]. Interestingly, the expression of *Dl* in R cells is under the control of EGFR. A series of gain and loss-of-function studies indicate that loss of EGFR signaling causes a loss of *Dl* expression and ectopic activation of the EGFR pathway causes increase expression of *Dl* [33]. The EGFR-related activation of *Dl* requires the usual downstream components Ras, Raf, and MAPK but also two novel nuclear proteins Ebi and Strawberry notch (Sno) [33]. Ebi encodes an F-box/WD-40 repeat containing protein [34] and Sno codes for a novel nuclear protein [35]. The regulation of *Dl* in photoreceptor cells upon EGFR signaling requires the disruption of a Su(H)/SMRTER repression complex and involves the function of ubiquitin-mediated proteolysis and nuclear export of the co-repressor protein, SMRTER. This study highlights a mechanism whereby the EGFR and Notch pathways are linked in a serial manner. Activation of EGFR triggers a proteasome pathway leading to de-repression of *Dl*, which in turn can activate the Notch signal to be received by the neighboring cone cell precursors (Fig. 2).

Parallel Linkage between EGFR and Notch

The four non-neuronal cone cells are recruited to the ommatidial cluster after the R cells have joined. These cells express specific transcription factors such as D-Pax2, Prospero, and Cut, which are required for proper specification of their fate. The mechanisms that govern the specific expression of these factors have been uncovered in some detail. The expression of D-Pax2 and Prospero depend upon EGFR signaling, Notch signaling, and the transcription factor, Lozenge (Lz), expressed in the pool of undifferentiated cells behind the morphogenetic furrow [27]. Loss-of-function mutations in any one of these three components will cause a

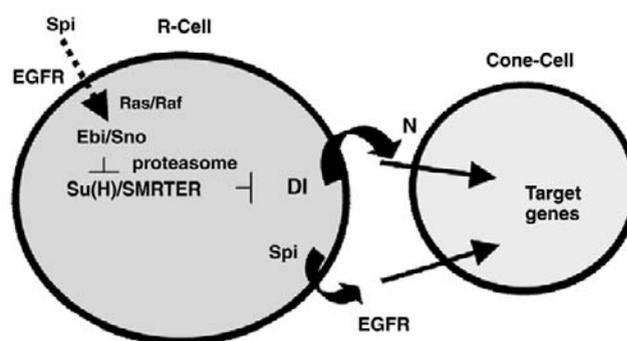

Figure 2 Sequential and parallel link between Notch and EGFR in cone cell specification. In R cells the EGFR and Notch pathways are linked sequentially. Activation of EGFR by its ligand Spi activates Ras/Raf/Sno/Ebi and leads to de-repression of the *Dl* locus by blocking its Su(H)/SMRTER-mediated repression. *Dl* protein expressed in R cells activates Notch signaling in cone cell precursors. These cells express the transcription factor, Lz, and also receive the EGFR signal from R cells. A combinatorial integration of the EGFR and Notch signals activates target genes required for cone cell specification.

complete loss of D-Pax2 and Prospero expression [8,36] (Nagaraj and Banerjee, unpublished). A 350 bp minimal enhancer element within the *D-Pax2* locus recapitulates its expression in the four cone cells in each cluster of the eye disc. Sequence analysis of this enhancer revealed functional binding sites for Lz and for Pointed and Su(H), the nuclear effectors of EGFR and Notch pathways, respectively. *In vivo* mutational analysis of these binding sites established that they are essential for the expression of D-Pax2 in the cone cells. Furthermore, ectopic activation of combinations of Notch, EGFR, and Lz using cell-specific drivers will cause D-Pax2 expression in different combinations of cell types in the eye disc that do not normally express this protein [8]. These results established that EGFR and Notch signals function combinatorially to specify cell fates among a group of pluripotent precursors.

Pigment Cell Differentiation and Apoptosis

The cooperativity and antagonism between EGFR and Notch is also evident in pigment cell differentiation. Cell ablation studies show that cone cells provide an inductive signal for the differentiation of the primary pigment cells [37]. In this function, Notch works combinatorially with EGFR as activation of EGFR is also needed for the specification of primary pigment cells. In contrast, the EGFR and the Notch pathways antagonize each other in promoting the survival of the secondary and tertiary pigment cells [37]. While EGFR promotes survival, Notch signaling in these cells has been proposed to promote cell death. The mechanisms by which these pathways function to regulate apoptosis remain to be established.

Conclusion

This review highlights how EGFR and Notch pathways function together in different ways within the same tissue and within small temporal windows to promote a diversity of cell fate specification events. These pathways can be linked to function in either a synergistic or an antagonistic manner; they can combine in series or in parallel to generate different outcomes. It is unlikely that these two pathways are chosen randomly to function together in so many different developmental decisions. Rather, this suggests the co-evolution of the two pathways to generate an efficient network involving possibilities for crosstalk. This intricate interplay between the EGFR and the Notch pathway can be seen from worms to man. During the induction of vulval fate in *C. elegans*, the anchor cell provides the EGF signal and induces the closest vulval precursors to differentiate into primary fate. This cell in turn uses the Notch signal to influence its neighbors to differentiate into secondary cells [38]. In mouse, differentiation of hematopoietic cells requires RTK and Notch signaling for proliferation and cell fate specification [39]. Finally, in tumor progression, Ras activation causes expression of

DI [40] similar to that observed in the developing *Drosophila* eye [33]. It is likely that the lessons learned from *Drosophila* will be useful in interpreting interactions between these pathways across species.

Introduction

Genes encoding bone morphogenetic proteins (BMPs) and their signaling components are found in many animal phyla, suggesting an ancient function as morphogens in metazoan development [1]. Where it has been possible to make comparisons (e.g., dorsal-ventral patterning and restriction of neuronal fate) there is a remarkable conservation of the roles of BMP signaling components in establishing and interpreting BMP gradients. A full discussion of the roles of BMPs in development is beyond our scope. Rather, we discuss recent concepts that have emerged from analysis of the BMP pathway in the fruit fly (*Drosophila*) embryo. We relate these concepts to the analysis of BMP function in vertebrates.

A fundamental task of the developing embryo is to inform individual cells of their relative positions through either direct cell-cell interactions, or soluble molecules that act as morphogens. To qualify as a morphogen, the factor must act directly on distant cells, generate a gradient of signaling activity, and elicit different patterns of gene expression at different concentrations [2,3]. Strong evidence for activity as a morphogen is available for only a few secreted proteins. BMP family members are among the best characterized examples [2–4].

Gradients of BMP Activity

BMPs satisfy the most critical requirement for morphogens: They act in a concentration-dependent manner to elicit differential gene expression [2,4]. For example, in *Drosophila*, neural cells form ventrally where BMP signaling is absent, ectoderm forms laterally where intermediate levels of BMP signaling take place, and peak levels induce

the most dorsal tissue, the amnioserosa (Fig. 1). The most direct method to determine where BMP signaling pathways are active is the use of antibodies that specifically detect the active (phosphorylated) forms of Smads (pMAD and pSmad, in *Drosophila* and vertebrates, respectively). BMP activity gradients have been seen along the *Drosophila* and *Xenopus* dorso-ventral (D/V) axis, in the wing disc of the fly, and in the chick [5–9]. A common finding is that the shapes of the BMP ligand and activity gradients are considerably different. For example, along the *Drosophila* D/V axis, although pMAD levels form a gradient with highest levels dorsally, mRNAs for the ligands DPP and SCW are uniform dorsally (DPP) or are ubiquitously expressed (SCW) (Fig. 1) [8]. This finding underscores the substantial level of control over the shapes of BMP activity gradients that occurs extracellularly via ligand interactions with antagonists, and at the intracellular level by regulating BMP receptor and Smad degradation.

Establishing BMP Ligand Gradients

Many mechanisms are employed to establish BMP gradients, even within a single species. The propagation of endogenous BMP ligand gradients has not been studied directly in vertebrates, but in *Xenopus*, the TGF β family member activin forms a gradient by diffusion [2]. On the other hand, BMP4 does not diffuse freely, perhaps due to its ability to bind proteoglycans [10], which are abundant in the extracellular matrix. In the *Drosophila* wing disc, the DPP gradient is controlled by receptor-mediated endocytosis [11]. DPP binds to its receptor (Thickveins, Tkv), and repeated cycles of endocytosis and re-secretion transport DPP from its source. DPP is also distributed extracellularly, and binding of DPP to Tkv limits its diffusion [6]. Little is

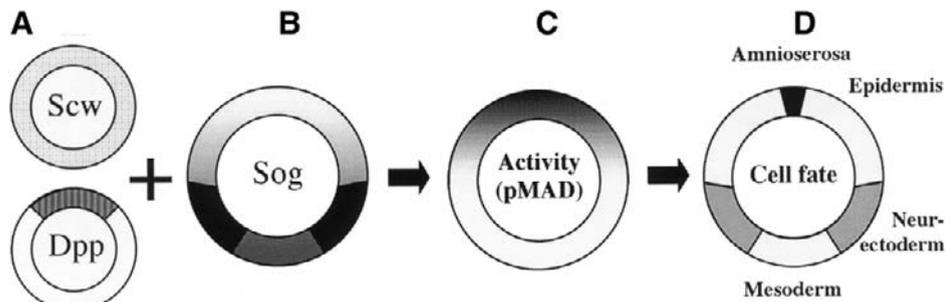

Figure 1 Formation of the BMP activity gradient along the *Drosophila* D/V axis. (A) mRNAs for the ligands are distributed uniformly (Scw) or broadly on the dorsal side of the embryo (Dpp). (B) Sog, the Scw/Dpp antagonist, is distributed in a ventral high-dorsal low gradient due to its expression in ventrolateral regions (black), and destruction in the dorsal region. (C) As a result of the Sog gradient, Dpp and Scw are antagonized ventrally, leading to a dorsal high-ventral low gradient of BMP signaling activity, as monitored by distribution of pMAD. (D) Different cell types are specified along the D/V axis. The amnioserosa is the most dorsal cell type.

known about how levels of BMP receptor expression are regulated, but BMPs can repress expression of their receptors [12], which limits the duration of responsiveness to BMP signals and prevents sequestration of BMPs close to the source of expression.

Extracellular Modifiers of BMP Activity

Antagonists that act by binding BMPs in the extracellular space play a pivotal role in shaping BMP gradients, and a large number of such antagonists have been identified [13]. The best characterized example, conserved through evolution, is the Short Gastrulation (Sog) protein, and its vertebrate homolog Chordin (Chd). They are the primary architects of the BMP activity gradients that specify the D/V axis in vertebrates and invertebrates (reviewed in references [13] and [14]).

Controlling the availability of these antagonists allows the embryo to create a BMP activity gradient despite uniform expression of the ligands. Sog/Chd is cleaved by the protease Tolloid (Xolloid in *Xenopus*). Along the *Drosophila* D/V axis, Sog is expressed in a ventral to dorsal gradient that opposes the gradient of DPP activity [9] (Fig. 1B). As a result of the Sog gradient, SCW is antagonized ventrally (where Sog levels are highest), but is active dorsally, where Sog is removed by endocytic degradation and cleavage by Tolloid [9]. Similar mechanisms are likely operational in vertebrates. For example, in zebrafish, the BMP2/4 homolog Swirl is not asymmetrically distributed, but it patterns the entire D/V axis through localized expression of zChd [15].

Twisted Gastrulation (Tsg), a protein that interacts with Sog/Chd and BMPs to affect the activity of Tolloid/Xolloid, brings an additional level of regulation. Tsg acts as an antagonist by forming a complex with Sog and SCW [16–19]. This promotes cleavage of Sog into a truncated form, Supersog, that can inhibit DPP in addition to SCW [16–19]. Thus, Tsg serves to steepen the Sog activity gradient, leading to more potent antagonism of BMP activity.

The consequences of this complex formation are not fully understood, and BMP binding proteins may not act solely as antagonists. For example, genetic studies indicate that Tsg and Sog have positive effects on BMP signaling, perhaps by mediating ligand diffusion (reviewed in references [9] and [14]). Moreover, in *Xenopus*, Tsg is multifunctional, acting as both a BMP agonist and antagonist depending on experimental conditions [18–20]. In addition, loss-of-function studies suggest that many antagonists have redundant functions that will be uncovered only through construction of double mutants. For example, although unrelated structurally, the antagonists Noggin [21] and Chd have a redundant function in induction of anterior neural tissues in mammals [22].

Interpreting the Gradient-Role of BMP Receptors

BMP signal transduction is initiated by formation of complexes of type I and type II receptors, leading to Smad phosphorylation. It is clear that different type I receptors activate common signaling pathways. How can such a simple system lead to differential gene expression? First, BMPs trigger different responses when different numbers of receptors are activated [2]. Second, different BMP receptors have different affinities for specific BMP ligands. Thus, two groups of cells might respond differently to a single BMP concentration because they express different type I BMP receptors.

A striking example of this latter mechanism is the synergy observed between some type I receptors. In *Drosophila*, Thickveins (Tkv) can act independently of the Saxophone (Sax) type I receptor, but signaling through Sax takes place only when Tkv is active. Moreover, Tkv and Sax strongly synergize when co-expressed, and this synergy is required for formation of the amnioserosa (reviewed in [4]). Evidence for a synergistic relationship has also been found in mammals [23]. BMPRIA and BMPRII are structurally related to Tkv and function equivalently in that constitutively active (ca) forms induce chondrogenesis independently.

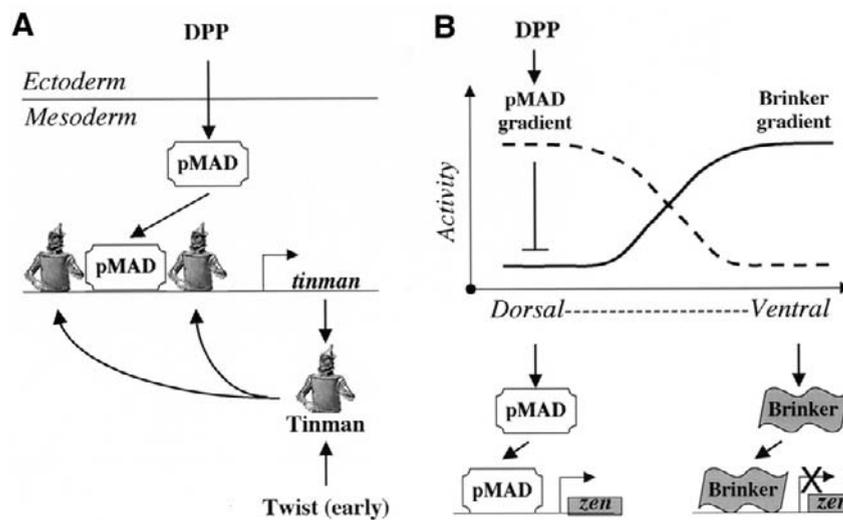

Figure 2 Regulation of target genes by BMP signaling. (A) The *Drosophila tinman* gene is expressed in dorsal mesoderm. At early stages, *tinman* is induced by Twist. The mesoderm subsequently migrates, and mesoderm located dorsally is exposed to high levels of DPP produced by the overlying ectoderm, resulting in high levels of pMAD activity. pMAD binds directly to the *tinman* promoter and cooperates with Tinman to maintain high levels of *tinman* expression. (B) Brinker is a transcriptional repressor of DPP target genes. *Brinker* expression is repressed by DPP. Hence, Brinker is present in areas of low pMAD activity. pMAD binds to the *zen* promoter to promote *zen* transcription. Brinker competes for binding and represses *zen* transcription. This mechanism would sharpen the boundary between *zen*-expressing and nonexpressing cells.

In contrast, ALK1 and ALK2 are structurally related to Sax, and *ca* forms of these receptors cannot induce chondrogenesis. However, *ca* BMPRIA or *ca* BMPRIB synergizes with *ca* ALK2 to promote chondrogenesis [23]. The mechanistic basis for the synergy is unknown, but may involve formation of a more stable receptor complex, differences in Smad activation, or effects on Smad cofactors.

Differential Gene Activity in Response to BMP Signal Transduction

The mechanisms by which changes in levels of activated Smads (pSmads) lead to changes in patterns of gene expression is an area of intensive investigation (reviewed in [24]). The ability of pSmads to interact with a myriad of transcriptional regulators is responsible for the dose-dependent effects of BMPs on gene expression [25]. The developmental history of the responding cell (i.e., its competence) determines which specific co-activators and co-repressors are present, thus defining the nature of the response. An example is the induction of *tinman* in dorsal mesoderm in *Drosophila* [26] (Fig. 2). The bHLH protein Twist activates *tinman* in the entire trunk mesoderm. During gastrulation, some of this mesoderm migrates to a position under the DPP-expressing dorsal ectoderm. The *tinman* promoter contains binding sites for Tinman and MAD, and in response to DPP, pMAD acts synergistically with Tinman to maintain *tinman* expression.

Different BMP target genes are activated by different levels of pSmads. One molecular explanation for this is that

they have binding sites that recognize pSmad-containing complexes with different affinities. Another mechanism involves competitive binding of pSmads and repressors. For example, the *zen* promoter in *Drosophila* contains overlapping binding sites for pMAD and the repressor Brinker [27] (Fig. 2B). *zen* is active in the dorsal mesoderm, where the high levels of pMAD outcompete Brinker for binding to the *zen* promoter; DPP signaling also represses transcription of *Brinker*, leading to a sharp boundary of *zen* expression [28].

Intracellular Negative Regulation of BMP Signaling

BMP signaling pathways are subject to several levels of negative intracellular regulation that impact developmental outcomes. One of these involves inhibitory Smads (I-Smads) that stably associate with BMP receptors and/or other Smads to interfere with signaling. Expression of I-Smads is induced by BMP signaling, generating a feedback inhibition loop [25].

An additional level of modulation occurs at the level of Smad stability. Smurf1 and Smurf2 are Smad binding proteins that promote ubiquitin-mediated proteolysis of Smads and ligand-activated receptors (see references in [8]). The *Drosophila* cognate DSmurf is essential for establishing proper spatial control over DPP signaling, as *DSmurf* mutants exhibit expanded domains of DPP activity, leading to lethality [8]. In vertebrates, Smurfs may play an additional role; overexpression of Smurf1 not only decreases signaling through BMP pathways, but also enhances signaling through the TGF β pathway [29]. This may occur through

relief of competition for the common signal transduction component, Smad4 [30]. Competition between TGF β and BMP pathways for limiting signal transduction components may be a widespread mechanism for modulating responsiveness to BMPs in vertebrates, as a number of examples of such competition have been described [31,32].

Lessons from Loss-of-Function Studies in Mammals

Over 15 different BMPs have been described in mammals, and expression of at least one is seen in almost every tissue type and stage of development, reflecting the universal importance of BMP pathways in vertebrates. Mutant strains have now been produced for most of the ligands, receptors, and Smads. Another useful approach has been to overexpress BMP antagonists or dominant-negative receptors in transgenic mice [33]. It has not been possible to uncover evidence that BMPs act as morphogens in mammals owing to the complexities of mammalian development and the lack of suitable markers. However, several important features have emerged from genetic analyses in mammals. First, they confirm widespread roles for BMP pathways in gastrulation, axis determination, and organogenesis. Second, the similar phenotypes of some mutant strains reveal the framework of the BMP pathways controlling specific developmental events. An example is the finding that mutations in the ligand nodal and the receptor ActRIIB are associated with defects in left/right asymmetry [34]. Another example is the nearly identical phenotype of mice lacking *Gdf5* or *Bmpr1B*, which suggests that GDF5 is a ligand for BMPRII *in vivo* [35,36]. Third, mutant phenotypes are often more restricted than predicted from patterns of expression. One explanation that is consistent with analyses of double mutants is functional redundancy. For example, *Bmp7*^{-/-} or *Bmpr1B*^{-/-} mice have minor skeletal defects, but double mutants exhibit severe defects in long bones [35]. Hence, BMP7 and a different BMP (that acts through BMPRII) have redundant functions in skeletal development. Surprisingly, ligands that act redundantly by genetic criteria are often not co-expressed in the affected tissues [37]. The molecular basis for the ability of ligands with nonoverlapping patterns of expression to compensate for each other genetically is not known, but may involve altered expression of other BMP ligands and/or signaling components, and reflects inductive interactions between adjacent tissues.

Conclusions

BMPs act as morphogens in both vertebrates and invertebrates. The distribution of BMP ligands often does not predict the shape of the BMP activity gradient. Clearly, ligand availability is highly regulated at the extracellular level by numerous BMP binding proteins. Many of these binding proteins can act both positively and negatively. How this occurs at a molecular level is not completely understood. Tissue-specific loss-of-function studies are needed to

determine which BMP binding proteins act as positive and/or negative effectors of BMP signaling in particular developmental events.

Receptor synergy appears to play an important role in shaping BMP activity gradients in *Drosophila* and vertebrates. Additional studies will be required to delineate the mechanistic basis for this synergy, and to assess its role in specific developmental events in vertebrates. Our knowledge of how BMP signaling regulates the expression of specific target genes is increasing. It is clear from the large number of transcriptional regulators known to collaborate with Smads that multiple growth factor signaling pathways are integrated to control the nature of the response to the BMP signal. Understanding this integration on a molecular level will be challenging, but vital to our understanding of all developmental decisions in which BMPs participate.

Neurotrophin Signaling in Development

Introduction

The formation of the vertebrate nervous system is characterized by widespread programmed cell death, which determines cell number and appropriate target innervation during development. The neurotrophins, which include nerve growth factor (NGF), brain-derived growth factor (BDNF), NT-3, and NT-4, represent an important family of trophic factors that are essential for survival of selective populations of neurons during different developmental periods.

The neurotrophic hypothesis postulates that during nervous system development, neurons approaching the same final target vie for limited amounts of target-derived trophic factor [17]. In this way, the nervous system molds itself to maintain only the most competitive and appropriate connections. Competition among neurons for limiting amounts of neurotrophin molecules produced by target cells accounts for selective cell survival. Two predictions emanate from this hypothesis. First, the efficacy of neuronal survival will depend upon the amounts of trophic factors produced during development. Second, specific receptor expression in responsive cell populations will dictate neuronal responsiveness.

Neurotrophins exert their cellular effects through the actions of two different receptors, the tropomyosin-related kinase (Trk) receptor tyrosine kinase and the p75 neurotrophin receptor (p75^{NTR}), a member of the tumor necrosis factor (TNF) receptor superfamily. On one level, neurotrophins fit well with the neurotrophic hypothesis, as many peripheral neuronal subpopulations exhibit a predominant dependence on a specific neurotrophin during the period of naturally occurring cell death (Fig. 1). However, the biological reality

appears much more complex. In the central nervous system, the overlapping expression of multiple neurotrophin receptors and their cognate ligands allows for the creation of diverse connectivity, which extends well into adulthood; even in the periphery complexities remain, such as the molecular mechanisms underlying the retrograde signal, a pathway that must efficiently transmit information over long distances, at times over a meter. The role of the neurotrophin system in development has been reviewed [12]. This chapter will focus upon new views concerning ligand-receptor interactions, signal transduction, and retrograde transport in the peripheral nervous system.

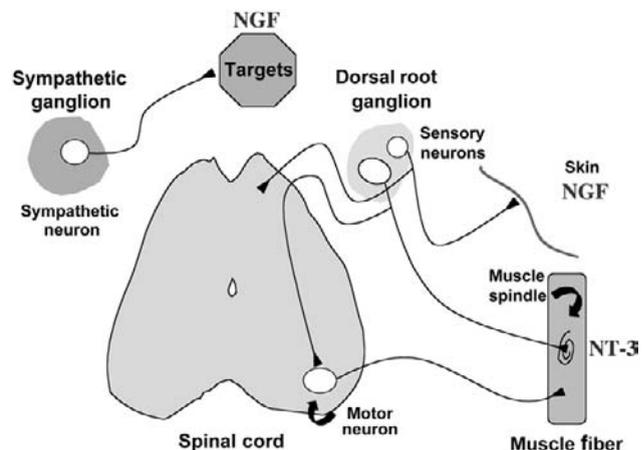

Figure 1 Neurotrophins serve as target-derived survival factors. NGF and NT-3 display specific survival and differentiative effects upon sympathetic and sensory neuron populations in the peripheral nervous system.

The Neurotrophin Ligands

The neurotrophins are initially synthesized as precursors or pro-neurotrophins that are cleaved to release the mature, active proteins. The mature proteins form stable, noncovalent dimers and are normally expressed at very low levels during development. Pro-neurotrophins are cleaved intracellularly by furin or pro-convertases utilizing a highly conserved dibasic amino acid cleavage site to release carboxy-terminal mature proteins of approximately 13 kDa. These extensively studied mature proteins mediate neurotrophin actions by selectively binding to members of the Trk family of receptor tyrosine kinases to regulate neuronal survival, differentiation, and synaptic plasticity. In addition, all mature neurotrophins interact with p75^{NTR}, which can modulate the affinity of Trk:neurotrophin associations.

Neurotrophins promote cell survival and differentiation during neural development. Paradoxically, they can also induce cell death. p75^{NTR} serves as a pro-apoptotic receptor during developmental cell death and after injury to the nervous system. Increases in p75^{NTR} expression are responsible for apoptosis in embryonic retina and sympathetic neurons during the period of naturally occurring neuronal death [3,7]. Whereas BDNF binding to p75^{NTR} in sympathetic neurons causes rapid cell death, NGF binding to the TrkA receptor on the same neurons provides a survival signal. In the context of neurotrophin processing, pro-neurotrophins are more effective than mature NGF in inducing p75^{NTR}-dependent apoptosis [16]. These results suggest that the biological action of the neurotrophins can be regulated by proteolytic cleavage, with pro-forms preferentially activating p75^{NTR} to mediate apoptosis and mature forms selectively activating Trk receptors to promote survival.

Neurotrophin Receptors

One way of generating more specificity during development is by imparting greater discrimination of ligands for the Trk receptors. NGF binds most specifically to TrkA; BDNF and NT-4 to TrkB; and NT-3 to TrkC receptors. The p75^{NTR} receptor can bind to each neurotrophin but has the additional capability of regulating a Trk's affinity for its cognate ligand. Trk and p75^{NTR} receptors have been referred to as high- and low-affinity receptors, respectively. However, this is not correct since TrkA and TrkB actually bind their ligands with an affinity of 10^{-9} – 10^{-10} M, which is lower than the high-affinity site ($K_d = 10^{-11}$ M). Also, the precursor form of NGF displays high-affinity binding to p75^{NTR}. Trk-mediated responsiveness to low concentrations of NGF is dependent upon the relative levels of p75^{NTR} and TrkA receptors, and their combined ability to form high-affinity sites.

Although p75^{NTR} and Trk receptors do not appear to bind to each other directly, there is evidence that complexes form between the two receptors [5]. As a result of these interactions, increased ligand selectivity can be conferred onto Trks by p75^{NTR}. NGF and NT-3 both can bind to TrkA,

but p75^{NTR} restricts signaling of TrkA to NGF and not to NT-3 [4]. Sympathetic neurons express TrkA and p75^{NTR} receptors and depend upon NGF for survival. In the absence of p75^{NTR}, NT-3 compensates for a lower level of NGF *in vivo*. Though NT-3 binds weakly to TrkA, the survival effects of NT-3 can be attributed to activation of TrkA receptors in the absence of p75^{NTR}. These observations support a role for p75^{NTR} in enhancing the specificity of Trk receptors for neurotrophins *in vivo*. Hence, p75^{NTR} and Trk receptors may interact to provide greater discrimination among different neurotrophins.

In addition to increasing ligand-receptor affinity and selectivity, p75^{NTR} contains a death domain sequence similar to the intracellular domains of the Fas and p55 TNF receptors [18]. Several examples of p75^{NTR}-mediated cell death now exist; these events appear to depend upon cell-specific interactions with adaptor proteins. It has been generally assumed that the mechanism of p75^{NTR}-mediated cell death is similar to apoptotic signaling by the TNF receptor and Fas. However, a number of experimental findings indicate that cell death by p75^{NTR} occurs quite differently from that of other TNF receptor family members [6,10]. First, regions of p75^{NTR} other than the death domain are responsible for apoptosis. Second, whereas recruitment of caspase-8 to the death domains of the p55 TNF and Fas receptors is critical for the initiation of apoptosis, other caspases are responsible for p75^{NTR}-mediated killing of oligodendrocytes.

What are the reasons for having a Trk receptor that mediates neuronal survival and a p75^{NTR} receptor that mediates apoptosis? One reason neurotrophins use a death receptor may be to prune neurons efficiently during periods of developmental cell death. In addition to competing for trophic support from the target, neurons must establish connections with the proper target. In the event of mistargeting, neurons may undergo apoptosis if the appropriate set of trophic factors is not encountered. In this case, a neurotrophin may not only fail to activate Trks but also bind to p75^{NTR} and eliminate cells by an active killing process [21]. For example, BDNF causes sympathetic neuronal death by binding to p75^{NTR} when TrkB is absent [3]. Likewise, NT-4 causes p75^{NTR}-mediated cell death in BDNF-dependent trigeminal neurons [1], due presumably to preferential p75^{NTR} rather than TrkB stimulation. Therefore, Trk and p75^{NTR} receptors can give opposite outcomes in the same cells. Cell death mediated by p75^{NTR} may be important for the refinement of correct target innervation during development.

Signaling Specificity during Development

Specific Trk receptor expression patterns determine the development of peripheral neuron populations. In the dorsal root ganglion, small-diameter unmyelinated neurons predominantly express TrkA whereas larger sized neurons express TrkC receptors. Many of the small diameter neurons are nociceptive and frequently terminate in the epidermis (Fig. 1). NGF is important for the development of these neurons

during early postnatal periods. The large-diameter neurons are proprioceptive and are most responsive to NT-3. Consistent with the receptor expression, a lack of NGF leads to a lack of responsiveness to nociceptive stimuli, and a lack of NT-3 leads to a loss of muscle spindle afferents. Due to altered expression of specific Trk receptors, neurons change their dependency upon specific neurotrophins [27].

Trk receptors exhibit very high conservation in their intracellular domains, including the catalytic tyrosine kinase and the juxtamembrane NPXY motif that serves as the Shc binding site. However, several pronounced differences among the Trks exist. In a sympathetic neuronal background, TrkA relies predominantly upon phosphoinositide-3-kinase (PI3-K) activation for survival, whereas TrkB uses both PI3-K and ERK pathways [2]. Thus, each Trk receptor carries distinctive signaling properties. For example, TrkB may contain sequences that bind to factors that favor alternative pathways. Since there are now a number of different adaptor proteins and enzymatic functions associated with Trk receptors (Fig. 2), preferential interactions with these proteins must take place. Receptor utilization of substrates with differential association/dissociation kinetics, competition for binding among different substrates, or recruitment of unique target proteins, such as FRS-2, rAPs, and SH2-B for the Trk receptors, represent mechanisms by which each receptor may differentially utilize common substrates for signaling.

Alternatively, receptor processing or targeting into different membrane compartments may dictate function. A comparison of TrkA and TrkB receptors in neuronal cell lines has revealed a difference in turnover of each receptor. While NGF binding to TrkA does not lead to a significant downregulation of TrkA, BDNF binding to TrkB results in rapid turnover of TrkB receptors at the cell surface [28].

Additionally, the number of surface TrkB receptors is highly influenced by depolarization and levels of cAMP [22]. These observations hint at other receptor mechanisms that confer greater signaling specificities to the neurotrophins.

The Importance of Retrograde Transport

During development, neurotrophins are produced and released from the target tissues and become internalized into vesicles, which are then transported to the cell body. The biological effects of neurotrophins require that signals are conveyed over long distances from the nerve terminal to the cell body. Therefore, a central theme of the neurotrophic hypothesis is that neuronal survival and differentiation depend upon retrograde signaling of trophic factors produced at the target tissue.

Each neurotrophin binds to transmembrane receptors and undergoes internalization and transport from axon terminals to neuronal cell bodies [8,11,23]. Measurements of ^{125}I -NGF transport from distal axons to the cell body in compartment chambers indicate a rate from 3–10 mm/h. Both Trk and $p75^{\text{NTR}}$ receptors undergo retrograde transport. The term “signaling endosome” has been coined to describe membrane vesicles that carry Trk, $p75^{\text{NTR}}$, and NGF [9].

A complex of NGF-TrkA has been found in clathrin-coated vesicles and endosomes, giving rise to the model that NGF and Trk are components of the retrograde signal. Several tyrosine phosphorylated proteins are associated with the TrkA receptor during transport, suggesting that signaling by neurotrophins persists following internalization of their receptors. Internalization of NGF from axon terminals is necessary for phosphorylation and activation of the

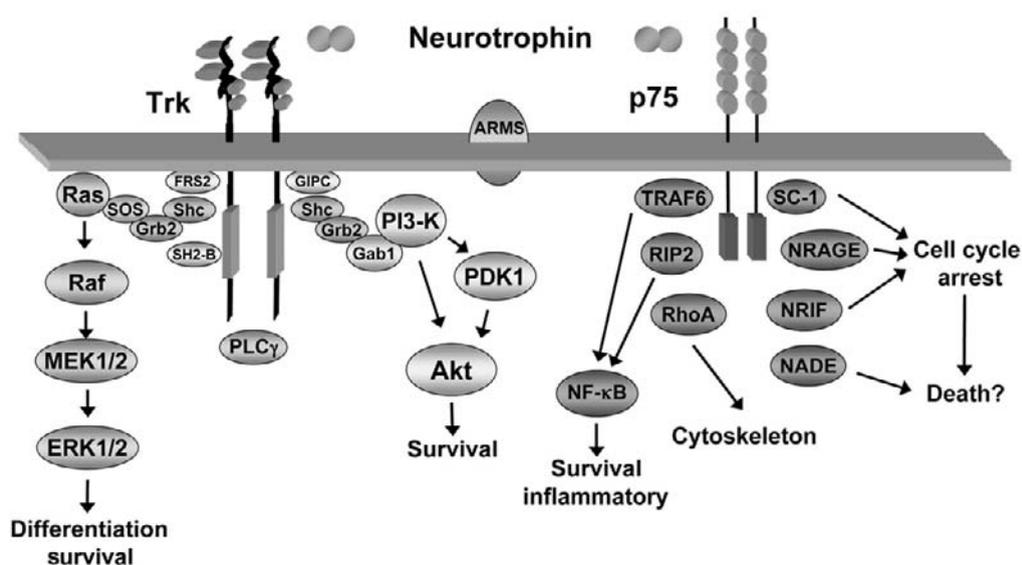

Figure 2 Neurotrophin receptors utilize multiple adaptor proteins. Each receptor undergoes ligand-induced dimerization that results in the recruitment of multiple cytoplasmic proteins, which serve to increase the activities of phospholipase C γ , PI3-K, and MAP kinases. The p75 receptor is capable of initiating a cell death program in selected cells and signaling that leads to ceramide production and NF- κ B or JNK activation.

CREB transcription factor, which leads to changes in gene expression and increased neuronal cell survival [25,30]. In addition, stimulation of Erk5 occurs in the cell body of DRG neurons after retrograde signaling by neurotrophins [29], as well as activation of PI3-K and Akt [14]. These events likely require internalization and transport of activated Trk receptors and result in a survival response. An alternative mechanism suggests that survival signals can be transmitted in the absence of NGF internalization and transport [20]. This explanation would account for the rapid appearance of phosphorylated TrkA in the cell body [26] and raises the possibility that a molecule other than endocytosed NGF may propagate a signal from distal axons to TrkA receptors at the cell body.

Interacting Proteins

The existence of neurotrophin-receptor complexes during their axonal transport suggests that other proteins may be associated with this complex. Neurotrophin receptors undergo ligand-induced dimerization that activates multiple signal transduction pathways. Neurotrophin binding to Trk family members produces biological responses through rapid increases in the phosphorylation of phospholipase C- γ and PI3-K. Increased *Ras* activity, a common signal from all tyrosine kinase receptors, results from the stimulation of guanine nucleotide exchange factors coupled to adaptor proteins which directly interact with Trk after ligand binding. These adaptor proteins include Shc, Grb2, SH2-B, and FRS-2 (Fig. 2).

A number of adaptor proteins also bind to p75^{NTR} (Fig. 2). Three different proteins, NRIF, NADE, and NRAGE contribute to apoptosis in immortalized cell lines or are correlated with neurotrophin-dependent cell death. Each protein binds to a separate sequence in the cytoplasmic domain of the p75^{NTR} [12]. Another protein that interacts with both p75^{NTR} and Trk receptors is ARMS, an ankyrin-rich transmembrane protein [13]. ARMS is rapidly tyrosine phosphorylated after binding of neurotrophins to Trk receptors. This protein may act as a scaffold to cluster proteins essential to neurotrophin signaling. Other proteins, including RhoA GTPase, SC-1, and NRAGE, exert nonapoptotic activities, such as neurite elongation and growth arrest. These proteins expand the functional scope of neurotrophins [15]. Still other proteins, such as cytoplasmic dynein and the PDZ-domain-containing GIPC protein may serve to target neurotrophin receptors intracellularly during important cellular processes such as internalization, retrograde transport, axonal and dendritic localization, and synapse formation.

Given the wide number of activities of neurotrophins and the small number of neurotrophins and neurotrophin receptor genes, it is likely other signaling systems are used. This includes ion channels such as TRP and glutamate receptors. How these signals are integrated to yield higher level neuronal functions, such as behavior, is unknown. But there are hints from knockout animals that lowering the levels of BDNF or its receptors TrkB and p75^{NTR} give rise to prominent

aggressive behavior and abnormalities in eating and memory [19,24]. These findings bolster the notion that neurotrophins, in addition to their potent properties on the cellular level, possess abilities to influence cognitive functions.

PDGF Receptor Signaling in Mouse Development

Richard A. Klinghoffer

CEPTYR, Inc., Bothell, Washington

Introduction

Highly defined characterization of the biochemical and cellular functions of platelet-derived growth factors (PDGFs) and their receptors (PDGFRs), set the stage to use this system as a genetic model to study receptor tyrosine kinase (RTK) signaling in mammalian development. Following binding to PDGF, PDGFRs autophosphorylate, enabling them to bind and then activate intracellular proteins that relay the receptor's signals throughout the cell. PDGF stimulates cellular functions including mitogenesis, survival, and chemotaxis (for a detailed review of PDGFR signal transduction see Volume 1, Chapter 70 and the references therein). Several features of the PDGFR system make it an appropriate model to investigate whether specific signals transmitted by RTKs translate into unique physiological functions *in vivo*. First, genetic analysis is facilitated as signaling is mediated by just two highly related yet distinct RTKs, the PDGFRs α and β (PDGF α R and PDGF β R) [1]. Second, the two PDGFRs bind a highly overlapping but nonidentical repertoire of signaling proteins [2]. Third, autophosphorylation site mutant PDGFRs, which lack the ability to activate specific intracellular signaling pathways, have been well characterized [3–5]. Finally, the phenotypes of the PDGF α R $-/-$ mice and the PDGF β R $-/-$ mice are easily distinguishable, demonstrating that each PDGFR mediates specific functions during embryonic development [6,7]. Since the phenotypes of PDGF and PDGFR-null mutants have recently been reviewed in detail [8], only the basics will be given here. This chapter focuses on what has been learned by analyzing mice bearing specific alterations in the intracellular signaling domains of the two PDGFRs.

PDGF β R Signaling *In Vivo*

PDGF β R signaling is required at late gestation (E16.5–E18.5), as deletion of the PDGF β R results in lost integrity of the developing microvasculature leading to capillary microaneurysm and perinatal lethality [7]. Abnormal capillary development is observed in multiple organs but is prominent at the kidney glomerulus, which completely lacks a well-formed capillary tuft. This is due to the absence of mesangial cells, matrix-secreting cells related to vascular smooth muscle cells (vSMCs), which coat and maintain the integrity of glomerular capillaries. The defects observed are strikingly similar to those displayed by mice harboring a null mutation of PDGFB [9]. This is not surprising, as dimeric PDGFBB is a predominant ligand for the PDGF β R [10]. Combined analysis of the two mutant lines revealed that PDGFBB/PDGFB signaling is required for proper communication between the two major vascular cell types: endothelial cells, which express PDGFB, and vSMCs/pericytes (vSMC/PC), which express the PDGF β R [11,12]. Consistent with identified roles of PDGFBB as a mitogen and chemoattractant for vSMCs, disruption of this signaling axis results in a failure of preexisting vSMC/PC to migrate to, and proliferate along angiogenic sprouts of the developing microvasculature [11,12].

PDGF α R Signaling *In Vivo*

While loss of PDGF β R signaling results in defects restricted primarily to vSMCs and related cells, loss of PDGF α R signaling affects multiple cell types. These include

derivatives of sclerotome and non-neuronal neural crest cells [6]. Consequently, PDGF α R-null embryos exhibit a complex and variable phenotype. The hallmarks of this phenotype include a cleft face, defects of the axial and proximal appendicular skeleton, subepidermal blebbing, and hemorrhaging. Mice lacking the PDGF α R typically die at mid-gestation starting at E8.5 and very few embryos survive past E15.5. Consistent with a role for PDGF α R signaling in cell survival, the cranial defects appear to be due to increased apoptosis of migrating neural crest cells. The trunk defects, including skeletal malformations, appear to arise from a deficiency in myotome formation suggesting that PDGF α R signaling participates in somite patterning. In contrast to the high phenotypic similarity between PDGFB and PDGF β R-null mice, a substantial population of PDGFA-null mice (~20%) survives well beyond gestation, a stage never achieved by PDGF α R-null animals [13]. This is explained by the fact that the PDGF α R binds multiple PDGFs including homodimers of PDGFA, PDGFB, and PDGFC in addition to heterodimers of PDGFA and PDGFB [10,14]. Studies on postnatal PDGFA-/- mutants have revealed roles for PDGF α R signaling in development of oligodendrocytes, lung alveolar myofibroblasts, intestinal mesenchyme, and Leydig cells [8].

Specificity of PDGFR Signaling *In Vivo*

One important concern in signal transduction is whether individual RTKs transmit distinct biochemical signals that translate into the ability to direct unique functions *in vivo*. Different ligand-binding affinities, patterns of gene expression, and/or mechanisms of signal transduction could all account for the functional specificity displayed by the two PDGFRs *in vivo*. Although both PDGFRs bind to many of the same signaling proteins including PI3 kinase, PLC γ , SHP-2, and Src family kinases, each receptor also binds to some proteins in an exclusive fashion. Prominent examples include binding of RasGAP to the PDGF β R but not the PDGF α R, and binding of Crk family adaptor proteins to the PDGF α R but not the PDGF β R [15–17]. Whether such differences convey an intrinsic ability upon RTKs to transmit functionally distinct signals *in vivo* is a highly debated issue. This issue was addressed in part by analysis of two complementary lines of PDGFR knockin mice [18]. In each line, the intracellular signaling domains of one PDGFR were removed and replaced with those of the other PDGFR. Since the novel chimeric PDGFR retains the ligand binding capacity and the spatiotemporal expression of the replaced PDGFR, only differences in intracellular signaling should account for any abnormal phenotypes. Mice harboring PDGF β R intracellular domains in the place of the endogenous PDGF α R regions (called $\alpha\beta$) developed no overt defects as homozygotes ($\alpha\beta/\alpha\beta$) or hemizygotes ($\alpha\beta/-$). This suggests that signals transmitted by the two PDGFRs are interpreted in a highly redundant manner in cells normally expressing the PDGF α R. Furthermore, mice expressing the

converse chimeric receptor at the PDGF β R locus ($\beta\alpha$) are also viable and largely normal. However, suboptimal function of cells normally regulated by PDGF β R signaling in these animals is revealed by modest heart enlargement and an impaired mesangial cell response to induced glomerular injury. Furthermore, exacerbated systemic vascular defects are observed in $\beta\alpha/-$ hemizygotes. Consistent with loss of normal PDGF β R function, the defects are due to abnormal development of vSMC/PCs and subsequent failure to coat the microvasculature. The $\beta\alpha/-$ phenotype includes perinatal lethality (~40%), substantial heart enlargement, glomerulosclerosis, and retinopathy. The retinopathy, which results in retinal detachment and migration into the vitreous body, bears striking resemblance to retinopathy of diabetes. Diabetic retinopathy primarily affects the retinal capillaries and is characterized initially by loss of PCs. Indeed, marker analysis on $\beta\alpha/-$ animals clearly demonstrates that loss of retinal PCs is the underlying cause of the observed phenotype. Cellular analysis suggests that inability of PDGF α R-type signaling to sustain MAPK activation may contribute to the decreased function of $\beta\alpha$ -expressing vSMC/PCs. Taken together, these results indicate that while the functional specificity displayed by the two PDGFRs is largely due to differences in ligand affinities and/or patterns of gene expression, PDGF β R-specific signals are required for optimal function of vSMC/PCs. Further lines of knockin mice have since been generated in which the intracellular domains of the PDGFRs have been replaced with those of further divergent RTKs. Analysis of these lines clearly shows that increased divergence from PDGFR-type signaling reduces the ability to rescue the embryological functions of the PDGFRs [19].

Another major focus of signal transduction studies is to define the contributions of distinct intracellular signaling pathways to RTK function. Many RTK-associated signaling proteins contain phosphotyrosine-binding modules such as SH2 or PTB domains [20]. Mutation of receptor tyrosine residues can be used to uncouple RTK activation from activation of specific effector proteins. Knockin mice harboring such point mutations in the PDGFRs provided a means to test contributions of distinct signaling pathways to PDGFR function *in vivo*. Studies on cultured cells expressing PDGF β R mutants identified PI3 kinase and PLC γ as the major effectors of PDGF β R-triggered mitogenesis and chemotaxis [21,22]. These analyses also demonstrated that the functions promoted by these two effectors are highly redundant. Consistent with maintenance of this redundancy *in vivo*, homozygous mutant mice expressing a PDGF β R that cannot activate PI3K still develop normally [23]. More surprising is the finding that elimination of both PI3-K and PLC γ binding sites on the PDGF β R is still compatible with normal viability [24]. *In vivo* challenge assays and chimeric analysis does reveal that loss of these signals decreases vSMC/PC function. However, the relatively normal phenotype indicates that compensating mechanisms exist, which promote a threshold level of signaling permitting vascular integrity. Microarray experiments suggest that activation of

other PDGF β R-associated signaling proteins compensate for loss of PI3-K and PLC γ signals [25]. However, PDGF β R signaling mutant mice have recently been generated that lack binding sites for SHP-2, RasGAP, Grb2, and Src family kinases, in addition to PI3-K and PLC γ , without loss of viability [26]. It is possible that a threshold of signaling required for viability is met by activating PDGF β R signaling pathways through a surrogate receptor. An obvious candidate is the PDGF α R, as heterodimerization between the two PDGFRs occurs in response to certain PDGF ligands. Thus far, PDGF α R signaling has not been shown to compensate for loss of PDGF β R signaling in cell types dependent upon PDGF β R function [24]. Perhaps interaction with less obvious cell surface receptors compensates for loss of direct PDGF β R binding to signaling proteins. Interactions between PDGFRs and integrins have been demonstrated and both activate many of the same intracellular signals [27–29]. Examination of mice harboring compound mutations in the PDGF β R and specific integrin subunits should shed light on this possibility.

In contrast to the apparent resilience of the PDGF β R to lost signals, mutations that uncouple the PDGF α R from distinct pathways cause developmental defects of varying severity. An allelic series of three PDGF α R signaling mutants has been analyzed [30]. Included in this series were mutants that prevented the PDGF α R from activating Src family kinases (α^{Src}), or PI3-K ($\alpha^{\text{PI3-K}}$), or multiple pathways including the two previously mentioned in combination with PLC γ and SHP-2 (α^{F7}). α^{Src} animals are viable past birth but suffer from neurological-related defects including shaking, seizures, and decreased limb mobility. This is due to a specific defect in oligodendrocyte development and consequent hypomyelination of the central nervous system. Consistent with the interpretation that multiple PDGF α R signals are required for oligodendrocyte development, $\alpha^{\text{PI3-K}}$ mutants also displayed this phenotype. However, while the α^{Src} phenotype is restricted to oligodendrocytes, the $\alpha^{\text{PI3-K}}$ mutation affects multiple cell types. Most $\alpha^{\text{PI3-K}}$ mutants die perinatally and exhibit defects that are similar to, albeit less severe than, PDGF α R-null embryos. While $\alpha^{\text{PI3-K}}$ mutants do not exhibit an overt cleft face, they typically display a cleft palate. This suggests that PDGF α R signaling through PI3-K is required for optimal function of non-neuronal neural crest cells. Other skeletal abnormalities resulting from loss of PI3K signaling include spina bifida, misshapen cervical vertebrae, and malformations of the shoulder girdle. Furthermore, $\alpha^{\text{PI3-K}}$ mutants exhibit abnormal placental vascularization demonstrating a requirement for PDGF α R-initiated PI3-K signaling in extra-embryonic development [19]. While signaling through PI3-K is clearly essential for PDGF α R function *in vivo*, the receptor is still able to drive development to late embryogenesis. This is not likely due to compensatory signaling by other PDGF α R-associated proteins as the α^{F7} mutation essentially phenocopies $\alpha^{\text{PI3-K}}$. Instead, it is likely that a low level of PI3-K signal, activated via heterodimer formation between mutant PDGF α R and wild type PDGF β R, is the compensating factor. This is

based on the observation that double homozygous embryos harboring mutations in the PI3-K binding sites of both PDGFRs recapitulate the severity and the hallmark phenotypes of the PDGF α R-null mutants. These results indicate that PI3-K is the major effector of PDGF α R function *in vivo*, and that PDGF α R-initiated signals direct both specific and overlapping functions during mammalian development.

Building on work that established how PDGFRs transmit intracellular signals to carry out functions at the cellular level, genetic analysis in mice is beginning to demonstrate how these signals are utilized in the context of a living mammal. Studies are now beginning to reveal that most RTKs do not work alone, but instead participate as parts of a complex signaling matrix. Given that receptors such as integrins have been shown in cell culture systems to cooperate with PDGFRs for signal transmission, exploration of these interactions in genetic systems should be rewarding. Furthermore, while studies on mice have focused on signaling events that occur immediately following PDGFR activation, the significance of later events is largely unknown. To address this issue, gene trap screens in embryonic stem cells designed to find genes that exacerbate or ameliorate the PDGFR knockin mutant phenotypes are now underway. Such screens should provide a powerful means to identify novel players in PDGFR signal transduction *in vivo*.

VEGF and the Angiopoietins Activate Numerous Signaling Pathways that Govern Angiogenesis

Christopher Daly and Jocelyn Holash

Regeneron Pharmaceuticals, Inc., Tarrytown, New York

Angiogenesis is critical for both the growth and repair of tissues as well as for the advancement of many diseases. While there is great therapeutic potential in regulating angiogenesis, much is still to be learned about the processes that govern it. In order to design appropriate therapies to promote or inhibit blood vessel growth, we must identify factors that act selectively on the vasculature and define the mechanisms by which they act. Here we explore the signaling pathways regulated by members of two families of growth factors that act largely specifically on blood vessels: Vascular endothelial growth factor (VEGF) and the angiopoietins. These factors are involved in multiple steps of blood vessel growth where they play overlapping yet very distinct roles.

Introduction

While the great majority of endothelial cells (ECs) in the adult vasculature are quiescent, certain conditions can induce preexisting blood vessels to give rise to new vessels, a process termed angiogenesis. In some circumstances, such as wound healing, angiogenesis supports tissue repair, while in others, such as in tumors or diabetic retinopathy, angiogenesis is associated with the destruction of normal tissue. Although there are a number of processes that may contribute to angiogenesis, including vessel sprouting and branching, intussusceptive vessel growth and the recruitment of circulating endothelial cells into preexisting blood vessels, for this chapter we will focus on the expansion of the vascular

tree that occurs as a consequence of the sprouting and branching of preexisting vessels.

Several events must occur in order for a vasculature to expand via sprouting angiogenesis. Endothelial cells must divide, migrate, and survive. Once a new vessel is formed, perivascular cells must be recruited to the vessel wall, and their interactions with ECs must be stabilized. Multiple factors regulate each of these events, and in some instances several factors appear to act redundantly; thus, there are numerous signaling events and interactive pathways that are associated with the growth of blood vessels. We have chosen to focus on the signaling pathways activated by VEGF and the Angiopoietins, Ang-1 and Ang-2, since these factors act far more specifically on the vasculature than other factors that regulate angiogenesis [1]. VEGF, for which both VEGFR-1 and VEGFR-2 act as receptors, appears to signal predominantly through VEGFR-2, and is required for both embryonic and adult angiogenesis [2]. Angiopoietins, which are ligands for the Tie 2 receptor, also appear to be involved in both embryonic and adult angiogenesis, although their functions are distinct from those of VEGF. Ang-1, in contrast to VEGF, is not required for the earliest stages of vascular formation in the embryo, but rather is necessary for the remodeling and stabilization of the primary vasculature [3–4]. Ang-2, which in some instances can antagonize the activation of Tie 2 by Ang-1 [5], appears to play an important role in sprouting angiogenesis, possibly by destabilizing existing vessels [5–7]. Despite the cooperation between VEGF and the angiopoietins in vessel formation, these factors can also have opposing effects on vascular processes, for example, on permeability [8,9].

Endothelial Cell Proliferation

VEGF is highly expressed in angiogenic settings and drives EC proliferation [10]. Similar to other growth factors, induction of proliferation by VEGF requires activation of the ERK (MAP kinase) cascade. In cells that are normally adherent, such as endothelial cells, the ability of receptor tyrosine kinases (RTKs) to activate the ERK pathway and to induce proliferation is dependent on integrin-mediated adhesion to matrix [12,13]. Activation of ERK in ECs by VEGF and other mitogens is enabled by multiple integrins, suggesting a general requirement for cytoskeletal assembly [14,15]. Recent data suggest that colocalization of RTKs and integrins at sites of cell attachment results in assembly of signaling complexes that enhance the coupling of RTKs to downstream effectors [16]. The specific integrins with which VEGFR-2 cooperates may depend on the composition of the matrix in a particular vessel.

In the classical model of ERK activation by RTKs, the adaptor protein Grb2, in a complex with Sos (a Ras guanine nucleotide exchange factor or GEF), binds to an activated receptor [17]. Sos promotes GTP loading of Ras, which then triggers the Raf-MEK-ERK cascade. Activated ERK translocates to the nucleus where it induces transcription of immediate early genes, thereby promoting cell cycle progression [18]. Epidermal growth factor (EGF) and bFGF, which are potent mitogens for HUVECs, stimulate the Ras-ERK pathway in this fashion [19,20]. However, the Ras-ERK pathway can also be activated via protein kinase C (PKC), which can induce formation of a Ras/Raf complex through a mechanism that is distinct from the Grb2/Sos-dependent mechanism [21]. Strong evidence suggests that VEGF, in contrast to EGF and bFGF, activates Ras-ERK signaling primarily via the PLC γ -Ca²⁺-PKC pathway [19,20,22,23], although this appears to be cell-type dependent [24,26]. VEGF signaling

to ERK via the less conventional pathway ensures that the Ras-ERK and PLC γ -Ca²⁺ pathways are activated in concert (Fig. 1). Although the functional significance of linking Ca²⁺ mobilization and ERK activation in a single signaling cascade is unclear, since bFGF can stimulate EC proliferation *in vitro* without activating the PLC γ -Ca²⁺ pathway [20], it is possible that Ca²⁺ signaling helps to create an environment that is permissive for angiogenesis. *In vivo*, EC proliferation may require disruption of interendothelial junctions, a process which may be critically dependent on Ca²⁺ (see the following section).

Interestingly, Ang-1 does not induce EC proliferation *in vitro* [3]. The inability of Ang-1 to drive proliferation may reflect its relatively weak (as compared to VEGF) stimulation of the ERK pathway [27] or its failure to activate the PLC γ /Ca²⁺ pathway (C. Daly and J. Holash, unpublished data).

VEGF Promotes Vascular Permeability

VEGF rapidly and potently increases the permeability of vessels to plasma proteins (e.g., fibrinogen)[28]. Although it has been proposed that extravasated plasma proteins provide a scaffold for EC migration during angiogenesis [28], the precise role of VEGF-induced permeability is unclear. It is possible that the destabilizing effects of VEGF on interendothelial junctions, which lead to plasma protein leak, are also important in allowing ECs to adopt a proliferative and/or migratory phenotype.

Plasma protein extravasation in response to VEGF appears to occur via intercellular gaps [29], although a transcellular route dependent on vesicular transport has also been reported [30]. Studies of other permeability-inducing agents such as thrombin indicate that formation of actomyosin

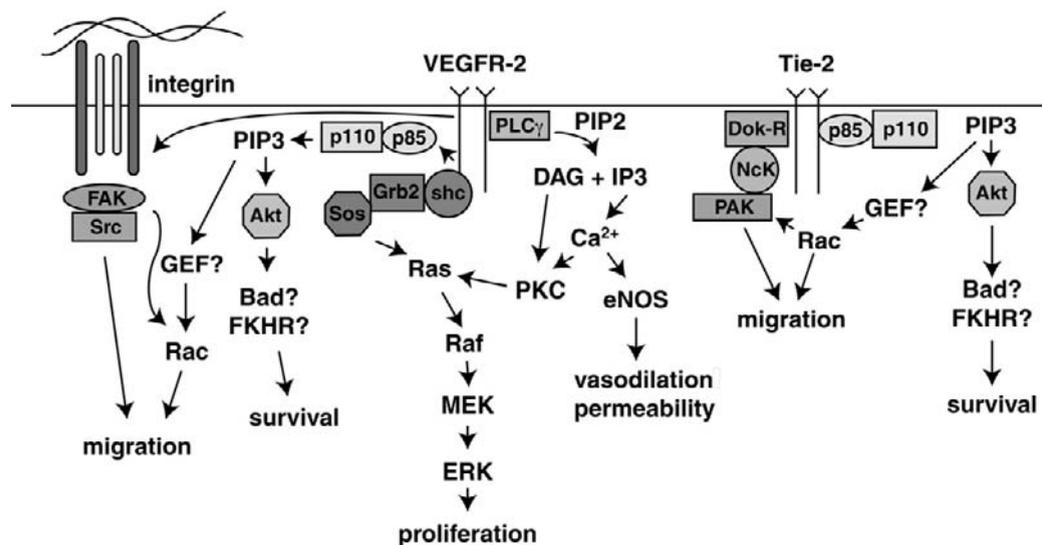

Figure 1 Major signaling pathways activated by VEGFR-2 and by Tie 2. The diagram is not meant to be comprehensive, but outlines some of the better characterized pathways employed by these two receptors. See the text for details.

stress fibers, which presumably create the tension required to form intercellular gaps, is important in controlling permeability [31]. Stress fiber formation is promoted by phosphorylation of myosin light chain, which can occur via Ca^{2+} -mediated activation of myosin light chain kinase or via activation of the small GTPase Rho [32]. Ca^{2+} mobilization is required for VEGF-induced permeability, consistent with a possible role for myosin light chain kinase [33]. In addition, VEGF appears to activate Rho and to promote stress fiber formation in HUVECs (J. Connolly and A. Hall, personal communication), although a requisite role for Rho in VEGF-induced leak remains to be demonstrated.

In addition to stress fiber formation, increases in permeability are likely to involve destabilization of the protein complexes at cell-cell junctions. VEGF has been reported to promote tyrosine phosphorylation of multiple components of EC adherens junctions, a modification which likely decreases junctional stability [34]. However, the precise mechanisms through which VEGF modulates cell-cell junctions remain to be elucidated.

eNOS, which is activated downstream of Ca^{2+} mobilization, is required for VEGF-induced permeability [35]. The generation of NO activates guanylate cyclase, resulting in cGMP production. cGMP appears to promote permeability, at least in part, by decreasing cAMP levels, although the mechanism(s) through which cAMP levels directly influence permeability are unknown [33].

Ang-1 Inhibits Vascular Permeability

Unlike VEGF, Ang-1 makes vessels resistant to leak. Transgenic overexpression of Ang-1 in the skin, or systemic administration of Ang-1, can block permeability induced by a number of inflammatory mediators including VEGF [8,9]. Intraocular injection of Ang-1 in diabetic mice reduces the edema that results from breakdown of the blood-retinal barrier, suggesting that it may be therapeutic in diabetic retinopathy [36]. The signaling mechanisms whereby Ang-1 blocks vascular permeability remain unknown, but might involve effects on the cytoskeleton and/or on cell-cell junctions.

Vessel Destabilization and EC Migration

Sprouting and migration of ECs requires the disruption of EC-perivascular cell interactions. Although signaling mechanisms controlling these interactions are not completely understood, Ang-1, as well as PDGFB [37] and TGF β [38] appear to play important roles. The notion that Ang-1 contributes to vessel stabilization derives from the observation that Ang-1-null embryos exhibit disrupted endothelial-perivascular cell interactions [4]. Several studies have correlated Ang-2 expression in ECs with angiogenic sprouting [5,6,39], consistent with a role for Ang-2 (by antagonizing Ang-1 action [5]) in vessel destabilization [7]. However, the mechanisms through which Tie 2 signaling

affects EC-perivascular cell interactions remain to be elucidated, and other factors are likely to contribute to vessel destabilization.

An essential aspect of cell migration is cytoskeletal rearrangement, a process in which Rho family GTPases play a critical role [40]. Rac, a member of the Rho family, is required for growth-factor-induced cell movement [40,41]. Through activation of a number of effector proteins, Rac promotes polymerization of actin in lamellipodia at the leading edge of motile cells [40]. VEGF has been shown to promote EC migration in a Rac-dependent fashion [42]. The pathway by which VEGF activates Rac is undefined, but may involve PI3-K-dependent stimulation of a Rac GEF [43]. Subsequent to Rac-induced lamellipodia formation, focal complexes containing clustered integrins are formed, presumably stabilizing the newly formed cell protrusion [44,46]. Focal complexes contain a variety of signaling molecules, including focal adhesion kinase (FAK), which is inducibly phosphorylated on tyrosine in response to integrin clustering and/or RTK activation [47]. VEGF has been shown to promote tyrosine phosphorylation of FAK [48], which in turn couples to multiple downstream signaling pathways, including Rac and the kinase Src [47]. Interestingly, Src appears to be required for VEGF-induced migration and angiogenesis [49,50].

Ang-1 has also been shown to induce EC migration *in vitro* [51,53], via a pathway involving Rac and the Rac effector PAK (Fig. 1) [54]. PAK, a kinase that inhibits actin depolymerization [55] and that is required for EC migration [56], is recruited to tyrosine-phosphorylated Tie 2 by the adaptors Dok-R and Nck [54,57], and subsequently becomes activated [54]. Understanding the significance of Ang-1-mediated activation of the PAK pathway will require further investigation, since the conditions under which Ang-1 is an important regulator of EC migration remain to be determined.

Regulation of EC Survival during Angiogenesis

ECs depend upon cell-cell and cell-matrix contacts for survival [58,59]. During angiogenesis, when matrix attachments and cell-cell contacts within stable vessels are disrupted in preparation for EC migration, the cells become dependent on VEGF for survival [60–63]. Once vessels mature and recruit pericytes, their dependence on VEGF is reduced [61,64], perhaps because pericytes elaborate additional survival factors or promote maturation of EC-matrix contacts.

Consistent with *in vivo* observations, VEGF promotes the survival of ECs *in vitro* under conditions of serum withdrawal [65,66]. The pro-survival effect of VEGF, like other growth factors, depends on activation of the PI3-K pathway [65,66]. Although VEGF induces tyrosine phosphorylation of the p85 subunit of PI3-K [67,68], it is unclear whether p85 interacts directly with VEGFR-2; it has been proposed that VEGF activates p85 indirectly, via a FAK dependent mechanism [69]. One critical component of the PI3-K pathway is AKT, a kinase which phosphorylates and inhibits

several pro-apoptotic proteins, including Bad and the transcription factor FKHR [70]. Whether these AKT targets are relevant to VEGF signaling is unknown. In terms of pro-survival genes, VEGF induces the expression of bcl-2, survivin, Al, and xiap [71–74], by signaling pathways that remain to be characterized.

Ang-1 also promotes survival of ECs *in vitro* via the PI3-K/AKT pathway [75–77]. Interestingly, Ang-1 is a significantly more potent activator of the AKT pathway than is VEGF [78], suggesting that Ang-1 is likely to be an important regulator of EC survival *in vivo*. The AKT targets which are important in Ang-1 signaling remain to be identified. Like VEGF, Ang-1 increases survivin expression, although the underlying mechanism is unknown [77]. Recent data from partially-rescued Tie 2 knockout mice suggest that the Ang-1/Tie 2 signaling system is important for EC survival during vascular development [79]. Interestingly, activated Tie 2 can be detected in the quiescent vasculature of several adult tissues [80], suggesting that Ang-1 has a role in vascular maintenance, possibly including a pro-survival role.

Conclusion

The development of new blood vessels is an extraordinarily complex process. Although numerous growth factors have been evaluated for their angiogenic potential, very few factors that have specificity for the vasculature have been identified. It seems that most factors that are believed to have angiogenic activity also mediate numerous other processes, limiting the therapeutic potential of manipulating these systems. Thus, in this chapter we have focused on how VEGF and the angiopoietins, which are largely specific for the vasculature, may mediate a number of steps that are required for blood vessel formation.

Vascular Endothelial Growth Factors and their Receptors in Vasculogenesis, Angiogenesis, and Lymphangiogenesis

Marja K. Lohela and Kari Alitalo

Molecular/Cancer Biology Laboratory and Ludvig Institute for Cancer Research, Haartman Institute and Helsinki University Central Hospital, Biomedicum Helsinki, University of Helsinki, Helsinki, Finland

Vasculogenesis, Angiogenesis, and Lymphangiogenesis

During embryogenesis, blood and lymphatic vasculature develops through the regulated proliferation, migration, and differentiation of endothelial cells. Initially, a primary blood vascular plexus is formed in the process of vasculogenesis, where mesoderm-derived angioblasts differentiate into endothelial cells and assemble to form a network of uniformly sized primitive vessels [1]. The subsequent remodeling of the primary plexus to form a more complex treelike hierarchy of large and small vessels is called angiogenesis. Angiogenesis occurs by sprouting and branching of new vessels from the preexisting ones, followed by progressive pruning and remodeling of the vessels into a mature vascular system [1]. Periendothelial support cells, such as vascular pericytes and smooth muscle cells, are then recruited to the vessel wall and the extracellular matrix is reconstituted [2]. Vasculogenesis is probably restricted to early development, but physiological angiogenesis occurs in adult organisms during the female reproductive cycle and in wound healing. Pathological angiogenesis occurs in several diseases such as rheumatoid arthritis and diabetic retinopathy and during tumor growth [3]. The observation that solid tumors are

dependent on neovascularization has brought endothelial cell signaling mechanisms and molecules into focus in the field of cancer research.

The lymphatic vessels arise from the embryonic veins through a process termed lymphangiogenesis. The lymph vessels become organized parallel to the blood vascular system and function to transport interstitial fluid, extravasated plasma proteins, and cells back into the blood circulation [4]. The lymphatic vessels also form a part of the immune system together with the lymphoid organs. Lymphatic capillaries consist of a thin, permeable layer of endothelial cells that are anchored to the surrounding connective tissue by elastic filaments called anchoring fibrils. The capillaries have a discontinuous basement membrane and only a few scattered support cells. The lymphatic capillaries transport the fluid into progressively larger collecting vessels consisting of endothelial, muscular, and adventitial layers, which ultimately drain into the venous circulation via the thoracic duct. Movement of lymph is brought about by the intrinsic contractility of the smooth muscle cells surrounding the larger vessels, and backflow is prevented by luminal valves [4]. Lymphedema, the accumulation of protein-rich fluid in interstitial tissues, occurs in humans either as hereditary disease or due to lymph vessel damage or removal. Because of

the metastatic spread of tumor cells via the lymphatic system and tumor lymphangiogenesis, the lymphatic endothelial cell signaling is also of interest in cancer biology.

The Vascular Endothelial Growth Factors and their Receptors

Signaling by the vascular endothelial growth factor (VEGF) family members and their receptors (VEGFRs) is essential in vasculogenesis and angiogenesis, and has more recently been shown to be critical in lymphangiogenesis as well. The VEGF family consists of five members thus far, namely VEGF, VEGF-B, VEGF-C, VEGF-D, and placenta growth factor (PlGF). All family members are secreted glycoproteins that possess a VEGF homology domain belonging to the cysteine knot growth factor family, and they function as disulfide-linked anti-parallel dimers [5,6]. Out of the VEGF family, only VEGF itself is induced by hypoxia, via an intricate signal transduction mechanism involving prolyl hydroxylation and specific ubiquitin ligase complexes [7].

VEGFs transduce signals mainly via three known VEGFRs, VEGFR-1/Flt-1, VEGFR-2/Flk-1/KDR, and VEGFR-3/Flt-4. VEGFRs are high-affinity receptor tyrosine kinases, restricted largely to endothelial cells, and they are structurally and functionally related to the PlGF receptors [8].

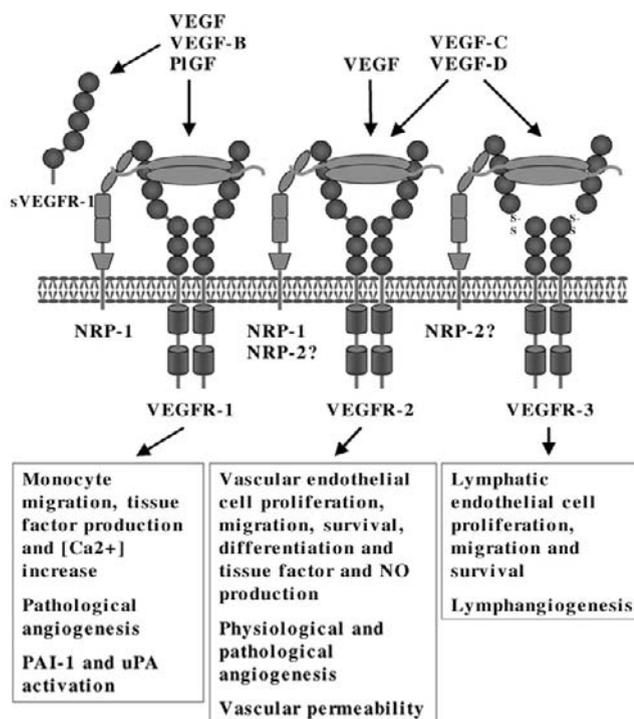

Figure 1 The VEGF receptors and their ligands. VEGFR-1 and VEGFR-2 have seven extracellular immunoglobulin homology domains (circles); in VEGFR-3 the fifth immunoglobulin domain is cleaved on receptor processing into two disulfide-linked subdomains. sVEGFR-1, soluble VEGFR-1; NRP, neuropilin; PAI-1, plasminogen activator inhibitor-1; uPA, urokinase-type plasminogen activator; NO, nitric oxide.

The VEGFRs have seven immunoglobulin homology domains in their extracellular part, and an intracellular tyrosine kinase domain split by a kinase insert sequence. VEGFR-1 exists also in a soluble form produced by alternative splicing. The VEGF family members have different binding specificities for the VEGFRs, schematically shown in Fig. 1. Neuropilins-1 and -2, which were originally characterized as receptors for semaphorins in the nervous system, also selectively bind members of the VEGF family in an isoform-specific manner and seem to act as co-receptors with VEGFRs, possibly acting by clustering of receptors (Fig. 1) [9,10]. Several excellent reviews have appeared that detail the structures of VEGFs and their receptors and their function in angiogenesis [5,8,11,12].

VEGF and VEGFR-1 and -2 are Essential for Vasculogenesis and Angiogenesis

Hemangioblasts, as yet ill-defined precursor cells for both the vascular endothelial and hematopoietic lineage [13,14], are thought to differentiate from pluripotent epiblastic precursor cells under the inductive influence of several factors, including the fibroblast growth factor [15]. VEGFR-2 is the earliest marker for hemangioblasts [16], and the importance of both VEGF and its receptors VEGFR-1 and VEGFR-2 in vasculogenesis and hematopoiesis is clear from the knockout mouse phenotypes. Inactivation of a single VEGF allele resulted in embryonic lethality between embryonic days 11 and 12 (E11–12), indicating that the effect of VEGF on vasculogenesis is dosage-dependent [17,18]. The VEGF^{+/−} embryos appeared growth retarded and exhibited a number of developmental anomalies, including severe cardiovascular defects and reduced number of red blood cells. Mouse embryos lacking VEGFR-2 died at E8.5–9.5, and showed a total lack of vasculogenesis and hematopoiesis [19]. *In vitro* studies indicate that VEGFR-2 is not required for the formation of hemangioblasts, but is necessary for endothelial cell commitment [20]. Knockout studies have demonstrated the necessity of VEGFR-1 for vasculogenesis. VEGFR-1-null mice died at E8.5–9.5, and while their endothelial cells differentiated normally, they showed an increase in numbers and failed to organize into proper channels [21,22]. Disruption of VEGFR-3 also led to embryonic death due to defective remodeling of the vascular plexus and cardiovascular failure, but vasculogenesis appeared to occur normally [23].

VEGFR-2 appears to be the major receptor that conveys VEGF-induced signals in endothelial cells. In various endothelial cell types VEGF induces strong VEGFR-2 autophosphorylation, activation of the MAP kinase cascade, and the PI3-K-Akt pathway, cell survival, proliferation, and chemotaxis. The signal transduction via VEGFRs is summarized in Fig. 2; for reviews on VEGF signaling, see references [24] and [25]. Experiments with mice having the VEGFR-1 tyrosine kinase domain deleted have shown that the ligand-binding and transmembrane domains of the receptor are sufficient for normal vasculogenesis and angiogenesis [26].

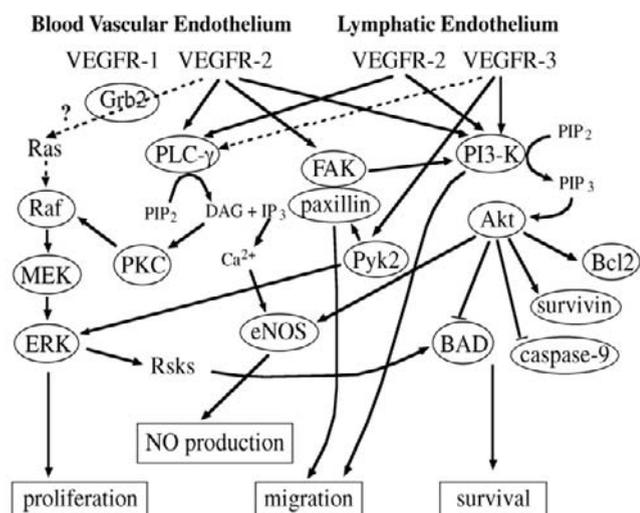

Figure 2 The major known VEGFR signaling pathways in blood, vascular, and lymphatic endothelium. PLC- γ , phospholipase C- γ ; FAK, focal adhesion kinase; PI3-K, phosphatidylinositol 3' kinase; PIP₂, phosphatidylinositol 4,5-bisphosphate; PIP₃, phosphatidylinositol 3,4,5-trisphosphate; PKC, protein kinase C; DAG, diacylglycerol; IP₃, inositol 1,4,5-trisphosphate; MEK, MAPK/ERK kinase; MAPK, mitogen-activated protein kinase; ERK, extracellular signal-regulated kinase; Rsk, ribosomal protein S6 kinases; eNOS, endothelial nitric oxide synthase; NO, nitric oxide. (Figure modified from Karkkainen, M. J. *et al.*, *Nat. Cell Biol.*, 4, E2–E5. With permission. See also references [24] and [43]).

