It has been observed that transformed cells possess a heightened state of sensitivity to stress/apoptotic signals as compared to their parental nonmalignant cells [2,54]. This sensitized state renders the cancer cells higher sensitivity to stress/apoptotic agents such as *cis*-Platin (CDDP) and pro-apoptotic ligands such as FasL. As the cancer progresses, the potentiated state of sensitivity to stress is covered up by a massive shield of anti-apoptotic signaling networks. Thus, when one applies an anti-apoptotic agent, the potentiated state of the cell is uncovered and the cancer cell becomes hypersensitive to the pro-apoptotic stress agent. This is probably why PTK inhibitors synergize with cytotoxic drugs or pro-apoptotic proteins such as FasL. The first example demonstrating this principle was reported for Her-2/neu-expressing lung cancer cell lines. It was shown that the degree of synergism between a Her-2 kinase inhibitor (AG 825) (Fig. 1) and the cytotoxic agents CDDP, etoposide, or doxorubicin increases with the level of expression of Her-2/neu in a series of isogenic patient-derived NSLC cell lines [55]. It seems that the degree of anti-apoptotic signaling of Her-2 is proportional to the latent potentiated sensitivity of the cancer cell; thus, the degree of synergism is proportional to the level of Her-2/neu signaling. The fact that PTK inhibitors can synergize with pro-apoptotic agents is already being implemented in the clinic. ZD 1839 (Iressa), a potent EGFR kinase inhibitor developed by AstraZeneca, is currently in clinical trials as a single agent and in combination

with cytotoxic agents such as Taxol® [56]. Another interesting case is advanced glioblastoma multiforme (GM), where the truncated EGFR Δ (2–7 EGFR) is responsible for its resistance to chemotherapy and radiation therapy. Blockade of the EGFR by the EGFR kinase inhibitor AG 1478 sensitizes the tumor to CDDP and enhances the survival of tumor-bearing nude mice treated with the two agents [30,31]. This combination is in clinical development for the treatment of GM. As mentioned previously, STI 571/Gleevec shows remarkable activity against chronic CML, and patients on STI 571 have been in complete remission for nearly 3 years, but it is much less effective as a single agent in blast crisis CML, where the disease recurs in 80% of the patients within a few months. These patients are likely to be given a combination of STI 571 with pro-apoptotic agents early in the treatment. So far, PTK inhibitors have not been tried in humans in combination with pro-apoptotic proteins or antibodies. In tissue culture, the synergy between PTK inhibitors, cytotoxic agents [55,56], FasL, or anti-Fas receptor antibody [38,57] was established.

PTK Inhibitors for the Treatment of Non-Cancer Diseases

The enhanced activity of PTKs has been related to diseases other than cancer. The enhanced activity of EGFR is the hallmark of psoriasis and papilloma. In both instances, EGFR is overexpressed and the diseased cells produce EGFR-stimulating ligands. This is the reason why EGFR kinase inhibitors inhibit the growth of both psoriatic keratinocytes [58–61] and keratinocytes immortalized with human papillomavirus 16 (HPV-16) [62,63]. It has been suggested that EGFR kinase inhibitors be used as topical agents to treat these conditions. PDGFR is the key player in restenosis following balloon angioplasty; therefore, PDGFR kinase inhibitors have been tested as inhibitors of balloon-induced stenosis. Local application of AG 1295 [64] and AGL 2043 [27] during balloon angioplasty has indeed been shown to be highly effective against the development of stenosis after balloon angioplasty. One can envisage the utilization of PTK inhibitors for other indications, such as pulmonary fibrosis, in which the enhanced activity of PTKs plays an important role in the pathophysiology of the disease.

PTK Inhibitors as Cancer Prevention Agents

Over the past few years, interest has increased in agents that are natural components of foods and have anticancer properties [65]. It has been suggested that males from the Far East suffer less from prostate cancer because they consume food rich in genistein, which is a nonselective PTK inhibitor. Studies suggest that genistein prevents the growth of metastatic cancer [66–68]. Dietary genistein downregulates the expression of the androgen receptor and estrogen receptor- α and - β in the rat prostate, at concentrations comparable to those found in humans on a soy diet [69]. Thus, downregulated sex steroid receptor expression may be responsible for the lower incidence of prostate cancer in

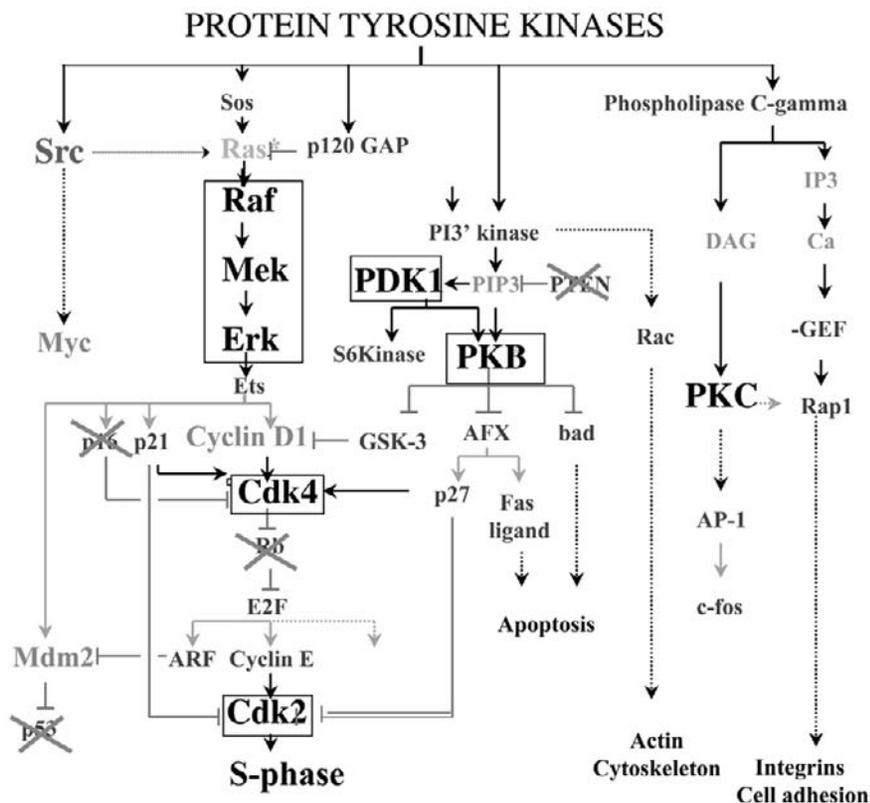

Figure 7 Key signaling Ser/Thr kinases. A small fraction of Ser/Thr kinases are valid targets for drug development; these are indicated by bold type in boxes. Crosses appear on tumor suppressors for which activities are compromised in cancer and therefore augment the activation of various kinases.

populations living on a diet containing high levels of phytoestrogens. Clinical trials are therefore planned for patients with metastatic prostate cancer who will receive genistein to examine whether this agent does, indeed, have any antimetastatic effects. Also, it has been suggested that polyphenols, which are components of wine, possess antineoplastic effects. These effects are largely attributed to their antioxidant properties, but it is possible that the inhibitory effects on PTKs are also responsible.

PTK Inhibitors for Diagnostic Purposes

It is always essential to establish a treatment modality based on the presence of the drug target in the diseased tissue. For example, it is extremely important to know ahead of treatment with an EGFR kinase inhibitor if the tumor does, indeed, overexpress the receptor. This can be achieved by imaging the tumor utilizing an EGFR kinase inhibitor, which is a positron emitter. Recent studies show that a reversible EGFR kinase inhibitor [70] is inferior to an irreversible one [71] for achieving this goal. Positron emission tomography (PET) imaging of the EGFR is extremely important for the determining which patients with non-small-cell lung carcinoma are eligible for treatment with Iressa. Because many of the tumors express either EGFR or Her-2, or both, a dual PET imager based on GW 2016 (Fig. 4) may also be useful.

SER/THR Kinase Inhibitors

Among the few hundred Ser/Thr kinases a handful are involved in transmitting the signals of upstream PTKs, and their activity is essential for cell proliferation and the onset of anti-apoptotic signaling (Fig. 7). Their abnormal enhanced activities are augmented by the deletion of negative regulators such as protein inhibitors of Cdks and the deletion of the tumor suppressor PTEN, the negative regulator of the PI3' kinase pathway. Thus, the activities of these kinases are enhanced by the synergistic action of the enhanced upstream PTKs combined with the inactivation of downstream negative regulators. As an example, Cdks execute the cell cycle and their activity has been found to be enhanced not only as a result of enhanced upstream signaling but also as a result of the overexpression of cyclin D1 and the deletion of Cdk inhibitors such as p15 and p16. Thus, Cdk2, Cdk1/Cdc2, and Cdk4 have become targets for new antineoplastic agents. Similarly, PI3' kinase signaling has been found to be enhanced by the deletion of its negative regulation PTEN. This deletion, characteristic of high-grade tumors, potentiates the already strong positive regulation of the PI3' kinase/PKB/mTor module complex by PTKs. Because of findings such as these, inhibitors of PKB and mTor are in development as antitumor agents.

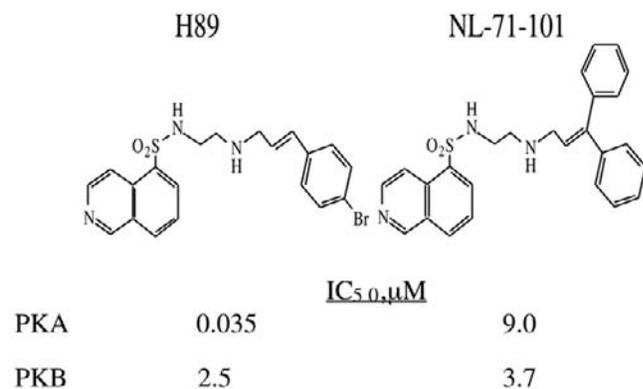

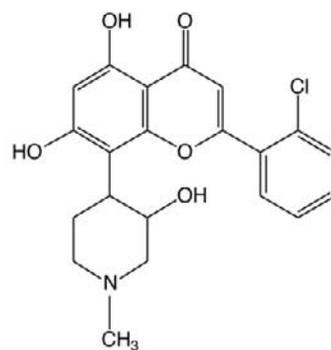

Figure 8 Development of PKB/Akt inhibitors. One of the avenues to develop PKB inhibitors is to reverse the specificity of H-89, a PKA inhibitor. The advantage of this approach is the greater selectivity of the compound against other kinases and the relative simplicity of the experimental protocols.

PKB/Akt Inhibitors

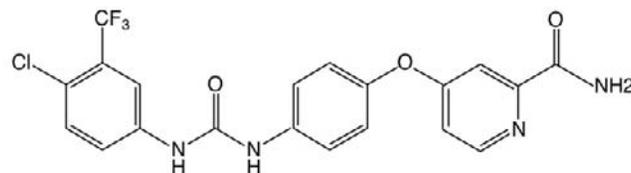

Progress toward generation of PKB inhibitors (Aktstatis) has been recently reported [72]. In this study, the PKA inhibitor H-89 was modified to reduce its affinity to PKA but retaining and even improving its affinity to PKB/Akt (Fig. 8). Attempts are currently being made to widen the gap in selectivity towards PKB/Akt and increase the affinity.

Inhibitors of the Ras Pathway: Raf and Mek Inhibitors

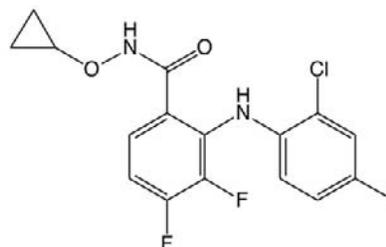

Inhibitors of the Ras–Raf–Mek–Erk pathway have great therapeutic potential, as mutated Ras is the hallmark of many cancers. Mutated Ras occurs in 30% of all human tumors, in 80% of pancreatic cancers, in 50% of colorectal cancers, in 40% of lung cancer, and in 20% of hematopoietic malignancies. So far, no real success has been achieved in developing Ras inhibitors, but promising developments are reported in the development of Raf and Mek inhibitors. A recent study [73] shows that mutations that activate the kinase activity in B-Raf occur in ≈66% of human melanomas, suggesting that Raf kinase inhibitors (such as the recently reported Onyx/Bayer compound BAY 43-9006 [74]) (Fig. 9) may be utilized to treat metastatic melanoma. Mek inhibitors such as PD 184352 [75] are also very promising. PD 184352 (Fig. 9) is a highly potent and selective inhibitor of Mek that is orally active. Tumor growth has been inhibited as much as 80% in mice with colon carcinomas of both mouse and human origin after treatment with this inhibitor [75]. Efficacy was achieved with a wide range of doses with no signs of toxicity and were correlated with a reduction in the levels of mitogen-activated protein kinase in excised tumors. These data indicate that Mek inhibitors represent a promising, noncytotoxic approach to the clinical management of colon cancer. It is highly likely that many more inhibitors of this pathway will emerge in years to come.

Flavopyridol

BAY 43-9006

PD 184352

Figure 9 Cdk, Raf, and Mek inhibitors.

Cdk

Inhibitors of Cdks are being developed as anticancer agents [76–81]. Flavopyridol (Fig. 9) inhibits Cdk4/cyclin D and Cdk1/CyclinB1, with an IC₅₀ value of 200 nM as compared to PKA and PKC, which it inhibits with IC₅₀ of 960 μM and 10 μM, respectively [82]. This inhibitor is currently in clinical development (Table 1) [83].

PKC Inhibitors

Although we have been aware of PKC isozymes for a long time, little progress has been made in utilizing PKC inhibitors as therapeutic agents. Some agents are in development as anticancer drugs [77,84–86]. PKC-β inhibitors are also potential agents against vascular dysfunction [87] and are being evaluated as agents against vascular retinopathy, a complication of diabetes.

Rapamycin

Rapamycin, the inhibitor of mTor, is effective as an inhibitor of angiogenesis and therefore is a potential anticancer

drug [88]. Rapamycin is also effective in the inhibition of restenosis when applied on coated stents [89].

University of Virginia Health System,
Charlottesville, Virginia*

Introduction

Integrins are a family of heterodimeric, transmembrane receptors that mediate attachment of cells to the surrounding extracellular matrix (ECM) [1]. Different combinations of α and β subunits dictate specificity for the extracellular ligands [2]. The cytoplasmic tail of the β subunit is both necessary and sufficient to mediate the linkage of integrins to the actin cytoskeleton [3]. Although α -subunit cytoplasmic tails bind to cytoskeletal proteins [2], the major functional role of the α subunit is to modulate cytoskeletal interactions by directly interacting with the cytoplasmic tail region of the β subunit. Thus, integrins are ligand-dependent sensors of the ECM environment. As such, they are responsible for directing biochemical signals and cellular forces, which together regulate cell migration, cell growth, and cell survival.

Integrins Nucleate the Formation of Multi-Protein Complexes

A central function of the integrins is to mediate a structural linkage between the dynamic intracellular cytoskeleton and the ECM. More than 50 proteins have been identified either as direct integrin-binding proteins or as proteins that localize to adhesion complexes (e.g., focal adhesions) [4]. The proteins found in adhesion complexes fall into two broad categories: those that serve a structural role to anchor and regulate the actin cytoskeleton and those that are responsible for integrin-mediated signaling and the remodeling of adhesion complexes.

The association of talin, α -actinin and vinculin with integrin receptors serves to illustrate how integrins are linked to actin filaments and the cytoplasm (Fig. 1). Talin is a major structural component of focal adhesions [3]. Talin binds directly to the tails of β 1, β 2, and β 3 integrins. In addition, talin contains binding sites for actin, vinculin, focal adhesion kinase (FAK), and phospholipids. Cells deficient for the expression of talin exhibit significant increases in membrane blebbing, defects in cell adhesion and spreading, and a failure to assemble focal adhesions and stress fibers, underscoring the role of talin in the organization of adhesion structures [5]. α -Actinin is an actin-binding protein that binds the cytoplasmic tails of β 1, β 2, and β 3 integrins [3] as well as several additional focal adhesion proteins, including vinculin and zyxin. Localization of α -actinin to adhesion complexes occurs by a direct interaction with β -integrin cytoplasmic tails. Vinculin is one of the most abundant focal adhesion proteins, although it does not bind integrins directly [3]. Vinculin binds F-actin and the adhesion-associated proteins paxillin and VASP and is recruited to focal adhesions indirectly via an interaction with an integrin cytoplasmic tail binding protein (e.g., talin or α -actinin). Vinculin functions as a molecular bridge to stabilize integrin-F-actin linkages. Vinculin-deficient cells exhibit decreased mechanical stiffness and increased cell motility [3,5].

Integrins also serve to recruit proteins that are directly involved in regulating the formation and turnover of adhesion complexes and the promotion of intracellular signals (Fig. 1). FAK is a focal-adhesion-associated, nonreceptor protein tyrosine kinase. FAK binds *in vitro* to the cytoplasmic tails of β 1 and β 3 integrins, although to date this interaction

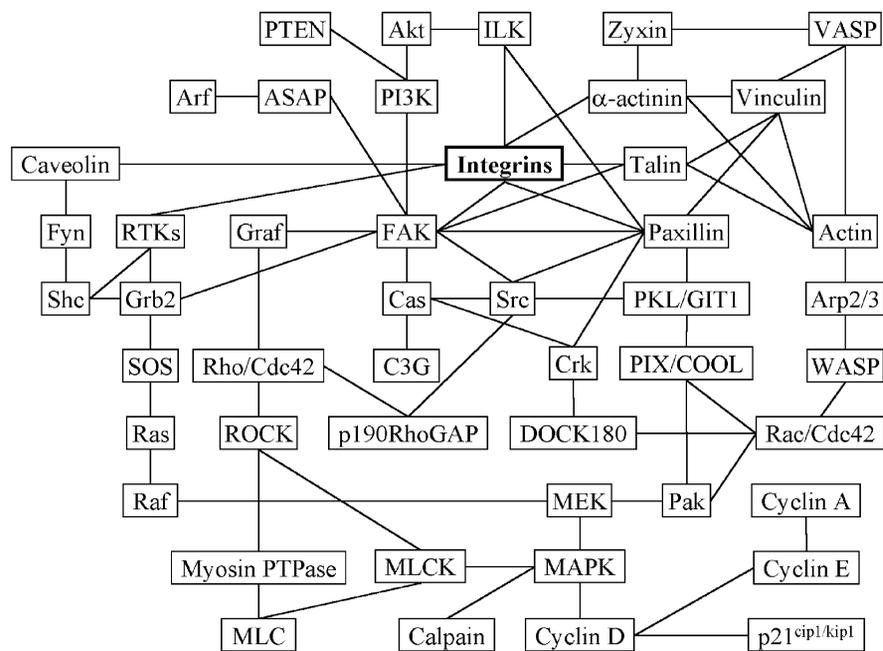

Figure 1 Integrin connections. Schematic diagram of protein interactions initiated by integrin receptors, as described in the text. The following abbreviations are used: ARF (ADP-ribosylation factor), Arp2/3 (actin-related protein 2/3 complex), ASAP (ARF-GAP containing SH3, ankyrin repeats, and PH domain), C3G (Crk SH3-binding GNRP), Cas (Crk-associated substrate), Crk (CT10 regulator of kinase), FAK (focal adhesion kinase), GRAF (GTPase regulator associated with FAK), ILK (integrin-linked kinase), MAPK (mitogen-activated protein kinase), myosin PTPases (myosin phosphatase), p190RhoGAP (p190 Rho GTPase-activating protein), PAK (p21-activated kinase), PI3K (phosphatidylinositol 3-kinase), PIX/COOL (Pak-interacting exchange factor/cloned out of library), PKL/GIT1 (paxillin-kinase linker/G-protein-coupled receptor kinase-interacting protein 1), PTEN (phosphatase and tensin homolog deleted on chromosome ten), ROCK (Rho kinase), RTKs (receptor tyrosine kinases), SOS (Son of Sevenless), VASP (vasodilator-stimulated phosphoprotein), and WASP (Wiskott-Aldrich syndrome protein).

has not been demonstrated *in vivo* [6]. FAK contains an approximately 100-amino-acid domain that is both necessary and sufficient to target FAK to focal adhesions [7]. In addition, FAK also contains sequences that mediate its association with focal adhesion proteins paxillin and talin, as well as to the cytoskeletal adaptor protein Cas and GTPase-activating proteins (GAPs) for Rho (GRAF [8]) and ARF1 (ASAP1 [9]) (Fig. 2). Paxillin is a multidomain protein that not only binds to FAK, but also serves as a scaffold to recruit and organize a number of additional signaling molecules at the sites of adhesion. Paxillin binds Src, Crk, vinculin, actopaxin, and the serine/threonine kinase ILK, as well as the ARF GAPs PKL and GIT1 [10,11]. In addition, paxillin binds directly to the cytoplasmic tails of $\alpha 4$ integrins [12]. Like FAK-deficient cells, paxillin-null cells exhibit defects in cell spreading and cell migration, as well as decreased tyrosine phosphorylation of FAK and Cas [13,14]. Cas is another adaptor protein that binds to both FAK and Src and serves to recruit additional signaling molecules to focal adhesions. Cas associates with the guanine nucleotide exchange factor C3G, protein phosphatases, and adaptor proteins Crk and Nck [15]. Coupling between FAK, Src, and Cas appears to be important for FAK-stimulated cell migration [16].

A number of other proteins and kinases have been classified as integrin binding or integrin-associated proteins, including adaptor proteins and kinases (for example, RACK1, Shc, Grb2, and ILK); growth factor receptors (EGF receptor, ErbB2, PDGF receptor- β , insulin receptor, VEGF receptor); cytoplasmic, chaperone, calcium-binding proteins (calnexin, calreticulin, CIB, endonexin); and membrane-associated proteins (tetraspanins, Ig superfamily proteins, GPI-linked receptors, transmembrane proteins, and ion channels). The functional and structural diversity amongst these integrin-associated proteins underscores the importance of integrins as initiators of many intracellular signaling pathways. How integrins function in a structural versus a signaling role and how such complexes are organized temporally and spatially within the cell remain important and unanswered questions.

Cell Migration: A Paradigm for Studying Integrin Signaling

Cell migration provides an exceptionally relevant model to study integrin signaling. Migration is a complex cellular process that involves the extension of lamellipodia, adhesion

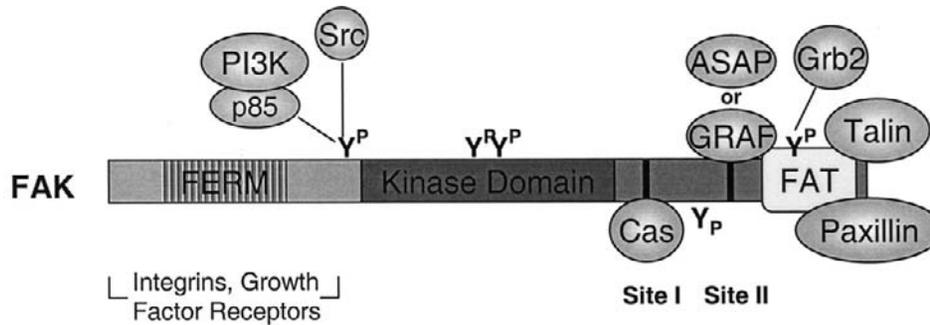

Figure 2 Focal adhesion kinase and its binding partners. FAK consists of a centrally located kinase domain flanked by an amino-terminal FERM domain and a carboxy-terminal region containing proline-rich sequences (site I and site II), as well as the focal adhesion targeting (FAT) domain. FAK autophosphorylation at Y397 in the amino-terminal domain creates a binding site for Src as well as the p85 subunit of PI3K. The carboxy-terminal domain of FAK binds the adaptor protein Cas, the GAP proteins GRAP and ASAP, and focal adhesion proteins talin and paxillin. Phosphorylation of FAK on Y925 creates a binding site for Grb2, potentially leading to the activation of the Ras-MAPK pathway.

at sites within newly formed lamella, organization of force-generating adhesions, contraction and cell-body displacement, and detachment of the cell rear. These events require the coordination of multiple signaling pathways.

Lamellipodia Extension and Formation of New Adhesions

The initial steps in cell migration require the formation of protrusive structures (lamellipodia) at the leading edge of the cell and the stabilization of the protrusion by newly formed adhesion complexes. Cell protrusions are regulated by the activity of surface receptors and Rho family GTPases Cdc42 and Rac [17]. Actin polymerization at the cell front is regulated by Cdc42 and Rac via their interaction with members of the Wiskott–Aldrich syndrome protein (WASP)/Scar1 superfamily [18]. Binding of Cdc42/Rac to WASP/Scar proteins activates the Arp2/3 complex [19], triggering its binding to the sides of preexisting actin filaments and stimulating new filament formation, which results in branched actin networks [20]. The formation of the branched actin network serves to drive the forward extension of the cell membrane, leading to the formation of lamellipodia [20,21].

Formation of new adhesions within lamellipodia involves integrin-induced assembly of FAK/Src complexes and the recruitment of two adaptor proteins, Cas and paxillin. Formation of this signaling complex is likely important to sustain activation of Rac and activation of serine/threonine kinase PAK (p21-activated kinase). FAK/Src-mediated phosphorylation of Cas or paxillin creates binding sites for the adaptor protein Crk. Cas/Crk complexes mediate Rac activation by binding DOCK180 [22,23], the human counterpart of the *Drosophila* and *Caenorhabditis elegans* genes *mbc* and *ced-5*, respectively [24,25]. While paxillin binds Crk following FAK/Src-mediated phosphorylation and signals to Rac, FAK mutants deficient in binding to paxillin efficiently restore migration of FAK null cells to a wild-type level [26]. Thus, in this setting, signaling to Cas appears to be sufficient to mediate adhesion formation.

Paxillin is an important regulator of Cdc42 and Rac through its binding to PKL and the subsequent interaction of PKL with two members of the Cdc42/Rac GEF family PIX/COOL [27–29]. The PIX/COOL family of proteins was originally reported to exhibit GEF activity for Rac and Cdc42 [30], although recently this property has been questioned, raising speculation that PIX/COOL proteins might activate PAK by binding the GTP form of Cdc42/Rac rather than directly activating the GTPases [27]. While the formation of the paxillin/PKL/PIX complex has been reported to activate PAK, recent data indicate that the interaction of paxillin with Rac leads to the downregulation of Rac activity [31], providing a possible mechanism for Rac turnover/downregulation. A suggested pathway (Fig. 1) may be integrin recruitment and activation of FAK/Src, binding and phosphorylation of Cas, and activation of Rac via Cas/Crk/Dock180 complexes. GTP-Rac may then bind to PIX/COOL proteins complexed with paxillin/PKL, resulting in PAK activation and Rac downregulation.

Maturation of Newly Formed Adhesions

Activation of Rho is required for the organization of F-actin into stress fibers and the formation of focal adhesions [32]. Both functions are regulated by the ability of Rho to promote the generation of directional forces, via its regulation of Rho kinase and myosin phosphatase and the subsequent regulation of myosin light chain (MLC) phosphorylation. Rho activation of Rho kinase inhibits myosin phosphatase, thereby maintaining MLCs in a highly phosphorylated (contractile) state. The resultant contractile forces are essential for the organization of actin filaments and adhesion complexes [32].

During cell migration, Cdc42/Rac and Rho signaling are regulated in a reciprocal fashion, leading to the breakdown of stress fibers and focal adhesions (due to the downregulation of Rho) and the commensurate reorganization of cortical actin networks at the leading edge of the cells [33–35]. Plating cells on ECM stimulates a transient decrease in Rho

activity, which is necessary for cell spreading [36,37]. FAK appears to contribute to the transient decrease in Rho activity, as such changes in Rho activity are not observed in cells deficient for FAK expression [38]. The mechanism by which FAK regulates the initial decrease in Rho activity may involve its interaction with the Rho GTPase-activating protein GRAF [8] or its ability to activate Src, which has been shown to phosphorylate p190RhoGAP, resulting in decreased Rho activity upon integrin engagement [36,39]. A subsequent increase in Rho activity is necessary to restore contractile forces, leading to strengthening of attachment sites, stress fiber formation, and generation of the forces necessary for continued cell movement [32].

Detachment and Release of Adhesions

In addition to stabilizing lamellipodia formation at the front of the cell, detachment at the rear of the cell requires sustained contraction and disassembly of integrin complexes. Mitogen-activated protein kinase (MAPK), like Rho kinase, phosphorylates MLCK, stimulating MLC phosphorylation and cell contraction [40]. In addition, phosphorylation of focal-adhesion-localized calpain by active MAPK [41] stimulates calpain-mediated cleavage of adhesion proteins and cell detachment [42,43]. Integrins activate MAPK through three different Ras-dependent pathways. Integrin-mediated activation of FAK and recruitment of Src results in phosphorylation of FAK on Tyr925 [44,45]. Phosphorylation on Tyr925 creates a binding site for Grb2 [44], an SH2/SH3 adaptor protein that links growth factor receptor tyrosine kinases to the Ras/MEK/MAPK pathway through the Ras guanosine diphosphate (GDP)/guanosine triphosphate (GTP) exchange protein SOS (Fig. 1). Integrins also activate SOS through caveolin-1-mediated recruitment of Shc to integrins and subsequent phosphorylation by Fyn [46] (Fig. 1). Finally, integrin engagement results in phosphorylation and activation of the epidermal growth factor (EGF) receptor in the absence of EGF stimulation [47]. Activated EGF receptor recruits Shc to the receptor, where phosphorylation creates a binding site for Grb2/SOS [47] (Fig. 1). Indeed, in this setting, ECM-mediated phosphorylation of Shc and activation of MAPK is blocked by inhibitors of EGF receptor tyrosine kinase activity. Integrin-stimulated migration is inhibited by MAPK inhibitors and stimulated by expression of active MEK [40]. Interestingly, dominant-negative Ras expression has little effect on ECM-stimulated migration [48,49], indicating the existence of Ras-independent mechanisms of MAPK activation.

Several studies show that Rac synergizes with Raf to stimulate MAPK-dependent migration in response to EGF [50]. Rac-dependent activation of PAK stimulates phosphorylation of MEK, resulting in an increased affinity of MEK for Raf [51]. An important consequence of Rac activation may be the enhancement of Raf–MEK interaction, leading to maximum MAPK activity in a setting of only basal Ras and Raf stimulation. This may provide a mechanism by which integrins potentiate signals from growth factor receptors,

allowing cells to respond to low levels (gradients) of chemotactic signals in the environment.

Integrin Regulation of Cell Proliferation and Survival: Links to Cancer

The ECM plays a critical role in the altered growth and metastatic behavior of cancer cells. In the case of both normal and cancer cells, these signals contribute to the balance of cell growth and death by regulating the apoptotic machinery of the cell. Under appropriate circumstances, integrin signals regulate G₀-to-G₁ and G₁-to-S progression [52–55], as well as the expression of growth-related gene products associated with these transition states. Transient MAPK activation stimulated by either growth factors or cell adhesion is sufficient to initiate G₀-to-G₁ phase transition and the coincident expression of immediate-early response genes, including c-Fos, c-Myc, and c-Jun [56–59]. Serum stimulation in the absence of adhesion to the ECM abrogates progression through G₁ into S phase by increasing the accumulation of cdk2 inhibitors p21^{cip1} and p27^{kip1} [60]. Cyclin D1 functions to promote G₁ progression by sequestering p21^{cip1} and p27^{kip1} [61]. Cyclin D1 expression requires cell adhesion to mediate sustained MAPK activity initiated by growth factors [62]. Growth factor stimulation of cells held in suspension results in a modest, transient activation of MAPK compared to the robust MAPK stimulation following serum treatment of adherent cells [63]. Maximal, sustained MAPK activation requires FAK and Rho activity [64,65]. Indeed, FAK and Rho have both been implicated in regulating cyclin D1 expression and progression through G₁ [52,65]. Cyclin-D-dependent downregulation of p21^{cip1} and p27^{kip1} is necessary for cyclin E/Cdk2 activity, which induces the expression of cyclin A [60], a key regulator of S-phase progression [66,67]. Therefore, cell-substrate adhesion indirectly promotes cyclin A expression and S-phase progression by stimulating cyclin E/Cdk2 activity. Collectively, these data indicate that the G₀-to-G₁ transition and progression through the G₁ cell cycle is regulated by either serum or adhesion; however, progression through the S phase requires both serum and adhesion.

Cell proliferation is in dynamic balance with cell death. Shifts in this equilibrium, as a result of increasing cell proliferation or decreasing cell death, often result in tumorigenesis. Integrins provide key signals to regulate this balance. Depriving epithelial or endothelial cells of contact with the ECM rapidly induces apoptosis [68,69]. (This specialized form of cell death is referred as *anoikis*). Normal epithelial cells acquire resistance to anoikis upon expression of certain oncogenes [70–72]. A number of studies have implicated integrin signaling to the PI3K (phosphoinositide-3-kinase)–AKT pathway as a central regulator of anoikis [71]. FAK is thought to regulate anoikis by direct activation of PI3K and AKT and perhaps indirectly via interactions with Cas/Crk/DOCK180/Rac [68]. ILK has also been implicated in signaling to AKT, although this pathway is poorly understood.

However, ILK binds to the cytoplasmic tails of $\beta 1$ and $\beta 3$ integrin and over-expression of ILK results in activation of AKT [73,74]. Finally, the role of death receptors in anoikis is controversial. In one study, removal of cells from the ECM activated caspases and cell death by a mechanism involving FADD, a death-domain-containing protein [75]. Whether this pathway is important for all forms of anoikis remains to be determined.

In cancer, increasing evidence indicates that integrins synergize with growth factor receptor signals to promote cell proliferation and to stimulate the migration of tumor cells from the primary site and function to promote growth and survival at distant metastatic sites [76]. Growth of tumor cells is influenced by the tissue environment of the tumor (metastasis), and reflects both the upregulation of growth factors and induction of anti-apoptotic signals. Whereas, in most tumors, the exact mechanisms involved in this process are poorly understood, it is important to note that loss of the tumor suppressor gene PTEN leads to the upregulation of AKT and the suppression of anoikis [77]. In addition, many human cancers (including breast, prostate) exhibit upregulation of FAK. Clearly, understanding the complex changes in integrin signaling in cancer cells is a major challenge.

Concluding Remarks

The recognition that integrins are not only adhesive receptors but also “integrators” of growth factor and ECM signaling has had a profound impact on our understanding of cellular processes, including cell migration, differentiation, and cancer. The challenge for the next decade is to understand how different ECM proteins, growth factors, and chemotactic molecules function in coordinating multiple signaling pathways in the context of individual tissues and the organism itself.

Downstream Signaling Pathways: Modular Interactions

Bruce J. Mayer

*Department of Genetics and Developmental Biology,
University of Connecticut Health Center,
Farmington, Connecticut*

Introduction

One of the hallmarks of proteins involved in signal transduction is their modularity. Like the proverbial Swiss army knife, signaling proteins often bristle with small, independently folded domains, each of which confers a specific function [1]. Some of these domains have enzymatic activity, catalyzing phosphate transfer, lipid metabolism, or the regulation of GTPases, while others play a purely structural role. The majority of these modular domains, however, mediate specific, high-affinity interactions with proteins or lipids. Indeed, some critical signaling proteins have evolved to the point where they consist entirely of modular interaction domains, serving as adaptors or scaffolds to mediate assembly of protein complexes.

The prominence of modular interaction domains in signaling proteins reflects the critical role played by localization in signaling, particularly in multicellular organisms. It is self-evident that a cell is not a homogeneous aqueous solution, any more than a house is a homogeneous pile of wood, metal, and cement. The specific subcellular localization of a protein within the cell has obvious consequences for its activity; in the case of an enzyme, the local concentration of its activators, inhibitors, and substrates will determine whether the catalytic domain can act on a particular substrate to generate a particular output (i.e., a change in concentration of the modified substrate). Unlike housekeeping processes such as metabolism, which need not occur in a very precise locale in the cell, many signal-induced processes such as assembly of the actin cytoskeleton must be exquisitely regulated in space and time. It is difficult to

imagine how such a feat could be performed in a world of solution biochemistry; only in the solid-state world of multifunctional proteins complexes, assembled on surfaces such as membranes, can such spatiotemporal control be achieved [2].

General Properties of Interaction Modules

Modular interaction domains have been introduced in this volume (see Chapter 66), and this chapter considers only the properties specifically relevant to their role in signal transmission. One can divide these domains into two fairly distinct groups based on their mode of interaction. In one group are common folds that have been used over and over to mediate interactions, but for which the specifics of each interaction might vary considerably. These modules include such examples as the ankyrin repeat, WD40 repeat, and LIM domain, among others. Interactions tend to occur over broad surfaces of the folded domain and to be mediated by variable residues that are not conserved among different members of the family [3,4]. For these interaction domains, the common recognizable fold serves as a scaffold upon which variable residues involved in binding are displayed. Because the details of each specific interaction are different, it is therefore difficult or impossible to predict *a priori* what the binding partner for a such a module might be, though closely related members of a family may bind recognizably similar ligands [5].

The second class of modules, and the ones that are most closely associated with signal transduction, are those that

bind to stereotyped linear peptide ligands. Examples of such domains are the SH2, SH3, WW, PDZ, and PTB domains. In these cases, all of the ligands for a particular class of module have the same general properties: Virtually all SH2 ligands consist of phosphorylated tyrosine and a few proximal amino acids, the great majority of SH3 ligands will have a Pro-X-X-Pro core, and so on. In general, the domain can bind with similar affinity to an intact ligand protein or to a short linear peptide derived from it, indicating that the domain does not recognize an extensive surface of the ligand. Many high-resolution structures exist for such domains, and in all cases (with a few instructive exceptions) highly conserved residues of the domain play a crucial role in binding, and the overall orientation of the peptide ligand is virtually identical for a particular class of domains [6]. This general concept also holds true for lipid binding modules such as the pleckstrin homology (PH) domain, where the same binding surface is used to interact with phosphorylated inositol lipids [7].

One important implication of this mode of binding is that discrimination between different ligands cannot be absolute. If all SH3 domains must recognize peptides consisting of a Pro-X-X-Pro core plus a few surrounding residues, there is no great latitude for specificity [8]. Given that there are literally hundreds of SH3 domains, all with very similar conserved residues in the peptide binding groove, it is inevitable that different SH3 domains bind with similar affinity to overlapping sets of ligands. This implies that there cannot be a one-ligand, one-domain correspondence; a particular SH3 domain (or a particular SH3 ligand) is likely to bind a variety of partners in the cell, depending of course on their local concentrations. Thus, in terms of understanding the function of proteins that contain these domains, the news is both good and bad: One can predict with confidence what type of ligand will bind to the domain, but it is very difficult to say which specific ligand might actually be bound at a particular time and place in the cell.

Interactions mediated by binding modules can be either constitutive or induced. Induced interactions are generally regulated by phosphorylation, though other modifications (such as methylation, acetylation, and proline hydroxylation) may also be used. The most venerable example is the SH2 domain, which binds only to peptides containing phosphorylated tyrosine residues. Thus, changes in tyrosine phosphorylation, induced, for example, by activation of mitogen, adhesion, or cytokine receptors, can dramatically alter the subcellular distribution of proteins with SH2 domains. In one sense SH2-containing cytosolic proteins act as sensors, ready to respond at a moment's notice to the creation of phosphorylated binding sites. Other phosphorylation-dependent binding modules have recently been identified, including several whose binding requires serine or threonine phosphorylation [9]. Similarly, a number of modules are now known to bind to specific phosphorylated inositol lipids, thus allowing recruitment of proteins to the membrane in response to changes in phosphoinositide metabolism [10].

Roles in Signaling

From the perspective of the overall logic of signaling mechanisms, overlapping binding specificity means that a particular input is likely to have many different outputs. This is particularly clear for adaptor proteins, which function solely to mediate protein interactions [11]. In the case of SH2/SH3 adaptors, for example, the SH2 domain can recruit it to many different tyrosine-phosphorylated sites in a cell, and the SH3 domains can bring many different effectors along for the ride. This property allows the signaling process to be very sensitive to the potential binding partners available in the cell, their local concentrations, and their state of posttranslational modification—ideal for a system that must integrate many inputs and generate outputs that are precisely controlled in time and space. Such an ability also allows flexibility, in that a limited number of component parts can respond to and generate a diverse array of signals depending on need and context. This is conceptually similar to the ability of an enzyme (e.g., a kinase) to modify many different substrates, thereby radiating an activating signal to many disparate effectors.

It is also important to consider the kinetics of protein interactions mediated by modular domains. Where they have been measured, most of the dissociation constants for such interactions are in the range of 10^{-8} to 10^{-5} M, strong enough to be biologically meaningful but hardly so tight as to be functionally irreversible. Assuming reasonably rapid association rates, these modest K_d values imply that the half-times of the interactions are on the order of seconds. Thus, even “constitutive” complexes mediated by these interactions are not at all like the stably associated subunits of a holoenzyme, but are more a dynamic ensemble of interactions that are constantly breaking apart, resorting, and swapping partners. The components of a complex may change rapidly to adjust to an altered landscape of potential partners due to changes in subcellular localization or as other partners are recruited to the vicinity. Despite this overall plasticity, modular binding interactions also have the potential to mediate relatively stable complexes. Many signaling proteins contain multiple modular binding domains and/or binding sites, allowing the formation of multidentate contacts between binding partners. Protein complexes that are held together by multiple interactions are much less likely to dissociate, even if the individual interactions are quite weak.

Although modular protein interaction domains are usually thought of as mediating interactions between two (or more) different proteins, it is now appreciated that there is often a dynamic equilibrium between intra- and intermolecular interactions. In these cases, a relatively weak intramolecular interaction constrains the protein in one conformation; high local concentrations of either an exogenous domain or ligand can out-compete the intramolecular interaction, leading to global changes in the overall conformation of the protein (Fig. 1). The now classic example of this *cis-trans* switch is the Src family of kinases, where the catalytic domain is held inactive by a series of intramolecular

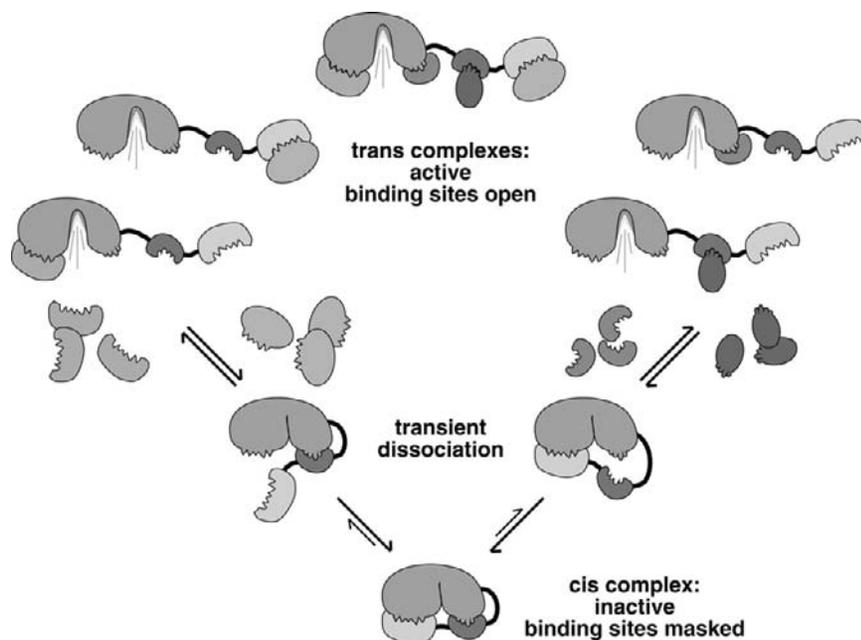

Figure 1 Regulation of protein activity by *cis-trans* binding equilibria. A hypothetical protein (loosely modeled on the Src family of tyrosine kinases) is depicted, consisting of a catalytic domain and two modular protein binding domains. In the absence of high concentrations of binding partners, the protein binding domains interact in *cis* with other regions of the enzyme, inhibiting its catalytic activity and masking binding sites for other proteins (bottom). Occasionally these intramolecular interactions will dissociate, transiently making the binding sites available for interaction with other proteins in *trans* (middle). If high enough concentrations of binding partners are present, binding in *trans* will be favored and the *cis* complex will be disrupted (top). The catalytic domain is now active and multiple binding sites are available to interact with other partners (substrates, scaffold proteins, etc.). Thus, the activity of such a protein will be very sensitive to the local concentration of potential binding partners.

interactions involving its SH2 and SH3 domains [12]. Disruption of these interactions with high-affinity ligands leads to a more open conformation, unleashing the catalytic activity and freeing the SH2 and SH3 domains to bind to other ligands, such as substrates or proteins that can anchor the kinase to a particular subcellular location. This regulatory scheme permits activation of the kinase at very precise sites in the cell or by high local concentrations of a particular substrate which can disrupt the intramolecular interactions and then bind tightly to the activated kinase. A host of other examples could be cited, such as activation of the neutrophil cytosolic oxidase [13], assembly of membrane signaling complexes by MAGUK proteins [14], and regulation of guanine nucleotide exchange factors for small GTPases. Therefore it is important to bear in mind that identification of binding partners may reveal only one part of the role played by modular binding domains in a protein.

Prospects

The fact that signaling pathways are critically dependent on interactions mediated by modular protein domains is fortunate from an experimental perspective, because it gives us a ready means to move up and down signaling pathways by

defining interaction partners. Because most interaction domains are easily identified by sequence analysis programs, we know for any protein of interest what domains are present and thus what type of ligands are likely to interact with it. Because the domains fold independently we can assess their role by destroying their activity in the native protein by mutagenesis, or we can express the domain in isolation to fish out its binding partners. Despite these considerable advantages, however, it has proven quite difficult in practice to move from domain to interaction partner to function. In large part this is due to the overlapping binding specificities of modular domains—it is easy to identify partners but frustratingly difficult to assign any functional role to a particular interaction.

In order to truly define the signaling networks in a particular cell, we will ultimately need several types of information. First, we will need to define all of the high-affinity interactions in which a particular domain (or a particular binding site) can engage, preferably with some sense of the relative affinity of each interaction. Genome-wide yeast two-hybrid and phage display projects are well on their way to providing this information for relatively simple organisms [15–17]. Of course many of the possible interactions defined by such projects cannot actually occur in a specific cell, because the two proteins may not be expressed at the same

time or may be localized to different subcellular compartments. Thus, we need to develop tools to identify those interactions that actually occur in a cell of interest, at the time of interest and in the appropriate locale. Co-purification strategies will address some of these issues [18,19], as will simple far-western profiling experiments [20], but more sensitive high-throughput methods are clearly needed. The final piece of the puzzle, and perhaps the most challenging, is to assess the functional significance of a particular interaction. This is remarkably difficult at the moment; we can mutate domains or binding sites but, given that each is likely to interact with multiple partners, we cannot say with any certainty what phenotypic effects are due to a particular pairwise interaction. High-throughput methods to constitutively or inducibly force specific pairs of proteins to interact in the absence of competing interactions must be developed. Once these technical hurdles are overcome, we will be well on our way to truly defining the signaling state of the cell, a complex and dynamic equilibrium of interactions from which arises its precise spatial organization and its ability to integrate and respond appropriately to a diverse array of signals.

Introduction

Engagement of antigen receptors expressed on T and B cells utilize four distinct families of cytoplasmic protein tyrosine kinases (Src, Syk, Tec, and Csk) that are required for the efficient generation of second messengers necessary for lymphocyte function and development. The coordinated activation of these PTKs by the antigen and coreceptors modulate both quantitative and qualitative aspects of signaling that control the biological fate of a given lymphocyte. Loss of any of these cytoplasmic PTKs abrogates antigen receptor function and induces developmental abnormalities of the immune system. Studies over the past 5 years utilizing molecular, structural, and genetic approaches have elucidated multiple mechanisms by which antigen and coreceptors can modulate PTK function. This review captures the basic concepts that have evolved from these studies.

T-Cell Antigen Receptor Structure

Antigen receptors functionally consist of both an antigen binding and a signaling module. In T cells, the predominant T-cell antigen receptor expressed on peripheral T cells is encoded by an antigen-specific and highly divergent disulfide-linked heterodimer consisting of α and β subunits. The antigen-binding module is noncovalently associated with a

large signaling complex consisting of one γ , one δ , two ϵ and two ζ subunits, the latter of which exists predominantly as a disulfide-linked homodimer (Fig. 1) [1]. Each of these signaling subunits contains at least one copy of a signaling motif, the ITAM (for immunoreceptor tyrosine based activation motif); the ζ subunit encodes three ITAM sequence and has a consensus sequence of D/E XXYXXL X₆₋₈ YXXL [2,3]. The two tyrosine residues within the ITAM are constitutively phosphorylated in resting T cells [4–6], although the precise stoichiometry of each of basal phosphorylation sites remains unclear. While studies in a T-cell hybridoma had suggested a hierarchy and an ordered sequence of ζ -chain phosphorylations [7], studies in thymocytes and in mice expressing mutant ζ -chain subunits indicate substantial redundancy in ITAM-mediated lymphocyte functions [8,9].

Src PTKs

Two members of the Src PTKs, Lck and Fyn, have been implicated in T-cell antigen receptor function and development. Studies of lymphocytes lacking the Lck and Fyn members of the Src family of PTKs have implicated Lck and, to a lesser degree, Fyn, as being responsible for the phosphorylation of the T-cell receptor (TCR) ITAM sequences [6,10–13]. Fyn was the first cytoplasmic PTK

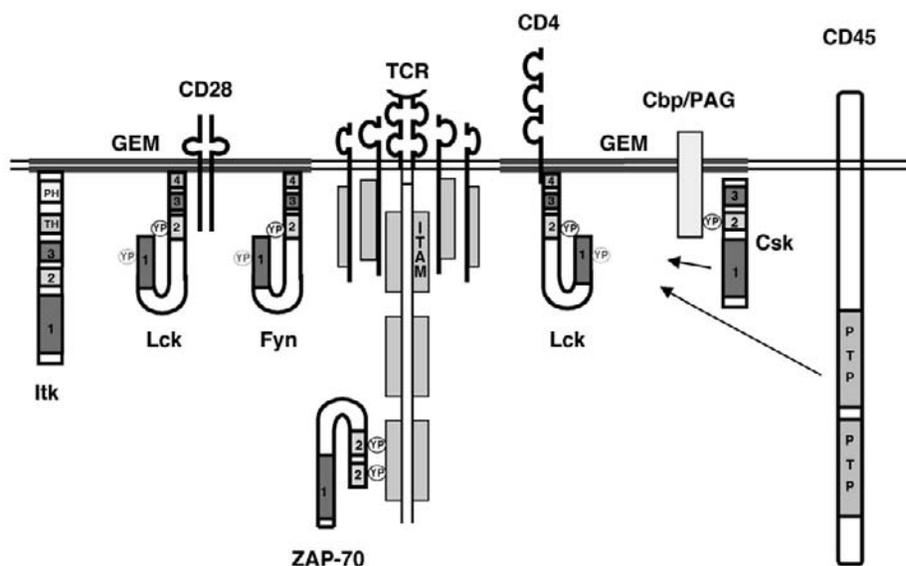

Figure 1 Schematic representation of PTKs in T-cell antigen receptor function. 1=SH1, 2=SH2, 3=SH3, 4=SH4, PH=pleckstrin homology, TH=Tec homology, YP=phosphorylated tyrosine, PTP=protein tyrosine phosphatase domains, ITAM=immunoreceptor tyrosine-based activation motif.

found associated with the TCR subunits and Lck is non-covalently associated with the CD4 and CD8 coreceptors that colocalize with the antigen receptor upon receptor engagement [14–17]. How the basal phosphorylation of the TCR ITAMs is controlled remains unclear, but undoubtedly represents a net balance of continued phosphorylation, dephosphorylation, and internalization of antigen receptors.

Similar to other Src PTKs, Lck and Fyn contain four structural domains (SH1, SH2, SH3, and SH4) [18,19]. The SH4 domain encodes the amino (N)-terminal 15 amino acids and facilitates the subcellular localization of the kinase through post- and cotranslational modifications that include myristoylation and palmitoylation [20–22]. These modifications preferentially localize Lck and Fyn into subspecialized domains within the plasma membrane referred to as *glycolipid enriched microdomains* (GEMs) [23,24]. These microdomains differ in their cholesterol and phospholipid content which results in differences in the lateral mobility of proteins that reside within GEM and non-GEM fractions. In addition, the association of Lck with the CD4 and CD8 coreceptors that are also enriched within the GEMs further preferentially localizes Lck within these microdomains. T cells that express mutants of Lck that cannot localize into the GEMs are unable to initiate TCR activation events [25,26]. Hence, proper subcellular localization of the Src PTKs, through the SH4 domain, is requisite for TCR functions.

Carboxy (C)-terminal to the SH4 domain are the SH3 and SH2 modules, which bind a variety of signaling proteins to mediate the assembly of signaling complexes as well as to regulate SH1 (kinase) domain enzymatic activity. Determining the structures of the Src family PTKs has provided major insights into their regulation [27,28]. First, a greater understanding of how phosphorylation of the activating autocatalytic and inhibitory C-terminal tyrosine

residues regulates kinase activity has been established. Phosphorylation of the C-terminal tyrosine residue (Tyr 505 in Lck and Tyr 527 in Fyn) by Csk (c-Src kinase) downregulates Lck and Fyn activity by promoting an intramolecular interaction with its SH2 domain. This intramolecular binding event favors a “closed, less active” conformation by altering substrate accessibility into the catalytic pocket. Conversely, dephosphorylation of the C-terminal tyrosine residue by the CD45 protein tyrosine phosphatase disengages the inhibitory conformation and permits greater substrate access to the enzymatic core. The SH3 and SH2 domains further contribute to the effect of the C-terminal inhibitory tyrosine by stabilizing the closed conformation with tail phosphorylation [29].

Second, an additional role for the SH3 domain of Src PTKs in regulating Src PTK function has been demonstrated [27]. Binding of a high-affinity SH3-binding peptide or the HIV-Nef viral protein contributes to Hck (another Src family PTK) activation. Recently, SH3-binding peptides derived from the cytoplasmic domain of CD28 have been shown to be capable of activating Lck and Fyn PTKs [30]. Moreover, mutation of the corresponding proline residues within this motif results in loss of CD28-mediated coreceptor functions.

Finally, the mode of lymphocyte activation can also affect the activation status of Lck. While crosslinking of the TCR with anti-CD3 monoclonal antibodies is unable to induce Lck autophosphorylation on Tyr 394, crosslinking of CD4 or CD28 coreceptors alone can induce Lck autophosphorylation [31]. As each of these structural domains contributes to Src PTK activation, receptor and coreceptor engagement likely contributes to maximal Lck functional activity through distinct mechanisms involving relocation within membrane subdomains as well as direct enzymatic activation.

Csk (c-Src PTK)

Phosphorylation of the negative regulatory C-terminal tyrosine residue of Src PTKs is mediated by a balance between the Csk PTK and the CD45 protein tyrosine phosphatase (PTPase). The Csk PTK is structurally similar to Src PTKs, although they lack the auto- and negative regulatory tyrosine residues within their catalytic cores as well as the SH4 domain responsible for GEM localization [32]. The recent description of the CBP (Csk-binding protein; also known as PAG, for phosphoprotein associated with GEMs) has provided some intriguing insights into Csk regulation. CBP/PAG is a palmitoylated transmembrane adaptor protein that is enriched in GEMs [33,34]. CBP/PAG is phosphorylated on tyrosine residues that mediate its interaction with the SH2 domain of Csk. This interaction mediates the colocalization of Csk to the GEM fraction, which as discussed previously is also enriched in Src PTKs, and facilitates Csk phosphorylation of the negative regulatory tyrosine residue of Src PTKs [35]. In turn, Src PTK enzymatic activity is inhibited. Following receptor engagement, CBP/PAG is thought to be dephosphorylated, resulting in dissociation of Csk from the GEM-localized fraction. Hence, Csk regulation of Src PTKs may regulate the threshold of antigen receptor and provide an inhibitory feedback loop for antigen receptor function [36].

More recently, CBP/PAG has also been implicated in the anchoring of GEMs to the T-cell cytoskeleton. CBP/PAG contains a C-terminal VTRL sequence that mediates its interaction with EBP50 (ezrin/radixin/moesin-ERM binding protein of 50 kDa and also known as NHERF [Na⁺/H⁺ exchanger regulatory protein]) [37,38]. In light of this cytoskeletal connection, overexpression of CBP/PAG in T cells inhibits GEM mobilization and formation of the immunologic synapse, in addition to inhibiting TCR-mediated signaling functions. How the cytoskeleton interaction may regulate Csk function requires additional investigation.

ZAP-70/Syk PTKs

Tyrosine phosphorylation of the receptor-encoded ITAMs mediates the binding of the ZAP-70 and Syk PTKs to the TCR. This family of cytoplasmic PTKs is unique in that they encode tandem SH2 domains that mediate their interaction with the TCR-encoded ITAMs [39,40]. While studies in transformed T-cell lines initially demonstrated that the TCR-encoded ITAMs undergo tyrosine phosphorylation following TCR crosslinking, subsequent studies of nontransformed T cells indicate that the receptor already contains a substantial amount of constitutively phosphorylated ITAMs [39]. Phosphorylation of both tyrosine residues within the ITAM is required for the high-affinity and functional binding of the ZAP-70/Syk PTKs [41–43]. Solution of the N-terminal domains of these two PTKs demonstrates that they adopt a head-to-tail configuration to bind the dually phosphorylated ITAM [44,45]. Hence, the N-terminal

SH2 domain binds the C-terminal phosphorylated tyrosine residue while the C-terminal SH2 domain binds the N-terminal phosphorylated tyrosine residue. Mutation of either tyrosine residue or inactivation of either SH2 domain decreases the activity of the interaction by >100-fold and results in an inactive antigen receptor.

As ZAP-70 is constitutively associated with the TCR, regulation of the ZAP-70 PTK is achieved through transphosphorylation of ZAP-70 by the Src PTKs [46,47]. Phosphorylation of Tyr 493 within the transactivation domain of ZAP-70 results in an upregulation of ZAP-70 enzymatic activity. Intriguingly, the transactivation loop also contains a second tyrosine residue (Tyr 492), which, when subsequently phosphorylated following Tyr 493 phosphorylation, downregulates ZAP-70 enzymatic activity. Hence, sequential tyrosine phosphorylation of the transactivation loop tyrosine residues positively and negatively modulates ZAP-70 enzymatic function.

While ZAP-70 and Syk are structurally homologous, these two PTKs differ in some aspects of their enzymatic activation. Binding of Syk to the doubly phosphorylated ITAM results in an alteration in structural conformation that leads to Syk autophosphorylation and auto-activation [48]. In addition, the intrinsic Syk kinase activity has been estimated to be 10- to 100-fold greater than ZAP-70 [49]. Hence, ZAP-70 appears to be a less active kinase that is subject to greater degrees of enzymatic regulation. In addition, overexpression of Syk in transformed T-cell lines can overcome the requirement for the CD45 PTPase in TCR activation [50,51]. These intrinsic differences between these two structurally homologous PTKs may provide a mechanistic basis for their different roles in cellular and developmental distribution and function.

The *in vivo* functions of ZAP-70 and Syk also differ. During T-cell development, CD4⁻CD8⁻ thymocytes signal through the pre-TCR (consisting of invariant pre-T α ; and β subunits) to mature into CD4⁺CD8⁺ thymocytes. The pre-TCR utilizes either ZAP-70 or Syk to facilitate this transition [52]. In contrast, the $\alpha\beta$ -TCR, which facilitates the later transition from CD4⁺CD8⁺ to single positive (CD4⁺ or CD8⁺) thymocytes utilizes ZAP-70 and not the Syk PTK [53]. These differences may relate to the differential distribution of the ZAP-70 and Syk kinases during T-cell development as well as to distinct signaling requirements of the pre- and $\alpha\beta$ -TCRs [54].

In addition to regulation by tyrosine phosphorylation of the transactivation loop and structural conformation changes induced by binding to a doubly phosphorylated ITAM, the interdomain B region of ZAP-70 and Syk PTKs contains three tyrosine residues that are phosphorylated following receptor activation. Phosphorylation of Tyr 292 in ZAP-70 (and Tyr 319 in Syk) serves as a binding site for the N-terminal SH2-like domain of the Cbl E3 ubiquitin ligase [55–63]. Mutation of these tyrosine residues within interdomain B results in a hyperactive antigen receptor with prolonged phosphorylation of cellular substrates. Conversely, overexpression of c-Cbl results in decreased antigen receptor function but requires the

presence of Tyr 292 in ZAP-70. Hence, the interaction of Cbl with the ZAP-70/Syk PTKs may play an important role in the downregulation of antigen receptor function through a proteasome-dependent mechanism.

While phosphorylation of Tyr 292 within the interdomain B of ZAP-70 serves an inhibitory function in TCR-mediated activation, phosphorylation of two other interdomain B tyrosine residues (Tyr 315 and 319 of ZAP-70) are required for TCR functions [64–69]. Mutation of either tyrosine residues diminishes, but does not abrogate, activation of phospholipase C γ (PLC γ)-mediated signaling pathways. Phosphorylation of these residues appears to provide docking sites for the stable assembly of macromolecular signaling complexes that include Lck and PLC γ 1. Hence, tyrosine phosphorylation of ZAP-70/Syk is required for enzymatic activation, protein turnover, and the efficient stabilization and phosphorylation of signaling complexes required for lymphocyte function.

Tec PTKs

Two members of the Tec PTKs, Itk/Emt/Tsk and Rlk/Txk, are expressed in T cells and play critical roles in TCR function [70–72]. Studies of mice deficient in either Itk or Rlk demonstrate that these PTKs serve overlapping roles, as these mice exhibit mild T-cell developmental and functional abnormalities [73,74]. Consistent with this functional redundancy, overexpression of Rlk/Txk partially rescues the TCR-mediated signaling defects observed in *itk*^{-/-} T cells [75]. Moreover, mice deficient in both *itk* and *rlk* demonstrate more significant functional defects in coupling to TCR-induced PLC γ -mediated signaling pathways [74]. In turn, these two members of the Tec PTKs are required for T-cell proliferation, differentiation, cytokine production, and immunity against intracellular pathogens [76–79].

The Tec PTK family represents a unique class of non-receptor tyrosine kinases that is regulated by both Src- and lipid (PI3K) kinases. The structure of the Tec PTKs resembles Src PTKs in that they contain a C-terminal SH1 and N-terminal SH2 and SH3 domains. However, Tec PTKs lack the N-terminal myristoylation signal and the C-terminal inhibitory tyrosine signatures of Src PTKs. In addition, the Tec PTKs have a unique Tec homology (TH) domain, which consists of a Btk homology region, a proline-rich sequence, and an N-terminal pleckstrin homology (PH) domain (except for Rlk/Txk, which has a palmitoylated cysteine string motif). The PH domain and the cysteine string motif facilitate proper subcellular localization of Itk to the GEMs within the plasma membrane [80].

Activation of Itk is first initiated by its localization to GEMs (with the exception of Rlk/Txk, which is constitutively localized) through a PI3K-dependent mechanism [81–83]. TCR engagement activates PI3K to convert PtdIns(4,5)P₂ (PIP₂) to PtdIns(3,4,5)P₃ (PIP₃). The direct interaction of PIP₃ with the Itk PH domain, localizes Itk with Src PTKs within GEMs, and facilitates Itk transphosphorylation by the Src PTKs [84].

Solution of the NMR structure of the SH3 domain of Itk has also provided further insights into Tec PTK regulation. The SH3 domain of Itk interacts through an intramolecular interaction with a proline motif in the TH domain and has been proposed to hold the kinase in an inactive state [85,86]. In addition to SH3 domain engagement, binding of ligands to SH2 and PRR domains of Itk can coordinate an open conformation and allow for transphosphorylation by Src PTKs [83].

One such mechanism is facilitated through the interaction of Itk interaction with a number of tyrosine phosphorylated adaptor proteins. The LAT adaptor protein is a transmembrane, GEM-localized protein that is phosphorylated by the ZAP-70/Syk PTKs following TCR crosslinking. Tyrosine phosphorylation of LAT facilitates its binding to a number of signaling complexes that include PLC γ 1, PI3K, the Grb2/Sos/Ras complex, and the Gads/SLP-76 signaling complex [87]. Tyrosine phosphorylation of SLP-76 facilitates the cooperative binding of the Itk SH2/SH3 domain with the tyrosine phosphorylated SLP-76 molecule [88]. Association of Itk with phosphorylated SLP-76 relieves the intramolecular inhibition of Itk and allows for transphosphorylation of Itk by the Src PTKs. Hence, the dual mechanisms of appropriate subcellular localization mediated by the PH domain of Itk and intermolecular interactions of the Itk SH2/SH3/PRR domain with adaptor proteins regulate Itk activation.

The SH2 domain of Itk also binds and serves as a substrate for the peptidyl-prolyl isomerase cyclophilin A [89]. Nuclear magnetic resonance (NMR) analysis of the Itk SH2 domain has revealed both *cis*- and *trans*-proline conformers in solution. Interestingly, these two conformers bind distinct ligands, with the *cis*-conformer being favored in the presence of the Itk SH3 domain and the *trans*-conformer being favored in the presence of a phosphotyrosine binding peptide. Hence, ligand binding to Itk not only regulates enzymatic function but also may control distinct downstream signaling pathways that result in different biologic fates.

Finally, Itk also plays a role in CD28 coreceptor function [82,90]. The proline-rich motifs within the cytoplasmic domain of CD28 associate with the SH3 domain of Itk and contribute to Tec and Itk enzymatic activation [72,91,92]. While the extracellular domain of CD28 contributes to intercellular adhesion between the antigen presenting and T cells, the cytoplasmic tail of CD28 amplifies PLC γ 1 activation through an Itk dependent mechanism [93]. Together, these data further support the notion that multiple triggering mechanisms contribute to efficient Itk function.

Summary

Structural, biochemical and genetic studies have significantly enhanced our understanding of PTK function in T cell antigen receptor activation. While much has been learned, a precise understanding of the kinetic and spatial arrangements of these mechanisms is still lacking. The application

of more sophisticated techniques of analysis using microscopy and reagents that specifically recognized the activated forms of enzymes and phosphorylated adaptor proteins will undoubtedly further our understanding of this process and how altered forms of signaling may contribute to human disease.

Cbl: A Physiological PTK Regulator

Wallace Y. Langdon

*Department of Pathology, University of Western Australia,
Crawley, Western Australia, Australia*

Introduction

Protein tyrosine kinases (PTKs) are powerful biochemical switches that require regulatory mechanisms to restrain their potency following activation by physiological stimuli. Indeed, sustained signaling from PTKs promotes tumorigenesis and is involved in the progression of some human cancers. For this reason, members of the *Cbl* protooncogene family are of interest because of their role as negative regulators of PTKs. Three key discoveries led to this classification: first, the identification of a Cbl protein in the nematode *Caenorhabditis elegans* that negatively regulates signaling from a receptor protein tyrosine kinase (RPTK); second, the presence of a unique domain in all Cbl proteins that recognizes phosphorylated tyrosine residues present on activated PTKs; and, third, the ability of all Cbl proteins to recruit ubiquitin conjugating enzymes (E2s) to, and direct polyubiquitylation and degradation of, activated PTKs. Cbl proteins therefore function by specifically targeting activated PTKs and mediating their downregulation, thus providing a mechanism by which signaling processes can be controlled.

Domains of Cbl Proteins

The *c-Cbl* protooncogene was first identified as part of a recombinant mouse retrovirus that induced pre-B-cell lymphomas. Since then, two additional mammalian homologs (Cbl-b and Cbl-3) have been found, as well as orthologs in *Drosophila* (D-Cbl) and *C. elegans* (Sli-1) [1–3]. These proteins share a highly conserved amino-terminal region consisting of three domains—a four-helix bundle,

a calcium-binding EF hand domain, and a variant SH2 domain—which together recognize specific phosphotyrosine residues present on activated PTKs (Fig. 1). Because all three domains are required to form this unique phosphotyrosine-binding module, the region is commonly referred to as a tyrosine kinase binding (TKB) domain [4]. Two other regions highly conserved among all Cbl proteins are a zinc-binding C3HC4 RING finger and a short linker sequence connecting the TKB and RING finger domains, which together recruit E2 proteins [5–8]. Sequence homology is less extensive C-terminal to the RING finger; however, with the exception of D-Cbl, all Cbl proteins possess proline-rich regions involved in interactions with Src homology domain 3 (SH3)-containing proteins (Fig. 1). *c-Cbl* is also a prominent substrate of PTKs and is phosphorylated following the engagement of many cell-surface receptors. Phosphorylation of *c-Cbl* by PTKs provides docking sites for Src homology domain 2 (SH2)-containing proteins (Fig. 1) and is required for its E3 ligase activity [6,9]. The C termini of *c-Cbl* and Cbl-b encompass a conserved domain known as a ubiquitin-associated (UBA) domain. The UBA domain interacts with ubiquitin and was identified by sequence homology to regions found in subsets of E2 conjugating enzymes and E3 ligases. The UBA domain in Cbl proteins is of interest, as *c-Cbl* has been shown to be subject to ubiquitylation [9,10].

Sli-1: A Negative Regulator of RPTKs

Evidence that Cbl proteins have functions regulating PTKs initially came from genetic studies in *C. elegans* [11].

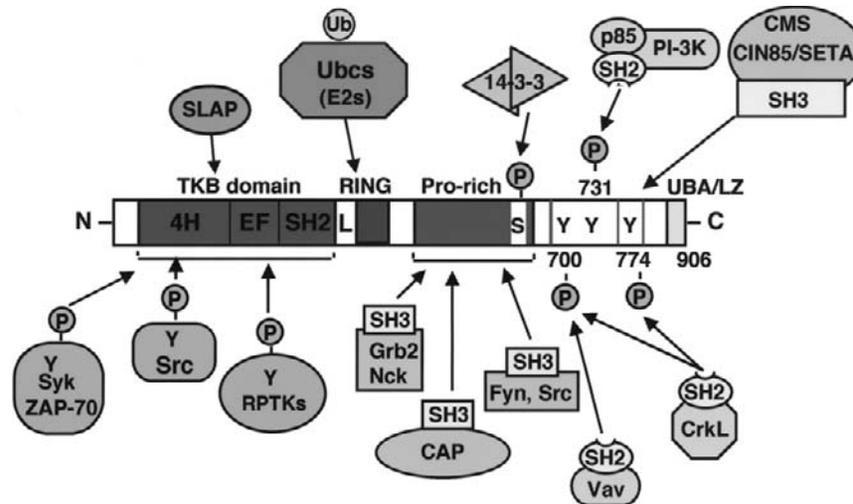

Figure 1 c-Cbl interacts with many signaling proteins. Some of these interactions occur after the activation of PTKs which results in recruitment of c-Cbl to receptor complexes and the targeting of phosphorylated tyrosines on PTKs by the TKB domain. This enables PTKs to be downregulated by c-Cbl-associated proteins such as E2 ubiquitin-conjugating enzymes recruited by the RING finger and linker (L) domains and CIN85, which is recruited by proline and phosphotyrosine motifs and is involved in mediating RPTK internalization. c-Cbl phosphorylation on tyrosine (Y) and serine (S) residues promotes associations with many SH2-containing proteins and 14-3-3 proteins, respectively. Some associations are constitutive, such as those with SH3-containing proteins that bind one or more of the 15 potential SH3-binding proline motifs within the C-terminal half of c-Cbl.

Loss-of-function mutations in *Sli-1* restored signaling for vulval induction and survival through a weakly active epidermal growth factor receptor (EGFR) homolog LET-23, whereas introducing additional copies of *Sli-1* suppressed vulval induction. These experiments indicated that *Sli-1* is a negative regulator of LET-23 that functions upstream of LET-60/Ras. Studies in *Drosophila* also suggest that Cbl can negatively regulate RPTK signaling: D-Cbl suppresses the development of R7 photoreceptor cells in flies on a sensitized genetic background [12] and functions as a negative regulator of a dose-sensitive EGFR pathway involved in dorsoventral patterning during oogenesis [13].

PTK Downregulation by Polyubiquitylation

The demonstration of a prominent and inducible association between Cbl proteins and the activated EGFR in mammalian cells clearly demonstrated that genetic studies in *C. elegans* had correctly predicted the site of Cbl action [1–3]. In addition, introducing a corresponding loss-of-function mutation from *Sli-1* into c-Cbl blocks interaction of the TKB domain with activated PTKs and abolishes fibroblast transformation by oncogenic forms of Cbl [1–3]. The identification of specific phosphotyrosine residues within the EGFR (pY1045), Met receptor (pY1003), Src (pY416), Syk (pY323), and ZAP-70 (pY292) that are recognized by the TKB domain also supports the proposal that Cbl is involved in their regulation [6,14–16].

A significant breakthrough in identifying a regulatory mechanism that could explain the function of *Sli-1* came

from observing the profound effect of c-Cbl overexpression on the promotion of PDGF, EGF, and colony-stimulating factor 1 (CSF-1) receptor polyubiquitylation and downregulation [17–19]. Receptor polyubiquitylation was found to be directly mediated by c-Cbl and to be dependent on the integrity of the TKB, linker, and RING finger domains [20,21]. Thus, c-Cbl can promote the polyubiquitylation of activated RPTKs, which targets them for degradation and prevents their recycling from early endosomes back to the cell surface (Fig. 2). *In vitro* reconstituted ubiquitylation assays demonstrated that the c-Cbl RING finger has intrinsic E3 ligase activity and can independently recruit E2s and direct ubiquitin transfer to substrates [5–7]. Furthermore, the structure of c-Cbl bound to an E2 (UbcH7) identified multiple contacts between the RING finger and linker domain of c-Cbl and UbcH7 [8]. These studies defined Cbl proteins as RING-type E3 ubiquitin protein ligases that direct RPTK polyubiquitylation and downregulation. c-Cbl has also been shown to mediate the polyubiquitylation and degradation of active Src, indicating that c-Cbl can also function as an E3 ligase for non-receptor PTKs [22,23]. Interestingly, the E3 ligase activity of Cbl is not solely restricted to PTKs, as Cbl-b overexpression can promote polyubiquitylation of the p85 subunit of PI3-kinase, and c-Cbl polyubiquitylates the T-cell receptor (TCR) ζ chain [24,25].

Cbl-Deficient Mice

The negative regulatory function of Cbl has also been demonstrated in c-Cbl- and Cbl-b-deficient mice, which

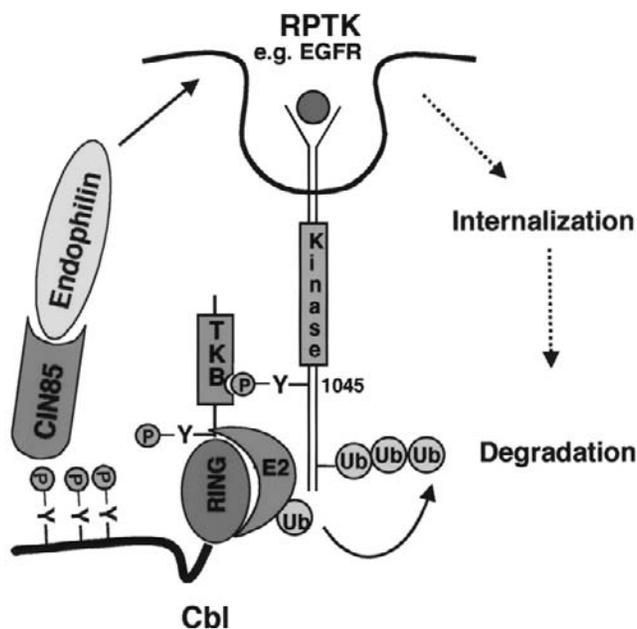

Figure 2 Cbl directs internalization, polyubiquitylation, and degradation of activated RPTKs. Ligand binding induces tyrosine phosphorylation of RPTKs and recruitment of Cbl to the activated receptor (by adaptor proteins not shown). This results in the TKB domain targeting of specific phosphotyrosines on the activated RPTKs (e.g., Y1045 on EGFR). c-Cbl also becomes tyrosine phosphorylated, and this results in the recruitment of a CIN85–endophilin complex that is required for receptor internalization. The E3 ligase function of Cbl catalyzes the transfer of a ubiquitin molecule from the RING-finger-bound E2 to the RPTK. Continued addition of ubiquitin moieties leads to polyubiquitylation, which marks the RPTK for lysosomal or proteosomal degradation. Whether or not the ubiquitin chain assembly that is directed by Cbl involves lysine 48 linkages has not been determined.

show perturbations associated with thymocyte and peripheral T-cell activation, respectively [1,26]. Thymocytes in c-Cbl^{-/-} mice show marked activation of ZAP-70 in response to TCR stimulation, in contrast to wild-type thymocytes, which require costimulation of both the TCR and the coreceptor CD4. The crucial role of CD4 stimulation is to activate Lck, which phosphorylates ZAP-70 to trigger kinase activity. Remarkably, however, in c-Cbl^{-/-} thymocytes ZAP-70 activation can be attained in the absence of Lck activation. The fact that this occurs without hyperactivation of signaling molecules upstream of ZAP-70 suggests that c-Cbl directly regulates ZAP-70, not its activators. The Cbl-b-deficient mouse shows a similar phenomenon, but it occurs in peripheral T cells as opposed to thymocytes. In this case, T-cell proliferation and IL-2 production are uncoupled from a requirement for activation of the coreceptor CD28. Thus, a lowered threshold for TCR signaling is a common theme in both mutant mice. Intriguingly, the uncoupling of a CD28 requirement for T-cell activation in Cbl-b-deficient mice does not involve enhanced ZAP-70 activation but instead results in a significant enhancement in the activation of Vav1. Furthermore, Cbl-b deficiency restores TCR-induced Cdc42 activity and cell proliferation in Vav1^{-/-} mice. Recently, it was shown that the p85 regulatory

subunit of PI 3-K, an upstream activator of Vav1, is polyubiquitylated by Cbl-b [24]; however, this does not promote proteolysis of p85 but rather inhibits its recruitment to CD28 and TCR ζ , thereby preventing the activation of Vav1 [27]. The Cbl mutant mice have therefore raised interesting questions about the abilities of c-Cbl and Cbl-b to negatively regulate different signaling molecules in distinct T-cell populations.

Future Directions

Recent discoveries have provided a clearer understanding of Cbl function, but key questions remain unanswered. A priority will be to understand whether E3 ligase activity is solely for the purpose of PTK degradation or whether Cbl-directed polyubiquitylation alters the function and fate of PTKs in ways not currently appreciated. Determining the nature of the ubiquitin chain assembly that is directed by Cbl proteins should provide important clues in this area. Furthermore, little is known about the role of Cbl interactions with many other signaling proteins that do not appear to be associated with PTK polyubiquitylation. Indeed, recent findings that loss of E3 activity alone is insufficient to promote transformation [28] and the fact that the RING finger of Sli-1 is partially dispensable for its negative regulation of LET-23 [29] demonstrate that E3 activity is not the sole inhibitory function of Sli-1/Cbl proteins. Clues about how best to approach this aspect of Cbl function may be revealed by further analyses of TKB domain function and a greater reliance on genetically altered organisms using knowledge from the recently resolved structures of the TKB, linker, and RING finger domains. Furthermore, the recent finding that the evolutionary divergent C terminus of Cbl mediates ligand-induced internalization of EGF and Met receptors by recruiting a CIN85/endophilin complex to these receptors is further evidence that Cbl has many adaptations to downregulate PTKs (Fig. 2) [30,31].

Mount Sinai Hospital, Toronto, Canada*

Introduction

Transforming growth factor beta (TGF β) superfamily members are important regulators of many diverse developmental and homeostatic processes, and disruption of their activity has been implicated in a variety of human diseases ranging from cancer to chondrodysplasias and pulmonary hypertension. The superfamily can be divided into functionally distinct subgroupings of ligands; the prototypic TGF β s themselves, the bone morphogenetic proteins (BMPs), and the activins. All members of these TGF β family subgroups that have been investigated utilize a unique class of signaling receptors that are characterized by the presence of a Ser/Thr kinase domain in their cytoplasmic region. Only 12 transmembrane Ser/Thr kinases have been identified in mammals, and this small family of receptors is further subdivided into two subclasses: the type II and type I receptors. TGF β family ligands initiate signaling through these receptors by inducing the stable assembly of heterotetrameric complexes of type II and type I receptors. This brings the type II kinase domain, which is constitutively active, into proximity of the type I receptor kinase, thereby allowing the type II receptor to phosphorylate the type I receptor on a Gly/Ser motif called the GS region, which lies on the amino-terminal side of the kinase domain [1]. This phosphorylation event allows the type I receptor to recognize and phosphorylate Smad proteins, which form a key TGF β signal transduction pathway (Fig. 1).

The Smad Pathway

Smads form a unique class of signaling molecules [2–5]. Eight Smads have been identified in the mammalian

genome, and these Smads are subdivided into three distinct classes: the receptor-regulated Smads (R-Smads 1, 2, 3, 5, and 8); the common mediator Smad, of which only one member has been found, Smad 4; and the inhibitory Smads (I-Smads 6 and 7). All Smads are structurally related. They possess an amino-terminal MH1 domain (for MAD homology domain 1) that is poorly conserved in the I-Smads, followed by the linker region and in the carboxy-terminal region a MH2 domain. Each of these domains fulfills critical effector functions in Smad signaling by mediating protein–protein and protein–DNA interactions.

The R-Smads function as direct substrates of the receptor and possess a binding surface on their MH2 domain that accommodates phosphoserine residues separated by single amino acids [6,7]. Thus, phosphorylation of the GS region of the type I receptor likely provides a direct contact point between R-Smads and the receptor that works in conjunction with additional interactions between the MH2 and a specificity loop of the receptor that lies between β -strands 4 and 5 of the kinase domain [8,9]. These interactions are important to mediate matched binding between different type I receptors and specific R-Smads. Consequently, type I receptors that bind BMPs only recognize and phosphorylate R-Smad1, 5, and 8, whereas the TGF β and activin type I receptors activate R-Smad2 and 3. In addition, an anchor protein called SARA can facilitate activation of R-Smads in the TGF β /activin pathway by directly binding unphosphorylated Smad2 and recruiting it to cell membranes [10]. SARA has a FYVE domain that binds phosphatidylinositol-3'-phosphate (PI-3'-P). Interestingly, Hrs, another receptor binding protein, also has a FYVE domain and appears to cooperate with SARA in TGF β signal transduction [11]. Because PI-3'-P and FYVE domain proteins are particularly enriched in the early endosome, these data suggest that trafficking of

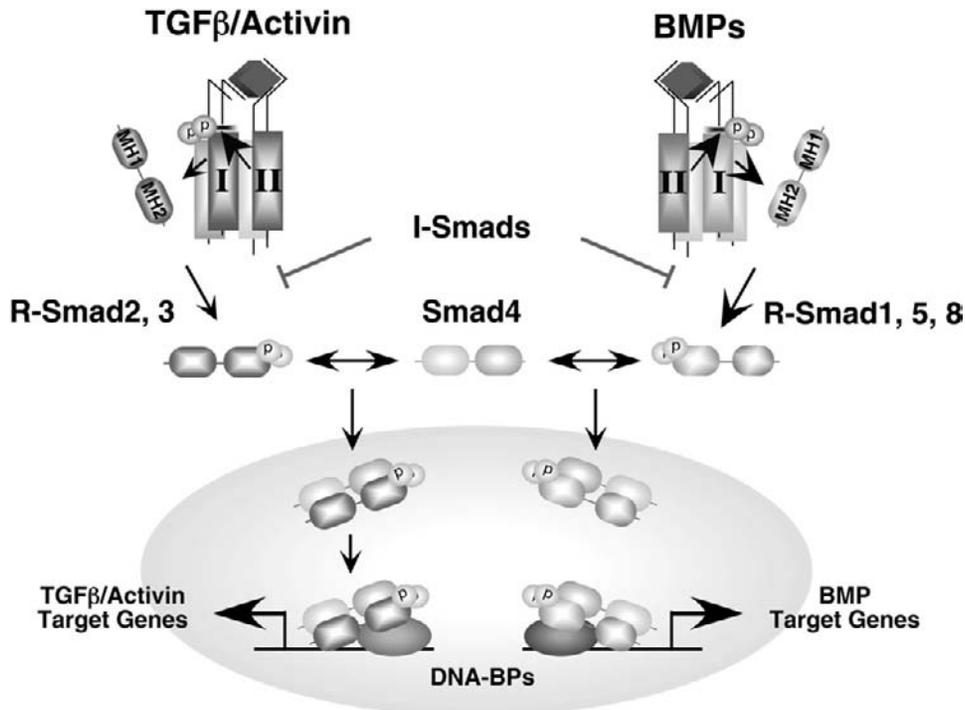

Figure 1 TGFβ/activin and BMPs signal through distinct receptors and Smads. TGFβ/activin and BMPs bind to different receptor complexes that phosphorylate distinct R-Smads. Phosphorylated R-Smads then bind Smad4 and the complexes accumulate in the nucleus. R-Smad complexes associate with different DNA-binding proteins (DBP-BPs) to regulate distinct target genes and generate diverse biological responses.

the receptors may be important for signaling. Indeed, endocytosis has been noted to be important for initiating TGFβ signal transduction in certain cell systems [12,13]. Another receptor-associated protein that may be involved in this pathway is Disabled-2, which interacts with the TGFβ receptor complex and is important for receptor-dependent activation of Smad2 [14]. This may be particularly important in the visceral endoderm during gastrulation in the mouse [15].

Once bound to the receptor, the type I kinase domain phosphorylates the R-Smad on a carboxy-terminal SXS motif that is found in all R-Smads [16]. Phosphorylation of R-Smads causes their dissociation from SARA and the receptor and drives homomeric, as well as heteromeric, interactions with the common Smad, Smad4. Interestingly, the same binding surface that likely contacts the phosphorylated GS region also stabilizes the homomeric and heteromeric Smad complexes by binding to the phosphorylated tail of an adjacent R-Smad [6,7]. In addition, phosphorylation drives the R-Smad homomers and R-Smad–Smad4 heteromers to accumulate in the nucleus, where they regulate transcription by interacting directly with DNA and DNA binding partners [2–5]. DNA binding is mediated by the MH1 domain, but in most cases this interaction is not of sufficient affinity and specificity to allow Smad on its own to regulate transcription. Thus, Smad binding to high-affinity DNA binding partners (DNA-BPs) is a critical aspect for recruitment of the Smad complex to specific regulatory elements and functions to facilitate interaction of the MH1 domain of Smads with

DNA at sites that lie adjacent to the DNA binding partner site. Contact of Smads with DNA in turn plays an important role in stabilizing DNA binding by the ternary Smad–DNA–BP complex. Smads thus bound to regulatory elements can control the transcriptional response by recruiting coactivators such as histone acetyltransferase, MSG, and SMIF or corepressors such as TGIF, SnoN, or histone deacetylases. In this regard, the role of Smad4 in TGFβ-dependent transcriptional activation seems particularly important, and Smad4 can bind directly to the p300/CBP histone acetyltransferases. Thus, many, but not all, transcriptional responses to TGFβ are lost or blunted in Smad4-deficient cell lines, and, because, Smad4 binds all activated R-Smads, it likely fulfills similar general activation functions in the BMP pathways. Exactly what determines whether Smad complexes recruit coactivators or corepressors is unknown; however, a correlation between the ability of Smad3 to bind DNA via its MH1 domain and suppress transcriptional responses of model promoters has been observed [17].

One of the interesting aspects to emerge from this mode of regulation is that many of the Smad DNA-BPs themselves function to mediate transcriptional responses to other cell signaling pathways. For example Smads interact with AP-1, ATF2, vitamin D receptors, and LEF/TCF DNA binding partners which themselves function in MAPK, p38, vitamin D, and WNT signaling pathways, respectively. This leads to an important area of cross-talk between the TGFβ–Smad pathway and other signal transduction pathways. Cross-talk between the Smad pathway can also occur upstream of

transcriptional activation via phosphorylation of Smads in sites other than the carboxy-terminal SXS motif. Thus, MAP kinases that function downstream of receptor tyrosine kinase pathways can phosphorylate Smads in the linker region and modulate their activity [18], whereas PKC has been shown to phosphorylate Smad3 in the MH1 domain and inhibit DNA binding and activation of Smad3 target elements [19].

In contrast to the R-Smads and Smad4, the two inhibitory Smads, Smad6 and Smad7, function as antagonists of Ser/Thr kinase receptor signal transduction [20–22]. These I-Smads form complexes with the activated type I receptor, prevent access of R-Smads to the receptor, and can mediate ubiquitin-dependent downregulation by recruiting Smurf ubiquitin ligases to the receptor complex [23,24]. Smad6 appears to preferentially target the BMP pathway, whereas Smad7 potentially blocks both TGF β and BMP pathways. Interestingly, expression of the I-Smads is regulated by a variety of signaling pathways that include interferon γ , TNF α , and EGF, as well as TGF β and BMPs themselves [3]. These latter observations suggest that I-Smads form part of a negative regulatory loop that serves to dampen the activity of ligand-activated Ser/Thr kinase receptor complexes.

Smads and the Ubiquitin–Proteasome System

TGF β family members are important morphogens that can control distinct cell fate outcomes in response to different concentrations of ligands. By transducing signals directly from the cell-surface receptor to specific gene promoters, the Smad pathway is ideally suited to interpret morphogenetic signals, as the concentration in the nucleus can provide a direct readout of the external concentration of the ligand. Indeed, studies on Smads in *Xenopus* showed that cell fate could be regulated by the concentration of Smad proteins [25]. Smad protein levels are subjected to regulated degradation in the cell by the ubiquitin–proteasome system. In the BMP pathway a C2-WW-HECT domain ubiquitin ligase called Smurf1 (for Smad ubiquitin regulatory factor 1) can block BMP signaling and regulate cell fate by interacting with the R-Smads Smad1 and Smad [26] or MAD in *Drosophila* [27] and target them for ubiquitination and degradation. In certain systems high-level expression of a second Smurf, Smurf2, can also regulate the turnover of R-Smad1 [28] or R-Smad2 [29]. In the nucleus phosphorylated R-Smad2 and 3 can be regulated by ubiquitin-mediated degradation [30], mediated at least in part by the ubiquitin ligase Roc1 [31], and Smad4 turnover can be regulated by the ubiquitin ligase Jab1 [32]. Moreover, analysis of Smad mutations found in human cancer has shown that some of these mutations inactivate Smads by targeting them for ubiquitin-dependent proteolysis [33]. Thus, Smads are tightly controlled by the ubiquitin–proteasome system.

More than simply targets for ubiquitin-mediated degradation, Smads can also regulate the ubiquitination of associated

proteins by functioning as adaptor proteins. The I-Smads play an important role in regulating receptor turnover and do so by forming stable complexes with Smurf1 and Smurf2 and recruiting these C2-WW-HECT domain proteins to the TGF β and BMP receptor complexes [23,24]. Furthermore, phosphorylated R-Smad2 and 3 can recruit Smurf2 to the nuclear corepressor SnoN, which is a binding partner of Smad2 and Smad3 [34]. This complex potentially induces ubiquitin-mediated degradation of SnoN. Interestingly, the anaphase promoting complex ubiquitin ligase also targets SnoN for degradation, and this is enhanced by Smad2- and Smad3-mediated recruitment [35,36]. In addition, Smad3 may mediate degradation of Hef1, which is member of the Cas family of cytoplasmic docking proteins [37]. Thus, Smads may fulfill important roles in regulating protein levels of partner proteins by functioning as adaptors in the ubiquitin–proteasome system.

Smad-Independent Signaling Pathways

Activation of TGF β family receptors also regulates a number of Smad-independent pathways. One of these involves Daxx, which was found to interact with the carboxy-terminal tail of the TGF β type II receptor [38]. Dominant-negative Daxx or blocking Daxx expression interferes with TGF β -dependent apoptosis, and Daxx is important for TGF β -dependent activation of Jun kinase. As Daxx also mediates similar responses downstream of the Fas receptor, this pathway may reflect a common output of both Fas and TGF β signaling pathways. Studies on the regulation of S6 kinase have shown that TGF β can induce protein phosphatase 2A to bind to and dephosphorylate S6 kinase, which, in cooperation with the Smad pathway mediates TGF β growth arrest in the G1 phase of the cell cycle [39]. As the protein phosphatase 2A regulatory subunit B α also binds to the receptor [39,40], it suggests that the TGF β receptor may somehow regulate the activity of PP2A. Whether this pathway plays any role in regulating the phosphorylation status of other substrates in response to TGF β is unknown.

TGF β family receptors also can activate numerous other kinases in a cell-type-specific manner. In addition to JNK activation, which is important for induction of fibronectin expression in fibrosarcomas [41], TGF β has also been reported to stimulate ERK activity in intestinal epithelial cells [42], also, in a variety of cells p38 is activated by TGF β and BMPs and this may lead to apoptotic responses [43–45]. Furthermore, in epithelial cells derived from the mouse mammary gland, TGF β can also regulate the Akt/PKB pathway [46]. TAK1, a MAPK kinase kinase that functions in multiple signaling pathways, and its associated activators, TAB 1 and TAB2, have also been implicated to be involved in both TGF β and BMP pathways [47,48]. Binding of the TAB–TAK complex to Ser/Thr kinase receptor complexes may be mediated by XIAP, which can bind both TAB and the receptor complex [49]. In *Xenopus* systems, this pathway appears to play a role in transducing BMP ventralizing

signals [50]. In addition to kinase cascades, TGF β also can regulate actin cytoskeletal dynamics by regulating the activity of Rho family GTPases. Thus, Cdc42 and RhoA have been reported to be activated by TGF β [51,52], with the latter pathway playing a key role in the assembly of stress fibers during TGF β -induced epithelial-to-mesenchymal transitions. How heteromeric Ser/Thr kinase receptor complexes regulate many of these downstream Smad-independent signaling pathways has to date remained very much a mystery.

Other Receptor Interacting Proteins

A number of other Ser/Thr kinase receptor interacting proteins have been identified through a variety of means [3]. FKBP12 was first identified through yeast two-hybrid screens as a binding partner of multiple type I receptors. FKBP12 binds preferentially to the unphosphorylated GS region of the type I receptors and dissociates upon formation of an active receptor complex. Thus, the protein may function to maintain the type I receptor in an inactive state and prevent spurious activation of the pathway in the absence of ligand. Other proteins that have been shown to associate with receptors include farnesyltransferase- α ; TRIP1, which binds the type II receptor; STRAP, which can cooperate with Smad7 to inhibit signaling; TRAP, which also inhibits receptor activity; ARIP, a PDZ and WW domain-containing protein; BRAM, a BMP-receptor-associated molecule; and SNX proteins, which are sorting nexins that might regulate receptor trafficking. Whether these proteins function solely to modulate receptor activation of the Smad pathway or might modulate the activity of the receptor toward Smad-independent pathways is unknown.

Elucidation of the molecular components of the TGF β superfamily signal transduction pathways has provided important insights into human disease; many human syndromes and illnesses, both hereditary and spontaneous, have been attributed to mutations in this signaling pathway. For instance, mutations in receptors are associated with hereditary hemorrhagic telangiectasia, primary pulmonary hypertension, persistent müllerian duct syndrome, juvenile polyposis syndrome, and colorectal and gastric carcinomas. Mutations in Smads have also been associated with cancers, particularly those of the colon and gastrointestinal tract. Undoubtedly, further elucidation of the molecular mechanisms in this signaling pathway promises to provide new insights into cellular regulation and physiology in health and disease.

Toronto, Ontario, Canada*

Introduction

The identification in the late 1970s of protein tyrosine kinases (PTKs) as products of oncogenes and growth factor receptors revealed a gaping hole in our understanding of signal transduction. How did such molecules couple to the far more abundant protein serine/threonine kinases that had been known about for several decades? One possibility was that certain serine kinases were themselves phosphorylated on tyrosine. In a search for protein kinases regulated by the insulin receptor-tyrosine kinase, Ray and Sturgill [1] identified a microtubule-associated protein-2 kinase (MAP2 kinase) that, upon treatment of cells with insulin, became phosphorylated on tyrosine (and threonine) and catalytically activated. Many other growth factors were found to activate this enzyme, which led to a refinement of its name to mitogen-activated protein kinase (MAPK). Although MAPKs were soon found not to be the “missing link” for coupling receptor and oncogene tyrosine kinases to intracellular events, their critical role in transducing a variety of signals soon became apparent.

Subsequent molecular cloning of MAPKs revealed additional surprises [2]. First, relatives of the MAPKs were found in other species, most notably yeast [3–5]. With hindsight, the first MAPK to be molecularly cloned [3] was a budding yeast gene termed *Fus3* (and a related protein termed *Kss1*) that encodes a component of the pheromone response pathway. This provided a bonus in that genetic analysis of the pheromone pathway in yeast had revealed several other gene products that regulated the yeast MAPK. Moreover, these components had been ordered and formed a protein kinase cascade [5]. It also became clear that nature had generated multiple variants of MAPKs that played different functions and responded to distinct stimuli. The term *MAPK* is now commonly used to denote an entire class of

protein serine kinases that share several key features, including regulation by tyrosine and threonine phosphorylation and organization into a hierarchical cascade of kinases. Generically, the MAPKs are phosphorylated at a threonine–X–tyrosine motif that lies in the T-loop of their kinase domain [6]. Both threonine and tyrosine phosphorylations are catalyzed by a single, dual specificity protein kinase known as MAPK kinase (MAPKK). These enzymes are, in turn, phosphorylated (at serine/threonine residues only) and activated by another class of enzymes, the MAPKK kinases (MAPKKKs) (Fig. 1).

As mentioned, yeast *FUS3* was the first MAPK to be genetically identified [3]. Additional genetic analysis in budding yeast identified components for five distinct MAPK pathways. These MAPK pathways are essential for processes such as mating, sporulation, osmoregulation, cell wall integrity, starvation, and filamentous growth [5,7,8]. To date, the sequences of over 100 eukaryotic MAPKs have been reported. In mammals, three major MAPK signaling modules have been described: the original MAPK or extracellular signal-regulating kinase (ERK) and two MAPK cascades that respond to cellular stresses, Jun kinases (SAPK, or c-Jun NH₂-terminal kinase [JNK]) and p38 MAPKs (Fig. 1) [9].

The ERK Module

In mammals, the prototypical MAPKs are encoded by two genes, *Erk-1* and *-2*, generating proteins of 44 and 42 kDa, respectively [2]. Like most of the MAPK proteins, these enzymes are widely expressed and are generally not regulated at the transcriptional level. These enzymes are phosphorylated and activated by MAPK/ERK kinases (MEKs) 1 and 2, which target a threonine and a tyrosine residue within the T-loop of the kinase domain [10,11].

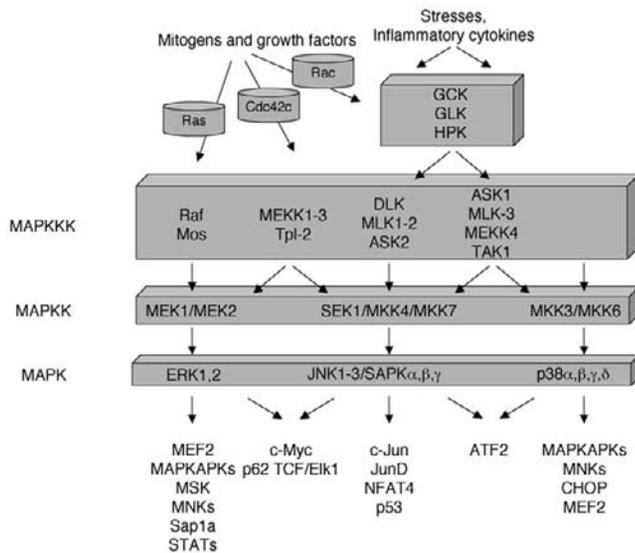

Figure 1 Mammalian MAPK modules. The MAPK module consists of a MAPKKK, MAPKK, and a MAPK. These pathways respond to extracellular signals, including growth factors, hormones, cell stresses, and cytokines. Once activated, MAPKs can phosphorylate a wide variety of proteins, including transcription factors and other kinases. See text for details.

When phosphorylated, this loop swings out, allowing adenosine triphosphate (ATP) and substrate to access the catalytic pocket [6]. MEK activity is similarly dependent upon phosphorylation at two T-loop serine residues by upstream kinases, typically Raf1 but also B-Raf, Mos, or MEKK1 [12].

The availability of phospho-specific antibodies selective for the T-loop phosphorylation sites of ERKs and MEKs has simplified monitoring of the modification of these enzymes following cellular stimulation. Perhaps unexpectedly, such studies have shown that the triad of protein kinases that lead to MAP activation does not function as an amplification circuit, as occurs, for example, in cAMP-dependent activation of glycogen phosphorylase. Instead, the three kinases appear to interact in a one-to-one linear system. So why invest in three kinases when one could do the same job? The answer may lie in the exquisite levels of regulation and sensitivity that are made possible by this arrangement, as well as enhanced specificity. For example, work by Ferrell and colleagues in *Xenopus* has revealed that the MAPK and JNK/SAPK pathways act like switches [13,14]. A stimulus triggers a binary response, on or off with nothing in between. The effect is termed *bistability* and relates to the quantum change required to overcome the activation hurdle (which is opposed by different phosphatases acting on the various MAPK triad components). In yeast, there is another rationale for the three-kinase module. In this case, the same three components can be utilized in different responses, depending on their association with the STE5 scaffolding protein [15]. STE5 acts to insulate the MAPK module by cloistering the kinases together such that they are functionally coupled to a particular stimulus. Loss of STE5 releases

the STE11 MAPKKK, which can then couple to a MAPK module activated by hyperosmolarity. Such clustering of signaling molecules is now recognized as a common means to achieve specificity and to counter entropic forces that tend to equalize cellular protein distribution.

Substrates of ERKs include additional protein kinases such as MAPKAP-kinase, signaling molecules such as phospholipases, and transcription factors such as Elk-1/ternary complex factor [9]. These and other ERK targets share an ERK phosphorylation motif minimally comprised of Pro-X-Ser/Thr-Pro, although high-affinity substrates usually harbor additional binding interfaces for the kinase. Online databases such as Scansite [16] are useful tools that use such consensus sequences to predict phosphorylation sites (and the corresponding kinases that modify them) within any protein.

ERK activation is often associated with proliferation (for example, Raf induction is tightly coupled to growth-induced or oncogenic Ras activation), but the consequences of ERK stimulation depends on the signal and cell type. Even in the same type of cell, the kinetics of ERK activation play a defining role in the ultimate response. For example, in PC12 pheochromocytoma cells, slow but sustained ERK activation by nerve growth factor induces neurite outgrowth and differentiation. By contrast, short but sharp activation of the same pathway by epidermal growth factor results in cell proliferation [17]. Thus, the same signaling machinery can deliver different messages within a cell.

Stress-Activated MAPKs, Part 1: SAPK/JNKs

While the ERK family of MAPKs is primarily activated by growth factors and mitogens, the SAPK/JNK and p38 MAPK families are preferentially induced by stress signals, including irradiation, pro-inflammatory cytokines, environmental stress (temperature, osmolarity, pH), oxygen tension, intracellular calcium, and other insults that interfere with cellular integrity.

SAPK/JNKs are encoded by three genes (α , β and γ or JNK2, JNK3, and JNK1, respectively) [18,19]. Differential splicing of the three SAPK/JNK genes generates at least 10 isoforms that encode 54-kDa or 46-kDa proteins. The SAPK/JNKs were originally identified as the major serine/threonine kinases responsible for the phosphorylation of c-Jun, a component of the AP-1 transcription factor [20]. Other SAPK targets include additional Jun proteins (JunB, JunD, and the related activating transcription factor 2 [ATF2]); the ternary complex factor (TCF) subfamily of ETS-domain transcription factors; the tumor suppressor p53; SMAD3; and nuclear factor of activated T cells (NFAT4) [9]. Most characterized SAPK/JNK targets are transcription factors. This is in contrast to ERK and p38 MAPKs, which target proteins throughout the cell. Although the three primary SAPK/JNK proteins exhibit similar substrate specificities, analysis of mice engineered to lack one or more of these genes has revealed differential effects. For example, unlike

the generalized expression of the other two SAP/JNK gene products, SAPK β /JNK3 is preferentially expressed in neuronal tissue, hinting toward a specialized function. Mice lacking SAPK β /JNK3 are relatively resistant to kainic acid-induced seizures [21]. Similar results were obtained in mice with a knock-in c-Jun mutation that eliminated the SAPK/JNK phosphorylation sites [22], suggesting that c-Jun is the essential target for SAPK β /JNK3 in stress-induced neuronal apoptosis. The general consequence of chronic SAPK/JNK signaling is induction of apoptosis, although acute signaling appears protective. In this respect, perhaps this pathway is akin to a long fuse that is lit at the first sign of trouble but if not doused (by subsequent damage control?) it triggers elimination of the cell.

Stress-Activated MAPKs, Part 2: p38 MAPKs

The second family of MAPKs that react to stress is named after the first member to be identified—a lipopolysaccharide (LPS)-inducible kinase activity from mouse peritoneal macrophages [23]. Like the SAPK/JNKs, p38 MAPK activation is often associated with regulation of apoptosis; however, this protein kinase plays a role in skeletal differentiation, inflammatory responses, and the cell cycle.

Mammalian genomes harbor four genes encoding p38 MAPKs that are 60 to 70% identical at the amino acid level: p38 α /Mpk2/CSBP, p38 β , p38 γ /ERK6, and p38 δ . p38 MAPKs phosphorylate a number of different proteins, including MAPK-activated protein kinase 2 and the transcriptional regulators myocyte enhancer factor 2 (MEF2), CHOP/GADD153, CREB, and ATF2.

Study of the physiological functions of the p38 MAPKs has benefited from the potent inhibition of the α and β isoforms by pyridinylimidazoles such as SB 203580 which, due to their immunosuppressive effects, are also known as cytokine-suppressing antiinflammatory drugs (CSAIDs) [24].

MAPKKs

As noted above, one of the defining characteristics of the MAPKs is their hierarchical organization within kinase cascades. All of the MAPKs (ERK, SAPK/JNK, and p38 MAPKs) require phosphorylation on threonine and tyrosine for activity. The Erks are specifically phosphorylated by MEK1 and 2 [10]. Two MAPKKs have been identified as upstream activators of the SAPK/JNKs: SEK1 (SAPK/ERK kinase 1, also known as MKK4) [25] and MKK7 (MAPK kinase 7) [26]. Sek1 and MKK7 are not redundant, as mice lacking Sek1 die during embryogenesis of liver malformation, suggesting that these two MAPKKs are coupled to at least partially distinct upstream regulatory proteins [27]. There are also two MAPKKs that phosphorylate and activate the p38 MAPKs: MKK3 and MKK6 [28]; therefore, some six distinct MAPKKs act to selectively induce different MAPKs (see Table 1).

Table 1 Components of Mammalian Stress-Regulated MAPK Signaling Pathways

<i>MAPKs</i>	
ERK1, 2	Extracellular signal regulated kinases
SAPK α / β / γ	Stress-activated protein kinase (JNK2/3/1, respectively)
p38 α / β / γ / δ	p38 MAPK, p38/HOG1, MPK2, Mxi2, CSBP1/2
<i>MAPKKs</i>	
MEK1,2	MAPK/ERK kinases 1, 2
MKK3	MAPK/ERK kinase 3
MKK6	MAPK/ERK kinase 6
SEK1	SAPK/ERK kinase 1 (MKK4)
MKK7	MAPK/ERK kinase 7 (SEK2)
<i>MAPKKKs</i>	
ASK1/2	Apoptosis signal-regulating kinase (ASK1 = MAPKKK5)
DLK	Dual leucine-zipper bearing kinase (MUK, ZPK)
MEKK1–4	MAPK/ERK kinase kinase (MEKK4 = MTK1)
MLK2	Mixed-lineage kinase (MLK2 = MST; MLK3 = SPRK)
Raf	Raf oncoprotein
PAK	p21-activated kinase
TAK1	TGF-activated protein kinase
Tpl2	Tumor progression locus 2 (Cot)
<i>STE20s</i>	
GCK	Germinal center kinase
GCKR	GCK-related
GLK	GCK-like kinase
HGK	HPK/GCK-like kinase
HPK1	Hematopoietic progenitor kinase 1
MST1	Mammalian Ste20-like protein kinase
NESK	NIK-like embryo specific kinase
NIK	Nck-interacting kinase
TAO1/2	One thousand and one amino acid protein kinase 1
<i>Scaffold Proteins</i>	
IB1	Islet-brain 1
JIP1	JNK-interacting protein 1
MP1	MEK partner 1

MAPKKKs

While the MEKs are targeted by only a small number of MAPKKKs (e.g., Raf, Mos, MEKK, Tpl2), over 12 different enzymes act on the stress-activated MAPKs (see Fig. 1 and Table 1). These molecules include the MEKKs that are homologous to yeast STE11. Of note, the mixed lineage

kinase (MLK) group of MAPKKKs contains a Cdc42/Rac1 interaction and binding (CRIB) motif that mediates association with Rho family small GTPases [29]. These molecules are key regulators of the actin cytoskeleton and are implicated in secretion and migratory responses. Expression of activated (GTP-bound) forms of Rac1 and Cdc42 activates the SAPK/JNK and p38 pathways, providing an important link between regulation of the cell shape and control of gene expression by the stress-activated protein kinases [30]. Another MAPKKK, apoptosis signal regulated kinase (ASK1), couples tumor necrosis factor- α (TNF- α) via an adaptor molecule (TRAF2) to activation of SAPK/JNK/p38 MAPK [31,32]. This same MAPKKK also acts as a redox sensor via association with thioredoxin, providing one mechanism for coupling cellular oxidative status to transcription [33,34].