Thus it has been postulated that VEGFR-1 does not have a signaling role in these processes, but acts as a VEGF sink to negatively regulate VEGFR-2 signaling. Yet, PlGF, which only binds VEGFR-1 is essential for all forms of pathological angiogenesis in adult tissues [27].

Lymphangiogenesis is Regulated by VEGFR-3 and its Ligands VEGF-C and -D

VEGFR-3 is initially expressed in all embryonic endothelial cells, but becomes restricted to lymphatic vessels later in development [23,28]. VEGF-C and -D bind to and activate VEGFR-3 and in their fully mature, proteolytically processed forms, are also ligands for VEGFR-2 [29,30]. Both VEGF-C and -D have been shown to be lymphangiogenic. VEGF-C can induce lymphangiogenesis when administered as a recombinant protein onto the avian chorioallantoic membrane [31] or when overexpressed as a transgene in mouse skin [32]. A VEGFR-3-specific mutant form of VEGF-C also induced lymphangiogenesis in the skin [33], indicating that the lymphangiogenic effects of VEGF-C are transduced via VEGFR-3. Furthermore, a soluble form of VEGFR-3 expressed under the control of the same skin-specific promoter caused regression of developing lymphatic vessels by inducing endothelial cell apoptosis [34]. The dermal blood vessels were not affected, confirming the specificity of VEGFR-3 function in lymphatic endothelial cells in later development. In this model, lymphatic vessels were initially lost in several internal organs, but partially regenerated in adult mice [34].

Human early-onset primary lymphedema has been shown to be linked to mutations in the *VEGFR-3* gene that inactivate the tyrosine kinase [35,36]. Chy mice that have a similar mutation developed lymphedema of limbs due to lack of subcutaneous lymphatic vessels, but new lymphatics were induced to grow by VEGF-C therapy via viral gene delivery, suggesting that human lymphedema could also be treated with VEGF-C/D therapy [37]. Interestingly, VEGF-C and -D have also been shown to promote tumor lymphangiogenesis and lymphatic metastasis in mouse tumor models [38–42], and both soluble receptors and blocking antibodies could inhibit lymphatic metastasis [38,42].

Little is known about the signaling mechanisms involved in lymphangiogenesis. VEGFR-3 signaling has been investigated in isolated lymphatic endothelial cells utilizing the VEGFR-3-specific mutant form of VEGF-C. It was found that VEGFR-3 signaling can promote the growth, survival, and migration of lymphatic endothelial cells. VEGFR-3 phosphorylation leads to PI3-kinase-dependent Akt activation and protein kinase C-dependent activation of the p42/p44 MAPK (Fig. 2) [43].

Concluding Remarks

The complicated signaling networks regulating the growth and maintenance of blood- and lymphatic vasculature are only beginning to be elucidated. In addition to the VEGF/VEGFR system, two other receptor tyrosine kinase systems have been shown to be important in endothelial cells of vasculature (reviewed in [44]). Tie 1 and Tie 2/Tek receptors and the angiopoietins, which are Tie 2 ligands, seem to be especially important in regulating the stability of the vasculature. The Eph receptors and their Ephrin ligands, were originally discovered as regulators of the nervous system. There are interesting parallels between vascular and nervous development, and also the VEGF/VEGFR system may have a function in nervous development. The intricate interactions between the different signal transduction systems and the similarities and differences between the regulation of endothelial cell signaling in different parts of blood and lymphatic vasculature pose additional challenges in this field of research.

Signaling from FGF Receptors in Development and Disease

Monica Kong-Beltran and Daniel J. Donoghue

*Department of Chemistry and Biochemistry, Center for Molecular Genetics,
University of California San Diego, La Jolla, California*

Introduction

Fibroblast growth factor receptors (FGFRs) are members of the receptor tyrosine kinase family which consists of four structurally related members: FGFR 1, 2, 3, 4, and their alternatively spliced variants. Each receptor contains two to three immunoglobulin (Ig)-like domains in the extracellular region, an acidic box between Ig-1 and Ig-2, a transmembrane domain, and a split intracellular tyrosine kinase domain (Fig. 1). Normal activation of FGFRs relies on interaction with their ligands: fibroblast growth factors (FGFs). At least 22 FGFs are known to date, and each FGFR member interacts with a specific subset of FGFs, as summarized in Fig. 1 (reviewed in [38] and reviewed in [11]). Heparan sulfate proteoglycans facilitate FGF binding with FGFR to induce FGFR dimerization and activation [44]. Crystal structure analyses have indicated that heparin binds to two FGFs such that the FGFs are not directly interacting with each other, and that each FGF is binding to an FGFR (reviewed in [19]). Another study has shown, however, that the heparin-FGF monomer alone can activate FGFR dimerization [39]. After ligand stimulation, FGFRs undergo dimerization and autotyrosine phosphorylation, resulting in kinase activation. The phosphorylated tyrosine residues may then serve as binding sites for secondary signaling molecules.

Expression of FGFR during Development

FGFRs are widely expressed during development and in adult tissues [18]. FGFR1 is expressed in the central nervous

system and developing limbs during development. During early neurogenesis, FGFR1 expression is upregulated in the ventricular zone of the neural tube and is expressed in the mesenchyme of developing limbs [35,52]. At later stages of development, FGFR1 can be found in maturing neurons in the brain and in motor neurons in the spinal cord [17,35]. FGFR2 is also expressed in the brain, particularly in the developing mid- and hindbrain [35,47,52]. In addition, FGFR2 and FGFR3 expression occurs highly in the trophoderm and to some degree in the mesenchyme [30,35,36]. Importantly, FGFR3 is expressed in the hypertrophic and proliferative zones of the bone growth plate, cochlea, brain, and spinal cord [6]. Expression levels of FGFR4 have not been examined as thoroughly as other FGFR family members, but FGFR4 has been shown to be expressed in definitive endoderm and skeletal muscle lineages, as well as the ventricular zone of developing spinal cord and dorsal root ganglia [27,34,45].

Role of FGFR in Development

Genetic alterations in mice reveal the importance of FGFR during development. In FGFR1 and FGFR2, null mutations result in embryonic lethality due to defects of mesodermal patterning or trophoblast cell proliferation [2,7,53,55]. FGFR1 chimeric mice further demonstrate that FGFR1 is necessary for neural tube and limb development [9], while FGFR2 chimeras indicate that FGFR2 is required for both limb outgrowth and branching morphogenesis of the lungs [2]. Additionally, FGFR2 has been shown to be important for keratinocyte differentiation [50]. FGFR3 null mice exhibit

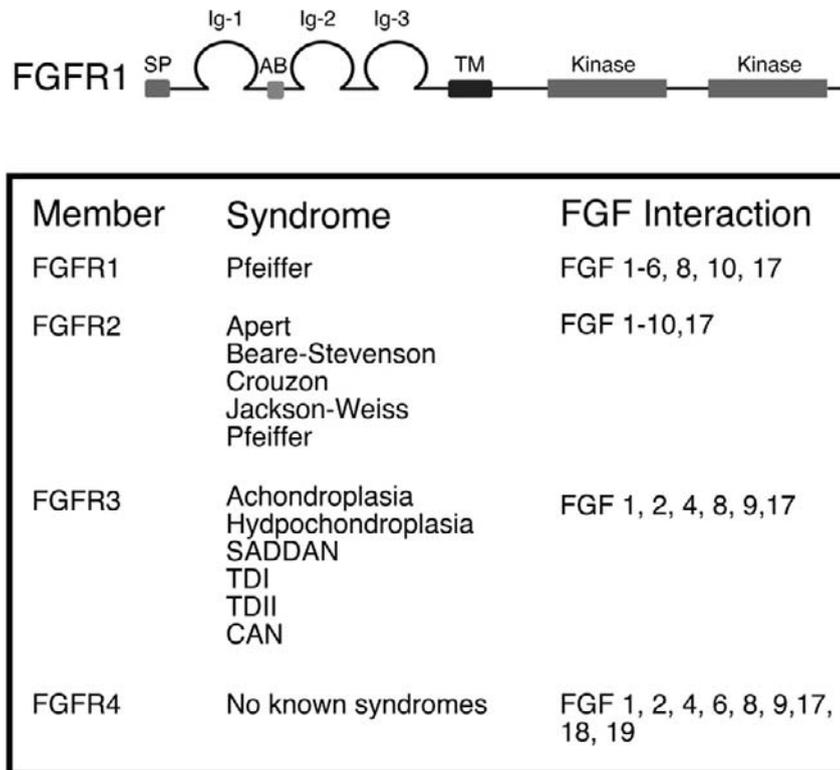

Figure 1 Structure of FGFR1 is shown as representative of FGFR1, FGFR2, FGFR3, and FGFR4. SP, signal peptide; Ig, immunoglobulin-like domain; AB, acidic box; TM, transmembrane domain. Developmental syndromes associated with different FGFRs are summarized. SADDAN, severe achondroplasia with delayed development and acanthosis nigricans; TD, thanatophoric dysplasia; CAN, Crouzon syndrome with acanthosis nigricans.

bone defects and deafness, demonstrating that FGFR3 is important for normal skeletal and ear development [6,8]. The FGFR4 null mutant mice appear to be normal, but have depleted gallbladders and elevated liver bile acids [56].

Syndromes Associated with FGFRs

Activating mutations of FGFR1, FGFR2, and FGFR3 can lead to craniosynostosis syndromes of various degrees of severity as listed in Fig. 1. Craniosynostosis is characterized by the premature fusion of the cranial sutures between the developing flat bones of the skull, resulting in abnormal head shape, midface hypoplasia, and other skeletal defects. Related syndromes can be distinguished by examining the extremities [16,49,51]. For example, a mutation in FGFR1 which causes Pfeiffer syndrome, a classic form of craniosynostosis, is characterized by broad, sometimes medially deviated thumbs and big toes. Mutations in FGFR2 result in a broad group of craniosynostosis syndromes, including Pfeiffer, Apert, Beare-Stevenson, Crouzon, and Jackson-Weiss syndromes. Mutations in FGFR3 are generally responsible for skeletal dysplasia syndromes, including thanatophoric dysplasia (TD) types I and II, hypochondroplasia, achondroplasia, severe achondroplasia with developmental delay and acanthosis nigricans (SADDAN), and Crouzon syndrome

with acanthosis nigricans (CAN). These FGFR3 syndromes range from a mild form of dwarfism (hypochondroplasia) to neonatal lethal dwarfisms (TD I and II). There are no known craniosynostoses or skeletal syndromes associated with mutations of FGFR4.

Signaling Pathways Mediated by FGFRs

FGFRs play key roles in cell proliferation, differentiation, migration, wound healing, survival, and angiogenesis. Ligand activation of FGFR results in kinase activity and autophosphorylation of tyrosine residues, thereby creating specific binding sites for downstream effector molecules that coordinate FGFR-mediated signaling. For example, phospholipase C- γ (PLC- γ) binds to activated FGFR1 and is phosphorylated by FGFR1, resulting in protein kinase C (PKC) activation (reviewed in [4]).

FGF receptor substrate 2 (FRS2), a membrane-associated docking protein, binds to the juxtamembrane of FGFR1 via its phosphotyrosine binding (PTB) domain [53]. The Grb2/Sos complex is recruited to the plasma membrane via FRS2 and activates Ras to trigger the mitogen-activated protein kinase (MAPK) pathway and expression of nuclear proteins including Fos and Myc [12,13,22,32]. In addition, activated FGFR1 results in FRS2 binding to Grb2 and leads to tyrosine

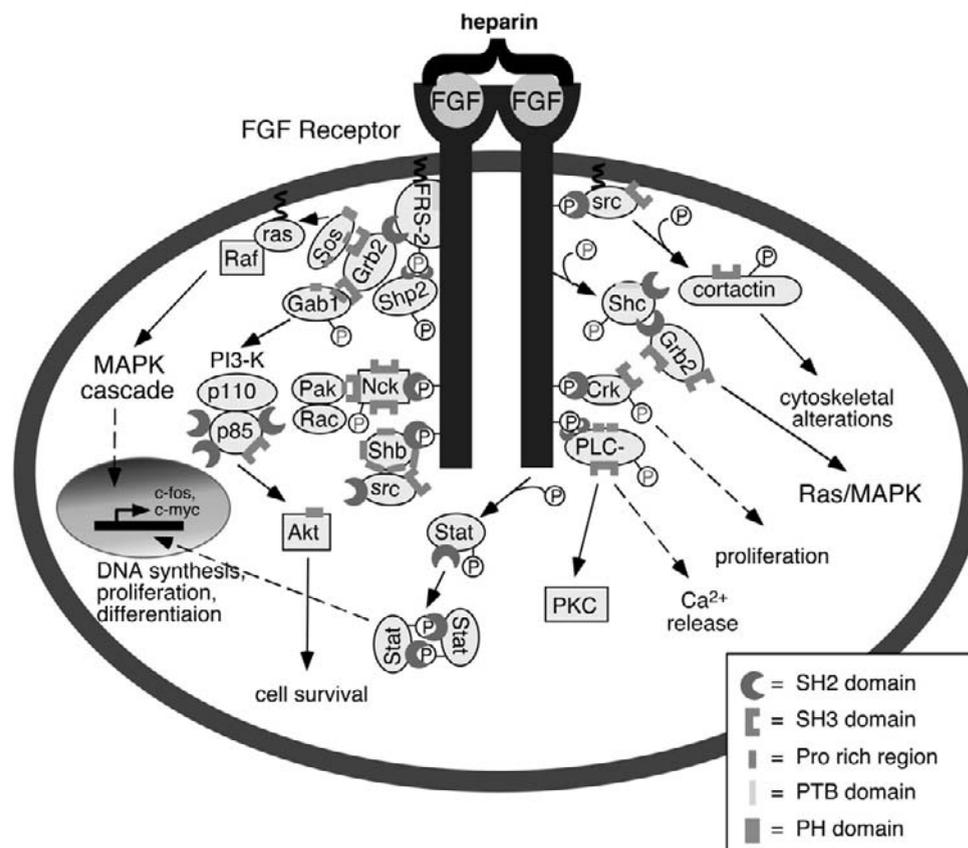

Figure 2 Intracellular signaling pathways activated by FGFRs are summarized. Tyrosine phosphorylation of receptor subunits facilitates recruitment and assembly of activated signaling complexes.

phosphorylation of a Grb2-associated docking protein named Gab1, which recruits and activates the phosphatidylinositol 3-kinase (PI3-kinase)/Akt pathway for cell survival [33]. Interestingly, Grb2 can interact with Sos and Gab1 simultaneously, allowing activation of both Ras/MAPK and PI3-kinase/Akt pathways [33]. Furthermore, the tyrosine phosphatase Shp2 becomes phosphorylated and interacts with the SH2 domain of Grb2 to form a complex with tyrosine phosphorylated FRS2, providing another link of activated FGFR to the Ras/MAPK signaling cascade [14,31,32,22]. Shp2 can also interact with Gab1 [31].

Adapter proteins play significant roles in FGFR-mediated signaling. Activated FGFR1 results in tyrosine phosphorylation of Shc. Shc binds to Grb2 and may link FGFR1, but not FGFR4, to the Ras signaling pathway [3,41,48]. The adapter protein Crk also interacts with phosphorylated FGFR1, becomes tyrosine phosphorylated, and results in cell proliferation [24]. In addition, Nck binds to activated FGFR1 and becomes tyrosine phosphorylated, potentially linking FGFR1 to the actin cytoskeleton since Nck facilitates the interaction between Pak and Rac [42], and reviewed in [26]. The adapter protein Shb also binds to FGFR1 and is tyrosine phosphorylated; Shb thus appears to be an adaptor protein linking SH3 domain proteins to tyrosine kinases or other tyrosine phosphorylated proteins [5,20]. Chimeric receptors composed of the extracellular domain of PDGFR- β and the transmembrane

and intracellular domains of FGFR1, FGFR3, and FGFR4 were able to activate phospholipase C γ , Shc, FRS2, and the mitogen-activated protein kinases, ERK1 and 2 [40]; in this study, however, these chimeric receptors did not appear to couple through Shc.

FGFRs are also implicated in other signaling pathways. Src is a non-receptor tyrosine kinase recruited by FGFRs and phosphorylates cortactin to affect cell migration; it remains unclear whether Src directly binds to FGFR1 [23,25,57]. Furthermore, activated FGFR 1, 3, and 4 promote Stat1 and Stat3 activation [15,46]. In the case of FGFR3, the adapter protein SH2-B has been found to activate Stat5 [21]. Most of these interactions and signaling pathways activated by FGFR mentioned above are summarized in Fig. 2, using FGFR1 as the model.

Summary

FGFRs play vital roles in growth, development, differentiation, and migration. Genetic analyses of FGFRs indicate their importance in organ and neuronal development. In addition, FGFs activate FGFRs to trigger multiple signaling pathways in the cell. Unfortunately, space has not permitted a discussion of the role of somatic FGFR mutations in human cancer. Many new pathways of FGFR signaling undoubtedly

remain to be discovered that will be important in understanding mammalian development and also the control of abnormal cell proliferation in cancer.

The Role of Receptor Protein Tyrosine Phosphatases in Axonal Pathfinding

Andrew W. Stoker

*Neural Development Unit, Institute of Child Health,
University College London, London, United Kingdom*

Introduction

One of the most impressive processes that occurs during development is the establishment of countless connections between neurons and their targets. Such precise connectivity requires long-distance growth and pathfinding by axons and short-range detection of target cells. This chapter reviews one family of molecules, the receptor-like protein tyrosine phosphatases (RPTPs), which direct axons in this astonishing feat. In the human genome there are around 22 RPTP genes, most of which have either orthologs or homologs in other species. Most RPTPs are strongly expressed, some times exclusively, in developing nervous systems, in particular within axons and their motile, pathfinding growth cones [1,2]. Evidence is reviewed here for RPTP roles in axon growth and guidance. Their potential signaling mechanisms are also briefly discussed. Due to space limitations, readers will, in most cases, be referred to two reviews and the references therein [1,2]. Figure 1 summarizes the axon growth and guidance events discussed in the following sections, and the RPTPs implicated in each. Other axonal receptor types are reviewed elsewhere in this volume.

Axons of photoreceptors project to the optic lobe where they terminate either in the lamina (R1–R6) or in proximal layers (R8) or distal layers (R7) of the medulla. DPTP69D and DLAR control these axonal termination events [1,3,4]. If axons of R1–R6 are made DPTP69D-deficient, they will overshoot their target and terminate in the medulla. Loss of DPTP69D in R7 causes its axon to stop short in the R8 termination zone. DPTP69D thus appears to control the ability of growth cones to de-adhere (defasciculate) from R8 at correct navigational decision points. Interestingly, R7 axons that lack DLAR can reach and recognize medulla targets, but they later retract [3,4]. DLAR-deficient axons from R1–R6, however, terminate normally. DLAR may therefore be involved in specifically stabilising adhesion of R7 to its targets. DLAR mutants and cadherin mutants have similar phenotypes, suggesting that they may regulate similar adhesive signaling pathways [3]. The collective data also indicate that DPTP69D and DLAR function cell autonomously, although DLAR also shows evidence of nonautonomous function in R8. In contrast to their guidance roles, DRPTPs do not appear to be necessary for axon elongation in the visual system, unlike their vertebrate counterparts.

RPTPs and the Visual System

Drosophila

The compound eye of the fly contains about 800 ommatidia, each with photoreceptor neurons R1 through R8.

Vertebrate Retinotectal System

In vertebrate eyes, retinal ganglion cell (rgc) axons relay visual signals from the eye to the brain. Neighboring rgc axons establish precise topographic connectivity with neighboring neurons in the optic tectum. Several studies in cell culture demonstrate a role for RPTPs in rgc neurite growth.

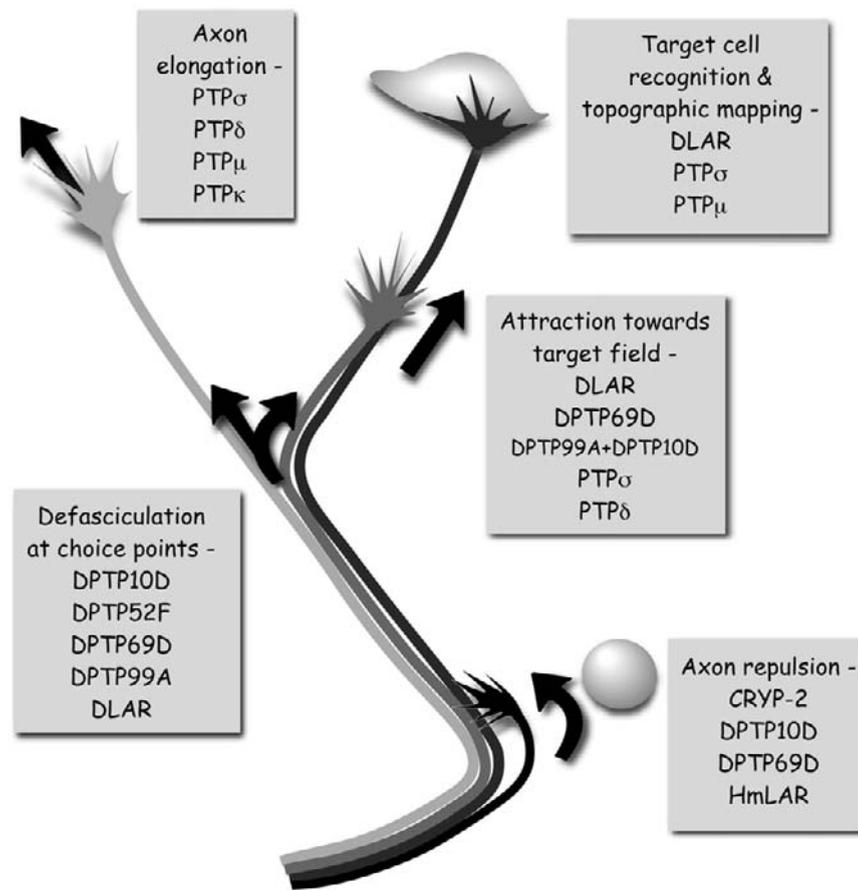

Figure 1 Schematic diagram showing the RPTPs implicated at different stages of axon growth and guidance. See text for details.

Signaling from chick PTP μ enhances cadherin-dependent retinal axon outgrowth [1]. Furthermore, PTP μ expression varies topographically across the retina and tectum and PTP μ has a selective, growth cone-collapsing function [5]. PTP μ may therefore differentially influence axon growth within the retinotectal projection. *Xenopus* PTP δ promotes both rgc axon growth along the optic tract *in vivo* and neurite growth on basement membranes in culture [6], while soluble ectodomains of human PTP δ can attract growth cones of cerebellar neurites [1]. Since both PTP δ and PTP μ bind homophilically, they may trigger signals directly between axons. Another retinal RPTP, CRYP-2 (encoded by avian *Ptpro*), is anti-adhesive in rgc cultures [7]. CRYP-2 may have an axon navigation role, since its ectodomain induces growth cone collapse and ectodomain gradients cause repulsive growth cone turning [7]. The interaction between chick PTP σ and a ligand(s) on basement membranes and glial endfeet maintains optimal retinal neurite outgrowth [1]. Perhaps counterintuitively, interference with intracellular signaling of *Xenopus* PTP σ causes faster neurite outgrowth in culture [6], suggesting a possible signaling model (see the section on ligands). The first evidence for RPTP function in axon targeting *in vivo* has come from chick PTP σ . Perturbation of the interactions between PTP σ and its ligands in the optic tectum causes retinal axon

stalling and rostral mistargeting [8]. PTP σ may therefore function by maintaining retinal axon growth over the tectum and facilitating the recognition of correct target sites.

Neuromuscular System

Drosophila genetics has highlighted key RPTP functions during motor axon guidance. The segmental and intersegmental motor nerves ISN, ISNb, and SNa of the fly larva innervate body wall muscles in a highly stereotypical manner. Nerve defects arise after loss of function in *DLAR*, *DPTP69D*, *DPTP99A*, *DPTP10D*, and *DPTP52F* [2,9]. DPTP69D and DPTP99A are required for ISNb axons to defasciculate from the ISN at the correct choice point. Gene deficiency causes a “bypass” phenotype where axons fail to leave the ISN and thus travel past their targets. DLAR influences not only this defasciculation step, but also both the entry of axons into the muscle target field and synapse formation [10]. DPTP10D collaborates with other DRPTPs in guiding SNa, but antagonizes them during navigation of the ISN. Similarly, DLAR and DPTP99A antagonize each other within SNb axons. There is therefore a complex pattern of interaction between these RPTPs with “partial redundancy, competition, and collaboration” as described by Sun and co-workers [11].

Further Axon Growth and Guidance Roles

In the leech, LAR homolog HmLAR2 is expressed in growth cones of neurite-like processes of comb cells, where it controls the orderly outgrowth of these processes [1]. Evidence supports a homophilic interaction between HmLAR2 molecules, signaling a mutual repulsion between growth cones and neighboring processes.

In the ventral nerve cord of *Drosophila*, axon guidance across the midline is influenced by DLAR, DPTP99A, DPTP69D, and DPTP10D. The latter two in particular cooperate with Robo receptors to transduce repulsive signals from midline Slit protein [1]. How these receptors cooperate biochemically is unclear at present.

Several RPTP gene-deficiency models have been developed in mice. Loss of PTP σ function causes motor function deficits and hyposmia, as well as quite severe defects in sciatic nerve myelination and maturation [1]. Deficiency in PTP δ also causes milder motor defects as well as memory alterations, while loss of LAR causes a reduction in forebrain cholinergic neuron numbers and some mild defects in hippocampal innervation [1]. The developmental bases for all these neuronal and axonal defects have yet to be characterized.

Axonal Signaling by RPTPs

Instructive or Permissive?

Do axonal RPTPs send permissive or instructive signals during axon guidance? With DLAR, the fact that R7 growth cones reach targets, but then retract, supports an instructive role in securing adhesion to targets. DLAR may also control the instructive process of muscle cell recognition by motor axons [11]. For DPTP69D, the consensus is more in favor of a permissive role in controlling defasciculation rather than target recognition, although this remains under discussion [1]. In fact, the many complex interactions between *Drosophila* RPTPs may ultimately make simple instructive/permissive distinctions untenable. Vertebrate PTP δ and CRYP-2 may have instructive signaling roles given that they can force growth cone turning on otherwise permissive substrates [1,7]. In contrast, chick PTP σ may control a permissive event during axonal targeting in the tectum, given that its known ligands are uniformly distributed [8].

Ligands

PTP μ and PTP δ bind homophilically, with no evidence to date of heterophilic ligands. Ectodomains of these RPTPs can act as neurite growth-promoting substrates in culture, suggesting that the growth of fasciculated axons *in vivo* may be promoted by their homophilic action. Paradoxically, PTP μ ectodomains also have negative effects on growth cones [5], although we do not know yet if this signal is transduced by PTP μ receptors. The heparin-binding chemokine pleiotropin is a ligand for PTP ζ , an RPTP expressed in both

glia and some neurons. Pleiotropin can inhibit the PTP ζ phosphatase and this leads to increased tyrosine phosphorylation of potential targets [12]. The heparan sulfate proteoglycans agrin and collagen XVIII are strong binding partners for chick PTP σ , although we await direct evidence for their roles in controlling PTP σ signaling in axons [13]. One of several models proposed also suggests that chick PTP σ ligands may inactivate the phosphatase, thereby facilitating neurite growth [6]. The effects of RPTP ligands are discussed further in part B of this Handbook. Although RPTP ectodomains have adhesive capacities, it is generally believed that their signaling roles require intact catalytic functions. For example, enzymatically active PTP μ is required for neurite outgrowth on cadherins [1]. Furthermore, genetic rescue studies with *Drosophila* RPTPs indicate that the rescuing genes must encode active phosphatases [1,3,4,11].

Downstream Signals

Figure 2 contains a summary of some of the known substrates and binding partners of neuronal RPTPs. Most of these impinge ultimately on the actin cytoskeleton, providing a logical handle on growth cone dynamics. DLAR interacts with several molecules including the tyrosine kinase Abl and its substrate Enabled (Ena, a VASP family member). Ena can be dephosphorylated by DLAR [1]. Dephosphorylation of Ena activates downstream signals that pass through profilin and on to actin. DLAR also interacts genetically with Trio, a large protein with two exchange factor domains for Rho family GTPases. *Drosophila* Trio also signals through the SH2–SH3 adaptor Dock and the p21-activated kinase Pak,

RPTPs	Interacting protein	Downstream effector	Refs.
LAR, PTP σ	> Trio >	Rac, Rho	1, 2
LAR, PTP δ , PTP σ	liprins		2, 10
DLAR	< Abl* <	ena*	1, 2
DLAR, DPTP69D	> ena* >	profilin	1
PTP α	> grb2 >		2
PTP α	> c-src* >		2
PTP μ	> RACK1 >	PKC δ	16
PTP μ , PTP κ , LAR family, PTP ζ	< cadherins & catenins* <		15
DPTP10D, DPTP99A	gp150*		2

Figure 2 Table showing some of the proteins that interact with axonal RPTPs, and some of the predicted downstream effectors where known. Symbols > and < indicate either stimulation or repression of function by the RPTP, respectively. Asterisks indicate that the protein is a phosphatase substrate.

again impinging on the cytoskeleton. Mammalian Trio binds directly to LAR family members and signals through Rho family GTPases. Human Trio promotes neurite outgrowth in PC12 neurons, although it is not known yet if LAR RPTPs are involved in this event [14]. Catenins are a key target of several RPTPs, including PTP μ , PTP κ , PTP ζ and LAR members [12,15]. These RPTPs may well antagonize cadherin/catenin-regulated cell adhesion by dephosphorylating β -catenin and p120(ctn), thereby directly influencing growth cone adhesion. PTP μ also binds to the adaptor protein RACK and in turn requires PKC δ to promote neurite outgrowth [16]. Other RPTP targets include the cell adhesion molecule-like gp150 and the tyrosine kinase c-src, but it is not clear yet if these are involved in RPTP signaling within axons. Finally, adaptor proteins of the liprin family bind to LAR family RPTPs and may be important for localizing these RPTPs in membranes and in forming complexes with roles in signaling, adhesion, and synapse function [2,10].

Attractive and Repulsive Signaling in Nerve Growth Cone Navigation

University of California, Berkeley, California*

Introduction

The function of the nervous system depends on complex and precise connections between nerve cells [1]. The formation of specific connections during development often requires the growing axon to navigate over considerable distances to reach their final target cells. This long-range navigation is achieved by guidance factors within the developing tissue that regulate the motility or directionality of the growing tip of the axon, the growth cone [2]. During the last decade several families of guidance factors have been identified, including netrins, semaphorins, ephrins, and slits [3,4]. In addition, inhibitory factors associated with the myelin that exert repulsive actions on the navigation of regenerating axons have also been discovered. Different classes of membrane receptors for these factors have been identified and their intracellular signal transduction mechanisms are beginning to be elucidated.

How does a guidance factor affect the navigation of the growing axon? A general scheme of signal transduction cascades from the receptor activation to cytoskeletal rearrangements is shown in Fig. 1 [4]. It starts with the binding of the guidance factor with the receptor protein or protein complexes at the cell surface. Ligand-receptor binding in general stimulates the activities of the cytoplasmic domain of the receptor, which in turn interacts specifically with cytoplasmic adaptor proteins. These adaptors may then recruit or activate their downstream effectors to further mediate the guidance signal. The effectors (or mediators) can be enzymes or second messengers that activate or inhibit cytoskeleton-associated

proteins, leading to polymerization or depolymerization of cytoskeletal structures and steering of the growth cone.

Two types of guidance signals may be distinguished: signals that convey a “stop or go” command regulating growth cone motility and signals that provide directional instructions to the growing axon, triggering turning responses of the growth cone. For nondirectional signals, mediators may simply alter the global cytoskeletal activity at the growth cone. For directional guidance signals, however, a gradient of cytoskeletal rearrangements must be created in order to induce directional motility. In the latter case, mediators must be activated or distributed in a gradient across the growth cone, and such a gradient may also need to be amplified in the cytoplasm in order to achieve a reliable directional response [4]. Although a number of cytoplasmic components have been implicated in such a scheme of signal transduction, definitive identification of signaling pathways are yet to be established for any one of the major families of guidance factors. This chapter summarizes some of the putative signaling pathways that have been shown to participate in growth cone navigation.

Netrin Signaling

Netrins are a family of secreted proteins and their receptors were identified to be DCC (deleted in colorectal cancer) and UNC-5 [5], two interacting transmembrane proteins that set the polarity of growth cone responses. Ectopic expression of UNC-5 in neurons converted netrin (UNC-6)-dependent

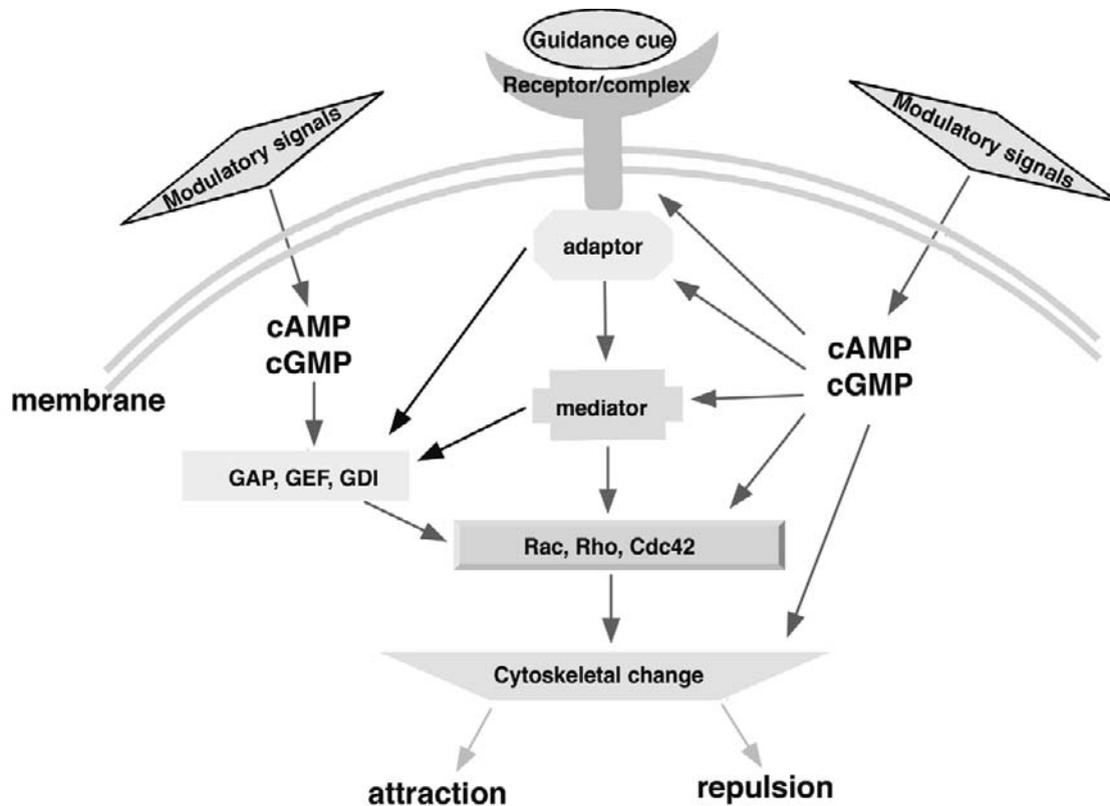

Figure 1 Signal transduction mechanism for nerve growth cone guidance.

chemoattraction to chemorepulsion in both *Caenorhabditis elegans* [6] and in dissociated *Xenopus* spinal neurons [7], a conversion that involves a netrin-dependent interaction between the cytoplasmic domain of DCC and UNC-5 [7]. The level of DCC can be actively regulated through degradation mediated by Sina/Siah protein [8] or through metalloprotease-mediated shedding [9], resulting in changes in the growth cone's sensitivity to netrin-1. Extracellular signal-regulated kinase 1/2 (Erk 1/2) was found to be recruited to DCC receptor complex in rat commissural neurons [10] and activation of phosphoinositide 3-kinase (PI3-K) and phospholipase $\text{C}\gamma$ appear to mediate attractive turning of *Xenopus* spinal neurons induced by a gradient of netrin-1 [11]. More recently, it has been shown that activation of MAPK, local protein synthesis, and protein degradation are involved in the netrin-induced chemoattraction of *Xenopus* spinal and retinal neurons [13,14]. These downstream events were shown to be critical for adaptive changes of growth cone sensitivity to netrin-1 as the extracellular concentration of netrin-1 is increased [13]. How these cytoplasmic factors are linked to the cytoskeleton changes remains largely unclear. Two members of the Rho GTPase family, Rac1 and Cdc42, appear to be involved in netrin signaling [15,16], thus providing potential links to cytoskeletal regulation [17]. To serve for directional guidance signals, a mediator is not only required for the guidance responses, but must also be activated in a gradient across the growth cone. Furthermore, such a gradient should be sufficient to induce a turning response of the growth cone. None of the putative signaling components described

above fulfill these criteria. Interestingly, the well-known second messenger Ca^{2+} appears to satisfy these criteria for netrin-1 signaling. Elevation of cytoplasmic Ca^{2+} , through both Ca^{2+} influx and release from internal stores, is required for netrin-1-induced turning responses and a netrin-1 gradient can trigger Ca^{2+} elevation and transient Ca^{2+} gradients across the growth cone [7,12]. Experimentally creating a gradient of Ca^{2+} across the growth cone in the absence of netrin-1 signals is sufficient to induce the turning of the growth cone [18]. However, it remains unclear how Ca^{2+} signals are linked to receptor activation upstream and cytoskeletal rearrangements downstream.

Semaphorin Signaling

The semaphorin family includes both membrane-bound and secreted molecules, thus it may work for both short- and long-range guidance [19,20]. Neuropilins were identified as semaphorin receptors and the plexin family of receptors was shown to be a co-receptor that transduces the signal. Several proteins have been shown to bind to neuropilins or plexins. These include a transmembrane protein OTK (off-track) [21], cytoplasmic protein NIP—a PSD-95/Dlg/ZO-1 domain-containing protein that may be involved in membrane trafficking [22], and MICAL, a flavoprotein oxidoreductase [23]. There is also evidence for the involvement of heterotrimeric G proteins [24]. The precise role of these receptor-interacting proteins and whether they mediate or modulate the signaling

process remain to be determined. More is known about the downstream cascades that mediate cytoskeleton changes induced by semaphorins. Of particular interest is Rac1, a small Rho family GTPase. Introduction of dominant-negative Rac1 [25] or an inhibitory peptide for Rac1 or C3 transferase, a Rho GTPase inhibitor, blocks Sema3A-induced growth cone collapse in sensory neurons [26,27]. A major downstream mediator of Rac1 and Cdc42 is P21-associated kinase (PAK), and LIM-domain-containing kinase (LIM-kinase), a direct substrate of PAK, are necessary for Sema3A-induced growth cone collapse [28]. LIM-kinase is a serine-threonine kinase that inhibits cofilin's actin-severing function. Thus at least one of the mechanisms for semaphorin-mediated cytoskeletal changes is mediated through the activation of small GTPases and their targets PAK, which then regulates actin dynamics through a LIM-kinase- and cofilin-dependent pathway. Other small GTPases such as Rho and Rnd1 [29,30] and kinases such as GSK-3 (glycogen synthase kinase) [31] and Fes/Fps tyrosine kinase [32] have also been implicated in semaphorin signaling.

Slit Signaling

Slits are a family of secreted proteins that can exert short- and long-range guidance functions by activating their receptors, the roundabout (Robo) family of proteins [33]. Slits appear to act not only as directional guidance factors but also as stop signals through activation in a combinatorial manner of different Robo receptors expressed on the growth cone surface [34–36]. Both Abelson tyrosine kinase (Abl) and its substrate Enabled (Ena) can bind directly to the cytoplasmic domain of Robo and modulate its function [37]. Interfering with the binding between Ena and Robo partially impairs the Robo function, while a mutation in a conserved tyrosine residue that can be phosphorylated by Abl generates a hyperactive Robo. Small GTPases and their regulators also affect slit-Robo signaling. A slit-Robo-GTPase activating protein 1 (srGAP1) can bind to Robo and inactivate Cdc42, resulting in repulsion of growth cones [38], while GEF64C, a Dbl family guanine nucleotide exchange factor (GEF), can activate Rho and block Robo-induced repulsion [39]. Thus, Robo-mediated cytoskeleton changes also appear to be mediated by activation of GAP or GEF of small GTPases.

Ephrin Signaling

Ephrins and the Eph family of tyrosine kinase receptors are membrane-bound molecules that mediate short-range axon guidance via cell-cell contacts [40]. Ephrin-A ligands are attached to the plasma membrane via a glycosphosphatidylinositol (GPI) linkage, whereas the ephrin-B ligand contains a transmembrane domain and a cytoplasmic tail [41]. Similar to slits, ephrins can function as either directional or nondirectional guidance factors. In addition, the signaling activated by ephrin-Eph binding is bidirectional [41], so that

cytoplasmic activities are triggered in both interacting cells. A GEF, ephexin, binds to the kinase domain of EphA constitutively through its Dbl homology-pleckstrin homology (DH/PH) domain and activates both RhoA and Cdc42, thus regulating cytoskeletal structures [42]. In addition, focal adhesion kinase (FAK) and its downstream factor P130(cas) which are two proteins involved in actin reorganization, are also implicated in EphA-induced cytoskeletal changes [43].

Nogo and Myelin-Associated Glycoprotein Signaling

Two proteins associated with myelin, Nogo, and myelin-associated glycoprotein (MAG), have been identified as the major inhibitory factors that prevent axon regeneration after CNS injury [44]. Although the full length of these proteins are membrane-anchored, they can be released in a truncated form and function in repelling and inhibiting axon growth [45,46]. The receptors for Nogo (NogoR) [46] and for MAG (GD1a and GT1b) [47] have been identified. Interestingly, MAG also binds to NogoR [48]. Since NogoR is a GPI-anchored protein at the cell surface [46], and an as yet unidentified co-receptor(s) is required for transducing the cytoplasmic signal. The downstream signal cascade for NogoR signaling is largely unknown, although Ca^{2+} and PI3-K are required for MAG-induced repulsion of *Xenopus* spinal neurons [11,49]. Rho is activated by MAG through receptor GD1a and GT1b [47]. Inhibition of Rho activity can promote CNS axon regeneration, suggesting that Rho may also be involved in MAG-induced cytoskeletal rearrangement [50].

Critical Roles of Modulatory Signals

For a growth cone to make its navigational decisions, it must integrate information provided not only by the guidance factors, but also by other modulatory signals. *In vitro* studies have shown that cytoplasmic cyclic nucleotides play key roles in modulating signal transduction events triggered by most guidance factors identified thus far [4]. For example, the growth cone responses to netrin and MAG are modulated by a cAMP-dependent pathway, whereas Sema3A and slit signaling is modulated by a cGMP-dependent pathway. Elevating the cytoplasmic level of cyclic nucleotides favors attraction/growth, while lowering their level favors repulsion/collapse [4]. Many extracellular ligands, including neuromodulators, adhesion molecules, and extracellular matrix (ECM) components, may change the level of cyclic nucleotides within the cell, thus altering the growth cone behavior when they are present concurrently with the guidance signal [51]. For example, laminin, an abundant ECM protein, reduces the cAMP level in *Xenopus* retinal ganglion neurons and converts the growth cone response to a netrin-1 gradient from attraction to repulsion both *in vitro* and *in vivo* [52]. Conversely, the repulsive response of DRG and cortical axons induced by Sema3A can be converted to attraction by exposure to soluble LI-Fc chimeric molecules; activation of

guanylate cyclase activity is required for the conversion [53]. The targets of PKA/PKG that are involved in regulating the polarity of growth cone turning responses remain to be identified.

Concluding Remarks

An emerging view of axon guidance factors is that they are multifunctional molecules capable of conferring attractive, repulsive, or stop signals. The precise behavior of a growth cone is determined by the nature of specific receptors and the status of cytoplasmic signal cascades, which are under the influence of a variety of extrinsic and intrinsic factors (Fig. 1). The combinatorial expression pattern of various receptors at the surface of a growth cone may trigger a differential downstream event [54]. In addition, the efficacy of receptor signaling across the plasma membrane can be modulated by various factors both extra- and intracellularly [4]. Recruitment of different adaptors and mediators in the cytoplasm can result in different growth cone behaviors. An area of interest for future studies is determining the mechanisms that control or modulate the recruitment and activation of these cytoplasmic factors and that amplify the signals conveyed by the receptors. Signal cascades triggered by all known guidance factors appear to eventually converge upon different members of the Rho family GTPases or their activators/inhibitors. It is of interest now to determine how spatiotemporal patterns of GTPase activation account for distinct navigational behaviors of the growth cone.

The Semaphorin Family

Semaphorins are a large family of proteins originally identified as axon guidance factors of the developing nervous system. Over 30 family members are grouped into 8 classes based on structural and phylogenetic relationships (reviewed in [1]). Classes 1 and 2 are expressed in invertebrates, classes 3 through 7 are vertebrate semaphorins, and Class V is expressed in non-neurotropic DNA viruses. All semaphorins share a highly conserved 500 amino acid "Sema" domain at their amino terminus, but different classes possess divergent sequences in their carboxyl regions. Classes 1, 4, 5, and 6 are transmembrane proteins, class 7 has a GPI-anchor, and classes 2, 3, and V are secreted proteins. The presence of both membrane-bound and secreted semaphorins suggests that semaphorins act as both short- and long-range cues. In addition, the diversity of structural properties between the classes implies roles in a diversity of biological processes.

The best-documented function of semaphorins is their role in central nervous system (CNS) development. Semaphorins act as both repellents and attractants for growing axons. The first identified vertebrate semaphorin, *Sema3A*, causes retraction of axons and the collapse of the growth cone, a specialization at the tip of growing axons [2]. While repellents for certain neurons, *Sema3C* and *3F* also serve as attractants for cortical and olfactory neurons, respectively. Within the large semaphorin family, certain semaphorins can exert antagonistic activity by competitively blocking the activity of other family members at certain receptors [3]. Semaphorins may guide growing dendrites as well as axons. Specifically, *Sema3A* attracts the apical dendrite of pyramidal neurons in the cerebral cortex toward the

pial surface [4]. Many types of neurons are responsive to semaphorins, including dorsal root ganglion, sensory, motor, hippocampal, cortical, cerebellar, and olfactory. In addition to guiding axons and dendrites, semaphorins appear to play a role in fasciculation of nerve bundles, neuronal cell migration, axoplasmic transport, and apoptosis [5]. Like developing neurons, adult neurons of the regenerating CNS are responsive to semaphorins and semaphorin expression is upregulated after nerve injury [6].

Semaphorin signaling is not restricted to the CNS as evidenced by widespread expression throughout the embryo and adult tissue. Migrating non-neuronal cells are responsive to semaphorins, and cardiovascular abnormalities are observed when semaphorin signaling is disrupted [7]. In the immune system, expression of *Sema4D* (CD100) is regulated upon B- and T-lymphocyte activation and migrating monocytes are responsive to *Sema3A* and *Sema4D* [8]. Malignant lung cells show reduced levels and a cytoplasmic localization of semaphorins [9]. Taken together, it can be concluded that semaphorins act as guidance cues for many types of migrating cells in developmental, adult, and pathological tissue.

Receptors for Semaphorins

Neuropilins

Neuropilins are high-affinity transmembrane receptors for the secreted class 3 semaphorins in the CNS, but play no role in the activity of other semaphorins. A neuropilin family is composed of neuropilin-1 and several splice variants

of neuropilin-2 [1]. Neuropilin-1 and -2 contain a number of conserved motifs on their extracellular domain including two CUB domains, FV/FVIII, and a MAM domain. The CUB domains are required for ligand binding and the MAM domain mediates neuropilin oligomerization [10]. Neuropilins have a short intracellular domain containing a PDZ binding motif that targets receptor localization to signaling components in the membrane of the cell [11]; however, the intracellular domain is not required to transduce the semaphorin signal [10]. The neuropilin isoforms bind differentially to various class 3 semaphorins [12], and the specificity of binding is determined by the CUB domains [10]. Although neuropilins are sufficient to bind class 3 semaphorins, the fact that the intracellular domain is not required for signaling suggests that a co-receptor transmits the semaphorin signal into the cell.

Outside of the CNS, neuropilins are found in the mesenchyme surrounding blood vessels and act as co-receptors for vascular endothelial growth factor (VEGF). Upon binding VEGF, neuropilins potentiate the kinase activity of the VEGF receptors flt-1 and KDR, resulting in endothelial cell migration [13]. There is some evidence to suggest that semaphorins and VEGF compete for neuropilin binding and a dysregulation of the competition may lead to pathological conditions [9].

Plexins

Plexins are the predominant receptors for membrane-bound, GPI-linked and viral semaphorins, and they bind to neuropilins to act as signaling co-receptors for the secreted class 3 semaphorins [14]. The initial discovery of Plexins as semaphorin receptors occurred with the identification of virus-encoded semaphorin protein receptor (VESPR; plexinC1) as a binding site for a class V semaphorin [15]. Currently, at least ten Plexins have been identified and are classified into four groups, Plexin A–D, which have different specificities for different semaphorins [1]. Plexins are distantly related to semaphorins since they possess the conserved Sema domain on their extracellular surface [16] and also share some sequence homology with the HGF receptor Met on their extracellular surface [17]. The intracellular domain of Plexin is highly conserved among family members, but is not significantly homologous to any known signaling motif. In their native state, Plexins are autoinhibited by their Sema domain and binding to semaphorin-neuropilin complexes or cleavage of the sema domain leads to activation of the protein and growth cone collapse in sensory neurons [18].

Intracellular Signaling Pathways

Actin Cytoskeleton and Monomeric GTPases

The actin cytoskeleton in growth cones undergoes dramatic rearrangement upon exposure to Sema3A. There is a

relative decrease in F-actin within the lamellipodia [19] and actin colocalizes with neuropilin-1/PlexinA1 receptor complexes [20]. The actin reorganization is linked to increased endocytosis [20]. It was thought that semaphorins might regulate the actin cytoskeleton through monomeric G proteins due to the weak similarity of the conserved intracellular domain of Plexins to an R-Ras-GAP. However, no Plexin protein has been shown to possess GAP activity and semaphorin responses are not dependent on R-Ras. Instead, Rho family G proteins, namely Rac and Rho, seem to mediate the semaphorin response [21] (also reviewed in [22]). Active Rac binds directly to the intracellular domain of vertebrate and invertebrate PlexinB1, and this interaction is enhanced by the presence of ligand binding [23]. Activation of PlexinB1 appears to sequester active Rac from its endogenous substrate, p21-associated kinase, PAK [24–26]. RhoA is also activated as a result of PlexinB1, although it is not clear whether this is due to a direct or indirect action of PlexinB1 on RhoA [26], or is downstream of Rac-Plexin interactions [24]. Together, Rac sequestration and RhoA activation appear to mediate axon repulsion by PlexinB receptors.

Although the intracellular domain is highly conserved among all Plexin family members, it is not clear whether PlexinA functions in a similar fashion as PlexinB. PlexinA1 binds to both RhoD and Rnd1, and Rnd1 binding has been suggested to induce growth cone collapse [27,28], perhaps due to Rnd1-dependent inhibition of Rac [29]. Direct Rac-PlexinA interactions have not been demonstrated. It is possible that Plexins regulate monomeric GTPases indirectly by regulating Rho family GEFs and GAPs, factors that activate or inactivate monomeric GTPases, respectively.

A direct link between Sema3A and actin dynamics was recently demonstrated. Activated complexes of NP1 and PlexinA2 lead to the phosphorylation and deactivation of cofilin by LIM kinase [30]. Cofilin leads to F-actin turnover and plays a role in protrusion of lamellipodia and filopodia [31]. Further, LIM kinase is a substrate for both PAK and Rho kinase, which is consistent with the requirement for Rac and Rho, respectively, for Sema3A-induced collapse [31].

CRMP

Collapsin-response-mediator protein (CRMP) was identified in a *Xenopus* oocyte expression screen of mRNAs required for Sema3A responses [32]. The protein sequence of CRMP shares sequence homology with the *Caenorhabditis elegans* unc-33, a protein required for proper axonal pathfinding [33]. At least five isoforms of CRMP have been identified and they form heterotetramers *in vivo* [34]. Function blocking antibodies to CRMP block Sema3A-mediated growth cone collapse in chick DRG neurons [32], and CRMP is upregulated after axotomy of the sciatic [35] and olfactory [36] nerves. The mechanism of CRMP action is still unclear. Studies have shown that it is phosphorylated

by Rho kinase, but this is not required for Sema3A-induced collapse [37]. The microtubule abnormalities of *unc-33* mutants and the observation that CRMP colocalizes with microtubules at certain stages of the cell cycle [38] suggest that Plexin/CRMP signaling may regulate microtubule dynamics. There is also evidence demonstrating CRMP binds to and inactivates phospholipase D2, an enzyme implicated in a variety of cell processes including actin dynamics, vesicle trafficking, and mitogenesis [39]. Finally, CRMP may act to mediate the cytoskeleton through Rho GTPases. Neuroblastoma cells overexpressing CRMP and constitutively active RhoA showed a Rac1-like morphology, whereas cells co-expressing CRMP and active Rac1 showed a RhoA-like morphology [40]. Thus, it seems likely that CRMP enhances the function of a Plexin-Rho family G-protein axis in axon repulsion.

Protein Phosphorylation

Receptors for several other axon guidance molecules, such as ephrins and neurotrophins, act via kinase cascades. Although semaphorin receptors themselves show no kinase activity, indirect evidence suggests that protein phosphorylation occurs and is required [41]. The involvement of PAK and LIM kinase downstream of Plexins is mentioned above. A recent study has shown that *Drosophila* PlexinA associates with the membrane-bound receptor tyrosine kinase-related protein Off-Track (Otk; [42]). In addition, two proteins with kinase activity have been co-purified with CRMP [38,43]. The serine/threonine kinase, glycogen synthase kinase (GSK)-3 is activated as a result of Sema3A in both neuronal cells and human breast cancer cells, and GSK-3 inhibitors prevent Sema3A-induced growth cone collapse [44].

Other Signaling Mechanisms

Another pathway that has been implicated in semaphorin signaling may utilize heterotrimeric G proteins. Much of the evidence for this has come from experiments with pertussis toxin (PTX), which blocks G-protein function [21,45]. Indeed, neuropilins were found to bind to a G α -interacting protein (GIPC, SEMPCAP-1) that associates with a regulator of G-protein signaling (RGS) protein via its PDZ domains [11]. Interestingly, some transmembrane semaphorins interact with SEMPCAP-1 as well, suggesting that semaphorins may act as receptors to transduce signals into the cell [46]. Semaphorin reverse signaling is further supported by the fact that Sema6B binds to Src both *in vitro* and *in vivo* [47], Sema4D interacts with a serine kinase [48], and Sema6A binds to the actin binding protein EVL [49].

Semaphorin-mediated signaling can be modulated by other pathways. Cyclic nucleotides can alter the response of growth cones to various signaling molecules [50,51]. Increasing levels of cGMP switches Sema3A responses from repulsion to attraction and decreasing cGMP potentiates

the repulsive activity of Sema3A. Apical dendrites of cerebral cortical neurons are attracted to Sema3A while the axons of the same cells are repelled [4]. Remarkably, soluble guanylate cyclase (SGC) is asymmetrically localized to the dendrites of these cells, implicating an endogenous regulation of cGMP *in vivo*. The cell adhesion molecule, L1, is also able to modulate growth cone responses to Sema3A [52]. DRG neurons from L1-deficient mice show no response to Sema3A and soluble L1 protein switched repulsion to attraction. Finally, one or more of these pathways may impinge on protein synthesis and degradation within axons. Evidence indicates that local regulation of protein levels participates in multiple growth cone responses [53].

Semaphorin Signaling in the Immune System

Semaphorin signaling in activated lymphocytes does not rely on neuropilins and Plexins, but utilizes a different receptor called CD72 [54]. Under normal conditions, CD72 is phosphorylated on its intracellular domain by a Src tyrosine kinase. This phosphorylation leads to the recruitment of an SH2-domain-containing tyrosine phosphatase SHP-1, which then dephosphorylates and inactivates signaling proteins involved in lymphocyte activation [8]. Sema4D binding prevents the phosphorylation of CD72 therefore potentiating lymphocyte activation [54]. The migration of monocytes is inhibited by Sema4D and Sema3A; this effect is likely to be mediated via Plexins and neuropilins since monocytes do not express CD72 [55].

Summary and Future Directions

Many biological systems in the developing embryo and adult animal are dependent on semaphorin signaling. Although the importance of semaphorins in the developing CNS is well documented, their involvement in the immune response, the cardiovascular system, and in pathology is still being clarified. Most of the work to date has focused on the identification and classification of the various semaphorin families and their receptors, with less clarification of downstream signaling mechanisms. Regulation of the cytoskeleton is the most obvious effect of semaphorin signaling, and a number of studies have demonstrated a signaling connection of semaphorin receptors with actin filaments and microtubules. In particular, Rho family G proteins and CRMP appear to play major roles in this connection (see Fig. 1).

Signaling Pathways that Regulate Neuronal Specification in the Spinal Cord

Ann E. Leonard and Samuel L. Pfaff

*Gene Expression Laboratory,
The Salk Institute for Biological Studies, La Jolla, California*

A cascade of signaling events triggers the differentiation of specific neuronal and glial cell populations that comprise the central nervous system (CNS). Epidermal ectoderm deprived of bone morphogenic protein (BMP) signaling differentiates into “neural” ectoderm [1], the precursor of the CNS. These neural cells are multipotential and respond to signals in their environment in order to generate the appropriate types of neurons and glia at the correct positions. In this chapter we focus on the spinal cord, the most caudal region of the CNS, since it has served as a useful model in which to investigate signaling events that give rise to neuronal and glial populations within the developing neural tube.

Emerging from a combination of modern molecular studies and classical cellular studies, a central theme in spinal cord development is one in which inductive factors signal along the dorsoventral and rostrocaudal axes of the developing spinal cord to specify cell fate in a Cartesian-coordinate-like manner [2]. This signaling leads to the generation of dorsal spinal cord interneurons that process sensory information and relay it to the brain, while the ventral spinal cord forms interneurons and motor neurons involved in locomotor control (Fig. 1A). Along the rostrocaudal axis, discontinuous subclasses of motor neurons are generated in register with the peripheral targets that they innervate. In addition, numerous glial cell types are formed including the roof plate and floor plate, which act as organizing centers within the spinal cord, and astrocytes and oligodendrocytes, which support neuronal function and myelinate neurons, respectively.

Patterning along the Dorsoventral Axis

Two classes of factors play prominent roles in specifying distinct cell types along the dorsoventral axis of the spinal cord: members of the transforming growth factor β (TGF β) superfamily acting dorsally, and Sonic hedgehog (Shh) ventrally (Fig. 1A) [3,4]. TGF β signaling from the epidermal ectoderm flanking the dorsal neural tube leads to the differentiation of the roof plate [5], and Shh expression from the notochord below the neural tube triggers the formation of the floor plate [6]. These two glial structures in the spinal cord then express TGF β s dorsally and Shh ventrally. In this way, signals from the periphery are propagated into the spinal cord to control cell differentiation locally.

The dividing progenitor cells within the ventricular (medial) region of the spinal cord monitor the types and concentrations of TGF β s and Shh in order to determine their position, and consequently their fate, as they become postmitotic and migrate laterally into the mantle region (Fig. 1A). The signaling pathways triggered by these inductive factors lead to the activation of transcriptional networks that first define distinct domains along the dorsoventral axis of the ventricular zone, and ultimately lead to the expression of genes involved in controlling cell function (Table I) [7–10].

Dorsal Spinal Cord Development

In the embryonic dorsal spinal cord, four classes of interneurons (INs) termed D1–D4 arise in an orderly fashion

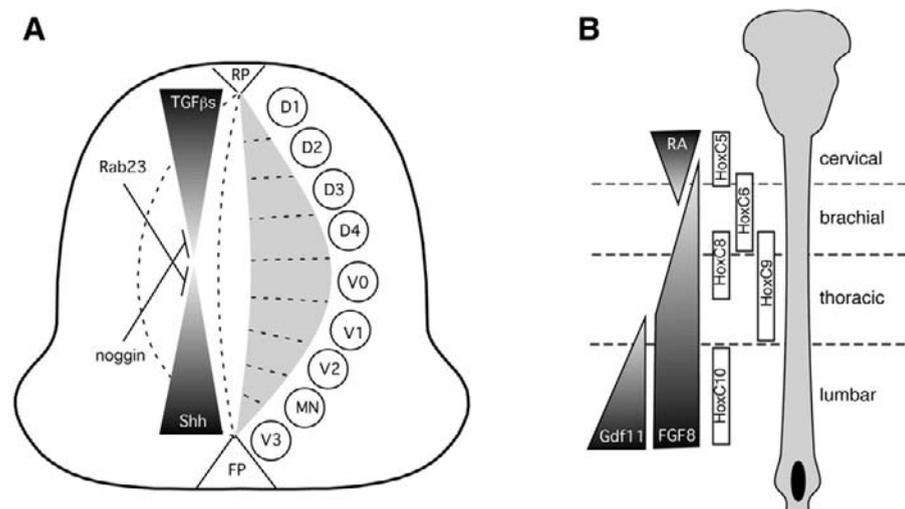

Figure 1 Patterning signals along the dorsoventral and rostrocaudal axes of the developing spinal cord. (A) Transverse view of the spinal cord in which the gray area represents the ventricular zone containing progenitor cells and the white area represents the mantle layer with mature cell types. FP, floor plate; RP, roof plate. (B) Rostrocaudal view of the spinal cord and the graded pattern of signals expressed by paraxial and axial mesoderm adjacent to the neural tube.

from specific regions of the progenitor zone (Fig. 1A). These INs, while not absolutely defined, consist of association and commissural cells that process and relay sensory information and depend upon the formation of the roof plate in order to develop [5,11]. The roof plate and adjacent neural epithelial cells express overlapping and nested combinations of several TGF β members including BMP4/5/7, Gdf6/7, and Dsl1 [5,9]. How might the TGF β s produce different cell types in the spinal cord? Several strategies are likely to be involved including quantitative, qualitative, and timing differences in TGF β activity. The expression pattern of the TGF β s suggests that a high-dorsal to low-ventral gradient of these proteins is present within the neural tube (Fig. 1A). Although more studies are needed to determine whether graded levels of TGF β s contribute to spinal cord patterning, *in vitro* experiments with neural explants have detected concentration-dependent activities for Activin A in the induction of D1 and D2 IN classes [5].

The clearest example of how TGF β s trigger the differentiation of specific IN types is based on the finding that individual members of this family have different qualitative activities [5]. The most convincing evidence for such a mechanism is found in the *Gdf7* mutant mice where a specific subpopulation of D1 INs fails to be generated [12]. These results suggest that the specificity of dorsal IN patterning is mediated, at least in part, by various TGF β signaling molecules, some of which act directly to render class specificity (Table I). An additional mechanism for generating cellular diversity in the dorsal spinal cord involves a temporal switch in the way neuroepithelial cells respond to TGF β signals. Early in development, progenitor cells produce neural crest cells when exposed to BMP4 or Activin A, but later, they give rise to dorsal INs in response to the same signals [5].

The basis for qualitative differences in TGF β signaling and the mechanisms underlying the developmental switch in TGF β responsiveness by neural epithelial cells remain important questions.

Shh signaling for ventral cell differentiation is attenuated by TGF β signaling [13]. What limits the range of TGF β activity to the appropriate areas of the developing spinal cord? Several TGF β antagonists have been identified including noggin, chordin, and follistatin which bind directly to and sequester-specific TGF β s [14]. These antagonists are expressed by the somites and notochord near the ventral surface of the neural tube, and therefore are expected to limit the exposure of ventral cells to certain TGF β s. In *noggin* mutant mice, TGF β signaling in the ventral neural tube is unmasked (Fig. 1A), which leads to a progressive loss of ventral cell differentiation [15].

The receptors of the TGF β s are serine/threonine kinases comprised of type I and type II dimers. These receptor complexes have not been well characterized in the spinal cord, but may select for different ligands and serve as the basis for the qualitative differences in cell differentiation induced by different TGF β family members. The best known transducers of TGF β signaling are the SMAD transcription factors [16], though the role of SMADs in spinal cord development also requires further characterization. Recently, a better understanding of the downstream targets of TGF β s has begun to emerge (Table I). For instance, it is now known that D1 INs, characterized postmitotically by the markers Lhx2/9, arise from progenitor cells that express the bHLH transcription factor mATH1 involved in establishing the fate of these cells [9,10]. Likewise, D3 IN progenitor cells marked by Lhx1/5 arise from progenitors that express the bHLH protein Ngn1. Thus, the identification of target genes activated by TGF β

Table I Signaling Events in the Developing Spinal Cord

Signal	Dorsal patterning Lateral ectoderm → Roof plate		Ventral patterning Notochord → Floor plate			Rostral/Caudal patterning Hensen's node, paraxial mesoderm		
		<i>TGFβ Superfamily</i> BMP 4, 5, 6, 7 Gdf 6, 7 Activin B; Ds11		Sonic Hedgehog			Retinoic Acid	FGF 8
Inhibitors	Follistatin, Noggin, Chordin		Hedgehog-interacting Protein (Hip) Rab23 (vesicle transporter)			Cellular Retinoic Acid Binding Protein		Follistatin, Noggin, Chordin
Receptor(s)	Type I/II TGFβ receptors (serine/threonine receptor kinases)		Patched : ligand binding Smoothed : transducing			<i>Nuclear Receptors</i> RAR RXR	FGFR (receptor tyrosine kinase)	TGFβR (receptor serine/ threonine kinase)

signaling should help to work backward to characterize the signal transduction pathways.

Ventral Spinal Cord Development

Genetic studies as well as *in vitro* explant experiments have implicated Shh in the differentiation of ventral spinal cord cell types involved in locomotor control (V0–V3 INs and MNs), as well as oligodendrocytes (Fig. 1A) [3,8]. Unlike the nested combinations of TGF β molecules in the dorsal spinal cord; however, only one hedgehog member appears to be involved in ventral spinal cord patterning in higher vertebrates. This raises the question of how different ventral cell types are induced by a single factor. Extensive studies with *in vitro* explants have shown that Shh concentration differences of approximately two- to threefold dramatically influence the types of cells that are triggered to differentiate. Decreasing concentrations of Shh progressively induce cell types found further from the ventral midline, recapitulating the normal organization of cells in the ventral spinal cord [17]. As with TGF β signaling, there are also important temporal mechanisms that modify progenitor cell responses to Shh signaling during development. At early stages Shh acts on progenitor cells to trigger MN differentiation, but, later in development, oligodendrocytes are produced instead of MNs. The basis for this switch is not well understood but seems to involve the regulation of the transcription factor Nkx2.2 [18,19].

The active Shh signaling molecule is autoprocessed and cholesterol-modified, and binds to the patched/smoothed receptor complex [20]. In the absence of Shh, patched is thought to inhibit smoothed from signaling, and this inhibition is relieved when Shh binds patched. Many additional components of the Shh signaling pathway have been identified through genetic studies in *Drosophila*, including the downstream Gli family of zinc finger transcription factors [20]. Genetic studies of *Gli3* and *Gli3/Shh* compound mouse mutants indicate that this transcription factor is likely an intermediary in the Shh pathway, although it seems to function indirectly as a transcriptional repressor [21,22].

How might small gradations in the level of Shh signaling produce sharp progenitor cell domains that serve as the precursors for different ventral cell types? Studies of the factors regulated by Shh in the ventricular zone have uncovered a network of homeodomain proteins that mark distinct progenitor domains (Table I) [7]. The expression of these factors is controlled at two levels. First, Shh either represses (class I) or activates (class II) the expression of the homeodomain factors. If this were the only mechanism operating to control these factors, it might be expected that the interpretation of the fine Shh gradient would lead to imprecise boundaries of gene expression. However, the domains appear to be further refined by cross-repressive transcriptional interactions between factors from different domains. In this two-step manner, graded Shh leads to the activation of unique combinations of homeodomain transcription factors in precise

progenitor cell domains [3,8]. The combinatorial activities of these homeodomain factors lead to the activation of downstream transcriptional regulators involved in cell specification and function (Table I) [23].

The opposing nature of the ventral Shh gradient meeting the dorsal TGF β factors suggests that inhibitors of Shh activity might constrain its activity, much like the inhibitors of TGF β s. Hedgehog interacting protein (Hip) is a surface membrane protein that binds Shh and attenuates its activity [24]. In addition, characterization of the mouse *open brain* (*opb*) mutant, in which ventral cell types form inappropriately in the dorsal region of the spinal cord, has led to the identification of a member of the Rab family of vesicular transporters, Rab23, important in limiting the activity of Shh dorsally (Fig. 1A) [25]. Interestingly, mice deficient in both Shh and Rab23 regain many of the ventral cell types lost in Shh mutants. This, together with the observation that *Gli3/Shh* double mutants also regain many ventral cell types [22], suggests additional Shh-independent pathways might contribute to ventral spinal cord development. Studies to understand the basis for Shh-independent signaling have uncovered a parallel pathway involving retinoic acid (RA) expressed by paraxial mesoderm beside the neural tube [26]. It will be interesting to examine in more detail the interplay between Shh and RA signaling pathways in order to fully understand the molecular basis for neuronal specification along the dorsoventral axis of the neural tube.

Rostrocaudal Specification

The spinal cord can be subdivided into four broad, functional regions along the rostrocaudal axis: cervical, brachial, thoracic, and lumbosacral. The IN classes of the spinal cord extend continuously throughout these regions, while specific MN subclasses are found at each level [27]. Individual MN subclasses form discontinuous columns in register with their targets, such that MNs of the cervical region innervate axial muscles, brachial region MNs innervate the forelimb, MNs of the thoracic region innervate body wall muscle, and lumbar MNs innervate hindlimbs. Much like the initiation of dorsoventral patterning in the spinal cord, embryonic manipulations and *in vitro* explant studies suggest that members of several families of signaling molecules originating initially from sources outside the spinal cord contribute to the diversification process that leads to the generation of specific classes of MNs along the rostrocaudal axis [28–31].

Studies of the signals that control segmental identity along the rostrocaudal axis have used *Hox* gene expression patterns as downstream molecular correlates of the regional specification of cell identity (Table I). Furthermore, there is increasing functional data to suggest that *Hox* genes contribute to the proper development of MN subclasses [27,32,33]. As neuroepithelial cell identity is first established, it is thought to have a rostral identity which is then modified by “caudalizing” signals [4]. Hindbrain studies have found that increasing levels of RA activate more caudal-type *Hox* genes [34–36].

Likewise, the pattern of *Hox* gene expression in the cervical spinal cord is regulated by RA synthesized by the cervical paraxial mesoderm flanking the neural tube (Fig. 1B) [31].

However, at more caudal regions of the spinal cord, RA is insufficient to confer positional identity. A major source of additional regionalizing signals is detected in Hensen's node (HN), a precursor of the axial mesoderm that moves in a caudal direction below the nascent neural tube as development progresses. Interestingly, HN tissue taken from different stages (i.e., different rostrocaudal levels) is able to specify different regional values in neural explants [31]. Studies utilizing fibroblast growth factor (FGF) receptor antagonist SU5402 and expression of constitutively active FGF receptors are found to alter the *Hox* coding in neural cells, implicating FGF signaling as a mediator of HN activity. FGF8 is expressed by the HN and *in vitro* studies have found that this factor can act in a concentration-dependent manner to induce progressively more caudal positional values in neural explants. The *Cdx* family of transcription factors represents possible downstream mediators of both RA and FGF8 signaling in the regulation of *Hox* expression [36].

Taken together, these findings suggest that the signaling activity of FGF8 increases as the HN moves caudally (Fig. 1B) [31]. An additional mechanism that appears to contribute to the increased activity of FGF8 at more caudal positions is the involvement of accessory factors that enhance FGF signaling. One such example is the TGF β superfamily member *Gdf11*. This factor is expressed in HN as it progresses through lumbosacral levels, where FGF signaling is expected to be highest (Fig. 1B). Unlike other TGF β members, *Gdf11* does not influence the dorsoventral pattern of the spinal cord, but rather acts to enhance FGF8 signaling activity. In this way, progressively more caudal regions of the spinal cord are defined by the composite functions of FGF8 and *Gdf11* through the regulation of *Hox* codes involved in establishing regional levels of the spinal cord that will generate different MN subclasses (Table I).

Cadherins: Interactions and Regulation of Adhesivity

Barbara Ranscht

*The Burnham Institute, Neurobiology Program,
La Jolla, California*

Introduction

The ability of cells to distinguish between its neighbors and to recognize and associate with cells of specific subtypes is a prerequisite for the organization of the vertebrate and invertebrate body plan [1,2]. Cadherins are a class of transmembrane cell surface glycoproteins that regulate tissue morphogenesis and are necessary for maintaining the integrity of adult tissues [3–7]. The hallmark of cadherin molecules is their ability to confer calcium-dependent cell-to-cell adhesion, predominantly in a homophilic manner (e.g., molecules on one cell surface bind to molecules of the same molecule type on opposing cell surfaces [8]). This function plays profound roles in developing embryos as cells segregate from each other to form and distinguish specialized tissues from surrounding cells [9–12]. In the vertebrate nervous system, cadherins are implicated in the embryonic formation of specific brain subdivisions and the establishment of functional circuits [13]. Cadherins are clustered at synapses where they straddle the active zone [14,15] and regulate synaptic morphology and strength [16–18]. In epithelial tissue, cadherins are prominent components of adherens junctions [19,20]. In their junctional most adhesive configuration, they associate with the armadillo-repeat protein β -catenin (or plakoglobin) that connects the transmembrane cadherins via α -catenin to the actin-based cytoskeleton. Modulation of cadherin function is one of the central events that initiates cell spreading and migration during morphogenetic movements and cancer. Moreover, the transition from an epithelial to an invasive phenotype during growth and metastasis of malignant tumors is often associated with the loss of E-cadherin, and reintroduction of E-cadherin into

metastatic cells can suppress the tumor phenotype [21,22]. Because of the recognized importance of cadherin cell adhesion molecules, major research efforts have concentrated on understanding the structural properties, dynamics, and signal transduction mechanisms by which cadherins regulate adhesive strength. Significant evidence has accumulated demonstrating that the fine-tuned balance of cellular signaling pathways that either enforce or reduce adhesion dynamically controls cadherin function. Moreover, it has become clear that cells regulate the degree of cadherin-mediated adhesion by diverse mechanisms. This chapter will summarize the mechanisms that contribute to the regulation of cadherin-mediated adhesivity.

The Members of the Family

Classical Cadherins

The vertebrate classical cadherins are transmembrane proteins composed of five tandemly arranged cadherin domains and a highly conserved cytoplasmic tail (Fig. 1). Cadherin domains (CD) are defined by a stretch of approximately 110 amino acids that contains characteristic motifs involved in calcium binding [3,23]. Classical cadherins or vertebrate type I cadherins, such as E-, P-, N-, and R-cadherin, display in the amino terminal CD1, a conserved HAV motif that has gained attention as a potential cell recognition sequence [24]. Although peptides containing this motif indeed inhibit cadherin-mediated functions [25,26], structural studies are inconsistent with this suggestion [27]. Atypical or vertebrate classical type II cadherins share the structural

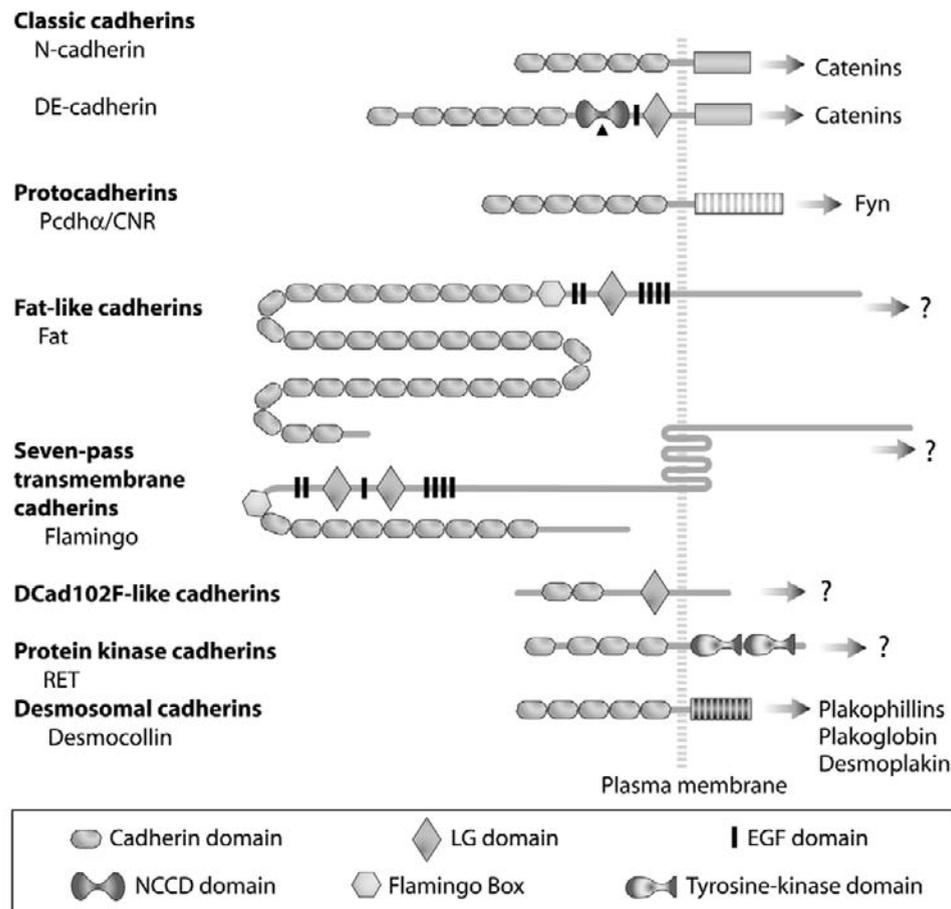

Figure 1 Molecular diversity of the cadherin family. The domain organization of representative members of each of the identified cadherin families is depicted. Arrows indicate the linkage with indicated intracellular molecules.

organization with the type I cadherins, but are less related based on sequence homology [28]. The intracellular domains of both groups are highly conserved. Transmembrane classical cadherins associate through interactions with the armadillo repeat family proteins β -catenin/plakoglobin with the actin cytoskeleton. This interaction is critical for dynamically regulating cadherin-mediated adhesivity. Classical cadherins exert profound functions in animal morphogenesis. Deletions of E- or N-cadherin gene expression in mice result in embryonic lethality respectively at the embryo preimplantation stage [29,30] and at embryonic day 10 due to defects in cardiac development [31].

Invertebrate classical cadherins including *Drosophila* DE- and DN-cadherin [32–34], *Caenorhabditis elegans* HMR-1 [35], and sea urchin LvG-cadherin [36] diverge in their extracellular domain organization from their vertebrate counterparts and contain additional CDs, cysteine-rich EGF repeats, laminin A G domains, and often a nonchordate classic cadherin domain (NCCD) [37] (Fig. 1). The cytoplasmic domain of invertebrate classical cadherins associates with *armadillo*, a molecule of the catenin family that can be linked to the actin cytoskeleton [5]. Mosaic analysis of mutations in the classical DE-cadherin-encoding *shotgun*

(*shg*) gene provides evidence for homophilic binding activity [38]. Thus, despite structural divergence of their extracellular domains, the signaling mechanisms and principal functions of the classical cadherins are conserved between vertebrate and nonvertebrate species [39].

Cadherins with Divergent Structures

Bioinformatics has revealed CD-like structures in yeast and bacteria [40] suggesting that the CD represents an ancient structural motif. With the evolution of multicellular organisms, the diversity of proteins containing CDs has expanded enormously, and in humans more than 180 genes encoding proteins with cadherin domains have been reported (www.pfam.wustl.edu). Most, but not all of these genes are classified into distinct subgroups based on sequence homologies, domain organization, CD number, and genomic organization [5,28,39]. Representative members of the major subclasses are shown in Fig. 1.

PROTOCADHERINS

The largest subgroup of cadherin-related proteins is represented by the transmembrane protocadherins, which are composed of up to seven cadherin domains and contain

divergent and distinct cytoplasmic regions [41,42]. Protocadherins are most abundant in the nervous system. Three gene clusters *Pdch α* , *Pdch β* and *Pdch γ* located on human chromosome 5q31 are predicted to encode 52 cadherin-related molecules with a variable ectodomain and a characteristic cytoplasmic region [43]. *Pdch α* orthologs were independently identified as cadherin-related neuronal receptors (CNR) in mouse brain by their ability to interact with Fyn [44], an Src-related intracellular kinase that supports synaptic plasticity [45]. The observation that CNRs demarcate specific synapse populations [44] raises the possibility that these proteins regulate synaptic function or plasticity. Indeed, one of the synaptic protocadherins, Arcadlin (activity-regulated cadherin-like protein), was identified as a gene product induced by synaptic activity [46]. The functions of specific protocadherins during CNS development and in synaptic function are not yet known. Outside of the nervous system, the paraxial protocadherin (PAPC) was found to control cell movements during gastrulation [47] and establish segmental boundaries during somite formation [48]. These functions together with the demonstrated homophilic binding activity indicate that PAPC function resembles that of the classical cadherins [49,50], although its divergent cytoplasmic region indicates a different intracellular signaling mechanism.

FAT-LIKE CADHERINS

Drosophila Fat, the prototype of the fat-like cadherins, acts as a tumor suppressor as indicated by recessive lethal gene mutations that cause overgrowth of larval imaginal discs and other morphogenetic defects [51–54]. The hallmark of the fat-like transmembrane cadherins is their large extracellular domain that is composed of 17–34 tandemly arranged cadherin domains, EGF repeats, laminin A G domains, and, in some cases, a flamingo box [5,52]. *Drosophila fat* and the fat-like *dachsous* gene product are predominantly expressed in epithelial cells and contribute to planar polarity, the coordinated orientation of cells, in the eye and the wing [55,56]. Fat-like cadherins with functions in tissue morphogenesis are reported for the nematode *C. elegans* [57,58] and mammalian homologs have been identified [59,60], although their functions remain to be elucidated.

SEVEN-PASS TRANSMEMBRANE CADHERINS

This group of cadherins is anchored within the membrane by a seven-pass transmembrane domain similar to G-protein-coupled receptors. The extracellular domain of *Flamingo/starry night*, a *Drosophila* seven-pass transmembrane cadherin, consists of nine amino terminal cadherin domains, a flamingo box, EGF repeats and laminin A G domains [61]. *Flamingo/starry night* acts in concert with *fat*, *dachsous* and components of the *wnt/frizzled* pathway to establish planar polarity of hair cells in the *Drosophila* wing [53,56,61,62]. Seven-pass transmembrane cadherin receptors including mouse *Celsr1* [63], mouse *Fmi* [61], and rat *MEGF2* [64] have also been isolated from the vertebrate nervous system and remain to be assessed for their functions and molecular associations.

DCAD 102F-LIKE CADHERINS

Drosophila Dcad 102F and *C. elegans* CDH-11 represent a separate subclass of cadherin molecules with yet unknown functions. These transmembrane cadherins are composed of two cadherin domains, a laminin A G domain and a Glu-Ser-rich cytoplasmic domain region unrelated to other members of the cadherin family. They share significant homology with two proteins of unknown function from human brain (KIA0911 and KIAA0726) [65].

PROTEIN KINASE CADHERINS

The protein kinase cadherins are represented by Ret, which consists of four cadherin-like domains and an intracellular kinase region [66,67]. Ret is part of a tripartite receptor complex that is activated by interactions with neurotrophic factors of the glial cell-line-derived neurotrophic factor (GDNF) family. GDNF induces or stabilizes a complex between Ret and GPI-linked alpha receptors (GFR alpha 1–4) resulting in dimerization and activation of the Ret kinase [68]. Mutagenesis studies have shown that Ret, GFR alpha 1, and GDNF affect multiple developmental events including development of the enteric nervous system affected in Hirschsprung's disease [69–71].

DESMOSOMAL CADHERINS

The desmosomal cadherins comprise two separate subfamilies, the Desmocollins (DSC) and the Desmogleins (DSG) [72,73]. Each subfamily is represented by three members (DSC-1, -2, -3 and DSG-1, -2, -3) and each of these molecules displays a cell type- or differentiation-specific expression profile [74,75]. The extracellular domain of desmosomal cadherins is composed of five cadherin domains and confers homo- or heterophilic binding interactions with other members of the desmosomal cadherin family. DSCs and DSGs contain characteristic intracellular domains that diverge from those of the classical cadherins and interact with either of the armadillo family proteins plakoglobin and plakophilin. The latter provide a link (via desmoplakin) to intermediate filaments. The complex constituted by desmosomal cadherins and associated intracellular proteins is essential for the assembly of desmosomal plaques [76–79]. Several autoimmune skin blistering diseases (such as pemphigus vulgaris or foliaceus) are caused by desmoglein autoantibodies that act on disrupting desmosomes within epidermal layers [80].

Cadherin Structure-Function Relationships

Cadherin activity is typically measured by the ability of transfected cells to confer calcium-dependent cell-to-cell adhesion and is well established for the classical cadherins. Accordingly, analyses probing cadherin structure and function have focused on classical cadherin subtypes. Earlier work has established that the active binding configuration of these cadherins is only accomplished in the presence of calcium [3]. Mutation of one of the calcium-binding sites renders E-cadherin inactive in conferring homophilic binding [81].

Calcium binds to conserved motifs (DXD, DRE, and DXNDNXPXF) at the interface between cadherin domains and provides for the structural rigidity and dimerization of the extracellular cadherin domain. In the absence of calcium, E-cadherin polypeptides appear collapsed and disorganized by rotary shadowing and electron microscopy, while the addition of calcium at low concentration (50 μM) enforces the formation of rigid rod-like structures [82,83]. An increase in the calcium concentration (500 μM) supports *cis* association of adjacent cadherin extracellular domains, and concentrations above >1mM drive *trans* interactions between opposing *cis* strand dimers [83–85]. The strongest adhesive force between cadherin molecules is exerted in the *trans* dimer configuration. These and cell biological studies have corrected the previous concept that the classical cadherins are inactive without their linkage to the actin cytoskeleton [86–90]. It is now accepted that the cadherin extracellular domain alone suffices to induce cell-to-cell adhesion and the interaction of the full-length molecules with the cytoskeleton is required for compaction. Thus, dimerization is a critical parameter in regulating the strength of cadherin-mediated adhesivity.

Initial structural studies of the specificity-determining cadherin extracellular domain CD1 [91] revealed a β -strand organization similar to the immunoglobulin fold [92,93]. The crystal structures suggest that calcium plays an important role in cadherin dimerization [92,94–96]. Dimerization can occur between identical cadherin molecules (homodimerization) and heterodimers [97]. One of the suggested major features for cadherin dimerization is the association of Trp-2 of mature cadherin polypeptides with Ala-80, which is presented within a hydrophobic acceptor pocket formed around the HAV sequence [27,94,96–98].

Several experimental approaches provide evidence for multiple binding sites along the cadherin extracellular domain. First, biophysical studies demonstrate that the distance between opposing cadherin-covered lipid bilayers (250 \AA) corresponds to the length of the cadherin extracellular domain [99,100]. Force application results in the step-wise increase of the intermolecular distance between cadherin molecules and suggests additional binding sites along the molecule [99,100]. Second, analyses of the binding properties of C-cadherin domain constructs show that the highest homophilic binding activity is conferred by the entire extracellular domain, while CD1 polypeptides exhibit only low binding activity [101]. Third, the crystal structure of the full C-cadherin ectodomain displays *cis*- and *trans* associations of the CD1 domain with multiple sites along the cadherin extracellular domain [27].

These cumulative data on cadherin structure-function relationships are consistent with a model in which adhesion occurs in multiple steps (Fig. 2). First, in the presence of calcium, cadherins adopt a rigid structure that is able to undergo *cis* dimerization. Lateral cadherin clustering into strand dimers enables subsequent engagement with *cis* dimers from opposing cell surfaces. One may speculate that the initial interactions occur between opposing CD1 domains.

Upon favorable conditions, the adhesive bonds tighten and the cadherin extracellular domains fully interdigitate to bring adjacent cell surfaces into tight contact. Despite these seminal insights into the structure and interactions of the cadherin extracellular domains in these models, interactions *in vivo* may be more complex as cadherins were recently shown to also communicate at adherens junctions with another adhesion system, the actin-linked nectin-afadin-ponsin complex [102,103]. Studies of the molecular and structural interactions between these combinatorially expressed protein complexes may reveal new insights into the adherens junction assembly.

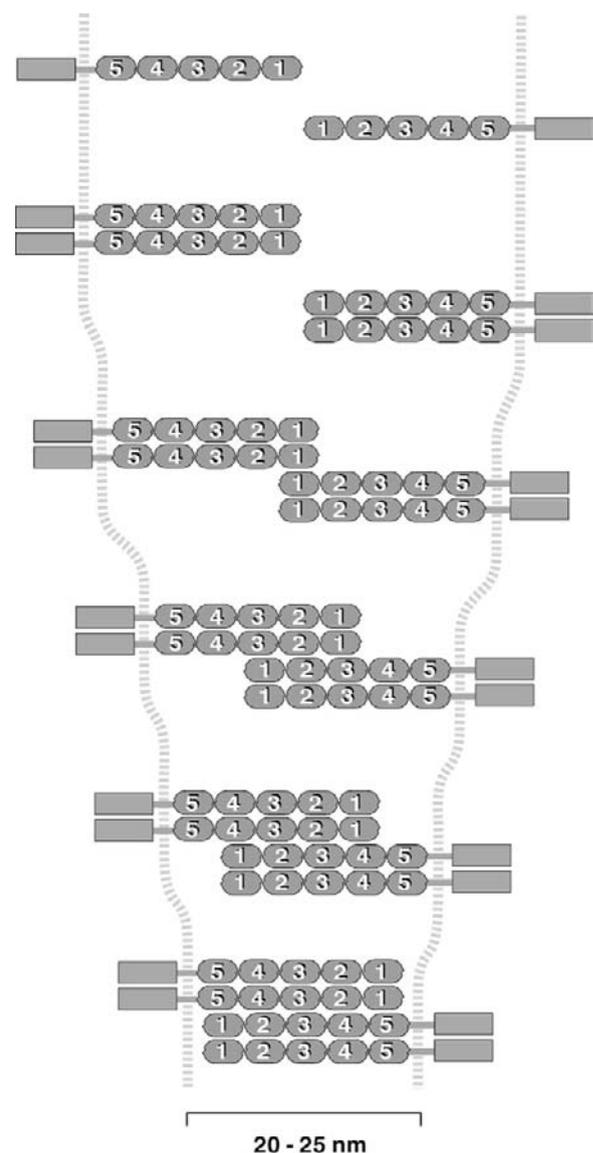

Figure 2 Stages of cadherin-mediated adhesive interactions. Cadherin monomers associate into strand dimers that subsequently engage with *cis* dimers from opposing cell surfaces. Initial interactions may occur between opposing CD1 domains. Upon favorable conditions, the adhesive bonds tighten and the cadherin extracellular domains fully interdigitate to bring adjacent cell surfaces into close contact.

Multiple Modes for Regulating Cadherin Adhesive Activity

During tissue morphogenesis, cells undergo dynamic rearrangements that require the spatial and temporal regulation of adhesive strength. The dynamic expression patterns of cadherins in developing embryos, and the functional correlation of cadherin-mediated adhesion with tissue reorganization during development suggest that regulation of cadherin function is critical for morphogenetic processes. In their most activate state, cadherins contribute to the formation and maintenance of tight adhesive contacts between adjacent cells. In this configuration, cadherin clusters at the contact site link adjacent cell surfaces to the filamentous actin cytoskeleton [104,105]. Cell migration requires the loosening of strong adhesive bonds and the downregulation of cadherin function. For example, neural crest cells modulate N-cadherin-mediated adhesion prior to migrating and ectopic cadherin expression in crest cells prevents migration [106]. The demonstrated role of N-cadherin in neurite extension *in vitro* [107,108] and axon guidance *in vivo* [109,110] requires low stringency adhesive interactions to allow cell motility. A myriad of studies have established that cadherin function is regulated at multiple levels, including gene transcription, proteolysis, endocytosis, and association with intracellular proteins. The highly conserved cadherin cytoplasmic domain provides selective target sites for regulating the cadherin-actin association that in turn influences the adhesive cell properties (Fig. 3).

Association with Intracellular Proteins

β -CATENIN/PLAKOGLOBIN

The central player in regulating the function of the classical cadherins is the armadillo repeat protein β -catenin (or the closely related plakoglobin) that binds to a conserved sequence within the cadherin carboxy-terminal cytoplasmic domain [3,81]. Deletion of the catenin-binding domain renders the mutant cadherin polypeptides inactive in promoting cell-to-cell aggregation [86,87]. The central status of β -catenin is derived from its ability to associate in a mutually exclusive manner with different cellular signaling pathways that regulate the formation of adherens junctions, gene transcription, and protein degradation [111–113]. In association with the cadherin cytoplasmic tail, β -catenin complexes with the actin-binding protein α -catenin to regulate cadherin association with actin filaments [86,114]. The small GTPases Rac, Rho, and Cdc42 are well known for regulating and specifying membrane interactions with cortical actin filaments [115], and thus it is not surprising that cadherin function is modified by such proteins. IQGAP1, an effector of the Rho family GTPases Rac and Cdc42, can modify the association of the cadherin cytoplasmic region with actin filaments [116,117]. At cell-to-cell contact sites, IQGAP1 is associated with active GTP-bound Rac and Cdc42 which prohibits binding to β -catenin. In their inactive GDP-bound

form, Rac and Cdc42 do not associate with IQGAP1, which can then bind to β -catenin and dissociate the cadherin- β -catenin complex from α -catenin and the actin cytoskeleton thereby downregulating adhesivity [118]. The association of β -catenin with the cadherin cytoplasmic domain is also regulated by the $G\alpha$ subunit of heterotrimeric G proteins. Binding of activated GTP-bound $G\alpha_{12/13}$ to the cadherin cytoplasmic region dissociates β -catenin from the complex and negates adhesive interactions [119,120]. These and many other studies provide evidence that cadherin-mediated adhesive interactions are controlled to a large extent by the available pool of β -catenin in binding configuration to interact with cadherin cytoplasmic tails.

The pool of intracellular β -catenin that is not bound to cadherins can associate with a large protein complex that contains the adenomatous polyposis coli (APC) tumor suppressor gene product, axin, conductin, and the glycogen synthase kinase-3 (APC complex). In association with this complex, β -catenin becomes rapidly phosphorylated and is subsequently targeted for ubiquitination and degradation in the proteasome [121]. An effective way to counteract β -catenin phosphorylation and degradation is by activation of the Wnt signaling pathway. Wnt plays an important role in cell fate determination during embryonic development and in cancers [121,122]. Wnt-binding to a receptor of the Frizzled family antagonizes β -catenin phosphorylation and degradation. Free unphosphorylated β -catenin can then bind to unoccupied cadherin cytoplasmic domains and enforce adhesive interactions through the cytoskeletal link. When the free β -catenin pool exceeds the number of available cadherin binding sites, it accumulates in the nucleus where it can bind to DNA binding proteins of the T-cell specific factor (TCF)/lymphoid enhancer binding factor (LEF) family. β -catenin binding to TCF/LEF transcription factors enhances expression of new genes that contribute to regulating the cell cycle [121]. Thus, β -catenin serves as a molecular switch for regulating cell behavior. The pool of β -catenin, its posttranslational modifications, and its association with the cytoskeleton are central to the regulation of cadherin-mediated adhesive activity.

p120ctn

An earlier study [9] attributed functional importance to the cadherin membrane proximal cytoplasmic domain, and it has now become clear that this site is a target for a complex regulation of cadherin-mediated adhesivity. The membrane proximal cadherin cytoplasmic region contains the binding site for the armadillo repeat protein, p120ctn. Similar to β -catenin, it is dynamically regulated by phosphorylation [90,123,124]. Phosphorylated p120ctn does not interact with the binding site on cadherins, and other proteins to regulate cadherin-mediated adhesivity can occupy the binding region (see Fig. 3). P120ctn function is also affected by Rho family GTPases which act on the actin cytoskeleton to increase or decrease cell motility [118,125,126]. As p120ctn per se seems dispensable for adhesive interactions, it may

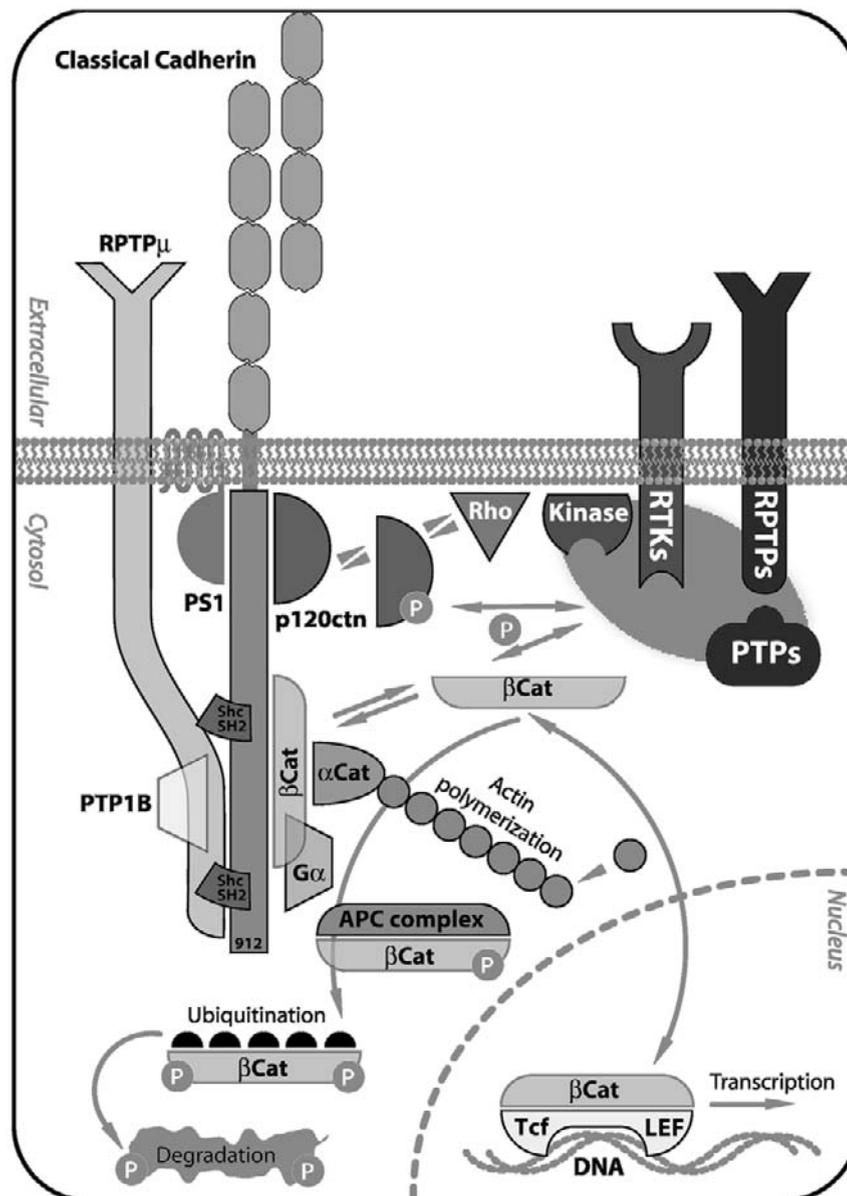

Figure 3 Regulation of cadherin function by associated intracellular proteins. The conserved cytoplasmic region of the classical cadherins interacts with multiple proteins that regulate adhesivity. Cadherin association with β -catenin and linkage of the complex to actin filaments (via α -catenin) play a central role in this regulation. Receptor protein kinases (RTKs), receptor tyrosine phosphatases (RPTPs), and intracellular phosphatases (PTPs) balance cadherin, β -catenin, and p120ctn phosphorylation. PS1 = Presenilin-1, β cat = β -catenin, α cat = α -catenin, and RPTP μ = receptor tyrosine phosphatase α .

serve as a molecular switch that can promote or prevent adhesion depending on its state of phosphorylation and the cellular context [90,124,127].

Protein Phosphorylation and Dephosphorylation

Structural studies of the interacting cadherin- β -catenin domains show that the cadherin domain is structured only when it is phosphorylated on serine residues [128]. The cadherin cytoplasmic region displays serine phosphorylation consensus sites for casein kinase II and glycogen synthase.

Serine phosphorylation seems to strengthen the association between the cadherin cytoplasmic region and β -catenin and strengthen adhesion [129]. In contrast, tyrosine phosphorylation of the cadherin cytoplasmic tail and β -catenin dramatically decreases the interaction between these proteins and weakens adhesive bonds [130–132]. Both nonreceptor- and receptor-type kinases regulate phosphorylation of the cadherin cytoplasmic tail and β -catenin. Overexpression of the nonreceptor tyrosine kinases Src or Fer in cultured cells induces phosphorylation of tyrosine residues on cadherins and β -catenin [130,133,134] and decreases adhesive interactions

in favor of a motile phenotype. Interestingly, in cancer cells, the lipid phosphatase activity of PTEN can counteract Src-induced cell scattering and invasiveness and stabilize the E-cadherin junctional complex through an as yet unknown mechanism [135]. Similarly, E-cadherin and β -catenin tyrosine phosphorylation by receptor kinase type growth factor receptors results in cell scattering [136,137]. Tyrosine-phosphorylated cadherin can bind the adaptor protein Shc, which participates in stimulating mitogenic signaling pathways by growth factor activation of Ras [138]. An alternate pathway for tyrosine-phosphorylated E-cadherin is ubiquitination and rapid endocytosis. Recent work has identified Hakai, an E3 ubiquitin-ligase that can interact with E-cadherin in a tyrosine-phosphorylation-dependent manner and stimulate endocytosis [139]. Cell surface removal of E-cadherin through this pathway decreases adhesion and enhances cell scattering. Thus, cadherin function is controlled by multiple cell signaling pathways, which regulate the availability of cadherins on the cell surface and balance the cadherin association with β -catenin and hence with the cytoskeleton.

Formation of the cadherin-catenin complex is also fine-tuned by the balance between protein kinase and phosphatase activity. Several phosphatases associate with and stabilize the cadherin- β -catenin complex, presumably by preventing phosphorylation. The nonreceptor-type phosphatase PTP1B is targeted to the cadherin complex where it interacts with sequences partially overlapping with the binding site for β -catenin [140]. The receptor tyrosine phosphatase μ (PTP μ) can interact with a largely overlapping site [141], indicating that the contributions of these proteins are mutually exclusive. Downregulation of either PTP1B or PTP μ suppresses N-cadherin-mediated neurite extension [142,143] by an as yet unresolved mechanism. Also, the nature of the interactions between phosphatases and β -catenin during cell adhesion and the process of neurite growth has not been determined. Other phosphatases including LAR, receptor tyrosine phosphatase β/ζ , and the Meprin/A5/Mu domain receptors κ and γ do not associate directly with cadherins, but may regulate cadherin function through β -catenin modifications.

Regulation by Proteolytic Cleavage

An effective strategy for regulating cadherin activity is cleavage by extra- and intracellular proteases. Mature classical cadherins are derived from precursor proteins that are cleaved at the RKQR sequence in transit to or at the cell surface [144]. Mutation of the cleavage site renders the mutant E-cadherin protein inactive in conferring cellular aggregation [144]. The proprotein convertase furin can exert proprotein cleavage of E-cadherin *in vitro* [145]; however, the expression and activity of furin *in vivo* have not been established.

The cadherin extracellular domain is subject to cleavage by metalloproteases. A 90-kDa soluble extracellular fragment of N-cadherin is generated during retinal development and may partake in modulating retinal axon guidance [146,147]. Numerous studies have implicated the loss of E-cadherin with tumor cell growth and metastasis [21].

E-cadherin is proteolytically cleaved in noncancerous mammary epithelial cells by ectopically expressed metalloprotease stromelysin-1 [148]. E-cadherin cleavage triggers the progressive conversion of the epithelial into a mesenchymal-invasive phenotype characterized by the disappearance of E-cadherin and β -catenin from cell-cell contacts and induction and activation of growth factors and endogenous metalloproteases [148]. Stromolysin, however, could not be detected in cancer cells or in the embryo, and the tissue-endogenous metalloproteases cleaving E-cadherin [149] remain to be defined.

Cellular responses to apoptotic signals are characterized by the disruption of cell-to-cell and cell-to-extracellular matrix contacts and cytoskeletal reorganization. During programmed cell death, adherens junctions disintegrate due to the actions of both metalloproteases and caspases on cadherin and β -catenin/plakoglobin molecules [150,151]. A metalloprotease activity releases most of the E-cadherin extracellular domain, while caspase-3 cleaves at an intracellular membrane proximal site [150]. These data enforce the suggestion that the structural integrity of cadherins, their assembly within adherens junctions, and their linkage to the actin filament network are critical for cell survival [152].

Lastly, in response to apoptotic stimuli, the γ -secretase activity of presenilin-1, a protein associated with Alzheimer's disease, can cleave E-cadherin at the membrane-cytoplasm interface [153]. The cleavage releases the cadherin intracellular domain, increases the intracellular pool of β -catenin, and facilitates the disassembly of adherens junctions by disconnecting cadherins from the cytoskeleton. However, under conditions that favor cell-to-cell adhesion, presenilin-1 binding stabilizes the junctional complex [154]. Such dual functions have also been reported for p120ctn which competes for the presenilin-1 binding site on E-cadherin in a mutually exclusive manner [154]. Presenilin-1 has also been demonstrated to bind to and regulate β -catenin function and trafficking thereby providing an additional mechanism for regulating adhesivity [155–157]. As presenilin-1 can be recruited to sites of synaptic contact [158] and synaptic morphology and function are regulated by the cadherin-catenin system [16–18], the cadherin-catenin-presenilin-1 interaction may favor the loss of synaptic structures at an early stage of Alzheimer's disease and increase vulnerability to neuronal apoptosis.

Conclusions and Perspectives

Over the years, it has become clear that the adhesive function of the classical cadherins is dynamically regulated. While beginning to grasp some of the principal mechanisms of this regulation, we are faced with new challenges. First, a large number of new cadherin-like molecules with cytoplasmic sequences different from those of the classical cadherins have been revealed. Little is known about the distribution, function, and modes of signaling of these molecules. Second, recent work suggests that cadherins may be far more

promiscuous in their binding specificities than previously assumed [159]. N-cadherin-deficient mutant mice die of defects in heart development [31]. This phenotype can be rescued by the cardiac-specific ectopic expression of E-cadherin [160], suggesting that cadherin-mediated adhesivity but not adhesive specificity is required. Moreover, recent work has demonstrated that cadherin function is required for the sorting of motor neurons into specific pools [161]. While cadherin-mediated sorting has been attributed to the binding specificity of one cadherin type, motor neuron pools are defined by the combinatorial expression of multiple cadherins. Overexpression of one of these cadherins, MN cadherin, disrupts pool sorting. Although the mechanism for MN-cadherin function remains to be determined, there is good evidence to suggest that the cadherin homophilic binding activity is not required as ectopic expression of E-cadherin in motor neurons has no effect on pool sorting [161]. The myriad of data that speak to the regulation of cadherin function have made it clear that cadherin-mediated adhesivity is a multifaceted issue. The diversity and magnitude of the cadherin family adds a new level of complexity to understanding the cellular interactions conferred by the combinatorial cadherin expression during development and in adult organisms.

Acknowledgments

I thank Dr. Chris Kintner for critical reading of this manuscript and Kosi Gramatikoff for preparing the illustrations. Cadherin research in our laboratory is supported by NIH Grant HD 25938.

PART III

Nuclear and Cytoplasmic Events: Transcriptional and Post-Transcriptional Regulation

Michael Karin, Editor

This Page Intentionally Left Blank

Introduction

Michael Karin

All living organisms, whether unicellular or multicellular, animals or plants, need to be able to constantly adapt to changing environmental conditions and be capable of successfully handling stressful and life-threatening challenges. This requirement for constant adjustment and adaptation is the major evolutionary driving force underlying the development of signal transduction systems that control and modulate the use of genetic information stored in the cell's DNA in response to extracellular conditions and stimuli. Thus the *raison d'être* for the various receptors, channels, adaptors, GTP binding proteins, protein kinases, and protein phosphatases discussed in Parts I and II is to allow the regulation of the cellular gene expression program in response to the cell's environment, neighborhood, and history. Part III of the Handbook is therefore focused on the different mechanisms through which signal transduction systems regulate the utilization of genetic information.

The process of gene expression in both prokaryotes and eukaryotes can be divided into several mechanistically and temporally distinct steps: transcription and generation of the primary RNA transcript, processing and transport of the RNA transcript, translation of the mRNA into protein, turnover (decay) of the mRNA, and, finally, turnover of its protein product. In a eukaryotic cell, the first two steps (transcription and RNA processing) take place in the nucleus, whereas the last three steps (translation, mRNA turnover, protein turnover) take place in the cytoplasm (although nuclear proteins are turned over in the nucleus). Regardless of locale, all of these processes are subject to regulation by signal transduction pathways.

The first two sections of Part III deal with transcriptional control mechanisms that are targeted by signal transduction pathways. The most common form of regulation is based on phosphorylation of either sequence-specific transcription factors or proteins that directly interact with such transcription factors. The phosphorylation event can either affect the subcellular distribution of the transcription factors (e.g., NFAT, NFκB), their ability to bind DNA, or their ability to activate or

repress transcription (e.g., CREB, c-Jun). As mentioned earlier, regulation can be achieved through phosphorylation of the transcription factor itself (e.g., CREB) or through phosphorylation of an interacting protein, for instance, an inhibitor (e.g., IκB) that regulates the activity or subcellular distribution of the transcription factor. Rather than being extensive and cover every single transcription factor known to be regulated via phosphorylation, Section B of Part III includes authoritative reviews that highlight the general aspects and principles governing this form of regulation.

In addition to posttranslational modifications, such as protein phosphorylation, sequence-specific transcription factors are also subject to allosteric regulation. In this case the binding of a small ligand has a dramatic effect on either the DNA binding or transcriptional activation properties of the transcription factor. This type of regulation is most relevant to members of the nuclear receptor family that play very important roles in signal transduction and cell regulation. Members of this family of ligand-regulated transcription factors, reviewed in Section A, form the core of signal transduction pathways that regulate gene expression in response to steroid and thyroid hormones, fatty acids, bile acids, and cholesterol metabolites as well as certain xenobiotic compounds. Unlike the multicomponent pathways that control transcription in response to activation of cell surface receptors, nuclear receptors are multifunctional proteins that incorporate signal detection, amplification, and execution in one molecule.

Although sequence-specific transcription factors represent the most common target for signal transduction pathways, as far as transcriptional regulation is concerned, new evidence is emerging that some of the coactivators, corepressors, or mediators with which these factors interact may also be subject to regulation. Coactivators, corepressors, and mediators are often large multicomponent protein complexes that are recruited to promoters or enhancers through interactions with sequence-specific transcription factors. We have much more to learn about the regulation of these protein complexes,

which may act either through chromatin modifications or direct interactions with the RNA polymerase holoenzyme. In addition to modulation of chromatin structure via recruitment of chromatin modifiers to sequence-specific transcription factors, evidence also exists to show that signal-responsive protein kinases may directly phosphorylate histones and regulate chromatin structure via a more direct route. All of these modes of transcriptional regulation are discussed in Sections A and B. Evidence is also growing to indicate that the activity of various transcription factors and chromatin components can be regulated via additional posttranslational modifications, such as acetylation and methylation. However, it remains to be demonstrated that signal transduction pathways can directly regulate the activity of protein acetylases or methylases in a way that does not involve protein phosphorylation. Finally, another important form of regulation discussed in Section B is regulated proteolysis, which is responsible for both activation and inactivation of transcription factors.

While transcriptional regulation has received most of the attention, it is quite clear that every single step in the gene expression process, including RNA processing, RNA transport, RNA translation, and RNA and protein turnover can be subject to regulation. Therefore a section of Part III is dedicated to posttranscriptional regulation of gene expression. Because much of the available information pertains to translational control and regulation of mRNA turnover, these topics receive most of the coverage. However, regulated RNA processing (splicing) and transport are also discussed.

Although the currently available information regarding posttranscriptional regulation is far from being extensive, it is our hope that this largely neglected area of gene regulation will receive more attention in the near future and that, one day, it will be as well understood as transcriptional regulation.

Given the important role of transcriptional and posttranscriptional control of gene expression in adaptation to adverse environmental conditions, an entire section of this volume is dedicated to the signaling mechanisms underlying various stress responses. Among the topics covered are the heat-shock and UV responses and the different responses that are elicited by DNA damage, which have provided valuable basic information relevant to many other aspects of cell regulation and signal transduction. In addition to metabolic control, these stress responses are evolutionarily ancient and are conserved in many eukaryotic orders.

Like all of the other parts of this Handbook, the prevailing approach was thematic in spirit, intended to provide a state-of-the-art understanding of fundamental principles rather than detailed coverage of the entire field. One remaining challenge for the future is to be able to identify all of the transcription factors and their target genes that fall under the influence of a given cell surface receptor or a signal responsive protein kinase. Such information will be essential both for the ultimate understanding of biological specificity and for being able to predict the biological and pathophysiological outcomes of activation or inhibition of a particular signaling molecule.

SECTION A

Nuclear Receptors

History of Nuclear Receptors

Elwood V. Jensen

*Department of Cell Biology,
University of Cincinnati College of Medicine,
Cincinnati, Ohio*

Introduction

Nuclear receptors comprise a group of intracellular proteins found either in the cytosol, weakly bound in the nucleus, or both, that, in combination with small molecule ligands, bind tightly in the nucleus, recruit appropriate cofactors, and regulate transcription in target genes. Included in this “superfamily” are receptors for the steroid hormones (estrogens, progestins, androgens, glucocorticoids, mineralocorticoids, ecdysteroids, vitamin D), for thyroid hormone and retinoids, and for an ever-increasing number of “orphan” receptors, which show structural similarity to the other receptors but for which ligands are only now being gradually identified.

Progress in the understanding nuclear receptors and their action is summarized in Table I. Because studies with estrogens began earlier than those for the other agents, the first six discoveries, identifying receptor proteins and establishing the basic action pattern, as well as the preparation of specific antibodies, were first made with estrogen receptors and later extended to other types of cellular regulators. For the most part, the remaining findings were first obtained with progestins or glucocorticoids and then shown to apply to estrogens. Thus, this short history of the receptor concept focuses on the earlier studies with estrogens that provide the general model, with a brief summary of more recent discoveries that have expanded our understanding. For the most part, only the initial reports, which stimulated other investigations, are cited for each phenomenon, in some cases along with relevant review articles. Detailed references to the many studies that have contributed to our current knowledge of hormone-receptor interaction can be found in comprehensive review articles or monographs [1–13].

Discovery of Receptors and Shift in Research Direction

The synthesis in 1957 of estradiol labeled with carrier-free tritium provided a means for determining what actually happens to the steroid itself as it exerts its hormone action. Knowledge about what the target cell does to the steroid, taken together with the influence of the hormone on cellular processes, has provided a better understanding than would have been possible from either approach alone [14].

The demonstration that rat uterus and other estrogen-responsive tissues contain characteristic hormone-binding components [15], with which estradiol associates to induce growth without itself undergoing chemical alteration [16], directed thinking away from earlier concepts that had linked estrogen action to participation in the enzymatic processes of steroid metabolism. It became apparent that interaction with the steroid must in some way alter the properties of macromolecules involved in RNA and protein biosynthesis, processes that were known to be enhanced by hormone action [17]. But in the 1960s the idea that steroid hormones must interact with enzymes was so firmly entrenched that many biochemists questioned whether the observed binding had any direct role in hormone action. The finding that the progressive inhibition of estradiol uptake in the rat uterus by increasing amounts of the antiestrogen, nafoxidine, closely parallels its inhibition of uterine growth [18] provided evidence that hormone binding actually is involved in uterotrophic action and that binding components could be regarded as true receptors.

Receptor Forms and Physiological Action

When tritiated estradiol of high specific activity became commercially available in late 1962, other investigators

Table I Steps in Development of the Receptor Concept

confirmed its specific uptake in target tissues of various species. Cell fractionation and autoradiographic studies from several laboratories showed that most of the hormone becomes tightly bound in the nucleus, with a smaller amount present in the cytosol fraction, whereas, before hormone treatment, the binding substance appears entirely in the cytosol fraction. Similar results were obtained with excised uteri exposed to hormone at physiological temperature *in vitro*.

The application of sucrose gradient centrifugation to characterize the cytosol receptor complex as an 8 S entity (originally called 9.5 S) was an especially valuable contribution [19], because it provided a means to show that the complex bound in the nucleus is different from that in the cytosol. After exposure of rat uteri to estradiol *in vivo* or at physiological temperature *in vitro*, extraction of their nuclei with 400mM KCl was found to solubilize the bound hormone as a 5 S estradiol–receptor complex [20], readily distinguished [21] from the 4 S entity produced from the cytosol complex by exposure to similar salt concentrations. After several studies suggested that the 5 S nuclear receptor is not present as such in target cells but is derived from the 8 S cytosol receptor [22,23], direct evidence was provided by the fact that simply warming cytosol to physiological temperature in the presence, but not the absence, of estradiol converts the receptor to the 5 S form [24], a process that is accelerated by the presence of DNA [25].

Based on observations first made with progesterin and glucocorticoid receptors, the 8 S cytosol complex was shown to be a conglomerate of the 4 S receptor protein associated with a variety of molecular chaperones, including heat-shock proteins and immunophilin [10], which is dissociated by interaction with the hormone, as well as by exposure to salt. The 5 S “transformed” receptor was recognized as a dimer

of the 4 S protein thus produced [26,27]. When it was found that the 5 S, but not the 4 S, complex stimulates RNA synthesis in isolated nuclei from hormone-responsive cells [28], the biochemical role of the hormone became clear, namely, to produce a functional transcription factor from an inactive precursor [29].

After analogous receptor systems were identified for other classes of steroid hormones (summarized in [7]), similar hormone-induced conversion of the native receptor to a nuclear binding form was observed. Subsequent molecular biological studies demonstrated that all hormone-transformed receptors react in dimeric form with their target genes to regulate transcription [30,31], but only with the estrogen receptor is the dimer stable enough to permit its identification in the absence of target cell DNA.

Subsequent Discoveries Relevant to Receptor Structure and Function

As summarized in Table I, more recent investigations, especially those involving techniques of molecular biology, have greatly increased our understanding of the processes by which nuclear receptors serve as regulators of cellular processes. After several investigators had tried unsuccessfully to obtain specific antibodies to estrogen receptors by conventional immunochemical techniques, application of sucrose density sedimentation to identify the nonprecipitating immune complexes formed with tritiated estradiol–receptor complexes provided specific polyclonal [32] and monoclonal [33] antibodies. Subsequently, antibodies were obtained for all classes of steroid hormone receptors, permitting the cloning and sequence determination, first of the glucocorticoid receptor [34], followed by the estrogen receptor [35,36] and other members of the nuclear receptor family.

Early studies with the glucocorticoid receptor indicated that it contained at least three distinct functional domains [37]. After cloning and sequencing, it became evident that receptors for steroid and thyroid hormones, vitamin D, and retinoids represent a superfamily of regulatory agents [4], consisting of DNA-binding (C) and ligand-binding (E) domains, a small, highly conserved hinge region (D) joining these two units, and, at the amino acid terminus, a large region (A/B) that shows little homology among the different receptors. Receptors for estrogens and thyroid hormones contain a small additional region (F) at the carboxy terminus, the function of which is not entirely clear.

For the regulation of transcription, it was found that the transformed hormone–receptor complex does not interact with the site of transcription but with a *hormone response element*, an enhancer located at the promoter area in the 5′-flanking area of the target gene [38,39]. Palindromic sequences appear to make up the binding site for the hormone–receptor complex. This interaction leads to the recruitment of coactivators or corepressors that modulate the resulting transcription [40–43].

Regulation of Basal Transcription by RNA Polymerase II

Sohail Malik and Robert G. Roeder

*Laboratory of Biochemistry and Molecular Biology,
Rockefeller University, New York*

Introduction

Transcription of protein-encoding target genes by RNA polymerase II (Pol II) represents the end point of many signal transduction pathways. A wide variety of cell type- and gene-specific transcriptional regulators (activators and repressors), including nuclear receptors, are the conduits through which these signals are transmitted to Pol II. These regulators typically function by binding to cognate promoter or enhancer elements located distal to the transcription start sites of target genes. From there they relay their regulatory effects to Pol II, which is directly controlled by the general transcription factors (GTFs: TFIIA, TFIIB, TFIID, TFIIE, TFIIIF, and TFIIH) (Table I) [1,2]. A primary function of the GTFs is to position and orient Pol II on core promoter elements that determine the transcription start site and to provide the active site of Pol II with initial access to the transcribed strand of the template. Despite the potential of Pol II and GTFs to support low levels of accurately initiated transcription *in vitro* (*basal transcription*), as well as the structural complexity (>40 polypeptides) of this machinery, responsiveness to regulatory factors is dependent on additional cofactors (coactivators and corepressors, see later discussion) [3]. The most general cofactors include TATA box binding protein (TBP)-associated factors (TAF_{II}s) in TFIID [4,5], positive cofactors (PC1, PC2, PC3, PC4, and PC52) derived from the USA cofactor fraction [3,6], and a multi-protein Mediator complex [7–9]. Together, Pol II, GTFs, and these cofactors constitute an intricate piece of machinery that makes it possible for the signals borne by activators and repressors to be translated into the appropriate genetic response on specific target genes.

This chapter discusses structural and functional aspects of the basal transcription apparatus and also addresses the role of regulatory cofactors that in turn, ultimately appear to function by directly or indirectly impacting Pol II and GTFs.

The Preinitiation Complex

Structural Organization

Multiple approaches, including X-ray crystallography and protein–DNA cross-linking, have led to a detailed description of the Pol II- and GTF-containing preinitiation complex (PIC) (Fig. 1), the key protein–DNA intermediate whose efficient assembly (and subsequent function) dictates, to a large extent, the level of expression of target genes. The crystal structure of Pol II from yeast cells reveals a complex machine that can effectively carry out RNA synthesis from double-stranded DNA templates [10–12]. Like their bacterial counterparts, with which they share extensive sequence homology [13], the two largest subunits (RPB1 and RPB2) of Pol II constitute the core of the structure and are surrounded by various smaller subunits. The catalytic site contains (at least) one magnesium ion that is buried deep within the cleft of the jaw-like assembly, from where it can drive templated incorporation of nucleotides into the growing RNA chain [12].

Pol II has not yet been visualized in the context of the PIC. However, subsets of the PIC components have been analyzed by X-ray crystallography. Together with other biophysical and biochemical approaches that have probed the fully assembled PIC, it has been possible to construct a working model of this multiprotein complex. On the paradigmatic TATA-containing core promoter, the TBP subunit of TFIID

Table I Subunit Composition of RNA Polymerase II and Associated Factors

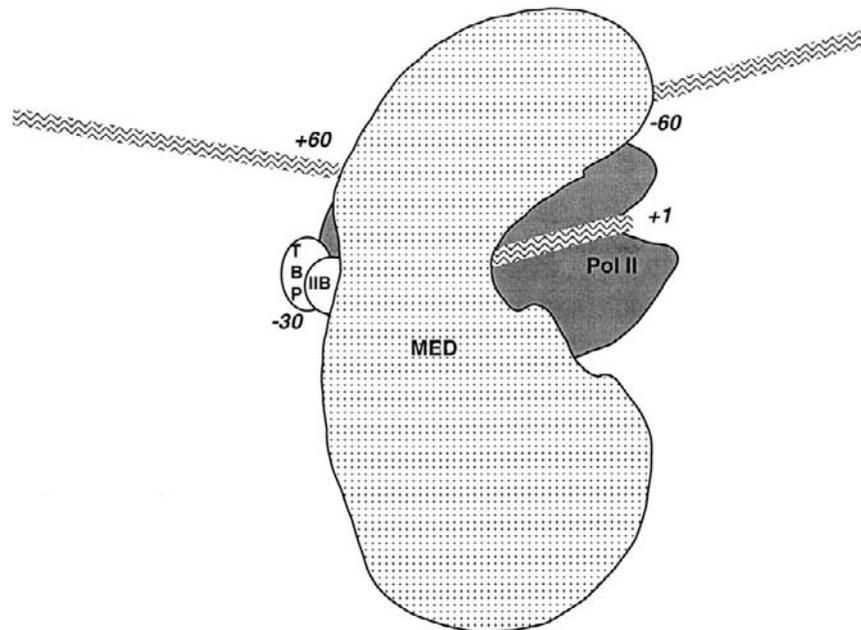

Figure 1 A schematic drawing showing a partial preinitiation complex. See text for details. For clarity, the TFIID-associated TAF_{II}s, TFIIF, TFIIE, and TFIIH are not shown. The figure is meant to emphasize the interaction of Pol II with Mediator and to highlight how the PIC likely consists of a central protein core wrapped within the template DNA (wavy lines). Although the positions of the factors are conjectural, care has been taken to ensure that they conform with previously published structural data. Activators and other cofactors, which are predicted to impinge on this machinery, have also been left out.

provides the main recognition contacts with promoter DNA. X-ray crystal structures of the TBP–promoter [14,15] and the TBP–TFIIB–promoter [16] complexes have revealed that the saddle-shaped TBP molecule interacts with the minor groove of DNA through its concave underside and induces both an unusual distortion of the central TATA element and a sharp bend in the template DNA. This arrangement leaves available large areas on the relatively convex upper surface of TBP for potential interactions with TAF_{II}s within TFIID and other factors.

The interaction of TBP with promoter DNA is stabilized by TFIIA, which binds upstream of TBP and makes contacts both with TBP and with phosphates in the DNA backbone upstream of the TATA box [17,18]. The TFIIA requirement in transcription, which appears to be variable [2], is also reflected in its ability to alleviate repression by negatively acting cofactors such as NC2 [6] (see later discussion also) and may be related to how TFIIA is positioned within the complex.

The TBP–promoter complex is also stabilized by interactions with the C-terminal core repeat domains of TFIIB, which essentially slots into the TBP–promoter complex and makes contacts both with the underside of TBP and with promoter DNA upstream and downstream of the TATA element [16]. Fluorescence anisotropy measurements suggest the presence of a conserved element (TFIIB recognition element, BRE) through which TFIIB makes specific contacts with the DNA [19]. These conclusions are directly confirmed by the crystal structure of a promoter complex containing archaeal TBP and TFB, its TFIIB ortholog [20]. Together these results establish the underlying basis for polarity in transcription start site selection. The N-terminal zinc-ribbon region of TFIIB has not been structurally analyzed in the context of the PIC, but the well-documented role of TFIIB in transcription start selection [21] suggests that it must be positioned toward the start site in order to make necessary contacts with Pol II and the RAP30 subunit of TFIIF [21–23].

Although high-resolution three-dimensional structures are available for segments of TFIIE [24] and TFIIF [25,26], currently it has only been possible to deduce the positions and function of these and other GTFs (including TFIIF) in the PIC using different approaches. Photo cross-linking analyses, in which the trajectory of the promoter DNA was mapped onto the PIC components [27,28], suggest that TFIIF plays a critical role in the fully assembled complex both in recruiting Pol II and in compacting the complex by tightly wrapping the promoter DNA around Pol II. This wrapping involves DNA contacts both upstream and downstream of the start site and may be further enhanced by TFIIE, which appears to be primarily positioned close to the transcription site [27,28]. Consistent with these results, a low-resolution three-dimensional structural analysis [29] has localized TFIIE close to the DNA binding cleft of Pol II. An important structural role for TFIIE is to recruit TFIIF to the PIC [30–32]. However, it has been suggested that, at the structural level, TFIIE also might contribute to the establishment of the PIC by a TFIIF-independent mechanism

involving direct stabilization of TBP binding to the TATA element [33].

PICs on Nonstandard Core Promoters

Most of our understanding of PIC structure is based on analyses of TATA-containing promoters, but these may represent only a minority of cellular gene promoters [34]. Additional distinct elements that dictate core promoter function have been identified. These include the initiator (Inr), which spans the transcription site [35], and the downstream promoter element (DPE) [36], located approximately 30 nucleotides downstream of the start site. As expected, PIC assembly on promoters with these elements requires additional factors. Thus, transcription from Inr-containing promoters has been shown to require distinct TAF_{II}s in TFIID [37,38]; uncharacterized activities designated TIC1, TIC2, and TIC3 [39]; and possibly other transcription factors as well [40]. DPE promoter activity also appears to require TAF_{II} interactions [36] and, intriguingly, the cofactor NC2 [41], which was previously thought to possess only a negative modulatory function [6] (see later discussion also). An altogether novel strategy may be employed by core promoters that utilize the various TBP-related factors (TRFs) [42] in place of TBP-containing TFIID, and whose target sites differ considerably from the canonical TATA box [43,44].

In all of these cases of divergent core promoter usage, the precise composition of the final PIC that is competent for transcription initiation remains to be determined. Inasmuch as the function of the basal machinery is to enable selective transcription initiation by Pol II, these elements would be expected, *a priori*, to nucleate a PIC whose overall architecture would be rather similar to that described earlier for PICs formed on canonical TATA boxes. However, the primary recognition would be unlikely to be mediated by a TBP–promoter interaction. This expectation is strengthened by the observation that the TATA binding function of TBP is dispensable for transcription of an Inr-containing promoter [38] and by the presence of TBP in initiation factors required by Pol I and Pol III for transcription of promoters that contain no discernible TATA-like sequences [45].

Global Mechanisms of PIC Function

Promoter Melting

Kinetic and structural analyses have revealed a series of well-orchestrated events that precede processive RNA synthesis by Pol II [46,47]. In the broadest terms, the PIC described earlier, which is experimentally isolated in the absence of nucleotides, can be thought of as corresponding to the “closed complex” originally described for *Escherichia coli* RNA polymerase [48]. The isomerization of the eukaryotic closed complex to the open complex (in which the double-stranded promoter DNA around the start site is partially unwound) is dependent on energy derived from the hydrolysis of ATP [46,47,49,50]. Although the details are

still not clear, initial promoter melting appears to entail multiple transitions involving TFIIE and the helicase activity of the ERCC3 subunit of TFIIH [51,52]. In the first step, the promoter region between positions -9 and +2 relative to the start site is unwound. In the next transition, the downstream edge of the unwound region is extended to +4 [46]. Templated phosphodiester bond formation ensues, but, perhaps because of the intrinsic thermodynamic instability of the complex, appears to result only in abortive synthesis of short RNA products [46].

Two distinct models have been proposed for how the TFIIH helicase catalyzes promoter melting [53]. As a conventional helicase, it could simply peel the two DNA strands apart until intrinsic Pol II functions, which are also involved in this process, take over. Alternatively, coupled with ATP hydrolysis, TFIIH could twist the DNA and crank it into an unwound state by strongly gripping DNA surrounding the melted region [54]. Although the role of TFIIE in this process is, in part, to deliver TFIIH, there also are indications that under some circumstances it directly contributes to promoter melting independently of TFIIH and ATP hydrolysis [50]. Consistent with the primary roles of TFIIE and TFIIH in promoter melting, the requirement for these factors can be partially obviated either with supercoiled templates [55] or with templates containing nonpaired regions at the start site [51,56].

Promoter Clearance

As the melted region is extended (in an ATP hydrolysis-independent fashion) to +9, longer RNA chains begin to form [46,50]. Concomitantly, the upstream DNA abruptly reanneals, whereas the downstream DNA is melted in a continuous motion into a more or less stable *transcription bubble* that is further propagated as Pol II moves into an elongation mode. This process, referred to as *promoter clearance*, prepares the promoter for a second incoming Pol II molecule for additional rounds of transcription [57].

Promoter clearance involves extensive rearrangements of transcription factor interactions, including relinquishing of contacts that hold Pol II in a stable structure. Thus, in addition to the changes in the DNA template structure and the Pol II movements discussed earlier, the PIC undergoes loss of a subset of GTFs. Early studies (of basal transcription only) suggested that TFIID remains bound to the promoter [58,59], whereas other GTFs are sequentially released as Pol II advances along the template; TFIIB and TFIIE are released by register +10 and TFIIH after +30. On the other hand, TFIIF appears to travel with Pol II. A more recent study analyzing activator-dependent transcription in extracts from yeast cells points to a somewhat different mechanism [60]. In this case, a “scaffold” consisting of TFIIA, TFIID, TFIIH, TFIIE, and Mediator (see later discussion) remains behind at the promoter after the Pol II departs. In both situations, the residual PIC is thought to serve as an efficient intermediate for a second round of transcription (reinitiation), requiring, in the latter case, only TFIIB and TFIIF [60].

Phosphorylation of the Pol II CTD

Cyclical changes in the phosphorylation status of the CTD repeats of the largest subunit (RPB1) of Pol II have long been correlated with promoter escape by Pol II [61,62]. It has been proposed that hypophosphorylated Pol II (form IIA) preferentially associates with the PIC [63]. Following promoter melting, and either concomitant with or immediately subsequent to promoter escape, the CTD is phosphorylated at specific serine residues by the cdk7 kinase subunit of TFIIH [62]. Thus, in the cell, the hyperphosphorylated form of Pol II (IIO) is predominantly engaged in transcription elongation [61]. The observation that the CTD is dispensable for transcription of many promoters in purified cell-free systems [64,65] has suggested that its phosphorylation is unlikely to be a causative factor in the initiation-to-elongation transition. However, in less-purified systems and *in vivo*, other constraining factors could impose a CTD phosphorylation requirement for this transition [66]. A role for CTD phosphorylation in transcription elongation has also been suggested, consistent with the identification of an elongation factor (pTEFb) that actively phosphorylates the CTD [67]. However, new evidence strongly suggests that CTD phosphorylation also might be a device to couple transcription and RNA processing [68,69]. Importantly, CTD phosphorylation does not constitute a unidirectional pathway because Pol IIO may be converted back to the IIA form by a variety of phosphatases, such as the TFIIF-regulated FCP [70], thereby allowing it to reinitiate.

Gene-Specific Regulation of PIC Function by Transcriptional Activators

Each of the steps in PIC assembly and function is a potential target for transcriptional regulators, especially activators. Early work emphasized direct interactions of activators with GTFs. Beginning with the original observations that TFIID could be directly targeted by activators [71], interactions of various regulators with each of the GTFs have now been reported [72–76]. However, GTFs do not suffice to support activator function *in vitro* [77] and mutations in some GTF residues that are critical for activator interactions *in vitro* do not affect transcriptional activation in functional tests [78].

Identification of the Mediator as a Key Coactivator

As mentioned, initial biochemical analyses in metazoan systems strongly suggested that TAF_{II} subunits of TFIID [4] and various USA-derived PCs [3,6] are essential coactivators for activated transcription from DNA templates. In yeast, concurrent genetic studies aimed at delineating the role of the Pol II CTD and various regulatory pathways, as well as biochemical studies aimed at eliciting activator function *in vitro*, led to the identification of SRB/Mediator (or Mediator) as the key coactivator [8,9,79]. Although the yeast

Mediator was isolated as a holoenzyme complex with Pol II, this association is reversible [80]. Variable levels of subsets of GTFs were also found to be present in the Pol II holoenzyme [80,81]. A genome-wide analysis has further suggested that, like Pol II, the Mediator is required for essentially all genes [82]. These observations have suggested that Mediator function in transcriptional regulation might be intimately associated with basal transcriptional control.

Subsequently, in metazoan systems, parallel efforts to recapitulate thyroid hormone receptor activity *in vitro* and to purify complexes containing orthologs of yeast Mediator subunits converged with the description of the TRAP [83] and SMCC [65] coactivator complexes, which proved to be identical [84]. Similar complexes were independently identified based on different criteria [7]. These include DRIP [85], ARC [86], and hMediator [87], which were isolated on the basis of their ability to interact with distinct activators. Furthermore, USA-derived PC2 also was identified as a Mediator-like complex [88]. The variously isolated complexes may all represent the same cellular entity or its derivatives [7], which by analogy to the yeast complex is also referred to here as the Mediator.

The metazoan Mediator complex consists of about 25 polypeptides (Table I) that include RGR1, SRB10/CDK8, MED7, MED6, SRB11/cyclin C, SRB7, SOH1, and NUT2, which are phylogenetically conserved from yeast to human [7]. Other polypeptides that are specific to the metazoan complex include the various TRAP polypeptides, as well as additional less-well characterized polypeptides. As for the yeast Mediator, which the metazoan complex resembles in its overall three-dimensional structure [89], the metazoan Mediator subunits are predicted to be organized in a modular fashion. There appears to be a relatively stable core (likely represented by the subunits found in PC2) surrounded by somewhat more reversibly associating polypeptides such as the kinase-cyclin pair that consists of SRB10/CDK8 and SRB11/cyclin C [7,88].

Potential Mechanisms of Mediator Function

Although no stable, stoichiometric Mediator–Pol II complex akin to the yeast holoenzyme has been reported in metazoans, there is evidence for direct interactions of metazoan Mediator with Pol II [7]. Furthermore, activators appear to contact distinct subunits within the Mediator. Thus, nuclear receptors primarily target TRAP220 [90], whereas activation domains of the viral activator VP16 and the tumor suppressor p53 interact with TRAP80 [84]. Based in part on these data, as well as similar data from yeast [80,81], a simple model for the mechanism of action of the Mediator postulates that it functions as an adaptor that links activators with the basal transcription machinery. Nonetheless, it remains to be established whether the initial PIC-forming entity is the Pol II holoenzyme or whether, as some recent reports suggest, PIC formation involves temporally separable recruitment of Mediator and Pol II [91,92].

It is possible that Mediator effects are exerted both at the level of recruitment (that is, by enhancing PIC formation) and by alterations in the function of the PIC (Fig. 1). In this regard, note that both the yeast and metazoan Mediators directly enhance basal (activator-independent) transcription [80,93,94], especially in the context of a complement of other nuclear factors. Direct interactions with the basal transcription machinery that could stabilize the PIC may be involved. Thus, in yeast, SOH1 displays genetic interactions with Pol II and TFIIB [95]. (Note, however, that although SOH1 appears to be an integral subunit of the human Mediator [7,65], it has not yet been directly implicated as such in yeast.) Similarly, the GAL11 subunit of the yeast Mediator (which has no apparent ortholog in the metazoan complex) interacts both physically and genetically with TFIIE [96]. Related, *in vitro* recruitment experiments have revealed that the Mediator-containing yeast holoenzyme is dependent on both TBP and TFIIB for PIC formation in some assays [97]. Functionally, the Mediator can also modulate the TFIID CTD kinase activity and, thus, potentially also intervene at a postinitiation stage [80]. On the other hand, it has been proposed that the SRB10/CDK8 kinase subunit down-regulates TFIID activity by phosphorylating its cyclin H subunit [98]. Effects at the level of promoter opening have not been reported. However, a role for the Mediator in efficient multiple-round transcription is likely because, in a yeast transcription system, the scaffold that remains after Pol II clears the promoter contains Mediator [60].

It is intriguing that multiple subunits in the Mediator have been identified as targets of activators [7,84,85,87,90,99]. Given that many activator signals emanate from enhanceosome-type assemblies that are composed of various activators [100], and that distinct activators may simultaneously interact with the Mediator [84], this provides a basis for synergistic activation mechanisms. Furthermore, these observations are consistent with coactivators (especially the Mediator) being devices for processing diverse signals into an integrated output for the Pol II machinery.

Mediator in Relation to Other Coactivators

An unresolved issue related to the mechanisms by which the various coactivators affect the basal machinery is whether they act synergistically or whether they are functionally redundant and thus reflect alternative activation pathways. In the case of USA-derived positive cofactors, we have previously found that Mediator-like PC2 functionally synergizes with PC4 and PC3/topoisomerase I [88]. Here, PC4 and PC3/topoisomerase I are believed to fulfill a structural role in stabilizing the PIC. In the case of the TAF_{II} subunits of TFIID, the relative contributions of these components and the Mediator in activated transcription have been harder to dissect. Earlier biochemical studies in yeast systems demonstrated Mediator function, including transcriptional activation, in reactions that contained TBP rather than the intact TFIID [80,81]. Moreover, genetic analysis revealed that at least a subset of TFIID-specific TAF_{II}s was dispensable for

general activator function in yeast cells [101,102]. In the small number of cases in which a strong TAF_{II} dependence was demonstrable, the TAF_{II} requirement appeared to be dictated by the core-promoter sequences [103]. However, more recent genome-wide analyses in yeast have identified a subset of genes whose expression is critically dependent on histone-like TAF_{II}s [104] (including yTAF_{II} 17, a component shared by both the TFIID and SAGA complexes [105]). These genes display a requirement of their upstream activating sequences for this dependence [104,106].

In metazoan systems, differential requirements for TAF_{II}s have been observed depending on the experimental system employed [107,108]. Nonetheless, under some conditions in unfractionated extracts, TAF_{II}s within TFIID and Mediator appear to be jointly required both for activator-dependent and activator-independent transcription [94]. An interesting possibility is also suggested from a recent study in which the relative contributions of TAF_{II}s and Mediator in activation of several *Drosophila* promoters were examined [109]. It was observed that TBP sufficed to support activation from a TATA-box containing promoter (albeit still in a Mediator-dependent manner). However, activation through another promoter, which lacks a TATA box but contains a DPE, required intact TFIID (and simultaneously also displayed a Mediator dependence). These results are consistent with the idea that TAF_{II}s are required primarily for core promoter recognition, whereas Mediator is required for both activator-dependent and activator-independent effects. Therefore, it may be that, ultimately, both the TAF_{II} and Mediator requirements are intertwined, and reflect, at least in part, how each of these complexes interacts with the basal transcription machinery.

Although factors and mechanisms involved in transcription from DNA templates have been stressed in the foregoing discussion, it is important to keep in mind that in the cell transcription takes place within the constraints of a chromatin template. This necessitates other coactivator functions such as those associated with histone acetyl transferases like CBP/p300 and the p160 family of nuclear receptor coactivators [105]. A sequential mode of action of the factors, entailing an initial activator-mediated chromatin remodeling step followed by the recruitment of Pol II, GTFs, and Mediator, has been proposed [3,7]. Thus the mechanisms discussed earlier are likely to be relevant regardless of the nature of the template (chromatin or DNA). Indeed, in a sense, the PIC, with promoter DNA wrapped around a central protein core, can be viewed as being in competition with the structurally similar nucleosomes (Fig. 1) [110].

Negative Control of GTF Function

In addition to constraints imposed by chromatin structure, the basal machinery is subject also to other kinds of negative control. This introduces antirepression as an additional mode of gene activation [3]. It is noteworthy that some of the USA-derived PCs contain intrinsic repressive capabilities that are not only reversed during transcriptional activation but also are exploited to effect net transcription levels that

exceed the basal (unregulated) levels [3]. Similarly, TFIID-associated TAF_{II}s, especially TAF_{II} 250, can also be repressive in the absence of an activator [111]. Part of the mechanism by which TAF_{II} 250 represses basal transcription involves molecular mimicry. Thus, the TAF_{II} 250 N-terminal domain resembles the unwound DNA structure of the TBP-TATA complex and makes repressive contacts with the underside of the TBP saddle that normally interacts with the TATA sequences [112]. In the presence of an activator, this interaction can be eliminated, thus allowing PIC formation to proceed. NC2 also is a negative cofactor that interacts directly with the basal transcription machinery [6]. A recent crystal structure of a ternary complex containing TBP, NC2, and promoter DNA nicely illustrates how a potential steric clash with TFIIB would preclude productive PIC assembly [113]. While the precise mechanisms are unknown, antagonism of this repression could be an important regulatory step in the cell.

Other negatively acting cofactors that have functional links to TBP and that have been identified both in yeast and metazoans include MOT1 [114,115] and the various NOT proteins [116,117]. In yeast, MOT1 may function to “remodel” TBP complexes in an ATPase-dependent fashion. Although regarded as a negative cofactor, MOT1 also has been localized to active genes [118]. This situation is somewhat reminiscent of the apparent functional duality associated with NC2 [119], and it is not immediately apparent how the various observations can be reconciled. The NOT proteins form heterogeneous complexes that include the CCR4 protein [120]. Their mechanism of action also is unclear, although one recent report has identified an ubiquitin ligase activity associated with the metazoan ortholog of one of the NOT proteins [121].

GTF Regulation by Covalent Modification

GTFs also undergo covalent modifications that might have regulatory consequences, but which at present are largely uncharacterized. The effect of the SRB10/CDK8 kinase on TFIID was mentioned earlier. Other modifications include TAF_{II} 250-mediated phosphorylation of the RAP74 subunit of TFIIF [122] and acetylation of the large subunit of TFIIE by p300 [123]. In some cases, such as for the extensive phosphorylation of TFIID subunits (TBP and TAF_{II}s) during mitosis [124], these modifications may not reflect gene-specific controls in the context of the PIC but, instead, global control mechanisms that operate, for example, during progression through the cell cycle.

Conclusion

As summarized here, strong evidence linking activator function to the basal transcription machinery has been obtained. At the same time, structural, mechanistic and kinetic details of how this machinery carries out its basic functions have begun to emerge. Therefore, a main task for the future

is to understand more completely how the various sub-processes that constitute PIC function are modulated by activators and coactivators. The description in recent years of the Mediator as a key transcriptional regulator has opened up the possibility of understanding these mechanisms in greater depth.

Structural Mechanisms of Ligand-Mediated Signaling by Nuclear Receptors

H. Eric Xu and Millard H. Lambert

*Nuclear Receptor Discovery Research, GlaxoSmithKline
Research Triangle Park, North Carolina*

Introduction

Nuclear receptors (NRs) contain three major domains: an N-terminal domain, a central DNA-binding domain (DBD), and a C-terminal ligand-binding domain (LBD). The N-terminal domain contains, in some NRs, an “activation function 1” (AF-1) but little is known about its structure. The DBD, consisting of two highly conserved zinc-finger motifs, recognizes specific DNA sequences in the target promoters, and is responsible for the specificity of gene regulation. The LBD, as its name suggests, is responsible for ligand recognition and subsequent signaling cascades. In most NRs, the LBD also contains dimerization functions and a C-terminal “activation function 2” (AF-2) that promotes ligand-dependent transcription. The LBD is thus the key to the ligand-dependent regulation of NR signaling and, as such, has been the focus of intense structural studies. In this brief review, we focus on structural insights into the molecular basis of ligand binding and signaling by nuclear receptors.

Overall Structure of the LBD

All of the NR LBD structures determined to date share a similar fold, where about a dozen α -helices are packed into a three-layer sandwich with a cavity for binding ligands (Fig. 1). The C-terminal AF-2 region also adopts an α -helical

conformation, but can pack onto alternative sites on the core structure depending on the presence and nature of the ligand. Aside from the AF-2 helix, the core helical structure is relatively stable and well preserved among different receptors, particularly in the top half of the LBD. The conservation of the overall structure suggests that the LBD fold is selected through evolution for the binding of small molecule ligands despite a wide divergence in their amino acid sequences.

Ligand-Binding Pockets

Helices 3, 5, 6, 7 and 10 enclose a ligand-binding pocket in the bottom half of the LBD. This pocket is covered by a β -sheet on one side, and it can be covered by the C-terminal AF-2 helix on the other side. Although different NR LBDs have similar overall structures, their ligand-binding pockets are remarkably diverse, with pocket volumes ranging from 390 to 1440 \AA^3 (Table I). The receptors with smaller pocket volumes, such as the retinoid and steroid receptors, seem to recognize specific ligands, whereas the receptors with larger pockets, such as the pregnane X receptor (PXR) and the peroxisome proliferator-activated receptors (PPARs), are able to bind a broader range of ligands. The ligand promiscuity in the PXR and the PPARs may be essential for their physiological functions as sensors of diverse xenobiotic substances and diverse fatty acids and eicosanoids, respectively.