MAPKKKs

An early indication that there may be a further level of protein kinases in the MAPK cascade, above the MAPKKKs, was discovery of the yeast kinase STE20. Genetic analysis placed this gene as acting upstream of MAPKKK STE11, but physical evidence of direct regulation of STE11 by STE20 has been sparse. Several STE20-related proteins were subsequently identified, such as germinal center kinase (GCK) and GCK-related (GCKR/KHS1) and GCK-like kinase (GLK). The precise mechanisms by which these enzymes interact with the MAPK cascades is not completely understood. For example, although over-expression of these molecules induces SAPK/JNK activity, in some cases mutants that disable the kinase activity or delete the kinase domain entirely retain their ability to activate the MAPKs. In addition to SAPK/JNK induction, some of the MAPKKKs induce NF- κ B activation, suggesting that they impact multiple and distinct signaling pathways [35].

Instead of acting like conventional protein kinases, the MAPKKKs appear to operate more as kinase scaffolds and physically interact with a variety of the MAPKKKs (not necessarily directly phosphorylating them). As mentioned earlier, the pheromone pathway in yeast again led the way in our understanding of scaffolds. In this case, the MAPK FUS3 binds to the scaffold protein STE5 together with the MAPKK STE7 and MAPKKK STE11 [15]. More recently, mammalian scaffolding proteins have been characterized. MEK partner 1 (MP1) interacts with ERK1 and MEK1 [36], whereas the JNK-interacting protein (JIP) family of proteins binds to SAPK/JNK, MKK7, mixed-lineage protein kinases, and the STE20-like protein kinase HPK [37]. As is the case for STE5, the mammalian scaffolds appear to be important for clustering pathway components. The stoichiometry of association, however, is quite low, suggesting that these scaffolds also act to sequester signaling modules within certain subcellular locations, with the majority of the protein kinases remaining untethered and free to diffuse.

Summary

The MAPKs are one of Nature's preferred "solutions" for signaling, and the basic three-kinase module has been replicated for various tasks in all eukaryotes. While the overall structure of the module is remarkably conserved, the inputs and outputs are diverse and unpredictable. Although MAPKs did not turn out to be the "missing link" between tyrosine and serine/threonine kinases, their importance transcends such a simple bridge in acting as adaptable conduits between the environment and the appropriate cellular response. As has already been demonstrated for p38 MAPK, pharmaceutical modulation of the pathways may have therapeutic benefit. Indeed, MEK and Raf inhibitors are undergoing clinical trials for the treatment of certain cancers. As more selective, small-molecule inhibitors are developed, additional indications such as inflammation, arthritis, and autoimmunity may benefit from MAPK medicinal chemistry.

Cytoskeletal Regulation: Small G-Protein–Kinase Interactions

Ed Manser

*Glaxo-IMCB Group,
Institute of Molecular and Cell Biology, Singapore*

Introduction

Work from many laboratories has established that molecular switches of the Rho GTPase family, that including Rho, Rac, and Cdc42, alter the cytoskeleton by recruiting protein effectors. These, in turn, act in cascades that are responsible for altering the three major cytoskeletal networks: the microfilament, intermediate filament, and microtubule systems. The many signals that can impinge on cells to alter their morphology act via a common set of such Rho switches. This chapter discusses three well-studied protein kinases regulated by Rac, Cdc42, and Rho. A comprehensive description of other Rho effectors can be found elsewhere [1]. Lessons learned about the control of these kinases have begun to tell us how cells use the common currency of protein phosphorylation to coordinate complex spacial and temporal signaling events, as is required for processes such as cell movement.

A number of studies have pointed to Rac as playing a critical role in cell migration [2], a property of many cultured cells that can be directly observed and quantified. Recent real-time imaging techniques have allowed visualization of the production of active Rac GTP by growth factors directly to the leading edge [3], confirming that the GTPase is activated in a polarized fashion. Cdc42 drives formation of filopodia [4] and is important for cells to orientate correctly towards a chemotactic gradient [5] or for fibroblasts to align themselves during wound healing [6].

Rho-dependent actin stress fibers are responsible for the contractile forces generated in cultured cells, both within leading-edge structures [7] and between integrin-containing focal-adhesion complexes (FCs), particularly in the retracting

tail of migrating cells [8]. Rho, acting through its effector, Rho kinase (ROK), plays a key role in producing these structures by organizing myosin II [9]. In the immune and nervous systems, Rho GTPases function in migration, phagocytosis, neurite outgrowth, and axonal pathfinding. We now have some understanding of how cytosolic protein kinases are coupled to cytoskeletal driven processes (Table 1).

p21-Activated Kinases

The most prominent downstream targets of Rac and Cdc42 in blot overlays are the mammalian p21-activated kinases (PAKs) [10] with homologs Ste20 and Cla4 in *Saccharomyces cerevisiae*; these proteins have been implicated in cell-cycle control, dynamics of the actin cytoskeleton, apoptosis, and transcription (for reviews, see Bagrodia and Cerione [11]). One of the effects of PAK expression is a loss of F-actin; this is thought to result in part from effects on myosin light chain kinase (MLCK; see Fig. 1). However, an opposite effect is thought to result from activation of LIM kinases; cofilin inactivation by LIM kinases facilitates the assembly of actin. LIM kinase 1 is activated by Rac1 [12] and its effector, PAK1/ α PAK [13]. It has recently been shown that the related Cdc42 effector PAK4 is a potent *in vivo* activator of LIM kinase 1 [14]. In spite of the close connection between Rho GTPases and focal adhesion complexes, PAKs are the only identified effector (kinase or otherwise) that have been localized to adhesion complexes [15], where PAK is probably locally activated in these fledgling structures [16].

PAKs (α , β , γ isoforms equivalent to PAK1, 3, 2) are 60- to 68-kDa proteins that contain an N-terminal p21 (Cdc42/Rac)

Table I Protein Kinase Effector Proteins of Rho GTPases

Effector	GTPase selectivity	Protein type	Target	Cytoskeletal effect
MRCK (α,β)	Cdc42,	S/T kinase	MBS	Actin/myosin II Increased focal adhesions
PAK (α,β,γ) (PAK1, 2, 3)	Cdc42, Rac,	S/T kinase	LIM-K MLCK	Actin polymerization Inhibits myosin II
PAK4, 5	Cdc42	S/T kinase	LIM-K	Actin polymerization
PAK6	Cdc42	S/T kinase	Androgen receptor	—
PKN1, 2 (PRK1, 2)	Rac, Rho	S/T kinase	Vimentin (?)	Actin/myosin II IFs disassembly
ROK (α,β) (ROCK, Rho kinase)	Rho	S/T kinase	MBS Vimentin LIM-K	Actin/myosin II Increased focal adhesions IFs disassembly Actin polymerization

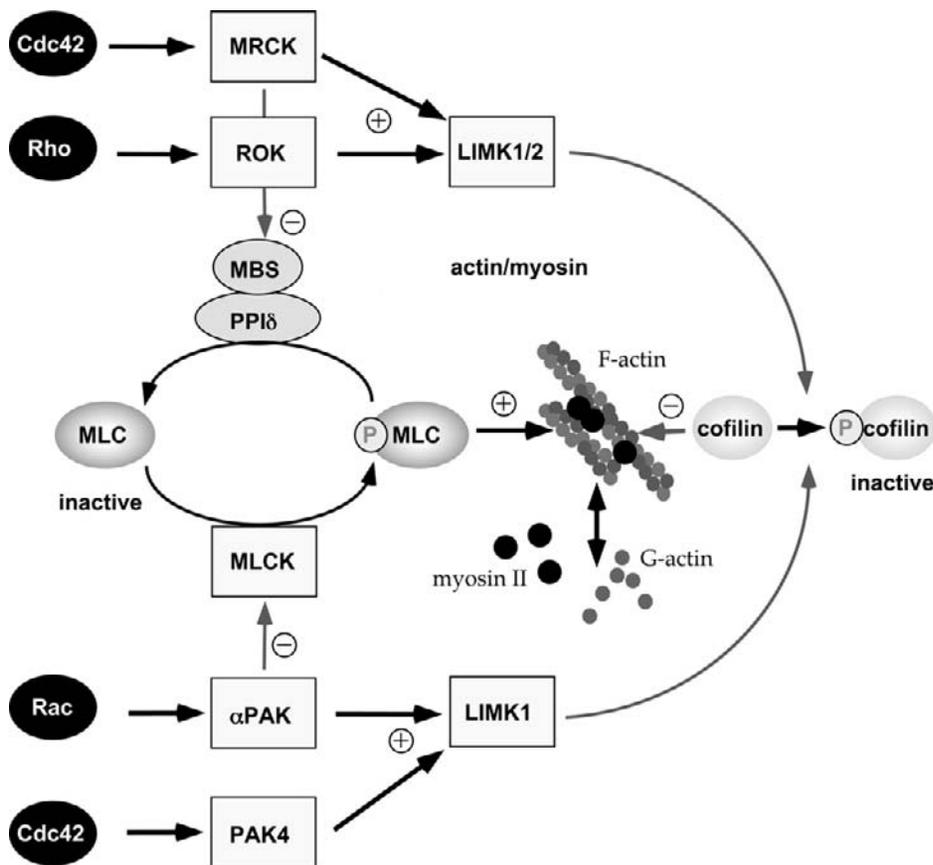

Figure 1 Pathways linking Rho GTPase-associated kinases to actin/myosin II. Rho regulation of actin organization occurs through multiple effectors. The Rho-associated kinase (ROK) and the myotonin-related Cdc42-binding kinase (MRCK) block protein phosphatase delta (PP1 δ) activity by phosphorylating the myosin binding subunit (MBS) p85 or p130 subunits. This prevents inactivation of phosphorylated MLC-P assembled into actin stress fibers. Myosin-II-driven assembly of stress fibers favors the formation of focal adhesion complexes. Myosin light chain kinase (MLCK) is a key enzyme for maintaining the myosin heavy chain–light chain complex in an active state but is negatively regulated by Rac via the p21-activated kinase (PAK). It appears that both Cdc42-binding kinases PAK4 and MRCK can act via LIM-kinases (LIMKs) to inactivate cofilin. This stabilizes actin filaments, because cofilin serves to accelerate actin dissociation and may drive the net peripheral actin assembly characteristic of active Cdc42.

binding domain (PBD) and a flanking kinase inhibitory domain (KID) that maintain the C-terminal kinase domain in an inactive state (Fig. 2). The ability of the PBD to bind with high affinity to Cdc42 GTP and Rac GTP forms the basis for biochemical pull-down assays of the active GTPase species. Mutations in the KID lead to constitutive activation of PAK in the absence of GTPase [15]. The binding of Cdc42 GTP or Rac GTP was proposed to allosterically induce activation of the kinase by affecting the KID structure [17]. The structures of an autoinhibited PAK [18] and of complexes between Cdc42 and a CRIB-containing fragment [19] seem to support the model. Cdc42-GppNHp binds with low affinity ($K_d \approx 0.6 \mu\text{M}$) to intact kinase, whereas the affinity to the isolated regulatory fragment is much higher (K_d 18 nM), indicating that the difference in binding energy is used for the conformational change leading to activation [20].

PAKs can also be activated by lipids, including sphingosine [21], which may act synergistically with Cdc42 [22]. Proteolytic digestion of α PAK produces a heterodimeric complex consisting of a regulatory fragment (residues 57 to 200) and a catalytic fragment (residues 201 to 491), which is active in the absence of Cdc42 [20]. In the physiological context, this is relevant as PAK2 is caspase activated [23].

It is of particular interest that PAK1 may be autoinhibited *in trans* [24], as illustrated in Fig. 2, a characteristic that could prevent spontaneous N-terminal autophosphorylation of PAK on sites such as Ser144 in the KID segment which

is involved in activation. Although Parrini *et al.* [24] propose that Cdc42-binding dissociates PAK1 dimers, different results are seen with PAK/Cdc42 complexes on gel filtration columns [20]. Here, the data suggest that an allosteric control mechanism induces autophosphorylation, which in turn induces the release of the KID and full kinase activation. This finding is contrary to the view that phosphorylation is a late event in the p21-mediated activation mechanism and serves primarily to stabilize the open conformation. The complexity of the PAK activation mechanism requires further analysis.

Myotonic Dystrophy Kinase-Related Cdc42-Binding Kinase

Myotonic dystrophy kinase-related Cdc42-binding kinase (MRCK) is a Cdc42-binding serine/threonine kinase with multiple functional domains that belongs to the myotonic dystrophy family of kinases, which includes ROK and myotonic dystrophy protein kinase (DMPK). These kinases share homology in their N-terminal kinase domains and, to a certain extent, the arrangement of other C-terminal domains. Interestingly, they all contain an N-terminal dimerization domain of approximately 70 amino acids referred to as the leucine-rich domain in DMPK, which is required for kinase activity. MRCK α is implicated in Cdc42-mediated peripheral actin formation and neurite outgrowth in HeLa and PC12 cells, respectively [25]. Its expression is ubiquitous but is highest in the brain. MRCK acts downstream of Cdc42 in actin cytoskeletal reorganization, particularly Cdc42-mediated peripheral actin formation, which may be due to its effects on myosin II (see Fig. 1). One of the major MRCK targets appears to be the myosin binding subunit of PPI δ [26] which allows inactivation of the phosphatase. In *Drosophila*, mutations of the Gek locus (a *Drosophila* homolog of MRCK) exhibit abnormal F-actin accumulation, a phenotype downstream of *Drosophila* Cdc42 [27]. The involvement of MRCK in the regulation of neurite outgrowth in PC12 cells [28] is consistent with the view that Cdc42, Rac-1, and their effectors are important for neuronal outgrowth [29].

MRCK exists in high-molecular-weight complexes in which three independent coiled-coil domains (numbered CC1 to 3; see Fig. 2) and an N-terminal region preceding the kinase domain are responsible for intermolecular interactions leading to MRCK α multimerization [30]. An N-terminus-mediated dimerization and consequent autophosphorylation regulate MRCK α catalytic activity. The N-terminus-mediated dimerization and the autoregulatory kinase/distal coiled-coil (CC) interaction are two mutually exclusive events that tightly regulate the catalytic state of the kinase. Disruption of this interaction occur when cells are treated with phorbol ester, which can interact directly with a cysteine-rich domain next to the distal CC domain. Diacylglycerol production downstream of phospholipase C therefore causes MRCK activation, but localization of

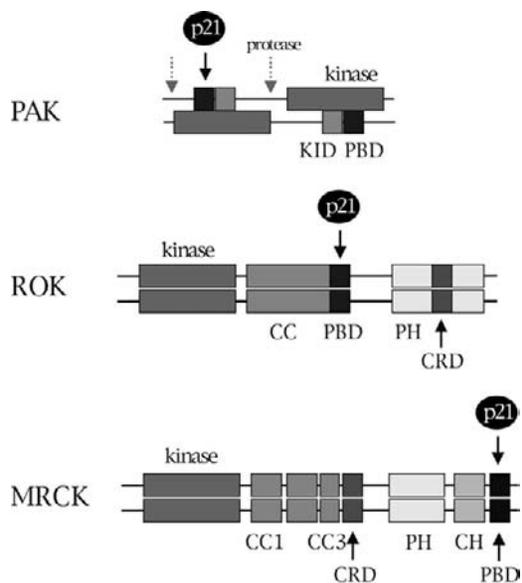

Figure 2 Structural features of Rho GTPase-regulated kinases PAK, MRCK, and ROK. These proteins have in common a p21-binding domain (PBD), which interacts with only the GTP-bound form of the p21, and a catalytic serine/threonine kinase domain. All three kinases exist as dimers in the cell (as illustrated). While PAK is autoinhibited in a head-to-tail fashion, ROK and MRCK are thought to be aligned in parallel. The kinase inhibitory domain (KID) of PAK is a conserved motif that makes numerous contacts with the catalytic domain in the crystal structure [18]. Structures are not available for the other two kinases, which are dimerized via their coiled-coil domains. Abbreviations: PH, pleckstrin homology; CRD, cysteine-rich domain; CC, coiled-coil; CH, citron homology.

MRCK is regulated by Cdc42 GTP [30]. The regulation of MRCK probably involves kinase phosphorylation in the activation loop and a hydrophobic motif C-terminal to the kinase domain by autophosphorylation and/or phosphorylation by heterologous kinases.

Rho-Associated Kinase (ROK)

The serine/threonine kinases ROK (also described as Rho-kinase or ROCK) promote maintenance of the phosphorylated state of myosin light chain (P-MLC) by blocking the action of the key phosphatase in the cycle [31]. ROK and MRCK target a single inhibitory threonine phosphorylation site on the p85 [26] or p130 [25] myosin-binding subunit (MBS) of protein phosphatase 1 δ . This MBS phosphorylation activates a domain that directly blocks the activity of the phosphatase. Such activity occurs in the context of other Rho effectors—for example, the mammalian Diaphanous (mDia), a formin that can generate F-actin in combination with the action of ROK [32]. Cofilin, which promotes F-actin disassembly, is negatively regulated by LIM kinases and, therefore, by ROK (Fig. 1).

Rho-associated kinase contains an N-terminal serine/threonine kinase domain that is flanked by an extended coiled-coil region and other C-terminal domains such as GTPase binding, pleckstrin homology (PH), and cysteine-rich zinc finger domains (Fig. 2). In ROK, the C terminus contains an unconventional PH domain with an inserted cysteine-rich motif [33]. Besides the formation of stress fibers and focal adhesions, ROK has also been implicated in other Rho-mediated cellular functions, such as the regulation of intermediate filament assembly [34,40], neurite remodeling [35], cytokinesis [36], and transcriptional regulation [37].

An autoinhibitory region for ROK, including the PH domain, has been mapped to the C terminus. Binding of the GTP-bound form of Rho is known to activate ROK; the interaction is believed to disrupt the negative regulatory interaction between the kinase domain and the C-terminal autoinhibitory region to give rise to an active kinase. The compound Y-27632 is widely used as a specific inhibitor of the ROK (ROCK) family of protein kinases. Y-27632 and related Y-30141 compounds inhibit the kinase activity by competing with adenosine triphosphate (ATP) [38]. Their affinities for ROK kinases as determined by K_i values are 20 to 30 times higher than those for two other Rho-binding kinases, citron kinase and protein kinase PKN. Y-27632 abolishes stress fibers in Swiss 3T3 cells at 10 μ M, but the G₁-to-S phase transition of the cell cycle and cytokinesis are not affected at this concentration. Activation of RhoA leads to phosphorylation of ERMs (ezrin/radixin/moesin) on a conserved regulatory threonine residue [39]. Activated Cdc42 also drives such phosphorylation of ERMs, but at the tips of filopodia via MRCK[40]. Although ROK has been implicated in this process [41,42], other *in vivo* experiments have shown that phosphorylation of ERMs is not suppressed

by the ROK inhibitor Y-27632; rather, overexpression of the lipid kinase effector PIPK α is capable of increasing levels of phosphorylated ERM and concomitant formation of microvilli [43].

Introduction

The finding that Src homology domain 2 (SH2) and phosphotyrosine binding (PTB) domains could bind to Tyr-phosphorylated motifs on proteins, but not to Ser- or Thr-phosphorylated sequences, suggested that modular domain-mediated regulation of protein-protein complexes might be a feature unique to tyrosine kinase signaling cascades. However, the subsequent discovery of a diverse group of molecules and domains that specifically recognize phosphorylated serine- and threonine-based motifs has dispelled this idea and is leading to a more general appreciation of the role of protein phosphorylation in regulating the reversible assembly of multiprotein complexes [1].

14-3-3 Proteins

The first phosphoserine/threonine-binding molecules that were identified were members of a family of dimeric proteins called 14-3-3 that were first identified as abundant polypeptides of unknown function in brain [2]; they were later identified as activators of tryptophan and tyrosine hydroxylase [3,4] and as inhibitors or activators of PKCs [5]. Mammalian cells contain 7 distinct 14-3-3 gene products (denoted β , γ , ϵ , η , σ , τ , and ζ), while plants and fungi

contain between 2 and 15. Several of the mammalian 14-3-3 isotypes are subject to phosphorylation, although the role that phosphorylation plays in 14-3-3 function remains speculative.

The initial observation that 14-3-3-binding might be regulated by ligand phosphorylation emerged from studies of tryptophan hydroxylase [6] and Raf, the upstream activator of the classical mitogen-activated protein (MAP) kinase pathway [7]. Detailed investigation of the 14-3-3 binding sites on Raf [8], together with oriented peptide library screening on all mammalian 14-3-3s [9] led to the identification of two optimal pSer/threonine-containing motifs, RSXpSXP and RXXXpSXP, that are recognized by all 14-3-3 isotypes (pS denotes both pSer and pThr, and X denotes any amino acid, although there are preferences for particular amino acids in different X positions). Over 100 14-3-3 binding proteins have been identified to date, and many, though not all, use phosphorylated sequences that closely match the optimal 14-3-3 consensus motifs for binding.

Comprehensive referenced and tabulated lists of 14-3-3-binding proteins are available within detailed reviews [10,11]. In many cases, the mechanistic role of 14-3-3-binding is not known, though for a smaller subset of ligands detailed studies are beginning to uncover general mechanisms through which 14-3-3 may regulate their function. For some ligands, 14-3-3 proteins can directly regulate their

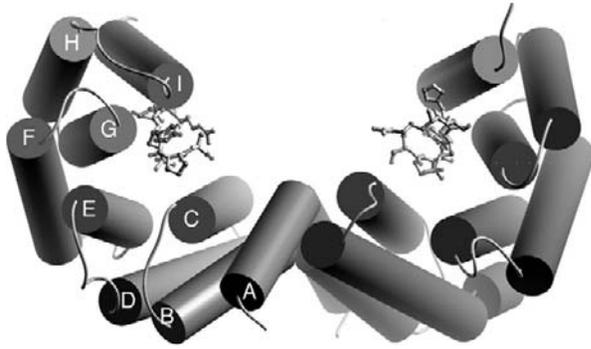

Figure 1 14-3-3/phosphopeptide interactions. Dimerization of two 14-3-3 monomers, each of which is composed of nine α -helices, forms a cleft within which phosphoserine-containing ligands bind (shown in ball-and-stick representation). A single, multiply phosphorylated protein ligand may bind simultaneously to both available sites. Alternatively, two singly phosphorylated proteins can bind, one to each monomer, allowing 14-3-3 to act as a molecular scaffold for the assembly of diverse signaling complexes [9,24]. Reprinted from Yaffe and Smerdon [75], with permission.

catalytic activity, as observed, for example, with Raf, exoenzyme S, and serotonin *N*-acetyltransferase [12–14]. For others, 14-3-3 appears to regulate interactions between its bound protein and other molecules within the cell. For example, growth-factor-mediated phosphorylation of the pro-apoptotic Bcl-2 family protein BAD at Ser-136 and/or Ser-112 facilitates its interaction with 14-3-3 proteins and blocks its association with anti-apoptotic Bcl-2 family members at the mitochondrial membrane [15–17]. Finally, in a number of cases, 14-3-3 proteins appear to play an important role in controlling the subcellular localization of bound ligands such as Cdc25 and Forkhead family transcription factors [18–21].

The X-ray structures of 14-3-3 τ and ζ revealed that the molecule is a cup-shaped dimer [22,23] in which each monomeric subunit consists of nine α -helices (Fig. 1). The dimer interface is formed from helices α A, α C, and α D, creating a 35-Å \times 35-Å \times 20-Å central channel where binding to peptide and protein ligands occurs. Ligand-bound 14-3-3 structures have shown that peptides bind within an amphipathic groove along each edge of the central channel [9,24,25] with the entire phosphopeptide main chain in a highly extended conformation until two residues after the pSer, when there is a sudden sharp change in peptide chain direction required to exit the 14-3-3 binding cleft. More recently, the structure of 14-3-3 ζ bound to a *bona fide* protein ligand, serotonin *N*-acetyltransferase, has been solved [26]. In this structure, the 14-3-3 binding portion of the enzyme displays a conformation very similar to that seen in isolated phosphopeptide:14-3-3 complexes, including the extended conformation and sudden alteration in chain direction. Furthermore, 14-3-3-binding at least partially restructures the substrate binding site on serotonin *N*-acetyltransferase, rationalizing some of the 14-3-3 effects on enzyme activity. Additional X-ray structures of 14-3-3-bound complexes are required before a detailed mechanistic understanding of 14-3-3 function emerges.

FHA Domains

Forkhead-associated (FHA) domains are a recently recognized pThr-binding module found in several prokaryotic and eukaryotic proteins including kinases, phosphatases, transcription factors, kinesin-like motors, and regulators of small G proteins. FHA domains are \approx 140 amino acids in length and extend significantly beyond the core homology region first identified by sequence profiling [27–33].

Recognition that FHA domains were pThr-binding modules came from findings that the FHA domain of KAPP, a protein phosphatase in *Arabidopsis*, was critical for its interaction with phosphorylated receptor-like kinases [28,34] and that the FHA domains within the *Saccharomyces cerevisiae* cell-cycle checkpoint kinase Rad53p were essential for interaction with the phosphorylated DNA damage control protein Rad9p [35,36]. Durocher *et al.* [36] were the first to demonstrate that FHA domains could bind directly to short pThr-containing peptides in isolation. Data regarding the specificity of different FHA domains for pThr-based sequence motifs comes from peptide library experiments that show sequence-specific binding involving amino acids from the pT–3 to the pT + 3 position [32,37]. Curiously, substitution of pSer (pS) for pThr (pT) completely eliminates phosphopeptide binding, presumably due to a structurally conserved van der Waals interactions with the threonine γ -methyl group or to entropic constraints that are unique to phosphothreonine. Tsai and co-workers found that the C-terminal FHA domain of Rad53 binds to pTyr-containing peptides *in vitro* [29,31] although the *in vivo* relevance of pTyr-dependent signaling mechanisms in budding yeast is not yet clear.

The *in vivo* binding partners for most FHA domain proteins are unknown, though a number of studies and clinical observations involving naturally occurring or engineered mutations or deletions within the FHA domains of key signaling molecules have verified their functional importance. Mutations that impair the ability of the N-terminal FHA domain of the yeast checkpoint kinase Rad53p to bind to phosphopeptides also result in increased sensitivity to DNA damage, whereas mutations within the FHA domain of Chk2, the human homolog of Rad53p, have been implicated in a variant form of the human cancer-prone Li-Fraumeni syndrome [38]. In addition, other mutations in FHA-domain-containing proteins including p95/Nbs1 and Chfr also appear to contribute to human tumor formation [38–41]. Chfr appears to function as a subunit of an E3 ubiquitin ligase, targeting Polo kinase for degradation to establish a cell-cycle checkpoint [42], although the role of the FHA domain in this process is not yet known.

Structures of both FHA domains from Rad53p [29,31,32], together with FHA domains from Chk2 [43] and Chfr [44], have been determined by nuclear magnetic resonance (NMR) spectroscopy or X-ray crystallography (Fig. 2). The FHA domain consists of an 11-stranded β -sandwich, with a topology essentially identical to that of the MH2 domain from Smad tumor suppressor molecules [29,32].

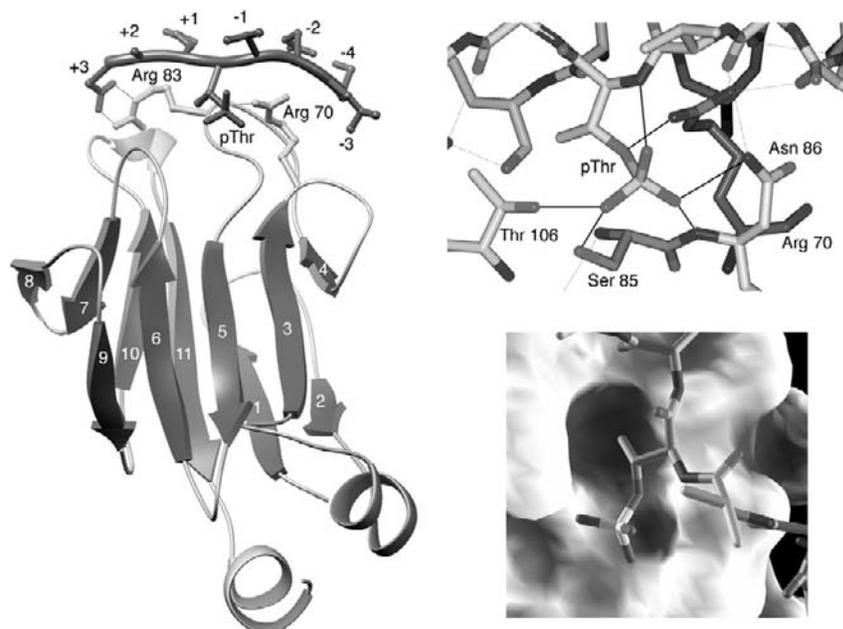

Figure 2 FHA/phosphopeptide interactions. The FHA domain architecture as exemplified by the X-ray structure of Rad53p FHA1 in complex with a Rad9p phosphopeptide (left panel [32]). The peptide binds at one end of the β -sandwich domain in an extended conformation. The highly conserved arginine (Arg70) makes a crucial contact with the phosphate group, while a non-conserved arginine (Arg83) acts to select an Asp at the pT + 3 position (right panel, top). The phosphate group interacts with a constellation of conserved and semi-conserved FHA domain side chains (top panel), while the γ -methyl group of the phosphothreonine binds in a pocket on the domain surface (right panel, bottom), likely explaining the observed preference for pThr over pSer in peptide-selection experiments. Reprinted from Yaffe and Smerdon [75], with permission.

This structural relationship, together with the remarkable similarities in phospho-dependent binding interactions of FHA and MH2 domains, suggests the existence of a superfamily of FHA-like phospho-binding domains [43,45,46]. In all pThr peptide complexes, binding occurs at one end of the domain, through interactions between selected residues in the phosphopeptide and loops connecting the β 3/4, β 4/5, and β 6/7 β -strands. Of the seven most highly conserved residues in the FHA family, three make direct interactions with the peptide (two bind directly to the pThr residue), while the remainder form the structural core or stabilize loop regions of the β -sandwich structure. Interestingly, the Chfr FHA domain structure shows a segment-swapped dimer with the C-terminal half of β 7 and β 8–10 exchanged between monomers. Whether or not these dimers exist *in vivo* or contribute to Chfr function is not known.

WW Domains

WW domains contain ~40 amino acids with two invariant tryptophan residues (labeled W in single-letter amino acid code, hence the name *WW domain*) that bind to short proline-rich sequences containing PPXY, PPLP, or PPR motifs [47]. A small subclass of WW domains within the proline isomerases Pin1/Ess1 and their homologs, the splicing factor Prp40 and the ubiquitin ligase Rsp5, show specific binding to phosphoserine-proline motifs within mitotic

phosphoproteins [48] and the phosphorylated C-terminal domain (CTD) of RNA polymerase II [49–51].

Phospho-specific WW domain function is best understood for the proline isomerase Pin1, a protein that slows progress through mitosis [52] but is also required for mitotic exit [53] and for the DNA replication checkpoint [53]. In addition to its WW domain, Pin1 contains a proline isomerase (rotamase) domain at its C terminus that catalyzes the specific *cis-trans* isomerization of pSer/Thr–Pro bonds [54,55]. Both the WW-domain-mediated pS–P binding and the rotamase-catalyzed pS–P isomerization are necessary for Pin1 biological activity [53,56]. In addition, Pin1 also enhances the dephosphorylation of substrates by protein phosphatases, all of which requires the pSer–Pro bond to be in *trans*. Because the WW domain can only bind to the *trans* geometric isomer, its major role may be to stabilize the *trans*-isomerase product for dephosphorylation [57,58]. WW-domain-facilitated substrate dephosphorylation is likely to be a general mechanism for WW domain function in both cell-cycle progression and regulation of transcriptional elongation.

WW domains fold into three anti-parallel β -strands, forming a single groove that recognizes proline-rich ligands in the context of a type II polyproline helix (Fig. 3). Specificity for different proline-rich motifs is determined largely by residues within the loop regions that connect the β 1/ β 2 and β 2/ β 3 strands, somewhat akin to the mechanism of ligand binding utilized by FHA domains. The structure of the Pin1 WW domain in complex with a *YpSPTpSPS*

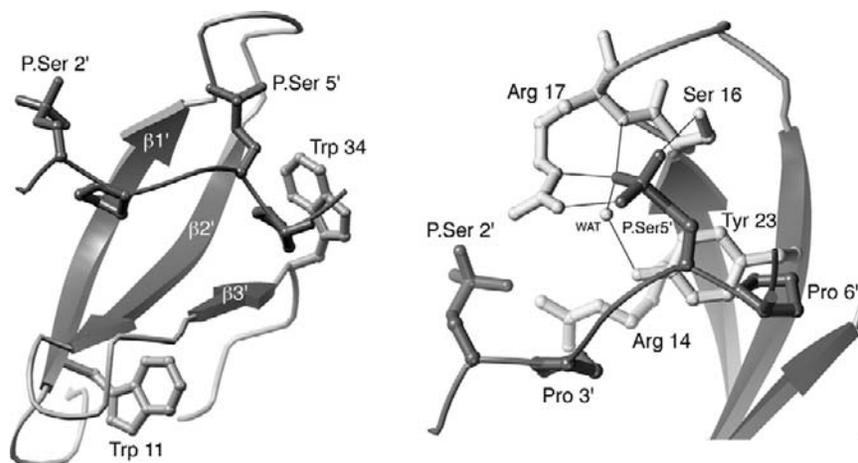

Figure 3 WW/phosphopeptide interactions. WW domains are named after two conserved Trp residues that form the structural core of the three-stranded domain (left panel). The pSer-Pro containing phosphopeptide (purple) derived from RNA polymerase II binds in an extended conformation across the β -sheet (right panel [59]). The oxygen atoms from only one of the two phosphates binds to residues located on the $\beta 1$ – $\beta 2$ loop. Reprinted from Yaffe and Smerdon [75], with permission.

peptide from the CTD of RNA polymerase II [59] revealed that all of the phosphate contacts were made between the second pSer and two residues of the peptide in the $\beta 1/\beta 2$ loop (Ser-16 and Arg-17) along with one in the $\beta 2$ strand (Tyr-23). These findings explain why only a few WW domains are competent to bind phosphorylated sequence motifs, as the majority of WW domains lack an Arg residue within loop 1 [59].

Leucine-Rich Repeats and WD40 Domains

In addition to 14-3-3 proteins, FHA domains, and WW domains, several other modular signaling domains have been shown to bind to their substrates following serine/threonine phosphorylation, most notably leucine-rich regions, and WD40 repeats. These phosphospecific-binding modules are key participants in phosphorylation-dependent ubiquitin conjugation reactions catalyzed by Skp1-Cdc53-F-box protein (SCF) protein complexes that target the ubiquitinated substrates for proteasome-mediated degradation [60–64].

The SCF complexes are E3 ubiquitin ligases that consist of Skp1, Cul1/Cdc53, Roc1, and an F-box-containing protein that confers substrate specificity in a phosphospecific manner [60–64]. The leucine-rich repeats or WD40 domain within the F-box-containing protein appears to directly mediate phosphospecific binding. The yeast F-box protein Cdc4 binds to the phosphorylated form of the yeast Cdk inhibitors Sic1 [62,65,66] and Far1 [66,67], while the mammalian F-box protein Skp2 binds to the phosphorylated form of the Cdk inhibitor p27 [68,69]. In both yeast and mammalian cells, these interactions promote the ubiquitin-mediated destruction of the inhibitor, leading to activation of G_1 cyclin–Cdk complexes. Later in mitosis, an alternative set of F-box proteins is involved in the opposing process of

inactivating the cyclin–Cdk complexes through ubiquitin-mediated proteolysis of the cyclin subunit [60–64,70]. Thus, temporally regulated substrate phosphorylation coupled with combinatorial interchange of different F-box proteins with the core SCF complex can result in waves of proteolysis that drive the cell cycle [70]. Similarly, phosphorylation-dependent recognition of I κ B α and β -catenin by the WD40 repeat of the F-box protein β -TrCP targets these substrates for ubiquitin-mediated proteolysis to alter patterns of gene expression [71,72].

The WD40 repeat of Cdc4 is sufficient to bind tightly to a singly threonine-phosphorylated peptide from Cyclin E1 containing the consensus motif L/I-L/I/P-pT-P-X where X denotes all amino acids except R and K [66]. However, Sic1, the physiological substrate of Cdc4, does not contain a perfect match to the consensus motif and relies instead on the phosphorylation of multiple suboptimal motifs to provide cooperative binding. Thus, by using a series of weak distributed phospho-dependent motifs to bind Sic1, Cdc4 ensures that a threshold of phosphorylation must be overcome prior to the initiation of DNA replication [66].

Leucine-rich repeats adopt a C-shaped structure built of single α -helix/ β -strand repeats [73], while WD40 repeats form β -propeller structures [74]. Currently, no structure of either domain has been found to bind to a phosphopeptide, although site-directed mutagenesis experiments have identified several Arg residues within the propeller blades of Cdc4 likely to be involved in ligand recognition [66].

Concluding Remarks

The identification of several families of pSer/Thr-binding modules has provided fascinating insights into how cellular signaling events are regulated by protein–protein interactions

mediated by Ser/Thr phosphorylation. The structural diversity of these domains suggests that, in general, their phospho-binding functions have evolved through convergent evolution. Importantly, the phosphorylated motifs recognized by different phosphoserine/threonine binding modules differ somewhat from the optimal phosphorylated motifs generated by various protein kinase families which provides specificity in assembly of signaling complexes by requiring a unique overlap motif between the activating kinase and the binding domain and also allows abrupt on-and-off activation states to be created through cooperative binding between multiple weak motifs.

Acknowledgments

We are grateful to Thanos Halazonetis for communicating results prior to publication, and to Lewis C. Cantley and Tony Pawson for helpful discussions. Introduction

Stimulation of cells with growth factors, survival factors, and hormones leads to recruitment to the plasma membrane of a family of lipid kinases known as class 1 phosphoinositide 3-kinases (PI 3-kinases, [1]). In this location PI 3-kinases phosphorylate the glycerophospholipid phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P₂), at the D-3 position of the inositol ring, converting it to PtdIns(3,4,5)P₃, which is then converted to PtdIns(3,4)P₂ through the action of the SH2-containing inositol phosphatases (SHIP1 and SHIP2) or back to PtdIns(4,5)P₂ via the action of the lipid phosphatase PTEN (phosphatase and tensin homolog deleted on chromosome 10).

PtdIns(3,4,5)P₃ and perhaps PtdIns(3,4)P₂ play key roles in regulating many physiological processes, including controlling cell apoptosis and proliferation, most of the known physiological responses to insulin, and cell differentiation and cytoskeletal organization [2]. PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ exert their cellular effects by interacting with proteins that possess a certain type of pleckstrin homology domain (PH domain). A number of types of PH domain containing proteins that interact with PtdIns(3,4,5)P₃ and/or PtdIns(3,4)P₂ have now been identified. These include the serine/threonine protein kinases protein kinase B (PKB; also known as Akt) [3], tyrosine kinases of the Tec family [4,5], numerous adaptor molecules such as the Grb2-associated protein (GAB1 [6]), the dual adaptor of phosphotyrosine and 3-phosphoinositides (DAPP1 [7–10]), and the tandem PH-domain-containing proteins (TAPP1 and TAPP2 [11]), as well as guanosine triphosphate (GTP)/guanosine diphosphate

(GDP) exchange [12–14] and GTPase-activating proteins [15,16] for the ARF/Rho/Rac family of GTP binding proteins (Fig 1). This chapter focuses on research aimed at understanding the mechanism by which PtdIns(3,4,5)P₃ regulates one branch of its downstream signaling pathways, namely enabling PDK1 to phosphorylate and activate a group of serine/threonine protein kinases that belong to the AGC subfamily of protein kinases. These include isoforms of PKB [3,17], p70 ribosomal S6 kinase (S6K) [18,19], serum- and glucocorticoid-induced protein kinase (SGK) [20], p90 ribosomal S6 kinase (RSK) [21], and protein kinase C (PKC) isoforms [22]. Once these diverse AGC kinase members are activated, they phosphorylate and change the activity and function of key regulatory proteins that control processes such as cell proliferation and survival as well as cellular responses to insulin [2,3,23].

Mechanism of Activation of PKB

The three isoforms of PKB (PKB α , PKB β , and PKB γ) possess high sequence identity and are widely expressed in human tissues [17]. Stimulation of cells with agonists that activate PI 3-kinase induce a large activation of PKB isoforms within a few minutes. The activation of PKB is downstream of PI 3-kinase, as inhibitors of PI 3-kinase such as wortmannin or LY294002, or the over-expression of a dominant-negative regulatory subunit of PI 3-kinase inhibit the activation of PKB in cells by virtually all agonists tested [24–26]. Over-expression of a constitutively active mutant of PI 3-kinase induces PKB activation in unstimulated cells [27],

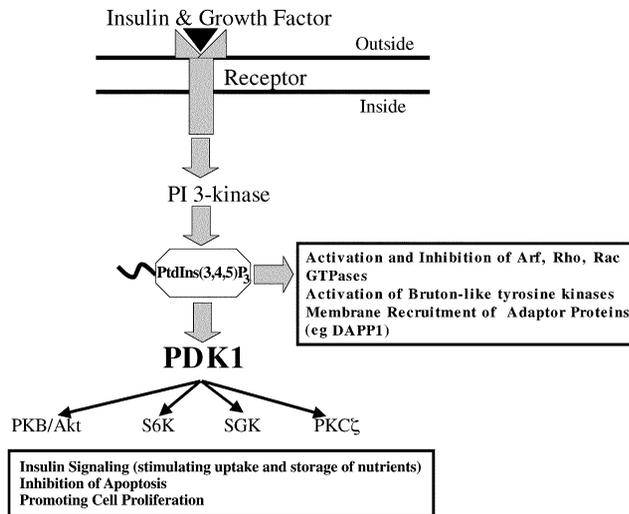

Figure 1 Overview of the PI 3-kinase signaling pathway. Insulin and growth factors induce the activation of PI 3-kinase and generation of PtdIns(3,4,5)P₃. In addition to leading to the activation of PKB/Akt, S6K, SGK, and atypical PKC isoforms such as PKC ζ , PtdIns(3,4,5)P₃ also recruits a number of other proteins (outlined in the text) to the plasma membrane to trigger the activation of non-PDK1/AGC-kinase-dependent signaling pathways. Key challenges for future experiments are not only to define the specific cellular roles of the individual AGC kinase but also to understand the function and importance of other branches of signaling pathways activated by PI 3-kinase.

as does deletion of the PTEN phosphatase which also results in increased cellular levels of PtdIns(3,4,5)P₃ [28–32].

All PKB isoforms possess an N-terminal pleckstrin homology (PH domain) that interacts with PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ followed by a kinase catalytic domain and then a C-terminal tail. Stimulation of cells with agonists that activate PI 3-kinase induces the translocation of PKB to the plasma membrane, where PtdIns(3,4,5)P₃ as well as PtdIns(3,4)P₂ are located and, consistent with this, translocation of PKB is prevented by inhibitors of PI 3-kinase or by the deletion of the PH domain of PKB [33–35]. These findings strongly indicate that PKB interacts with PtdIns(3,4,5)P₃ and/or PtdIns(3,4)P₂ *in vivo*. The binding of PKB to PtdIns(3,4,5)P₃ or PtdIns(3,4)P₂ does not activate the enzyme but instead recruits PKB to the plasma membrane where it becomes phosphorylated at two residues at this location, namely Thr308 and Ser473. Inhibitors of PI 3-kinase and dominant-negative PI 3-kinase prevent phosphorylation of PKB at both residues following stimulation of cells with insulin and growth factors [17]. Thr308 is located in the T-loop (also known as *activation loop*) between subdomains VII and VIII of the kinase catalytic domain, situated at the same position as the activating phosphorylation sites found in many other protein kinases. As discussed later, Ser473 is located outside of the catalytic domain in a motif that is present in most AGC kinases and which has been termed the *hydrophobic motif*. The phosphorylation of PKB α at both Thr308 or Ser473 is likely to be required to activate PKB α maximally, as mutation of Thr308 to Ala abolishes PKB α activation, whereas mutation of Ser473 to Ala reduces the

activation of PKB α by approximately 85%. The mutation of both Thr308 and Ser473 to Asp (to mimic the effect of phosphorylation by introducing a negative charge) increases PKB α activity substantially in unstimulated cells, and this mutant cannot be further activated by insulin [3]. Attachment of a membrane-targeting domain to PKB α results in it becoming highly active in unstimulated cells and induces a maximal phosphorylation of Thr308 and Ser473 [33,36]. These observations indicate that recruitment of PKB to the membrane of unstimulated cells is sufficient to induce the phosphorylation of PKB α at Thr308 and Ser473. Furthermore, there must be sufficient basal levels of PtdIns(3,4,5)P₃/PtdIns(3,4)P₂, T308 kinase, and Ser473 kinase located at the membrane to stimulate phosphorylation and activation of membrane-targeted PKB. PKB β and PKB γ are activated by phosphorylation of the equivalent residues in their T-loops and hydrophobic motifs [37,38].

PKB Is Activated by PDK1

A protein kinase was purified [39,40] and subsequently cloned [41,42] that phosphorylated PKB α at Thr308 only in the presence of lipid vesicles containing PtdIns(3,4,5)P₃ or PtdIns(3,4)P₂. Because of these properties it was named 3-phosphoinositide-dependent protein kinase 1 (PDK1) and is composed of an N-terminal catalytic domain and a C-terminal PH domain which, like that of PKB, interacts with PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ [42,43]. The activation of PKB by PDK1 is stereospecific for the physiological D-enantiomers of these lipids, and neither PtdIns(4,5)P₂ nor any inositol phospholipid other than PtdIns(3,4)P₂ can replace PtdIns(3,4,5)P₃ in the PDK1-catalyzed activation of PKB [39,42].

Although co-localization of PKB and PDK1 at the plasma membrane through their mutual interaction with 3-phosphoinositides is likely to be important for PDK1 to phosphorylate PKB, the binding of PKB to PtdIns(3,4,5)P₃ or PtdIns(3,4)P₂ is also postulated to induce a conformational change in PKB, exposing Thr308 for phosphorylation by PDK1. This conclusion is supported by the observation that in the absence of 3-phosphoinositides, PDK1 is unable to phosphorylate wild-type PKB under conditions where it is able to efficiently phosphorylate a mutant form of PKB that lacks its PH domain, termed Δ PH-PKB [40,41]. Consistent with this, a PKB mutant in which a conserved Arg residue in the PH domain is mutated to abolish the ability of PKB to bind PtdIns(3,4,5)P₃ cannot be phosphorylated by PDK1 in the presence of lipid vesicles containing PtdIns(3,4,5)P₃ [40]. Moreover, artificially promoting the interaction of PDK1 with wild-type PKB and Δ PH-PKB by the attachment of a high-affinity PDK1 interaction motif to these enzymes is sufficient to induce maximal phosphorylation of Thr308 in Δ PH-PKB but not in wild-type PKB in unstimulated cells [44].

More recently, the three-dimensional structure of the isolated PH domain of PKB complexed with the head group of

PtdIns(3,4,5)P₃ has been solved [45]. Interestingly, the structure of the PH domain of PKB complexed to the inositol head group of PtdIns(3,4,5)P₃ revealed that the 3- and the 4-phosphate groups form numerous interactions with specific basic amino acids in the PKB PH domain, but in contrast the 5-phosphate group does not make any significant interaction with the protein backbone and is solvent exposed, thus providing the first structural explanation of why PKB interacts with both PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ with similar affinity [45].

The interaction of PDK1 with PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ is thought to be the primary determinant in enabling PDK1 and PKB to colocalize at membranes and permitting PDK1 to phosphorylate PKB efficiently. These conclusions are supported by the finding that the rate of activation of PKB α by PDK1 *in vitro*, in the presence of lipid vesicles containing PtdIns(3,4,5)P₃, is lowered considerably if the PH domain of PDK1 is deleted. Furthermore, the mutant of PKB that lacks its PH domain is also a very poor substrate for PDK1, compared to wild-type PKB, as it is unable to interact with lipid vesicles containing PtdIns(3,4,5)P₃.

Activation of Other Kinases by PDK1

The finding that the T-loop residues of PKB are very similar to those found on other AGC kinases suggested that PDK1 might phosphorylate and activate these members [46,47]. An alignment of the T-loop sequences of insulin and growth-factor-stimulated AGC kinases is shown in Fig. 2. It was found that the AGC kinases activated downstream of PI 3-kinase (namely, S6K1 [48,49], SGK isoforms [50–52], and atypical PKC isoforms [53,54]) were phosphorylated specifically at their T-loop residue by PDK1 *in vitro* or following the over-expression of PDK1 in cells. Moreover, AGC kinases that were not activated in a PI 3-kinase-dependent manner in cells—such as the p90 ribosomal S6K (p90RSK)

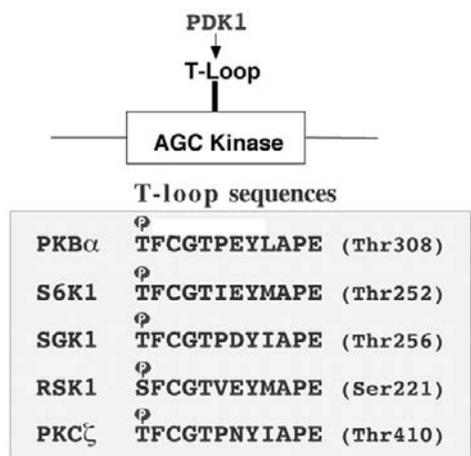

Figure 2 Alignment of the amino acid sequences surrounding the T-loop of insulin and growth-factor-stimulated AGC kinases.

isoforms [55,56], conventional and related PKC isoforms [57–60], PKA [61], and the non-AGC Ste20 family member PAK1 [62]—were also proposed to be physiological substrates for PDK1, as they could all be phosphorylated by PDK1 at their T-loop residue *in vitro* or following over-expression of PDK1 in cells.

Genetic evidence for the central role that PDK1 plays in mediating the activation of these AGC kinases was obtained from the finding that in PDK1^{-/-} ES cells, isoforms of PKB, S6K, and RSK could not be activated by agonists that switch on these enzymes in wild-type cells [63]. In ES cells lacking PDK1, the intracellular levels of endogenously expressed PKC α , PKC β I, PKC γ , PKC δ , PKC ϵ , and PRK1 are also vastly reduced compared to wild-type ES cells [64], consistent with the notion that PDK1 phosphorylation of these enzymes plays an essential role in post-translational stabilization of these kinases [65,66]. The levels of PKC ζ were only moderately reduced in the PDK1^{-/-} ES cells and PKC ζ in these cells is not phosphorylated at its T-loop residue [64], providing genetic evidence that PKC ζ is a physiological substrate for PDK1. In contrast, PKA was active and phosphorylated at its T-loop in PDK1^{-/-} ES cells, to the same extent as in wild-type ES cells [63], thus arguing that PDK1 is not rate limiting for the phosphorylation of PKA in ES cells. It is possible that PKA phosphorylates itself at its T-loop residue *in vivo*, as it has been shown to possess the intrinsic ability to phosphorylate its own T-loop when expressed in bacteria. Thus far, we have no genetic data in PDK1-deficient cells as to whether or not PAK1 is active, but it should be noted that PAK1 can also phosphorylate itself at its T-loop in the presence of Cdc42-GTP or Rac-GTP, stimulating its own activation in the absence of PDK1 [67].

Phenotype of PDK1 PKB- and S6K-Deficient Mice and Model Organisms

PDK1^{-/-} mouse embryos die at day E9.5, displaying multiple abnormalities that include a lack of somites, forebrain, and neural-crest-derived tissues, although the development of the hind- and midbrain proceeds relatively normally [68]. Other eukaryotic organisms also possess homologs of PDK1 that activate homologs of PKB and S6K in these species [69]. As in mice, knocking out PDK1 homologs in yeast [70–72], *Caenorhabditis elegans* [73], and *Drosophila* [74,75] results in nonviable organisms, confirming that PDK1 plays a key role in regulating normal development and survival of these organisms. Elegant genetic analysis of the PI 3-kinase/PDK1/AGC kinase pathway in *Drosophila* has demonstrated that this pathway plays a key role in regulating both cell size and number [76,77]. For example, the over-expression of dPI 3-kinase [78,79] or inactivation of the PtdIns(3,4,5)P₃ 3-phosphatase dPTEN [80–82] results in an increase in both the cell number as well as the cell size of *Drosophila*. Moreover, loss-of-function mutants of Chico, the fly homolog of insulin receptor substrate adaptor protein [83], dPI 3-kinase, or over-expression

of dPTEN results in a decrease in cell size and number. More recently, a partial loss-of-function mutation in dPDK1 was shown to cause a 15% reduction in fly body weight and a 7% reduction in cell number [74]. Loss of function mutants of dS6K1 [84] or dPKB reduce *Drosophila* cell size without affecting cell number [82,85]. PKB and S6K have also been knocked out in mice, but these studies are complicated by the presence of two isoforms of S6K (S6K1 and S6K2) and three isoforms of PKB (PKB α , PKB β , and PKB γ) encoded for by distinct genes, in contrast to *Drosophila*, which have one isoform of these enzymes. Mice lacking S6K1 were viable, but adult mice were 15% smaller and possessed 10 to 20% reduced organ masses [86]. It was subsequently shown that S6K1 knockout mice possessed a reduced pancreatic islet β -cell size but the size of other cells types investigated was apparently unaffected [87]. Mice lacking PKB α were also reported to be 20% smaller than wild-type animals, but it was not determined whether the lack of PKB α resulted in a reduction of cell size or cell number [88,89]. In contrast, deletion of PKB β caused insulin resistance without affecting mouse size [90].

PDK1 hypomorphic mutant mice that express only $\approx 10\%$ of the normal level of PDK1 in all tissues have been generated [68]. These mice are viable and fertile, and despite the reduced levels of PDK1, injection of these mice with insulin induces the normal activation of PKB, S6K, and RSK in insulin-responsive tissues. Nevertheless, these mice have a marked phenotype, being 40 to 50% smaller than control animals. The volumes of the kidney, pancreas, spleen, and adrenal gland of the PDK1 hypomorphic mice are reduced proportionately. Furthermore, the volume of adrenal gland zona fasciculata cells is 45% lower than control cells, whereas the total cell number and the volume of the nucleus remains unchanged. Cultured embryonic fibroblasts from the PDK1 hypomorphic mice are also 35% smaller than control cells but proliferate at the same rate. Embryonic endoderm cells completely lacking PDK1 from E7.5 embryos were 60% smaller than wild-type cells [68]. These results establish that, as in *Drosophila*, PDK1 plays a key role regulating cell size in mammals. However, the finding that AGC kinases tested are still activated normally in the PDK1 hypomorphic mice may suggest that PDK1 regulates cell size by a pathway that is independent of PKB, S6K, and RSK, although this hypothesis requires further investigation. In this regard, Tian *et al.* [91] have recently reported that PDK1 can interact via its noncatalytic N terminus with the PI 3-kinase-regulated Ral GTP exchange factor, leading to its activation. The Ral GTPase has not been implicated in regulating cell size, but it will be important to investigate whether activation of Ral GTPases is defective in PDK1 hypomorphic or knockout cell lines or mice tissues.

Hydrophobic Motif of AGC Kinases

All insulin and growth-factor-activated AGC kinases, in order to become maximally activated, require phosphorylation

of a residue located in a region of homology to the hydrophobic motif of PKB α that encompasses Ser473. This is located ≈ 160 amino acids C-terminal to the T-loop residue lying outside the catalytic regions of these enzymes. This hydrophobic motif is characterized by a conserved motif: Phe-Xaa-Xaa-Phe-Ser/Thr-Tyr/Phe (where Xaa is any amino acid and the Ser/Thr residue is equivalent to Ser473 of PKB). Atypical PKC isoforms (PKC ζ , PKC λ , PKC τ) and the related PKC isoforms (PRK1 and PRK2), instead of possessing a Ser/Thr residue in their hydrophobic motifs, have an acidic residue. PKA, in contrast, possesses only the Phe-Xaa-Xaa-Phe moiety of the hydrophobic motif, as the PKA amino acid sequence terminates at this position [92]. PDK1 is the only AGC kinase member that does not appear to possess an obvious hydrophobic motif [92], and the implications of this are discussed below. A major outstanding challenge is to characterize the mechanism by which PKB and other AGC kinases are phosphorylated at their hydrophobic motifs. In spite of considerable effort to discover the kinases responsible for the phosphorylation of AGC kinase members, no convincing evidence has thus far been obtained. The extensive literature and considerable controversy in this area have been extensively reviewed [93]. The only exception is for RSK and conventional PKC isoforms. For RSK, the phosphorylation of the C-terminal non-AGC kinase domain of this enzyme by ERK1/ERK2 triggers this domain to phosphorylate the N-terminal AGC kinase domain at its hydrophobic motif [21]. In the case of conventional PKC isoforms, there is good evidence that these enzymes can autophosphorylate themselves at their hydrophobic motifs following phosphorylation of their T-loops by PDK1 [22].

Mechanism of Regulation of PDK1 Activity

An important question is to determine the mechanism by which the ability of PDK1 activity to phosphorylate its AGC kinase substrates is regulated by extracellular agonists. When isolated from unstimulated or cells stimulated with insulin or growth factors, PDK1 possesses the same activity toward PKB or S6K1 [41,49,94]. Furthermore, although PDK1 is phosphorylated at 5 serine residues in 293 cells, insulin or insulin-like growth factor 1 (IGF1) did not induce any change in the phosphorylation state of PDK1 [95]. Only one of these phosphorylation sites (namely, Ser241) was essential for PDK1 activity. Ser241 is located in the T-loop of PDK1, and, because PDK1 expressed in bacteria is stoichiometrically phosphorylated at Ser241, it is likely that PDK1 can phosphorylate itself at this residue [95]. Although PDK1 becomes phosphorylated on tyrosine residues following stimulation of cells with peroxovanadate (a tyrosine phosphatase inhibitor) or over-expression with a Src-family tyrosine kinase [96–98], no tyrosine phosphorylation of PDK1 has been detected following stimulation of cells with insulin [95,96].

Taken together, these observations suggest that PDK1 might not be activated directly by insulin/growth factors.

Instead, one possibility that might explain how PDK1 could phosphorylate a number of AGC kinases in a regulated manner is that PDK1, instead of being activated by an agonist, is constitutively active in cells and that it is the substrates that are converted into forms that can interact with PDK1 and thus become phosphorylated at their T-loops. In the case of PKB as discussed above, it is the interaction of PKB with PtdIns(3,4,5)P₃ that converts it into a substrate for PDK1. In the case of other AGC kinases that are activated downstream of PI 3-kinase, such as S6K, SGK, and PKC isoforms, which do not possess a PH domain and thus do not interact with PtdIns(3,4,5)P₃ and whose phosphorylation by PDK1 *in vitro* is not enhanced by PtdIns(3,4,5)P₃, it is not obvious how PtdIns(3,4,5)P₃ can regulate the phosphorylation of these enzymes *in vivo*. Recent studies indicate that a conserved motif located C-terminal to the catalytic domains of isoforms of most AGC kinases (the hydrophobic motif of S6K1, or SGK1 [44]) and atypical (PKC ζ) and related PKC (PRK2) isoforms [57] can interact with a hydrophobic pocket in the kinase domain of PDK1 (the PIF pocket) [92]. Evidence indicates that this results in a docking interaction, which is required for the efficient T-loop phosphorylation of AGC kinases that do not interact with PtdIns(3,4,5)P₃/PtdIns(3,4)P₂. These experiments indicate that the interaction of S6K and SGK with PDK1 is significantly enhanced if these enzymes are phosphorylated at their hydrophobic motifs in a manner equivalent to that of the Ser473 phosphorylation site of PKB [44]. It is therefore possible that PtdIns(3,4,5)P₃ does not activate PDK1 but instead induces phosphorylation of S6K and SGK isoforms at their hydrophobic motifs, thereby converting these enzymes into forms that can interact with PDK1 and hence become activated. Consistent with this notion, the expression of mutant forms of S6K1 and SGK1 in which the hydrophobic motif phosphorylation site is altered to Glu to mimic phosphorylation is constitutively phosphorylated at their T-loop residues in unstimulated cells [50,99,100]. It is currently not clear how PtdIns(3,4,5)P₃ could stimulate the phosphorylation of the hydrophobic motif, but it is possible that it could either activate the hydrophobic motif kinases or inhibit the hydrophobic motif phosphatases.

Frodin *et al.* [101] demonstrated that phosphorylation of the hydrophobic motif of p90RSK (which is induced following phosphorylation of p90RSK by ERK1/ERK2 [21]) strongly promotes its interaction with PDK1, therefore enhancing the ability of PDK1 to phosphorylate p90RSK at its T-loop motif. Thus, the phosphorylation of p90RSK by ERK1/ERK2 converts RSK into a form that can interact with and be activated by PDK1. Thus, the mechanism by which PDK1 recognizes isoforms of RSK is analogous to that by which it recognizes SGK/S6K, the only difference being the mechanism regulating phosphorylation of the hydrophobic motifs of these enzymes. The model of how isoforms of PKB, S6K, SGK, and RSK are activated by PDK1 is summarized in Fig. 3.

Related PKC isoforms (PRK1 and PRK2) and atypical PKC isoforms (PKC ζ and PKC τ) possess a hydrophobic

motif in which the residue equivalent to Ser473 is Asp or Glu, and these enzymes can in principle interact with PDK1 as soon as they are expressed in a cell [57]. However, it is possible that the interaction of related PKC isoforms and atypical PKC isoforms with PDK1 could be regulated through the interaction of these enzymes with other molecules. For example, the interaction of PRK2 with Rho-GTP [60] or PKC ζ with hPar3 and hPar6 [102] might induce a conformational change in these enzymes that controls their interaction with PDK1.

PDK1 would be expected to activate PKB at the plasma membrane and its other non-3-phosphoinositide binding substrates in the cytosol. Consistent with this finding, PDK1 has been found to be localized in mainly the cytosol and plasma membrane of both stimulated and unstimulated cells [43,94]. It is controversial as to whether or not PDK1 translocates to the plasma membrane of cells in response to agonists that activate PI 3-kinase. Three reports [43,94,96] indicate that a small proportion of PDK1 is associated with the membrane of unstimulated cells, and they do not report any further translocation of PDK1 to membranes in response to agonists that activate PI 3-kinase and PKB. However, other groups have reported that PDK1 translocates to cellular membranes in response to agonists that activate PI 3-kinase [103,104]. Indeed, as mentioned earlier, there is evidence that at least some PDK1 is likely to be located at cell membranes of unstimulated cells as the expression of a membrane-targeted PKB construct in such cells is active and fully phosphorylated at Thr308 [33,36].

Structure of the PDK1 Catalytic Domain

Further insight into the mechanism by which PDK1 interacts with its AGC kinase substrates has been obtained recently from the high-resolution crystal structure of the human PDK1 catalytic domain. The structure defines the location of the PIF pocket on the small lobe of the catalytic domain—a marked hydrophobic pocket in the small lobe of the kinase domain [105] that corresponds to the region of the catalytic domain predicted from previous modeling and mutational analysis to form the PIF pocket [92]. Interestingly, mutation of several of the hydrophobic amino acids that make up the surface of this pocket abolish or significantly inhibit the ability of PDK1 to interact and activate S6K1 and SGK1 [44], indicating that this hydrophobic pocket does indeed represent the PIF pocket. As phosphorylation of the hydrophobic motif of S6K1 and SGK1 promotes the binding of S6K1 and SGK1 with PDK1, this suggests that a phosphate-interacting site is located near the PIF pocket. Interestingly, close to the PIF pocket in the PDK1 crystal structure, an ordered sulfate ion was interacting with four surrounding side chains (Lys76, Arg131, Thr148, and Gln150). Mutation of Lys76, Arg131, or Q150 to Ala reduces or abolishes the ability of PDK1 to interact with a phospho-peptide that encompasses the phosphorylated residues of the hydrophobic motif of S6K1, thereby

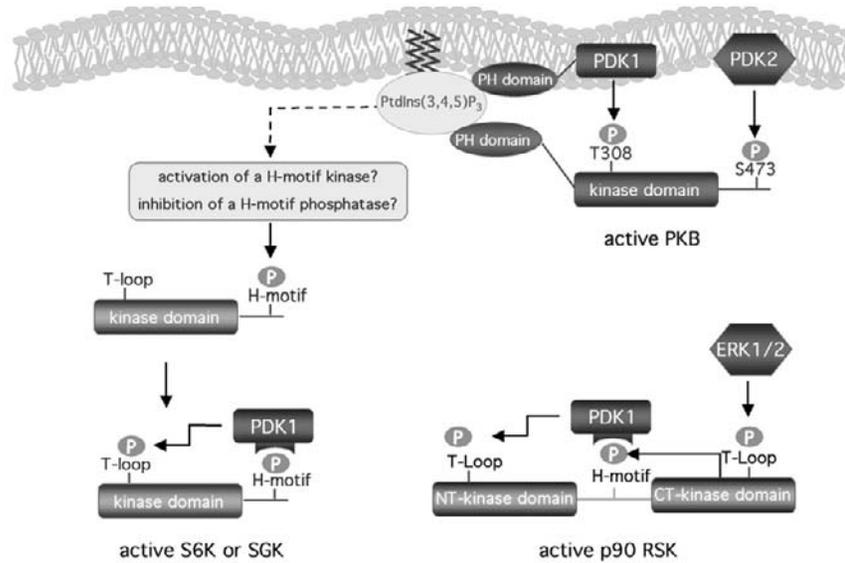

Figure 3 The mechanism by which phosphorylation of PKB, S6K, SGK, and RSK by PDK1 is regulated. It should be noted that in this model of how PKB, S6K, SGK, and RSK are phosphorylated at their T-loop, PDK1 activity is not directly activated by insulin or growth factors, consistent with the experimental observation that PDK1 is constitutively active in cells. Instead, it is the substrates of PDK1 that are converted into forms that can be phosphorylated. In the case of PKB, it is the interaction of PKB with $\text{PtdIns}(3,4,5)\text{P}_3$ at the plasma membrane that colocalizes PDK1 and PKB and also induces a conformational change in PKB that converts it into a substrate for PDK1. In the case of S6K and SGK, which do not possess PH domains and cannot interact with $\text{PtdIns}(3,4,5)\text{P}_3$, this is achieved by the phosphorylation of these enzymes at their hydrophobic motif (H-motif) by an unknown mechanism, which thereby generates a docking site for PDK1. RSK isoforms possess two catalytic domains: an N-terminal AGC-kinase-like kinase domain and a C-terminal non-AGC kinase domain. The activation of RSK isoforms is initiated by the phosphorylation of these enzymes by the ERK1/ERK2 classical MAP kinases, which phosphorylate the T-loop of the C-terminal kinase domain. This activates the C-terminal kinase domain, which then phosphorylates the hydrophobic motif of the N-terminal AGC kinase. This creates a binding site for PDK1 to interact with RSK isoforms, leading to the phosphorylation of the T-loop of the N-terminal kinase domain and activating it. Phosphorylation of all RSK substrates characterized thus far is mediated by the N-terminal kinase domain; however, it is possible that the C-terminal domain of this enzyme will phosphorylate distinct substrates that have not as yet been identified.

suggesting that this region of PDK1 does indeed represent a phosphate docking site [105]. The only other AGC kinase for which the structure is known (namely, PKA) also possesses a hydrophobic pocket at a region of the kinase catalytic domain equivalent to that of PKA which is occupied by the four C-terminal residues of PKA(FXXF) and resembles the first part of the hydrophobic motif phosphorylation site of S6K and SGK (FXXFS/TY) in which the Ser/Thr is the phosphorylated residue [92]. Occupancy of this pocket of PKA by the FXXF residues is likely to be essential to maintaining PKA in an active and stable conformation, as mutation of either Phe residue drastically reduces PKA activity toward a peptide substrate, as well as reducing PKA stability [106,107]. In contrast to the PIF-pocket in the PDK1 structure, PKA does not possess a phosphate docking site located next to the hydrophobic FXXF binding pocket. Sequence alignments of the catalytic domains of AGC kinases, including PDK1, indicate that all AGC kinases possess a PIF pocket, and kinases such as isoforms of RSK, PKB, S6K, and SGK possess a phosphate docking site next to this pocket. The role of these pockets of the AGC kinases

is probably to interact with their own hydrophobic motifs, and this interaction may account for the ability of these kinases to be activated following the phosphorylation of their hydrophobic motif. However, unlike other AGC kinases, PDK1 does not possess a hydrophobic motif C-terminal to its catalytic domain and therefore utilizes its empty PIF/phosphate binding pocket to latch onto its substrates that are phosphorylated at their hydrophobic motifs, thereby enabling PDK1 to phosphorylate these enzymes at their T-loop residue and activate them.

Concluding Remarks

Elucidation of the mechanism by which PKB was activated by PDK1 in cells provided the first example of how the second messenger $\text{PtdIns}(3,4,5)\text{P}_3$ could activate downstream signaling processes. However, there remain many major unsolved questions for future research to address. A major challenge will be to clarify the mechanism by which $\text{PtdIns}(3,4,5)\text{P}_3$ induces the phosphorylation of the

hydrophobic motif of PKB and other AGC kinases members, which is a key trigger for the activation of these enzymes. The results discussed in this chapter also provide a framework within which drugs could be developed to inhibit the PDK1/AGC kinase pathway to treat forms of cancers in which this pathway may be constitutively activated. Indeed, it is now estimated that PTEN is mutated in up to 30% of all human tumors, resulting in elevated PtdIns(3,4,5)P₃ levels and hence PKB and S6K activity which are likely to contribute to the proliferation and survival of these tumors [108]. It could be envisaged that a PDK1 inhibitor would be effective at reducing the PKB and S6K activities that contribute to growth and survival of these tumors.

Regulation of Cell Growth and Proliferation in Metazoans by mTOR and the p70 S6 Kinase

Joseph Avruch

Boston, Massachusetts*

Introduction

TOR, a ubiquitous 290-kDa polypeptide, is the founding member of the PI-3-kinase-related protein (Ser/Thr) kinase (PIKK) family. The TOR proteins were discovered by investigating the mechanism of action of the drug rapamycin, a natural product of a strain of *Streptomyces hygroscopicus* collected on Easter Island (Rapa Nui). The agent was initially investigated because of its substantial antifungal activity and subsequently was found to have potent immunosuppressant and antitumor activity. Rapamycin is structurally related to another potent macrolide immunosuppressant agent, FK506 [1]. These two agents in fact share the same cellular receptor, an abundant (□□) basic 12-kDa polypeptide named FK506 binding protein-12 (FKBP-12), one of a family of peptidylprolylisomerases. Despite their structural similarity, common receptor, and shared ability to inhibit prolyliso-merase activity, FK506 and rapamycin exhibit entirely distinct cellular actions. FK506 potently inhibits T-cell receptor (TCR) activation of interleukin-2 (IL-2) and other cytokine gene expression, in part by preventing the calcium-dependent dephosphorylation and nuclear entry of the transcription factor NFAT. Rapamycin, in contrast, has no effect on TCR signaling, but strongly inhibits T-cell proliferation by interrupting IL-2R signaling. In addition, the two agents are mutually antagonistic [2–3]. These features pointed to the likelihood that the active pharmacophore was the drug–FKBP complex rather than the drug itself, an idea first

verified for FK506 by the demonstration that FK506 in complex with FKBP-12, but neither component alone, binds directly and inhibits the protein phosphatase (2B), Calcineurin.

Progress on the molecular basis of rapamycin action was first achieved in *Saccharomyces cerevisiae*; elimination of both alleles encoding the *S. cerevisiae* homolog of FKBP-12, although having no effect on viability, rendered yeast completely resistant to growth inhibition by rapamycin. A genomic library prepared from *S. cerevisiae* selected for rapamycin resistance enabled the isolation of a gene that conferred a dominant form of rapamycin resistance; this gene encoded a mutant form of TOR2, one of two yeast TOR genes. The TOR2 mutation, Ser1972 Arg or Asn, abolishes the ability of TOR to bind the FKBP–rapamycin complex [4,5]. Mammalian homologs (called variously FRAP [6], RAFT [7], RAPT [8], and mTOR [9]) were independently isolated soon thereafter, through a variety of approaches.

Functions of TOR

The two TOR proteins of *S. cerevisiae* serve in a nutrient sensing pathway; a decrease in ScTOR activity, whether by exposure to low-quality sources of N or C, by treatment with the specific inhibitor rapamycin, or by gene deletion, results in a 90% inhibition in overall mRNA translation [10],

cell-cycle arrest, and activation of autophagy [11] and the N-and-C discrimination programs of gene expression [12–14], which reorient the metabolism to maximize glutamine synthesis and energy yield from suboptimal N and C sources (Table 1).

TOR activity is also the dominant regulator of overall mRNA translation in the primitive metazoan *Caenorhabditis elegans* [15]; in higher metazoans, such as *Drosophila*, and in vertebrates, the control of translation by TOR is narrowed to specific classes of mRNAs and shared with the class 1 PtdIns(3')OH kinase [16]. Together, these two signaling elements control the facultative component of protein synthesis necessary for insulin/mitogen-induced cell growth by exerting joint control over the activity of the p70 S6 kinases; the phosphorylation state of eIF-4E inhibitory proteins, 4E-BPs, which control the efficiency of eIF-4F-mediated translation; and other translational and metabolic targets [17–21].

The p70 S6 kinases are responsible for the phosphorylation of the 40S ribosomal subunit protein S6, a rapid and ubiquitous response to all growth-promoting stimuli. The ability of rapamycin to rapidly cause the dephosphorylation and deactivation of p70 S6K in all cultured mammalian cells while having no effect on the activity of mitogen-activated protein kinase (MAPK) or ribosomal S6 kinase (RSK) [3,4]

immediately suggested a role for the target of rapamycin in the regulation of mRNA translation in mammalian cells. The deletion of the gene encoding p70 S6 kinase in *Drosophila* (and, to a lesser extent, S6K1 in mice) has established that the p70 S6 kinase is a critical determinant of cell growth [22]. Nevertheless, the function of S6 phosphorylation and its role in translational regulation remain unknown; although several other plausible *in vivo* substrates for the p70 S6 kinases have been identified (CREM [23], CBP80 [24], EF2 kinase [25], GSK3 [26], and BAD [27]), the molecular targets through which p70 S6 kinase controls cell growth and the specific role of the p70 S6 kinase in translational regulation are not known [28].

The discovery of the eIF-4E binding proteins (4E-BPs) and the finding that 4E-BPs, like p70 S6K, are rapidly dephosphorylated in response to rapamycin, provided a more secure example of TOR regulation of translation [16]. The 4E-BPs are small (11-kDa) acidic proteins that bind to eIF-4E, the mRNA cap-binding protein, in a manner competitive with the scaffold protein eIF-4G; the latter protein also binds the RNA helicase, eIF-4A, which, together with eIF-4B (to create the eIF-4F complex), functions to unwind secondary structure in mRNA 5'UT segments, enabling efficient scanning of mRNAs by the 43S pre-initiation complex. By blocking the binding of eIF-4E–mRNA complexes to the eIF-4F assembly, the 4E-BPs interfere most strongly with the translation of mRNAs whose 5'UT segments contain substantial secondary structures. The 4E-BPs were first detected as a family of heat- and acid-soluble polypeptides whose phosphorylation was greatly stimulated by insulin (PHAS-I) [29]. The discovery of their association with eIF-4E [30,31] was followed by the demonstration that their binding to eIF-4E is inhibited by a PI-3-kinase-stimulated, rapamycin-sensitive, multisite 4E-BP phosphorylation [32,33]. The ability of rapamycin to inhibit the phosphorylation of p70 S6K and 4E-BP is clearly due to the binding of a rapamycin–FKBP12 complex to mTOR and inhibition of the mTOR kinase activity, inasmuch as expression of recombinant, rapamycin-resistant, mutant mTOR proteins (Ser2035Thr or Ile) can rescue both p70 S6K and 4E-BP [34–36] from rapamycin-induced dephosphorylation, but only if the mTOR kinase domain is intact.

Thus, the ability of TOR to control at least some components of mRNA translation has persisted during metazoan evolution. With regard to the specific mRNAs whose translational initiation is regulated by mTOR, one set includes those with extensive secondary structure in their 5'UT regions, such as ornithine decarboxylase, c-Myc, IGF-2 promoter 2, and others [16]. A second class includes mRNAs characterized by a 5' polypyrimidine tract (5'TOP), a run of 5 to 14 consecutive pyrimidines immediately at the transcriptional start site [37]. This motif, found only in metazoan mRNAs, occurs in all mRNAs encoding ribosomal polypeptides, as well as in those encoding other components of the translational apparatus (e.g., EF1 α , EF2, PABP). The translation of these mRNAs is especially sensitive to the presence of insulin or mitogens and is inhibited by rapamycin and

inhibitors of the class I PtdIns(3')OH kinases. Considerable evidence indicates that the regulation by TOR of these translational targets [17–20], together with other anabolic actions (e.g., diminished degradation of nutrient transporters [21] or stimulation of glycogen synthesis [26]) and anticatabolic actions (e.g., inhibition of autophagy [38,39]), underlies the stimulated cell growth induced by growth factors, especially the component mediated by PI-3 kinase (PI-3K).

Cell growth (i.e., accumulation of mass) and cell proliferation, while closely related, are to some degree mechanistically separable processes [40]. Cell growth requires global protein synthesis, whereas cell proliferation depends on the timely expression and/or activation of a small group of cell-cycle regulatory proteins, as well as their timely degradation/removal [41]. In organisms where TOR controls a major portion of overall protein synthesis, control of cell-cycle progression probably follows *pari passu*. In mammalian cells, the ability of rapamycin to interrupt cell-cycle progression both *in vivo* and in cell culture varies dramatically despite the unflinching inhibition of p70 S6 kinase and 4E-BP phosphorylation. The ability of mTOR to control cell-cycle transit is best correlated with its ability to regulate the level of the cyclin D and p27^{KIP} polypeptides. Thus, in NIH3T3 cells, rapamycin causes a reduction in cyclin D1 polypeptide, with a consequent decrease in cyclin D1/Cdk4 kinase activity, reduced Rb phosphorylation, and a slowing of progress into S phase [42]. Multiple mechanisms appear to underlie the rapamycin inhibition of the accumulation of cyclin D1 (e.g., inhibition of cyclin D1 gene transcription, destabilization of the mRNA, and accelerated degradation of the cyclin D1 polypeptide through a proteosomal pathway).

In T lymphocytes, as in many other cells, phosphorylation of Rb sufficient to enable progression into the S phase requires the sequential combined actions of cyclin D/Cdk4 and cyclin E/Cdk2 [41]. Activation of cyclin E/Cdk2 in response to IL-2 or TCR stimulation is due to an increase in the expression of Cdk2 and cyclin E polypeptides as well as to a decrease in the level of the general Cdk inhibitor protein p27^{KIP} [41,43]. The content of p27 is regulated at the level of transcription [44], translation [45], and polypeptide degradation [46]. The availability of p27 may also be regulated by the abundance of cyclin D/Cdk4; it has been suggested that the mitogen-induced increase in the abundance of cyclin D/Cdk4 complexes creates a reservoir for binding of p27, further facilitating the activation of Cdk2/cyclinE [47]. IL-2 induces the proteasome-dependent degradation of p27 [48]; this requires the phosphorylation of p27 (Thr187), which is catalyzed by active cyclin E/Cdk2 itself as well as other, as yet unidentified, kinases, and the subsequent ubiquitination of p27, which is mediated by the E3 ubiquitin ligase SCF. PI-3K, through PKB, upregulates the expression of Skp2, the substrate-targeting subunit of SCF, and thereby promotes p27 degradation [49]. Rapamycin blocks the IL-2 induced degradation of p27, and this effect is crucial to the inhibition of cell-cycle progression in T cells [48]. In addition, the ability of rapamycin to block cyclin D1 expression may further contribute to maintaining p27 at levels sufficient

to prevent cyclin E/Cdk2 activation. Thus, T cells and MEFs from p27 knockout mice exhibit substantial resistance to the inhibition of proliferation by rapamycin [50]. Similarly, several cell lines selected for continued growth in the presence of rapamycin exhibit low levels of p27 that are unresponsive to further suppression by serum. In summary, it appears that a significant component of the ability of rapamycin to inhibit cell cycle progression in T cells, a critical pharmacologic target in immunosuppression, is attributable to the inhibition of p27 degradation. Rapamycin also inhibits p27 degradation in vascular smooth muscle cells, which appear to be particularly sensitive. Rapamycin inhibits not only proliferation but also vascular smooth muscle cell migration. As a consequence, rapamycin-impregnated vascular stents have shown considerable efficacy in inhibiting intimal hyperplasia and restenosis after percutaneous transluminal catheter (balloon) angioplasty (PTCA) [51].

Early studies of rapamycin pharmacology demonstrated a potent ability of the drug to inhibit the growth of a variety of human tumor cell lines, and recent work has reinvigorated the application of rapamycin derivatives as antitumor agents [53]. Aoki *et al.* [54] observed that chick embryo fibroblasts (CEFs) transformed with oncogenic versions of PI-3K or PBK/Akt are rendered extremely sensitive to growth inhibition by rapamycin, whereas rapamycin was without substantial effect on CEFs transformed with a variety of tyrosine kinase oncogenes, *v-crk*, *v-mos*, *v-jun*, or *v-fos*. Moreover, human tumors with spontaneous overactivity of the PI-3K/Akt pathway (e.g., those exhibiting PTEN loss of function) are very common and exhibit great sensitivity to growth inhibition by rapamycin or the rapamycin derivative, CCI779 [55]. A similar sensitivity to rapamycin is evident in tumors arising in *Pten*^{+/-} mice [56]. Overexpression of the GLI transcription factor, a proproliferative element in the Sonic Hedgehog pathway [57], also confers rapamycin sensitivity, whereas transformation of these same cells by Ras or Myc does not. GLI expression is upregulated in the embryonal type of rhabdomyosarcoma, a childhood tumor that is frequently rapamycin sensitive.

In summary, the potent and highly specific mTOR inhibitors related to rapamycin have found clinical application in three circumstances: (1) as effective immunosuppressants through their ability to halt T-cell proliferation; (2) as antitumor agents, because the growth of human tumors characterized by overactivity of PtdIns(3')OH kinase pathways is strongly and selectively inhibited by rapamycin derivatives; and (3) as inhibitors of vascular stent occlusion, through their ability to inhibit the proliferation and migration of vascular smooth muscle cells.

Signaling from TOR

In addition to the kinase catalytic domain, all TORs contain three other functionally relevant, structurally conserved segments (Fig. 1). Amino-terminal to the catalytic domain is a conserved segment of about 500 amino acids, termed

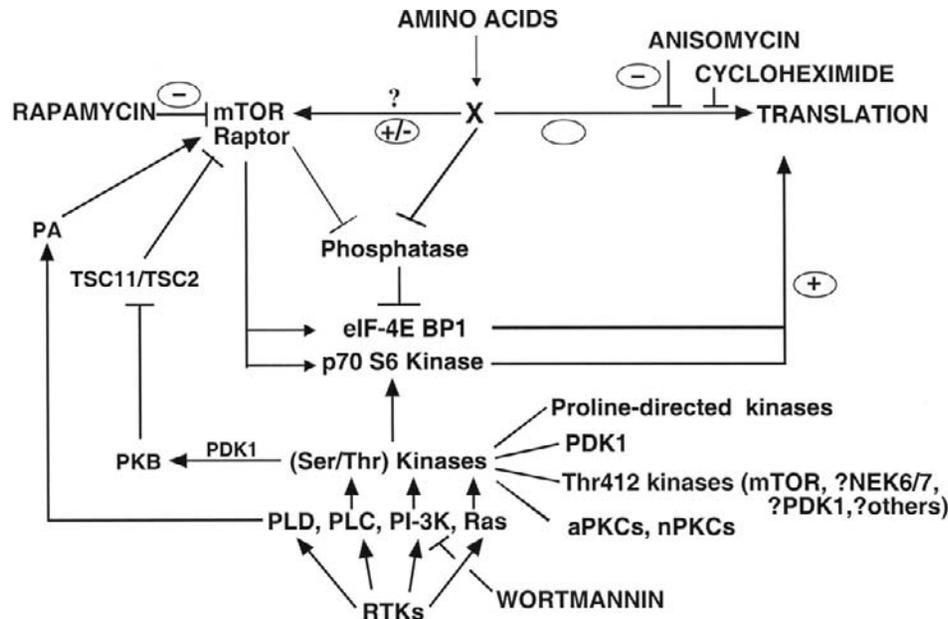

Figure 1

FAT (because it is found only in the FRAP/TOR, ATM, and TRRAP polypeptides). The FAT motif is always found in conjunction with a short motif at the polypeptide carboxy terminus, thus the name FATC. Mutations or deletions in these segments abolish mTOR kinase activity [58]. Situated between the FAT domain and the catalytic domain is a conserved segment that mediates the binding of the FKBP-12-rapamycin complex (the FRB domain). A crystal structure of the minimal binding domain expressed as a prokaryotic, recombinant 11-kDa fragment reveals four tight α -helices in a structure for which the N and C termini lie close together, suggestive of an independently folding module [59]. Within this segment, Ser 2035 (equivalent to Ser 1972 in yeast TOR2) is indispensable for binding the rapamycin/FKBP12 complex; replacement of Ser2035 by any amino acid other than alanine abolishes binding completely and, as in yeast TOR2, renders mTOR resistant to inhibition by rapamycin *in vivo*. At least several of the substitutions at Ser2035 (e.g., to Thr or Ile) do not appear to substantially interfere with mTOR kinase activity *in vitro* or *in vivo*, in that expression of these mTOR Ser 2035 mutants can rescue coexpressed p70 S6K [43,35] or 4E-BP [35,36] from rapamycin-induced dephosphorylation. Despite the conservation of overall amino acid sequence in the FRB domain, as well as of the universal presence (thus far) of a Ser at the residue equivalent to Ser1972 in yeast TOR2, not all TORs are sensitive to inhibition by rapamycin [60,61]. Nevertheless, the importance of this region in TOR signaling is reinforced by the finding that although *Schizosaccharomyces pombe* TOR does not bind FKBP-12/rapamycin complex, mutation of the serine in the FRB domain of *S. pombe* TOR homologous to ScTOR Ser 1972 inactivates *S. pombe* TOR function *in vivo* [61]. A fourth recognizable TOR domain is comprised by the multiple HEAT (Huntingtin, eIF3, PP2A-A subunit, TOR)

repeats, a motif of 37 to 43 amino acids, each of which (as first defined for the scaffold (A) subunit of PP2A) contains an anti-parallel pair of α -helices; the HEAT hairpin modules assemble in a linear, repetitive fashion to form an elongated stack of double helices [62]. The intrarepeat turns form a continuous ridge, presumably a protein interaction surface. mTOR has 20 HEAT motifs, which occupy nearly all of mTOR AA71-1147. The HEAT domains of yeast TOR have been reported to mediate membrane attachment [63]. The bulk of mTOR in mammalian cells is also particulate, although a precise localization is not available; a portion of mTOR polypeptides appears to be nuclear [64], and the nuclear entry may be critical for certain signaling functions (e.g., in transcriptional regulation).

As first shown by Brunn *et al.* [65], mTOR is capable of phosphorylating 4E-BP directly *in vitro*, preferentially at Thr 37 and 46 and possibly at all sites (Ser 65 and 82, Thr70) that undergo insulin/PI-3K-stimulated phosphorylation *in vivo* [66,67]. Subsequent work established the ability of mTOR to phosphorylate directly *in vitro* several functionally relevant sites on the p70 S6K [68,69]. The mTOR-catalyzed phosphorylation of 4E-BP, *in vitro* and probably *in vivo*, occurs in a hierarchical fashion, with phosphorylation of the sites (Thr37 and 46) amino-terminal to the 4E binding site (amino acids 54–60) occurring preferentially and those carboxy-terminal to the 4E-BP binding site occurring subsequently. The initial two phosphorylations have little impact on 4E-BP binding to eIF-4E; however, phosphorylation of the more carboxy-terminal sites, especially Ser65, potently inhibits eIF-4E binding. The phosphorylation at these carboxy-terminal sites also exhibits the greatest sensitivity to dephosphorylation in the presence of rapamycin and inhibitors of PI-3K; it is unclear whether this differential sensitivity is attributable to the properties of the relevant phosphatases, the dependence of TOR-catalyzed phosphorylation

at these more carboxy-terminal sites on the prior phosphorylation at Thr37 and 46, or the operation at these sites of a second, PI-3K-dependent protein kinase [66,67].

The properties of the mTOR-catalyzed *in vitro* phosphorylation of 4E-BP and p70 S6K differ in several ways. A striking difference is in the mTOR site selection on these two targets; all sites phosphorylated on 4E-BP by mTOR *in vitro* are Ser/Thr-Pro motifs [65,66]. In contrast, although mTOR catalyzes the phosphorylation at Ser/Thr-Pro sites on p70 S6K, in the SKAIPS domain and elsewhere (e.g., p70 S6K Ser394), the major site of mTOR-catalyzed phosphorylation is Thr412 in the motif FXXFTY [68,69]. Such diversity in site selection is unprecedented, and suggests the operation of a second, mTOR-associated protein kinase. Nevertheless, the mTOR-catalyzed phosphorylation of both p70 S6K and 4E-BP is inhibited *in vitro* by the addition of a rapamycin/FKBP12 complex, and mTOR mutated in its catalytic domain is unable to catalyze *in vitro* either phosphorylation. Thus, all these sites are phosphorylated *in vitro* directly by mTOR [69].

When extracted in a Tween-containing buffer [65], mTOR catalyzes detectable phosphorylation of both 4E-BP and p70 S6K. If, however, mTOR is extracted into a buffer containing Triton X-100, the ability of mTOR to phosphorylate 4E-BP *in vitro* is lost entirely, whereas mTOR-catalyzed phosphorylation of p70 S6K is unaltered or even increased [69]. Recent work [70,71] has established that the detergent-sensitive phosphorylation of 4E-BP by mTOR reflects the detergent-induced loss of an mTOR-associated scaffold protein, whose continued binding to mTOR is necessary for mTOR-catalyzed phosphorylation of 4E-BP *in vivo* and *in vitro*. This 150-kDa polypeptide (Raptor) is highly conserved from *S. cerevisiae* to humans and contains seven WD40 repeats in its carboxy-terminal segment. Raptor binds 4E-BP and p70 S6K as well as mTOR and is absolutely required for mTOR-catalyzed 4E-BP phosphorylation *in vitro*; Raptor binds selectively to hypophosphorylated forms of 4E-BP and physically links mTOR to eIF-4E. Insulin and amino acids promote the dissociation of the mTOR/Raptor complex from eIF-4E, in part by promoting the phosphorylation of 4E-BP [71]. The association of Raptor with mTOR may also be regulated by amino acid [70]. Remarkably, RNAi-induced inhibition of Raptor expression in *C. elegans* reproduces every phenotype seen with CeTOR deficiency, whether caused by CeTOR mutation or CeTOR RNAi [15,71], pointing to the likelihood that Raptor is central to all actions of TOR.

Another emerging chapter in the mTOR regulation of the p70 S6K is the role of the TSC1 and TSC2 gene products known as Hamartin and Tuberin, respectively. These two polypeptides, which occur as a heterodimer, together function as a tumor suppressor [72]. Mutation in either of the genes encoding these two polypeptides results in the syndrome tuberous sclerosis, which is characterized by the occurrence of multiple benign tumors, or hamartomas, particularly in the central nervous system, kidney, heart, lung, and skin, with the occasional emergence of a malignancy [73]. Deletion of the *Drosophila* homolog of TSC1 is the

cause of the *gigas* mutant, characterized by organ and cellular overgrowth [74]. Overexpression in *Drosophila* of TSC1 and TSC2 together, but neither one singly, reduces cell size and cell proliferation [75,76] and is capable of suppressing the cellular overgrowth seen with deletion of DmPTEN or with overexpression of DmPKB [75–77]; reciprocally, loss-of-function mutations in TSC cause an increase in cell size [75,77] and can compensate for the failure of cell growth caused by hypomorphic mutations in *Drosophila* InsR or PI-3K but not the growth failure resulting from loss of function for Dm S6K [75]. Biallelic deletion of murine TSC1 results in the constitutive activation of p70 S6 kinase in serum-deprived mouse embryonic fibroblasts (MEFs), without activation of MAPK, whereas the serum-induced activation of PKB (but not MAPK) is greatly diminished [78]. TSC2 is phosphorylated *in vitro* and *in vivo* by protein kinase B (PKB), and mutation of these PKB phosphorylation sites to Ala greatly increases the inhibitory potency of recombinant TSC2 on coexpressed p70 S6K [79]. Thus, the TSC1/TSC2 complex appears to function as a negative regulatory element in mTOR signaling to p70 S6K; the role of the TSC complex in the regulation of PKB function (if any) is yet unclear. TSC inhibition of p70 S6K is reduced through an insulin/PI-3K stimulated, PKB catalyzed-TSC2 phosphorylation. Interestingly, homologs of either TSC1 or TSC2 are not identifiable in the *C. elegans* genome, a species in which the PI-3K and TOR pathways show no evident cross-regulation. TSC2 thus appears to be a major locus at which the PI-3K/PKB pathway positively regulates the output of mTOR, at least toward the p70S6K.

Despite the well-documented ability of mTOR to directly phosphorylate *in vitro* 4E-BP and p70 S6K at functionally relevant, rapamycin-sensitive sites, a considerable body of indirect evidence, derived from studies of the regulation of S6K1, indicates that the major pathway of mTOR regulation of the p70 S6K *in vivo* is indirect, through the negative regulation of a p70 S6K phosphatase, rather than by direct mTOR-catalyzed phosphorylation of p70 S6K [80]. The p70 S6 kinase is activated by a complex multisite phosphorylation, regulated jointly by the type 1 PtdIns(3')OH kinase and mTOR. Activation is initiated by the phosphorylation of a cluster of Ser/Thr-Pro sites situated in a pseudosubstrate, autoinhibitory domain in the p70 S6 kinase noncatalytic carboxy-terminal tail. Although not activating *per se*, these phosphorylations, which can be catalyzed by a variety of proline-directed kinases as well as mTOR, enable the displacement of the tail from the centrally located catalytic domain, allowing access to the activating kinases. Activation is achieved by the phosphorylation of Thr252 [81,82], on the activation loop, and Thr412 [83], situated in a hydrophobic motif (FXXFTY) immediately carboxy-terminal to the canonical catalytic domain; although phosphorylation at either site gives some activation, the concomitant phosphorylation at both sites generates a strong positively cooperative activation of catalytic function [81]. The phosphorylation of Thr252 is catalyzed by the PtdIns(3,4,5)P₃-dependent kinase 1 (PDK1), although in a PtdIns(3,4,5)P₃-independent

manner, at least *in vitro* [81,82]. The identity of the kinase acting at Thr412 remains uncertain; mTOR itself can directly catalyze this reaction *in vitro* [68,69], as can PDK1 (although at <5% the rate of Thr252 [83]). ES cells lacking both alleles encoding PDK1 show no IGF-1-stimulated phosphorylation of either Thr252 or Thr412 [85]. Other elements that participate in p70 S6 kinase activation, although their roles are less well defined, include the atypical PKCs (λ or ζ) and Cdc42-GTP [80].

The p70 S6 kinase contains near its amino terminus a short (18 residues in S6K1) segment containing only acidic and hydrophobic amino acids. Deletion of this noncatalytic segment, when combined with deletion of the carboxy terminal noncatalytic tail, results in a mutant (p70 Δ 2-46/ Δ CT104) that, like the wild type, has a low basal activity and is strongly activated *in vivo* by insulin and mitogens in a PI3-K-dependent manner; activation is accompanied by increased phosphorylation at the (remaining) p70 S6K sites critical to activation (i.e., Thr 252 in the activation loop and Thr 412 in the hydrophobic motif). In the wild-type p70 S6K, phosphorylation at Thr 412 is most sensitive to inhibition of PI3K (by wortmannin) or mTOR (by rapamycin) [83,86]. The p70 S6K 2-46 Δ / Δ CT104 mutant remains fully sensitive to wortmannin, which results in dephosphorylation at Thr 412 and inactivation [86,87]. In contrast, the insulin/mitogen stimulated phosphorylation at Thr 412 and activation of the p70 Δ 2-46/ Δ CT104 mutant is entirely resistant to concentrations of rapamycin that far exceed those necessary to dephosphorylate Thr412 and inhibit the wild-type p70 S6K *in vivo* and that (in complex with FKBP12) inhibit the mTOR kinase activity assayed *in vitro* [86,87]. The unimpaired mitogen/PI-3K responsive activation of the Δ 2-46/ Δ CT104 variant in the presence of rapamycin establishes that mTOR kinase activity is not necessary for the insulin-mitogen activation by p70 S6K. Rather, it appears that the primary function of mTOR in p70 S6K regulation is to restrain a p70-S6K-inactivating element, most likely a p70 S6K phosphatase. Direct evidence in support of this idea is scant; however, Peterson *et al.* [88] have reported that the PP2A catalytic subunit can be coprecipitated with wild-type p70 S6K but not with the p70 S6K Δ 2-46/ Δ CT104 mutant, suggesting that the p70 S6K amino-terminal segment necessary for rapamycin sensitivity may serve as a binding site for the phosphatase or a phosphatase-associated regulatory protein. The function of this motif however is likely to be more complex, inasmuch as 4E-BP contains a motif similar in sequence to that in the p70 S6K amino terminus, and mutation of the motif in 4E-BP suppresses its insulin-stimulated 4E-BP phosphorylation [89]. In addition, overexpression of wild-type p70 S6K interferes with insulin-stimulated hyperphosphorylation of 4E-BP [89,90], but mutation or deletion of the p70 S6K amino-terminal rapamycin sensitivity segment abolishes the ability of coexpressed p70 S6K to suppress 4E-BP phosphorylation [89]. Thus, it appears that this motif is binding to some component critical for mTOR signaling; however, whether this is the mTOR polypeptide, a TOR scaffold protein, or a TOR-regulated phosphatase remains to be determined.

The idea that mTOR signaling is mediated in part through the modulation of protein phosphatase activity is entirely consistent with pathways elucidated in *S. cerevisiae*, wherein a mutation in the phosphatase regulatory protein TAP42 renders yeast significantly rapamycin resistant [91]. TAP42 associates with a small fraction of the yeast PP2A and SIT4 (homologous to mammalian PP6) phosphatase catalytic subunits and somehow restrains their activity toward specific substrates [92]. The TIP41 protein in turn negatively regulates TAP42 and TOR phosphorylates both. Nutrient deprivation or rapamycin inhibition of TOR causes dephosphorylation of TIP41, increasing its binding to TAP42, which releases the SIT4 phosphatase into an active state [93]. This results in the dephosphorylation of a number of mTOR target proteins (e.g., the cytoplasmic scaffold protein Ure2p, the transcription factor GLN3, or the protein [Ser/Thr] kinase NPR [94]). The mammalian homolog of TAP42, α 4 [95], binds to the PP2A, PP4, and PP6 phosphatase catalytic subunits [96–99]; however, the rapamycin sensitivity of these complexes is disputed, and their role in the rapamycin-induced dephosphorylation of p70 S6K, 4E-BP, or other mTOR targets is unknown.

In addition to its positive regulatory input into the p70 S6K, mTOR also controls the activity of certain isoforms of PKC in an analogous manner. Thus, phosphorylation of the novel PKC isoforms δ and ϵ at sites near their carboxy terminus that are situated in hydrophobic motifs homologous to that surrounding S6K1 (Thr412) are also regulated in a serum-stimulated, rapamycin-sensitive manner [100,101]. Phosphorylation at these nPKC sites augments activity dramatically and is one step in a complex regulatory mechanism involving PDK1, an atypical PKC isoform and the ligand diacylglycerol [102]. As with the p70 S6K, the ability of rapamycin to cause dephosphorylation of the nPKCs is thought to be mediated by activation of a protein phosphatase. PKC δ can be coprecipitated with mTOR (as well as the DNA PK, another PIK-related kinase) and inactive variants of PKC δ can partially suppress serum-stimulated 4E-BP phosphorylation [103].

Regulation of mTOR Activity (Fig. 2)

Regulation of mTOR by RTK-PI-3K

Several reports indicate that insulin [104–106] induces a modest (~twofold) increase in the activity of immunoprecipitated mTOR; a more robust increase in mTOR activity is observed in response to neurotrophin (CNTF, BDNF) treatment of primary neurons and cell lines [107,108]. Overexpression of active forms of PI-3K or PKB results in increased 4E-BP phosphorylation at the rapamycin-/wortmannin-sensitive sites [109] and activation of p70 S6K [110], although PKB itself does not phosphorylate either 4E-BP or p70 S6K. Whether the effects of insulin, neurotrophins, recombinant PI-3K, and PKB reflect a direct modification and activation of TOR kinase or more indirect mechanisms (e.g., phosphorylation of and disinhibition

from TSC [79], PDK1 and/or PKB recruitment of other 4E-BP and/or p70 S6K kinases, negative regulation of protein phosphatase, or some combination of these actions) is not known. In addition to the modest (twofold) increase in the activity of immunoprecipitated mTOR, activation of PKB *in vivo* is associated with increased phosphorylation of mTOR at Ser2448 [106,111], a canonical PKB site. The functional significance of PKB-catalyzed mTOR phosphorylation is unclear, as mutation of Ser2448 to Ala on the rapamycin-resistant mTOR (Ser2035 Thr) does not alter its ability to rescue 4E-BP or p70 S6K from rapamycin-induced dephosphorylation [106]. Nevertheless, deletion of the mTOR segment surrounding Ser2448 [106] or the binding of a polyclonal Ab [66,105] to this site each increase the *in vitro* mTOR kinase activity by five- to tenfold, suggesting that a regulatory input (e.g., TSC inhibition) whose mechanism remains to be elucidated may be effected through this segment of mTOR.

Microinjection of a prokaryotic recombinant FRB fragment into MG63 osteosarcoma cells, a cell line whose growth is reliably arrested in G₁ by rapamycin, prevents entry into S [112], suggesting that the function of the FRB domain in maintaining TOR activity might be regulatory rather than structural. An important insight into the function of the FRB domain was the finding that this segment binds selectively to lipid vesicles that contain phosphatidic acid (PA) [113]. This binding can be inhibited by addition of an FKBP12/rapamycin complex or partially by mutation of mTOR Arg2109 to Ala; introduction of this mutation into a rapamycin-resistant mTOR (S2035T) mutant reduces by approximately 40% its ability to rescue coexpressed p70S6K from rapamycin inhibition. PA added exogenously can activate p70 S6K and 4E-BP phosphorylation. Mitogens, though activation of PLD, increase cellular PA levels, and butanol, which sequesters intracellular PA as an ester, inhibits the serum-induced activation of p70 S6K and the phosphorylation of 4E-BP without affecting phosphorylation of PKB or MAPK. Moreover, a mutant of p70 S6K resistant to inhibition by rapamycin (see above) is also resistant to inhibition by butanol. The noncovalent interaction of PA with the mTOR FRB domain appears to provide one component of the mitogen activation of mTOR signaling.

In summary, mTOR kinase activity is regulated in mammalian cells by tyrosine-kinase-linked receptors through a PI-3K–PDK1–Akt pathway, at least in some cell backgrounds and possibly for some, but not all, substrates. This activation persists to some degree after extraction and immunoprecipitation and is probably attributable to PI-3K/PB-induced mTOR phosphorylation. An additional important site of PKB regulation is through the phosphorylation of, and disinhibition from, TSC2 [79]. Moreover, as described above, an RTK–PLD-induced accumulation of phosphatidic acid [113] probably promotes mTOR activity through a noncovalent interaction; this activation is unlikely to survive cell extraction. An understanding of the TOR scaffold protein Raptor [70,71] as a site of regulation will be necessary for understanding the specific mechanisms that regulate the mTOR kinase activity toward each of its physiologic substrates. Finally, the role of gephyrin [114] in the receptor regulation of mTOR remains unclear. Gephyrin is a ubiquitously expressed tubulin-binding protein necessary for the postsynaptic clustering of glycine receptors in neurons. Gephyrin binds to mTOR (AA1010–1128). Mutations in this region that abolish mTOR interactions with gephyrin abrogate the ability of a rapamycin-resistant mTOR (Ser2035Thr) to rescue p70 S6K and 4E-BP from rapamycin-induced dephosphorylation.

Regulation of mTOR by Amino Acids

The evidence that TOR retains its role as a nutrient-sensor in metazoans is entirely indirect; in contrast to the generally reproducible, if modest, stimulatory effects of insulin and neurotrophins, there has been no demonstration that alterations in the nutrient environment cause stable changes in mTOR kinase activity that can be measured by mTOR kinase assay *in vitro*, although it is reported that nutrient deprivation promotes an inhibitory interaction between Raptor and mTOR [70,71]. Nevertheless, there is persuasive evidence that TOR kinase activity *in vivo* is controlled by inputs related to amino acid and overall energy sufficiency. Thus, in a wide range of cultured mammalian cells, withdrawal of medium amino acids leads to progressive deactivation of the p70 S6K and dephosphorylation of eIF 4E-BP over 1 to 2 hours and completely inhibits the ability of insulin to promote these phosphorylations [87,115–117]. Amino acid withdrawal, however, does not significantly affect, at least over this initial interval, the upstream elements of the insulin signaling pathway (i.e., IR/IRS tyrosine phosphorylation, PI-3K activity, PKB or MAPK activation). Readdition of amino acids restores phosphorylation of p70 S6K on 4E-BP and their responsiveness to insulin. Moreover, elevation of ambient concentration of amino acids to higher than usual levels causes a progressive increase in p70 S6K activity and 4E-BP phosphorylation to levels observed with maximal insulin stimulation; at these high amino acid concentrations, addition of insulin gives no further stimulation of p70 S6K activity [87]. Thus, amino acid deficiency, like rapamycin, results in the selective

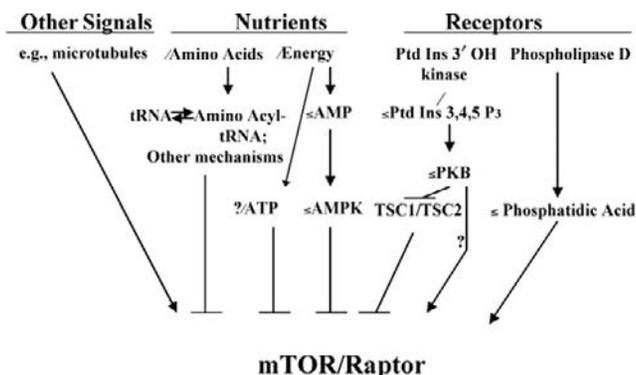

Figure 2

dephosphorylation of these two well characterized TOR targets in a manner that overrides the activating input of the RTK/PI-3K pathway. Notably, the doubly deleted rapamycin-resistant p70 S6K mutant, p70 Δ 2-46/ Δ CT104, is also highly resistant to deactivation/dephosphorylation by amino acid withdrawal [87]. This finding establishes that amino acid withdrawal, like rapamycin, does not inhibit any of the steps necessary for the insulin/PI-3K phosphorylation of p70 S6K Thr252 (the PDK1 site) and Thr412 (unknown kinase), but rather promotes the dephosphorylation of these sites; mTOR and amino acid sufficiency thus appear to inhibit the same p70 S6K phosphatase. Although rapamycin inhibits the ability of amino acid readdition to restore p70 S6K phosphorylation, it has not been formally established whether amino acids require mTOR to inhibit this putative p70 S6K phosphatase. Wortmannin also inhibits amino-acid-induced p70 S6K phosphorylation, but concentrations higher than those sufficient to inhibit type 1a PI-3K are required [39] and correspond to those necessary for inhibition of mTOR itself [118]. Subsequent work demonstrated that the rapamycin-sensitive phosphorylation sites in the nPKCs (δ and ϵ) are also dephosphorylated in response to amino acid withdrawal [100,101].

The complete restoration of p70 S6K and 4E-BP phosphorylation in cell culture requires the readdition of all 20 amino acids; readdition of single amino acids is without effect, except for leucine, which enables a variable extent of partial restoration in many cell lines [39,88,115,119]. Similarly, whereas removal of any single amino acid usually results in some dephosphorylation, the most substantial inhibition is observed on removal of leucine and occasionally arginine. A large body of *in vivo* experiments by Jefferson *et al.* [120–123] indicate that leucine exerts significant stimulatory action on the phosphorylation of p70 S6K and 4E-BP and is uniquely effective in promoting the synthesis of ribosomal proteins, providing strong evidence that the amino-acid-activated, mTOR-dependent pathways evident in cell culture are operative *in vivo* and are one component of the multiple mechanisms by which amino acids and insulin coordinately regulate protein synthesis especially in skeletal muscle.