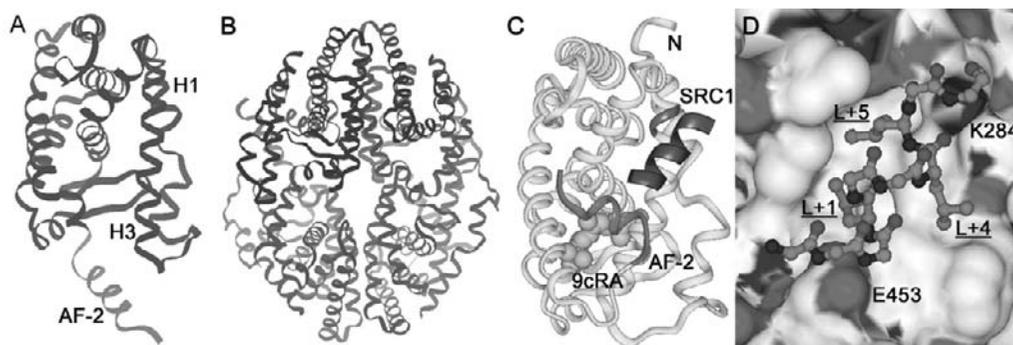

Figure 1 Structures of the RXR LBD in different conformational states. A, an overview of the apo-RXR LBD where the key helices are noted. B, the self-repressed tetrameric form consisting of two symmetric dimers packed together (dark and gray ribbons). C, RXR bound to 9-cis-RA (gray worm) with the SRC-1 LxxLL motif (dark) and D, a close-up view of the RXR charge-clamp groove where the leucine residues of the LXXLL motif are underlined.

Table I Volumes (\AA^3) of NR Ligand Binding Pockets

Receptor	Ligand	Pocket vol	Ligand vol	PDB ID
ER β	Genistein	390	236	1QKM
AR	DHT	422*	319*	1I37
RAR γ	Retinoic acid	429	335*	2LBD
ER α	Estradiol	450	245	1ERE
RXR α	9-cis RA	470	350	1FM6
TR α	T3	600	530	–
PR	Progesterone	603	349*	1A28
VDR	Vitamin D	697	390	1DB1
ROR β	Stearic acid	766	–	1K4W
PXR	SR12813	1150	552*	1ILH
USP	Phospholipid	1256	878*	1G2N
PPAR δ	EPA	1300	300	3GWX
PPAR α	GW409544	1400	524*	1K7L
PPAR γ	GI262570	1440	580	1FM6

Volumes indicated with an asterisk were calculated using the methodology of Gampe *et al.* [1]. Other values were compiled from the literature.

The shape of the ligand-binding pocket also varies greatly, allowing different NRs to accommodate ligands with different shapes. An interesting example of ligand selectivity between different subfamilies of receptors is provided by the retinoid X receptor (RXR) and the retinoic acid receptor (RAR), where 9-*cis* retinoic acid can bind to both receptors, but the all-*trans* retinoic acid binds only RAR. RXR has an L-shaped pocket, allowing it to accommodate the bent shape of the 9-*cis* isomer but not that of the extended all-*trans* isomer, [1]. By contrast, the RAR pocket is relatively straighter, and can accommodate both isomers [2]. The role of the pocket shape in ligand selectivity can also be found in receptors from the same subfamily. The three PPARs (α , γ , and δ) show different ligand preferences for fibrates, a class of lipid-lowering drugs, or glitazones, a class of diabetes drugs. A single residue variation that alters the shape of the PPAR headgroup pockets

has been shown to be responsible for the differential binding of these ligands [3]. These examples show that the pocket shape is a key factor in determining ligand specificity.

Ligand-Mediated Activation: Mouse Trap versus Charged Clamp

Activation of nuclear receptors depends on the precise positioning of the AF-2 helix, which in turn depends on the nature of the bound ligand. In the apo-RXR structure, the AF-2 helix was extended away from the main body of the domain, leaving an opening into the ligand-binding pocket [4,5]. In contrast, the AF-2 helix is packed over this opening in the agonist-bound structures. This observation led to a “mouse-trap” model for activation, in which the ligand enters the pocket through this opening, causing the AF-2 helix to close over the ligand like a mouse trap closes over a mouse. The mouse-trap model was confirmed, for RXR, by the subsequent PPAR γ /RXR heterodimer structure, in which the RXR monomer was bound to 9-*cis* retinoic acid [1]. However, the activation process has proven to be more complex than originally proposed because RXR activation requires the dissociation from its self-repressed tetrameric form (Fig. 1B) [4]. The apo structures of PPAR γ , PPAR δ , and PXR have shown that the AF-2 helix can be packed against the receptor in the active conformation even in the absence of ligand [6–8]. With the AF-2 opening blocked, the ligand instead enters the PPAR pocket through a large channel between helix 3 and the β -sheet. Ultraspiracle (the insect homolog of RXR) also has an alternate channel for ligand entry [9,10].

In contrast to multiple pathways of ligand entry, a conserved mechanism is employed by nuclear receptors for ligand-dependent activation. In the apo state, the lower half of the LBD is structurally unstable due to a large unfilled cavity inside the protein. Ligand binding, which partly fills this cavity, stabilizes the protein and allows the AF-2 helix to dock into the active conformation. In PPARs, the AF-2 helix is further reinforced in the active conformation by a direct

hydrogen bond with the acidic headgroup of the bound ligand. In this conformation, the AF-2 helix positions a conserved glutamate so as to form a charge clamp with a lysine from helix 3. Coactivators such as SRC-1 contain an LxxLL motif that forms two turns of α -helix, orienting the leucine side chains into a hydrophobic cleft between the two charge-clamp residues (Fig. 1). The charge-clamp residues make a network of hydrogen bonds with the ends of the LxxLL helical motif, further stabilizing the docking of the coactivator helix. This mode of coactivator interactions appears to be common for ligand-mediated activation because residues that contact coactivator are highly conserved among NRs.

Ligand-Mediated Repression

Some nuclear receptors can actively repress the transcription of target genes by recruiting corepressors such as *nuclear corepressor* (N-CoR) and *silencing mediator for retinoid and thyroid hormone receptors* (SMRT) [11,12]. The recent structure of a ternary complex of the PPAR α LBD bound to an antagonist and a segment from SMRT reveals that the corepressor interacts with the receptor through an α -helical LxxxIxxxL/I consensus sequence that packs into the same general site as the LxxLL motif of the coactivator [13]. However, the LxxxIxxxL/I helix is longer than the LxxLL helix, with three turns of α -helix instead of two (Fig. 2). Whereas the coactivator interacts with a glutamate residue in the AF-2 helix, the corepressor helix protrudes into volume normally occupied by the AF-2 helix, effectively displacing the AF-2 helix from its active position. The net effect is that coactivators recognize and bind to NRs when the AF-2 helix is in its “active” conformation, whereas corepressors recognize and bind to NRs when the AF-2 helix is in other, “inactive” conformations.

The antagonist in the PPAR α /SMRT structure was specifically designed, based on an earlier agonist-bound PPAR structure, to protrude into volume normally occupied by the AF-2 helix. The structure confirms that the designed antagonist displaces the AF-2 helix out of the active position. However, different from the antagonist-bound estrogen receptor structures, the AF-2 helix does not occupy the coactivator-binding groove but is loosely packed against helix 3 (Fig. 2). The displacement of the AF-2 helix out of its active position by the antagonist opens up a larger groove composed by helices 3, 4 and 5 and further reinforces the binding of the three-turn corepressor helix. These structural observations highlight the conformational flexibility of the AF-2 helix, which functions as a molecular switch to turn on or turn off NR transcriptional activities in response to the binding of an agonist or an antagonist.

Dimerization

As DNA-binding transcriptional factors, most NRs function as dimers. X-ray structures of the estrogen receptor (ER)

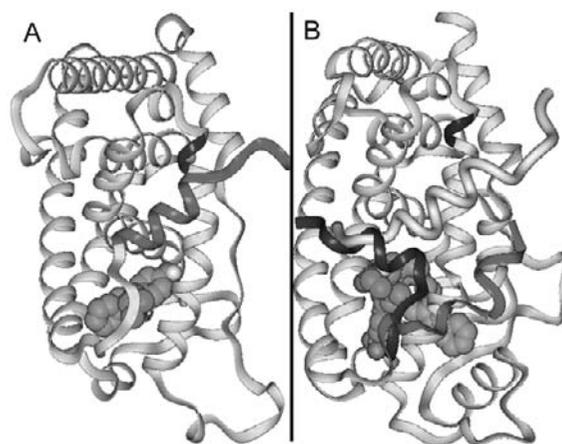

Figure 2 Antagonist-bound LBD structures. A, ER α bound to tamoxifen (spheres), with the AF-2 helix shown in a darker shade of gray; and B, the ternary complex of PPAR α with GW6471 (spheres), with the AF-2 helix and SMRT peptide in darker and lighter shades of gray, respectively. The active position of the AF-2 is shown with a very dark gray to illustrate how it would bump the SMRT corepressor helix.

homodimer and two different RXR heterodimers reveal a common mode of dimerization, in which the helix 10 from one monomer packs against the helix 10 from the other monomer in a parallel manner [4,5]. The dimerization involves only the N-terminal (upper) half of helix 10, with the lower half of the helix curving away from the partner monomer. Although the homodimers have perfect twofold symmetry, the PPAR γ /RXR heterodimer displays significant asymmetry. This can be seen in the contacts made by the AF-2 helix. In the homodimers, both AF-2 helices fail to contact the partner, whereas in the heterodimer, the PPAR γ AF-2 helix contacts RXR, but the RXR AF-2 helix fails to contact PPAR γ [1]. The RXR/RAR complex has a similar asymmetry, although the RAR AF-2 helix cannot make analogous interactions with RXR because the C-terminal end of its AF-2 helix is not conserved, and because the AF-2 helix lies in the coactivator pocket. Interestingly, the RXR/PPAR γ heterodimer is “permissive” in that it can be activated by RXR ligand alone, whereas the RXR/RAR heterodimer is nonpermissive, and cannot be activated by the RXR ligand alone. The asymmetric interactions between RXR and its partner’s AF-2 helix may provide a structural basis for the permissive activation by the RXR ligand.

The steroid receptors of progesterone (PR) and androgen (AR) reveal a distinct mode of dimerization involving the AF-2 helix (in its active conformation) and the C-terminal (lower) half of helix 10 [14,15]. The dimer interface in these steroid receptors is significantly smaller than that seen in the RXR heterodimer and ER homodimer, and its physiological relevance remains to be determined.

Summary

X-ray structures have now been solved for more than a dozen NR LBDs, bound to agonists and antagonists,

coactivators and corepressors, and as monomers, homodimers, heterodimers, and tetramers. These structures have illustrated the details of ligand binding, the conformational changes induced by agonists and antagonists, the basis of NR dimerization, and the mechanism of coactivator and corepressor binding. All of the NRs studied to date have broadly similar structures and mechanisms of activation, but functionally significant differences have arisen in different NRs over the course of evolution. We can expect more surprises as structural work continues on the remaining NRs, and as crystallographers tackle higher order complexes involving the LBD with the AF-1 domain, the DBD, and other proteins and nucleic acids involved in gene transcription.

Nuclear Receptor Coactivators

Riki Kurokawa and Christopher K. Glass

School of Medicine, University of California
at San Diego, La Jolla, California*

Introduction

Nuclear receptors (NRs) comprise a family of DNA-binding transcription factors that regulate programs of gene expression related to cellular growth, differentiation, and homeostasis in a ligand-dependent manner [1]. In addition to receptors for ligands such as steroid hormones, retinoids, and metabolites of fatty acids, the NR family also includes several so-called “orphan receptors,” representing members for which regulatory ligands are not known [2]. NRs activate transcription by binding as monomers, dimers, or heterodimers to specific hormone response elements (HREs) within target genes [3]. The central highly conserved DNA-binding domain (DBD) mediates sequence-specific recognition of HREs. Two distinct domains contribute to transcriptional activation functions, referred to as AF-1 and AF-2 [1]. The AF-1 domain is located in the N-terminal region and is poorly conserved among NR family members. In some NRs, particularly steroid hormone receptors, AF-1 plays a quantitatively important role in transcriptional activation. AF-2 resides in the C-terminal ligand-binding domain (LBD), which in addition to conferring the specific ligand-binding properties of each receptor, also contains a dimerization interface and ligand-regulated transcriptional activation and repression functions. Several lines of evidence have emerged in recent years indicating that ligand-dependent transcriptional activation involves the recruitment of a series of coactivator proteins to the NR LBD [1,4]. Several of these proteins are components of complexes that remodel chromatin, modify histone tails, or act to recruit core transcription factors (Fig. 1). In this chapter, we discuss general molecular mechanisms responsible for ligand-dependent interactions among NRs and coactivator proteins and provide examples of different classes of coactivators that have been linked to NR function.

Mechanism of Coactivator Recruitment

The ligand-dependent transactivation function of NRs has been demonstrated to depend on a short conserved sequence within the C terminus of the LBD [5,6]. Mutations within this region have been identified that have little or no effect on ligand binding, but abolish ligand-dependent transcription. Crystallographic analysis of several nuclear receptor LBDs has revealed a conserved structure in which a three-layered antiparallel α -helical sandwich encloses a central, hydrophobic ligand-binding pocket [7,8]. In the unliganded RXR structure, the AF-2 helix extends away from the ligand-binding domain [9]. In contrast, in the agonist-bound RAR, TR, and ER LBD structures, the AF2 helix is tightly packed against the body of the LBD and makes direct contact with ligand [10–13]. In concert, these studies are consistent with the idea that ligand-dependent changes in the conformation of the AF-2 helix result in the formation of a surface that facilitates coactivator interactions. Intriguingly, the structures of the estrogen receptor LBD bound to the antagonists raloxifene or dihydroxytamoxifen (OHT) demonstrate a distortion in the position of the AF-2 helix that prevents the binding of coactivators [12,13].

Extensive analysis of the amino acid sequences of several nuclear receptor coactivators revealed that a short helical sequence LXXLL (L: leucine and X: any amino acid) within the nuclear receptor interaction domain was necessary for ligand-dependent recruitment to the NR LBD [14–16]. LXXLL motifs have been identified within nearly all of the putative coactivators that interact with NRs in a ligand-dependent manner, including members of the p160/SRC family (Fig. 2A), CBP/p300, TRAP220/DRIP205/PBP, and PGC-1. Structural studies of the PPAR γ LBD complexed to a fragment of the SRC-1 nuclear receptor interaction domain containing two LXXLL motifs revealed that these motifs

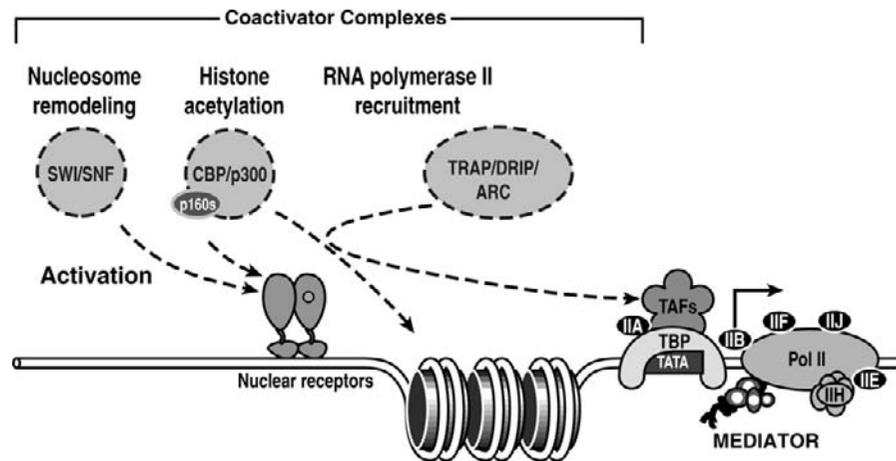

Figure 1 Ligand-dependent transcriptional activation of nuclear receptor target genes. Nuclear receptors bind to hormone response elements in promoter or enhancer elements and recruit one or more coactivator complexes in response to activating ligands. Many coactivator proteins have been identified that are components of multiprotein complexes, such as Swi/Snf complexes involved in nucleosome remodeling, p160/CBP complexes containing histone acetyltransferase activities, and TRAP/DRIP/ARC complexes involved in recruitment of basal transcription factors.

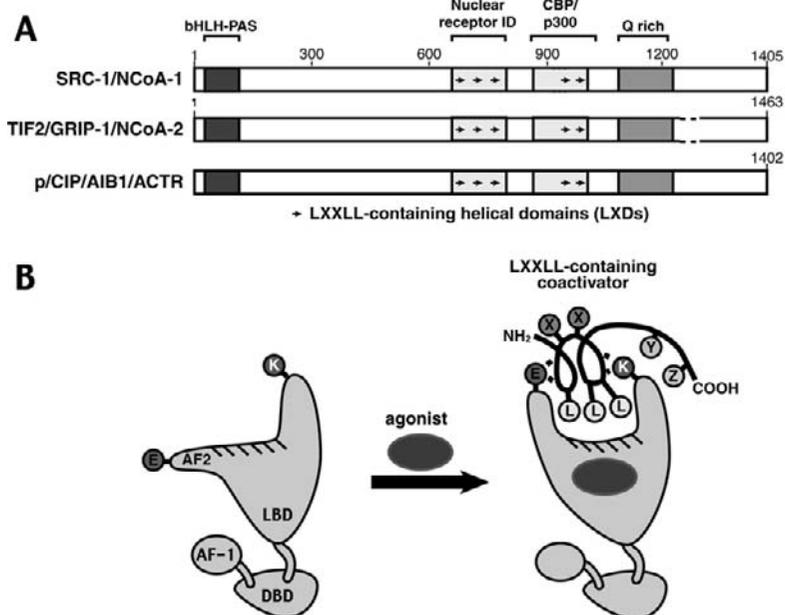

Figure 2 Mechanism of coactivator recruitment. (A) Alignment of members of the p160/SRC family of nuclear receptor coactivator illustrating the positions of LXXLL motifs mediating NR interaction and the CBP/p300 interaction domain. (B) Binding of agonist to the NR LBD induces a conformational change in the C-terminal AF-2 helix. This results in the formation of a charge-clamp that grips the ends of the LXXLL helix and allows the leucine residues to pack into an intervening hydrophobic cavity.

form short α -helices [17]. The two LXXLL motifs within this fragment of SRC-1 interacted with each subunit of a LBD dimer, suggesting a mechanism for cooperative interactions among coactivators and nuclear receptor dimers or heterodimers. The LXXLL helix was gripped at each end by a charge-clamp consisting of a conserved lysine in helix 3 of the LBD and a conserved glutamate in the AF-2 helix (Fig. 2B). This positioned the LXXLL helix so that the leucine

residues could pack into a hydrophobic pocket between the end of helix 3 and the AF-2 helix, stabilizing the interaction. Structures of the thyroid hormone receptor and estrogen receptor LBDs complexed to LXXLL peptides from other p160 family members exhibit the same structural basis for binding [13,18,19]. Although the LXXLL helix is necessary for ligand-dependent interactions, additional residues N and C terminal to the helix contribute to binding specificity [14,20].

General Classes of Coactivator Complexes

Since the initial biochemical characterization of p160 and p140 proteins as ligand-dependent estrogen receptor-associated proteins [21,22], dozens of additional proteins have been identified that interact with nuclear receptors in a ligand-dependent manner [1]. Functional assignment of these proteins as NR coactivators has generally been based on co-immunoprecipitation experiments demonstrating that they interact with liganded nuclear receptors in cells and that forced expression results in increased ligand-dependent transcriptional responses. The development of chromatinized *in vitro* transcription assays has allowed biochemical approaches to functional analysis of coactivator function [23]. More recently, demonstration of ligand-dependent recruitment of putative coactivators to NR target genes by chromatin immunoprecipitation assays has been considered as an additional line of evidence for physiological relevance [24]. Relatively few coactivators have been demonstrated to be required for NR action by loss of function (e.g., gene knock-out) experiments. Gene knock-out experiments are in some cases difficult to interpret because of the potential for coactivators to serve redundant functions. In many cases, proteins initially identified to function as nuclear receptor coactivators have proven to function as coactivators for other classes of transcription factors.

Coactivator proteins are generally considered to function by modifying chromatin architecture or by serving as adapters that recruit core transcription factors to the promoter [1,4]. Many coactivator proteins have been found to be components of stable, multiprotein complexes. Modifications of histone tails are becoming increasingly recognized to constitute a “code” that specifies overall chromatin architecture and the potential of genes to be silenced or transcribed [25]. Several proteins shown to function as nuclear receptor coactivators harbor histone acetyltransferase activity, including CBP and p300. Conversely, the nuclear receptor corepressors N-CoR and SMRT are components of protein complexes that contain histone deacetylase activities [4]. Histone methylation has also emerged as a modification that is associated with either transcriptional activation or gene silencing, depending on the specific histone and amino acid residue that is modified [26]. The nuclear receptor coactivator CARM-1 methylates histone H3 at arginine 3, and this modification is correlated with transcriptional activation [27]. Histone phosphorylation has been linked to transcriptional activation, but NR coactivators with histone kinase activities have not yet been described. A distinct type of chromatin modification is provided by ATP-dependent chromatin remodeling complexes, exemplified by the BRG/BAF complexes, which are highly related to SWI/SNF complexes originally identified genetically in yeast and *Drosophila*. SWI/SNF complexes mediate the repositioning of nucleosomes, presumably facilitating access to DNA-binding transcription factors. Although these proteins may not interact directly with NRs, there is evidence that they are recruited to promoters in a ligand-dependent manner and cooperate with other classes of coactivators [28].

The p160/SRC and TRAP220/DRIP205/PBP proteins are examples of nuclear receptor coactivators that appear to function as adapter proteins. SRC-1 and related proteins interact with liganded NRs via LXXLL motifs, as described earlier, and with CBP and p300 via a C-terminal domain (Fig. 2A). The ability of SRC-1 to function as a coactivator is based in part on its ability to recruit CBP/p300 [15,29,30]. TRAP220/DRIP205/PBP is a component of the TRAP/DRIP/ARC complex identified biochemically as a coactivator complex required for *in vitro* transcriptional activities of the thyroid hormone receptor, vitamin D receptor, and SREBP [31–33]. The TRAP220/DRIP205/PBP subunit contains two LXXLL motifs, which allow the entire complex consisting of more than a dozen proteins to be recruited to nuclear receptors in a ligand-dependent manner [34]. The TRAP/DRIP/ARC complex is proposed to function by recruiting RNA polymerase II holoenzyme to the promoter in a receptor- and ligand-dependent manner [35].

Coactivators as Targets of Signal Transduction Pathways

Components of coactivator complexes are emerging as targets for various signal transduction pathways, providing an additional level at which these pathways may be integrated. An example is provided by PGC-1, initially reported as a fat cell-specific coactivator for PPAR γ [36]. Recently, PGC-1 has been found to enhance the expression of key gluconeogenic enzymes, including phosphoenolpyruvate carboxykinase (PEPCK) and glucose-6-phosphatase in the livers of fasting mice, leading to increased glucose synthesis [37]. These genes are under combinatorial control of several sequence-specific transcription factors, including the glucocorticoid receptor and the orphan nuclear receptor HNF-4, which collectively utilize PGC-1 as a coactivator. The expression of PGC-1 is stimulated by glucagon and suppressed by insulin, suggesting that it may be a key target of these hormones in the maintenance of blood glucose homeostasis. These observations are of particular interest because they suggest that the expression of a specific coactivator is required for a specific program of gene expression that is regulated by transcription factors that have multiple physiologic roles.

Conclusion

The identification and functional characterization of nuclear receptor coactivators represent major current efforts being undertaken in the nuclear receptor field. Many fundamental questions remain to be answered, including why so many of these proteins exist, and how they exert their transcriptional effects. The study of these proteins could have practical benefits in that it may be possible to selectively regulate patterns of gene expression by developing synthetic NR ligands that differentially recruit coactivators to the LBD.

It is likely that differential recruitment of coactivators and corepressors underlies the tissue-specific actions of selective estrogen receptor modulators, and that ligands with similar properties can be developed for other members of the NR family. Such ligands would have potential therapeutic applications in a variety of human diseases, including metabolic syndromes, atherosclerosis, diabetes, and chronic inflammatory diseases.

Corepressors in Mediating Repression by Nuclear Receptors

Kristen Jepsen and Michael G. Rosenfeld

*Howard Hughes Medical Institute, Department and School of Medicine,
University of California at San Diego, La Jolla, California*

Introduction

Activation of gene transcription has long been recognized as an essential component of regulation of gene expression by nuclear receptors, but repression of transcription plays an equally important role in developmental and homeostatic gene regulation. Transcriptional repression by nuclear receptors requires the actions of the closely related receptor-associated corepressors, nuclear receptor corepressor (N-CoR) and silencing mediator of retinoic acid and thyroid hormone receptors (SMRT), which were identified based on their ability to associate with and mediate transcriptional repression by nuclear receptors. These corepressors recruit many classes of transcription factors as components of multiprotein complexes, some containing specific histone deacetylases (Fig. 1A). This association with histone deacetylase activity provides one component of the mechanism that allows DNA-binding proteins interacting with N-CoR or SMRT to repress transcription of specific target genes. However, both N-CoR and SMRT are components of additional complexes that can result in permanent repression. The biological importance of these corepressors has emerged from genetic studies both of humans and mice. In turn, various signaling pathways regulate levels of expression, subcellular localization, and function of these corepressors.

N-CoR and SMRT in Repression by Nuclear Receptors

Thyroid hormone and retinoic acid receptors (T₃R and RAR) actively repress transcription in the absence of their

cognate ligands via transferable repression domains [1] that can associate with N-CoR [2] and SMRT [3–5]. These corepressors contain a conserved bipartite nuclear receptor interaction domain [6–8] and three independent repressor domains that are capable of transferring active repression to a heterologous DNA-binding domain (DBD) [2–5] (Fig. 1B). The interaction domains contain related putative helical motifs LXXXIXXXI/L [9–11], one helical turn longer than the LXXLL recognition motif present in nuclear receptor coactivators [12,13] that binds in a hydrophobic pocket in the hormone binding domain, similar to coactivator binding. Specific sequences in the nuclear receptor interaction motif are suggested to account for the preference of RAR for SMRT and T₃R for N-CoR [14].

The mechanism by which N-CoR and SMRT function proved, in part, to reflect their association with mRpd3 and mSin3A and B, mammalian homologs of the yeast proteins Rpd3p/histone deacetylase 1 and Sin3p [15,16]. Previous observations that acetylation of specific lysine residues in the N termini of histones correlates with increased transcription, and that heterochromatic regions are generally hypoacetylated [17,18], led to studies of the role of HDAC proteins in transcriptional repression. There are now 10 HDACs, classified on the basis of their homology to two closely related yeast HDACs, RPD3 and Hda-1 [19,20], as class I or class II HDACs, respectively [21]. In some assays, specific HDAC proteins appear to require association with N-CoR or SMRT for full enzymatic activity [22,23]. Additionally, there is evidence of a combinatorial code based on distinct histone modifications, indicating a complex relationship between various recruited enzymatically active complexes [24].

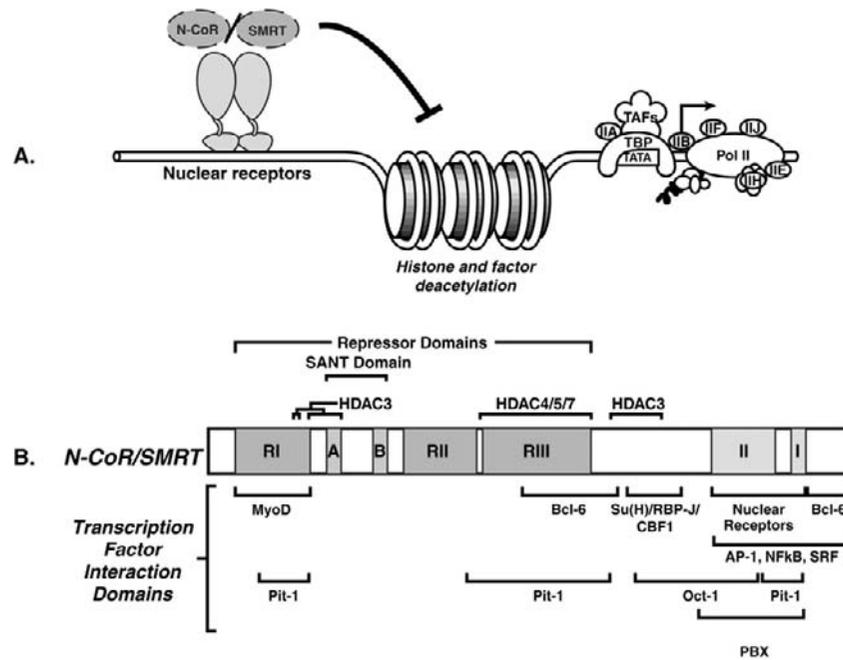

Figure 1 (A) Transcriptional repression by nuclear receptors is regulated by recruitment of the corepressors N-CoR and/or SMRT. (B) Schematic of domains of N-CoR/SMRT. Repression domains (RI, RII, RIII) and SANT domains (A and B) are indicated, as are interaction domains for HDACs, nuclear receptors (I and II), and other transcription factors.

Purification of Corepressor Complexes

Biochemical purification of complexes using anti-N-CoR or anti-HDAC3 antibodies revealed several corepressor-associated complexes, one which contains HDAC3, N-CoR, or SMRT, and transducin (beta)-like protein 1 (TBL1) [23,25–27]. TBL-1 has six WD-40 repeats [28], a motif also present in the Tup1 and Groucho corepressors, and is homologous to the *Drosophila* protein ebi, which is involved in epidermal growth factor receptor signaling pathways [29]. Under different conditions, an N-CoR–SMRT–HDAC3 complex can also contain Krab associated protein 1 (KAP-1), a TSA-sensitive corepressor that interacts with members of the heterochromatin protein 1 (HP1) family, and several members of the Swi/Snf ATP-dependent chromatin-remodeling complex family, which is reminiscent of the ATP-dependent chromatin-remodeling proteins found in the NURD complex (Fig. 1B) [27]. A third N-CoR/SMRT complex, which appears to be among the weakest, shares common components (HDAC1, HDAC2, and mSin3) with the Sin-associated protein (SAP) complex [30,31]. Several groups have also shown that the third repressor domain of N-CoR and SMRT can directly interact *in vitro* with class II HDACs, including HDAC4, HDAC5, and HDAC7 [32,33], suggesting that the full range of complexes has yet to be purified.

Other Nuclear Receptor and Transcription Factor Partners of N-CoR/SMRT

Although cloned based on their interactions with unliganded RAR and T₃R, N-CoR and SMRT are capable of conferring

transcriptional repression to an ever increasing number of transcription factors (Fig. 1B). N-CoR or SMRT serve as corepressors for several other members of the nuclear receptor superfamily, including v-ErbA, RevErb, COUP-transcription factors, PPAR α and DAX1 [34]. Although steroid hormone receptors do not appear to interact with N-CoR or SMRT in the absence of ligand [2,3], both the estrogen receptor (ER) and progesterone receptor (PR) can interact with these corepressors in the presence of their respective antagonists to repress transcription [35–38]. In chromatin immunoprecipitation assays (ChIP) performed in the breast tumor derived cell line MCF-7, N-CoR and SMRT were present on the estrogen-responsive cathepsin D and pS2 promoters in the presence of the antagonist tamoxifen but not estrogen [39]. These data suggest a role for N-CoR and SMRT in mediating the antagonist-associated effects of steroid hormone receptors [2,3] and provide a mechanism for the clinical application of antagonistic ligands.

In addition to their interactions with members of the nuclear receptor family, N-CoR and SMRT have been implicated as corepressors for a variety of unrelated transcription factors that regulate diverse cellular processes, including various homeodomain factors, MAD, SRF, BCL-6, MyoD, STAT5, HERP, and Su(H) [34].

Multiple Mechanisms of N-CoR/SMRT Regulation

The actions of N-CoR and SMRT are highly regulated. The N terminus of N-CoR interacts with mSiah2, the mammalian homolog of *Drosophila Seven in absentia* [40]. Consistent with evidence that mSiah2 regulates proteasomal

degradation of proteins [41], cotransfection of N-CoR and mSiah2 resulted in a dramatic decrease of N-CoR protein levels, an effect abolished by inclusion of a proteasome inhibitor [40].

Stimulation of the MAPK and PKC pathways resulted in decreased association of N-CoR and ER in the presence of the antagonist tamoxifen [38]. In one example, EGF-dependent phosphorylation of ER converted tamoxifen from an antagonist to an agonist [38]. Activation of the mitogen-activated protein kinase (MAPK) pathway by L-thyroxine (T_4) results in serine phosphorylation of TR β 1 and dissociation of SMRT in a hormone-independent manner [42], while phosphorylation of SMRT by MAPK-extracellular signal-regulated kinase 1 (MEK-1) and MEK-1 kinase (MEKK-1) is suggested to inhibit interactions between SMRT and nuclear receptors or PLZF [43]. In contrast, phosphorylation of SMRT by the protein kinase casein kinase II (CK2) is reported to stabilize the SMRT/nuclear receptor interaction [44]. Thus, different cell signaling pathways can effect different transcriptional outcomes.

Signaling pathways have also been shown to cause changes in subcellular distribution of the corepressors, as CamKIV, MEK-1, and MEKK-1 signaling are suggested to result in a redistribution of SMRT from the nucleus to the perinucleus or cytoplasm [43,45]. Indeed, specific signaling events influence the subcellular distribution of HDAC proteins [46–48].

Roles in Development and Disease

During normal development N-CoR is required for normal progression of specific developmental stages in erythrocyte and thymocyte development and in neural maturation [49] based on evidence from gene deletion studies. Expression of a dominant-negative N-CoR protein in hepatocytes of transgenic mice causes an increased proliferation of hepatocytes and derepression of T_3 -regulated hepatic target genes [50], while expression of a dominant-negative N-CoR protein in lactotropes abolishes long-term repression of the growth hormone gene [51]. In *Xenopus*, expression of a dominant-negative N-CoR protein can result in embryos exhibiting phenotypes similar to those treated by RA, namely, reduction of anterior structures such as forebrain and cement gland, suggesting that RAR-mediated repression of target genes is critical for head formation [52]. Resistance to thyroid hormone (RTH), characterized by an impaired physiological response to thyroid hormone, is associated with mutations in the T_3R - β gene that fail to release N-CoR or SMRT upon hormone treatment [53–55]. Gene repression appears to be a critical component of normal thyroid hormone physiology, and deletion of all known thyroid hormone receptors results in a phenotype less severe than that of thyroid-hormone-deficient mice [56], implying the role for repression by the unliganded T_3R . Roles for N-CoR and SMRT in several types of leukemia are also well characterized [57].

Other Mediators of Nuclear Receptor Repression

The p140 factor, RIP 140, has proven to be an example of an inhibitor of ligand-occupied receptor based on displacement of other activators [58–62], and perhaps based on its interactions with other corepressors [63]. In addition, other corepressors, acting both in the presence and absence of ligand, may act through nuclear receptors to exert critical biological roles [64,65].

Conclusion

Nuclear receptors can serve as repressors of transcription, characterized by association with proteins with enzymatic functions. In addition to a ligand-dependent switch, various signal transduction pathways can modulate interactions of corepressors with nuclear receptors or mediate their activity or distribution between nuclear or cytoplasmic compartments.

Steroid Hormone Receptor Signaling

Vincent Giguère

*Molecular Oncology Group, McGill University Health Centre,
Montréal, Québec, Canada*

Introduction

Steroid hormones are essential regulators of key physiological processes such as reproduction, glucose metabolism, and the response to stress and salt balance. The biological effects of steroid hormones are transduced by intracellular receptors that directly mediate the action of their cognate hormone [1]. Steroid hormone receptors (SHRs) were the first recognized members of the steroid/thyroid/retinoid nuclear receptor superfamily, a class of transcription factors whose activity is regulated by small lipid-soluble molecules. The SHR subgroup includes the receptors for estradiol: estrogen receptor α and β [ER α (NR3A1) and ER β (NR3A2)]; cortisol: glucocorticoid receptor [GR (NR3C1)]; aldosterone: mineralocorticoid receptor [MR (NR3C2)]; progesterone: PR (NR3C3); and dihydrotestosterone: androgen receptor [AR (NR3C4)]. In addition, the SHR subgroup contains three orphan nuclear receptors closely related to the ERs: the estrogen-related receptors α , β , and γ [ERR α (NR3B1), β (NR3B2), and γ (NR3B3)] for which a natural ligand remains to be identified. SHRs share a common modular structure composed of independent functional domains [2]. The DNA-binding domain (DBD) is centrally located, well conserved among SHRs, and comprised of two zinc-finger motifs involved in both protein–DNA and protein–protein contacts. The ligand-binding domain (LBD), located at the carboxy terminal of the receptor, is moderately conserved and folds into a canonical α -helical sandwich generally consisting of 12 α -helices (H1 to H12) [3]. The LBD can also contain a ligand-dependent nuclear translocation signal, determinants to bind chaperone proteins, dimerization interfaces, and a potent ligand-dependent activation domain

referred to as AF-2. A ligand-independent activation domain (AF-1) is encoded within the nonconserved amino-terminal region of the receptors.

Activation by the Hormone

The classic model of SHR action dictates that SHRs interact with chaperones in the cytoplasm and be dissociated in a ligand-dependent fashion, leading to the reorganization of the receptor and exposure of nuclear localization signal(s) and translocation to the nucleus. Although this model is widely accepted for SHRs, there are important exceptions [4]. The ERs are clearly localized to the nucleus despite being part of a complex with chaperone proteins. Perhaps more striking is the finding that the two forms of PR, PR-A and PR-B, that differ only in the length of their amino-terminal domains have distinct cellular localization. PR-A is found predominantly in the nucleus, whereas PR-B is mainly located in the cytoplasm in the absence of hormone [5]. Given that the nuclear localization and chaperone binding functions are identical for both forms of PR, these data strongly suggest that the interactions of SHRs with complexes containing coregulatory proteins might influence the intracellular distribution of SHRs.

Intracellular redistribution of ligand-bound SHRs is accompanied by the recognition of specific sites on chromatin, referred to as hormone response elements (HREs) [6]. The HREs are short *cis*-acting sequences located within the promoters or enhancers of target genes. SHRs bind DNA as homodimers to HREs composed of inverted repeats of AGGTCA (for the ERs and ERRs) or AGAACA (for the GR,

MR, PR, and AR) motifs spaced by three nucleotides. SHR isoforms such as ER α and ER β or PR-A and PR-B can also form functional heterodimeric complexes on DNA [7–9]. In the case of the ERs, the functional properties of each isoform are retained in the heterodimeric complex [10], whereas PR-A is dominant over PR-B [11].

The transcriptional activity of the SHRs is mediated by the independent AF-1 and AF-2 [12]. AF-1 is ligand independent and constitutive since it can activate transcription in the absence of the ligand when fused to a heterologous DBD. The structural determinants and mode of action of the distinct AF-1 domains found in each SHR have yet to be characterized. In contrast, the ligand-dependent AF-2 is well defined: a short amphipathic α -helix (H12) located at the carboxy-terminal end of the LBD is repositioned on hormone binding into a hydrophobic cleft formed mainly by residues from helices 3, 4, and 12. The resulting structural change provides a functional interface for coactivator recruitment by the receptor [13]. AF-1 and AF-2 recruit both common and specific cofactors. These regulatory proteins possess various enzymatic activities such as acetylase, deacetylase, methylase, kinase, and ubiquitinase functions [14]. One RNA molecule known as SRA has also been characterized as a SHR coactivator [15]. The cofactors participate in the remodeling of chromatin, the formation of a stable transcription initiation complex, the association or dissociation of other cofactors within the SHR-cofactor complex as well as recycling and degradation of the receptor [16].

Hormone-Independent Activation

SHRs are phosphoproteins and targets of kinase cascades involved in the response to growth factors and cytokines [17]. Many aspects of SHR function can be modulated in this way, including dimerization, DNA binding, and both ligand-independent and -dependent activation [18]. SHRs are the targets of protein kinase A, mitogen-activated protein kinase (MAPK), cyclin-dependent kinases, casein kinase, and glycogen-synthase kinase. The molecular mechanisms underlying modulation of SHR activity on phosphorylation have yet to be elucidated in most instances. However, in the case of ER β , phosphorylation of two serine residues within AF-1 promotes the recruitment of steroid receptor coactivator-1 (SRC-1) both *in vivo* and *in vitro* [19]. The physiological relevance of hormone-independent activation pathways was clearly demonstrated using the uterus of the ER α mouse knock-out as a model [20]. In wild-type animals, the uterus displays growth responses to epidermal growth factor (EGF) and insulin-like growth factor 1 (IGF-1). In the ER α knock-out animals, the uterus is unresponsive to the mitogenic actions of EGF and IGF-1, demonstrating an essential requirement for ER α in these biological responses [21, 22]. In cellular and *in vitro* models, EGF, IGF-1, and other agents can induce the phosphorylation of serine 118 in the ER α amino-terminal region [23]. Mutation of this residue abolishes the response of ER α to EGF and considerably reduces the ability of the receptor to respond to its cognate ligand.

Cross-Talk with Other Transcription Factors

Steroid hormone regulation of a number of target genes does not require the presence of a HRE within the transcriptional unit of those genes. Instead, SHRs can tether to a transcription factor and thus modify its activity. The formation of a SHR–transcription factor complex can lead to changes in cellular localization, DNA binding activity, and enzymatic function within the transcription initiation complex, or conversely can provide a hormone-dependent transcriptional activation function to a non-HRE site [24, 25]. The biological actions of SHRs have been linked to binding sites for more than a dozen transcription factors, as well as to non-HRE sites for unidentified factors. The *in vivo* relevance of the HRE-independent pathways was highlighted by the observation that, in contrast to GR-deficient mice, genetically engineered mice expressing a non-DNA binding form of the GR are viable [26].

Nongenomic Action of Steroid Hormones

Steroid hormones have been shown to elicit biological responses too rapid to involve gene transcription and subsequent synthesis of new proteins. Rapid effects of steroid hormones have been reported in blood vessels, bone, breast cancer cells, nervous system, sperm, and maturing oocytes [27–31]. These effects involve changes in the activities of enzymes such as phospholipase C, PI3 kinase, and adenylate cyclase, leading to increases in intracellular calcium levels, second messengers, and activation of kinase cascades [32,33]. It is not clear whether the membrane SHRs are identical to the nuclear isoforms, but responses to pharmacological agents and transfection experiments with SHR expression vectors indicate that the membrane SHRs must share common determinants with their nuclear counterparts [34, 35] and thus originate from the same genes. The ER has been shown to physically interact with c-SRC, the insulin-like growth factor, the p85 subunit of PI3 kinase and calveolin-1, whereas the PR possesses a proline-rich domain within its amino-terminal region that mediates direct hormone-dependent interaction with the SH3 domain of a variety of cytoplasmic signaling proteins, including c-SRC [35].

Estrogen Related Receptors

The ERRs were the first orphan nuclear receptors identified through a search for genes related to ER α [36]. Initial studies of the ERRs showed that they did not bind estradiol or other physiologically relevant steroid hormones and indicated that their biological roles could be quite distinct from those of the classic ERs [37–40]. However, the recent observation that the ERs and ERRs share target genes and coactivators [41, 42], coupled with the striking discovery that diethylstilbestrol, a potent synthetic estrogen, and 4-hydroxytamoxifen, a mixed estrogen agonist/antagonist, are ERR ligands [43–45], suggests that the ERRs are bona fide SHRs [46].

Selective Steroid Hormone Receptor Modulators

Pharmacological and toxicological studies of synthetic SHR ligands have led to the realization that certain drugs can have distinct effects on the same SHR depending on the target tissue. This concept has mainly emerged from the study of tamoxifen, a molecule that acts as an estrogen antagonist in the breast but as an estrogen agonist in bone and uterus [47]. The term *selective estrogen receptor modulator* (SERM) is now being used to describe estrogenic drugs that display cell type- and context-dependent actions, and this concept has now been extended to all SHRs. The mechanisms by which selective SHR modulators exert tissue-specific effects are not yet understood and are likely to be distinct for each class of compounds, targeted receptors, and site of action. However, our better understanding of the modes of action of SHR at the molecular level indicate that these mechanisms may include selective activation of receptor isoforms (e.g., ER α versus ER β), distinct behavior of the drug-receptor complex in the presence of different corepressor/coactivator ratios, preferential recruitment of specific coregulatory proteins (including other transcription factors involved in cross-talk with SHRs such as AP-1 and NF- κ B), and possibly selective activation of nongenomic pathways [48–50]. The future development of selective SHR modulators with improved therapeutic indexes and no undesirable side effects is likely to constitute the most significant outcome of the vast effort dedicated to understanding how SHRs work, and basic molecular and genetic studies of SHR action will continue to be the main driving force behind this process.

Acknowledgments

The literature on steroid hormone receptor signaling is extensive and only selected studies and reviews were cited in this article due to strict space limitation. I apologize to all investigators whose work was not included. Many thanks to members of my group for revising the manuscript. My laboratory is funded by the Canadian Institute of Health, the Canadian Breast Cancer Research Initiative and the National Cancer Institute of Canada.

PPAR γ Signaling in Adipose Tissue Development

Robert Walczak and Peter Tontonoz

UCLA School of Medicine, Los Angeles, California*

Introduction

Adipose tissue plays a central role in maintaining lipid homeostasis and energy balance in vertebrates by storing triglycerides or releasing free fatty acids in response to changing energy demands. Adipocytes also perform an important endocrine function by secreting numerous signaling molecules, which are involved in the regulation of food intake, energy balance, and whole-body lipid homeostasis. Excessive accumulation of adipose tissue leads to obesity and often to insulin resistance, whereas its absence is associated with lipodystrophic disorders. In contrast to rodents, which have no white adipose tissue until after birth [1], human preadipocytes begin to differentiate during late embryonic development, although the majority of the differentiation occurs after birth [2]. All vertebrates have the ability to induce adipose tissue differentiation throughout their lives in response to the body's energy storage demands.

During the past 10 years, work from a number of groups has outlined a pivotal role for PPAR γ in adipocyte development. Evidence from both cell culture and animal models indicates that this protein is absolutely required for adipogenesis. A member of the nuclear hormone receptor superfamily, PPAR γ is a transcription factor whose activity is regulated by the binding of specific small molecule ligands. Like many other nuclear receptors, PPAR γ binds to DNA in a heterodimeric complex with the retinoid X receptor (RXR). The discovery that the natural ligands for PPAR γ are likely to be native and modified polyunsaturated fatty acids provided a mechanism whereby changes in cellular or systemic lipid homeostasis might be translated into specific changes

in adipocyte gene expression and differentiation. Obesity, the development of excess adipose tissue, is invariably associated with insulin resistance. PPAR γ has also been identified as a key regulator of insulin sensitivity, an activity that is likely to be directly related to its function in adipose tissue biology. Synthetic ligands for this receptor are widely used for the treatment of type II diabetes.

PPAR γ : A Dominant Regulator of Adipose Tissue Development

Early insights into the function of PPAR γ in adipocyte differentiation came from studies of the aP2 gene. Through a combination of polymerase chain reaction (PCR)-mediated cloning and biochemical purification, PPAR γ was identified as the factor responsible for directing adipocyte-specific expression of the aP2 enhancer [3–5]. It was shown to be highly expressed in both white and brown adipose tissue and to be induced early during the time course of adipocyte differentiation [5,6]. Subsequent studies demonstrated that expression and activation of PPAR γ in fibroblastic cells is sufficient to trigger the adipocyte gene expression cascade and lead to the development of the adipose phenotype [7]. In addition to the fatty acid binding protein aP2, PPAR γ target genes in adipose tissue include phosphoenol pyruvate carboxykinase [8], acyl-CoA synthetase [9,10], fatty acid transport protein 1 (FATP-1) [11,12], CD36 [13], lipoprotein lipase (LPL) [14] and liver X receptor α (LXR α) [15]. Although activation of PPAR γ leads ultimately to the induction of all of the genes necessary to define an adipocyte, not all of these

genes are direct targets for PPAR γ . Execution of the differentiation program now appears likely to involve the sequential and coordinated action of PPAR γ and members of the CAAT/enhancer binding protein (C/EBP) and sterol regulatory element binding protein (SREBP) transcription factor families (see later discussion).

Although PPAR γ was once considered an orphan receptor, considerable evidence has emerged to suggest that the endogenous ligands of the PPARs are likely to be native or modified polyunsaturated fatty acids [16–18]. Thus, it appears that the substrates for energy storage in adipose tissue, fatty acids, are also signaling molecules that direct the differentiation of new adipocytes. The naturally occurring prostanoid 15-deoxyprostaglandin J₂ binds to PPAR γ with high affinity; however, its role as a signaling molecule *in vivo* is not yet clear [19,20]. Of particular pharmacological importance was the discovery that PPAR γ is the biological receptor for a class of insulin-sensitizing agents known as the thiazolidinediones [19,21–23]. Two of these drugs, rosiglitazone (Avandia) and pioglitazone (Actos), are in widespread clinical use for the treatment of type II diabetes. The availability of potent and highly specific ligands has greatly facilitated analysis of PPAR γ function. For example, both naturally occurring and synthetic PPAR γ ligands are potent stimulators of adipogenesis in cultured systems [19,23]. The thiazolidinediones have also been shown to increase adipose tissue mass *in vivo* [24].

Analysis of PPAR γ Function in Animal Models

The human and mouse PPAR γ genes extend over more than 100 kb of genomic DNA (Fig. 1). Each is composed of nine exons that give rise to three distinct mRNA molecules, PPAR γ 1, PPAR γ 2, and PPAR γ 3, by alternate promoter usage and differential splicing [25–28]. Fat and large intestine are the only tissues, where considerable amounts of PPAR γ 2 and PPAR γ 3 transcripts have been reported [26,27]. In rodents, PPAR γ appears late during embryonic development and is restricted to the brown adipose tissue (day 18.5), and only transiently appears in the central nervous system [29–31]. Rodents do not develop the white adipose tissue until after birth.

Homozygous inactivation of the PPAR γ gene in mice results in embryonic lethality [32]. PPAR γ -deficient fetuses can only survive until midgestation and die by day 10 of development. At day 9.5, PPAR γ -/- fetuses are alive and are similar to their wild-type counterparts; however, at day 10, embryos show serious vascular abnormalities in the placenta. Barak and colleagues [32] utilized a tetraploid-rescue approach to generate a single PPAR γ null pup that survived to term. This PPAR γ -deficient animal was completely devoid of both white and brown adipose tissues. Studies using embryonic stem cells have also pointed to an absolute requirement for PPAR γ in adipose tissue development. Injection of PPAR γ -deficient cells into wild-type blastocysts produces chimeric mice in which the adipose tissue is composed exclusively of PPAR γ +/+ cells [33]. Similarly, embryonic fibroblasts

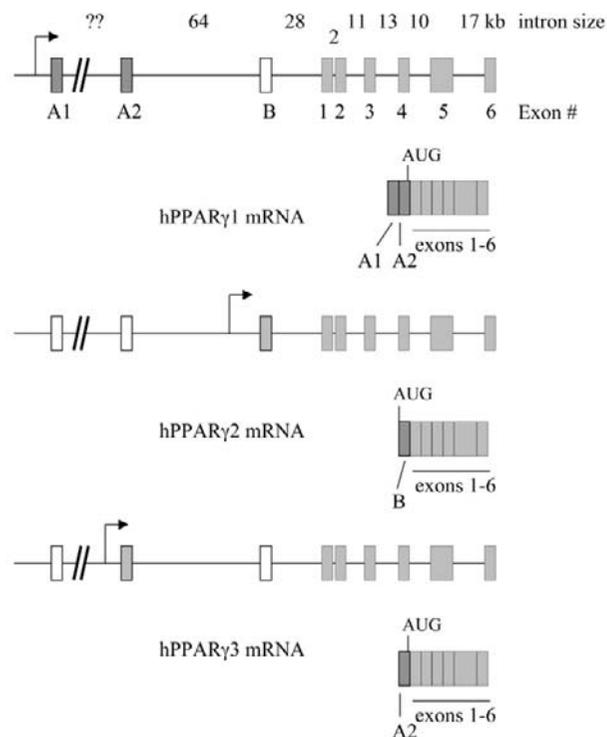

Figure 1 Structure of the murine and human PPAR γ genes. Three PPAR γ isoforms are produced by the differential use of three promoters and alternative splicing of the three 5'-exons (A1, A2, B). Exons 1–6 are common to all three transcripts. In the human PPAR γ 1 and PPAR γ 3 genes, the AUG translation initiation codon is located six nucleotides upstream of the one used in other species. Therefore, the human PPAR γ 1 protein has two additional amino acids at its N terminus compared with the rodent PPAR γ 1 protein. Note that transcription from the promoters 1 and 3 results in the same protein of 477 amino acids. The PPAR γ 2 protein of 505 amino acids is produced by transcription from the promoter 2. Distances between exons are based on the alignment of PPAR γ mRNA sequences with the Human Genome build #28.

derived from PPAR γ -deficient fetuses fail to differentiate into adipocytes *in vitro* [32,34]. Very recently, studies using PPAR γ -deficient fibroblasts have shown that it is the PPAR γ 2 isoform that is specifically required for the differentiation program [35].

A limited amount of data on genetic polymorphisms in human populations corroborate studies in animal models. Mutations that result in permanent activation of PPAR γ protein are associated with obesity [36]. In contrast, mutations that render PPAR γ less active are generally associated with a lower body mass index (BMI) and ameliorated insulin sensitivity [37–41].

Transcriptional Networks in Adipose Tissue Development

Adipocytic differentiation has been primarily studied *in vitro*. The 3T3-L1 and 3T3-F422A cell lines [42], are the most widely used adipocyte culture models. These cells are morphologically similar to the fibroblastic preadipose cells

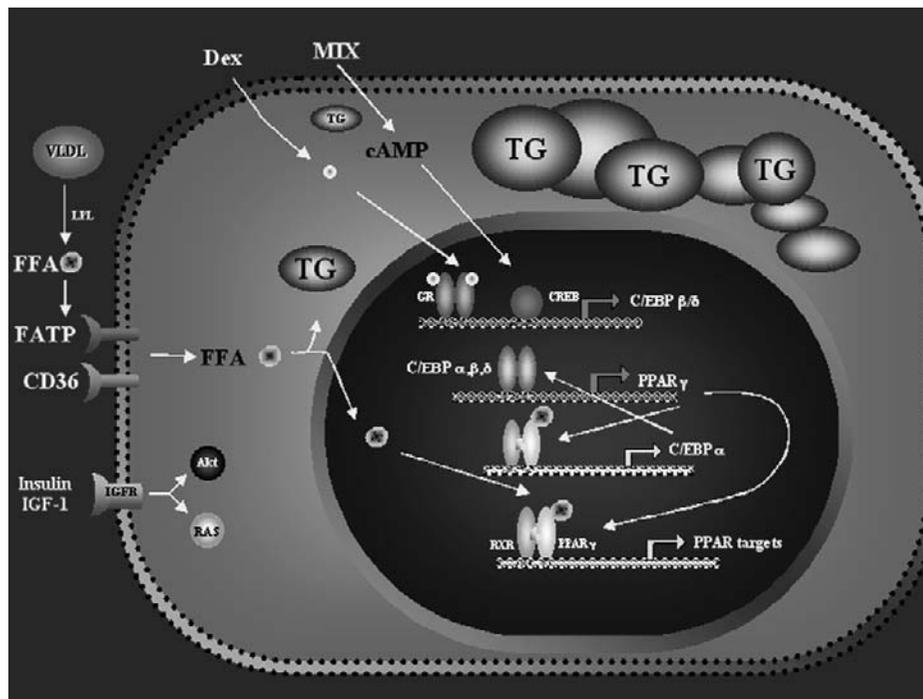

Figure 2 Transcriptional networks in adipocyte differentiation. Insulin and IGF act on the IGF receptor to activate signaling pathways involving ras and Akt. C/EBP β and C/EBP δ are induced following the hormonal stimulation of 3T3-L1 cells with MDI. C/EBP β expression is regulated by glucocorticoids through the glucocorticoid receptor (GR), whereas C/EBP δ expression is induced by cAMP via CREB. Both C/EBP β and C/EBP δ activate the expression of the PPAR γ gene. PPAR γ in turn induces the expression of C/EBP α . PPAR γ and C/EBP α cross-regulate each other to maintain their high level of expression as C/EBP β and C/EBP δ levels decline. Finally, PPAR γ and C/EBP α cooperate to induce expression of genes specific for the mature adipocyte phenotype.

found in the stroma of adipose tissue and, once differentiated, they exhibit virtually all of the characteristics associated with adipocytes present within the adipose tissue. When injected into mice, 3T3-L1 cells differentiate into adipocytes and form fat pads that are indistinguishable from normal adipose tissue [43]. Using these model systems a number of the molecular pathways that control adipogenesis have been elucidated (Fig. 2).

Confluent 3T3-L1 cells can be converted in adipocytes by a treatment with a mixture of insulin, dexamethasone, methyl-isobutyl-xanthine (MIX), and fetal bovine serum, commonly referred to in literature as MDI [44]. Insulin activates the insulin-like growth factor 1 (IGF-1) receptor in 3T3-L1 cells; therefore, IGF-1 can be substituted for insulin in the adipogenic cocktail [45]. Dexamethasone activates the glucocorticoid receptor pathway, which results in a rise in the intracellular cAMP levels. MIX, a cAMP-phosphodiesterase inhibitor, prevents cAMP hydrolysis and is used to stimulate the cAMP-dependent protein kinase pathway.

The developmental program of the 3T3-L1 preadipocytes can be divided into four distinct stages: (1) preconfluent proliferation, (2) confluence/growth arrest, (3) hormonal induction/clonal expansion, and (4) permanent growth arrest/terminal differentiation (Table I). Studies during the past 20 years have defined specific patterns of gene expression associated with each of these stages. Approximately 48 hours

after induction by MDI, 3T3-L1 cells complete the postconfluent mitosis and enter into an unusual growth arrest phase, called GD [46,47]. Following the growth arrest, cells are committed to become adipocytes and begin to express late markers of differentiation by day 3. These late markers consist of lipogenic and lipolytic enzymes, as well as other proteins responsible for modulating the mature adipocyte phenotype. Finally, the cells round up, accumulate triglyceride droplets, and become terminally differentiated adipocytes by days 5–7.

At confluence, within 1 hour after the addition of MDI, the transient expression of c-fos, c-jun, junB, c-myc is observed [48]. These factors have not been implicated directly in any differentiation-specific events but they are believed to have mitogenic properties. C/EBP β and C/EBP δ are the first transcription factors induced following the hormonal stimulation [49–52]. C/EBP β expression is regulated by glucocorticoids, whereas the promoter of C/EBP δ is responsive primarily to MIX. The activity of C/EBP β and C/EBP δ is believed to directly induce the expression of PPAR γ 2 via interaction with a C/EBP site in the PPAR γ 2 promoter [49,53,54]. PPAR γ 2 can be first detected on day 2 after addition of MDI and its expression acquires the maximum by days 3–4. In turn, PPAR γ 2 induces the expression of C/EBP α , which acquires its highest expression level on day 5 [55]. Finally, PPAR γ and C/EBP α cross-regulate each other to maintain their high level of expression when C/EBP β and C/EBP δ levels decline [53].

Table I Temporal Pattern of Gene Expression during *In Vitro* Adipocyte Differentiation^a

^aStages of differentiation are depicted in the first column: (1) preconfluent proliferation, (2) confluence/growth arrest, (3) clonal expansion, and (4) permanent growth arrest/terminal differentiation. The expression pattern of genes associated with each step of differentiation is shown.

It is now clear that PPAR γ and C/EBP α cooperate to activate gene expression and the full program of adipogenesis. Although, retroviral expression of either PPAR γ [7] or C/EBP α [53,56] alone is sufficient to induce *in vitro* adipogenesis in 3T3-L1 cells, this procedure is much more efficient if both factors are coexpressed [7,57,58].

Another protein implicated in the adipocyte differentiation pathway is a member of the basic helix-loop-helix protein family of transcription factors, called ADD-1/SREBP-1c (adipocyte differentiation and determination factor 1 or sterol regulatory element binding protein 1c) [59]. Ectopic expression of ADD1 alone renders 3T3-L1 cells differentiation competent [60], whereas the expression of the ADD1 dominant-negative form strongly inhibits 3T3-L1 differentiation [60]. Coexpression of both ADD1 and PPAR γ 2 results in a synergistic effect on adipocyte differentiation [60]. The mechanism by which ADD1/SREBP1c promotes differentiation is still unclear, however, it has been postulated that genes activated by this transcription factor lead to synthesis of endogenous ligands for PPAR γ [61]. Paradoxically, however, transgenic overexpression of ADD1/SREBP-1c in adipose tissue of mice was found to cause severe lipodystrophy [62]. The mechanism underlying this effect is not yet clear.

Negative Regulation of Adipocyte Differentiation

Exposure of preadipocytes to differentiating agents, such as the MDI cocktail, releases the cells from a number of inhibitory pathways that are antagonistic to terminal differentiation. Examples of such inhibitory factors include the CUP/AP-2 α transcriptional repressor, Pref-1, and members of the Wnt family. CUP/AP-2 α is a C/EBP family member abundantly expressed in preadipocytes, where it has been proposed to mediate repression of the C/EBP α gene through direct binding

to specific sequences in the C/EBP α promoter. Expression of the CUP/AP-2 α factor in preadipocytes is blocked upon hormonal stimulation [63,64]. Another postulated inhibitor of adipogenesis inhibition, Pref-1, is also highly expressed in 3T3-L1 preadipocytes. Pref-1 is a small, membrane associated, EGF-repeat-containing protein [65,66]. Pref-1 is elevated in the mouse model of congenital generalized lipodystrophy, a condition characterized by poorly developed white and brown adipose tissue [62]. Cleavage of the membrane associated Pref-1 in its extracellular domain results in the generation of a soluble signaling mediator that may interact with an as yet unidentified receptor. Pref-1 expression in preadipocytes is blocked by treatment with glucocorticoids [67]. Finally, the Wnt family of signaling factors has recently been implicated in the control of adipose differentiation. Forced expression of Wnt-1 in 3T3-442A cells inhibited the formation of adipose tissue when these cells were grafted into nude mice [68]. Furthermore, 3T3-L1 cells, which are engineered to express a dominant-negative form of the TCF4, a transcriptional mediator of the Wnt pathway, undergo adipogenesis without any hormonal induction. Activation of the Wnt pathway in these studies repressed expression of both the PPAR γ and C/EBP α genes, and this has been postulated to be the mechanism by which Wnts inhibit adipogenesis.

PPAR γ , TNF- α Signaling Antagonism and Insulin Resistance

Insulin resistance is a common feature of obesity, lipodystrophy, and non-insulin-dependent diabetes mellitus (NIDDM). A possible connection between PPAR γ and insulin sensitivity was first suggested by the critical role of PPAR γ in adipocyte development. However, the discovery that PPAR γ is the biologic target for the thiazolidinedione class

of antidiabetic drugs provided the definitive link [19,21–23]. In rodents, PPAR γ gene expression is down-regulated by fasting and by insulin-deficient diabetes, whereas exposure to a high-fat diet increases PPAR expression in adipose tissue and may result in obesity and insulin resistance (reviewed in [24]).

The cytokine tumor necrosis factor α (TNF- α) has long been recognized for its capacity to impair normal adipocyte physiology by inducing lipolysis, blocking insulin signaling, and antagonizing adipogenesis. Elevated TNF- α levels are observed in several rodent models of obesity and NIDDM [69]. Recent studies utilizing gene disruption in mice confirmed that absence of TNF- α or its receptor results in significantly improved insulin sensitivity [70,71]. It has been suggested that TNF- α blocks insulin signaling in adipocytes, at least in part, by down-regulating expression of the C/EBP α and PPAR γ genes. Recent studies have shed light on potential mechanisms for this repression. One mechanism by which TNF- α could inhibit adipogenesis is through activation of the MEK/MAPK signaling pathway [72,73]. It has been previously shown that MAP kinase mediated phosphorylation of the PPAR γ protein at Ser82 (Ser112 for PPAR γ 2) results in repression of its transcriptional activity [74]. Other groups have demonstrated that administration of TNF- α early during 3T3-L1 adipocyte differentiation could block clonal expansion due to the erroneous regulation of two retinoblastoma protein family members, p130 and p107. These proteins regulate cell cycle events through interactions with the E2F transcription factors. TNF- α disrupts the normal pattern of expression of both p130 and p107, leading to a complete block in mitotic clonal expansion and the activation of apoptosis [75].

TZDs, potent and specific PPAR γ ligands, appear to antagonize TNF- α -mediated inhibition of insulin signaling at several different levels. First, TZD treatment was shown to decrease circulating TNF- α levels in rodents [76,77]. Second, TNF- α affects insulin action through inhibition of the insulin receptor (IR) tyrosine kinase activity [78]. TZDs can antagonize this effect of TNF- α on IR itself as well as on IR downstream targets, such as IRS proteins, and restore insulin sensitivity in fat [79]. This effect has not been observed in tissues that do not express PPAR γ . Third, TZDs rapidly increase expression of genes that are crucial for insulin signaling in adipocytes, such as c-Cbl associated protein (CAP), IRS-2, and the p85 subunit of the PI3 kinase [80–83]. The question of whether these genes are direct PPAR γ targets has not yet been addressed. The concept that TNF- α is an important modulator of insulin sensitivity and adipocyte development is based primarily on data in animal models. The role of this factor in human adipose tissue biology is not yet clear.

PPAR γ and Cell Cycle Regulation

Given the strong correlation between growth arrest and terminal differentiation, it is not surprising that PPAR γ has been linked to cell cycle regulation. For many specialized

cell types, differentiation and division are mutually exclusive choices. In adipocytes, induction of the differentiation program by PPAR γ is accompanied by cell cycle withdrawal. Studies using tumor cell lines have shown that binding of the E2F/DP-1 complex to its target promoters, an event usually associated with cell cycle reentry, is significantly decreased on stimulation with the PPAR γ -specific ligand. PPAR γ is believed to participate in the silencing of the E2F/DP-1 transcriptional activity by down-regulating the PP2A protein phosphatase [84]. Another study revealed that PPAR γ , in concert with C/EBP α , may mediate cell growth arrest during adipogenesis by up-regulating the cyclin-dependent kinase inhibitors p18 and p21 [85]. It was also demonstrated that treatment with PPAR γ ligand could effectively bypass the block in adipocyte differentiation imposed by the retinoblastoma protein deficiency [86]. These authors proposed that the adipocyte differentiation observed in RB null embryonic fibroblasts is related to a severely reduced level of C/EBP β dependent transactivation and that pRB may participate in a pathway leading to the production of an endogenous PPAR γ ligand.

Classical Receptors versus Orphan Receptors

Endocrine Signaling Paradigm

Nuclear hormone receptors comprise a superfamily of ligand-modulated transcription factors that regulate gene transcription in response to their cognate ligands. The transcriptional effects of these receptors are mediated via two critical functional domains: the DNA-binding domain (DBD) and the ligand-binding domain (LBD). The DBD recognizes specific target genes, whereas the LBD modulates the gene transcription by interacting with transcriptional regulatory complexes in a ligand-dependent fashion.

Nuclear acting hormones such as steroid and thyroid hormones were identified nearly a century ago. These signaling molecules are secreted into the bloodstream at nanomolar concentrations and ultimately regulate transcription in distant target tissues. Tissues that respond to these hormones express receptors whose ligand-binding affinity closely matches the circulating concentration of the hormone. The combination of secreted hormones and high-affinity targets is a characteristic that defines the classical endocrine signaling system. This signaling paradigm provides an efficient means to simultaneously regulate gene expression at multiple sites throughout the body.

To date, 49 human nuclear receptors have been identified [1]. Although virtually all of these proteins possess the characteristic LBD, approximately 34 had not originally been associated with a cognate ligand. These proteins are known as *orphan receptors* and their existence implies that additional signaling molecules remain to be identified. Because more than 30 years had passed since a classical steroid hormone had been identified, it is reasonable to imagine

that ligands for orphan receptors may have escaped detection because they are not generated via classical endocrine paradigms.

Nature of Orphan Receptor Ligands

Specialized endocrine signaling molecules are common in higher organisms, but in lower organisms, intermediary metabolites commonly possess both metabolic and signaling functions. For example, in bacteria and yeast, numerous gene networks are regulated by sugars, amino acids, fatty acids, and adenosine triphosphate (ATP) derivatives [2–4]. These regulatory networks sense specific nutrients and modulate their levels by regulating, in a coordinated manner, the expression of genes required for their synthesis, degradation, or transport. In addition to metabolic signals, single-cell organisms have also developed networks to detect and minimize exposure to exogenous toxins such as antibiotics (e.g., tetracycline) [5] and heavy metal derivatives (e.g., mercury, arsenic) [6,7]. Because higher organisms must also regulate their exposure to nutrients and foreign toxins, it is possible that they possess receptors that respond to similar signals. Indeed, studies during the past 5–6 years have established a definitive role for orphan receptors in these processes.

An important component of all signaling networks is the ability to respond to signaling molecules at physiologically relevant concentrations. In contrast to endocrine hormones that are secreted at nanomolar concentrations, intermediary metabolites are by necessity present at much higher (micromolar) concentrations. Thus, an important distinction between endocrine and metabolite/toxin-controlled receptors is that the former are high-affinity sensors, whereas the latter bind their ligands with an appropriately lower affinity.

Orphan Receptors and Metabolite-Derived Signals

RXR, A Common Heterodimeric Partner

Many receptors function as an obligate heterodimer with the nuclear receptor RXR [8]. Although the identity of the endogenous RXR ligand remains controversial, it is clear that this receptor can be activated by synthetic retinoids [9], 9-*cis* retinoic acid [10], and very high concentrations of phytanic [11,12] and docosahexaenoic acids [13]. Receptors that heterodimerize with RXR fall into two classes: those that are “permissive” and respond to RXR ligands and those that are “silent” and fail to respond [14–16]. The permissive receptors include the PPARs, LXR, bile acid receptor (BAR), and constitutive androstane receptor (CAR). Although these receptors respond to their specific ligands, the potential also exists for cross-activation via RXR agonists.

PPARs: Regulators of Lipid and Glucose Homeostasis

The PPARs (peroxisome proliferator-activated receptors) include three different receptor genes (PPAR α , β/δ , and γ) whose ligands are lipid-derived compounds. PPAR α binds to endogenous polyunsaturated fatty acids and regulates hepatic genes involved in fatty acid oxidation. PPAR β/δ also binds polyunsaturated fatty acids and increases HDL cholesterol and reverse cholesterol transport from peripheral tissues. PPAR γ is expressed at high levels in adipose tissue where it regulates lipid storage and glucose homeostasis. These receptors (discussed elsewhere in this series) provide excellent examples of the nexus between metabolism and transcription in higher animals.

LXR, A Sterol and Fatty Acid Sensor

Two related LXR genes have been identified: LXR α and LXR β . The β -subtype is expressed ubiquitously and its physiological function is unclear [17]. In contrast, LXR α is expressed in a variety of tissues that contribute to lipid homeostasis including hepatocytes, intestinal epithelia, macrophages, and adipose tissue (Table I) [18]. LXR α exhibits partial constitutive activity that reflects a combination of ligand-independent activity [19] and activation by an endogenous mevalonic acid-derived metabolite [20]. LXR α can be further activated by a variety of oxysterols. The endogenous LXR ligand is unclear and different sterol ligands may be acting in different tissues, for example, 24(*S*),25-epoxycholesterol in the liver [18] and 27-hydroxycholesterol in macrophages [21]. Whereas oxysterols activate LXR α , the transcriptional activity of this receptor can be repressed by polyunsaturated fatty acids [22] and geranylgeranyl pyrophosphate [20]. LXR α is therefore a dynamic “integrator” of multiple lipid metabolites.

Studies using knock-out mice and synthetic agonists have demonstrated that LXR is not only a lipid sensor but also an effector of cholesterol and fatty acid homeostasis.

LXR α activation results in increased hepatic cholesterol degradation and a decrease in intestinal cholesterol absorption [23,24]. The increase in cholesterol turnover is due to enhanced transcription of *cyp7a1*, the rate-limiting step in the conversion of cholesterol to bile acids. *Cyp7a1* is regulated in rodents but not humans because the LXR response element is defective in the human promoter. In contrast, the decrease in intestinal cholesterol absorption is due to activation of the ABCA1 (ATP binding cassette A1) transporter in both humans and rodents. LXR α also activates expression of ABCG1 [25] and of ABCG5/G8 [26], which have been implicated in the efflux of sitosterol and other sterols.

In macrophages, LXR α coordinately activates expression of ABCA1 [27] and apolipoprotein E (apoE) [28], a secreted cholesterol-acceptor protein. The net effect is enhanced removal of cholesterol from atherosclerotic lesions (macrophage foam cells) and its transfer to the liver via HDL cholesterol. Interestingly, this process appears to be under feed-forward control in humans as a macrophage-specific LXR α promoter is activated by PPAR γ and autoregulated by LXR α [29–31].

The ability to reduce cholesterol absorption and to stimulate cholesterol efflux makes LXR α an attractive target for the treatment of atherosclerosis. Unfortunately, LXR α activation is also associated with an increase in circulating triglycerides [32]. This is likely a result of enhanced expression of SREBP-1c (sterol response element binding protein), a transcription factor that activates a battery of genes required for saturated fatty acid synthesis [33]. One of these genes, fatty acid synthase (FAS), is also a direct target of LXR α [34]. Because elevated triglycerides may be counterproductive in atherosclerosis, an ideal LXR α -based agent may be one that selectively activates certain genes (e.g., ABCA1, apoE) but not others (SREBP-1c, FAS). The identification of selective estrogen receptor modulators [35] raises the possibility that similar reagents may eventually be identified for other nuclear receptors.

FXR, A Bile Acid Receptor

As early as 1957 it had been appreciated that a biliary component could inhibit bile acid production [36]. A key feature of this negative feedback loop is the ability of bile acids to inhibit *Cyp7a* transcription [36]. The nature of the bile acid sensor remained elusive until 1999 when it was identified as the nuclear receptor FXR or BAR [37–39]. It is now clear that BAR plays a broader role in regulating bile acid homeostasis. In addition to inhibiting hepatic expression of *CYP7A1*, the rate-limiting enzyme in bile acid biosynthesis, BAR also inhibits expression of *CYP8B* [40], which acts downstream in the bile acid biosynthetic pathway. BAR also stimulates expression of the ABC cassette protein BSEP (bile-salt export protein, ABCB11) [41], which promotes biliary secretion of bile acids. Thus, the net effect of BAR activation is to limit bile acid accumulation in the liver. Indeed, BAR-deficient mice are highly sensitive to the toxic effects of excessive bile acids [42].

Table I Expression Patterns, Key Target Genes, Ligands and Physiological Functions of Selected Orphan Nuclear Receptors

H₂N—DNA BINDING DOMAIN—LIGAND BINDING DOMAIN AF2—COOH

Receptor	Gene symbol ^a	Key tissues of expression	Critical target genes ^b	Ligands ^c	RXR ligand response?	Function
LXR α	NR1H3	Hepatocytes, Intestinal Epithelium, Macrophage, Fat	cypa7a1 (rodent), ABCA1, apoE, ABCG1/G4/G5/G8, SREBP-1c, FAS, LXR α	Oxysterols, polyunsaturated fatty acids (-)	Yes	Cholesterol, triglyceride & bile acid homeostasis
BAR FXR	NR1H2	Hepatocytes, Intestinal Epithelium	BSEP, SHP, IBABP, PLTP, apoCII \downarrow CYP7A1, \downarrow CYP8B	<i>Bile Acids</i> Chenodeoxycholic, cholic & deoxycholic acids	Yes	Cholesterol, triglyceride & bile acid homeostasis
SXR PXR	NR1I2	Hepatocytes, Intestinal Epithelium	CYP3A4, CYP2C8, CYP2C9, CYP2B10, MDR1, MRP2, OATP2	<i>Xenobiotics</i> <i>Human:</i> rifampicin, ritonavir, taxol, clotrimazole, hyperforin <i>Mouse:</i> PCN ^d	No	Clearance of xenobiotics & endogenous toxins
CAR	NR1I3 NR1I4	Hepatocytes, Intestinal Epithelium	cyp2b10, cyp3a11, MRP2	<i>Xenobiotics</i> <i>Human:</i> ? <i>Mouse:</i> androstanol(-) TCPOBOP ^e	Yes	Clearance of xenobiotics & endogenous toxins

A schematic representation of an orphan nuclear receptor is shown above the table. Target gene specificity is determined by the DNA binding domain; ligand binding and transcriptional activation are mediated by the ligand binding domain.

^aGene symbols are according to the unified nomenclature system for the nuclear receptor superfamily (www.ens-lyon.fr/LBMC/laudet/nomenc.html).

^b \downarrow indicates genes that are down-regulated by agonist ligands; other genes up-regulated by agonist ligands.

^c(-) indicates an antagonist, inverse agonist or inhibitory ligand; other ligands are agonists or activating ligands.

^dPCN, pregnenolone-16 α -carbonitrile.

^eTCPOBOP, 1,4-bis[2-(3,5-dichloropyridyloxy)]benzene.

Bile acids are produced in the liver, secreted into the bile, and then efficiently absorbed via an ileal bile acid transporter. Thus, the ileal epithelium is exposed to extremely high levels of bile acids. The cytosolic ileal bile acid binding protein (IBABP) is thought to act as a shuttle protein that aids in transport and protects the cell from high levels of free bile acids. Interestingly, BAR is an extremely effective inducer of IBABP [43], which is consistent with the role of this receptor in protecting the body from excess bile acids.

The ability to inhibit CYP7A1 transcription implies that an antagonist of BAR could be a useful cholesterol-lowering agent. However, like LXR α , BAR induces a reciprocal relationship between cholesterol and triglyceride levels [42,44]. This is potentially related to BAR-mediated regulation of apolipoprotein CII (apoCII) [45] or phospholipid transfer protein (PLTP) [46]. Regardless of the mechanism, LXR α and BAR share similar caveats with regard to their potential use as targets for cholesterol lowering.

Orphan Receptors and Xenobiotic Signals

SXR, A Master Regulator of Drug Clearance

The ligand-binding properties of the steroid and xenobiotic receptor SXR (also known as PXR, PAR, PRR, NR1I2) are different from most nuclear receptors. Whereas most receptors possess a high degree of ligand-binding specificity, SXR is activated by a very large number of structurally unrelated pharmaceutical agents including rifampicin, clotrimazole, SR12813 [47–51], HIV protease inhibitors [52], taxol [53], and hyperforin [54], the active ingredient in the herbal remedy called St. John's wort. Many of these compounds bind directly to the receptor LBD with affinities in the micromolar range. In an effort to understand the basis for SXR's extreme promiscuity in ligand binding, Watkins and colleagues [55] determined the three-dimensional structure of human SXR. They found that SXR has a larger ligand binding cavity than most nuclear receptors as well as a flexible loop, which accommodates both small and large ligands. These studies highlight the broad ligand-binding specificity of SXR and confirm its designation as a xenobiotic receptor.

Many SXR activators were previously described as inducers of the hepatic cytochrome *P*-450 monooxygenase CYP3A (CYP3A4 in human, *cyp3a11* in mouse, CYP3A23 in rat, CYP3A6 in rabbit). A variety of biochemical and genetic studies have demonstrated that SXR directly regulates CYP3A induction via SXR response elements in the CYP3A promoter. CYP3A4 is the most abundant cytochrome *P*-450 in human liver and is responsible for the metabolism of approximately 50% of all drugs [56]. Subsequent studies have expanded the number of SXR target genes to include other *P*-450 enzymes including CYP2C8, CYP2C9, and CYP2B [52,53,57]. These enzymes metabolize a variety of drugs including nonsteroidal anti-inflammatory drugs, hypoglycemic agents, anti-epileptic agents, and taxol, an antineoplastic agent [56]. Thus, SXR is not only a xenobiotic sensor, but a direct effector of xenobiotic degradation.

In addition to being expressed in the liver, SXR is also highly expressed in the intestine [47–50], which raises the question as to the function of SXR in this organ. We have found that SXR regulates expression of MDR-1/*P*-glycoprotein, a broad-specificity efflux pump located on the luminal surface of intestinal enterocytes [58]. *P*-glycoprotein can severely limit the oral absorption of its substrates [58,59]. Because most drugs are administered orally, the SXR/*P*-glycoprotein linkage may limit the bioavailability of many pharmaceutical agents.

Other transporters including OATP2 (Na⁺-independent organic anion transporter 2) [60] and the ABC protein MRP2 (multidrug resistance protein 2, ABCC2) [52] also act as SXR target genes. OATP2 is present on the sinusoidal membrane of hepatocytes and promotes uptake of organic anions (e.g., bile acids and xenobiotics) into the liver. MRP2 resides on the canalicular membrane of hepatocytes and mediates the biliary excretion of its substrates. Taken together, these studies indicate that SXR is a master regulator of a diverse array of xenobiotic clearance pathways.

The ability to activate drug clearance has important implications. In particular, drugs that activate SXR may decrease their own bioavailability as well as the availability of coadministered drugs [61–65]. In principle, this type of drug–drug interaction could be overcome by screening for analogs that retain therapeutic activity but fail to activate SXR. An example of this is illustrated by the use of taxotere, a taxol analog that retains antineoplastic activity but fails to activate SXR [53]. The identification of such “SXR-transparent” drugs would be predicted to decrease the likelihood of drug–drug interactions. Finally, it is important to note that the LBDs of human and rodent SXR possess distinct ligand-response profiles (see Table I) [51]. This divergence is consistent with the observation that rodent models are poor predictors of drug metabolism in humans.

CAR, A Close Relative of SXR

The nuclear receptor CAR is a close relative of SXR. Both are highly expressed in the liver and intestine and these receptors share sequence identity in their DNA (66%) and ligand-binding domains (41%) [66,67]. Mouse CAR was originally identified as a constitutively active receptor whose activity could be repressed by androstanol [68]. Subsequent studies demonstrated that CAR was a receptor for TCPOBOP (1,4-bis[2-(3,5-dichloropyridyloxy)]benzene) [69–72], a highly potent inducer of *cyp2b10* expression in mouse hepatocytes. TCPOBOP had previously been demonstrated to be a member of the phenobarbital class of hepatic *P*-450 inducing agents suggesting that CAR played a role in mediating this xenobiotic response. This link became definitive with the demonstration that CAR knock-out mice fail to induce *cyp2b10* in response to either TCPOBOP or phenobarbital [67].

Although CAR is a strong inducer of *cyp2b10*, it also serves as a weaker regulator of SXR target genes [73]. Moreover, these receptors recognize a similar array of ligands, albeit with distinct dose-response profiles [74]. These findings

suggest that SXR and CAR may be partially redundant in their functions. This notion is confirmed by the observation that mice lacking either SXR or CAR are highly sensitive to the paralytic effects of zoxazolamine [67,75]. This presumably reflects a shared defect in the clearance of this drug. It is important to note that effective ligands have been identified for mouse CAR but not for its human counterpart. In the future, it will be important to test drugs for their ability to modulate human CAR and to elucidate the contribution of this receptor to drug metabolism in humans.

Future Directions

Orphan nuclear receptors provide convincing evidence that higher organisms regulate gene transcription in response to metabolic and xenobiotic cues. As metabolic disease (atherosclerosis, hypercholesterolemia, diabetes) represents the leading cause of death in industrialized societies, these receptors provide important targets for drug discovery. At the same time, discovery efforts will be enhanced by dual-screening strategies that select for therapeutic activity while minimizing interactions with xenobiotic receptors. Finally, orphan receptors represent a valuable source for future exploration because 26 orphans have yet to be associated with specific ligands.

Identification of Ligands for Orphan Nuclear Receptors

Steven A. Kliewer and Timothy M. Willson

*Nuclear Receptor Discovery Research, GlaxoSmithKline
Research Triangle Park, North Carolina*

Introduction

The nuclear receptors comprise a superfamily of transcription factors that are activated by small, lipophilic chemicals including the classic steroid, retinoid, and thyroid hormones. There are 48 members of this family encoded by the human genome [1], far more receptors than established lipophilic hormones. The work of a number of laboratories has shown that many of the remaining “orphan” members of the family function as metabolic sensors, linking physiological levels of intracellular metabolites to the transcriptional regulation of key biochemical pathways. In this brief review, we highlight recent progress that has been made in the identification of ligands for orphan nuclear receptors. With the exception of the hepatocyte nuclear receptor 4 (HNF4, NR2A) and estrogen related receptor (ERR; NR3B) subtypes, all of the receptors discussed in this review bind to their cognate DNA response elements as heterodimers with the 9-*cis* retinoic acid receptors (RXR, NR2B).

PPARs: Fatty Acid Sensors

A wealth of evidence now exists to support roles for the peroxisome proliferator-activated receptors (PPARs; NR1C) in lipid and carbohydrate metabolism [2]. Three PPAR subtypes are encoded by distinct genes: PPAR α , PPAR γ , and PPAR δ . Each PPAR subtype has a unique biology. PPAR α is abundantly expressed in the liver, kidney, heart, and muscle and plays a central role in fatty acid oxidation. PPAR γ is expressed at high levels in adipose and has a prominent role in fat cell formation and fatty acid storage.

PPAR δ is expressed in most tissues and was recently shown to regulate systemic cholesterol and lipid homeostasis.

Synthetic ligands have provided tremendous insight into the functions of the PPARs [2]. PPAR α is the molecular target for the fibrates (Fig. 1), a class of drugs used to lower triglyceride levels in dyslipidemic patients. PPAR γ is the target for the thiazolidinedione drugs (Fig. 1), which enhance insulin sensitivity and lower glucose levels in patients with type II diabetes. Although there are no marketed drugs targeted against PPAR δ , a potent, synthetic PPAR δ agonist was recently shown to increase serum levels of high-density lipoprotein and to decrease fasting triglyceride and insulin levels in insulin-resistant nonhuman primates [3]. Thus, PPAR δ agonists may have utility in the treatment of cardiovascular disease associated with metabolic syndrome X.

All three PPAR subtypes are activated in cell-based reporter assays by a variety of fatty acids and fatty acid metabolites [2]. Many of these fatty acids bind to the receptors at low micromolar concentrations, which are consistent with their levels in serum. These data suggest that rather than having a single, high-affinity ligand, the PPARs may function as more generalized sensors of free fatty acid levels. Recently, a higher affinity ($K_d \sim 40$ nM) PPAR γ ligand, hexadecyl azelaoyl phosphatidylcholine, was extracted from oxidized low-density lipoprotein [4]. Thus, higher affinity natural ligands may also exist for the PPARs.

LXRs: Cholesterol Sensors

Cholesterol is an essential component of cell membranes and serves as the precursor to the steroid hormones and

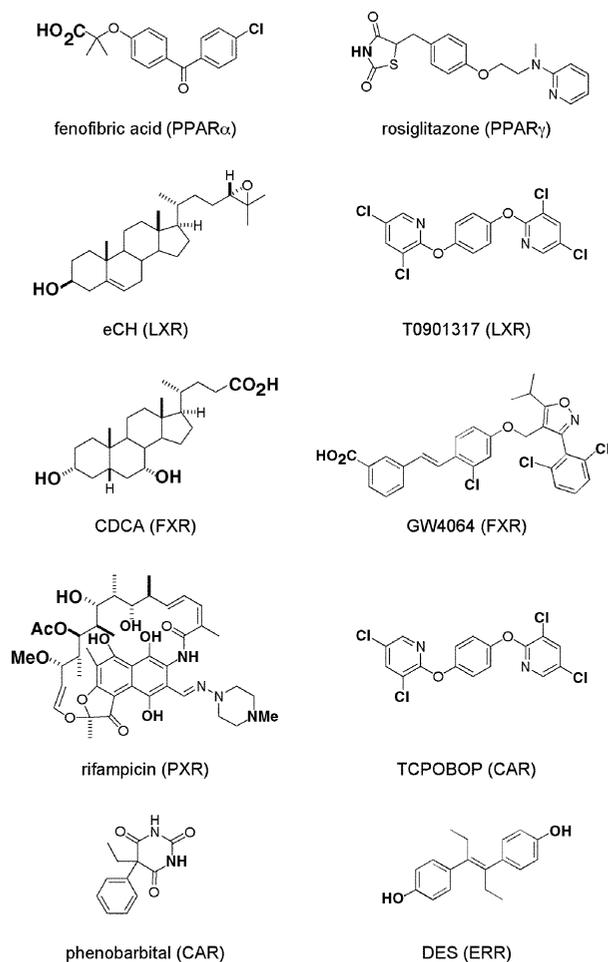

Figure 1 Orphan nuclear receptor ligands. The chemical structures of representative ligands for orphan nuclear receptors are shown.

bile acids. However, excess cholesterol is associated with diseases such as atherosclerosis and the formation of gallstones. Thus, a delicate balance must be maintained between the ingestion and synthesis of cholesterol and its elimination from the body. It is now established that the two liver X receptor (LXR; NR1H) subtypes, LXR α and LXR β , play important roles in the elimination of excess cholesterol from the body [5]. The LXRs regulate a variety of genes involved in cholesterol metabolism including CYP7A1, which catalyzes the rate-limiting step in the conversion of cholesterol to bile acids in the liver, and the ATP-binding cassette (ABC) proteins A1 and G1, which mediate the efflux of cholesterol from enterocytes and macrophages for elimination from the body. Thus, the LXRs are components of a physiological regulatory system that senses excess cholesterol and modifies gene expression accordingly.

The natural ligands for the LXRs are oxidized cholesterol derivatives including 24(*S*),25-epoxycholesterol (eCH) (Fig. 1), 22(*R*)-hydroxycholesterol, and 24(*S*)-hydroxycholesterol [5,6]. Each of these compounds has a distinct tissue distribution profile. eCH is produced in the liver from a shunt of the mevalonate pathway in which squalene epoxide is metabolized to the diepoxide prior to undergoing cyclization.

eCH is present in extracts from rat livers at 1–5 μ M concentrations and rises upon cholesterol feeding. 22(*R*)-hydroxycholesterol is present at micromolar concentrations in extracts of the adrenals. Interestingly, 24(*S*)-hydroxycholesterol is generated exclusively in the brain. Its abundance in this tissue has led to it being termed *cerebrosterol*. Recently, the first potent, selective synthetic LXR agonist (T0901317) (Fig. 1) was described [7]. T0901317 binds and activates both LXR subtypes at nanomolar concentrations.

FXR: Bile Acid Sensor

Bile acids are essential for the elimination of cholesterol from the body and the solubilization and transport of lipids in the intestine. However, bile acids are also detergents that are extremely toxic at high concentrations. Thus, their levels must be tightly regulated. In 1998, several groups reported that the farnesoid X receptor (FXR, NR1H4) is a bile acid receptor [5,8]. Several different naturally occurring bile acids bind and activate FXR at physiological concentrations including chenodeoxycholic acid (Fig. 1), cholic acid, deoxycholic acid, and lithocholic acid and/or their glycine or taurine conjugates. The first potent, selective nonsteroidal FXR agonist, GW4064, was recently described (Fig. 1) [9]. FXR is highly expressed in tissues that are critical in bile acid biology including the liver, intestine, and kidney, and it regulates the expression of genes involved in bile acid homeostasis including the intestinal bile acid binding protein, the bile salt export pump, and CYP7A1 [10].

PXR and CAR: Xenobiotic Sensors

The body must protect itself against myriad xenobiotics ingested in the diet or otherwise absorbed. Two nuclear receptors, the pregnane X receptor (PXR, NR1I2) and the constitutive androstane receptor (CAR, NR1I3), have evolved to detect xenobiotics as part of the body's detoxification machinery [11]. Both receptors are highly expressed in the liver and intestine and regulate the expression of a number of genes involved in the hydroxylation, conjugation, and transport of xenobiotics. PXR is activated by a remarkable diverse collection of natural and synthetic chemicals including macrocyclic antibiotics (e.g., rifampicin; Fig. 1), antimycotics (e.g., clotrimazole), steroids (e.g., dexamethasone), and the herbal antidepressant St. John's wort. Because it is activated by many widely used prescription medicines, PXR activation represents the basis for a common class of drug–drug interaction, in which one drug stimulates the metabolism of another. Although CAR can also function as a xenobiotic sensor, it differs from PXR in two important respects. First, CAR is sequestered in the cytoplasm in its inactive state. Second, once it has entered the nucleus, CAR has a high basal level of transcriptional activity even in the absence of an exogenous ligand. CAR can be activated by compounds such as phenobarbital (Fig. 1), which promote

its translocation from the cytoplasm into the nucleus without binding directly to CAR. However, once in the nucleus, CAR can also be modulated by compounds that bind directly to the receptor such as the androstanols, which suppress CAR's high basal activity, or TCPOBOP (Fig. 1), which further increases CAR's transcriptional activity [12].

Ligands for Other Orphan Nuclear Receptors

Recently, ligands have been identified for the three ERR subtypes (α , β , γ) [13,14] and two mammalian HNF4 subtypes (α , γ) [15]. All of these receptors have high basal activity in cell-based reporter assays in the absence of exogenous ligands. The three ERR subtypes are expressed in a number of different tissues and bind to DNA efficiently as monomers. The basal transcriptional activity of all three ERR subtypes can be directly suppressed by the estrogen receptor agonist diethylstilbestrol (Fig. 1), and the estrogen receptor antagonist 4-hydroxytamoxifen can efficiently deactivate ERR γ [13,14]. These data suggest that the ERRs may function as receptors for estrogens or related steroids. The HNF4s are known to bind to DNA as homodimers and regulate genes involved in lipid and carbohydrate homeostasis [16]. X-ray crystallography and mass spectroscopy revealed that both HNF4 subtypes bind to saturated and monounsaturated fatty acids with chain lengths of 14–16 carbon atoms [15]. The transcriptional activity of HNF4 α has also been reported to be higher in the presence of fatty acids in cell-based reporter assays [17]. However, unlike other nuclear receptors, the HNF4 subtypes do not appear to readily exchange their ligands [15]. Thus, HNF4 may define a new class of constitutively active nuclear receptors in which the lipophilic ligand serves as an integral component of the receptor complex rather than a reversible switch.

Conclusion

During the past decade, ligands have been identified for more than a dozen of the orphan nuclear receptors. Many of these are now known to be receptors for key intracellular metabolites including fatty acids and cholesterol derivatives. Others serve as sentinels in the body's defense mechanism

against xenobiotics. Studies of the ERRs suggest that additional steroid hormones may yet exist to be discovered. Finally, recent studies with HNF4 raise the possibility that some orphan nuclear receptors have high constitutive levels of transcriptional activity because they bind irreversibly to their lipophilic ligands. The availability of natural and synthetic ligands will aid tremendously in unraveling the biological functions of these orphan nuclear receptors.

Orphan Receptor COUP-TFII and Vascular Development

Fabrice G. Petit, Sophia Y. Tsai, and Ming-Jer Tsai

*Department of Molecular and Cellular Biology,
Baylor College of Medicine, Houston, Texas*

Introduction

Nuclear receptors belong to a large family of transcription factors, which can modulate gene expression [1,2]. Since the discovery of the steroid/thyroid hormone receptor superfamily, an increasing number of transcription factors with similar structural motifs have been added. A majority of these newly added members have unknown ligands, thus they are classified as orphan nuclear receptors. Like the other members of the steroid/thyroid hormone receptor superfamily, the orphan receptors are involved in development, differentiation, and homeostasis processes. The absence of ligand makes it more difficult to dissect the functional role of orphan receptors. However, the analysis of orphan receptor null mice will provide new insights into the physiological function of these receptors during development, organogenesis, and homeostasis. In this review, we attempt to describe the functional role of orphan receptors during vascular development.

Vascular Development

During embryogenesis, the vascular system plays an important role. It is in charge of the transport of oxygen and nutrients, which are indispensable to the growth and development of the different tissues in vertebrate embryos. For that reason, the development of the vascular system is one of the first events to occur. The vascular network formation requires two distinct phenomena, vasculogenesis and angiogenesis [3,4].

Vasculogenesis

Vasculogenesis is the formation of the early vascular plexus from mesodermal cells (hemangioblasts), which proliferate and differentiate to form the precursors of the endothelial cells of the vessel wall. During early development, vasculogenesis gives rise to a primary vascular plexus including the major vessels of the embryo, such as the aorta and major veins [3]. Factors such as fibroblast growth factors (FGFs), vascular endothelial growth factor (VEGF), and VEGFR-2 are important for this process.

Angiogenesis

The next step in formation of the vascular system is *angiogenesis*, which corresponds to the formation of new blood vessels from preexisting vessels. Two different processes characterize angiogenesis: angiogenic remodeling and angiogenic sprouting. The remodeling process consists of the modification of the initial vessel plexus in order to form interconnecting branching patterns present in the mature vascular network. The sprouting process corresponds to the formation of new capillaries originating from small venules or from other capillaries. It occurs both in the yolk sac and in the embryo (neural tube and retina). It also involves many factors responsible for the proteolytic degradation of the extracellular matrix, for the chemotactic migration and proliferation of endothelial cells, for the formation of a lumen, and for functional maturation of the endothelium. The involvement of factors such as VEGF, VEGFR-2, Tie1, Tie2, angiopoietin-1 (Ang1), Ang2, EphrinB2, platelet-derived

growth factor (PDGF), and PDGFR is primordial for the formation of a mature vascular network [3,4].

Transcription Factors Involved in Vasculogenesis and Angiogenesis

Recently, Roman and Weinstein [4] provided a concise overview of the molecules involved in the development and maintenance of the vertebrate embryonic vascular network. It appears that COUP-TFII is the only orphan nuclear receptor with a well-described role in angiogenesis during embryonic development in mice [5]. Some recent studies suggest that the orphan receptor, PPAR γ , may also play a role in the vascular development.

PPAR γ : Inhibitor of Angiogenesis

The peroxisome proliferator-activated receptor (PPAR, NR1C) group contains three subtypes: α , β (also known as δ or NUC1), and γ . Since the cloning of PPAR members, many pharmacological activators have been identified [6,7]. PPARs are known to regulate genes involved in lipid and glucose metabolism. Despite the ubiquitous expression of PPAR δ , its physiological function is not well known. In PPAR α knock-out mice, the liver accumulates droplets of lipid. PPAR α ligands can inhibit inflammatory responses in vascular smooth muscle cells *in vivo*, suggesting that PPAR α agonists may have a positive effect on vasculature in atherosclerosis [6,7]. The specific ligand for PPAR γ , 15d-PGJ₂, can inhibit endothelial tube formation and proliferation, as well as the induction of VEGF receptors *in vitro*. Moreover, 15d-PGJ₂ was shown to be an inhibitor of angiogenesis in the cornea *in vivo* [8]. It is not clear whether PPAR γ is involved because we do not know whether the ligand used acts through PPAR γ or another nuclear receptor [6,9]. The study of PPAR γ knock-out mice has revealed that the establishment and maintenance of the fetal and maternal vascular networks are abnormal in the placenta. However, all other vascular processes appear normal in the null embryos. Whether other PPAR members can compensate for PPAR γ has not yet been defined. Therefore, it appears that the vascularization of the placenta is dictated by PPAR γ -dependent trophoblast functions [10].

COUP-TFII: Positive Effector in Angiogenesis

COUP-TF (NR2F) is one of the best characterized orphan receptor among the nuclear receptor superfamily. Two members have been identified in mammals, COUP-TFI (also called v-ErbA related protein 3, EAR-3) and COUP-TFII (also called apolipoprotein regulating protein 1, ARP-1). COUP-TF members share a high degree of homology within and between species, so it is assumed they must play important physiological functions [11].

In the developing mouse embryo, COUP-TFI and COUP-TFII exhibit overlapping, but distinct, expression patterns.

They are also differentially expressed in the nervous system and during organogenesis [12]. The expression pattern of COUP-TFII in the nervous system is more restricted than that of COUP-TFI. During organogenesis, COUP-TFII is expressed in the mesenchymal compartment. Expression of COUP-TFII is lower than that of COUP-TFI in the nasal septum, tongue, follicles of vibrissae, and cochlea. Expression of COUP-TFII is higher than that of COUP-TFI in the developing salivary gland, atrium of the heart, lung, stomach, pancreas primordium, mesonephros, kidney, and prostate [12]. Because COUP-TFI and COUP-TFII have different expression patterns, they may have different physiological functions.

To study the physiological function of COUP-TFI and -II *in vivo*, we have generated null mice for these genes. COUP-TFI seems to be important for the neuronal development and differentiation. Accordingly, COUP-TFI null mutant mice die perinatally from starvation due to defects in formation of the glossopharyngeal nerve [12]. In contrast, the knock-out mice for COUP-TFII die early during embryonic development at 9.5–10.5 days from heart and vasculature defects [5]. COUP-TFII mutants probably die as a result of malformation of the vasculature, leading to extensive hemorrhage and edema in the brain and heart. Analyses of the mutant embryos revealed defects in angiogenesis, in the development of the atrium chamber and sinus venosus, and malformations of the cardinal veins.

Detailed observation of COUP-TFII null mice revealed that the major vessels, which arise through vasculogenesis, were formed and expressed the specific markers VEGF-R1, VEGF-R2, and PECAM, suggesting that COUP-TFII does not play an essential role in vasculogenesis. However, the remodeling of the vascular plexus was impaired. Therefore, the sprouting and branching from preexisting vessels was defective in COUP-TFII mutants, suggesting an angiogenesis defect. The defect in vasculature development observed in COUP-TFII mutants was similar to the one observed in mice deficient for Ang1 or its receptor, Tie2 [3]. Moreover, the Ang1 expression pattern is very similar to that of COUP-TFII. In fact, Ang1 mRNA expression is down-regulated 10-fold in the mesenchymal compartments of the brain, eyes, somites, and heart in COUP-TFII mutants. Because COUP-TFII may function through the Ang1-Tie2 signaling pathway, it is likely that it acts on the vasculature formation via mesenchymal–endothelial interactions. Further experiments, using subtraction library screening or P19 cells overexpressing COUP-TFII, also showed that Ang1 is a downstream target gene of COUP-TFII (Petit, F., Tsai, M.-J., and Tsai, S. Y., unpublished data). In the COUP-TFII mutants, there is no obvious alteration in the expression of Tie2, which is regulated by its own ligand, Ang1. This observation suggests that another signaling pathway must be affected by COUP-TFII. Taken together these data suggest that, in mesenchymal cells, COUP-TFII is the upstream regulator of Ang1 expression, which in turn activates its receptor, Tie2, to exert the differentiation of endothelial cells (Fig. 1).

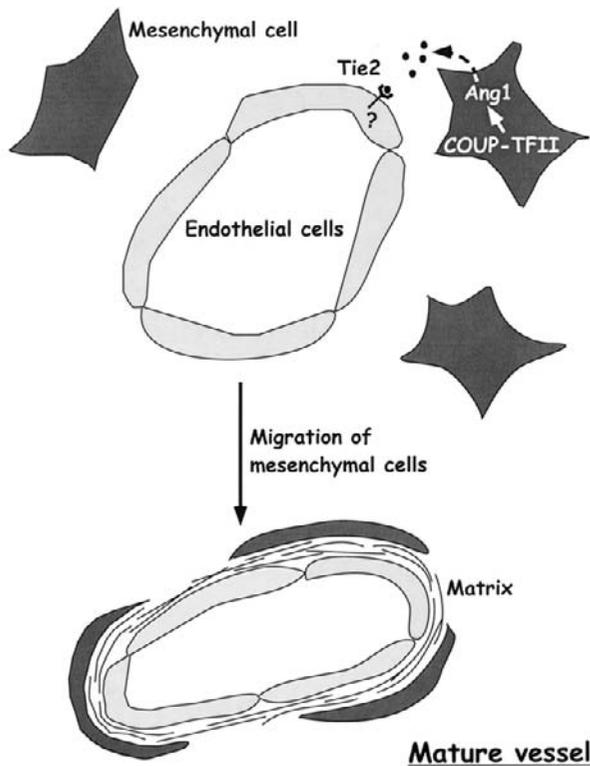

Figure 1 Role of COUP-TFII in the development of vessels. COUP-TFII induces the expression of Ang1, which is released by the mesenchymal cells, Ang1 activates its own receptor, Tie2, located on the endothelial cells, which in turn allow the migration of mesenchymal cells and subsequently the differentiation of mesenchymal and endothelial cells.

Conclusion

So far, among the orphan nuclear receptor group, COUP-TFII is the only member shown to play a role in vascular development. The involvement of COUP-TFII in angiogenesis suggests that it might play a role in tumor growth and progression. Indeed, COUP-TFII is highly expressed in

several tumor cell lines. The discovery of artificial or natural ligands for COUP-TFII will provide important tools for the therapeutic treatment of disease involving angiogenesis or vascular modeling. Moreover, these putative ligands will allow us to further study the function of COUP-TFII in other signaling pathways.

Introduction

All cellular processes depend on extracellular cues ranging from nutrient and oxygen supply, through cell density and contact with adverse agents, to highly specific stimuli originating within the multicellular organism. The extracellular cues are sensed by receptors and converted into responses through the intracellular signaling network. To maintain homeostasis of the cell and of the multicellular organism, the reactions to extracellular cues must be well controlled. Any change of condition requires finding a new balance of life processes achieved by constant readjustment of the cellular signaling network. Each stimulatory pathway is, therefore, counterbalanced by inhibitory components. For instance, receptor tyrosine kinases are associated with negatively regulating protein tyrosine phosphatases, which keep receptor autophosphorylation at a low level in the absence of ligand and limit the duration of activity on activation of the receptors. Similarly, dual-specificity kinases within pathways are balanced by dual-specificity phosphatases whose abundance or activities are up-regulated together with the pathway, thus limiting the extent and duration of stimulation. Upon mitogenic stimulation, cells enter and proceed through the cell cycle, itself an ordered circuit of consecutive positive and negative elements.

One can easily imagine what would happen if the control circuits did not operate: A wound-healing reaction would not stop once the damage was repaired; it would instead

form excessive keloid material (scar tissue). Excessive expression and activation of metalloproteases in response to inflammatory cytokines would cause various types of tissue damage, as seen in rheumatoid arthritis. The expansion of T and B lymphocytes upon antigen-specific stimulation would lead to leukemia-like cell numbers unless negative control mechanisms and ultimately induced apoptosis limited the expansion. A bacterial invasion would lead to uncontrolled and long-lasting release of tumor necrosis factor alpha (TNF- α), for example, by macrophages, which results in septic shock and death of the organism.

This chapter deals with a particular organismic control mechanism established by hormones. Glucocorticoid hormones or retinoic acid as well as vitamin D counteract proliferative, inflammatory, and immune responses. This is why glucocorticoids are widely used in treating unwanted inflammatory reactions, asthma, autoimmune diseases, and leukemia. Vitamin D is applied to psoriatic skin to block proliferation. Retinoids are being used for certain types of cancer. The presumable mechanistic principles were discovered in 1990 and in the years thereafter. The nuclear receptors, which are activated by the hormone ligands, interfere with several of the signal transduction and transcription steps that are relevant for the panel of reactions mentioned. The mechanisms of interference with components of signal transduction are briefly reviewed here before describing in more detail the most interesting mechanism: *cross-talk* between transcription factors.

Proliferative and Proinflammatory Pathways

If a process is to interrupt the immune response or unwanted proliferation, or even inhibit cancer cells, which signaling pathways and which gene expressions need to be addressed? Obviously, we need to address pathways and genes that turn on the cell cycle, which cause the release of cytokines and which control cellular migration, adhesion, and invasiveness. It is these properties that lymphocytes, macrophages, dendritic cells, and other inflammatory cells acquire in order to “squeeze” through endothelial barriers, to invade tissues, and to home into lymphoid organs. Cancer cells share many of these phenotypic features. Knock-out technology has revealed some of the pathways and transcription factors relevant for these processes in immune cells (see, e.g., [1]). Members of the Rel family of transcription factors, of the AP-1 family as well as NF-AT, Oct-1, and C/EBP, fulfill central functions in immune cells upon activation. These factors or the signaling pathways leading to their activation need to be targeted in order to inhibit the responses. AP-1 and NF- κ B are driven also by oncogenic pathways. Inhibiting their action or activation would be antiproliferative [2–5].

For instance, components of the bacterial cell wall such as lipopolysaccharides (LPS) activate toll-like receptors that are linked to the protein kinase complex (IKK) phosphorylating I- κ B α [6,7]. I- κ B α keeps NF- κ B in an inactive cytoplasmic state [5,8,9]. Upon phosphorylation, I- κ B α is subjected to degradation and NF- κ B is released and transported into the nucleus, where it acts on the promoters of numerous cytokine genes. In the case of macrophages the toll-like receptors trigger the synthesis and release of TNF- α . Important for the mechanism discussed here, nonlethal (to wild-type mice) doses of LPS become lethal in adrenalectomized mice (unable to produce glucocorticoid hormone [10]). Inflammatory cytokines can pass through the blood–brain barrier and exert central nervous system effects [11,12], including the stimulation of the hypothalamic–pituitary–adrenal axis, which leads to release of glucocorticoids from the adrenal gland if present [13].

Another central pathway involved in growth factor transcription as well as in transcription of cyclin D1, the entry step into the cell cycle, and of adhesion and migration components, originates from the small G protein Ras. The Ras–MEK–Erk pathway regulates a wide variety of features essential for the immune response as well as for a proliferative and invasiveness program. For instance, the pathway leads to expression of AP-1 subunits as well as to their activation. AP-1 and NF- κ B control the synthesis of several cytokines in T cells and macrophages. Interestingly, the Ras–MEK–Erk pathway controls also alternative splicing [14], yielding different CD44 transcripts and subsequently CD44 proteins that, in turn, are required for specific activation of certain receptor tyrosine kinases [15]. Thus, interference with inflammation, proliferation, and immune responses should address predominantly the pathways leading to AP-1 and NF- κ B activity.

Nuclear Receptors

The mediators of hormone-dependent interference with proliferative and inflammatory responses belong to the family of nuclear receptors that share several structural features [16,17]. Nuclear receptors are bona fide transcription factors whose action is turned on by the specific hormone ligand. The C-terminal half carries the ligand-binding domain and a transactivation domain (AF-2) whose accessibility depends on the presence of the proper ligand. AF-2 assembles coactivator complexes necessary for initiation of transcription. The monomeric nuclear receptor does not bind sufficiently to DNA; rather homodimerization (e.g., in the case of steroid hormone receptors) or heterodimerization with a common subunit, RXR (of the receptors for vitamin D, for thyroid hormone, and for retinoids) is required. A conserved structure in the middle of the nuclear receptor molecule is folded by coordinating zinc atoms into two finger-like structures, the N terminal of which confers, together with its dimer partner, binding to the specific promoter element. The C-terminal zinc finger mediates protein interactions; for example, through the extended so-called D-loop, it mediates homodimerization of steroid hormone receptors. The N-terminal half carries another transactivation domain (AF-1) that is ligand independent but requires modifications by other pathways. Recent evidence suggests that modifications by Erk or Rsk-1 enhance the transcriptional function of some nuclear receptors (e.g., ER α carries an Erk site at amino acid 118 [18] and a pp90rsk1 site at amino acid 167 [19,20]). Steroid hormone receptors are associated with chaperones that, in addition to other functions, are needed to keep the ligand-binding domain in a steroid hormone accepting conformation. Often the steroid hormone receptors are cytoplasmic in the absence of ligand [21].

Induced Expression of Inhibitory Molecules

The most straightforward explanation for an inhibitory role of nuclear receptors would be the hormone-induced synthesis of an inhibitory molecule. To what extent the transcription of such effector molecules plays a physiological role is still a matter of debate. Removal of the adrenal gland leads to thymic hypertrophy suggestive of reduced cell death because the thymus is the organ of high cellular apoptosis. Glucocorticoids induce apoptosis in isolated thymocytes for which proper transcriptional function of the GR is required [22,23]. Also several other nuclear receptors appear to exert functions in the thymus [24]. It is therefore plausible that nuclear receptors are involved in the control of synthesis of proapoptotic transcripts. Nevertheless, it is still unclear to what extent this is physiologically relevant [24].

Induced inhibitors of transcription and of signal transduction have been identified. In several types of cells, the abundance of the inhibitor of NF- κ B, I- κ B α , is enhanced upon treatment of cells with glucocorticoid hormone [10,23,25]. As we will see, the induction requires the presence of a

dimerization-competent glucocorticoid receptor. One could imagine that enhanced expression of I- κ B α terminates the action of NF- κ B and thus the release of cytokines. (For a recent discussion of NF- κ B:I- κ B shuttling between cytoplasm and nucleus see [5].) Another glucocorticoid receptor target is MKP-1, the phosphatase acting on Erk. The hormone-enhanced abundance (by both increased transcription and reduced turnover [26]) of MKP-1 counteracts the activation state of Erk. As one would expect for induced new synthesis, the inhibition occurs with a delay of more than 16 hr. Thus, the induced expression of inhibitory proteins represents one type of mechanism explaining how a hormone can terminate inflammatory processes. The induced synthesis will not lead to an instantaneous block.

Immediate Hormone Responses

Most of the anti-inflammatory and antiproliferative action of nuclear receptors does not depend on prior protein synthesis. Such immediate action implies that the liganded receptor exerts a molecular function by direct interaction with another component, for example, DNA or protein. The function could be exerted in the cytoplasm or in the nucleus. The steroid hormone receptors are associated with chaperones that keep the proteins in ligand-susceptible conformation, and they share prolonged periods of cytoplasmic localization. Thus, a cytoplasmic action would be feasible although difficult to reconcile with hormone-dependent activation of cytoplasmic components: The bulk of ligand-activated receptor is located in the nucleus, whereas signaling components including JNK remain by and large cytoplasmic [27,28]. Controversy still surrounds questions as to what extent and how nuclear receptors affect signal transduction pathways directly. Both inhibitory and stimulatory actions have been reported, the kinetics of which are often too slow to be taken as direct actions (e.g., 50% inhibition of JNK activity [29–32], Erk [33,34], p38 [35]). One of the signaling molecules addressed is JNK, the enzyme activating the AP-1 subunit Jun. Interference with JNK is possibly a nuclear event [28]. The more convincing data, which are based on the use of gene disruptions and coprecipitations, classify interactions with components of the signaling network as costimulatory. The associations, for instance, of the androgen or estrogen receptors with Src, PI3Kp85, Fyn, and other signaling molecules appear to enhance nuclear receptor function in transcription [36,37].

The inhibitory action of nuclear receptors is by and large nuclear. Two types of mechanisms for immediate inhibition appear to emerge: blocking of transcription by binding to a promoter element, and modulation of other transcription factors without obligatory binding of the nuclear receptor to DNA. The repressor function at the promoter element recognized by the nuclear receptor has been best documented for the thyroid receptor. In the nonliganded state, the receptor recruits corepressor molecules such as N-CoR and histone deacetylases [38]. Hormone binding converts the receptor into the transactivating molecule. Less well understood is

the action of the glucocorticoid receptor on so-called nGREs, negative glucocorticoid response elements [39]. nGREs seem to play roles in the autoregulatory circuit of the hypothalamus–pituitary–adrenal axis, for example, in the transcription of the genes for promelanocorticotropin and prolactin. The binding to nGREs appears to require dimerization or multimerization of the glucocorticoid receptor [39]. nGREs possibly induce a conformational change such that the GR cannot recruit the complex of components required for transcriptional initiation and instead binds inhibitory cofactors.

The modulation of transcription factors without direct binding to DNA is the more predominant mechanism relevant for the control of proliferation and of the immune reactions. It is also the most intriguing mechanism and presumably the evolutionarily more ancient one [40]. All nuclear receptors (perhaps with the exception of the mineralocorticoid receptor) appear to share this ability [41–48]. The evidence for the glucocorticoid receptor for which most data have been collected is described next.

Direct Modulation of Transcription Factors

Mutual Modulation, A Method of Maintaining Homeostasis

Rapid repression of phorbol-ester-induced transcription of collagenase (MMP-13) absence of phorbol synthesis led to the discovery of transcription factor modulation by nuclear receptors [41]. The collagenase promoter fragments sufficient for induced transcription and hormone-dependent repression comprised neither GRE or nGRE sequence elements. Similarly, the repressible promoter for interleukin-2 carried no GRE or nGRE [10]. These data led to the recognition that nuclear receptors interfere with other transcription factors. The glucocorticoid receptor modulates negatively the transcription by CREB [4,49], by the Jun:Fos heterodimer (AP-1) [41–43], and by, for example, Oct-1 [50], Spi-1/PU-1 [51], GATA-1 [52], and NF- κ B [53]. This list is probably not complete. As introduced earlier, interference with AP-1 and NF- κ B function is certainly most relevant in the inhibition of inflammation and of proliferation [3,54]. Interestingly, the modulation is mutual, liganded glucocorticoid receptor down-modulating AP-1- and NF- κ B-dependent transcriptions, activated AP-1 or p65 (NF- κ B) inhibiting GRE-dependent transcription [41]. Interestingly, less hormone was required for repression of AP-1 than for induction of a GRE-containing promoter [41]. Accordingly, the program of gene expression can be modeled by a fine-tuned transition from totally AP-1 (NF- κ B, or other factor) dependent transcription and complete inhibition of GRE promoters, through increasing repression of AP-1 and decreasing repression of GRE promoters to a totally hormone-dependent program [55]. This adjustment would be created by the relative concentrations of hormone activating the nuclear receptor versus growth factors activating AP-1 or NF- κ B [55].

Tethering

The mutual modulation of transcription factors AP-1 or NF- κ B by GR and the reverse is based on protein–protein interactions. By means of coimmunoprecipitations, low-affinity interactions between nuclear receptors and AP-1 were detected [41–43,56]. Although initially thought that mutual binding would interfere with DNA binding, this assumption turned out to be wrong. According to genomic footprints [4,57] and chromatin immunoprecipitations [58], the inhibited AP-1 (at the MMP-13 promoter) or NF- κ B (at the promoters for interleukins 2 and 8, as well as for ICAM-1) remain bound to their promoter elements [4,57,58]. Chromatin immunoprecipitation proved that the glucocorticoid receptor was associated with the complex. The molecules “tethered” together apparently exert molecular properties different from those as individual factors; that is, they “forget” to be positive transcription factors [59,60].

This hypothesis is not far-fetched. Theoretical and experimental arguments support that the binding to a specific DNA element determines the conformation of the partners: of DNA as well as of the protein factor [60]. It is thus not too surprising that protein–protein tethering also determines protein function. Synergy has been found for the tethering of nuclear receptors with AP-1 or NF- κ B in certain tissues [4,47]. Interestingly Jun:Jun homodimer function can be enhanced by glucocorticoids [4,56]. It is not clear, however, when Jun homodimers are formed under physiological conditions. In the organism, however, the negative interference of GR with AP-1 and NF- κ B appears to predominate.

Dissociation of GRE Promoter Activity from Tethering Action

I turn now to a discussion of the dissociation of GRE promoter activity from the tethering action, mainly by the dimerization-defective GR, and to cross-talk as the major mechanism of action for the anti-inflammatory and immunosuppressive functions of the glucocorticoid receptor.

What was already suggested by the different hormone concentration requirements became obvious by mutations created in the glucocorticoid receptor GR [61]. One mutation in particular was most informative: a point mutation in the D-loop responsible for subunit dimerization at the GRE element. This mutation was introduced into the mouse by knock-in strategy. The resulting GR^{dim/dim} mice carried a receptor that was unable to bind to GREs and to activate GRE promoters, but could perfectly repress AP-1 and NF- κ B promoters [22,23]. The GR^{dim/dim} mice were viable, suggesting that the induction of hormone-dependent genes was not essential for life under normal animal house conditions. The repressive action was, however, essential, a conclusion that could be derived from the nonviability of total GR knock-outs [62]. The dimerization-defective GR suffices to inhibit most proinflammatory responses [23] with the only exception being thymocyte apoptosis [63], which is counteracted by Bcl-2 in transgenic mice [64] and may involve

the activation of caspase-9 [65]. Thus cross-talk between GR and AP-1 and NF- κ B is possibly the decisive mechanism in the control of the immune system and most relevant for the medical use of glucocorticoid hormones as anti-inflammatories. For instance, inhibitions by hormone of phorbol ester induced inflammation, of the acute phase response or of LPS-induced TNF- α release, were perfectly normal in the mutant mouse. The synthesis and release of macrophage and T-cell cytokines as well as transcription of the cyclooxygenase-2 gene were blocked to the same degree as in wild-type mice. The role of GR in thymocyte development, however, has not been resolved and remains controversial [23,24].

Transcriptional Initiation Steps That Could Be GR Targets

Ever since the discovery of transcription factors and their binding to elements at a fair distance to the TATA box or to the site of RNA polymerase and initiation complex assembly, researchers have been puzzled about how they might activate transcription. According to an early hypothesis, the DNA between the enhancing factor and the initiation complex loops out to bring all partners into proximity, where they provide an unknown start stimulus. Consequently, the modulation of AP-1 by GR was seen as interrupting the contact between AP-1 and the basic transcription complex. When additional factors were found—coactivators—competition for shared coactivators was considered as a mechanism for how a nuclear receptor could affect another transcription factor [47]. One of the coactivators, CBP/p300, is of low abundance, making competition for CBP a plausible proposal [66]. CBP indeed collaborates with both AP-1 and nuclear receptors. However, other CBP-binding transcription factors such as STATs or NF- κ B should also compete for CBP, but do not repress AP-1. Even more convincingly, however, the activation domains of the receptors that recruit coactivators could be destroyed without any effect on cross-talk [67].

The discovery of corepressors and their association with histone deacetylase activity primed the hypothesis that recruitment of these negative counterplayers of coactivators may be responsible for hormone-dependent repression. However, inhibitors of histone deacetylase could not release repression [4,58,68].

What then is arrested and prevents transcription after the preinitiation complex has been formed? In chromatin immunoprecipitations, the GR-arrested preinitiation complex lacked one of the phosphorylations of the RNA polymerase II C-terminal tail [58]. This phosphorylation is thought to be important for the start of transcription and for elongation. Because the data are based on the specificity of an antibody, further confirmation is needed.

A current area of intensive research concerning gene expression addresses the state of the chromatin and its regulation. Transcribed genes are less densely packed, a state suggestive of better accessibility for protein factors. Regulated changes of chromatin accessibility occur prior to assembly

of the preinitiation complex, during or after assembly. This order of remodeling may differ among genes [69,70]. It is therefore possible that the nuclear receptor prevents the remodeling step at genes that require such a process after formation of the preinitiation complex. Studies with chromatin immunoprecipitations have yet not explored this possibility.

Whatever the mechanism, yet unknown additional factors are likely to be involved. A cofactor isolated by two-hybrid screens promises to reveal such a factor (tentatively named protein #198; unpublished data). The protein carries three LIM domains, zinc-finger-like structures that mediate protein-protein interactions. One of the LIM domains binds specifically to either Fos (one of the AP-1 subunits) or p65 (the NF- κ B subunit), while nuclear receptors interact with another LIM domain, offering the possibility that the protein forms a trimeric complex. Protein #198 carrying only one LIM domain acts as dominant-negative factor abolishing cross-talk between AP-1 and either GR, thyroid hormone receptor, or retinoic acid receptor. Loss of protein #198 by morpholino antisense oligonucleotide technique also prevented the cross-talk. What exactly this new cofactor does in conferring cross-talk modulation of transcription is currently being explored.

Conclusion

The cross-talk function of nuclear receptors is essential for adult life. It is exerted by interference with the activity of another transcription factor at a step after formation of the preinitiation complex. The cross-talk is mutual and offers a way to adjust pro- and antiproliferative transcription in an elegant and fine-tuned way. A new class of cofactors appears to be involved in the cross-talk. Because long-term systemic therapy with glucocorticoids can result in severe side effects such as osteoporosis and joint necroses, current efforts are directed toward distinguishing whether the side effects are caused by GRE-dependent genetic programs or whether they are intimately connected to the cross-talk function of GR, which is unavoidably used for these therapies. It may be possible to select ligands that activate only the cross-talk function.

Drosophila Nuclear Receptors

Kirst King-Jones and Carl S. Thummel

Howard Hughes Medical Institute, University of Utah, Salt Lake City, Utah

Introduction

The completion of the *Drosophila* genome sequence in early 2000 revealed 21 nuclear receptor (NR) genes [1], about half of the 49 NR genes identified to date in the human genome [2]. In striking contrast, ~270 NR genes have been described in *Caenorhabditis elegans* [3]. It seems likely that the ~255 nematode-specific NRs reflect an adaptation unique to the nematode group. The 21 *Drosophila* NRs represent all major subfamilies described previously [4], and 16 receptors appear to have orthologs in either vertebrates or nematodes, or both (Table I).

Only five receptors have not been identified outside the arthropod branch. Knirps, Knirps-related, and Eagle form a unique class of highly related proteins (often referred to as the Knirps group) that lack a ligand-binding domain (LBD).

The other two receptors, DHR39 and DHR83, are closely related to FTZ-F1 and dFAX-1, respectively, and probably represent—in evolutionary terms—relatively recent splits within the arthropod lineage. In general, it appears that most *Drosophila* NRs are more similar to their human counterparts than to the corresponding *C. elegans* homolog (Table I). The fruit fly, *Drosophila melanogaster*, provides an ideal system to analyze NR function in the context of a developing organism, with a wide range of genetic tools that allow the dissection of regulatory pathways and in-depth characterization of gene function.

Nuclear Receptors and Embryonic Pattern Formation

Drosophila embryogenesis is characterized by a succession of events that transform the early embryo into a segmented first instar larva. Maternally deposited transcripts create opposing protein gradients along the anterior-posterior axis

of the early embryo that trigger spatially restricted activation of the so-called gap genes, establishing more defined subdivisions. The gap genes, in turn, activate the next set of genes, the pair-rule genes, that divide the embryo into regions representing the precursors of the body segments.

The NR genes *tailless* (*tll*) and *knirps* (*kni*) are gap genes. Embryos mutant for *tll* exhibit deletions in the terminal domains of the embryo [5]. Once Tll expression is activated through the Ras signaling pathway, it sets up a posterior boundary, restricting the expression of other gap genes like *kni*, *krüppel*, and *giant* [6]. The *tll* gene also plays a role in establishing the optic lobe primordium, which, at a later stage, develops into the optic lobe neuropiles and the larval photoreceptor [7]. The *kni* gene is required for the proper development of A1–A7 abdominal segments [8]. Closely related to *kni*, *knirps-related* (*knrl*) has partially overlapping functions with *kni* in development of the nervous system [9]. *Kni* and *Knrl* also play a critical role in cell migration and branch morphogenesis during embryonic tracheal development [10].

The NR gene *FTZ-F1* encodes two isoforms with distinct functions. During embryogenesis, maternally supplied α FTZ-F1 interacts with the Fushi tarazu (FTZ) homeodomain protein. These two proteins constitute mutually dependent cofactors required for correct segmentation [11,12]. FTZ contacts the AF-2 domain of α FTZ-F1 via an LXXLL motif, a signature typically found in NR cofactors and previously unknown to exist in homeodomain proteins [13,14]. The other isoform, β FTZ-F1, which plays a crucial role in molting and metamorphosis at later stages, is first expressed in the late embryo and appears to be required for the completion of embryogenesis [15].

Ecdysone Regulatory Hierarchies

Following embryogenesis, *Drosophila* progresses through three larval stages and metamorphosis, a dramatic process in

Table I *Drosophila* Nuclear Receptors

<i>D. melanogaster</i>	Cytology	IF	<i>C. elegans</i>	<i>H. sapiens</i>	Ecd	Lethal phase	Function

Cytology: Chromosomal location was based on published polytene chromosome *in situ* hybridizations and on estimated positions by the genome project. IF: isoforms, only mRNA isoforms encoding different proteins are considered. Number is based on published cDNA and EST data. *C. elegans* and *H. sapiens*: homologs of corresponding *D. melanogaster* NR and percent identity in the DBD/LBD. N/A = no homolog was found, closest match was not significantly more similar than matches to other members of the NR family. Ecd: regulated by ecdysone, tested by organ culture experiments, (+) indicates a weak induction. lethal phase: The zygotic lethal phase of known null mutations. function: summary of key functions

¹T. Kozlova, personal communication.

²The NHR-41 sequence was kindly provided by A. Sluder and C. Gissendanner.

which the crawling larva is transformed into a reproductively active adult fly. These postembryonic developmental transitions are triggered by pulses of the steroid hormone ecdysone. An ecdysone pulse at the end of larval development signals the onset of metamorphosis and initiation of prepupal development, followed by another ecdysone pulse ~12 hr later that triggers the prepupal–pupal transition. The ecdysone signal is transduced through a heterodimer of two NRs: the EcR ecdysone receptor and an ortholog of vertebrate RXR, USP, which appears to function as an obligatory partner [16–18]. USP can also dimerize with DHR38, a NR involved in adult cuticle formation [19,20]. The EcR/USP and DHR38/USP dimers can recognize similar DNA sequences and may directly compete for binding to common regulatory targets [21]. Upon binding ecdysone, the EcR/USP receptor directly induces a set of primary-response genes, some of which encode transcription factors that, in turn, induce a larger set of secondary-response target genes. These gene cascades not only transduce and amplify the ecdysone signal, but also diversify it to achieve temporal and spatial specificity [22].

A surprising number of the key players induced in the ecdysone-regulatory hierarchies at the onset of metamorphosis are members of the NR family [23]. At least 10 NR genes are regulated by ecdysone (Ecd, Table I); most are induced by the hormone, whereas β FTZ-F1 is repressed by ecdysone [24]. The *E75* primary-response gene encodes three NR isoforms, designated E75A, E75B, and E75C [25]. *E75* plays a critical role in oogenesis [26] and is required for proper midgut constrictions during embryonic development [27]. *DHR3* is induced by ecdysone at puparium formation and is required for induction of β FTZ-F1 in the mid-prepupa [28]. E75B, a NR without a functional DNA-binding domain (DBD), can bind directly to DHR3, blocking its ability to induce β FTZ-F1 [29]. The timing of β FTZ-F1 expression thus appears to be controlled by induction of the DHR3 activator and decay of the E75B repressor. β FTZ-F1 provides competence for prepupal responses to ecdysone and is required for larval salivary gland cell death through stage-specific induction of the *E93* death gene [24,30]. *E78* and *DHR39*, two ecdysone-inducible NR genes, are expressed during the early stages of metamorphosis but do not carry out essential functions in the fly [31,32]. Among *Drosophila* NR genes, *E78* is most similar to *E75*. Intriguingly, one of the *E78* isoforms, E78B, is expressed in synchrony with E75B and is also missing its DBD, suggesting possible functional redundancy. DHR39 is closely related to FTZ-F1 and is almost as similar to DHR4, indicating that this NR group might share overlapping functions. *DHR4* mutations have not yet been described, although *DHR4* expression in early prepupae and its induction by ecdysone in organ culture suggest a role at the onset of metamorphosis (K. King-Jones, unpublished results).

Null mutations in the ecdysone-inducible *DHR78* NR gene lead to breaks in the tracheal respiratory system of the larva and lethality during the third instar [33]. Another *Drosophila* NR gene known to be regulated by ecdysone, *DHR96* [34], is an ortholog of *C. elegans* *daf-12*, which

functions at the intersection of pathways that regulate dauer larva formation and adult longevity [35,36]. No specific mutations have yet been reported in *DHR96*, or in two other *Drosophila* NR genes, *dERR* and *dHNF4*. Recent studies, however, have shown that vertebrate HNF4 α transcriptional activity can be modulated by long-chain fatty acids, and that diethylstilbestrol inactivates ERR β [37,38]. It will be interesting to determine whether dERR and dHNF4 are capable of binding similar ligands and if *in vivo* ligands for these NRs can be identified.

The Neuronal Connection

Several NRs are involved in neuronal development, and their expression is often limited to specific neuronal cells. In embryos, *eagle* (*eg*) is almost exclusively expressed in four neuronal lineages that arise from a specific neuroblast (NB 7-3), which ultimately develops into a set of serotonin neurons. Mutant alleles of *eg* exhibit the correct number of *eg*-expressing NB 7-3 progeny, but fail to establish the correct projections, suggesting that the specification of cell identity in this lineage is altered [39,40]. *seven-up* (*svp*) encodes a COUP-TFI-like NR and represents the most conserved member of the NR family between humans and flies. SVP is expressed specifically in four of the eight photoreceptor neurons in the developing eye (R1, R3, R4, R6). *svp* mutations cause a transformation of these cells toward an R7 cell fate [41]. Conversely, ectopic expression of SVP in R7 photoneurons drives them toward an R1–R6 cell fate [42]. Another NR gene known to be expressed in the nervous system is *dissatisfaction* (*dsf*), a *tll*-like gene. Curiously, the LBD of the human Tll ortholog, TLX, is more similar to Dsf than to Tll itself, suggesting that both *dsf* and *tll* are orthologs of the *TLX* gene. *Dsf* is required for appropriate courtship behaviors and sex-specific neural development, and is expressed in a few cells in the larval and adult brain. Sexually dimorphic transcripts of *dsf* have not yet been identified, suggesting that its distinct roles in males and females may be mediated by a sex-specific dimerization partner and/or ligand(s) [43,44].

The genome project revealed two previously unknown NR genes that we refer to here as *DHR83* and *dFAX-1*. Both are closely related, but *DHR83* appears to have no orthologs in either humans or worms. dFAX-1 was named after its *C. elegans* counterpart, FAX-1, which is required for axonal pathfinding [45]. Whether dFAX-1 plays a similar role in *Drosophila* is unknown, although the absence of any ESTs, as well as the fact that this gene was not identified before the completion of the genome project, argues that its expression is either highly cell-type specific or of low abundance. *DHR83* appears to encode a rare transcript as well, but it remains to be seen whether this gene has functions similar to *dfax-1*. Finally, *DHR3* mutants display defects in embryonic peripheral nervous system development, but it is not clear whether this contributes to the early lethality seen in these mutants [46].

JAK-STAT Signaling

Christian. W. Schindler

*Department of Microbiology and Medicine,
College of Physicians and Surgeons,
Columbia University, New York, New York*

Introduction

Characterization of the ability of interferon α (IFN- α) to rapidly induce genes led to the discovery of the JAK-STAT pathway. Subsequent studies determined that JAKs (Janus kinases) and STATs (signal transducers and activators of transcription) represent a families of proteins that play a critical role in mediating the biological response to the ~50 hematopoietins, all members of the mammalian cytokine family of ligands (see Table I). Although components of this pathway can be found in the most primitive metazoans, the pathway has grown in complexity as multicellular organisms evolved. In mammals, this pathway regulates pivotal aspects of cellular homeostasis and inflammatory response. This review will provide a brief overview of the significant progress that has been made in understanding this pathway since it was first discovered a decade ago. For a more detailed discussion, readers are directed to more comprehensive reviews [1–4].

The JAK-STAT Paradigm

Hematopoietins represent a family of secreted ligands, which exert their potent biological effects on target cells that express the corresponding receptors. These receptors can be divided into five subgroups based on their structures and the STATs that they activate (see Table I). Of note, a number of receptor tyrosine kinases and G-protein-coupled receptors have also been shown to activate STATs, but these signals do not appear to be as critical to their biological response [2]. Upon binding ligand, the dimeric receptors undergo a conformational change, bringing together and thereby activating associated JAKs (see Fig. 1; [5]). Activated JAKs in turn phosphorylate receptor tyrosine motifs, leading to the recruitment of

specific STATs (Table I). At the receptor, these STATs become activated by a single tyrosine phosphorylation event.

After release from the receptor, they dimerize through reciprocal phosphotyrosine–SH2 domain interactions (“classical dimerization”; [6,7]). Intriguingly, recent evidence indicates that STATs may actually form stable dimers prior to activation, but through a different mechanism (J. Braunstein and C. Schindler, unpublished observation). “Classically dimerized” STATs are competent for both DNA binding and robust nuclear translocation. Although structural studies have provided detailed insight into STAT DNA binding activity [6,7], little is known about the structural motifs that regulate nuclear import [2]. Once in the nucleus, STAT dimers bind to members of the gamma-activated site (GAS) family of enhancers, which culminates in the activation of target genes [2,8]. One well-established exception is the Stat1-Stat2 heterodimer. This unique heterodimer, which forms in response to stimulation with type I IFNs, associates with a DNA binding protein, IFN regulatory factor 9 (IRF-9), to form the transcription factor IFN stimulating gene factor 3 (ISGF-3). This factor binds to the IFN stimulated response element (ISRE) subset of the IRF family of enhancers [2].

STAT signals decay within a period of hours and the STATs are re-exported back to the cytoplasm, effectively resetting the cell for the next round of signaling. This appears to entail nuclear dephosphorylation and a Crm1/Ran-GTPase-dependent nuclear export process [2,9]. Some activated STATs may also undergo targeted degradation [10]. Intriguingly, recent studies suggest that the predominantly cytoplasmic distribution of STATs found in resting cells reflects a steady state, which represents a balance between basal (i.e., in the absence of tyrosine phosphorylation) nuclear import and export (S. Bhattacharya and C. Schindler, unpublished observation). This raises the possibility that STATs may regulate the expression of some genes in unstimulated cells [11].

Table I Hematopoietins Signal through JAKs and STATs

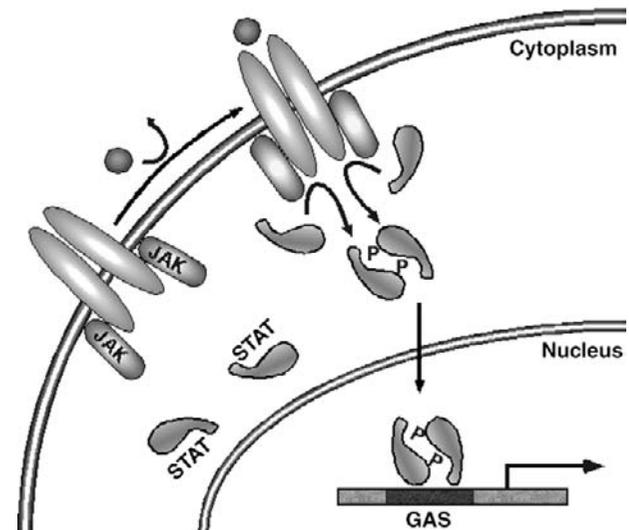

Ligands	JAKs	STATs
<i>IFN family</i>		
IFN-α's[†]/β/ω/Limitin	Jak1, Tyk2	Stat1, Stat2, (Stats3–6)
IFN-γ	Jak1, Jak2	Stat1, (Stat5)
IL-10*	Jak1, Tyk2	Stat3
IL-19	?	?
IL-20	?	Stat3
IL-22	?	Stat3, (Stat5)
IL-24	?	Stat3
<i>gp130 family</i>		
IL-6	Jak1, (Jak2)	Stat3, Stat1
IL-11	Jak1	Stat3, Stat1
OSM	Jak1, (Jak2)	Stat3, Stat1
LIF	Jak1, (Jak2)	Stat3, Stat1
CNTF	Jak1, (Jak2)	Stat3, Stat1
NNT-1/BSF-3	Jak1, (Jak2)	Stat3, Stat1
G-CSF	Jak1, (Jak2)	Stat3
CT-1	Jak1, (Jak2)	Stat3
Leptin	Jak2	Stat3
IL-12	Tyk2, Jak2	Stat4
IL-23	?	Stat4
<i>γC family</i>		
IL-2	Jak1, Jak3	Stat5, (Stat3)
IL-7	Jak1, Jak3	Stat5, (Stat3)
TSLP [‡]	?	Stat5
IL-9	Jak1, Jak3	Stat5, Stat3
IL-15	Jak1, Jak3	Stat5, (Stat3)
IL-21	Jak3, (Jak1),	Stat3, Stat5, (Stat1)
IL-4	Jak1, Jak3	Stat6
IL-13 [‡]	Jak1, Jak2	Stat6, (Stat3)
<i>IL-3 family</i>		
IL-3	Jak2	Stat5
IL-5	Jak2	Stat5
GM-CSF	Jak2	Stat5
<i>Single Chain family</i>		
Epo	Jak2	Stat5
GH	Jak2	Stat5, (Stat3)
Prl	Jak2	Stat5
Tpo	Jak2	Stat5

The JAKs and STATs activated by members of the hematopoietin family are indicated. Confidence in these assignments vary: very strong (based on knockout studies and shown in bold), reasonably strong (plain lettering) and least strong (shown in brackets).

[†]There are 12 IFN α 's.

^{*}IL-10 homologue AK155 has not yet been functionally characterized.

[‡]Bind to a related, but γ c independent receptor.

**Figure 1** The JAK-STAT signaling paradigm. See text for details.

The JAK Family

Four members of the mammalian JAK family, Jak1, Jak2, Jak3, and Tyk2, are associated with a proline-rich, membrane proximal receptor domain [1]. JAKs range in molecular weight from 120 to 130 kDa. Jak1, Jak2 and Tyk2 are expressed ubiquitously, but the expression of Jak3 is more restricted [3]. Seven conserved JAK homology (JH) domains have been identified. The JH1 and JH2 domains constitute the carboxy-terminal kinase and pseudokinase domains, which distinguish JAKs from most other protein tyrosine kinases [1]. The amino-terminal JAK homology domains, JH3–JH7, constitute a FERM (four-point-one, Ezrin, Radixin, Moesin) domain, which mediates receptor association [2].

Although biochemical studies have implicated differing sets of JAKs for each hematopoietin receptor subgroup, it appears they can be interchanged without affecting signaling specificity [1,2]. Gene targeting studies have demonstrated that Jak1 plays an important role in the biological response to members of the interleukin (IL)-2, IL-6, and IFN/IL-10 receptor families [12]. Because the Jak1 $^{-/-}$ mice exhibit a perinatal lethal phenotype, more complete analysis awaits adoptive transfer and tissue-specific knockout studies. The Jak2 knock-out mice exhibited a midgestational lethal phenotype (i.e., day 12.5), which has been attributed to a block in definitive erythropoiesis [13,14]. *Ex vivo* studies with Jak2 $^{-/-}$ fetal liver cells indicate defects in their responses to Tpo, IL-3, members of the IL-2 family, IFN- γ , but not IL-6 or IFN- α . Consistent with biochemical studies demonstrating a robust association of Jak3 with γ C [3], both the Jak3 $^{-/-}$ and γ C $^{-/-}$ mice demonstrate severe SCID-like defects in lymphopoiesis [3,15–17]. The phenotype of the Tyk2 knock-out mice is the most surprising of all. In contrast to earlier biochemical and genetic studies, these mice exhibit only relatively modest defects in their response to type I IFNs and IL-10. Defects in their response to IL-12 and LPS are considerably more remarkable [18,19].

The STAT Family

Mammals express seven STAT proteins, which range in size from 750 to 900 amino acids. Both the chromosomal distribution of these STATs and the identification of homologs in more primitive eukaryotes suggest that this family arose from a single primordial gene [2,20]. Duplications of this locus appear to reflect an increasing need for cell-to-cell communication. Homologs, most closely related to Stat3 and Stat5, have been identified in model eukaryotes, including *Dictyostelium*, *Caenorhabditis elegans*, and *Drosophila* [2]. Whereas in *Drosophila* the single STAT transduces signals through a “classical” JAK-STAT pathway, the STAT homologs in *Dictyostelium* and *C. elegans* appear to signal through different pathway(s).

STATs can be divided into five structurally and functionally conserved domains (see Fig. 2; [6,7]). The amino-terminal domain (NH₂; ~125 amino acids) is well conserved and promotes cooperativity in DNA binding [2,21]. This domain has also been implicated in nuclear translocation [2]. The coiled-coil domain (amino acids ~135 to ~315) consists of a four-helix bundle that protrudes laterally (~80 Å) from the core. This domain has been shown to associate with a number of potentially important regulatory modifiers including IRF-9 and StIP [2,4]. It has also been implicated in nuclear export [2]. The DNA-binding domain (DBD; amino acids ~320 to ~480) recognizes the palindromic GAS element, upon dimerization, and may also participate in nuclear export [6–9]. However, the Stat2 DBD, despite its sequence conservation, is unable to bind DNA directly. The linker domain (amino acids ~480 to ~575) structurally translates the dimerization signal to the DNA binding motif. Recent studies suggest it regulates a basal (i.e., in resting cells) nuclear export process [22]. The SH2 domain (amino acids ~575 to ~680) is the most highly conserved motif. It mediates both specific recruitment to the appropriate receptor, as well as STAT dimerization [2]. The tyrosine activation motif represents a conserved tyrosine near residue 700 that is activated by phosphorylation. This phosphotyrosyl residue is specifically recognized by a SH2 domain of the partner STAT [2]. Each STAT, except Stat2, has been shown to homodimerize *in vivo*. The carboxy termini of all STATs vary considerably in both length and sequence. They encode the transcriptional activation domain (TAD), which is conserved between mouse and man for every STAT, except Stat2 [2,23].

Gene targeting studies have provided important insight into the functional specificity of the STATs. Consistent with its identification during the purification of ISGF-3 and an

IFN- γ induced factor, Stat1 knock-out mice exhibit defects in their biological response to both type I and type II IFNs, but not other ligands [2,24,25]. Likewise, Stat2 knock-out mice are only defective in their response to type I IFNs [23]. Analysis of these mice has highlighted the role type I IFNs play in regulating both innate and acquired immunity ([23]; E. Cha and C. Schindler, unpublished observation). The Stat3 knock-out mice exhibit an embryonic lethal phenotype, reflecting the pleiotropism of Stat3 activating ligands (see Table I). Tissue-specific Stat3 knock-outs have identified important defects in responses to IL-6, IL-10, KGF, CNTF, and LIF [2]. The diverse role Stat3 plays is reminiscent of the more pervasive role STATs play in primitive metazoans. The Stat4 and Stat6 knock-out mice exhibit specific defects in their response to the cytokines that regulate the polarization of naïve T-helper cells into effector Th1 and Th2 subsets, where IL-12 (as well as closely related IL-23) promotes Th1 cells and IL-4 (as well as closely related IL-13) promotes Th2 cells [26–30]. Finally, the Stat5 knock-out mice have yielded the most unexpected findings [1,31–33]. Stat5a and Stat5b, which are 96% identical, are not completely redundant, as earlier biochemical studies had suggested. Stat5a null mice exhibit a defect in PRL-dependent mammary gland development. In contrast, Stat5b single knock-out mice exhibit defects in their response to GH. The Stat5a/b double knock-out mice have the most severe defects, yet these mice still develop a full complement of hematopoietic lineages. Defects in the response to GH and PRL are striking, while those to IL-2, IL-3, IL-5, IL-7, GM-CSF, G-CSF, and Tpo are more subtle [1,2]. The double knock-out mice have also been found to be defective in TEL/Jak2-dependent leukemogenesis [1].

A Promising Future

STATs, which were first identified as IFN-dependent transcription factors, are now known to transduce vital signals for all ~50 hematopoietins (see Table I). Although the basic outline for these JAK-STAT signaling cascades has been established, much work remains to be done in understanding how this pathway is regulated and how it mediates its potent biological effects. Future developments in STAT regulation are likely to include further insight into STAT modifications and signal decay. Likewise, studies on the wide variety of biological responses mediated by STATs are likely to include more precise and comprehensive identification of STAT target genes, as well as a better understanding as to how STATs interact with other transcription factors to achieve desired gene regulation.

The most compelling evidence that STATs are modified at residues in addition to the activation tyrosine comes from work on serine phosphorylation, which appears to enhance transcriptional activity of several STATs [34]. Gene targeting studies, which are under way, are likely to provide valuable insight into this potentially important regulatory loop. Data on other modifications, including acetylation, arginine-methylation, ubiquitination, and potentially SUMO-lation,

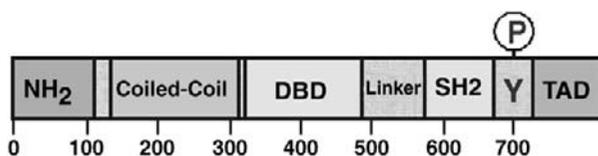

Figure 2 STAT structure. See text for details.

are more limited, but promising avenues for future study [2,4,10,35–37].

Studies on STAT signal decay have made considerable progress with the recent characterization of the SOCS family of counter-regulatory proteins. Several SOCS family members are themselves STAT target genes, thereby establishing a classic negative feedback loop [2,38]. Another important focus has been on phosphatases that dephosphorylate receptors, JAKs and STATs, but many remain to be identified [1,2]. Other studies have suggested that some signal decay is achieved by targeting activated STATs for ubiquitin-dependent degradation [10]. In addition, the role that structural changes play in both the activation and decay of STAT signaling has not been explored, but is likely to be important.

Lastly, there is increasing evidence that STATs interact with other transcription factors to regulate the expression of target genes. Although, a detailed characterization of STAT target gene promoters has not been completed, ongoing studies will provide important insight into the nature of these interactions and how they may regulate acetylation, nucleosome phasing, and stimulation of the basal transcriptional machinery [39,40]. Thus, it seems likely that the coming decade will continue to bring important developments in our understanding of how STATs mediate their potent biological responses.

Introduction

The development and integrity of multicellular organisms depend on the ability of each cell to integrate a wide range of external and internal cues and to trigger appropriate cellular responses. In recent years, Forkhead transcription factors of the FOXO subfamily have emerged as key players in controlling cell cycle progression, cell survival, detoxification, and DNA damage repair by integrating extracellular signals and triggering changes in gene expression. At the organismal level, FOXO transcription factors may play a critical role in the control of life span, a function that may be conserved throughout evolution.

Identification of the FOXO Subfamily of Transcription Factors

Forkhead transcription factors all share a conserved DNA-binding domain (DBD) of 100 amino acids that folds

into a winged helix structure termed the *forkhead box*. The Forkhead family is evolutionarily conserved from yeast to mammals, and in humans comprises around 30 members that have been divided into 17 subgroups (FOX for "Forkhead Box" A to Q) [1]. FOX transcriptional regulators play a wide range of roles during development, from organogenesis (FOXC) [2] to language and speech acquisition (FOXP) [3].