Although evidence has been provided for the existence of a membrane-localized leucine receptor, at least in regard to amino-acid-regulation of autophagy in hepatocytes [124], it is likely that the majority of amino-acid-dependent responses mediated by mTOR are initiated at an intracellular site [119]. Thus, inhibition of mRNA translation, either at the level of initiation (anisomycin) [125] or elongation (cycloheximide) [126], results in the activation of p70 S6K and hyperphosphorylation of 4E-BP [127] in a rapamycin-sensitive manner. Reciprocally, overexpression of eIF-4E (although transforming in many cell backgrounds) is accompanied by hypophosphorylation of 4E-BP and p70 S6K [127]. An attractive hypothesis is that the ability of protein synthesis inhibitors to stimulate the phosphorylation of p70 S6K and 4E-BP might reflect the activation of mTOR, induced by the accumulation of some intermediate in the

translational process (e.g., a minor acylated tRNA) or by a byproduct of stalled translation, analogous to the synthesis of guanosine tetraphosphate during the “stringent” response in bacteria [128]. Support for such a mechanism is provided by the observation that amino acid alcohols, which inhibit cognate tRNA synthetase activity and protein synthesis, nevertheless cause dephosphorylation of 4E-BP and p70 S6K (suggesting a decrease in mTOR activity), in contrast to anisomycin [129]. Moreover, cycloheximide overcomes the dephosphorylation of p70 S6K/4E-BP caused by amino acid withdrawal. Similarly, CHO cells bearing a temperature-sensitive mutant histidyl tRNA synthetase, when shifted to the nonpermissive temperature, exhibit dephosphorylation of 4E-BP and p70 S6K [129]. If mTOR is regulated by the charging of tRNAs, this is accomplished through a mechanism distinct from that regulating the GCN2 kinase [130], as well as that underlying the bacterial stringent response [131].

Regulation of mTOR by Energy Sufficiency

Although the phosphorylation of 4E-BP is suppressed by amino acid withdrawal, some degree of insulin-stimulated 4E-BP phosphorylation persists under these conditions, to a degree sufficient to displace 4E-BP from 4E and to promote an increased association of eIF-4E with eIF-4G [132]. In CHO cells deprived of both amino acids and glucose, the basal- and insulin-stimulated phosphorylation of Thr 36/45 is severely inhibited; readdition of glucose alone, although insufficient to enable detectable phosphorylation of p70 S6K1 Thr412 or Ser444/447, allows substantial insulin-stimulated Thr36/45 phosphorylation and significant basal and insulin stimulated protein synthesis. This effect of glucose requires its metabolism and can be reproduced in part by lactate [132]. Although the identity of the kinase responsible for the glucose-dependent, insulin-stimulated phosphorylation of 4E-BP Thr36/45 is not known, a plausible candidate is mTOR, inasmuch as these are the primary sites of mTOR-catalyzed 4E-BP phosphorylation. The dependence of this response on glucose metabolism suggests that mTOR kinase activity is itself, to some extent, dependent on and regulated by some product of glucose metabolism, independent of amino acid sufficiency, PI-3K, and PKB. Several observations indicate that this input is related to the state of overall energy sufficiency, as reflected by the concentration of adenine nucleotides. Thus, inhibitors of glycolysis such as 2-deoxyglucose (2DG) and inhibitors of mitochondrial oxidative phosphorylation, e.g., rotenone or CN⁻ both cause a marked inhibition of 4E-BP1 and p70 S6K phosphorylation, at concentrations that have little effect on PKB or MAPK activation [133]. Notably, a rapamycin-resistant mutant of p70 S6K previously shown to be resistant to inhibition on withdrawal of amino acids is also entirely resistant to the inhibitory effects of 2DG, strongly supporting the conclusion that the inhibitory effects of energy depletion on p70 S6K and presumably 4E-BP are mediated by inhibition of mTOR. It has been suggested that mTOR is directly sensing

the concentration of ATP itself, based on the apparently high ED_{50} for ATP (~ 1.0 mM) in the mTOR-catalyzed phosphorylation of 4E-BP *in vitro* [132]. This estimate of K_m for ATP, however, is probably compromised by the copurification with mTOR of protein phosphatases and other contaminants. A more plausible mediator of TOR inhibition in the setting of energy depletion is the AMP-activated kinase (AMPK) system [134,135]. AICAR, a precursor of the AMPK activator ZMP, can inhibit p70 S6K and 4E-BP phosphorylation in cell culture, at least in cells able to efficiently convert this precursor to ZMP, without inhibition of PKB and MAPK. In addition, mTOR directly and specifically associates with AMPK. AICAR given by subcutaneous injection to rats results in an inhibition in skeletal muscle of p70 S6K (Thr412) and 4E-BP (Thr37) phosphorylation, accompanied by a decrease in the association of eIF-4E with eIF-4G and an inhibition of protein synthesis [135]. The effects of AICAR in skeletal muscle may also be mediated by an inhibition of the PI-3K pathway inasmuch as AICAR injection *in vivo* also results in decreased phosphorylation of PKB (Ser473) and mTOR Ser2448, a canonical site of PKB-catalyzed phosphorylation *in vivo*; the latter responses are not seen upon glucose withdrawal from cultured cells. In summary, mTOR output is regulated by the cellular energy state, although this appears to be secondary in importance to regulation by amino acid sufficiency. Inhibition of mTOR by AMPK is likely to contribute an important component of the energy-dependent regulation of TOR.

AMP-Activated Protein Kinase

D. Grahame Hardie

School of Life Sciences and Wellcome Trust Biocentre,
Dundee University, Dundee, Scotland*

Introduction

The AMP-activated protein kinase (AMPK) is the downstream component of a kinase cascade that has multiple cellular targets [1–3]. It is switched on by cellular stresses that deplete cellular adenosine triphosphate (ATP), causing increases in the cellular adenosine diphosphate (ADP):ATP ratio. The AMP:ATP ratio is further amplified by adenylate kinase, the signal that activates the AMPK system [1]. Genome sequencing suggests that protein kinases related to AMPK may exist in all eukaryotes, including fungi and plants, as well as animals ranging from *Dictyostelium discoideum* to mammals. In budding yeast, the homolog of AMPK is the Snf1 complex, with the *snf1* gene (encoding the catalytic subunit) being originally characterized via mutations that caused failure to grow on carbon sources other than glucose [3]. A functional Snf1 complex is required for derepression of many glucose-repressed genes when glucose is removed from the medium. Similar protein kinases also exist in higher plants [4]. Although similar to the mammalian system in many respects, a puzzling feature is that the fungal and plant kinases do not appear to be allosterically activated by AMP.

Structure of the AMPK Complex

AMP-activated/SNF1 protein kinases are heterotrimeric complexes consisting of catalytic α subunits and regulatory β and γ subunits [5]. In mammals, each subunit is encoded by multiple genes ($\alpha 1$, $\alpha 2$, $\beta 1$, $\beta 2$, and $\gamma 1$ to $\gamma 3$), and these assemble into up to 12 different α , β , γ combinations [6]. Budding yeast contains single genes encoding the α (*snf1*) and γ (*snf4*) subunits and three genes encoding β subunits [7]. The α subunits contain N-terminal kinase domains and C-terminal

regulatory domains that inhibit the kinase in its inactive state [8,9]. In yeast, the γ subunit is an activator by genetic criteria, and in mammals the γ subunits appear to be involved in binding the allosteric activator, AMP [6]. All γ subunits contain four tandem repeats of a sequence motif known as a CBS (cystathionine- β -synthase) domain. These occur in a variety of other proteins, from archaea to eukaryotes [10], and, although their exact function is unknown, in the enzyme cystathionine- β -synthase mutations in the CBS domain result in failure to be activated by the allosteric effector, S-adenosyl methionine [11]. Because both S-adenosyl methionine and AMP contain adenosine, it is tempting to speculate that the CBS domains of the γ subunits bind the adenosine moiety of AMP. The β subunits of AMPK act as scaffolds on which α and γ ; assemble through interaction with the conserved KIS and ASC domains [7] and may also be involved in subcellular targeting [12] (Fig. 1).

Regulation of the AMPK Complex

AMPK/Snf1 complexes are inactive unless phosphorylated on a threonine residue within the activation loop of the α subunit [13,14] by upstream kinases that remain unidentified. AMPK complexes are allosterically activated by AMP, with the extent of activation (up to sevenfold) depending on the identity of the α and γ subunits [6]. AMP also promotes phosphorylation and activation of the kinase, via a three-fold mechanism of binding to AMPK and (1) making it a better substrate for the upstream kinase, (2) making it a worse substrate for the protein phosphatase, and (3) binding to and activating the upstream kinase. This multistep mechanism generates great sensitivity, such that over a critical range of concentrations a small change in AMP produces a large change in kinase activity [15]. Effects of AMP that are due

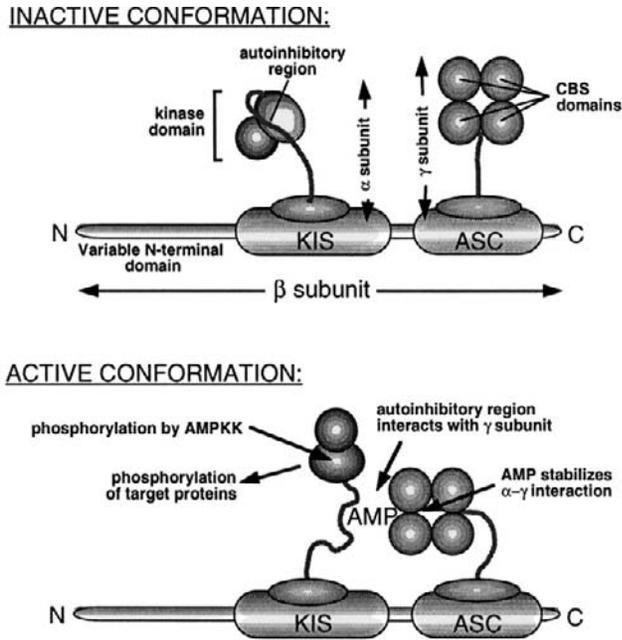

Figure 1 Model for the changes in interdomain interactions in the AMPK complex. In both the inactive and active conformations, the β subunit acts as a scaffold that binds α and γ via the conserved KIS and ASC domains. In the inactive conformation (top), the kinase domain of α is inhibited by interactions with the autoinhibitory region on the same subunit. In the active conformation (bottom), this interaction is prevented because the autoinhibitory region on α now interacts with the CBS domains on γ , instead of with the kinase domain. AMP promotes this conformation by stabilizing the $\alpha \leftrightarrow \gamma$ interaction, while ATP binding at the allosteric site disrupts it. In the active conformation, the kinase domain is free to be phosphorylated and activated by the upstream kinase and to phosphorylate downstream targets. (From Hardie, D. G. and Hawley, S. A., *BioEssays* 23, 1112–1119, 2001. With permission.)

to binding to AMPK itself are antagonized by high concentrations of ATP. The system therefore responds to rises in cellular AMP:ATP, leading to the concept that it is a sensor of cellular energy charge, or fuel gauge [16]. This view was reinforced by findings that the kinase is inhibited by phosphocreatine [17].

Regulation in Intact Cells and Physiological Targets

The AMPK system is activated by cellular stresses that inhibit ATP production or accelerate ATP consumption. Stresses of the former type include heat stress and metabolic poisons [18], ischemia and hypoxia [19,20], oxidative stress [21], and glucose deprivation [22], the latter also being the primary stress that activates the Snf1 complex in yeast [23]. A physiological stress that activates AMPK by increasing ATP consumption is muscle exercise [24]. Studies with transgenic mice expressing a dominant-negative mutant suggest that AMPK is wholly responsible for the effects of hypoxia and partly responsible for the effect of contraction on muscle glucose uptake [25].

A full description of known or putative physiological targets for AMPK is beyond the scope of this article, but

readers may refer to a recent review [1]. In general, AMPK switches on catabolic pathways that generate ATP (e.g., glucose and fatty acid oxidation) while switching off cellular processes that consume ATP, especially anabolic (biosynthetic) pathways. This has led to the concept that it acts as a “metabolic master switch” [26]. It achieves this task both by direct phosphorylation of metabolic enzymes and via effects on gene expression. The mechanisms by which AMPK regulates transcription remain unclear, although it has been shown to phosphorylate p300, leading to reduced interaction of this co-activator with nuclear hormone receptors, such as that for PPAR- γ [27]. In addition, AMPK inhibits expression of two transcription factors (i.e., HNF-4 α [28] and SREBP-1C [29]), thus indirectly regulating the transcription of entire classes of target genes.

Medical Implications of the AMPK System

Type 2 diabetes, which affects over 100 million people worldwide, is a hyperglycemic condition caused by reduced glucose uptake by muscle and increased glucose production by liver. Physical exercise is known to provide protection against its development, and because AMPK is activated by exercise it regulates the activity and expression of the insulin-sensitive glucose transporter GLUT4 and inhibits expression of enzymes of gluconeogenesis [30], this suggesting that AMPK could be a promising target for therapy of Type 2 diabetes [26]. This idea has been supported by recent findings that metformin, an important oral hypoglycemic agent used to treat Type 2 diabetes, activates AMPK *in vivo* [29].

Mutations in the AMPK $\gamma 2$ gene cause hereditary conditions that lead to sudden death by heart failure, such as Wolf-Parkinson-White syndrome (a type of arrhythmia) with or without associated hypertrophy [31,32]. The effects of these mutations on AMPK activity remain unclear, although intriguingly they occur within the CBS domains, the putative AMP-binding regions.

Acknowledgments

Studies in the author's laboratory are supported by a Programme Grant from the Wellcome Trust, a Project Grant from the Medical Research Council (U.K.), and a RTD Grant from the European Commission.

Introduction

Protein kinases comprise one of the largest protein families, corresponding to $\approx 2\%$ of eukaryote genes. Their prominence reflects the fact that protein phosphorylation is the most abundant form of cellular regulation, affecting essentially all cellular processes, including metabolism, growth, differentiation, motility, membrane transport, learning, and memory. To function as switches controlling all of these processes, kinases must be tightly regulated. Improper regulation leads to cancer and various other diseases. Regulation is an integral part of protein kinase function that controls the timing of catalytic activity and substrate specificity.

Protein kinase can be regulated in diverse ways, ranging from transcriptional control through subcellular localization and recruitment of substrates (using anchoring, adaptor, and scaffold proteins or domains [1]) to structural and chemical modifications of the proteins themselves. This short review focuses on the principles of regulation of protein kinase activity at the protein level (for further details, see related recent reviews [2,3]).

Protein Kinase Structure

Eukaryote protein kinase domains segregate into two large groups, phosphorylating either serine/threonine or tyrosine residues on target proteins. However, both groups have essentially similar three-dimensional structures comprised of two lobes with the active site located in the cleft between the small and large lobes [4,5]. The smaller, N-terminal (N-)

lobe contains mainly beta structures and one important helix termed helix C, whereas the C-terminal (C-) lobe is largely alpha-helical. Important structural motifs include the glycine-rich motif that forms a phosphate-binding (P-) loop that anchors the ATP phosphates; the activation loop, often containing phosphorylation sites, provides a surface for peptide substrate binding (Fig. 1).

All protein kinases catalyze the same reaction—the transfer of the gamma-phosphate from ATP to the hydroxyl group of a Ser, Thr, or Tyr—and adopt strikingly similar structures in their active forms. The active structure positions the substrates within the constellation of catalytic residues. By contrast, the mechanisms used to maintain protein kinases in inactive forms show remarkable diversity. These range from allosteric to intrasteric and everything in between [6] and are used to modulate the conformations of the activation loop and the P-loop, the position of helix C, the access to ATP and substrate binding sites, and the relative orientation of the two lobes (Figs. 1 and 2). The control can be exerted by internal regions of the kinase catalytic domains, by sequences outside the catalytic domain, or by additional subunits or interacting proteins; these regions or proteins may respond to second messengers, and their expression may be controlled by the functional state of the cell. They can target the kinase to different substrates or subcellular locations or inhibit the kinase activity. These possible regulatory sites affect each other, resulting in a rich spectrum of possible regulatory pathways. We first review allosteric and intrasteric behaviors in protein kinases, and then address how individual sites are regulated.

General Principles of Control

Allosteric Regulation

Allosteric regulation is a classic widespread mechanism of control of protein function; effectors bind to regulatory sites distinct from the active site, inducing conformational changes that profoundly influence the activity [7]. Allosteric effectors typically bear no structural resemblance to the substrate of their target protein. This form of regulation explains how end products of metabolic pathways could act at early steps of the pathway to exert feedback control. In protein kinases, allosteric control can be exerted by flanking sequences or separate subunits/proteins, such as, for example,

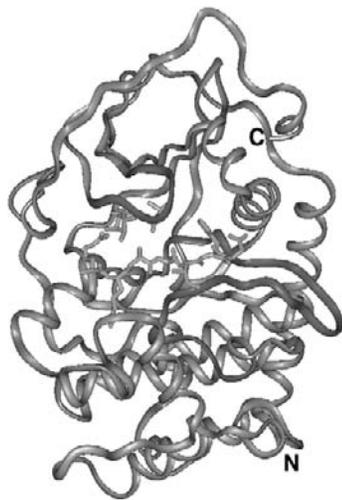

Figure 1 Ribbon diagram of the structure of the catalytic domain of PKA, with the various regulatory regions colored: activation loop, red; P-loop, blue; helix C, cyan. The bound ATP and peptide substrate (only seven residues are shown) are shown in stick representation in orange and green, respectively. The figure was generated using GRASP [32].

the N-terminal sequence in EphB2 receptor tyrosine kinase or cyclin in cyclin-dependent kinases (CDKs) influencing the orientation of the lobes and rotation of helix C.

Intrasteric Regulation

The term *intrasteric regulation* was introduced to describe autoregulation of protein kinases and phosphatases by internal sequences that resembled substrate phosphorylation sites (“pseudosubstrates”) and acted directly at the active site [8]. It is now clear that this form of control is used widely and extends to diverse enzyme classes as well as receptors and protein targeting domains [6]. Intrasteric interactions typically suppress protein functions, and diverse mechanisms can be used for activation, including protein activators or ligands, phosphorylation, proteolysis, reduction of disulfide bonds, or combinations of these. The best examples of intrasterically regulated protein kinases are the large subfamily activated either by calcium-binding proteins (e.g., calmodulin-dependent kinases [CaMKs], titin, twitchin) or calcium directly in the case of the plant calcium-dependent protein kinases that contain a calcium-binding domain fused with the kinase domain. In twitchin kinase, a C-terminal autoregulatory sequence threads through the active site cleft between the two lobes of the protein kinase domain, making a plethora of contacts with the peptide substrate binding site and ATP-binding residues as well as residues essential for catalysis [9] that completely shut down kinase activity. The binding site of the activator S100A1 has been mapped to one portion of the autoinhibitory sequence [9,10]. A very similar mechanism of inhibition occurs in the related giant kinase titin; however, here a combination of phosphorylation and calmodulin (CaM) binding (to a site analogous to the S100A1 binding site in twitchin) is required to activate the enzyme [11]. The more distantly related CaMK-I is also activated by CaM binding to an autoregulatory sequence, but the structure shows a modified mode of

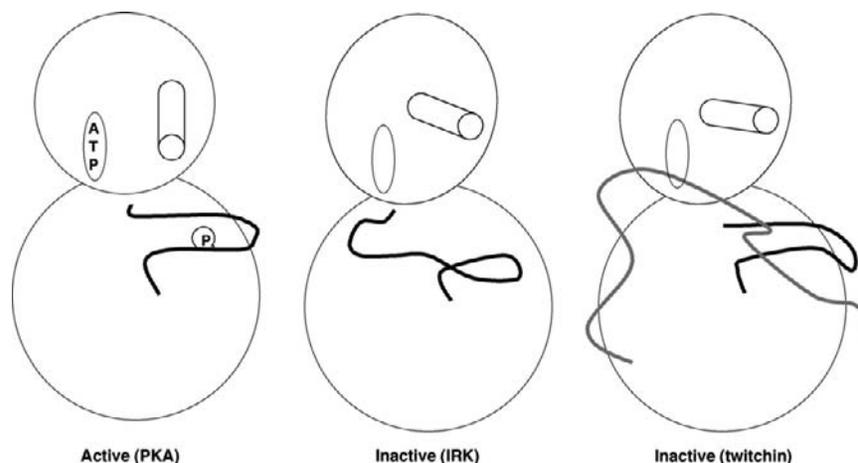

Figure 2 A schematic diagram showing prototypic kinase active structure (PKA) and inactive structures (IRK and twitchin), highlighting the regulatory regions. The two lobes of the catalytic domain, activation loop (thick line), helix C (cylinder), the ATP binding site (ATP), and the autoregulatory sequence (thick gray line) are shown.

inhibition where the autoregulatory sequence exits the active site before the P-loop and not over the activation loop, as is the case for twitchin kinase [12]. In p21-activated kinase (PAK), the autoregulatory sequence is located on a distinct “inhibitory switch domain” binding to the C-lobe of the kinase which both blocks the substrate binding site and causes various distortions to the kinase domain [13]. PAK is activated by the GTP form of the Rho family of G proteins. Other protein kinase families predicted to be intrasterically regulated include glycogen synthase kinase 3 β , which is proposed to be autoinhibited. In this case, phosphorylation of Ser-9 causes the N-terminus to bind to the small lobe and direct the autoregulatory sequence into the active site [14]. The protein kinase C family and cGMP-dependent protein kinases also have autoregulatory sequences N-terminal to the catalytic domain; the activators are phospholipids and diacylglycerol, and cGMP, respectively [15].

Insulin receptor tyrosine kinase (IRK) has revealed a more subtle autoinhibitory mechanism with a tyrosine residue bound to the active site [5]. This tyrosine may be considered a transient pseudosubstrate and is ultimately autophosphorylated in response to insulin binding to the extracellular part of the receptor. Phosphorylation of this and two other tyrosine residues results in a rearrangement, allowing access to the active site [16]. A similar blocking of the active site by a tyrosine is also observed in the inactive structure of the MAP kinase ERK2 [17]. In this case, the tyrosine is one of the two residues phosphorylated by a distinct upstream kinase to yield the active enzyme [18].

Regulatory Sites in Protein Kinase Domains

Activation Loop

The activation loop represents the most complex element of protein kinase structure and shows a great variety of behaviors. The loop has evolved a remarkable ability to rearrange in response to phosphorylation. Many kinases that require activation by phosphorylation in the activation loop contain an arginine residue immediately preceding the catalytic aspartate and have therefore been termed RD kinases [19]. The activation loop represents a part of the active site and also has an influence on the position of helix C; it must be in an open and extended conformation to allow substrate binding. The most dramatic examples of the modulation of activity by phosphorylation of the activation loop include the previously mentioned IRK and MAP kinase ERK2. The phosphorylation even modulates the oligomerization and nuclear localization of ERK2 [20]. The inactive conformation of the activation loop has even been exploited medically as a specific binding site for the anticancer drug Gleevec in Bcr–Abl [21].

Helix C

This helix modulates kinase activity because it is coupled through intramolecular contacts to both the ATP binding site

and the activation loop, by moving as a rigid body in response to intra- and intermolecular regulators. The best understood example is CDK2, where cyclin binding directly to the helix and its vicinity induces a rotation that reconstitutes the ATP binding site [22]. In Src family tyrosine kinases, the binding of the adjacent SH3 domain from the protein holds helix C in a conformation similar to the inactive state of CDK2; ligands to the SH3 domain (and the SH2 domain also present in the protein) allow helix C to resume the active conformation [23–25]. Both CDKs and Src family kinases simultaneously require phosphorylation in the activation loop for full activity.

P-Loop

The conformation of the P-loop differs subtly between the active kinases. It is likely flexible so it can both accommodate ATP binding despite subtle changes in the orientation of the two lobes and respond to regulators.

ATP Binding Site

Blocking the conserved ATP binding site is a common mechanism to regulate protein kinase activity, and the specificity stems from intermolecular protein–protein interfaces (e.g., p16-CDK6 interaction [26,27]) or complex intramolecular interactions (e.g., IRK, twitchin kinase).

Substrate Binding Site

The substrate peptide binding site is located in the groove between the N- and C-lobes with the activation loop constituting a part of it. It is most often blocked via intrasteric interactions or modulated via the conformation of the activation loop. In the case of CaMK-I, potent synthetic peptide substrates have been found that appear to induce the activation loop into a productive conformation without the need for phosphorylation [28], but it remains to be seen whether this phenomenon extends to protein substrates.

Flanking Segments

Polypeptide segments flanking the protein kinase domain either N- or C-terminally are responsible for autoinhibition in most kinases exhibiting intrasteric regulation (e.g., twitchin, CaMK-I, PAK). In some cases, the flanking regions are not directed to the active site but inhibit the catalytic activity allosterically through conformational change alone. EphB2 kinase is activated by phosphorylation in both the activation loop and the N-terminal flanking sequence. In the dephosphorylated state, this N-terminal sequence binds to the N-lobe and stabilizes helix C and the activation loop in a catalytically unproductive conformation [27]. Phosphorylation of the N-terminal segment also activates the type I TGF β receptor (TGF β -I). This N-terminal GS region inhibits the kinase activity when bound to the inhibitory protein FKBP12, distorting the N-lobe and particularly

helix C [29]. The activators of EphB2 and TGF β -I are various SH2 domains and Smad proteins, respectively.

Conclusions

The structures of different protein kinases in active and inactive states have revealed some fundamental principles of kinase regulation, as well as numerous variations on the major themes. It is expected that further variations exist, and additional structural information will be crucial in understanding them; currently, structural information is only available for less than 1% of the protein kinases. Attempts to gain further insights into the mechanisms of regulation are being made by combining structural analysis with computational [30], biophysical [31], and other approaches.

Calcium/Calmodulin-Dependent Protein Kinase II

Mary B. Kennedy

*Division of Biology, California Institute of Technology,
Pasadena, California*

Introduction

Ca²⁺/calmodulin-dependent protein kinase II (CaMKII) is the most complex in structure and regulation of the family of calmodulin-dependent protein kinases. It was first described as a calcium/calmodulin-dependent protein kinase with a relatively broad substrate specificity and highly expressed in brain [1–3]. We now know that CaMKII is expressed in many tissues, including spleen, heart, and skeletal muscle [2,4]; however, its level of expression in neurons of the forebrain is extraordinarily high. It constitutes approximately 2% of total protein in homogenates of the adult rat hippocampus and approximately 1% of total protein in rat forebrain homogenates [5]. This high level of expression suggested that it might carry out specialized functions in neurons and, indeed, this appears to be the case. Many studies now implicate CaMKII in regulation of multiple determinants of synaptic strength in excitatory neurons in the brain, as well as in regulation of homeostasis of synaptic components. This chapter discusses the structure of CaMKII and its regulation by autophosphorylation, as well as current ideas about how its characteristics are used to regulate synaptic function.

Structure of CaMKII

CaMKII was first purified from rat brain homogenates [6,7] and shown by study of its hydrodynamic properties to be a dodecameric hetero-oligomer of two subunits, termed alpha (50 kDa) and beta (60 kDa) [6]. These subunits are highly homologous to each other and are both catalytic.

They appear to assemble together into dodecamers that contain the same average proportions of α - and β -subunits as are present at the time of synthesis. Thus, the holoenzyme composition in a given cell is not homogenous but is instead distributed randomly according to the proportion of available subunits at the time of assembly. There does not appear to be an energetic preference for one holoenzyme composition over another; but this subject has not been studied exhaustively.

Subunits

Cloning of cDNAs encoding subunits of CaMKII demonstrated that the rat genome contains four different genes encoding subunits of CaMKII, each of which has a distinctive pattern of tissue-specific expression (see Table 1). These subunits all apparently associate into dodecameric holoenzymes, as do the α and β subunits [4]. The most significant differences in sequence among the subunits are found in a region between the amino-terminal catalytic domain (\approx 300 residues) and the carboxyl-terminal association domain (\approx 160 residues) [8]. In this variable region, each of the subunits contains unique sequences ranging from 0 to 70 residues in length; sometimes this region is also alternatively spliced. The variable sequences are believed to confer unique properties. For example, the β -subunit has a higher affinity for calmodulin than does the α -subunit [9,10], perhaps endowing it with greater sensitivity to cytosolic calcium. The β -subunit also displays a much stronger affinity for actin filaments than does the α -subunit [11]. On the other hand, the α -subunit has a higher affinity for the potential postsynaptic density docking protein, densin [12].

Table I Distinct Mammalian Genes Encode Four CaMKII Subunits

Subunit	Molecular weight	Tissue distribution	Refs.
α	54.1 kDa	Only in neurons, at very high levels in forebrain neurons	[8,15]
β	60.4 kDa	Only in neurons, at moderate levels in most neurons	[16]
γ	59 kDa	In most tissues, at moderate levels	[17,18]
δ	60.1 kDa	In most tissues, at moderate levels	[17]

Hence, the small differences in properties of the subunits may confer important differences in regulation and subcellular localization.

In the brain, the message encoding the α -subunit is transported into dendrites, whereas that encoding the β -subunit is confined to the soma [13]. Transport of the α -subunit message permits its synthesis in dendrites and, by deduction, assembly of new dendritic “ α -only” holoenzymes [14].

Structure of the holoenzyme

ASSOCIATION DOMAIN

Individual subunits associate with each other through their carboxyl-terminal association domains [19]. The two domains mediate formation of an antiparallel dimer. Six dimers then associate to form the dodecameric holoenzyme. The holoenzyme is extremely stable; there is no evidence for the existence of significant amounts of dimers or other intermediate structures in cells, nor is there any indication that holoenzymes can exchange subunits.

STRUCTURE DETERMINED BY CRYOELECTRON MICROSCOPY

The individual catalytic domains and the holoenzyme of CaMKII have not been crystallized, but a great deal of insight has come from determination of the structure of a homomeric α -subunit dodecamer at about 3-nm resolution by cryoelectron microscopy [20] (see Fig. 1). This unique structure consists of a hollow, gear-shaped, central cylinder approximately 20 nm in diameter and 10 nm thick. Six slanted flange-like “teeth” project from the surface of the cylinder and confer a six-fold rotational symmetry. Each of the teeth appears to be formed by an antiparallel dimer of the association domains of two subunits. The catalytic domains extend from each end of the teeth to form two parallel rings of six enzymes separated by the cylindrical central structure. The variable regions of the different subunits would form part of the central structure. Thus, specific subcellular association sites located in the variable region would be situated on the central cylinder. The symmetry of the structure suggests that each holoenzyme would contain six pairs of similar binding domains that can mediate subcellular localization. It will be interesting to learn whether this domain arrangement permits the kinase holoenzyme to act as a structural node within the postsynaptic density or other cytoskeletal structures.

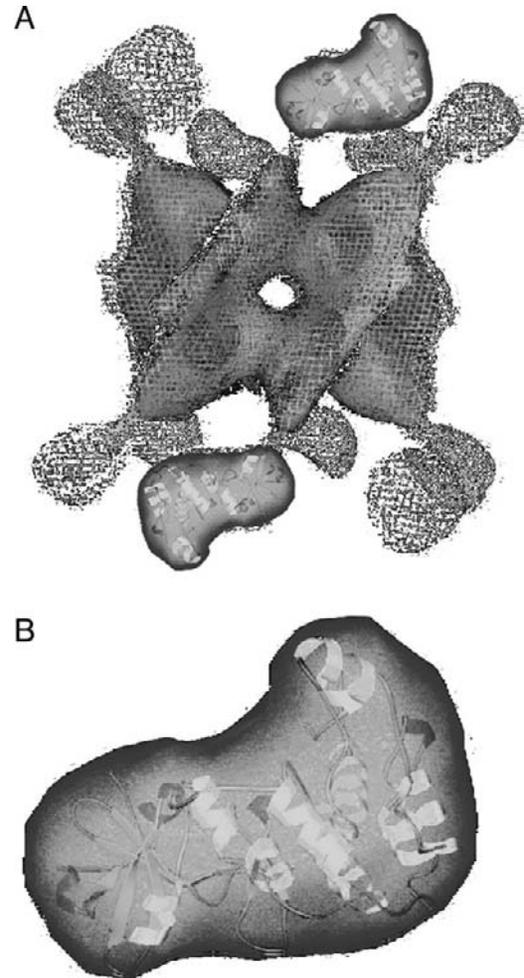

Figure 1 Structure of the holoenzyme of CaMKII. The structure of a holoenzyme of α subunits of CaMKII was determined by cryoelectron microscopy by Kolodziej *et al.* [20]. A surface representation (adapted from Fig. 5 of their paper) is shown in (A). The red central portion is the cylinder formed by the 12 association domains. The yellow, foot-like structures are individual catalytic subunits. Superimposed on two of the catalytic domains is a scaled representation (blue) of the fit of the x-ray structure of the catalytic domain of the cAMP-dependent protein kinase into the surface representation of the “feet.” A larger view of this fit (also from Fig. 5 of Kolodziej *et al.*) is shown in (B).

Regulation by Autophosphorylation

Production of Ca²⁺-Independent Activity

CaMKII is extensively regulated by autophosphorylation, and this property appears to be critical for its role in regulation of neuronal properties. Rapid autophosphorylation of a single threonine residue in the regulatory domain of the catalytic subunit (Thr286; or 287 in the beta subunit) causes the catalytic unit to remain active until it is dephosphorylated by cellular phosphatases [21–24]. The autophosphorylation occurs only within single holoenzymes [21,25,26] but requires intersubunit catalysis [25,26]. Calmodulin must bind to two neighboring subunits within one of the six-membered rings before either of the subunits can become autophosphorylated. Thus, calmodulin must be bound to both the substrate

subunit and the catalytic subunit [25]. Autophosphorylation of Thr286 allows activation of the subunit to outlast the triggering calcium transient [21,27], but it also decreases the rate of dissociation of calmodulin from the subunit by as much as 100-fold in the absence of calcium [28]. This latter property causes the kinase holoenzyme to respond more sensitively to high-frequency calcium transients than to low-frequency calcium transients [25], perhaps influencing which patterns of synaptic activity lead to changes in synaptic strength.

Desensitization

A second regulating autophosphorylation event takes place more slowly. If calmodulin dissociates from an activated subunit, one of two threonines (Thr305 or Thr306) that reside near the catalytic site becomes autophosphorylated [29]. Because these threonines are located in the calmodulin-binding domain, their phosphorylation blocks further binding of calmodulin, thus preventing reactivation of the subunit until the site is dephosphorylated [29–31]. Phosphorylation of these sites can thus desensitize the kinase to calcium signals. The physiological function of this second stage of autophosphorylation is not clear.

Regulatory Roles of CaMKII in Neurons

Although CaMKII is present throughout the neuronal cytosol, it is highly enriched in the postsynaptic density (PSD) [32,33], a specialization of the submembrane cytoskeleton that lies just underneath glutamatergic postsynaptic receptors across from the presynaptic active zone [34]. This finding was an early indication that CaMKII might play a special role at synapses. The conjecture was born out by the phenotype of mice from which the abundant α -subunit had been deleted. These mice are epileptic, do not display normal long-term potentiation at their hippocampal synapses, and perform poorly on learning paradigms [35,36]. Interestingly, mutant mice in which the critical autophosphorylated Thr286 is mutated to alanine have an equally severe phenotype [37].

CaMKII appears to be a major target of calcium ion flowing through activated *N*-methyl-D-aspartate (NMDA)-type glutamate receptors in dendritic spines [14,38,39]. Its activation there can lead to phosphorylation and upregulation of AMPA-type glutamate receptors [39] or addition of new AMPA receptors to the synapse through a distinct process that does not require direct phosphorylation of the AMPA receptor [40].

Additional targets for CaMKII in the PSD include the ras GTPase-activating protein synGAP [41] and the NMDA receptor itself [42,43]. Regulation of synGAP by CaMKII may provide a link to the many Ras-regulated processes within dendrites. Thus, CaMKII is situated at the hub of a variety of synaptic control mechanisms influenced by activation of the NMDA receptor. We have just begun to understand the complexity of its influence in neurons [44].

Glycogen Synthase Kinase 3

Philip Cohen and Sheelagh Frame

*MRC Protein Phosphorylation Unit,
University of Dundee, Dundee, Scotland*

Introduction

Glycogen synthase kinase 3 (GSK3) was identified over 20 years ago as a protein kinase that phosphorylated and inhibited glycogen synthase [1], the enzyme that catalyzes the transfer of glucose from UDPG to glycogen. Subsequently, two separate isoforms were cloned, termed GSK3 α and GSK3 β [2]. These enzymes have extremely similar catalytic domains, the major distinguishing feature being the glycine-rich N terminus present in the α -isoform. Over the past few years, GSK3 has re-entered center stage because it has become clear that it is a key player in two distinct signal transduction pathways: (1) the phosphatidylinositol (PtdIns)-3-kinase-dependent pathway that is triggered by insulin and growth factors, and (2) the Wnt signaling pathway that is required for embryonic development. The following account provides a short summary of the structure, substrate specificity, functions, and regulation of this protein kinase. For more detailed accounts, readers are referred to several recent reviews [3–5].

The Substrate Specificity of GSK3

Soon after its discovery, it was noted that GSK3 could only phosphorylate glycogen synthase efficiently if glycogen synthase had already been phosphorylated by CK2 [6]. Phosphorylation by CK2 did not inhibit glycogen synthase, but primed this enzyme for phosphorylation by GSK3. Elegant studies by Roach and his colleagues then established that the substrate specificity requirements of GSK3 are unique: the protein kinase phosphorylates serine and threonine residues that lie in Ser/Thr-Xaa-Xaa-Xaa-pSer/pThr, where pSer is phosphoserine, pThr is phosphothreonine, and Xaa is any amino acid [7]. In the case of glycogen synthase, the phosphorylation of Ser656 by CK2 forms the

recognition site for the GSK3-catalyzed phosphorylation of Ser652. This, in turn, acts as the recognition site for the phosphorylation of Ser648 and so on, leading to the sequential phosphorylation of Ser644 and Ser640, the phosphorylation of the last two residues having the major effect on activity [7].

GSK3 phosphorylates many proteins *in vitro*, some of which are likely to be physiological substrates. For example, it phosphorylates Ser535 on the ϵ -subunit of eukaryotic protein synthesis initiation factor eIF2B [8,9], which is the guanosine triphosphate (GTP)/guanosine diphosphate (GDP)s exchange factor that converts eIF2 to its active GTP-bound form, thereby allowing it to form a ternary complex with Met-tRNA and the 40S ribosome. The phosphorylation of Ser535 inactivates eIF2B, resulting in an inhibition of protein synthesis. The phosphorylation of Ser535 by GSK3 is dependent on the prior phosphorylation of Ser539. This residue is not phosphorylated by CK2 but, at least *in vitro*, is phosphorylated specifically by the dual-specificity, tyrosine-phosphorylated and -regulated kinase (DYRK) [10]. However, whether a DYRK isoform phosphorylates eIF2B at Ser539 *in vivo* has not yet been established. GSK3 is also reported to phosphorylate ATP-citrate lyase at Thr446 and Ser450 [11,12] and the cAMP-response element binding protein (CREB) at Ser129 [13]. In these cases, phosphorylation of ATP-citrate lyase and CREB depends on the prior phosphorylation of Ser454 and Ser133, respectively, by protein kinases such as cAMP-dependent protein kinase A (PKA). Thus, it is clear that the nature of the priming kinase varies from substrate to substrate. In the case of glycogen synthase and eIF2B, the level of phosphorylation of the priming site is high, even in quiescent cells, because CK2 and DYRK are constitutively active protein kinases. However, in the case of ATP-citrate lyase and CREB, the level of phosphorylation of the priming site increases in response to several extracellular signals, such as those that elevate cAMP and activate PKA.

The site on GSK3 that binds the priming phosphate of substrates has been identified. It is located in the N-terminal lobe of the catalytic domain near the activation loop present in many protein kinases and contains three crucial basic residues (Arg96, Arg180, and Lys205 in the β -isoform) that interact directly with the priming phosphate [14–16]. Interestingly, the three-dimensional structure of GSK3 most closely resembles that of mitogen-activated protein kinase (MAPK) family members. The activation of MAPKs requires the phosphorylation of a threonine and a tyrosine residue located in a Thr–Xaa–Tyr sequence in the activation loop, which is catalyzed by dual specificity MAPK kinases (MKKs). Intriguingly, the phosphothreonine residue in the activation loop of MAPKs interacts with the same three basic residues that bind the priming phosphate in substrates of GSK3 [15]. Moreover, GSK3 is itself phosphorylated at a tyrosine residue located in a position equivalent to that of the phosphotyrosine residue in MAPKs [17]. Thus, the way in which the active form of GSK3 is generated may be analogous to that of MAPKs, except that the active conformation is induced when the priming phosphate of the substrate binds to GSK3 [15]. Unlike the MAPKs, the phosphotyrosine residue in GSK3 (Tyr279 of GSK3 α , Tyr216 of GSK3 β) appears to be phosphorylated constitutively in most mammalian cells [17,18]. GSK3 β expressed in *Escherichia coli* (a bacterium thought to lack protein tyrosine kinase activity) is phosphorylated at Tyr216 and wild-type GSK3 β but is not a catalytically inactive mutant and becomes phosphorylated at Tyr216 when transfected into human HEK 293 cells (Frame and Cohen, unpublished data). These observations suggest that the phosphorylation of the tyrosine residue in GSK3 is catalyzed by GSK3 itself. In contrast, there is evidence that in the slime mold *Dictyostelium discoideum* GSK3 is activated by tyrosine phosphorylation, which is catalyzed by the protein kinase ZAK1 [19]. However, the tyrosine residues that become phosphorylated have not yet been identified, and ZAK1 homologs do not appear to be present in the human genome. Nevertheless, the possibility

that the tyrosine phosphorylation of GSK3 may be catalyzed by another protein kinase in some mammalian cells cannot be excluded, because the phosphorylation of GSK3 β at Tyr216 has been reported to increase in neuronal cells after cerebral damage or after withdrawal of nerve growth factor (NGF) from the culture medium [20,21].

The Regulation of GSK3 Activity by Insulin and Growth Factors

GSK3 can be inhibited via the phosphorylation of a serine residue near the N terminus of the protein (Ser21 in GSK3 α , Ser9 in GSK3 β) [22]. This serine lies in an Arg–Xaa–Arg–Xaa–Xaa–Ser sequence, which is a consensus motif for phosphorylation by several protein kinases that are components of different signal transduction pathways (Fig. 1). Protein kinase B (PKB, also called Akt) inhibits GSK3 in response to signals that activate class I phosphatidylinositol (PtdIns) 3-kinases and elevate the level of PtdIns(3,4,5)P3 [22]; MAPK-activated protein kinase 1 (MAPKAP-K1, also called RSK) inhibits GSK3 following stimulation by signals that activate the classical MAPK cascade [23, 24]; and S6K1 inhibits GSK3 in response to amino acids acting via the protein kinase mTOR [25].

In embryonic stem cells that do not express 3-phosphoinositide-dependent protein kinase 1 (PDK1), an essential upstream activator of both PKB and MAPKAP-K1, the PKB-mediated inhibition of GSK3 (induced by insulin-like growth factor 1) and the MAPKAP-K1-mediated inhibition of GSK3 (induced by the tumor-promoting phorbol ester TPA) do not occur [26]. This genetic evidence supports the view that GSK3 can be inhibited by PKB and MAPKAP-K1 *in vivo*.

The mechanism by which phosphorylation inhibits GSK3 has been elucidated. The phosphorylated N terminus becomes a pseudosubstrate occupying the same binding pocket as the priming phosphate of substrates [14,16]. This suggests that

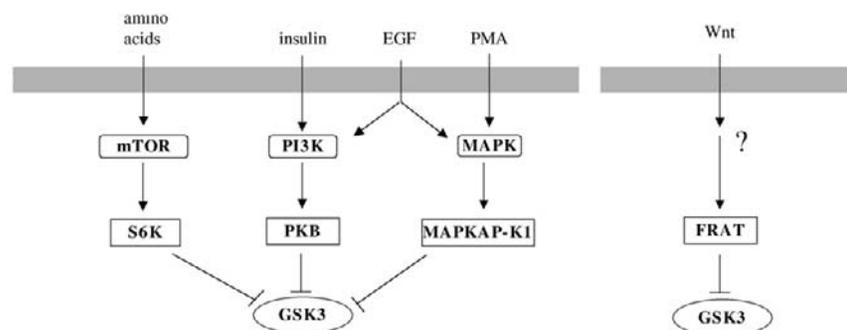

Figure 1 GSK3 can be inhibited by several different agonists. The inhibition of GSK3 by growth factors, amino acids, and hormones, such as insulin, occurs by a different mechanism than does inhibition of GSK3 by Wnts. Protein kinases that are activated by these agonists, such as PKB, MAPKAP-K1, and S6 kinase (S6K), phosphorylate the N terminus of GSK3 on a serine residue (Ser9 of GSK3 β and Ser21 of GSK3 α). In contrast, Wnt signaling does not lead to an increase in Ser9/Ser21 phosphorylation and instead may involve the displacement of Axin and β -catenin from GSK3 via the binding of FRAT and Dishevelled to GSK3.

the extent to which phosphorylation inhibits GSK3 activity *in vivo* may vary between substrates and will depend on the affinity of any particular substrate for GSK3.

GSK3 as a Drug Target

Insulin induces the activation of glycogen synthase, mainly by stimulating the dephosphorylation of the serine residues in glycogen synthase that are targeted by GSK3 [27] and stimulates the activation of eIF2B by promoting the dephosphorylation of Ser535 [9]. These dephosphorylation events, which are likely to be mediated (at least in part) by the PKB-catalyzed inhibition of GSK3, contribute to the insulin-induced stimulation of glycogen and protein synthesis. For these reasons, and because the level of GSK3 is elevated in animal models of diabetes [28], there has been considerable interest over the past few years in trying to identify GSK3 inhibitors for the treatment of Type 2 diabetes. Small-cell-permeant inhibitors of GSK3 have now been developed. These are relatively specific and can activate glycogen synthase and stimulate the conversion of glucose to glycogen in liver cells [29]. Related compounds have also been reported to lower blood glucose levels *in vivo* [30]. The efficacy of these compounds *in vivo* may be partly explained by the finding that they mimic the ability of insulin to repress transcription of the gluconeogenic enzymes phosphoenolpyruvate carboxykinase and glucose-6-phosphatase [31]. Thus, GSK3 appears to play a role in the insulin-regulated transcription of the genes encoding these enzymes, although the underlying molecular mechanism is unknown. In summary, inhibitors of GSK3 may lower the levels of blood glucose *in vivo* by suppressing the production of glucose as well as by enhancing the conversion of glucose to glycogen.

There is considerable evidence that the inhibition of GSK3 triggered by growth factors contributes to the anti-apoptotic effects of these signals. Moreover, lithium ions (which inhibit GSK3 relatively specifically) and the cell-permeant GSK3 inhibitors SB 216763 and SB 415286 protect cerebellar granule neurons from apoptosis resulting from the lowering of the concentration of potassium ions in the medium [32]. The same compounds also protect chicken dorsal-root-ganglion sensory neurons from apoptosis caused by the withdrawal of nerve growth factor from the medium or by the inhibition of NGF-induced PtdIns 3-kinase activity with the compound LY 294002 [32]. Reducing neuronal apoptosis is an important therapeutic goal in the context of head trauma, stroke, epilepsy, and motor neuron disease; therefore GSK3 is also an attractive therapeutic target for the design of inhibitory drugs to treat these diseases.

The Role of GSK3 in Embryonic Development

It is well established that GSK3 plays a key role in embryonic development as a central player in the Wnt signaling pathway. In this pathway, GSK3 is present in a complex that

contains at least three other proteins: Axin, β -catenin, and the adenomatous polyposis coli (APC) protein [33]. Axin acts as a scaffold by binding to GSK3, β -catenin, and APC, while APC also interacts with β -catenin. In this complex, GSK3 is active and phosphorylates Axin, β -catenin and APC. The phosphorylation of Axin stabilizes this protein, while the phosphorylation of APC appears to facilitate its interaction with β -catenin. In contrast, the phosphorylation of β -catenin targets it for destruction by the proteasome. In response to secreted glycoproteins (Wnts), the activity of GSK3 towards Axin and β -catenin is inhibited, resulting in the dephosphorylation of these proteins. The precise molecular mechanism is not fully elucidated but may involve the displacement of Axin (and hence β -catenin and APC) from GSK3 by a protein known as FRAT (frequently rearranged in advanced T-cell lymphomas; also called GSK3-binding protein (GBP) which is complexed to another protein called Dishevelled [34–36] (Fig. 1). The dephosphorylation of β -catenin leads to its stabilization, accumulation, and translocation to the nucleus, where it stimulates the transcription of genes that are critical for embryonic development.

The evidence implicating GSK3 in the Wnt signaling pathway was originally obtained in *Drosophila*, which expresses a single form of GSK3 that is very similar to GSK3 β . For these reasons, it has been widely assumed that GSK3 β is the only isoform that participates in the Wnt signaling pathway in mammalian cells. However, GSK3 β knockout mice develop normally to the late embryonic stage, implying that GSK3 α can compensate for GSK3 β in this pathway. GSK3 β knockout mice die at a late embryonic stage due to liver apoptosis, which appears to be caused by hypersensitivity to the proinflammatory cytokine tumor necrosis factor α [37].

GSK3 and Cancer

Many of the components of the Wnt signaling pathway are over-expressed or mutated in different tumors [38]. For example, virtually all colon tumors arise from an initiating mutation in the APC gene (85%) or in the β -catenin gene (10–15%) that makes β -catenin resistant to degradation. Axin mutations occur in hepatocellular carcinomas and FRAT1 in T-cell lymphomas. Alterations in these components would be predicted to lead to inappropriate accumulation of β -catenin.

These observations have implications for the development of GSK3 inhibitors to treat diabetes and other diseases, as compounds that target the ATP-binding site, such as SB 216763 and SB 415286, inhibit the phosphorylation of all GSK3 substrates, including Axin and β -catenin. They therefore mimic the Wnt signaling pathway and stimulate the accumulation of β -catenin [32]. The development of GSK3 inhibitors that do not have the potential to be oncogenic may therefore require the identification of compounds that prevent the phosphorylation of glycogen synthase but which do not inhibit the phosphorylation of Axin and β -catenin. This may be possible because Axin and β -catenin appear to bind to GSK3 at sites distinct from glycogen synthase

and eIF2B. Mutations in GSK3 have been identified that prevent the phosphorylation of glycogen synthase and eIF2B but not the phosphorylation of Axin and β -catenin, and vice versa [14, 39].

Protein Kinase C: Relaying Signals from Lipid Hydrolysis to Protein Phosphorylation

Alexandra C. Newton

*Department of Pharmacology, University of California at San Diego,
La Jolla, California*

Introduction

Protein kinase C (PKC) has been in the spotlight since the discovery a quarter of a century ago that, through its activation by diacylglycerol, it relays signals from lipid hydrolysis to protein phosphorylation [1]. The subsequent discovery that PKCs are the target of phorbol esters resulted in an avalanche of reports on the effects on cell function of phorbol esters, nonhydrolyzable analogs of the endogenous ligand, diacylglycerol [2–4]. Despite the enduring stage presence of PKC and tremendous advances in understanding the enzymology and regulation of this key protein, an understanding of the function of PKC in biology is still the subject of intense pursuit. Its uncontrolled signaling wreaks havoc in the cell, as epitomized by the potent tumor-promoting properties of phorbol esters. In fact, the pluripotent effects of phorbol esters, compounded with the existence of multiple isozymes of PKC, has made it difficult to uncover the precise cellular function of this key enzyme [5]. Studies with knockout mice have underscored the problem, with knockouts of most isozymes having only subtle phenotypic effects [6]. This chapter summarizes our current understanding of the molecular mechanisms of how protein kinase C transduces information from lipid mediators to protein phosphorylation.

Protein Kinase C Family

The 10 members of the mammalian PKC family are grouped into three classes based on their domain structure, which, in turn, dictates their cofactor dependence (Fig. 1). All members comprise a single polypeptide that has a conserved kinase core carboxyl-terminal to a regulatory moiety. This regulatory moiety contains two key functionalities: an autoinhibitory sequence (pseudosubstrate) and one or two membrane-targeting modules (C1 and C2 domains). The C1 domain binds diacylglycerol and phosphatidylserine specifically and is present as a tandem repeat in conventional and novel PKCs (C1A and C1B); the C2 domain nonspecifically binds Ca^{2+} and anionic phospholipids such as phosphatidylserine. Non-ligand-binding variants of each domain exist: atypical C1 domains do not bind diacylglycerol and novel C2 domains do not bind Ca^{2+} .

Conventional PKC isozymes (α , γ , and the alternatively spliced βI and βII) are stimulated by diacylglycerol and phosphatidylserine (C1 domain) and Ca^{2+} (C2 domain); novel PKC isozymes (δ , ϵ , η/L , θ) are stimulated by diacylglycerol and phosphatidylserine (C1 domain); and atypical PKC isozymes (ζ , ι/λ) are stimulated by phosphatidylserine (atypical C1 domain) [5–7]. (Note that PKC μ and ν were considered to constitute a fourth class of PKCs but are now generally regarded as members of a distinct family

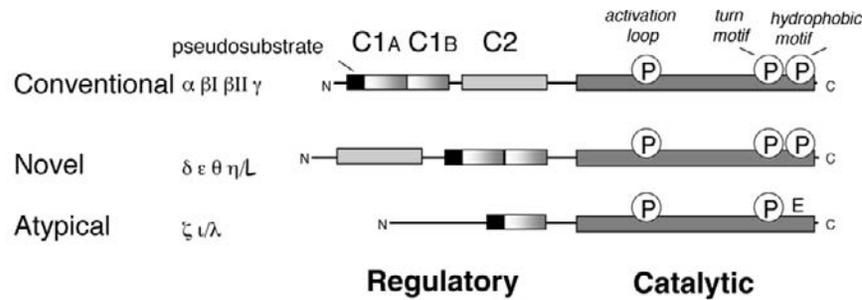

Figure 1 Domain composition of protein kinase C family members showing autoinhibitory pseudosubstrate, membrane-targeting modules (C1A and C1B and C2 domains), and kinase domain of the three subclasses: conventional, novel, and atypical isozymes. Also indicated are the positions of the three processing phosphorylation sites, the activation loop and two carboxyl-terminal sites, the turn motif, and hydrophobic motif. (Adapted from Newton, A. C. and Johnson, J. E., *Biochem. Biophys. Acta*, 1376, 155–172, 1998.)

called protein kinase D.) The role of the novel C2 domain in novel PKCs and that of the atypical C1 domain in atypical PKCs is not clear, but each may regulate the subcellular distribution of these isozymes through protein–protein interactions.

Regulation of Protein Kinase C

The normal function of PKC is under the coordinated regulation of three major mechanisms: phosphorylation/dephosphorylation, membrane targeting modules, and anchor proteins. First, the kinase must be processed by a series of ordered phosphorylations to become catalytically competent. Second, it must have its pseudosubstrate removed from the active site to be catalytically active, a conformational change driven by engaging the membrane-targeting modules with ligand. Third, it must be localized at the correct intracellular location for unimpaired signaling. Perturbation at any of these points of regulation disrupts the physiological function of PKC [7].

Phosphorylation/ Dephosphorylation

The function of PKC isozymes is controlled by phosphorylation mechanisms that are required for the maturation of the enzyme. In addition to the processing phosphorylations, the function of PKC isozymes is additionally fine-tuned by both Tyr and Ser/Thr phosphorylations [8,9]. The conserved maturation phosphorylations are described below.

PHOSPHORYLATION IS REQUIRED FOR THE MATURATION OF PROTEIN KINASE C

The majority of PKC in tissues and cultured cells is phosphorylated at two key phosphorylation switches: a loop near the active site, referred to as the *activation loop*, and a sequence at the carboxyl terminus of the kinase domain [10,11]. The carboxyl-terminal switch contains two sites: the turn motif, which by analogy with protein kinase A is at the apex of a turn on the upper lobe of the kinase domain, and the hydrophobic motif, which is flanked by hydrophobic

residues (note that, in atypical PKCs, a Glu occupies the phospho-acceptor position of the hydrophobic motif). It is the phosphorylated species that transduces signals. While it had been appreciated since the late 1980s that PKC is processed by phosphorylation [12], the mechanism and role of these phosphorylations are only now being unveiled [7,9].

The first step in the maturation of PKC is phosphorylation by the phosphoinositide-dependent kinase, PDK-1, of the activation loop. This enzyme was originally discovered as the upstream kinase for Akt/protein kinase B [13] and was subsequently shown to be the activation loop kinase for a large number of AGC kinases, including all PKC isozymes [14–16]. The name PDK-1 was based on the phosphoinositide-dependence of Akt phosphorylation and is an unfortunate misnomer because the phosphorylation of other substrates (for example, the conventional PKCs) has no dependence on phosphatidylinositol 3-kinase (PI3K) lipid products [17]. Rather, PDK-1 appears to be constitutively active in the cell, with substrate phosphorylation regulated by the conformation of the substrate [18–20].

Completion of PKC maturation requires phosphorylation of the two carboxyl-terminal sites, the turn motif and hydrophobic motif. In the case of conventional PKCs, this reaction occurs by an intramolecular autophosphorylation mechanism [21]. Autophosphorylation also accounts for the hydrophobic motif processing of the novel PKC ϵ [22]; however, it has been suggested that another member of this family, PKC δ , may be the target of a putative hydrophobic motif kinase [23].

Research in the past few years has culminated in the following model for PKC phosphorylation. Newly synthesized enzyme associates with the plasma membrane, where it adopts an open conformation with the pseudosubstrate exposed, thus unmasking the PDK-1 site on the activation loop [17,24]. It is likely held at the membrane by multiple weak interactions with the exposed pseudosubstrate, the C1 domain, and the C2 domain (because the C1 and C2 ligands are absent, these domains are weakly bound via their interactions with anionic phospholipids). PDK-1 docks onto the carboxyl terminus of PKC, where it is positioned to phosphorylate the activation loop [25]. This phosphorylation is

the first and required step in the maturation of PKC; mutation of the phospho-acceptor position at the activation loop to Ala or Val prevents the maturation of PKC and results in accumulation of unphosphorylated, inactive species in the detergent-insoluble fraction of cells [26,27].

Completion of PKC maturation requires release of PDK-1 from its docking site on the carboxyl terminus. Physiological mechanisms for this release have not yet been elucidated, but it is interesting that over-expression of peptides that have a high affinity for PDK-1 promotes the maturation of PKC [25]. One such peptide is PIF, the carboxyl-terminus of PRK-2, which has a hydrophobic phosphorylation motif with a Asp at the phospho-acceptor position [28]. Release of PDK-1 unmasks the carboxyl terminus of PKC, allowing phosphorylation of the turn motif and the hydrophobic motif [7,10].

DEPHOSPHORYLATION: DEACTIVATION SIGNAL

While the phosphorylation of conventional PKCs is constitutive, the dephosphorylation appears to be agonist stimulated [29]. Both phorbol esters and ligands such as tumor necrosis factor α (TNF α) result in PKC inactivation and dephosphorylation [29–31]. In addition, serum selectively promotes the dephosphorylation of the activation loop site in conventional PKCs, thus uncoupling the phosphorylation of the activation loop from that of the carboxyl-terminal sites [17]. The hydrophobic site of PKC ϵ has also been reported to be selectively dephosphorylated by a rapamycin-sensitive phosphatase [32]. It is likely that the uncoupling of the dephosphorylation of these sites has contributed to confusion as to whether the hydrophobic site is regulated by its own upstream kinase rather than autophosphorylation [23].

Membrane Translocation

The translocation from the cytosol to the membrane has served as the hallmark for PKC activation since the early 1980s [33,34]. The molecular details of this translocation have emerged from abundant biophysical, biochemical, and cellular studies showing that diacylglycerol acts like molecular glue to recruit PKC to membranes, an event that, for conventional PKCs, is facilitated by Ca²⁺ [35–37].

Both *in vitro* and *in vivo* data converge on the following model for the translocation of conventional PKC in response to elevated Ca²⁺ and diacylglycerol [35,38]. In the resting state, PKC bounces on and off membranes by a diffusion-limited reaction. However, its affinity for membranes is so low that its lifetime on the membrane is too short to be significant. Elevation of Ca²⁺ results in binding of Ca²⁺ to the C2 domain of this soluble species of PKC. This Ca²⁺-bound species has a dramatically enhanced affinity for the membrane, with which it rapidly associates. The membrane-bound PKC then diffuses in the two-dimensional plane of the membrane, searching for the much less abundant ligand, diacylglycerol. This search for diacylglycerol is considerably more efficient from the membrane than one initiated from the cytosol. Following collision with, and binding to, diacylglycerol, PKC is bound to the membrane with sufficiently

high affinity to allow release of the pseudosubstrate sequence and activation of PKC. Decreases in the level of either second messenger weaken the membrane interaction sufficiently to release PKC back into the cytosol. Note that if PMA is the C1 domain ligand, PKC can be retained on the membrane in the absence of elevated Ca²⁺ because this ligand binds PKC two orders of magnitude more tightly than diacylglycerol [39]. Similarly, if Ca²⁺ levels are elevated sufficiently, PKC can be retained at the membrane in the absence of a C1 ligand.

Novel PKC isozymes translocate to membranes much more slowly than conventional PKCs in response to receptor-mediated generation of diacylglycerol because they do not have the advantage of pre-targeting to the membrane by the soluble ligand, Ca²⁺ [40]. Atypical PKC isozymes do not respond directly to either diacylglycerol or Ca²⁺.

Anchoring Proteins

The control of subcellular localization of kinases by scaffold proteins is emerging as a key requirement in maintaining fidelity and specificity in signaling by protein kinases [41]. PKC is no exception, and a battery of binding partners for members of this kinase family have been identified [42–45]. These proteins position PKC isozymes near their substrates, near regulators of activity such as phosphatases and kinases, or in specific intracellular compartments. Disruption of anchoring can impair signaling by PKC, and *Drosophila* photoreceptors provide a compelling example. Mislocalization of eye-specific PKC by abolishing its binding to the scaffold protein, ina D, disrupts phototransduction [46].

Unlike protein kinase A binding proteins (AKAPs) [47], there is no consensus binding mechanism for interaction of PKC with its anchor proteins. Rather, each binding partner identified to date interacts with PKC by unique determinants and unique mechanisms. Some binding proteins regulate multiple PKC isozymes, while others control the distribution of specific isozymes. There are binding proteins for newly synthesized unphosphorylated PKC, phosphorylated but inactive PKC, phosphorylated and activated PKC, and dephosphorylated, inactivated PKC [43,45]. Anchoring proteins for PKC have diverse functions—some positively regulate signaling while others negatively regulate it. An emerging theme is that many scaffolds bind multiple signaling molecules in a signaling complex; for example, AKAP 79 binds PKA, PKC, and the phosphatase calcineurin [48]. The physical coupling of kinases and phosphatases underscores the acute regulation that each must be under to maintain fidelity in signaling.

Model for Regulation of Protein Kinase C by Phosphorylation and Second Messengers

Figure 2 outlines a model for the regulation of PKC by phosphorylation, second messengers, and anchoring proteins. Newly synthesized PKC associates with the membrane in a conformation that exposes the pseudosubstrate

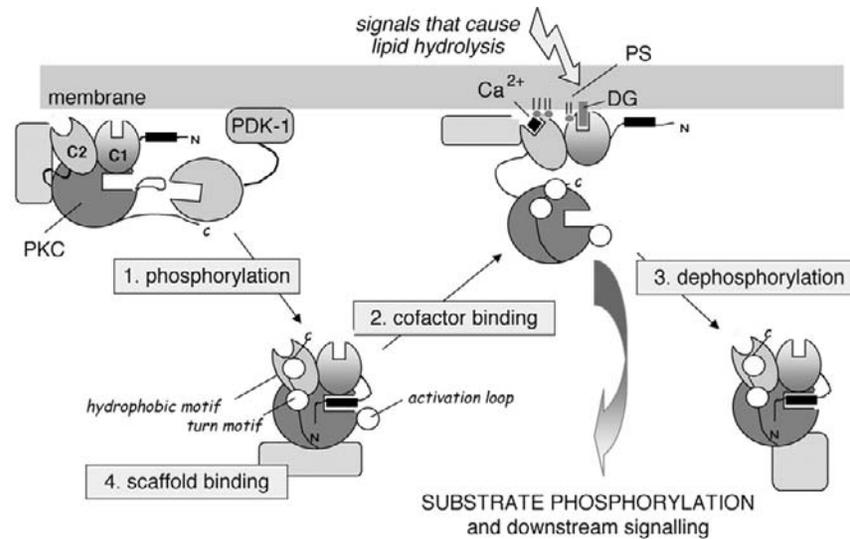

Figure 2 Model showing the major regulatory mechanisms for PKC function: (1) processing by phosphorylation, (2) activation by lipid mediators, (3) deactivation by dephosphorylation, and (4) spatial control by scaffold proteins. See text for details. (Adapted from Newton, A. C., *Chem. Rev.*, **101**, 2353–2364, 2001.)

(black rectangle), allowing access of the upstream kinase, PDK-1, to the activation loop. PDK-1 docks onto the carboxyl terminus of PKC. Following its phosphorylation of the activation loop and release from PKC, the turn motif and hydrophobic motif are autophosphorylated. The mature PKC is released into the cytosol, where it is maintained in an auto-inhibited conformation by the pseudosubstrate (middle panel), which has now gained access to the substrate-binding cavity (open rectangle in the large circle representing the kinase domain of PKC). It is this species that is competent to respond to second messengers. Generation of diacylglycerol and, for conventional PKCs, Ca²⁺ mobilization provide the allosteric switch to activate PKC. This is achieved by engaging the C1 and C2 domains on the membrane (Fig. 2, right panel), thus providing the energy to release the pseudosubstrate from the active site, allowing substrate binding and catalysis. In addition to the regulation by phosphorylation and cofactors, anchoring/scaffold proteins (stippled rectangle) play a key role in PKC function by positioning specific isoforms at particular intracellular locations [43,45]. Following activation, PKC is either released into the cytosol or, following prolonged activation, dephosphorylated and downregulated by proteolysis.

Function of Protein Kinase C

Despite over two decades of research on the effects of phorbol esters on cell function, a unifying mechanism for the role of PKC in the cell has remained elusive. An abundance of substrates have been identified, and the reader is referred to reviews summarizing these and potential signaling pathways involving PKC [5,6,49–52]. However, a unique role for PKC in defining cell function is lacking. This is epitomized

by the finding that there is no severe phenotype associated with knocking-out specific PKC isoforms in mice.

Closer analysis of the phenotypes of knockout animals of various PKC isoforms does suggest a common theme: animals deficient in PKC are deficient in adaptive responses. For example, PKC ϵ ^{-/-} mice have reduced anxiety and reduced tolerance to alcohol [53], PKC γ ^{-/-} mice have reduced pain perception [54], and PKC β II^{-/-} mice have reduced learning abilities [55]. This theme carries over to the molecular level, where many of the substrates of PKC are receptors that become desensitized following PKC phosphorylation.

Summary

PKC plays a pivotal role in cell signalling by relaying information from lipid mediators to protein substrates. The relay of this information is under exquisite conformational, spatial, and temporal regulation, and extensive studies on the molecular mechanisms of this control have provided much insight into how PKC is regulated. With novel approaches in chemical genetics, analysis of crosses of PKC isoform knockout mice, and proteomics, the PKC signaling field is poised to move to the next level of making headway into the *raison d'être* of this ubiquitous family of kinases.

Introduction

In the mid-1990s, a series of cloning papers announced the arrival of the phosphatidylinositol 3-kinase (PI3K)-related protein kinase (PIKK) family of proteins [1,2]. These reports and subsequent studies revealed two defining features of this protein family. First, all known members are very large, being between 280 and 470 kDa in size. Second, despite being protein serine/threonine kinases, the kinase domains of PIKK family members are markedly different from those of other protein serine/threonine or tyrosine kinases and, instead, are more related in sequence (≈ 20 to 25% identity) to the kinase domain of the PI3K family of phospholipid kinases. Members of the PI3K family play diverse roles in intracellular signaling triggered by mitogenic and other stimuli through phosphorylating the inositol ring of phosphatidylinositol derivatives, thus generating second messengers for downstream effector pathways [3]. Nevertheless, the available evidence indicates that PIKK family proteins have specificity toward proteins rather than lipid targets. Although the primary specificities of the PIKK and PI3K families therefore appear to be different, it is likely that they bring about catalysis by very similar mechanisms.

Over the past few years, it has become clear that members of the PIKK family exist in all eukaryotes studied, although none has so far been found in prokaryotes. Six human PIKK family members have been identified to date, and genome scanning suggests that this number is unlikely to increase. Since publication of the original biochemical and cloning papers of the PIKKs, extensive research on the

members of this family of kinases has taken place, leading to significant insights into their biological roles and biochemical functions. One emerging unifying concept for this class of kinases is that they may directly, or indirectly through partner proteins, be involved in monitoring or modulating of polynucleic acids. Here, we provide an overview of the PIKK family with particular emphasis on the human proteins.

Overview of PIKK Family Members

Members of the PIKK family are involved in a diverse set of biological functions. The DNA-dependent protein kinase catalytic subunit (DNA-PKcs) plays a crucial role in site-specific V(D)J recombination in the developing immune system and in the nonhomologous end-joining (NHEJ) pathway of DNA repair [4]. The protein product of the gene mutated in ataxia-telangiectasia (ATM) and the ATM Rad3-related (ATR) protein have key roles in the signaling of DNA damage [5–7]. SMG-1, originally identified in a *Caenorhabditis elegans* screen as a suppressor of morphogen gradient, is involved in the process of nonsense-mediated RNA decay (NMD) [8], while the mammalian target of rapamycin (mTOR; also termed FRAP or RAFT) is involved in controlling cellular growth in response to nutrients and amino acids by playing a pivotal role in controlling the translational machinery [9,10]. Another member of the PIKK family, TRRAP (transformation/transcription associated protein), is an essential cofactor for

both the c-MYC and the E1A/E2F transcription factor pathways through its interactions with the SAGA and PCAF histone acetyltransferase complexes [11–14].

Overall Architecture of PIKK Family Proteins

Figure 1 illustrates the domain architecture of the PIKK family. The PIKK kinase domain is located within the carboxy-terminal, ≈ 400 -amino-acid residues of these proteins, with the exception of hSMG-1, whose kinase domain lies more centrally within the polypeptide. Consistent with the crystal structure of the kinase domain of porcine PI3K (p110 γ), which shows gross overall structural similarity to the structures of classical protein Ser/Thr kinases [15], the kinase domains of PIKK family members generally contain residues that can be aligned with those playing key roles in adenosine triphosphate (ATP) coordination in other classes of kinase. A notable exception to this is TRRAP, which does not contain the DXXXXN and DFG motifs that are critical for ATP coordination within a kinase catalytic site [11]. The available data suggest that this renders the kinase domain of TRRAP catalytically inactive [14]. Nevertheless, the significant sequence homology between the C-terminal region of TRRAP and other members of the PIKK family suggests that this region of TRRAP will retain the overall structural features of the PIKK kinase domain.

In all cases, the kinase active site of PIKK family proteins is flanked N-terminally by a region of ≈ 500 -amino-acid residues, which has been named the FAT domain (derived from FRAP, ATM, and TRRAP) and C-terminally by a small (≈ 35 -amino-acid residue) FAT C-terminal (FAT-C) domain [16]. To date, FAT and FAT-C domains have only been found in proteins in combination. No function has been ascribed to these domains but they could be involved in intermolecular protein–protein interactions. Alternatively, they could modulate kinase activity either by intramolecular interactions with the PIKK kinase domain or by binding kinase substrates and thus bringing them into the proximity of the ATP binding site. Notably, the FAT-C domain found in SMG-1 is separated from the kinase domain by almost 1200 amino acid residues. Nevertheless, it is possible that these regions come together in the protein tertiary structure [8].

In mTOR, conserved HEAT repeats are found in two groupings in the first half of the protein [9]. The HEAT repeat is a tandemly repeated module of 37 to 47 amino acid residues

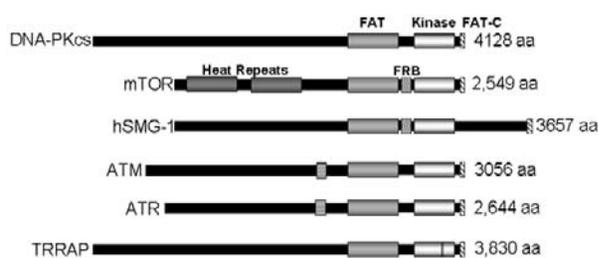

Figure 1 The domain architecture of the PIKK family; human proteins are shown (see text for details).

occurring in a range of cytoplasmic proteins (which include the four proteins from which the acronym was derived: Huntingtin, EF3, the alpha regulatory subunit of PP2A, and TOR). These motifs may be involved in protein–protein interactions within multiprotein complexes [17]. The FRB (FKBP12–rapamycin binding) domain has so far been found only within the mTOR and SMG-1 sequences [8,9]. When bound to this region of mTOR, the FKBP12–rapamycin complex is able to inhibit mTOR function [9]. The crystal structure of this beta-barrel-like domain in a complex with the rapamycin–immunophilin complex has been solved [18]. Other than this clearly soluble and surface domain of mTOR, no truly distinct or soluble domains have so far been identified in other members of the PIKK family. Finally, a small region of homology between ATM and ATR upstream of the FAT domain has been noted [6].

mTOR: A Key Regulator of Cell Growth

The first member of the PIKK family to be cloned was the target of rapamycin (TOR), which was identified through a yeast screen to identify mutants that were resistant to the growth inhibitory effect of rapamycin [19]. The mammalian protein is termed mTOR, FRAP (FKBP–rapamycin associated protein), and also RAFT (rapamycin and FKBP target) [20–23]. Recent research has indicated that mTOR is a central controller of cell growth. By targeting mTOR, rapamycin blocks T cells in the G₁ phase of the cell cycle [9]. This prevents T-cell activation and proliferation in response to mitogenic stimuli and results in immunosuppression [10]. Signaling to mTOR is thought to be mediated, in part, by activation of a PI3K-dependent pathway that may involve PKB/Akt (Fig. 2). Once activated, mTOR is believed to modulate cap-dependent translation and ribosome biogenesis through phosphorylation and regulation of 4E-BP1 and S6 kinase, respectively [9,10]. The TOR proteins have also been shown to be somehow involved in controlling other sets of cellular growth events including transcription, actin organization, membrane traffic, and protein degradation [9,10]. mTOR is also now regarded as an attractive target for chemostatic anticancer therapy, and an ester derivative of rapamycin (CCI-779) is currently undergoing evaluation as an anticancer agent [24].

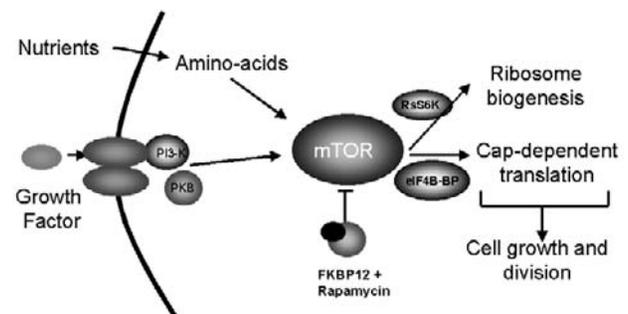

Figure 2 A model of mTOR signaling pathways that modulate translational control as elucidated from studies on mammalian cells.

DNA-PKcs: At the Heart of the DNA Nonhomologous End-Joining Machinery

Along with the high-affinity DNA end-binding protein Ku, DNA-PKcs forms the heterotrimeric holoenzyme termed DNA-dependent protein kinase (DNA-PK) [4,25]. DNA-PK was initially identified biochemically as a relatively abundant nuclear protein whose serine/threonine kinase activity is greatly stimulated by linear double-stranded DNA [4]. Subsequently, a series of radiosensitive mutant cell lines defective in DNA double-strand break repair were found to possess mutations in DNA-PKcs or in one of the two Ku subunits [26]. Thus, DNA-PKcs now has a clearly established role in the NHEJ pathway of DNA double-strand break repair. The immune-deficiency of mice lacking functional DNA-PK is due to a defect in V(D)J recombination—a cut-and-paste genome rearrangement process that occurs in developing B and T lymphocytes to generate the antigen-binding diversity of the immunoglobulin and T-cell receptor genes, respectively [27].

Recently, it has become clear that DNA-PK is also physically localized to telomeres, the physical caps at the ends of linear eukaryotic chromosomes, and functions there to help prevent the formation of chromosomal end-to-end fusions [28]. Importantly, the kinase activity of DNA-PKcs is essential for its biological functions [29]. When it becomes assembled at a DNA double-strand break, DNA-PK is believed to recruit and/or phosphorylate additional NHEJ factors, such as DNA ligase IV/XRCC4 and the recently identified Artemis protein, to bring about repair of the lesion (Fig. 3) [30,31]. Another *in vivo* target for DNA-PK that has been identified recently is interferon regulatory factor-3 (IRF-3), which is phosphorylated by DNA-PK during paramyxovirus infection [32].

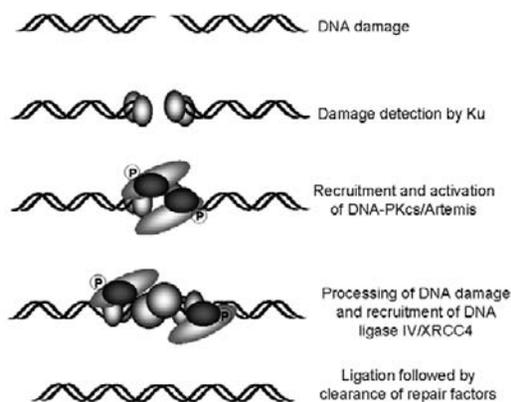

Figure 3 Model of NHEJ. Upon induction of a DNA double-strand break, the high-affinity DNA end-binding protein Ku is targeted to the site of damage. Ku end binding then permits the recruitment and activation of DNA-PKcs along with the newly identified Artemis. This complex is then believed to act as a scaffold at the site of damage and, through Artemis activation via DNA-PK phosphorylation, process the DNA ends for subsequent ligation by the DNA-ligase IV/XRCC4 complex. Once ligation is complete the complex is cleared from the site of damage by an unknown mechanism that may involve DNA-PK-mediated phosphorylation.

ATM and ATR: Signalers of Genome Damage

A homozygous deficiency of ATM in humans leads to ataxia-telangiectasia (A-T), a debilitating disorder in which progressive loss of motor coordination (ataxia) is brought about by the gradual loss of Purkinje cells in the cerebellum [33]. In addition, A-T patients have an increased cancer incidence, and cells derived from these individuals are hypersensitive to ionizing radiation and to chemical agents that induce DNA double-strand breaks [33]. Notably, whereas normal cells delay progression through the cell cycle after treatment with such agents, A-T cells are defective in these “checkpoint” responses [5,6]. Indeed, A-T cells are deficient in the G₁/S, G₂/M, and S phase checkpoints. Over the past few years, a large number of research papers have addressed these checkpoint defects and it is now clearly established that ATM phosphorylates, and therefore appears to modulate the activities of, the key cell-cycle control proteins p53, BRCA1, NBS1, MDM2, RAD17, and CHK2. Recent review articles give a clear and detailed analysis of downstream targets of ATM [5,6].

Unlike ATM, which appears to be primarily involved in responding to DNA DSBs, ATR acts to delay cell-cycle progression in response to other types of DNA damage, such as those induced by ultraviolet light. It also has a particularly important role in recognizing DNA damage or difficulties in genome replication during S phase [6,7]. Loss of ATR function leads to early embryonic lethality in mice, and ATR-deficient cells are incapable of successfully traversing S phase in culture. Although these phenotypes have highlighted the crucial role of ATR in genome maintenance, they have hampered studies to understand the precise functions of this enzyme. Nevertheless, by the use of cell lines over expressing a kinase-dead ATR, the functions of ATR in cellular responses to DNA damage produced by ultraviolet or infrared light and to DNA replication inhibitors has been established [34,35]. *In vivo* targets for ATR include p53, RAD17, BRCA1, and CHK1 [6]. Orthologs of both ATM and ATR have been identified in all eukaryotic species so far analyzed. In particular, work on the ATR orthologs in the genetically amenable organisms *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe* (Mec1p and Rad3, respectively) has been enormously helpful in elucidating the functions of these PIKKs in DNA-damage sensing and signaling [36].

SMG-1: A Regulator of Nonsense-Mediated mRNA Decay

The most recently cloned and probably the final member of the PIKK family is SMG-1, which plays a key role in the regulation of nonsense-mediated RNA decay (NMD) [8,37]. NMD serves to recognize and eliminate mRNA species that contain premature translation termination codons and thus code for nonfunctional or potentially harmful polypeptides [38]. It seems that SMG-1 is able to associate with other components of the mRNA surveillance pathway and,

in particular, acts to directly phosphorylate one of these proteins, hUPF1/SMG-2 [8]. Inhibition of SMG-1 by over-expression of a kinase-dead SMG-1 or by inhibition using small molecule inhibitors results in a marked suppression of the degradation of mRNAs with premature stop codons and an increase in truncated protein production [8].

TRRAP: A Crucial Transcriptional Co-Activator

TRRAP was first identified through its interaction with the N terminus of the product of the c-MYC oncogene and with the E2F-1 transcriptional activation domain, suggesting that TRRAP is an essential cofactor for both the c-MYC and E1A/E2F oncogenic transcription factor pathways [11]. Work in mammalian cells and in *S. cerevisiae* has shown that TRRAP (Tra1p in yeast) acts as a transcriptional cofactor that recruits histone acetyltransferase (HAT) complexes to sequence-specific transcriptional activators [12–14]. TRRAP appears not to act as a protein kinase, and its primary amino-acid sequence gives clues as to why this is the case [11]. However, the kinase domain has been shown to have a key noncatalytic role in that it is required for forming a structural core for the assembly of a functional HAT complex [39]. Null mutation of TRRAP has shown it to be essential for early mouse development and has revealed that it functions in the mitotic checkpoint and during normal cell-cycle progression [40].

PIKK Family Members as Guardians of Nucleic Acid Structure, Function, and Integrity?

It has been proposed that a common feature of the PIKK family may be an ability to interact with nucleic acids [41,42]. This is clearly established for DNA-PKcs, which stably binds to DNA upon interacting with DNA-bound Ku. Through this DNA–protein–protein interaction, the protein kinase potential of DNA-PK is released [4,25]. A role for DNA-PKcs in binding to telomeres has also been proposed [28]. In addition, ATM has been shown to bind *in vitro* to DNA with a preference for DNA termini or DNA that has been treated with ionizing radiation [43,44]. Also, within minutes of treating cells with ionizing radiation, ATM kinase activity is significantly increased [45,46] and the protein becomes associated with chromatin [47]. Likewise, stimulation of ATR activity by DNA *in vitro* has been observed [48,49], suggesting a direct interaction with DNA or potentially an indirect interaction through its newly discovered partner ATRIP [50]. Indeed, recent work has revealed that the *S. cerevisiae* ATR ortholog, Mec1p, is recruited to sites of DNA damage by Lcd1p, an ortholog of ATRIP [51]. SMG-1 is involved in cellular responses to mRNAs with premature termination codons, raising the possibility that it may be targeted to such mRNAs in order to modulate the process of NMD [8]. TRRAP acts as a scaffold for the SAGA/histone deacetylase complex and hence

may interact with packaged DNA to allow the chromatin-modulating enzymes with which it is associated to access their substrates. Finally, a mechanism has been proposed whereby mTOR senses amino-acid levels via its ability to detect the amino-acylation status of tRNAs [41]. Whether directly or indirectly through a protein partner, there is a growing body of evidence that PIKKs somehow detect and respond to cellular polynucleic acids. Could this activity be found in the N-terminal portions of these proteins that show no detectable sequence homologies with each other, thus representing a new set of nucleic acid binding domains?

University of Oklahoma, Norman, Oklahoma*

Autophosphorylating histidine protein kinases are predominantly found in bacterial organisms and to a more limited extent in archaeobacteria and nonvertebrate eukaryotic organisms where they function in two-component signal transduction pathways. These signaling systems typically consist of a sensor histidine kinase (HK) and a response regulator (RR) (Fig. 1A). HKs are responsive to extracellular stimuli and can undergo adenosine triphosphate (ATP)-dependent autophosphorylation of a conserved histidine residue. The phosphoryl group is then transferred to a conserved aspartic acid residue in the RR protein, which then acts as a molecular switch for activating an associated effector domain or triggering downstream signaling events. A large majority of RRs contain C-terminal effector domains that have DNA-binding activity and thus function in regulating gene expression. In some cases, expanded versions of the two-component system have evolved whereby additional response regulator domains and histidine-containing phosphotransfer (HPT) proteins have been incorporated, thus forming a multistep phosphorelay (Fig. 1B). It has been estimated that nearly 20% of all HKs are hybrid proteins that have a RR domain fused at the C-terminus [1]. These additional signaling modules presumably allow for more regulatory checkpoints and flexibility of the signaling pathway.

The importance of two-component regulatory systems is illustrated by the wide variety of essential cellular processes that are governed by HKs and RRs. In bacteria, for example, two-component systems regulate cell–cell communication, cell differentiation, pathogenesis, and adaptive responses to environmental stress. In plants, fungi, and slime molds, multistep histidine-to-aspartate phosphorelay systems play important regulatory roles in hormone signaling pathways, stress responses, virulence, cell-cycle progression, and cell differentiation. Our aim here is to provide an overview regarding the general functional properties and structural organization

of histidine protein kinases. We also refer the interested reader to several recent review articles [1–6] and monographs [7,8] that more comprehensively cover the subject of HKs and their role in two-component signal transduction systems.

A large majority of HKs are multidomain, membrane-bound proteins, which contain an N-terminal extracellular sensing domain and a cytoplasmic kinase domain. In contrast to many eukaryotic receptor tyrosine kinases that are induced to form dimers upon ligand binding, sensor HKs exist in a dimeric state within the bacterial inner membrane or plasma membrane of eukaryotic cells. The transmembrane signaling mechanism is proposed to involve a conformational change that affects juxtaposition of the two monomers relative to each other, which in turn affects kinase or phosphotransfer activities of the HK. It should be noted that not all HKs are associated with membranes; rather, there are also soluble cytoplasmic HKs that lack transmembrane spanning regions but interact with membrane-bound, receptor-like proteins. ATP-dependent phosphorylation of the HK monomers occurs intermolecularly. Subsequently, the phosphoryl group is transferred to a downstream RR. Some HKs have also been shown to exhibit phosphatase activity toward their cognate RR proteins. Thus, HKs can have at least three to four functional roles: sensory perception, autophosphorylation, phosphoryl transfer, and RR phosphatase activity. The effect of external stimuli on HK function can be to alter the rate of autophosphorylation or affect the relative ratios between autokinase, phosphotransfer, and RR phosphatase activities. Regardless of the particular mode of HK regulation, the net result is a change in the level of phosphorylated RR in the cell and the output response is elicited.

Histidine kinases can be identified on the basis of sequence similarities and to date comprise a large superfamily of more than 350 proteins [1,9,10]. HKs typically have two (or more)

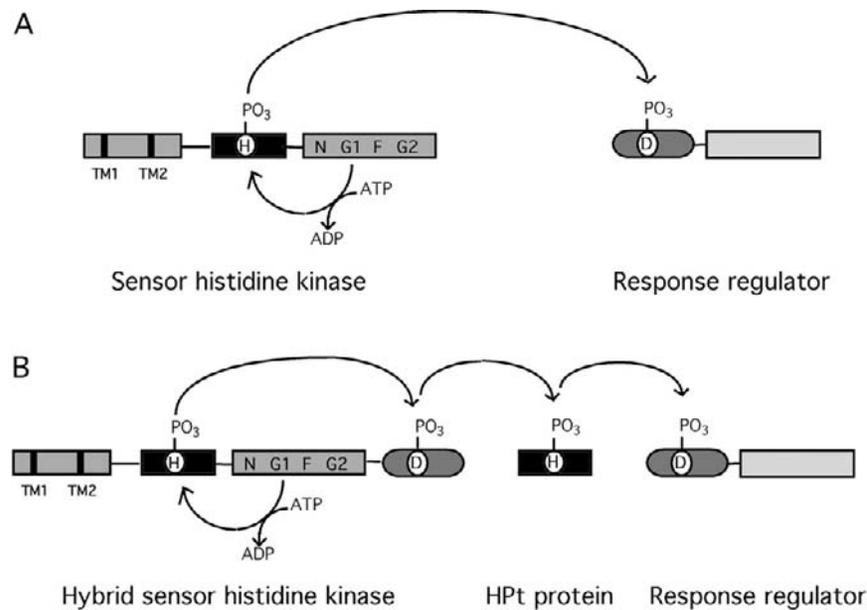

Figure 1 Two-component phosphotransfer systems. (A) Simple two-component phosphotransfer systems consist of a homodimeric membrane-bound sensor histidine kinase (shown here as a monomer) and a response regulator. The histidine kinase (with transmembrane segments indicated as TM1 and TM2) autophosphorylates on a conserved histidine (H) residue using ATP. The phosphoryl group (PO_3^{2-}) is then transferred to a conserved aspartic acid (D) residue in the cognate response regulator. The output response of the signaling pathway is regulated by phosphorylation/dephosphorylation of the response regulator protein. (B) Multistep phosphorelay systems often consist of a hybrid HK that contains an additional response regulator domain at the C terminus and a histidine-containing phosphotransfer (HPT) protein that signals to a downstream response regulator protein.

N-terminal membrane-spanning regions that effectively place a sensing domain outside the cell. As might be expected, the sequences of the sensing domains vary considerably, which is indicative of the wide variety of signals perceived by different HKs. Several conserved sequence motifs can be found within the cytoplasmic domains of HKs, and these are designated the H, N, G1, F, and G2 boxes [11,12]. The H box contains the phosphorylatable histidine residue, which is often found within the dimerization domain, whereas the N, G1, F, and G2 boxes are the hallmarks of the kinase domain and comprise the ATP-binding site. The linker region between the transmembrane domain and the cytoplasmic H box is predicted to form a coiled-coil structure consisting of two amphipathic helices (also known as a HAMP domain) [13]. This region has been demonstrated to be critical for signal transmission and most likely affects intermolecular and/or domain-domain interactions [14–16].

Three-dimensional structure information is available for domains of two HK proteins, the bacterial osmosensor EnvZ and the bacterial chemotaxis protein CheA, and has revealed several similarities and differences among HK proteins [17–20]. The histidine kinase domain is structurally distinct from other kinases for which structural information is available. However, the histidine kinase domain resembles other proteins that catalyze ATP hydrolysis such as DNA topoisomerase II, the chaperone Hsp90, and the DNA mismatch repair enzyme MutL [21,22]. Several structures are now available for full-length RR proteins and even activated RRs, but

full-length HKs have posed significant problems for structural biologists due to their multidomain architecture and membrane localization [4].

Chemically, phosphorylated histidines are one of the least stable of the known phosphoamino acids. Phosphorylation of the histidine residue in HKs results in the formation of a high-energy phosphoramidate (N–P) bond. In contrast, phosphorylation of hydroxyamino acids such as serine, threonine, and tyrosine results in formation of relatively stable phosphoester (O–P) bonds. The large standard free energy of hydrolysis of the N–P bond helps to explain why phosphohistidine-containing proteins are ideal as phosphodonors in two-component signaling pathways, bacterial sugar-phosphate transport systems, and as phosphoenzyme intermediates [6,23,24]. Phosphorylation of the aspartic acid residues in response regulators also produces a high-energy acyl phosphate linkage, and it has been proposed that this energy is used to drive long-range conformational changes in proteins [25].

Overall, HKs function to modulate the level of phosphorylation of their cognate RRs in response to environmental stimuli; therefore, a discussion of HKs would be incomplete without at least a brief description of RRs. Most RRs have a two-domain architecture in which an N-terminal regulatory domain controls the activity of a C-terminal effector domain in a phosphorylation-dependent manner. The majority of bacterial RRs have effector domains that specifically bind DNA and, therefore, function to activate or repress gene transcription.

These can be further divided into OmpR, NarL, NtrC, and LytTR subfamilies based on phylogenetic relatedness of the DNA-binding domain [26–28]. Other RRs have effector domains with enzymatic activity—for example, the methyltransferase CheB [29] and the cAMP-dependent phosphodiesterase RegA [30]. Some RRs, like the chemotaxis protein CheY, do not have an effector domain but rather signal to downstream effector proteins via protein–protein interactions.

Extensive biochemical and structural characterization of RR proteins have revealed some general features and functional properties of the conserved regulatory domain (also referred to as a receiver domain) [4]. These domains consist of about 125 amino acid residues and have a common doubly wound $\beta_5\alpha_5$ tertiary fold that supports an active site composed of several highly conserved carboxylate-containing side chains and an invariant lysine. The regulatory domain catalyzes phosphoryl group transfer from the phosphohistidyl residue of the cognate HK (or HPT protein) to a conserved aspartyl side chain within the active site of the RR in a Mg^{2+} -dependent manner. RR proteins most likely exist in a dynamic equilibrium between two (or possibly more) conformational states, and phosphorylation is thought to affect this equilibrium by promoting or stabilizing one particular conformation, the activated state. In some cases, such as CheB and PhoB, phosphorylation of the RR relieves inhibitory interactions between the regulatory and effector domains [31,32]. For other RRs, phosphorylation serves to increase the affinity of the RR for DNA, promote RR dimerization, or affect downstream protein–protein interactions. The phosphorylated lifetimes of RRs can vary substantially from one another, often reflecting the duration of the cellular response. RRs have an intrinsic (or self-catalyzed) phosphate hydrolysis rate, which in some cases can be influenced by auxiliary protein phosphatases. In addition, some RRs are subject to HK-catalyzed dephosphorylation.

Although HKs and RRs have been studied extensively and some two-component systems are well understood at the biochemical and structural levels, there are many unanswered questions in the field. For example, what is the mechanism of transmembrane signal transmission? How are different HKs regulated? How are signals transmitted and processed within individual two-component signaling systems? How do cognate HK and RR pairs interact with each other? These questions will undoubtedly be answered through combinatorial and interdisciplinary approaches. Given the vast number of critical processes that two-component signaling pathways control in the cell, HKs and RRs will continue to be a popular subject of many investigators in the years to come.

Introduction

The “classical” family of protein kinases represents one of the largest eukaryotic protein superfamilies, with at least 500 distinct members that are involved in a wide variety of roles in signal transduction [1]. These enzymes, which phosphorylate serine, threonine, and tyrosine residues, contain a conserved catalytic domain of ≈ 300 amino acids that is easily recognized by the presence of conserved motifs (20–40% amino acid identity). Based initially on the detailed structural analysis of protein kinase A [2] and now extended by the determination of the crystal structures of many catalytic domains [3], a great deal of information is available concerning the conserved fold of this enzyme class and the catalytic mechanism. In addition, a significant amount is known about the structural features that define their substrate specificity and individual functions.

Despite the knowledge that other structurally distinct proteins in eukaryotic genomes could catalyze protein phosphorylation—for example, the histidine kinases and related enzymes—recent studies have unexpectedly revealed the presence of a number of seemingly atypical serine/threonine protein kinases that have no obvious amino acid sequence similarity to the classical kinases. The best characterized of these atypical kinases are EF2 kinase, a family of myosin heavy-chain kinases, and a transient receptor potential (TRP)-related ion channel, termed ChaK (channel kinase). In addition, a number of related gene products have been identified through database searches. Despite the lack of detectable sequence similarity, the structure of the catalytic domain of

the atypical kinases reveals surprising homology to that of the classical protein kinases. Moreover, the atypical kinase domain is also related to metabolic enzymes that contain the so-called “ATP-grasp” domain. The discovery of this family of atypical kinases highlights the likely evolutionary link between protein kinases and metabolic enzymes. Moreover, these recent studies raise the possibility that other families of protein kinases exist that are not easily recognized from analysis of sequences alone.

Identification of an Atypical Family of Protein Kinases: EF2 Kinase, Myosin Heavy Chain Kinase and ChaK

EF2 kinase was originally identified as a Ca^{2+} /calmodulin-dependent enzyme (previously termed CaM kinase III) capable of phosphorylating eukaryotic elongation factor 2 (EF2) [4,5]. Biochemical studies indicated that EF2 kinase is a monomeric, elongated protein of ≈ 95 kDa [6,7]. Redpath *et al.*, isolated a cDNA that apparently encoded EF2 kinase, and it was suggested that a subdomain of the kinase was related to the catalytic region of the classical protein kinases [8]. However, based on additional analysis, the EF2 kinase sequence was clearly distinct in primary structure from the classical protein kinases. This lack of relationship was further clarified when Egelhoff and colleagues identified a novel *Dictyostelium* myosin heavy chain kinase (MHCK) that contained an ≈ 250 amino acid domain that exhibited a high degree of similarity with a central region of EF2 kinase [9].

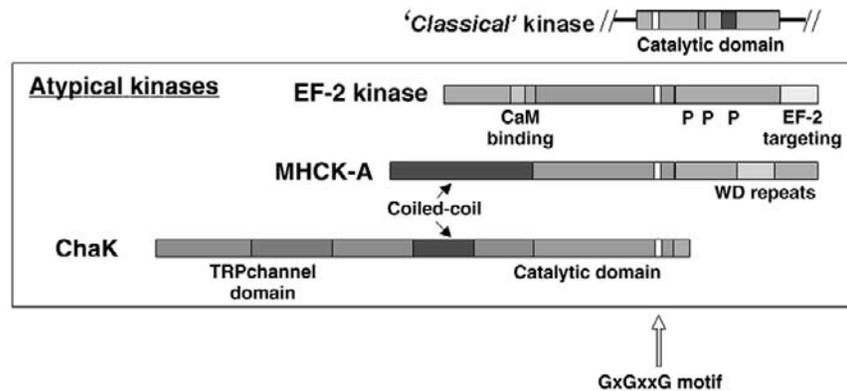

Figure 1 Domain organization of an atypical family of protein kinases. The illustration shows a comparison of EF2 kinase, MHCK-A, and ChaK, with the catalytic domain of the classical protein kinases. A GXGXXG motif that is involved in MgATP binding in classical kinases is not conserved in the atypical kinases. In contrast, the GXGXXG motif at the C-terminal end of the atypical kinases is likely to be involved in peptide substrate binding. In EF2 kinase, the CaM-binding domain is located N-terminal to the catalytic core; phosphorylation by PKA and other kinases at sites C-terminal to the catalytic core is involved in regulation of kinase activity. A region at the extreme C terminus of EF2 kinase is involved in binding eEF2. In MHCK-A, a C-terminal WD-repeat domain is involved in interaction with myosin II in *Dictyostelium*; the N-terminal coiled-coil domain is involved in binding to F-actin in lamellipodia. In ChaK, a long TRP-related channel is located toward the N terminus. The kinase domain of ChaK forms a stable dimer, presumably with another subunit within the presumed tetrameric channel; the function of the coiled-coil domain is unknown but could possibly also be involved in channel subunit interactions.

This conserved domain was unrelated in sequence to the catalytic domain of the classical kinases and was subsequently found to represent the catalytic domain of the atypical protein kinases (Fig. 1).

Additional cloning of EF2 kinase from rat, mouse, human, and *Caenorhabditis elegans* [10] and analysis of expressed sequence tag (EST) databases [11,12] revealed a homologous conserved domain in several additional genes distinct from either EF2 kinase or MHCK. Subsequent work by Egelhoff and colleagues identified three myosin heavy-chain kinases (A, B, and C) in *Dictyostelium* [13,14]. Several groups using different approaches identified ChaK (for channel kinase; also termed TRP-PLIK, LTRPC7, and TRPM7) [15–18]. In ChaK, the conserved atypical kinase domain is at the extreme C-terminus of a large polypeptide that contains a centrally located Ca²⁺ channel domain that is homologous to the family of transient receptor potential (TRP) channels [19]. The TRP family of channels are generally Ca²⁺ permeable, are often regulated via activation of G-protein-coupled receptors, and have been linked to a variety of cellular processes, including photoreception in *Drosophila* and detection of physical and chemical stimuli. Three subtypes of TRP channels—short, long, and Osm-9—have been identified based on the relationship of their N- and C-terminal extensions and their mechanisms of regulation. ChaK (and a related but slightly longer gene product, ChaK2) are members of the long TRP subgroup and are most highly related to melastatin 1, a long TRP channel that is expressed in melanocytes and is downregulated in metastatic melanoma cells [20,21]. While previous studies have indicated that ion channels are highly regulated by protein phosphorylation and may associate within complexes that contain protein kinases and

phosphatases, ChaK is unique in that it contains a protein kinase domain fused to an ion channel. Finally, Ryazanov and colleagues have begun to characterize several other polypeptides that contain atypical kinase domains, although nothing is known about their function at the present time [11,22]. These include a gene product cloned from lymphocytes that also contains predicted membrane-spanning regions and gene products cloned from heart and muscle. Genes encoding atypical kinases are also found in *Neurospora*, *Trypanosoma*, and possibly in other protozoans.

The Structure of the Atypical Kinase Domain Reveals Similarity to Classical Protein Kinases and to Metabolic Enzymes with ATP-Grasp Domains

The kinase domain of ChaK forms a dimer as a consequence of a domain-swapping exchange of an N-terminal 27-residue “dimerization segment” [17]. The isolated ChaK kinase domain is also a dimer in solution, and the dimeric property of ChaK may be relevant to the biological function or regulation of the kinase, as TRP channels, like other voltage-gated ion channels, are likely to be tetrameric. However, EF2 kinase and MHCK are monomers and would require an alternative extended polypeptide sequence to replace the buried dimerization segment. When considered as a monomer, the catalytic domain of ChaK is strikingly similar to that of the classical protein kinase (Fig. 2). As in protein kinase A (PKA), there are two lobes separated by the catalytic cleft. In particular, the N-terminal lobe consisting mainly of β -strands, is very similar in topology to the same

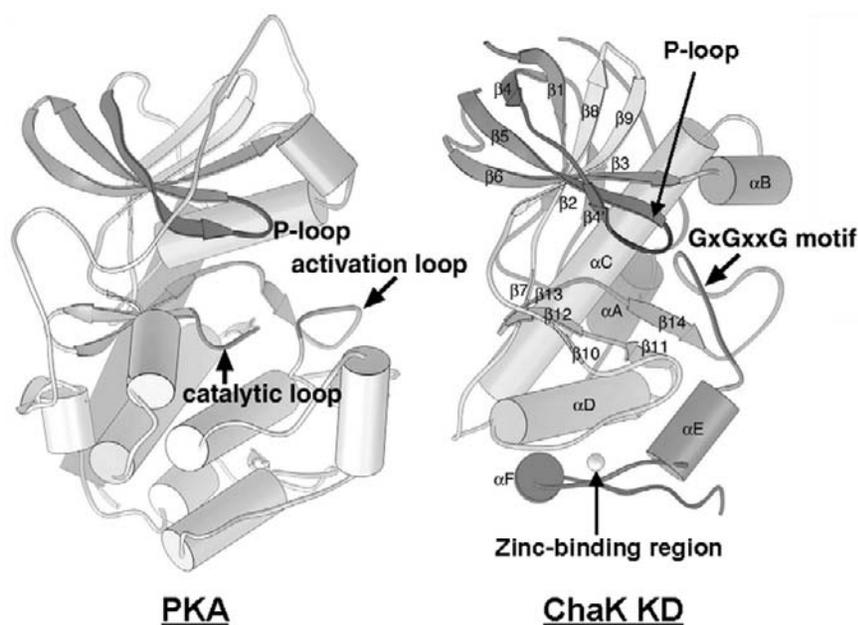

Figure 2 Structural comparison of the kinase domains of ChaK (ChaK KD) and protein kinase A (PKA). The upper N-terminal lobes of ChaK and PKA are largely comprised of β -strands and are related in structure. MgATP binds in a cleft formed between the upper and lower lobes of both classical and atypical kinases and involves the conserved P-loop. The catalytic loop in the classical kinases is not conserved in the atypical kinases. The GXGXXG motif in ChaK is contained in an extended loop that may play a similar role as the activation loop in the classical protein kinases. The zinc-binding region of the atypical kinases is unique to this class of enzymes.

region of PKA and contains a conserved phosphate-binding P-loop that is involved in adenosine triphosphate (ATP) binding in both atypical and classical kinases. The major difference between the ChaK and PKA catalytic domains is found in the C-terminal lobes, where ChaK contains a zinc-binding module that is likely to play an important role in the structural integrity of the kinase domain. A loop that connects the zinc-binding module to the catalytic cleft is poorly resolved in nucleotide-free ChaK but assumes a more defined structure in the presence of ADP or AMP-PNP (an ATP analog). This loop, which contains a glycine motif (GXGXXG) that is highly conserved in the atypical kinases, may be equivalent to the activation loop, a region important for regulation of classical kinases. Alternatively, the flexible loop in the atypical kinases may play a more fundamental role in peptide substrate recognition.

Despite the lack of amino acid sequence similarity, key residues involved in nucleotide binding and catalysis are conserved in the atypical kinase domain. These include the strictly conserved lysine residue that interacts with the α - and β -phosphates of ATP and which is invariant in classical protein kinases. In addition, three residues (Asp-1765, Gln-1767, and Asp-1775) are situated in positions equivalent to three essential residues in the classical kinases (Asp-166, Asn-171, and Asp-184 in PKA). Thus, the general features of catalysis are closely conserved between atypical and classical protein kinases and strongly suggest that they share a common evolutionary origin. Site-directed mutagenesis studies of several of these key residues has provided direct support for their

proposed roles in catalysis (Yamaguchi *et al.*, unpublished data). However, mutation of conserved cysteine residues in the zinc-binding module would be expected to seriously affect structural integrity of the protein rather than have a specific effect on kinase activity [15,23]. Mutation of a glycine in the GXGXXG motif has also been found to inhibit ChaK activity, presumably by affecting peptide substrate binding [15].

Notably, there are some significant differences between the atypical and classical kinases in terms of the detailed features of the nucleotide binding site. Moreover, the hydrophobic ATP-binding pocket of ChaK is not strictly conserved in other atypical kinases. The distinct features of the ATP binding region of the atypical kinases provides an explanation for the fact that small-molecule inhibitors of the classical kinases have little or no effect on EF2 kinase (Matsushita and Nairn, unpublished results), whereas a novel class of selenocarbonyl compounds are specific inhibitors of EF2 kinase but not of several members of the PKA family [24]. It seems likely that it should be possible to exploit the specific properties of the ATP binding site to develop molecules that selectively inhibit the different atypical kinases.

A notable feature of the active site of ChaK is the absence of the so-called catalytic loop (Fig. 2). This feature distinguishes the atypical kinase active site from that of the classical kinases, and highlights the similarity of the C-terminal lobe of ChaK to the family of metabolic enzymes that contain the ATP-grasp fold. The elucidation of the structure of the ChaK kinase domain, as well as other ATP-utilizing enzymes such as phosphatidylinositol phosphate kinase II β [25], lends

additional support to the idea that there is an evolutionary linkage among these various groups of proteins and the classical protein kinases [26,27].

Substrate Specificity of Atypical Kinases

Based on the general structural similarities and the conserved features of ATP binding and catalysis, it seems likely that peptide substrates will interact in a similar fashion with atypical and classical kinases. Possibly, the peptide substrate might replace a string of water molecules that is observed in the ChaK crystal structure between the terminal phosphate of ATP and the loop containing the glycine motif. Ryazanov and colleagues have speculated that EF2 kinase and MHCK might recognize target phosphorylation sites located in α -helices within their respective substrates, as MHCK phosphorylates residues within the α -helical coiled-coil tail of myosin II, and the phosphorylation sites in EF2 may possibly assume an α -helical conformation [11,22]. However, there is no direct biochemical evidence to support this model, and the structural features of ChaK suggest that the atypical kinases will recognize peptide substrates in an extended manner with multiple contacts in the catalytic cleft.

Notably, both EF2 kinase and MHCK phosphorylate threonine residues within their respective substrates [4,28,29]. In addition, studies using various protein substrates and model peptide analogs indicated that MHCK exhibited a consistent preference for threonine [14]. This result raised the possibility that atypical kinases might be selective for threonine. However, studies with ChaK have indicated that it both autophosphorylates and phosphorylates exogenous substrate proteins at serines and threonines [18]. Moreover, EF2 kinase and MHCK readily phosphorylated mutant substrates containing serine in place of the normally phosphorylated threonine [12,29]. These latter results suggest that atypical protein kinases are unlikely as a group to show preference for threonine in their respective substrates.