Among the large Forkhead family, the FOXO subgroup first attracted interest because all three members of this family, namely, FOXO1/FKHR, FOXO3a/FKHRL1, and FOXO4/AFX, were identified at the site of chromosomal translocations in human tumors. The chromosomal translocations involving FOXO family members result in the generation of a chimeric protein in which the transactivation domain of FOXOs is fused to the DBD of another transcription factor, creating a dysregulated and highly active transcriptional fusion protein (Table I) [4–7]. These initial findings suggested that, when mutated, FOXO transcription factors might play a role in tumor development.

Table I FOXO Family Members

New name	Old name	Chromosomal translocation	Fusion protein	Type of cancer	Expression
FOXO1	FKHR	2-13 1-13	PAX3-FOXO1 PAX7-FOXO1	Alveolar rhabdomyosarcoma	Ubiquitous but high in ovary
FOXO2 FOXO3a	AF6q21 FKHRL1	6-21	MLL-FOXO3a	Acute myeloblastic leukemia	Ubiquitous but high in brain and kidney
FOXO4	AFX	X-11	MLL-FOXO4	Acute myeloblastic leukemia	Placenta and muscle

Regulation of FOXO Transcription Factors by the PI3K-Akt Pathway

In recent years, a series of genetic and biochemical studies revealed that FOXO family members are regulated by the PI3K-Akt pathway in response to growth factor stimulation. Binding of growth factors or insulin to their receptors triggers the activation of the phosphoinositide kinase (PI3K), which in turn is responsible for the activation of several serine/threonine kinases, including Akt or SGK (serum glucocorticoid inducible kinase) [8]. The PI3K-Akt pathway is conserved in the nematode *Caenorhabditis elegans*, where this pathway is activated by an insulin-like signal [9,10]. Inactivation of the PI3K-Akt pathway during development of the nematode results in arrest in dauer, a long-lived stress-resistant larval stage, whereas in the adult, inactivation of this pathway increases life span by two- to threefold. Strikingly, two independently conducted genetic screens found that all suppressor alleles of the PI3K-Akt pathway mutants map to the gene encoding a FOXO transcription factor termed DAF-16 [11,12]. These results indicate that DAF-16 is a key target of the PI3K-Akt pathway.

Several studies conducted in mammalian cells provide a molecular mechanism that appears to explain the genetic link between the PI3K-Akt pathway and FOXOs. These studies show that the protein kinase Akt phosphorylates all FOXO family members at three key regulatory sites (Thr32, Ser253, and Ser315 for FOXO3a) that are conserved from *C. elegans* to mammals and are part of a perfect consensus sequence for Akt phosphorylation [RXXRXX(S/T)] (Fig. 1) [13-17]. Akt is not the only protein kinase that phosphorylates FOXOs at these regulatory sites; SGK also phosphorylates FOXO3a. However, the efficacy with which SGK and Akt phosphorylate the three phosphorylation sites of FOXO transcription factors. Whereas Thr32 is phosphorylated by both kinases, Akt preferentially phosphorylates Ser253, and SGK favors the phosphorylation of Ser315 [18].

The three FOXO regulatory sites are phosphorylated in response to a wide range of stimuli that activate Akt and SGK, including insulin-like growth factor 1 (IGF-1) [13], insulin [19], interleukin 3 [20], erythropoietin [21], epidermal growth factor [22], and transforming growth factor β [23]. The phosphorylation of FOXO transcription factors by Akt and SGK in response to growth factors triggers a change in the subcellular localization of FOXOs [13,14] (Fig. 2). In the

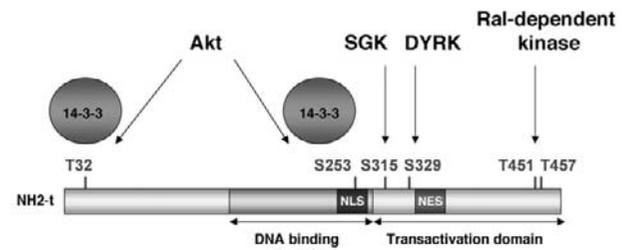

Figure 1 Domain structure and phosphorylation sites within FOXO family members. Numbering for FOXO3a: T32, S253, S315; numbering for FOXO1, S329; numbering for FOXO4: T451, T457.

absence of growth factors, when Akt and SGK are inactive, FOXOs are localized within the nucleus. When cells are exposed to growth factors, the PI3K-Akt/SGK cascade is activated and leads to the relocalization of FOXOs from the nucleus to the cytoplasm, away from FOXO target genes (Fig. 2). Mutation analyses of the three regulatory sites have shown that the phosphorylation of each site contributes to the relocalization of FOXOs from the nucleus to the cytoplasm [18]. This apparent redundancy of phosphorylation may represent a way of modulating the extent of the relocalization of FOXOs to the cytoplasm in different cell types or in response to different combinations of signals.

Other Regulatory Phosphorylation Sites in FOXOs

In addition to the sites on FOXOs that are phosphorylated in response to growth factors, several other sites of phosphorylation have recently been identified (Fig. 1). FOXO4 (AFX) is phosphorylated at two residues, Thr 447 and Thr 451, in response to the activation of the small G protein termed Ral, although the kinase directly responsible for the phosphorylation of these two threonines is not yet known [24]. Phosphorylation of Thr 447 and Thr 451 does not affect the subcellular localization of FOXO4, but instead appears to abolish FOXO4 transcriptional activity. Another study has reported that the MAP kinase family member DYRK catalyzes the phosphorylation of Ser 329 in FOXO1, a residue that is conserved in all FOXO family members [25]. However, the phosphorylation of Ser 329 is not modulated by growth factors and its role in the regulation of FOXO function is still unclear.

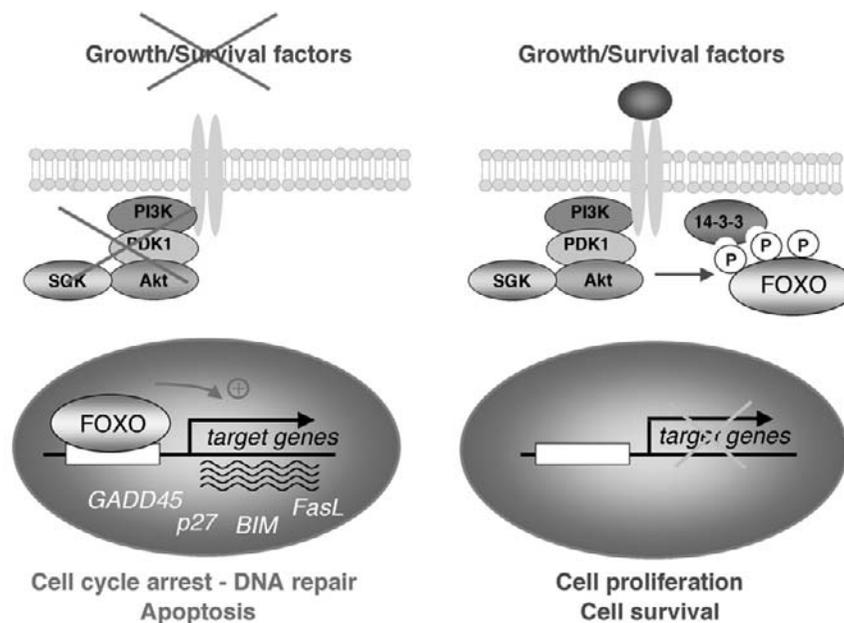

Figure 2 Regulation of FOXO family members by growth and survival factors. In the absence of growth/survival factors, FOXO family members induce the expression of death genes, cell cycle arrest genes or stress response genes, including Fas ligand, the proapoptotic Bcl-2 family member BIM, the cell cycle inhibitor p27KIP1, and the growth arrest and DNA damage response gene GADD45. In the presence of growth/survival factors, the PI3K-Akt/SGK pathway is activated. Akt and SGK promote survival and cell cycle progression by phosphorylating and inhibiting FOXOs.

Mechanism of the Exclusion of FOXOs from the Nucleus in Response to Growth Factor Stimulation

The translocation of FOXOs from the nucleus to the cytoplasm appears to be the primary mechanism of regulation of these transcription factors in response to growth factors. Experiments using leptomycin B, a specific inhibitor of nuclear export, show that the translocation of FOXO transcription factors from the nucleus to the cytoplasm is mediated by a nuclear export signal (NES)-dependent mechanism [14,26,27]. Mutation analyses have revealed that one (FOXO1) or two (FOXO3a) leucine-rich domains in the conserved C-terminal region of FOXOs function as NES [14,26,27] (Fig. 1). Furthermore, the phosphorylated forms of FOXOs have been shown to specifically interact with 14-3-3 proteins [13], which appear to serve as chaperone molecules. The phosphorylation of the first FOXO regulatory site (Thr 32 in FOXO3a) creates a perfect 14-3-3 binding site, and the phosphorylation of the second FOXO regulatory site (Ser 253 in FOXO3a)—although it does not create a canonical 14-3-3 binding site—also participates in 14-3-3 binding [13]. Several mechanisms have been proposed to explain how 14-3-3 binding to FOXOs may promote the relocalization of FOXOs from the nucleus to the cytoplasm. One study suggests that 14-3-3 binding decreases the ability of FOXOs to bind DNA, releasing FOXOs from a nuclear DNA anchor and allowing the relocalization of FOXOs to the cytoplasm [28]. A second study suggests that 14-3-3 binding to FOXOs occurs within the nucleus and actively promotes the nuclear

export of FOXOs, perhaps by inducing a conformational change in FOXOs that would expose the NES and allow interaction with Exportin/Crm1 [27].

Finally 14-3-3 binding to FOXOs has been shown to prevent the nuclear reimport of FOXOs by masking FOXOs' nuclear localization signal (NLS) [26,29], consistent with a known function of 14-3-3 in regulating the subcellular localization of several of its other binding partners. These various mechanisms for regulating the translocation of FOXOs from the nucleus to the cytoplasm may serve as a fail-safe mechanism to ensure a complete sequestration of FOXOs in the cytoplasm, away from FOXO target genes in the nucleus. The sequestration of a transcription factor in the cytoplasm upon phosphorylation is a mechanism by which the activity of a variety of transcriptional regulators, including NFAT [30,31] and the yeast transcription factor Pho4 [32], are controlled, and this mechanism may have been selected by evolution because it represents an efficient way to inhibit the function of a transcription factor.

Transcriptional Activator Properties of FOXOs

Like other FOX family members, FOXOs bind to DNA as a monomer via the Forkhead box, a 100-amino-acid region located in the central part of the molecule (Fig. 1). The NMR structure of the DBD of FOXO4 has been solved and shows that this domain adopts a winged helix structure similar to those of the other FOX family members that have been solved, FOXA (HNF3 γ) and FOXD (Genesis) [33]. The consensus

recognition site for FOXOs on DNA has been determined by three independent groups [34–36] and the core motif, GTAAA(C/T)A, is very similar to that of other Forkhead transcription factors [37]. Both more extensive DNA sequence motifs in promoters of FOXO target genes and regions of FOXO proteins outside the Forkhead box are likely involved in conferring binding specificity to particular FOXO family members under different conditions of stimulation.

When present in the nucleus and bound to DNA, FOXOs act as potent activators of transcription. The phosphorylation of FOXOs by Akt or SGK appears to regulate the transcriptional activity of FOXOs primarily by excluding this transcription factor from the nucleus [13,15,17,18,38]. When the phosphorylated form of FOXOs is artificially maintained within the nucleus either by leptomycin B treatment or by mutation of the FOXOs NES, FOXOs are transcriptionally active even in the presence of growth factors, indicating that the main function of phosphorylation at the growth factor-regulated sites is to relocalize FOXOs to the cytoplasm rather than to directly affect the DNA binding or transcriptional activity of FOXOs [26]. Deletion analyses have revealed that the transactivation domain of FOXOs spans the C-terminal region of the molecule (Fig. 1). In the chimeric protein PAX3-FOXO1 present in some human rhabdomyosarcomas, it is the transactivation domain of FOXO1 that is fused to PAX3 and that confers potent transactivation properties to PAX3 [39]. FOXOs' ability to bind

to the transcriptional coactivator CBP (CREB binding protein) may provide a connection with the basal transcriptional machinery resulting in FOXO/CBP-dependent changes in target gene expression [40].

FOXOs and the Regulation of Apoptosis

The expression of constitutively active mutants of FOXOs triggers cell death in several different cell types, ranging from primary neurons to lymphocytes [13,17,41–43]. FOXO-induced apoptosis is dependent on the ability of FOXOs to bind to DNA and to induce transcription, indicating that a subset of target genes that FOXOs transactivate consists of death genes (Table II). Thus, one way in which Akt and SGK promote cell survival is by sequestering FOXOs away from death genes. Several death genes contain FOXO binding sites in their promoters, including the genes encoding for death cytokines (Fas ligand, TNF α , CD30 ligand) or death cytokine receptors (Fas, TNFR). In particular, FOXO3a has been shown to bind to and activate the promoter for the Fas ligand gene [13,44]. Consistent with the hypothesis that FOXOs regulate Fas ligand transcription, the inactivation of Akt has recently been shown to induce Fas ligand expression [45]. Because FOXO3a-induced apoptosis is reduced in cells in which Fas ligand signaling is blocked [13], Fas ligand may relay in a paracrine manner the effects of FOXOs

Table II FOXO Target Genes

Genes	Function	Gene induction	Binding to promoter	Promoter activation	FOXO binding sites
Cell Death					
Fas ligand	Death cytokine	ICC	EMSA; ChIP	+	+

by triggering cellular pathways that culminate in apoptosis. FOXOs also appear to control the expression of several members of the Bcl-2 family, which are known to play a critical role in the balance between cell survival and cell death. FOXO3a induces the expression of Bim, a potent prodeath Bcl-2 family member, and apoptosis induced by the inactivation of the PI3K-Akt/SGK pathway is reduced in lymphocytes from Bim-deficient mice, indicating that Bim may be an important target gene of FOXO3a that mediates cell death [43,46]. In addition, FOXO4 indirectly down-regulates the expression of the prosurvival Bcl-2 family member Bcl-xL via the induction of a transcriptional repressor Bcl-6 [47]. Thus, one way in which FOXOs appear to trigger apoptosis is by modulating the ratio of prodeath and prosurvival members of the Bcl-2 family.

FOXOs Are Key Regulators of Several Phases of the Cell Cycle

In cycling cells such as fibroblasts, the main effect of the expression of FOXO family members is not apoptosis but cell cycle arrest at the G₁/S boundary [48]. One target gene that mediates FOXO-induced cell cycle arrest is the Cdk inhibitor p27KIP1, which inhibits Cdk2 activity, thereby blocking cell cycle progression at the G₁/S transition [20,48,49] (Table II). FOXOs induce p27 promoter activity, and FOXOs' ability to induce G₁ arrest is diminished in p27-deficient fibroblasts, suggesting that p27 is a critical FOXO target that mediates G₁ arrest [48]. The FOXO-mediated arrest at the G₁/S transition may be a critical first step in the differentiation process because transgenic mice expressing a dominant-negative form of FOXO1 have impaired T-cell differentiation [36].

Endogenous FOXO3a is localized to the nucleus in cells passing through the G₂ phase of the cell cycle, suggesting a role for FOXO3a at the G₂/M checkpoint [50]. Cells in which FOXO3a is activated in the S phase display a delay in their progression through the G₂ phase of the cell cycle. Microarray analyses led to the identification of several FOXO3a target genes that may mediate FOXOs' effect at the G₂/M boundary (Table II) [50]. As with the G₁/S checkpoint, the G₂/M checkpoint is critical in the cellular response to stress, in part to allow time for detoxification and the repair of damaged DNA. Indeed, when active, FOXO3a induces DNA repair [50]. One of the genes that may mediate both FOXO3a-induced arrest at the G₂/M checkpoint and DNA repair is the growth arrest and DNA damage response gene 45 (GADD45) since the GADD45 promoter is activated by FOXO3a, and FOXO3a-induced DNA repair is diminished in GADD45-deficient fibroblasts [50].

FOXO3a also promotes the exit from the M phase and allows the transition to the following G₁ phase [44]. FOXO3a binds to and induces the promoter of two genes that play a critical role in the exit from M phase, cyclin B and polo-like kinase (PLK) (Table II) [44]. These findings are consistent with the observation that the activation of

PI3K and Akt prevents the completion of the M phase [44]. As the two yeast Forkhead transcription factors Fkh1 and Fkh2 have been found to play a role in the completion of M phase [51], this function of FOXOs may have been conserved throughout evolution.

How can FOXOs induce both an arrest in G₁ and G₂ and promote the exit from the M phase? One possible explanation is that during normal cell cycles, FOXOs would be recruited to promoters of genes that promote the exit from the M phase. In contrast, under conditions of stress or absence of growth factors, FOXOs may be recruited to promoters of genes controlling cell cycle arrest at the G₁/S and G₂/M checkpoints, allowing repair of damaged DNA. Thus, FOXOs may integrate different extracellular cues, possibly by undergoing various posttranslational modifications, and elicit the appropriate cell cycle response by triggering a specific array of target genes.

FOXOs in Cancer Development: Potential Tumor Suppressors

In mammals, FOXOs' ability to induce a G₁ arrest, a G₂ delay, DNA repair, and apoptosis makes it an attractive candidate as a tumor suppressor. Loss of FOXO function may lead to a decreased ability to induce cell cycle arrest, leading to tumor development. A decreased ability to repair damaged DNA due to the absence of FOXOs may result in genomic instability. Finally, in the absence of FOXOs, abnormal cells that would normally die may instead survive, resulting in tumor formation. FOXOs' ability to induce cell cycle arrest, DNA repair, and apoptosis are reminiscent of the functions of the tumor suppressor protein p53. In that respect, it is interesting to note that genes such as GADD45, WIP1, and PA26 (Table II) that are induced in response to FOXOs have also been found to be regulated by p53 [52–54]. These observations raise the possibility that FOXOs and p53 may under some circumstances function in a cooperative manner.

One further link between the FOXO family and cancer is that all FOXO members had been initially characterized because of their presence at chromosomal breakpoints in cells from human tumors (Table I). However the expression of these human tumor fusion proteins in transgenic mice is not sufficient to promote cancer [55]. This finding suggests that the human tumors may have arisen not only as a result of the chimeric molecules but perhaps also as a consequence of the loss of one FOXO allele. If FOXOs function as tumor suppressors, then the haploinsufficiency of one FOXO family member could be a contributing factor to the development of the tumor.

Role of FOXOs in the Response to Stress and Organismal Aging

All mutants of the nematode that lead to the activation of the FOXO transcription factor DAF-16 are not only long lived but also display resistance to oxidative stress, heat

shock, and UV [9,10,56,57]. This observation suggests that one way in which DAF-16 activity may lead to an increase in organismal life span is by augmenting the resistance of cells to various stresses. In the nematode, expression of the manganese-dependent superoxide dismutase SOD3 is induced when DAF-16 is active [58]. The promoter of SOD3 contains a Forkhead binding site that is in a region conserved across species, suggesting that SOD may be a conserved target of FOXOs that detoxify cells of reactive oxygen species (ROS), thereby conferring resistance to oxidative stress [34]. Another gene that is induced when DAF-16 is active and contains FOXO binding sites in its promoter is the tyrosine kinase receptor OLD-1, which is distantly related to the mammalian PDGF receptor. Expression of OLD-1 increases nematode longevity in part by increasing the resistance to oxidative stress [59].

In mammals, FOXOs induce cell cycle arrest at two critical checkpoints that allow repair of damaged DNA [48,50]. An organism's ability to respond to stress and in particular to induce detoxification and repair damaged DNA, has been shown to correlate with an increased longevity in many organisms [60]. The GADD45 gene, which in part mediates FOXO-induced arrest and DNA repair [50], is up-regulated in old mice [61]. These correlative evidence suggest that this pathway may be up-regulated to protect against oxidative stress produced by metabolism as an organism ages. Thus, by up-regulating a program of gene expression that protects cells against both internal and external cellular stresses, FOXO transcriptional regulators might promote longevity in mammals as well as in *C. elegans*.

Mosaic analyses in *C. elegans* indicate that the longevity phenotype of the nematode mutants that leads to DAF-16 activation is noncell autonomous [62]. In addition, neurons are the cell types that appear to be critical regulators of the aging phenotype in the nematode [63]. These findings, combined with the indications that DAF-16 may protect cells against stress, raise the possibility that a subset of neurons in the central nervous system may represent a "longevity control center" that might be more sensitive than other organs to oxidative stress [63]. It is tempting to speculate that factor(s) released from these neurons would convey the life span signal to the whole organism. It will be interesting to determine if a central neuronal regulator of life span also operates in mammals.

FOXOs and the Regulation of Metabolism in Relation to Organismal Aging

Reduction in nutrient intake consistently correlates with an increase in life span from *C. elegans* to mammals [60]. In the nematode, nutrient deprivation induces the relocalization of the DAF-16 to the nucleus [56], suggesting that one way starvation may result in increased life span is by relocalizing FOXO transcription factors to the nucleus where they may in turn induce target genes that lead to the cellular resistance to stress.

In addition, FOXOs appear to themselves regulate target genes that are involved in the control of metabolism (Table II). FOXO1 induces the expression of glucose-6-phosphatase, a gene that catalyzes the hydrolysis of glucose-6-phosphate into glucose [64,65]. FOXO1 also regulates the gene encoding phosphoenolpyruvate carboxykinase (PEPCK), which mediates the conversion of pyruvate to glucose, although the mechanism by which FOXO1 up-regulates PEPCK expression is probably not via direct binding of FOXO1 to the promoter of the PEPCK gene [66,67]. The regulation of glucose metabolism by FOXOs may be one indirect mechanism by which FOXOs increase organismal longevity. Indeed, switching the cell metabolism toward glucose production and away from the oxidative phosphorylation at the mitochondria may decrease the production of ROS by this organelle. Thus, FOXOs may extend organismal life span both by decreasing the production of ROS and by increasing detoxification and repair of DNA damage caused by ROS.

Conclusion

A series of recent studies have shown that FOXO transcription factors are regulated in a conserved manner throughout evolution by the PI3K-Akt pathway. In mammalian cells, FOXOs' functions include cell cycle regulation at various key checkpoints, apoptosis, repair of damaged DNA, and the regulation of glucose metabolism. How can the same transcription factor induce such a range of biological responses, responses that appear in some cases even to be antagonistic? Depending on their posttranslational modifications or interaction with protein partners, FOXOs may be recruited to particular subsets of promoters. It is possible that FOXOs may act as rheostats depending on the stress level: In low stress conditions, FOXOs may promote cell cycle arrest and DNA repair, whereas in high levels of stress, FOXOs may induce apoptosis. This graded response to stress stimuli would protect cells from damage, but also facilitate the elimination of terminally damaged cells. The result would be a suppression of tumor formation or an increase in the life span of the organism.

Understanding the molecular mechanisms that generate specificity among the FOXO family members will help to define the role of this family in various cellular responses. In addition, the generation of mice models in which FOXO family members are either inactivated or constitutively activated will help to uncover the respective contribution of the FOXO family members to tumor development and the control of life span in mammals.

Acknowledgments

We thank members of the Greenberg lab, in particular S. R. Datta, S. E. Ross, and A. J. Shaywitz, for their helpful comments on the manuscript. This work was supported by a Senior Scholars Award from the Ellison Foundation, NIH grant PO1-HD24926, and Mental Retardation Research Center grant NIHP30-HD18655 (MEG). AB was supported by a Goldenson Berenberg Fellowship. MEG acknowledges the generous contribution of the FM Kirby Foundation to the Division of Neuroscience.

Multiple Signaling Routes to Histone Phosphorylation

Claudia Crosio and Paolo Sassone-Corsi

Institut de Génétique et de Biologie Moléculaire et Cellulaire Strasbourg, France

Introduction

The eukaryotic genome is organized in a nucleoprotein structure that enables essential biological processes such as regulation of transcription, DNA repair, apoptosis, and cell division [1–3]. A number of remodeling events lead to dynamic changes in the architecture of chromatin. These appear to be prerequisite steps to evolve from a condensed to a decondensed state, and vice versa, each state being coupled to specific cellular functions. Various mechanisms have been implicated in inducing modifications in chromatin structure, some involving the active participation of ATP-dependent remodeling factors such as Swi/Snf and NURF [4–7]; others implicate enzymatic activities that elicit a number of histone modifications, including acetylation, methylation, and phosphorylation. In the past years evidence has accumulated indicating that these covalent modifications occur on histones H2A, H2B, H3, and H4, all assembled with DNA to form nucleosomes, and on H1, the linker histone. In this chapter, we focus on histone phosphorylation and the influence that phosphorylation may have on other modifications.

Although the nucleosome is a highly compacted structure [8], the N-terminal regions, or tails, of the histones are exposed [9]. Indeed, the N-terminal tails of core histones are not essential for maintaining the integrity of nucleosomes since removal of these tails by trypsin treatment does not diminish nucleosome stability [10,11]. Instead, histone tails are thought to confer secondary and more flexible contacts with DNA that allow for dynamic changes in the accessibility of the underlying genome. In addition, the disposition of the tails renders these domains accessible to modifications that could reversibly modulate chromatin structure [12]. The concept that chromatin modifications had to be reversible in nature

was already implicit in some important early observations. For example, specific lysine residues were found to be acetylated and/or methylated on the histone H3 tail [13], and it was proposed that acetylation was a hallmark of active chromatin [14,15]. The cAMP-dependent kinase PKA was found to phosphorylate at least *in vitro* various chromatin substrates [16], and phosphorylation of H3 was thought to promote interactions with other chromatinic proteins [17]. In recent years fundamental advances have been made in the identification and characterization of histone modifications. These have pushed forward a unifying concept: the presence of a *histone code*, established by distinct combinations of histone modifications that can then be translated into different nuclear responses and dictate a particular biological outcome [18]. This model is strongly supported by experimental evidence indicating that posttranslational modifications are involved in gene-specific regulation [19]. Whether histone modifications modulate chromatin structure directly, by altering the contacts between histones and DNA, or indirectly, by presenting a special surface for interaction with other regulatory proteins, is still a subject of investigation.

Histone phosphorylation has been associated with extensive alteration of chromatin structure, and phosphorylation of the five individual histones has been shown. Although we focus here primarily on the role of histone phosphorylation, it is important to note that the central concepts are also applicable to other covalent modifications known to influence histone structure and function.

Histone Phosphorylation and Gene Activation

Phosphorylation of histones occurs by serine-threonine kinases at specific sites on the N-terminal tails. With the

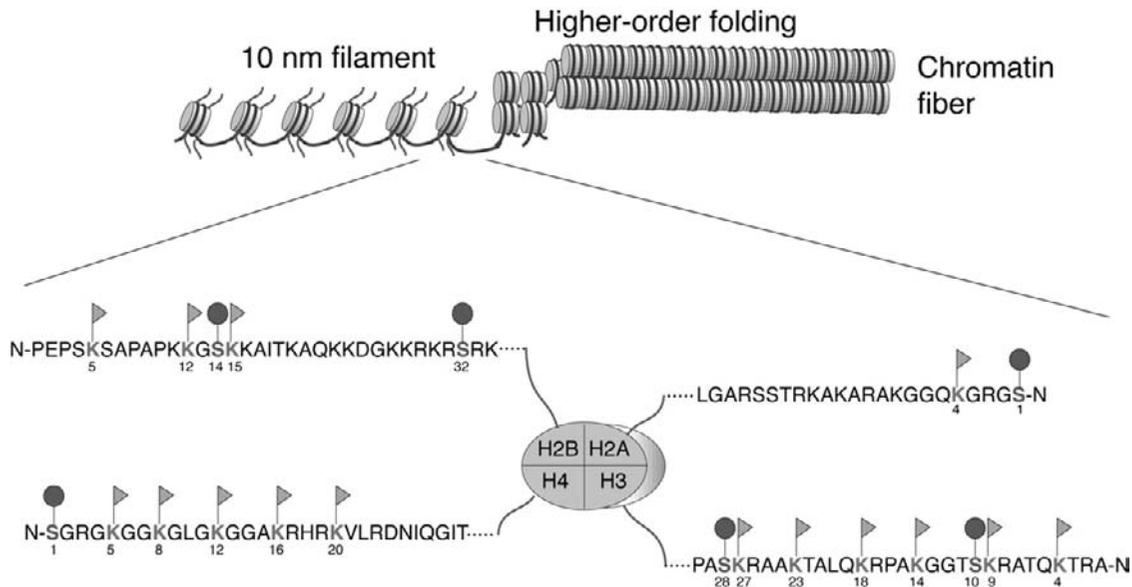

Figure 1 Chromatin organization and amino-terminal tails of core histones. Simplified representation of general chromatin organization. Histone tails (represented in fuchsia) are likely to be exposed or extended outward from chromatin fibers. The amino acid sequence of the N-terminal tails of the four human core histones is represented: red dots indicate known phosphorylation sites; whereas green flags are acetylation sites.

exception of H2A, where only one site has been demonstrated, for each histone tail there are two phosphoacceptor sites: histone H2A is phosphorylated on Ser18, H2B on Ser14 and Ser32, H3 on Ser10 and Ser28, and H4 on Ser1 and Ser18. Strikingly, the distance between phosphoacceptor sites is conserved among all histones: It is always 18 residues (Fig. 1). The significance of this constant spacing is unclear, but further supports the above-mentioned hypothesis of the histone code. Of all of these modifications, the best characterized is phosphorylation of H3 on Ser10 (also because of the very successful generation of phosphospecific antibodies directed to the site [20]).

The Remarkable Case of Histone H3

Since the first description of histone H3 phosphorylation upon mitogenic stimulation of quiescent fibroblasts [21], significant evidence has contributed to establishing a direct link between this posttranslational modification and gene activation. In fact, in a variety of cellular systems, it has clearly been shown that a given stimulation causes a rapid and transient induction in Ser10 phosphorylation, with kinetics that are reminiscent of the transcriptional induction of immediate-early genes (IEGs). Importantly, only a subset of histone H3 molecules becomes phosphorylated upon mitogenic stimulation [22], generating a speckled pattern of phospho-H3 immunostaining in the nucleus. The possibility that these speckles correspond to physical sites of active transcription in fascinating. This hypothesis seems supported by chromatin-immunoprecipitation (ChIP) assays demonstrating that the induced expression of a number of IEGs is associated with Ser10 transient phosphorylation [23]. Table I summarizes

the described cases of Ser10 H3 transient phosphorylation induced by various treatments and through different signaling pathways.

Although most of our knowledge of histone modifications is based on studies in cell culture systems, an important challenge is to reach a deeper understanding of the role that chromatin modifications play *in vivo* in physiological systems. We have observed that chromatin remodeling occurs in the vertebrate nervous system in response to a photic stimulation in neurons that constitute the mammalian circadian clock (SCN, suprachiasmatic nucleus) and after GABAergic stimulation in the supraoptic nucleus (SON) [24].

In most of the cellular systems analyzed, phosphorylation of Ser10 H3 involves the ERK/MAPK and p38 cascades, as shown by drug sensitivity studies (Fig. 2). The MAPK-activated RSK-2 (ribosomal S6-kinase) kinase has been identified as a candidate for EGF-induced H3 phosphorylation [25]. Interestingly, RSK-2 is also involved in EGF-induced CREB phosphorylation and *c-fos* expression in fibroblasts [26], establishing a direct link between signaling to chromatin and induction of IEGs. Also MSK-1 (mitogen- and stress-activated kinase-1) appears to function as H3 kinase at the same Ser10 site [23,27]. Both MAP and SAP kinase pathways can activate MSK-1; therefore, it is likely that different signaling pathways converge on a single kinase to phosphorylate serine 10 of histone H3. Salvador and colleagues [28], on the other hand, have described Ser10 H3 phosphorylation upon stimulation with follicle-stimulating hormone (FSH) in rat ovarian granulosa cells. FSH-stimulated H3 phosphorylation seems correlated with cAMP-dependent protein kinase A (PKA) activation. More recently the first Ser10 histone H3 kinase complex from *Saccharomyces cerevisiae* was

Table I Association of Phosphorylated Histone H3 with Promoters of IEGs in Response to Various Stimuli^a

^aChIP assays were performed on different cell types stimulated in various ways, using an antibody that recognizes histone H3 when phosphorylated on serine 10.

purified and identified as the catalytic subunit of Snf1. The Snf1/AMPK kinase phosphorylated Ser10 H3 to enhance the transcription of the INO1 and ACT1 genes [29].

Interestingly, all of the above-mentioned kinases belong to the AGC branch of cyclic nucleotide-regulated protein kinase, underscoring their fundamental role in transducing the signal to the nucleosomes. However, how one single class of kinases activated by separate pathways can elicit different responses remains to be clarified.

Coupling Acetylation and Phosphorylation

How phosphorylation at Ser10 of H3 affects gene expression is unclear. One possibility could be that—similar to what has been proposed for histone acetylation—the addition of negatively charged phosphate groups to the H3 tail may disrupt electrostatic interactions with the negatively charged DNA backbone, thereby increasing the accessibility of nuclear factors to underlying regulatory promoter elements. Another important observation concerns studies that have shown that H3 phosphorylation and acetylation may be coupled in response to EGF stimulation [30–32]. Indeed, nucleosomes containing phosphorylated and acetylated H3 are preferentially associated with the EGF-activated genes, suggesting that both modifications may operate in concert to elicit induced transcription. Kinetics studies suggest that H3 phosphorylation precedes acetylation in the formation of multiply modified H3 [31].

A mechanistic link between the enzymatic reactions of phosphorylation and acetylation is suggested by the fact that

various coactivators involved in signaling-dependent activation of early response genes act as histone acetyltransferases (HATs) and display strong preferences for H3 phosphorylated at serine 10 as substrate [29,31]. Therefore, it appears that a significant interplay exists between the different modifications occurring on the same histone tail.

As mentioned earlier, mitogen-induced H3 phosphorylation is involved in the regulation of only a selected set of genes, hinting at the existence of a highly regulated mechanism that targets the H3 kinase (and probably acetyltransferase) to the appropriate gene loci. These notions indicated that coupling of phosphorylation and acetylation at the level of the histone substrates could possibly be paralleled by a physical and functional interplay of the respective effectors, kinases, and acetylases. At least one case has been described that supports this view and concerns the coactivator CBP (CREB-binding protein), which has HAT activity [33]. In quiescent cells, CBP and RSK-2 proteins are found associated in a complex with low kinase and HAT activities. In serum-starved cells the basal phosphorylation levels of two RSK-2 substrates, CREB and histone H3, are also low. Upon EGF mitogenic stimulation, and consequent activation by phosphorylation of RSK-2 at Ser227, CBP and RSK-2 dissociate. Thus, in contrast to the well-characterized CREB–CBP interaction, where association requires CREB phosphorylation at Ser133, formation of the RSK-2–CBP complex is efficient only when RSK-2 is not phosphorylated. The dissociation results in increased Ser133 CREB and Ser10 H3 phosphorylation. Indeed, following the dissociation, RSK-2 becomes available to phosphorylate CREB in response to EGF. At the same time, CBP

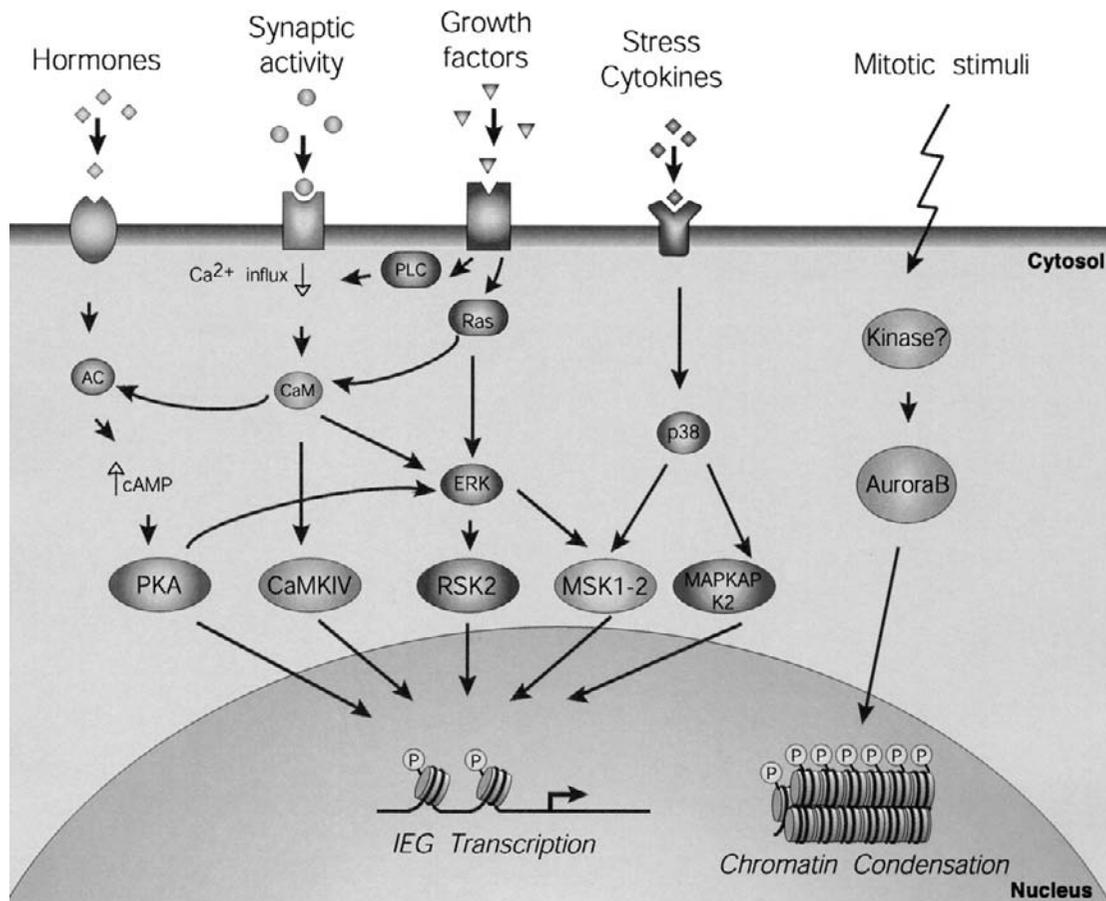

Figure 2 Duality of histone H3 phosphorylation in mammalian cells. A rapid and transient phosphorylation of histone H3 molecules, located in the nucleosomes of IEG promoters, is achieved after activation of different signaling pathways, upon stimulation of cells with hormones, cytokines, growth factors, or UV light. During mitosis, yet ill-defined cell cycle signals induce a robust histone H3 phosphorylation, which is likely to trigger the chromosome condensation process.

becomes available to interact with the newly phosphorylated CREB. The dynamics of this tripartite regulation fits well the kinetics of early gene transcriptional activation [33].

Histone Phosphorylation and DNA Repair

In addition to transcription regulation, histone phosphorylation is also linked to other cellular processes. For example, several reports have shown that following exposure to various agents that cause double-strand DNA breaks, the histone H2A.X, one of the H2A variants, is rapidly phosphorylated at its C-terminal tail, at serine 139 in mammalian cells [34,35], and at serine 129 in yeast [36]. The number of H2A.X molecules becoming phosphorylated is directly proportional to the amount of double breaks induced and it spans the megabase of DNA around the lesion [34]. H2A.X phosphorylation is not limited to repair of DNA breaks in somatic cells, but it is involved in a number of programmed genomic rearrangements, including recombination in lymphocytes [37,38] and germ cells [39].

Recently mice lacking H2AX have been generated [40]. Mutant mice show pleiotropic phenotypes, including radiation

sensitivity, growth retardation, immune deficiency, and male infertility. Those defects seem to be associated with chromosomal instability, repair defects, and impaired recruitment of many DNA repair factors to irradiation-induced foci, implying that H2AX is critical for facilitating the assembly of specific DNA repair complexes on damaged DNA.

Members of the phosphatidylinositol-3-OH kinase-related kinase (PIKK) family have been largely implicated in the response of mammalian cells to double-strand breaks [41], thus making them ideal candidates for the kinase responsible for H2A.X phosphorylation. Although PIKK family members are able to phosphorylate H2A.X *in vitro* and inhibition of PIKK kinase activity prior to double-strand break abolished H2A.X phosphorylation, repair-deficient cells still display normal phosphorylation of H2A.X, indicating functional redundancy with other as yet ill-defined kinases [42].

Histone Phosphorylation and Apoptosis

Chromatin condensation is a morphological hallmark of apoptosis and although commonly used as an indicator of

apoptosis, its biochemical basis remains unclear. Different lines of evidence indicate that histone phosphorylation occurs during programmed cell death, but at present there is little evidence of a mechanistic involvement of histone modification in triggering apoptosis in mammalian cells.

Using different mammalian cell lines and a wide range of apoptosis-inducing agents, H2A.X and H2B have been shown to be phosphorylated during apoptosis at, respectively, serine 139 and serine 32 [35,43]. These phosphorylation events initiate around the time of nucleosomal DNA fragmentation at early stages of apoptosis and seem to be dependent on activation of caspases, suggesting that caspase-induced pathways result in phosphorylation of multiple histone species.

More controversial are the data concerning the phosphorylation of histones H3 and H1 during apoptosis. Phosphorylation of histone H3 at serine 10 and histone H1 was observed upon treatment of rat thymocytes with phosphatase inhibitors [44]. Analogous results were obtained using gliotoxin, but not dexamethasone or thapsigargin [45]. In contrast to these findings, others have reported that apoptotic cells show no H1 and H3 phosphorylation [43,46]. The reasons for this discrepancy are not clear.

An analysis by mass spectrometry of posttranslational modification of histones after induction of apoptosis by okadaic acid (OA), a serine-threonine phosphatase inhibitor, has provided some important information [47]. Indeed, very soon (1 hr) after OA treatment, H2A becomes phosphorylated, whereas H3 and H4 phosphorylation became evident only 18 hr after treatment. Interestingly, H4 phosphorylation was not observed when apoptosis was induced by UV light, indicating that this event it is unlikely to occur as a secondary effect of apoptosis. Therefore, the identities of the residues phosphorylated in association with apoptosis—and the roles these modifications may play—still need to be clarified.

Histone Phosphorylation and Mitosis

Phosphorylation of histones H1 and H3 has been linked to mitotic chromatin condensation [48]. H1 hyperphosphorylation is temporally associated with entry into mitosis and depends on Cdc2 kinase activity [49]. Recent studies, however, have revealed that chromatin condensation can occur without H1 hyperphosphorylation [50] or even without H1 itself [51]. Therefore, the biological significance of mitotic H1 hyperphosphorylation remains undefined.

Histone H3 is phosphorylated during mitosis on at least two serine residues located on the N-terminal tail, serines 10 and 28 (for a review, see [52]). Thus, at least for Ser10, two distinct natures characterize its phosphorylation—one linked to gene transcription and local chromatin decondensation (see earlier section), and one coupled to condensation during mitosis. Whereas mitogenically induced Ser10 phosphorylation concerns only a subset of H3 molecules—generating the nuclear speckles mentioned previously—mitotic phosphorylation appears to involve all H3 proteins.

Phosphorylation at serine 10 begins in early G₂ in the pericentromeric heterochromatin of each chromosome and by metaphase spreads throughout all chromosomes, whereas phosphorylation on serine 28 starts to be evident only in early mitosis. The different timing of serine 10 and 28 phosphorylation suggests that diverse signaling routes are utilized for the two sites. Mitotic H3 phosphorylation at serine 10 is required for proper execution of mitosis in *Tetrahymena*, whereas *S. cerevisiae* strains bearing serine>alanine mutations at positions 10 and/or 28 in the H3 tail have no apparent mitotic defects [53]. This may indicate redundancy with modifications on other histones in some specific systems versus others. It has been proposed that H2B phosphorylation can compensate for loss of serine 10 of histone H3 in yeast [53,54]. Moreover, there is evidence for histone H2B as essential for chromosome condensation in *Xenopus* egg extracts [55]. Indeed, phosphorylation on H3 serine 10 appears to be involved in the initiation, but the maintenance, of mammalian chromosome condensation [56]. Additional evidence indicates that the N-terminal tail of histone H3 is able to stably bind its mitotic kinase, inhibiting chromatin condensation in an *in vitro* system [57]. In this study an H3 kinase activity could be sequestered *in vitro* by nucleosome complexes in peptide competition experiments.

Solid evidence has accumulated showing that in yeast, *Drosophila*, nematodes, *Xenopus* and mammals [53,58–61] members of the Aurora kinase family are responsible for mitotic phosphorylation at Ser 10 of histone H3. These findings have not been confirmed in *Aspergillus*, where NIMA was found to act as H3 kinase [62].

The role of Aurora kinases in phosphorylating H3 has also been explored by different approaches. RNAi experiments in *Drosophilla* and *Coenirhabditis elegans* indicate that targeting Aurora-B causes a reduction of histone H3 phosphorylation during mitosis [36,49], whereas at least in *C. elegans* Aurora-A does not appear to be implicated [49]. In *Xenopus*, both Aurora-A [59] and Aurora-B [58] were identified as potential histone H3 mitotic kinases. In mammals both Aurora-A and Aurora-B can directly phosphorylate H3 Ser 10 *in vitro* and *in vivo*. However, the spatiotemporal expression of Aurora-A and Aurora-B during the mitotic cell cycle of mammalian cells shows that the two kinases have a mutually exclusive localization: While Aurora-A is present in the centromeres, Aurora-B colocalizes with the phosphorylated form of histone H3. These results strongly implicate Aurora-B as the mitotic kinase for H3 (Fig. 2).

Conclusions

This review focused on a major histone modification, phosphorylation, and on its implication in different cellular process (Fig. 3). Increasing evidence shows that several types of modifications are linked and, in particular, one modification may influence the presence of another nearby modification. This has been demonstrated for acetylation at Ser10 and phosphorylation at Lys14 on the histone H3 tail

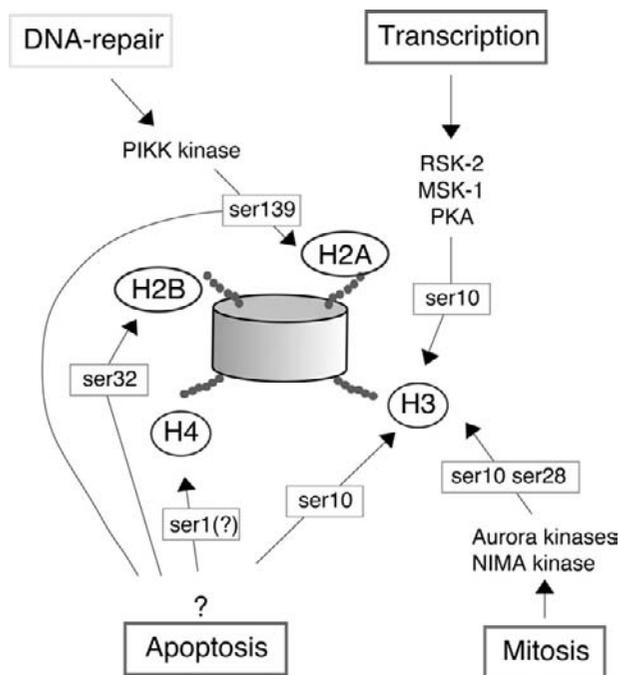

Figure 3 Multiple cellular processes are associated with histone phosphorylation. DNA damage induces phosphorylation in H2A-Ser132; transcription, upon mitogenic stimulation, on H3-Ser10; mitosis on H3-Ser10 and Ser28; apoptosis, depending on the stimulus used, on H4-Ser1, H3-Ser10, H2B-Ser32, and H2A-Ser32. The putative kinases responsible for these phosphorylation events are indicated.

(see earlier section) and for phosphorylation at Ser10 and methylation at Lys9 on the same tail [63]. While the first pair modifications have been coupled to activation of gene expression, increasing evidence indicates that methylation at Lys9 results in decreased Ser10 phosphorylation and is thereby responsible for silencing. In addition to an intrahistone *histone code* operating on the individual tail of a specific histone, interhistone codes may exist. An area of exciting research will be to study the influence that phosphorylation on a specific histone may have on the phosphorylation (or other modifications) on a tail of a different histone. The large number of possible signaling pathways involved in the many physiological scenarios discussed here (Fig. 2) provides a picture in which an impressive number of combinatorial possibilities exist. How can the same histone modification be linked with such a wide range of “chromatin states”? We favor a scenario in which histone tails function to integrate upstream signals that, in turn, impart regulatable dynamic changes to the chromatin structure of localized regions of the genome. Mitogenically induced phosphorylation of histone H3 on serine 10 is thought to cause a reduction of the overall positive charge, inducing a local decondensation. This decondensation event may be crucial for the binding of regulatory factors that could induce either chromatin condensation or transcription. Gaining further understanding of the molecules involved in signaling to chromatin and how phosphorylation can be targeted in a determined locus will be an exciting area for future investigations.

Note added in proofs

The field of histone modifications is moving very fast and some additional references need to be pointed out.

- Two recent reports indicate that phosphorylation of histone H3 at Ser10 may occur in response to cytokine stimulation by IKK- α . This event was coupled to activation of NF- κ B-responsive genes: Y. Yamamoto, U. N. Verma, S. Prajapati, Y. T. Kwak, and R. B. Gaynor, *Nature* **423**, 655 (2003); V. Anest, J. L. Hanson, P. C. Cogswell, K. A. Steinbrecher, B. D. Strahl, and A. S. Baldwin, *Nature* **423**, 659 (2003).
- An histone modification event that is uniquely associated with apoptotic chromatin, in species ranging from frogs to humans, is H2B phosphorylation at position Ser14. The kinase involved in this event was recently identified as Mst1 (mammalian sterile twenty), whose function is directly regulated by caspase-3. W. L. Cheung, K. Ajiro, K. Samejima, M. Kloc, P. Cheung, C. A. Mizzen, A. Beeser, L. D. Etkin, J. Chernoff, W. C. Earnshaw, and C. D. Allis, *Cell* **113**, 507 (2003).
- A case of regulation of inter-histone modifications has been reported, suggestive that several others may exist, all that will contribute to the ‘histone code’. Sun, Z. W. and Allis, C. D. *Nature* **418**, 104 (2002).

Multigene Family of Transcription Factor AP-1

Peter Angel

*Division of Signal Transduction and Growth Control,
Deutsches Krebsforschungszentrum,
Heidelberg, Germany*

Introduction

Much of our present knowledge about transcription factors comes from the discovery and study of the activating protein 1 (AP-1) family. AP-1 (and the transcription factor NF κ B) has served to detect one of the decisive DNA-binding motifs required for regulation of both basal and inducible transcription of several genes containing AP-1 sites (5'-TGAG/CTCA-3'), also known as TPA-responsive elements (TRE), by a variety of extracellular signals. These include growth factors; cytokines; tumor promoters, such as the phorbol ester TPA (12-*O*-tetradecanoyl-phorbol-13-acetate) and carcinogens; UV irradiation; and other DNA-damaging agents. The core of the AP-1 family of transcription factors is formed by heterodimeric associations of members of the Jun (c-Jun, JunB, and JunD), Fos (with c-Fos, FosB, Fra-1, and Fra-2), and ATF (ATFa, ATF-2, and ATF-3) proteins. In this chapter we summarize our current knowledge of (1) the characteristic structural features of AP-1 subunits, (2) mechanisms involved in modulation of AP-1 activity, and (3) function of AP-1 proteins in cellular processes using mouse genetics.

General Structure of AP-1 Subunits

According to their function in controlling gene expression, AP-1 subunits are composed of a region responsible for binding to a specific DNA recognition sequence (DNA-binding domain, DBD) and a second region that is required for transcriptional activation (transactivation domain) once the protein is bound to DNA. The DBD of AP-1 proteins, also

known as the *bZip* region, can be divided into two evolutionarily conserved, independently acting domains: the *basic domain* ("b"), which is rich in basic amino acids and responsible for contacting the DNA, and the *leucine zipper* ("Zip") region, which is characterized by heptad repeats of leucines forming a coiled-coil structure that is responsible for dimerization (Fig. 1). In addition to the leucines, other hydrophobic and charged amino acid residues within the leucine zipper region are responsible for specificity and stability of homo- or heterodimer formation between the various Jun, Fos, or ATF proteins. Jun-Jun and Jun-Fos dimers preferentially bind to the 7-base-pair (bp) motif 5'-TGAG/CTCA-3' whereas Jun-ATF dimers or ATF homodimers prefer to bind to a related, 8-bp consensus sequence 5'-TTACCTCA-3' [1,2]. Therefore, the characteristics of the AP-1 DNA-binding sites in promoters as well as the abundance of the individual AP-1 subunits are decisive for the selection of target genes.

In addition to the "classical" AP-1 members (Jun, Fos, ATFs), other bZip proteins have been discovered, some of which can heterodimerize with the core AP-1 subunits, for example, Maf, Maf-related proteins, Nrl, Smads, and Jun-dimerizing partners (JDs). Binding of AP-1 to DNA may also support binding of other transcription factors to adjacent or overlapping binding sites (composite elements) to allow the formation of "quaternary" complexes. The interaction of NF-AT and Ets proteins with the interleukin 2 (IL-2) and collagenase promoters, respectively, may serve as paradigms for this type of protein-protein interaction [3,4]. AP-1 has been reported to associate with NF κ B [5], the glucocorticoid receptor [6,7], and hypoxia-inducible factor 1 α [8].

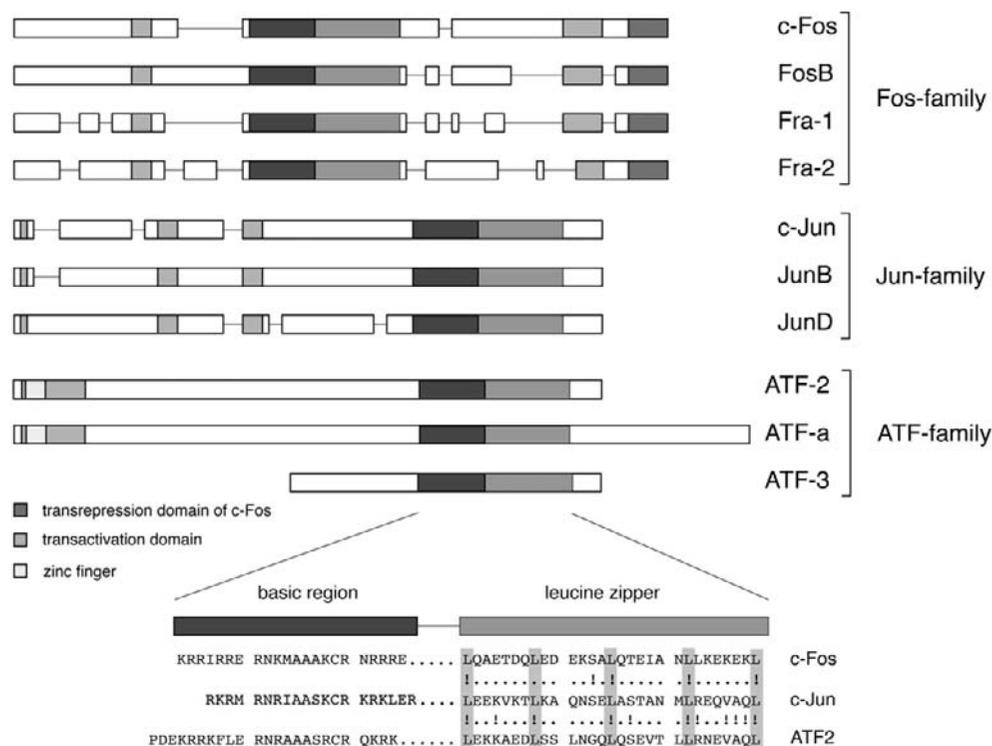

Figure 1 Structural organization of the Fos, Jun, and ATF proteins. Conserved regions are highlighted. On the bottom, the amino acid sequences of the bZip region of c-Fos, c-Jun, and ATF-2, the most extensively analyzed members of the Fos, Jun, and ATF protein families, are shown.

In contrast to the well-defined DBDs of AP-1 proteins, the structural properties of the domains mediating transcriptional activation of target genes (transactivation domain, TAD) are still ill defined. The TAD (and its function) can be transferred to heterologous DBDs that do not require heterodimerization, for example, to that of the yeast transcription factor GAL4. Such chimeric proteins are permitted to identify critical amino acids in TADs and to recognize that the TADs of individual Jun, Fos, and ATF proteins differ in their transactivation potential. Under specific circumstances, some subunits, such as Fra-1 or JunB, may even act as repressors of AP-1 activity by competitive binding to AP-1 sites, or by forming inactive heterodimers with other AP-1 members [9–11].

Transcriptional and Posttranslational Control of AP-1 Activity

Given the aspects of subunit heterogeneity, their dimerization and DNA binding rules, the control of transcription of AP-1 subunit genes, the time course of subunit synthesis, and the regulation of their function become important issues for an evaluation of the effect on target gene expression and on dependent phenotypes. The *jun* and *fos* genes represent the prototype of the class of “immediate-early” genes that are characterized by a rapid and transient activation of transcription in response to changes of environmental conditions, such as growth factors, cytokines, tumor promoters, carcinogens,

and expression of certain oncogenes [12]. Because this type of regulation of promoter activity is also observed in the absence of ongoing protein synthesis, it is generally accepted that preexisting factors, whose activity gets altered by changes in posttranslational modification (in particular phosphorylation), are responsible for the regulation of promoter activity.

Most of our current knowledge on transcriptional activation of immediate early genes is derived from studies on deletion and point mutations the *c-fos* and *c-jun* promoters, combined with *in vitro* and *in vivo* footprinting analyses. The serum-response element (SRE), which is bound by a ternary complex containing the transcription factors p67-SRF and p62-TCF, is required for the majority of extracellular stimuli including growth factors and phorbol esters. Changes in the phosphorylation pattern of SRF and, predominantly, TCF regulate *c-fos* promoter activity by these stimuli. Other elements include the c-AMP response element (CRE) and the Sis-inducible enhancer (SIE), which is recognized by the STAT group of transcription factors. The very transient induction of promoter activity by extracellular stimuli can be explained by increased phosphatase activity counteracting the activity of upstream protein kinases, which address promoter-associated transcription factors. On the other hand, negative autoregulation by newly synthesized c-Fos may also play an important role [13,14].

Analysis of deletion mutants of the *c-jun* promoter identified two AP-1-like binding sites (Jun1, Jun2), which are recognized by Jun/ATF heterodimers or ATF homodimers

and which are involved in transcriptional regulation in response to the majority of extracellular stimuli affecting *c-jun* transcription. In response to G-protein-coupled receptor activation, EGF, and other growth factors, the AP-1 sites and an additional element in the *c-jun* promoter recognized by MEF2 proteins cooperate in transcriptional control of the *c-jun* gene. Similar to the factors binding to the *c-fos* promoter, the activity of factors binding to the *c-jun* promoter is regulated by their phosphorylation status (for review, see [12,15]).

The most critical members of the class of protein kinases regulating the activity of AP-1 in response to extracellular stimuli are mitogen-activated protein kinases (MAPKs). Depending on the type of stimuli, these proline-directed kinases can be dissected into three subgroups: the extracellular signal-regulated kinases (Erk-1, Erk-2), which are robustly activated by growth factors and phorbol esters, but only weakly activated by cytokines and cellular stress-inducing stimuli (UV irradiation, chemical carcinogens). In contrast Jun-N-terminal kinases (JNK-1, -2, -3), also known as stress-activated kinases (SAPKs), and a structurally related class, p38 MAP kinases (p38 α , - β , - γ), are strongly activated by cytokines and environmental stress, but are poorly activated by growth factors and phorbol ester. These kinases themselves are under strict control of upstream kinases and phosphatases, which are part of individual signaling pathways initiated by specific classes of extra- and intracellular stimuli (growth factors, DNA-damaging agents, oncoproteins). This network, which exhibits a high degree of evolutionary conservation between yeast, *Drosophila*, and mammals is, however, far too complex to be discussed in greater detail in this review (for in-depth information on this subject, see [16,17]).

Erk1 and Erk2 mediate mitogen-stimulated phosphorylation of sites in the TAD of TCF proteins, resulting in enhanced transactivation activity. The JNK/SAPKs were originally identified by their ability to specifically phosphorylate c-Jun at two positive regulatory sites (Ser-63 and Ser-73) residing within the TAD [18]. Hyperphosphorylation of both sites is observed in response to stress stimuli and oncoproteins. The JNKs can also phosphorylate and stimulate the transcriptional activity of ATF-2 [19,20]. The same positive sites on ATF-2 also serve as phosphoacceptor sites for p38, whereas Ser-63 and -73 of c-Jun are not affected by p38 [21,22]. Most likely, hyperphosphorylation of Jun, ATF, and TCF proteins results in a conformational change of the TAD, allowing more efficient interaction with cofactors, which facilitate and stabilize the connection with the RNA polymerase II/initiation complex to enhance transcription of target genes. Interestingly, in addition to enhanced transactivation, hyperphosphorylation of the TAD of c-Jun also regulates the stability of c-Jun by reducing ubiquitin-dependent degradation of c-Jun [23,24]. Similarly, phosphorylation-dependent changes in the half-life of c-Fos have been observed [25].

The DBD of c-Jun is phosphorylated at multiple sites by GSK-3 and/or casein kinase II (CK-II), which results in reduced DNA binding. In response to extracellular stimuli, such as UV, phosphorylation is reduced, thus enhancing DNA binding [26,27]. The mechanism (reduced activity of

the kinase or enhanced activity of a phosphatase) has not yet been definitively clarified.

In addition to phosphorylation, other posttranslational modifications regulate AP-1 activity [28]. Oxidation of a cysteine in the basic region inhibits DNA binding and there is pronounced regulation of nuclear localization. Moreover, positive and negative interference of other cellular proteins with AP-1 activity (in addition to the protein kinases and coactivators described earlier) has been identified in, for example, Maf, MyoD, YY1, STAT, SMADs and Menin [2]. The mutual interference between AP-1 and nuclear receptors, particularly the glucocorticoid receptor (GR), which may be involved in the anti-inflammatory and immunosuppressive activities of glucocorticoids, represents the most extensively analyzed example for this type of cross-talk [6,7].

Function of Mammalian AP-1 Subunits: Lessons from Loss-of-Function Approaches in Mice

As described earlier, AP-1 activity is enhanced when cells are stimulated by agents that promote cell proliferation. Moreover, oncogenic versions of c-Jun and c-Fos have been isolated from retroviruses, and various membrane-associated or cytoplasmic oncogenes (Ras, Src, Raf) permanently up-regulate AP-1 abundance as part of their transforming capacity, suggesting that AP-1 members play an important role in cell proliferation and transformation [28–30]. Initial evidence for this assumption has been obtained by overexpression studies in mice and various cell lines, by blocking AP-1 activity either through expression of a transdominant-negative c-Jun mutants, by expression of antisense sequences, or by microinjection of Jun- and Fos-specific antibodies. Under these conditions cell cycle progression was disturbed and the efficiency of oncoprotein-mediated cell transformation was reduced. However, already in these systems, different lines of evidence, including variations in the expression pattern and phosphorylation status of AP-1 members during the cell cycle [31,32], suggested that the members of the Jun and Fos families play specific roles during these processes or may even antagonize each other. The generation of mice harboring genetic disruption and/or transgenic overexpression, as well as the availability of genetically defined mutant cells isolated from these animals, represents a major breakthrough in our understanding of the regulatory functions of AP-1 subunits. The distinct phenotypes of the individual knock-out mice (Table I), induced by defects in cells or tissues in which the subunit was particularly important or where its absence became first limiting, support the notion that AP-1 dimers exhibit specific and independent functions *in vivo*. As a general rule derived from all studies, the AP-1 subunits must be present in a complementary and coordinated manner to ensure proper development or physiology of the organism.

Loss of c-Jun, JunB, or Fra-1 results in embryonic lethality. c-Jun null embryos die at midgestation (E12.5 to 13.5 [33,34]) due to dysregulation in liver and heart development [35]. Mice carrying a conditional (floxed) allele of *c-jun*, survive

Table I

AP-1 member	Knockout/Knockin mice	References
c-Jun	Complete loss: embryonic lethal E13, hepatic failure, heart defect Liver-specific loss: viable, impaired postnatal hepatocyte proliferation and liver regeneration	33–35 36
<i>junB</i> in <i>c-jun</i> locus	Rescue of <i>c-jun</i> ^{-/-} phenotype by JunB (cardiac and liver defects); rescue of c-Jun/c-Fos-, but not c-Jun/ATF-dependent gene expression	39
JunB	Embryonic lethal E8.5-E10.0, placentation defect, Adult: myeloproliferative disease	40, 41
JunD	Viable, reduced postnatal growth, age-dependent defects in male reproductive function	50
c-Fos	Viable, defective bone remodelling, osteopetrosis, light-induced apoptosis of photoreceptors	43–46
<i>fra-1</i> in <i>c-fos</i> locus	Dose-dependent rescue of the <i>c-fos</i> ^{-/-} phenotype (bone remodeling, photoreceptor apoptosis)	48
FosB	Viable, nurturing defect	50
Fra-1	Embryonic lethal E10, placenta defect	42
ATF-2	Hypomorph allele: decreased postnatal viability and growth, defects in endochondral ossification, ataxic gait, hyperactivity, decreased hearing, decreased number of Purkinje cells Complete loss: Neonatal lethality, Meconium aspiration syndrome, decreased cytotrophoblasts in placenta	53 54

the specific postnatal gene inactivation in hepatocytes but show an impaired liver regeneration in response to partial hepatectomy [36].

Knock-in mice expressing a mutated c-Jun protein in which the N-terminal phosphorylation sites at serines 63 and 73 were changed into alanines (JunAA mice) developed normally and were viable and fertile as adults [37]. However, these JunAA mice are resistant to epileptic seizures and neuronal apoptosis induced by the excitatory amino acid kainate, and JunAA fibroblasts show proliferation defects as well as apoptotic defects on stress induction [37]. By contrast, T-cell proliferation and differentiation appear to be independent of c-Jun N-terminal phosphorylation, whereas efficient T-cell-receptor-induced thymocyte apoptosis is affected [38].

Interestingly, the JunB protein, when expressed at sufficient levels, can substitute at least for some of c-Jun's functions. Knock-in mice having the *c-jun* allele replaced by *junB* undergo normal embryogenesis and develop a normal liver and heart. Analysis of indicative marker genes showed that expression of genes regulated by Jun/Fos, but not those regulated by Jun/ATF dimers, are restored, thereby rescuing c-Jun-dependent defects *in vivo* as well as in primary fibroblasts and fetal hepatoblasts *in vitro* [39].

Targeted inactivation of JunB resulted also in embryonic lethality between days 8.5 and 10.0 due to multiple defects in extraembryonic tissues [40]. Affected cell types/organs comprise the trophoblast giant cells, yolk sac mesentelium and placental labyrinth. The observed phenotypes in JunB null embryos appear to result from severe impairment of general vasculogenic and angiogenic processes resulting in a failure to establish proper vascular interactions with the maternal circulation. The lethal phenotype can be rescued by an ubiquitously expressed *junB* transgene [40]. In such rescued mice lacking JunB in the myeloid lineage, a transplantable myeloproliferative disease resembling human chronic myeloid leukemia was observed [41].

Fra-1 is so far the only Fos member essential for embryonic development. Fra-1 null embryos died between E10.0 and 10.5 [42]. Similar to JunB null embryos, the vascularization of the placental labyrinth was impaired, suggesting that JunB and Fra-1, possibly as heterodimers, address common target genes responsible for the generation of a functional placental labyrinth. Fra-1-deficient embryos can be rescued from embryonic death by JunB overexpression [42].

Fos-null mice are viable and fertile but suffer from severe osteopetrosis caused by lack of mature osteoclasts [43–45]. Moreover, light-induced apoptosis of photoreceptors is lost in c-Fos-deficient mice [46]. The c-Fos-dependent functions in bone cells can be substituted by Fra-1, when the *fos* locus is deleted and replaced by the *fosl1* gene encoding Fra-1. *Fosl1* is a transcriptional target of c-Fos during osteoclast differentiation [47] and can fully complement for the lack of c-Fos in bone development in a gene-dosage-dependent manner. However, Fra-1 is not able to induce expression of c-Fos target genes in fibroblasts derived from the knock-in mice [48], suggesting the need for additional tissue-specific factors.

The embryonic development of FosB-deficient mice is normal [49]. Adult *fosB*^{-/-} females, however, nurture insufficiently [50]. JunD-null mice develop normally but postnatal growth of homozygous *junD*^{-/-} animals is reduced. JunD null males develop age-dependent defects in reproduction, hormone imbalance, and impaired spermatogenesis [51]. ATF-2 mutant mice that express small amounts of a mutant ATF-2 protein (ATF-2^{m/m}; [52]) are chondrodysplastic and neurologically abnormal [53], which might be explained by reduced expression of cyclin D1 in chondrocytes [52]. ATF-2-null mutant mice die shortly after birth and suffer from a disease resembling a severe type of human meconium aspiration syndrome [54].

Knock-out mice represent an excellent system for the isolation of genetically defined mutant cells. Primary and

immortalized fibroblasts can be isolated from almost all mice lacking individual AP-1 members. Analysis of these cells revealed that c-Jun acts as positive regulator of the cell cycle by suppressing p53 and, indirectly, the p53 target gene p21 [55]. Moreover, loss of c-Jun results in reduced cyclin D1 activity [56]. JunB, on the other hand, serves as a negative regulator of cell cycle progression by induction of the cyclin-CDK inhibitor p16 and down-regulation of c-Jun and cyclin D1 expression [32,57]. Data from fibroblasts lacking both c-Fos and FosB established a critical role for these AP-1 subunits in cyclin D expression [58]. Moreover, fibroblasts lacking either *c-jun* or *c-fos* cannot be transformed by oncogenes, such as Ras and Src [59]. JunD-deficient fibroblasts exhibit specific alterations in cell proliferation, depending on p53 and p19-ARF expression [60].

In addition to these cell-autonomous effects, critical and antagonistic functions of c-Jun and JunB in cell proliferation and differentiation *in trans* were observed. In an *in vitro* skin equivalent model system (which mimics many characteristics of cutaneous wound healing) composed of primary keratinocytes and mouse embryonic fibroblasts of wild-type, *c-jun*^{-/-} or *junB*^{-/-} genotype, c-Jun- and JunB-dependent expression of critical cytokines (KGF, GM-CSF) could be demonstrated [61,62].

As described before, AP-1 activity is greatly enhanced upon treatment of cells with genotoxic agents, implying that AP-1 target genes are involved in the cellular "stress response," such as DNA repair, induction of survival functions, or initiation of the apoptotic program. Indeed, analysis of fibroblasts from mice lacking specific AP-1 subunits provided experimental proof for this assumption. Fibroblasts lacking c-Fos are hypersensitive to UV irradiation when compared to wild-type cells, which is caused by a higher rate of apoptosis. In contrast to cells lacking c-Fos, the ability of *c-jun*-deficient fibroblasts to undergo apoptosis is greatly reduced. In contrast, overexpression of c-Jun induced apoptosis in fibroblasts. Reduced apoptosis in response to genotoxic agents was also observed in mice lacking members of the JNK/SAPK family of protein kinases, suggesting that c-Jun and ATF proteins are the major substrates of JNK/SAPKs to mediate the cellular stress response [30,63]. There is evidence that JunD participates in an anti-apoptotic pathway [60], whereas JunB appears to be part of a pro-apoptotic pathway, at least in myeloid cells, through negative regulation of anti-apoptotic genes [41]. However, it is important to note that AP-1 members depending on the cell type and extracellular stimuli may be involved in both apoptotic and anti-apoptotic responses. For example, primary liver cell cultures and erythroblasts derived from *c-jun*^{-/-} embryos exhibit increased apoptotic rates. On the other hand, the lack of c-Fos results in the loss of light-induced apoptosis of photoreceptors in retinal degeneration [30]. Obviously, in addition to the abundance of individual AP-1 subunits and other cellular proteins modulating AP-1 activity on the posttranslational level some of the specificity of the function of a given AP-1 subunit is presumably based on the choice of the heterodimeric partner, dictating sequence specificity and, in turn, the subsets of AP-1

target genes to be addressed [64]. A shift in the equilibrium of gene expression of such distinct classes of c-Jun target genes, in conjunction with alterations in c-Jun-independent pathways, will contribute to the decision of the cell to either proliferate, to activate survival factors or to induce the genetic program of cell death in response to extracellular signals.

Despite the fact that AP-1 has been identified more than a decade ago, it still maintains a lot of its mystery. Further research on tissue-specific inactivation of AP-1 members and the identification of subunit-specific target genes may yield an even more complex picture of function and regulation of AP-1 than exists at present.

NF κ B: A Key Integrator of Cell Signaling

**John K. Westwick, Klaus Schwamborn, and
Frank Mercurio**

Signal Research Division, Celgene, San Diego, California

Eukaryotic cells possess a number of distinct signal transduction pathways that couple environmental stimuli to specific changes in gene expression. One such pathway regulates the transcription factor NF κ B, which is known to orchestrate the expression of a diverse array of genes essential in host defense, inflammatory, cell survival, and immune responses. NF κ B is activated by a surprisingly broad array of cellular stimuli [1]. Likewise, NF κ B has been shown to induce the expression of a large functionally diverse array of genes [2]. The seemingly promiscuous nature of NF κ B biology raises the question as to how NF κ B proteins elicit a specific transcriptional program in response to a given environmental challenge. The discovery of several key regulatory proteins within this pathway has provided insight into the mechanism by which the NF κ B achieves specific coupling of these distinct cellular processes. As would be predicted of such a central signaling pathway, aberrant regulation of NF κ B activation has been associated with the pathogenesis of several diseases, including autoimmunity, arthritis, asthma, and cancer [3]. This chapter summarizes the mechanisms of NF κ B regulation and discusses emerging opportunities for target-based therapeutic intervention in various disease settings.

NF κ B was originally identified as a transcription factor required for B-cell-specific gene expression [4]. However, it was quickly recognized that NF κ B activity could be induced in most cell types in response to myriad stimuli, including proinflammatory cytokines, bacterial lipopolysaccharides, viral infection, DNA damage, oxidative stress, and chemotherapeutic agents (Fig. 1) [1]. The classic experiment by Baeuerle and Baltimore, which demonstrated that NF κ B exists in latent form in the cytosol of unstimulated cells and undergoes rapid translocation to the nucleus upon stimulation, set the

stage for what is now the hallmark of NF κ B regulation [5]. This paradigm provides a mechanism for NF κ B to undergo rapid induction in response to cellular stress, resulting in the up-regulation of NF κ B target genes. A wide variety of genes are regulated by NF κ B, including those encoding cytokines, chemokines, adhesion molecules, acute phase proteins, inducible effector enzymes, antimicrobial peptides, adaptive immune response, regulators of apoptosis, and cell proliferation (Fig. 1). Remarkably, specific subsets of NF κ B responsive genes can be activated in a cell- and stimulus-specific fashion. Biochemical and genetic characterization of molecular components that impinge on the NF κ B signaling pathway has greatly facilitated our understanding of this process.

NF κ B exists as a multigene family of proteins that can form stable homo- and heterodimeric complexes that vary in their DNA-binding specificity and transcriptional activation potential. Five proteins belonging to the NF κ B family have been identified in mammalian cells: RelA (p65), c-Rel, RelB, NF κ B1 (p50 and its precursor p105), and NF κ B2 (p52 and its precursor p100) (Fig. 2) [1]. NF κ B/Rel proteins share a highly conserved 300-amino-acid N-terminal Rel homology domain (RHD) responsible for DNA binding, dimerization, and association with the I κ B inhibitory proteins. The prototype NF κ B complex is comprised of p50 and p65, but a variety of NF κ B/Rel-containing dimers are also known to exist. The p50/p65 complex displays strong transcriptional activation, whereas the p50/p50 and p52/p52 homodimers function to repress transcription of NF κ B target genes [1]. Thus, the existence of a multigene family provides one tier of regulation by which the cell can fine-tune NF κ B-mediated gene expression. Moreover, knock-out mice lacking distinct NF κ B subunits display distinct phenotypes, further implicating

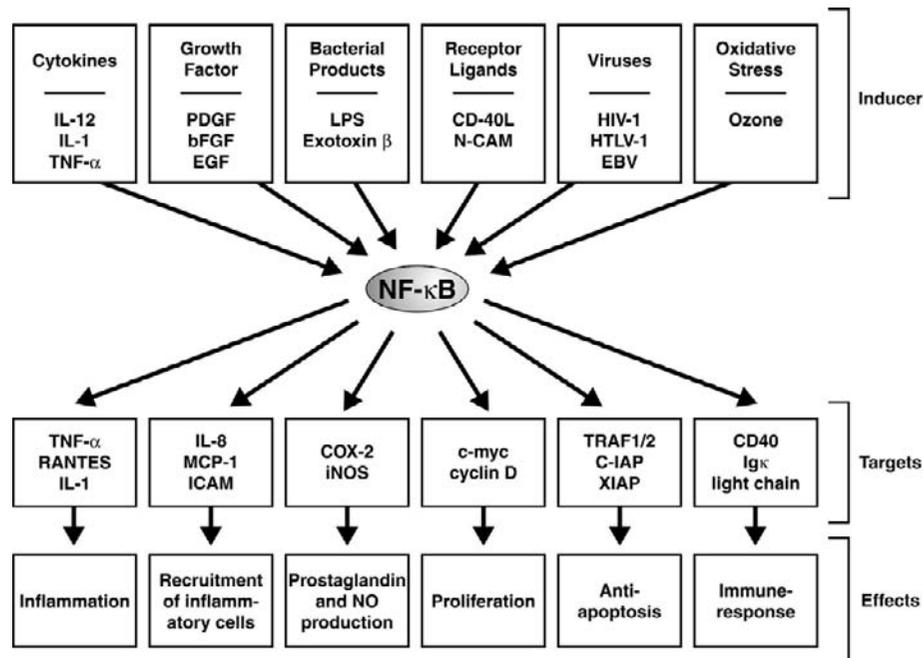

Figure 1 NF κ B plays a central role in gene regulation: Stimulus-dependent activation of NF κ B results in the modulation of specific subsets of NF κ B target genes that are involved in distinct cellular processes. IL, interleukin; TNF, tumor necrosis factor; bFGF, basic fibroblast growth factor; PDGF, platelet-derived growth factor; EGF, epidermal growth factor; LPS, lipopolysaccharide; CD-40L, CD 40 ligand; N-CAM, neural cell adhesion molecule; HIV, human immunodeficiency virus; HTLV, human T-cell leukemia/lymphoma virus; EBV, Epstein-Barr virus; RANTES, regulated on activation, normal T cells expressed and secreted; MCP, monocyte chemoattractant protein; COX-2, cyclooxygenase-2; iNOS, inducible nitric oxide synthetase; TRAF1/2, TNF receptor associated factor; c-IAP, cellular inhibitors of apoptosis protein; XIAP, X-chromosome-linked inhibitor of apoptosis protein.

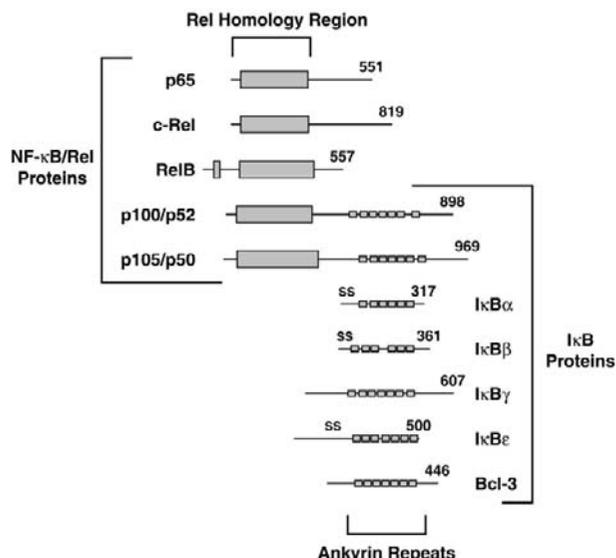

Figure 2 Schematic representation of members of the NF κ B/Rel and I κ B family of proteins. The position of the Rel homology region and the ankyrin repeat domain are indicated in the figure. p100/p52 and p105/p50 Precursor proteins comprise a unique subgroup of proteins that contain both a Rel homology and an ankyrin repeat domain. p100 and p105 Proteins have been shown to function in an I κ B-like capacity. The number of amino acids of each protein is indicated to the right. For RelB, the shaded box N terminal to the Rel homology region represents a putative leucine zipper region.

specific NF κ B dimers as activators of distinct sets of NF κ B target genes [6–10].

NF κ B resides in the cytoplasm in an inactive form by virtue of its association with a class of inhibitory proteins termed I κ Bs. Seven I κ Bs have been identified: I κ B α , I κ B β , I κ B ϵ , I κ B γ , Bcl3, NF κ B1 precursor (p105), and the NF κ B2 precursor (p100) (Fig. 2) [11]. The I κ B family members, having in common ankyrin repeat domains, regulate the subcellular localization, and hence the DNA-binding and transcriptional activity, of NF κ B proteins. The basis for the cytoplasmic localization of the inactive NF κ B:I κ B complex is thought to be due to masking of the nuclear localization signals (NLS) on the NF κ B subunits by the I κ B proteins. Thus, I κ B degradation would lead to unmasking of the NLS, allowing NF κ B to undergo translocation to the nucleus (Fig. 3). The I κ Bs display a preference for specific NF κ B/Rel complexes, which may provide a means to regulate the activation of distinct Rel/NF κ B complexes. Interestingly, NF κ B induces the expression of I κ B α ; the newly synthesized I κ B molecules enter the nucleus and remove NF κ B from DNA [12–14]. The NF κ B:I κ B is then expelled from the nucleus as a result of potent nuclear export signals on I κ B and p65 [15]. The I κ Bs provide yet another tier of regulatory complexity to modulate NF κ B-mediated gene expression.

Activation of NF κ B is achieved primarily through the signal-induced proteolytic degradation of I κ B that is mediated by

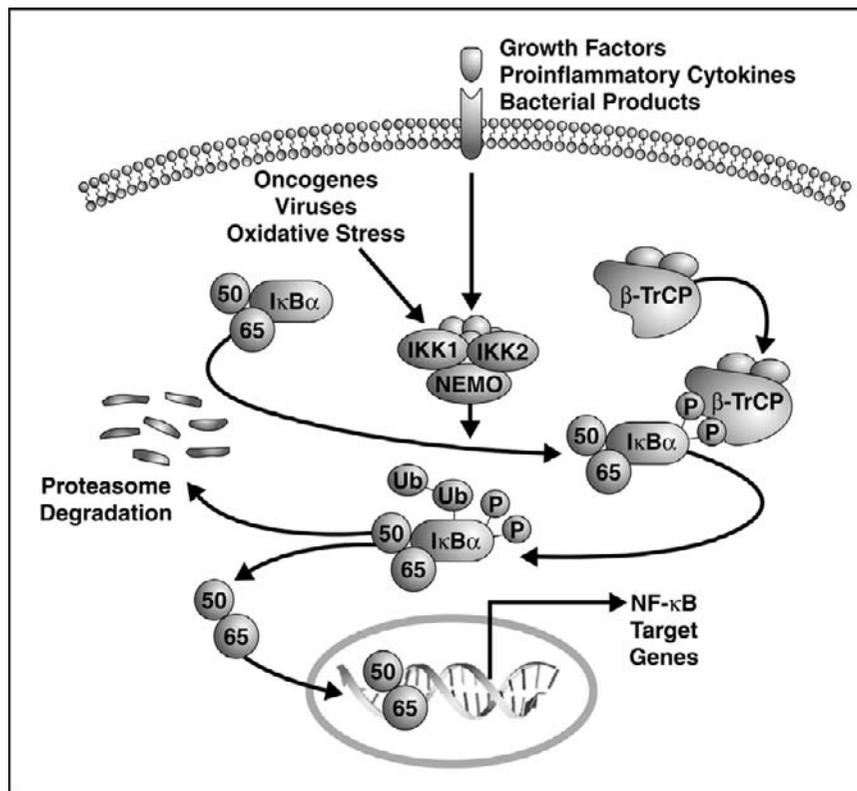

Figure 3 Schematic representation of components of the classical NFκB signal transduction pathway. In response to extracellular signals, the IKK complex becomes activated by a poorly defined series of membrane proximal events. The activated IKK complex phosphorylates (P) IκBα at serines 32 and 36, leading to site-specific ubiquitination (Ub) and degradation by the proteasome. The released NFκB complex (p50/p65) is then free to undergo nuclear translocation and activate transcription of NFκB target genes.

the ubiquitin/proteasome system [2]. The critical event that initiates the degradation of IκB is the stimulus-dependent phosphorylation of IκB at specific N-terminal residues (S32/S36 for IκBα, S19/S23 for IκBβ) [16,17]. Mutation of IκBα at either of these residues was found to block stimulus-dependent IκB phosphorylation, thereby preventing IκB degradation and subsequent activation of NFκB. Phosphorylation of IκB serves as a molecular tag leading to its rapid ubiquitination and subsequent degradation by the proteasome. β-TrCP, an F-box/WD-containing component of the Skp1-Cullin-F-box (SCF) class of E3 ubiquitin ligases, is required for recognition of phosphorylated IκB and recruitment of the degradation machinery [18,19].

Phosphorylation of IκBα on serines 32 and 36 is mediated by IκB kinases (IKKs), whose activity is induced by activators of the NFκB pathway [20–24]. IKK activity exists as large cytoplasmic multisubunit complex (700–900 kDa) containing two kinase subunits, IKK1 (IKKα) and IKK2 (IKKβ), and a regulatory subunit, NEMO (IKKγ, IKKAP1, FIP3) [25–28]. Hence the “core” IKK complex is comprised of IKK1, IKK2, and NEMO. IKK1 and IKK2 are highly homologous kinases, both containing an N-terminal kinase domain and a C-terminal region with two protein interaction motifs, a leucine zipper (LZ), and a helix–loop–helix (HLH) motif. The LZ domain is responsible for dimerization of IKK1 and IKK2 and is

essential for activity of the IKK complex. The IKK1/2 complex associates with NEMO through a short interaction motif located at the very C terminus of either catalytic subunit. Short peptides derived from the interaction motif can be used to disrupt the IKK complex and prevent its activation [29]. NEMO is thought to serve an important regulatory function by connecting the IKK complex to upstream activators through its C terminus, which contains a Zn finger motif (Fig. 4). Further support for the regulatory function of NEMO is found by the observation that NEMO undergoes stimulus-dependent interaction with components of the TNF receptor complex [30]. More recently, a report described two potentially novel components of the IKK complex, namely, Cdc37 and Hsp90 [31]. Apparently, formation of the core IKK complex with Cdc37/Hsp90 is required for TNF-induced activation and recruitment of the core IKK complex from the cytoplasm to the membrane.

Sequence analysis revealed that both IKK1 and IKK2 contain a canonical MAP kinase kinase (MAPKK) activation loop motif. This region contains specific sites whose phosphorylation induces a conformational change that results in kinase activation. Phosphorylation within the activation loop typically occurs through the action of an upstream kinase or through transphosphorylation enabled by regulated proximity between two kinase subunits. IKK2 activation loop mutations,

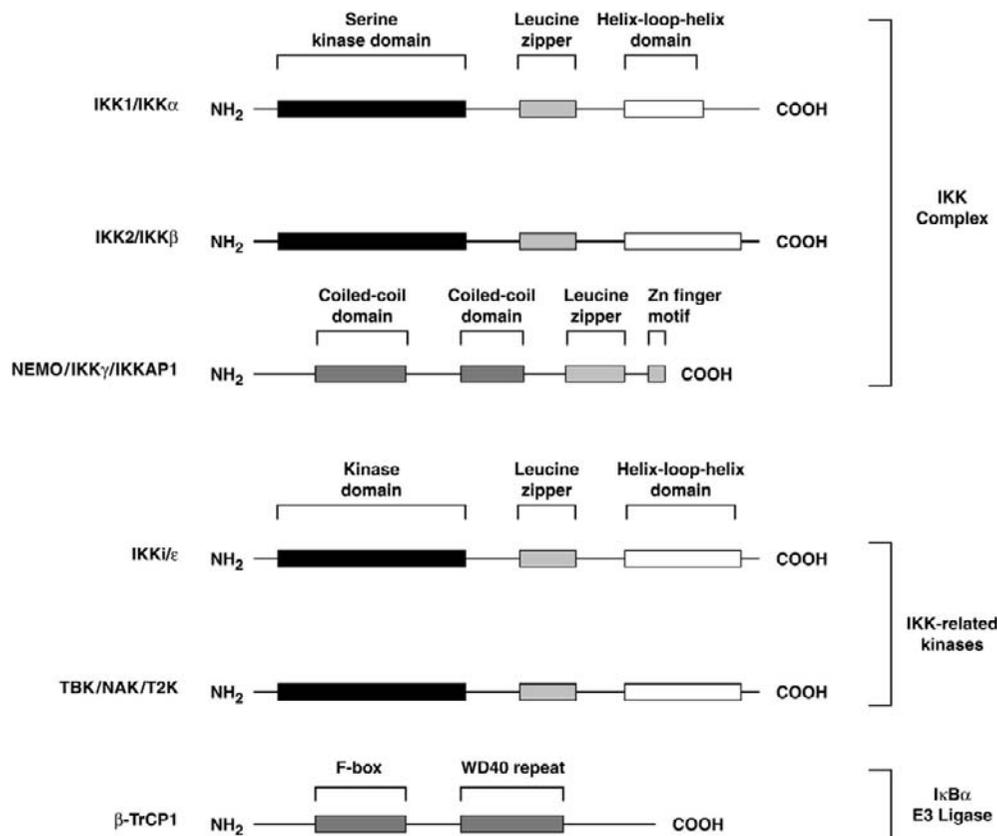

Figure 4 Schematic diagram showing the known subunits of the IKK complex, IKK-related kinases and β -TrCP, the I κ B α E3 ubiquitin ligase. The name(s) of the protein is indicated to the left and the putative structural and functional motifs are indicated on top.

in which serines 177 and 181 were replaced with alanine, render the kinase refractory to stimulus-dependent activation. In contrast, replacement of serine 177 and 181 with glutamic acid, to mimic phosphoserine, yielded a constitutively active kinase, and was capable of inducing NF κ B-mediated gene expression in the absence of cell stimulation [21]. The corresponding mutations in IKK1 did not interfere with NF κ B activation in response to IL-1 or TNF, providing the first data suggesting that IKK2 plays a more prominent role in NF κ B activation in response to proinflammatory cytokines [21,23,24]. Subsequent studies with IKK knock-out mice further validate that IKK2, and not IKK1, is required for NF κ B activation in response to most proinflammatory stimuli [32–35]. The mechanism by which diverse stimuli converge to activate the IKK complex remains unresolved. For example, a number of kinases have been reported to function in the capacity of an IKK kinase, including NIK, IKK ι/ϵ , NAK/T2K/TBK, MEKK1, MEKK3, and Cot/TPL2 [36]. However, with the exception of MEKK3, no effect was observed on either IKK activation or induction of NF κ B DNA-binding activity in mice devoid of these kinases [37].

Biochemical and genetic analyses demonstrate that IKK1 and IKK2 have distinct cellular functions [2]. Disruption of the IKK2 gene results in embryonic lethality due to extensive liver apoptosis [32,34,38]. This phenotype is remarkably similar to that seen previously for RelA $^{-/-}$ mice [39].

Interestingly, IKK2 $^{-/-}$ and RelA-mice could be rescued by ablation of the TNF receptor I gene, which is consistent with the role of NF κ B in preventing TNF-induced hepatocyte apoptosis [34,40]. In addition, IKK2 $^{-/-}$ mouse embryonic fibroblasts were demonstrated to be refractory to activation of NF κ B in response to inducers of NF κ B, including TNF, IL-1, LPS, and dsRNA [34,38]. In contrast, the IKK1 $^{-/-}$ mice were born alive but died within 30 min, and IKK1 $^{-/-}$ -derived mouse embryonic fibroblasts display normal activation of IKK activity and induction of NF κ B DNA binding in response to proinflammatory stimuli. These mice exhibit a plethora of developmental defects, the most striking of which is defective epidermal differentiation [32,33]. Interestingly, IKK1 was found to play a prominent role in regulating keratinocyte differentiation, which is independent from its kinase activity or modulation of NF κ B [32,41].

More recently, a series of eloquent studies revealed a unique function of IKK1 in the lymphoid system [42]. Specifically, lethally irradiated mice that were reconstituted with IKK $^{-/-}$ hematopoietic stem cells displayed a diminution in B-cell maturation, germinal center formation, and antibody production, as well as defective splenic microarchitecture. Interestingly, it was discovered that IKK1 $^{-/-}$ B cells exhibit a specific deficiency in NF κ B2/p100 processing [42]. Moreover, independent studies demonstrated that NIK induces ubiquitin-dependent processing of NF κ B2/p100 [43]. Subsequently, it

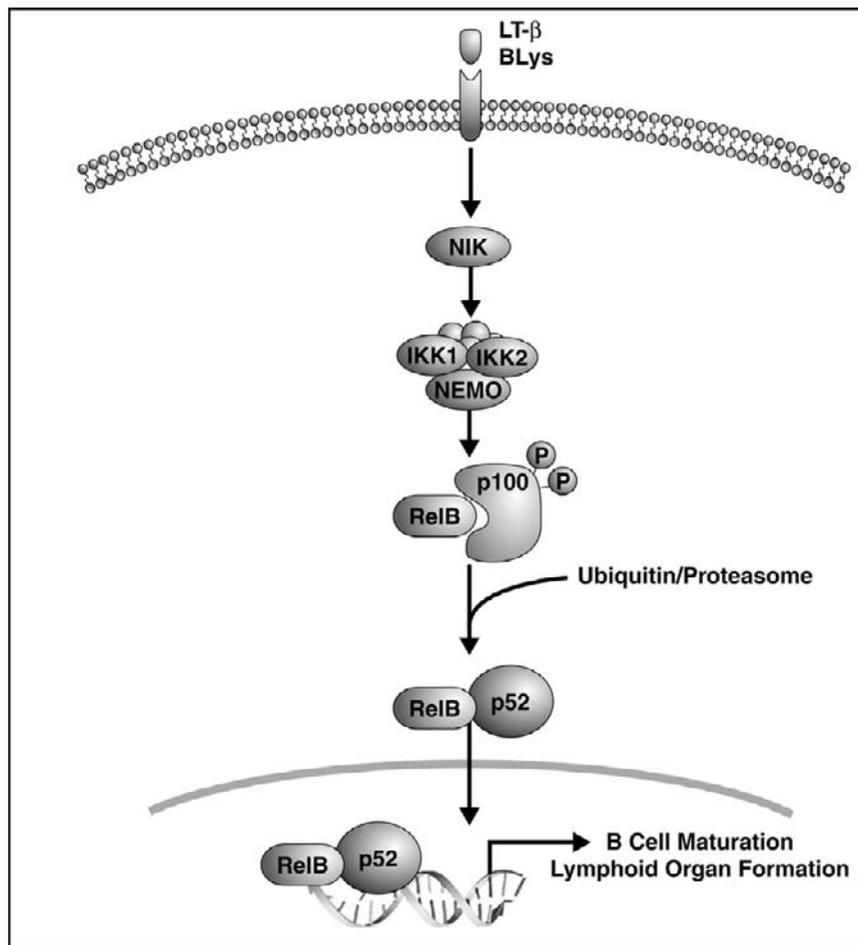

Figure 5 Activation by IKK1 is involved in an alternative NFκB signaling pathway. Select members of the TNF family, namely, lymphotoxin-beta (LT-beta) and B-lymphocyte stimulator (BLyS), activate IKK1 through NIK (NFκB-inducing kinase). Activation of this pathway leads to IKK1-dependent phosphorylation (P) and processing of NFκB2/p100. The active p52:RelB heterodimer undergoes nuclear translocation and regulates specific NFκB target genes involved in B-cell maturation and lymphoid organ formation.

was demonstrated that an inactive variant of IKK1 blocked NIK-induced NFκB2/p100 processing. Together, these studies suggest that NIK-mediated activation of IKK1 may lead to the phosphorylation and ubiquitin-dependent processing of NFκB2/p100 (Fig. 5). NFκB2/p100 is unique in that it contains both a Rel homology domain and an ankyrin domain and, consequently, possesses an intrinsic IκB-like capacity. Thus, enhanced proteolytic removal of the inhibitory C-terminal ankyrin domain will generate increased levels of transcriptionally active p52-containing NFκB complexes, perhaps leading to up-regulation of a specific subset of NFκB target genes. It is quite intriguing that, although IKK1 and IKK2 display high similarity and form stable heterodimers, they modulate distinct signaling pathways with unique biological consequences.

NFκB proteins may play a role in any disease possessing one of the cytokines, including TNF, IFNγ, IL-2, IL-6, IL-8, and IL-12, as a component of their pathophysiology (Fig. 1). The likely diseases for an NFκB-targeted therapeutic strategy may be those with a chronic, unresolved inflammatory

component characterized by constitutively elevated systemic or local cytokine levels. Rheumatoid and osteoarthritis, inflammatory bowel disease, atherosclerosis, diabetes, multiple sclerosis and cachexia, among other conditions, fall into this category. Note that the chronic inhibition of NFκB likely to be necessary to ameliorate these conditions may have unknown repercussions. However, agents such as glucocorticoids inhibit NFκB and are used chronically, so we may predict that long-term NFκB-based therapy can be tolerated [44].

Despite the emphasis on NFκB's role as a regulator of cytokine gene expression and immune function, the initial application of therapeutic modulators of NFκB is likely to be in the field of oncology. If this is indeed the case, it will recapitulate the initial discovery of *v*-Rel proteins as transforming oncogenes nearly 20 years ago [45]. While the genetics of viral Rel proteins were being worked out, simultaneous work was proceeding on the transcription factors (including NFκB) regulating immunoglobulin and MHC genes [4,46]. It was several years before these divergent fields of research coalesced with the discovery that NFκB

proteins are the cellular homologs of v-Rel [47,48]. The functional roles of NF κ B proteins, of course, extend far beyond regulation of immunoglobulins and are quite widely expressed.

More recent information has shown a wide variety of genetic aberrations of these genes in human neoplasms, from overexpression to rearrangement and amplification. The list of such observations is beyond the scope of this review, and details can be found elsewhere [49,50]. Transforming viral proteins of SV40, EBV, adenovirus E1A, and HTLV-1 activate NF κ B [51–54]. Regardless of the mechanism, it is clear that the NF κ B transcription factor is constitutively active in a wide variety of human cancers, including but not limited to colon, gastric, pancreatic, ovarian, hepatocellular, breast, head and neck carcinomas, melanoma, lymphoblastic leukemias, and Hodgkin's disease [55–65].

As described earlier, NF κ B activity is controlled to a large extent by the activity of the IKKs, and this represents the most tractable point for therapeutic intervention. However, other mechanisms for activation and avenues for intervention exist. For example, the DNA-binding and transcriptional activity of NF κ B proteins can be controlled by phosphorylation of multiple sites in both the Rel homology and transactivation domains [66–69]. Well-characterized oncogenes such as Ras, Rac, and Bcr-Abl as well as integrin-activated signals induce NF κ B signaling both through the traditional IKK/I κ B pathway and through direct phosphorylation of the p65 subunit of the transcription factor [66–70]. Recent results with agents selectively inhibiting the IKKs (e.g., PS-1145) or acting in part on other aspects of NF κ B signaling (e.g., proteasome inhibitors, NSAIDs, and thalidomide) are beginning to show great promise in the treatment of various cancers [50,71,72].

From a functional standpoint, NF κ B proteins have been suggested to play a role in cellular transformation via two general routes: direct stimulation of growth (cell cycle dysregulation) and/or inhibition of differentiation, and inhibition of programmed cell death (apoptosis). Both are likely to be involved to varying degrees based on the type of neoplasm, but the protection from apoptosis has garnered the most attention of late and may be the most important aspect from a therapeutic standpoint. With respect to direct cell cycle control, NF κ B has been shown to up-regulate cyclin D1 transcription, a crucial step in the G₁ to S phase cell cycle transition [73,74]. NF κ B activity peaks at multiple points in the mammalian cell cycle, including G₀/G₁, late G₁, and S phase [75]. In support of this concept, analysis of tumor cells treated with selective inhibitors of IKKs reveals a G₂/M phase blockade as well (unpublished observation), suggesting the existence of additional cell cycle targets.

NF κ B activates central players in the programmed cell death pathways, including c-IAP-1 and -2, Bcl-XL, and A1/Bfl-1 [76,77]. NF κ B activation of protective proteins holds the key to the promise of NF κ B inhibitors as chemotherapeutic agents. Of particular importance is the observation that diverse classes of chemotherapeutic agents are potent activators of NF κ B, a response that proceeds at least in part

through the activation of IKKs. Agents known to activate NF κ B include etoposide, CPT-11, and TRAIL [78–80]. *In vitro* and *in vivo* experiments using the I κ B super-repressor, a mutant version of I κ B resistant to stimulus-induced degradation, have shown that inhibition of NF κ B activity acts synergistically with chemotherapeutic agents to decrease tumor cell growth and tumor burden. Small molecule inhibitors of IKK2 show the same effect *in vitro* (unpublished observations). It is likely that agents previously used in chemotherapeutic regimens, such as glucocorticoids and proteasome inhibitors in multiple myeloma, are working at least in part through the inhibition of NF κ B. It is interesting to note that specific inhibitors of IKK are only partially efficacious when used as monotherapy compared to a general proteasome inhibitor, suggesting other proteasome targets contribute to efficacy [71]. On the other hand, the side effect profile of more specific inhibitors is likely to be superior.

The development of potent and selective inhibitors of NF κ B, targeting multiple aspects of NF κ B signal transduction, is imminent. An important task for the near future is to determine the human diseases most likely to be resolved with these agents. Chronic inflammatory conditions are intriguing possibilities, but we must first define the consequences of long-term NF κ B inhibition. The optimal tumor types to approach have not been completely defined, but are likely to include multiple myeloma [71] and one of the many neoplasms with chronically elevated NF κ B (as described earlier). Tumors in which traditional chemotherapy elicits a robust (and presumably activating or protective) induction of NF κ B will be likely targets for combination therapy. The molecular correlates of sensitivity to NF κ B inhibitors, alone or in combination with other agents, need to be identified. For example, tumors lacking the PTEN tumor suppressor may be more sensitive to NF κ B inhibitors [81]. It is clear that continued work on the basic aspects of NF κ B biology is necessary. In concert with development of potent and specific modulators, these efforts have the potential to yield novel therapeutics for a wide variety of human diseases.

Transcriptional Regulation via the cAMP Responsive Activator CREB

Marc Montminy and Keyong Du

*Peptide Biology Laboratories, The Salk Institute for Biological Studies,
La Jolla, California*

The Transcriptional Response to cAMP

Phosphorylation constitutes a predominant mechanism by which transcription factors are regulated in response to extracellular signals. The first phosphorylation-dependent activator to be described, the cAMP responsive factor CREB, belongs to the basic region/leucine zipper family of activators, which includes, among others, jun, fos, and myc [1,2]. CREB binds as a homodimer to a conserved cAMP responsive element (CRE), which often appears as a palindromic sequence (TGACGTCA), but also occurs as a lower affinity half site (TGACG) [3]. Treatment with cAMP agonist stimulates cellular gene expression by promoting phosphorylation of CREB at Ser133 [4]. A characteristic burst-attenuation pattern of transcription ensues, with maximal rates of transcription and Ser133 phosphorylation evident after 30 min [5]. This burst in transcription is rate limited by nuclear entry of a PKA catalytic subunit (PKAc), a passive process that is triggered by liberation of PKAc from the inactive holoenzyme in response to cAMP. The amplitude of target gene expression achieved in response to cAMP agonist is proportional to signal strength [5]. Following induction, target gene expression declines during the next 2–4 hr, reflecting the PP-1 and PP-2a mediated dephosphorylation of CREB [6,7].

Mechanism of Transcriptional Activation via CREB

Although phosphorylation can regulate activators by modulating their nuclear targeting or DNA-binding activities, CREB belongs to a group whose transactivation potential is specifically affected. The CREB transactivation domain

is bipartite, consisting of kinase inducible (KID) and constitutive (Q2) activators that act synergistically in response to cAMP stimulus [8,9]. Following phosphorylation at Ser133, KID promotes transcription via an association with the KIX domain of the histone acetylase (HAT) paralogs CBP and P300 [10–12]. By contrast, Q2 stimulates target gene expression via an interaction with the hTAF_{II}130 component of TFIID [13–15].

The mechanism by which the KID and Q2 domains promote transcription has been studied extensively by *in vitro* transcription analysis on naked DNA and chromatin templates. CREB behaves as a constitutive activator when assayed with crude nuclear extracts on a naked DNA template; and Ser133 phosphorylation has only marginal effects on transcription [15,16]. Indeed, the glutamine-rich Q2 domain is highly active in this context; and reconstitution studies using purified basal transcription factors indicate that Q2 stimulates target gene expression by recruiting TFIID to the promoter [13,17].

By contrast, basal CREB activity is strongly repressed on a chromatin template [18]. And recruitment of P300/CBP in response to Ser133 phosphorylation is required for target gene activation. CBP/P300 HAT activity is essential for transcriptional induction in this setting [19]; disruption of CBP/P300 HAT activity either by mutagenesis or by addition of CBP/P300 specific inhibitor (LysCoA) impairs transcription [18]. Coincident with this observation, promoter bound histones H4 and H3 are inducibly acetylated *in vivo* on CREB target promoters in response to cAMP agonist.

Recruitment of CBP HAT activity to the promoter does not appear sufficient for transcriptional induction, however. CREB polypeptides lacking the Q2 domain are not competent for target gene activation despite wild-type CBP binding

activity in the Ser133 phosphorylated state [18]. These experiments suggest that the activity of the Q2 domain, and more specifically its ability to associate with TFIID, is impaired in the chromatin context under basal conditions. The recruitment of CBP HAT activity to the promoter via association with Ser133 phosphorylated KID may promote target gene expression by disrupting the chromatin imposed barrier to the Q2–TFIID interaction.

A key aspect to this regulatory model is the presence of repressive complexes that inhibit CREB activity under basal conditions. In this regard, histone deacetylases (HDACs) have been shown to repress transcription from a variety of promoters, often by associating with certain activators and blocking recruitment of the transcriptional apparatus. Recent studies suggest that CREB associates with type I HDAC complexes, and these complexes appear important for maintaining low levels of histone acetylation over the promoter [20]. Indeed, treatment with HDAC inhibitors such as butyrate or trichostatin A (TSA) has been found to potentiate target gene expression in part by prolonging Ser133 phosphorylation of CREB during the attenuation phase [21]. The mechanism by which TSA and butyrate potentiate CREB phosphorylation is unclear, but current data suggest that HDACs inhibit CREB activity via an association with Ser/Thr phosphatases.

Signal Discrimination via CREB

Although first characterized as a cAMP-dependent activator, CREB also promotes cellular gene expression in response to a wide range of signals including growth factors, cytokines, UV irradiation, and neuronal depolarization [22]. At least three major intracellular pathways have been implicated in this process: cAMP, MAPK, and calcium. Despite inducing Ser133 phosphorylation with comparable kinetics and stoichiometry, non-cAMP pathways appear far less potent in stimulating target gene expression [3].

Activation of the MAPK pathway in response to growth factors promotes Ser133 phosphorylation of CREB in large part via the mitogen and stress-activated kinase MSK1 [23]. Highly related to pp90RSK, MSK1 and its paralog MSK2 appear to phosphorylate CREB with high efficiency in response to most if not all non-cAMP stimuli [23]. Importantly, CREB phosphorylation in response to non-cAMP stimuli is severely impaired in MSK1/2 null cells [24].

Despite the high stoichiometry of CREB phosphorylation via MSK1 and MSK2, CREB target gene activation via these kinases is much lower than that via PKA. Using a CREB–CBP complex specific antiserum, Wagner and colleagues [25] found that this association was strongly induced in response to cAMP but not other stimuli, suggesting that signal discrimination via CREB reflects the relative ability of CBP to be recruited to the promoter. Using fluorescence resonance energy transfer (FRET), Mayr and colleagues [26] found that relevant interaction domains in CREB and CBP, referred to as KID and KIX, respectively, are sufficient for signal

discrimination in response to cAMP and non-cAMP stimuli. The process of signal discrimination appears to reside in the nucleus; cytoplasmic KID and KIX peptides showed no preference for various stimuli.

Secondary Phosphorylation of CREB: Ser142

The nature of the discriminatory signal remains elusive; but current work has drawn considerable attention to a second phosphorylation site in CREB: Ser142. In earlier studies, Sun and colleagues [27] and Sun and Maurer [28] had observed that the calcium/calmodulin-dependent kinase (CaMKII) strongly induces Ser133 phosphorylation of CREB. But target gene induction via this kinase was blocked due to concomitant phosphorylation of CREB at Ser142. Indeed, mutagenesis of Ser142 to alanine rescued target gene induction by CaMKII, whereas a Ser142Asp substitution, which mimicked Ser142 phosphorylation, reduced CREB activation in response to cAMP.

The solution structure of the KID/KIX complex has provided insight into the mechanism by which Ser142 phosphorylation blocks CREB activity [29,30]. The structure reveals that KID undergoes a random coil-to-helix transition upon binding to KIX. Ser133 appears to nucleate this interaction by forming direct contacts with residues in KIX. Hydrophobic residues lining one face of the inducible helix in KID further stabilize the complex via interactions with a hydrophobic groove in KIX. Remarkably, Ser142 projects into this groove and appears to destabilize the KID–KIX interaction by electrostatic repulsion [30].

Whether Ser142 is phosphorylated *in vivo* and whether this site explains signal discrimination via CREB are somewhat controversial questions. Substitution of Ser142 with alanine does not appear to rescue target gene in response to certain non-cAMP stimuli [26]; and Ser142 phosphorylation is not detectable using two-dimensional tryptic mapping studies on ³²P-labeled cells [31]. Using phosphospecific antisera, however, Kornhauser and colleagues [31] found that Ser142 and Ser143 were indeed phosphorylated in neurons following depolarization in response to KCl or glutamate. Despite their inhibitory effect on the CREB–CBP interaction, Ser142/143 phosphorylation appeared essential, in conjunction with Ser133 phosphorylation, for target gene activation in response to these stimuli. Confirming this notion, Gau and colleagues [32] found that light-induced shifts in locomotion and in CREB target gene activation in the suprachiasmatic nucleus were compromised in Ser142/Ala knock-in mice. In contrast with these findings, Impney and colleagues [33] found that CBP was actually critical for CREB target gene expression in neurons following exposure to glutamate, and that inducible phosphorylation of CBP at Ser301 was important in this process. One clear limitation in the former studies is the absence of data concerning the stoichiometry of Ser142/143 phosphorylation, particularly since phosphorylation at this site is not detectable using standard 2-D tryptic mapping experiments.

Methylation of the KIX Domain

In addition to secondary phosphorylation of KID at Ser142, formation of the KID/KIX complex is also modulated by modification of the KIX domain in CBP. In the process of evaluating the mechanism by which the methyltransferase CARM1 potentiates nuclear hormone receptor activity, Xu and coworkers [34] found unexpectedly that CARM1 blocked target gene activation via CREB in response to cAMP stimulus. Biochemical studies reveal that CARM1 disrupts CREB activity by catalyzing the methylation of CBP at Arg600 within the KIX domain. Indeed, Arg600 was first identified in a genetic screen for mutants in KIX that were unable to bind to phospho (Ser133) CREB *in vitro* [35]. NMR studies reveal that Arg600 does not participate directly in surface interactions with KID; rather, modification of this residue appears to disrupt KIX activity by destabilizing its structure. Thus Arg600 may serve as a methylation-sensitive switch that regulates the ability of CBP to associate with phospho (Ser133) CREB. The development of methylation-specific antisera should reveal under what conditions this switch is activated.

Cooperative Binding with MLL

In addition to covalent modification, CREB–CBP complex formation also appears to be regulated via allosteric mechanisms. In an elegant three-hybrid screen, Ernst and colleagues [36] found that the *Drosophila* trithorax homolog mixed lineage leukemia (MLL) protein stabilized CREB–CBP complex formation following its association with the KIX domain. NMR studies indicate the MLL stabilizes the CREB–CBP complex upon binding to a surface in KIX that is distinct from the CREB binding surface [37]. Whether MLL potentiates CREB activity *in vivo*, however, remains unclear.

The presence of several distinct mechanisms by which CREB–CBP complex formation is modulated suggests that signaling pathways may impose specific constraints on target gene activation by employing a combination of modifications and allosteric regulators. A complete characterization of these modifications will be critical in understanding how CREB has such different effects on cellular activity in response to distinct stimuli.

The NFAT Family: Structure, Regulation, and Biological Functions

Fernando Macian and Anjana Rao

*Center for Blood Research and Department of Pathology,
Harvard Medical School, Boston, Massachusetts*

Introduction

Originally identified as regulators of the immune response in T cells, the NFAT family of transcription factors controls various biological processes in diverse tissues and stages of development. NFAT proteins share a high degree of structural homology with the Rel/NF κ B family of transcription factors. Four calcium-regulated family members, NFAT1–4, mediate gene transcription in response to calcium/calcieneurin signals, while NFAT5 transduces the hypertonic stress response and is also regulated by signals through an integrin receptor and the T-cell receptor. Once activated, NFAT proteins cooperate with other transcriptional factors and induce specific patterns of gene expression that control distinct biological programs. This chapter reviews recent data on NFAT structure and regulation and summarizes some biological functions controlled by NFAT transcription factors.

NFAT is a small but important family of transcription factors originally described in T cells [1–6]. It is now well established that NFAT proteins direct specific biological programs in a variety of cells and tissues. The NFAT family consists of five members. The primordial family member NFAT5 (TonEBP) is found in *Drosophila*, and the genes encoding the four calcium-regulated NFAT proteins, NFAT1–4 (also known as NFATc1–c4), appear to have emerged simultaneously early in the course of vertebrate evolution. The five NFAT proteins are classified into one family based on

the sequence and structural similarity of their DNA-binding domains: the degree of sequence identity is ~60% to 70% when NFAT1–4 are compared among themselves, and ~40% to 50% when NFAT1–4 are compared with NFAT5.

The primordial NFAT family member NFAT5/TonEBP is expressed ubiquitously in mammalian cells and regulates the response to hypertonic stress [4,7]. NFAT5 is also likely to be involved in regulating diverse other biological programs. Genetic analysis in *Drosophila* suggests that NFAT5 plays a role in the Ras signal transduction pathway, and this function may be conserved in evolution [8]. NFAT5 protein levels are increased by antigen receptor stimulation of T cells, suggesting a role for this protein in lymphocyte responses downstream of the TCR [9,10]. NFAT5 is also activated by α 6 β 4 integrin stimulation of carcinoma cells, suggesting a role in tumor metastasis [11].

Except for NFAT2, which is the only family member expressed at a specific stage of development of cardiac valves [12,13], one or more calcium-regulated NFAT proteins are expressed redundantly in many cell types of the embryo and the adult [5,6]. Three structural features are common to all four calcium-regulated NFAT proteins: an N-terminal transactivation domain, a highly phosphorylated regulatory domain that binds and is dephosphorylated by the calcium/calmodulin-regulated phosphatase calcineurin, and a DNA-binding domain that is monomeric in solution, forms dimers on certain κ B-like DNA elements, and interacts with Fos and Jun proteins on “composite” NFAT:AP-1 DNA elements [1–5].

Structure and DNA-Binding

The NFAT family is evolutionarily related to the Rel/NF κ B family [10,14,15]. The level of sequence identity between these two families is marginal (~17%) but the structural similarity is remarkable. The DNA-binding domains of all NFAT and NF κ B/Rel family members have two domains, an N-terminal specificity domain (~180 amino acids) involved in making base-specific DNA contacts, and a C-terminal domain (~100 amino acids) involved in dimer formation [14,16,17]. Together these domains constitute the Rel homology region common to all members of the extended NFAT/NF κ B/Rel family. Comparison of the structures of NFAT5/TonEBP and NF κ B p50 dimers on DNA illustrates the striking structural similarity between the NFAT and NF κ B families [15–17]. The C-terminal domains of NFAT5 and NF κ B p50 utilize a similar interface to form the dimer contacts, but NFAT5 has an additional surface for dimer formation, which involves the N-terminal domain [15–17]. NFAT5 and Rel proteins are stable dimers in the absence of DNA, whereas the calcium-regulated NFAT proteins are monomeric [10,18]. Nevertheless, NFAT1–4 can also form dimers on certain κ B-like sites, a finding now confirmed by crystallography of two NFAT1 dimer–DNA complexes [S. Harrison and L. Chen, personal communication]. An interesting point is that all NFAT proteins, including NFAT5, prefer monomeric binding sites on DNA, whereas Rel proteins bind loosely palindromic DNA elements [19].

Regulation

NFAT1–4

NFAT1–4 proteins are activated by ligand binding to a variety of cell-surface receptors [1–3,5,6]. The common feature of the receptors is their ability to activate phosphatidylinositol-specific phospholipase C (PLC), thereby inducing calcium influx across the plasma membrane. In the immune system, the ability of immunoreceptors (T- and B-cell antigen receptors, Fc ϵ receptors on mast cells, and Fc γ receptors on NK cells and monocytes) to activate NFAT is well documented [1]. Stimulation of immune cells through these receptors activates a cascade of several tyrosine kinases, leading to tyrosine phosphorylation and activation of PLC- γ . In other cell types, NFAT activation has been shown to result from stimulation of G-protein-coupled receptors leading to PLC β activation, or stimulation of receptor tyrosine kinases leading to PLC γ activation. This leads to PIP₂ hydrolysis and generation of IP₃, which by binding to the IP₃ receptor and depleting intracellular endoplasmic reticulum (ER) calcium stores, initiates the process of store-operated calcium entry through the plasma membrane [20,21].

NFAT-dependent gene transcription is exquisitely sensitive to changes in intracellular calcium concentration ($[Ca^{2+}]_i$). Even in the continuous presence of stimulus, $[Ca^{2+}]_i$ levels may oscillate depending on specific parameters of receptor

occupancy and desensitization [20]. $[Ca^{2+}]_i$ levels are thus modulated at two levels—amplitude and oscillation frequency—and NFAT activation is sensitive to both types of modulation [22–24]. This is well illustrated by T cells from two severe combined immunodeficiency patients with a primary defect in store-operated calcium entry [25]. When activated, these cells show a small $[Ca^{2+}]_i$ spike resulting from store depletion, but they lack the ability to sustain increased $[Ca^{2+}]_i$ levels for several hours as observed in wild-type T cells. The brief increase in $[Ca^{2+}]_i$ suffices for transient dephosphorylation and nuclear localization of NFAT, manifested by transcription of a small number of NFAT target genes [25,26]. However, optimal activation of NFAT-dependent genes requires sustained calcium/calcineurin signals [25,26], which are most effectively elicited by slow $[Ca^{2+}]_i$ oscillations or low sustained $[Ca^{2+}]_i$ increases [22–24]. The differing sensitivities of NFAT target genes to intracellular free calcium levels are likely to reflect the multiple configurations of NFAT sites in gene regulatory regions; for instance, the requirement for sustained activation could be either because NFAT itself needs to remain within a transcription complex for many hours, or because formation of a cooperative NFAT:AP-1 complex is important for gene transcription (*de novo* synthesis of Fos proteins is required for optimal AP-1 activation).

Interaction with calcineurin is central to the calcium responsiveness of NFAT1–4. The major calcineurin docking site on NFAT is located at the N terminus of the regulatory domain and has the consensus sequence PxIxIT [27]. Substitution of the PxIxIT sequence of NFAT1 with a higher affinity version obtained by peptide selection increases the basal $[Ca^{2+}]_i$ sensitivity of NFAT [28]. The surface of NFAT–calcineurin interaction is unlikely to be limited to the PxIxIT motif, however; a second interacting region is present at the C terminus of the regulatory domain [29,30]. By mass spectrometric analysis, NFAT1 isolated from resting cells was shown to contain at least 21 phosphoserine residues, of which 14 were located in characteristic conserved sequence motifs in the regulatory domain [31]. Following cell stimulation, 13 of these residues were dephosphorylated by calcineurin. Dephosphorylation of 5 phosphoserines in one of these conserved motifs (SRR-1) sufficed for exposure of a nuclear localization signal in the regulatory domain, while dephosphorylation of all 13 residues was required for masking of a nuclear export sequence, complete nuclear localization, and full transcriptional activity [31]. In NFAT2, dephosphorylation of the conserved SPxx motifs has been correlated with increased DNA binding [32]. It is interesting that the gene for an endogenous calcineurin inhibitor, MCIP1, is itself an NFAT target, implying the existence of a negative feedback loop that down-modulates NFAT activity [33].

When calcium entry is prevented or calcineurin activity is inhibited in stimulated cells, NFAT is rephosphorylated by NFAT kinases and rapidly leaves the nucleus. A variety of constitutive and inducible kinases, including casein kinase 1, casein kinase 2, GSK3, and the MAP kinases p38 and JNK, have been suggested as NFAT kinases ([32,34–40] and reviewed in [3]). Different NFAT proteins can be differentially

regulated, even in a single cell type under identical cell culture or stimulation conditions, a finding most likely explained by differential susceptibility of individual NFAT proteins to signal-activated kinases [41,42].

Mass spectrometric analysis indicated that in stimulated cells, NFAT1 becomes phosphorylated on a serine residue in its transactivation domain [31,43]. It remains to be determined if this modification is necessary for transcriptional function in the context of the full-length protein. Pim1, Cot, and protein kinase C zeta have been suggested as candidate kinases, because when overexpressed, they enhance reporter activity dependent on the NFAT transactivation domain [44–46]. However, as previously suggested in a similar study using calmodulin-dependent kinase II, such enhancement could arise from indirect effects on coactivator function rather than through direct NFAT phosphorylation [43].

NFAT5

The mechanism of NFAT5 regulation is not yet fully understood. In most cell types examined, NFAT5 is present in both the nucleus and the cytoplasm; however, in at least one subline of Jurkat T cells, NFAT5 is cytoplasmic and is translocated to the nucleus following hypertonic stimulation [7,19]. NFAT5 is basally phosphorylated in resting cells and hyperphosphorylated following stimulation [10], but it is not known how (or whether) phosphorylation contributes to its function. The kinases responsible for inducible NFAT5 phosphorylation have not been identified; in particular, NFAT5 does not appear to be regulated by p38, a kinase known to be responsive to osmotic stress (C. Lopez-Rodriguez and A. Rao, unpublished). Dimerization of NFAT5 is required for transcriptional activity; however, hypertonic stress does not regulate dimerization, since NFAT5 is already a dimer in resting cells [10]. Direct binding studies have not provided evidence for interaction of NFAT5 with any of the known I κ Bs, despite the fact that this protein conserves many I κ B-interacting residues common to Rel proteins (C. Lopez-Rodriguez and A. Rao, unpublished). Potentially, the DNA binding or nuclear localization of NFAT5 could be regulated intramolecularly, by masking interactions with other protein domains, in a manner sensitive to phosphorylation. Alternatively, NFAT5 function might be regulated by cooperation with nuclear partner proteins whose expression or function was modulated in a signal-dependent manner.

Transcriptional Functions

All NFAT proteins contain intrinsic transactivation domains, and thus are bona fide transcription factors that can independently induce gene transcription. The large C-terminal region of NFAT5 contains a transactivation domain that functions in reporter assays when fused to the GAL4 DNA-binding domain [10]. By the same criterion, NFAT1 and NFAT4 possess two transactivation domains, at their N and C termini, respectively [47,48]; both are strongly acidic and contain a

DELDF[S/K] sequence that may serve as a docking site for the SAGA histone acetyltransferase complex [49]. Similar motifs are found in the corresponding regions of NFAT3 and the constitutive isoforms of NFAT2. The transactivation domain of NFAT2 has surprisingly been mapped to the beginning of its regulatory domain, overlapping a sequence utilized as the major docking site for calcineurin [50]. Constitutively active NFAT1 and NFAT2, which mimic the corresponding dephosphorylated proteins, have been shown to induce or potentiate target gene expression in resting cells [31,51,52].

NFAT-Fos-Jun cooperation constitutes a major mechanism of NFAT-dependent gene transcription. This subject has been recently reviewed [4] and we will only briefly elaborate on it here. Whereas the residues required for Fos-Jun contact are almost completely conserved in the DNA-binding domains of all four calcium-regulated NFAT proteins [53], they are absent from NFAT5, suggesting that the ability to cooperate with Fos and Jun was a relatively late evolutionary development [19]. NFAT has also been shown to cooperate functionally with many other families of transcription factors including GATA [54,55], MEF2 [56], Maf [57], IRF4 [58], and PPAR γ [59]. Unlike the NFAT:AP-1 interaction, which cannot be detected in solution, these interactions appear to be mediated by direct protein–protein contact and are not cooperative on DNA. In at least one case (the NFAT–GATA interaction), the surface of interaction of these other transcription factors with NFAT is known not to overlap the surface of NFAT:AP-1 interaction; a mutant NFAT1 protein engineered to lack completely the ability to cooperate with AP-1 [60] was as or more effective than wild-type NFAT1 in its ability to synergize functionally with GATA3 in a transient reporter assay in T cells [61].

The shortest isoform of NFAT2 (NFATc/A) is induced in a CsA-sensitive manner by NFAT itself, in a process suggested to constitute a positive autoregulatory loop [62]. This protein is generated through utilization of a distinct inducible promoter that is preferentially coupled to the most proximal polyadenylation site [63]. As a result, NFATc/A lacks the entire C-terminal domain and contains an alternate N-terminal domain that is not highly acidic and lacks the SAGA interaction sequence DELDF[S/K]. It is not clear whether this protein would be transcriptionally active in the absence of partner proteins such as AP-1.

Biological Programs Regulated by NFAT

NFAT1–4

The calcium-regulated NFAT proteins have been implicated in a variety of gene expression programs in diverse cell types and tissues. These include cardiac hypertrophy, slow- and fast-twitch fiber differentiation, cardiac valve development, vascular patterning during embryogenesis, chondrocyte development, and adipose differentiation among others. These developmental and differentiation processes have been recently reviewed and are not discussed further here [5,6].

Cooperation of NFAT proteins with members of the AP-1 family of transcription factors is known to play an important role in the establishment of a productive immune response. Activation of both transcription factors is achieved upon full stimulation of B and T cells through their antigen receptors and costimulatory molecules. Composite sites for NFAT and AP-1 have been described in promoters and enhancers of many cytokine genes [1]. Paradoxically, NFAT without AP-1 induces an unresponsive or tolerant state in lymphocytes [51]. This response is induced in T cells by TCR stimulation that is caused by stimulation through the TCR without engagement of costimulatory receptors. This results in increased $[Ca^{2+}]_i$ levels with minimal MAP kinase or I κ B kinase activation, thereby leading to NFAT activation without appreciable AP-1 or NF κ B activation. Under these conditions NFAT initiates a distinct gene expression profile associated with a profound block in TCR signaling [51]. Anergic T cells are unable to respond to a subsequent complete stimulation by producing IL-2 or initiating a proliferative response. Thus, NFAT proteins play a central role in the control of two opposite aspects of T-cell function by activating two different genetic programs depending on the presence or absence of AP-1 cooperation.

NFAT5

NFAT5 has been shown or suggested to play a role in several cellular responses including the osmoprotective response, the TCR response, Ras signaling, and tumor invasion. It was independently cloned in a yeast one-hybrid system as TonEBP (tonicity element binding protein) [7]. NFAT5 activates a large number of target genes implicated in osmoprotective responses, including those encoding aldose reductase, the betaine transporter, and the inositol transporter [64]. In *Drosophila*, NFAT5 has been implicated in modulating Ras signaling: NFAT5 overexpression affects Ras-1-dependent photoreceptor cell development, suppressing a rough-eye phenotype produced by activated Ras [8]. In carcinoma cells, NFAT5 activity is induced in response to α 6 β 4 clustering and specific inhibition of NFAT5 results in reduced carcinoma invasion [11], suggesting a novel role for NFAT5 as an inducer of integrin-mediated tumor metastasis. In hyperosmotically stressed lymphocytes, NFAT5 up-regulates transcription of TNF α and LT β and may play a role in organogenesis, apoptosis, and various pathological responses [10]. In human T cells, activation through the TCR increases NFAT5 levels and activates transcription from NFAT5-dependent reporters. The signal transduction pathways that induce NFAT5 in response to TCR engagement seem to be calcineurin dependent and, therefore, different from the mechanisms controlling NFAT5 activation in response to hyperosmotic stimuli [9,10]. These results suggest an additional function for NFAT5 as a mediator of responses downstream of the TCR.

Perspectives

Although a great deal has been discovered about the NFAT family in the 10 years since the founding family members

were cloned, much still remains to be understood. It is clear that the individual family members can be independently regulated even in the same cell types, but the basis of this specificity is unclear. The genes regulated by NFAT1–4 in immune cells and by NFAT5 under hypertonic conditions in kidney cells are by large known, but the target genes for these proteins and their cell specific biological functions in other cell types remain to be identified.

Transcriptional Control through Regulated Nuclear Transport

Steffan N. Ho

*Departments of Pathology and Cellular and Molecular Medicine,
University of California at San Diego, La Jolla, California*

Introduction

A defining characteristic of eukaryotic cells is the compartmentalization of the genome into the nucleus, a membrane-bound subcellular organelle that is essentially impermeable to the passive diffusion of macromolecules. This spatial segregation of genomic DNA within the cell provides a means to control the expression of genome information that takes place during cell growth and differentiation through the regulated localization of transcriptional control proteins to the nucleus. The regulation of nuclear transport has thus been widely utilized in a variety of biological contexts to regulate transcription in a signal-dependent manner.

Regulated Nuclear Transport: Overview

The flow of information (i.e., proteins, RNA) into and out of the nucleus represents a dynamic balance between nuclear import and nuclear export. The signal-dependent localization of a protein to the cytoplasm or the nucleus can be altered by regulating either import or export, or by regulating both of these processes in a coordinated manner (Fig. 1). Transport occurs through interactions with soluble transport receptors of the karyopherin/importin family that interact or “dock” with components of the nuclear pore complex [1,2]. The interaction between a transport receptor and a target protein is mediated through specific nuclear localization (i.e., import) sequences (NLSs) or nuclear export sequences (NESs) present within the transported protein [3]. Directionality of transport is established in part by the differential interaction of transport receptors with the small GTPase, Ran, which is

present in a GDP-bound form in the cytoplasm and a GTP-bound state in the nucleus [1].

Nuclear transport can be regulated by three distinct mechanisms (Fig. 2). First, the nuclear targeting signal itself, represented schematically as a black box in Fig. 2, can be directly modified to alter the binding affinity between the signal sequence and the relevant transport receptor. This is achieved by phosphorylation of residues typically located within or adjacent to the NLS or NES that are directly involved in the interaction with a transport receptor. One well-characterized example of direct phosphorylation influencing the interaction between an NLS or NES and a transport receptor is provided by the yeast Pho4 transcription factor, which translocates to the nucleus upon dephosphorylation in response to phosphate-free growth conditions. Phosphorylation within the Pho4 NLS inhibits interaction with the import receptor Pse1, whereas phosphorylation at other sites is necessary for interaction with the export receptor Msn5 in the nucleus [4–6].

The second and perhaps more common means of regulating nuclear transport is through regulation of protein–protein interactions, either intramolecular or intermolecular, which alter the accessibility of the transport signal sequence to the transport receptor. This strategy is often referred to as the *masking* or *unmasking* of the signal sequences. The interaction between the NF κ B transcription factor and I κ B α provides a structurally defined example of intermolecular masking in which association of I κ B α blocks accessibility of the NF κ B nuclear localization signals [7,8]. The induced degradation of I κ B α that occurs upon receptor-dependent signaling results in the unmasking of these NLSs and subsequent nuclear translocation of NF κ B.

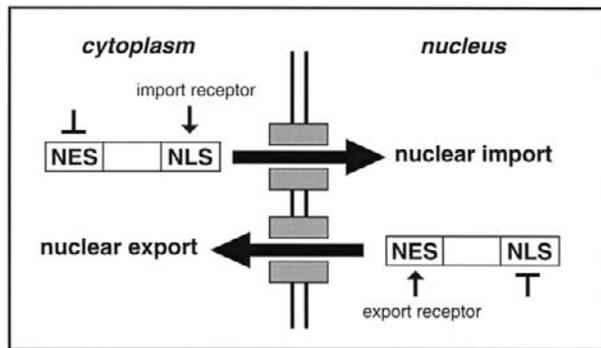

Figure 1 Dynamics of nuclear transport. Nuclear import results from association between a NLS and an import receptor or from the inhibition or disruption of the interaction between a NES and an export receptor. Conversely, nuclear export results from association between an NES and an export receptor or from the inhibition or disruption of the interaction between an NLS and an import receptor. Nuclear transport occurs through the nuclear pore complex. The coordinated regulation of both nuclear import and export provides a rapid, sensitive, and highly responsive means to dynamically translate intracellular signaling events into transcriptional responses in the nucleus.

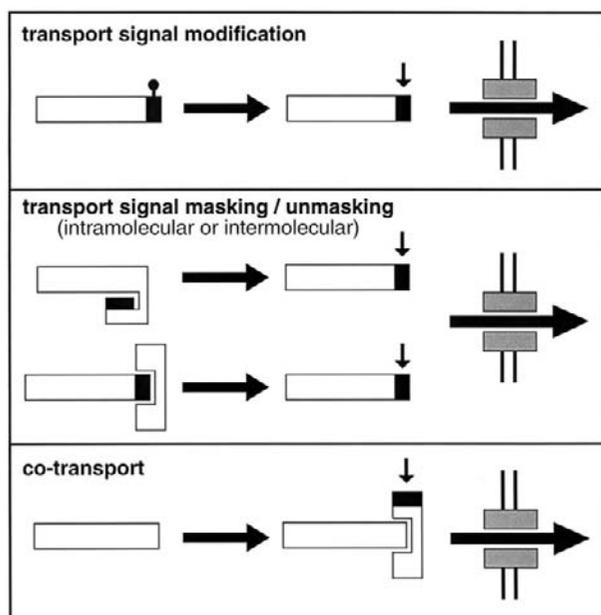

Figure 2 Mechanisms regulating nuclear transport. Nuclear import and export can be regulated by either direct modification of transport signals, masking or unmasking of transport signals through intramolecular or intermolecular protein interactions, or by interaction and cotransport with a carrier protein that contains a transport signal. The black box represents a transport signal. An arrow directed to the transport signal reflects accessibility and association with a transport receptor. The black circle represents protein phosphorylation. The direction of transport (import versus export) is not shown because the indicated mechanisms may affect either import (via NLS) or export (via NES).

The third strategy involves cotransport, whereby the import or export of a given protein is dictated by the interaction and cotransport with another protein that is itself differentially localized or expressed in a signal-dependent manner. Regulation of the NF κ B transcription factor also provides an

example of cotransport. The termination of signaling events that activate NF κ B via I κ B degradation results in reexpression of I κ B. In addition to masking NLSs of NF κ B and preventing nuclear import, I κ B α also contains a functional NES that allows cotransport of NF κ B out of the nucleus, thus providing a mechanism to actively terminate NF κ B-dependent transcription upon cessation of upstream signaling [9–11].

Coordinate Regulation of Nuclear Import and Export: Calcium-Dependent Nuclear Localization of NFATc Transcription Factors

The coordinate regulation of both nuclear import and nuclear export in a signal-dependent manner is clearly illustrated in studies of the regulated nuclear transport of the NFATc family of transcription factors. NFATc transcription factors link calcium-dependent signaling to transcriptional responses that mediate a wide spectrum of biological processes, ranging from cardiac and vascular development to T-cell development and activation [12–14]. NFATc proteins localize to the cytosol in unstimulated cells and undergo rapid nuclear translocation in response to receptor-dependent increases in intracellular free calcium, which activate the calcium/calmodulin-dependent phosphatase calcineurin. In the absence of calcium-dependent signaling (i.e., at basal concentrations of cytoplasmic-free calcium), cytoplasmic NFATc proteins are constitutively and heavily phosphorylated, predominantly within a conserved regulatory domain consisting of a serine-rich region (SRR) and three SP repeat regions. The calcium-dependent activation of calcineurin results in NFATc dephosphorylation and nuclear localization.

Mutations of residues that are the target of calcineurin-dependent phosphatase activity result in constitutive, calcium-independent nuclear localization mediated by functionally defined NLSs [15–17]. Similarly, export of NFATc proteins from the nucleus requires phosphorylation-dependent interaction between the Crm1 export receptor and variably defined NESs, mutation of which results in impaired nuclear export [17–20]. The state of NFATc protein phosphorylation thus dictates the accessibility of both NLSs and NESs through phosphorylation-dependent alterations in protein conformation, hence, representing a mechanism of signal-dependent intramolecular masking and unmasking of nuclear transport signals [15,17].

Several kinases have been identified that are capable of phosphorylating NFATc proteins and functionally regulating the balance of nuclear import/export by antagonizing calcineurin-dependent phosphatase activity, thereby effecting NFATc-dependent transcription. These include glycogen synthase kinase 3, casein kinase I, JNK, ERK, p38, and casein kinase II [16,21–24]. Thus, in addition to calcium-dependent activation of calcineurin, signal-dependent alterations in NFATc kinase activities may also influence NFATc-dependent transcriptional responses by altering the dynamic balance between NFATc nuclear import and export. Calcineurin and NFATc protein kinases also form stable complexes with

NFATc proteins [20,24,25], providing an additional means of regulating the state of NFATc protein phosphorylation and the accessibility of transport sequences. The coordinated, calcium-dependent regulation of both the nuclear import and export of NFATc proteins thus provides a rapid, sensitive, and highly responsive mechanism through which the frequency and duration of receptor-dependent calcium signals can be differentially translated into appropriate transcriptional responses [26–28].

Regulated Nuclear Transport of Non-DNA-Binding Transcriptional Regulatory Proteins

Although regulated nuclear transport of site-specific DNA-binding transcription factors represents an important means of regulating transcription of those target genes that contain appropriate DNA-binding sites, more recent studies have demonstrated that non-DNA-binding transcriptional regulatory proteins that influence chromatin structure are also subject to signal-dependent nuclear transport, thus revealing a novel perspective on signal-dependent transcriptional control mechanisms. The epigenetic modification of histones, proteins that function to package DNA into chromatin, represents an important means of regulating transcription. Histone acetylation is a particularly important modification regulated by a dynamic balance between histone acetyltransferase (HAT) and histone deacetylase (HDAC) activity, with histone acetylases typically associated with active transcription and histone deacetylases associated with repressed transcription [29]. The expression of muscle-specific genes that are induced during myocyte differentiation is controlled by the MyoD and MEF2 family of transcription factors [30]. The class II histone deacetylases HDAC4 and HDAC5 bind to MEF2 and repress MEF2-dependent transcription [31–33]. Myogenic signals induce not only the dissociation of HDACs from MEF2 but also the export of the HDACs from the nucleus [34,35]. Export of HDAC5 from the nucleus is dependent on phosphorylation at Ser-259 and Ser-498 and mediated by activation of the calcium/calmodulin-dependent protein kinase (CaMK) pathway, specifically CaMKI and CaMKIV [34,35]. Alanine substitutions at these positions result in the constitutive nuclear localization of HDAC5 and inhibition of myocyte differentiation [35,36].

The regulated nuclear export of HDAC4 and HDAC5 involves the phosphorylation-dependent association with the intracellular chaperone protein 14-3-3 [36–38]. Phosphorylation-site mutants that constitutively localize to the nucleus also fail to interact with 14-3-3, suggesting that binding of 14-3-3 is necessary for nuclear export [36]. The recent identification of an NES present at the extreme carboxy terminus of HDAC5 (also present in HDAC4 and HDAC7) capable of mediating phosphorylation-dependent nuclear export suggests a model of intramolecular masking in which amino-terminal sequences mask the carboxy-terminal NES [39]. Thus, induction of calcium-dependent signaling activates CaMK, which phosphorylates HDAC5 at

Ser-259 and Ser-498, allowing the association of 14-3-3 and unmasking of the carboxy-terminal NES. 14-3-3 has also been shown to decrease the affinity of HDAC4 for the import receptor importin α [37], suggesting that phosphorylation-dependent association of 14-3-3 may regulate HDAC nuclear transport by simultaneously masking an NLS and unmasking an NES.

Nuclear export of HDAC5 may not be essential for activation of MEF2-dependent transcription given that a HDAC5 nuclear export mutant that is competent to bind 14-3-3 continues to exhibit CaMK-dependent activation of MEF2 [36]. Thus, the phosphorylation-dependent binding of 14-3-3 to HDAC5 resulting in the dissociation of MEF2 and HDAC5 appears to be sufficient to allow activation of MEF2-dependent transcription independent of the nuclear export of HDAC. What then is the function of HDAC nuclear export? As suggested by McKinsey et al. [36], localization of HDACs out of the nucleus may allow for a more sustained activation of MEF2-dependent transcription. Alternatively, perhaps the signal-dependent nuclear export of HDACs, by altering the balance between acetylase and deacetylase activity in the nucleus, results in a more global reduction in transcriptional thresholds that facilitates the optimal execution of subsequent steps in a contingent program of transcriptional responses regulating cellular differentiation.

Conclusion

The regulated nuclear transport of DNA-binding transcription factors as well as non-DNA-binding transcriptional regulatory proteins represents an important means of regulating transcription in response to receptor-mediated signaling events. Both nuclear import and export can be regulated by either direct modification of transport signals, masking or unmasking of transport signals through intramolecular or intermolecular protein interactions, or by interaction and cotransport with a carrier protein that contains a transport signal. The coordinated regulation of both nuclear import and export by various combinations of these mechanisms provides a rapid, sensitive, and highly responsive means to dynamically translate intracellular signaling events into transcriptional responses in the nucleus.

Protein Degradation and the Ubiquitin/Proteasome System

Although most cellular proteins are long lived, a large class exists of normally short-lived proteins. Within this class one finds mainly regulatory factors, of which transcription factors constitute the largest group. One explanation for the short half-life of many regulatory factors is that it enables the rapid modulation of the steady-state concentration of the protein: The levels of constitutively short-lived proteins will respond much faster to changes in their rate of synthesis than that of long-lived ones. Additionally, many factors, rather than being constitutively short lived, can be conditionally stabilized or degraded in response to various stimuli. The question of how extracellular stimuli ultimately can determine the stability of specific transcription factors is central to the understanding of many signaling pathways.

The ubiquitin/proteasome pathway is the principal cellular system for selective protein degradation of normally short-lived proteins and of damaged or unfolded proteins (see [1] for a more extensive review). The ubiquitin system covalently ligates the conserved, 76-amino-acid protein ubiquitin to target proteins by creating an isopeptide bond linking the terminal carboxyl group of the ubiquitin polypeptide to an ϵ amino group of an internal lysine of the target polypeptide (or, occasionally, to the α amino group of the target polypeptide chain). An internal lysine residue of the first ubiquitin adduct can then serve as acceptor for an additional ubiquitin moiety, eventually yielding a cross-linked polyubiquitin chain that can contain tens of molecules. The polyubiquitin chain serves as a tag for recognition and destruction of the target protein by the 26S proteasome, a large, multicatalytic cytoplasmic protease. The ubiquitination reaction requires a number of enzymes and recognition factors that act sequentially: the ubiquitin-activating enzyme, or E1; an ubiquitin-conjugating

enzyme, or E2; and an ubiquitin/protein ligase, or E3. Ubiquitin is initially conjugated in an ATP-requiring reaction to E1 via a thiolester bond, then transferred via a transesterification reaction to a cysteine residue in the active site of the E2, which finally transfers the activated ubiquitin moiety to an amino group of the target protein (Fig. 1). The E3—or ubiquitin/protein ligase—is responsible for substrate recognition; it serves to bring together the E2 and the substrate in a single complex, thereby allowing ubiquitination to occur. Ubiquitin ligases form a heterogeneous group of proteins that appears to consist of two main subgroups: RING finger domain-containing ligases (the larger group) and HECT domain-containing ligases. With the HECT domain ligases, the catalytic cascade of ubiquitination includes an additional transthiolation step in which the activated ubiquitin is transferred from the E2 to a cysteine residue on the E3 prior to its conjugation to the target.

The main site of regulation of the various ubiquitination reactions is at the level of the ubiquitin ligase–substrate interaction, which can be modulated either by modification of the substrate, or by modulation of ubiquitin ligase activity. In the next sections, we review pathways in which the ubiquitin system plays a role in the regulation of transcription factor activity in response to extracellular signals.

Regulation of Ubiquitination by Substrate Modification

Stimulation of Ubiquitination by Substrate Phosphorylation

Modification of proteins by the addition of phosphate groups can modulate their function in a multitude of ways, including by enabling interactions with other proteins. In the event that such an interaction occurs with a proteolytic system,

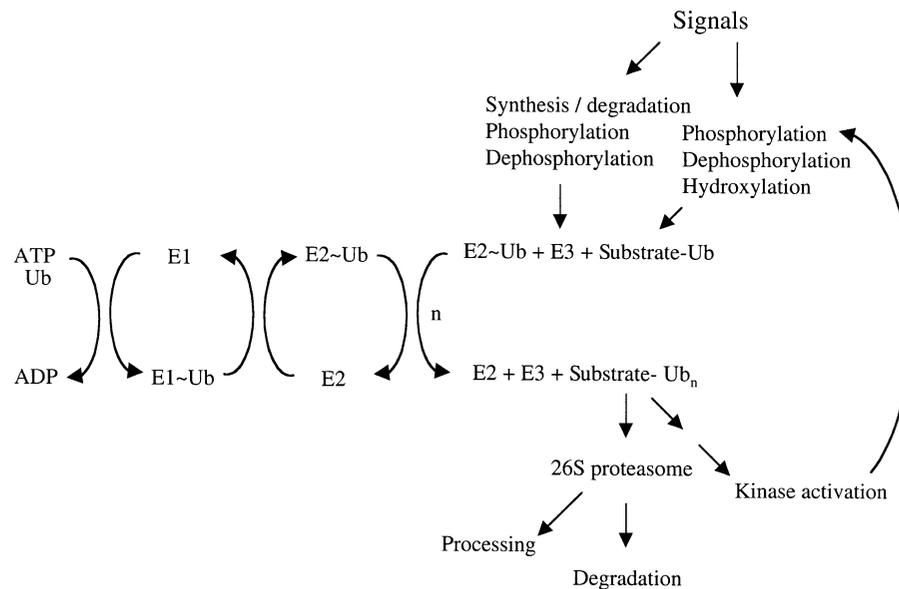

Figure 1 Schematic representation of the ubiquitination reaction cycle. Known points of regulation of the ubiquitin system by signaling pathways are indicated. See text for details.

phosphorylation will result in degradation of the protein. A number of ubiquitin ligases were described that require phosphorylation of the substrate prior to ubiquitination. The known ubiquitin ligases requiring prior phosphorylation of the substrate are primarily of the SCF class. SCF ubiquitin ligases form a complex of at least four proteins: the three components that were initially isolated, which gave the complex its name (SCF stands for Skp1, Cdc53 or Cullin, and F-box protein [2,3]), and a subsequently identified RING finger domain-containing component, Rbx1 or Roc1 (reviewed in [4]). The F-box protein is the variable component of the complex. Given that SCF complexes with different F-box proteins exhibit different substrate affinities, the F-box proteins are thought to carry the substrate recognition function of the complex (see [5] for a review). The SCF complex containing a specific F-box protein is marked with a superscript, for example, SCF^{CDC4}.

Several transcription factors are known to date to be regulated by SCF-mediated ubiquitination, including Gcn4 [6] and Met4 [7] in yeast, and NFκB [8], β-catenin [9], ATF4 [10], and E2-F1 [11] in mammalian cells. Some of these factors were shown to be regulated at the level of protein stability by signaling pathways that modulate the phosphorylation state of the substrate, and therefore recognition by the SCF complex.

IκBα

One of the most thoroughly investigated signaling pathways is that of NFκB activation (reviewed in [8]). IκBα is an inhibitor of NFκB, which normally sequesters it in the cytoplasm. Upon stimulation of the pathway, IκBα becomes phosphorylated at two specific serine residues, whereupon it becomes a substrate for ubiquitination by the SCF^{β-TrCP} complex. Interestingly, ubiquitination plays additional roles in the NFκB pathway: at the level of processing of the

NFκB precursor, p105 (see later section), and at the level of activation of the IκBα kinase (see later section).

GCN4

Another example of phosphorylation being required for degradation is that of the yeast transcription factor Gcn4. Gcn4 degradation depends on SCF^{CDC4} and on phosphorylation at a single specific site by a cyclin-dependent kinase, Pho85 [6] in conjunction with the Pho85 cyclin Pc15 [12], or, alternatively, on phosphorylation on an undefined site by another cyclin-dependent kinase, Srb10 [13]. Regulation of Gcn4 turnover by the availability of nutrients or, more generally, by the protein biosynthetic capacity of the cell, is mediated by regulation of Pho85 activity [6,12].

β-CATENIN

As a last example, turnover of the mammalian transcriptional coactivator β-catenin depends on phosphorylation by glycogen synthase kinase 3β (GSK3β), which leads to ubiquitination of β-catenin by SCF^{β-TrCP} (reviewed in [9]). Activation of the Wnt pathway leads to inhibition of the kinase and, consequently, to stabilization of β-catenin. Interestingly, another pathway of β-catenin destruction was recently identified that also depends on an SCF complex, but in this case the interaction with the substrate is phosphorylation independent and regulation occurs at the level of the ubiquitination complex (see later section).