Structure–function studies of EF2 kinase and MHCK have suggested that binding to substrate requires additional protein–protein interactions outside of the immediate contacts at the active site [12,23,30–32]. Using a variety of deletion mutants of EF2 kinase, these studies found that the catalytic domain (\approx residues 1 to 350) maintained the ability to autophosphorylate itself, but C-terminal truncated proteins did not phosphorylate EF2. Indeed, removal of as few as 19 amino acids from the C-terminus of the enzyme resulted in an almost total loss of EF2 kinase activity, but not of autophosphorylation. Comparison of EF2 kinase from different species, including mammals and *C. elegans* indicates that a stretch of \approx 100 amino acids at the C terminus of the protein is highly conserved [10]. A C-terminal domain containing the last \approx 300 residues can pull down EF2 [30]. Moreover, addition of a recombinant C-terminal fragment inhibited EF2 phosphorylation (Matsushita *et al.*, unpublished results). Together, these studies support the idea that EF2 interacts directly with the extreme C terminus of EF2 kinase,

a region removed from the catalytic domain by \approx 300 amino acids. In the case of MHCK-A, the catalytic domain is flanked at the N terminus by a coiled-coil region and at the C terminus by a seven-fold WD repeat motif. Removal of the WD repeat domain decreased significantly the rate of phosphorylation of full-length myosin but had no effect on the kinetics of phosphorylation of a short synthetic peptide that served as a substrate for the kinase [31,32]. Presumably, these additional targeting interactions stabilize the interaction of EF2 or myosin with their respective kinase and perhaps orient the region containing the phosphorylation sites of EF2 or myosin in the correct position in the active sites of either kinase.

Regulation of Atypical Kinases

A substantial amount of evidence indicates that EF2 kinase is highly regulated by second messengers, in particular Ca^{2+} , and serves to integrate the effects of several signaling pathways on the regulation of protein synthesis [12]. EF2 kinase is essentially inactive in the absence, but highly active in the presence, of Ca^{2+} /calmodulin. In the subfamily of classical kinases that are regulated by Ca^{2+} /calmodulin, the enzymes are maintained in an inactive autoinhibited state through the interaction of a “pseudosubstrate” sequence within a C-terminal regulatory domain with the active site of the kinase [33,34]. Binding of calmodulin to the regulatory domain relieves the autoinhibitory interaction and allows access of MgATP and peptide substrate to the active site. In EF2 kinase, site-directed mutagenesis, as well as peptide binding and competition studies, have identified a fairly typical amphipathic α -helical calmodulin-binding domain within residues 80 to 100 [12,23,30]. However, there is no evidence to suggest that EF2 kinase contains an autoinhibitory domain. Thus, the domain organization of EF2 kinase is distinct from that of the classical Ca^{2+} /calmodulin-dependent protein kinases, and possibly the autoinhibitory mechanism is also different. Consideration of the structure of the catalytic domain of ChaK indicates that the calmodulin-binding domain of EF2 kinase would be in a position equivalent to the helical region of the dimerization segment. Conceivably, the calmodulin-binding domain could interact in an autoinhibitory manner with the active site of EF2 kinase, or, alternatively, binding of calmodulin could stabilize an active conformation of the enzyme.

In the presence of Ca^{2+} /calmodulin, EF2 kinase autophosphorylates through an intramolecular mechanism, and as many as five serine or threonine residues are phosphorylated [7]. EF2 kinase is also phosphorylated at multiple sites by PKA [6,35]. Autophosphorylation or phosphorylation by PKA is associated with generation of a partially Ca^{2+} /calmodulin-independent enzyme activity. Ser365 and Ser499 were identified as the major PKA sites and mutagenesis studies indicated that phosphorylation of probably both sites is involved in generation of Ca^{2+} /calmodulin-independent activity [12,36]. The phosphorylation of EF2 kinase by PKA

suggests a mechanism whereby increased cAMP levels would be linked to inhibition of protein synthesis [37]. Moreover, activation of PKA is frequently associated with activation of Ca^{2+} channels and would, in turn, lead to direct activation of EF2 kinase. However, chronic activation of PKA is associated with downregulation of EF2 kinase protein levels (for example, PC12 cells), where it may play a role in the action of nerve growth factor [12,38]. Thus, the regulation of EF2 kinase by cAMP appears complex.

EF2 kinase has been found to be phosphorylated and regulated by several other kinases. Previous studies had shown that insulin could reduce EF2 phosphorylation via inactivation of EF2 kinase [39]. A recent follow-up study has now found that Ser365 is phosphorylated by p70 S6 kinase leading to inactivation of the enzyme [40]. Thus insulin inactivates EF2 kinase via a pathway that involves phosphatidylinositol 3-kinase (PI3K), phosphoinositide-dependent protein kinase (PDK1), and mTor (the mammalian target of rapamycin). Decreased EF2 phosphorylation is associated with an increased rate of polypeptide elongation, and dephosphorylation of EF2 presumably contributes together with other processes to the positive effect of insulin on protein synthesis. Interestingly, the same study showed that Ser365 of EF2 kinase was also phosphorylated by p90RSK as part of a separate signal transduction pathway that lies downstream of the classical mitogen-activated protein (MAP) kinase cascade. Finally, EF2 kinase is phosphorylated at Ser359 by SAPK4/p38 δ , another member of the MAP kinase family [41]. Phosphorylation of EF2 kinase is increased by anisomycin, an activator of stress-activated protein kinase 4 (SAPK4), and leads to inhibition of enzyme activity. It is notable that these various phosphorylation events involve residues in a similar region of EF2 kinase that is 20 to 150 amino acids C-terminal to the catalytic domain. It is not immediately obvious how phosphorylation of these sites, which has both positive and negative effects, influences kinase activity. Indeed, phosphorylation of Ser365 has been found to have opposite effects on enzyme activity in different studies. Clearly, additional studies will be needed to clarify the complex pattern of regulation of EF2 kinase by other protein kinases.

Recent studies suggest that the kinase domain, but not activity, of ChaK (termed TRP-PLIK) may be subject to regulation. The kinase domain of ChaK was identified in one study as a result of its ability to interact with phospholipase C (PLC) in a yeast two-hybrid system [15]. An additional study has confirmed this interaction, and indicated that the C2 domain of PLC- β 1, - β 2, and - β 3, but probably not - β 4, interacts with the kinase domain [42]. In the same study, ChaK (also termed TRPM7) permeation by Ca^{2+} was suggested to be regulated by a circuitous mechanism that involves constitutive activation by phosphatidylinositol 4,5-bisphosphate (PIP₂), and hydrolysis of PIP₂ by PLC. Presumably, the pool of PLC that interacts with ChaK is responsible for the localized hydrolysis of PIP₂ and is responsible for the observed inhibition of ChaK in response to activation of several G α q-coupled receptors. In other

recent studies directed at examining the potential relationship of ChaK to store-operated Ca^{2+} currents (CRAC), it has been found that ChaK exhibits a unique feature whereby ChaK channel activity (but not CRAC) is inhibited by Mg^{2+} [43,44]. It is unclear if the regulation by Mg^{2+} is of any physiological significance, and it seems unlikely to be related to the Mg^{2+} -dependence of ChaK kinase activity.

Functions of the Atypical Family of Protein Kinases

The functions of EF2 kinase, MHCK, and presumably ChaK are diverse, and it seems likely that further studies of the uncharacterized atypical kinases will bring surprises. Of the atypical kinases, the functional role of EF2 kinase is the most thoroughly characterized (for review, see Nairn *et al.*, [12]). Phosphorylation of EF2 results in inhibition of the elongation step of protein synthesis, and activation of EF2 kinase by Ca^{2+} /calmodulin inversely couples the intracellular level of Ca^{2+} to rates of protein synthesis. The precise physiological role of Ca^{2+} -dependent regulation of protein synthesis is not fully understood but appears to be involved in selective translation of specific mRNAs [45]. These studies also highlight a potential role for phosphorylation of EF2 in the regulation of "local protein synthesis." Within cells, Ca^{2+} levels are regulated in a precise spatial and temporal fashion. Thus, localized phosphorylation of eEF2 could modulate protein synthesis in specific subcellular compartments in cells.

Three MHCKs have been identified in *Dictyostelium*, where they are all likely to phosphorylate the heavy chain of myosin II. Phosphorylation of the helical coiled-coil tail of myosin II inhibits its assembly and is a major mechanism that limits the function of myosin II in *Dictyostelium* [46]. Recent studies indicate that the N-terminal coiled-coil domain, which is unique to MHCK-A, is involved in binding to F-actin in lamellipodial protrusions in *Dictyostelium* [47]. Moreover, MHCK-A redistributes to actin-rich membrane protrusions following stimulation with a chemoattractant. This targeting mechanism for MHCK-A, therefore, may be responsible for the lack of myosin II filament assembly within F-actin-containing lamellipodia [48].

Although little is known concerning the physiological role of ChaK, the unusual inclusion of an enzyme domain within the same polypeptide as an ion channel suggests that the intrinsic kinase activity will be involved in regulation of some aspect of the properties of the channel. However, the kinase activity does not appear to be necessary for channel function [16,18]. An initial study that suggested that kinase activity was associated with channel activity most likely is explained by a failure of mutated proteins to be properly expressed [15]. The kinase domain of ChaK is capable of autophosphorylating multiple sites, and these conceivably might be involved in inactivation of channel activity. Alternatively, the kinase activity might play a role in channel assembly or localization. An intriguing possibility is that the kinase is also able to phosphorylate substrates that

are associated with the channel or are involved in some novel manner in responding to ion permeation of the channel.

Acknowledgments

Research by ACN was supported by USPHS grant GM50402. I wish to thank John Kuriyan and Hiroto Yamaguchi for providing the images of the kinase structures shown in figure 2.

Casein Kinase I and Regulation of the Circadian Clock

Saul Kivimäe, Michael W. Young, and Lino Saez

Laboratory of Genetics,
The Rockefeller University,
New York, New York

Introduction

A multitude of physiological responses and behavioral outputs are expressed with a daily rhythm reflecting adaptation to day/night changes in environmental conditions [1–6]. In the fruit fly circadian clock, a complex of two proteins, CLOCK (CLK) and CYCLE (CYC), activate expression of two genes, *period* (*per*) and *timeless* (*tim*). PERIOD (PER) and TIMELESS (TIM) proteins associate physically in the cytoplasm and after several hours translocate to the nucleus, where they interfere with the transactivation potential of CLK/CYC. Delays are built into this circuit to generate sustained cycling with a period of ~24 hours. For example, TIM is degraded upon light exposure, and PER is degraded in the absence of TIM. Two serine/threonine protein kinases, *double-time* (*dbt*)/casein kinase I (CKI) and *shaggy*/GSK3, phosphorylate PER and TIM, respectively, establishing the time-course of their activities [7,8]. Thus, protein phosphorylation plays a critical role in circadian rhythmicity.

double-time: A Casein Kinase I Homolog in *Drosophila*

Several mutations have been characterized that affect the *Drosophila* casein kinase I-like gene, *double-time*. These lengthen, shorten, or completely abolish fly locomotor activity rhythms [8,10,11]. Analysis of the molecular clock of *Drosophila* reveals that the phenotypes of the mutants are correlated with changes in stability and phosphorylation of

the PER protein [8,9]. In the period shortening *dbt^S* mutant, PER appears to be phosphorylated and degraded prematurely in the nucleus, decreasing the duration of the effects of PER on transcription, and promoting an earlier start of a new circadian cycle. The period lengthening mutations *dbt^L*, *dbt^E*, and *dbt^H* conversely increase stability of PER and lengthen the interval of repression, leading to a delay in the start of the next cycle [8,10]. In these long-period flies, the pattern of PER phosphorylation and its abundance do not change when compared to wild-type flies, until morning, when PER degradation in the nucleus is delayed by about 4 to 6 hours. *dbt^E*- and *dbt^H*-like mutations strongly reduce activity of a yeast CKI (HRR25) when measured using a synthetic peptide as substrate [10].

Molecular analysis of a strongly hypomorphic allele, *dbt^P*, indicates little or no PER phosphorylation and highly increased stability of the protein [8]. PER protein levels in *dbt^{ar}*, a less severe but similarly arrhythmic mutant, are also elevated. *dbt^{ar}* flies show an intermediate level of PER phosphorylation, never reaching the maximum level necessary for cyclical degradation [11]. *dbt^{ar}* is a His 126-to-Tyr missense mutation, a change found naturally in the closely related CKI γ isoform, suggesting that the specificity of *dbt^{ar}* kinase may be changed but not its activity. The arrhythmicity in *dbt^{ar}* can be rescued (to long-period rhythmicity) by short-period *per* mutations that are known to destabilize the PER protein [11]. This indicates that both mutations affect the same molecular step that controls PER degradation in the nucleus. Together, these findings have led to the conclusion that one of the major functions of DBT in the circadian clock is to destabilize PER by phosphorylation.

In biochemical assays, DBT has been shown to bind PER directly *in vivo* and *in vitro* and phosphorylate PER *in vitro* (unpublished data). The kinase domain of DBT, the region in which all mutations affecting rhythmicity reside, binds to PER [9]. It is unclear however, how DBT activity is regulated in the circadian cycle. In wild-type cells, DBT is produced at a constant rate, unlike TIM and PER, which oscillate in their abundance. However, the subcellular localization of the bulk of the DBT protein oscillates in phase with PER in *Drosophila* lateral neurons, the pacemaker cells of the brain that regulate locomotor activity rhythms [12]. This cycling between cytoplasm and nucleus is apparently driven by PER, as DBT constitutively localizes to the nucleus in PER-deficient cells. PER phosphorylation is temporally regulated; PER becomes progressively phosphorylated and its stability decreases after TIM leaves nuclear PER-TIM-DBT complexes in the late night. Phosphorylation increases through the early morning [13]. Thus, DBT phosphorylates PER and marks it for degradation. Binding of TIM to the PER-DBT complex may regulate the accessibility of PER as a substrate for DBT (Fig. 1).

DBT has also been implicated in the regulation of nuclear entry of PER/TIM dimers. Nuclear translocation of PER is reportedly delayed in *dbr^S* flies. Cytoplasmic PER in the *dbr^S* flies appears to have a normal half-life, unlike nuclear PER in this mutant, thus the function of DBT in nuclear entry may not be mediated by regulating the stability of PER [14].

Casein Kinase I in the Mammalian Clock

Two highly related casein kinase I isoforms, ϵ and δ , are components of the mammalian circadian oscillator. These two kinases are 97% homologous and have over 80% homology to DBT in the kinase domain; their C-terminal tails are unrelated to the corresponding region in DBT. CKI ϵ and CKI δ bind mammalian PER1 and PER2 proteins in tissue culture and *in vivo* and also phosphorylate both PER proteins *in vitro* [15,16,17,18].

In cultured cells CKI ϵ and CKI δ regulate nuclear entry and stability of the mammalian PER proteins. CKI ϵ has been implicated in regulating the subcellular localization of PER1 by trapping otherwise nuclear PER1 protein in the cytoplasm in cultured human embryonic kidney cells, but translocating PER1 and PER3 to the nucleus in COS-7 cells [17,18]. Contradictory results from tissue-culture experiments may reflect cell-line-dependent variability in the expression of other factors required for CKI-regulated PER nuclear translocation. CKI also seems to regulate CLK/BMAL-dependent transcription. Reduction of CKI activity inhibits transcriptional activation by CLK/BMAL [19,20]. Immunoprecipitations from mouse liver show both CKI isoforms interacting with PER1 and PER2 proteins, specifically with the phosphorylated forms of the PER proteins [21]. In mice, the subcellular location of CKI ϵ also varies with circadian time, as originally found in *Drosophila*.

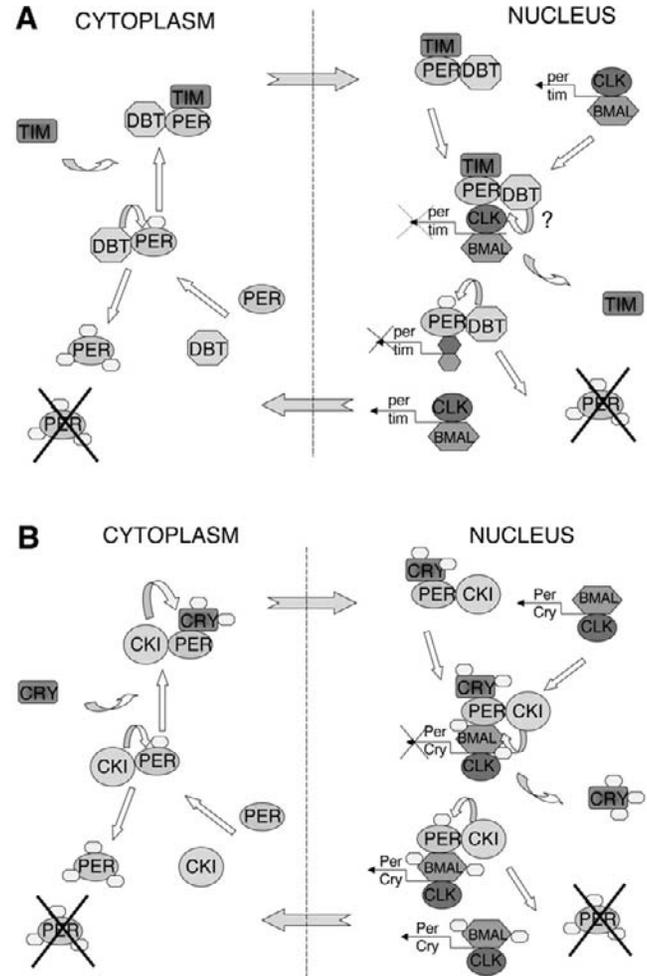

Figure 1 Regulatory activities of DBT/CKI within models of the *Drosophila* (A) and Mammalian (B) circadian clocks. PER is found in a complex with CKI throughout the circadian cycle. In the middle of the day cytoplasmic, newly synthesized PER interacts with CKI and is phosphorylated and degraded. In the early evening, TIM in *Drosophila* and CRY in mammals, accumulate and associate with PER. Such complexes are no longer destabilized by CKI. In *Drosophila* cells, PER bound to TIM and DBT translocates to the nucleus. In mammals, PER forms cytoplasmic complexes with CRY and CKI preceding nuclear translocation. CRY is phosphorylated in the latter complexes by CKI in a PER dependent manner. In the nucleus PER-containing complexes bind two transcription factors, CLK and BMAL. When expressed alone, CLK and BMAL activate *per* and *tim* (flies) or *Per* and *Cry* (mammals) expression, but further association with PER-containing complexes suppresses this activity. These interactions also suppress clock controlled genes that function downstream of the central oscillator. In the multiprotein complex CKI phosphorylates BMAL in mammalian cells, which increases its activity and may be required to overcome the repression in the end of the circadian cycle. In the early morning, at the peak of transcriptional inhibition in *Drosophila*, TIM is degraded and CKI phosphorylates PER. Hyperphosphorylated nuclear PER is ubiquitinated and degraded in the early morning allowing a new transcriptional cycle to start.

The majority of the kinase is located in the cytoplasm but a fraction translocates to the nucleus during the night when PER proteins are expected to enter the nucleus [21]. Nuclear localization of CKI ϵ and δ is dramatically reduced in *cryptochrome 1* and *2* double-knockout mice where PER proteins show a strong reduction in nuclear translocation. In the

nucleus, both kinases appear to be part of a larger protein complex that contains all known clock proteins [21].

Genetic evidence for CKI involvement in the mammalian clock comes from the identification of two mutations that cause shortened behavioral rhythms in the Syrian golden hamster mutant *tau* and in humans with familial advanced sleep phase syndrome (FASPS). The *tau* mutation in the Syrian golden hamster leads to a fast-running circadian clock with a period of 20 hours [22]. The mutation lies in the hamster homolog of CKI ϵ . *In vitro*, this mutation leads to a decrease in kinase activity to about 15% of the wild-type level. *In vivo*, there is also a reduction in the abundance of CKI ϵ to half the wild-type level [23]. PER proteins are fully phosphorylated in the mutant hamster, indicating that CKI δ may compensate for reduced CKI ϵ activity and suggesting a dominant-negative function for the *tau* mutant CKI ϵ [21]. FASPS in humans is an inherited, dominant circadian clock disorder that involves slightly reduced period length to 23 hours and a significant phase advance. Patients with FASPS typically awaken prematurely (~4:00 a.m.) and sleep onset is similarly advanced by 3 to 4 hours [24]. The FASPS-causing mutation in one recently studied kindred lies in the human ortholog of the mouse *per2* gene changing Ser 662 to Gly in a potential CKI phosphorylation site [23]. The mutant protein is phosphorylated *in vitro* with a reduced rate by CKI ϵ [23]. Sequences immediately downstream of the mutation contain several potential CKI phosphorylation sites that may be phosphorylated in a cascade starting from the first site. Human PER2 does indeed become progressively phosphorylated over time in an *in vitro* kinase assay supporting the idea of consecutive phosphorylation of these sites [23].

Casein Kinase I in the *Neurospora* Clock

The bread mold *Neurospora crassa* may also use CKI as a part of the molecular clock. In *Neurospora*, most protein components of the clock are apparently unrelated to those of *Drosophila* and mammals but perform similar functions. The Frequency (FRQ) protein contributes to a feedback loop by negatively regulating its own transcription. Activation of *frq* transcription is carried out by two factors White Collar-1 and White Collar-2 [2,4]. FRQ undergoes progressive phosphorylation during the circadian cycle, similar to PER proteins in the fly and mammalian clocks [26]. As in animals, phosphorylation appears to be required for subsequent FRQ degradation [26]. Two protein destabilization sequences or PEST domains have been recognized in the FRQ protein which serve as substrates *in vitro* for *Neurospora* CKI [27]. One of these regions, PEST-1, is phosphorylated *in vitro* by CK-1a, the DBT ortholog in *Neurospora*. Deletion of the PEST-1 sequence in FRQ leads to a more stable FRQ protein. The increased stability of FRQ correlates with its reduced phosphorylation and is phenotypically manifested in a slow-running molecular oscillator with a lengthened period of approximately 28 hours [27].

Similarities and Differences of CKI Function in Different Clock Systems

Experimental results described above suggest similar functions for *Drosophila* DBT, mammalian CKI ϵ and CKI δ , and *Neurospora* CK-1a in the molecular clock. In these three systems, a central clock protein appears to be the major target for the kinases. In flies and mammals, two distinct steps in the circadian cycle are affected by CKI. In the first step, CKI regulates the nuclear entry of the PER proteins in the early night, providing a delay in nuclear accumulation that is likely required for sustained molecular cycling. In mammalian cells, PER1 nuclear translocation is delayed in an enzyme-dependent manner. CKI seems to mask the nuclear localization signal of PER1 by phosphorylation of a nearby region in the protein [16]. Although in *Drosophila* action of DBT in the cytoplasm should delay PER accumulation through effects on PER degradation rate, a short-period mutation of *dbt* leads to a delay in PER nuclear import by another mechanism that does not seem to involve protein stability [14]. One common function of CKI in the three model systems is the destabilization of nuclear PER proteins and FRQ. CKI-dependent phosphorylation reduces the half-life of PER proteins, helping to overcome the transcriptional repression by PER and thus starting a new circadian cycle. The mode of regulation of CKI activity in the clockworks is less clear. CKI proteins are constantly synthesized, but the subcellular localization of the kinase and its binding to other proteins in complex with PER (such as TIM) is under circadian control. This may lead to circadian phosphorylation of some substrates located in the nucleus by rhythmically regulating substrate accessibility.

In spite of many similarities between the *Drosophila* and mammalian enzymes, there are important differences. Structurally the C-terminal tails of the enzymes differ significantly, suggesting a possible difference in enzyme regulation. Mammalian CKI ϵ and CKI δ have been shown to autoinhibit their activity by phosphorylating their C-terminal tails [28]. The specific sequences required for this autophosphorylation are as poorly conserved between the mammalian and *Drosophila* enzymes as the rest of the C-terminal region. Regulation of DBT activity may also be affected by post-translational modifications as evidenced by dramatic differences in the activity of the enzyme purified from bacterial and eukaryotic sources (unpublished data). The mammalian and fly kinases may also differ in substrate selectivity. In the mammalian clock, in addition to PERs, other clock proteins appear to be important substrates for CKI. In cultured mammalian cells, Cryptochrome (CRY) is phosphorylated by CKI in a PER-dependent fashion, where PER acts as a scaffolding protein by simultaneously binding the kinase and its additional (CRY) substrate [20].

The Leucine-Rich Repeat Receptor Protein Kinases of *Arabidopsis thaliana*: A Paradigm for Plant LRR Receptors

¹John C. Walker and ²Kevin A. Lease

¹*Division of Biological Sciences, University of Missouri, Missouri;*

²*Department of Biology, University of Virginia, Virginia*

Introduction

The importance of receptor protein kinases as mediators of cellular communication in plants is illustrated by the plethora of genes encoding these proteins [1]. Although only a few of these receptors have been analyzed in detail, it is clear that they function in the coordination and integration of numerous developmental and adaptive responses. The sequence of *Arabidopsis thaliana* offers a view of the genes and proteins found in plants and establishes a foundation for a complete understanding of plant cellular communication. This overview focuses on the leucine-rich repeat (LRR) receptors in *Arabidopsis* because of the wealth of information derived from analysis of *Arabidopsis* mutants and from the genome sequence. A comprehensive review of structures, expression, and functions of the plant receptor protein kinases is available to those interested in additional information on these important signaling proteins [1].

LRR Receptor Protein Kinases: The Genomic Point of View

One of the surprising findings from analysis of the *Arabidopsis* genome is the large number of genes encoding proteins kinases. There are almost 1100 genes in *Arabidopsis* that are predicted to encode proteins related to the eukaryotic serine/threonine/tyrosine protein kinases ([2]; <http://PlantsP.sdsc.edu>). This represents approximately 4.2% of

the genome. Even more remarkable is the observation that 610 [3] to 669 [2] of these genes belong to a large, yet distinct, family of related protein kinases. This large family, designated the receptor-like kinases (RLKs), is most closely related to the Pelle and interleukin-1 (IL-1)-receptor-associated kinases and shares a common ancestry with the animal receptor tyrosine kinases, receptor serine kinases, and Raf protein kinases [1,3].

The RLK family is divided into two types, the RLKs that have an extracellular domain and the receptor-like cytoplasmic kinases (RLCKs) that do not have an extracellular domain. The relationship of the RLKs and the RLCKs is reminiscent of the similarity between the receptor and nonreceptor tyrosine kinases and suggests a shared origin. However, little is known about the *Arabidopsis* RLCKs, and it is not yet clear how the sequence similarities shared between the RLCKs and RLKs reflect shared biochemical mechanisms of action.

Over 400 RLK genes contain an extracellular domain [3]. Thus, the RLKs represent the largest group of cell surface receptors in plants, as there are only 27 G-protein-coupled receptor (GPCR)-related domains detected in *Arabidopsis*, and components of many other common signaling pathways found in animals, flies, and worms are not found in *Arabidopsis* [4]. Moreover, the number of *Arabidopsis* RLKs is six to ten times higher than the 40 to 60 receptor tyrosine kinases observed in worms and humans [5]. The large number of RLKs in *Arabidopsis* in part reflects the gene redundancy seen in this organism; it is estimated that only 35% of the predicted proteins in the *Arabidopsis* genome are unique. However, 21 classes of RLKs in *Arabidopsis* differ in their

extracellular domains, including 12 groups of LRR RLKs. These 12 groups of LRR RLKs include 235 genes that have 1 to 32 LRRs [3].

LRR Receptor Protein Kinases: The Functional View

Although some information has been obtained from expression studies and biochemical analysis of the RLKs [1], genetic approaches have provided the most information about the roles of the LRR RLKs in cellular communication. Of particular significance for this review is the fact that the functions of only five *Arabidopsis* RLKs have been described, all of which encode LRR RLKs. These *Arabidopsis* RLKs of known function include ERECTA (ER), CLAVATA 1 (CLV1), HAESA (HAE), BRASSINOSTEROID-INSENSITIVE 1 (BRI1), and FLAGELLIN SENSING 2 (FLS2).

ERECTA

The *er* mutant plants have a compact inflorescence, with shorter, blunt fruits and round leaves. The *er* phenotype is expressed throughout much of the plant's life [6], and the common developmental pattern observed among affected organs suggests that *er* controls cell expansion. ER kinase assays show that this RLK, like all of the LRR RLKs examined to date, is a serine/threonine protein kinase [7]. Numerous *er* alleles have been identified, and phenotypic variation among alleles suggests both the extracellular domain and the protein kinase domains are critical for function. Essentially all mutants that have been identified have a strong *er* phenotype very similar to that observed in an *er*-null plant [7]. Although little is known about other components of an ER signaling pathway, the recent identification of a mutation in a putative heterotrimeric G-protein β subunit gene (*agbl*) that has some phenotypic similarities with *er* suggests a connection between LRR RLK and GPCR signaling [8]. This connection is supported by an analysis of *agbl-er* double mutants that indicates these two genes may function in a common developmental pathway that controls fruit shape; however, a biochemical connection between *agbl* and *er* has not been established.

CLAVATA 1

CLV1 is thought to promote differentiation of cells in shoot and floral meristems. Many alleles of CLV1 accumulate undifferentiated cells in the meristem of the *Arabidopsis* shoot. This leads to the formation of enlarged shoot and floral meristems, fasciated stems, extra floral organs, and fruit with extra cells at the tip, which give these fruits their characteristic club-like appearance [9]. Biochemical and genetic analyses of CLV1 have led to the identification of several other proteins that may mediate CLV1 signaling. Size exclusion chromatography of immunoprecipitated CLV1 from plant extracts indicates that CLV1 is part of a multimeric complex [10], which is consistent with genetic data on dominant interference of some mutant alleles [11]. Analysis of the CLV1 complex has also led to the identification of an

associated Rho-like GTPase and the type 2C protein phosphatase KAPP (kinase-associated protein phosphatase). Small G proteins have well-established roles in many signaling cascades [12], but their relevance to plant signal transduction is uncertain. KAPP was initially identified as a protein that binds several RLKs [13,14] in a phosphorylation-dependent manner via a fork head-associated domain [15]. Overexpression of KAPP in a wild-type background caused a weak *clv* phenotype [16], and cosuppression-based loss of KAPP expression in a *clv1* background suppresses the *clv* phenotype [17]. These results suggest a role for KAPP as a negative regulator of CLV1 signaling.

Another partner for CLV1 is the CLV2 protein. *clv2* is the second of three mutants that express the *clv* phenotype. CLV2 encodes a transmembrane LRR protein with a short cytoplasmic domain but lacks the protein kinase domain found in CLV1 [18]. Analysis of protein extracts prepared from *clv2* mutants shows an overall reduction of CLV1 protein and a shift in the distribution of CLV1 from the wild-type high-molecular-weight complex to a lower molecular weight complex [18]. Because CLV2 has no protein kinase domain or other identifiable enzymatic function, CLV2 may be required to form stable CLV1 signaling complexes.

A third mutant gene, *clv3*, shares many of the same traits expressed by *clv1* mutants, and genetic analyses of *clv1-clv3* double mutants place these genes in the same pathway [11]. CLV3 is predicted to encode a small secreted polypeptide [19] and is a member of a large family of genes that are putative secreted signaling peptides in plants [20]. Two lines of evidence support the role of CLV3 as a ligand for CLV1. CLV3 has been shown to be required for the formation of an active CLV1 signaling complex, and CLV3 will bind to yeast cells expressing CLV1 and CLV2 [21].

HAESA

HAESA is an LRR receptor protein kinase that belongs to the same family as CLV1 [3], yet it appears to have a very different function. Like CLV1, HAE is a transmembrane serine/threonine protein kinase located in the plasma membrane [22]. HAE is expressed in abscission zones of floral organs, as well as at the base of petioles and pedicels. Expression in flowers is stage dependent and first observed in maturing flowers, coinciding with competence to self-pollinate. Transgenic plants expressing a constitutive anti-sense HAE construct have defective floral organ abscission, which suggests HAE plays a role in abscission [22].

BRASSINOSTEROID-INSENSITIVE 1

The *bri1* mutant plants are dwarfs that do not respond to plant steroid hormones known as brassinosteroids. This insensitive phenotype indicates BRI1 is a brassinosteroid receptor or signaling component [23]. This hypothesis was supported with the cloning of *bri1* which showed that *bri1* encodes a plasma-membrane-localized LRR receptor protein kinase. This was an unexpected finding because in animals steroid hormones act by diffusing across the plasma membrane and

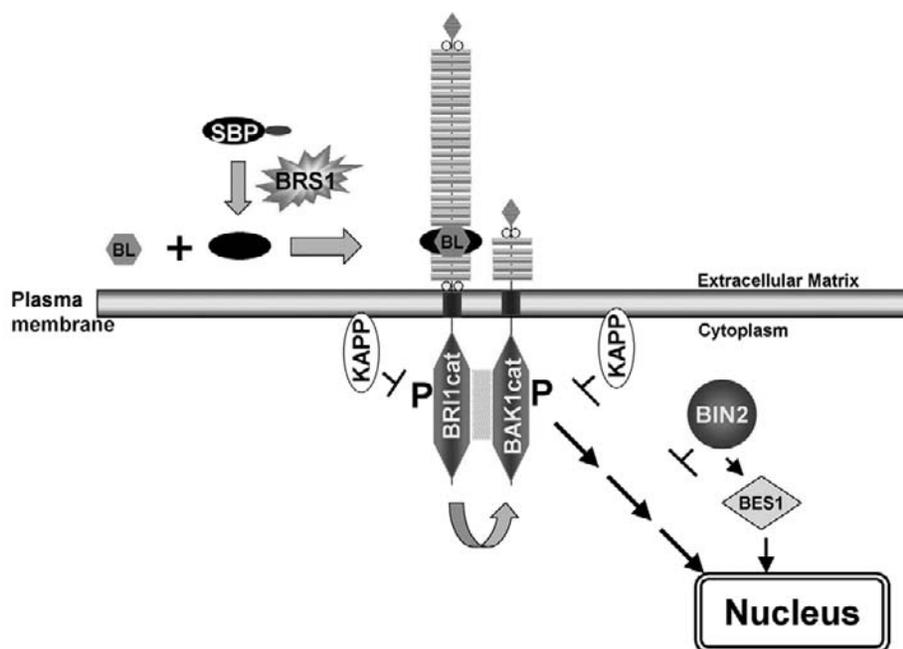

Figure 1 Model for BRI1 signaling. A putative steroid binding protein (SBP) is processed by BRS1, a secreted serine carboxypeptidase. Activated SBP binds brassinolide (BL) and the ligand complex then can interact with BRI1. Upon binding, the BRI1 protein kinase is activated and stimulates the activity of BAK1, a co-receptor, which can further trigger a phosphorylation cascade. Both KAPP and BIN2 are negative regulators in the BRI1-mediated signaling pathway. BES1 is a potential transcription factor that is substrate of BIN2. A direct connection between BIN2 and BRI1/BAK1 is still unclear.

binding to transcription factors in the cytoplasm or nucleus, resulting in a change in gene expression [24].

Evidence supporting the role of BRI1 in brassinosteroid signaling includes the observation that a chimeric receptor containing the LRR domain of BRI1 and the protein kinase domain of XA21 (an LRR RLK from rice that functions in disease resistance) triggers defense responses when treated with brassinosteroids [25]. In addition, brassinosteroids stimulate BRI1 autophosphorylation in plants and bind to immunoprecipitated BRI1 [26]. Thus, a combination of genetic and biochemical analyses show the LRR receptor BRI1 is a critical element in steroid hormone signaling in *Arabidopsis* (Fig. 1).

Recent genetic screens have revealed additional components of brassinosteroid signaling, *BIN2* and *BRS1*. Plants with mutant alleles of *BRASSINOSTEROID-INSENSITIVE 2 (BIN2)* are semidominant dwarfs with phenotypes similar to *BRI1*. *BIN2* encodes a GSK2/SHAGGY-like protein kinase and when overexpressed *BIN2* interferes with BRI1 signaling [27]. This suggests that *BIN2* is a negative regulator of brassinosteroid signaling. *bri1 SUPPRESSOR 1 (BRS1)* encodes a carboxypeptidase that was identified in an activation tagging screen of a weak *bri1* allele [28]. Overexpression of *BRS1* suppresses the *bri1* phenotype and results in increased growth. *BRS1* is predicted to be a secreted type II carboxypeptidase, and overexpression of *BRS1* suppresses two different weak alleles of *bri1* that have extracellular domain lesions, but not a *bri1* allele with a mutation in the protein kinase domain. Thus, *BRS1* is thought to be involved in proteolytic processing of a protein involved in an early step in BRI1 signaling.

FLAGELLIN-SENSING 2

Peptides derived from flagellin, a bacterial flagellar protein, activate plant defense responses, such as callose deposition, production of reactive oxygen species, and induction of pathogenesis-related gene expression in many plants. In *Arabidopsis*, flagellin peptides also alter growth of seedlings. Using this altered growth response as a screen, flagellin-insensitive plants have been identified. One of these, *FLS2*, encodes a LRR receptor protein kinase [29], and a *fls2* allele with an extracellular domain mutation does not bind flagellin [30]. *FLS2* is related to two other plant disease resistance genes, *XA21* from rice and *Cf9* from tomato [31]. As described above, *XA21* is a LRR receptor that has a protein kinase domain, while *Cf9* is similar to *CLV2* because it is an LRR receptor with a short cytoplasmic domain and no protein kinase domain [31].

Summary

The LRR receptors represent the largest group of cell surface receptors in *Arabidopsis thaliana* and probably in all plants. Although this review has focused on the LRR receptor protein kinases, another 30 genes in *Arabidopsis* encode LRR receptors with a short cytoplasmic domain [31]. Although the functions of only a few of the *Arabidopsis* LRR receptors have been established, it is clear that these proteins have diverse roles in coordinating cellular signaling in plants. *CLV1* and *HAE* belong to the same family of LRR RLKs yet have very different patterns of expression and are

involved in distinct developmental processes. BRI1 and ER, which are also related to CLV1 and HAE, are expressed in most parts of the plant but have dissimilar mutant phenotypes. In contrast, FLS2 is involved in binding an elicitor of plant defense responses and thus reflects the role of some LRR receptors as disease resistance genes.

A combination of genetics and biochemistry has advanced our understanding of the signaling molecules associated with the LRR receptors, including ligands and downstream effectors. Although we are not yet able to describe an entire signal transduction cascade for any one of the plant LRR receptors, approaches such as functional genomics and proteomics promise to provide important insights into the molecular mechanisms by which the LRR receptors control development and adaptive responses in plants.

UPDATE

Several recent publications have identified the functions of additional Plant LRR receptors. The receptors for Phytosulfokine, a five amino acid sulfated peptide involved in plant growth and Systemin, an 18 amino acid peptide involved in triggering wound responses, are LRR-RLKs related to BRI1 (Matsubauashi *et al.*, 2002 *Science* **24**:1470; Scheer and Ryan, 2002 *Proc. Natl. Acad. Sci.* **99**:9585). SYMRK and NORK are related LRR-RLKs involved in the regulation of root nodule symbioses in plants (Stracke *et al.*, 2002 *Nature* **417**:959; Endre *et al.*, 2002 *Nature* **417**:962). BAK1 is an LRR-RLK involved in modulating brassinosteroid signaling (Li *et al.*, 2002 *Cell* **110**:in press; Nam and Li, 2002 *Cell* **110**:in press). In addition, BES1 and BRZ1 have recently been identified as nuclear localized proteins that function in brassinosteroid signaling (Yin *et al.*, 2002 *Cell* **109**:181; Wang *et al.*, 2002 *Dev Cell* **2**:505).

Berkeley, California

A major challenge of the post-genomic era is to derive a complete map of all signaling networks in mammalian cells. One difficulty in mapping signaling pathways is determination of the substrates of each protein kinase [1,2]. Kinase substrates are difficult to identify chiefly because of the large size of the kinase superfamily (over 500 human kinases) and the large number of low-abundance substrates that kinases are predicted to phosphorylate. Current methods for identification of kinase substrates include: (1) searching protein sequence databases for known phosphorylation motifs [3], (2) screening for efficient substrates in expression libraries [4], and (3) detecting stable association between kinase and substrates by screening yeast two-hybrid libraries [5]. Each of these methods has identified interesting candidate substrates, some of which have been validated using various biochemical tests.

The vast majority of kinase substrates remain to be identified, however, because these methods do not take into account key aspects of kinase substrate recognition, such as subcellular localization, colocalization of kinase and substrate in large supramolecular protein complexes, and temporal activation/deactivation of kinase activity. In particular, tyrosine kinases do not possess high intrinsic specificity for short linear sequences flanking substrate phosphorylation sites [6]; this severely limits the application of sequence database searching for kinase substrates. Most biochemical and genetic screens require putative substrate proteins to be

isolated from their cellular context. The physiological relevance of these *in vitro* substrates is questionable because it is known that the formation of signaling complexes (which colocalize kinases and their substrate proteins via many associated proteins) is critical to the observed signaling specificity *in vivo* [7]. To address the challenge of identifying direct kinase substrates, our laboratory has developed a novel chemical approach to accelerate the process of kinase substrate identification (*vide infra*).

A related, yet distinct hurdle in mapping kinase function is the generation of selective inhibitors for individual kinases. Small molecule inhibitors have advantages for deciphering the function of a kinase in that they can be used at any point in development (and thus do not suffer from poor temporal control over gene function as do knockout approaches), and they can be readily removed to restore kinase function, thereby providing rapid conditional on/off control [8]. Furthermore, many protein kinases are considered potential drug targets for treatment of various human diseases [9]. The key challenge in the design of kinase inhibitors for research or drug development has been to achieve target specificity. In order to be used as a therapeutic agent, a small molecule inhibitor should be very specific for its target kinase in order to minimize the off-target effects, which can be substantial in such a large and highly conserved family of enzymes. Despite the tremendous efforts spent in developing selective kinase inhibitors, only a few relatively specific inhibitors for

protein kinases have been found to date [10–12]. One notable example is PD 98059, which specifically prevents the activation of MAPK/ERK kinase 1 (MEK1) by the upstream kinase MEKK due to the rare mode of action of the inhibitor [13]. Clinically, Gleevec, an inhibitor that is known to inhibit BCR-ABL as well as at least three other kinases, was approved by the U.S. Food and Drug Administration (FDA) for the treatment of chronic myeloid leukemia disease. This is significant because it suggests that perfect specificity may not be essential for the development of kinase inhibitors as drugs [14,15]. However, truly mono-specific kinase inhibitors would greatly facilitate functional studies of individual protein kinases.

To address this need, our lab has developed a chemical/genetic approach, combining chemical synthesis with protein engineering, that circumvents the difficulties of both substrate identification and specific inhibitor design associated with this important gene family [16–18]. The approach we developed is to engineer one kinase in the cell to be structurally unique from all other kinases, yet functionally identical to its wild-type allele. By identifying a highly conserved active site residue that can be mutated to render it distinct from all other protein kinases in nature, the idea is to make specific binding easy to achieve. Of course, the mutation to the kinase must be silent in terms of phospho-acceptor specificity recognition, regulation of catalytic activity, etc.

By examining the crystal structures of protein kinases for residues within the adenosine triphosphate (ATP) binding site, yet distant from catalytically essential residues, one residue (in the hinge region between the N terminal lobe and C terminal lobe) was noted to be in close contact with the N6 amino group of ATP. (The N6 position of ATP is distant from the gamma-phosphate group that is transferred in the catalytic step of the reaction.) This residue is located in subdomain V of the kinase domain in the primary sequence and is always occupied by a large hydrophobic residue in the kinase superfamily based on sequence alignment (Fig. 1). This residue has been termed the *gatekeeper* because it governs access to a large hydrophobic pocket in the ATP binding site. When the gatekeeper residue is mutated to a small residue, Gly or Ala (such mutant alleles are referred to as as1 or as2 for analog-sensitized allele 1 or 2), a much larger pocket is created in the active site of the mutant kinase (which is not found in any wild-type protein kinase because no natural kinases contain a Gly or Ala gatekeeper residue). This feature can

then be exploited to distinguish the mutant from all wild-type kinases. For example, the engineered kinase can efficiently use ATP analogs with large substituents at the N6 position that are very poorly used (orthogonal ATP analogs) by wild-type kinases [16,19]. Importantly, the mutation has been shown not to alter the structure and specificity profile of the kinase [20] and is functionally silent in most kinases examined [18]. Therefore, the engineered kinase together with [γ - 32 P] orthogonal ATP analogs can be used to radiolabel the *bona fide* substrates of the target kinase in the background of any pool of proteins including whole cell lysates (Fig. 2).

The strategy was first explored with the oncogenic tyrosine kinase v-Src where it was shown that v-Src I338G (v-Src-as1) could use orthogonal ATP analogs efficiently, while wild-type v-Src cannot [16,19]. Next, a screen using NIH3T3 cell lysates containing v-Src-as1 and [γ - 32 P] N^6 -benzyl ATP identified several novel candidate substrates of v-Src including Cofilin, Calumenin, and Dok-1 [21]. Further studies suggested that v-Src phosphorylation sites on the scaffold protein Dok-1 are critical for its binding to negative regulators of the Src signaling pathway (RasGAP and Csk), which led to a model of the precise order of assembly of a retrograde signaling pathway in v-Src transformed cells [21]. A wide variety of protein kinases (including both tyrosine and serine/threonine kinases) were later shown to be amenable to this approach, highlighting its generality [16,22–24]. Habelhah *et al.* [22] used the approach to identify direct substrates of the stress-activated protein kinase, JNK. In this case, a second mutation in the active site, adjacent to the DFG motif (Fig. 1), was required for the engineered JNK (JNK-as3) to efficiently use N^6 -phenylethyl ATP. JNK-as3 was then used together with [γ - 32 P] N^6 -phenylethyl ATP to identify heterogeneous nuclear ribonucleoprotein K, hnRNP-K, as a direct substrate of JNK. Interestingly, hnRNP-K was also found to be a substrate of another MAP kinase, ERK, and further study established the role of MAPK/ERK in phosphorylation-dependent cellular localization of hnRNP-K, which is required for its ability to silence mRNA translation [23]. Several dozen other kinases are currently being investigated using the same approach for substrate identification, including CDK2 [24] and Cdc28 (D. O. Morgan, unpublished results).

In addition to their ability to accept orthogonal ATP analogs, the analog-sensitized kinases can be selectively inhibited by inhibitor analogs with enlarged groups at the proper position based on the same principle [17,18,25]. The pyrolozolo[3,4-*d*]pyrimidine-based molecule PP1 is a known potent inhibitor of Src family kinases. The crystal structure of a PP1/Hck complex revealed that the pyrolozolo[3,4-*d*]pyrimidine ring of PP1 occupies the active site in essentially the same orientation as the adenine ring of ATP, and that the phenyl group at the C3 position is in direct contact with the gatekeeper residue [26]. Therefore a series of PP1 analogs with large substituents at the C3 position were synthesized and screened against an array of kinases (wild-type and analog-sensitized) from several divergent families (v-Src, c-Fyn,

Figure 1 Sequence alignment of several engineered kinases in subdomains V and VII. The gatekeeper residue in each kinase and the second mutation (N-terminal to the DFG motif) in Cla4 and JNK are highlighted.

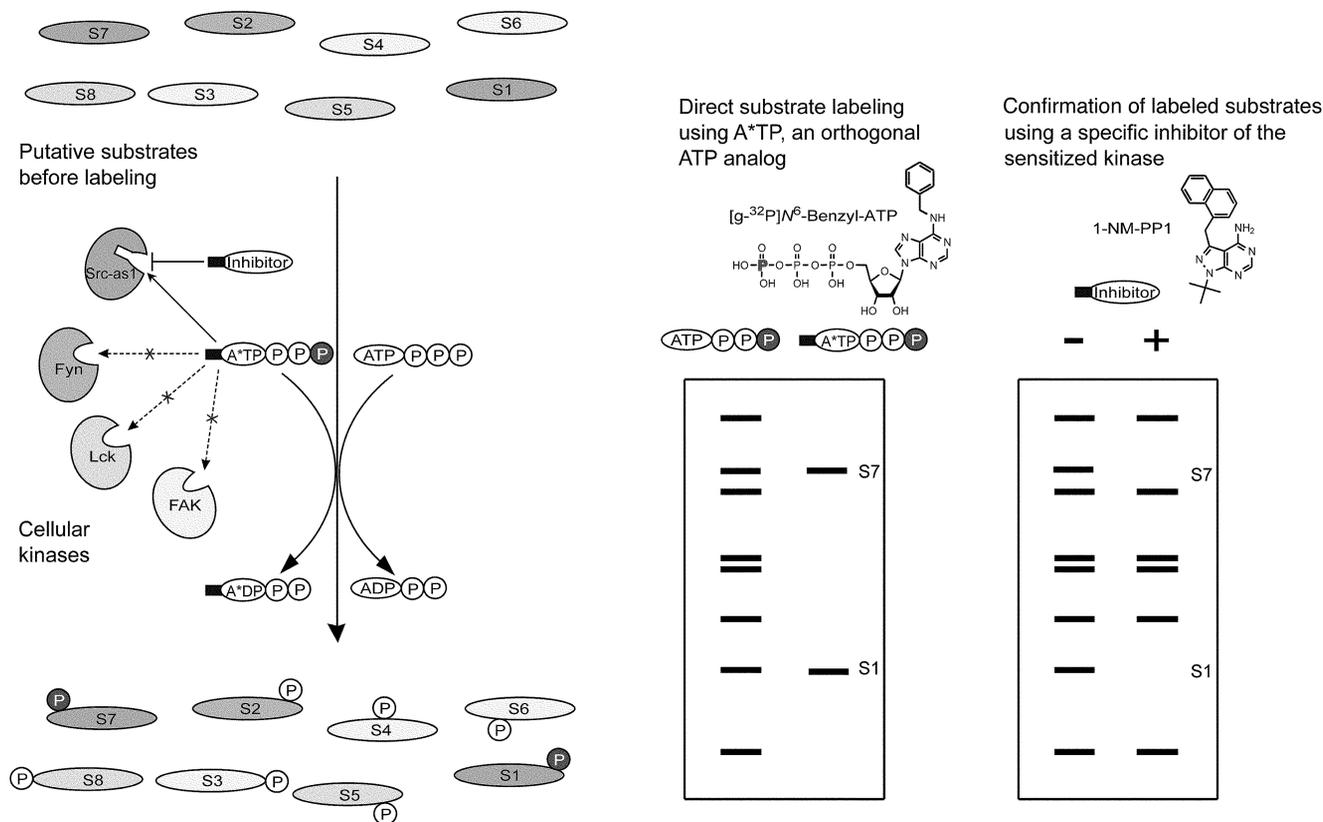

Figure 2 Schematic diagram of two complementary methods to identify substrates of Src-as1. A $[\gamma\text{-}^{32}\text{P}]$ -orthogonal ATP analog (A*TP) radiolabels only substrates of Src-as1 (represented by S1 and S7 proteins) as can be visualized by autoradiography. A specific inhibitor (Inhibitor) of Src-as1 can then be used to confirm the phosphorylation using autoradiography or western blot.

c-Abl, CDK2, CAMKII) [17,18]. It was found that derivatives of PP1 could effectively inhibit the sensitized alleles of each of these kinases with high target selectivity. This chemical genetic approach provided inhibitors of the sensitized kinases with both high potency and unparalleled specificity, which enabled their use to reveal unexpected kinase-activity-dependent functions of various kinases, including v-Src [17], Cdc28 [18], Fus3 [18], Cla4 [27], Cbk1 [28], PKA (G. S. McKnight, unpublished results), v-erbB (W. Weiss, unpublished results), CAMKII α (J. Z. Tsien, unpublished results), Ime2 (I. Herskowitz, unpublished results), and Apg1 (D. J. Klionsky, unpublished results).

Bishop *et al.* used kinase sensitization to study the effects of target-specific inhibition of the Cdc28p kinase from *Saccharomyces cerevisiae* [18]. Cdc28p is the major CDK in budding yeast and is essential for advancement through multiple stages of the cell cycle [29]. 1-Naphthylmethyl-PP1 (1-NM-PP1) was found to be a potent and specific inhibitor of Cdc28-as1 (Cdc28 F88G) from studies both *in vitro* and *in vivo*. Interestingly, a low concentration of 1-NM-PP1 (500 nM) caused *cdc28-as1* cells to arrest at G₂/M with a 2C DNA content and large hyperpolarized buds, while a higher concentration of 1-NM-PP1 (5 μ M) caused *cdc28-as1* cells to arrest in G₁ with a 1-C DNA content. This suggested that the G₂/M transition is more sensitive to inhibition of Cdc28p activity than the G₁/S transition in the yeast cell cycle.

This result was completely unexpected because previous studies showed that most temperature-sensitive *cdc28* mutants arrested as unbudded cells in G₁ at elevated temperatures, suggesting that the G₁/S transition is more sensitive to the inhibition of Cdc28p activity [30]. The discrepancy between genetically (*ts*) and pharmacologically induced phenotypes can be explained by the possibility that Cdc28p has other critical cellular functions that are not directly attributable to its enzymatic activity. This demonstrates that chemical studies using small molecules complement traditional genetic studies in cell biology by revealing otherwise hidden functions of proteins.

Weiss *et al.* [27] utilized this kinase-sensitization strategy to study the physiological functions of Cla4p in budding yeast. Cla4p is an effector for Rho-family GTPase Cdc42p and is known to be involved in various actin-polarization-related processes [31]. A genetic approach using temperature-sensitive mutants for the study of Cla4 is not ideal because actin-polarization-related processes are intrinsically temperature sensitive [32]. Weiss *et al.* generated an inhibitor-sensitized Cla4 allele (Cla4-as3), which (similar to JNK) contained a second mutation (Fig. 1) necessary for high sensitivity to 1-NM-PP1. It was observed that the identity of the residue N-terminal to the DFG motif strongly affects sensitivity to inhibitor analogs: Thr or a larger residue at this position often abolishes binding of analogs, presumably due

to a clash with the naphthyl moiety in 1-NM-PP1 [26]. The inhibitor was then used to block Cla4-as3 activity at different stages of the cell cycle to reveal the roles of Cla4 during these different processes. Again, this revealed functions of the target kinase different from those revealed by genetic studies [27].

Besides their use in cell biological studies, monospecific inhibitors can also be used for kinase substrate identification. These inhibitors should significantly reduce the phosphorylation of the substrate proteins of the target kinase *in vivo*, which could be utilized to confirm those substrates identified in direct *in vitro* labeling experiments using orthogonal ATP analogs (Fig. 2). Therefore, the same approach provides two complementary methods for kinase substrate identification and validation.

It should be noted that a small number of kinases are not active when the gatekeeper residue is mutated to Gly or Ala. Such kinases display reduced stability or activity as purified proteins or in cellular assays (unpublished results). This problem can be addressed by introducing additional mutations to regain stability or activity, which was demonstrated by the work done on two isoforms of PKA, PKA α and PKA β (G. S. McKnight, unpublished results). It was shown that PKA α tolerated the modification at the gatekeeper residue, while modified PKA β showed a substantial loss of catalytic activity. This difference due to mutation of the gatekeeper residue was unexpected due to the high level of conservation between the two isoforms. Sequence alignment revealed that the differences between the two isoforms are all conservative except at position 47 (I47 in α and K47 in β). When Lys47 in PKA β was substituted with Ile, as in PKA α , kinase activity was increased to a level near that of wild-type, based on a reporter assay. Thus, second-site-suppressor mutations can be rationally found based solely on sequence information with homologous kinases that are known to tolerate mutation of the gatekeeper residue to Ala or Gly. Currently, we are in the process of identifying positions important for stability or activity of kinases aided by the data we have on all the kinases in which the gatekeeper residue has been modified.

To summarize, a novel chemical genetic approach has been developed that possesses many advantages over purely genetic or chemical approaches for the study of protein kinase function. Most importantly, it is generalizable, with the potential of being applied to every protein kinase in the genome. We expect this method will be increasingly used in cell biology studies and will significantly accelerate the elucidation of various functions that kinases carry out in eukaryotic cells.

Acknowledgments

We thank members of the Shokat lab, particularly P. J. Alaimo, for helpful advice and critical reading of the manuscript. This work was supported by NIH grants CA70331 and AI44009 and NSF grant MCB-9996303.

Protein Dephosphorylation

Jack E. Dixon, Editor

This Page Intentionally Left Blank

Overview of Protein Dephosphorylation

Jack E. Dixon

*Department of Biological Chemistry,
University of Michigan,
Ann Arbor, Michigan*

There are two classes of enzymes that regulate signaling through the phosphorylation and dephosphorylation of proteins: protein kinases and protein phosphatases. This section of the *Handbook on Cell Signaling* will focus on the regulation, structure, and function of the protein phosphatases. Protein phosphatases are generally divided into two main groups based on substrate specificity. Protein phosphatases (PPs) specifically hydrolyze serine/threonine phosphoesters, while protein tyrosine phosphatases (PTPs) are phosphotyrosine specific. A subfamily of PTPs, the dual-specificity phosphatases, are capable of efficient hydrolysis of both phosphotyrosine and phosphoserine/threonine. Although both PPs and PTPs catalyze phosphoester hydrolysis, they employ different catalytic mechanisms.

The PPs comprise a large family of metallo-protein phosphatases whose functions within the cell are extremely diverse and highly regulated. Amino acid sequence comparisons within the catalytic domains revealed that two main gene families exist. PP1, PP2A, and calcineurin (PP2B) are members of the same gene family, whereas PP2C shares no sequence homology to PP1, PP2A, or PP2B and thus represents a distinct gene family. This section of the Handbook

addresses the regulation, structure, and function, as well as the importance, of PP inhibitors in understanding the roles of PPs.

PTPs also play important roles in cellular regulation. All PTPs are characterized by the active-site sequence motif, HCxxGxxRS(T), within a catalytic domain of approximately 200 to 300 residues. The receptor-like PTPs often have two of these catalytic motifs, while intracellular PTPs have a single catalytic domain. Unlike the PPs, the PTPs do not require metal ions for catalysis. Outside of the catalytic domain, the amino acid sequences generally show limited identity. X-ray structures of intracellular receptor-like and dual-specificity phosphatases have led to a detailed understanding of the biology and catalytic mechanism of this family of proteins. In addition to structure, this section of the Handbook also focuses on important receptor phosphatase regulation and the functions of PTPs in disease states. Two important families of PTPs (PTEN and myotubularin), which do not function on protein substrates, are reviewed in the lipid second messengers section of the Handbook. Finally, a chapter is devoted to a family of “Styx/dead” PTPs (catalytically dead) that appear to be of biological importance.

Protein Serine/Threonine Phosphatases and the PPP Family

Patricia T. W. Cohen

*Medical Research Council Protein Phosphorylation Unit,
School of Life Sciences, University of Dundee,
Dundee, Scotland*

Current Classification of Protein Serine/Threonine Phosphatases

Protein serine/threonine phosphatases are enzymes that reverse the actions of protein kinases by cleaving phosphate from serine and threonine residues in proteins. They are structurally and functionally distinct from the acid and alkaline phosphatases and are also separate from the family of protein phosphatases encompassing the tyrosine and dual specificity (tyrosine and serine/threonine) phosphatases.

The current classification of protein serine/threonine phosphatases is based upon the primary structures of their catalytic subunits. The amino acid sequences of the catalytic subunits fall into two main groups that have been termed the PPP family, of which the prototypic member is Ppp1c (PP1), and the PPM family, of which the prototypic member is Ppm1c (PP2C). The protein serine/threonine phosphatase that dephosphorylates the carboxy-terminal domain (CTD) of RNA polymerase II possesses a distinct amino acid sequence and thus represents the founding member of a third family, FCP (Table 1).

Background

The discovery that protein phosphatases regulate cellular functions originated from studies on the dephosphorylation of a single serine residue in glycogen phosphorylase [1,2]. Many different high-molecular-weight protein phosphatase activities dephosphorylating a variety of protein substrates

were subsequently identified. A classification based on sensitivities to inhibitor proteins and activation by metal ions proposed that most known eukaryotic cytosolic phosphatase activities could be accounted for by four distinct types of protein phosphatase catalytic subunits: PP1, PP2A, PP2B, and PP2C [3]. Type 1 phosphatases (PP1 and its complexes) dephosphorylate the β subunit of phosphorylase kinase and are potently inhibited by inhibitor-1 and inhibitor-2. Type 2 protein phosphatases preferentially dephosphorylate the α subunit of phosphorylase kinase and are insensitive to the inhibitor proteins. PP2A is unaffected by metal ions, PP2B (found to be identical with a major calcium binding protein, calcineurin, isolated from brain [4]) is dependent on calcium ions and calmodulin, and PP2C is dependent on magnesium ions for activity. The primary structures for mammalian PP1 (GenBank Acc. Nos. X07798, X14832, X61639, M27071, M27073, D90163-D90166), PP2A (M16968, X06087, Y00763, M20192, M20193, J03804, X14159, X14087) and PP2B/calcineurin (J04134, M29551, D90035, D90036) deduced from the complementary DNA demonstrated that these catalytic subunits belong to the same family [5]. In contrast, analysis of cDNA encoding PP2C (J04503, S87757, S87759, S90449) and pyruvate dehydrogenase phosphatase (L18966) revealed an unrelated amino acid sequence [6]. These studies therefore identified two distinct gene families encoding the protein serine/threonine phosphatases: the PPP family, which includes PP1, PP2A, and PP2B, and the PPM (Mg^{2+} -dependent protein phosphatase) family, for which PP2C is the founding member.

Table I Families of Protein Serine/Threonine Phosphatases

Family	PPP	PPM	FCP
Signature motifs	–GDxHG– –GDxVDRG– –GNHE–	–ED– –DG– –DG–	–Lx(I/V/L)xLxxx(L/I)(V/I)H– –RPxxxxF–
Active site	Bimetal (Fe ³⁺ + Zn ²⁺ in native PPP3)	Bimetal (both Mn ²⁺ in expressed Ppm1)	Not determined
Catalytic mechanism	Metal-ion-catalyzed dephosphorylation	Metal-ion-catalyzed dephosphorylation	Not determined
Other characteristics	Some active in absence of metal ions, others activated by Ca ²⁺ ; some members inhibited by naturally occurring toxins	Dependent on Mg ²⁺ or Mn ²⁺ for activity where tested; some members are also activated by Ca ²⁺	Dependent on Mg ²⁺ , Mn ²⁺ or Ca ²⁺ for activity
Human genes	≥13	≥9	≥5
Common names of some members	Ppp1c/protein phosphatase 1/ PP1 Ppp2c/protein phosphatase 2A/ PP2A Ppp3c/protein phosphatase 2B/ PP2B calcineurin/ Ca ²⁺ -calmodulin-regulated protein phosphatase	Ppm1/protein phosphatase 2C Ppm2/pyruvate dehydrogenase phosphatase <i>S. cerevisiae</i> PTC <i>A. thaliana</i> KAPP and ABII <i>B. subtilis</i> SpoIIE	RNA polymerase II CTD phosphatase
Evolution	Present in eukaryotes and some prokaryotes	Present in eukaryotes and some prokaryotes	Present in lower and higher eukaryotes
Proteins with a similar domain that are not known to have protein Ser/Thr phosphatase activity	Diadenosine tetraphosphatase (<i>E. coli</i>) and related phosphatases (Purple acid phosphatases have weak sequence similarities to PPPs)	N-terminal domain of adenylyl cyclase (<i>S. cerevisiae</i>) TAK-1 binding protein	Not determined

Note: The nomenclature for the human genes and encoded proteins of the PPP and PPM families proposed by a committee at the FASEB Conference on Protein Phosphatases in 1992 is used in Tables 1 and 2 [28]. Other terms and synonyms in current usage for the proteins are also included. The PPP family are reviewed in [21,29,30] and the FCP family described in [31,32]. For the PPM (PP2C) family (see section by Russell).

Evolution and Conserved Features of the PPP Family

Members of the PPP family of protein phosphatases are widely distributed in all eukaryotic phyla (Fig. 1). Although initially believed to be absent from prokaryotes, a truncated PPP domain with protein serine phosphatase activity was detected in bacteriophages [7,8], cyanobacteria, and other (but not all) eubacteria [9–11], and an entire PPP domain was discovered in archeobacteria [12] (Fig. 2). These studies indicated that PPPs were present before the divergence of prokaryotes and eukaryotes, although acquisition of some PPPs by horizontal gene transfer to prokaryotes cannot be entirely ruled out.

The PPP catalytic domain, which spans ≈270 amino acids in eukaryotes, possesses the signature motifs –GDxHG–, –GDx(V/I)DRG–, and –GNHE–, which are virtually invariant among prokaryotic and eukaryotic protein phosphatases and are located in the amino terminal half of the molecules (Fig. 2). These invariant residues play crucial roles in binding divalent metal ions (probably Fe²⁺ and Zn²⁺ in the native enzymes), which are located at the catalytic center. They also interact with the phosphate group of the substrate and are considered to be the essential motifs for the phosphomonoesterase activity. The carboxy-terminal half of the

eukaryotic catalytic domain contains four other motifs (–HGG–, –WxD–, –RG–, and –RxH–) that are virtually invariant among eukaryotes and archeobacteria [10,13] and are mainly involved in further interactions with one of the metal ions (see Chapter 100 for the crystal structures of Ppp1 and Ppp3). The –SAxNY– motif, invariant in eukaryotes but absent from prokaryotes, including archaeobacteria, is in a flexible loop region that has been implicated in the binding of toxins and inhibitor-2 to the eukaryotic PPPs.

Catalytic Activities of the PPP Family Members

PPPs dephosphorylate phosphoserine and phosphothreonine residues in proteins *in vivo* and *in vitro*. Mammalian PP1, PP2A, and PP2C have also been shown to dephosphorylate histidine residues in proteins *in vitro* [14]. Mammalian PPPs expressed in *Escherichia coli* display properties that are slightly different from the native enzymes, including dependence or partial dependence on divalent metal ions such as Mn²⁺ or Mg²⁺ [15]. Bacterially expressed mammalian Ppp1c also exhibits protein-phosphotyrosine activity, in addition to serine/threonine phosphatase activities, but this disappears when the enzyme is refolded in the presence

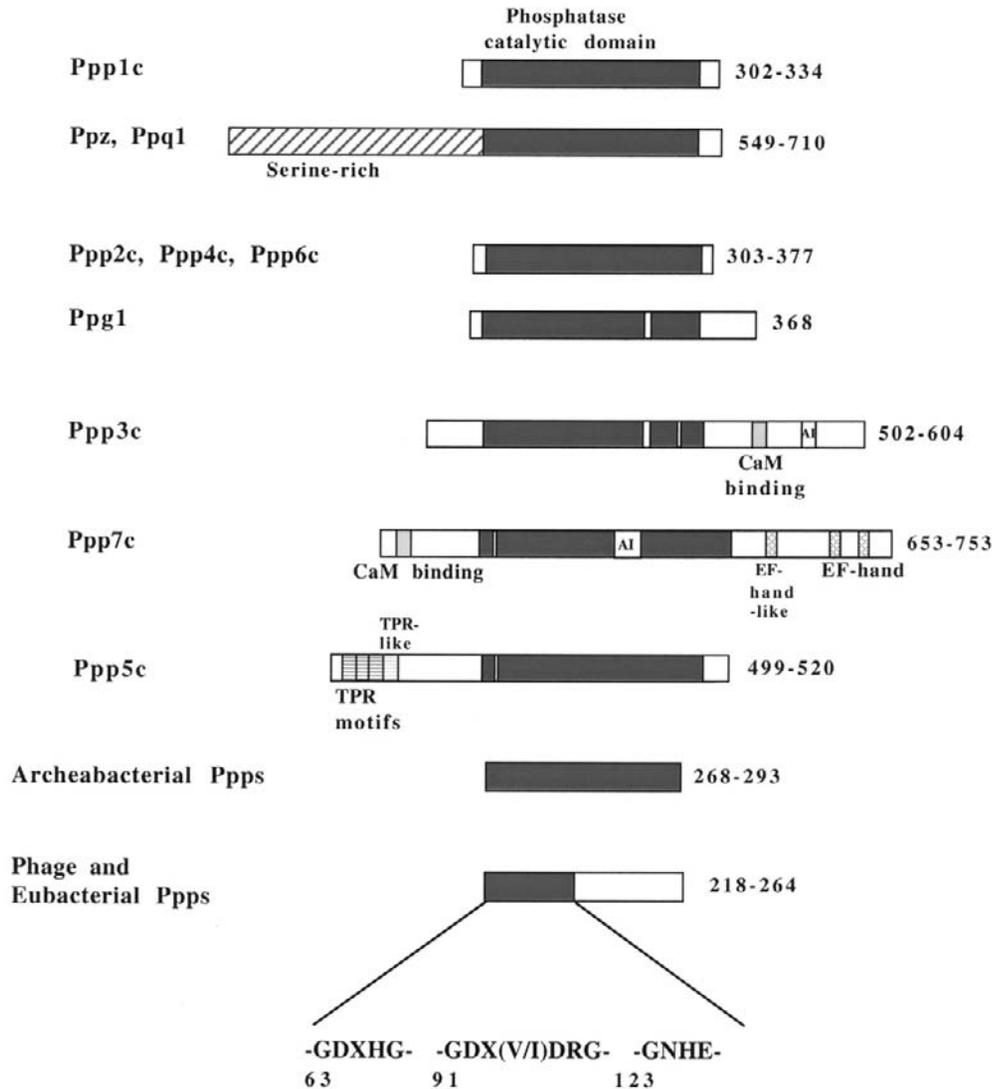

Figure 2 Domain organization of protein phosphatases in the PPP family. Bacteriophage and eubacteria Ppps show homology to the eukaryotic and archeabacterial protein phosphatases in the amino-terminal half of the catalytic domain, but the carboxy-terminal halves show little similarity. Autoinhibitory regions (AIs), Ca^{2+} -binding EF hands, tetratricopeptide repeats (TPRs), and calmodulin (CaM) binding sites are indicated. The numbers of amino acids in different phosphatases with each type of structure are given on the right. The three invariant amino acid motifs found in all PPP family members are shown at the bottom of the figure (numbers refer to the amino acid position in PP1 α_1 /PP1 γ_1).

of inhibitor-2, indicating that it is unlikely to be a property of the native enzyme *in vivo* [16]. Ppp2 (PP2A) exhibits some protein tyrosine phosphatase activity in the presence of the protein PTPA [17]. Bacterially expressed phage lambda Ppp exhibits protein-serine, -threonine, -histidine, and -tyrosine phosphatase activities [18], while native cyanobacterial PPP exhibits protein-serine, -tyrosine, -histidine, and -lysine phosphatase activities *in vitro* [11]. Thus, the activities of some Ppps may be wider than dephosphorylation of protein-bound phosphoserine and phosphothreonine residues. The discovery that the diadenosine tetraphosphatases have sequence similarities to the PPP family provides evidence that the essential PPP signature motifs for phosphomonoesterase activity have been utilized for the hydrolysis of biomolecules other than protein-bound phosphoesters [13].

PPPs dephosphorylate serine and threonine residues that lie in unrelated amino acid sequences, suggesting that, in contrast to many protein kinases, specificity is not determined primarily by the linear sequence of amino acids of either side of the phosphorylated residue. Rather, these observations suggest that higher order structures and/or interaction with regulatory subunits are involved [19].

Eukaryotic PPP Subfamilies

In eukaryotes, the PPP family was found to include four different subfamilies by comparison of the amino acid sequences of the catalytic domains: PPP1, PPP2, PPP3, and PPP5/PPP7, although the PPP5 and PPP7 groups are only

slightly more closely related to each other than to other phosphatase subfamilies (Fig. 1). The PPP2 subfamily includes recognizable subgroups PPP2, PPP4, and PPP6. Prokaryotic Ppps are highly divergent from eukaryotic Ppps but show the most similarities to members of the PP5/PPP7 subfamily.

Virtually all eukaryotes possess members of the PPP subgroups 1 to 7, an exception being Ppp3c, which does not appear to have been identified in plants. In addition, some protozoan species may not have representatives of all family members. Twelve PPP family members are known in *Saccharomyces cerevisiae* and 13 in the human species [20–22]. Somewhat surprisingly, sequencing of the human genome does not appear to have uncovered any more readily identifiable PPP members, indicating that there has not been a significant increase in the number of PPP catalytic subunits from yeast to humans. Interestingly, *Drosophila* possesses 19 PPP family members. Two are located on the Y chromosome (Ppp1-Y1 and Ppp1-Y2) and at least two others are related to male-specific functions (PppY-55A and Ppp N-58A, all of which appear to lack homologs in *Homo sapiens*). Some Ppps in *S. cerevisiae* (Ppq1, Ppz1, Ppz2, Ppg1) also have no homologs in humans. Thus, it is possible that gene duplication within different eukaryotes may be a mechanism used to produce regulation by Ser/Thr dephosphorylation of processes specific to particular organisms. In plants, at least 8 Ppp1c isoforms have been produced by gene duplication [23]. Most mammalian PPP members in the Ppp1-6 subgroups are present in all tissues that have been examined, but Ppp7c is restricted to retina and brain. The functions regulated by PPPs are extremely diverse (Table 2).

Domain and Subunit Structure of PPP Family Members

Many protein serine/threonine phosphatases in the PPP family are high-molecular-weight complexes containing one or more regulatory subunits. A large number of different regulatory subunits bind in a mutually exclusive manner to the Ppp1c catalytic subunit [24,25] or the Ppp2(PP2A) core complex of the catalytic subunit and a regulatory subunit [17]. These interactions allow a single PPP catalytic subunit to participate in many different cellular functions. Details of these PPP regulatory subunits and the functions they confer on their catalytic subunit are discussed in other chapters.

Although Ppp1c (PP1) and Ppp2c (PP2A) possess only very short amino- and carboxy-terminal regions outside the catalytic region, other PPP family members may possess fused amino- and carboxy-terminal domains that, at least in some cases, impart distinct properties to the catalytic domain. Thus, Ppp3c (PP2B, calcineurin) has a carboxy-terminal domain that allows the enzyme to be activated by Ca²⁺/calmodulin, as well as an autoinhibitory pseudosubstrate domain [26]. Ppp7c has EF hand sequences that confer Ca²⁺ sensitivity and a calmodulin-binding motif that is distinct from that of Ppp3c [22]. PP5 has an inhibitory amino terminal domain containing three tetratricopeptide repeats (TPRs) that are likely to allow interaction with other proteins [21,27].

The amino acid sequences of Ppp1c and Ppp2c have been extremely conserved throughout the evolution of multicellular eukaryotes, and these enzymes are among the most slowly evolving proteins known. This may be because they interact with a wide variety of regulatory proteins and also because of

Table II Structures and Properties of the Human PPP Catalytic Subunits

Human gene name	Chromosomal location	Protein name	Number of amino acids ^a	Fused regulatory domain	Regulatory subunits	Subunit structure of complexes	Activators/inhibitors	Functions regulated
<i>PPP1CA</i>	11q13	Ppp1c α /PP1 α	α_1 330; α_2 341	No	>50 different regulatory subunits	Mainly heterodimeric, some heterotrimeric species	<i>Inhibitor-1</i> <i>Inhibitor-2</i> <i>Okadaic acid</i> <i>Microcystin</i> <i>Tautomycin</i>	Many, diverse; determined by variable regulatory subunit (see Chapter 102 references [24] and [25])
<i>PPP1CB</i>	2p23	Ppp1c β / PP1 β /PP1 δ	β 327					
<i>PPP1CC</i>	12q24	Ppp1c γ /PP1 γ PP1c γ	γ_1 323; γ_2 337					
<i>PPP2CA</i>	5q23-q31	Ppp2c α /PP2-A α PP2A α	α 309	No	Core regulatory PPPR1(A) + ≥ 14 different regulatory subunits	Mainly heterotrimeric, some heterodimeric species	<i>Okadaic acid</i> <i>Microcystin</i>	Many, diverse; determined by variable regulatory subunit (see chapter reference [17])
<i>PPP2CB</i>	8p12-p11	Ppp2c β / PP2A β PP2Ac β	β 309		OR α 4			
<i>PPP4C</i>	16p12-p11	Ppp4c/PP4/ PPX	307	No	PPP4R1, PPP4R2 α 4	Heterodimeric + higher molecular mass structures	<i>Okadaic acid</i> <i>Microcystin</i>	Organization of microtubules at centrosomes [33–35]; signaling pathways (?) [36,37]

^bThe names PPP7CA (AF027977) and PPP7CB are used here for genes referred to as PPEF1 and PPEF2 in some databases.

their many crucial roles in cellular processes, such as the cell cycle. The structural conservation of these phosphatases may explain why they have become targets of so many structurally distinct toxins.

Medical Importance of the PPP Family

The discovery that eukaryotic Ppp1 and Ppp2 are potently inhibited by naturally occurring toxins and tumor promoters, such as okadaic acid and microcystin, brought this group of enzymes to the attention of the general public, and the importance of protein serine/threonine phosphatases to the study of medicine was highlighted when it was discovered that Ppp3c (PP2B /calcineurin) was the target of the widely

used immunosuppressive drugs cyclosporin and FK506 (see Chapter 101). In addition, DNA tumor viruses (SV40 and polyoma virus) and HIV-1 have been shown to compromise the function of PP2A by producing proteins that compete with specific regulatory subunits [17]. Somewhat similarly, the dsRNA virus herpes simplex produces PP1-binding proteins that recruit Ppp1c from host cell complexes in order to enhance its own replication and evade host cell defense mechanisms [25].

Introduction

Structural studies of the two families of protein phosphatases responsible for dephosphorylating serine and threonine residues have revealed that, although these families are unrelated in sequence, the architecture of their catalytic domains is remarkably similar and distinct from the protein tyrosine phosphatases. The diversity of structure within the PPP and PPM families is generated by regulatory subunits and domains that function to modulate protein specificity and to localize the phosphatase to particular subcellular locations [1].

Protein Serine/Threonine Phosphatases of the PPP Family

The protein Ser/Thr phosphatases PP1, PP2A, and PP2B of the PPP family, together with PP2C of the PPM family, account for the majority of the protein serine/threonine phosphatase activity *in vivo*. While PP1, PP2A, and PP2B share a common catalytic domain of 280 residues, these enzymes are divergent within their noncatalytic N and C termini and are distinguished by their associated regulatory subunits to form a diverse variety of holoenzymes. Major members of the PPP family are encoded by numerous isoforms that share a high degree of sequence similarity,

especially within their catalytic domains. Greater sequence diversity occurs within the extreme N and C termini of the proteins. Although these isoforms have similar substrate specificities and interact with the same regulatory subunits *in vitro*, the phenotype of a functional loss is isoform specific, indicating they perform distinct functions *in vivo*.

Overall Structure and Catalytic Mechanism

Structural analyses of members of the PPP family have begun to reveal the molecular basis for catalysis, inhibition by toxins, and aspects of their regulatory mechanisms. Crystal structures are available for (1) various isoforms of PP1 in complex with natural toxins [2,3], the phosphate mimic tungstate [4], and a peptide of the RVxF targeting motif [5]; (2) PP2B in the auto-inhibited state [6] and as a complex with FK506/FKBP [6,7]; (3) the PR65/A-subunit of PP2A [8]; and (4) a regulatory TPR domain of PP5 [9]. The catalytic domains of the PP1 catalytic subunit (PP1c) and PP2B share a common architecture consisting of a central β -sandwich of two mixed β -sheets surrounded on one side by seven α -helices and on the other by a subdomain comprised of three α -helices and a three-stranded β -sheet (Fig. 1A). The interface of the three β -sheets at the top of the β -sandwich creates a shallow catalytic site channel. Conserved amino acid residues present on loops emanating from the β -strands of this central β -sandwich are responsible for coordinating a pair of

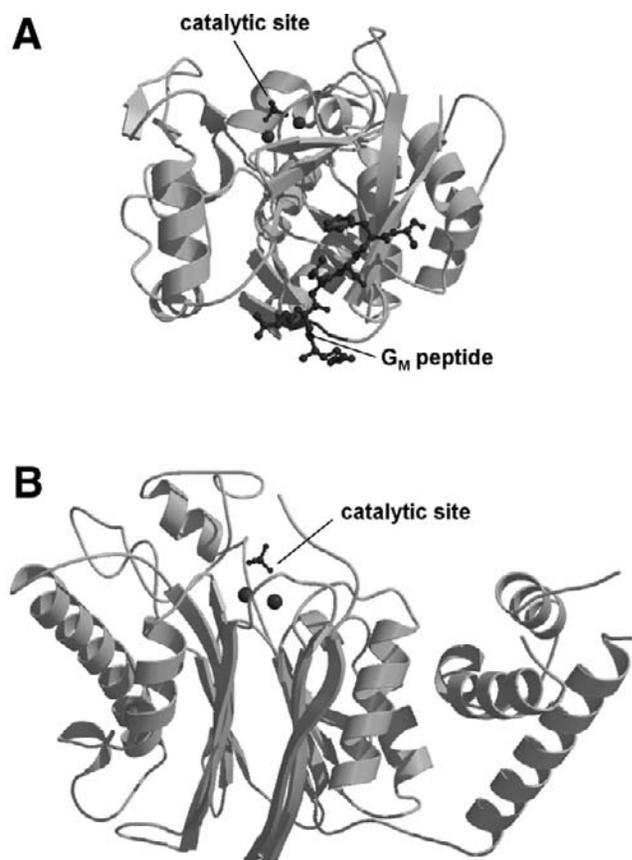

Figure 1 Ribbon diagrams showing an overview of the structures of protein Ser/Thr phosphatase catalytic domains. (From Egloff, M. P. *et al.*, *EMBO J.*, 16, 1876–1887, 1997. With permission.) (B) Human PP2C α the catalytic site is indicated by the two metal ions and bound phosphate ion. (From Das, A. K. *et al.*, *EMBO J.*, 15, 6798–6809, 1996. With permission.)

metal ions to form a binuclear metal centre (Fig. 2A). Crystallographic data on PP1c and PP2B provided the first compelling insight regarding the role of metal ions in the catalytic reaction of the PPP family. The identity of the two metal ions is slightly controversial. Proton-induced X-ray emission spectroscopy performed on PP1c crystals produced from the protein expressed in *Escherichia coli* indicated that the metal ions were Fe²⁺ (or Fe³⁺) and Mn²⁺ [4], whereas atomic absorption spectroscopy of bovine brain PP2B indicated a stoichiometric ratio of Zn²⁺ and iron [10]. There have also been conflicting reports concerning the iron oxidation states, with both Fe²⁺ and Fe³⁺ being observed. Native PP2B is most likely to contain Fe²⁺, explaining the time-dependent inactivation of PP2B that results from the oxidation of the Fe–Zn center [11]. Oxidation of the binuclear metal center and phosphatase inactivation may represent a mechanism for PP2B regulation by redox potential during oxidative stress or as a result of reactive oxygen species generation following receptor tyrosine kinase activation, in a process reminiscent of the inactivation of protein tyrosine phosphatases by oxidation of the catalytic site Cys residue by

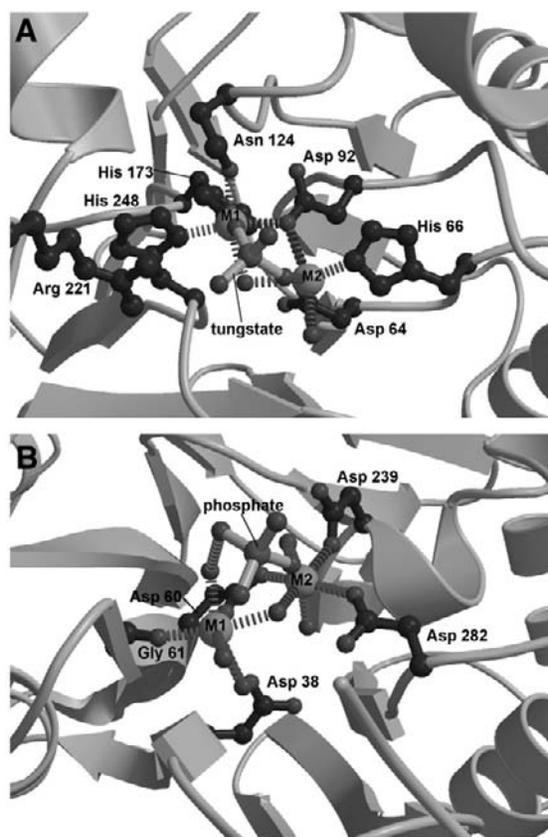

Figure 2 Comparison of the catalytic sites of the protein Ser/Thr phosphatases, showing the common binuclear metal center, coordinating the phosphate of the phosphorylated protein substrate: (A) human PP1 γ (for clarity Arg 96 is not shown) and (B) human PP2C α .

hydrogen peroxide and perhaps analogous to a possible PP2C regulatory mechanism, discussed later [10].

The structure of PP1c with tungstate and PP2B with phosphate indicated that two oxygen atoms of the oxyanion-substrate coordinate the metal ions (Fig. 2A) [4,7]. Two water molecules, one of which is a metal-bridging water molecule, contribute to the octahedral hexa-coordination of the metal ions. The metal coordinating residues (aspartates, histidines, and asparagines) are invariant among all PPP family members. These residues, together with Arg and His residues that interact with the phosphate group of the phosphorylated residue, occur within five conserved sequence motifs found in other enzymes, including the purple acid phosphatase, whose common function is to catalyze phosphoryl transfer reactions to water [12]. These observations suggest that PPP and purple acid phosphatases evolved by divergent evolution from an ancestral metallophosphoesterase. Consistent with roles in catalysis, mutation of these residues either eliminates or profoundly reduces catalytic activity.

PPPs catalyze dephosphorylation in a single step with a metal-activated water molecule or hydroxide ion. The most convincing evidence for this notion is that the purple acid phosphatase, which is generally related in structure to the PPPs at both the tertiary level and at the catalytic site [13], promote dephosphorylation with inversion of configuration

of the oxygen geometry of the phosphate ion [14]. This indicates that a phosphoryl-enzyme intermediate would not occur. The two metal-bound water molecules are within van der Waals distance of the phosphorous atom of the phosphate bound to the catalytic site, and one of them is likely to be metal-activated nucleophile.

Interactions with Regulatory Subunits

PP1 and PP2A are responsible for regulating diverse cellular functions by dephosphorylating multiple and varied protein substrates. This seemingly paradoxical situation was resolved by the discovery that distinct forms of PP1 and PP2A holoenzymes occur *in vivo*, where essentially the same catalytic subunit is complexed to different targeting and regulatory subunits. For PP1 it has been shown that targeting subunits confer substrate specificity by directing particular PP1 holoenzymes to a subcellular location and by enhancing or suppressing activity toward different substrates. The control of PP1 holoenzyme structure and activity by the combinatorial selection of different targeting/regulatory subunits has recently been the subject of numerous reviews [15,16] and will not be discussed at length here, although the contrasting structural mechanism by which the conserved PP1 and PP2A catalytic subunits are able to form diverse holoenzyme structures will be discussed.

In the case of PP1, it is known that the binding of targeting subunits to its catalytic subunit is mutually exclusive, suggesting that there are one or more common or overlapping binding sites, recognized by all PP1-binding subunits. It is therefore a little surprising that PP1-binding subunits are highly diverse structurally and share little to no overall sequence similarities. The key to understanding this paradox came from the crystal structure of PP1c in complex with a short, 13-residue peptide derived from a region of the PP1-glycogen targeting subunit (G_M) responsible for PP1c interactions (Fig. 1A). This structure showed that the peptide associated with the phosphatase via two hydrophobic residues (Val and Phe), which engage a hydrophobic groove on the protein surface formed from the interface of the two β -sheets of the central β -sandwich and remote from the catalytic site [5]. Two basic residues of the peptide immediately N-terminal to the Val residue form salt-bridge interactions with Asp and Glu residues at one end of the peptide binding channel. Alanine substitutions of either the Val or Phe residues of the peptide abolish PP1-peptide interactions. Analysis of other PP1-binding subunit sequences revealed the presence of the identical or related sequence motif RRVxF, found to mediate the interactions between the G_M peptide and PP1c [5]. The role of the degenerative RVxF motif in mediating PP1-regulatory subunit interactions is now supported by numerous experimental observations. First, for various regulatory subunits, mutation of either hydrophobic residue of the motif in native proteins weakens or eliminates their association with PP1c. Second, peptides corresponding to the RVxF motif competitively disrupt the interactions of regulatory subunits with PP1c. Third, the use of a common or overlapping PP1c

binding site explains why the interactions of regulatory subunits is mutually exclusive. The number of PP1 holoenzyme structures that could be generated in this manner is potentially infinite, and to date over a hundred PP1 regulatory subunits have been characterized.

The residues of PP1 that interact with the RVxF peptide are conserved in all isoforms of PP1 in all eukaryotic species, although not within PP2A and PP2B, explaining why PP1-binding subunits are unique to PP1. The mechanism of combinatorial control of PP2A holoenzyme structure is different from that of PP1 and is mediated by a scaffolding subunit termed the PR65/A subunit, which simultaneously associates with the PP2A catalytic subunit and a variable regulatory B subunit. The ability to recognize a variety of regulatory subunits (perhaps over 50) is conferred by the architecture of the PR65/A subunit, which consists of 15 tandem repeats of a 39-amino-acid sequence termed the HEAT motif and related in structure to ARM repeats. These repeats assemble to create an extended molecule ideally suited for mediating protein-protein interactions [8]. Combinatorial generation of variable PP2A holoenzymes is achieved by the ability of different combinations of HEAT motifs to select different regulatory B subunits [8].

Interactions of Natural Toxins with PP1

PP1 and PP2A are specifically and potently inhibited by a variety of naturally occurring toxins such as okadaic acid, a diarrhetic shellfish poison and powerful tumor promoter, and microcystin, a liver toxin produced by blue-green algae [17]. Whereas PP2B is only poorly inhibited by the toxins that affect PP1 and PP2A, it is known to be the immunosuppressive target of FK506 and cyclosporin in association with their major cellular binding proteins, the *cis-trans* peptidyl prolyl isomerase FKBP12 and cyclophilin, respectively [18]. The mechanism of inhibition of PP1 by okadaic acid and microcystin LR have been defined by structures of PP1 in complex with these inhibitors. Both inhibitors, although structurally different, bind to a similar region of the phosphatase, occupying the catalytic channel to directly block phosphatase-substrate interactions. Regions of PP1 that contact the toxins include the hydrophobic groove and the $\beta 12/\beta 13$ loop, the latter undergoing conformational changes to optimize contacts with microcystin [2,3]. Both toxins disrupt substrate-phosphatase interactions by competing for sites on the protein that coordinate the phosphate group of the substrate. For example, carboxylate and carbonyl groups of microcystin interact with two of the metal-bound water molecules [2], whereas okadaic acid contacts the two phosphate-coordinating arginine residues (Arg-96 and Arg-221) [3]. A similar mechanism of phosphatase inhibition by steric hindrance of substrate binding is observed in the structure of the full-length PP2B holoenzyme, for which the autoinhibitory domain lies over the substrate binding channel of the catalytic domain in such a way that a Glu side chain accepts a hydrogen bond from two of the metal-bound water molecules [6].

Protein Serine/Threonine Phosphatases of the PPM Family

Protein phosphatases of the PPM family are present in both eukaryotes and prokaryotes for which the defining member is PP2C. Biochemically, the PPM family was distinguished from the PPP family by its requirement for divalent metal ions (Mg^{2+}) for catalytic activity, although it is now known from crystal structures that both PPP and PPM phosphatases catalyze dephosphorylation reactions by means of a binuclear divalent metal center. Within the PPM family, the PP2C domain occurs in numerous structural contexts that reflect structural diversity [19]. For example, the PP2C domain of the *Arabidopsis* ABI1 gene is fused with EF hand motifs, whereas in KAPP-1, a kinase interaction domain associated with a phosphorylated receptor precedes the phosphatase domain. Other less closely related examples include the Ca^{2+} stimulated mitochondrial pyruvate dehydrogenase phosphatase, which contains a catalytic subunit sharing 22% sequence identity with that of mammalian PP2C, and the SpoIIE phosphatase of *Bacillus subtilis*, which has ten membrane-spanning regions preceding the PP2C-like catalytic domain. A surprising homolog is a 300-residue region of yeast adenylyl cyclase present immediately N-terminus to the cyclase catalytic domain that shares sequence similarity with PP2C. This domain may function to mediate Ras-GTP activation of adenylyl cyclase activity and is not known to possess protein phosphatase activity. In eukaryotes, the various isoforms of PP2C have been implicated in diverse functions such as regulation of cell-cycle progression mediated by dephosphorylation of CDKs [20], to regulation of RNA splicing [21], control of p53 activity [22], and regulation of stress response pathways in yeast [23].

The sequences of protein phosphatases of the PPM family share no similarity with those of the PPP family, and the natural toxins that inhibit the PPP family have no effect on PPM family phosphatases. It therefore came as a surprise when the crystal structure of human PP2C α revealed a striking similarity in tertiary structure and catalytic site architecture to the PPP protein phosphatases (Fig. 1B) [19]. Mammalian PP2C consists of two domains; an N-terminal catalytic domain common to all members of the PP2C family is fused to a 90-residue C-terminal domain, unique to the mammalian PP2Cs [19]. The catalytic domain is dominated by a central, buried β -sandwich of 11 β -strands formed by the association of two antiparallel β -sheets, both of which are flanked by a pair of antiparallel α -helices inserted between the two central β -strands, with four additional α -helices. The C-terminal domain is formed from three antiparallel α -helices remote from the catalytic site, suggesting a role in defining substrate specificity rather than catalysis.

At the catalytic site of PP2C, two Mn^{2+} ions, separated by 4 Å, form a binuclear metal center and are coordinated by four invariant aspartate residues and a nonconserved Glu residue (Fig. 2B) [19]. These residues are situated at the top of the central β -sandwich that forms a shallow channel

suitable for the dephosphorylation of phosphoserine- and phosphothreonine-containing proteins. Six water molecules coordinate the two metal ions. One of these water molecules bridges the two metal ions and four form hydrogen bonds to a phosphate ion at the catalytic site. Dephosphorylation is probably catalyzed by a metal-activated water molecule that acts as nucleophile in a mechanism similar to that proposed for the PPP family. A recent kinetic analysis of PP2C α by Denu and colleagues [24] indicated that Mn^{2+} and Fe^{2+} are the most effective divalent metal ions in promoting dephosphorylation reactions, suggesting that at least one of these ions must be present at the catalytic site. In contrast, Zn^{2+} and Ca^{2+} competitively inhibit PP2C Mn^{2+} -dependent activity. An Fe^{2+} -containing catalytic site would be analogous to the PPP protein phosphatases and possibly explains the H_2O_2 -mediated inactivation of PP2C [25] consequent on the redox sensitivity of Fe^{2+} and its oxidation to the inactive Fe^{3+} valence state [24]. The finding that an ionizable group with a pKa of 7.0 has to be deprotonated for catalysis was fully consistent with the notion from the crystal structure that a metal activated water molecule acts as a nucleophile [19,24]. Fluoride has long been used as an inhibitor of both PPP and PPM phosphatases, and the rationale for this inhibition is now clear from the catalytic mechanism of serine/threonine phosphatases revealed by the crystal structures. By substituting for the metal-bound nucleophilic water molecule, fluoride prevents metal-activated nucleophilic attack on the phospho-protein substrate. Substitution of Ala for the Asp residues of the catalytic site in yeast and plant PP2C homologs and in the related phosphatase SpoIIE from *B. subtilis* abolishes catalytic activity, supporting a role for the metal ions in catalysis [26,27].

Conclusions

Although the PPP and PPM phosphatases share a similar tertiary structure, characterized by a central β -sandwich and flanking α -helices, with related catalytic site architectures and mechanisms, two observations suggest that these protein families have evolved from distinct ancestors. First, the secondary structure topology of the PPP and PPM families are unrelated and there is no simple rearrangement of chain connectivities that would allow the PPP topology to be transformed into the PPM topology. Second, the conserved sequence motifs of the PPP family required for metal binding and catalysis, typical of some metallophosphoesterases, are distinct from the conserved sequence motifs of the PPM family. The comparison of the PPP and PPM families of Ser/Thr protein phosphatases provides interesting contrasts with the protein phosphatases of the C(X)₅R-motif superfamily composed of three distinct gene families: (1) the conventional protein tyrosine phosphatases (PTPs), including dual-specificity phosphatases and PTEN lipid phosphatases; (2) low-molecular-weight protein tyrosine phosphatases (LmPTPs); and (3) Cdc25 dual-specificity phosphatases [28]. These proteins

share a similar overall tertiary structure composed of a central β -sheet surrounded on both sides by α -helices which results in an identical catalytic site architecture in all three families characterized by the nucleophilic Cys-residue located within a phosphate binding cradle. What distinguishes the three protein families are differences in their secondary structure topology; however, the topologies of the PTP and ImPTP families are related by a simple permutation of secondary structure connectivity, suggesting that these families may have evolved from the same ancestor and diverged as a result of exon shuffling events. In recent years, much has been learned of the structural details of Ser/Thr protein phosphatases relating to their overall folds, catalytic mechanisms, and interactions with regulatory subunits and toxins. However, still elusive is the structure of a Ser/Thr protein phosphatase in complex with a phosphoprotein substrate that would explain the basis for the selectivity for Ser/Thr residues and reveal the mechanism of substrate selectivity by regulatory subunits. It is hoped that future studies of Ser/Thr phosphatase will address these questions.

Naturally Occurring Inhibitors of Protein Serine/Threonine Phosphatases

Carol MacKintosh and Julie Diplexcito

*MRC Protein Phosphorylation Unit,
School of Life Sciences, University of Dundee,
Dundee, Scotland*

Introduction

A variety of natural products (Fig. 1) operate in diverse ecological contexts as mating lures and defense toxins. Humans encounter them as killers, water and food contaminants, a diarrhetic shellfish poison, an aphrodisiac, horse dope, suspect tumor promoters, valuable research reagents, and cures for mild afflictions and cancer, while microcystin was branded a potential bio-weapon in the recent U.K. Antiterrorism, Crime and Securities Act. The distinctive effects and associations of each toxin are attributable to its site of production, cell permeability, stability, abundance, and potency, for every one of these chemicals exerts its biological effects by binding tightly to active sites of protein serine/threonine phosphatases in the eukaryotic PPP family [1]. Considering how much effort and money are invested by pharmaceutical companies to find even one useful inhibitor of many signaling enzymes, the number and variety of very potent protein phosphatase inhibitors found in Nature is remarkable.

Effects of Inhibitors in Cell-Based Experiments

The myriad biological effects of these cell-permeable inhibitors have provided many compelling demonstrations that reversible phosphorylation of serine/threonine residues is an all-pervasive mechanism of cellular control.

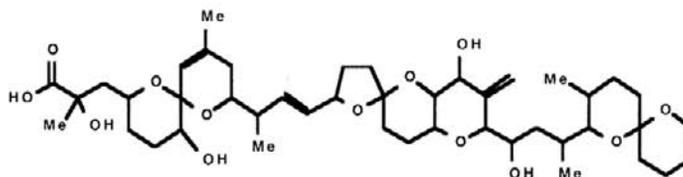

When protein phosphatases are inhibited, phosphate is trapped in phosphorylated substrates and accumulates if the relevant protein kinases are at least slightly active. Thus, use of protein phosphatase inhibitors in combination with protein kinase inhibitors and other effectors has provided clues about many signaling pathways. By way of example, protein phosphatase inhibitors cause sustained backward swimming of *Paramecium* in response to depolarizing stimuli (but only in the presence of external Ca^{2+} [2]), activate some and block other antifungal defense responses in plants [3], and promote apoptosis of mammalian cells [4]. Interestingly, fibroblasts that are resistant to okadaic acid-induced apoptosis have been selected from a population of cells expressing a human cDNA library which provides a novel approach to identifying those components of the apoptotic machinery for which phosphorylation is deregulated by the inhibitor [4].

Of course, the major limitation in using protein phosphatase inhibitors inside cells is that they inhibit many closely related enzymes, albeit with different relative potency (see Fig. 1), making dissection of cellular functions for each individual protein phosphatase difficult or impossible. The best we can do is to provisionally assign roles for PP1 when tautomycin has more potent effects than okadaic acid [5], or implicate PP2A, PP4, or PP5 when fostriecin is most effective [6].

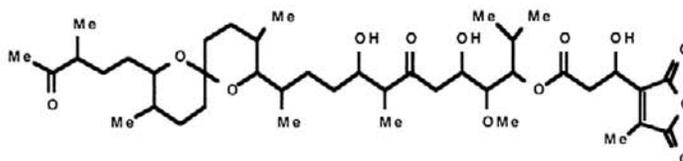

One way around the problem of discriminating among homologous family members might be to replace the natural

Okadaic acid

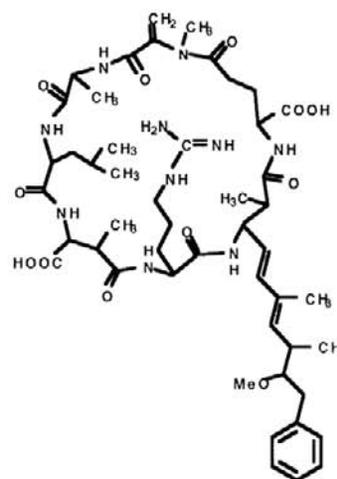

Diarrhetic shellfish poison,
produced by dinoflagellates.
Tumour promoter.
IC₅₀'s: PP2A=PP4<PP1.

**Tautomycin**

Produced by species of *Streptomyces*.
IC₅₀'s: PP1>> PP2A.

**Microcystin-LR**

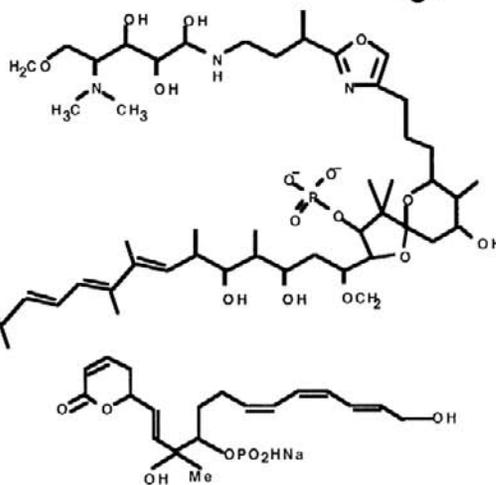

Hepatotoxic cyclic heptapeptide from species of freshwater cyanobacteria. Suspect tumour promoter.
IC₅₀'s: PP2A [= or slightly <] PP1.

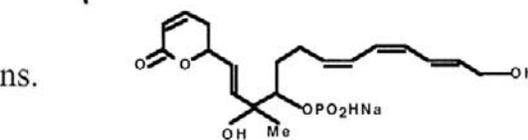

The nodularins are hepatotoxic pentapeptides from species of *Nodularia* cyanobacteria.
IC₅₀'s and toxicity of nodularins are similar to microcystins.

Calyculin A

Isolated from the marine sponge *Discodermia calyx*.
IC₅₀'s: PP1=PP2A.

**Fostriecin**

Produced by *Streptomyces pulveraceus*.
Has shown promise in treating cancers.
IC₅₀'s: PP2A=PP4<<<PP1.
Inhibits topoisomerase II at higher concentrations.

**Cantharidin**

Transferred as a mating 'gift' from male to female blister beetles. Horses killed by beetles in hay. Causes blistering and irritation, regarded by some as an aphrodisiac 'Spanish Fly' but has killed humans. Wart treatment. IC₅₀'s: PP2A<PP1.

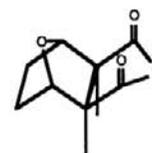

Figure 1 Naturally occurring inhibitors of PP1, PP2A, and related enzymes in the PPP family. None of these toxins is an effective inhibitor of PP2B (the rapamycin and FK506 drugs that target PP2B are not considered in this chapter). Representatives of each toxin are shown, although variants exist in Nature; for example, more than 60 congeners of microcystin exist. The toxins generally bind to the enzyme with nanomolar and subnanomolar affinities, except for cantharidin, which operates in the micromolar range.

enzymes in cells with forms that are more or less toxin sensitive. Another would be to use the natural toxins as “leads” for the synthesis of more specific inhibitors.

As well as soothing the frustrations of cell biologists, there are also medical reasons to seek specific inhibitors. Fostriecin is reported to confer an antitumor effect [7] at concentrations that probably inhibit PP2A, PP4, and PP1 in cells. In contrast, okadaic acid and microcystin are potent tumor promoters [8]. Which actions underpin the pro- and antitumor properties of these toxins? Can more specific cancer therapies with fewer side effects than fostriecin be designed?

The Toxins Bind to the Active Sites of Protein Phosphatases

The microcystins, nodularins, okadaic acid, and tautomycin adopt similar tadpole shapes in solution, and crystal structures show that okadaic acid and microcystin-LR bind to common residues in three distinct regions of the PP1 active site [9,10]. Carboxylates of both toxins interact directly with the hydrated metal ions in the substrate-phosphate binding center, while their rigid hydrophobic tails tuck into a hydrophobic groove that runs out from the active site. The third major contact is with the C-terminal β 12– β 13 loop, which protrudes over the catalytic center. When microcystin-LR binds, the β 12– β 13 loop is pulled closer into the active site, and the dehydroalanine residue of microcystin-LR forms a Michael adduct with Cys-273 in the β 12– β 13 loop of PP1 γ [9,11,12]. This covalent bond is not essential, because neither reducing the dehydroalanine nor mutating Cys-273 has much impact on the inhibitory potency [12]. However, when the adjacent Tyr-272 is mutated or the enzyme truncated at the Ala-268 of the ${}_{267}\text{SAPYNYC}_{273}$ motif of the β 12– β 13 loop, the sensitivity to okadaic acid and microcystin-LR is lowered dramatically, although the phosphorylase phosphatase activity of the enzyme is unchanged [13,14].

Molecular modeling, binding kinetics, enzyme mutagenesis, and toxin modification studies suggest that the other inhibitors share the same binding site as okadaic acid and microcystins but depend on contacts with the common residues to different extents. Thus, unlike okadaic acid and microcystin-LR, fostriecin binds equally well to intact PP1C and the enzyme with an incomplete β 12– β 13 loop [13,14]. Paradoxically, however, when yeast PP2AC α was mutated within its predicted β 12– β 13 loop, binding to both fostriecin and okadaic acid was impaired [6]. Perhaps fostriecin forms a bridge between the catalytic center and the β 12– β 13 loop in PP2A but cannot find complementary contacts in the β 12– β 13 loop of PP1 [6]. This scenario might explain the much higher potency of fostriecin for PP2A and PP4, compared with PP1.

Dissecting further details of contacts at the catalytic center and β 12– β 13 overhanging loop should explain the distinct potencies of the toxins for the different protein phosphatases. Why is PP2B so toxin resistant? Does the unsaturated lactone in fostriecin bind covalently to the cysteine in the β 12– β 13 loop of PP2A (analogous to microcystin) [6]?

How do cantharidides and calyculin A bind? A consensus is being reached that calyculin A binds in a position similar to okadaic acid, with its phosphate group slotting into the substrate-phosphate binding pocket. However, phosphate docking cannot be a major binding determinant because a dephospho-calyculin A is also a potent PP1 inhibitor [15].

Clearly, binding at the active site limits possibilities for changing the toxin sensitivity of enzymes without accompanying changes in catalytic properties. Expressing PP2A with a mutated β 12– β 13 loop has been useful in implicating this enzyme in effects of fostriecin in yeast [6]. However, this loop may also mediate allosteric regulation of the protein phosphatase catalytic subunits by their regulatory subunits. More immediate possibilities for altering inhibitory specificity may come from redesigning the toxins.

Chemical Synthesis of Protein Phosphatase Inhibitors

These toxins have been a challenge to synthetic chemists, requiring innovative strategies to form multiple bonds and control many chiral centers. Nevertheless, total syntheses of okadaic acid, tautomycin, calyculins, cantharidides, microcystin, and fostriecin, as well as several fragments and analogs, have been successful [16–19]. Analogs of cantharidin, microcystin, and tautomycin with improved selectivity for either PP1 or PP2A compared to the parent compounds have been made [20,21]. These results give rise to hopes of the rational design of even more selective inhibitors.

Another goal is to improve the chemical stability of fostriecin [19]. Phase I clinical trials of fostriecin as a cancer treatment were halted before reaching therapeutic or maximum-tolerated toxic doses, reportedly due to problems of poor drug stability in storage and *in vivo* [7].

Microcystin Affinity Chromatography and Affinity Tagging

Microcystins have unique attributes that enhance their utility. First, the dehydroalanine of microcystins can be linked by simple Michael addition to small, reactive thiols carrying an amine group that can, in turn, be linked to N-hydroxy-succinamide-activated Sepharose, biotins, or other compounds [22,23]. Recall that similar Michael chemistry is used in Nature to link the dehydroalanine to a conserved cysteine in the β 12– β 13 loop of the protein phosphatases [9,11,12]. The covalent link is not essential for potent inhibition however [12], which means that the synthesized adducts can be used to affinity-purify protein phosphatases and their regulatory subunits. Active native forms of PP1 can be eluted from microcystin–Sepharose using chaotropic salts, while denaturing buffers are needed to remove PP2AC from the column [22]. Perhaps electroelution would work?

The covalent link to the enzymes means that microcystin can also be used as an enzyme affinity tag. Microcystin–protein phosphatase complexes can be detected after

SDS-PAGE or column chromatography by using a radiolabeled microcystin or antimicrocystin antibodies [22,24,25] (Diplexcito *et al.*, unpublished data). We suggest that microcystin tagging may have untapped potential for probing cellular regulation of protein phosphatases.

Avoiding the Menace of Toxins in the Real World Outside the Laboratory

Our enthusiasm for using the toxins in biomedical research was tempered by news of a most tragic case of microcystin poisoning in 1996. More than 100 dialysis patients in Caruaru, Brazil, were infused with microcystic water and most died of liver failure [26]. The scale of tumor promotion and liver damage worldwide is more difficult to assess. However, microcystin levels above the WHO limit (1 µg/liter) and suspected human and animal poisonings are often reported [8].

How can researchers who understand toxin–phosphatase interactions help? One need is for better toxin tests. Identifying microcystins is a trivial matter in a research laboratory, but a test intended for wider use must be very robust and preferably give a visual signal. Several laboratories are working to design both simple dipstick tests and methods to destroy microcystins. As more and more cellular effects of microcystins are documented, microcystin-specific biomarkers may emerge to track whether this toxin is at the root of many cases of chronic liver damage.

Perhaps more challenging than the science, though, are issues of communication and politics. In contrast to the rapid enactment of legislation to prevent malevolent use of microcystin by terrorists, several nations are currently moving toward the development of health guidance levels for microcystins in drinking water. Maybe the new reputation of microcystin as a potential danger to national security will motivate systematic action to ensure that no one ever has to imbibe this toxin in drinking water from natural sources.

Protein Phosphatase 1 Binding Proteins

Introduction

The vast majority of cellular activities occur within microenvironments such as those of the nucleus, membrane, cytoskeleton, ribosome, mitochondria, glycogen particles, and other organelles. Because protein phosphorylation is a primary regulatory mechanism, the key interconverting enzymes, protein kinases and phosphatases, must also be localized. The paradigm for regulation by targeting was established for the striated muscle glycogen-associated phosphatase PP1G [1], in which the regulatory subunit R_{GL}/G_M directs the enzyme to the glycogen particle, in proximity to its substrates. This basic concept was expanded to include not only other forms of protein phosphatase 1 (PP1), but also other protein phosphatases and protein kinases [2]. Targeting is often achieved by interaction of domains in protein kinase and phosphatase regulatory subunits with various cellular structures. This implies that control of phosphorylation depends not simply on the activity of protein kinases and phosphatases, but also on their location in the cell and the partners with which they associate. By this mechanism, broad specificity kinases and phosphatases can acquire selectivity toward a specific subset of substrates. Further specificity is achieved if associated subunits participate in the recognition of substrate. In recent years, targeting/anchoring/scaffolding proteins such as A-kinase anchoring proteins (AKAPs) have been identified that tether both protein kinases and protein phosphatases to distinct intracellular locales [2].

Completion of the genome sequences of various organisms predicts that 2 to 3% of the genome encodes protein kinases and phosphatases. The protein kinases (over 500 in

the human genome) outnumber the phosphatases. This is especially true for the serine/threonine protein phosphatases. It is estimated that ~300 serine/threonine kinases are encoded by the human genome but only some two dozen catalytic subunits of serine/threonine protein phosphatases. The question of how such a limited number of protein phosphatases can dephosphorylate the myriad of cellular phosphoproteins in a specific and regulated manner appears to be satisfied by the existence of a multitude of regulatory/targeting subunits. In this review, discussion is limited to mammalian PP1-binding subunits and how they can account for the pleiotropic functions of the enzyme in the cell. The reader is also referred to other recent reviews on this topic that include a more extensive citation list than permitted in this chapter [3–5].

Protein Phosphatase 1 (PP1)

Protein phosphatase 1 belongs to the PPP family of phosphatases and is involved in the regulation of a wide variety of cellular processes ranging from intermediary metabolism to apoptosis. In mammals, three genes code for four or five highly conserved (~90%) isoforms of catalytic subunits of PP1 (PP1c), PP1c α_1 and α_2 , PP1c δ (also called PP1c β) and PP1c γ_1 and γ_2 , the subscripts indicating forms generated by alternative splicing. In the cell, PP1c does not exist as a free monomer but is present in oligomeric holoenzyme forms consisting of a catalytic subunit complexed with one or two regulatory and/or targeting subunits. Studies *in vitro* have failed to reveal either specificity of interaction between PP1c isoforms and various regulatory components or to

demonstrate isoform-related substrate specificity. Evidence, however, is accumulating that some PP1c isoforms may be involved in distinct cellular processes *in vivo* [6].

PP1 Regulatory or Targeting Subunits

Protein phosphatase 1 enzymes acquire specificity of function by their association with targeting/regulatory proteins that direct the enzyme to distinct subcellular structures or compartments in proximity to physiological substrates, confer substrate specificity and/or modulate enzyme activity. Over 40 PP1-associated proteins are currently known. Most interact with PP1c through multiple sites, a shared site recognizable in many of the subunits, and other sites unique to the individual proteins. The common docking site on PP1c is formed by a hydrophobic channel situated opposite the catalytic site and is flanked by an acidic region. This domain accommodates any of the variant forms of the binding motif [R/K][V/I/L]X[F/W/Y] (often given as RVXF) found in a large number of PP1c-bound proteins. However, the presence of the tetrapeptide does not necessarily define a PP1c-binding protein, as this sequence is found in more than 10% of proteins. Furthermore, its presence is not an absolute requirement for association with PP1c. The initial proposal of a mutually exclusive association of polypeptides harboring this motif with PP1c has been weakened by the recent findings that at least two polypeptides containing the motif can simultaneously associate with PP1c [7], supporting the notion that additional sites participate in the binding.

Based on analysis of eukaryotic genome sequences, Ceulemans and coworkers [5] have traced the evolution of 13 families of PP1 regulatory/targeting proteins and have suggested the existence of nine additional isoforms not previously recognized. Table 1 presents a classification of over 40 PP1c-binding proteins, and Fig. 1 shows a schematic diagram of the structure of representative members of the different groups. Some of the binding subunits function as inhibitors/modulators of activity and do not contain domains for targeting to specific locations. Others function as targeting subunits to direct the phosphatase to specific subcellular structures or substrates and have no known regulatory role. Yet other PP1c-binding proteins may perform both a targeting and a regulatory function.

PP1 Inhibitors or Modulators

The proteins in this group inhibit or modulate the activity of PP1 but do not contain targeting domains. In fact, PP1 was originally defined by its sensitivity to heat-stable protein inhibitor 1 (I-1) and 2 (I-2). I-1 and its brain homolog DARPP-32 (dopamine- and cAMP-regulated phosphoprotein of apparent M_r 32,000), I-2, inhibitor-3/HCGV (I-3), and the G substrate inhibit the free PP1c, whereas the PKC-phosphorylated inhibitor protein CPI-17 and its homologs PHI and KEPI are able to inhibit holoenzymes containing targeting subunits such as the glycogen- and myosin-associated

phosphatases [8,9]. Furthermore, I-1, DARPP-32, I-2, and I-3 all contain a variant of the PP1c-binding consensus RVXF motif (Fig. 1). The $^8\text{KIQF}^{12}$ sequence (homologous to RVXF) in I-1 and DARPP-32 is essential for inhibition, whereas the equivalent sequence $^{144}\text{KLHY}^{147}$ in I-2 is dispensable [10]. However, the N-terminal $^{12}\text{IKGI}^{15}$ residues in I-2 are required for inhibitory activity. This sequence occupies a unique site on PP1c, located adjacent to the hydrophobic groove [11]. Three additional PP1c-interacting sites have been identified in I-2 (Fig. 1) [10], establishing the paradigm that high-affinity binding may be achieved by multiple contacts. The activity of the majority of the inhibitory/modulatory subunits is controlled by phosphorylation. I-1 and DARPP-32 become potent inhibitors after phosphorylation by the cAMP-dependent protein kinase (PKA) at a conserved threonine residue, whereas phosphorylation by cyclin-dependent kinase 5 (Cdk5) prevents phosphorylation by PKA, rendering I-1 and DARPP-32 less effective inhibitors. The inhibitory activity of CPI-17, PHI, and G-substrate is also enhanced by phosphorylation. I-2 does not require phosphorylation and is a complex modulator of PP1 activity. Its stable interaction with PP1c at five distinct sites forms the inactive ATP-Mg²⁺-dependent holoenzyme that is activated by phosphorylation at T72 by glycogen synthase kinase 3 (GSK3), mitogen-activated protein kinase (MAPK), or Cdc2. Reactivation does not cause dissociation, arguing against a proposed chaperone role for I-2. The importance of these inhibitor proteins in the control of the phosphatase activity is highlighted by the phenotype of the DARPP-32 and I-1 knockout mice. DARPP-32 disruption impairs dopamine signaling, and the animals show decreased learning and reduced responses to substances of abuse [12]. I-1 knockout mice lack long-term potentiation at the perforant path–dentate cell synapses and have an impaired cardiac β -adrenergic response that is less severe than that caused by the over expression of PP1c [13].

Glycogen Targeting Subunits

Four glycogen-targeting subunits have been characterized and three more putative forms, encoded by *PPP1R3E*, *F*, and *G*, have been identified in the human genome based on homology to PP1c-binding and targeting motifs [5]. Whether or not they represent *bona fide* PP1 glycogen-targeting components remains to be determined. R_{GL} , also called G_M , was the first glycogen-binding subunit of PP1c identified and is exclusively expressed in striated muscle [14,15]. The N-terminal region contains binding sites for PP1c, glycogen, and possibly glycogen synthase (GS), whereas a hydrophobic region in the C-terminus anchors the protein to membranes. Interaction with PP1c most likely involves multiple contacts, one of which is the $^{65}\text{RVSF}^{68}$ sequence.

It has been proposed that muscle PP1G/ R_{GL} plays a major role in insulin and epinephrine control of glycogen metabolism via phosphorylation of the targeting subunit [1]. Insulin would cause phosphorylation of R_{GL} at S48 and activation toward glycogen synthase, whereas epinephrine would

Table I Mammalian Regulatory/Targeting Subunits of Protein Phosphatase 1

Regulatory/targeting subunit	Gene name ^a	Established or putative cellular function controlled and/or effect on PP1c
<i>Inhibitors/modulators</i>

^aThe human genome nomenclature recently redefined by Ceulemans *et al.* [5] for the PP1c-binding proteins is indicated.

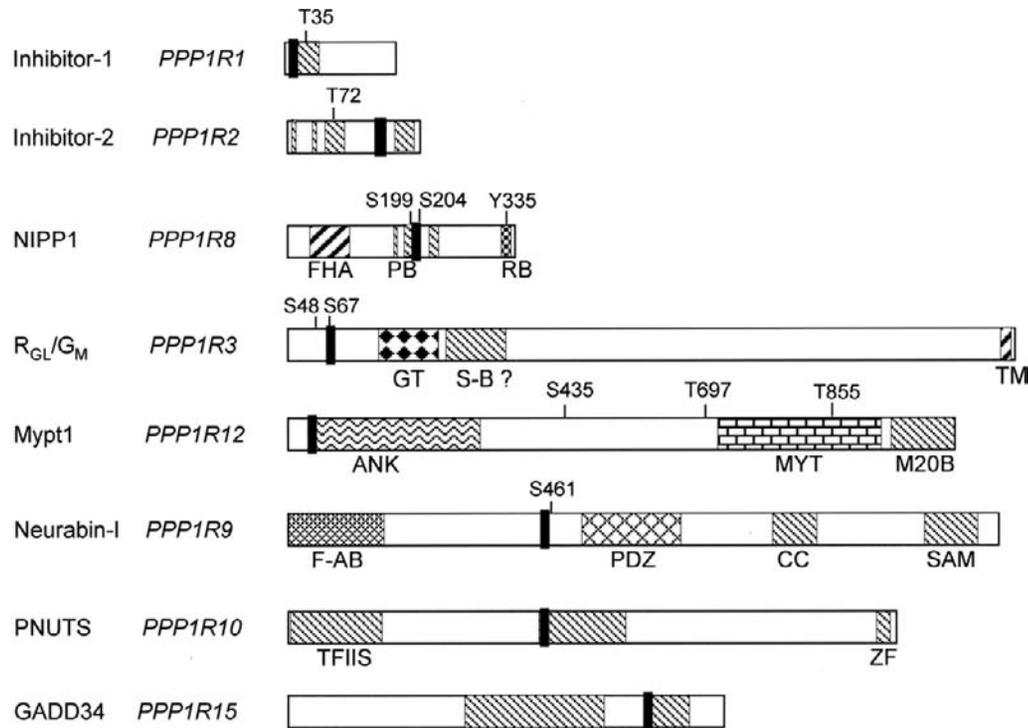

Figure 1 Domain structure of representative members of PP1c-binding proteins. Phosphorylation sites and various domains are indicated. The filled black box indicates the common PP1c-binding motif. Targeting domains are indicated by various patterns and abbreviations: FHA, forkhead associated; PB, polybasic; RB, RNA-binding; GT, glycogen targeting; S-B?, putative substrate-binding; TM, transmembrane; ANK, ankyrin repeats; MYT, myosin targeting; M20B, M20-binding; F-AB, F-actin binding; CC, coiled-coil; SAM, sterile alpha motif; TFIIIS, transcription factor IIS; ZF, zinc finger.

induce phosphorylation at S67, mediated by PKA, and cause dissociation of PP1c. The released PP1c would be less active toward glycogen-associated and perhaps membrane-bound substrates. Furthermore, activation of PKA would lead to phosphorylation of I-1, which then becomes a potent inhibitor of the released PP1c. However, recent studies have shown that R_{GL} is not phosphorylated at S48 in response to insulin [16,17], and disruption of the R_{GL} and I-1 genes has shown that neither is required for either insulin or epinephrine control of glycogen metabolism [17–19]. R_{GL} , though, is essential for control of GS by exercise and muscle contraction [20]. Direct phosphorylation of GS by GSK-3 and PKA, the protein kinases regulated by insulin and epinephrine, respectively cannot account for the effects on glycogen metabolism, as changes in phosphorylation at the GS sites recognized by these individual kinases are insufficient to account for the alterations of activity caused by the two hormones.

Of the other three glycogen-targeting subunits, G_L was thought to be liver specific, but a recent report describes G_L in human, but not in rodent, skeletal muscle [21]. PTG expression is higher in skeletal muscle, liver, heart, and fat, whereas R6 is more ubiquitously expressed. G_L , PTG, and R6 share homology to the N-terminal region of R_{GL} and lack the extended C-terminal tail and the membrane-binding domain [22,23]. All three contain the PP1c-binding motif and the glycogen-binding domain, but the two phosphorylation sites of R_{GL} are not conserved. PTG interacts with

glycogen metabolizing enzymes but, unlike the liver-specific PP1G/ G_L complex, PP1G/PTG is not controlled allosterically by phosphorylase *a*. Expression of the G_L subunit is downregulated in diabetic rats. Overexpression of PTG in Chinese hamster ovary cells increases the basal and insulin-stimulated GS activity, but neither insulin nor forskolin induce detectable PTG phosphorylation [23]. A mechanism has been proposed whereby PTG would affect PP1 activity by relieving inhibition by DARPP-32. However, neither I-1 nor DARPP-32 is required for insulin activation of glycogen synthase [19]. Thus, the mechanisms for control of PTG- and R6-containing phosphatases are largely unknown. Homozygous disruption of PTG results in embryonic lethality. Heterozygous PTG knockout mice retain activation of GS by insulin in skeletal muscles but appear to develop impaired glucose disposal with aging [24].

Myosin Targeting Subunits

Three subunits target PP1c to myosin [25]. The best characterized, Mypt1/M110, interacts with myosin type II and is involved in control of smooth muscle contraction, cell shape, and migration. The myosin phosphatase complex is a heterotrimer containing also a smaller polypeptide, M20 (~20 kD), that does not bind to PP1c but interacts with Mypt1 and myosin. In addition to a targeting function, Mypt1 confers substrate specificity, enhancing phosphatase activity

toward the regulatory myosin light chains while decreasing it toward phosphorylase. Two other actin-binding proteins, adducin and moesin, are also associated with and regulated by Mypt1 in non-muscle cells, supporting a role in actin cytoskeleton organization. The RVXF motif in the N-terminal region of Mypt1 is followed by seven or eight ankyrin repeats that may be involved in interaction with PP1c and/or myosin. The C-terminus harbors domains that bind to myosin and M20. Phosphorylation by a RhoA-activated kinase (ROCK), ZIP-like kinase, or the myotonic dystrophy protein kinase (DMPK) at T697 inhibits phosphatase activity, leading to increased light-chain phosphorylation and contraction in smooth muscle in the absence of changes in intracellular calcium levels. In contrast, phosphorylation at S435 during mitosis increases myosin light-chain phosphatase activity. Another feature of this phosphatase is that it is potently and specifically inhibited by CPI-17 [25], providing an additional mechanism for enhancement of myosin phosphorylation and smooth-muscle contraction. CPI-17 does not contain an RVXF motif. Phosphorylation by PKC causes a conformational change that appears to expose a region that may interact with PP1c.

Of the other two members of the family, Mypt2 is expressed in skeletal muscle, heart, and brain, whereas p85 is more widely distributed and appears to be required for assembly of the actin cytoskeleton. Both share structural similarity with Mypt1, including the PP1c-binding motif and the N-terminal ankyrin repeats. Interestingly, the small M20 subunit appears to be generated by alternative splicing of *PPP1R12B*, the gene that codes for Mypt2. A newly identified protein was named Mypt3, due to the presence of ankyrin repeats in addition to the RVXF motif [26]. However, based on the absence of a myosin-binding domain and on gene structural similarity, Ceulemans and coworkers [5] have reclassified it as a member of the TIMAP family, which may be involved in TGF β signaling (Table 1).

Nuclear Targeting Subunits

Protein phosphatase 1 is abundantly expressed in the nucleus, where it is complexed with a variety of regulatory subunits to control such processes as cell-cycle progression and division, transcription, and pre-mRNA splicing. Sds22, a protein required for exit from mitosis, and HCF-1 (human factor C1) have no discernable RVXF motif [27]. Disruption of the PP1c hydrophobic docking channel does not impair Sds22 binding, indicating that interaction involves other sites. Multiple contacts are also established between PP1c and NIPP1, nuclear inhibitor of PP1 (Fig. 1) [28]. Binding of the RVXF motif is not inhibitory by itself. A polybasic sequence preceding the common motif as well as a C-terminal region are required for high potency inhibition. Similar to I-2, phosphorylation is not required for inhibitory activity, and the action of two protein kinases, PKA and casein kinase II, relieves the inhibition without causing dissociation of the NIPP1/PP1c complex. NIPP1 is localized to nuclear "speckles" where it interacts with splicing factors

through its N-terminal forkhead-associated domain. The C-terminus binds RNA, supporting a role of NIPP1 in pre-mRNA splicing [29]. The splicing-factor-associated protein PSF1 also binds PP1c, perhaps allowing control of SF1, which inhibits early spliceosome formation once phosphorylated. Two proteins, AKAP350 and Nek2 (NIMA-related protein kinase 2), may localize PP1c to the centrosome [30,31]. Nek2 has been implicated in centrosome separation and, together with its substrate C-Nap1, is a PP1 substrate. PNUMS/p99 is another putative nuclear targeting subunit of PP1c [32]. An N-terminal sequence related to domains present in other transcriptional factors, TFIIS, elongin A, and CRSP70, and the presence of a zinc finger motif in the C-terminus may account for its chromatin association and a potential role in transcription.

Membrane or Cytoskeleton Targeting Subunits

A number of proteins associated with membrane and cytoskeletal structures have been shown to bind PP1c. Neurabin I and neurabin II (also known as spinophilin) are actin cross-linking proteins enriched in postsynaptic densities and dendritic spines [33,34]. Recent studies have shown that both neurabins and neurofilament-L display binding selectivity for the PP1c α and γ 1 isoforms [6]. Neurabins contain an N-terminal F-actin-associating domain that accounts for localization at the actin cytoskeleton, C-terminal coiled-coil and SAM (sterile alpha motif) modules that mediate homo- and heterodimerization, and a central PDZ protein-binding domain that may link PP1c to transmembrane proteins (Fig. 1). Phosphorylation of neurabin I by PKA at S461, immediately C-terminal to the RVXF sequence, reduces PP1c-binding, and a S461E mutation decreases inhibitory potency, suggesting regulation by cAMP signaling. Spinophilin knockout mice have provided evidence for a role in α -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid (AMPA) and *N*-methyl-D-aspartate (NMDA) receptor channel activity and in dendritic spine development [35].

A defining feature of the AKAPs is the localization of PKA to different intracellular structures, including cytoskeleton, mitochondria, nucleus, membrane, and vesicles [2]. Several AKAPs also interact with protein phosphatases, resulting in colocalization of enzymes that potentially exert opposite effects [30]. The AKAP Yotiao, an NMDA-receptor-associated protein, binds PP1c. Although Yotiao contains the RVXF motif, this sequence is not essential for interaction. The tethered PP1c is active and may negatively regulate receptor activity. Recently, it has been shown that Yotiao, complexed with PKA and PP1c, also associates with cardiac potassium channels. Mutations that disrupt the interaction correlate with inherited cardiac arrhythmias [36]. AKAP149, an integral protein of the endoplasmic reticulum/nuclear envelop network, recruits PP1c to the lamina of the nuclear membrane where it may function to dephosphorylate B-type lamins for reassembly of the nuclear envelop at the end of mitosis. AKAP220 binds to and inhibits PP1c through multiple contacts and recruits the phosphatase to vesicles.

Endoplasmic Reticulum/Ribosome Targeting Subunits

Biochemical and genetic studies have implicated PP1 in the control of protein synthesis. Several components of the translational machinery are controlled by phosphorylation. In response to various stress stimuli, such as ultraviolet irradiation, viral infection, and nutrient deprivation, the eIF2 α subunit becomes phosphorylated and translation initiation is inhibited. GADD34, a growth arrest and DNA-damage-induced gene, has been implicated in growth arrest and apoptosis induced by endoplasmic reticulum (ER) stress signals and has been shown to be associated with reticular structures. In response to stress signals, protein synthesis is shut off through phosphorylation of eIF2 α . GADD34 forms a complex with PP1c that specifically promotes the dephosphorylation of eIF2 α . The stress-dependent expression of GADD34 implies that it may provide for a negative feedback mechanism to evade or promote recovery from the translational inhibition. GADD34 interacts with PP1c through its C-terminus, a region homologous to the herpes virus ICP34.5 protein domain that also interacts with PP1c and that redirects the phosphatase to dephosphorylate eIF-2, enabling continued protein synthesis in virally infected cells. Interestingly, I-1 binds both GADD34 and PP1c via different domains [7]. The C-terminus of I-1 is essential for interaction with a central region of GADD34, whereas the N-terminus binds PP1c, raising the possibility for formation of a heterotrimeric complex containing two PP1 regulatory components, each of which harbors a canonical docking site. Similarly, hSNF5/INI1, a member of the hSWI/SNF chromatin remodeling complex, binds to free GADD34 and PP1c as well as to the GADD34/PP1c complex to form a stable heterotrimer [37]. These findings indicate that association of different regulatory subunits with PP1c may not necessarily be mutually exclusive even if each contains an RVXF sequence. Another ER protein that binds PP1c is the glucose-regulated protein chaperone GRP78 [38], which is involved in protein translocation and folding and is induced by ER stress. Although the role of this phosphatase in the ER is not clearly understood, it may be part of a general mechanism to overcome the inhibition of translation in response to cellular stress conditions.

Other PP1c-binding proteins that may be involved in control of translation are the large ribosomal protein L5 and RP111. L5 [39] is located at the interphase between the small and large ribosomal subunits where translation initiation takes place and is therefore positioned for potential control of this step. In addition, the phosphorylated S6 (small ribosomal subunit) protein promotes the preferential recruitment of polypyrimidine-track-containing mRNAs. The phosphatase that dephosphorylates S6 is a type 1 enzyme.

Other PP1c-Binding Proteins

Although much has been learned about localization and function of PP1, the precise roles of most PP1c-binding proteins are not completely understood. Not all physically

target the enzyme to subcellular compartments. Some of the reported binding proteins may simply be substrates. Included would be the retinoblastoma protein pRb, phosphofructokinase (PFK), the ryanodine receptor, and the Na-K-Cl co-transporter NKCC1, all of which are controlled by phosphorylation and some of which do not contain any recognizable PP1c docking site. The 53BP2 [40] interacts with p53 and Bcl2 and may specifically direct the phosphatase activity toward proteins whose phosphorylation state is critical for the control of apoptosis. The ability of PRIP-1 to bind inositol1,4,5-trisphosphate [41] may allow recruitment of PP1c to membranes in response to stimuli that generate the phospholipid. The two heat-stable inhibitors of PP2A, I₁^{PP2A} and I₂^{PP2A} have recently been shown to enhance *in vitro* PP1c activity toward specific substrates [42]. These polypeptides also do not contain a recognizable PP1c-binding site. However, whether or not they can function as activators of PP1 *in vivo* remains to be determined.

Conclusions

All forms of PP1 holoenzymes contain a similar, highly conserved catalytic subunit but differ in the associated regulatory subunits. The large number of associating proteins provides compelling evidence that the distinctive features of different PP1 holoenzymes reside in the regulatory components. Thus, functionally distinct forms are generated by combination of a similar catalytic component with different regulatory subunits that are responsible for targeting the enzyme to specific cellular locales, for conferring substrate specificity, or for controlling the enzyme activity. The large number of targeting/regulatory subunits of PP1 can thus account for the pleiotropic function of the type 1 phosphatase in the cell.

Role of PP2A in Cancer and Signal Transduction

Introduction

PP2A is the most abundant serine/threonine-specific phosphatase in mammals, representing approximately 0.3% of the total cellular protein [1]. Over the last decade, PP2A has been recognized as a major player in many biological processes, including differentiation, development and morphogenesis, organ function, and growth control. As a consequence of its role in growth control, PP2A is implicated in the development of cancer. On the cellular level, PP2A acts in numerous signaling pathways by counteracting protein kinases. It can function in the nucleus, in the cytosol, or at the plasma membrane. The great versatility of PP2A is based on the large number of regulatory subunits, which, in combination with two isoforms of the catalytic subunit, could in theory give rise to over 70 different forms of PP2A. Furthermore, PP2A interacts with an ever-increasing number of other cellular proteins (approximately 40 at the latest count) as well as viral proteins. We are only beginning to appreciate the complexity and importance of PP2A. In this review, current knowledge regarding the structure of PP2A and its presumed role in cancer and signaling are reviewed. Because of space limitations, the review is inevitably incomplete and the reader is referred to excellent recent reviews for more detailed discussion of various aspects of PP2A [2–7].

Structure of PP2A

PP2A exists in cells as two major forms: holoenzyme and core enzyme [8,9]. The core enzyme consists of a 36-kDa

catalytic C subunit and a 65-kDa regulatory A subunit. Holoenzymes are composed of a core enzyme to which one of several regulatory B subunits is bound (Fig. 1). It has been proposed that the core enzyme is an artifact of enzyme isolation and does not exist in cells. This is highly unlikely, however, as under the gentlest conditions of enzyme purification the core enzyme represents one-third to one-half of total cellular PP2A [8,9]. Recently, it has been suggested that the core enzyme is unstable unless associated with a regulatory B subunit [10]. It remains to be seen, however, whether in these experiments the absence of core enzyme is a consequence of eliminating all B subunits, which is not physiological, or whether it has resulted from toxic experimental conditions. The A and C subunits exist as two isoforms: A α and A β and C α and C β , respectively. Thus, four core enzymes, A α C α , A β C α , A α C β , and A β C β , might exist in cells that could have distinct substrate specificities and distinct abilities to interact with regulatory subunits or other cellular proteins. Therefore, the question of whether core enzymes are a physiological reality is an important one.

The B subunits fall into four families, designated B, B' (also called B56), B'', and B''' which appear unrelated by sequence alignment. The B family has four members: B α , B β , B γ , and B δ . The B' family consists of five genes encoding B' α , B' β , B' γ , B' δ , and B' ϵ . Including isoforms and splice variants, there are a total of at least eight B' subunits. The B'' family has four members, designated PR48, PR59, PR72, and PR130. The latter two are splice variants of the same gene. The B''' family has two members: striatin and SG2NA. The existence of so many regulatory subunits suggests that PP2A is a highly regulated phosphatase and that its various forms fulfill

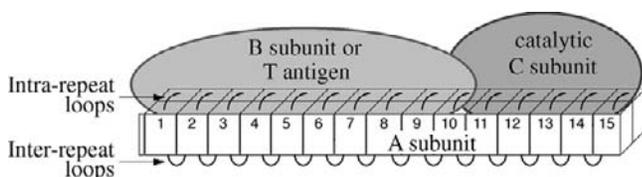

Figure 1 Model of PP2A.

numerous distinct functions. Another class of proteins able to associate with PP2A core enzyme are tumor (T) antigens encoded by polyoma viruses. Their binding domains on the A subunit overlap with those of B subunits. T antigens play a key role in neoplastic transformation by polyoma viruses, and their association with PP2A is essential for transformation [11].

Subunit Interaction

To elucidate the function of PP2A, it is important to understand how its subunits interact with each other and what controls the interaction. A model of the core and holoenzymes and of complexes of the core enzyme with T antigens is shown in Fig. 1 [12,13]. The A subunit consists of 15 non-identical repeats [14–16]. Each repeat is composed of two α -helices connected by a loop (intra-repeat loop). Adjacent repeats are connected by inter-repeat loops. Collectively, the repeats form an extended, hook-shaped molecule that is stabilized by hydrophobic interactions. The intra-repeat loops are involved in binding B and C subunits as well as T antigens. The B subunits bind to repeats 1 to 10 and the C subunits to repeats 11 to 15 of the A subunit. SV40 small T binds to repeats 3 to 6, and polyoma virus small T and middle T bind to repeats 2 to 8 [12,13].

Determining how the different B subunit family members and T antigens, although largely unrelated by sequence, bind to overlapping regions of the A subunit has been approached by site-directed mutagenesis, showing that some $A\alpha$ mutations in loops 1 to 10 affect binding of all B subunits (B, B', and B'') whereas others affect binding of specific B subunits. Thus, the binding sites on the A subunit for different types of B subunits are composed of both common and distinct amino acids [17]. Interestingly, a recent study revealed that all members of the B, B', and B'' families, but not B''', share two evolutionary conserved domains, 103 and 58 residues in length, which are involved in binding to $A\alpha$ [18]. The limited homology of these domains escaped detection when the complete sequences of B, B', and B'' were aligned. Another study identified two adjacent arginine residues in B γ (R165 and R166) which form an essential salt bridge to a pair of glutamic acid residues (E100 and E101) in the intra-repeat loop of repeat 3 of $A\alpha$ [19].

Carboxymethylation of Leu 309 at the C terminus of the catalytic subunit is important for recruiting B subunits to the core enzyme [20]. In addition, phosphorylation at tyrosine 307 affects holoenzyme formation as well as phosphatase activity [9].

Association of PP2A with Cellular Proteins

PP2A associates with numerous cellular proteins involved in growth regulation or apoptosis. These include several protein kinases, Rb-related protein p107, heat shock protein HSF2, translation termination factor eRF1, homeobox protein HOX11, myeloid-leukemia-associated protein SET, caspase 3, Bcl2, and cyclin G [2,6]. The mechanisms by which these interactions may affect growth regulation or apoptosis are largely unknown. PP2A also forms complexes with the tumor suppressor proteins adenomatous polyposis coli (APC) [21] and axin [22,23], two key players in the Wnt signaling pathway, as discussed in detail later [24–26].

Alteration or Inhibition of PP2A Is Essential in Human Cancer Development

When it was proposed over 10 years ago that PP2A might be a tumor suppressor [27], based on findings that okadaic acid acts as a potent tumor promoter as well as a strong inhibitor of PP2A, most regulatory B subunits had not yet been discovered and our view of PP2A was much simpler. Now it is clear that PP2A exists in numerous forms, some of which might suppress growth (see later discussion), while others might be growth stimulatory [28,29]. Strong support for the idea that PP2A is involved in growth control comes from the discovery that SV40 small T antigen and polyoma virus small T and middle T antigen form stable complexes with PP2A (Fig. 1) [2,11]. Of particular interest are two recent publications on the role of SV40 small T in the transformation of primary human cells. Yu *et al.* [30] reported that the transformation of primary human diploid fibroblasts and of mesothelial cells in culture depends on both SV40 large T and small T. Transformation of human cells does not occur without SV40 small T, and small T cannot be replaced by oncogenic Ras, in contrast to primary rodent cells, which can be transformed by the combination of SV40 large T and oncogenic Ras. Expression of telomerase is not required for transformation of human cells but only for growth beyond the point of senescence [30]. Similar results were reported by Hahn *et al.* [31] using human fibroblasts and human embryonic kidney cells. However, these authors found that Ras *is* required for transformation in addition to SV40 large T and small T, and transformation does not occur in the absence of either Ras or small T. This difference in Ras requirement between these two studies could be due to the time at which the transformation assay was scored (one group scored earlier than the other), the amount of small T expressed (one group used retroviral vectors, the other transfection), or the difference in cell type (K. Rundell, personal communication). The importance of both reports lies in the recognition that inhibition or alteration of PP2A by SV40 small T is required for transformation of primary human diploid fibroblasts and epithelial cells. In addition, transformation requires inactivation of p53 and pRb by complex formation with SV40 large T. Expression of telomerase is essential for the purpose of immortalization.

Further evidence for the importance of SV40 small T in transformation comes from experiments showing that human mesothelial cells expressing SV40 large T *and* small T are easier to transform by carcinogens than cells expressing large T only [32]. The potency of small T was also demonstrated in a transgenic mouse model in which only small T is expressed in breast epithelial tissue under the control of the acidic milk protein promoter [33]. Cyclin D1 is constitutively overexpressed in the small-T-expressing mammary epithelial cells, and mammary gland differentiation is inhibited. Importantly, 10% of the transgenic animals develop breast tumors. In contrast, transgenic mice expressing only large T in breast epithelium develop breast cancer at a lower rate and after a longer latency period [33].

Mutation of A α and A β Isoforms in Human Cancer

An independent line of evidence for PP2A playing a role in human cancer development comes from recent findings that PP2A is mutated in a variety of human malignancies, including cancer of the lung, breast, colon, and skin. Wang *et al.* [34] discovered that the gene encoding the A β subunit of PP2A is mutated or deleted in 15% of primary lung and colon cancers. Takagi *et al.* [35] described mutations in the A β subunit gene in four colon cancer cases. Furthermore, Calin *et al.* [36] reported that *both* the A α and A β subunit isoforms are genetically altered in a variety of primary human cancers. These findings lend strong support to the idea that PP2A is a tumor suppressor.

We investigated many of the cancer-associated A α and A β mutants described by Wang *et al.* and Calin *et al.* Based on the location of the mutated amino acids in intra-repeat loops or nearby, we suspected that the mutant A subunits might be defective in binding B and/or C subunits. Indeed, we found that all A α and most A β subunit mutants are defective in binding B or both B and C subunits [37,38]. Most importantly, the A α subunit mutants Glu64 \rightarrow Asp (E64D) and Glu64 \rightarrow Gly (E64G) found in lung and breast cancer, respectively, were specifically defective in binding the B' α 1 subunit, a member of the B' family, whereas binding of B α and B'' (PR72) was normal, as was C α and C β subunit binding. The finding that the most specific A α mutants affect binding of B' subunits only suggests that B' subunits or B'-containing holoenzymes play a crucial role in the presumed tumor suppressor function of PP2A as described below. It is important to note that reduced expression of the A α subunit in human gliomas occurs in the absence of mutations in the A α and A β subunit genes [39].

Differences between A α and A β Subunits

The discovery that A β is mutated in human cancer has drawn attention to this subunit, which is 86% identical to A α . Previously, the main focus had been on A α , and all biochemical studies of PP2A have been carried out with

enzyme preparations containing A α . Now there is growing evidence that A α and A β have different properties in regard to expression, binding of B and C subunits, and function [38,40]. Therefore, it seems possible that they play different roles in growth control.

PP2A and Wnt Signaling

During embryogenesis, the Wnt signaling pathway regulates cell proliferation and development [26]. An inappropriate activation of the Wnt pathway has been found in a wide variety of human cancers [24], where it promotes the growth of cancer cells by inducing cyclin D and *c-myc*. Currently, three genetic changes that cause an increase in β -catenin levels and activation of the Wnt signaling pathway are known. First, some mutations in the β -catenin gene alter specific N-terminal serine or threonine residues, thereby preventing β -catenin phosphorylation by GSK3 β and degradation by the ubiquitin/proteasome pathway. Second, mutations in the APC gene that cause loss of APC binding to axin prevent recruitment of β -catenin into the β -catenin-destabilizing complex. Therefore, β -catenin escapes from degradation. Third, axin mutations in the β -catenin binding site destroy the ability of axin to recruit β -catenin into the destabilizing complex, also resulting in β -catenin accumulation. In addition, mutating PP2A may represent a fourth mechanism to activate the Wnt pathway as suggested by Seeling *et al.* [21], who reported that regulatory B' subunits bind to APC (Fig. 2, site Z). Furthermore, they found that overexpression of B' in 293 cells dramatically decreases the level of β -catenin. Importantly, B' inhibits β -catenin-dependent transcription by the transcription factor LEF. Seeling *et al.* proposed that PP2A may act as a tumor suppressor by down-regulating Wnt signaling through dephosphorylation and activation of GSK3 β . Cancer-associated A α or A β mutations might prevent B'-mediated recruitment of PP2A into the β -catenin-destabilizing complex, resulting in downregulation of GSK3 β and upregulation of Wnt signaling [37]. Yamamoto *et al.* [23] discovered that B' also binds to axin. The site of interaction (site X) is different from the binding sites for GSK3 β , β -catenin, APC, and dishevelled (Dvl) (Fig. 2). They also found that B' suppresses β -catenin- and Tcf-dependent transcription [21]. Axin associates not only with the B' subunit but also with the catalytic C subunit [22]. The C subunit binding region (site Y) is separate from the B' binding region. It has been suggested that binding to site Y may stimulate Wnt signaling [41]. Ratcliffe *et al.* [42] studied the role of PP2A in early *Xenopus* embryos. They discovered that the B' subunit strongly inhibits secondary axis formation and Wnt signaling. The C subunit, on the other hand, appears to stimulate Wnt signaling [23,42].

The precise mechanism by which PP2A affects Wnt signaling remains to be elucidated. Willert *et al.* [43] suggested that PP2A dephosphorylates axin, resulting in release of β -catenin from the β -catenin-destabilizing complex [43]; however, according to this model, PP2A would actually

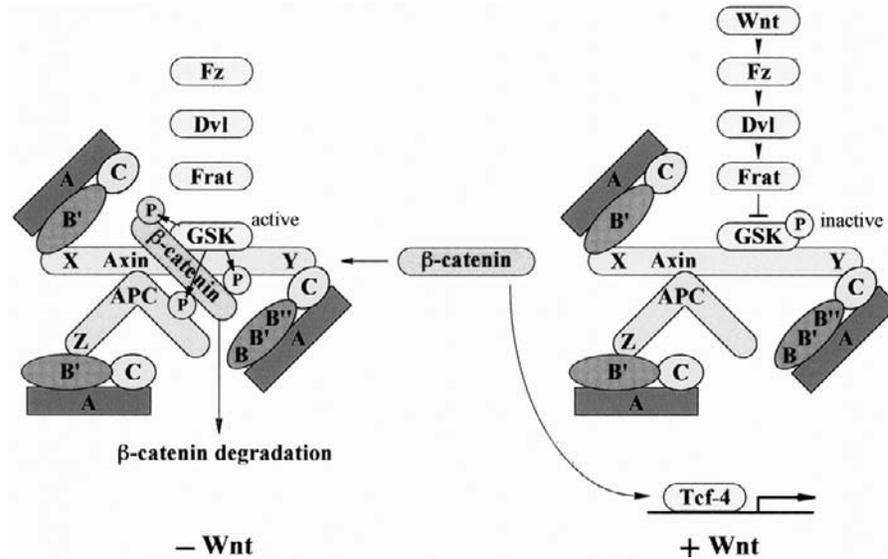

Figure 2 Multiple binding sites of PP2A in the β -catenin degradation complex.

stimulate Wnt signaling. Yamamoto *et al.* [23] discussed whether PP2A controls APC-mediated nuclear export of β -catenin or acts on the transcription factor Tcf. In order to resolve these questions, it is important to identify the substrates for each PP2A molecule bound to the different sites on the β -catenin-destabilizing complex. At present, GSK3 β , axin, β -catenin, and APC all have to be considered as potential substrates. While published reports on the role of PP2A in Wnt signaling are conflicting, there is general agreement that the B' subunit inhibits the Wnt pathway. All findings are consistent with the idea that the B' subunit, or the B'-containing holoenzyme, is a tumor suppressor that functions by downregulating the Wnt pathway. It is important to note that CKI δ and CKI ϵ , which phosphorylate several components of the β -catenin degradation complex, are regulators of the Wnt signaling pathway[44,45].

PP2A and the MAP Kinase Pathway

Growth factors and cell adhesion to the extracellular matrix stimulate growth through the Ras \rightarrow Raf \rightarrow MEK \rightarrow ERK signaling pathway by inducing cyclin D and activating G1-phase cyclin-dependent kinases [46]. Evidence that PP2A negatively controls the MAPK \rightarrow ERK pathway and inhibits growth comes from experiments with SV40 small T, which inhibits PP2A [47,48], thereby preventing dephosphorylation and inactivation of MEK and ERK [49]. A recent report suggests that this direct inhibitory effect of PP2A on MEK and ERK is mediated by a B-containing holoenzyme, while a B'-containing holoenzyme has antiapoptotic activity [10]. Sontag *et al.* [50] provided further evidence that PP2A inhibits growth using SV40 small T as a tool to inhibit PP2A in cells. They demonstrated that inhibition of PP2A by small T induces growth through activation of PI3K, which acts upstream of protein PKC ζ and

MEK: ST (PP2A) \rightarrow PI3K \rightarrow PKC ζ \rightarrow MEK \rightarrow ERK. They proposed that small T stimulates PKC ζ -dependent but not serum-dependent growth; therefore, its effect can only be measured in serum-starved cells. It is difficult to determine the contribution of the PKC ζ \rightarrow MEK pathway to cell growth as compared to the growth-factor-dependent pathway involving Ras and Raf. The substrate of PP2A acting upstream of PI3K remains to be determined. While these reports emphasize the growth inhibitory role of PP2A, Kubicek *et al.* [51] showed that PP2A is a positive regulator of the MAP kinase pathway. The PP2A core enzyme binds to Raf-1 and dephosphorylates Ser 259. This causes activation of Raf-1, not by affecting its specific activity but by facilitating its association with the plasma membrane. Taken together, PP2A plays opposing roles at different sites in the MAPK \rightarrow ERK pathway. Whether PP2A acts at all sites simultaneously or whether its positive and negative effects occur in different cells or in response to different environmental stimuli remains to be investigated.

Summary

PP2A plays a critical role in growth control and cancer. Importantly, loss or alteration of PP2A activity is an essential step in the development of human cancer, consistent with the idea that PP2A functions as a tumor suppressor. However, PP2A has many, sometimes seemingly conflicting, functions that are poorly understood. On the one hand, it suppresses cell growth, but on the other it is required for cell-cycle progression. Also, it positively and negatively regulates the MAPK/ERK and Wnt signaling pathways. Other important functions of PP2A are its inhibitory role in the interleukin-3-stimulated JAK2-STAT5 signaling pathway [52] and its involvement in NF- κ B signaling [50,53], protein kinase B/Akt signaling [54], and integrin-mediated regulation

of Akt and GSK3 β [55]. Furthermore, the catalytic subunit of PP2A binds to the alpha-4 protein, a homolog of yeast TAP42 involved in translational control [9,56].

Serine/Threonine Phosphatase Inhibitor Proteins

Shirish Shenolikar

Duke University Medical Center,
Durham, North Carolina*

Introduction

Reversible protein phosphorylation is the most widely used mechanism for regulating the physiology of eukaryotic cells. Current estimates indicate that as much as 10% of the human genome is utilized in the control of protein phosphorylation. Up to 1000 human genes encode protein kinases; however, significantly fewer genes encode phosphatase catalytic subunits. This finding promoted the viewpoint that selectivity in hormone signaling is principally derived from activation of protein kinases, with the phosphatases playing a more pleotropic role in the control of protein phosphorylation. A number of protein kinases respond to changes in intracellular second messengers but only one serine/threonine phosphatase, calcineurin (or PP2B), is activated by the second messenger calcium. This observation fostered the opinion that most phosphatases are unregulated, and it was suggested that hormone-induced increases in protein kinase activity must be sufficiently high as to overcome the opposing actions of phosphatases. It also meant that hormone signals are severely dampened and/or slowed by the constitutive activity of phosphatases. However, it was found that phosphatase inhibitors allow cells to lower this barrier and accelerate or even amplify the kinase signals. The inherent appeal of this mechanism prompted an active search for hormone-regulated phosphatase inhibitors. Work over the last two decades has identified numerous gene products that regulate protein serine/threonine phosphatases, firmly dismissing the idea of unregulated serine/threonine phosphatases.

Protein Phosphatase 1 (PP1) Inhibitors

Huang and Glinsmann [1] and Lee and co-workers [2] first noted changes in phosphorylase phosphatase activity in extracts of rabbit skeletal muscle stimulated by adrenaline. Later studies [3] revealed two inhibitory activities, inhibitor-1 (I-1) and inhibitor-2 (I-2), which potently inhibit the skeletal muscle phosphorylase phosphatase. I-1 is an effective inhibitor only after it is phosphorylated by cAMP-dependent protein kinase (PKA) and is most likely responsible for hormone-induced reduction in phosphorylase phosphatase activity in the muscle extracts. In contrast, I-2 was found to be a constitutive inhibitor. The availability of these inhibitor proteins made it apparent that not all muscle phosphorylase phosphatase activity is eliminated by these proteins, opening the way for separation of muscle serine/threonine phosphatase activity into two general groups. Type 1 phosphatase (PP1) was defined as phosphorylase phosphatase activity that is potently inhibited by I-1 and I-2, and type 2 phosphatases are insensitive to low concentrations of these inhibitors [4]. Subsequent studies further separated type 2 phosphatases based on subunit structure and substrate specificity. Protein phosphatase-2A (PP2A) dephosphorylates phosphorylase *a*, while protein phosphatases 2B and 2C have been observed to have little activity against this substrate and are much more effective against other phosphoproteins. PP2A, PP2B, and PP2C are all insensitive to I-1 and I-2.

I-1, DARPP-32, and Other Phosphorylation-Dependent Phosphatase Inhibitors

Protein phosphatase 1 (PPI) is responsible for most of the serine/threonine phosphatase activity in skeletal muscle and was the first phosphatase catalytic subunit to be purified to homogeneity. Thus, much of our current knowledge of phosphatase regulation is derived from studies of PPI. I-1 and its structural homolog, DARPP-32 (dopamine and cAMP-regulated phosphoprotein of apparent M_r 32,000) are both PKA-activated PP1 inhibitors. It has been speculated that phosphorylation of I-1 (and DARPP-32) is among the earliest events that follow PKA activation. This results in PP1 inhibition and greatly enhances the phosphorylation of other substrates by PKA. PP1 inhibition also promotes protein phosphorylation by other protein kinases, thus I-1 and DARPP-32 broaden the cAMP signals and impose cAMP regulation on proteins that are not directly phosphorylated by PKA. The most compelling evidence for the importance of cAMP-mediated phosphatase inhibition in amplifying hormone signals comes from the disruption of mouse genes encoding I-1 and DARPP-32. The DARPP-32 mutant mouse, in particular, was impaired in nearly all aspects of dopamine signaling. The importance of this finding was recognized by the 2000 Nobel Prize for Medicine or Physiology being awarded to Paul Greengard of Rockefeller University. A more complex phenotype was seen in the I-1 null mouse, in part reflecting the presence of multiple I-1 genes. Recent studies also show that I-1 associates with PP1 complexes that contain other regulators, such as the protein product of growth arrest and the DNA-damage-inducible gene, GADD34. This suggests that I-1 functions may be directed or restricted by other PP1 regulators, and this cooperation is necessary for the function of I-1 in regulating protein translation.

Both I-1 and DARPP-32 are the most extensively studied phosphatase inhibitors. A considerable amount of data points to a critical role for PKA phosphorylation in the function of these proteins as PP1 inhibitors. Deletion analyses have also highlighted an N-terminal tetrapeptide sequence conserved in I-1 and DARPP-32 as also being essential for PP1 inhibition. Crystallization of a PP1 catalytic subunit with a peptide containing a homologous sequence has demonstrated its docking at a unique site on the PP1 catalytic subunit [5]. It is now clear that the PP1-docking motif (KIXF) is also conserved in many other PP1 regulators. Virtually all PP1-binding proteins containing this motif inhibited the *in vitro* dephosphorylation of phosphorylase *a* by PP1. Some of these proteins, such as the glycogen-binding and the myosin-binding subunits, promote PP1-mediated dephosphorylation of other substrates—glycogen synthase and myosin, respectively. They also associate with subcellular structures, such as glycogen and myofibrils, defining them as PP1-targeting subunits. Unless a substrate or a location can be defined for a KIXF-containing PP1-binding protein, it is impossible to predict whether this putative regulator acts a PP1 inhibitor or targeting subunit.

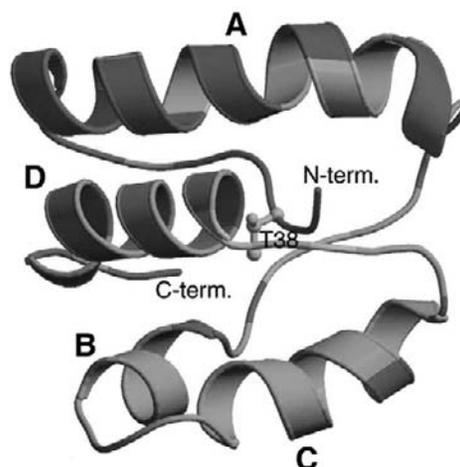

Figure 1 Three-dimensional structure of the PKC-activated PPI inhibitor, CPI-17. NMR structures of both unphosphorylated and PKC-phosphorylated CPI-17 were solved. Overlap of the two structures shows a bundle of four helices, labeled A, B, C and D. Regions that undergo little significant modification (blue) following phosphorylation and those most significantly modified (red) are shown in color. The threonine-38 phosphorylated by PKC is shown in yellow.

Protein phosphatase 1 activity also responds to PKC activation, and several PKC-activated phosphatase inhibitors have been identified. The forerunner of this family of inhibitor proteins is CPI-17 (C-kinase-activated phosphatase inhibitor of apparent M_r 17,000). Several kinases (PKC α and δ , ROCK, PKN, and Zip-like kinase) promote CPI-17 phosphorylation and increase its activity as a PP1 inhibitor. While the precise mode of action of this inhibitor is unclear, CPI-17 does not contain a KIXF motif. This suggests that other molecular determinants can also specify PP1 selectivity. The three-dimensional structure of CPI-17 has recently been determined (Fig. 1). The most significant conformational change induced by PKC phosphorylation in the four-helix bundle that is CPI-17 is the rotation of helix A to create a new surface that may facilitate PP1 binding and inhibition [6]. CPI-17 and its structural homologs PHI-I, PHI-II, and KEPI most effectively target the PP1 holoenzyme containing the myosin-binding subunit. How the regulatory subunit and inhibitor collaborate to regulate myosin dephosphorylation is currently under investigation. The KEPI mRNA is elevated in brain in response to morphine. This suggests that G-protein-coupled receptors activate PKC signaling to promote KEPI expression and phosphorylation and lower PP1 activity to transduce hormone signals.

Latent Phosphatase Complexes Activated by Inhibitor Phosphorylation

I-2 is a complex regulator of PP1 activity, requiring as many as five distinct interactions with the PP1 catalytic subunit to inhibit (rapid and reversible suppression of PP1 activity) and inactivate (slower and more stable reduction in

activity) the enzyme. PP1 inactivation by I-2 can be reversed by glycogen synthase kinase 3 (GSK3), mitogen-activated protein kinase (MAPK), or Cdk5, which phosphorylate I-2. Thus, the PP1/I-2 complex may represent a latent cytosolic pool of serine/threonine phosphatase that is commissioned into action by growth factors and hormones. Over-expression of I-2 (and its budding yeast homolog, Glc8) has paradoxical effects on cell physiology, consistent with both activation and inhibition of PP1. The ability of I-2 to refold denatured PP1 *in vitro* has prompted the hypothesis that I-2 may be a PP1 chaperone that refolds the newly synthesized phosphatase catalytic subunit. Subsequent exchange or delivery of PP1 to various targeting subunits may account for the increase in PP1 activity.

NIPP-1 (nuclear inhibitor of PP1) is another phosphatase inhibitor protein that is stably associated with the nuclear pool of PP1 catalytic subunits. The activity of this phosphatase complex is increased by NIPP-1 phosphorylation by PKA or casein kinase II. Interestingly, the two protein kinases have additive effects on activation of the PP1/NIPP-1 complex and may integrate distinct hormone signals to control nuclear PP1 activity. NIPP-1 also demonstrates functions independent of PP1 binding. Recent studies showed that the NIPP-1 mRNA suppresses protein translation, while the NIPP-1 protein possesses endonuclease activity. Elevated NIPP-1 mRNA levels have been correlated with increased malignancy of rat hepatomas but it is uncertain which of the NIPP-1 functions contributes to carcinogenesis.

Inhibitors of Type-2 Serine/Threonine Phosphatases

A number of proteins bind type 2 phosphatases and inhibit their activity. Following a strategy similar to that used to isolate I-1 and I-2, two thermostable protein inhibitors of PP2A were isolated. I_1^{PP2A} and I_2^{PP2A} not only inhibit PP2A but also activate PP1 *in vitro*, suggesting that they function as molecular switches that reciprocally regulate the two major eukaryotic serine/threonine phosphatases. Over-expression of both proteins increased *c-jun* expression and transcription of genes regulated by the AP-1 transcription factor in cultured cells, consistent with PP2A inhibition. Protein products of two DNA tumor viruses, SV40 and polyoma, also inhibit PP2A activity. Unlike I_1^{PP2A} and I_2^{PP2A} , SV40 small T and polyoma middle T do not directly associate with the PP2A catalytic subunit. Instead, the viral proteins displace B subunits from selected cellular PP2A heterotrimers composed of A, B, and C subunits. This suggests that cellular proteins such as the many B-subunits can also modulate PP2A activity in cells, inhibiting some functions while activating others.

In contrast to PP1 and PP2A, PP2B or calcineurin shows a much more restricted panel of substrates, at least *in vitro*. A number of cellular proteins sharing a conserved PP2B-binding

sequence, first identified in the transcription factor NFAT (nuclear factor of activated T cells), a PP2B substrate. These include CAIN, MCIP, and the product of the disease gene associated with Down's syndrome, the thyroid hormone-inducible protein ZAKI-4. Over-expression of these proteins suppresses PP2B functions consistent with their actions as PP2B inhibitors. PP2B also binds to immunophilins that in turn bind the immunosuppressive drugs cyclosporin and FK506 to inhibit calcineurin activity. Experimental evidence suggests that some immunophilins bind PP2B in the absence of drugs and may regulate its phosphatase activity.

Conclusions

Emerging evidence suggests that mammalian cells express a multitude of serine/threonine phosphatase inhibitors, many of which are not fully analyzed. Comparison of known serine/threonine phosphatase inhibitor proteins suggests that they utilize many different mechanisms to inhibit phosphatases. Moreover, the phosphatase inhibitors may be regulated by hormone-induced changes in expression, alternate splicing, or reversible phosphorylation. Finally, inhibitor proteins most likely collaborate with other phosphatase regulators to control unique phosphatase populations and integrate multiple physiological signals that regulate protein phosphorylation.

Acknowledgments

Introduction

Calcineurin (also called PP2B), a protein phosphatase under the control of Ca^{2+} and calmodulin (CaM), is ideally suited to play an important role in modulating cellular responses in response to the second messenger Ca^{2+} . The identification of calcineurin as the target of the immunosuppressive drugs cyclosporin A (CsA) and FK506, complexed with their respective binding proteins cyclophilin A (CypA) and FKBP12 (FK506 binding protein), revealed the key role of calcineurin in the Ca^{2+} -dependent steps of T-cell activation [1]. This discovery led to purification of the transcription factor NFAT (nuclear factor of activated T cells) and the first identification of a complete transduction pathway from the plasma membrane to the nucleus [2,3]. The specific inhibition of calcineurin by FK506 and CsA and the over-expression of the catalytic subunit of a CaM-independent derivative of calcineurin (calcineurin $\text{A}\alpha$, residues 1 to 392) have been widely used to identify the roles of calcineurin in the regulation of cellular processes as diverse as gene expression, ion homeostasis, muscle differentiation, embryogenesis, secretion, and neurological functions. It is no wonder that alteration of calcineurin activity has been implicated in the pathogenesis of such diseases as cardiac hypertrophy, congenital heart disease, and immunological and neurological disorders. For further information, the reader is referred to comprehensive reviews and references therein [2–5b].

Enzymatic Properties

The serine/threonine phosphatase activity of calcineurin is completely dependent on Ca^{2+} concentrations found in stimulated cells (0.5–1 μM). A 19-residue synthetic peptide containing the phosphorylation site of the RII subunit of

cAMP-dependent protein kinase (PKA) is routinely used to measure the phosphatase activity of the purified enzyme. A small activation is observed upon addition of Ca^{2+} ($K_{\text{act}}=0.5 \mu\text{M}$), while addition of an equimolar amount of CaM results in a 50- to 100-fold increase of the V_{max} [4]. The cooperative Ca^{2+} dependence of the CaM stimulation (Hill coefficient of 2.5 to 3) allows calcineurin to respond to narrow Ca^{2+} thresholds following cell stimulation. Because of its high affinity for CaM ($K_{\text{act}} \leq 10^{-10} \text{M}$), the activation of calcineurin in response to a Ca^{2+} signal can precede the activation of most, if not all, CaM-regulated enzymes.

In crude extracts, calcineurin activity is distinguished from that of PP1, 2A, and 2C by (1) its Ca^{2+} and CaM dependence; (2) its resistance to the endogenous inhibitors (inhibitor-1, DARPP-32, inhibitor-2), okadaic acid, microcystin, and calyculin; and (3) its specific inhibition by FK506 (but not rapamycin) and CsA in the presence of saturating amounts of their respective binding proteins, FKBP12 and CypA [2]. The crude enzyme, with a specific activity 10 to 20 times that of the purified enzyme, is subject to a time- and Ca^{2+} /CaM-dependent inactivation that is prevented by superoxide dismutase and reversed by ascorbate. This observation suggested that *in vivo* calcineurin activity may also be modulated by reactive oxygen species [6]. This reversible inactivation provides a mechanism for the temporal regulation of the protein phosphorylation by CaM-dependent kinases and phosphatases [7]. Determination of calcineurin activity *in vivo* can only be achieved by monitoring the extent of dephosphorylation of endogenous substrates, such as the transcription factor NFAT, if they are present at detectable levels [2].

The substrate specificity of calcineurin depends not only on recognition of the sequence surrounding the phosphorylated residues but to the presence of docking domains. NFAT contains two such domains responsible for its Ca^{2+} -dependent and phosphorylation-independent anchoring to

calcineurin [2,8]. The anchoring of NFAT allows its dephosphorylation, despite its low intracellular concentration, and the nuclear cotranslocation of calcineurin and NFAT.

Structure

Calcineurin is also characterized by a unique and highly conserved subunit structure. It is a heterodimer of a 58- to 64-kDa catalytic subunit, calcineurin A (CnA), tightly bound even in the presence of EGTA, ($K_d \leq 10^{-13} M$), to a regulatory 19-kDa regulatory subunit, calcineurin B (CnB). CnB is an EF-hand Ca^{2+} binding protein of the CaM family. It binds 4 mol of Ca^{2+} , two with high affinity ($K_d^{-7} M$) and two with moderate affinity, in the micromolar range [9,10]. The crystal structure of the recombinant α -isoform of human calcineurin (Fig. 1A) confirmed the domain organization of CnA predicted by limited proteolysis and site-directed mutagenesis [2,4]. The N-terminal two-thirds of the molecule contains the catalytic domain, the structure of which is similar to those of PP1 and PP2A. The active site contains an Fe^{3+} - Zn^{2+} dinuclear metal center [11]. Iron and zinc are bound to residues provided by the two faces of a β -sandwich. The last β -sheet extends into a five-turn amphipathic α -helix, the top polar face of which is covered by a 33-Å groove formed by the N- and C-terminal lobes and the C-terminal strand of CnB. With the exception of two short α -helices corresponding to the inhibitory domain blocking the catalytic center, the C-terminal regulatory domain (including the CaM binding domain), not visible in the electron density map, is flexible and sensitive to proteolytic attack in the absence of CaM. The catalytic and CnB binding domain (residues 1 to 392), associated with the fully liganded form of CnB, is resistant to proteolysis. It is fully activated in the absence of CaM but still requires the presence of less than $10^{-7} M Ca^{2+}$ [2].

The crystal structure of a proteolytic derivative of bovine calcineurin (residues 15 to 392) complexed with FKBP12–FK506 (Fig. 1B) is similar to that of the recombinant protein. Myristic acid, covalently linked to the N-terminal glycine of CnB, lies parallel to the hydrophobic face of the N-terminal helix of CnB. This perfectly conserved posttranslational modification of CnB is apparently not involved in membrane association or required for enzymatic activity. It may serve as a stabilizing structural element and is required for interaction with phospholipids [2,4,12]. The polar bottom face of the CnB binding helix of CnA and CnB forms the site of interaction with the FKBP–FK506 and CsA–Cyp complexes. The key role of CnB in forming the drug binding site provides a molecular basis for the exquisite specificity of FK506 and CsA as calcineurin inhibitors.

Regulation

Role of CaM

The crystal structure of calcineurin helps to define the different roles and mechanisms of action of the two structurally

similar Ca^{2+} -regulated proteins, CaM and CnB, in the regulation of calcineurin. The catalytic center blocked by the inhibitory domain and the flexible calmodulin binding domain, freely accessible for calmodulin binding, is consistent with the widely accepted mechanism of CaM stimulation of CaM-regulated enzymes. According to this mechanism, binding of CaM results in the displacement of the inhibitory domain and exposure of the catalytic center [4]. The requirement for Fe^{2+} (as opposed to Fe^{3+}) for calcineurin activity explains the redox sensitivity of calcineurin activity in crude tissue extracts [13,14]. Crude and ascorbate-activated purified calcineurin is an Fe^{2+} - Zn^{2+} enzyme with an optimum pH of 6.1 [14]. The Ca^{2+} /CaM-induced exposure of Fe^{2+} facilitates its oxidation, which is responsible for the inactivation of the enzyme. Partial depletion of iron and zinc as well as oxidation of the iron during the purification procedure are responsible for the low activity of the purified enzyme and its stimulation by 0.1-mM Mn^{2+} and 6-mM Mg^{2+} [14].

Role of CnB

CnB serves both a structural and a regulatory role. Ca^{2+} -independent binding of CnB to CnA, mediated by the high-affinity C-terminal sites, ensures the folding of active enzyme [9,10]. Ca^{2+} binding to the N-terminal sites induces a conformational change of the regulatory domain resulting in the exposure of the drug and CaM binding domains [1,15].

Endogenous Regulators

The presence of anchoring and inhibitory proteins, for which expression varies from tissue to tissue, adds another level of complexity to calcineurin regulation. The PKA scaffold protein, AKAP79, anchors calcineurin to specific sites of action but also inhibits its activity (see Volume II, Chapter 185). Calsarcin-1 and -2, which tether calcineurin to α -actinin at the z-line of the sarcomere in cardiac and skeletal muscle, respectively, have been proposed to couple calcineurin activity to muscle contraction [16]. Calsarcins interact with calcineurin close to its active site and inhibit its activity. What is not clear is how the Ca^{2+} -independent binding of AKAP79 ($K_1 = 200 nM$) and the inhibition of calsarcin are reversed.

Cain/Cabin1, a 240-kDa nuclear protein of yet unknown function, has been identified as a noncompetitive inhibitor of calcineurin [17,18]. It is abundant in brain, kidney, liver, and testis, but is absent in muscle. *In vivo* binding of Cabin1 to calcineurin requires Ca^{2+} and PKC activity and is inhibited by FK506–FKBP, suggesting that it binds at the drug interacting site. A basic domain in the C terminus of Cabin1 has been identified as a calcineurin binding site [17].

A family of 22- to 24-kDa proteins identified in yeast (RCn1p) and mammalian cells (calsuppressins; MCIP1, 2, and 3) are believed to be feedback inhibitors of calcineurin [19,20]. The mammalian proteins are identical to proteins encoded in the DSCR1 (Down's syndrome critical region 1) gene on chromosome 21 (ZAKI-4, DSCRIL1, and DSCRIL). Their expression in heart and skeletal muscle is upregulated

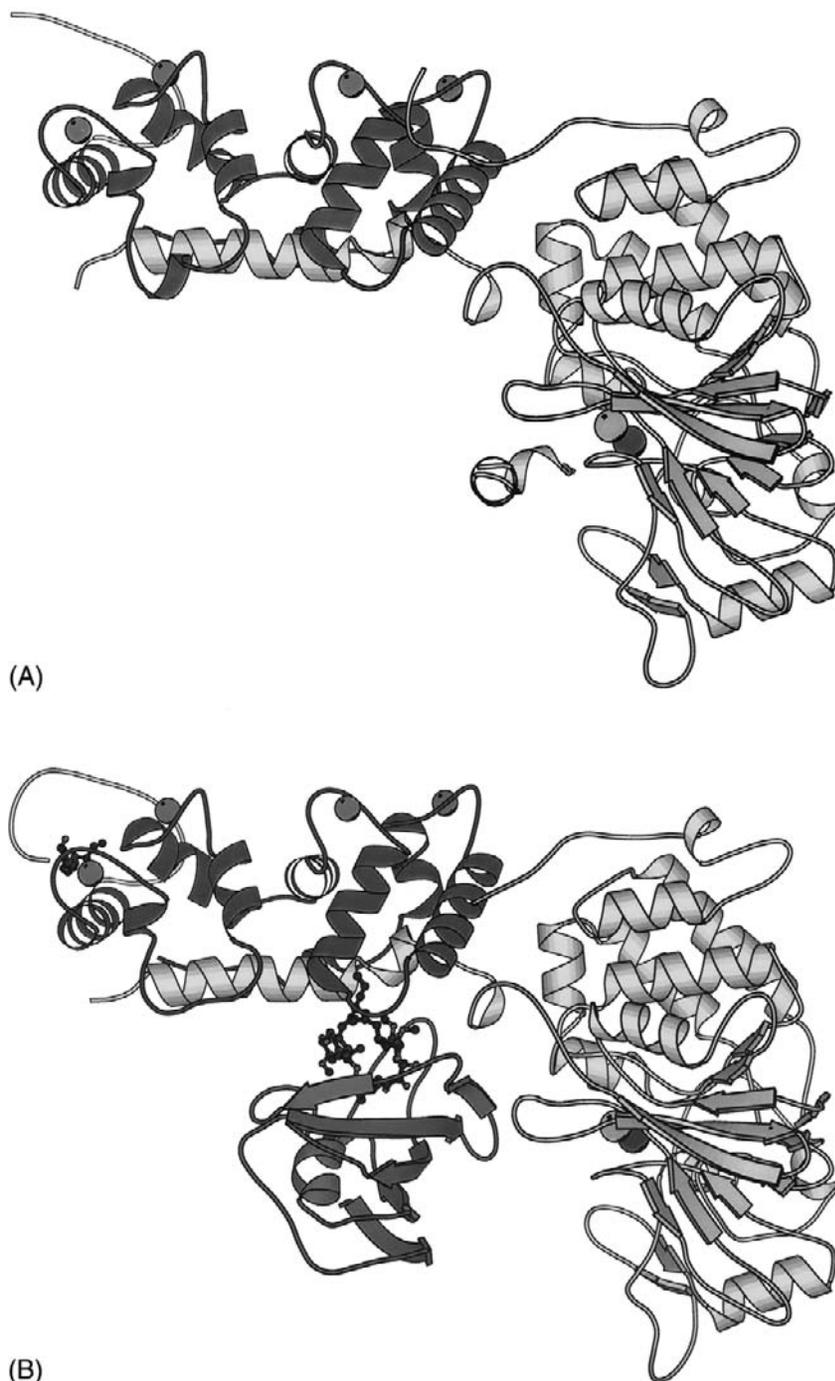

Figure 1 Ribbon representation of (A) the crystal structure of human recombinant α -calcineurin and (B) truncated calcineurin complexed with FKBP12–FK506. CnA is shown in light gray, CnB in dark gray, Iron and zinc are shown as light gray and black spheres, respectively. The four Ca^{2+} bound to CnB are shown as dark gray spheres, and FKBP12 is shown in dark gray. Myristic acid, covalently linked to the N-terminal glycine, and FK506 are shown in ball and stick representations (PDB code 1AUI [43] and 1TCO [44]).

by a calcineurin/NFAT-dependent mechanism. MCPs inhibit both calcineurin activity and expression. They do not compete with CaM or FK506/FKBP but interact with calcineurin in a Ca^{2+} -independent fashion through a highly conserved ISPPxSPP motif, similar to the SP motifs of NFAT; they inhibit calcineurin activity *in vitro* as well as NFAT activation *in vivo*.

Distribution and Isoforms

Although found predominantly in neural tissues, calcineurin is present in all eukaryotes and in all tissues examined. There are three mammalian isoforms (α , β , γ) of calcineurin. The human genes (PPP3CA, PPP3CB, PPP3CC) are located on human chromosomes 4, 10, and 8, respectively.

Additional isoforms, products of alternative splicing, have not been characterized at the protein level. An N-terminal polyproline motif is a conserved feature of the β isoform. A C-terminal nuclear localization signal and stretch of basic residues are responsible for the high pI (7.1) of the testis-specific γ isoform, whereas the neural α and the broadly distributed β isoform have pIs of 5.6 and 5.8, respectively [2,4]. Two mammalian isoforms of calcineurin B—CnB1 (associated with the α and β isoforms of CnA) and CnB2 (expressed only in testis)—are the products of two genes: PPP3R1 (located on chromosome 2) and PPP3R2 [2]. The α and β isoforms have been expressed in SF9 cells and bacteria where coexpression of the two subunits is required to yield a soluble recombinant β isoform [2].

Functions

T-Cell Activation

The T-cell Ca^{2+} /calcineurin/NFAT pathway, also shown to be applicable to other cell types [2,3–5], requires a sustained release of Ca^{2+} from IP_3 -sensitive stores [21]. Four NFAT isoforms (NFAT1–4) share a conserved N-terminal regulatory domain composed of a serine-rich motif, a nuclear localization signal, and three SP motifs flanked on both sides by two calcineurin binding motifs [2,8]. The N-terminal motif, PxIxIT, missing in NFAT5, binds calcineurin ($K_d = 2.5 \mu\text{M}$) at a site tentatively identified as residues 1 to 14 [22], and the C-terminal motif binds calcineurin ($K_d = 1.3 \mu\text{M}$) at a site that may overlap with the drug binding domain [8]. Dephosphorylation of NFAT results in nuclear translocation of the calcineurin–NFAT complex and enhancement of DNA binding and transcriptional activity [2,3]. Nuclear export depends on NFAT rephosphorylation upon removal of Ca^{2+} or calcineurin inactivation (or dissociation?). Identifying the mechanisms and kinases involved in the process has been elusive. GSK3, casein kinase 1/MEKK1, and Jun N-terminal kinase (JNK) have all been implicated [2,3]. The specificity of these kinases for different isoforms of NFAT as well as the complexity due to cell background may be responsible for the failure to identify a single kinase responsible for this process [2,3].

Muscle Differentiation

Calcineurin-mediated dephosphorylation of two transcription factors, NFAT3 and MEF2, plays a critical role in the switch of muscle fiber subtype that follows the onset of innervation and nerve activity [5]. This contractile phenotype transition consists of an increased expression of slow fiber proteins (slow MHC-1, SERCA 2a) and decreased expression of the fast fiber proteins (MHC2a, SERCA1, creatine kinase, citrate synthase). It is achieved by NFAT as well as by MEF2D activation through calcineurin-mediated dephosphorylation and a Ca^{2+} -dependent phosphorylation of MEF2D at specific serines residues [23]. The previously

reported role of calcineurin in muscle hypertrophy is controversial. No hypertrophy is observed in transgenic mice over-expressing calcineurin [24]; activation of the mTOR (phosphatidylinositol 3-kinase [PI3K]/AKT) pathway plays a major role in the insulin-like growth factor 1 (IGF-1)-induced hypertrophy of preformed myotubes [25]; and calcineurin inhibitors do not block the increase of fiber size induced by nerve stimulation in regenerating muscle [26].

Cardiac Hypertrophy

Calcineurin-mediated activation of NFAT3, which, in conjunction with the transcription factor GATA4, leads to the induction of fetal cardiac genes along with natriuretic factor, have been shown to play a major role cardiac hypertrophy [5]. Calcineurin can also induce cardiac hypertrophy acting synergistically with a Ca^{2+} -dependent kinase to activate MEF2D. Regardless of its cause (over-expression of CaM-independent calcineurin, pressure overload, induction by hypertrophic agonists), cardiac hypertrophy is prevented by over-expression of MCP1 and the inhibitory domains of Cabin1/Cain or AKAP79 [5,27,28]. Less reproducible inhibition by FK506 and CsA may be due to high levels of calcineurin or low levels of binding proteins [5]. Furthermore, the hypertrophic response to calcineurin activation is impaired in transgenic mice expressing a constitutive form of GSK3 [28], and transgenic mice lacking the β -isoform of calcineurin (the predominant isoform in heart) have impaired ability to develop cardiac hypertrophy in response to hypertrophic agonists [29]. The calcineurin-mediated activation of PKC by calcineurin [30,31] suggests that calcineurin, acting upstream of PKC, can also be implicated in cardiac hypertrophy through the activation of the PKC and JNK in parallel or downstream of MAP kinase pathways.

Cell Death and Differentiation

Emphasizing the general role of calcineurin in the regulation of gene expression is the broad tissue distribution of NFAT and the many genes for which expression is directly induced by NFAT—NFAT2; the cytokines IL-2, -3, -4; $\text{TNF}\alpha$ GM-CSF; $\text{IFN}\gamma$ the chemokines IL-8 and MIP-1a; and the receptors FasL, CD40L, CTLA-4, NF-AT2, Oct2, Egr, NF- κB 50p—as well as other genes activated by calcineurin, such as Elk-1 and BAD) [2,3]. Three calcineurin-mediated pathways—NFAT activation of NF- κB and FasL, synergistic induction of a member of the steroid/thyroid receptor family, Nur77, by NFAT and MEF2D; and dephosphorylation of BAD—perhaps explain the involvement of calcineurin in Ca^{2+} - and possibly H_2O_2 -induced apoptosis [2,32,33]. The calcineurin/NFAT pathway is essential for the development of heart valves and the vascular developmental pattern during embryogenesis [34].

Ion Homeostasis

In yeast and fungi, calcineurin plays a major role in the regulation of ion homeostasis by a mechanism similar to the

NFAT-mediated transcriptional control in mammalian cells [35–37]. In addition to its regulation of the Na⁺/K⁺ pump in kidney, recent evidence indicates that the Ca²⁺/calcineurin/NFAT pathway is also responsible for the regulation of expression of the inositol 1,4,5-triphosphate (IP3) receptors, the plasma membrane Ca²⁺ pumps, and the Ca²⁺ exchanger in mammalian cells [38]. It was also reported that the regulation of Ca²⁺ fluxes from the IP3 and ryanodine channels was mediated by an FKBP-mediated interaction of calcineurin with the receptors acting as endogenous analogs of FKBP, but recent evidence indicates that calcineurin does not interact with either one of these two receptors [39].

Neuronal Functions

Consistent with the high concentration of calcineurin in the brain (1% of total protein), the list of neuronal functions modulated by calcineurin is continuously expanding. A major role of calcineurin in brain is to trigger a protein phosphatase cascade initiated by the dephosphorylation of two endogenous inhibitors of PP-1 (inhibitor-1 and DARPP-32). It is sensitive to PP-1 as well as calcineurin inhibitors. The dephosphorylation of these inhibitors, which do not contain anchoring domains, is not inhibited by specific inhibitors of NFAT [2]. This cascade counteracts the stimulatory effects induced by cAMP- and Ca²⁺-regulated kinase. It has been shown to explain the antagonistic effects of glutamate binding to the NMDA receptor and dopamine binding to the D1-like dopamine receptors in striatal neurons [40], as well as the complex regulation of synaptic plasticity that includes induction of long-term potentiation (LTP) and long-term memory [41,42] and the modulation of the activity of the transcription factor CREB [7]. Calcineurin plays an important role in cellular trafficking by dephosphorylating a family of proteins involved in endocytosis and in the release of neurotransmitters [2]. Dephosphorylation of other calcineurin substrates involved in the downregulation of receptor- and voltage-gated channels remains to be identified. Two other potentially important substrates of calcineurin are NO synthase and adenylate cyclase [2].

Conclusion

The importance of calcineurin in the regulation of cellular processes and its involvement in the pathogenesis of many diseases is now well established, but the role of other signaling molecules should not be underestimated. To fully assess the contribution of calcineurin in the transduction of so many diverse signals it is evident that we must understand how different pathways interact with each other.

Protein Serine/Threonine-Phosphatase 2C (PP2C)

Hisashi Tatebe and Kazuhiro Shiozaki

*Section of Microbiology, University of California,
Davis, California*

Introduction

In early biochemical studies of protein phosphatase activities in mammalian tissues, protein serine/threonine-phosphatase 2C (PP2C) was defined as a Mg^{2+} - or Mn^{2+} -dependent serine/threonine-specific activity that is insensitive to a phosphatase inhibitor, okadaic acid [1]. Subsequent isolation of PP2C genes from yeast to humans demonstrated that PP2C is an evolutionarily conserved phosphatase family that shares no apparent similarity in amino acid sequence with other phosphatase families. However, the crystal structure of the PP2C catalytic core shows significant resemblance to those of other serine/threonine phosphatases, such as PP1 [2]. PP2C functions as a monomer, and no regulatory subunit has been reported.

Eukaryotic organisms appear to have multiple PP2C genes; even the simplest eukaryotes, the budding yeast *Saccharomyces cerevisiae* and the fission yeast *Schizosaccharomyces pombe*, have five PP2C genes in their genomes. In humans, there are at least four isoforms of the PP2C phosphatase: α , β , γ , and δ . Several genes encoding PP2C-like phosphatases have also been found in the genomes of other organisms such as the fruit fly *Drosophila melanogaster* and the nematode *Caenorhabditis elegans*. *Arabidopsis thaliana*, the most popular plant model system, has more than 30 PP2C genes in its genome. Intriguingly, several Mg^{2+} -dependent phosphatases in prokaryotes also possess clear sequence similarities with eukaryotic PP2C enzymes.

PP2Cs and related protein phosphatases are implicated in numerous biological processes in different organisms. In this chapter, we will review various signal transduction mechanisms from bacteria to mammals for which the

molecular functions of PP2C enzymes have been relatively well elucidated.

Regulation of the Stress-Activated MAP Kinase Cascades

One of the well-defined roles of PP2C in cell signaling is the downregulation of the stress-activated MAP kinase cascades in eukaryotes. A MAPK cascade is composed of three kinases: mitogen-activated protein kinase (MAPK), MAPK kinase (MAPKK), and MAPKK kinase (MAPKKK). Extracellular stimuli are transmitted into the nucleus through sequential phosphorylation of these kinases; a signal-stimulated MAPKKK phosphorylates a specific MAPKK, which in turn phosphorylates the conserved threonine and tyrosine residues of its cognate MAPK [3]. Subsequently, an activated MAPK phosphorylates and activates nuclear transcription factors, inducing a set of genes for cellular responses. Consequently, dephosphorylation of any of the kinases in the cascade results in downregulation of the final outcome.

Studies in the budding yeast *S. cerevisiae* have shown that the multicopy expression of PP2C genes rescues the mutations that cause hyperactivation of the Hog1 osmosensing MAPK cascade [4]. In the fission yeast *S. pombe*, inactivation of the stress-activated MAPK Spc1 (also known as Sty1) suppresses the phenotypes of PP2C-deficient cells [5,6]. These genetic data suggested that PP2C phosphatases negatively regulate the MAPK pathways through dephosphorylation of one or more components. Subsequent biochemical studies demonstrated that the fission yeast PP2C enzymes

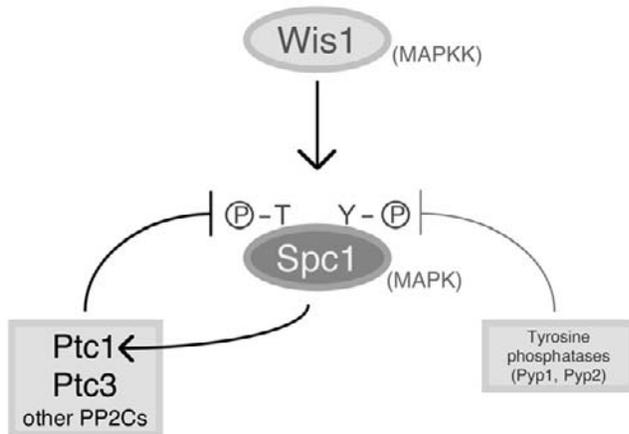

Figure 1 Downregulation of the Spc1 MAP kinase by PP2Cs. The Wis1 MAPKK is activated by extracellular stress phosphorylate Thr-171 and Tyr-173 residues in the activation loop of the Spc1 MAPK. Subsequently, activated Spc1 phosphorylates downstream transcription factors, which in turn induce stress response genes as well as *ptc1*⁺ encoding a PP2C phosphatase. Ptc1 dephosphorylates Spc1 Thr-171 to inactivate the Spc1 pathway. Ptc3, the other PP2C dephosphorylating Spc1, is expressed constitutively. Phosphorylation of Spc1 Tyr-173 is negatively regulated by two tyrosine-specific phosphatases, Pyp1 and Pyp2.

Ptc1 and Ptc3 dephosphorylate the Spc1 MAPK at Thr-171 [7], for which phosphorylation is essential for Spc1 activity [8]. Interestingly, the *ptc1*⁺ gene is transcriptionally induced by activation of the Spc1 pathway, while the *ptc3*⁺ gene is expressed constitutively [9]. Thus, PP2C participates in suppressing the Spc1 MAPK under normal growth conditions and in a negative feedback regulation of Spc1 activated by stress (Fig. 1). In budding yeast, a PP2C enzyme, Ptc1, dephosphorylates Thr-173 of Hog1 MAPK, the equivalent of Spc1 Thr-171 in fission yeast [10].

PP2C regulation of stress MAPK cascades is also conserved in mammalian and plant systems. Mammalian cells have two stress-activated MAP kinases, p38 and JNK. PP2C α inhibits both MAPK cascades by dephosphorylating p38 and its MAPKK, MKK6, as well as the SEK1 MAPKK upstream of JNK [11]. The p38 MAPK is also inactivated by a PP2C δ isoform, Wip1 [12]. Wip1 is transcriptionally induced in a p53-dependent manner in response to a variety of stresses such as γ -irradiation, ultraviolet irradiation, and H₂O₂. Moreover, Wip1 induction depends on the p38 MAPK, which phosphorylates and stimulates p53 in response to ultraviolet irradiation. Thus, like the Spc1 MAPK and the Ptc1 phosphatase in fission yeast, the mammalian p38 MAPK and Wip1 PP2C δ form a negative feedback loop. Recently, Wip1-deficient mice have been generated that exhibit defects in reproductive organs, immune function, and cell-cycle control [13]. In alfalfa plants, a stress-inducible PP2C, MP2C, was identified as a negative regulator of the stress-activated MAPK cascade [14].

Control of the CFTR Chloride Channel by PP2C

Cystic fibrosis is the most common autosomal lethal genetic disease among Caucasians, and the protein product

of the disease-causing gene is known as the cystic fibrosis transmembrane conductance regulator (CFTR) [15]. CFTR is the known only member of the ATP-binding cassette (ABC) transporter family that forms an ion channel. It is located mostly in the apical membrane of epithelia, where it mediates transepithelial salt and liquid movement. CFTR consists of five domains: two transmembrane domains, two nucleotide-binding domains, and a large cytoplasmic domain called the regulatory domain. The regulatory domain has about 20 potential sites for phosphorylation by protein kinase A (PKA) and C (PKC). Phosphorylation of the regulatory domain by PKA is essential for the Cl⁻ channel activity of CFTR, which is also positively regulated by PKC.

PP2C has emerged as the most likely phosphatase that negatively regulates CFTR through dephosphorylation [16–18]. PP2C dephosphorylates CFTR *in vitro*, leading to reduction of the Cl⁻ channel activity. On the other hand, a PP1/PP2A inhibitor (okadaic acid) and a PP2B inhibitor (FK506) do not affect CFTR activity. Coexpression of PP2C with CFTR in epithelia decreases the Cl⁻ current and increases the rate of the CFTR channel inactivation. PP2C and CFTR form a stable complex *in vivo* that may facilitate inactivation of CFTR in the absence of cAMP stimulation.

Plant Hormone Abscisic Acid Signaling

As described above, the large number of PP2C genes found in the *Arabidopsis thaliana* genome may reflect the importance of PP2C in plant physiology. Among those are *ABI1* and *ABI2* encoding PP2C enzymes in the abscisic acid (ABA) signaling pathway [19,20]. ABA is a plant hormone important for the maintenance of seed dormancy, stomatal closure, and growth inhibition. The loss-of-function mutations in *abi1/abi2* genes cause hypersensitivity to ABA. On the other hand, dominant mutations that retain the ABI phosphatase activities are insensitive to ABA, indicating that *ABI1* and *ABI2* are likely to be negative regulators of ABA signaling. Interestingly, the amount of the *ABI1* and *ABI2* mRNA increases in response to ABA [21], suggesting that ABI PP2Cs are part of a negative-feedback loop in the ABA pathway. The target substrate of the *ABI1* and *ABI2* phosphatases remains unknown.

Fem-2: A Sex-Determining PP2C in Nematode

The mechanism to achieve sexual dimorphism in the nematode *Caenorhabditis elegans* has been a subject of extensive research. The determinant of sex in this organism is the ratio of X chromosomes to autosomes. Genetic studies have identified a large number of genes required for the induction of sexual dimorphism, including a PP2C gene, *fem-2* [22,23]. *Fem-2* has a PP2C-like domain and an amino-terminal, non-catalytic extension, both of which are essential for *Fem-2* function [24]. PP2C activity of *Fem-2* has been demonstrated biochemically, and the *fem-2* gene can complement

the budding yeast PP2C mutant. Recently, human and rat phosphatases similar to Fem-2 have been isolated [25]. Interestingly, the rat Fem-2 homolog is identical to the previously identified phosphatase that specifically dephosphorylates Ca^{2+} /calmodulin-dependent protein kinases [26].

Stress-Responsive PP2Cs in *Bacillus subtilis*

Bacillus subtilis has five PP2C-like phosphatases, SpoIIE, PrpC, RsbU, RsbX, and RsbP, with the latter three involved in the regulation of the general stress-responsive σ^B factor. The σ^B transcription factor can be activated by energy stress (i.e., starvation of carbon, phosphate, or oxygen) or environmental stress (i.e., high salt, heat shock, or ethanol), leading to the induction of many stress-response genes [27]. Energy and environmental stresses are transmitted by distinct signaling cascades, which are linked by the RsbV anti-anti- σ factor (Fig. 2). Energy stress signaling is mediated by the RsbP phosphatase dephosphorylating RsbV to induce the general stress response through inhibition of the anti- σ factor RsbW [28]. Environmental stress signals are conveyed through dephosphorylation of RsbV by the RsbU phosphatase, which is activated by upstream regulators, including the RsbX phosphatase [29]. In the absence of

stress, the kinase activity of the RsbW anti- σ factor represses the pathway via phosphorylation of RsbV.

RsbP contains a PP2C-like catalytic domain as well as a PAS domain essential for its function *in vivo*. In bacteria, PAS domains with associated chromophores are found in a variety of signal transduction proteins, regulating the activity of a linked output domain in response to changes in the redox potential. The expression level of RsbP is not regulated in response to the energy stress [28], and it is possible that the stress signals modulate the phosphatase activity of RsbP through its PAS domain.

Overview of Protein Tyrosine Phosphatases

Nicholas K. Tonks

*Cold Spring Harbor Laboratory,
Cold Spring Harbor, New York*

Background

The phosphorylation of tyrosyl residues in proteins is of paramount importance to the control of such fundamental physiological functions as cell proliferation, differentiation, survival, metabolism, and motility. Initially, research in this area focused on the protein tyrosine kinases (PTKs), following their identification as receptors for growth factors and hormones and as the products of oncogenes. The first description of the existence of protein tyrosine phosphatases (PTPs) can be traced back to early studies of the PTKs. When cells expressing temperature-sensitive mutants of Src were shifted from the permissive temperature for PTK function to the nonpermissive temperature, a rapid decrease in the extent of tyrosine phosphorylation of cellular proteins was observed, reflecting the activity of potent PTPs [1]. However, a description of the nature and properties of these enzymes was harder to obtain. Originally, it was suggested that there would be a small number of PTPs that served essentially a housekeeping function, with the subtlety and sophistication of the regulation of signal transduction exerted at the level of the PTKs. Today, we know that this original concept was incorrect and that signal transduction is tightly regulated at the level of both protein phosphorylation and dephosphorylation. Unlike the protein kinases, which are all descended from a common ancestor, the phosphatases have evolved in separate families. Thus, the PTPs are structurally and functionally distinct from the family of Ser/Thr phosphatases [2]. This overview introduces the structural diversity of the PTP family and highlights some of the recent developments that have stimulated interest in these enzymes as critical regulators of cell function.

Structural Diversity within the PTP Family

The first PTP to be purified and characterized was termed PTP1B [3,4]. Following the determination of its amino acid sequence, its homology with CD45, a transmembrane receptor-like protein of hematopoietic cells, was established [5]. Shortly thereafter, it was demonstrated that CD45 possessed intrinsic PTP activity [6]. This observation was important because it established the existence of receptor-like PTPs with the potential to regulate signal transduction directly through ligand-controlled dephosphorylation of tyrosyl residues in proteins. This triggered great interest in the PTPs and, following application of PCR and low-stringency screening, a wide variety of these enzymes were identified in diverse organisms. The availability of the first draft of the human genome sequence, together with data on the whole genomes of various organisms, now offers the potential to define the composition of the PTP family and to explore evolutionary relationships. Current estimates suggest that the family of PTPs in humans will comprise a total of ~ 100 enzymes.

The PTPs are defined by the presence of a signature sequence motif, [I/V]HCXXGXXR[S/T]. This motif, which is referred to as the PTP loop, forms the base of the active site cleft. Within this motif, the Cys and Arg residues are invariant and essential for catalysis [7,8]. Due to the environment of the active site, in particular the presence of the invariant Arg residue, this Cys displays an unusually low pK_a , which enhances its ability to execute a nucleophilic attack on the phosphate group of the substrate in the first step of the catalytic mechanism [9,10]. An invariant Asp residue (D181 in PTP1B), which is located in a conformationally flexible loop (the WPD loop), is also essential and

functions as a general acid to protonate the phenolate leaving group of the substrate [11]. This first step in catalysis results in formation of a cysteinyl-phosphate intermediate. In the second step, this invariant Asp functions in combination with a Gln residue, equivalent to Q262 in PTP1B, to activate a water molecule and promote hydrolysis of the phosphoenzyme intermediate [12]. Although all members of the PTP family use this same basic catalytic mechanism, structural differences allow them to be subdivided into two broad categories, those enzymes that are specific for phosphotyrosyl residues in proteins, termed the classical PTPs, and the dual-specificity phosphatases (DSPs), which have the ability to recognize Ser/Thr, as well as Tyr residues.

is flanked on either the N- or C-terminal side by noncatalytic sequences that serve a regulatory function. Similarities in the catalytic domain sequence, which coincide with similarities in the structural and functional domains present in the regulatory segments, allow the PTPs to be grouped into 17 subtypes, including receptor-like and nontransmembrane categories (Fig. 1) [2].

The specificity of the enzymes for phosphotyrosyl residues is explained in part by the depth of the active site cleft. This is defined by a tyrosyl residue (Y46 in PTP1B), which forms one side of the cleft [13]. Thus, a pTyr residue in a substrate is of sufficient length to gain access to the nucleophilic Cys at the base of the active site cleft, whereas pSer and pThr residues would be too short to be dephosphorylated. Recently, a search of cDNA sequences in the GenBank database revealed the existence of 113 such PTPs in vertebrates, including 37 in humans [2]. Additional mining of the human genome sequence increased the number of classical PTPs to 38 and identified 12 pseudogenes (see Chapter 109

The Classical PTPs

In the classical PTPs the signature motif is contained within a conserved catalytic domain of 280 residues, which

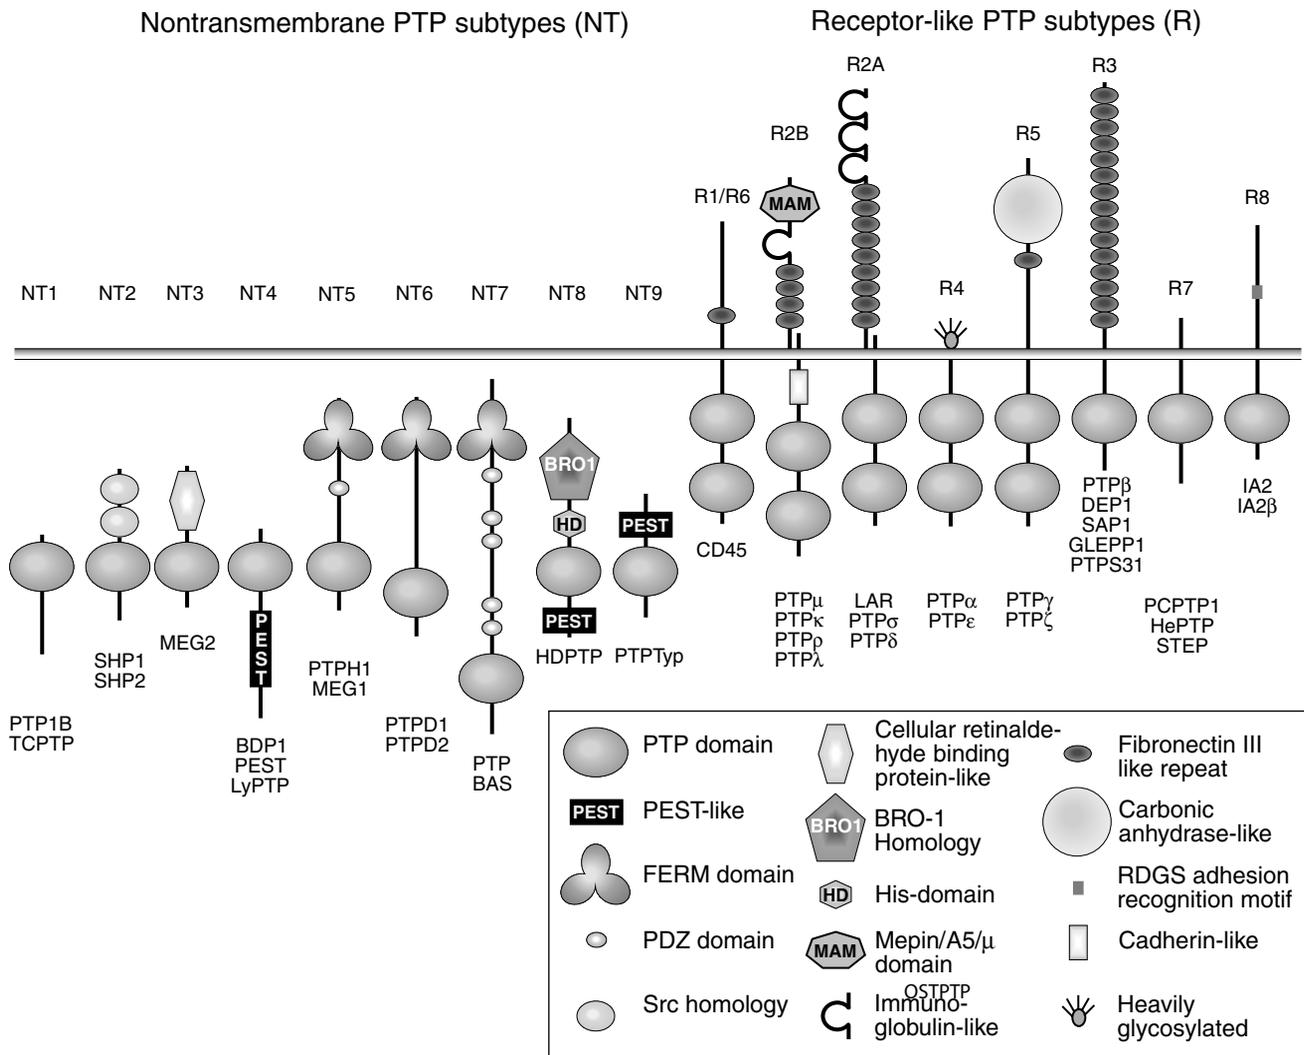

Figure 1 Schematic representation of PTP family members. The PTPs have been classified into nine non-transmembrane (NT) and eight receptor-like (R) subtypes based on sequence similarity. Only the human PTPs are listed, and a representative of each subtype is shown. (From Andersen, J. N. *et al.*, *Mol. Cell. Biol.* 21, 7117–7136, 2001. With permission.)

and Andersen *et al.* submitted). To provide a framework for a genome-wide analysis of the PTPs we have compiled a comprehensive online resource for sequence analysis of the pTyr-specific members of the PTP family. The website includes amino acid sequence alignments, phylogenetic classification of family members, and evaluation of amino acid conservation in three dimensions using X-ray crystal structures of PTP domains and low-resolution homology modeling. The PTP database is available online at <http://ptp.cshl.edu> or <http://science.novonordisk.com/ptp>. In the future, we plan to expand this resource to include pseudogenes, intron/exon organization, and splice variants as well as mutations, polymorphisms, and disease linkages.

The Dual Specificity Phosphatases (DSPs)

The DSPs display greater variation in structure than the classical PTPs and, although there is conservation in the fold of the catalytic domain, sequence similarity between the two groups is largely restricted to the signature motif. The DSPs are characterized by a more open active site cleft than the classical PTPs which allows them to accommodate different phosphorylated residues [14,15]. The first of these enzymes to be described was VH1, the product of an open reading frame from the pox virus *Vaccinia* that is essential for virion infectivity [16,17]. The study of the DSPs not only highlighted the structural diversity within the family but also provided some of the first illustrations of specificity and functional importance. Links between the DSPs and phosphorylation events that are critical for normal cell function were soon established. For example, the MKPs (MAP kinase phosphatases) comprise a group of DSPs that dephosphorylate particular members of the MAP kinase family [18] and the different *cdc25* gene products regulate transition through the cell cycle by dephosphorylation of the cyclin-dependent kinases (Cdks) [19]. Although described as “dual specificity,” certain DSPs within this group can display preference for one particular type of amino acid. For example, VHR preferentially dephosphorylates the tyrosyl residue of the activation loop of Erk MAP kinases [20] and KAP dephosphorylates T160 from the activation loop of Cdks [21,22]. Interestingly, DSPs can also recognize non-protein substrates. For example, PTEN, the product of the tumor suppressor gene on human chromosome 10q23, is specific for phosphate on the 3 position of the sugar ring of the phosphatidylinositol phospholipids PI(3,4,5)P3 and PI(3,4)P2 and, therefore, regulates PI 3-kinase-dependent signaling pathways [23,24]. In addition, myotubularin, the product of the gene that is mutated in X-linked myotubular myopathy, dephosphorylates phosphatidylinositol 3-phosphate (PI3P) [25,26].

The DSPs can be divided into three groups. The largest includes the VH1-like DSPs, and a summary of those that have been described in the literature to date is presented in Table 1. In addition, there are the myotubularins (MTMs) [27,28] and the *cdc25s* A, B, and C [19]. We have conducted exhaustive searches and phylogenetic analyses of the VH1-like

Table I Mammalian VH1-Like Dual-Specificity Phosphatases

Name	Aliases
MKP-1 [86]	3CH134 (mouse) [87], CL100 (human) [88], ERP [89], HVH1 [90], DUSP1
MKP-2 [91]	TYP 1 [92], HVH2 [93], DUSP4 [94]
HVH3 [95]	B23 [96], CPG21 [97], DUSP5
PAC-1 [98]	DUSP2 [99]
MKP-3 [100]	Pyst1 (human) [101], rVH6 (rat) [102], DUSP6 [94]
Pyst2 [103]	MKP-X [94], B59 [104], DUSP7 [94]
MKP-4 [105]	Pyst3, DUSP9
MKP-5 [106]	MKP5 [107], DUSP10 [108]
MKP-7 [109]	MKP-M [110]
HVH5 [111]	M3/6 (mouse) [112], DUSP8
MKP6 [113]	DUSP14, MKP-L
VHR [114]	DUSP3
TMDP [115]	DUSP13
JSP1 [116]	LMW-DSP2 [117], VHX [118], JKAP [119], MKPX
SKRP1 [120]	LDP-2 [121]
hSSH-1 [122]	
hSSH-2 [122]	
hSSH-3 [122]	
hYVH-1 [123]	GKAP (rat) [124], DUSP12
PTEN [77]	MMAC-1 [78], TEP [125]
TPTE [126]	
TPIP [127]	
PIR1 [128]	DUSP11
PRL1 (rat) [129]	PTP(CAAX1) [130], PTPIVA1 [131], OV-1 [132]
PRL2 (mouse) [133]	PTP(CAAX2) [130], PTPIVA2 [131]
PRL3 (mouse) [133]	PTP(CAAX3), PTPIVA3
hCdc14A [134]	
hCdc14B [134]	
KAP-1 [135]	Cdi1 [136]
Laforin [137]	EPM2 [138]
HCE1 [139]	mRNA Capping Enzyme
STYX [140]	
MK-STYX [141]	STYX 2

A list of mammalian DSPs is provided, with a primary name assigned in the left column and alternatives found in the literature provided on the right. Appropriate references for each name are provided.

DSPs from various genomes, revealing many novel enzymes and illustrating structure–function relationships within the group. Thus far, we have identified a total of 43 VH1-like DSPs in humans. A detailed description of this analysis is in preparation and will be added to the website listed above.

Regulation of PTP Function

It was apparent from early in the study of these enzymes that members of the PTP family have the potential to represent a formidable barrier to PTK function [4], suggesting

that mechanisms must exist to attenuate their activity and permit a tyrosine phosphorylation-dependent signaling response. The fact that PTPs may not only antagonize PTK function, but also act in concert with PTKs to promote signaling, as in the activation of Src family PTKs by CD45 [29], introduces further levels of complexity. Obviously, for receptor-like PTPs there is the potential for regulation of activity in response to ligands. With the exception of homophilic binding interactions between the extracellular segments of certain receptor-like PTPs (RPTPs) [30], however, the identity of such ligands has proven elusive. Many RPTPs display structural features of cell adhesion molecules and have been implicated in the regulation of phenomena associated with cell-cell contact, such as neuronal pathfinding during development [31]. More recently, both soluble (e.g., the interaction of pleiotrophin with PTP ζ/β [32]) and surface-bound (e.g., interaction of heparin sulfate proteoglycans with PTP σ [33]) ligands for RPTPs have been described. Nevertheless, the effects of ligand binding on RPTP activity remain to be fully characterized. Structural analyses of PTP α led to a proposal, which gained wide acceptance in the field, that ligand-regulated dimerization of RPTPs may inhibit activity due to occlusion of the PTP active site in the dimer [34]. Interestingly, biological data consistent with such a model have been presented [35]. Nevertheless, a direct demonstration that dimerization regulates activity has yet to be provided and further structural analyses of other RPTPs [36,37] suggest that this model, if correct, may not apply broadly across the family. There have now been suggestions that ligand binding may activate certain PTPs, such as following engagement of the extracellular segment of DEP-1 by components of the extracellular matrix [38], but the mechanisms underlying such effects remain to be explored.

An important aspect of regulation of the nontransmembrane PTPs is that of subcellular targeting, which has been referred to as the "Zip Code" model [39]. Structural motifs within the noncatalytic segments of these PTPs target the enzymes to defined subcellular locations. Thus, the physiological functions of these PTPs are restricted by the nature of the substrates to which they have access at these defined locations. For example, the SH2 domain-containing PTPs (SHP1 and 2) are recruited into signaling complexes at the plasma membrane via binding of the SH2 domains to specific pTyr sequence motifs [40,41]. The enzyme TC-PTP occurs in two alternatively spliced forms that share the same catalytic domain, but have different C termini that target the enzyme either to the endoplasmic reticulum (ER) or the nucleus [42]. Recent elegant studies using fluorescence imaging techniques have shown that PTP1B, which is targeted to the cytoplasmic face of membranes of the ER, functions in a "dephosphorylation compartment" acting upon RPTKs that have been downregulated by endocytosis [43]. Nevertheless it is important to note that PTP function and specificity are not solely regulated by control of location. PTPs have the ability to display intrinsic specificity for particular substrates which is determined by features of both the active

site of the phosphatase and the structure surrounding the phosphorylation site in the target. Furthermore, in addition to targeting, the noncatalytic segments of the PTPs can regulate activity directly. For example, the C-terminal segment of TC-PTP contains an inhibitory sequence, the effects of which can be overcome *in vitro* by proteolytic removal of the segment or its engagement with antibodies [44]. Presumably, the interaction of TC-PTP with physiological regulatory proteins modulates activity *in vivo*. In addition, in the absence of an appropriate ligand, the N-SH2 domain of the SHPs binds to and occludes the active site, thereby inactivating the enzyme [45]. Thus, interaction of specific pTyr sequences with the SH2 domains of the SHPs both targets the enzyme to particular substrates and directly activates the enzyme.

Many PTPs are phosphoproteins *in vivo*. Such phosphorylation events may create docking sites that promote protein-protein interactions, such as in the association of Grb2 with SHPs [46] or 14-3-3 with PTPH1 [47] and cdc25 [48]. Phosphorylation may also modulate activity directly, such as in the phosphorylation of PTP-PEST by PKC and PKA, which inhibits PTP activity and thus may underlie a mechanism for cross-talk between Ser/Thr- and Tyr-phosphorylation-dependent signaling pathways [49]. Thus, inhibition of PTP function by phosphorylation of Ser/Thr residues could indirectly promote Tyr phosphorylation of other cellular proteins. PTPs are also susceptible to proteolysis. This has been implicated in the generation of isoform diversity, such as in the production of cytosolic forms of RPTP ϵ [50], as well as in generating forms of a PTP in which regulatory constraints are removed, such as following calpain-induced cleavage of PTP1B [51].

Oxidation of PTPs in Tyrosine Phosphorylation-Dependent Signaling

Reactive oxygen species (ROS) are produced in response to a wide variety of cellular stimuli [52]. A substantial body of data emphasizes the importance of ROS production as a mechanism for fine-tuning tyrosine-phosphorylation-dependent signaling through the transient oxidation and inactivation of members of the PTP family [53]. In the unique environment of the PTP active site, the invariant Cys residue of the signature motif, which displays an unusually low pK α , is present predominantly as the thiolate anion [9,10]. This not only enhances its nucleophilic properties but also renders it susceptible to oxidation. Oxidation can yield a stable, single-oxidized sulfenic acid modification of the Cys (Cys-SOH), which inhibits activity because the oxidized Cys can no longer function as a nucleophile. This modification is reversible and thus can form the basis for a mechanism of reversible regulation of PTP activity. Glutathionylation of the sulfenic acid form of PTPs has been reported [54] which may not only promote reduction back to the active state but also prevent further, irreversible oxidation by the addition of two (sulfinic acid) or three (sulfonic acid)

oxygens to the active site Cys. Treatment of both PTPs and DSPs with H_2O_2 *in vitro* results in oxidation and inactivation [55]. More importantly, oxidation and inactivation of PTPs have now been demonstrated in response to physiological stimuli. For example, PTP1B is oxidized and inactivated in response to growth factors, such as epidermal growth factor (EGF) [56], and hormones, such as insulin [57].

In order to examine this issue further, we developed a modified “in-gel” PTP assay to visualize the oxidation of PTPs in response to a stimulus in a cellular context. We observed the reversible oxidation of multiple PTPs in response to treatment of Rat 1 cells with H_2O_2 and demonstrated that this oxidation was required for the mitogenic effects of H_2O_2 [53]. We also demonstrated that stimulation of Rat 1 fibroblasts with platelet-derived growth factor (PDGF) led to the production of reactive oxygen species, which induced the rapid and reversible oxidation of the PTP SHP2 [53]. Ligand-induced autophosphorylation of the PDGF receptor (PDGFR) generates docking sites for various signaling proteins, including SHP2. We showed that mutant forms of the PDGFR that were unable to bind to SHP2 displayed enhanced autophosphorylation and enhanced activation of MAP kinase. Thus, SHP2 appears to recognize the PDGFR as a substrate and functions as an inhibitor of PDGFR signaling. Interestingly, it was only the population of SHP2 that was bound to the PDGFR that was susceptible to reversible oxidation and inhibition. We propose that PDGF stimulation induces localized production of ROS, leading to the rapid oxidation of the pool of SHP2 that has been recruited into a complex with the PDGFR. This augments autophosphorylation of the receptor and initiation of the signaling response.