Inhibition of Ubiquitination by Substrate Phosphorylation: p53

The tumor suppressor protein p53 is regulated at several levels, including degradation by the ubiquitin system. p53 Ubiquitination requires mdm2, a RING finger-containing ubiquitin ligase [14]. Genotoxic stress leads to phosphorylation of p53 at several serine residues, including serine 20.

Phosphorylation of serine 20 was found to stabilize the protein, probably by preventing its interaction with mdm2 [15]. Thus, in the case of p53, phosphorylation exerts a stabilizing effect on the protein.

Stimulation of Ubiquitination by Substrate Hydroxylation: HIF-1 α

Although phosphorylation is the most common protein modification, other types of modification could, in principle, regulate the interaction between a protein and the ubiquitin system. The global transcriptional regulator of the hypoxic response, HIF-1 α , provides an example of regulation by an alternative type of modification. HIF-1 α is rapidly degraded under normoxic conditions, but stabilized under hypoxic conditions. Degradation of HIF-1 α depends on ubiquitination by an ubiquitin ligase complex, the VBC complex (Von Hippel-Lindau protein–Elongin B–and Elongin C), which resembles the SCF complex in general architecture, and which contains the Von Hippel-Lindau tumor suppressor protein as a substrate recognition component [16–18]. However, rather than phosphorylation, hydroxylation of a specific proline residue in HIF-1 α was recently found to be responsible for the interaction of the protein with the VBC complex [19,20]. This hydroxylation occurs only under normoxic conditions, thereby explaining the dependence of HIF-1 α degradation on the oxygen concentration. A specific proline hydroxylase, the activity of which is directly regulated by the oxygen concentration, is responsible for the modification of HIF-1 α [21,22]. This pathway thus represents a case where a very short signaling cascade links the stimulus (oxygen concentration) to the response (HIF-1 α degradation).

Regulation of Ubiquitin Ligase Activity

Signaling pathways can modulate degradation of proteins by modification of the substrate, as shown earlier. In principle, the same effect could be achieved by modification of the ubiquitination system in response to extracellular signals. The ubiquitin/protein ligase, being the substrate recognition component of the ubiquitin system, would *a priori* be the preferred site of regulation. Regulation of the ubiquitin ligase is best established in the case of the E3 anaphase promoting complex/cyclosome (APC/C), which is responsible for the degradation of the regulators that govern, among other processes, the various mitotic transitions. Regulation of APC/C activity by signals emanating from the cell cycle machinery is essential for orderly cell cycle progression. However, it is not known whether the APC/C also responds to extracellular signals (reviewed in [23,24]).

F-Box Protein Stability

Activity of SCF-type ligases can be modulated at the level of regulation of the F-box component, the substrate recognition component of the complex. Many F-box proteins were

found to be intrinsically unstable [25] and, therefore, could be tightly regulated at the level of their synthesis. The transcription factor E2F-1 accumulates in the late G₁ phase and is rapidly degraded in the S phase, following ubiquitination by the SCF^{SKP2} complex. Regulation of E2F-1 degradation was shown to be due to the cell-cycle-dependent synthesis of the F-box protein SKP2 [11]. Another example is that of the yeast transcription factor Met4, which is regulated by the SCF^{MET30} ubiquitin ligase [7]. Met30 is transcriptionally regulated by Met4 [7], but it is also regulated at the level of protein stability by the availability of methionine, so that in the absence of methionine, Met30 is destabilized and disappears from the cell, leading to increased Met4 activity [26]. Here again, regulation appears to be exerted by the concentration of an intracellular metabolite, rather than by extracellular signals.

Regulation of SCF Complex Activity by NEDD8

The recent convergence of several lines of investigation raises the possibility that SCF activity may be subject to direct regulation by cellular signaling pathways. First, the Cullin subunit of the SCF was found to be subject to modification by the addition of an ubiquitin-like protein, Rub1 (in yeast)/NEDD8 (in mammals) to a specific lysine residue. This modification (henceforth “neddylation”) appears to activate the SCF [27]; it is essential for SCF activity in fission yeast [28], although not in budding yeast [29]. The enzymatic machinery of neddylation, which consists of dedicated, Rub1/NEDD8-specific E1 and E2 enzymes, has been characterized, but it is not known whether it is subject to regulation [30]. A protein complex that contains a deneddylation activity, the COP9 signalosome, was also identified [31]. The COP9 signalosome is a conserved protein complex first identified in plants, where it plays a role in photomorphogenesis [32]. The signalosome complex is structurally similar to a part (the “lid”) of the regulatory subcomplex (19S) of the 26S proteasome [33]. Although the functional significance of this homology is not yet clear, the signalosome and the “lid” subcomplex of the proteasome include homologous subunits, Jab1 and Rpn11, that appear to carry the catalytic activity of the deneddylation and deubiquitination activities of the respective complexes [34,35]. In mammalian cells, the NEDD8 pathway was recently shown to participate in the p105 processing pathway by affecting the activity of the SCF ^{β -TrCP} ubiquitination complex [36]. In *Arabidopsis*, COP9 activity modulates the activity of at least one specific ubiquitination complex, SCF^{TIR1} [31], previously implicated in the cellular response to the plant hormone auxin. Thus, the deneddylation function of the signalosome might connect extracellular signals (in the case of *Arabidopsis*, light) to cellular responses via modulation of the activity of the ubiquitin system.

Protein Processing by the Ubiquitin System

The p50 subunit of the transcription factor NF κ B is generated by proteolytic processing of a 105-kDa precursor, p105.

Processing is mediated by the proteasome, in what constituted the first instance of partial degradation of an ubiquitinated protein [38]. The proteasome degrades the C-terminal half of the precursor, but arrests degradation and releases the mature, N-terminal half because of the presence of a “stop-transfer” signal of ill-defined nature in the middle of the precursor [39]. The only salient feature of the signal is that it is rich in glycine residues; how such a sequence would inhibit complete degradation of a protein is unclear, but it is notable that a similar glycine-rich region is found in the viral protein EBNA-1, where in contrast to p105, it confers complete protection of the protein against degradation by the proteasome [34]. p105 Processing can occur in two modes at least, constitutive and stimulated. The constitutive mode probably depends on signals near the glycine-rich region and on an undefined ubiquitin ligase [39]. The second, stimulated mode of processing, depends on phosphorylation of residues in the C terminus of p105 by the I κ B kinase. The phosphorylated precursor is then recognized and ubiquitinated by SCF ^{β -TrCP}, and processed or degraded by the proteasome [40,41]. This second mode ensures that upon activation of the NF κ B pathway, not only are NF κ B molecules formerly sequestered in the cytosol recruited to the nucleus upon degradation of I κ B, but new NF κ B molecules are rapidly generated.

The yeast transcription factors Spt23 and Mga2 present another example of processing by the ubiquitin/proteasome system [42]. These two proteins are required for expression of *OLE1*, encoding a fatty acid desaturase essential for the synthesis of the monounsaturated fatty acids, palmitoleic and oleic acid. Regulated synthesis of these compounds is essential for the maintenance of proper membrane fluidity. Spt23 and Mga2 are normally membrane bound due to a C-terminal transmembrane domain. The N-terminal domain of the transcription factor is released from its membrane anchor via ubiquitination and selective degradation of the C-terminal domain by the proteasome. This processing is inhibited by addition of unsaturated fatty acids to the medium. The simplest hypothesis is that in this case, the signal for processing of the precursor is not extracellular, but rather consists of variations in membrane fluidity or thickness that depend on the ratio of unsaturated to saturated fatty acids.

Modulation of Kinase Activity by Ubiquitination

The ubiquitin system is best known for its role in protein degradation; however, examples are emerging of nondestructive roles for ubiquitin. In signal transduction, a recent example for such a nondestructive role is the function of ubiquitination in the activation of the I κ B kinase (IKK) [43]. The NF κ B pathway is activated by proinflammatory factors such as interleukin 1 that bind to their cognate receptors and ultimately lead to phosphorylation and degradation of I κ B, thereby releasing NF κ B to the nucleus [8].

One of the first proteins in the NF κ B pathway is TRAF6, a signal transducer that links receptor activation to activation

of IKK. TRAF6 activation depends on a complex of two ubiquitin conjugating enzymes, Ubc13/Uev1A, that catalyze the polyubiquitination of TRAF6 following receptor activation and (probably) TRAF6 oligomerization [43]. IKK activation depends on phosphorylation by a complex that includes the kinase TAK1. TAK1, in turn, is activated by binding to activated TRAF6. The fact that polyubiquitinated TRAF6 escapes destruction is probably due to the nature of the ubiquitin chain: Whereas “classical” ubiquitin chains are cross-linked via lysine 48 of ubiquitin, the Ubc13/Uev1A ubiquitin conjugating enzymes catalyze the formation of a lysine 63-cross-linked chain, which is probably not recognized by the proteasome. The mechanistic details of how this polyubiquitination of TRAF6 activates TAK1, however, remain obscure.

Conclusion

In the interplay between cellular signal transduction and the ubiquitin system, the latter was often thought of as lying near the bottom of the signaling cascade, in the role of executioner of phosphorylated proteins, merely carrying out the verdict of the kinases. However, not only have we seen instances where the ubiquitination complex is itself the recipient of the signal, but in one case so far, that of the NF κ B pathway, the ubiquitin system can even interfere with signaling by directly modulating the activity of kinases. It is likely that the NF κ B pathway, which exemplifies the versatility of the ubiquitin system, will serve as a useful paradigm for the role of the ubiquitin system in other signal transduction pathways.

Introduction

Signal transduction pathways are typically represented as linear, connect-the-dot diagrams that terminate within the cell nucleus. The dots represent different protein complexes, each functioning sequentially to convey information that the cell will interpret into changing patterns of gene expression. Understanding how the cell assembles these signaling protein complexes is critically important to unraveling disease processes, and to the design of therapeutic strategies. This knowledge is being gained through the combination of biochemical, genetic, and molecular approaches. Importantly, these *in vitro* approaches are now being complemented by noninvasive techniques that allow direct visualization of dynamic protein interactions in their natural environment within the living cell.

Monitoring the social interactions of proteins inside the cell became possible with the cloning of fluorescent proteins (FP) from marine organisms [1,2]. Extensive mutagenesis of the jellyfish green fluorescent protein (GFP) and the cloning of a second FP from coral have yielded genetically encoded tags that emit light from the blue to red range of the visible spectrum [3,4]. These different color protein tags can be used in combinations that are distinguishable by multispectral imaging [4–7]. Because the FPs have no intrinsic intracellular targeting, they usually adopt the subcellular localization of the linked protein. Therefore, the intracellular distribution of several different labeled proteins relative to one another can be monitored in real time in the same living cell, and overlap in

their distributions can be determined. The colocalization of the labeled proteins can be an indication that the proteins are assembled in common signaling complexes.

Unfortunately, the diffraction of light limits the resolution of the microscope to approximately $0.2\ \mu\text{m}$ ($2000\ \text{\AA}$), and objects that are closer together than this will appear as a single object. For perspective, the basal transcription factor IID is an ensemble of three different interacting proteins forming a complex approximately $200\ \text{\AA}$ across. This complex was visualized *in vitro* by electron microscopy [8], but falls well below the detection limit of the light microscope (Fig. 1). Therefore, considerable distances may actually separate proteins that appear to be colocalized by fluorescence microscopy, and detecting the physical interactions between proteins within a signaling complex would appear to be beyond the reach of the light microscope.

FRET Microscopy Improves Spatial Resolution

Fortunately, it is possible to achieve this degree of spatial resolution by conventional light microscopy by using the technique of fluorescence resonance energy transfer (FRET) microscopy (Fig. 1). FRET has been used as a spectroscopic technique for many years [9,10], but the emergence of the genetically encoded FP tags has dramatically increased the utility of FRET microscopy of living cells [11]. FRET is the radiationless transfer of energy from a donor fluorophore to a nearby acceptor fluorophore resulting in sensitized

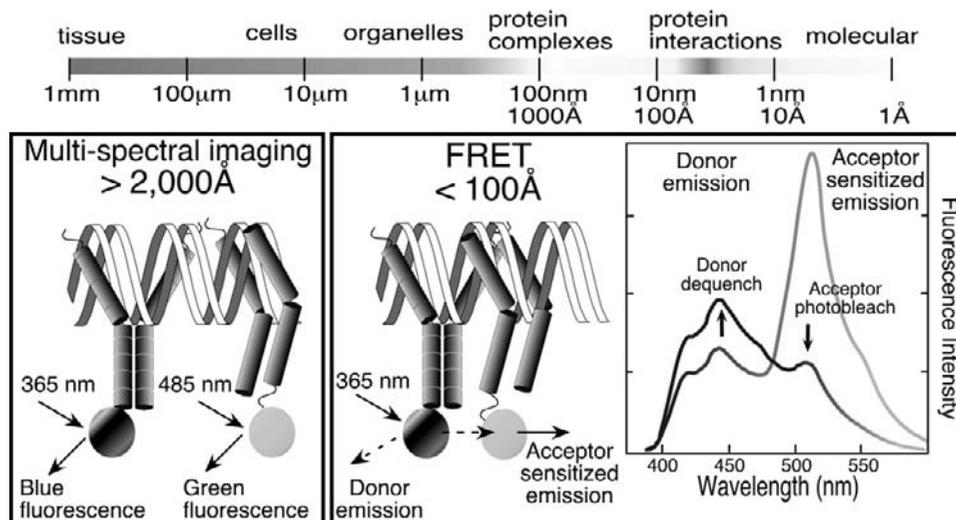

Figure 1 The optical resolution of the microscope is limited to approximately 2000 Å, but this resolution can be improved 50-fold by using FRET microscopy. The detection of sensitized fluorescence emission from acceptor fluorophores upon illumination of the donors can indicate that the tagged proteins are less than 100 Å apart. When energy transfer occurs, the donor fluorescence signal is quenched. Thus, FRET can also be measured by detecting the dequenching of the donor following acceptor photobleaching.

fluorescence emission from the acceptor (Fig. 1). Because the efficiency of the energy transfer drops precipitously as the inverse of the sixth power of the distance separating the donor and acceptor fluorophores, FRET is limited to distances of less than 100 Å. Therefore, the detection of sensitized fluorescence emission from acceptor fluorophores upon illumination of the donors can provide strong evidence for the physical interaction of the tagged proteins.

Limitations of FRET Microscopy

In practice, the detection of FRET signals from living cells expressing independent donor- and acceptor-tagged proteins is difficult because of limited control over the relative amounts of the expressed proteins in any given cell. This produces a highly variable spectral background signal, contributed by both the donor and acceptor fluorophores, from which weak FRET signals must be extracted [12]. Importantly when energy transfer occurs, the donor fluorescence signal is quenched because of the direct transfer of excitation energy to neighboring acceptors (Fig. 1). By measuring donor dequenching following acceptor photobleaching, FRET signals can be mapped to precise subcellular locations [13]. Here, we demonstrate how acceptor photobleaching FRET microscopy can detect the localized interactions of the transcription factor C/EBP α in specific subnuclear domains in the living pituitary cell.

The C/EBP family members are determinants of cell differentiation, and they regulate the expression of genes involved in energy metabolism. The basic region-leucine zipper of C/EBP α forms dimers through contacts in the leucine zipper and binds to specific DNA elements via the basic region. Our studies show that GFP-C/EBP α localizes to

regions pericentromeric chromatin in pituitary GHFT1-5 and preadipocyte 3T3-L1 mouse cell lines. This pattern of subnuclear localization is identical to the location of endogenous C/EBP α in differentiated mouse adipocyte cells [14]. In Fig. 2, we show FRET signals originating from these subnuclear sites occupied by C/EBP α tagged with the yellowish (YFP) and blue (BFP) color variants. This fluorescent probe combination was selected for three reasons. First, despite its low quantum yield and sensitivity to photobleaching, the BFP variant used here provides a sufficient signal from the nucleus, where there is a low autofluorescence background. The much higher autofluorescence signal in the cytoplasm makes the BFP variant a poor choice for studies outside the nucleus. Second, the overlap of the BFP emission and YFP excitation spectra is suitable for energy transfer, but this pair has a reduced spectral background when compared to the CFP/YFP combination commonly used for these types of studies [13]. Third, the YFP variant is sensitive to photobleaching [13,15], making it a good choice for acceptor photobleaching FRET.

Detecting C/EBP α Intersections

The results shown in Fig. 2 illustrate the application of acceptor photobleaching FRET to detect the physical association of C/EBP α proteins in specific subnuclear domains. A GHFT1-5 cell coexpressing YFP- and BFP-C/EBP α was selected and a reference image was acquired using the YFP filter set (for details, see [13]). Images were then acquired using the FRET filter set (donor excitation, acceptor emission) and the donor filter set (donor excitation, donor emission) at the same focal plane and under identical conditions (Figs. 2B and C, prebleach). The acceptor (YFP-C/EBP α) was then

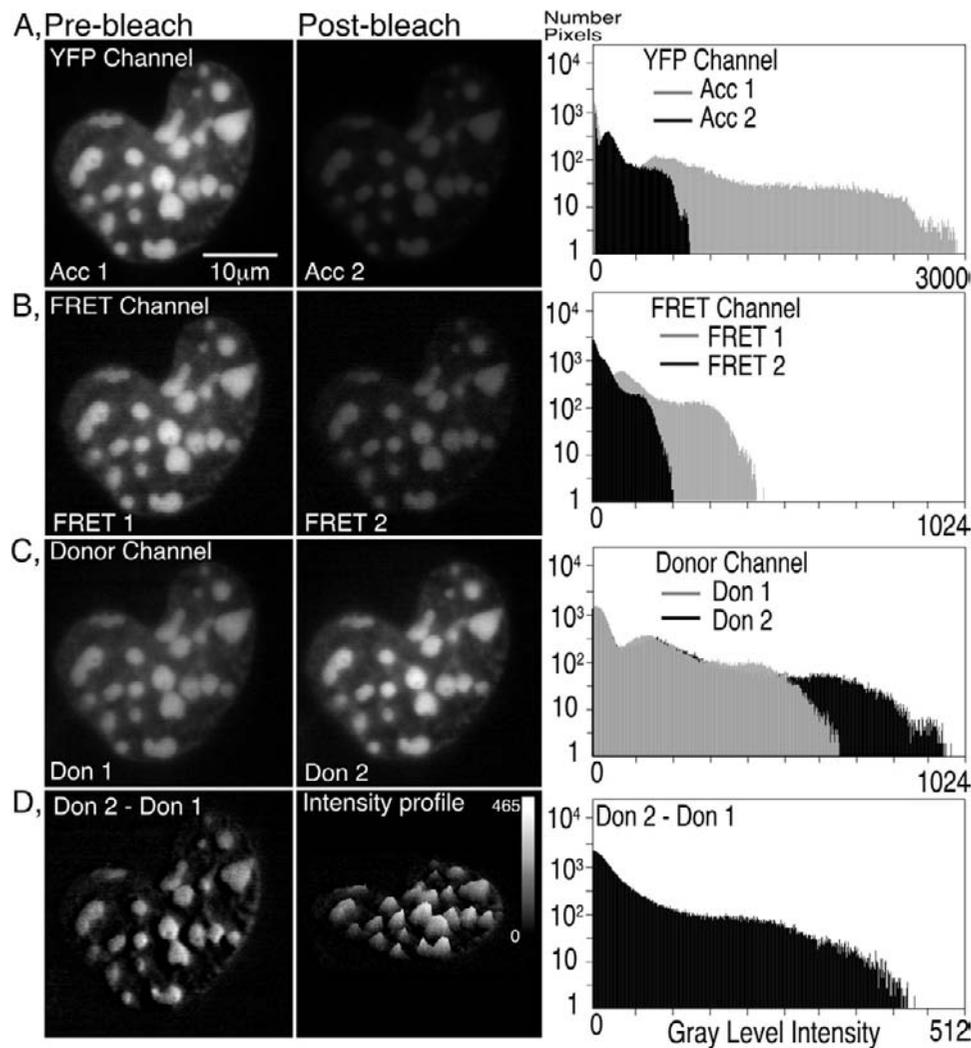

Figure 2 Acceptor photobleaching FRET microscopy of a pituitary GHFT1-5 cell expressing BFP- and YFP-C/EBP α . *Prebleach panels:* (A) The reference image showing subnuclear foci occupied by YFP-C/EBP α (Acc 1); bar = 10 μ m. (B) Acceptor emission with donor excitation (FRET 1) and (C) the donor emission (Don 1) obtained under identical conditions. *Postbleach panels:* (A) YFP signal after 5-min bleach period obtained using the same conditions as for the first image. (B) The effect of selective acceptor photobleaching on the FRET signal (FRET 2) and (C) the donor fluorescence intensity (Don 2). (D, left panel) The dequenching of the donor was quantified by subtracting the Don 1 digital image from the Don 2 image, and (D, right panel) The subnuclear location where FRET occurred was mapped in the intensity profile; the calibration bar indicates the gray-level intensity.

photobleached by exposure to 500-nm excitation light for 5 min. A second YFP reference image was then acquired under identical conditions (Fig. 2A, postbleach), showing that the acceptor signal was reduced by approximately 70% (see histogram, Fig. 2A). This selective acceptor photobleaching abolished the FRET signal and revealed the contribution of the donor spectral background signal to the FRET signal (see histogram, Fig. 2B). In contrast, the donor fluorescence intensity was increased following acceptor photobleaching because of donor dequenching (Don 2, Fig. 2C, compare histograms). The donor dequenching was quantified by digital subtraction of the Don 1 image from the Don 2 image (Fig. 2D, left), and the subnuclear location of the dequenched donor signal was mapped by plotting the intensity profile (Fig. 2D, right). Together, the demonstration of a FRET signal above

the expected spectral cross-talk background and the observed increased donor signal after acceptor photobleaching provide strong evidence for the physical association of these proteins at discrete subnuclear sites in these living pituitary cells.

Concluding Remarks

The detection of FRET in the living cell is limited by the accuracy of quantifying the intensity and position of the fluorescence signals in space. Accuracy is most severely compromised when measuring low signal intensities near the background noise of the system. Therefore, microscope systems used for FRET studies must be optimized to increase

sensitivity and reduce noise. The FRET efficiency will be improved by selecting donor and acceptor fluorophores with substantial spectral overlap, but the cost of the improved efficiency is an increased spectral cross-talk background from which FRET signals must be extracted. The FRET signal can also be improved by optimizing the ratio of the expressed donor- and acceptor-tagged proteins to favor productive interactions. In this regard, however, artifacts can arise from fusion protein overexpression, and control experiments confirming the normal function of the labeled proteins are essential. Further, there are many potential reasons FRET may not be detected from fusion protein partners that interact, including competition by endogenous proteins for the tagged proteins or incorrect orientation of the donor or acceptor fluorophore relative to one another. Therefore, the failure to detect FRET from a pair of labeled proteins carries no intrinsic information regarding the association of the proteins.

Finally, the mobility of higher order protein complexes within the three-dimensional space of the living cell interior represents a major problem for intensity-based measurements of sensitized acceptor emission and donor dequenching. The example shown here is a dimerized transcription factor that localizes to discrete and relatively immobile structures in the cell nucleus. Detecting FRET from signaling protein complexes that are highly mobile requires a temporal resolution that is difficult to achieve using intensity-based measurements. The technique of fluorescence lifetime imaging (FLIM) microscopy, however, can achieve both the spatial and temporal resolution necessary to detect highly dynamic protein interactions. FLIM measures the nanosecond duration of the excited state of a fluorophore, and when combined with FRET, this approach can provide direct evidence for dynamic protein interactions in four dimensions [16,17].

The Mammalian Circadian Timing System

University of Geneva,
Geneva, Switzerland*

Introduction

Many aspects of mammalian physiology follow daily oscillations controlled by a circadian pacemaker. Clock-regulated processes include sleep–wake cycles, heartbeat, blood pressure, body temperature, most functions of the digestive tract, renal physiology, liver metabolism, acuity of sensorial systems, and many endocrine functions [1]. Remarkably, this clock produces such daily oscillations indefinitely in the absence of external time cues such as changes in light intensity or temperature. Nevertheless, it can measure a 24-hour period only approximately, and thus it has to be readjusted every day by a separate input pathway in order to remain in resonance with geophysical time [2].

The central mammalian pacemaker resides in the suprachiasmatic nuclei (SCN) of the hypothalamus and drives all known overt circadian rhythms in physiology and behavior [3]. The photoperiod is the major *Zeitgeber* (timing cue) for the SCN clock, and SCN neurons receive photic information directly via the retino-hypothalamic tract [4]. The oscillations generated in SCN neurons are translated into overt circadian rhythms via mechanisms that are as yet poorly understood. Surprisingly, circadian oscillators with a molecular makeup similar to that of the SCN oscillator are also operative in most peripheral body cells, but these peripheral clocks dampen after a few days if they do not receive periodic phase-resetting inputs from the SCN pacemaker [5,6].

In this chapter we briefly summarize recently acquired information about the molecular circuitry generating daily oscillations, the input pathways by which light synchronizes these oscillations, and the output pathways by which the SCN clock governs circadian fluctuations in physiology and behavior. Most of the observations described here have been made in the mouse; however, the major conclusions are likely to apply to most mammalian organisms.

The Molecular Oscillator

During the past few years, seven mammalian clock genes have been isolated and studied by genetic and biochemical approaches: *Clock*, *Bmal1/Mop3*, *Cry1*, *Cry2*, *Per1*, *Per2*, and *CK1ε*. With the exception of *Clock*, which was identified and cloned via a forward genetics approach in the mouse, all mammalian pacemaker genes were identified by their sequence homology with known *Drosophila* clock genes (see reviews in [7,8]).

Circadian oscillations are generated by feedback loops in gene expression that involve both transcriptional and post-transcriptional mechanisms (Fig. 1). The two PAS domain helix–loop–helix transcription factors CLOCK and BMAL1 (also termed MOP3 in some publications) heterodimerize and bind to E-box sequences to activate transcription of the *Per* and *Cry* genes [9,10]. PER and CRY proteins are translocated into the nucleus, where they repress transcription

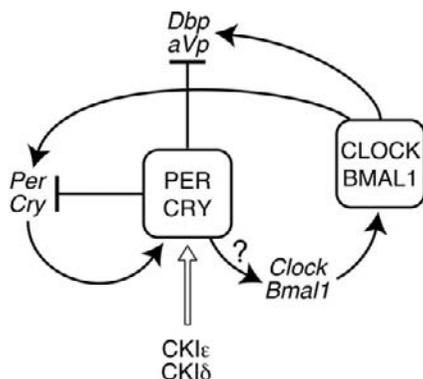

Figure 1 Simplified model of the mammalian circadian oscillator. At the heart of the oscillator is a multi-protein complex composed of period (PER) and cryptochrome (CRY) proteins. Transcription of the genes encoding these proteins is enhanced by CLOCK:BMAL1 heterodimers. When the CRY/PER proteins reach a critical threshold concentration, these proteins enter into the nucleus and repress transcription of their own genes by a yet unknown mechanism. Concomitantly, they provoke an anticyclic accumulation of CLOCK and BMAL1 proteins, probably via an indirect mechanism (?) (see note added in proof and reference 12). Upon decay of the CRY and PER proteins, transcription of the *Per* and *Cry* genes is reestablished, and a new cycle can occur. Casein kinase I ϵ and δ (CKI ϵ , CKI δ) affect the nuclear translocation and the stability of the CRY/PER multi-protein complex by specific phosphorylations. The transcription of some clock-controlled genes, such as albumin D-element binding protein (*Dbp*) or arginine vasopressin (*aVp*), is regulated by the same mechanism as *Per* and *Cry* genes.

of their own genes as multisubunit complexes. Once the concentration of PER:CRY complexes falls below the critical threshold required for autorepression, *Per* and *Cry* transcription can resume (see review in [2]). This transcriptional feedback loop is assisted by several post-transcriptional control mechanisms [11]. For example, PER1, PER2, BMAL1, and CLOCK undergo robust daily cycles in protein phosphorylation, and these posttranslational modifications may affect their stability and function. CKI ϵ and CKI δ are among the protein kinases that phosphorylate PER and BMAL1 proteins, and the existence of protein complexes containing PER1, CRY2, CLOCK/BMAL1, CKI ϵ , and CKI δ was demonstrated by coimmunoprecipitation [11].

In liver, all of the clock genes specifying transcriptional regulatory components are transcribed in a circadian fashion, although the amplitudes of the various mRNA accumulation cycles vary greatly between genes (from less than 2-fold for *Cry2* to more than 20-fold for *Bmal1* and *Per2* [11]; J. A. Ripperger and U. Schibler, unpublished results). The circadian accumulation of *Cry* and *Per* mRNA is roughly in antiphase with that of *Bmal1* and *Clock* mRNA, suggesting that the rhythmic expression of positively and negatively acting clock components is governed by different mechanisms. Indeed, while CLOCK and BMAL1 stimulate the transcription of *Cry* and *Per* genes [9], they down-regulate transcription of their own genes via an indirect mechanism [12].

Photic Entrainment of the Central Pacemaker

SCN neurons receive photic information from the retina through the retino-hypothalamic tract. Glutamate is the major neurotransmitter used in this synaptic communication [13,14]. Surprisingly, rare light-sensitive ganglion cells in the inner retina layer, rather than the classical rods and cones in the outer retina layer, could be the photoreceptor cells required for the photic entrainment of the circadian pacemaker. These ganglion cells express the photopigment melanopsin and establish direct synaptic connections with SCN neurons as well as with other brain regions [15,16]; however, a disruption of the melanopsin gene will be needed to adequately assess its candidacy for the locus that encodes the circadian photopigment (see note added in proof and references 41 and 42). Light resets the phase of circadian rhythms in a highly gated manner. Thus, in nocturnal laboratory rodents kept in constant darkness, only light pulses delivered during the subjective night can elicit phase shifts. Furthermore, exposure to light during the first half of the subjective night provokes phase delays, whereas exposure during the second half of the subjective night causes phase advances [17].

Light pulses capable of phase shifting also elicit a transient activation of immediate early genes. These include *Per1*, *Per2*, and about a dozen other genes encoding transcriptional regulatory proteins (e.g., *cFos*, and *JunB*) [18]. cAMP serves as a second messenger both in the photic activation of immediate early gene transcription and in phase shifting ([19] and references therein). Increased cAMP levels activate the protein kinase PKA, which in turn phosphorylates the transcription factor CREB at serine residues S133 and S142 ([19] and references therein). Phosphorylated CREB then stimulates the transcription of immediate early genes, such as *Per1* and *c-Fos*. Light also provokes extensive histone H3 phosphorylation in the nuclei of SCN neurons, a phenomenon that is usually associated with changes in chromatin structure [20]. Whether these changes are causally related to immediate early genes has not yet been determined.

Outputs of the SCN Pacemaker

Most probably, the SCN controls overt circadian rhythms in behavior and physiology through neuronal and humoral outputs. In fact, SCN neurons project into various other brain centers (see reviews in [21,22]). These projections may affect circadian outputs directly through electrical signaling or via the rhythmic secretions of hormones of the hypothalamic-pituitary gland axis and other endocrine glands (e.g., the pineal gland). Some of these oscillating hormones, especially those of the hypothalamus-pituitary gland axis like glucocorticoids and thyroid hormones, may serve as phase-resetting cues for oscillators in non-neuronal cell types (see later sections). Cyclically secreted

SCN-derived neuropeptides such as arginine vasopressin and vasoactive intestinal peptide (VIP) may also participate in the regulation of rhythmic behavior and physiology [23,24].

Transforming growth factor- α (TGF- α), which signals through epidermal growth factor receptors, has recently been identified as a key regulator in the control of circadian locomotor activity. TGF- α is rhythmically expressed in SCN neurons, and constant infusion of this cytokine into the third ventricle abolishes circadian sleep-wake cycles in hamsters [25].

Outputs via Subsidiary Clocks

A second facet of the SCN's regulation of circadian physiology involves peripheral clocks. Circadian oscillators of a molecular makeup similar to that of SCN neurons exist in most peripheral tissues. Nevertheless, circadian gene expression in these tissues is not maintained in SCN-lesioned animals [26]. Hence, in intact animals, ongoing oscillations in peripheral organs depend on periodic inputs from the SCN. In immortalized tissue culture cells, circadian transcriptional oscillations can also be achieved by "jump starting" the cells with a serum shock or with substances that activate known signaling pathways. These involve tyrosine receptor kinases, G-protein-coupled receptors, nuclear hormone receptors (e.g., the glucocorticoid and retinoic acid receptors), protein kinases (e.g., PKA, PKC, and MAPK), and Ca²⁺ channels [27–31]. It is noteworthy that the immediate-early genes activated by these pathways before circadian gene expression is initiated include the same genes that are light induced in SCN neurons. This observation suggests that phase shifting by light in the SCN and signaling to the periphery by the SCN could share similar elements.

A similar conservation may exist in the direct regulation of output genes by the molecular clock. E-box sequences, similar to those used by CLOCK and BMAL1 proteins to activate *Per* gene transcription (see earlier section), are probably also important for the circadian expression of output genes such as DBP or arginine vasopressin [32,33]. Hence, these genes may be directly regulated by peripheral clock components in their cognate tissues.

Synchronization and Functions of Peripheral Oscillators: Time and Food

A functional SCN is required for the maintenance of circadian oscillations in peripheral cell types [6,26]. The output pathways by which the SCN synchronizes peripheral clocks are still poorly understood, but they are likely to

be complex, given the panoply of signaling pathways that can affect circadian gene expression in peripheral cell types (see earlier section). Important clues on the phase entrainment of peripheral clocks have recently come from restricted feeding experiments [34,35]. Although feeding time does not affect the phase of the SCN pacemaker, it is the dominant *Zeitgeber* for many peripheral oscillators. Hence, the SCN may control the phase of peripheral timekeepers simply by determining the activity phase—and thus feeding time. Food entrainment may involve hormones related to metabolism, such as glucocorticoids [36] or metabolite-induced changes in the NAD(P)H/NAD(P)⁺ redox potential [37].

The dominant role of feeding time for peripheral phase resetting suggests that the anticipation of food uptake and processing may be a major purpose of peripheral clocks, at least in tissues such as the liver. This conjecture is strongly supported by recently published transcriptome profiling studies [38]. Indeed, a large fraction of cycling liver transcripts encodes proteins that are related to pathways implicated in sugar and fat metabolism, redox potential, and the detoxification of potentially harmful substances that may be present in the food.

Conclusions and Perspectives

Figure 2 summarizes our current view of the mammalian circadian timing system. Although impressive progress has been made in the analysis of all its aspects, much remains to be done. For example, the definitive identification of melanopsin as the key circadian photopigment will require genetic studies (see note added in proof and references 41 and 42). In addition, the presynaptic and postsynaptic light-signaling components downstream of melanopsin will have to be characterized. The possible role of mammalian cryptochrome as an additional circadian photopigment still remains a matter of debate, and compelling genetic evidence for or against such a function is still lacking. Considerable efforts will also have to be invested in the biochemical dissection of the mechanisms by which CRY and PER proteins repress CLOCK:BMAL1 mediated gene expression. Furthermore, studies aimed at the signaling pathways by which the SCN governs overt rhythms in physiology and behavior are still in their infancy. Finally, and perhaps most surprisingly, irrefutable experimental evidence supporting a strong benefit of circadian clocks is still scarce. Two studies, in which the survival of arrhythmic SCN-lesioned chipmunks and antelope ground squirrels in natural habitats have been recoded, showed only moderate advantages for the intact control animals [39,40]. Further studies conducted under conditions in which the survival of a species depends on predator avoidance, competition for mating partners and food, and resistance to extreme environmental variations will be required to evaluate the selective advantage that the circadian timing system may provide to its owners.

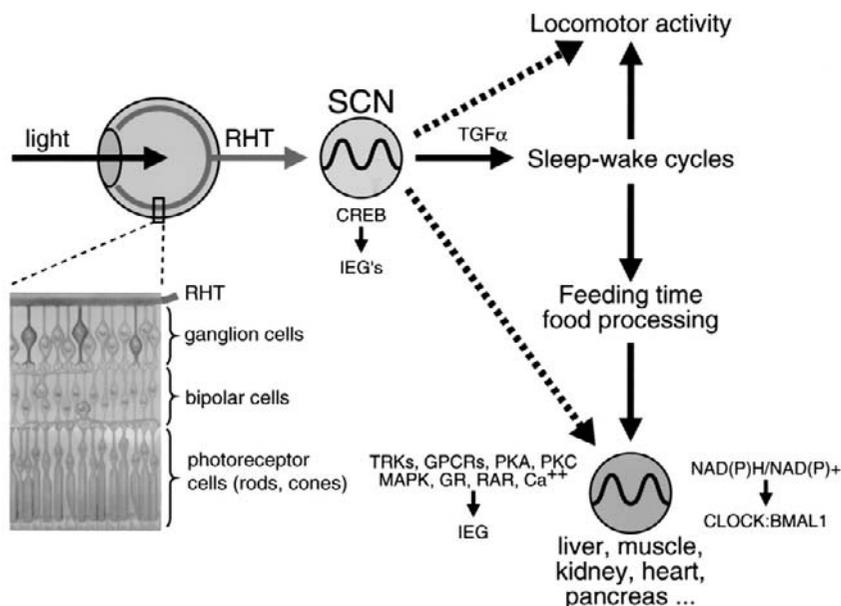

Figure 2 Phase-entrainment of central and peripheral circadian oscillators. Recent evidence suggests that photic cues are perceived by specific, melanopsin-expressing ganglion cells within the eye's retina. This light information is transmitted to the SCN via the retino-hypothalamic tract (RHT) and provokes the transcriptional stimulation of immediate early genes (IEG's, see text) via activation of the transcription factor CREB. Immediate early gene expression is thought to change the phase of the SCN pacemaker. In addition, specific diffusible molecules are secreted by SCN neurons to regulate physiological processes. One of these, TGF α , appears to regulate sleep-wake cycles. In turn, these cycles may affect locomotor activity and food uptake. Peripheral oscillators may be linked to the SCN directly via specific signaling cascades activating tyrosine receptor kinases (TRKs), G-protein coupled receptors (GPCRs), nuclear hormone receptors like the glucocorticoid (GR) and retinoic acid receptors (RAR), protein kinases like PKA, PKC, and MAPK, and Ca²⁺ channels. Alternatively, the SCN may control the phase of peripheral oscillators indirectly via food uptake and/or processing. The metabolism of nutrients may affect the redox-potential (the ratio of NADH to NAD⁺) within the cells, which in turn may regulate the DNA-binding activity of CLOCK:BMAL1 heterodimers.

Notes Added in Proof

Two important issues that had been unanswered (or unpublished) at the time of writing have been solved during the preparation of this book. First, the orphan nuclear receptor REV-ERB α has been identified as the transcriptional regulator connecting the positive and negative limbs of the circadian oscillator (see Reference 12). Second, genetic loss-of-function studies clearly revealed that melanopsin plays an important role in the photic entrainment of the mouse circadian clock. Thus, mice deficient in the conventional rod and cone photoreceptor cells and without a functional melanopsin allele are unable to light-entrain the phase of their circadian oscillator (see references 41 and 42).

Protein Arginine Methylation

Michael David

*Molecular Biology Section, Division of Biology,
University of California at San Diego,
La Jolla, California*

Introduction

Posttranslational modification of proteins is a hallmark of signal transduction, allowing cells to alter existing proteins to react rapidly to changes and events in their extracellular environment. Protein phosphorylation on serine, threonine, or tyrosine residues as a mechanism of intracellular signal transduction has been extensively studied. In contrast, the role of protein methylation at lysine, arginine, or histidine residues is much less understood. The subject of this chapter, methylation of arginine residues, was discovered more than 30 years ago, but has only recently received appreciation as a novel mechanism of signal transduction, transcriptional regulation, and protein sorting. As more arginine methylated substrates are discovered, and as novel functions of arginine methylation are reported at a very rapid pace, it appears that this protein modification may be of equal importance to protein phosphorylation in the regulation of cellular functions. This chapter summarizes the current knowledge on protein arginine methyltransferases and the function of arginine methylation in signal transduction.

Arginine Methylation and Arginine-Methyltransferases

The transfer of a methyl group from S-adenosylmethionine (SAM) onto arginine can occur on either or both of the guanidino nitrogen atoms. As such, arginine methylation, which is restricted to eukaryotic cells, can be found in three distinct forms— N^G -monomethylarginine, $N^G N^G$ (asymmetric) dimethylarginine, and $N^G N^G$ (symmetric) dimethylarginine (Fig. 1)—frequently in the context of RGG tripeptides [1,2].

Two classes of protein arginine methyltransferases have been characterized and classified based on the symmetry of

their reaction products. Both, type I and type II enzymes generate N^G -monomethylarginine. However, whereas type I protein arginine methyltransferases account for the formation of asymmetric $N^G N^G$ -dimethylarginine, type II enzymes catalyze the formation of symmetric $N^G N^G$ -dimethylarginine (Fig. 1). The best conserved region within this enzyme family is the SAM-interacting methyltransferase motif, which is closely related to that found in other methyltransferases that use SAM as a methyl donor [3].

Five related enzymes that catalyze asymmetric arginine methylation have thus far been identified. The majority of type I arginine methyltransferase activity in eukaryotic cells appears to be accounted for by PRMT1 and its functional yeast homolog Hmt1/Rmt1 [4]. These enzymes contain only a few residues outside the methyltransferase core domain, and their enzymatic activity appears to correlate with dimer formation. In contrast, PRMT2 contains an N-terminal SH3 domain, whereas PRMT3 harbors an N-terminal zinc-finger motif that modulates its substrate specificity [5]. The crystal structures of the conserved core regions of Hmt1 and human PRMT3 revealed significant structural similarity between these enzymes [6]. PRMT4 (Carm1) contains both N- and C-terminal extensions to the methyltransferase core region [7]. The recently identified PRMT6 resembles PRMT1 most closely in that it is comprised solely of the catalytic core without any additional domains [8]. PRMT5 (JBP), which was identified as a Janus kinase binding protein, is the only arginine methyltransferase identified to date that has type II enzyme activity [9,10]. As such, it is capable of catalyzing the symmetric arginine methylation of myelin basic protein, which was one of the first arginine-methylated proteins identified. In addition, two other symmetrically dimethylated RNA-binding proteins, spliceosomal snRNP proteins SmD1 and SmD3, can function as substrates for PRMT5 *in vitro* [11].

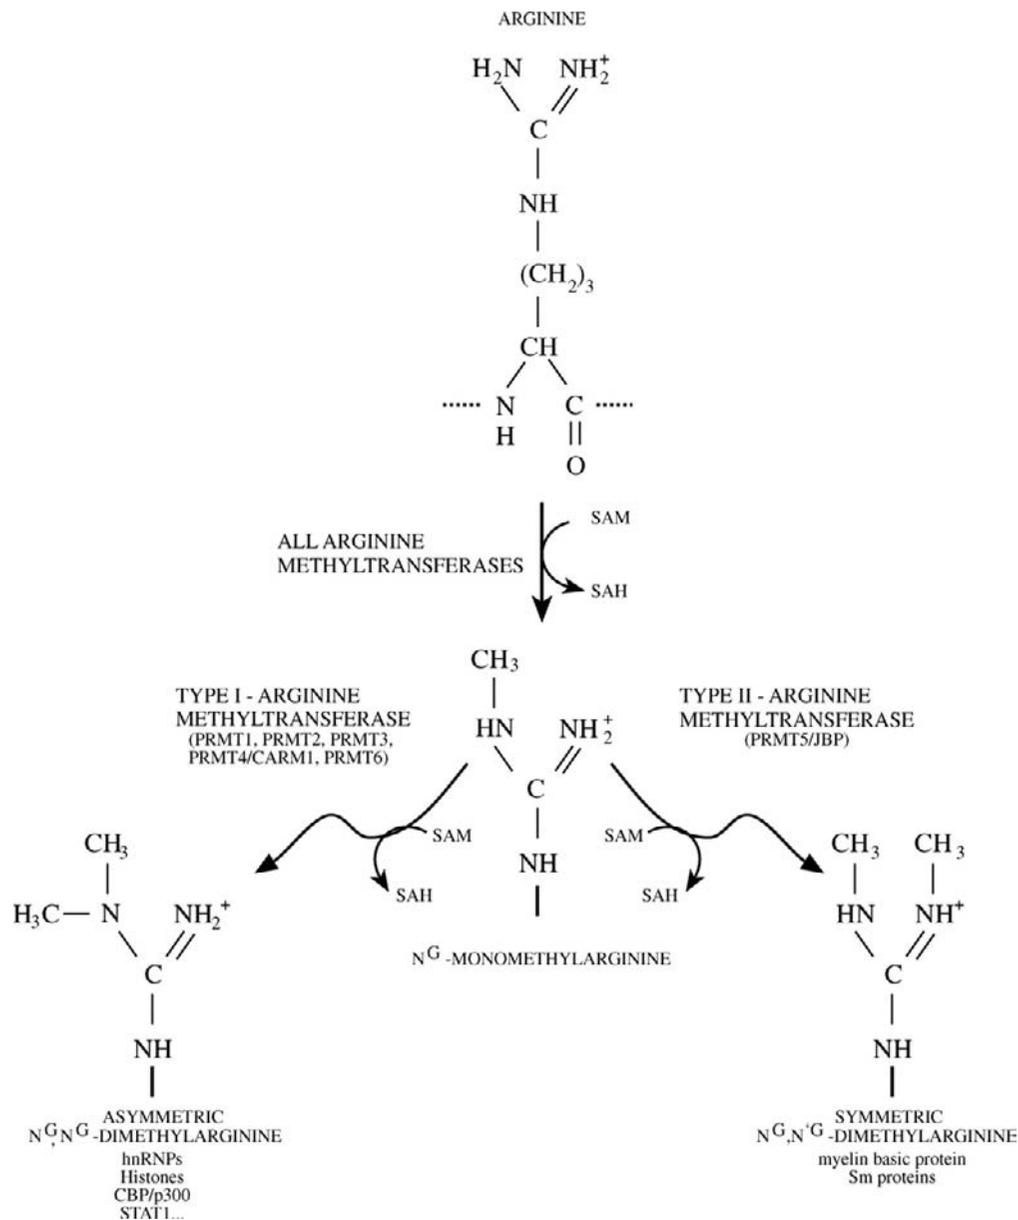

Figure 1 Protein arginine methyltransferases use SAM as methyl donor to catalyze mono- and dimethylation of the guanidino nitrogen atoms, generating SAH in the process.

Function of Arginine Methylation

Addition of methyl groups to the guanidino nitrogen atoms of arginine residues increases steric hindrance and reduces the ability to form hydrogen bonds without altering the overall charge of the amino acid. This suggests a role for methylation in the modulation of intra- or intermolecular interactions. Although the heterogeneous nuclear ribonucleoproteins (hnRNPs) involved in nucleocytoplasmic RNA transport comprise the majority of dimethylarginine containing proteins in the nucleus, their methylation appears to have no effect on their affinity for their respective RNA targets [12]. In contrast, several recent studies have illustrated an important function of arginine methylation in the regulation of protein–protein interactions. Methylation of Sam68, a proline-rich

src-kinase substrate known to interact with WW- or SH3-domain containing signaling proteins, decreases its affinity for SH3 domains, but does not alter binding to WW-motif containing proteins [13]. Similarly, arginine methylation of the STAT1 (signal transducer and activator of transcription) transcription factor decreases its affinity for its inhibitor PIAS1 (protein inhibitor of activated STAT 1). In the absence of STAT1 arginine methylation, PIAS1 associates with STAT1 and prevents its binding to DNA, thereby modulating interferon induced gene transcription [14]. A positive modulatory effect of arginine methylation on protein–protein interaction is observed with the type II arginine methyltransferase substrates SmD1 and SmD3, which require methylation for efficient binding to the spinal muscular atrophy gene product, SMN [11,15].

Role of Arginine Methylation in Signal Transduction

Very little is still known about the regulation of enzymatic activity and the biological functions of arginine methyltransferases. PRMT1, the first mammalian enzyme, was discovered through its physical interaction with the immediate-early proteins TIS21 and the related BTG1, which have the ability to modulate the activity and substrate specificity of PRMT1 [16]. Deletion of PRMT1 in mice through gene targeting resulted in early embryonic lethality, demonstrating an important role for the enzyme in mammalian development. Interestingly, PRMT1 deficiency does not cause lethality on a cellular level [17]. PRMT1 has been implicated in intracellular signaling by its ability to bind the cytoplasmic domain of the type I interferon receptor [18] and to methylate an arginine residue conserved between the N-terminal regions of all mammalian STAT proteins. Indeed, methylation of the STAT1 transcription factor was shown to be essential for interferon α/β -mediated transcriptional induction [14].

Arginine methylation of histones H2A and H3 [7], as well as the transcriptional coactivators CBP/p300 [19], supports a model in which protein methylation contributes to chromatin remodeling and initiation of transcription [20]. PRMT4 or coactivator-associated arginine methyltransferase (Carm1) cooperates with p160 family coactivators to stimulate transcriptional activation by nuclear receptors [7]. Furthermore, PRMT4 interacts with myocyte enhancer factor 2C (MEF2C) to promote myocyte differentiation [21].

PRMT5 or Jak-binding protein 1 (JBP1) participates in the assembly of a large arginine methyltransferase complex that targets several spliceosomal Sm proteins of the snRNPs [22]. Direct interaction of survival of motor neurons (SMN), the spinal muscular atrophy gene product, with the arginine-rich domain of the Sm proteins to form functional snRNP core particles increased upon symmetric dimethylation of the Sm proteins. Interestingly, anti-Sm autoantibodies detected in lupus erythematosus patients specifically recognize symmetric arginine-dimethylated Sm proteins [11]. Autoimmune responses against myelin basic protein (MBP), the only other protein known to be symmetrically dimethylated on arginine residues, account for the development of multiple sclerosis. These observations raise the possibility that posttranslational modification by arginine methylation plays an important role in the development of autoimmune disorders.

With the number of identified arginine methyltransferases and arginine methylated proteins rapidly increasing, the question remains whether this modification is similarly reversible as phosphorylation. Thus far, no arginine demethylase activity has been reported. Although it is possible that this modification persists over the lifetime of the protein, other enzymatic reactions such as protein arginine diiminination could in theory catalyze the removal of methylated nitrogens.

Much additional work is still required to elucidate the regulation of arginine methylation and its role in cellular function. Arginine methylation has just recently begun to be appreciated as a posttranslational modification that contributes significantly to signal transduction, protein sorting,

transcriptional regulation, chromatin remodeling, and perhaps disease progression.

Transcriptional Activity of Notch and CSL Proteins

Elise Lamar and Chris Kintner

*Molecular Neurobiology Laboratory,
Salk Institute for Biological Studies,
La Jolla, California*

Introduction

The Notch receptor controls diverse cell fate decisions developmentally and functions in a variety of processes in adults (for reviews, see [1–8]). Because the Notch intracellular domain (ICD) was shown to translocate to the nucleus following receptor activation and cleavage [9,10], its transcriptional activity has been actively investigated. In this capacity, ICD interacts with its DNA binding partner and alters its function from that of a repressor to an activator (for reviews, see [11,12]). This protein is known variously as Su(H) (for *Suppressor of Hairless*), CBF1, RBP-J, and LAG-1, depending on the species, and all orthologs are collectively referred to as CSL proteins [for CBF1, *Su(H)*, and *Lag-1*]. [For simplicity, we use the designation Su(H) in this review.] Here we present a summary of the biochemical functions of Su(H), ICD, and proteins participating in the Notch transcriptional complex, followed by evidence supporting models of Notch transcriptional activity *in vivo*. Although Su(H)-independent pathways of Notch signaling have been described [13–17], the transcriptional role of Notch has been examined largely in relationship to Su(H); therefore we address Notch activity only in that context.

Components of the Notch Transcriptional Complex

Architecture of the Notch ICD

The domain structure of the Notch ICD is shown in Fig. 1, which uses the 110-kDa *Xenopus* Notch1 ICD as a model. The number of Notch subtypes varies from organism to

organism, that is, *Drosophila* expresses one receptor subtype, *Caenorhabditis elegans* two, and vertebrates four (for a review, see [18]). Data derived from several species and receptor subtypes suggests that all Notch intracellular domains exhibit the conserved structural motifs shown in Fig. 1 and that these domains mediate common functions.

The notable exception to this rule is the activity of the Notch3 ICD, which is in some contexts a poor transcriptional activator and antagonistic to Notch1 ICD [19]. The N-terminal RAM domain of ICD interacts directly with Su(H) and is required for high-affinity binding to ICD *in vitro* [20]. Su(H) also binds weakly *in vitro* to the ankyrin repeats immediately downstream of the RAM domain [21]. All Notch ICDs contain six ankyrin repeats; however, structural studies of *Drosophila* ICD indicate a motif resembling a seventh [22]; human Notch1 mutant in this region binds Su(H) but is nonfunctional, suggesting that the motif is required for transactivation [23]. Immediately downstream of the ankyrin repeats is a conserved region known both as the ICD TAD (for transactivation domain), containing one of the two nuclear localization signals [9] and sequences required for transactivation; this region is discussed in detail later. The ICD C terminus contains a glutamine-rich opa repeat domain and a C-terminal PEST domain associated with protein turnover [24] (see later discussion).

Notch Signaling Antagonizes Su(H)-Mediated Repression

Notch ICD does not bind DNA but activates transcription through interaction with Su(H), which binds to the motif YGTGRGAA *in vitro* [225]. Sites identical or highly

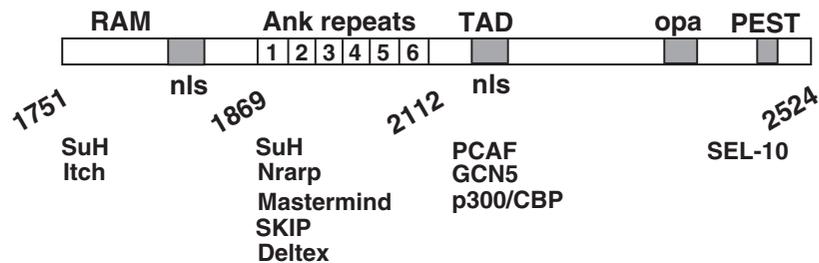

Figure 1 Domain structure of the 773 amino acid intracellular domain (ICD) of *Xenopus laevis* Notch1. Structural motifs shown are conserved in most Notch proteins, and numbering corresponds to amino acid residues of the unprocessed Notch receptor. Interacting proteins are listed below (for their functions see Table I). In some cases, namely Itch and SEL-10, potential interaction domains are fairly broad. Itch interacts with constructs of ICD containing the RAM domain and ankyrin repeats, while SEL-10 interacts with the C-terminus of ICD. SuH protein interacts with both the RAM domain and the reiterated ankyrin repeats, and both regions are required for Notch function. Six ankyrin repeats are shown, although there is some evidence for the existence of a seventh (see text). Sequences required for transactivation, designated the TAD, lie C-terminal to the ankyrin repeats and as indicated are known to bind several histone acetylases. Downstream from the TAD is a glutamine-rich domain designated opa and a PEST domain, which may be involved in protein turnover. ICD has two nuclear localization signals (nls): one C-terminal to the RAM domain and the other in the TAD.

homologous to this site (designated here as high-affinity sites) have been mapped in Notch-responsive promoters *in vivo* [26–31], as have divergent sites [32]. In the absence of Notch signaling, Su(H) has been shown to be a transcriptional repressor, by blocking interactions between TFIIA and TAF110 of TFIID on a viral promoter [33], but more generally by recruiting corepressors containing histone deacetylase (HDAC) activity. In vertebrates, Su(H) interacts with the corepressors SMRT [34], CIR [35], and a third repressor KyoT2 [36], and antagonizes Notch activation of Su(H)-dependent reporters in transient transfection assays. In *Drosophila*, Hairless, a nuclear protein that binds Su(H), genetically antagonizes Notch signaling in *Drosophila* [37–39] and mediates Su(H) repressor functions by acting as an adaptor protein between Su(H) and the corepressors CtBP [12,40] and Groucho [12,41]. Together, all of these corepressors can recruit both Class I and Class II HDACs (for a review, see [42]).

The implication of these findings is that in the absence of Notch signaling Su(H) acts as a local repressor; biochemical evidence for this hypothesis comes from chromatin immunoprecipitation assays showing that Su(H) binds to target promoters in the absence of Notch signaling [43]. *In vivo* support for a Su(H) repressor function comes from further analysis of both artificial enhancers and enhancers derived from Notch target genes, as described later [29,44].

Notch Signaling Derepresses Su(H) and Activates Transcription

Significantly, the physical interaction of corepressors and ICD with Su(H) is mutually exclusive, suggesting that Notch signaling leads to changes in gene expression in part by derepression. However, a large body of evidence also indicates that ICD activates transcription by recruiting additional

proteins that contain histone acetyltransferase (HAT) activity. One line of evidence suggests that these HAT-containing proteins are recruited by directly binding to sites on ICD; specifically, to a TAD located in a 200-amino-acid stretch downstream of the ankyrin repeats (see Fig. 1) [45–47]. Deleting or mutating this region in ICD attenuates Notch-mediated transcription in frog embryos [438], *in vitro* [49], in cell culture models [46], and in *in vivo* models of ICD-mediated oncogenesis [50]. This region has been shown to bind the HAT-containing proteins, PCAF and GCN5, in both mouse Notch1 and *Drosophila* ICD, while a similar region in mouse Notch1 has been shown to bind the HAT-containing coactivator, p300/CBP.

Another line of evidence suggests that HAT-containing proteins are recruited indirectly by ICD through interactions with large, glutamine-rich nuclear proteins referred to here as the Mastermind (mam) proteins [49,51–53]. Loss-of-function analysis of the mam proteins in *Drosophila* [54], *C. elegans* (where it is known as Lag-3) [51], and vertebrates [49,55] suggests that these proteins are required for Notch signaling and the activation of Notch target genes. The mam proteins form a tight ternary complex with Su(H) and the ankyrin repeats of ICD [51–53] and this complex appear to potentiate ICD transcriptional activity in transient transfection assays [52,53], suggesting that mam is a Notch coactivator. Indeed, when assayed *in vitro* on chromatin templates, ICD requires mam to initiate transcription [49]. Activity in this assay requires a region of mam between amino acids 74 and 301 that binds tightly to CBP/p300; disrupting this binding markedly decreases the ability of ICD to initiate transcription *in vitro* and to promote the expression of Notch target genes *in vivo* [49]. CBP/p300 binds to mam under conditions that are more stringent than those that allow binding to ICD, suggesting that mam is the key element in recruiting HAT-containing proteins to the Notch transcriptional complex [49].

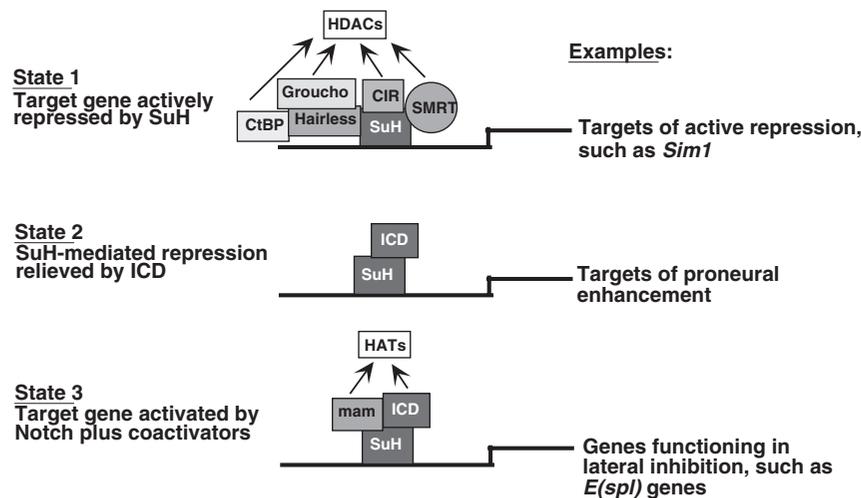

Figure 2 The SuH/ICD transcriptional switch can exist in several states. In State 1, SuH functions to actively repress transcription by interacting with several factors, such as the SMRT/NCOR, CIR, CtBP, and Groucho co-repressors. In *Drosophila*, both CtBP and Groucho interact with SuH through the adaptor protein Hairless. For the sake of simplicity not all of the numerous proteins interacting with SuH in a repressive state are depicted. All of these co-repressors function to recruit HDACs, suggesting that chromatin remodeling occurs in the course of changes in Notch signaling. Active repression has been demonstrated in *Drosophila* not only on artificial enhancers but in vivo as being required for regulation of expression of *sim1*. State 3 represents the opposite activity; through interaction with ICD, co-repressors and accompanying HDACs are dismissed from SuH, and several HATs (See Figure 1 and Table 1) are recruited to the promoter through ICD and its dedicated co-activator mastermind (*mam*). Transcriptional activation by Notch is thought to be required for processes such as lateral inhibition and is best represented by upregulation of *E(spl)* genes in *Drosophila*. Evidence for an intermediate state (State 2), in which repression is off but activation through Notch is not required, comes from studies of eye development in SuH-*files*, which lack both SuH-mediated repression and Notch signaling. These studies indicate that relief from SuH-mediated repression is sufficient to activate, or “enhance”, expression of putative targets, such as proneural genes, which function in differentiation.

The current model suggests that the Su(H)/ICD repressor/activator switch is mediated by HDAC/HAT recruitment, respectively, and strongly suggests that changes in the acetylation state of nucleosomes occurs in the course of Notch signaling [56]. This model posits several states in which Su(H) can exist, thus regulating gene expression in an ICD-regulated manner. In the absence of ICD, Su(H) acts as a local transcriptional repressor by recruiting HDAC-containing corepressors (state 1; Fig. 2). By associating with Su(H), ICD relieves this repression and may weakly recruit coactivators (state 2). The combination of Su(H) and ICD recruits additional coactivators such as *mam*, resulting in strong transcriptional activation (state 3).

This model will certainly undergo revision as various components of the Notch transcriptional complex are revealed. For example, we already know that ICD is more than a tether for *mam* because its TAD acts cooperatively with *mam* to promote transcription both *in vivo* and *in vitro*. How this TAD acts is unknown. In addition, *mam* contains a second TAD within the carboxy terminus that is required for Notch transcription *in vivo* but not *in vitro* [49], suggesting interactions with yet another group of transcriptional cofactors.

Additional Proteins Interacting with Su(H)/ICD

A number of proteins have been identified that interact with ICD and/or Su(H) (see Table I). In some cases, it remains

unclear whether these proteins function in transcription *per se*, or whether they are regulatory subunits that modulate the activity of the transcriptional complex.

NRARP

Nrarp (for Notch regulated ankyrin repeat protein) is expressed in many cases where Notch signaling regulates cell fate in the vertebrate embryo, and its expression is dependent on Notch signaling [57–59]. *Nrarp* binds to ICD and Su(H) but only as part of a ternary complex, interacting with the ICD ankyrin repeats. On the one hand, *Nrarp* promotes Notch transcription in transient transfection assays presumably by promoting the formation of a complex between ICD and Su(H). On the other hand, when misexpressed in frog embryos, *Nrarp* blocks Notch signaling and promotes the loss of ICD protein, suggesting that it inhibits Notch signaling by destabilizing ICD. Further genetic analysis is required to determine whether *Nrarp* is primarily a positive or negative factor in the Notch transcriptional complex, and whether it is required for Notch signaling in some or all cases *in vivo*.

SKIP

The *v-ski-interacting protein* SKIP interacts physically with both Su(H)/corepressor complexes, through interaction with both Su(H) and SMRT, and with ICD, through the fourth

Table I Proteins Interacting with ICD/Su(H) or Su(H)^a

Interactor	Function	References
<i>Interactors with ICD/Su(H)</i>		
Mastermind	Coactivator	51–53
Nrarp	Unknown; mediates ICD degradation	57–59
SKIP	Unknown; potential coactivator	60
Deltex	Unknown; may antagonize activators	63–66
GCN5, PCAF	HATs; coactivators	46
CBP/p300	HAT; coactivator	47
Itch	E3 ligase; ICD degradation	83
SEL-10	E3 ligase; ICD degradation	86
<i>Interactors with Su(H)</i>		
SKIP	Unknown	60
SMRT/NCoR	Corepressor	34
CIR	Corepressor	35
KyoT2	Corepressor	36
CtBP	Corepressor	12, 40
Hairless	Adaptor; interacts with corepressors	37–39
TFIIA, TFIID	Coactivators; antagonized by Su(H)	33

^aThese proteins interact with either ICD/Su(H) or Su(H) alone in a manner suggesting they modulate or regulate transcriptional activity.

ankyrin repeat [60]. When expressed as Gal4 fusion proteins, human and *Drosophila* SKIP repress transcription. However, evidence that SKIP's primary role is to facilitate ICD transcription is more compelling. First, SKIP potentiates Su(H)-dependent ICD activity in transient transfection assays. Furthermore, antisense SKIP can rescue a block in muscle cell differentiation promoted by ICD [60], suggesting that SKIP is required for ICD function in this context. Finally, SKIP interacts with and transcriptionally coactivates several other proteins, including viral transactivators [60], nuclear receptors [61], and Smads [62].

DELTEX

Found in flies and vertebrates, Deltex proteins interact through their N terminus with the ICD ankyrin repeats [63]. Deltex proteins also contain a proline-rich domain and a C-terminal ring-finger motif, which promotes oligomerization [64]. What role Deltex plays in Notch signaling is currently unclear; furthermore, assigning a role for Deltex in transcription is speculative, because it is predominantly cytoplasmic [14,65] and also plays a role in Su(H)-independent Notch pathways [16,66]. On the one hand, genetic screens in *Drosophila* indicate that Deltex positively regulates Notch [67]. However, in functional assays Deltex proteins [66,68,69] can block ICD/Su(H) transcriptional activity, an activity requiring the ICD TAD and PEST sequences [69]. Similarly, Deltex inhibits transactivation of Gal4 reporters by both ICD and full-length mam fused to Gal4 [69]. This study, taken together with evidence that both ICD [47] and mam [49] interact with p300/CBP and that Deltex inhibits p300/CBP

activity [66], suggests that in some contexts Deltex may negatively regulate Su(H)-dependent Notch activity by interfering with p300/CBP recruitment.

Modification of ICD

Notch ICD, like several transcription factors, is modified posttranslationally, primarily by phosphorylation but also by ubiquitination. Although ICD modification is likely to have transcriptional consequences, those consequences are not well understood at this time.

PHOSPHORYLATION

Following receptor activation and cleavage ICD becomes hyperphosphorylated [70–73]. Biochemical analysis of phosphorylation of Notch1 indicates that it occurs in two kinetically separable steps, in which ICD is phosphorylated in the cytoplasm and then hyperphosphorylated in the nucleus [74]. Although correlated with receptor activation, the mechanism and role of ICD phosphorylation remain unclear. Highly phosphorylated forms of *Drosophila* ICD immunoprecipitate with Su(H), suggesting that phosphorylation does not preclude inclusion in a transcriptional complex [70,72]; however, dephosphorylated ICD also immunoprecipitates with Su(H), indicating that ICD's phosphorylation state is unlikely to regulate complex formation.

It is not known whether phosphorylation of ICD is required for Su(H)-dependent transcription per se. Differential phosphorylation in response to growth factors alters Notch2 ICD function, although the transcriptional consequences

are unknown [75]. In labeling experiments, much of the phosphate incorporated by ICD maps to the region required for transactivation [72], suggesting a transcriptional role, although the C-terminal half of mouse Notch1 ICD, containing both the TAD and PEST sequences, incorporates phosphate at multiple sites [72].

The activity of the coactivator mam suggests that phosphorylation regulates ICD turnover. Mam promotes hyperphosphorylation of *Xenopus* ICD in a Su(H)-dependent manner, an event correlating with loss of ICD protein from cell extracts [49]. Truncated ICD containing the TAD but lacking the C-terminal PEST domain is neither hyperphosphorylated nor destabilized in the presence of mam; likewise, full-length ICD is not hyperphosphorylated and destabilized by mam truncations containing only the N terminus and N-terminal TAD. Given that truncated forms of ICD initiate transcription in the presence of mam [49], these observations support the following model: that ICD/Su(H)/mam interaction favors recruitment of a kinase to catalyze the nuclear phosphorylation of sequences in the ICD C terminus, and that such hyperphosphorylation may function in a downstream transcriptional event such as elongation, in ICD turnover, or in both. Some ubiquitin ligases such as SEL-10 target phosphorylated ICD substrates for degradation (see later discussion); although loss of ICD protein from cell extracts accompanies mam-mediated hyperphosphorylation, it is not known whether a kinase activity potentially recruited by mam is required for ICD recognition by SEL-10.

An opposite role for phosphorylation in regulating ICD turnover comes from reports that the serine kinase GSK β (Shaggy) phosphorylates the Notch1 ICD *in vitro* and thereby enhances the stability of ICD protein [76]. *In vivo* cells lacking GSK β activity exhibit less extensively phosphorylated forms of ICD, which is attributable to either direct or indirect interaction with GSK β [76]. Given that ICD is so highly phosphorylated, these data and the activity of mam indicate that phosphorylation, which is likely mediated by several kinases, plays multiple roles in regulating ICD stability and potentially transcriptional activity.

UBIQUITINATION

Ubiquitination not only marks proteins for degradation but is required for activation of some transcriptional factors (for a review, see [77]). Numerous studies indicate a role for ubiquitination in the turnover of proteins in the Notch pathway [74,78–84]; furthermore, disabling the proteasome stabilizes misexpressed ICD in both fly embryos and cultured cells [81,85]. As yet, however, there is no evidence for an activating role of ubiquitination in Notch transcription, although the observation of paradoxical degradation/activation activity by proteins such as Nrarp and mam suggests that ICD activation could be linked to turnover.

The F-box E3 ligase, SEL-10, was first identified as a suppressor of hypomorphic Notch alleles in *C. elegans* genetic screens [86]. Vertebrate Sel-10 homologs promote the ubiquitination of ICD, preferentially recognizing

hyperphosphorylated forms of ICD [74,81,82]. Interaction with SEL-10 requires sequences downstream of the ICD ankyrin repeats, the domain shown to be highly phosphorylated as noted earlier [72]. Ubiquitination by SEL-10 apparently leads to turnover given that dominant-negative forms of SEL-10 stabilize ICD protein [81]. Dominant-negative SEL-10 potentiates ICD activity on Su(H)-dependent reporters [81,74], while full-length SEL-10 reduces transcriptional activity [82]. These observations coupled with genetic evidence suggest that SEL-10-mediated ubiquitination does not activate Notch transcription but primarily acts to promote ICD turnover.

A HECT-type ubiquitin ligase known in flies as Suppressor of Deltex (Su(dx)) and in mouse as Itch also ubiquitinates Notch ICD [83]. Although genetic evidence indicates that Su(dx) negatively regulates Notch signaling [87], the phenotype of Itch^{-/-} mice, which exhibit inflammation and immune defects [88,89], does not immediately suggest a role in Notch signaling. Therefore the relevance of Itch to Notch signaling *in vivo* in vertebrates remains unclear.

Notch Transcriptional Activity *In Vivo*

Biochemical analysis of the Notch transcriptional complex has revealed the mechanism by which ICD converts Su(H) from a transcriptional repressor to an activator. We next consider how this transcriptional complex alters gene expression during Notch signaling based on *in vivo* analysis of Notch-responsive enhancers. This analysis has been primarily pioneered in *Drosophila* where a large number of Notch-responsive enhancers have been characterized molecularly. One issue addressed by these studies is whether ICD regulates transcription by simply promoting derepression of Su(H), or whether it also promotes transcriptional activation by recruiting coactivators. These two possibilities can be distinguished genetically in *Drosophila* because they predict that Su(H) loss-of-function mutants will exhibit increased Notch signaling phenotypes in the former case, but decreased Notch signaling phenotypes in the latter. We review here cases in which Notch acts by derepression, although even in these cases, Notch signaling also acts by switching Su(H) to a transcriptional activator.

A second issue addressed here is how Notch activates expression of targets in a context-dependent fashion. For example, Notch signaling directly regulates related genes that encode bHLH repressors in the *Enhancer of Split* locus even though these genes differ dramatically in both their spatial and temporal expression patterns during development. This finding implies that specificity in Notch signaling is derived from other factors, which act in combination with ICD. We discuss here support for such a combinatorial mechanism, which has been observed in *Drosophila* on both native and artificial Notch-responsive enhancers. Finally, we conclude with a brief discussion of vertebrate Notch response elements and enhancers, some of which reflect the molecular organization and/or activities seen in flies. Table II provides a summary of Notch response elements including bona fide Notch enhancers.

Table II Notch Responsive Enhancers/Promoters^a

Target gene	Function	References

^aFunction is defined as follows: enhancer, tissue specific enhancer responsive to Su(H)-dependent Notch signaling *in vivo*; response element, genomic fragment from a likely Notch target gene containing Su(H) binding sites and responsive to ICD activation, Su(H)-mediated repression, or both in cultured cells; binding site, element DNA binding Su(H) *in vitro* and derived from genomic DNA flanking a potential Notch and/or Su(H) target gene.

Repression by Su(H)

The role of Notch in relieving Su(H)-mediated repression is supported by the analysis of the *Drosophila single minded* (*sim*) gene, which is expressed in a single row of cells in the embryonic ventral mesectoderm. High levels of *sim* expression within this single row of cells require Su(H)-dependent Notch signaling [44]. However, expression of *sim* in Su(H) null mutants is not only reduced, as one would predict, but also ectopic, suggesting that in the absence of Notch signaling Su(H) represses *sim* expression in cells adjacent to the stripe. This possibility was tested by characterizing sequences in the *sim* enhancer required for proper transgene expression. The *sim* enhancer contains 10 Su(H) sites, 6 of which are high-affinity sites, and several in proximity to binding sites for two other positive regulators of *sim* expression, Dorsal and Twist, and to binding sites for a negative regulator, Snail [44]. When all 10 Su(H) sites are mutated, the enhancer no longer drives high levels of expression at the midline but is also expressed ectopically in adjacent cells in a manner analogous to the *sim* expression pattern in Su(H) null flies.

These data suggest strongly that Su(H) not only mediates activation of target gene expression in areas of Notch signaling, but also repression of genes outside this area where Notch signaling is silent.

Transcriptional repression mediated by Su(H) is also revealed by analysis of a synthetic enhancer containing different combinations of binding sites for the bHLH protein Grainyhead and for Su(H) [90]. In general, reporters driven by Grainyhead sites alone are expressed widely and at moderate levels. When Grainyhead sites are combined with Su(H) sites, expression of the enhancer is inhibited in tissues where Notch signaling is absent, suggesting that Su(H) without ICD represses the activity of Grainyhead. However, transgene expression driven by the same enhancer is robust in regions where Notch signaling and Grainyhead expression coincide, suggesting that ICD not only depresses Su(H) but cooperatively interacts with Grainyhead to activate transcription. These findings support those observed with the *sim* enhancer, revealing a role of Su(H) mediated repression in preventing ectopic expression of Notch target genes.