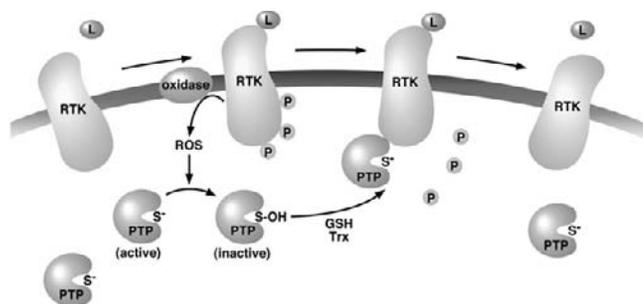

Figure 2 Regulation of protein tyrosine phosphatase (PTP) activity by reversible oxidation. Ligand-dependent activation of a receptor protein tyrosine kinase (RTK) triggers the activity of a Rac-dependent NADPH oxidase leading to production of reactive oxygen species (ROS). ROS oxidize the active site Cys residue of members of the PTP family, converting it from a thiolate ion (the active form) to sulfenic acid. Oxidation results in inhibition of PTP activity, thereby promoting tyrosine phosphorylation. However, due to the action of glutathione or thioredoxin, oxidation of the PTPs is transient. Restoration of PTP activity following reduction back to the thiolate form of the active site Cys residue terminates the tyrosine-phosphorylation-dependent signal. A variety of growth factors, hormones, and cytokines induce ROS production and stimulate tyrosine phosphorylation. We are developing methods to identify the PTPs that become oxidized in response to a physiological stimulus as a way of establishing links between particular PTPs and the regulation of defined signaling pathways.

The transient nature of the oxidation ensures reduction and reactivation of the pool of SHP2, which promotes dephosphorylation of the PDGFR and termination of the signal. These data illustrate how ligand-induced production of ROS may augment tyrosine-phosphorylation-dependent signaling in general through inactivation of PTPs (Fig. 2).

The production of ROS is observed in response to a wide variety of stimuli, including growth factors, hormones, cytokines, and activators of G-protein-coupled receptors, leading to PTK activation. The operating principle is that the stimulus enhances tyrosine phosphorylation directly by activation of a PTK or indirectly by inactivation of a PTP. Thus, one function of ROS produced following agonist stimulation is transient inactivation of the critical PTP that provides the inhibitory constraint upon the system, thus facilitating initiation of the signaling response to that stimulus. We propose that stimulus-induced oxidation may be used as a means of “tagging” and identifying those PTPs that are integral to the regulation of the signaling events triggered by that stimulus. It is hoped that this will provide further insights into the physiological function of members of the PTP family.

Substrate Specificity of PTPs

Studies of protein and peptide dephosphorylation *in vitro* have illustrated the importance of residues flanking the site of phosphorylation in a substrate for optimal PTP activity [58]. Now the issue of substrate specificity in a cellular context has been explored in a variety of experimental approaches, which illustrate that, contrary to initial expectations, the PTPs exhibit exquisite substrate specificity *in vivo*. For example, the function of several PTPs has been investigated through the generation of knockout mice. Interestingly, in several cases, ablation of closely related PTPs has yielded dramatically different phenotypes. This is illustrated by comparisons of the phenotypes generated by knockouts of PTP1B [59] and TC-PTP [60], SHP-1 [40], and SHP-2 [41] or within the LAR group of RPTPs [61–66]. These distinct phenotypes are consistent with exquisite specificity in substrate recognition and function.

The crystal structure of PTP1B in a complex with a phosphotyrosyl peptide substrate revealed that a profound conformational change accompanied substrate binding. The WPD loop that forms one side of the active site cleft closes around the side chain of the pTyr residue and positions the invariant Asp residue for its catalytic function [13]. This imagery of the jaws of the active site closing around the substrate stimulated an analysis by site-directed mutagenesis, in which we generated a form of PTP1B that maintains a high affinity for substrate but does not catalyze dephosphorylation effectively [67]. Thus, we converted an extremely active enzyme into a “substrate trap.” Furthermore, the residue that is mutated to generate the substrate-trapping mutant is the invariant catalytic acid (Asp181 in PTP1B) that is conserved in all members of the PTP family. This has afforded us a unique approach to identification of physiological substrates of PTPs in general.

Following expression, the mutant PTP binds to its physiological substrates in the cell but, because it is unable to dephosphorylate the target efficiently, the mutant and substrate become locked in a stable, dead-end complex. Potential substrates can be identified by immunoblotting lysates of cells expressing the mutant PTP with antibodies to pTyr to reveal proteins for which the phosphorylation state is altered as a consequence of expression of the mutant. In addition, the complex between the mutant PTP and the pTyr substrate can be isolated by immunoprecipitation and associated proteins identified by immunoblotting or, on a larger scale, by primary sequence determination. We have used this method to demonstrate specificity of PTP-PEST for p130cas [68] and PTPH1 for VCP [69], as well as differences in specificity of the spliced variants of TC-PTP (see Chapter 110) [70].

Specificity in substrate recognition is now further emphasized by the demonstration of examples in which a PTP not only recognizes a specific target substrate but also shows preference for particular phosphorylation sites within that target. A dramatic example is the specificity of PTEN for the 3 position in the inositol ring of phosphatidylinositol phospholipids [23,24]. Furthermore, there are similar examples with protein substrates, such as the preferential recognition of Tyr 239 in Shc by TC45 [70]. The mechanisms underlying such substrate specificity are now being defined at the molecular level. For example, an X-ray crystal structure of a complex between PTP1B and the activation loop of the insulin receptor as a substrate led to the definition of a consensus sequence motif of D/E-pY-pY-R/K for optimal substrate recognition [71,72]. In several cases, interactions between the PTP and substrate at sites remote from the active center have been shown to be important. This is illustrated by PTPs such as PTP-SL and STEP [73] and DSPs such as MKP-3 [74,75], which dephosphorylate Erk MAP kinases. In addition, the highly specific nature of the interaction between PTP-PEST and p130cas appears to result from a combination of two distinct substrate recognition mechanisms; the catalytic domain of PTP-PEST contributes specificity to the interaction with p130cas, whereas the SH3 domain-mediated association of p130cas and PTP-PEST dramatically increases the efficiency of the interaction [76].

PTPs and Human Disease

The importance of PTPs to the control of signal transduction has been further reinforced by numerous examples in which the disruption of normal PTP expression or function has been implicated in human disease. A summary of developments in this area is presented in Table 2. In light of the large number of PTKs that have been shown to play a role in oncogenesis, it was anticipated that many of the PTPs may be the products of tumor suppressor genes. Although PTPs have been linked to inhibition of cell proliferation, it was not until the demonstration that PTEN was encoded by the locus at human chromosome 10q23, which is mutated in a large number of tumors, that the first tumor suppressor

PTP was identified [77,78]. Even then, PTEN is unusual within the PTP family, displaying specificity for phosphatidylinositol phospholipids [23,24]. More recently, the RPTP DEP-1 has been identified as a tumor suppressor associated with cancers of colon, breast, and lung [79]. Although PTP1B has been implicated in the dephosphorylation of several growth factor receptor PTKs, mice in which the gene for PTP1B has been ablated display disruption of signaling in response to insulin and leptin but no increased incidence of tumors [59,80–82]. Recent studies have shown that disruption of the *PTP1B* gene does lead to hyperphosphorylation of the EGF and PDGF receptors, but with only minimal changes in signaling [83]. Thus, it would appear that mechanisms exist within the cell to compensate for disruption in PTP expression. Such mechanisms may apply broadly across the PTP family, explaining why so few tumor suppressor PTPs have been identified.

The current environment of fear regarding the potential for acts of bioterrorism has also drawn attention to the PTP family of enzymes. The prototypic DSP, encoded by the VH1 open reading frame of *Vaccinia*, is essential for normal virion infectivity [16,17], and homologs of this enzyme are also known to be essential for the viability of other poxviruses [71]. *Variola* virus, the cause of small pox, is closely related to *Vaccinia*, suggesting that its VH1-like DSP is an essential element of small pox infections. PTPs have also been implicated in bacterial infections, and, in this context, the function of the PTP Yop of *Yersinia*, the causative agent of bubonic plague, is of interest. Progress has been made in defining the function of this enzyme, which has been shown to target p130cas at focal adhesions in infected host cells [84]. The importance of these PTPs in infection suggests that development of inhibitors of the enzymes may offer strategies to counter the threat posed by these organisms. Furthermore, the ability of a variety of infectious agents to usurp normal tyrosine phosphorylation-dependent signaling pathways suggests that drugs designed to inhibit members of the PTP family may yield new classes of anti-infectives.

Recent progress in establishing links between PTPs and human diseases, together with developments in understanding the function of several of these enzymes, has raised awareness of the PTPs in the pharmaceutical industry. The appreciation that PTPs have the ability to display specificity for substrates *in vivo* and, therefore, to exert effects that would be restricted to specific signaling pathways suggests that PTP-directed drugs would induce defined, rather than global, changes in cellular tyrosine phosphorylation. A spectacular example of the potential importance of PTPs in the development of novel therapeutic strategies was provided by the phenotype of the PTP1B knockout mouse. The mice show no obvious deleterious effects; however, they display enhanced sensitivity to insulin and a resistance to obesity induced by a high-fat diet, which is accompanied by increased basal metabolic rate and total energy expenditure [59,80]. These effects have been defined in terms of a regulatory function for PTP1B in signaling through the insulin and leptin receptors [59,80–82]. Therefore, an inhibitor of PTP1B

Table II Linkages Between Protein Tyrosine Phosphatases and Disease

PTP1B	Diabetes and obesity	Phenotype of PTP1B ^{-/-} mice. QTL at chromosome 20q12–13 (containing <i>PTP1B</i> gene) linked to NIDDM and obesity. Polymorphisms in PTP1B segregate with diabetes.
DEP1	Tumor suppressor	Positional candidate for the colon cancer susceptibility locus Scc1 (QTL in mice). Frequently deleted in human cancers of colon, breast and lung.
CD45	Autoimmunity	Links to SCID and HIV-1 infection and possible links to multiple sclerosis. Antibody to CD45 prevents transplant rejection. Lupus-like phenotype of CD45-E613R mutant mice.
SHP1	Inflammation	Autoimmune/proinflammatory phenotype in motheaten mice. Factor in infection of glial cells by TMAV encephalomyelitis virus. Downregulated in human T cell malignancies and patients with Sezary syndrome.
SHP2	Noonan syndrome Stomach ulcers	Developmental disorder affecting 1 : 2500 newborns. Target of <i>Helicobacter pylori</i> .
FAP-1	Apoptosis	Upregulated in human cancers; inhibits CD95-mediated apoptosis.
IA2	Type I diabetes	Major autoantigen in Type I diabetes; role in glucose-stimulated insulin secretion.
YopH	Infectious disease	Virulence determinant of <i>Yersinia</i> .
PTEN	Tumor suppressor	Mutated in human cancers; Cowden disease.
PRL-3	Metastasis	Upregulated in metastases of colon cancer.
MTM1	X-linked myotubular myopathy	Mutations reduce phosphatidylinositol phosphatase activity.
MTMR2	Charcot-Marie-Tooth disease type 4B	Neuropathy associated with truncation mutations in the MTMR2 gene.
Laforin	Progressive myoclonus epilepsy	Mutations or microdeletions of Lafora disease phosphatase.
Cdc25	Cell cycle control	Target of <i>Myc</i> oncogene and overexpressed in primary breast cancer.
VH1	Infectious disease	Essential for production of infectious virions of <i>Vaccinia</i> .

The table summarizes some of the links that have been established between members of the PTP family and disease states. A detailed discussion of information summarized in this Table, including a comprehensive list of citations, is presented in "A genomic perspective on protein tyrosine phosphatases: Gene structure, pseudogenese and genetic disease linkage" by Anderson, J. N. *et al.*, submitted 2002). The information will also be added to the web sites <http://ptp.cshl.edu> and <http://science.novonordisk.com/ptp>.

would offer a strategy to counteract both obesity and diabetes, which is provoked by obesity. Given the increasing prevalence of obesity and its related illnesses in Western society, the potential for a PTP1B-based drug is obvious. The crystal structure of a complex between PTP1B and the activation loop of the insulin receptor as a substrate has revealed unique features of the interaction that could be targeted by an inhibitor [71]. Highly potent inhibitors have been developed [85]; however, the charged nature of the PTP active site presents several challenges to the development of small-molecule inhibitors that maintain the ability both to inhibit PTP function potently and to cross the plasma membrane.

Perspectives

In this post-genomic era, in which composition of the family of PTPs has largely been defined, one can move toward a characterization of function. It is now apparent that the PTPs have the capacity to display selectivity in their recognition of target substrates *in vivo* and that such substrate specificity underlies functional specificity. Broadly speaking, PTPs have the ability to function as either inhibitors or activators of particular signaling pathways, depending upon the signaling context. At present, although data attest to the importance of several members of the PTP family as regulators of cell signaling under normal conditions and in

the etiology of human disease, the majority of these enzymes are known primarily by their sequence with little information available regarding their function. It is anticipated that in the near future studies of the PTP family as a whole will generate novel insights into function and perhaps establish new links to disease with the possibility of new avenues for therapy.

Acknowledgments

I apologize for the fact that, due to space limitations, many exciting papers in the PTP field have not been cited. Work in my lab is supported by grants from the NIH, CA53840, and GM55989, as well as the Cold Spring Harbor Laboratory Cancer Center Grant CA45508. I am indebted to my colleagues May Chen and Jannik Andersen for their help in compiling Tables 1 and 2, respectively.

Introduction

The protein tyrosine phosphatase (PTP) family of enzymes dephosphorylate target signaling proteins and are involved in the diverse regulation of numerous cell functions. PTPs comprise a large gene-family (112 genes) with the minimal catalytic motif CX₅R, where C is the cysteine nucleophile that attacks the phosphate group, R is the arginine residue that binds phosphate and stabilizes the transition state, and X represents any amino acid. A large subgroup of the PTPs are capable of efficient hydrolysis of both phosphotyrosine and phosphothreonine/serine residues and are often referred to as dual-specificity PTPs. Members of the PTP family can be soluble or membrane-associated proteins, as in the receptor-like PTPs. The common feature of these phosphatases appears to be the basic catalytic mechanism involving the formation of a phospho-cysteinyl enzyme intermediate, using the conserved cysteine, arginine, and general acid/base aspartate residue. The catalytic domain of PTPs consists of an α/β fold composed of a highly twisted core of β -strands flanked by α -helices. Domains outside of the catalytic fold serve as regulatory and/or targeting modules. The structure, substrate recognition, catalytic mechanism, and modes of regulation are discussed in this review.

Introduction to the Protein Tyrosine Phosphatase Family

Protein tyrosine phosphatases (PTPs) are signaling enzymes involved in the regulation of numerous cell functions. PTPs dephosphorylate target proteins such as mitogen-activated

protein (MAP) kinases and receptor kinases, leading to the appropriate regulation of a variety of signal transducing pathways. PTP families include receptor-like transmembrane and soluble proteins. Dual-specificity phosphatases (DSPs) are a subfamily of intracellular PTPs that catalyze dephosphorylation of the three most prevalent phospho-amino acids (phosphotyrosine, phosphoserine, and phosphothreonine). Analysis of the human genome indicates that tyrosine-specific protein phosphatases and DSPs are one of the more abundant gene families (112 genes, ranked 29th overall) [1].

Structure

Determining the three-dimensional structures of over a dozen PTPs has facilitated the identification of critical residues involved in catalysis, substrate binding, and regulation. Although PTPs share a low percentage of amino acid sequence identity among all family members, their overall structures are similar. The catalytic domain of PTPs consists of an α/β fold, composed of highly twisted core β -strands flanked by α -helices [2–4]. The PTP signature motif HCXXGXXR(T/S) (and minimally CX₅R) defines the active site center, where the catalytic cysteine resides at the base of the active site cleft. Residues in the PTP signature motif form the phosphate-binding loop, where the main-chain N–H groups and the guanidinium side chain of the invariant arginine residue are oriented to coordinate oxygens of the phosphate group during substrate binding and catalysis. The active site is surrounded by intervening loops that are important in providing additional residues for catalysis and substrate specificity. A highly conserved aspartic acid

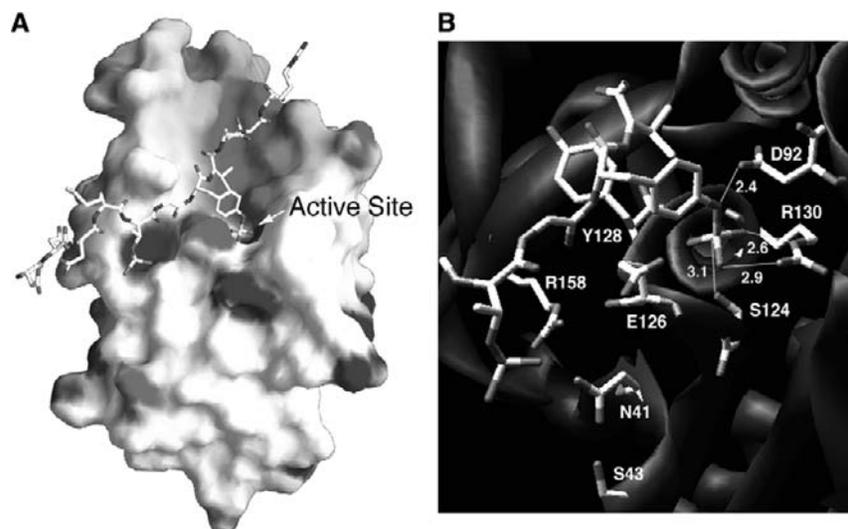

Figure 1 Crystal structure of C124S mutant VHR bound to bisphosphorylated peptide DDE(Nle)pTGpYVATR [24]. (A) Electrostatic surface of the VHR–peptide complex. Surfaces are shaded according to the local electrostatic potential, ranging from -13 V in gray to $+13$ V in dark gray. The peptide is represented as a stick, with carbon, nitrogen, oxygen, and phosphate atoms. This figure was generated with GRASP. (B) Close-up view of the phosphotyrosine and phosphothreonine binding sites. The peptide is shown as a stick, and the atoms are colored as in panel (A). This figure was generated with Swiss Pdb Viewer v3.5 and POV-Ray v3.1. A color representation of this figure can be viewed on the CD version of *Handbook of Cell Signaling*.

residue is required for general acid/base catalysis and is located on a separate loop (general acid loop) near the top of the active site.

Outside the catalytic domain, amino acid sequences vary dramatically among the PTPs. Additional regions may include modular domains such as SH2 (Src homology 2) domains, fibronectin repeats, and immunoglobulin domains [5]. SH2 domains serve as protein interaction modules recognizing specific phosphorylated tyrosines in proteins or peptides. The SH2 domains of SHPs (Src homology phosphatases) target these phosphatases to specific tyrosyl phosphorylated proteins within cells. Also, the N-terminal SH2 domain of SHPs regulate catalytic activity directly. In the absence of an appropriate phosphotyrosine ligand, the N-SH2 binds to and inactivates the PTP domain by blocking substrate access. This restricts SHP activation to particular locations within the cell where the substrates reside [6,7]. Fibronectin repeats and immunoglobulin domains are found in many receptor protein tyrosine phosphatases (RPTPs). Several RPTPs are believed to play a role in the regulation of cell–cell contact and adhesion through homophilic binding interactions between adjacent cells. RPTPs contain one or two intracellular catalytic domains (membrane-proximal D1 and membrane-distal D2). D1 domains are catalytically active, but most D2 domains lack several of the critical catalytic residues, resulting in a domain that displays little or no phosphatase activity [8–10].

Despite low sequence identity between the tyrosine-specific phosphatases and DSPs, crystal structures of several DSPs (VHR, Pyst1/MKP3, PTEN, and KAP) show a highly conserved active site core similar to PTPs [11–14].

Figure 1 shows the crystal structure of VHR (*Vaccinia* H1 related) bound to a bisphosphorylated peptide substrate [15]. VHR represents the minimal catalytic domain among PTPs, which has made VHR a good model in studies of PTP structure and mechanism. The crystal structure of the DSP Cdc25 catalytic domain reveals that Cdc25 has a unique topology [16,17] that identifies Cdc25 as a more distinct family member of the PTPs. Cdc25 upregulates cyclin-dependent serine/threonine protein kinases (Cdks) by dephosphorylating two adjacent phosphothreonine and phosphotyrosine residues, which are inhibitory to Cdk kinase activity. Although Cdc25 appears to use a similar catalytic mechanism [18], sequence homology within the catalytic domains of other PTPs and DSPs is restricted to the CX_5R motif. Like Cdc25, low-molecular-weight PTPs (LMW-PTPs) constitute a distinctive class. The crystal structure of bovine LMW-PTPs reveals a unique fold [19,20]. The LMW-PTPs also contain the conserved arginine, aspartate, and cysteine residues within their active sites.

Structural features of PTPs have provided evidence for peptide substrate specificity and for selectivity toward the nature of the phosphorylated residue. Peptide specificity appears to be defined largely by residues both N- and C-terminal to the substrate pTyr residue. The structure of PTP1B in a complex with insulin receptor peptides indicates that a second pTyr residue adjacent to the substrate phosphorylation site plays a critical role in specificity [21]. Similarly, the DSP VHR displays a preference for diphosphorylated peptide substrates [15,22]. The peptide-interacting residues in PTP1B and VHR are poorly conserved throughout the entire PTP family, implying that PTPs have distinct protein substrate specificity.

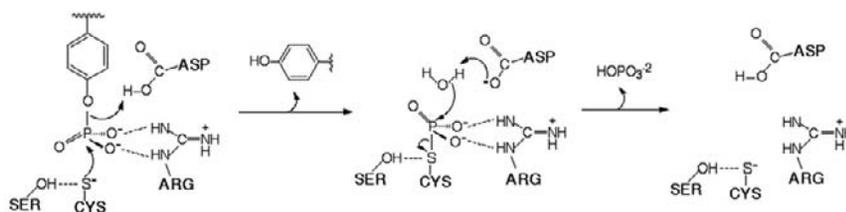

Figure 2 Catalytic mechanism of protein tyrosine phosphatases.

The phosphorylated residue specificity appears to be determined by the depth of the active site pocket, the general acid loop, and the PTP signature motif. Tyrosine-specific PTPs have an $\approx 9\text{-}\text{\AA}$ -deep active site cleft; therefore, only phosphotyrosine residues can reach the cysteine nucleophile in the active site. For example, the structure of PTP1B in a complex with a peptide derived from epidermal growth factor receptor (EGFR) revealed that Arg221 at the base and Asp48 at the rim of the active site exactly match the length of pTyr residues [23]. The general acid loop also provides some level of substrate specificity. The PTP1B general acid loop (also called WPD loop, where D is Asp181 general acid) closes over the active site upon phosphorylated peptide binding. This allows the Asp181 to be positioned to act as a general acid in the catalytic reaction and for Trp179 and Pro180 to interact with Arg221 in the active site. These interactions stabilize the catalytically competent conformation of the loop [24]. The crystal structure of the *Yersinia* PTP also shows the ligand-induced conformational change of the general acid loop [25].

In contrast, DSPs have a shallower active site cleft for accommodating both phosphotyrosine and phosphoserine/threonine residues. Also, the PTP signature motif in the DSPs provides substrate discrimination. Though VHR belongs to the DSP family, VHR prefers phosphotyrosine over phosphoserine/threonine [15,22]. While most DSPs contain alanine and isoleucine in the X_2 and X_3 positions of the signature motif $\text{HCX}_1\text{X}_2\text{GX}_3\text{X}_4\text{R(S/T)}$, VHR harbors a glutamate and a tyrosine, respectively. The crystal structure of VHR bound to a bisphosphorylated peptide (shown in Fig. 1) reveals that the side chains of glutamic acid-126 and tyrosine-128 in the signature motif impart substrate specificity for phosphotyrosine by creating a deep and narrow active site [15]. The smaller residues (isoleucine and alanine, found in many DSPs) allow more efficient phosphothreonine and phosphoserine dephosphorylation activity [15]. Another putative DSP family member, PTEN (phosphatase and tensin homolog deleted on chromosome 10), is unique among known PTPs, as it has two basic lysine residues within the signature motif. These positive charges are believed to interact with the negative charges of inositol phospholipid PIP3 (phosphatidylinositol 3,4,5-triphosphate), the biological substrate for PTEN [13,26].

Mechanism

Protein tyrosine phosphatases share a similar active site structure despite their low amino acid sequence homology.

A common mechanism employed by PTPs is represented in Fig. 2. In the first step of the reaction, the cysteine nucleophile in the active site attacks the phosphorus atom of the substrate, forming a phosphoenzyme intermediate. As the ester bond is cleaved, a general acid (conserved aspartic acid residue) donates a proton to the leaving group oxygen, releasing dephosphorylated substrate. In the second step of the reaction, a water molecule is activated by the aspartic acid acting as a general base. The activated water molecule hydrolyzes the phosphoenzyme intermediate, yielding free enzyme and inorganic phosphate.

Numerous kinetic and biochemical data support the reaction mechanism outlined here. The cysteinyl-phosphate intermediates have been observed using a variety of methods [24,27,28]. The conserved cysteine nucleophile has been shown to be essential in all PTP families. The pK_a value of the active site cysteine is quite low, ranging from 4.7 to 5.5. Under physiological pH, the low pK_a of cysteine ensures that it exists as the thiolate anion. The hydroxyl group of a serine or threonine residue in the signature motif is important for facilitating the hydrolysis of the phosphoenzyme intermediate, perhaps by stabilizing the leaving group thiolate [29,30]. The conserved histidine residue in the signature motif has a considerable effect on lowering the pK_a of the cysteine [31,32]. The invariant arginine residue in the signature motif is important for both substrate binding and transition-state stabilization, as it coordinates two of the oxygen atoms on the phosphoryl group via its guanidinium side chain. When the arginine is replaced with lysine or alanine in the *Yersinia* PTP, these interactions are disrupted and the resulting enzyme displays substantially reduced catalysis and substrate binding [33]. As mentioned, the conserved aspartic acid residue in the general acid loop facilitates general acid/base catalysis in PTPs. Substitution of the aspartic acid residue produces an enzyme that is incapable of general acid catalysis [27,30,34,35].

To better understand the transition-state structure, heavy-atom kinetic isotope effects have been measured using *para*-nitrophenyl phosphate (*p*NP) labeled with ^{15}N and ^{18}O isotopes. These studies have indicated that phosphoenzyme intermediate formation is highly dissociative, where bond formation to the incoming nucleophile cysteine is minimal and bond breaking between phosphorus and the leaving group oxygen is substantial [36,37]. Moreover, the analysis of conserved aspartic acid mutants of PTPs indicates that the leaving group departs as the *p*-nitrophenolate anion and that the aspartic acid is responsible for the protonation of the leaving group in the wild-type enzymes.

Regulation

Although PTPs do not appear to be governed by a universal regulatory mechanism, three basic types of mechanisms are described in the literature: (1) redox regulation of the catalytic cysteine, (2) phosphorylation, and (3) regulation mediated by the inherent flexibility in the general acid loop. In the redox regulatory model, PTP activity is inhibited when the nucleophilic cysteine is reversibly oxidized to either a sulfenic acid ($-SOH$) or to disulfide ($-S-S-$) [38,39]. Some PTPs, such as Cdc25, are phosphorylated themselves, resulting in enhancement in catalytic activity [40]; however, the scope of such phosphorylation-dependent regulation appears to be limited. One intriguing mechanism of regulation takes advantage of the inherent flexibility in the general acid loop of PTPs. Crystal structures of ligand-free and ligand-bound PTPs indicate conformational differences in this general acid loop [41]. For example, the general acid loop of MAP kinase phosphatase 3 (MKP3) is flipped away from the active site, where, upon binding, its substrate ERK induces closure of the general acid loop, converting the low-activity form of MKP3 to the activated form [12,42–44]. The recent crystal structure of KAP (kinase-associated phosphatase) with phosphoCDK2 indicates that CDK2 binding to KAP is responsible for the formation of a complex where the catalytic site of KAP is correctly positioned for catalysis [14]. Consistent with this idea, RPTP α is thought to be regulated by dimerization. Based on the crystal structure of the D1 catalytic domains of RPTP α , it was found that the amino-terminal helix–turn–helix region of one monomer is inserted into the active site of the dyad-related D1 monomer in RPTP α , preventing closure of the general acid loop [45]. Similarly, the catalytic activity of SHP2 is regulated by the N-terminal SH2 domain acting as a conformational switch. The N-SH2 domain blocks the PTP active site and closure of the general acid loop, thus inactivating the enzyme in the absence of phosphorylated substrates. The binding of phosphorylated substrates to the N-SH2 domain relieves this inhibition and results in activation of enzyme [46]. Future questions in the PTP research field will need to address both specific and general regulatory mechanisms, as well as identification of the authentic protein substrates for this large and important class of signaling molecules.

Introduction to Bioinformatics

Removal of phosphate from phosphotyrosine residue (pTyr) on cellular proteins plays a key role in many different signaling pathways and is catalyzed by three classes of enzymes [1–6]: (1) classic protein tyrosine phosphatases (PTPs), (2) dual-specificity phosphatases (dsPTPs), and (3) low-molecular-weight phosphatases (LMW-PTPs). The classic (tyrosine-specific) PTPs, which are the focus of this bioinformatics analysis, have traditionally been classified into receptor-like and intracellular PTPs based on the presence or absence of a transmembrane-spanning region (Fig. 1).

Bioinformatics is a relatively novel scientific discipline that combines several areas of research [7]. As it is also a rapidly developing field, there is currently not even general agreement on the definition of the word *bioinformatics*, which nonetheless has gained huge popularity as a buzzword intimately connected with the assembly and analysis of the human genome [8,9]. The definition of bioinformatics depends on the context in which the word is used. As a consequence, the English language has recently been enriched with a number of new terms (e.g., *structural genomics*, *toxicogenomics*, *oncogenomics*, *metabolomics*, *proteomics*, *pharmacogenomics*, *chemogenomics*; see Table 1). However, a unifying feature in bioinformatics is the collection and analysis of large assemblies of biological datasets, most often depending heavily on powerful computers and development of software tools. Despite tremendous progression in the collection and annotation of sequence information at

a few central sites, it is still a major challenge to review and compile large datasets from various sources that are updated with different speeds.

In this chapter, we present a template approach to database mining and bioinformatics analyses of classic PTPs that include the following elements: (1) compilation of a comprehensive and nonredundant database of PTP cDNA and protein sequences; (2) utilization of this database to create a homology-based classification of PTP proteins based on amino acid sequence alignments and phylogenetic analysis (neighborhood-joining trees); (3) low-resolution homology modeling to identify conserved regions (PTP structure–function) and nonconserved selectivity-determining regions (substrate specificity and inhibitor design); (4) identification of the genomic complement of the PTP protein family by mapping all PTP-like sequences in the human genome; (5) determination of the chromosomal location and genomic structure of each PTP and use of this information to group novel PTPs as either pseudogenes or true novel PTPs; (6) establishing an initial framework for future disease association studies and studies of the genetic elements controlling PTP expression and regulation.

It is our aim to introduce the reader to the most important bioinformatics databases and analytical tools as we delineate the structural and evolutionary relationships among PTP domains, analyze the PTP family in a genomic context, and finally provide some initial tools for functional analyses of PTPs in health and disease. Although in-house-developed software tools have been employed, we believe that the

approach is generally applicable and that it (with some patience) can be utilized for bioinformatics analyses of other protein families.

Amino Acid Homology Among PTP Domains and Structure-Function Studies

Databases: Genome, mRNA, and Protein Sequences

Monitoring the avalanche of primary sequence data entering archives such as GenBank and EMBL is a daunting task; however, the biological community is increasingly well prepared with secondary databases that extract and annotate subsets from the primary data. The RefSeq resource maintains a nonredundant set of human mRNAs, which are mapped onto genomic sequence via LocusLink or the UCSC genome browser (Table I). A nonredundant catalog of human proteins is maintained in the SwissProt/TrEMBL protein database (Table I, Swall) or in the RefSeq database of mRNA translation products. In addition, protein families and conserved domains (including amino acid sequence alignments and consensus motifs) are found in the InterPro database (Table I), which provides automated annotation of all SwissProt/TrEMBL proteins, including the human proteome (i.e., the gene product inventory of the human genome) [10,11]. Although the human proteome set is some way from completion, the Ensembl project (Table I) provides a source of homology-based predicted gene products based on the current human genome assembly. On the European Bioinformatics Institutes website (Table I, EBI), the current predicted protein index stood at 29,076 sequences as of May 2002. In contrast, the nonredundant mRNA total in RefSeq now stands at 15,846. This means that approximately half of the human genes are already represented as full-length coding sequences if considering only one gene-one-mRNA-one protein.

Collection of Unique Vertebrate PTP Sequences

Establishment of a nonredundant collection of amino acid sequences is a key first step for a comprehensive bioinformatics analysis of any protein family, and a simple text search (Table I, SRS) in the above protein databases retrieves the majority of human PTPs (e.g., the query "tyrosine" and "phosphatase" retrieves 28 human PTPs, including links to their cDNAs). The conserved catalytic domains of these well-characterized cDNAs were next used in a BLAST search to retrieve the entire set of PTP-like sequences deposited in GenBank [12]. Initially, more than 3500 database hits were discovered. Exclusion of expressed sequence tags (ESTs) and high-throughput genome (HTG) sequences reduced this number to 254 sequences, and, after further exclusion of PTP splice variants, partially overlapping clones, and duplicate entries, a total of 113 distinct vertebrate PTP catalytic domains were identified, 37 of which were human. A database of full-length proteins corresponding to this larger set of unique human PTP cDNAs forms

the basis for our bioinformatics analyses (Fig. 2). In addition, because most PTPs deposited in GenBank have been identified through low-stringency hybridization and PCR-based cloning techniques, the above review of all PTP accession numbers allowed assignment of synonyms to PTP sequences which were characterized in independent studies and consequently given different names in the literature.

Primary Sequence Alignment: Classification of PTPs and Phylogenetic Trees

Multiple sequence alignments (generated with ClustalW [13]) allow assessment of the degree of residue conservation among homologous proteins and hence provide a powerful basis for their classification. For the classic PTPs, a phylogenetic analysis of 113 aligned vertebrate PTP-domain amino acid sequences (available at <http://science.novonordisk.com/ptp/> or <http://ptp.cshl.edu>) reveals that this group of enzymes can be divided into 17 subtypes: 9 nontransmembrane subtypes (NT-PTPs or intracellular PTPs) and 8 receptor-like PTPs (RPTPs) subtypes (Fig. 1).

The nine intracellular PTP subtypes identified by the phylogenetic analysis correlate well with a classification based on regulatory or targeting domains residing outside the catalytic domains (Fig. 1): *NT1*: PTP1B and TC-PTP; *NT2*: SHP-1 and SHP-2; *NT3*: MEG2; *NT4*: PEST, LyPTP, BDP1; *NT5*: MEG1 and PTPH1; *NT6*: PTPD1 and PTPD2; and *NT7*: PTPBAS. Four of these subtypes each consist of only one enzyme: *NT3*: MEG2; *NT7*: PTPBAS; *NT8*: PTPTyp; and *NT9*: HDPTP.

For tandem-domain RPTPs, the membrane-proximal PTP domains (D1 sequences) cluster into one major trunk of the phylogenetic tree, whereas the single-domain RPTPs define three distinct subtypes (R3, R7, and R8). When including 49 membrane-distal PTP domains (D2 sequences) from vertebrate tandem-domain PTPs in the analysis, these sequences define a separate subfamily that is phylogenetically distinct from the subfamilies defined by the PTP catalytic D1 domains, thus indicating structural and perhaps functional conservation among the D2 sequences [12].

Of note, one RPTP subtype contains both receptor-like and nontransmembrane PTPs (R7), and two RPTP genes also encode cytoplasmic variants as a result of alternative splicing (GLEPP1; mouse RPTP ϕ [14]) or alternative promoter usage (PTP ϵ [15]). Except for these discrepancies, the phylogenetic classification based on PTP domain sequence homology is in overall accordance with previous topological classifications based on the presence or absence of an extracellular region.

Conserved Regions and Residues: A Three-Dimensional Comparison

Already during the first years of PTP research, when only a few different PTP cDNAs had been isolated, it became apparent that certain motifs were conserved. At that time, neither the structural nor functional significance of these motifs was known. However, they served as useful priming

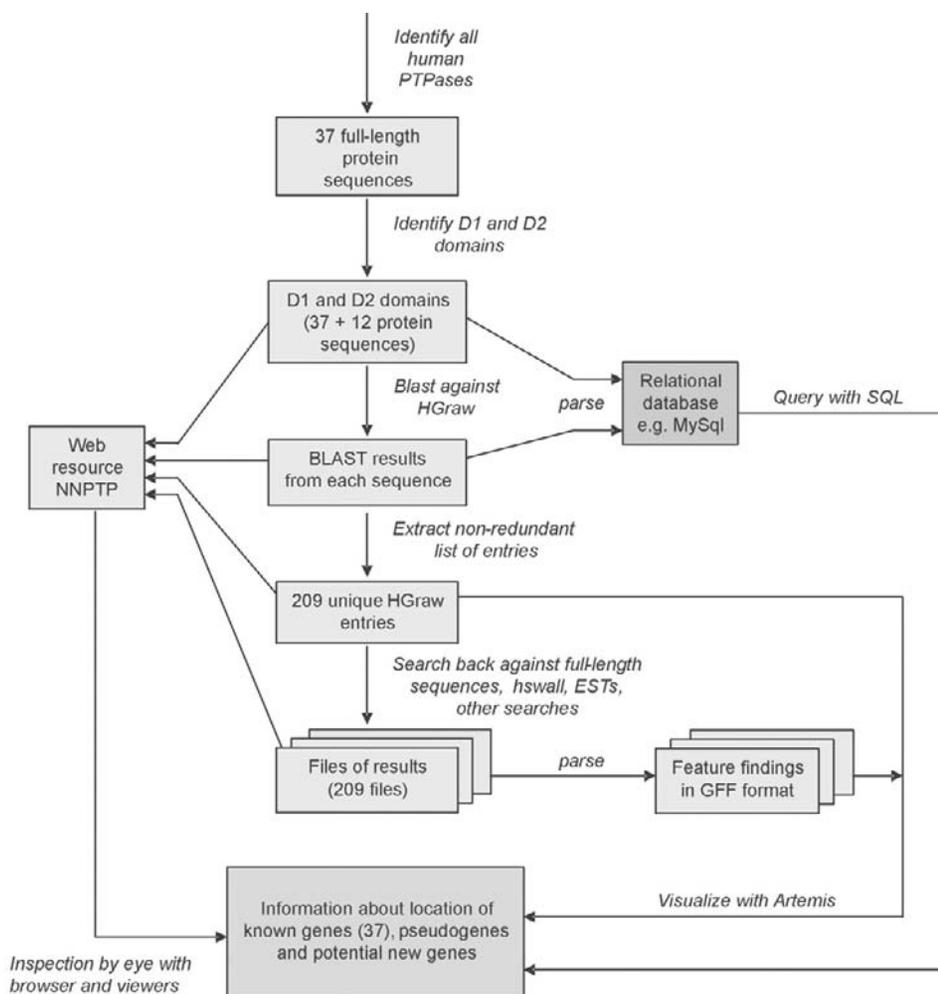

Figure 2 Flow diagram for identification of PTP-like sequences in the human genome. (For abbreviations and links, see Table 1.)

sites for identification of novel PTPs using degenerate oligonucleotide primers and helped significantly in advancing the field in a timely fashion. Equally impressive has been the speed of determining the structures of different PTPs. Thus, following the seminal study on the structure of PTP1B [16], X-ray protein crystallographic structures are currently available for nine different PTP catalytic domains: PTP1B, TC-PTP, SHP-1, SHP-2, PTP μ , PTP α , PTP-LAR, PTP-SL, and *Yersinia* PTP (Table I, Entrez). Moreover, a remarkable number of studies have reported PTPs in complex with various peptide substrates and inhibitors (see below). We and others have superimposed these PTP domains and found a striking conservation of the tertiary structure [12]. This structural conservation allows the combination of primary sequence analysis and low-resolution homology modeling and thus identification of conserved regions and residues at the three-dimensional level. The catalytic domains of PTPs consist of about 280 residues arranged as a three-layer, α - β - α core domain with a central β -sheet sandwiched between α -helices (see Chapter 108).

Primary sequence alignment of the catalytic domains of PTPs reveals 10 discrete, highly conserved motifs (M1–10,

detailed at <http://science.novonordisk.com/ptp/>) and 7 single conserved residues (Glu19, Glu115, Arg156, Arg169, Leu192, Arg254, and Arg257; hPTP1B numbering, which is used throughout this chapter). Several of these motifs play critical roles in maintaining the stability of the PTP domain (e.g., extensive hydrophobic packing is observed for motifs M3–M7), while other motifs and conserved single residues are essential for catalysis. The most highly conserved area within the PTP tertiary structure is defined by the PTP signature motif, HisCysSerXxxGlyXxxArg[Thr/Ser]Gly (M9), and the structural motif [Phe/Tyr]IleAlaXXxGlnGlyPro (M4).

The Catalytic Machinery

While the molecular mechanisms underlying PTP mediated catalysis are treated in detail elsewhere (see Chapter 108), the primary sequence and three-dimensional analyses allow a first glimpse into the intricate catalytic machinery. The PTP signature motif ValHisCysSerXxxGlyXxxGlyArg-[Thr/Ser]Gly (residues 213–223 in PTP1B) defines the PTP family and represents one of Nature's elegant designs of a highly efficient binding pocket for phosphate. The PTP

motif, also called the P-loop or PTP-loop, forms a half-circle with the main chain nitrogens pointing toward the cysteine (Cys215 in PTP1B), which is positioned almost in the center. At physiological pH, this cysteine residue is deprotonated and acts as a nucleophile accepting phosphate transiently during catalysis [17]. Two of the highly conserved single residues help stabilize the PTP-loop (Glu115 and Arg257), which is positioned at the bottom of an approximately 9-Å-deep pocket (i.e., corresponding to the length of the side chain of phosphotyrosine, pTyr, but not the shorter side chains of phosphoserine and phosphothreonine). The phenyl ring of the pTyr substrate interacts with the aromatic Phe182 and Tyr46 residues and the hydrophobic residues Val49, Ala217, and Ile219. Upon binding of pTyr substrates, a major conformational change takes place that moves the WPD loop to close the active site pocket, literally trapping the substrate [18–20]. The WPD loop closure brings Asp181 close to the scissile oxygen of pTyr, where it is in a favorable position to function as a general acid during the first step of catalysis. In the second step, the highly conserved Gln262 positions a catalytic water molecule (for hydrolysis), thereby releasing phosphate from Cys215 [18].

Conserved Surface-Exposed Areas in Tandem PTPs: The D1/D2 Interface

The invariant residues in domain D1, which show considerable substitution in the D2 domains, are positioned close to the active site. In some RPTPs (e.g., PTP α , PTP ϵ , LAR) only two point mutations in D2 domains are required to restore robust catalytic activity against conventional PTP substrates, whereas critical substitutions present in D2 domains of other RPTPs (e.g., CD45, PTP ζ , PTP γ) indicate that these domains are truly inactive. While low-resolution homology modeling (so-called C α -regiovariation score analysis) of the catalytic domains of intracellular PTPs and the membrane-proximal D1 domains of RPTPs shows that the conserved residues converge around the active site, much greater variation is observed in the vicinity of the putative active sites in the D2 domains of receptor-type PTPs [12]. Thus, this analysis supports the notion that most of the catalytic activity is found in proximal D1 domains in tandem RPTPs [21,22], whereas the membrane-distal D2 domains, at least for some RPTPs, seem to play regulatory roles, as has been demonstrated for CD45 [23]. The D2 domains could act as phosphotyrosine recognition units, similar to Src homology 2 (SH2) and phosphotyrosine binding (PTB) domains [24].

So far, the crystal structure of tandem PTP domains has only been reported for PTP-LAR [25]. The relative orientation of the LAR D1 and D2 domains, constrained by a short linker, is stabilized by extensive interdomain interactions. In the present context, it seems significant that the C α -regiovariation analysis has identified conserved areas on both the D1 and D2 domains that correspond to the interaction area in LAR. In addition, the sequences corresponding to the linker sequence in LAR were found to be conserved in the D2 domains, but not in the D1 domain [12]. Thus, it seems likely that the

overall structure of receptor-like PTPs is well represented by the X-ray structure of PTP-LAR.

Nonconserved Residues in the Vicinity of the Active Site: Implications for a Bioinformatics Approach to Structure-Based Drug Design

At this point, the prototype PTP1B has in particular attracted the attention of the pharmaceutical industry. Mice in which the PTP1B gene has been removed (i.e., knocked out) show increased insulin sensitivity and resistance to diet-induced obesity [26,27]. Hence, inhibitors of PTP1B could potentially be useful for the treatment of type 2 diabetes and obesity.

The highly conserved structure of the PTPs and the consequential apparent difficulties related to developing selective active site-directed inhibitors initially discouraged the pharmaceutical industry from considering this group of enzymes as useful drug targets. A similar myth kept the industry away from the kinase field as it was considered impossible to develop kinase inhibitors with the requisite specificity [28]. However, basic research on protein kinases was leading the way for the PTP field, and applied pharmaceutical research has shown that even subtle differences or combinations of differences can be utilized in structure-based design of highly selective inhibitors that bind to the conserved ATP binding pockets in kinases. The PTP inhibitor field is now rapidly catching up, and both academic and industrial laboratories have convincingly demonstrated that selective, active site-directed PTP inhibitors can indeed be made [29–31]. In our laboratory, we used the above C α -regiovariation score analysis to identify residues or combinations of residues in the vicinity of the active site that would uniquely identify a particular PTP and thus could potentially be used for structure-based design of selective inhibitors. Because the intention is to develop orally active inhibitors, a number of compound characteristics must be taken into account; hence, poor absorption and cell permeation are often observed when the “rule of five” is violated, including exceeding a molecular weight of 500 [32]. Therefore, to allow design of low-molecular-weight, active, site-directed inhibitors, it is a requirement that selectivity be achieved by addressing residues in the vicinity of the active site.

Using the above low-resolution homology modeling approach revealed that four residues (47, 48, 258, and 259) were especially important for the design of selective PTP inhibitors. None of these residues is unique for one specific PTP, but the combination of these four residues constitutes a selectivity-determining region, a signature motif. Even closely related members within one PTP subfamily often differ in this region (e.g., PTP α and PTP ϵ). We and others have used this selectivity-determining region for structure-based design of selective PTP1B inhibitors [33–36] (see Chapter 111 for further details).

From a drug discovery point of view, bioinformatics analyses can contribute significantly to avoiding problems due to lack of specificity which otherwise might show up late in a

development phase as adverse or toxicological effects. Thus, when developing selective PTP inhibitors it is essential to have complete structural knowledge of all members of this enzyme family. As indicated, the conserved three-dimensional fold of PTPs allows relatively accurate structural comparisons of catalytic domains, even of PTPs for which no X-ray structures have yet been obtained. As an example, we have used Asp48 as an important interaction point (for salt-bridge formation) to develop selective PTP1B inhibitors [33]. Using combined structural and genomic analyses, which we have termed *structural bioinformatics*, we have identified all PTPs with an aspartic acid in the equivalent position. By introducing these PTPs as counter screens at an early stage in preclinical development of PTP1B inhibitors, we expect to avoid selectivity problems within the PTP family. In other words, complete mapping and analyses of all PTPs (and all other potential drug target families) are a must in the postgenomic era.

Identification of the Genomic Complement of PTPs

A. Chromosomal Localization of PTP Genes

With access to the human genome assembly (currently “Build” 28 at the National Institutes of Health), it is an easy task to identify the chromosomal localization of the 37 known human PTPs using LocusLink or the BLAST search platform in the UCSC genome browser (Table II). Importantly, the chromosomal localization could be mapped for all published PTPs consistent with the estimated 95% coverage of the human genome. This chromosomal assignment is important to resolve whether homologous proteins are splice variants derived from the same gene or are recently duplicated genes or pseudogenes. In addition, the current refinement of PTP chromosomal localization allows for disease association studies.

Mapping of Intron/Exon Structures: Alignment of mRNA with Genomic Sequences

To visualize PTPs in a genomic context, mRNA or protein sequences were fine-mapped (i.e., unequivocally aligned at the exon level) onto the assembled genome via LocusLink, Ensemble, or the UCSC genome browser (Fig. 2). NCBI provides a convenient tool for aligning mRNA or EST sequences to a genomic sequence (Table I, Spidey) in cases where PTP genome sequences are not present in the genome assembly but are found only in the raw sequences from the sequencing centers.

To distinguish between potentially novel PTPs and PTP pseudogenes in the humane genome, knowledge of the exon/intron structures for the known PTPs is essential. In addition, the genomic organization of a particular PTP is important when analyzing alternative splicing events or promoter elements. Finally, our mapping of PTP exon/intron structure revealed that the above classification of the PTP protein family into 17 PTP subtypes, based exclusively on

^bNot a HUGO-approved name.

catalytic domain amino acid sequence homology, is consistent with a classification based on PTP gene structure.

Searching the Human Genome for PTP-Like Sequences

The collection of unique full-length human PTP protein sequences formed the basis for mining the human genome

for novel PTPs and pseudogenes. A strategy for a BLAST-based homology search [37] with PTP D1 and D2 domain sequences as the origin is shown schematically in Fig. 2. To improve the specificity and reduce noise, the conserved PTP domain sequences were used as origin in this search, rather than the full-length sequences. Using the *tblastn* algorithm (part of the BLAST package) with default settings, D1 and D2 sequences from each of the 37 human protein sequences were searched against the six-frame translation of the human genome (raw sequences from the sequencing centers Human Genome Centers; see Table I). Each of the searches produced a results file with a substantial number of sometimes overlapping hits to various entries in the human genome database (HGraw). A nonredundant list of 295 genome entries was compiled from these files, and each entry was examined by hand for PTP catalytic domains using a number of iterative searches and predictions, including searches against the full-length protein sequences, hswall, and the EST database. In addition, selected genome sequences were analyzed with NetGene2 to predict splice sites, and putative PTP motifs were identified with the *fuzztran* program from the EMBOSS package. To allow quick navigation in the genome entries and the associated search results files, everything was organized in a web environment. To visualize see the Novo Nordisk website, NN-PTP; see Table I. To visualize the genome entries and their associated features (e.g., homology to full-length protein sequences, areas with EST hits, motifs), the results files were parsed to produce feature annotation in GFF format. Artemis provides a user-friendly graphical viewer of genome entries that can be loaded with the associated GFF files.

Using the web environment and the Artemis tool, each genome entry was carefully inspected by hand. This procedure reduced the 295 overlapping hits to: (1) the 37 published PTPs, (2) 9 intron-less PTP pseudogenes, (3) 4 or more potential novel PTPs with exon/intron structure, (4) 11 dsPTPs, and (5) 14 false-positive entries (low complexity hits). Although definitive classification of these potentially novel PTPs awaits a combined analysis of the finished genome sequence and experimental verification of cDNAs, it seems clear that the total number is far below earlier expectations in this protein family [38].

To complement the tedious manual data analyses with brute-force SQL queries, all hits between the origin protein sequences and the genome entries were uploaded to a relational database (MySQL), which also assists in (1) keeping track of hits, (2) generating statistics, and (3) more in-depth database mining in the future.

PTP Pseudogenes

As indicated previously, the human genome contains at least nine intronless PTP-like sequences that are closely related (>94% nucleotide identity) to the mRNA of TCPTP (two sequences), SHP2 (five), MEG1 (one), or RPTP α (one). Closer inspection of these sequences revealed multiple inframe stop codons due to insertions and deletions. Only two of the nine sequences had perfect matches with ESTs.

As an example, in addition to the TCPTP gene on chromosome 18 (Table 2), two TCPTP-like sequences were identified on chromosomes 1 and 13 (TCPTP-P1 and TCPTP-P13) which share 94 to 95% nucleotide identity over 1440 bp with the TCPTP cDNA. The lack of introns and the presence of polyadenylated tails indicate that these sequences are pseudogenes that arose by retrotransposition. Both TCPTP sequences harbor frameshift mutations and premature stop codons. If transcribed, this would generate short PTP-unfunctional polypeptides of 41 or 149 amino acids, respectively. Of note, TCPTP-P13 is associated with an EST sequence (aw401979), thus it may be expressed, although the function of such an mRNA/truncated protein is unknown.

When reviewing the *in situ* hybridization data published in the pregenomic era, we discovered that both the TCPTP and SHP2 pseudogenes identified in this study *in silico* also had been detected experimentally [39–41]. In the case of TCPTP, Johnson and coworkers [39] compared the specificity of genomic and cDNA probes and demonstrated that, under identical conditions, the genomic TCPTP probes (containing both exon and intron sequence) readily identified a single specific site of hybridization (18p11.3-p11.2), whereas the TCPTP cDNA probe identified sites of both the gene and its pseudogenes (1q22-q24 and 13q12-q13). Likewise, Jirik and coworkers [40], when using a SHP2 cDNA probe, found hybridization signals over 4q21 and 5p14 as well as to a lesser degree over chromosomes 3q1-3q13.2, 6q23-q24, and 8q12, in addition to 12q24.1 (the SHP2 gene; see Table 2) [40]. In light of today's genome assembly, we conclude that these signals correspond to the exact localization of five intronless SHP2 pseudogenes.

Novel PTPs

In addition to the intronless PTP pseudogenes, our analysis revealed a few novel PTP-like sequences and fragments that have an exon/intron structure consistent with the genomic organization of the PTP gene family. Some of these sequences are only fragments, and the final verification of these putative novel PTP genes awaits completion of the human genome sequence or experimental demonstration of their expression. However, one novel human PTP could be assigned to chromosome 1q32 (Fig. 3). The PTP gene located here has approximately 80% homology to both rat osteotesticular PTP (OST-PTP) and mouse embryonic stem cell phosphatase (PTP-ESP). Together with fluorescence *in situ* hybridization studies, which map OST-PTP to mouse chromosome 1 (region F–G, a region syntenic to human chromosome 1q32-q33), the similarity in gene structure suggests that this novel PTP is the human ortholog of OST-PTP. Because the human OST-PTP has not yet been cloned, the identification of its genomic sequence will facilitate future characterization of this PTP. As a first step, the human genome browser (Table 1, UCSC) allowed us to retrieve a hypothetical amino acid sequence for this PTP, as predicted by the Ensembl project. Only two EST sequences map to this region of chromosome 1 (Fig. 3), suggesting a highly

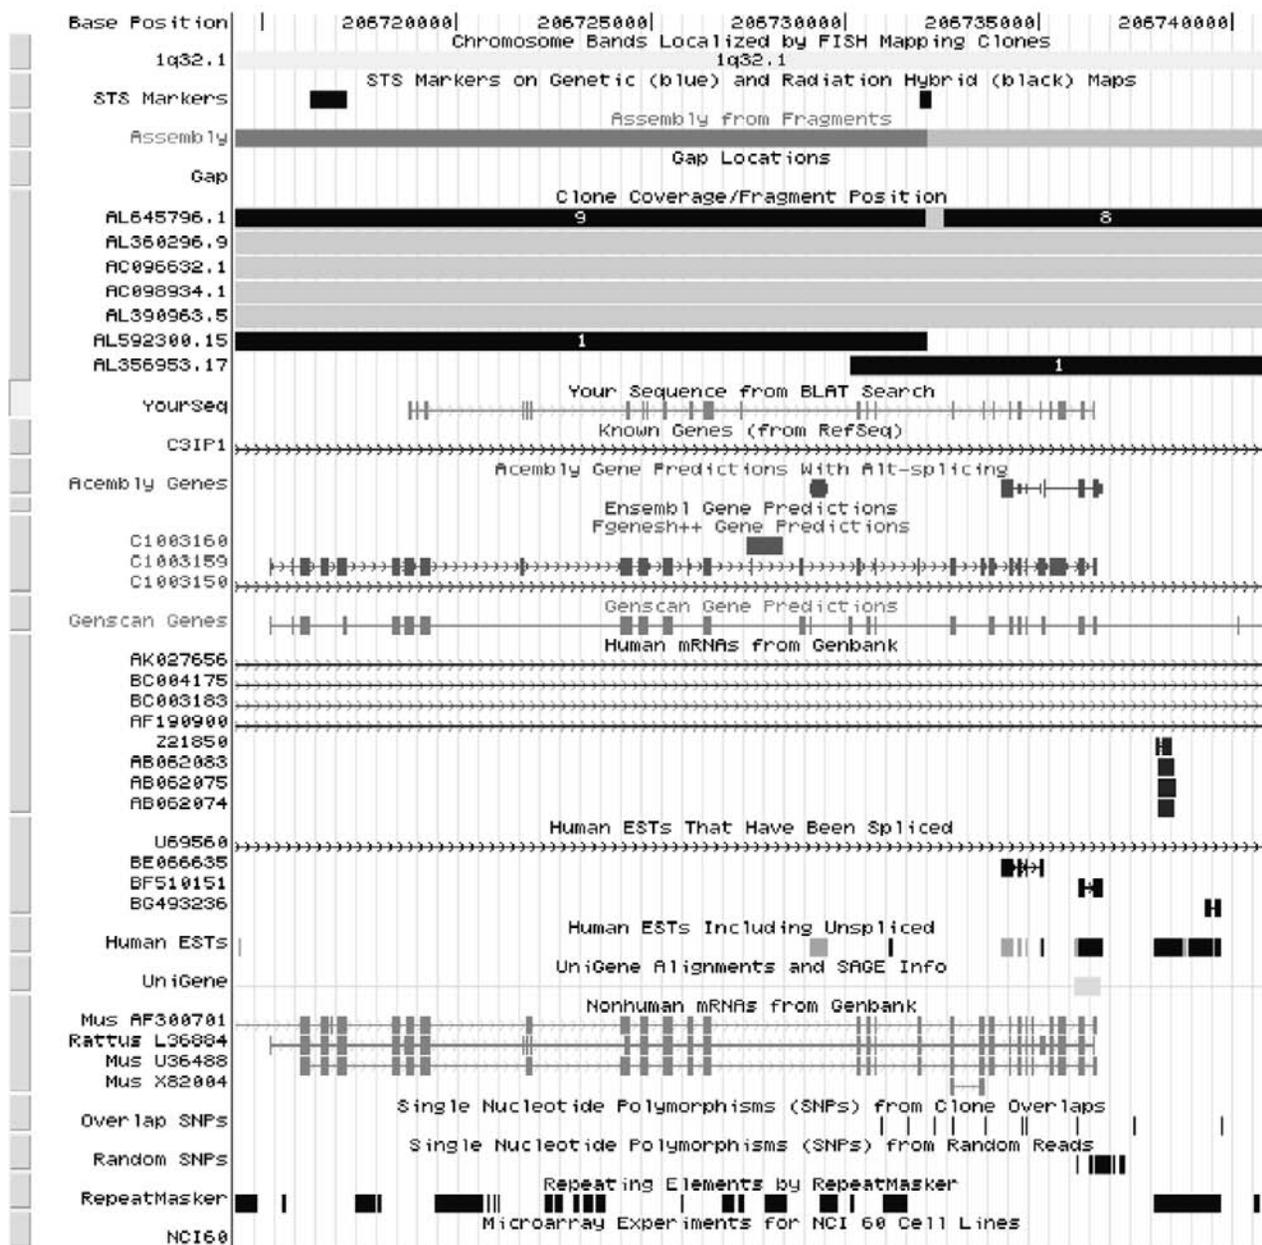

Figure 3 Identification of a novel human PTP (OST-PTP) and its genomic context in a selected browser (UCSC, Table I). From top to bottom the features include the nucleotide base position that refers to the coordinates in the NIH genome assembly, with the cytogenetic band immediately underneath, and a graphic view of clone coverage (gaps and overlap) in the assembly and accession numbers of the raw sequence. The identifier ‘YourSeq’ is the exon-intron structure we have predicted for human OST-PTP and underneath are homology-supported gene models (Acembly, Ensembl, Fgenesh and GenScan). Below the automated gene predictions are mRNA and ESTs sequences from human (black) and rodents (grey) aligned to the genome. Finally, additional display options can be selected, e.g. location of repeats, SNP, sequence-tagged-sites (STS), genetic markers and microarray expression data.

regulated and specific expression pattern similar to that observed for its mouse and rat counterparts [42].

Functional Aspects of PTPs in Health and Disease: Bioinformatics

Phosphorylation of cellular proteins regulates most signal transduction processes, and many diseases have been associated with abnormal phosphorylation patterns. An intricate

balance and regulatory machinery are required to maintain the exact levels of phosphorylation. How can less than 50 different classic PTPs be sufficient to regulate and fine-tune phosphotyrosine levels in a human from conception, during embryonic life, and through childhood, puberty, and adulthood? In addition to inherent substrate specificity that resides within the catalytic domains of protein tyrosine kinases and PTPs, other regulatory measures must be at play. As an example, compartmentalization may influence the accessibility to substrates and associated proteins [43,44], and the

subcellular localization may be further affected by proteolytic processing [45]. In addition, the activity of PTPs may be influenced by covalent modification [46]. Bioinformatics analyses of gene structure may provide further insight into PTP regulation by predicting alternative splicing, as recently demonstrated for PTPrho [47].

The present refinement of PTP chromosomal localization allows for disease-association studies using information from genetic disease databases such as the Online Mendelian Inheritance in Man (OMIM) database, which is an authoritative and comprehensive genetic knowledge database integrated in NCBI's Entrez suite (Table 1, OMIM) which provides full-text overviews of genetic disorders and gene loci as well as links to other genetic databases [48,49]. A recent candidate disease gene study illustrates this point. The relatively common Noonan syndrome maps to a 5-cM region on chromosome 12q24.1. Because PTPN11 (encoding SHP2) maps to the same region (Table 2) and SHP2 is known to play an important role in animal development, Tartaglia *et al.* hypothesized that mutations in this gene could be the cause of the syndrome [50]. Indeed, missense mutations in *PTPN11* were found in more than 50% of the cases. Of note, the identified amino acid substitutions affect highly conserved residues of SHP2 that are predicted to be important for the regulatory autoinhibition caused by binding of the N-terminal SH2 domain to the active site of SHP2 [51] (see Chapter 117).

The ultimate definition of the exact functions of a protein is often elusive and requires inter- and multidisciplinary approaches. Rarely is the function of a protein defined unequivocally in one study; rather, a general understanding evolves through a series of stepwise and iterative investigations where corrections are required as information is gathered over the years. Although there still remains much work to be done to complete the sequencing and analysis of the human genome, the next gold rush is on to accelerate the process of defining the function of proteins: proteomics [52].

While the human proteome may be considered endless or at least one order of magnitude more complex than the genome, from a practical point of view the functions of a gene product may be inferred from combined experimental studies, such as (1) tissue-distribution analyses (mRNA/protein), (2) over-expression of dominant-negative mutants, (3) *in vitro* and *in vivo* gene knockouts and transgenes, (4) antisense or RNA-mediated interference (RNAi) studies, (5) disease-association studies, or (6) the use of selective small molecule inhibitors or drugs. Provided that an evolutionary relationship has been established, deletion of an ortholog of a human gene in *Caenorhabditis elegans* or *Drosophila melanogaster* may further assist in assigning a function to such a gene [53]. Novel public and proprietary databases (e.g., Incyte, Celera) and bioinformatics tools will undoubtedly in the postgenomic area contribute significantly to initial insights or formulation of hypotheses for the functions of a given protein, from both a structural and functional genomics/proteomics point of view (important resources and links may be found via NCBI or 123Genomics; see Table I).

In the field of protein tyrosine phosphatase, PTP1B has received particular attention, and an understanding of its function is emerging from the above combined approaches. Thus, it seems likely that PTP1B is a key regulator of leptin signaling [54–56] and potentially an important drug target in obesity and type 2 diabetes (see Chapter 118). In the current bioinformatics context, it is of particular interest that PTP1B maps to 20q13.1-q13.2 (Table 2), a region linked to obesity and diabetes [57–60], and recently a rare P387L variant of the PTP-1B gene was found to be associated with relative risk of type 2 diabetes in a Danish study [61].

PTP Substrate Trapping

Andrew J. Flint

CEPTYR, Inc., Bothell, Washington

Introduction

In the early 1990s, many protein tyrosine phosphatases (PTPs) had been identified yet very few had been linked to a physiological function. For some, very little was known about them except for their primary amino acid sequence, which was sufficient only to identify them as members of a rapidly growing family of PTPs. During this time, many efforts were underway to attempt to ascribe functions to some of these PTPs. In the lab of Tonks *et al.* [1,2] at Cold Spring Harbor, one approach that was developed with this purpose in mind was termed *substrate trapping*. The fundamental concept behind this method was to identify a mutant form of a PTP that met three criteria: (1) it retained normal substrate binding specificity, (2) it was incapable of dephosphorylating substrates, and (3) it would form a sufficiently stable dead-end complex such that the substrates could be isolated in association with the mutant PTP. Any substrates present in the complex could be visualized with antiphosphotyrosine antibodies and upon identification could suggest potential physiological functions of that PTP. Since its initial development, this method has been applied widely to this class of enzymes, members of which utilize a similar catalytic mechanism but vary in their ability to dephosphorylate phosphotyrosine, phosphoserine, phosphothreonine, or phospholipids.

By far, the most common use of the method has been to carry out immunoprecipitation-type experiments similar to those originally described [1,2], in attempts to further one's understanding of the physiological function of a particular PTP. Other experiments have utilized trapping mutants to perturb cellular function. Interpretation of these experiments is not always simple, however, as sometimes the mutant PTP serves only to block the action of the normal PTP and in other cases the trapping mutant not only subverts the action of the active PTP but also interferes with the normal function of the substrate itself. Studies of the tumor suppressor

gene PTEN illustrate the former case as well as demonstrate that trapping mutants can be effective when the substrate is a lipid, in this case phosphatidylinositol 3,4,5-triphosphate (PIP3) [3,4]. Expression of the C124S mutant of PTEN in 293 cells overwhelmed endogenous PTEN to cause an increase in levels of the substrate PIP3 and did not decrease survival rates of LnCaP cells, while active PTEN did [4]. Conversely, experiments with D181A-PTP1B and p210^{bcr-abl} showed that not only did this mutant antagonize endogenous PTP1B, resulting in increased tyrosine phosphorylation of p210^{bcr-abl} [5], but it also blocked the downstream actions of p210^{bcr-abl} by binding to the tyrosine phosphorylation site required for signaling via grb2 [6].

Practical considerations related to use of the substrate-trapping methodology, including purifying or expressing appropriate mutants, choosing a source of potential substrates, deciding whether to trap proteins from a cell lysate or to isolate a complex following expression of the substrate-trapping phosphatase in cells, and isolating the trapping mutant/substrate complex, have been thoroughly described [7]. This chapter first discusses the current understanding of how trapping mutants work, some new and improved trapping mutants and how noncatalytic site regions of PTPs can contribute to substrate recognition. Next, some new approaches to identifying substrates with these mutants are discussed as well as some uses of these mutants for purposes other than the identification of substrates.

Original C → S and D → A Substrate-Trapping Mutants

The substrate-trapping methodology developed in the Tonks lab focused originally on a conserved catalytic aspartate residue (181 in PTP1B) [8], the mutation of which results in a severely reduced catalytic capacity (0.001% of wt activity for D181A-PTP1B assayed with RCML) [1].

Whereas mutation of the essential catalytic cysteine to either serine or alanine was known previously to produce a protein without measurable catalytic activity [9], this mutant form of several tyrosine-specific phosphatases (e.g., PTP1B, TCPTP, PTP-PEST, PTP-H1) did not effectively trap any tyrosine-phosphorylated substrate proteins. However, replacement of the catalytic aspartate residue with alanine (D → A) created a mutant with the ability to form a sufficiently stable complex with substrates that allowed the complex to be isolated and studied.

The reason why complexes between PTP1B-D181A and its substrates survive isolation (e.g., immunoprecipitation and washing conditions) better than those formed with PTP1B-C215A (or S) is still not completely understood. Presumably significant differences exist in the kinetics (dissociation and/or association rate constants) of substrate binding to each mutant. Nonetheless, a significant increase in understanding of the thermodynamic parameters of substrate binding by these mutants has been gained. Isothermal titration calorimetry measurements of binding of a nonhydrolyzable difluoromethylene-phosphono-phenylalanine peptide by wild-type and mutant forms of PTP1B have shown that the D181A mutant of PTP1B exhibits a fivefold higher affinity for this ligand than does the wt or C215S protein [10]. For both the D181A and C215S mutants, a reduction in electrostatic repulsion between the bound dianionic phosphate-containing ligand and the negatively charged D181 or thiolate C215 might have been predicted to result in higher affinities for both mutants; however, for the C215S protein the gain in enthalpy upon ligand binding is offset by an increased entropic barrier. The explanation that the C215S protein exhibits greater mobility or flexibility in the catalytic site region [10] has been confirmed visually in rather dramatic fashion in a crystal structure of the C215S protein [11]. In this structure, the PTP loop that contains the C215S mutation and contributes to binding the phosphate oxygens in substrates has adopted a conformation in which it is almost perpendicular to its normal orientation [11]. This conformation is clearly incompatible with substrate binding, and the increased entropic term measured by Zhang *et al.* [10] likely reflects the energy required to flip the loop back to the conformation observed in the crystal structures of PTP1B-C215S (or C215A) bound to phosphotyrosine-containing peptide substrates [12–14].

Second-Generation Trapping Mutants

While the use of D → A mutants initially appeared to be a useful, somewhat general method for identifying PTP substrates it was not long before modifications and improvements in the technique began to appear. For the phosphatase PTPH1, the D → A single mutant was used successfully to isolate tyrosine-phosphorylated VCP out of a lysate from pervanadate-treated cells and to identify it by peptide sequencing [15]. However, when the D811A mutant was expressed in 293 cells, to confirm that the interaction between PTPH1

and VCP could occur in cells where each protein would be present in its correct subcellular location, the PTP itself was the only tyrosine-phosphorylated protein present in the complex. Further study showed that mutation of a second residue within the catalytic site, a conserved tyrosine that forms one side of the substrate binding site, was critical for successful intracellular trapping of the substrate VCP [15]. With the Y676F-D811A double mutant, the tyrosine phosphorylation of PTPH1 itself was almost completely eliminated, and the VCP substrate was now trapped in a complex with the isolated PTPH1 [15].

Recently, the combination of the D181A mutant of PTP1B with Q262A has been shown to result in a substrate binding protein with an affinity for substrate 6-fold greater than for the D181A mutant alone and 30-fold greater than for wt enzyme [16]. Several other PTP1B mutations were tested in combination with D181A. The rationale for each was either to decrease further the residual amount of phosphatase activity present in the D181A mutant or to increase the affinity for substrate. Completely eliminating PTP activity by combining D181A with mutations of C215 resulted in unusually complex binding curves (C215S) or reduced instead of improved affinity (C215E) [16]. In agreement with these binding data, combining the D181A and C215A mutations of PTP1B did not result in any better trapping of substrates (Flint and Tonks, unpublished data) compared to D181A alone [1]. However, introduction of the Q262A mutation into D181A-PTP1B further reduced the k_{cat} toward pNPP by 10-fold and enhanced the affinity for a nonhydrolyzable peptide substrate by 6-fold as compared to D181A alone [16]. Q262 normally functions in PTP1B to promote hydrolysis of the phosphoenzyme intermediate via activation of a water molecule. Mutation of this residue enabled Pannifer *et al.* to trap this unstable catalytic intermediate and examine it crystallographically [17]. The Q262A mutant enzyme has a reduced K_m for substrate as well as a lower k_{cat} [1,18]. When the D181A-Q262A double mutant was transfected into COS cells, it trapped slightly more tyrosine phosphorylated epidermal growth factor (EGF) receptor substrate than did the single mutant D181A-PTP1B [16].

Accessory or Noncatalytic Site Contributions to Substrate Recognition

For some PTPs, mutation of the catalytic aspartate residue renders them much better trapping mutants than does a mutation of the catalytic cysteine residue—for example, PTP1B, TC-PTP, and PTP-PEST. However, for others, a C → S mutation at the catalytic site has been an effective tool for identifying potential substrates. These differences may be explained by variations in the way the enzymes recognize their substrates. For PTPs in which recognition of substrate is restricted to the portion of the substrate protein immediately surrounding the phosphorylation site, the intrinsic affinity of the D → A mutant vs. the C → S may be

a critical factor for isolating the complex. However, for PTPs in which the recognition of substrate utilizes contacts beyond the immediate vicinity of the phosphorylation site, then a C → S mutant can form a catalytically inert complex with the substrate that is stable enough to be isolated and detected. PTP-PEST is a useful illustrative example of this point. The D199A mutant of PTP-PEST uniquely identified p130^{cas} out of a complex array of tyrosine-phosphorylated proteins from pervanadate-treated HeLa cells. This interaction was mediated via the catalytic site as it was disrupted by vanadate and was detected using a truncated form of PTP-PEST containing little more than the phosphatase domain [2]. However, when the full-length form of PTP-PEST was used in trapping experiments, the tyrosine phosphorylated substrate p130^{cas} could be isolated with either the D199A or the C231S mutant [2]. Further characterization showed that a proline rich region around P337 was responsible for enhancing the interaction with p130^{cas} through binding to its SH3 domain [19].

Other examples of phosphatases for which accessory substrate binding sequences or domains have been discovered include CD45, YopH, KAP, and the MAP kinase phosphatases (MKPs). For CD45, the zeta-chain of the T-cell receptor complex was identified as a substrate and its second (noncatalytic) PTP domain (D2) was required for the interaction [20,21]. Replacement of its D2 with the second PTP domain of the closely related receptor PTP LAR prevented the association with the phosphorylated zeta-chain. YopH is a tyrosine-specific PTP that is a virulence factor from the pathogenic bacterium *Yersinia*. It dephosphorylates paxillin and p130^{cas} upon infection of HeLa cells, and expression of a C → S mutant traps these substrates [22,23]. Additionally, a noncatalytic N-terminal domain of YopH has been identified as an important contributor to recognition of these substrates [23,24].

The crystal structure of the C → S mutant of KAP in a complex with its substrate phospho-Thr-160 cdk2 provides an example of the majority of the interaction between the substrate and PTP being remote from the catalytic site, with interactions at the catalytic site restricted to little more than binding of the phosphate group [25]. A final, well-studied class of noncatalytic, site-mediated interactions has been found for the MKPs and their substrates, the mitogen-activated protein kinases (MAPKs), also known as extracellular signal-regulating kinases (ERKs). Before the advent of D → A trapping mutants, the C → S mutant of MKP-1 was shown to effectively trap phospho-ERK2 from serum-stimulated cells [26]. An extensive body of more recent literature documents the specificity of MKP3 for its substrate ERK2. The N-terminal, noncatalytic domain of MKP3 is responsible for mediating a high-affinity interaction with ERK2 that not only brings the two proteins together but also activates the catalytic function of MKP3 [27–30]. One facet of the activation appears to be the induction of a conformational change that swings the catalytic aspartic acid into a position where it is now capable of greatly enhancing the rate of dephosphorylation [31].

New Twists on Trapping

One natural extension of more commonly practiced substrate-trapping procedures is to carry out the final analysis of the trapped complexes on two-dimensional polyacrylamide gels instead of by western blotting after the usual one-dimensional SDS-PAGE (sodium dodecyl sulfate polyacrylamide gel electrophoresis). Potential substrate proteins in the complex can be visualized by blotting to specifically detect phosphotyrosine or could be silver stained to detect all components. With the current sensitivity of mass spectrometry (MS) methods for identifying minute amounts of proteins, the contents of the complex could be determined directly. A different two-dimensional approach was described by Pasquali *et al.* [32] in which substrate-trapping mutants are used in a “far-western” procedure. A complex mixture of tyrosine-phosphorylated proteins (e.g., lysate from cells treated with pervanadate) is separated on two-dimensional gels and transferred to a membrane. The trapping mutant is used as a probe to seek out its substrates on the membrane, and the putative substrate is subsequently identified by MS methods. While these authors were technically successful in identifying α -tubulin as the spot on the gel to which FAP-1 bound, they also pointed to limitations of the method, such as a requirement that the PTP recognize its substrate as it is stuck to a membrane in a partially folded state, that the conditions of the probing might require optimization, and that under these conditions a PTP would have the opportunity to associate with a protein that it might never normally encounter in the cellular milieu. Nonetheless, for substrates of dual-specificity phosphatases that may not necessarily be detectable with antiphosphotyrosine antibodies, methods such as these may be required to detect and identify these substrates.

An alternate approach to substrate trapping that bypasses the need to detect the phosphorylated substrate directly was developed by Kawachi *et al.* [33]. Using a variation of the yeast two-hybrid method developed for identifying SH2-domain-binding proteins [34], the authors engineered a strain of yeast with inducible expression of v-Src, a substrate-trapping PTP–lexA fusion, and a library of potential substrates fused to the GAL4 activation domain. Transcriptional activation of the reporter gene occurs when v-Src phosphorylates one of the GAL4 fusions which is then bound by the substrate-trapping PTP–lexA fusion. Sequencing of the plasmid encoding that particular GAL4 fusion identifies the potential substrate. Transcriptional activation should not occur in the absence of v-Src expression when the GAL4 fusion should not be phosphorylated. With this system, the GIT1/Cat-1 protein was identified as a substrate for the neuronal receptor PTP ζ [33]. Two obvious advantages of this method are that it might enable identification of low-abundance substrates and that interactions having rapid on/off rates that would likely be disrupted by standard immunoprecipitation wash procedures might now be detected. A limitation of this method is that for the substrate trapping to occur, the PTP substrate also must be a substrate for the kinase

used (v-Src in this case). Presumably, one could tailor the choice of kinase to be relevant to any particular signal transduction pathway of interest.

Along the lines of tuning the substrate-trapping system to a specific signaling paradigm, Walchli *et al.* [35] published a “brute-force” approach to substrate trapping that might be more accurately referred to as phosphatase trapping. Instead of attempting to identify substrates for a PTP of interest, this method uses a substrate of interest, the autophosphorylated kinase domain of the insulin receptor, to screen through a collection of 37 different PTP trapping mutants to identify which phosphatases exhibit a preference for that substrate. Wild-type/active forms of the candidate PTPs were then tested for their ability to dephosphorylate a phosphotyrosine peptide substrate derived from the insulin receptor kinase. Interestingly, these activity assays matched the binding data reasonably well except for some unresolved exceptions. With such a collection of mutant PTPs in hand, the potential exists to screen all of them against other substrates of interest to trap the corresponding phosphatases.

Other Applications of Substrate Trapping Mutants

One other area in which substrate trapping mutants of PTPs have shown interesting results is in the identification of the subcellular sites at which substrate dephosphorylation is thought to occur. For the C → S mutant of YopH, described above, it was shown to localize to focal adhesions [22] in cells infected with *Yersinia* harboring this form of YopH. This localization pattern matched the subcellular location of the focal-adhesion-related substrates p130^{cas} and paxillin that YopH dephosphorylates and its C → S mutant traps. In a remarkable, high-tech application of substrate trapping, the intracellular site of dephosphorylation of EGF and platelet-derived growth factor (PDGF) receptors by PTP1B was visualized with fluorescence resonance energy transfer (FRET) measurements and fluorescence lifetime imaging microscopy (FLIM) [36]. The D181A mutant of PTP1B was expressed in PTP1B-deficient mouse fibroblasts and then examined for its interaction with transiently expressed GFP fusions of the EGF and PDGF receptors. The images revealed that 30 minutes after growth factor stimulation distinct, punctate, vesicular structures contained both D181A-PTP1B and endocytosed growth factor receptors. Experiments such as these suggest that in the future we can look forward to seeing other innovative uses of the substrate trapping mutants of PTPs.

Inhibitors of Protein Tyrosine Phosphatases

Zhong-Yin Zhang

*Department of Molecular Pharmacology,
Albert Einstein College of Medicine, Bronx, New York*

Introduction

Protein tyrosine phosphatases (PTPs) are a large family of enzymes whose structural diversity and complexity rival those of protein tyrosine kinases (PTKs). Unlike PTKs, however, which share sequence identity with protein serine/threonine kinases, the PTPs show no structural similarity with the protein Ser/Thr phosphatases. Not surprisingly, inhibitors of protein Ser/Thr phosphatases such as okadaic acid and microcystin are not effective against PTPs. In addition, these two classes of protein phosphatases have evolved to employ completely different strategies to accomplish the dephosphorylation reaction. Thus, while the protein Ser/Thr phosphatases are metalloenzymes with bimetallic centers containing iron and effect catalysis by direct attack of an activated water molecule at the phosphorus atom of the substrate [1], the PTPs do not require metals and proceed through a covalent phosphocysteine intermediate during catalytic turnover [2]. The hallmark that defines the PTP superfamily is the active-site amino acid sequence (H/V)C(X)₅R(S/T), also called the PTP signature motif, in the catalytic domain. An analysis of the nearly completed human genome sequence suggested that humans may have more than 100 PTPs, including both the tyrosine-specific and dual-specific phosphatases, which can utilize protein substrates that contain pTyr, as well as pSer and pThr.

Although all PTPs share a common catalytic mechanism and catalyze the same biochemical reaction, the hydrolysis of phosphoamino acids, they have distinct (and often unique) biological functions *in vivo* [3]. Genetics and biochemical studies indicate that PTPs are involved in a number of disease processes [4,5]. However, because PTPs can

both enhance and antagonize cellular signaling, it is essential to elucidate the physiological context in which PTPs function. One of the major challenges of the PTP field is to establish the exact functional roles for individual PTPs, both in normal cellular physiology and in pathogenic conditions. Potent and specific PTP inhibitors could serve as very powerful tools to delineate the physiological roles of these enzymes. They can also be good starting points for therapeutic developments. This chapter provides a summary and update of currently known PTP inhibitors. Both specific and nonspecific small-molecule competitive and reversible PTP inhibitors are discussed. In addition, some examples of covalent and time-dependent PTP inactivators are also presented.

Covalent PTP Modifiers

The PTPs employ covalent catalysis, utilizing the thiol group of the active-site Cys residue as the attacking nucleophile to form a thiophosphoryl enzyme intermediate (E-P) [6]. Substitutions of the Cys residue completely abrogate PTP activity. The nucleophilic cysteine is housed within the active-site architecture specifically designed to bind a negatively charged phosphoryl group. Consequently, the pKa for the sulfhydryl group of the active-site Cys is extremely low (≈ 5) [7]. Thus, the PTPs are very sensitive to thiol-specific alkylating agents. For example, the PTPs can be irreversibly inactivated by iodoacetate, *N*-ethylmaleimide, and 5,5'-dithio-2-nitrobenzoic acid [7-9]. In addition, PTPs can also be inactivated by heavy metals including Zn²⁺, Cu²⁺, and *p*-(hydroxymercuri)benzoate, possibly through covalent bond formation with the active-site thiol group. There were

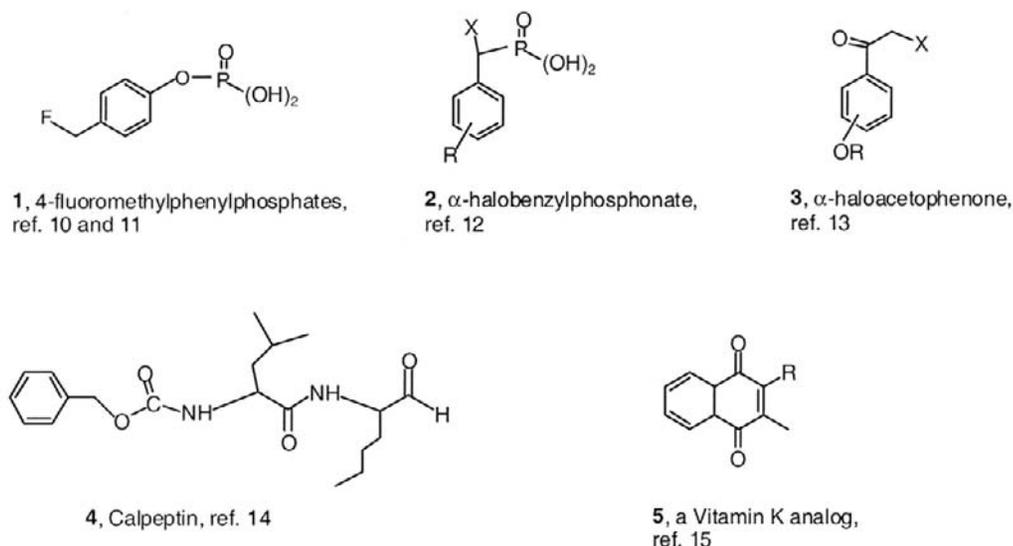

Figure 1 Structures of covalent inactivators of PTP.

several attempts to design specific, PTP-active-site-directed, alkylating agents, taking into consideration the architecture of the PTP catalytic site and the nature of the thiol-mediated phosphate hydrolysis. The 4-fluoromethylphenylphosphate (Fig. 1, compound **1**) was designed as a mechanism-based phosphatase inactivator [10,11] that, upon cleavage of the phosphate ester bond by the phosphatase, rapidly liberates the fluoride ion and forms a reactive quinone methide intermediate. Subsequent attack by PTP nucleophilic residues would result in formation of covalent adducts. Unfortunately, the lack of selectivity among various phosphatases and the unfavorable kinetics prevent the wide use of this compound in PTP research. The α -halobenzylphosphonate (Fig. 1, compound **2**) is an irreversible inactivator of the *Yersinia* PTP and PTP1B [12]. Mechanistically, this compound would be expected to undergo nucleophilic displacement of the halide without cleavage of the carbon–phosphorus bond. More recently, α -haloacetophenone derivatives (Fig. 1, compound **3**) have also been shown to be capable of covalently modifying SHP1 and PTP1B, possibly via nucleophilic displacement of the halide by the active-site thiol group [13]. A unique feature of these compounds is that the inhibition can be reversed upon photoactivation. Interestingly, the dipeptide aldehyde calpain inhibitor Calpeptin (Fig. 1, compound **4**) was recently shown to preferentially inhibit membrane-associated PTPs [14]. Although the exact mechanism of inhibition has not been investigated, it is possible that the aldehyde functionality may react with residues in the PTP active site to form covalent adducts. Finally, several vitamin K analogs (Fig. 1, compound **5**) have been shown to be effective PTP inactivators, possibly involving Michael-type nucleophilic addition of the active site Cys to the menadione moiety [15].

Due to the extremely low pKa of the active-site thiol group, the PTPs are also prone to metal ion-catalyzed oxidation by O_2 in the air. Thus, it is a common practice to

include EDTA and DTT in PTP assay buffers in order to keep the active-site Cys in the reduced form. In addition to molecular oxygen, exposure of the PTPs to reactive oxygen species (ROS) can also result in PTP inactivation. For example, it has been shown that treatment of various PTPs with hydrogen peroxide [16,17], superoxide radical anion [18], and nitric oxide [19] all lead to the oxidation of the active-site Cys. Because ROS can be generated endogenously in the cell and because the oxidation of the active-site Cys by ROS in many cases is reversible, it has been suggested that PTP inactivation by ROS may provide a means for temporal negative regulation of PTP activity.

Oxyanions as PTP Inhibitors

Inorganic phosphate is a hydrolytic product of the PTP reaction and serves as a reversible competitive PTP inhibitor ($K_i \approx 5 \text{ mM}$) [20]. Because of the similar physical and chemical properties, many oxyanions, including sulfate, arsenate, molybdate, and tungstate, can competitively inhibit PTPs to various degrees ($10 \mu\text{M}$ to millimolar levels). These oxyanions could inhibit PTPs by simply mimicking the tetrahedral geometry of the phosphate ion. The crystal structure of the PTP complexed with tungstate reveals the interactions between the enzyme and the phosphoryl moiety of the substrate [21]. The oxyanions adopt a tetrahedral configuration, and the oxygen atoms of the oxyanion make hydrogen bonds with the guanidinium group of the invariant Arg residue in the active site as well as the NH amides of the peptide backbone making up the PTP signature motif (H/V)C(X)₅R(S/T).

Vanadate is by far the most potent oxyanion inhibitor of PTPs, with K_i values of less than $1 \mu\text{M}$ [22]. Thus, the binding affinity of vanadate for PTPs is several orders of magnitude higher than that of phosphate. Because vanadate is known to be able to adopt five-coordinate structures readily,

such observations have led to the hypothesis that vanadate may inhibit the PTPs by forming complexes that resemble the trigonal-bipyramidal geometry of the transition state. The crystal structures of the PTP–vanadate complexes show that indeed the vanadate moiety in the PTP complex is trigonal bipyramidal, with three short, equatorial, nonbridging V–O bonds, one apical bridging V–O bond, and one long V–S bond to the active site Cys [23–25]. Interestingly, a detailed kinetic and Raman spectroscopic study indicates that the PTP–vanadate complex may not be a true transition state analog for the PTP reaction [26], which occurs via a highly dissociative metaphosphate-like transition state [27]. However, even if only a fraction of the transition-state energy is captured by vanadate, it may be sufficient to account for its higher potency against PTPs.

It is important to point out that vanadate does not display any selectivity against individual members of the PTP family. Because there are no readily available PTP inhibitors with potencies comparable to that of vanadate, vanadate has been widely used as a pharmacological reagent for global inhibition of PTPs. Of note is the ability of vanadate to mimic the effects of insulin and to stimulate cellular proliferation. In many of the *in vivo* studies, the effective vanadate concentration used was well into the millimolar range. This may be caused by the presence of chelating and reducing agents, which reduce the free vanadate concentration. Because vanadate inhibits many classes of phosphoryl transfer enzymes, including phosphatases, ATPases, and nucleases, interpretation of cellular effects by vanadate should always be exercised with care.

Pervanadate, which is the complex of vanadate with hydrogen peroxide, is a more potent general PTP inhibitor than vanadate [28]. Unlike vanadate, which inhibits the PTPs reversibly and competitively, pervanadate inhibits the PTPs by irreversibly oxidizing the catalytic Cys [22]. Because pervanadate retains the vanadyl moiety, which is directed to the phosphate-binding pocket, and at the same time gains a peroxide group, which targets the active site Cys, it serves as a more efficient and specific reagent for global suppression of PTP activity at concentrations much lower than those employed for vanadate.

pTyr Surrogates as PTP Inhibitors

X-ray crystallographic studies have revealed a very similar active site (the pTyr binding site) for PTPs. In the substrate-bound form of PTP1B, the terminal non-bridge phosphate oxygens of pTyr form an extensive array of hydrogen bonds with the main-chain nitrogens of the PTP signature motif (residues 215–221) and the guanidinium side chain of Arg221. The phenyl ring of the pTyr is engaged in hydrophobic interactions with the active-site cavity, formed by the nonpolar side chains of Val49, Ala217, Ile219, and Gln262 and the aryl side chains of Tyr46 and Phe182, which sandwich the pTyr ring and delineate the boundaries of the pTyr-binding pocket [29,30]. Consistent with the fact that pTyr is essential

for peptide/protein substrate binding, the interactions between pTyr and the PTP active site represents the dominant driving force for pTyr-containing peptide recognition. With this in mind, major efforts have been made to develop nonhydrolyzable pTyr surrogates that contain both a phosphate mimic that substitutes the phosphoryl group and an aromatic scaffold that can occupy the active-site pocket in a manner reminiscent of the benzene ring in pTyr. A variety of nonhydrolyzable pTyr surrogates have been reported (Fig. 2).

The most commonly used nonhydrolyzable pTyr surrogate is phosphonodifluoromethyl phenylalanine (F₂Pmp; Fig. 2, compound **6**) [31], which is over 1000 times more potent than phosphonomethyl phenylalanine (Pmp; **7**) when incorporated into a peptide. This may be attributed to a direct interaction between the fluorine atoms and PTP active-site residues [32]. Other nonhydrolyzable pTyr surrogates include sulfotyrosine (**8**) [33], *O*-malonyltyrosine (**9**) [34], fluoro-*O*-malonyl tyrosine (**10**) [35], aryloxymethyl phosphonate (**11**) [36], cinnamic acid (**12**) [37], 3-carboxy-4-(*O*-carboxymethyl) tyrosine (**13**) [38], salicylic acid (**14**) [39], aryl difluoromethylene phosphonate (**15**) [40], aryl difluoromethylene sulfonate (**16**) and tetrazole (**17**) [41], 2-(oxalylamino)-benzoic acid (**18**) [42], 5-carboxy-2-naphthoic acid (**19**) [43], and α -ketocarboxylic acid (**20**) [44]. Like pTyr, none of these nonhydrolyzable pTyr surrogates alone exhibits high affinity toward PTPs. However, when attached to an appropriate structural scaffold, the pTyr surrogate-containing compounds can be very effective PTP inhibitors.

Bidentate PTP Inhibitors

Although pTyr is essential for peptide/protein substrate recognition, pTyr alone does not possess high affinity for PTPs [45]. This and the fact that the PTP active site (pTyr binding site) is highly conserved among various PTPs present a serious challenge for the development of potent and selective PTP inhibitors targeted primarily to the active site. The discovery of a second aryl phosphate-binding site in PTP1B (defined by residues Arg24, Arg254, Met258, Gly259, and Gln262), which is not conserved among the PTPs and is adjacent to the active site, provides a novel paradigm for the design of tight-binding and specific PTP1B inhibitors that can span both sites [30]. Moreover, kinetic and structural studies have shown that amino acid residues flanking the pTyr are also required for efficient PTP substrate recognition [29,45–48]. These results suggest that subpockets adjacent to the PTP active site may also be targeted for inhibitor development. Consequently, an effective strategy for PTP inhibitor design is to attach a nonhydrolyzable pTyr surrogate to a properly functionalized structural element, which interacts with the immediate surroundings beyond the catalytic site. This strategy produces bidentate PTP inhibitors that simultaneously bind both the active site and a unique adjacent peripheral site, thereby exhibiting both enhanced affinity and specificity.

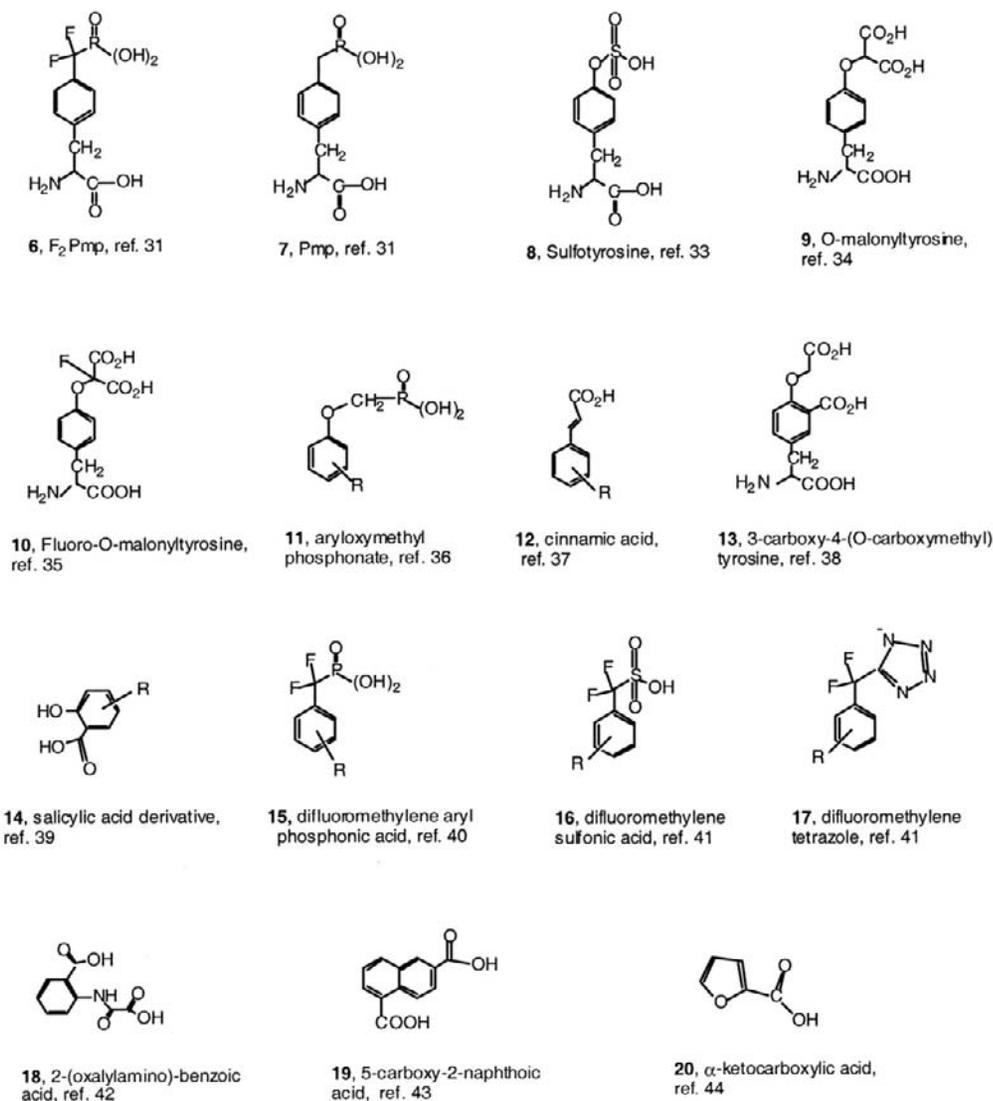

Figure 2 Structures of nonhydrolyzable pTyr surrogates.

Initial attempts to exploit this strategy generated several *bis*-aryldifluorophosphonate inhibitors that display modest selectivity for PTP1B [40,49,50]. Recent medicinal chemistry efforts directed to optimization of the 3-carboxy-4-(*O*-carboxymethyl) tyrosine core (Fig. 2, compound **13**) and its attached peptide template led to several small molecule peptidomimetics (e.g., compounds **21** and **22** in Fig. 3) that displayed sub- to micromolar potency against PTP1B and augmented insulin action in the cell [51,52]. Using a structure-based approach, the Novo Nordisk group was able to introduce a substituent into the core structure of 2-(oxalylamino)-benzoic acid (Fig. 2, compound **18**) to address the second aryl phosphate-binding pocket in PTP1B [53]. This transformed a general, low-affinity, and nonselective PTP inhibitor into a reasonably potent ($K_i=0.6 \mu\text{M}$) and selective inhibitor for PTP1B (Fig. 3, compound **23**). A completely different approach (namely, combinatorial chemistry) was employed to identify bidentate PTP1B inhibitors capable of simultaneously occupying both the active site and a unique peripheral site in PTP1B [54]. This effort resulted in the identification of

compound **24** in Fig. 3, which displays a K_i value of 2.4 nM for PTP1B and exhibits several orders of magnitude selectivity in favor of PTP1B against a panel of PTPs. Compound **24** is the most potent and selective PTP1B inhibitor identified to date. Subsequent structural and mutagenesis studies reveal that the distal element in compound **24** does not interact with the second aryl phosphate-binding pocket, but rather occupies a distinct area involving residues Lys41, Asn44, Tyr46, Arg47, Asp48, Lys116, and Phe182 [62]. The interactions between compound **24** and PTP1B are unique and provide the molecular basis for its potency and selectivity for PTP1B. Collectively, these results demonstrate that it is feasible to acquire potent, yet highly selective, PTP inhibitory agents.

Other PTP Inhibitors

PTP1B was the founding member of the PTP family, and a large amount of structural and mechanistic information is

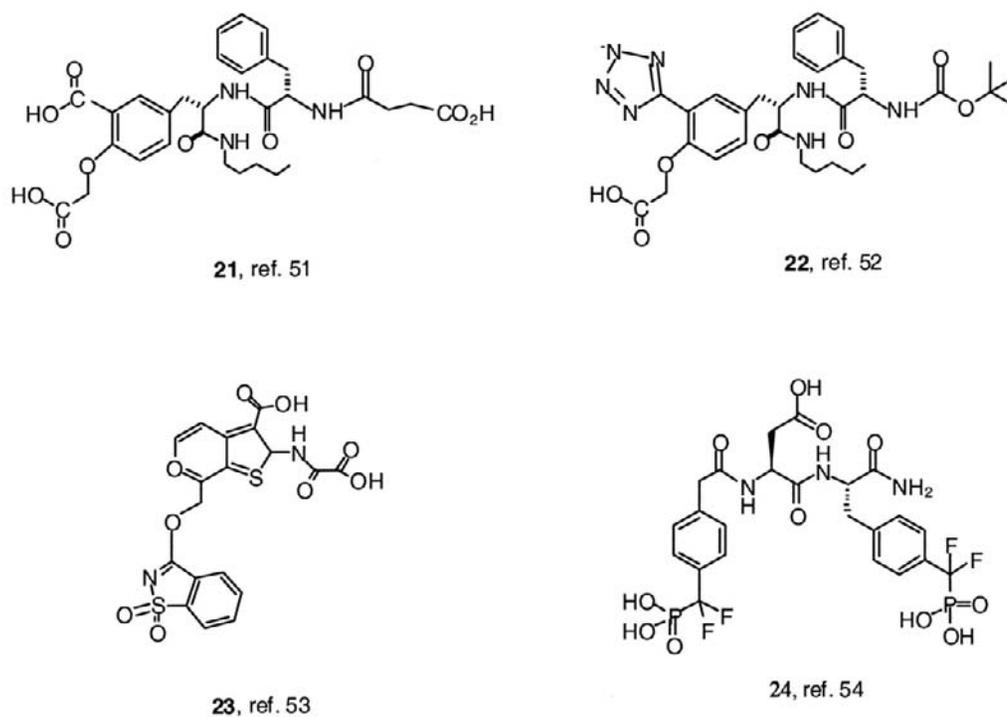

Figure 3 Structures of potent and selective bidentate PTP1B inhibitors.

available for PTP1B. Furthermore, biochemical and genetic data suggest that PTP1B is a negative regulator for both insulin and leptin signaling. Consequently, most of the PTP inhibitors that are reported in the literature are directed to PTP1B. However, other PTPs have also received considerable attention, notably CD45 and Cdc25. Most of the inhibitors described earlier for CD45 and Cdc25 display only modest potency ($\approx 10 \mu\text{M}$) with very limited selectivity [55–57]. Many of them were identified from natural product screens. In most cases, the manner in which these compounds interact with the target PTPs is unclear, rendering structure-based optimization of new analogs difficult. A recent high-throughput evaluation of 10,070 compounds in a publicly available chemical repository of the National Cancer Institute led to the discovery of NSC 95397 (2,3-bis-[2-hydroxyethylsulfanyl]-[1,4]naphthoquinone) (Fig. 4, compound **25**), which displayed mixed inhibition kinetics, with *in vitro* K_i values for Cdc25A, -B, and -C of 32, 96, and 40 nM, respectively [58]. Compound **25** showed significant growth inhibition against human and murine carcinoma cells and blocked G₂/M phase transition. Medicinal chemistry efforts around the 9,10-phenanthrene-1,10-dione core resulted in potent CD45 inhibitors (Fig. 4, compound **26**), some of which inhibit T-cell-receptor-mediated proliferation with activities in the low micromolar range [59]. Interestingly, suramin (Fig. 4, compound **27**), one of the oldest synthetic therapeutics, which has long been used for the treatment of sleeping sickness and onchocerciasis, has been shown to be a potent reversible and competitive inhibitor of PTPs [60]. This is consistent with the observation that suramin leads to enhanced levels of tyrosine phosphorylation in several cell lines. More recently, sodium stibogluconate (Fig. 4, compound **28**), a pentavalent antimonial used

for the treatment of leishmaniasis, has been suggested as a potent inhibitor of PTPs [61]. Although sodium stibogluconate augments cytokine responses in hemopoietic cell lines, its exact mode of action against PTPs is not clear and requires further investigation.

Concluding Remarks

The importance of PTPs in the regulation of cellular signaling is well established. In spite of the large number of PTPs identified to date and the emerging roles played by PTPs in human diseases, a detailed understanding of the role played by PTPs in normal physiology and in pathogenic conditions has been hampered by the absence of PTP-specific agents. Such PTP-specific inhibitors could potentially serve as useful tools in determining the physiological significance of protein tyrosine phosphorylation in complex cellular signal transduction pathways and may constitute valuable therapeutics in the treatment of several human diseases. Despite the difficulties in obtaining such compounds, there are now several relatively specific inhibitors for PTP1B. It appears that significant differences exist within the active site and the immediate surroundings of various PTPs such that selective, tight-binding PTP inhibitors can be developed. In principle, an identical approach (i.e., to create bidentate inhibitors that could span both the active site and a unique adjacent peripheral site) used for PTP1B could also be employed to produce specific small-molecule inhibitors for all members of the PTP family that would enable the pharmacological modulation of selected signaling pathways for treatment of various diseases. Combinatorial solid-phase library synthesis is

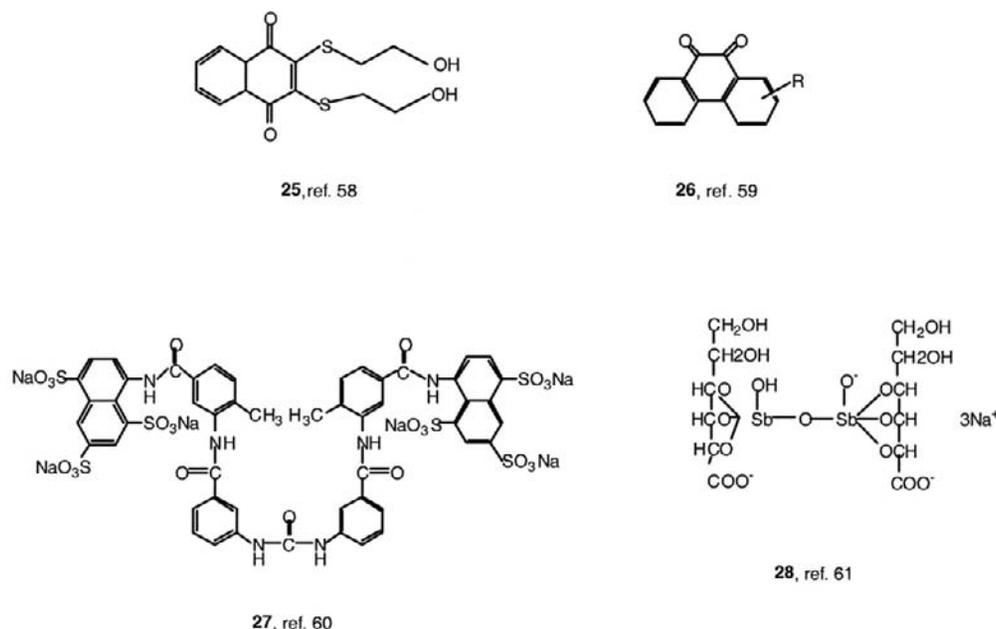

Figure 4 Other PTP inhibitors.

finding wide applicability throughout the pharmaceutical industry, and, not surprisingly, this technique has begun to yield fruitful results in the area of PTP inhibitors.

Regulating Receptor PTP Activity

Introduction

The receptor protein tyrosine phosphatases (RPTPs) are a family of transmembrane phosphatases that catalyze the removal of the phosphate moiety from a phosphotyrosine residue (pTyr), resulting in a variety of intracellular responses including long-term potentiation, axonal path finding and neural transmission, and transformation. RPTPs consist of an extracellular domain, a transmembrane region, and two tandem intracellular tyrosine phosphatase domains, with the exception of four of the RPTPs that contain only one intracellular phosphatase domain. The greatest dissimilarity between RPTPs occurs in the extracellular region, in which diverse protein modules including immunoglobulin (Ig)-like domains, fibronectin type III (FnIII)-like domains, and extensively glycosylated domains are found. In contrast, the intracellular tyrosine phosphatase domains share high sequence and structural homology not only within the RPTP family but with the nonreceptor tyrosine phosphatases as well. The majority of the phosphatase activity resides in the first, membrane-proximal domain (D1). The second, membrane distal domain (D2), although very homologous to D1, possesses little or no catalytic activity. Notably, the primary sequence of this domain is well conserved among RPTPs, suggesting that D2 plays a functionally significant role in overall RPTP activity in cells.

In order to maintain control over pTyr-mediated cellular signaling, the phosphatase activity of a given RPTP must be carefully regulated. To date, various modes of regulation have been associated with directing RPTP enzymatic activity, including receptor dimerization, phosphorylation, substrate recruitment via protein-protein interactions, and extracellular domain ligand binding. Here, we review some of the mechanisms employed by the RPTP family to ensure its proper regulation in the context of pTyr signaling cascades.

Regulation by Dimerization

Dimerization plays a critical role in the regulation of another family of transmembrane proteins, the receptor tyrosine kinases. Specifically, ligand binding to the extracellular domain allows the intracellular kinase domain to dimerize and cross-phosphorylate at regulatory sites, leading to activation of the intracellular kinase domain. Two independent crystal structures of the membrane-proximal phosphatase domain, D1, of RPTP α reveal a symmetrical dimer in which the active site of one domain is occluded by a helix-turn-helix wedge of its dimer forming partner [1]. Disulfide-bonding experiments demonstrate that this dimeric configuration renders RPTP α catalytically inactive *in vivo* [2]. Since the initial RPTP α crystal structure was revealed, a plethora of evidence has surfaced supporting the idea that dimerization is an important regulatory tool in RPTPs. Most notably, Tertoolen *et al.* [3] used fluorescence resonance energy transfer to demonstrate that RPTP α dimerizes constitutively in living cells and that the transmembrane region is sufficient for dimer formation. RPTP α dimerization is a negative regulatory event, in contrast to activation of receptor tyrosine kinases by dimerization (see Fig. 1A). Dimerization also plays a crucial role in the regulation of another RPTP family member, CD45. Recombinant D1 from CD45 exists primarily as a dimer as assessed by gel filtration chromatography [4]. EGF-enhanced dimerization of the CD45 intracellular domain linked to the extracellular ligand binding and transmembrane domain of EGFR results in CD45 inactivation consistent with a regulatory model in which dimerization serves as a negative regulatory signal [5]. Like RPTP α , CD45 dimerization is dependent on the wedge region located in the membrane-proximal D1 phosphatase domain. A knock-in mutant mouse containing a point mutation in the wedge region of CD45 (Glu⁶¹³ to Arg) that inhibits dimer formation

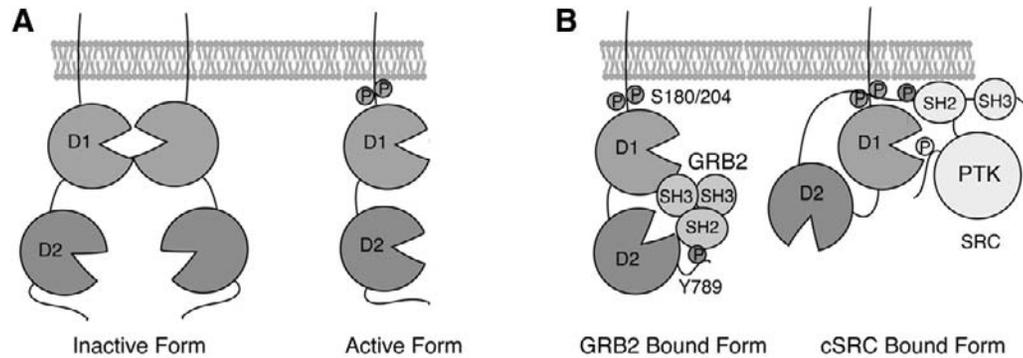

Figure 1 (A) The membrane-proximal phosphatase domain, D1, of RPTP α forms an inhibited dimer in which the active site of one monomer is sterically occluded by a wedge region of its dimer partner; perhaps serine phosphorylation in the juxtamembrane region serves to regulate dimer formation. (B) The C-terminus of RPTP α is tyrosine phosphorylated, allowing binding of the SH2-domain-containing protein Grb-2. This binding does not result in the recruitment of associated factors but may mask the site to inhibit binding of the SH2 domain of cSRC. Under the proper conditions, cSRC can bind the pTyr C-terminus, allowing RPTP α to dephosphorylate and activate cSRC.

exhibits a variety of phenotypes, including polyclonal lymphocyte activation consistent with an increase in cellular CD45 activity [6].

The dimerization model for RPTP regulation may not be a universal mechanism employed by all RPTPs. The crystal structures of the membrane-proximal phosphatase domain of RPTP μ and the tandem phosphatase domains of LAR failed to show dimer formation through the inhibitory wedge region [7,8]. Nevertheless, both structures contained an intact wedge that is not shared with cytosolic PTPs. It is important to note that the constructs used to crystallize both RPTP μ and LAR did not contain the transmembrane region that Tertoolen *et al.* demonstrated is sufficient for dimer formation in RPTP α [3]. It is unlikely that the wedge region provides sufficient binding energy to drive dimerization of RPTP α *in vivo*; therefore, additional regions such as the transmembrane segment are likely important for dimer formation [8A].

Regulation by Phosphorylation

Phosphorylation is a ubiquitous modification used to regulate the catalytic activity of a myriad of signal transducing proteins, and the RPTPs are no exception. RPTPs use both serine and tyrosine phosphorylation to regulate phosphatase activity and the formation and dissociation of protein-protein interfaces. RPTP α and CD45 have been the most extensively studied with respect to phosphorylation and its regulatory implications for *in vivo* RPTP activity.

RPTP α is phosphorylated on Ser¹⁸⁰ and Ser²⁰⁴ located in the membrane-proximal region in response to treatment of cells with phorbol ester, a potent protein kinase C activator, resulting in an increase in RPTP α phosphatase activity [9,10]. Further evidence that serine phosphorylation regulates catalytic activity surfaced upon investigation of RPTP α activity at different stages in the cell cycle. Zheng and Shalloway [11] identified an increase in RPTP α activity during mitosis, coincident with serine phosphorylation. Dephosphorylation of RPTP α with the serine/threonine

phosphatase PP2A reduces RPTP α phosphatase activity to premitotic levels, although the specific residues undergoing phosphorylation and dephosphorylation were not identified. The importance of serine phosphorylation in the regulation of RPTP α was further demonstrated by over-expression of a Ser^{180/204} Ala double mutant that results in the elimination of ERK/MAPK stimulation [12]. These observations clearly show that serine phosphorylation plays a role in regulating the catalytic activity of RPTP α ; however, further work is necessary to elucidate the exact mechanism of action. One possibility is that phosphorylation affects the dimeric state of RPTP α , perhaps favoring the activated monomeric form through electrostatic repulsion of the phosphorylated juxtamembrane region (see Fig. 1A).

In addition to RPTP α , CD45 is also regulated by serine phosphorylation but through a distinct site. CD45 differs from other RPTPs in that it contains an acidic 19-amino-acid insert in the second phosphatase domain, D2, that is phosphorylated *in vivo* on multiple serine residues by CK2. Mutation of these residues to glutamates, which serve as effective phosphate mimics, results in a threefold increase in CD45 phosphatase activity. The mechanism of this activation is unclear [13].

Most RPTPs contain a conserved tyrosine residue at the extreme C terminus that for some RPTPs is constitutively phosphorylated. Much of the work examining the role of this pTyr residue has been carried out on RPTP α (Tyr789). The C-terminal segment encompassing the Tyr789 residue is also a consensus Src homology domain 2 (SH2) binding domain that serves as a docking platform for the SH2-domain-containing protein GRB2. Curiously, the GRB2-associated protein SOS is not detected in immunoprecipitates with RPTP α , suggesting that GRB2 binding is functionally distinct from SOS-mediated signaling events [14]. The C-terminal phosphorylation site of RPTP α is also capable of binding the SH2 domain of the tyrosine kinase cSRC. This binding event is necessary to open up the inhibited cSRC conformation and allow subsequent RPTP α -mediated hydrolysis of the inhibitory pTyr site of cSRC, resulting in cSRC activation.

One attractive hypothesis to explain the role of GRB2 in RPTP α regulation involves masking of the RPTP α C-terminal pTyr from cSRC by GRB2 binding when cSRC activation is not desirable. Recent work by Zheng *et al.* [15] suggests that binding of GRB2 or cSRC to the C-terminal pTyr of RPTP α is regulated by phosphorylation at Ser^{180/204}. Specifically, a Ser^{180/204} to Ala double mutant abolishes the ability of RPTP α to dephosphorylate and coimmunoprecipitate cSRC, while enhancing GRB2 coimmunoprecipitation with RPTP α . The authors propose that, upon Ser^{180/204} phosphorylation, the C terminus of RPTP α forms an intramolecular interaction with the juxtamembrane region, causing the C terminus to adopt an extended conformation preferred by the SH2 domain of cSRC. In contrast, the SH2 domain of GRB2 binds pTyr residues in a β -turn conformation, presumably the conformation of the C terminus of RPTP α in the absence of Ser^{180/204} phosphorylation (Fig. 1B) [15].

These brief examples demonstrate the potential of RPTPs to utilize serine and tyrosine phosphorylation to regulate their catalytic activity and proximity to pTyr-containing substrates such as cSRC. It remains to be seen how widely phosphorylation is used to regulate RPTP activity and whether there are shared mechanisms of regulation within the family of tyrosine phosphatases. Interestingly, RPTP ϵ contains an SH2 binding motif identical to RPTP α at its C terminus, making it an excellent candidate for similar modes of SH2 domain binding and regulation.

Regulation by D2 Domain

The membrane-distal phosphatase domain of RPTP α (D2) is highly conserved among all RPTPs and exhibits little or no phosphatase activity, despite the fact that most D2 domains possess the catalytic cysteine residue required for pTyr turnover. The X-ray crystal structures of both D1 and D2 domains of LAR [8] and RPTP α [1] (Sonnenburg *et al.*, in preparation) reveal that both phosphatase domains share a very similar overall three-dimensional architecture. The lack of D2 enzymatic activity appears to be the result of two residues, Val⁵⁵⁵ and Glu⁶⁹⁰ in RPTP α . Mutation of these residues to the corresponding residues found in the D1 domain (Tyr and Asp, respectively) restores catalytic activity to levels comparable to D1 [16]. Therefore, D2 possesses the architecture necessary for efficient pTyr turnover, yet has maintained low or nonexistent activity through replacement of two key catalytic residues in the RPTP active site. One possible noncatalytic role for D2 in RPTP function is the regulation of target protein turnover through participation in protein–protein interactions critical for either substrate recognition or RPTP sequestration. X-ray crystallographic studies of the D2 domain of RPTP α reveal that the linker between the D1 and D2 domains is flexible, an observation confirmed by limited proteolysis studies (Sonnenburg *et al.*, in preparation). Perhaps the D2 domain has been maintained to recruit substrates by way of its catalytically inert active site, similar enough to an active phosphatase to bind substrate but

not capable of rapid catalysis. Through such multipoint binding, the substrate remains in close proximity to the active D1 domain to be acted upon when the proper signal is transmitted. D1/D2 interdomain flexibility may allow substrates bound to the D2 domain to be presented to the active D1 domain. The RPTP LAR binds to phosphorylated insulin receptor, a substrate, via its D2 domain, an association weakened by mutation of the active site cysteine to serine [17].

In addition to interacting with substrate molecules, D2 domains can interact with RPTPs in either an intramolecular or intermolecular fashion. An intramolecular interaction between D2 and D1 was observed for CD45, as well as between D2 and the region N-terminal to D1 (juxtamembrane region) in RPTP μ [4,18]. Although an exact role for these interactions has not been established, it has been proposed that they may regulate dimerization by inhibiting intermolecular D1 homodimer formation. Yeast two-hybrid screens have identified a variety of intermolecular interactions between D2 domains and the wedge region of D1 domains from various RPTP family members [19,20]. This raises the possibility that RPTPs are capable of forming heterodimers *in vivo*. Heterodimer formation may serve multiple roles in RPTP signaling, including enhancement of the diversity of signaling roles possible for RPTPs or activating RPTPs by disrupting wedge-mediated D1 inhibitory dimer formation. Further work is required to determine how both intra- and intermolecular interactions in RPTPs affect their catalytic activity, location, and downstream signaling events.

RPTPs employ multiple mechanisms to ensure the proper regulation of their catalytic activity. These mechanisms include, but are not limited to, dimerization, phosphorylation, and potentiation and dissolution of regulatory protein–protein interactions. An additional area of growing exploration is the identification of ligands for the extracellular domains of RPTPs. Recently, RPTP σ has been shown to bind to the heparan sulfate side chains of heparan sulfate proteoglycans via its first extracellular Ig domain [21]. Another cell-surface ligand, the neuronal glycosylphosphatidylinositol (GPI)-anchored receptor contactin, binds the extracellular domain of both RPTP α and β in a *cis* conformation. Interestingly, contactin is able to recruit SRC family member kinases, a known substrate of RPTP α , perhaps creating an efficient signal transducing complex [22,23]. All RPTP ligands, however, are not membrane associated. A soluble cytokine, pleiotrophin is a ligand for RPTP β and RPTP γ which, upon binding, leads to inactivation of RPTP phosphatase activity through receptor dimerization [24]. Subcellular localization also appears to play an important role in regulating RPTP function. RPTP μ localizes to regions of cell–cell contact in complex with cadherins, the function of which is regulated by reversible tyrosine phosphorylation, perhaps through RPTP phosphatase activity [25]. The RPTP LAR binds to LAR-interacting protein 1 (LIP1) through its association with the D2 domain, resulting in localization of LAR to disassembling focal adhesions, potentially regulating this cellular phenomenon [26]. However, RPTPs are not confined to locations near the cell membrane. Gil-Henn *et al.* [27]

have shown that a cytoplasmic form of RPTP consisting of the intracellular D1 and D2 domains from RPTP α and RPTP ϵ exists in cells as a result of calpain cleavage. Coincident with the appearance of this soluble form of RPTP is a decrease in cSRC activation. Presumably, cytosolic RPTPs would access different cellular substrates than when attached to the membrane, opening up the possibility of an entirely novel set of RPTP substrates and downstream signaling cascades. Recent observations indicate that oxidative stress may be another regulator of RPTP phosphatase activity, in this case by inducing the inhibitory dimeric state of RPTP α [28]. It is clear that a complete picture of all the molecular and cellular mechanisms used by RPTPs for biological function will require a multidisciplinary approach carried out in numerous cooperating laboratories.

Introduction

CD45 (also known as LCA, EC3.1.3.48, T200, Ly5, PTPRC, and B220) constitutes the first and prototypical receptor-like protein tyrosine phosphatase. CD45 was originally identified as leukocyte common antigen (LCA) and is expressed on all nucleated hematopoietic cells as one of the most abundant cell-surface glycoproteins. Its homologs have been identified in various mammals, chicken, shark, and the pufferfish *Fugu rubripes* [1,2].

Structure

CD45 is a type I transmembrane molecule consisting of a heavily glycosylated extracellular domain, a single transmembrane domain, and a large cytoplasmic tail (Fig. 1). The extracellular domain contains an N-terminal region with three alternatively spliced exons (4, 5, and 6), which encode multiple sites of O-linked glycosylation that are variably modified by sialic acid. Alternative splicing generates various isoforms with molecular weights ranging from 180 kDa for RO (lacking all three) to 235 kDa for RABC (including all three) and differing substantially in size, shape, and negative charge (Fig. 1). Isoform expression is highly regulated in a cell- and activation-state-specific manner. For example, naïve T cells predominantly express the larger isoforms (including one or two of the exons) while activated, and memory T cells primarily express the smallest RO isoform [1,2]. The remaining extracellular domain is heavily N-glycosylated and contains a cysteine-rich region followed by three fibronectin type III (FnIII) repeats. An analogous cysteine-rich region

exists in the receptor tyrosine kinase EGFR (epidermal growth factor receptor), where it is important for ligand binding [3]. The three FnIII repeats are unusual because of their high cysteine content [4].

The cytoplasmic region is highly conserved between all mammalian species analyzed. It contains two tandemly duplicated protein tyrosine phosphatase (PTPase) domains [1,2]. Only the first one has enzymatic activity and is necessary to rescue T-cell receptor (TCR) signaling in a CD45-deficient cell line [5]. The function of the second domain is currently unclear. It has a unique 19-amino-acid acidic insert that can be phosphorylated by casein kinase II [6,7]. In addition, the crystal structure of the membrane-proximal phosphatase domain of RPTP α and sequence similarity between RPTP α and CD45 suggest that the juxtamembrane region may form a structural wedge [8].

Function

Studies using CD45-deficient T and B cell lines demonstrate that CD45 is an obligate positive regulator of antigen receptor signaling. Ablation of the murine CD45 gene by three independent groups reveals its critical positive role in lymphocyte development and activation [2,9]. For example, thymocyte development is largely blocked and the few mature T cells produced are refractory to TCR stimulation. Loss of CD45 in humans results in a form of severe combined immunodeficiency (SCID) [2,9].

Src family kinases (SFKs) are a primary substrate for CD45. SFKs are responsible for initiating antigen receptor signaling. They also modulate signal transduction cascades

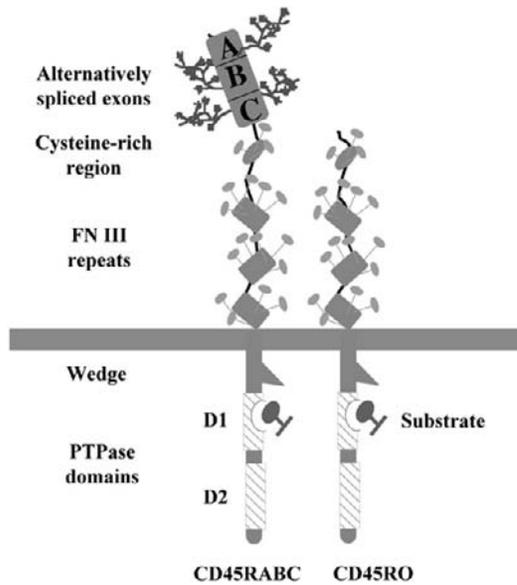

Figure 1 Structure of CD45. CD45 exists as multiple isoforms due to alternative splicing of three exons (4, 5, and 6, designated A, B, and C) in the extracellular domain. The largest isoform, RABC (including all three exons), and the smallest isoform, RO (lacking all three exons), are shown. These three exons encode multiple sites of O-linked glycosylation. As a result, various isoforms differ substantially in size, shape, and negative charge. The remaining extracellular domain is heavily N-glycosylated and contains a cysteine-rich region followed by three fibronectin type III repeats. CD45 has a single transmembrane domain and a large cytoplasmic tail containing two tandemly duplicated PTPase domains, D1 and D2. Only D1 has enzymatic activity and is necessary to rescue T-cell receptor (TCR) signaling in a CD45-deficient cell line. The function of D2 is currently unclear. In addition, molecular modeling indicates that the juxtamembrane region may form a structural wedge.

emanating from growth factors, cytokines, and integrin receptors [1,2,10]. In most CD45-deficient cells, SFKs are hyperphosphorylated at the negative regulatory tyrosine [1,2]. Moreover, expression of a constitutively active Lck Y505F mutant in CD45-deficient mice largely rescues the block in T-cell development [11]. By preferentially dephosphorylating the negative regulatory tyrosine, CD45 can maintain SFKs in a primed, or signal-competent, state capable of full activation upon receptor stimulation.

Although CD45 clearly plays a positive role in antigen receptor signaling, it can also function as a negative regulator in other settings. For example, CD45-deficient macrophages and T cells are abnormally adherent [12,13]. Despite hyperphosphorylation of the negative regulatory tyrosine of the SFKs, kinase activity is enhanced due to hyperphosphorylation at low stoichiometry of the autophosphorylation site, explaining the increased adhesiveness of these cells. This finding suggests that both the autophosphorylation site and the negative regulatory tyrosines can serve as CD45 substrates in some contexts. Interestingly, similar findings have been described for antigen receptor signaling in some CD45-deficient T and B cell lines [9,10]. The discrepancy of positive and negative effects of CD45 can be explained by its inclusion in or exclusion from clustered signaling complexes.

Physical separation from the TCR during antigen recognition at the immunological synapse results in a net positive effect, while access to its substrate during integrin-mediated adhesion results in a negative effect [10].

In addition to SFKs, CD45 may also negatively regulate cytokine- and interferon-receptor-mediated activation by dephosphorylating Janus tyrosine kinases (JAKs) [14]. Other possible, but controversial, substrates include ZAP-70 and CD3 ζ [2].

Regulation

The alternative splicing of CD45 is highly conserved and tightly regulated [1]. Naïve T cells predominantly express the larger isoforms and, following activation over the course of 3 to 5 days, switch to expression of the smallest RO isoform [15]. This regulated event is likely under the control of splicing factors that are induced in a PKC- and Ras-dependent manner after T-cell activation [16]. A point mutation in exon 4, which disrupts the function of an exonic splicing silencer [17] and causes abnormally high levels and persistent expression of the larger isoforms [18], has been linked to the development of multiple sclerosis in German patient cohorts [19]. These observations provide support for a contribution by the extracellular domain in regulating CD45 activity and suggest differences in regulation of the various isoforms. Surprisingly, despite the structural similarity between CD45 and receptor tyrosine kinases, a definitive ligand for CD45 has not been identified. Alternative means of regulation include spontaneous homodimerization, membrane localization, and interactions with other molecules.

Dimeric forms of CD45 can be detected through chemical cross-linking of cellular lysates [20] or by using a cysteine dimer-trapping method [21]. Dimerization of a CD45 chimera inactivates its catalytic function via the putative juxtamembrane wedge that blocks the catalytic site of the partner monomer during dimerization [3]. Introduction of a point mutation at the tip of this wedge abolishes the inhibitory effect of dimerization on TCR signaling in a transformed T cell line [8]. Mice bearing this wedge mutation develop a lymphoproliferative syndrome and severe autoimmune nephritis with autoantibody production, resulting in early death [21]. In addition, fluorescence resonance energy transfer (FRET) analysis suggests preferential homodimerization of the smallest RO isoform [22]. Together, these data indicate a role for differential homodimerization in negative regulation of CD45 function.

Cellular localization and access to substrate may contribute to the effect of CD45 on signaling. Redistribution of an intracellular pool of CD45 upon T-cell activation has been observed [23]. Most studies on the localization of CD45 show that it is absent from membrane lipid rafts and excluded from the central region of the interface between the T cell and the antigen-presenting cell. The latter is presumably due to the large size of CD45 and the relatively small size of molecules involved in antigen-specific recognition [2].

The function of CD45 may also be modulated through its interactions with other proteins. CD45 has been reported to associate at the cell surface with CD2, LFA-1, IFN receptor α chain, Thy-1, CD100, and CD26 [1,2,24]. Moreover, compared to larger isoforms, RO is found to preferentially associate with CD4 and TCR via its extracellular domain [22,25]. CD22, galectin 1 and glucosidase II can bind CD45 and other glycoproteins through specific sugar residues [1,2,26], although the functional consequences of these interactions are unclear. The transmembrane domain of CD45 mediates its interaction with lymphocyte phosphatase-associated phosphoprotein (LPAP) [27]. The cytoplasmic tail of CD45 is associated with the cytoskeletal protein fodrin [1]. Other possible means to modify CD45 function include serine phosphorylation of its second PTPase domain by casein kinase II [6,7] and inhibition of CD45 activity during neutrophil activation by reactive oxygen intermediates [28].

Properties of the Cdc25 Family of Cell-Cycle Regulatory Phosphatases

William G. Dunphy

California Institute of Technology,
Pasadena, California*

Introduction

In all eukaryotic cells, the progression of the cell cycle is regulated by a family of cyclin-dependent kinases (Cdks). The first identified member of this family is maturation-promoting factor (MPF), which consists of three subunits. In vertebrates, MPF contains the protein kinase Cdc2, a regulatory partner called cyclin B, and a small ancillary subunit known as the Suc1 or Cks protein [1]. The control of MPF involves a number of distinct regulatory mechanisms, including phosphorylation, proteolysis, and changes in intracellular localization. For example, the activity of the Cdc2 subunit is dramatically dependent on its state of phosphorylation. In the case of human Cdc2, protein kinase activity absolutely requires phosphorylation on threonine-161 (Thr-161). However, Thr-161 appears to be phosphorylated throughout the G₂ and M phases of the cell cycle. The abrupt activation of MPF at the G₂/M transition can be explained by the existence of two inhibitory phosphorylation sites on Cdc2, namely tyrosine-15 (Tyr-15) and threonine-14 (Thr-14).

For MPF to become active at M phase, Cdc2 must undergo dephosphorylation at Tyr-15 and Thr-14 by a phosphatase in the Cdc25 family (Fig. 1). Prior to mitosis, Tyr-15 and Thr-14 are phosphorylated by the inhibitory kinases Wee1 and Myt1. Wee1 is a predominantly nuclear kinase that phosphorylates Tyr-15. The kinase Myt1, which is an integral membrane protein that resides in the endoplasmic

reticulum and Golgi apparatus, modifies Thr-14 and to a lesser extent Tyr-15 [2,3]. Due to its central role in the biochemistry of Cdc2, Cdc25 plays a pivotal role in mitotic control and is the target of extensive regulatory networks. The focus of this chapter is on the biochemistry and regulation of the Cdc25 family of phosphatases.

Physiological Functions of Cdc25

Cdc25 was identified initially in the fission yeast *Schizosaccharomyces pombe* [4]. In this organism, cells with conditional mutations in the Cdc25 protein are unable to enter mitosis at the restrictive temperature and thus continue to grow into highly elongated cells. In further studies, it was shown that the timing of mitosis is highly dependent on the intracellular concentration of Cdc25. Cells with a reduced amount of active Cdc25 undergo mitosis at abnormally late times. Conversely, cells with elevated levels of Cdc25 enter mitosis with accelerated kinetics.

Biochemical studies in the early 1990s established that Cdc25 contains an intrinsic phosphatase activity [5–7]. Cdc25 is capable of dephosphorylating both phosphotyrosine and phosphothreonine and is thus a member of the dual-specificity phosphatase family [8]. Like other dual-specificity phosphatases, Cdc25 absolutely requires a key cysteine residue for catalysis. Accordingly, Cdc25 requires a

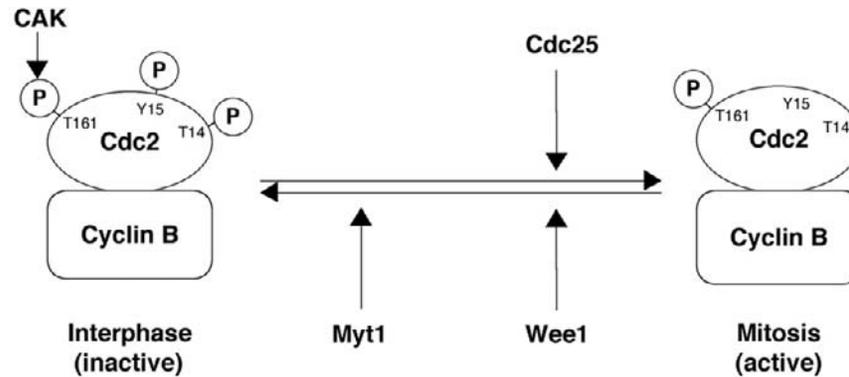

Figure 1 Posttranslational regulation of MPF. Cdc2 is positively regulated by phosphorylation on Thr-161 by the Cdk-activating kinase (CAK). Cdc2 is negatively regulated by phosphorylation on Thr-14 and Tyr-15.

reducing agent (e.g., dithiothreitol) for activity and is highly sensitive to alkylating agents such as N-ethylmaleimide. Cdc25 is also potentially inhibited by phosphomimetic compounds such as sodium orthovanadate.

In vertebrates, the Cdc25 family contains three distinct members: Cdc25A, Cdc25B, and Cdc25C [9–11]. The existence of these distinct enzymes can be rationalized by the fact that the Cdk family is more elaborate in vertebrates than in yeast. For example, a complex consisting of Cdk2 and cyclin E has a role in the G_1/S transition. Cdc25A can remove inhibitory phosphate groups from Cdk2 [11]. Cdc25B and Cdc25C have both been implicated in mitotic regulation. Cdc25C can dephosphorylate the Cdc2–cyclin B complex effectively. Evidence has been presented that Cdc25B acts at some point upstream of Cdc25C in the mitotic control circuit [11]. Intriguingly, knockout mice that do not express Cdc25C are viable, suggesting that there is a functional redundancy among Cdc25 family members [12].

Regulation of Cdc25

Among the Cdc25 family, our understanding of Cdc25C regulation is perhaps the most comprehensive at this time. Broadly speaking, two general mechanisms regulate the action of Cdc25C. A kinase network activates Cdc25C at mitosis by catalyzing the stimulatory phosphorylation of its regulatory domain, and, prior to mitosis, suppressive controls downregulate Cdc25C.

Activation of Cdc25C at M Phase

At the G_2/M transition, Cdc25C undergoes extensive hyperphosphorylation, which results in a substantial decrease in its electrophoretic mobility [13,14]. This phosphorylation elicits a marked increase in the phosphatase activity of Cdc25C toward Cdc2. The mitotic phosphorylation of Cdc25C is carried out by the Cdc2–cyclin B complex itself and the Polo-like kinase (Plx1 in *Xenopus*, Plk1 in humans) [15–17]. The Cdc2–cyclin B complex appears to act in an

“autocatalytic” activation loop. According to this scheme, a small amount of active Cdc2–cyclin B would contribute to the activation of Cdc25C, which in turn would produce more active Cdc2–cyclin B. This scenario would nicely explain the abrupt and precipitous activation of MPF at M phase; however, this model would apparently require some distinct triggering mechanism to initiate the process. The Polo-like kinase is an excellent candidate for a factor that would kick-start the activation of Cdc25C. The phosphorylation of Cdc25C by the Polo-like kinase also increases its activity but occurs at sites that are largely distinct from those that are phosphorylated by Cdc2. Thus, the phosphorylation of Cdc25C by the Polo-like kinase represents a discrete pathway that could regulate the timing of mitosis.

Suppression of Cdc25 during Interphase

Cdc25 is maintained in a low-activity state during interphase by inhibitory mechanisms that suppress its action or activation or both. These inhibitory mechanisms remain in place if checkpoint controls detect the presence of incompletely replicated or damaged DNA. This facet of regulation involves phosphorylation of Cdc25 on one or more sites by the so-called effector checkpoint kinases [18,19]. These kinases include Chk1 (in fission and budding yeast, *Xenopus*, and humans). Another effector kinase with this substrate specificity has different names according to the species (Rad53 in budding yeast, Cds1 in fission yeast and *Xenopus*, and Chk2 in humans).

In vertebrates, Chk1 phosphorylates Cdc25C on a major serine residue (Ser-216 in humans and Ser-287 in *Xenopus*) [20–22]. This serine group resides in consensus site for the binding of 14-3-3 proteins. 14-3-3 proteins are widespread polypeptides that recognize phosphopeptide motifs in target proteins. In *Xenopus* and humans, the 14-3-3 binding site is immediately adjacent to a bipartite nuclear localization sequence (NLS). For this reason, binding of 14-3-3 has a dramatic effect on the localization of Cdc25C [23–27]. The phosphorylation of Cdc25 by Chk1 most likely has other functional consequences. For example, the binding of 14-3-3

to Cdc25C appears to reduce its catalytic activity modestly and inhibit the interaction of Cdc25C with cyclin B [22,28]. In fission yeast, the phosphorylation of Ser-99 on Cdc25 by Chk1 leads to an inhibition of its phosphatase activity [29]. This inhibition apparently does not require binding of 14-3-3 proteins. Overall, it appears that phosphorylation by Chk1 can suppress Cdc25 by 14-3-3-dependent and 14-3-3-independent mechanisms. Moreover, the suppression of Cdc25 by 14-3-3 may involve multiple effects.

Localization of Cdc25

In vertebrates, the localization of Cdc25 is very dynamic. In *Xenopus* and humans, Cdc25C contains both an NLS and one or more nuclear export sequences (NESs) [23,24,26,27,30,31]. Cdc25C can be predominantly nuclear or cytoplasmic, depending on how the NLS and NES regions are modulated. For example, binding of 14-3-3 can occlude recognition of the NLS by nuclear import factors. Furthermore, the NES region appears to be regulated by phosphorylation. For example, Ser-198 in the NES of human Cdc25C undergoes phosphorylation at mitosis [31]. This phosphorylation reduces the effectiveness of the NES and thus promotes nuclear accumulation. Human Plk1 has been implicated as the enzyme that phosphorylates Ser-198. In this event, the Polo-like kinase may regulate both the activity and localization of Cdc25C. The nuclear accumulation of Cdc25C correlates strongly with mitotic entry in vertebrates, which implies a causal relationship between nuclear entry of Cdc25C and mitotic initiation. In fission yeast, however, nuclear accumulation of Cdc25 is not required for mitosis [32].

Stability of Cdc25

Like other key cell-cycle proteins, one or more members of the Cdc25 family are subjected to regulated proteolysis. For example, Cdc25A undergoes prompt destruction following DNA damage in human cells [33,34]. Chk1 and Chk2 have been implicated in these processes, depending on the type of DNA damage. In *Drosophila*, the Tribbles protein regulates the stability of String, a fly homolog of Cdc25, at a key point in morphogenesis [35]. In fission yeast, the ubiquitin ligase Pub1 has a role in controlling the abundance of Cdc25 [36].

Concluding Remarks

The importance of Cdc25 phosphatases in cell-cycle regulation is underscored by the diversity of molecular mechanisms that are employed in their regulation. In vertebrates, there is still much to learn about how different Cdc25 family members collaborate in progression through the phases of the cell cycle and how distinct regulatory mechanisms contribute to the coordinated regulation of these enzymes.

Cell-Cycle Functions and Regulation of Cdc14 Phosphatases

Harry Charbonneau

*Department of Biochemistry, Purdue University,
West Lafayette, Indiana*

Introduction

The *CDC14* gene of the budding yeast *Saccharomyces cerevisiae* encodes a protein phosphatase that is essential for cell-cycle progression [1] and serves as a prototype for a group of closely related enzymes within the protein tyrosine phosphatase (PTP) family. Orthologs of yeast Cdc14 have been identified in protists, fungi, flowering plants, and animals, suggesting that this phosphatase, like many other cell-cycle regulators, is conserved among all eukaryotes. Cdc14 from budding yeast is the founding member of this subgroup of protein phosphatases and has been most thoroughly studied.

The Cdc14 Phosphatase Subgroup of PTPs

The Cdc14 phosphatases [1,2] utilize the Cys-dependent catalytic mechanism shared by all PTPs, but outside of a short segment surrounding their active sites they exhibit no sequence similarity to the classical tyrosine-specific enzymes of this family. Cdc14 phosphatases dephosphorylate Ser/Thr as well as Tyr residues in artificial substrates *in vitro* [1,2], placing them among the dual-specificity phosphatases (DSPs), a distinct subgroup of the PTP family. The Cdc14 orthologs have little in common with other DSPs, many of which regulate MAP kinases. Cdc14 orthologs and these MAP kinase phosphatases differ in their domain organization, and the only sequence similarity is restricted to a 60-residue region flanking their active sites.

The basic structural organization of the prototypical budding yeast Cdc14 is shared by all orthologs identified to date (Fig. 1). The 62-kDa yeast enzyme contains a conserved

N-terminal catalytic domain (residues 1–374) and an Asn/Ser-rich, noncatalytic C-terminal segment that is not essential for its cell-cycle function [1]. The oligomerization of budding yeast Cdc14, observed both *in vitro* and *in vivo*, is mediated through an interaction requiring the catalytic domain [1,3]. A noncatalytic domain is present at the C termini of all Cdc14 orthologs, but it varies in length and has diverged during speciation (Fig. 1). Apart from a nuclear export sequence identified in human Cdc14A [4], no other functions have been assigned to the noncatalytic domain.

Budding Yeast Cdc14 is Essential for Exit from Mitosis

Exit from Mitosis

Following their association with B-type cyclins, the activation of cyclin-dependent kinases (Cdk) triggers the onset of mitosis. At anaphase after sister chromatids have separated, mitotic Cdks must be inactivated in order for cells to exit from mitosis. During exit from mitosis, cells restore the nucleus to its premitotic state (e.g., disassemble the mitotic spindle) and prepare for cytokinesis (for review, see Morgan [5]). A prevailing mechanism for mitotic Cdk inactivation is the regulated destruction of mitotic cyclins.

The anaphase-promoting complex (APC) ubiquitinates cyclins and other mitotic regulators, triggering their recognition and proteolysis by the 26S proteasome [5]. In budding yeast, specificity factors known as Cdc20 and Cdh1/Hct1 interact with the APC to govern substrate selectivity and the order in which crucial regulators are ubiquitinated and

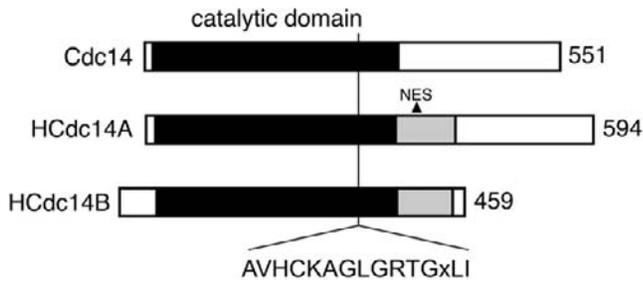

Figure 1 Schematic diagram illustrating the structural organization of budding yeast and human Cdc14 phosphatases. The yeast and human Cdc14A and B phosphatase sequences are depicted (accession numbers NP_116684, NP_003663, and NP_003662, respectively) with the total number of amino acid residues shown on the right. The solid black boxes delineate the position of the catalytic domain (≈ 330 residues) conserved among all Cdc14 orthologs, whereas the open boxes show divergent non-catalytic regions. The gray boxes depict additional sequences conserved only among the human enzymes and several other vertebrate orthologs. The vertical line denotes the position of the catalytic site; the active site sequence that is identical among all Cdc14 phosphatases is shown underneath (x indicates a variable position). The position of the nuclear export signal (NES) identified in human Cdc14A [4] is indicated by the triangle.

destroyed during mitosis [5]. APC^{Cdc20} acts first to initiate anaphase by ubiquitinating the yeast securin Pds1. Upon its destruction, Pds1 liberates a protease necessary for sister chromatid separation. Subsequently, Cdh1 promotes the APC-mediated ubiquitination of mitotic cyclins and other targets that are destroyed during exit from mitosis. Cdh1 is expressed throughout the cell cycle but Cdk-mediated phosphorylation prevents its interaction with the APC during early mitosis [5].

Cdc14 Substrates

In budding yeast, Cdc14 dephosphorylates at least three substrates (Cdh1, Swi5, and Sic1) [6,7] that ensure the inactivation of mitotic Cdk activity through two pathways: degradation of mitotic cyclins and expression of Sic1, a Cdk inhibitor (see Fig. 2). Upon its dephosphorylation by Cdc14, Cdh1 activates the APC and directs the ubiquitination of mitotic cyclins and other protein targets [7]. Expression of the Cdk inhibitor Sic1 is dependent on the zinc finger transcription factor, Swi5. Prior to anaphase, Swi5 accumulates in the cytoplasm but is prevented from entering the nucleus because of Cdk-dependent phosphorylation at Ser residues adjacent to its nuclear localization signal (Fig. 2). Cdc14 dephosphorylates Swi5, thus permitting it to enter the nucleus and activate Sic1 transcription [6]. Cdc14 also targets the Sic1 protein itself, preventing its destruction as a result of inopportune phosphorylation [6]. Cdh1, Swi5, and Sic1 undergo Cdk-dependent phosphorylation, and it is generally assumed that Cdc14 phosphatases prefer substrates phosphorylated by this group of kinases. Considerable evidence supports this notion, but it is premature to assume that Cdc14 opposes only Cdks as no sites dephosphorylated by this phosphatase, either *in vitro* or *in vivo*, have been directly mapped, and the substrate preference of Cdc14 has not yet been investigated.

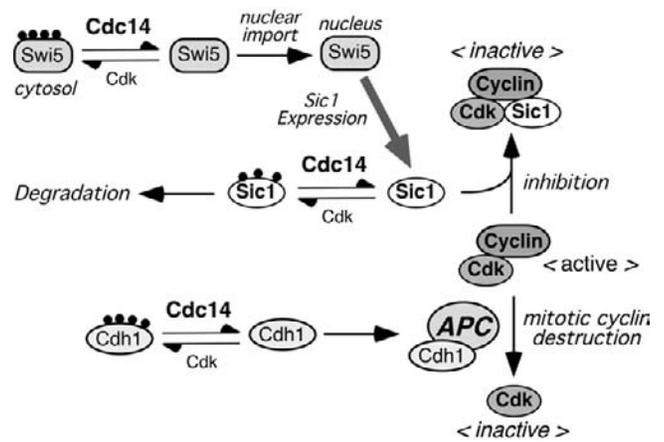

Figure 2 The role of budding yeast Cdc14 in promoting exit from mitosis. The schematic diagram illustrates how Cdc14 dephosphorylates Swi5, Sic1, and Cdh1 to drive Cdk1 inactivation by two mechanisms: APC-mediated cyclin destruction and protein inhibition [6].

The Nucleolus and Cdc14 Regulation

Genetic and biochemical studies have begun to reveal how Cdc14, which is present at constant levels throughout the cell cycle, is held in check until its activity is required between anaphase and early G₁. Net1 (also known as Cfi1) [8,9], a major player in the cell-cycle-dependent regulation of Cdc14, is a core subunit of the nucleolar RENT complex [8]. The RENT complex is also involved in maintenance of nucleolar integrity, repression of recombination among tandem rDNA repeats, recruitment of Pol I, and stimulation of rDNA transcription [10]. In interphase and early mitosis, most if not all Cdc14 is sequestered in the nucleolus by Net1 [8,9], where its activity is fully inhibited [11] and its access to substrate is limited. Net1 is a highly specific and potent competitive inhibitor ($K_i = 3$ nM) that contains a Cdc14-binding region (residues 1–341) at its N terminus [11].

Two distinct signaling pathways, known as the FEAR [12] and MEN [13] networks, control Cdc14 release from Net1 (Fig. 3). For both pathways, it is not known how the protein kinases and other signaling components act on the RENT complex to induce the release of Cdc14, but it may involve phosphorylation of Net1 [14]. The FEAR pathway (Fig. 3) is activated first at early anaphase when the securin Pds1 is degraded and active separase is released [12]. FEAR signaling triggers a transient release of Cdc14 into the nucleus that is not sufficient for exit from mitosis but ensures it occurs with proper timing [12]. The MEN pathway (Fig. 3) is activated at late anaphase when the dividing nucleus spans the bud neck bringing the Tem1 G-protein into contact with its guanine nucleotide exchange factor Lte1 [15,16]. Activation of MEN signaling is essential for exit from mitosis and produces a sustained release of Cdc14 into the nucleus and cytoplasm that promotes Cdk inactivation. Cdc14 released by FEAR signaling may act to potentiate subsequent signaling through the MEN pathway [12] by dephosphorylating the Cdc15 kinase that is known to be a Cdc14 substrate [17,18]. It is likely that the FEAR network has additional

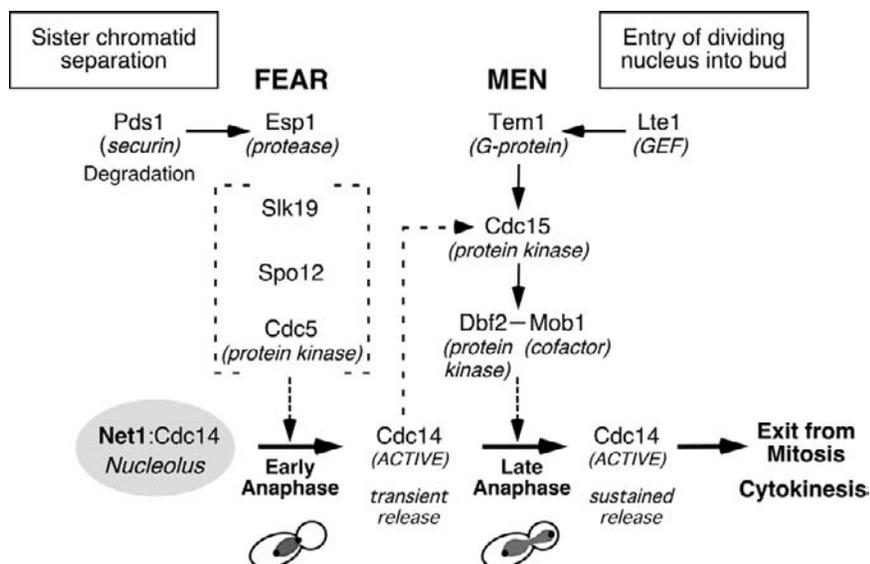

Figure 3 A model for the cell-cycle-dependent regulation of Cdc14 by the FEAR and MEN networks. The signaling proteins involved in the FEAR [12] and MEN [26] pathways are depicted. Arrows are shown where the order of signaling within the pathways is known. The components (Slk19, Spo12, and Cdc5) enclosed in large brackets are necessary for FEAR signaling, but it is not clear how they interact or in what order they operate in the network. The dashed arrow depicts the potential role of Cdc14 in potentiating MEN signaling by targeting Cdc15 [12]. Although Cdc5 is thought to act in both pathways, it is shown here only in the FEAR network. As indicated by the dashed arrow, the exact mechanism triggering Cdc14 release from Net1 is not known for either pathway.

roles during early anaphase. The dependency of Cdc14 release on the proteolysis of Pds1 [19–21] is not explained by the FEAR pathway alone, indicating there must be at least one other mechanism linking the two events. The FEAR and MEN pathways in conjunction with the requirement for Pds1 degradation ensure that mitotic exit does not occur unless sister chromatids are separated and the segregated chromosomes are correctly partitioned to mother and daughter cells (Fig. 3). Like several other proteins of the MEN pathway, the role of Cdc14 may not be limited to mitotic exit but could also include functions required for cytokinesis [22].

Fission Yeast Cdc14 Coordinates Cytokinesis with Mitosis

An ortholog of *S. cerevisiae* Cdc14, named *clp1* [23] or *flp1* [24], has been identified in the fission yeast *Schizosaccharomyces pombe*. The role of fission yeast Cdc14 in cell-cycle progression differs considerably from that of the budding yeast enzyme. *S. pombe* Cdc14 is not an essential phosphatase and is not necessary for mitotic cyclin degradation or exit from mitosis [23,24]. This is not completely surprising, as the fission yeast Cdc20 ortholog instead of Cdh1 appears to control the APC-dependent destruction of mitotic cyclins. Instead of exit from mitosis, *S. pombe* Cdc14 is involved in controlling the onset of mitosis [23,24]. Through an undefined mechanism, Cdc14 suppresses Cdk activation at the G₂/M transition by opposing

Tyr 15 dephosphorylation, a requirement for full mitotic kinase activity.

Recent analyses suggest that *S. pombe* Cdc14 is also involved in coordinating cytokinesis with the events of late mitosis [23]. In contrast to budding yeast, *S. pombe* divides by medial fission instead of budding [25]. During mitosis, *S. pombe* first assembles a medial ring containing actomyosin and then forms a septum at the middle of the cell. At the end of anaphase, a signaling pathway initiates septation, contraction of the medial actomyosin ring, and completion of cytokinesis [25]. Interestingly, most of the components of this signaling pathway, known as the septation initiation network (SIN), are orthologs of the MEN pathway of budding yeast, and the two pathways are thought to have the same organization and to propagate signals via similar mechanisms [25,26]. Surprisingly, Cdc14 is not a major effector or target of the SIN pathway [24]. Instead, Cdc14 appears to potentiate the SIN pathway by suppressing Cdk activity that is known to antagonize SIN signaling and cytokinesis.

Like its budding yeast counterpart, *S. pombe* Cdc14 is localized to the nucleolus during interphase [23,24]. Upon its release at early mitosis, Cdc14 diffuses throughout the nucleus and cytoplasm and accumulates at the spindle pole bodies, mitotic spindle, and medial ring [23,24]. Fission yeasts have no homolog of budding yeast Net1 and it is not known whether Cdc14 is active within the nucleolus, but its sequestration could restrict access to substrates. The SIN network does not trigger Cdc14 release; instead, it is required to exclude the phosphatase from the nucleolus until cytokinesis is complete [23]. How Cdc14 is initially released

is unknown. *S. pombe* Cdc14 is phosphorylated during mitosis, but how this modification might regulate the enzyme is not known [24]. Identification of substrates will be required to define how *S. pombe* Cdc14 modulates the G₂/M transition and coordinates cytokinesis with mitosis.

Potential Cell-Cycle Functions of Human Cdc14A and B

Two distinct Cdc14 phosphatases are expressed in humans [2] and several other vertebrates. Human Cdc14A and B exhibit 62% sequence identity over a 400-residue segment. Evidence suggests that Cdc14A is involved in regulating cell division, but so far there are few clues about the function of the B form.

Although many details differ, regulation of the APC during vertebrate mitosis is fundamentally the same as that observed in yeast. A Cdh1 ortholog must be dephosphorylated to direct the APC-dependent ubiquitination of mitotic cyclins that results in Cdk inactivation and exit from mitosis. A recent study [27] showed that human Cdc14A dephosphorylates Cdh1 *in vitro*, allowing it to activate APC-mediated cyclin ubiquitination. Moreover, human Cdc14A is found in a major fraction of Cdh1 phosphatase activity isolated from HeLa cell lysates [27]. Although this study [27] using *in vitro* reactions is not definitive, it provides evidence that human Cdc14A has the capacity to regulate the APC and to promote exit from mitosis. Thus, the function of budding yeast Cdc14 in promoting mitotic exit may have been conserved in humans.

Besides Cdh1, the only other potential substrate identified for human Cdc14 phosphatases is the tumor suppressor p53 [28]. Cdc14A and B associate with p53 *in vivo* and both dephosphorylate Ser 315 *in vitro* [28]. Ser 315 is targeted by Cdks, consistent with the notion that Cdc14 phosphatases oppose these kinases. Its binding to sequences in the N termini of the Cdc14 phosphatases [28] suggests that the interaction with p53 may be independent of its recognition as a phosphosubstrate and could permit the constitutive association of the two proteins. Thus far, evidence that Cdc14 controls the phosphorylation state of Ser 315 in cells is lacking, and there are conflicting reports regarding the role of this site in p53 regulation.

Several observations suggest that the regulation of human Cdc14A and B may differ from that observed in budding yeast. Both human phosphatases are insensitive to the yeast Net1 inhibitor, and no gene encoding a Net1 homolog can be identified in the human genome [11]. Targeting to specific organelles or subcellular compartments is at least partly responsible for human Cdc14 regulation. The majority of Cdc14A is localized to the centrosome, but some enzyme is also found in the cytosol [4]. During mitosis, most but not all of the Cdc14A leaves the centrosome and appears in the cytosol. A nuclear export signal (residues 352–367) (Fig. 1) is necessary for the translocation of Cdc14A out of the nucleus and to prevent its sequestration in nucleoli, where

Cdc14B is localized [4]. The nuclear export signal as well as N- and C-terminal sequences appear to be required for localization to the centrosome [4].

Recent findings have implicated human Cdc14A in centrosome duplication [4]. Like chromosomes, centrosomes must be duplicated exactly once in every round of cell division, and defects in this process lead to aberrant chromosome segregation and aneuploidy [29]. Over-expression or depletion of Cdc14A in human cells resulted in defective chromosome segregation that could be attributed to aberrations in the centrosome duplication cycle [4]. These data are fully consistent with the well-documented role of phosphorylation in regulating centrosome duplication. It will be important to identify substrates in order to define the role of Cdc14A in centrosome duplication. In this regard, it is intriguing that the potential Cdc14 substrate p53 has been linked to centrosome function [30,31]. Cells lacking p53 accumulate multiple centrosomes, suggesting that they have defects in the duplication cycle [30]. The phosphorylation of Ser 315 is required for the binding of p53 to unduplicated centrosomes [31]. The possibility that Cdc14A could modulate centrosome duplication by controlling the phosphorylation state of Ser 315 in p53 certainly merits further study. Research on the human Cdc14 phosphatases is in its infancy; nevertheless, the clues we have obtained highlight the importance of investigating potential links between this group of enzymes and tumorigenesis.

Introduction

Mitogen activated protein kinases (MAPKs) are functionally dependent on specific upstream MAPK kinases (MAPKKs) that in turn are activated by MAPKK kinases (MAPKKKs). Together, these enzymes constitute a functional cassette that is highly conserved in a wide-range of animal species. Genetic analysis and molecular and biochemical studies have revealed the existence of several distinct MAPK cascades that play an essential role controlling functions as diverse as morphological development, learning and memory, stress responses, proliferation, differentiation, and apoptosis. One property that all MAPK pathways share is their transient activation. Hence, while cell stresses and growth factors induce MAPK enzymatic activation by phosphorylation on critical threonine and tyrosine residues, this activity generally peaks within a few minutes and thereafter falls back to basal levels. Such observations suggest that, as with pathways leading to MAPK activation, processes controlling dephosphorylation are also likely to play a critical role controlling cell function. Consistent with this, over recent years a pivotal role for protein phosphatases acting at the level of MAPKs in modulating the extent and duration of MAPK enzymatic activation has been demonstrated in organisms as diverse as yeast, worms, flies, and mammals (Fig. 1).

Eukaryotic protein phosphatases comprise three classes of enzymes: the serine/threonine phosphatases PPP and PPM and the protein tyrosine phosphatases (PTPs). The PPP family includes the phosphatases PP1, PP2A, and PP2B, whereas PP2C is the prototypic member of the PPM family [1]. The PTP superfamily is characterized by the structural CX5R motif in the active site and can be further subclassified into four classes based on protein structure: (1) the tyrosine specific phosphatases, (2) low-molecular-weight phosphatases, (3) Cdc25-like phosphatases, and (4) VH1-like dual-specificity

phosphatases [2]. In the following sections, we will describe how organisms as diverse as yeast and mammals have used similar classes of phosphatases to achieve tight regulation of MAPK.

MAPK Phosphatases in Yeast

In the budding yeast *Saccharomyces cerevisiae*, five distinct MAPK pathways have been identified. These pathways regulate mating, sporulation, filamentous growth, cell wall integrity, and responses to osmotic shock. One of the first genetic screens for genes controlling MAPK revealed a functional redundancy, as several distinct phosphatases appeared to be important in the inactivation of a single target MAPK, in this case Hog1. Hence, double deletion of the PP2C serine/threonine phosphatase *PTC1* together with the tyrosine-specific phosphatase *PTP2* is lethal, and this phenotype is reversed by inactivating components in the Hog1 MAPK pathway. This implies that in the double-phosphatase-mutant yeast the Hog1 pathway is constitutively activated. Subsequent studies revealed that the osmotic response MAPK Hog1 is regulated by Ptc1, Ptp2, and its homolog Ptp3, although Ptp2 appears to be the major regulator in this pathway [3].

While Hog1 controls responses to osmotic stress, Fus3 is a distinct MAPK underlying pheromone responses in *S. cerevisiae*. When screening for gene suppressors of the yeast mating response, the VH1-like dual-specificity phosphatase *MSG5* was identified as an inactivator of Fus3 activity [4]. Importantly, *MSG5* is also induced by mating pheromone, indicating that this phosphatase functions as a negative-feedback regulator of Fus3 actions. Subsequent studies revealed that *Msg5* is not the only phosphatase regulating this MAPK, and that Ptp2 and Ptp3 also play a role, although, in contrast to the case of Hog1, Ptp3 appears to be more important.

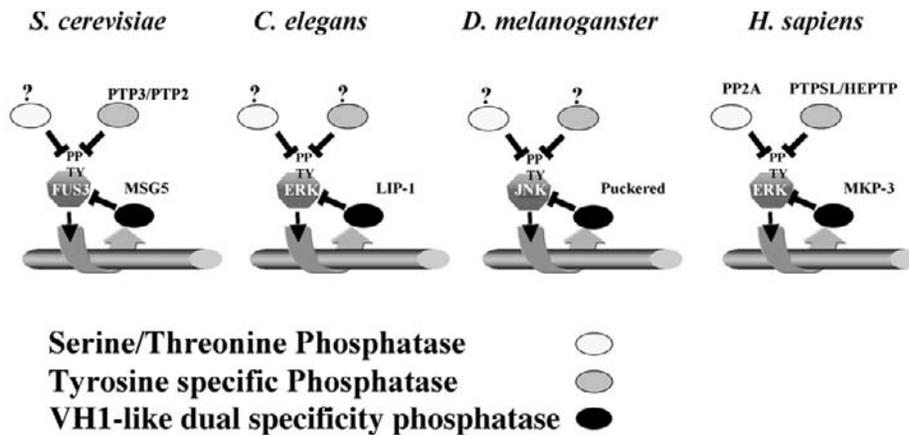

Figure 1 Schematic representation of protein phosphatases important for inactivation of MAPKs in yeast, worm, fruit fly, and human. Genetic and biochemical studies reveal that conserved members of serine/threonine, tyrosine-specific, and VH1-like dual-specificity phosphatases all play a role in inactivating various target MAPKs. Shown are specific phosphatase gene family members known to inactivate selected MAPKs. Powerful transcriptional induction of phosphatase genes, tight MAPK binding, and phosphatase catalytic activation, as well as regionalized subcellular localization, are emerging as important mechanisms for allowing tight and specific control of MAPKs by these various phosphatases (see text for details).

As with Hog1, Fus3 therefore represents a further example of a MAPK inactivated by both a tyrosine-specific as well as a VH1-like dual-specificity phosphatase. In fact, it appears that Ptp3 is required for maintaining a low basal activity of Fus3, while Msg5 plays a major role following pheromone stimulation [3]. It is of note that Ptp3, similar to mammalian MKPs, interacts with Fus3 via a cryptic CH2 (Cdc25 homology) domain, and this targeted binding is responsible for its *in vivo* substrate selectivity. Mutations in either Ptp3 or Fus3 that abolish this interaction cause a dysregulation of the Fus3 MAPK [3]. When considering specificity of interaction, it is worth noting that although Msg5 does not affect Hog1 activity it has been shown to act on a third yeast MAPK, Mpk1 [3].

A MAPK Phosphatase in *C. elegans*

Despite a recognized role for the ERK MAPK pathway in vulval development and the identification of both stress-activated protein kinase (SAPK)/c-Jun N-terminal kinase (JNK) and p38/Hog MAPK components in the nematode *Caenorhabditis elegans*, only one MAPK phosphatase (LIP-1) has so far been described. A genomic sequence search identified LIP-1 as a homolog of the human MKP3/PYST1 (see below). LIP-1 was shown to be genetically upregulated by the notch signaling pathway in the vulval neighboring cells P5.p and P7.p. This upregulation seems likely to result in inactivation of the MAPK MPK1, an event critical for generating an appropriate pattern of cell differentiation in developing worms [5].

MAPK Phosphatases in *Drosophila melanogaster*

A screen for genes regulating *Drosophila* embryonic dorsal closure identified Puckered, a VH1-like dual-specificity

phosphatase, mutations of which lead to cytoskeletal defects and a failure in dorsal closure. Such phenotypic effects are similar to those associated with mutations in the MAPK basket, a *Drosophila* JNK homolog. Loss-of-function mutations in Puckered result in hyperactivation of DJNK, and mRNA expression is regulated by the JNK pathway. This indicates that Puckered regulates SAPK/JNKs and that, as with Msg5, it is a feedback regulator of this MAPK pathway [6]. Remarkably, the Puckered catalytic domain is related to the mammalian dual-specificity phosphatase MKP-5, which selectively interacts and inactivates p38 and SAPK/JNK MAPK family members and is regulated by stress stimuli.

Fruit fly eye differentiation is driven by the *ras* ortholog RAS1 and is dependent on a downstream MAPK belonging to the ERK family. In searching for regulators of this pathway a tyrosine-specific family phosphatase, PTP-ER, was isolated as a negative regulator of eye development acting downstream of RAS1. PTP-ER complexes with and inactivates wild-type ERK but not the gain-of-function ERK mutant Sevenmaker. PTP-ER is a homolog to mammalian PTP-SL and STEP and, like its mammalian counterparts, also contains stretches of basic residues that act as docking sites for binding and specific inactivation of the target ERK MAPK [7].

Despite its functional importance, PTP-ER might not act alone to inactivate ERK, as a recent search of the *Drosophila* EST Expressed Database identified a homolog of the mammalian ERK-specific dual-specificity phosphatase MKP-3/PYST1. Like its mammalian counterpart, DMKP-3 inhibits ERK but is ineffective on SAPK/JNK and p38 MAPKs. Furthermore, DMKP-3 interacts with *Drosophila* ERK via its N-terminal domain and is catalytically activated following interaction with this target MAPK [8].

MAPK Phosphatases in Mammals

The human protein phosphatase CL100, its mouse ortholog 3CH134 (also named Erp), and PAC1 were the first phosphatases recognized to play a role in the inactivation of mammalian MAPKs. Similar to yeast MSG5, CL100 and PAC1 undergo rapid transcriptional activation following exposure to growth factors. Furthermore, inactivation of ERK in fibroblast and Jurkat cell lines correlates with accumulation of CL100 and Pac1 protein, respectively, suggesting a direct role of these phosphatases as feedback regulators of MAPK [9,10]. CL100 belongs to the VH1-like dual-specificity family of phosphatase and consistently was found to dephosphorylate both threonine and tyrosine residues of ERK. These studies also showed that CL100 was specific for MAPK when compared with a number of other phosphoproteins [11]. These observations combined with the ability of catalytic inactive CL100 to coprecipitate with ERK suggested that CL100 is specific for MAPK, leading to its being renamed MAPK phosphatase-1 (MKP-1) [12].

CL100/MKP-1 was originally characterized as an ERK-specific phosphatase but was later also shown to inactivate SAPK/JNK and p38 MAPKs. In fact, another dual-specificity phosphatase gene family member, MKP-3/PYST1 [13,14], has emerged as a more specific inactivator of ERK MAPKs. Interestingly, the MKP-3/PYST1 N-terminal domain binds selectivity to ERK1 and ERK2, but not JNK2, JNK3, or p38 which mirrors its selectivity for inactivating these MAPKs [15]. It turns out that MKP-3/PYST1 binding results in a powerful increase in phosphatase activity with consequent inactivation of the ERK MAPK to which it is complexed [16]. MKP-3/PYST1 enzymatic activation is independent of ERK kinase activity but requires specific charged residues within the noncatalytic N terminus for binding to this MAPK [17–19]. Such a mechanism of MKP-3/PYST1 enzymatic activation is supported by its crystal structure, which shows that in the absence of its target substrate the catalytic domain displays a distorted, probably less active, conformation [20]. Interestingly, a Sevenmaker ERK mutant (ERK2 D319N) is disabled in its ability to either bind or catalytically activate MKP-3/PYST1, suggesting that this deficiency contributes to the gain-of-function activity displayed by this MAPK mutant when expressed in cells.

CL100/MKP-1, PAC1, and MKP-3/PYST1 turned out to be founding members of a large family of MKP dual-specificity phosphatases which now include 10 distinct gene products [3,17,21]. MKP family members share a common VH1-like phosphatase catalytic domain as well as noncatalytic regions homologous to the cell-cycle phosphatase regulator CDC25, designated as CH2 domains. These MKP N-terminal regions contain stretches of basic residues that appear essential for mediating specific and tight binding to target MAPKs [3,17–19]. Interestingly, matching these basic charges is a stretch of acid groups present on MAPKs within a conserved motif that has been shown to mediate interaction with dual-specificity phosphatases and upstream MAPKs, as well as substrates [18,19].

Despite the importance of MKP-3/PYST1 for inactivating ERK, other phosphatases also appear likely to play a role in control of mammalian MAPKs. Hence, biochemical studies, using protein phosphatase inhibitors, have revealed that serine/threonine phosphatases, such as PP2A, are also important for rapid dephosphorylation and inactivation of ERK following EGF stimulation in PC12 cells [22]. Similarly, a serine/threonine phosphatase of the PP2C class, PP2C α , was recently shown to inactivate stress-responsive SAPK/JNK as well as p38 MAPK pathways in mammalian cells [23]. In addition to serine/threonine and VH1-like phosphatases, several tyrosine-specific phosphatases have also been implicated in the inactivation of MAPK in mammals. Hence, PTP-SL and its homolog STEP were shown to associate with ERK1/2 *in vitro* and to inactivate this MAPK in transfected cells [24]. Another tyrosine-specific phosphatase selectively expressed in hematopoietic tissue, HEPTP/LCPTP, also inactivates ERK1/2 and p38 in transfected cell [25,26]. As seen with the dual-specificity MKPs, binding of HEPTP/LCPTP and STEP to target MAPKs is dependent on conserved basic residues within their noncatalytic N-terminus. This motif is also present in the *Drosophila* homolog PTP-ER [7,23].

Summary

Overall, a wide range of genetic and biochemical studies now indicate an emerging theme in which a combination of serine/threonine, tyrosine-specific, and VH1 dual-specificity phosphatases all play an important role in inactivation of different MAPKs. In many cases, the tight binding of the phosphatase, which appears to be critical for specific MAPK inactivation, together with highly targeted subcellular localization for some family members, indicates a regionalized inactivation of MAPK by different classes of phosphatases. Powerful transcriptional induction also suggests that some phosphatases play selective roles in inactivating MAPK function under different states of stress, endocrine, or growth factor stimulation. Future studies of the complexities of protein phosphatase functions will no doubt reveal further details on the importance this diverse enzyme family in controlling MAPK function.

History and Nomenclature

Shp1 was cloned by four groups, using polymerase chain reaction (PCR) methodology [1–4]. Later, mammalian Shp2s were cloned using similar approaches [5–9], and Shp homologs in *Xenopus* [10] and chicken [11] were reported. This caused a profusion of synonyms for the same genes. A subsequent agreement resulted in the adoption of single names for each mammalian Shp [12], with “Shp1” replacing PTP1C [1], SH-PTP1 [2], HCP [3], and SHP [4]; SH-PTP2 [5], Syp [6], PTP1D [7], PTP2C [8], and SH-PTP3 [9] are now termed “Shp2”. Recently, genome sequencing efforts have reintroduced some confusion. The Human Gene Mapping Nomenclature Committee employs a standardized naming system for protein-tyrosine phosphatases (PTPs) in which human Shp1 is termed PTPN6 and Shp2 is PTPN11 (the “N” indicates “non-transmembrane”; the number specifies the order in which the PTP was reported to the database). The *Drosophila corkscrew* (*csw*) gene was identified in a screen for modifiers of the Torso receptor tyrosine kinase (RTK) pathway [13]. Although initially believed to be an Shp1 homolog, sequence analysis [5] and functional studies [14] indicate that *Csw* is the homolog of Shp2. *Caenorhabditis elegans* has a single Shp, *ptp-2*, the function of which also appears most analogous to Shp2 [15]. It remains unclear whether *Csw* and *Ptp-2* also have some functions similar to Shp1, or if Shp1 evolved to carry out functions unique to vertebrates.

Structure, Expression, and Regulation

Primary Structure

Shps (Fig. 1A) all have two SH2 domains at their N termini (hereafter, N-SH2 and C-SH2), a classical protein-tyrosine phosphatase (PTP) catalytic domain, and a C-terminal tail (C-tail). The *Csw* PTP domain is split by a cysteine/serine-rich insert (≈ 150 amino acids) that is unrelated to known protein motifs [13]. The function of the *Csw* insert is unknown, but its conservation in other *Drosophila* species implies an important role, perhaps in protein-protein interaction. Because vertebrate Shp2 orthologs lack an insert, its function either is specific to insect signaling pathways or is encoded on another vertebrate protein. Some *csw* splice variants fail to encode the insert, suggesting that it is important only in some signaling pathways (L. Perkins, personal communication).

Shps also differ in their C-tails (Fig. 1A, B). Shp1 and Shp2 have two tyrosyl phosphorylation sites in this region, which are phosphorylated differentially by RTKs and non-receptor protein-tyrosine kinases (PTKs) [6,7,16–23]. The *Csw* C-tail retains only the more proximal tyrosine (Y542 in Shp2), whereas *Ptp-2* lacks both sites. Shp2 and *Csw* (but again, not *Ptp-2*) have proline-rich domains that may bind SH3-domain-containing proteins, although specific interacting proteins have not been reported. Shp1 lacks a proline-rich domain but has a basic sequence that functions as a nuclear localization sequence (NLS) [24,25].

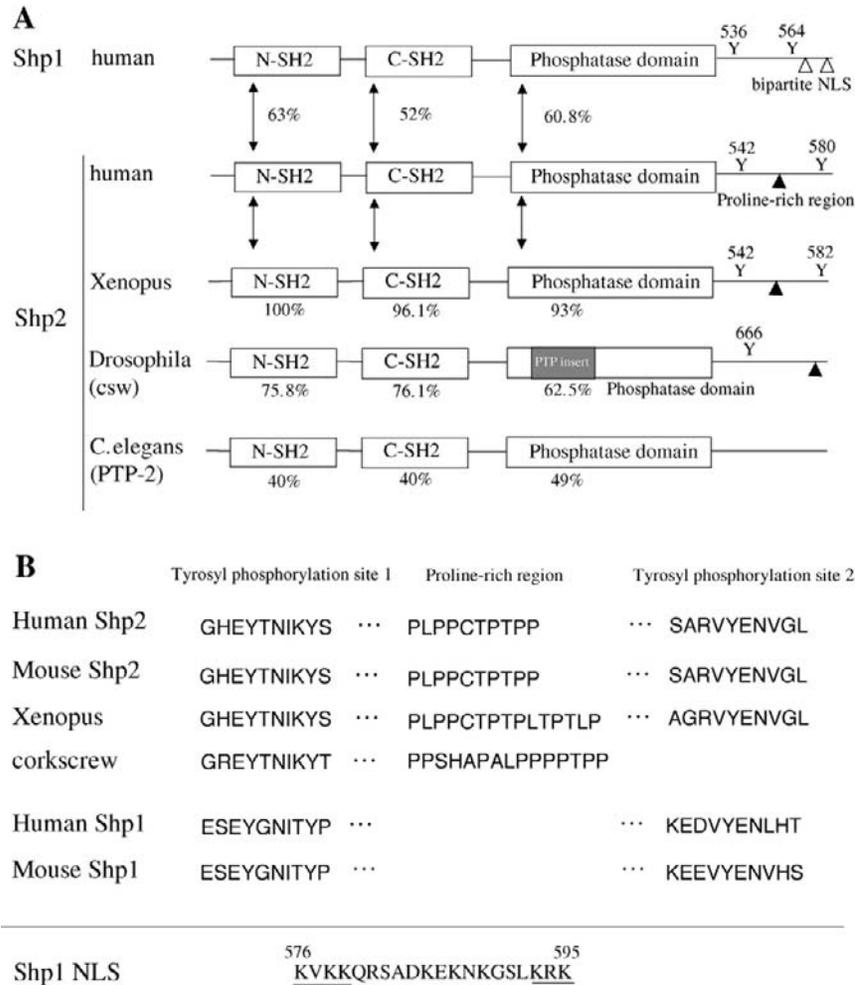

Figure 1 The Shp family. (A). Schematic structures of Shp family members. The SH2 and PTP domains and C-tail are indicated, and the relative positions of tyrosyl phosphorylation sites, proline-rich domains, and nuclear localization sequences are shown. (B) Features of Shp C-tails. Shown are sequences surrounding potential tyrosyl phosphorylation sites and proline-rich domains. Also shown is the potential bipartite NLS found in Shp1, but not other family members.

Expression

Shp2 and its orthologs are expressed ubiquitously, although at variable levels in different tissues [5,6,8,13]. Shp1 is more restricted, with high levels in hematopoietic cells, lower amounts in most epithelia and some neuronal cells, and few or none in fibroblasts [2,4,26]. The Shp1 gene has two promoters that function in a tissue-specific fashion, generating Shp1 isoforms with slightly different N termini [27,28]. In humans, the more 3' (downstream) of these promoters is expressed only in hematopoietic cells, whereas the upstream promoter is expressed only in epithelia. The murine 3' promoter may be active in epithelial cells as well, but the upstream promoter retains epithelial-specific expression [28]. A third Shp1 isoform, generated by alternative splicing, has a C-terminal extension [29]. Splice variants within the PTP domain of Shp2 and Csw also have been defined [5,13,30]. The Shp2 isoforms reportedly have different PTP activities [30], but their physiological significance has not been determined. Although differential expression may

explain some differences in the roles of the Shps, they clearly are not the whole story. Many cells and tissues, particularly hematopoietic cells, express high levels of both Shps, yet the consequences of loss of either molecule are strikingly different.

SH2 Domain Function

Not surprisingly, the SH2 domains of Shps target them to phosphotyrosyl-containing (pTyr) proteins. Little is known about the binding properties of invertebrate Shps, but multiple proteins are known to bind the SH2 domains of the mammalian orthologs. Most fall into three distinct categories: receptors (RTKs or cytokine receptors), scaffolding adapters (e.g., IRS, DOS/Gab, and FRS proteins), and so-called immune inhibitory receptors (commonly termed *inhibitory receptors*). The latter comprise a large number of glycoproteins, first described in immune cells, hence the name [31]. However, several inhibitory receptors are

expressed more widely. Some Shp-binding proteins (e.g., Shps1/Sirp α , Pir-B) bind both Shps [32–35], whereas others (e.g., Gab/Dos family proteins) exhibit specificity in Shp binding [36].

Unlike the case for most SH2 domains, residues at both the N and C terminals of pTyr contribute to binding. The consensus for binding an Shp SH2 domain conforms to the immunoreceptor tyrosine-based inhibitory motif (ITIM), I/V/L-X-pY-X-X-I/V/L [37–45]. However, why some pTyr-peptides that fit the ITIM consensus bind the N- vs. C-SH2 of one or both Shps had remained unclear. Recently, mass spectrometric screening of a combinatorial peptide library was used to assess the specificity of the N- and C-SH2 domains of Shp1 [46]. This novel approach, together with direct affinity measurements, suggests a single consensus for binding to the C-SH2 (V/I/L-X-pY-A-X-L/V) and two distinct motifs for the N-SH2 (L-X-pY-A-X-L and L-X-pY-M/F-X-F/M). Notably, in this analysis, the N-SH2 strongly prefers Leu at Y–2 (although Ile, Val, and Met substitute equally well in direct binding assays), whereas peptides with other hydrophobic residues at –2 can bind the C-SH2. Importantly, these consensus sequences show strong agreement with earlier binding studies of known Shp1-interacting proteins. It will be interesting to apply this approach to the SH2 domains of Shp2. A recent study did assess Shp2 SH2 domain binding, using a different combinatorial method. This analysis locked in a valine at Y–2, preventing assessment of the relative contribution of this position to binding [47]. However, it did reveal similar binding preferences for the two SH2 domains, with positions +1 (threonine/alanine/valine), +3 (valine, isoleucine, leucine), and +5 (tryptophan, phenylalanine) being most important for specificity. Although the same general consensus appears to apply to N- and C-SH2s of Shp2, the two domains differ quantitatively in their preferences for individual amino acids at each position. Consistent with previous binding [48] and structural [49] studies, and in marked contrast to many other SH2 domains, selection for residues at the +5 position (which was not tested in the earlier work on Shp1 binding preferences) was quite strong. Surprisingly, however, there was no apparent preference for acidic residues at the +2 and +4 positions, in contrast to earlier work on Shp2 binding sites in IRS-1, which identified Y1172 (YIDL) as the optimal site [48].

Some reported Shp SH2-domain-binding interactions fail to follow the above rules. CTLA-4 reportedly binds Shp2 via a G-X-pY-X-X-M motif [50]. Mast cell function-associated antigen (MAFA) contains an ITIM-like motif with Ser at Y–2, and a pTyr peptide bearing this sequence can bind to both Shps [51]. Also, Shp1 reportedly binds several tumor necrosis factor (TNF) family (death) receptors via a conserved A-X-pY-X-X-L motif. Even more surprisingly, binding could be competed by a short peptide lacking any residue at Y–2 [52]. These reports stand in marked contrast to earlier studies, which revealed an essential role for positions upstream of pTyr [39,53,54] and a specific requirement for hydrophobic residues at the –2 position. Conceivably, some of these

nonconforming interactions are indirect, but further work is required to resolve these inconsistencies.

Additional complexity arises from the ability of some ITIMs to bind to the SH2 domain of the inositol phosphatase SHIP; however, the SHIP SH2 does not require a hydrophobic residue at the Y–2 position [51,53–55]. Also, leucine at the Y+2 position favors SHIP binding [56], whereas bidentate ligands enjoy an obvious avidity advantage for Shps. The binding sites for Shp2 and the E3 ubiquitin ligase SOCS3 on several cytokine receptors also overlap [57–61]. Peptide library screening confirms the similar specificity of the Shp2 and SOCS3 SH2 domains, although pTyr peptides with considerable (>30-fold) specificity for the latter can be identified [47]. SOCS SH2 domains bind with markedly higher affinity than Shp2 to these shared binding sites [47]. Nevertheless, the overlapping specificity of their SH2 domain has complicated analyses of the respective roles of the Shps, SHIP, and SOCS proteins in several signaling pathways.

Regulation of PTP Activity

Shps have very low basal activity, but addition of a pTyr ligand for the N-SH2 substantially enhances catalysis [48,62–65]. Appropriate bis-phosphorylated (bidentate) pTyr ligands have an even greater effect, resulting in a \approx 50-fold increase in activity [66]. Comparable stimulation results from N-SH2 truncation [63,64,67,68]. A molecular explanation for these findings was provided by the crystal structure of Shp2 lacking its C-tail (i.e., containing the N- and C-SH2 and PTP domains) [69]. In the structure, the backside of the N-SH2 (the surface opposite the pTyr-peptide-binding pocket) is wedged into the PTP domain. This physically and chemically inhibits the catalytic cleft, and contorts the N-SH2 pTyr-peptide-binding pocket. Thus, in the basal state, the PTP domain is inhibited by the N-SH2, and pTyr-peptide binding is incompatible with binding of the N-SH2 backside to the PTP domain. The C-SH2 has minimal interactions with the PTP domain, and its pTyr-binding pocket is unperturbed in the basal state. Thus, the C-SH2 probably serves a search function, surveying the cell for appropriate pTyr targets. If it binds to a bidentate ligand (one that also has an N-SH2 binding site), the effective increase in local concentration of the N-SH2 ligand can reverse inhibition by the PTP domain, allowing release of the N-SH2 and enzyme activation. Recent studies support such a model for Shp1 interactions with gp49B [70]. Alternatively, high-affinity ligands for the N-SH2 might be able to cause activation in the absence of C-SH2 binding (Fig. 2A).

The biological relevance of the Shp2 structure was verified by analyzing mutants of the N-SH2/PTP domain interface. Such mutants have increased basal activity *in vitro*, retain the ability to bind N-SH2 ligands, and behave as gain-of-function (activated) mutants *in vivo* [71]. More dramatic confirmation came with the recent finding that analogous mutants are the cause of Noonan syndrome in humans. The structure of full-length Shp1 (or a form lacking its C-tail)

unpublished observations], whereas under basal (randomly growing) conditions Shp1 is cytoplasmic in hematopoietic cells [24,25,74]. However, cytokine stimulation can result in nuclear translocation of Shp1 in hematopoietic cells [25]. Translocation occurs with delayed kinetics (>1 hr post-stimulation), which might reflect a requirement for synthesis of a new protein to promote nuclear import or repress nuclear export. Most studies of Shp signaling have focused on immediate events following receptor stimulation; this new work argues that attention should be paid to later events as well.

Besides these conventional mechanisms of regulation, Shp2 (and other PTP family members) may be regulated by reversible oxidation. Increasing evidence suggests that hydrogen peroxide and other reactive oxygen intermediates (ROIs) are generated upon growth factor and cytokine stimulation and act as second messengers [85]. A recent study showed that Shp2 undergoes transient inactivation by ROI in response to platelet-derived growth factor (PDGF) stimulation of Rat 1 fibroblasts, and argued that Shp2 inactivation is required for normal PDGFR function in these cells [86]. However, other work indicates that Shp2 plays a signal-enhancing role in PDGF signaling [87–90]. Further studies are required to clarify these discrepancies and to test whether Shps are targets for ROIs in other pathways.

Biological Functions of Shps

Genetic models for murine Shp1 and for Shp2 orthologs in mouse, *Drosophila*, and *C. elegans* have been invaluable for defining the biological functions of the Shps. The phenotypes of Shp-deficient organisms will be described briefly here; more complete descriptions are available in several other reviews.

The *motheaten* Phenotype

Two naturally occurring point mutations exist in the murine Shp1 gene, each of which causes abnormal splicing of Shp1 transcripts [91,92]. The *motheaten* (*me*) allele generates an early frameshift; consequently, *me/me* mice are protein null. The *motheaten viable* (*me^v*) allele encodes two aberrant Shp1 proteins; one with a small deletion, the other with a small insertion in the PTP domain. Together, these retain only about 20% of wild-type (WT) Shp1 activity, demonstrating the essential role for PTP activity in Shp1 function.

The phenotypes of *me/me* and *me^v/me^v* mice differ only in severity, with *me/me* mice succumbing to abnormalities earlier (2–3 weeks) than *me^v/me^v* (9–12 weeks) [93–98]. For this reason, we use **me** to refer generically to Shp1-deficient mice. The **me** phenotype derives its name from patchy hair loss, which gives the mice a motheaten appearance. The hair loss, in turn, results from sterile dermal abscesses consisting of neutrophils. Inflammation also is prominent elsewhere, including the joints, liver, and lungs. The latter leads to the early demise of **me** mice, due to severe interstitial pneumonitis caused by

accumulations of alveolar macrophages and neutrophils. The macrophage population in **me** mice is expanded and exhibits abnormal differentiation, with a dramatic increase in CD5⁺ monocytoid cells and a decrease in cells expressing tissue/marginal zone macrophage markers [99,100]. Some dendritic cell populations are increased, whereas others are diminished [100]; osteoclast numbers and function are enhanced, leading to osteopenia in **me** mice [101]. Shp1-deficient mice on either a *nude* or *rag* knockout background still develop inflammatory disease [102], and the disease can be reproduced by transplantation of bone marrow cells and prevented by treatment with Mac-1 antibodies [103]. Thus, lymphoid cells are dispensable, and defects in the myeloid lineage are critical, if not sufficient, for development of the **me** inflammatory syndrome.

Although from the host standpoint, the myeloid defects present the gravest problems, every other hematopoietic lineage is affected by Shp1 deficiency [93–98]. The thymus undergoes premature involution, possibly due to defective homing of a thymic accessory cell [104,105]. Indeed, thymocytes and peripheral T cells lacking Shp1 actually exhibit increased mitogenesis in response to T-cell antigen receptor (TCR) stimulation [106,107]. Consistent with enhanced responsiveness, crosses to TCR transgenic mice show that Shp1 deficiency lowers the threshold for thymic selection [108–111]. Normal B (B2 cell) lymphopoiesis is reduced, but there is a marked increase in B1a (CD5⁺) cells. The remaining B cells appear hyperactivated and produce autoantibodies [93,98]. Proliferation [112,113] and calcium flux [114] in response to B-cell antigen receptor (BCR) stimulation are reportedly enhanced in **me** lymphocytes, and the response threshold of a transgenic BCR is lowered in **me** mice [114]. Natural killer (NK) cell activity is decreased [115], but the remaining NK cells show enhanced lytic activity [116]. Motheaten mice are anemic, probably due to chronic hemolysis, although their erythroid progenitors are hyper-responsive to erythropoietin (EPO) [117–119]. Increased numbers of certain mast cell populations also have been reported [120,121]. Because the lymphohematopoietic system is highly interactive, identifying which **me** abnormalities are primary (i.e., cell autonomous) defects, as opposed to secondary consequences of the myeloid defects, has posed major (and ongoing) challenges. Nevertheless, many of the abnormalities have been ascribed to loss of negative regulation of specific signaling pathways in the absence of Shp1.

Invertebrate Models of Shp2 Deficiency

Csw is a maternal effect mutation affecting the so-called terminal class pathway [13], which is initiated by the RTK Torso and controls embryonic head and tail development [122]. Loss-of-function mutations in *csw* were found to have a phenotype similar to, although less severe than, *torso* mutations, which provided the first evidence of a positive (i.e., signal enhancing) function for an Shp2 ortholog [13]. Csw also is a required positive component of the *sevenless*,

breathless (fibroblast growth factor receptor [FGFR]), and *Drosophila* epidermal growth factor receptor (EGFR; DER) pathways [14,123,124].

Ptp-2 functions in at least two RTK signaling pathways. In vulval development, which is controlled by the EGFR ortholog Let-23, *ptp-2* mutation alone has no obvious effect. However, *ptp-2* deficiency suppresses the multivulva phenotype induced by mutation of the negative regulator *lin-15*. Interestingly, *lin-15* mutations cause Let-23 activation even in the absence of the EGFR ligand, Lin-3, implying that Ptp-2 may play an important role in a ligand-independent Let-23 pathway [15]. Ptp-2 also is important for signaling by the FGFR ortholog EGL-15 [125] and has an essential role in an as yet unidentified pathway required for oogenesis [15].

Functions of Vertebrate Shp2

Studies of *Xenopus* embryogenesis provided initial evidence of a role for Shp2 in vertebrate development [10]. Expression of dominant-negative Shp2 disrupts gastrulation, causing severe tail truncations reminiscent of, but less severe than, the effects of dominant-negative FGFR. Dominant-negative Shp2 also blocks FGF-induced mesoderm induction and elongation of ectodermal explants. Recently, two activated mutants of Shp2 (similar to those found in Noonan syndrome) were found to induce elongation of ectodermal explants in the absence of exogenous FGF. Activated mutants do not, by themselves, induce mesodermal gene expression, although they potentiate induction of the Erk pathway by FGF [71].

Targeted mutations of murine Shp2 indicate a key role for Shp2 in mammalian development. Homozygotic deletion of either Exon 2 [126] or Exon 3 [127] results in early embryonic lethality. Exon 3 (*Ex3*^{-/-}) embryos die between E8.5 and E10.5, with a range of abnormalities consistent with defective gastrulation and mesodermal differentiation [127,128]. These defects resemble the effects of dominant-negative Shp2 (and FGFR) mutants in *Xenopus* and the effects of vertebrate FGFR mutations [129]. Chimeric analyses using *Ex3*^{-/-} embryonic stem (ES) cells reveal an essential role for Shp2 in limb development and branchial arch formation, two other pathways controlled by FGFR signaling [130,131]. Studies of hematopoietic differentiation in *Ex3*^{-/-} ES cells [132] and in chimeric mice [130] indicate a stringent requirement for Shp2 in the earliest progenitors, consistent with a role for Shp2 in Kit (stem cell factor receptor) signaling [133].

The *Ex3* mutation generates a truncated Shp2 protein that lacks part of its N-SH2 domain and is expressed at $\approx 25\%$ of WT levels in *Ex3*^{-/-} cells. Due to the N-SH2 deletion, however, the *Ex3* mutant is activated markedly; consequently, *Ex3*^{-/-} cells actually have increased Shp2 activity [127,132], although the mutant protein is defective at localizing to at least some signaling pathways [134]. This finding raised the possibility that some effects of *Ex3* deletion might be neomorphic.

Recent studies of other targeted mutations argue against this possibility. *Ex2*^{-/-} embryos die earlier (\approx E6–E6.5) than *Ex3*^{-/-} embryos. Despite earlier reports (which used antibodies against the N terminus to assess expression), *Ex2*^{-/-} mice also express an N-terminally truncated protein. However, for reasons that are unclear, this mutant protein is not hyperactivated. More convincingly, a variant *Ex2* mutation (*Ex2*^{*}), in which a strong splice acceptor sequence was introduced into the targeting construct, is, in fact protein null, and *Ex2*^{*-/-} embryos also die at E6 to E6.5. Total Shp2 deficiency causes defective inner cell mass expansion, due to markedly increased apoptosis (W. Yang and B.G.N., manuscript in preparation). The timing and nature of the lethality of *Ex2*^{*-/-} embryos are consistent with roles for Shp2 in FGF-4 [135] and/or $\beta 1$ integrin [136] signaling.

Shp Signaling and Substrates

Shp1

Shp1 is implicated as a regulator of signaling by RTKs, cytokine receptors, multichain immune recognition receptors (MIRRs), chemokine receptors, and integrins. Many of these studies utilized cells from *me/me* or *me^v/me^v* mice. Such cells provide the advantage of a genetic model of Shp deficiency, but the reported defects may reflect altered development caused by Shp1 deficiency, rather than the effects of Shp1 on a specific signaling pathway *per se*. Remarkably, despite much progress in defining signaling pathways affected by Shp1, its direct targets remain controversial and/or elusive.

SIGNALING PATHWAYS IN MYELOID CELLS

Bone marrow macrophages (BMMs) from *me* mice were reported to show increased proliferation in response to colony-stimulating factor 1 (CSF-1; MCSF) [137]. Subsequent studies found no effect of Shp1 on proliferation *per se* [138,139], although *me* BMMs required less CSF-1 for survival [139]. The target(s) of Shp1 in this pathway also are controversial. In one study, the CSF-1R was found to be hyperphosphorylated, albeit for short times, following stimulation [137]. Others failed to confirm these observations, noting instead that p62Dok (Dok) is the major hyperphosphorylated species [139]. The reason for this discrepancy is not clear. Regardless, because Dok is primarily a negative regulator, acting to recruit RasGap [140–142], it remains unclear how Dok hyperphosphorylation might explain the lower CSF-1 dependency of *me* BMMs. Shp1 does not bind directly to either the CSF-1R or Dok. Instead, two inhibitory receptors, Shps1 (Sirp α /BIT/MFR) and PirB (p91A) are the major Shp1 binding proteins in BMMs [35,143–145]. Both also are Shp1 substrates [35], but it does not appear as if dephosphorylation of these proteins plays a major negative regulatory role. Also, it is not clear if either regulates RTK signaling in BMMs or has another function, such as in integrin signaling [146].

Shp1 also negatively regulates cytokine signaling in BMMs. IFN α/β signaling is dramatically enhanced in **me** BMMs, as shown by increased JAK1 and STAT1 tyrosyl phosphorylation [147]. These data are consistent with other studies implicating Shp1 in Janus PTK dephosphorylation. Others have reported that granulocyte–macrophage colony-stimulating factor (GM-CSF)-evoked proliferation is enhanced in Shp1-deficient BMMs [138]. These workers observed no change in JAK/STAT phosphorylation but did notice a hyperphosphorylated 126-kDa species, which is most likely Shps1 and/or PirB. As indicated previously, hyperphosphorylation of these proteins alone is unlikely to explain increased GM-CSF responsiveness.

Shp1-deficient BMMs are markedly hyperadherent to ligands for both β 1 and β 2 integrins, suggesting a negative regulatory role for Shp1 in integrin signaling [148]. The direct targets of Shp1 in this pathway also remain unclear, although actions on *src* family PTKs (SFks) and/or the p85 subunit of phosphatidylinositol 3-kinase (PI3K) have been suggested. If SFks are, in fact, Shp1 targets, presumably only specific members mediate the increased adhesiveness, because SFk activity also is increased in CD45^{-/-} BMM yet these cells fail to sustain integrin-mediated adhesion [149]. Although p85 is reportedly hyperphosphorylated, and phosphatidylinositol 3,4,5-triphosphate (PIP3) levels are elevated in **me** BMMs [148], a direct stimulatory effect of p85 tyrosyl phosphorylation on PI3K activity has not been demonstrated. Shps1 (and possibly PirB) probably play an important role in mediating Shp1 action in integrin signaling. Shps1 becomes rapidly phosphorylated in response to BMM adhesion, most likely by SFks [146], and recruits Shp1. Immunostaining experiments suggest targeting of Shps1 to sites of adhesion (K. Swanson and B.G.N, unpublished data). Shps1 also forms complexes with other proteins that probably play important roles in integrin signaling. One contains the adapter proteins Skaphom/R and SLAP130/Fyb (now known as ADAP). ADAP is essential for inside-out signaling in T cells [150–152], perhaps by virtue of its ability to bind Ena/Vasp family proteins [153]. The other Shps1 complex contains the focal adhesion kinase (FAK)-related PTK Pyk2, and FAK regulates fibroblast adhesion [154]. Skaphom, ADAP, and Pyk2 associate constitutively with Shps1, but all undergo inducible phosphorylation in response to adhesion [146]. It is tempting to speculate that upon recruitment to tyrosine-phosphorylated Shps1, Shp1 dephosphorylates one or more of these associated proteins. Although tyrosyl phosphorylation activates Pyk2, its effect on Skaphom and ADAP remains to be determined, as does whether any of these proteins are direct Shp1 targets. In any case, it is unlikely that all effects of Shp1 on BMMs are mediated via Shps1, as mice lacking the cytoplasmic domain of Shps1 do not exhibit a **me** phenotype, their only obvious defect being mild thrombocytopenia [155]. Interestingly, while haplotaxis is defective in **me** BMMs, probably owing to defective deadhesion, BMMs show markedly increased chemotaxis in response to chemokines [156]. Chemokines signal via G-coupled receptors, so it

remains unclear what the targets are for a PTP in chemokine signaling, although Pyk2 is a possibility [157].

Phagocytosis is also regulated by Shp1. BMMs from **me** mice show increased ingestion of IgG-opsonized sheep red blood cells (RBCs), indicating defective negative regulation of Fc γ R signaling [158]. Complement-mediated phagocytosis, which utilizes β 2 integrins, also is enhanced in **me** BMMs. Recent data indicate that both of these negative regulatory pathways involve Shps1/Shp1 complexes. CD47, a ubiquitously expressed glycoprotein [159], is a ligand for Shps1 [160]. CD47 on the RBC surface engages macrophage Shps1, leading to its tyrosyl phosphorylation, Shp1 recruitment, and inhibition of Fc γ R signaling [161,162]. Interestingly, unopsonized RBC phagocytosis is unaffected in **me** BMMs, indicating that Shps1/Shp1 complexes do not regulate the receptor responsible for phagocytosis of unopsonized RBC.

Neutrophil signaling is also affected by Shp1 deficiency. The number and size of colonies evoked by G-CSF are increased in bone marrow from **me**, compared with WT mice, and also differ qualitatively, containing increased numbers of macrophage-like cells [163]. Increased G-CSF responsiveness also is apparent in short-term proliferation assays and is reflected by an increased magnitude of STAT activity in progenitors [163]. Cell lines expressing dominant negative Shp1 [164] and Shp1^{-/-} DT40 B cells expressing the G-CSFR [165] also show increased G-CSF-evoked STAT activation. Under endogenous conditions, no association between the G-CSFR and Shp1 can be detected, although an unidentified 92-kDa species coprecipitates [163]. When Shp1 and the G-CSFR are massively overexpressed in 293 T cells, a small amount of coprecipitation is detected. Despite the lack of strong association, the G-CSFR C terminus is necessary for Shp1 to mediate its effects on G-CSF signaling, although the receptor tyrosines are dispensable [165]. Thus, the mechanism by which Shp1 regulates GCSF signaling, including its direct targets, remains unclear.

A provocative study indicates that Shp1 also acts as an effector of death receptors, such as the TNF receptor (TNFR) and Fas [52]. These receptors contain a conserved AXYXXL motif in their cytoplasmic domains and undergo tyrosine phosphorylation upon activation. Despite its non-canonical nature, pTyr peptides containing this motif were found to bind to Shp1 from neutrophils. Death receptor activation antagonizes cytokine-evoked neutrophil survival and depends on the presence of the pYXXL motif. Moreover, *me/4* neutrophils appear relatively resistant to death receptor stimuli. These effects correlated with increased cytokine-evoked Lyn phosphorylation, suggesting that Lyn may be a target for death receptor/Shp-1 complexes.

Neutrophil function is also altered in **me** mice. Oxidant production, surface expression of the integrin subunit CD18 and adhesion to plastic are enhanced in **me** neutrophils, whereas chemotaxis is diminished, perhaps due to increased adhesion [166]. However, it is not certain whether all of these defects reflect direct effects of the absence of Shp1 or altered granulocytic differentiation in **me** mice.

REGULATION OF LYMPHOCYTE AND NK CELL SIGNALING BY SHP1

Multiple studies have shown that Shp1 negatively regulates antigen receptor (TCR and BCR) signaling [167–169]. In these pathways, Shp1 is recruited to specific inhibitory receptors that block cell signaling (Fig. 3A). CD5 [170] and members of the ILT family (LIR, MIR, CD85) [171] probably negatively regulate TCR signaling in different types of T cells. In B cells, knockout studies have established roles for CD22 [172–174], CD72 [175], and CD5 [176]. Other inhibitory receptors, such as PirB/p91A, ILT2, PECAM-1, and CEACAM, are also expressed in B cells and can transduce inhibitory signals [168]. Shp1 initially was suggested to mediate inhibitory signaling by Fc γ RIIB, the Fc receptor that mediates inhibition of B cell activation by immune complexes [112]. Subsequent studies showed that Shp1 is dispensable for Fc γ RIIB-mediated inhibition, which instead is transmitted via the inositol phosphatase SHIP [177–180].

There is less agreement over the targets that Shp1 dephosphorylates to mediate inhibition. Lck and Fyn activities are elevated in **me** thymocytes, suggesting that Shp1 might dephosphorylate SFK activation site tyrosyl residues [106]. Transient and stable expression of catalytically impaired Shp1 also causes elevated Lck activity [110,181], and recent studies show that Shp1 has preference for dephosphorylating the activating phosphorylation site (Y394) of Lck [182]. Others have argued that Shp1 dephosphorylates ZAP-70 [183,184] and possibly the TCR ζ chain [107]. There also is no agreement over the target of Shp1 in B cells, with suggestions including Syk [185] and more downstream substrates, such as BLNK [186] and Vav [187].

In NK cells, Shp1 mediates inhibitory signaling by killer inhibitory receptors (KIRs; Ly49 family in the mouse) and CD94/NKG2. These receptors bind to host human leukocyte antigen (HLA)/major histocompatibility complex (MHC) and prevent cytolysis by recruiting Shp1 to interrupt signaling by NK cell activating receptors [31,169,188]. Again, the precise targets for Shp1 remain unclear. Initial work indicated that the earliest events in NK cell activation were blocked by KIR engagement, suggesting action of Shp1 on a proximal NK cell PTK [189]. Subsequent studies indicate that SLP-76 may be a direct target [190].

The reasons for these disagreements are unclear. Various groups have studied different lymphocyte or NK cell lines. If Shp1 has several different targets, perhaps reflecting the action of different inhibitory receptor/signaling complexes, the targets in each system might differ. Some studies have compared signaling in cells from **me** and WT mice or WT with inhibitory receptor knockout mice. Because Shp1 and/or inhibitory receptor deficiency can result in altered development, these studies can end up comparing cells at different developmental stages. Such “apples and oranges” comparisons make it difficult to know whether differences are primary or secondary. New approaches such as inducible knockouts and/or RNAi, combined with substrate trapping mutants, may help to resolve these important questions.

The role of Shp1 in other lymphocyte signaling pathways is controversial. Shp1 has been reported to regulate interleukin-2 (IL-2) receptor signaling in human T cells [191]; however, **me** thymocytes show no difference in their IL-2 response [106]. Shp1 reportedly is required for Fas-induced cell death [192,193], analogous to its role in mediating death receptor signaling in neutrophils, but two subsequent reports failed to find such a requirement [106,194].

SHP1 SIGNALING IN ERYTHROID CELLS

Shp1 binds directly to the EPO receptor (EpoR) [195, 196]. Studies with EpoR mutants suggest that upon recruitment, Shp1 dephosphorylates the receptor-associated kinase, Jak2 [196]. This model (Fig. 3B) provides a possible molecular explanation for the phenotype of a family that inherits an EpoR truncation and exhibits erythrocytosis [197]. Knock-in mice bearing a similar truncation do not have erythrocytosis but show increased EPO sensitivity [198].

The recent finding that SOCS3 can be recruited to the same region raises the question of whether the effects of these EpoR mutants are due to loss of Shp1 or SOCS binding [59]. Conceivably, Shp1 and SOCS proteins act in combination to negatively regulate the EpoR and possibly other cytokine receptors. Upon activation, JAK2 (and other Janus PTKs) become phosphorylated on two adjacent sites, Y1007 and Y1008. Monophosphorylated Y1007-containing peptides bind SOCS3, but it is unclear (although it is unlikely) if bis-phosphorylated (i.e., pY1007/pY1008) peptides can bind. Perhaps Shp1 first dephosphorylates Y1008, thereby allowing a SOCS protein to bind via pY1007 and mediate degradation (Fig. 3B). An analogous model may explain the positive actions of Shp2 in cytokine signaling. Shp1 also binds to [18] and negatively regulates [120,121] Kit. Loss of this regulation may contribute to the enhanced erythrogenic potential of progenitors from **me** mice.

SHP1 SIGNALING IN EPITHELIAL CELLS

The few studies that have explored Shp1 actions in epithelial cells have yielded surprising results. First, as indicated above, a significant amount of Shp1 appears to be nuclear in these cell types [24,84]. Also, in at least some cell types and signaling pathways, Shp1 may play a positive signaling role [199], although how it does so remains to be determined. Nevertheless, Shp1 clearly plays a negative regulatory role in other epithelial signaling pathways. For example, it binds directly to and dephosphorylates the RTK Ros. Loss of this regulation may help explain the sterility of **me** mice [200].

Signaling by Shp2 and Its Orthologs

Shp2 is also implicated in a wide variety of signaling pathways, yet, unlike Shp1, in most cases it appears to have a positive role. There are, however, exceptions, as described below.

SHP2 IN RTK SIGNALING

In most, if not all, RTK signaling pathways, Shp2 is required for full activation of the Erk MAP kinase pathway.

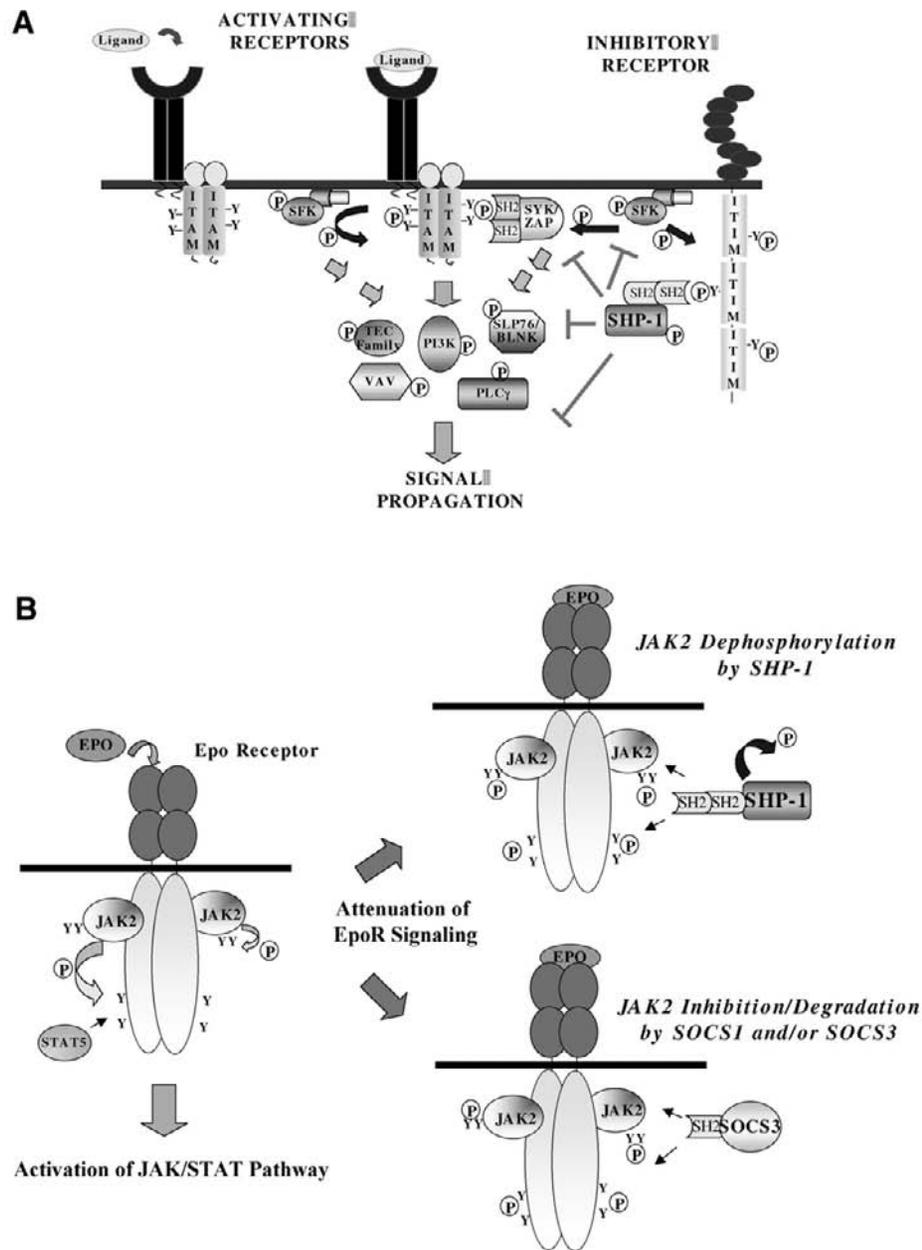

Figure 3 Signaling by Shp1. (A) Regulation of MIRR signaling by inhibitory receptor/Shp complexes. Shown is a typical activating multichain immune recognition receptor (e.g., TCR, BCR, FcR, activating NK receptor) and a typical inhibitory receptor. Upon cell activation, signals from the activating MIRR result in tyrosyl phosphorylation of the inhibitory receptor, which in turn recruits Shp1 (and possibly Shp2 and/or SHIP). Recruitment both localizes and activates the Shp, which then dephosphorylates one or more targets in the vicinity of the activating receptor complex. Possible direct targets are indicated; however, for most pathways, the direct substrates of Shp1 remain unknown or controversial. For many MIRR pathways, cross-linking of inhibitory receptors to activating receptors may be important for inhibitory signaling. (B) Regulation of cytokine signaling. Shown is a model of the EpoR, which couples to JAK2. Upon ligand binding, the receptor-associated PTK becomes activated and phosphorylates the receptor on multiple sites, including the binding site for Shp1. Shp1 may directly dephosphorylate JAK2, leading to its inactivation. However, SOCS proteins also are important for inactivating cytokine receptors. How Shps and SOCS proteins interact to effect negative regulation is unknown. Shown is a highly speculative model in which Shp1 and SOCS proteins might collaborate to negatively regulate cytokine receptor signaling. In this model, Shp1 is responsible for dephosphorylating the adjacent pY1008 on JAK2, thereby allowing an appropriate SOCS protein to bind at pY 1007. For details, see text.

For some RTKs and in some cell types, such as insulin-like growth factor 1 (IGF-1) signaling in fibroblasts, there is virtually no ERK activation in the absence of Shp2; in other RTKs, initial ERK activation is normal, but Shp2 is required for sustained signaling [89,90,127].

Although Shp2 binds directly to some RTKs (e.g., platelet-derived growth factor receptor [PDGFR]), in many other pathways, it binds to one or more scaffolding adapters [201]. For example, Shp2 binds to Gab1 upon EGFR, hepatocyte growth factor (HGF), and FGFR stimulation [202,203], to IRS family proteins following insulin/IGF stimulation [204], and to FRS2 (SUC1-associated neurotrophic factor [SNT]) downstream of the FGFR [205]. Studies using fibroblasts derived from Gab1^{-/-} [206,207] and FRS2^{-/-} [208] mice and experiments with chimeric and mutant forms of scaffolding adapters [209,210] indicate that these scaffolding adapter/Shp2 complexes mediate the effects of Shp2 on ERK activation, at least in some RTK pathways. Genetic analysis of the DER and EGL-15 pathways suggests similar roles for Dos/Csw [124] and Soc-1/Ptp-2 complexes [125].

Despite intensive study, how Shp2 mediates ERK activation remains incompletely understood (Fig. 4A). Cells expressing dominant-negative Shp2 [211] or Ex3^{-/-} fibroblasts [89,134] show defective Ras activation in response to multiple RTKs, indicating that Shp2 acts upstream of Ras. Initial work suggested an “adapter” model, in which Shp2 becomes tyrosyl phosphorylated in response to RTK stimulation and then binds Grb2/SOS [22,212,213]. Although this mechanism may contribute to Ras activation in some RTK pathways, it is unlikely to be generally required, as Shp2 is not tyrosyl phosphorylated in all RTK signaling pathways. Studies of *Xenopus* [214] and *Drosophila* [215] showed no absolute requirement for the C-terminal tyrosyl residues in Sevenless and XFGFR signaling, respectively; an important caveat is that these studies involved overexpression of mutant forms of Csw/Shp2.

Instead, multiple studies indicate that the PTP activity of Shp2 is vital for its positive signaling function. Shp2 dephosphorylates the RasGap binding site on the PDGFR preferentially, which suggested a model in which RasGap is recruited precociously to the PDGFR in the absence of Shp2, thereby limiting Ras activation [216]. Similar findings were reported in studies of Torso (which is structurally related to the PDGFR) signaling [217]. Although this model and these observations are attractive, they cannot provide the entire explanation. Dos (*daughter of sevenless*), a *Drosophila* Gab ortholog, is required for embryogenesis, presumably in Torso signaling, and Csw binding to Dos appears to be essential for this function [218–220]. Gab1^{-/-} fibroblasts and Shp2 Ex3^{-/-} fibroblasts [89,90] also have defective PDGF-evoked Erk activation [206]. Thus, mere recruitment of Shp2/Csw to PDGFR/Torso (and consequent regulation of RasGap binding) cannot account for the role of Shp2 in Ras activation.

One can imagine three general models by which Shp2, acting via scaffolding adapter/Shp2 complexes, might signal to Ras. Shp2 could regulate the phosphorylation of another

site(s) on the scaffolding adapter, controlling binding of an SH2 or PTB domain protein. Alternatively, Shp2 could regulate the phosphorylation of a protein that binds to the scaffolding adapter in either a pTyr-dependent or -independent manner. Finally, the scaffolding adapter could merely target Shp2 to where the substrate resides, presumably a membrane compartment given that scaffolding adapters have membrane-targeting modules such as pleckstrin homology (PH) domains.

Recent data strongly support the third model. The only Tyr residues on Dos required to rescue Dos loss-of-function mutants are the Csw binding sites, thus arguing strongly against Dos itself being the relevant substrate. A Gab1–Shp2 fusion protein can lead to growth-factor-independent ERK activation in mammalian cells and potentiates activation in response to ligand [221]. Fusion of the Gab1 PH domain alone (or several other membrane-targeting sequences) to the PTP domain has a similar effect [221]. Ligation of the N terminus of Src to Csw also produces a gain-of-function mutant [123,124].

What, then, is the key substrate(s) that Shp2 (or its orthologs) must dephosphorylate to mediate Ras (and ultimately, ERK) activation? Cells expressing the Gab1–Shp2 fusion exhibit enhanced Src activity, and Src inhibitors block the ability of the fusion to activate ERK [222]. These findings suggest that Shp2 acts upstream of, and even directly on, Src in the Ras/ERK pathway, an attractive idea as SFKs have negative regulatory C-terminal tyrosyl phosphorylation sites. However, several lines of evidence raise questions about this simple model. First, receptor-like PTP α (RPTP α) is required for most SFK activation, at least in fibroblasts, and PTP α directly dephosphorylates SFK inhibitory Tyr residues [223,224]. It is not clear how Shp2 might fit into this scheme of Src regulation. Conceivably, Shp2 regulates a critical pool of SFKs (or specific SFKs), amounting to only a fraction of total cellular SFK, with PTP α regulating the rest. An intriguing alternative is that Shp2 regulates the recruitment of Csk (the kinase that phosphorylates Y527) to the membrane through PAG/CBP, a transmembrane phosphotyrosyl protein, which can bind Csk upon phosphorylation. The lack of sufficiently sensitive immunoreagents has prevented an adequate test of this possibility. A significant problem with any “Src activation” model of Shp2 action is that several studies have failed to find a role for SFK in RTK-evoked ERK activation [88,225]. Thus, the effects of the Gab–Shp2 fusion on Src activation may not reflect the normal role of Gab1/Shp2 complexes in RTK-evoked ERK activation, but rather an artificial gain of function. It would be interesting to know whether tethering of other PTPs has similar effects on Src and ERK activity in this system.

Although Shp2 clearly regulates Ras/ERK activation, genetic and biochemical evidence indicates other key roles in RTK signaling (Fig. 4A). In the Torso pathway, Csw mutations have far more severe effects than mutation of either Drk (Grb2) or Ras [226]. Epistasis analysis places Csw both upstream and downstream of Raf or in a parallel pathway in Sevenless signaling [123], as well as upstream and downstream of (or parallel to) Ras in the DER pathway [124].

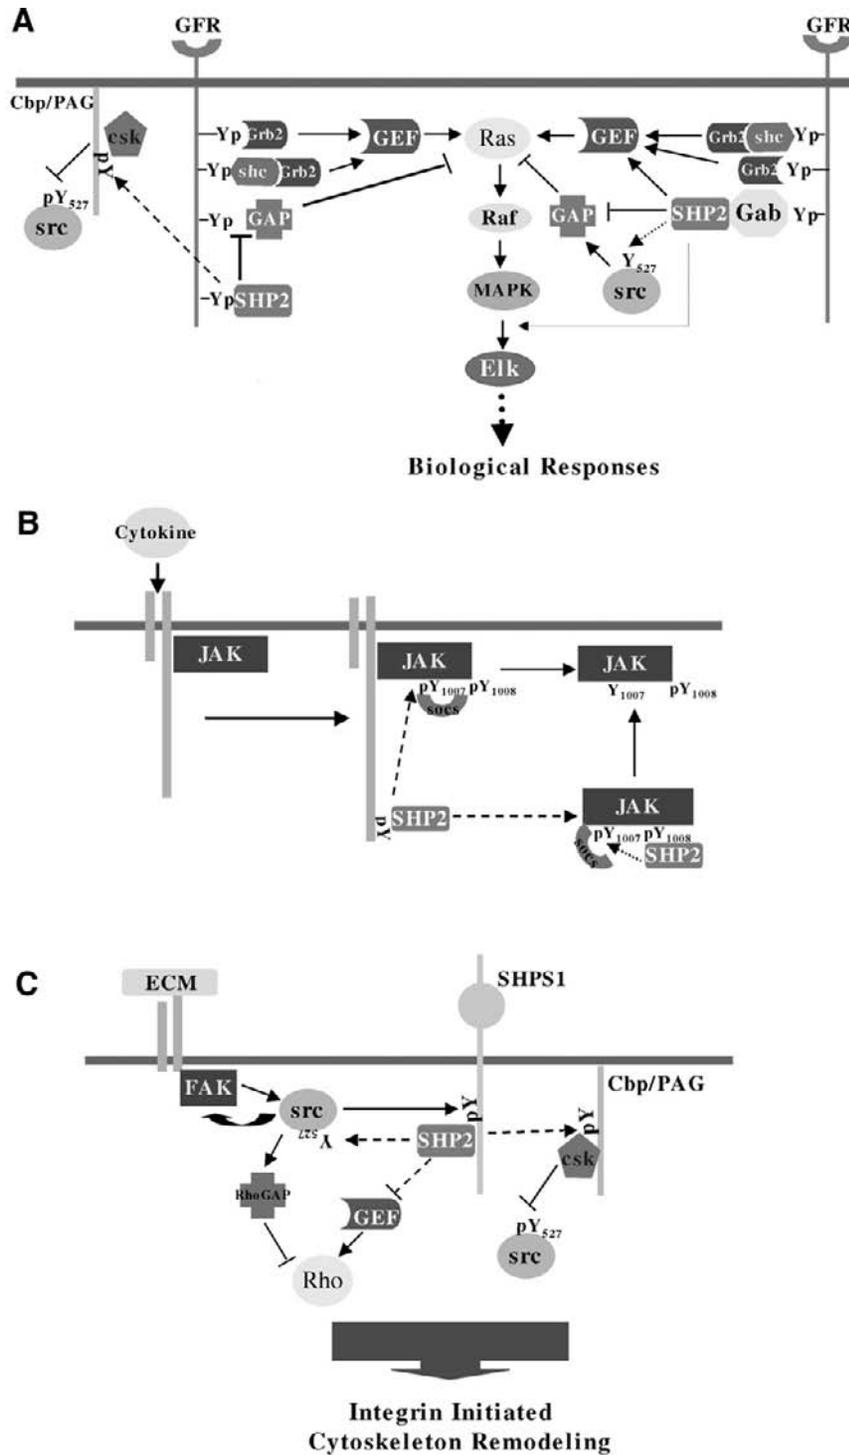

Figure 4 Signaling by Shp2. (A) Role in RTK signaling. Shp2 (and its orthologs) can be recruited directly to some receptors, such as the PDGFR (and Torso). Part of its positive signaling role may involve preventing dephosphorylation of RasGAP binding sites until appropriate signaling has occurred. Shp2 also binds to several scaffolding adapters, such as Gab/Dos, IRS, and FRS-2, and genetic and biochemical studies indicate that scaffolding adapter/Shp2 complexes are critical for the ability of Shp2 to fully activate Ras, even in PDGFR and Torso signaling. The precise targets that Shp2 must dephosphorylate to mediate Ras activation are unknown, as is whether adapter/Shp2 complexes act upstream of Ras exchange factors or RasGAP, or both. Potential direct targets include SFK inhibitory tyrosyl residues or the Csk binding partner PAG/CBP, but none of these has been shown convincingly to be a target. In addition to its role upstream of Ras activation, substantial evidence suggests that Shp2 also is required for some downstream (or parallel) function needed for transcription factor activation. Studies of Csw suggest that, besides its likely function in Ras activation, it may regulate nuclear transport of ERK via the importin β homolog, Dim-7. For details, see text. (B) Role in cytokine signaling. In cytokine signaling pathways, Shp2 may function analogously to its role in RTK signaling. A highly speculative alternative, however, is that Shp2 acts on pY1007 to regulate SOCS protein recruitment and consequent degradation. Note that this model is the converse of that in Fig. 3B. (C) Role in integrin signaling. Upon adhesion to appropriate ligands, Shp2 is recruited to tyrosyl phosphorylated Shps1. Shp2 is required for normal integrin-evoked ERK activation and for control of the cytoskeleton and cell motility. The latter may be mediated via its ability to regulate the small GTPase Rho. However, the extent to which Shps1 participates in each of these signaling pathways remains unclear. Also, unclear are the direct targets of Shp2 in integrin signaling, although several candidate proteins are shown.

The latter function may involve regulation of nuclear import, as Csw associates with the importin β ortholog Dim-7, which controls nuclear transport of the ERK ortholog Rolled [227]. This notion is consistent with the studies of the role of Gab2/Shp2 complexes in cytokine signaling [36]. In some RTK (e.g., PDGFR, IGFR, FGFR) pathways, Shp2 is required for PI3K activation [90,228]. However, in the EGFR pathway, Shp2 has the converse role, negatively regulating PI3K activation by dephosphorylating the PI3K binding sites on Gab1 [90]. Shp2 mutant fibroblasts also exhibit increased c-Jun N-terminal kinase (JNK) activation in response to a variety of stress stimuli [89]. Further studies are required to unravel the molecular details of these actions of Shp2.

SHP2 IN CYTOKINE SIGNALING

Multiple studies also indicate that Shp2 is important for Erk activation in response to a variety of cytokines. Most workers probably assume that Shp2 has a similar mechanism of action (i.e., acting upstream of Ras) and similar targets in cytokine receptor and RTK signaling. However, the possibility of a unique action in cytokine signaling should not be excluded. For example, as indicated above, Janus PTKs undergo dual phosphorylation within their activation loops, with one site (Y1007 in JAK2) being required for binding to SOCS proteins (and thus for degradation). Conceivably, Shp2 might dephosphorylate Y1007, thereby preventing premature access of SOCS proteins to this site (Fig. 4B).

Although there is virtual agreement that Shp2 is a positive regulator of cytokine-evoked ERK activation, its role in cytokine-evoked STAT activation is controversial. Studies using dominant-negative mutants and STAT-dependent transcriptional reporters indicate that Shp2 is required for STAT activation [36,229,230]. Subsequent studies, most of which examined the effects of mutant cytokine receptors unable to bind Shp2, reached the opposite conclusion; namely, that Shp2 negatively regulates the STAT pathway, either by dephosphorylating or inactivating (not activating, as in the model described earlier) Janus PTKs, STAT proteins, and/or STAT binding sites on the receptors themselves [231–234]. The discovery that Shps and SOCS proteins bind to the same sites on several cytokine receptors complicates interpretation of these mutant receptor studies. Nevertheless, interferon α/β (IFN- α/β)-evoked STAT activation is enhanced in immortalized fibroblasts from Ex3^{-/-} mice, consistent with a negative regulatory role for Shp2 on the JAK/STAT pathway [235]. Conceivably, Shp2 might have positive effects on some Janus PTKs and negative effects on others, or it could act on more than one target in cytokine receptor signaling.

SHP2 IN INTEGRIN SIGNALING

Studies of Ex3^{-/-} fibroblasts [236,237] and with dominant negative mutants [237–239] established a role for Shp2 in integrin signaling. Shp2 function is required for integrin-evoked cell spreading, migration, and ERK activation, and Shp2-deficient cells exhibit increased stress fibers.

Consistent with the latter, recent studies indicate that activation of the small G protein Rho, which controls stress fiber formation [240], is enhanced in Shp2^{-/-} fibroblasts [241].

How Shp2 mediates these effects also remains unclear. Shp1 becomes tyrosine phosphorylated following integrin activation, probably by one or more SFKs, and recruits Shp2 [33,237,242], raising the possibility that the effects of Shp2 on adhesion are mediated by Shp1/Shp2 complexes (Fig. 4C). However, studies of fibroblasts from mice lacking the Shp1 cytoplasmic domain reveal a more complicated picture. Whereas Rho activation is enhanced in Shp2 mutant cells, it is inhibited in Shp1 mutants, despite the fact that both types of cells have increased stress fibers and defective migration [155]. The effect of Shp2 on early events in integrin signaling is controversial. Whereas some workers report no effect of dominant-negative Shp2 on FAK tyrosine phosphorylation [239], others have found that phosphorylation is enhanced [238]. Studies on Shp2 mutant fibroblasts also disagree, with one report showing that Shp2 is required for normal integrin-evoked Src and FAK phosphorylation [237], whereas another found no effect on integrin-evoked FAK phosphorylation but a decrease in the rate of FAK dephosphorylation upon de-adhesion [243]. It is unclear whether these discrepancies reflect differences in experimental details and design, reagents, or experimental systems. An interesting possibility is that Shp2 helps to integrate some RTK/integrin signals, as stimulation of the RTK EphA2 was reported to cause Shp2-mediated FAK dephosphorylation and inhibit integrin function [244].

SHP2 IN ANTIGEN RECEPTOR SIGNALING

Upon TCR activation, Shp2 becomes tyrosyl phosphorylated and associates with the scaffolding adapter Gab2 [36,245–247]. Shp2 tyrosyl phosphorylation and association with Gab1 have been reported in B cells [248], although Shp2/Gab2 complexes also form in some B-cell lines [36]. The functional consequences of these interactions remain somewhat unclear. Stable expression of dominant-negative Shp2 in a T-cell line inhibits ERK activation [246]; however, overexpression of Gab2 inhibits TCR-evoked activation of ERK-dependent and nuclear factor of activated T cells (NFAT)-dependent reporters [249,250]. One group found that only the PI3K binding sites were required for this inhibitory effect [249], whereas another observed a requirement for both Shp2 and PI3K binding [250]. Studies of the effects of Gab family-deficient B and T cells should help to resolve these issues.

Shp2 also may mediate some inhibitory receptor signals. Shp2 was reported to bind the CD28 family member CTLA-4 and dampen TCR activation, most likely by dephosphorylating TCR-associated kinases [50]. The purported binding site for Shp2 on CTLA-4 is quite atypical, raising questions as to whether Shp2 binds directly to CTLA-4. Moreover, subsequent studies indicate that the Shp2 binding site is dispensable for CTLA-4-mediated inhibition [251–253]. The inhibitory receptor PD1 contains two potential ITIMs, and

a chimera between the extracellular domain of Fc γ RIIB and the intracellular domain of PD1 inhibits BCR activation upon co-crosslinking. Shp2, but not Shp1 or SHIP, binds the chimeric receptor, implicating Shp2 as the mediator of inhibitory signaling [254]. Because Shp2 binding sites can overlap with those of other inhibitory molecules, such as SOCS proteins, confirmation using dominant-negative, RNAi, or B-cell-specific knockout approaches is desirable. Shp2 also is implicated in inhibitory signaling by CD31 (PECAM-1) in B cells [255] and platelets [256]. Finally, Shp2 binds to several other inhibitory receptors, most of which also bind Shp1 [31]. Whether or not Shp2 has a role in mediating these inhibitory signals remains unknown.

Determinants of Shp Specificity

Shp1/Shp2 chimeras have been used to probe the determinants of Shp specificity in *Xenopus* [214] and mammalian cell [257] systems. These studies show that both the SH2 and the PTP domains contribute, and, surprisingly, the PTP domain contains the more critical specificity determinants. Even more surprisingly, the C-tails, which differ the most among Shps, do not confer specificity, at least in these systems. This suggests a combinatorial model of Shp specificity, whereby the SH2 domains direct Shps to appropriate cellular locations and the PTP domain then selects appropriate substrates.

Recent work has begun to address how the PTP domain selects substrates. Only the PTP domain of Shp1 has been co-crystallized with relatively “good” and “poor” substrate peptides [258,259]. These structures suggest that the α 0 helix and the loop α 1/ β 1, α 5–loop– α 6, and β 5–loop– β 6 motifs make contacts with bound peptides. The residues in the α 1/ β 1 motif involved in binding are identical in Shp1 and Shp2, whereas the two Shps have only relatively minor differences in the β 5–loop– β 6 and α 5–loop– α 6 motifs. Thus, the more divergent α 0 helices may be of greatest importance in determining differences in substrate specificity.

There are several caveats to this interpretation. First, these studies predict that hydrophobic residues should be preferred at the Y–2 position, which conflicts with combinatorial library approaches that assigned acidic amino acids as the preferred Y–2 residues [260]. Second, the WPD loop, which contains the general acid critical to all PTP catalysis [261], remained open in these co-crystals, raising questions as to whether they represent authentic views of enzyme/substrate complexes. Third, the enzyme–peptide contacts extend at least four residues to either side of the pTyr; conceivably, additional interactions important for specificity may extend even further and thus would have been missed. Finally, it remains possible that specificity is not due to *bona fide* differences in substrate preferences between Shp1 and Shp2, but instead reflects the higher intrinsic catalytic rate of the Shp1 PTP domain [262–265]. Additional structural, biological, and biochemical studies will be required to resolve these issues.

Shps and Human Disease

The most exciting recent discovery about Shps has been the finding that Shp2 mutations occur in \approx 50% of the cases of Noonan syndrome (NS) [266]. NS is a fairly common (incidence \approx 1:2000 births), autosomal-dominant disorder characterized by abnormal facies featuring a broad forehead, downward-slanting palpebral (eyelid) fissures, low-set ears, and hypertelorism (abnormal distance between paired organs, such as the eyes); a webbed neck resembling that observed in Turner syndrome; proportionate short stature; and cardiac abnormalities, most frequently pulmonic stenosis and hypertrophic cardiomyopathy. Chest and spine deformities, mental retardation, delayed puberty, cryptorchidism, and bleeding diathesis occur with variable penetrance [267–270]. Also, case reports have noted a possible association between NS and increased incidence of malignancy, notably leukemia [271–274].

Nearly all NS mutations are found in either the N-SH2 or PTP domains and involve residues that participate in basal inhibition of PTP activity (Fig. 2B). For example, one NS mutation is D61G, and another is E76D; by means of biochemical and biological assays, quite similar mutations (D61A, E76K) were shown to be activating mutants [71]. Together with molecular modeling studies [266], and the autosomal dominant inheritance pattern, these results strongly suggest that activating mutations of Shp2 are the cause of a substantial number of NS cases.

Recently, other NS-associated mutations have been identified that fail to conform to this simple model [275]. One (D106A) occurs in the linker between the N-SH2 and C-SH2 domains; this mutation might kink the N-SH2, thereby disrupting its ability to mediate basal repression and resulting in a novel type of activated mutant. Two other mutations—one in the N-SH2 (T42A), the other in the C-SH2 (E139D)—are more difficult to explain. Both involve residues in the SH2 domain pTyr-peptide-binding pocket. Conceivably, T42A mimics N-SH2 domain engagement by a pTyr peptide and thereby prevents binding of the backside of the N-SH2 to the PTP domain. However, the C-SH2 does not make direct contact with the catalytic cleft, and the role of the C-SH2 domain in direct enzyme activation remains controversial. If, as suggested [73], phosphorylated Y580 can activate Shp2 by engaging the C-SH2, E139D might act as if it is similarly engaged. Additional enzymatic and biological studies are required to resolve this issue.

The precise mechanisms and pathways by which Shp2 mutations cause the various NS abnormalities remain to be elucidated, but previous studies yield several clues. The cardiac abnormalities, particularly the valve defects, probably stem from abnormal regulation of the EGFR (and other EGFR family) signaling pathways [276], whereas the facial and skeletal abnormalities are reminiscent of activating mutations in FGFR signaling pathways [277]. Proportionately shortened stature may be due to defective GH and/or IGF-1 signaling. The origins of the cognitive and coagulation abnormalities are less clear and may reflect the role of Shp2

in several signaling pathways. Modeling NS by gene knock-in approaches should help to resolve these issues.

The genetic basis of the other 50% of NS cases remains to be defined. At least some cases of NS exhibit autosomal recessive inheritance [278]. Others are autosomal dominant but unlinked to the Shp2 locus [275]. Clues to the identity of some of these may be provided by rare chromosomal translocations that have been associated with NS [279]. Identifying these genes is of great importance, as they may encode key Shp2 substrates and regulators. However, recent studies indicate differences between the spectrum of abnormalities in NS patients with and without Shp2 mutations [275], so it remains possible that cases of NS caused by mutations in genes other than Shp2 actually represent a different disorder.

Inappropriate activation of Shp2 also appears to be important in bacterial pathogenesis. *Helicobacter pylori*, the major cause of gastric ulcer and carcinoma worldwide, encodes a number of virulence determinants, one of which, CagA, becomes tyrosyl phosphorylated in infected cells. Recent studies indicate that tyrosylphosphorylated CagA recruits and activates Shp2. Shp2 binding is essential for the morphological effects of CagA on gastric epithelial cells, which are similar to the effects of HGF. Remarkably, previous studies established a critical role for Gab1/Shp2 binding in mediating the morphogenetic effects of HGF in epithelial cells [209, 210]. It remains to be seen whether overexpression of scaffolding adapters that bind Shp2 or somatic activated mutants of Shp2 are involved in *H. pylori*-negative gastric cancers and/or other malignancies.

At least one Shp2-binding protein probably does play an important role in human disease; Gab2 is a critical determinant of the lineage (myeloid vs. lymphoid) and severity (latency) of Bcr-Abl-evoked leukemia [280]. Gab2^{-/-} cells expressing Bcr-Abl exhibit defective activation of the PI3K/Akt and ERK pathways; although the former probably reflects Gab2 binding to PI3K, defective ERK activation may be due to failure to recruit Shp2. Because Gab2 is overexpressed in a significant number of breast cancers [281], it may play a wider role in carcinogenesis.

The jury remains out on whether Shp1 deficiency plays a causal role in human disease. EpoR mutations that result in loss of Shp1 binding are associated with familial erythrocytosis, but it is unclear whether loss of Shp1 binding (or Shp1 binding alone) is important. Shp1 deficiency was implicated in the pathogenesis of polycythemia vera [282], but these findings are in dispute [283]. Markedly decreased Shp1 expression has been reported in human lymphoma [284], HTLV-1-induced leukemia [191], and Sezary syndrome [285], suggesting a possible role for Shp1 in suppressing these malignancies. The mechanism and physiological consequences of decreased expression are not known.

On the other hand, several human pathogens may hijack Shp1 to help suppress the host immune response and/or to effect tissue damage. Binding of Shp1 to CD46, the measles virus receptor, in macrophages, is associated with the production of IL-12 and nitric oxide [286]. The Opa52 protein

produced by *Neisseria gonorrhoeae*, binds to CEACAM (CD66a) on primary CD4⁺ T cells. This leads to recruitment of Shp1 and Shp2 and suppression of T-cell activation and proliferation [287]. Finally, elevated levels of Shp1 and Shp2 are associated with congenital neutropenia [288], although whether or not the Shps play a causal role in this disorder remains unclear.

Summary and Future Directions

Substantial progress has been made since the discovery of Shps in the early 1990s. We know many of the pathways in which Shps participate and the biological consequences of loss-of-function and, in the case of Shp2, gain-of-function mutations in Shps. Shp structures have been solved to atomic resolution, and the basics of regulation of Shp activity are well understood. Still, many important questions remain. Chief among these is the identification of the proximate targets of each of the Shps. We also do not understand Shp specificity in detail, and questions remain about the role of phosphorylation and, indeed, the C-tail (and, for Csw, the PTP insert) domain in general. Finally, it remains to be seen whether mutations in human Shps themselves or in Shp binding proteins other than Gab2 play causal roles in diseases such as autoimmunity and cancer. With the availability of powerful technologies such as inducible and tissue-specific knockout mice, RNAi, and substrate-trapping mutants, answers to these and other questions about the Shp subfamily should be found soon.

Acknowledgments

Work in the authors' laboratories is supported by NIH R01 CA49152, DK50693, and P01 DK50654 (to B.G.N.) and AI 51612 (to H.G.) L.P. is the recipient of a postdoctoral fellowship from The Medical Foundation. Insulin Receptor PTP: PTP1B

Alan Cheng and Michel L. Tremblay

*McGill Cancer Center and Department of Biochemistry,
McGill University, Montreal, Quebec, Canada*

Introduction

The dramatic increase in obesity and diabetes mellitus is reaching epidemic proportions and emphasizes our need to understand the mechanisms that coordinate body composition and energy metabolism. In humans, diabetes is characterized by an inability to maintain glucose homeostasis due to perturbations in insulin secretion (Type I) and/or signaling (Type II). Over 90% of diabetic patients exhibit resistance to insulin action, and it is well accepted that the molecular defect for this occurs at a level of postreceptor signaling [1]. The insulin receptor (IR) is a transmembrane tyrosine kinase that becomes activated upon ligand binding. This leads to subsequent tyrosine phosphorylation of its substrates, which in turn activate downstream signaling cascades [2]. Although several mechanisms for attenuation of insulin signaling are known, it has long been suggested that protein tyrosine phosphatases (PTPs) that dephosphorylate the IR play a key role in this aspect [3]. One such PTP, protein tyrosine phosphatase 1B (PTP1B), is well established in the insulin signaling pathway and has attracted immense interest as a target for pharmaceutical companies. This review focuses on the biological function of PTP1B, its known modulation, the substrates that it recognizes, and the signaling pathways that it controls.

PTP1B as a *Bona Fide* IR Phosphatase

PTP1B is the prototype for the superfamily of PTPs and was initially thought to indiscriminately dephosphorylate phosphorylated tyrosine residues (a housekeeping function) [4]. Although it is widely expressed in most cell types, it is one of the few identified PTPs found in the major tissues controlling insulin-mediated glucose metabolism (liver, muscle, fat). It has long been known that PTP1B can

dephosphorylate the activated IR and attenuate insulin signaling and its biological effects [3]. Within the IR, three tyrosine phosphorylation sites (pTyr1146, 1150, 1151) are involved in the binding to PTP1B [5–7], although structural and kinetic studies suggest that PTP1B has a preference for the tandem tyrosine phosphorylated motif (pTyr1150, pTyr1151) [8]. One issue that remains is where the action of PTP1B actually occurs within the cell. Although PTP1B is predominantly localized to the endoplasmic reticulum (ER) and the IR at the plasma membrane, recent data suggest that its action on receptor protein tyrosine kinases requires endocytosis of the receptors to intracellular sites that coincide with ER markers [9].

The *in vivo* confirmation for the role of PTP1B in insulin signaling was first established with knockout mice [10,11]. Evidently, PTP1B is not required for embryonic development, and no gross histological abnormalities have been observed in PTP1B-deficient mice. However, loss of PTP1B results in increased insulin sensitivity. PTP1B-deficient mice maintain moderately lower glucose levels at half the circulating insulin levels, compared to wild-type controls. Loss of PTP1B also results in the ability to maintain lower glucose levels during an insulin or glucose-tolerance test. This increased insulin sensitivity is even more evident when PTP1B-deficient mice are challenged to an insulin-resistant state by a high-fat diet, indicating that PTP1B plays a role in insulin resistance. Thus, PTP1B could be a promising target for the therapeutic treatment of Type II diabetes.

At the molecular level, PTP1B-deficient mice display an enhanced and/or prolonged ligand-dependent IR phosphorylation in liver and muscle tissues. Interestingly, this increased IR phosphorylation has not been observed in fat tissue, suggesting that other PTPs may play a crucial role in IR dephosphorylation there. Perhaps regulation of insulin signaling by PTP1B is tissue specific. For example, in 3T3-L1 adipocytes, over-expression of PTP1B does not affect

insulin-stimulated Akt activation or glucose uptake [12], whereas over-expression of PTP1B in L6 myocytes and Fao hepatoma cells attenuates insulin-induced Akt activation and glycogen synthesis [13].

Widespread genetic ablation of PTP1B in mice unequivocally demonstrates the importance of this enzyme in insulin signaling and glucose homeostasis. However, an emerging and exciting concept is that central insulin signaling [14], in addition to peripheral insulin signaling, also plays a key role in whole body metabolism. Because PTP1B-deficient mice seem to display tissue-specific insulin specificity, it will be intriguing to see if PTP1B contributes to central insulin signaling as well.

PTP1B Gene Polymorphisms and Insulin Resistance

The human PTP1B locus maps to chromosome 20 in the region q13.1–q13.2 [15] and its mouse ortholog to the syntenic H2–H3 region of chromosome 2 [16]. Interestingly, this region was also identified as a quantitative trait loci (QLT) linked to insulin and obesity [17]. Consistent with a role for PTP1B in insulin resistance, single nucleotide polymorphisms have been found within the coding [18,19] or 3' UTR region [20] that are associated with diabetic parameters.

Insulin-Mediated Modulation of PTP1B

Not only does PTP1B act on and modulate the IR, but recent evidence suggests that the reverse is also true. Insulin stimulates phosphorylation of PTP1B on both serine and tyrosine residues, although their effects on PTP1B are not entirely clear. In Rat1 fibroblasts over-expressing human IRs, insulin stimulation results in tyrosine phosphorylation of PTP1B on three sites (Tyr66, Tyr152, Tyr153) crucial for its binding to the IR [5]. Furthermore, this also increases the activity of PTP1B [21], thus providing a potential negative-feedback loop to prevent prolonged insulin signaling. On the other hand, insulin stimulation of muscle and fat tissue also results in PTP1B tyrosine phosphorylation; however, this seems to decrease PTP1B activity [22].

An insulin-mediated decrease in PTP1B activity also occurs via Ser50 phosphorylation by Akt and impairs its ability to dephosphorylate the IR [23]. PTP1B is also phosphorylated on other serine residues by enzymes such as protein kinase C (PKC) or protein kinase A (PKA) [22,24], thus it will be intriguing to discover how both tyrosine and serine phosphorylation regulate PTP1B in a temporal fashion.

Reversible oxidation of the invariant cysteine in the catalytic center of PTPs is also becoming an emerging theme for their regulation. In fact, insulin-stimulated hydrogen peroxide production is thought to temporarily inactivate PTP1B to promote insulin signaling in 3T3-L1 adipocytes [25].

Genetic Evidence for Other PTP1B Substrates

From biochemical and cell culture studies, many potential PTP1B substrates have been identified; however, only a few to date have been found to be hyperphosphorylated in PTP1B-deficient cells, suggesting that only a subset may represent important PTP1B substrates. These are described in brief below.

Src

In addition to the IR, the adaptor protein p130Cas was one of the first candidate substrates for PTP1B [26], implicating the phosphatase in both integrin signaling [27] and transformation [28]. However, p130Cas is not hyperphosphorylated in PTP1B-deficient fibroblasts during fibronectin signaling, thus raising the possibility that this function might be redundant or nonphysiological. Nevertheless, at least in immortalized cells, PTP1B does seem to be a positive regulator of fibronectin signaling, possibly via dephosphorylation of the inhibitory site (Tyr527) of Src [29]. This is, in fact, in agreement with the previous studies in L cells [30] and breast cancer cell lines [31].

IGF-IR

Previous studies have implicated PTP1B in insulin-like growth factor I (IGF-I) signaling. By virtue of similarity between the IR and IGF-IR, this seems quite expected. In particular, the tandem-phosphorylated tyrosines found in the IR are also found in the IGF-IR. Indeed, loss of PTP1B in immortalized fibroblast cells leads to increased IGF-I-mediated receptor phosphorylation, Akt activation, and increased cell survival under apoptotic stress [32]. Interestingly, though, IGF-I-mediated Erk activation is significantly diminished in the absence of PTP1B, despite the enhanced IGF-IR phosphorylation and Akt activation. One possibility is that the positive effects of PTP1B on Src may contribute to this impaired Erk activation. It is also possible that PTP1B may regulate other pathways leading to Erk activation that have yet to be identified.

JAK2

PTP1B-deficient mice are resistant to diet-induced obesity and display lower leptin levels than their wild-type counterparts. Leptin is a peptide hormone that regulates adiposity primarily by inhibiting food intake and increasing energy expenditure. Despite the fact that PTP1B-deficient mice exhibit lower leptin levels, their food intake is not dramatically affected, suggesting that perhaps they present enhanced leptin sensitivity. Indeed, preliminary results suggest that PTP1B-deficient mice are more sensitive to the effects of exogenously administered leptin [33,34]. This provides one mechanism for the obesity resistance of the PTP1B knockout mice and suggests that PTP1B would also be a likely target for treating obesity due to leptin resistance.

Based on the findings that PTP1B preferentially acts on the tandem phosphorylated tyrosines on the IR, it was soon realized that there might be additional proteins with a similar PTP1B-binding site. Indeed, both Janus tyrosine kinase 2 (JAK2) and tyrosine kinase 2 (TYK2), which possess tandem tyrosine-phosphorylated residues, were found to be hyperphosphorylated in PTP1B-deficient fibroblasts upon interferon stimulation [35]. At the same time, using the PTP1B knockout mice, we and others independently found that JAK2 is a key substrate whereby PTP1B negatively regulates leptin signaling [33,34].

Concluding Remarks

Several laboratories have now documented multiple physiological PTP1B substrates, from the initial hypothetical housekeeping function in cells to unique IR dephosphorylation. PTP1B appears to modulate a class of substrates that preferentially but not exclusively include tandem tyrosine-phosphorylated proteins. The substrate specificity of PTP1B can therefore be thought of as a combination of its catalytic domain structure and the potential contribution of its proline-rich domains to bind associated-proteins, as well as spatial and temporal regulation. It is intriguing that PTP1B controls signaling pathways downstream of two major regulators of metabolism (i.e., insulin and leptin). Yet, the PTP1B-deficient mice are well and thriving. One potential view could be that this enzyme is part of a core of signaling molecules that are responsible for sensing and responding to basic metabolic survival needs. A potential model could be that, in a stress period, an increase in expression (or activation) of PTP1B would be protective and contribute to survival. For example, it stands to reason that in a period of food deprivation, PTP1B activity would be extremely useful. By its action on the IR, animals decrease their glucose uptake and thus prevent hypoglycemia. Similarly, during starvation conditions, PTP1B action on leptin signaling would reinforce hunger and the need to seek food. These phenomena are reversed in the PTP1B-deficient mice. Together, they provide us with a glimpse of the complex signaling events that must be investigated in order to understand all the prospective benefits of PTP1B inhibitor therapies.

Low-Molecular-Weight Protein Tyrosine Phosphatases

Robert L. Van Etten

Department of Chemistry,
Purdue University, West Lafayette, Indiana

Introduction

The eukaryotic low-molecular-weight protein tyrosine phosphatases (LMW PTPases) are cytoplasmic enzymes with molecular weights of approximately 18,000. This family of PTPases shares no sequence identity with the various high-molecular-weight (HMW) families except for the CXXXXXR signature sequence of the phosphate binding site (Fig. 1). In the HMW PTPases, the conserved signature sequence, HCXAGXGR(S/T), is typically found in the C-terminal third of the protein, while in the LMW PTPases the related invariant motif XCXGNXCRS is found close to the N terminus [1,2]. This motif forms the phosphate binding loop (P-loop). The P-loop peptide backbone in LMW PTPase has effectively the same structure as that found in a representative HMW PTPase from *Yersinia*, with C α positions exhibiting only 0.37-Å root mean square deviation [3,4]. Thus, despite apparent differences in the consensus sequences, the phosphate binding regions of these proteins are surprisingly similar.

Bovine liver and brain and human red cell, liver, and placenta enzymes were among the first to be extensively characterized. A LMW PTPase was partially purified from bovine liver [5] and characterized as an acid phosphatase due to its apparent optimal activity at pH 5 when assayed with *p*-nitrophenyl phosphate (*p*NPP). The LMW enzymes from bovine liver and heart and human placenta and liver were later purified to homogeneity and shown to exhibit catalytic activity *in vitro* toward phosphotyrosyl substrates [6–11]. The bovine enzyme was the first to be cloned and expressed [12]. The use of this clone opened the way to a critical advance when the human placenta and red cell isoenzymes

(HPTP-A and -B) were purified, cloned, sequenced, and shown to be identical and expressed in all human tissues [13]. The enzyme was also shown to be active against several phosphotyrosyl substrates [11,14]. Subsequently, many other putative LMW PTPases from eukaryotic and prokaryotic organisms have been identified. The predicted proteins generally share a high level of amino acid sequence identity in addition to the active site consensus sequence that is characteristic of LMW PTPases. However, reflecting recent rapid advances in DNA sequencing, many of the putative gene products have not been expressed, purified, and characterized.

The human red cell enzyme (red cell acid phosphatase) was the first enzyme shown to be genetically polymorphic and, as a result, the associated ACP1 gene and gene products assumed important roles as genetic markers [15,16]. The human enzyme and some other eukaryotic LMW PTPases were known to exist as isoenzymes that could be separated on the basis of their electrophoretic mobility [17]. The ACP1 gene has been localized to chromosome two (2p25) by fluorescence *in situ* hybridization (FISH), and the majority of the gene has been sequenced [18]. Two major human isoenzymes occur, and they differ only in the sequence of 34 amino acids from residues 40 to 73 (Fig. 2). The human LMW phosphatase gene is comprised of seven exons interrupted by six introns [19]. Two alternatively spliced exons, 114 bp in length, encode the 34-amino-acid variable region sequence. These exons are separated by a short 41-bp intron [18,20]. RNA blot hybridization analysis has shown that the human LMW PTPase is present in all human tissues, thus the name “red cell acid phosphatase” is inappropriate [13]. Two isoenzymes are also present in *Drosophila* retina and in chicken and rat brain, where they have been suggested to be associated with

Figure 1 Phosphate binding loop of several of LMW PTPases compared with other PTPases. The active site motif of the LMW PTPases is V/ICXGNI/FCRSP. The first Cys is the active-site nucleophile, Arg is essential for substrate binding and catalysis, Ser serves a role in stabilizing the thiolate form of the nucleophile, and the side chain of Asn plays a critical structural role in altering the main-chain conformation such that a backbone NH is pointed into the P-loop so that it can more effectively bind substrate and transition-state structures. In other PTPases, this function is served by the presence of a second glycine.

The shaded region corresponds to a 34-amino-acid segment that differs in human isoenzymes A and B and is the result of alternative mRNA splicing.

neurogenesis or synaptic function [21–23]. Other clinical and genetic studies suggest that the *ACPI* gene locus may be associated with a number of developmental and hemolytic disorders, including hemolytic favism, megaloblastic anemia, Alzheimer's disease, and even malaria, but direct causal relationships have not been demonstrated.

Structures of LMW PTPases

The crystal structure of bovine protein tyrosine phosphatase (BPTP) has been determined to 1.9 Å, and the solution structure was simultaneously established by isotope-edited, multidimensional nuclear magnetic resonance (NMR) [24–27]. Crystal structures of the human isoenzyme A (the fast isoelectric form) and the *Saccharomyces* enzymes have also been published [28,29]. The structure of BPTP consists of a four-stranded central parallel β -sheet with α -helices flanking both sides (Fig. 3). The overall structure of BPTP resembles a classical dinucleotide binding or Rossmann fold, with two right-handed $\beta\alpha\beta$ motifs. The variable region (which distinguishes the two human isoenzymes) exists as two extended loops connected by a short segment of α -helix. These loops wrap around the active site and appear positioned to play a role in substrate specificity.

The phosphate binding site of BPTP exists as a loop connecting the first β -strand and the first turn of the α -helix. The phosphate molecule sits at the center of this loop, positioned near the N-terminal end of α_1 , and embraced by the side chains of Cys 12 and Arg 18 (Fig. 4). Backbone and side-chain NHs from residues 13 to 18 provide multiple hydrogen bonds to each of the three oxygens of the phosphomonoester. These serve to tightly position the phosphate at the active site while the rigid geometry of the P-loop enforces even stronger hydrogen bonding interactions in the trigonal bipyramidal transition state [30]. Mutagenesis of Arg 18 to Ala completely abolishes catalytic activity, consistent with a critical electrostatic role [31,32]. The side chain of Cys 12 is directly centered between the three oxygens on the tetrahedral face of the phosphate ion, in an optimal position for an S_N2 displacement on phosphorus [12,24,31]. Figure 3 also shows the location of Asp 129, a catalytically essential general acid catalyst, at the entrance to the active site [33]. This group serves to protonate the leaving group oxygen.

The high-resolution structures of human, bovine, and yeast LMW PTPases show several extended hydrogen bond networks that participate in structural roles and in catalysis (Fig. 4). The conserved arginine (Arg 15), histidine (His 72), and two serines (Ser 19 and 43) are at or near the active site. His 72, Ser 19, and Ser 43 interact with the Asn 15 residue of the active-site loop. The interaction of these residues with Asn 15 stabilizes the left-handed α -helical conformation of the latter residue and modifies the structural orientation of the backbone so that the NH groups in the active site P-loop are oriented toward the phosphate ion. Asn 15, Ser 19, His 72, and to a lesser extent Ser 43 serve important structural roles

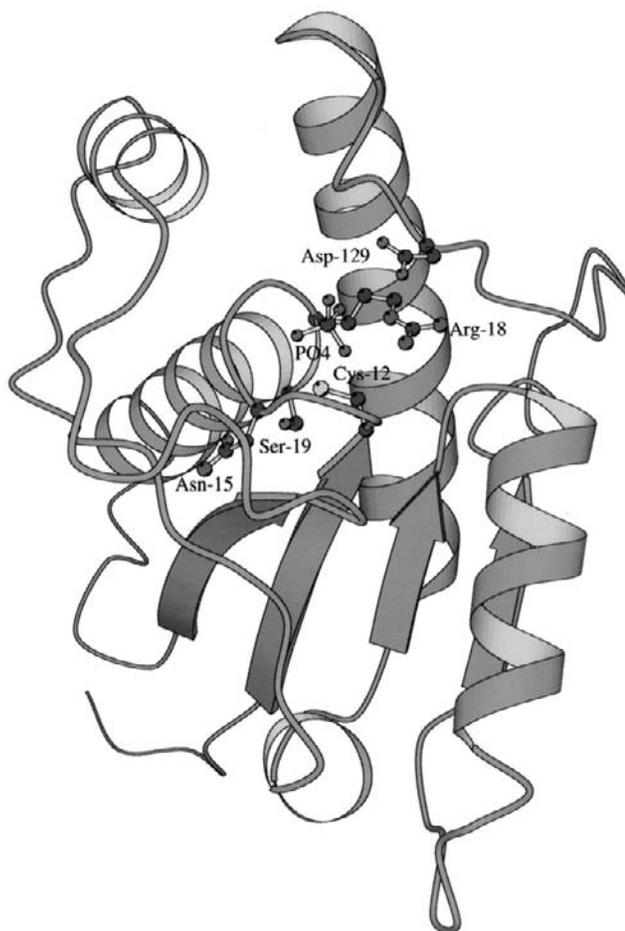

Figure 3 Ribbon diagram of bovine protein tyrosine phosphatase (BPTP). The structure of BPTP consists of a four-stranded central parallel β -sheet with α -helices flanking both sides [24]. A phosphate ion is shown at the active site, together with the locations of the active site general acid (Asp 129) and nucleophile (Cys 12). (Residue numbering is for the human and bovine enzymes.) The phosphate binding site (P-loop) is positioned at the N-terminal end of the prominent $\alpha\alpha_1$ -helix.

in stabilizing the geometry of the active-site loop region for optimal substrate binding and catalytic activity [34,35]. The hydroxyl group of Ser 19 is in very close proximity to Cys 12 (2.98 Å) and forms a hydrogen bond with the thiolate anion. Mutagenesis, pH dependence studies, leaving group dependence studies, partition experiments, and computational results all support the conclusion that the hydrogen bond to Cys 12 is a significant factor in causing the unusually low pK_a (<4) of this nucleophilic residue [32,35].

In solution and in certain crystal structures, the LMW PTPases can form dimers involving protein side chains located at the active site region [36,37]. The physiological significance of these interactions remains to be established.

Catalytic Mechanism

The chemical mechanism of catalysis by LMW PTPases has been studied extensively. Early experiments using chiral phenyl-[^{16}O , ^{17}O , ^{18}O] phosphate demonstrated that transfer to

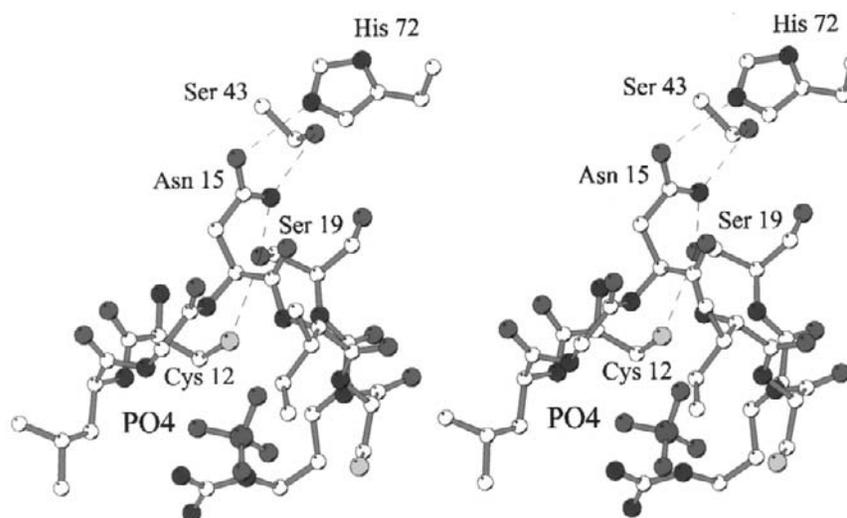

Figure 4 Phosphate binding loop of BPTP. Stereo view of the active site of BPTP shows the position of a bound phosphate ion together with residues Ser 19, Ser 43, and His 72, which interact with Asn 15 to stabilize the conformation of the active-site P-loop. The phosphate binding site is viewed from the rear.

an acceptor alcohol occurs with complete retention of configuration around phosphorus [38]. Thus, the overall catalytic pathway is consistent with a double displacement mechanism in which both phosphorylation and dephosphorylation proceed with inversion of configuration at phosphorus. The existence of a phosphoenzyme intermediate during hydrolysis of phosphate monoesters has been confirmed by a variety of methods such as pre-steady-state and steady-state kinetic measurements as well as ^{18}O -exchange experiments, ^{31}P NMR and direct trapping [12,39]. Burst titration kinetics and leaving group dependence experiments also show that the reaction occurs via a two-step mechanism. The first step is a relatively rapid transfer of the phosphate group from the substrate to form a cysteinyl phosphoenzyme intermediate. Proton inventory experiments and D_2O solvent isotope effects indicate that only one proton is “in flight” in the transition state of the phosphorylation step [40]. This step is followed by a rate-limiting dephosphorylation in which water attacks the phosphoenzyme intermediate with the release of inorganic phosphate [40].

The human and bovine LMW PTPases contain eight cysteine residues, all in the free sulfhydryl form [41]. Cys 12 mutants are completely inactive, consistent with the identification of Cys 12 as the catalytic nucleophile [31]. In contrast, C17S and C17A represent 5 and 30%, respectively, of the activity of wild-type enzyme. Thus, it is clear that although the loss of Cys 17 may cause some reduction in enzyme activity, the residue is not critical for catalysis, in contrast to artifactual results obtained for a maltose-binding fusion protein [42]. However, C17 may play a role in enzyme regulation [43].

Bovine LMW PTPase is inactivated by diethyl pyrocarbonate (DEP), and the inactivation is reduced in the presence of inorganic phosphate [44]. However, neither of the two histidines present in the protein is located at the active

site, and they are not essential for catalysis. Indeed, a mutant lacking histidine is still inactivated by DEP, thus showing that DEP is not a histidine-specific reagent [34]. NMR pH titration studies revealed that His 66 and His 72 have unusually high pK_a values of 8.4 and 9.2, respectively [34,45]. The three-dimensional structure of BPTP reveals that two acidic residues (Glu 23 and Asp 42) are found near His 72, and one acidic residue (Glu 139) is located near His 66 [24]. pK_a perturbation studies utilizing site-directed mutants of the acidic residues together with computational approaches confirm that electrostatic interactions are responsible for the unusually elevated pK_a values of the histidine residues [32,46].

Inhibitors and Activators

Low-molecular-weight PTPases are strongly inhibited by common PTPase inhibitors such as vanadate, molybdate, and tungstate, but not tartrate and fluoride [10]. It was previously proposed that the early transition metal oxoanions such as vanadate and molybdate bind to many phosphomonoesterases because they form complexes that resemble the trigonal bipyramidal geometry of the $\text{S}_{\text{N}}2$ transition state [47]. This was confirmed for the LMW PTPases by the crystal structure of the vanadate complex of the bovine enzyme, which showed that vanadate ion forms a covalent linkage with Cys 12 at the active site and exhibits a trigonal bipyramidal geometry [30]. Pyridoxal phosphate (PLP) binds tightly to LMW PTPases and can even act as a competitive inhibitor of a good substrate. However, PLP is in fact a slowly reacting substrate, because the pyridinium nitrogen of PLP forms a salt linkage to Asp-129 and prevents it from acting as a general acid in catalysis [48]. Despite a claim to the contrary, Cys 17 plays no significant role in the binding of PLP to the bovine LMW PTPase [49].

LMW PTPases are activated in an isoenzyme-selective manner by certain purines [50–53]. Structural studies with the homologous *Saccharomyces* enzyme have established that the purine effector binds to the phosphoenzyme covalent intermediate and facilitates dephosphorylation [54]. However, the physiological significance of such purine activation effects is uncertain, because activation is seen at purine concentrations well above normal cellular levels. Compounds such as sodium nitroprusside that generate NO and NO itself are able to inactivate LMW PTPases *in vitro* [55]. Mass spectrometry has confirmed that the NO modifies Cys 12 and Cys 17 at the active site. This result may be of regulatory significance.

Substrate Specificity, Regulation, and Biological Role

A number of synthetic and biological substrates have been used to investigate the catalytic mechanism and substrate specificity of the LMW PTPases. These enzymes demonstrate strong catalytic activity toward phosphotyrosyl but not phosphoserine or phosphothreonine substrates [10]. They also show a steric preference with certain aryl phosphates. For example, these enzymes hydrolyze β -naphthyl phosphate at a rate that is comparable to the rate of hydrolysis of *p*NPP but show very low activity toward α -naphthyl phosphate, thus reflecting the sensitivity of these enzymes to steric factors. These enzymes generally do not hydrolyze alkyl phosphates, with the exception of substrates such as flavin mononucleotide (FMN) that have significant hydrophobic substituents as part of their structure [10]. The reason for the latter selectivity is clear from the x-ray crystal structure. The side chains of Trp 49, Tyr 131, and Tyr 132 extend out from either side of the active site, forming two large hydrophobic walls of a deep groove on the surface of the structure [24]. These hydrophobic walls also provide some selectivity against phosphoserine and phosphothreonine peptides.

The discovery of the LMW PTPase in budding and fission yeast appeared to provide an attractive model for exploring the physiological role of this enzyme. However, studies of the *Saccharomyces cerevisiae* LTP1 gene have shown that neither a disruption of this gene nor a tenfold overexpression of the product result in any apparent changes in phenotype [56]. The *Schizosaccharomyces pombe* gene STP1 was isolated by screening temperature-sensitive Cdc25 mutants [57]. Here, too, disruption of STP1 resulted in no detectable changes in phenotype in wild-type or mutant Cdc25⁻ strains, indicating that STP1 is not normally involved in mitotic control [57]. However, all such studies are complicated by effects of overlapping phosphatase enzyme activities. LMW PTPases have been isolated from a number of prokaryotes, but their substrate specificities and physiological roles are also uncertain. The genes for *Erwinia amylovora*, *Pseudomonas solanacearum*, and *Klebsiella* LMW PTPases are found clustered with genes

associated with exopolysaccharide biosynthesis [58,59], which is necessary for pathogenicity [60,61]. Overexpression of the *amsI* gene, which codes for a LMW PTPase in *E. amylovora*, causes a strong reduction in exopolysaccharide synthesis [62].

The human “red cell” PTPase dephosphorylates a number of phosphotyrosyl substrates including erythrocyte B and 3, angiotensin, and tyrosine kinase P⁴⁰ [8,10,11,14]. The bovine enzyme shows activity toward phosphotyrosyl immunoglobulin G (IgG) and phosphotyrosyl casein, while rat liver PTPase hydrolyzes phosphotyrosyl peptides derived from the insulin receptor, epidermal growth factor (EGF) receptor, platelet-derived growth factor (PDGF) receptor, and Band 3 [63]. Both the EGF and PDGF receptor have been reported to be targets of the LMW PTPase. The bovine liver enzyme reportedly dephosphorylates the EGF receptor *in vitro* with a nanomolar K_m value [9]. Other studies suggest that the cytoplasmic domain of activated PDGF receptor is an *in vivo* target of the LMW PTPase, with dephosphorylation leading to receptor inactivation [64]. Overexpression of the bovine PTPase in normal NIH/3T3 cells as well as several oncogene-transformed cells has been reported to result in an inhibition of proliferation [65]. Overexpression of the small enzyme also results in decreased mitogenic activity and decreased autophosphorylation of the PDGF receptor [66]. An increase in PDGF receptor autophosphorylation was seen in PDGF-stimulated cells overexpressing the inactive C12S mutant. Such C12S-transfected cells also show increased proliferation, c-Src activation, and serum-induced mitogenesis compared to control cells overexpressing the wild-type PTPase gene [64,67]. Effects on cell adhesion are reportedly influenced by phosphorylation of LMW PTPase following PDGF stimulation [68,69]. The activity of the LMW PTPase toward artificial substrates reportedly can be increased by phosphorylation on two tyrosine residues (Tyr-131 and -132) that are at the entrance to the active site, but the effects are difficult to control for protein stability [70,71]. Regulatory effects due to reversible oxidation-reduction as well as protein-phosphorylation reactions have been postulated to be involved in PDGF-induced mitogenesis [43,72].

Human LMW PTPase isoenzymes have been shown to have a role in endothelial cell migration and proliferation mediated by vascular endothelial growth factor (VEGF) [73]. Another significant developmental role for LMW PTPase involves the role of the enzyme in assembly and attachment of endothelial capillaries mediated by clustered ephrin-B1 tetramers [74]. Indeed, the interactions of vertebrate LMW PTPases with the ephrin receptor tyrosine kinases offer a particularly promising target for investigation. Human LMW PTPase has recently been demonstrated to be overexpressed in many transformed cell lines, including mammary epithelial cells [75]. Strikingly, the overexpression of LMW PTPase was found to be sufficient to confer transformation upon non-transformed cell lines. The oncogenic potential of LMW PTPase appears to be mediated through its interactions with EphA2.

STYX/Dead-Phosphatases

Matthew J. Wishart

*Department of Pharmacology,
University of California, San Diego
La Jolla, California*

Introduction

Protein tyrosine phosphatases (PTPs) catalyze the removal of phosphate from cellular substrates [1]. Individual PTPs exhibit distinct preferences for protein phosphoserine (pS), phosphothreonine (pT), or phosphotyrosine (pY), phosphoinositol phospholipid, and even 5' triphosphorylated nucleotide moieties [1]. In addition to phosphatases, a number of structurally unique, noncatalytic protein domains recognize the phosphorylated substrates of PTPs. So-called 14-3-3, FHA, and WW domains bind pS/pT sequences [2]; SH2 and PTB domains recognize pY motifs [3]; and PH, PX, FYVE, and ENTH domains interact with specific pools of phosphoinositides [4,5]. These noncatalytic modules serve as focal points for protein interaction and for targeting effectors to specific sites within the cell.

STYX is a modular domain originally identified in a protein that mediates pS, pT, and pY signaling *in vivo* [6]. Although structurally related to phosphatases, the archetype STYX domain contains a glycine in place of the PTP catalytic active-site cysteine. Commensurate to crossing the river Styx in Greek mythology, this single amino acid substitution mechanistically abolishes phosphatase activity and functionally demarcates catalytically dead STYX from active PTPs. Similarly deleterious substitutions have been identified in other proteins that harbor phosphatase-like domains, including Sbf1, 3-PAP, IA-2, receptor-like PTPs (RPTPs) and mitogen-activated protein kinase phosphatases (MKPs) [7]. Rather than simply being the evolutionary relics of active phosphatases, individual dead-phosphatase domains perform noncatalytic roles in substrate recognition and regulation of PTP activity. Moreover, abnormal phenotypes resulting from genetic disruption in mice and yeast, fundamentally establish the importance of STYX/dead-phosphatase expression in complex biological systems. This chapter highlights the

diversity of function and mechanism of action for dead-phosphatases in phosphorylation signaling.

Gathering Styx: Structure Implies Function

A summary of proteins with dead-phosphatase domains is provided in Table 1. In practice, dead-phosphatases are identified by similarity in amino acid sequence and predicted secondary structure to active PTPs. Distinguishing dead-phosphatases from PTP pseudogene products requires empirical evidence and an understanding of the components of phosphatase active-site structure.

The superfamily of PTPs is comprised of tyrosine-specific, dual-specific, Cdc25-like, and low-molecular-weight phosphatases [1]. Despite a limited sequence identity within the superfamily, all PTPs contain elements of a conserved structural core and share a catalytic mechanism involving the active-site motif, CXXXXXR (CX₅R) (Table 1). Low-molecular-weight, tyrosine-specific and most dual-specific PTPs also contain a catalytic aspartic acid residue topologically distinct from the CX₅R loop (Table 1) [1]. To catalyze substrate hydrolysis, the active-site cysteine thiolate undertakes nucleophilic attack of the substrate phosphoryl group to form a phospho–enzyme intermediate. Active-site Arg and catalytic Asp play direct roles in the formation, stabilization, and subsequent breakdown of the phospho–enzyme intermediate [1]. Surprisingly, mutations of the catalytic Cys, Arg, or Asp do not abolish substrate interaction, *in vitro* or *in vivo*, and substitution of the active site Cys or Asp has become the basis of PTP–substrate trapping strategies [8]. PTP crystallographic studies also show that catalytically dead Cys mutants bind sulfate and phosphorylated peptides in a manner identical to native enzymes [1], indicating that determinants for substrate specificity and targeting reside outside the active site (Table 1).

Table I Dead-Phosphatases

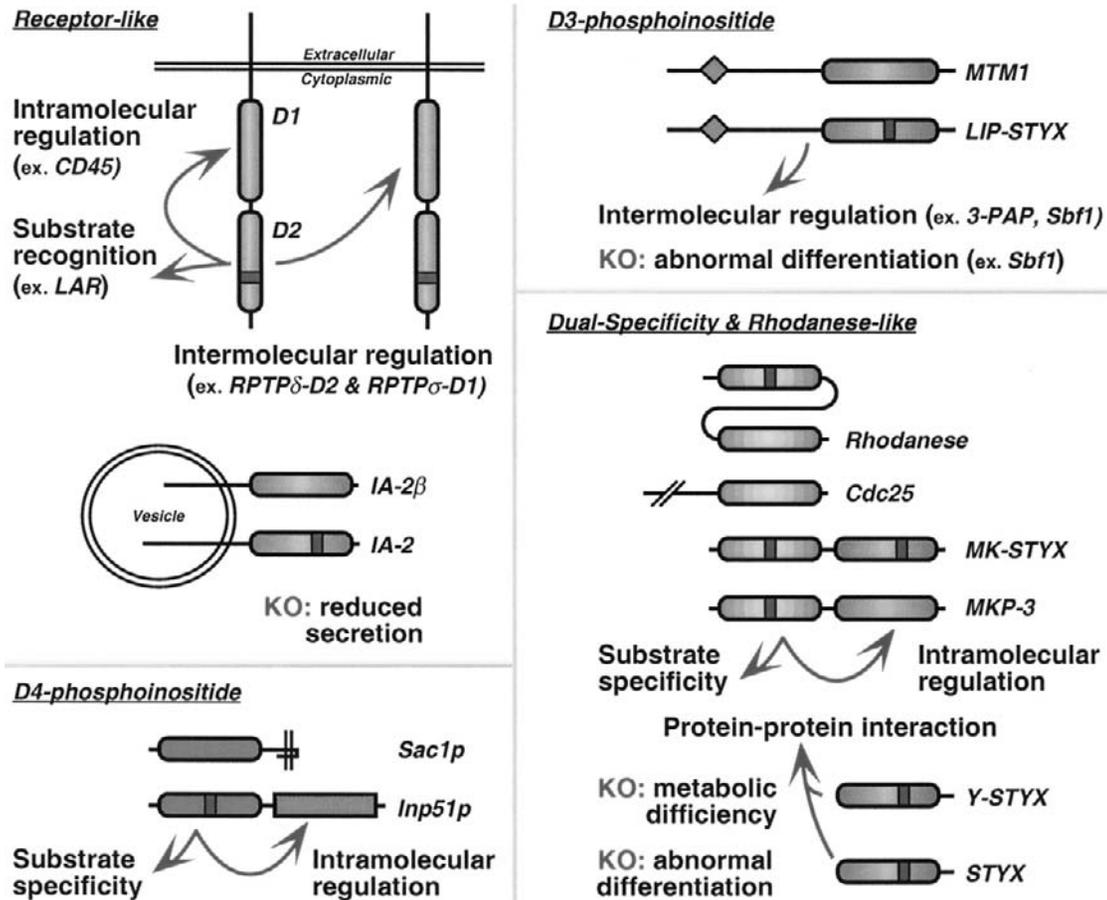

Figure 1 STYX/dead-phosphatases are functionally active proteins. Representative proteins containing catalytically active (open oval) and/or inactive (barred oval) PTP-like domains are depicted for each subclass of dead-phosphatase. Proposed functions and null phenotypes are listed for individual STYX/dead-phosphatases (arrows). Domains involved in protein targeting (diamond) or non-PTP enzymatic activity (rectangle) are provided for MTM1 and Inp51p, respectively.

One form of dead-phosphatase appears to mimic experimental PTP catalytic mutants, in that germline substitution of an active-site residue abolishes activity while preserving affinity toward phosphorylated substrates. In the case of STYX, conversion of the active-site glycine to the corresponding PTP nucleophilic cysteine (Table 1) confers a level of catalytic efficiency to the mutant protein that resembles endogenous phosphatases [6]. This suggests that a subset of STYX/dead-phosphatases possesses the structural components necessary for PTP substrate interaction but not hydrolysis and therefore could act as antagonists of endogenous phosphatase function [9]. In contrast, another subset of dead-phosphatases usurps PTP structure for noncatalytic roles that do not involve the active site. One example is the amino-terminal sequence of MKP3 [10], which adopts a rhodanese-like fold also seen in the Cdc25 family of active phosphatases (Fig. 1) [11]. In all MKPs, the corresponding Cdc25-like catalytic loop bears little sequence similarity to active phosphatases (Table 1) [11] and does not appear to be involved in MKP-3 substrate interaction [10]. Instead, a kinase interaction motif removed from the active site crevice (Table 1) mediates high-affinity binding and specificity for the substrate MAP kinase [10]. Upon substrate binding, the

dead-phosphatase also allosterically induces full activation of the constituent MKP dual-specificity phosphatase domain through a process that enhances both PTP–substrate binding and turnover of the catalytic intermediate [12]. Thus, dead-phosphatases with low amino acid identity within the corresponding PTP active-site sequence have evolved functions distinct from mimicking phosphatase–substrate interaction.

The Gratefully Undead: STYX/Dead-Phosphatases Mediate Phosphorylation Signaling

The following sections illustrate the range of functions ascribed to STYX/dead-phosphatase domains. Descriptions of corresponding active PTP subfamilies are found elsewhere in this volume (see Chapters 98, 112, and 116).

Receptor PTP-D2 Domains

The PTP superfamily includes a large subclass of transmembrane receptor proteins that function in cell–cell and cell–matrix adhesion [13]. Intracellular segments of RPTPs contain either one or two tyrosine-specific, phosphatase-like

domains (Fig. 1). In dual-domain phosphatases, the majority of catalytic activity resides in the membrane proximal (D1) region, with little or no intrinsic PTP activity exhibited by the membrane distal (D2) domain. The molecular basis of the relative inactivity of RPTP-D2 sequences likely arises from alterations to the phosphotyrosine specificity motif and catalytic Asp (Table 1), which destabilize formation of the substrate phosphoenzyme intermediate [13]. In addition, the D2 domains of RPTPs β/ζ , γ , CD45 and OSTPTP contain substitutions of catalytic Cys and/or Arg residues that independently abrogate phosphatase activity (Table 1). Despite the sequence divergence of D2 and active phosphatases, crystallographic analysis indicates that the D2 domain of LAR mimics D1 structure [14], and the D2 domains of RPTP ϵ , α , and LAR can be converted into efficient D1-like catalysts by limited amino acid substitution [14–16]. These observations suggest that D2-mediated functions could resemble PTP–substrate binding and are supported by the binding of calmodulin within the active-site cleft of RPTP α -D2 [17]. Alternatively, the RPTP α -D2 domain has also been shown to function as a phosphorylated scaffold for binding the SH2 domain of its D1 substrate, c-Src [18]. The D2 domains of CD45 and LAR are similarly required for D1 recognition of their respective substrate receptors [19,20], although the mechanism of action is unknown. Finally, binding and inhibition of the D1 region of RPTP σ by the D2 domain of RPTP δ , provides a direct role for dead-phosphatase domains in regulating catalytically active phosphatase function [21].

IA-2 (ICA512, PTPN)

IA-2 was first identified as an islet cell autoantigen specifically recognized by insulin-dependent diabetes mellitus (IDDM) sera [22] and subsequently described as a 979-amino-acid transmembrane protein containing a single cytoplasmic PTP-like domain [23]. Autoantibodies to IA-2 recognize the intracellular region and are a major diagnostic predictor for IDDM, although a role in the etiology of disease is unknown [24]. The phosphatase-like domain of IA-2 shares an active-site sequence (Table 1) and $\approx 80\%$ overall identity with the tyrosine-specific PTP IA2 β (Fig. 1) [25]. Unlike A2 β , IA-2 contains an Ala in place of the catalytic Asp that is critical for both formation and breakdown of substrate phosphoenzyme intermediates (Table 1) [1]. Neither recombinant nor endogenous IA-2 catalyze the hydrolysis of pY from artificial or cellular substrates; however, restoration of the catalytic Asp increases the maximal rate of pY hydrolysis by mutant IA-2 [26], consistent with its function in PTPs. Thus, the dead-phosphatase domain of native IA-2 is structurally intact, and as such may function *in vivo* by sequestering A2 β or related PTP substrates. Binding partners for IA-2 include β IV spectrin and the PDZ domains of β 2-syntrophin and neuronal nitric oxide synthase, which likely form a complex that tethers the cytoplasmic IA-2 domain to the actin cytoskeleton [27–29]. Although the mechanism of IA-2 function is not known, its

expression on the dense core secretory vesicles of neuronal and neuroendocrine tissues in *Caenorhabditis elegans*, *Drosophila melanogaster*, and vertebrate species [30,31], suggests an important role in vesicle regulation (Fig. 1). In support of this view, endogenous IA-2 is proteolytically cleaved upon insulin stimulation of cultured cells [29], and ablation of IA-2 expression results in abnormalities of glucose tolerance in mice [32]. Likewise, glucose-stimulated insulin release is significantly reduced in islets of nullizygous animals [32], which collectively points to a role for IA-2 in regulating the biogenesis, trafficking, or exocytosis of neurosecretory vesicles.

phosphoSerine, -Threonine, or -Tyrosine Interaction Domain Protein

STYX has the distinction of being the first example of a naturally occurring binding domain structurally related to dual-specificity PTPs (dsPTP) [6]. Consisting of 223 amino acids, the 25-kDa cytoplasmic STYX protein represents little more than a phosphatase-like domain (Fig. 1) [6]. In contrast to all PTPs, STYX contains a Gly in place of the active-site Cys which abrogates catalytic activity (Table 1). Restoration of the active-site nucleophile in STYX(G120C) mutants confers potent phosphatase activity toward peptide pS/pT and pY and suggests that the native protein functions by interacting with the substrates of dsPTPs [6]. The importance of STYX structure, including the active-site glycine, is reflected in $>90\%$ amino acid similarity among proteins from vertebrate and lower chordate species. The presence of an orthologous gene product in the basidiomycetes fungus, *Cryptococcus neoformans* (Table 1), indicates that a progenitor STYX gene predated the advent of metazoan RPTPs and other dead-phosphatase domains. The physiological importance of STYX expression has been demonstrated by gene disruption in mouse, with pathological consequences to normal spermatogenesis (Fig. 1) [33]. Male mice homozygous for a disrupted *Styx* allele are infertile and devoid of normal epididymal sperm and exhibit a derangement of the orderly differentiation of round spermatids into spermatozoa. Coimmunoprecipitation of endogenous STYX with a multiply phosphorylated RNA-binding protein, Crhsp-24, suggests that they may form a translational checkpoint governing this process [33].

Myotubularin-Like Phosphatases

Myotubularin-related (MTMR) inositol lipid phosphatases comprise the largest known group of dsPTP-like enzymes conserved from yeast to human [34]. Of the 13 MTMR genes in human, eight are predicted to be enzymatically active, while the remaining genes encode proteins with a variety of substitutions to catalytically essential residues (Table 1) [34]. All active myotubularin-related proteins contain the extended PTP catalytic motif, CSDGWDRT (Table 1) and exhibit a marked substrate preference for phosphatidylinositol 3-phosphate, or PI(3)P, *in vitro* and *in vivo* [35,36].

PI(3)P is a lipid second messenger known to function as a targeting motif for various lipid-binding modules, including FYVE, PH, and PX domains [4,5]. Although the specific physiologic roles of myotubularin family phosphatases as regulators of intracellular PI(3)P have yet to be identified, the association of myotubularin and MTMR2 mutations with human neuromuscular diseases underscore their importance in developmental signaling pathways [37].

The most extensively characterized catalytically dead MTMR protein is the cytoplasmic Set-binding factor 1 (Sbf1), also known as MTMR5 (Table 1) [38]. In addition to its dead-phosphatase domain, Sbf1 contains a lipid-targeting PH domain and sequence similarity to a Rab3 guanine nucleotide exchange factor [39]. The function of Sbf1 appears to depend on the noncatalytic state of its phosphatase-like domain, as conversion of active-site residues that abrogate activity, Leu>Cys and Ile>Arg (Table 1), confers hydrolytic activity to mutant Sbf1 toward substrates pY and pS and suppresses the effect of native Sbf1 on differentiation and growth [39]. While the cellular function of Sbf1 is unknown, an ortholog from *D. melanogaster* is found within the polycomb and histone acetyltransferase complexes on nuclear chromatin [40,41], and male mice deficient for Sbf1 protein are infertile and azoospermic [42]. Unlike the spermatid abnormalities of STYX nullizygous males [33], however, the primary defect caused by the absence of Sbf1 is first observed within the Sertoli cells of the seminiferous tubule [42]. Germ-cell differentiation is also disrupted during the transition from pachytene spermatocytes to round spermatids, possibly as a byproduct of Sertoli cell dysfunction [42].

Perhaps a clue into the molecular function of Sbf1 can be gleaned from the dead-MTMR protein, 3-PAP (Table 1), which stimulates D3-specific lipid phosphatase activity from a cellular complex [43]. Likewise, subcellular colocalization of MTM1 with the dead-MTMR Lip-STYX [34,44] suggests that MTMR-like dead-phosphatases may act as scaffolds for assembling active phosphatase complexes.

Conclusions

This chapter highlights the functional diversity of STYX/dead-phosphatase domains. The emergence of additional catalytically inactive, phosphatase-like proteins from human, yeast, and viral sources (Table 1) [45–51], implies an ancient origin for participation of dead-phosphatases in phosphorylation-dependent signaling. Proposed mechanisms of dead-phosphatase function range from being antagonists of PTP–substrate interaction to allosteric regulators of active PTPs and even structural scaffolds for protein complex formation. Perhaps a diversity of function for dead-phosphatases is expected given the multiplicity of substrates and strategies employed in regulating active PTPs [1]. A crystallographic study of an inactive mutant of the PTP, KAP, and its phosphorylated substrate, CDK2, illustrates how non-catalytic binding at the PTP active site can modulate the conformation and function of its bound substrate molecule [52].

Co-crystallization of STYX/dead-phosphatases with their interacting proteins will likely provide naturally occurring examples of this and other phosphorylation regulatory mechanisms.

Introduction

The phospholipase C enzymes that hydrolyze phosphatidylinositol 4,5-bisphosphate in mammalian cells are subdivided into four families, denoted β , γ , δ , and ϵ , based on sequence similarities. Each family has a unique organization of regulatory sequence motifs or domains that facilitate protein:protein and/or protein:phospholipid interactions. Utilizing these motifs, each family responds to distinct hormonal signals or intracellular cues to produce the second messenger molecules inositol 1,4,5-trisphosphate and diacylglycerol. These metabolites in turn control intracellular levels of free Ca^{2+} and protein kinase C activity, respectively. This review, in addition to discussing molecular structure/function and activation mechanisms for phospholipase C enzymes, presents the physiologic consequences of PLC genetic knockouts.

This review is focused on the phosphoinositide-specific phospholipase C (PLC) isozymes expressed in mammalian cells. This family of isozymes is defined on the basis of sequence similarities and the capacity to mediate the hydrolysis of phosphatidylinositol 4,5-bisphosphate (PI 4,5- P_2) to the second messenger molecules inositol 1,4,5-trisphosphate and diacylglycerol. The former provokes mobilization of intracellular Ca^{2+} by regulating the release of stored Ca^{2+} from within intracellular organelles into the cytosol and nucleus. The latter functions as an endogenous and required activator of protein kinase C isozymes. Hence, this enzyme uniquely activates two second messengers, which in turn may control a variety of signaling pathways and thereby influence a panoply of cellular events. This review is constrained by space, and readers are referred to other recent reviews [1–3] for additional information and pertinent references.

PLC Anatomy

The eleven mammalian PI 4,5- P_2 specific PLCs are divided into four subgroups (designated β , γ , δ , ϵ) based on sequence similarities that produce an organization of structural motifs unique to each subgroup [1]. The organization of these motifs or domains is illustrated in Fig. 1. All PLC isozymes have motifs designated X and Y, which in the native protein are folded together to constitute the catalytic domain. An X-ray structure of PLC- $\delta 1$ provides the clearest picture of exactly how this enzymatic center is organized and suggests potential catalytic mechanisms [2]. In addition to conserved catalytic function, each PLC subgroup is characterized by additional motifs that are involved in regulating aspects of enzyme function, such as topological localization within the cell and sensitivity to protein:protein and protein:lipid interactions.

PLC Activation Mechanisms

PLC- β . The activity of four PLC- β isozymes is regulated by hormones that bind to G-protein coupled receptors (GPCRs) [1]. These receptors typically have multiple membrane spanning domains, have no intrinsic catalytic activity, and utilize heterotrimeric G proteins to communicate with downstream second messenger producing enzymes, such as PLC isozymes. When GPCRs are stimulated by hormone binding, G protein complexes containing α , β , γ subunits are activated with the following characteristics: GDP bound to the α subunit is replaced by GTP, dissociating the trimeric complex into two active species—a GTP-bound free α subunit and a $\beta\gamma$ dimeric complex. Both of these act as signal transducers to activate PLC- β isoforms in a manner that may depend on both for maximal activation.

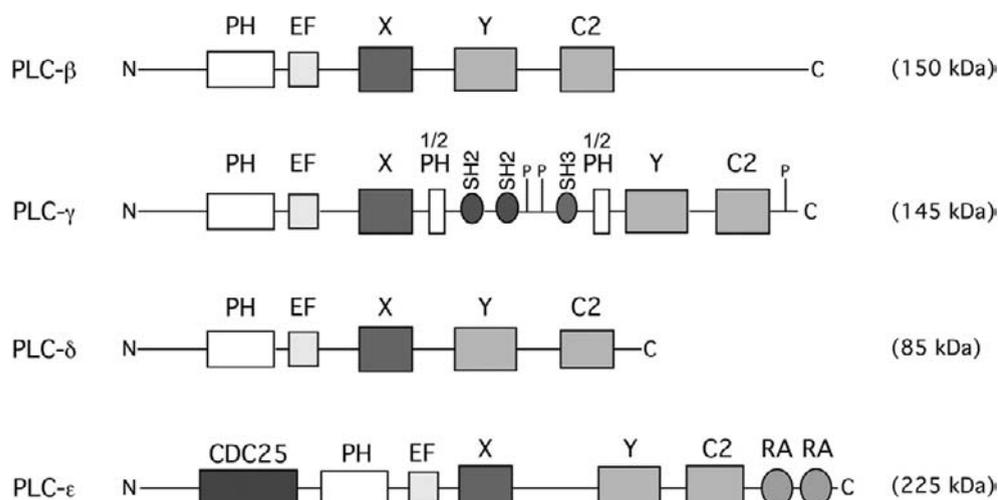

Figure 1 Schematized arrangement of domains within PLC isozymes. Functional domains or motifs (PH, EF, SH2, SH3, C2, RA, CDC25, X, Y) are explained in the text. Tyrosine phosphorylation sites are depicted by Y in the γ isozymes.

The α ·GTP subunit interacts with a region in PLC- β that includes a portion of the C2 domain, while the $\beta\gamma$ complex interacts with part of the PH domain. The region within PLC- β that binds the α ·GTP subunit also appears to function as a dimerization interface, suggesting that PLC- β may function as a dimer [4,5]. Since α subunits and $\beta\gamma$ complexes are constitutively anchored by lipid modifications to the cytoplasmic face of the plasma membrane, one consequence of these interactions is to promote a catalytically competent association of PLC- β with the plasma membrane. In unstimulated cells, PLC- β s are usually found loosely associated with the plasma membrane in what can be termed a catalytically incompetent association.

There is evidence for most PLCs that formation of a highly specific plasma membrane association is necessary for hydrolysis of the plasma membrane-localized substrate PI 4,5- P_2 . Productive membrane association by PLC- β is further facilitated by interaction of its PH domain with phosphatidylinositol 3-phosphate. Separate regions of the PH domain accommodate this phosphoinositide and $\beta\gamma$ complexes. Although the C2 domain in PLC- δ does mediate a Ca^{2+} -dependent phospholipid interaction, there is no evidence for this in PLC- β . While interactions of the C2 and PH domains of PLC- β with membrane-bound molecules might seem sufficient to explain formation of a productive membrane:enzyme complex, it is unclear whether this association *per se* is sufficient for increased catalytic activity or whether these interactions also provoke changes within the X/Y catalytic domain.

Signal transduction mechanisms are, by definition, reactions that are readily reversible. In the case of PLC- β , the most readily reversible component resides in the α ·GTP subunit, which can be rapidly converted by intrinsic GTPase activity to α ·GDP.

PLC- γ . This subgroup contains two members, $\gamma 1$ and $\gamma 2$ [1,3]. Initially, the cloning and sequencing of the isozymes

indicated significant differences in the COOH terminal sequences; however, more recent data indicate that these apparent differences resulted from sequencing errors for $\gamma 2$ [6]. As shown in Fig. 1, PLC- γ uniquely contains motifs known as SH2 and SH3 domains in addition to the PH and C2 domains present in other PLC subgroups. The SH2 motifs, in particular, are important to facilitate activation of γ isozymes by growth factor receptor tyrosine kinases (RTKs). RTKs possess a single transmembrane domain separating the ligand-binding ectodomain from a cytoplasmic domain that contains sequences encoding tyrosine kinase activity [7]. Ligand binding facilitates dimerization of RTKs and this in turn facilitates activation of the tyrosine kinase domain. Substrates for the tyrosine kinase include the receptor itself and other proteins, such as PLC- γ .

The initial step in growth factor-dependent activation of PLC- γ involves the recognition of autophosphorylation sites in a RTK by the SH2 domains of PLC- $\gamma 1$ [1,3]. This recognition event is a prerequisite for tyrosine phosphorylation of PLC- γ by the RTK, which constitutes a major step in the activation mechanism. Receptor association may also relocalize PLC- $\gamma 1$ from the cytosol to the cytoplasmic face of the plasma membrane, much like the association of PLC- β with membrane-anchored G protein subunits.

Compared to other PLCs, PLC- γ has an elongated linker segment between the X and Y domains. This linker contains not only the SH2 and SH3 domains, but also a split PH domain and at least two important tyrosine phosphorylation sites, which are close together between the C-SH2 and SH3 domains and are conserved in the $\gamma 1$ and $\gamma 2$ isoforms. It is possible that modulation of the structure of this linker region, by protein: protein interaction and/or by tyrosine phosphorylation, contributes to activation of the catalytic site [3]. One additional site of tyrosine phosphorylation is located C-terminal to C2 domain in both the $\gamma 1$ and $\gamma 2$ isoforms [1,3], while a fourth site in $\gamma 2$ is located between the Y and C2 domains [8].

Evidence has been presented that in some cell systems PI-3 kinase activity and the formation of phosphatidylinositol 3,4,5-trisphosphate (PI 3,4,5-P₃) is necessary for maximal PLC- γ 1 activation [1,3]. The site of action of PI 3,4,5-P₃ is most likely the N-terminal PH domain of PLC- γ 1. However, not all reports are in agreement on this and data have been presented to support an interaction of PI 3,4,5-P₃ with the C-SH2 domain of PLC- γ 1. The possible contributions of the SH3 and C2 domains of PLC- γ 1 to the activation mechanism are unclear. Evidence has been presented to indicate that the SH3 domain of PLC- γ 1 can associate with PIKE, a nuclear GTPase, and stimulate its activation [9].

In hematopoietic cells, adaptor proteins, such as LAT in T cells, are localized in specialized membrane microdomains termed lipid rafts and are also tyrosine phosphorylated following antigen activation [1,3]. In T cells, phosphorylated LAT becomes associated with PLC- γ 1, and this interaction is necessary for PLC- γ 1 activation. Whether similar membrane components are involved in PLC- γ 1 activation in non-hematopoietic cells is unknown. However, there is evidence that RTK activation provokes the preferential association of tyrosine phosphorylated PLC- γ with caveolae [10,11], which resemble raft membrane microdomains but contain the protein caveolin.

PLC- δ . The activation mechanisms for this subgroup of PLC isozymes, which are not activated by GPCRs or RTKs, are perhaps least understood. Studies *in vitro* indicate that while all PLCs require free Ca²⁺, the δ isozymes are the most sensitive to free Ca²⁺ levels [1]. This has led to the notion that this enzymes activity may be enhanced by increased levels of intracellular Ca²⁺, and there is evidence consistent with this in a few cell-based systems. Available data also indicate that the PH and C2 domains facilitate membrane association of the δ isozymes. The PH domain of PLC- δ recognizes PI 4,5-P₂ and may not only tether the enzyme to the plasma membrane but may also facilitate a processive mechanism of hydrolysis. The C2 domain mediates membrane association by recognition of a Ca²⁺-phospholipid complex in the membrane. It is interesting that the PH domain of PLC- δ also binds inositol 1,4,5-P₃, the product of PI 4,5-P₂ hydrolysis, and this may represent a mechanism to decrease PLC- δ activity when product levels become high.

PLC- ϵ . This is the most recent addition to the mammalian PLC family and was foreshadowed by the isolation of a *C. elegans* cDNA that has the same organization [1]. Within the PLC family, PLC- ϵ has novel protein:protein interaction motifs that indicate that its activation is directly controlled by the G protein Ras, which is a particularly important molecule in signal transduction pathways initiated by growth factor RTKs.

Near its N-terminus, PLC- ϵ contains a sequence identified as a CDC25 or a RasGEF (guanine nucleotide exchange factor) motif, which in other proteins facilitates the activation of Ras by mediating the exchange of GDP for GTP. Evidence indicates that expression of exogenous PLC- ϵ in cells does

promote increased levels of Ras \equiv GTP. This would place PLC- ϵ upstream of Ras in a signal transduction pathway. PLC- ϵ also has RA or Ras association motifs near its C-terminus. This sequence motif allows recognition of PLC- ϵ by the GTP-bound, or activated, form of Ras. Evidence shows that PLC- ϵ is indeed recognized with high affinity by Ras·GTP and is not recognized by Ras·GDP. This predicts that Ras is an activator of PLC- ϵ and would place this PLC isoform downstream of activated Ras. Also, recognition of PLC- ϵ by activated Ras could also facilitate membrane translocation of PLC- ϵ , as Ras is constitutively membrane-localized by the presence of covalent lipid constituents. The complex relationship of PLC- ϵ to Ras is analogous to the reported observation that PLC- β 1 acts as a GAP (GTPase activating protein) toward the α ·GTP subunit that is its direct activator [12]. Ras is a prototype for a large family of single subunit GTPases, and there are data suggesting that PLC- ϵ also participates in signaling dependent on Rap 1 [13] and Rap2B [14], members of the Ras superfamily.

It also appears that PLC- ϵ can be activated by heterotrimeric G protein subunits, including $\beta\gamma$ complexes [15] and at least one α ·GTP subunit [16]. The former proceeds through recognition of a PH domain in PLC- ϵ . Hence, PLC- ϵ may be activated by growth factor RTKs through Ras or by GPCRs through heterotrimeric G proteins. This finding raises the prospect that the PLC activity downstream of these receptors may represent contributions by more than one PLC subgroup.

PLC Physiology

While structural and biochemical questions regarding PLC isozymes have yielded significant information regarding the molecular mechanisms by which these enzymes are activated in cells, there is much less information available regarding the role of these PLC isozymes in physiologic or pathophysiologic processes. Given the ubiquitous occurrence of PLC isozymes and the pleiotropic potential of the second messengers that they generate, this may seem either too obvious or too complex a question to resolve. In view of the multiplicity of isoforms in each PLC subgroup, one might expect substantial functional redundancy to exist, although this expectation is partially offset by the differing patterns of expression for each isoform. Also at play is the extent to which PLC-dependent signal transduction is necessary, sufficient, or dispensable for any given cell response. These issues can to some extent be addressed by selective abrogation of each PLC isozyme through targeted gene disruption technology. The contents of Table I describe results that have been obtained to date by the application of this technology to PLC genes. The results, in some cases, represent phenotypes obtained at the first crucial point in development when a particular PLC isoform becomes required for further development of the organism.

In the case of *Plcb3* knockouts, discordant results have been reported that may reflect the manner in which the gene was actually disrupted. When *Plcb3* genomic information corresponding to exons encoding the last one-third of the

Table I Phenotypes Resulting from Targeted Disruption of PLC Genes in Mice

Gene (Protein)	Phenotype	Reference
<i>Plcb1</i> (PLC- β 1)	Death 2–6 weeks after birth, increased level of recurrent seizures due to decrease in muscarinic acetylcholine signaling	17
<i>Plcb2</i> (PLC- β 2)	Normal life span, increased neutrophil chemotactic response	18
<i>Plcb3</i> (PLC- β 3)	Embryonic lethal E2.5	19
	Normal life span, decreased opioid-dependent behavioural responses	20
	Increased skin ulcers	21
<i>Plcb4</i> (PLC- β 4)	Normal life span, locomotor ataxia due to metabotropic glutamate receptor signaling	17
	Impaired visual response	22
	Decreased climbing fiber elimination	23
	Decreased long-term depression, decreased conditioned motor learning	24
<i>Plcg1</i> (PLC- γ 1)	Embryonic lethal E9.0, impaired erythropoiesis, vasculogenesis	25
	Chimeric mice (<i>plcg1</i> $-/-$ and $+/+$) mice, impaired hematopoiesis, polycystic kidney	26
<i>Plcg2</i> (PLC- γ 2)	Normal life span, decreased mast cell function, decreased B cell numbers	27
<i>Plcd4</i> (PLC- δ 4)	Normal life span, male infertility due to deficiency in acrosome reaction	28

X domain plus the first two-thirds of the Y domain was deleted, embryonic lethality was produced at approximately 2.5 days in gestation [19]. In the second knockout [20], a genomic deletion representing one exon encoding some residues in the X domain was produced and the mice were normal as far as development and growth are concerned. At this time the discrepancy between these two studies has not been resolved. It is possible that in one knockout a mutant protein was produced that acted as a dominant-negative molecule affecting other pathways. Alternatively, one of the knockouts may represent only a partial loss of PLC- β 1 function.

Inositol 1,4,5-trisphosphate 3-kinase and 5-phosphatase

**Valérie Dewaste and
Christophe Erneux**

*Interdisciplinary Research Institute (IRIBHN)
Université Libre de Bruxelles,
Brussels, Belgium*

Introduction

Inositol 1,4,5-trisphosphate (InsP₃) 5-phosphatase and 3-kinase are the two major enzyme activities that metabolize InsP₃ in mammalian cells. Distinct forms of inositol and phosphatidylinositol 5-phosphatase selectively remove the phosphate from the 5-position of the inositol ring from both soluble and lipid substrates, i.e. InsP₃, inositol 1,3,4,5-tetrakisphosphate (InsP₄), phosphatidylinositol 4,5-bisphosphate (PtdInsP₂) or phosphatidylinositol 3,4,5-trisphosphate (PtdInsP₃). This reaction is often associated with the deactivation pathway of both soluble and lipid second messengers involved in Ca²⁺ signalling, proliferation, growth factor mediated events, and apoptosis [1–3]. Type I InsP₃ 5-phosphatase is unable to use the phosphoinositides as substrates and therefore is specific for InsP₃ and InsP₄. It is a quite different and unique enzyme as compared to the type II isoforms (sometimes also called type II, III, and IV and considered as inositol lipid phosphatases *in vivo*, for review, see [2]).

The InsP₃ 3-kinase catalyses the phosphorylation of InsP₃ to InsP₄. This enzyme is particularly interesting in view of the rapid increase in InsP₄ levels in cells upon stimulation by agonists [4] and of several second messenger functions that had been proposed for InsP₄ [5]. cDNAs encoding three human isoenzymes of InsP₃ 3-kinase (3-kinases A, B, and C) have been reported (Table I). A mammalian inositol polyphosphate multikinase has been shown

to phosphorylate inositol 4,5-bisphosphate, thereby providing an alternative biosynthesis for InsP₃ [6].

Type I InsP₃ 5-phosphatase

Initially detected in human erythrocyte membranes [7], type I InsP₃ 5-phosphatase has a 10-fold higher affinity but 100-fold lower V_{max} for InsP₄ than it does for InsP₃ [8]. Molecular cloning revealed that it is a 412 amino acid protein with a C-terminal isoprenylation site CCVVQ (Fig. 1) [9,10]. Type I InsP₃ 5-phosphatase is targeted to plasma membranes and perinuclear regions as shown in several transfection studies [12]. The activity of this enzyme could be modified by targeting mechanisms and by phosphorylation. Direct interaction with platelet proteins such as pleckstrin and 14-3-3ξ has been reported [13,14]. In several cell models (e.g. rat cortical astrocytes), this enzyme has been shown to be stimulated by an InsP₃ mobilizing agonist such as ATP or carbachol. This effect is triggered by Ca²⁺/calmodulin kinase II protein phosphorylation, resulting in an inhibition of enzyme activity [15]. Underexpression of type I InsP₃ 5-phosphatase in rat kidney cells is associated with increasing levels of InsP₃ and InsP₄ and increasing levels of intracellular Ca²⁺ [16]. Antisense-transfected cells grow faster as compared to cells transfected with vector alone. Antisense-transfected cells formed colonies in soft agar and tumors in nude mice [17]. In overexpression studies in CHO cells, prenylation of type I InsP₃

Table I Characteristics of Type I InsP₃ 5-phosphatase and InsP₃ 3-kinase Isoforms

Protein (human)	Accession numbers	Pest regions	Stimulation of activity by Ca ²⁺ /CaM	Tissue distribution
Type I InsP ₃ 5-phosphatase	X77567	—	—	Heart, skeletal muscle, and brain [10]
InsP ₃ 3-kinase A	X54938	2	2–3 fold	Brain and testis [11]
InsP ₃ 3-kinase B	Y18024, AJ242780	5	8–10 fold	Ubiquitous [24]
InsP ₃ 3-kinase C	AJ290975	4	Insensitive	Ubiquitous [25]

The PESTfind program (at www.embnet.org) developed by Rogers *et al* [26] was used. The tissue distribution was obtained by Northern blotting.

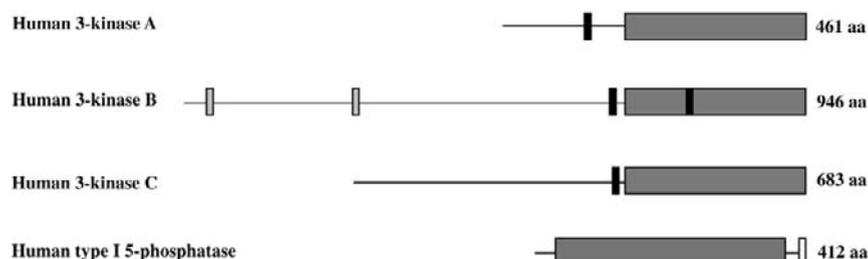

Figure 1 Schematic representation of the enzymes that metabolize InsP₃. Dark blue boxes represent the C-terminal catalytic domain of the InsP₃ 3-kinase enzymes and the red one of the type I InsP₃ 5-phosphatase. Potential phosphorylation sites are represented by black boxes. Two proline rich regions are found in the sequence of the InsP₃ 3-kinase B (light blue boxes). The yellow box shows the isoprenylation site of the type I InsP₃ 5-phosphatase enzyme.

5-phosphatase appears to be critical in the control of Ca²⁺ oscillations in response to agonists [18].

InsP₃ 3-kinase

This enzyme activity that specifically produced InsP₄ was initially reported in rat brain and T lymphocytes [19,20]. Purification of the protein and microsequence determination allowed the cloning of a 459 amino acid protein referred to as the A-isoform of 50 kDa. When it was expressed in bacteria, it showed an activity that was stimulated upon the addition of Ca²⁺ and calmodulin as shown for the native enzyme [21]. Transfection studies in HeLa cells show the importance of a 66-aminoacid N-terminal sequence in targeting the InsP₃ 3-kinase A to the actin cytoskeleton [22]. The first demonstration of two distinct sequences was reported in 1991 with the isolation of two different cDNAs from a cDNA library. These were referred to as human InsP₃ 3-kinases A and B, respectively [23]. The full-length sequence of human InsP₃ 3-kinase B has been recently reported and encodes a protein of 946 amino acids [24]. A third human isoenzyme, i.e. InsP₃ 3-kinase C, has been isolated following the screening of a human thyroid cDNA library. Its open reading frame encoding 683 amino acids has been expressed in *E. coli* and also in COS-7 cells [25]. Full-length sequences of human InsP₃ 3-kinases A, B, and C have been reported in databases (Table I).

The three human isoforms are members of a large family of inositol phosphate kinases present in mammalian but also

in yeast that contain a C-terminal catalytic domain and specific residues involved in binding inositol substrates [3]. The mammalian InsP₃ 3-kinases A, B, and C show the presence of four conserved motifs in the catalytic C-terminal domain that are not present in inositol hexakisphosphate kinase or in the inositol multikinase [25]. Human InsP₃ 3-kinases A, B, and C contain potential PEST-sequences as identified by the PESTfind program (Table I). This suggests that the enzymes are particularly sensitive to proteolysis as noticed during purification of the native enzyme in several tissues.

Several data in the literature suggest that InsP₄ by itself shows second messenger function(s) in neurons or in endothelial cells [27,28]. One approach to address the function of InsP₄ is to look for the distribution and relative expression of the proteins responsible for its metabolism or action in cells. In this context, a particularly high level of the A isoform is found in the dendritic spines of neurons (Purkinje cells and hippocampal CA1 pyramidal cells) [22,29], thus supporting a role of InsP₄ in LTP. The A isoform was reported to associate with F-actin, whereas the B isoform was shown to exist in the cytosol and also to be associated to the cytosolic face of endoplasmic reticulum membranes [22,30]. The localization of the inositol type I 5-phosphatase in plasma membranes was reported to be critical in the control of Ca²⁺ oscillations [18]. The mammalian InsP₃ 3-kinases A, B, and C could also control the concentration of several inositol phosphates, InsP₃ isomers, and/or higher phosphorylated inositol phosphates such as InsP₄ isomers, InsP₅, or InsP₆. In particular, Ins(1,3,4)P₃, the product of InsP₄ dephosphorylation by type I inositol

5-phosphatase, is a potent inhibitor of Ins(3,4,5,6)P₄ 1-kinase, resulting in an increase of Ins(3,4,5,6)P₄ and a decrease in chloride efflux [31]. The situation is also complicated by the fact that the three InsP₃ 3-kinase isoforms in animals can be distinguished by their N-terminal sequence, presumably targeting sequences and sensitivity to Ca²⁺/calmodulin [24,25].

Cyclic ADP-ribose and NAADP

Antony Galione and Grant C. Churchill

*Department of Pharmacology, Oxford University, Mansfield Road,
Oxford, United Kingdom*

Introduction

Cyclic adenosine diphosphate ribose (cADPR) and nicotinic acid adenine dinucleotide phosphate (NAADP) are endogenous pyridine nucleotide metabolites with potent Ca^{2+} mobilizing activities. Although the Ca^{2+} mobilizing properties of these two molecules was first discovered in sea urchin eggs, their actions seem to extend to many mammalian, invertebrate, and plant systems where they may function as Ca^{2+} mobilizing intracellular messengers.

In a seminal study, Lee and colleagues reported in 1987 that not only could the established Ca^{2+} mobilizing messenger inositol 1,4,5 trisphosphate (IP_3) release Ca^{2+} from intracellular stores in sea urchin egg homogenates, but so too could the two pyridine nucleotides, NAD and NADP [1]. However, NAD and NADP were not Ca^{2+} mobilizing agents themselves. The active principles were subsequently identified as a cyclic metabolite of NAD, cADPR [2] (Fig. 1A) and a contaminant of commercially available NADP, NAADP [3] (Fig. 1B). Both cADPR and NAADP were shown directly to mobilize Ca^{2+} from intracellular stores by microinjection into intact sea urchin eggs [3,4].

A useful property of the sea urchin homogenate system is that Ca^{2+} release by different Ca^{2+} mobilizing agents displays homologous desensitization. After stimulation of maximal Ca^{2+} release by a given agent, Ca^{2+} stores become refractory to Ca^{2+} release by that same agents. Sequential additions of IP_3 , cADPR and NAADP to the same aliquot of egg homogenate all evoked Ca^{2+} releases regardless of the order in which they were added, while a second addition of any of these agents failed to elicit any response. (see [5] for review.) From these data it was proposed that these three Ca^{2+} releasing agents mobilized Ca^{2+} stores by three distinct mechanisms. Further studies with selective pharmacological agents confirmed this view. Heparin, a competitive IP_3 receptor (IP_3R) antagonist,

selectively inhibited IP_3 -evoked Ca^{2+} release, while cADPR or NAADP-induced Ca^{2+} release were unaffected [4]. Ca^{2+} release by cADPR was found to be selectively blocked by ryanodine receptor (RyR) inhibitors [6] and chemically synthesized 8-substituted analogues of cADPR [7]. In contrast, NAADP-evoked Ca^{2+} release was neither affected by IP_3 or RyR antagonists nor cADPR analogues, but selectively blocked by inhibitors of voltage-gated Ca^{2+} and K^+ channels [8].

cADPR has now been implicated in the regulation of Ca^{2+} release via RyRs in many different cell types, while NAADP, which similarly has also been shown to mobilize Ca^{2+} in a number of cell types from different organisms [9], appears to act on a novel Ca^{2+} release channel. While IP_3Rs and RyRs are well-characterized Ca^{2+} release channels of intracellular organelles, the molecular nature of the NAADP-sensitive Ca^{2+} release channel is unknown. IP_3 and cADPR appear to predominantly mobilize Ca^{2+} from the endoplasmic reticulum [10,11] while NAADP releases Ca^{2+} from a distinct organelle [10,12], possibly an acidic compartment.

A key property of both IP_3Rs and RyRs is that both are modulated by Ca^{2+} itself. This property is responsible for Ca^{2+} -induced Ca^{2+} release (CICR), which serves to amplify normally locally restricted Ca^{2+} transients as global Ca^{2+} signals and is thought to be critical in determining the complex patterns of Ca^{2+} signals widely observed in cells such as repetitive Ca^{2+} spikes and regenerative Ca^{2+} waves [13]. Both IP_3 and cADPR appear to sensitize IP_3Rs and RyRs, respectively, to activation by Ca^{2+} , thereby promoting CICR. The molecular interactions of IP_3 with its receptors have been relatively well defined [14]; however, the molecular mechanisms by which cADPR activates RyRs are not, and the possibility exists that cADPR binds to an accessory protein that in turn modulates RyR openings [15,16]. Indeed, two known RyR associated proteins, calmodulin [17] and FKBP12.6 [18],

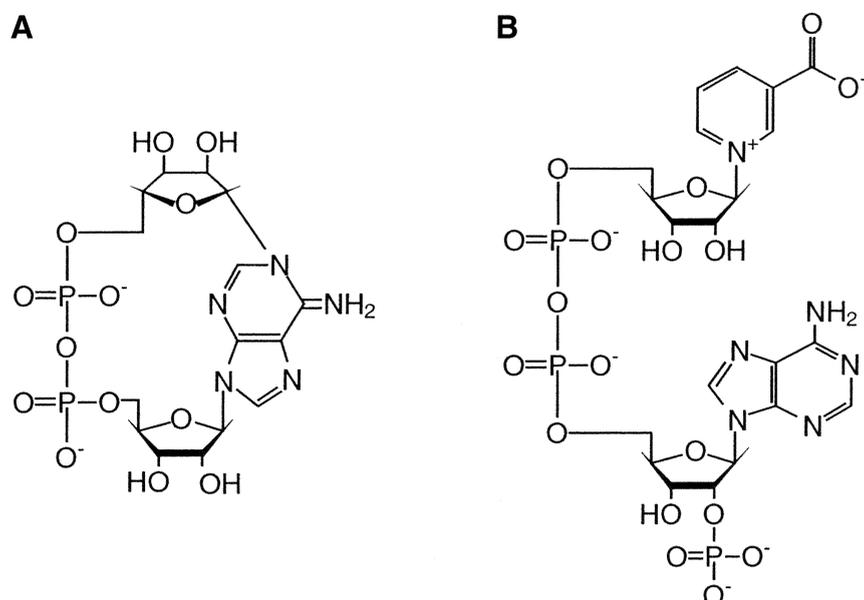

Figure 1 The chemical structures of cyclic adenosine dinucleotide phosphate ribose (cADPR) (A) and nicotinic acid adenine dinucleotide phosphate (NAADP) (B).

have been implicated in cADPR-induced Ca^{2+} release. However, NAADP elicits local Ca^{2+} signals unless amplified by triggering CICR by recruiting IP_3 Rs and RyRs [19] or through its own diffusion through cells [20].

Two types of evidence exist to suggest that cADPR or NAADP function as intracellular messengers for Ca^{2+} signaling in cells and tissues. The first is that endogenous levels of these compounds are modulated by cellular stimuli and the second is that the selective block of cADPR or NAADP-sensitive Ca^{2+} release mechanisms can inhibit Ca^{2+} mobilization or functional responses to a range of hormones, transmitters, and other cell regulators. ADP-ribosyl cyclases are a class of enzyme that can synthesise cADPR and NAADP from alternate substrates NAD and NADP, respectively, with pH and phosphorylation state determining which product is produced [21,22]. The best-characterized example of such an enzyme is CD38, which has been implicated in cADPR-based Ca^{2+} signaling in a number of cell types [23]. It was originally thought to be an ectoenzyme, although several reports indicate that it is also present in several intracellular compartments. Studies from tissues and cells derived from CD38 knockout mice implicate CD38 in both cADPR synthesis and Ca^{2+} signaling [24,25], and perhaps also NAADP synthesis as well [21,26], although other synthetic pathways are possible. CD38 is a complex enzyme in that it also catalyzes the hydrolysis of cADPR as well, while NAADP may be metabolized by a calcium-dependent phosphatase [27]. A number of approaches have been employed to determine changes in cADPR levels in cells, including thin layer chromatography, hplc, radioimmunoassay, radioreceptor binding [28], and a new cycling assay [29]. A variety of cell stimuli have been shown to increase cADPR levels in cells [30], including G protein-linked receptors and those linked to tyrosine kinase activities [31], although

the precise coupling mechanisms are unknown. There are no data at present on changes in NAADP levels in cells and tissues, although endogenous levels have been reported in plant tissues [32].

The role of cADPR in the generation of Ca^{2+} signals in response to cellular stimuli have been dissected by use of selective cADPR antagonists [30], and for NAADP by injecting high concentrations of NAADP into cells to desensitize NAADP-evoked Ca^{2+} release [19], since no selective antagonists for NAADP exist at present. Such studies have suggested a key role for the use of multiple messengers and multiple Ca^{2+} stores in dictating the complex patterns of Ca^{2+} signals observed in cells, which may be linked differentially to specific cellular responses. In T cells, IP_3 elicits a brief Ca^{2+} transient, while cADPR prolongs the Ca^{2+} signal [31]. In ascidian oocytes, different Ca^{2+} releasing messengers regulate different cell functions with IP_3 inducing Ca^{2+} spiking, cADPR regulating exocytosis, and NAADP modulating plasma membrane Ca^{2+} currents [33]. In pancreatic acinar cells, different Ca^{2+} mobilizing transmitters and hormones appear to be coupled to one or more types of Ca^{2+} mobilizing messengers [34]. The different Ca^{2+} release mechanisms appear also to be coupled in different ways depending on cell phenotype. For example, in pancreatic acinar cells and sea urchin eggs the NAADP mechanism couples to CICR channels to elicit global Ca^{2+} signals, while in T cells and ascidian oocytes, desensitization of NAADP receptors rather puzzlingly renders cells insensitive to IP_3 [9,33,35].

Although much work still remains to be done in elucidating many of the molecular details of the cADPR and NAADP signaling pathways, it is clear that through their involvement along with IP_3 in regulating Ca^{2+} signaling, they provide another layer of regulation in determining

complex Ca^{2+} signaling patterns. They are thus likely to be important components of the Ca^{2+} code whereby a single ion can specifically regulate a diverse array of cellular functions.

Sphingosine 1-phosphate

Kenneth W. Young and Stefan R. Nahorski

*Department of Cell Physiology and Pharmacology,
University of Leicester,
Leicester, United Kingdom*

Introduction

Sphingosine 1-phosphate is a putative intracellular second messenger for Ca^{2+} release. The metabolic pathways controlling sphingosine 1-phosphate levels are beginning to be understood, and it is clear that intracellular levels of this molecule can be actively regulated. However, the signaling machinery through which sphingosine 1-phosphate releases Ca^{2+} from intracellular stores remains poorly characterised. This chapter addresses recent issues in this area of Ca^{2+} signaling.

It is well established that sphingolipids, which are ubiquitous structural membrane constituents, are also capable of giving rise to a number of lipid signaling metabolites. In particular, sphingosine 1-phosphate (SPP) (Fig. 1) has been implicated in a variety of processes at both the intracellular and extracellular levels [1–3]. The extracellular targets for SPP, which is present in serum and can be released into the extracellular environment by activated platelets [4], have been clearly identified as members of the endothelial differentiation gene (Edg) family of heptahelical G protein-coupled receptors (GPCRs) [2]. These receptors couple to a variety of heterotrimeric G proteins, and can stimulate intracellular Ca^{2+} release through activation of the inositol (1,4,5)-trisphosphate [$\text{Ins}(1,4,5)\text{P}_3$] signaling pathway. However, SPP has also a number of attributes associated with a role as an intracellular messenger molecule. Thus intracellular levels of SPP can be regulated, often within seconds of an appropriate extracellular stimulus, through the action of the enzyme sphingosine kinase (SPHK). In this case, the resultant increases in cytosolic SPP appear capable of directly activating cell growth and intracellular Ca^{2+} mobilization [1,3,5]; however, unlike the extracellular effects of SPP, the intracellular targets for SPP remain to be defined.

Sphingolipid Metabolism

SPP is formed from the membrane lipid sphingomyelin via a series of enzymatic reactions [see 2,6]. Hydrolysis of sphingomyelin produces ceramide (N-acyl sphingosine), and this appears to be a central molecule in the SPP metabolic pathway. Subsequent removal of the amide-linked fatty acid side chain of ceramide produces sphingosine, which can then be phosphorylated by SPHK to produce SPP. Out of the sphingolipid metabolites, only SPP appears to have any direct Ca^{2+} release activity [7,8], and there is now clear experimental evidence that a variety of extracellular stimuli can activate SPHK and increase intracellular SPP levels (see below). Consistent with a second messenger role, SPP can be rapidly degraded either by dephosphorylation back to sphingosine, or irreversibly removed from the sphingolipid cycle via the enzyme SPP lyase, which hydrolyses a carbon-carbon bond in the sphingosine backbone of the molecule [9]. It is interesting that platelets, a noted source of extracellular SPP, lack SPP lyase [9].

Activation of SPHK

Two distinct forms of human SPHK have been cloned. The type 1 form is a 49 kDa protein that contains putative phosphorylation sites for PKC, PKA, and casein kinase II, as well as Ca^{2+} /calmodulin and SH3 binding domains. The type 2 form is notably larger (65 kDa) and has a different tissue distribution [6, 10,11]. Both these proteins are predominantly cytosolic [5,12] (Fig. 2). SPHK activity has been quantified by measuring the ability of cell lysates (whole cell or fractionated, stimulated vs. unstimulated) to [$\gamma^{32}\text{P}$]-label added

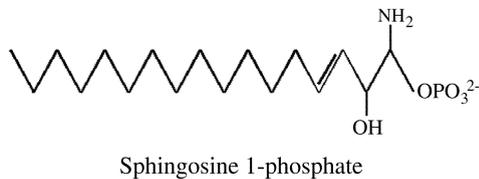

Figure 1 Structural representation of sphingosine 1-phosphate.

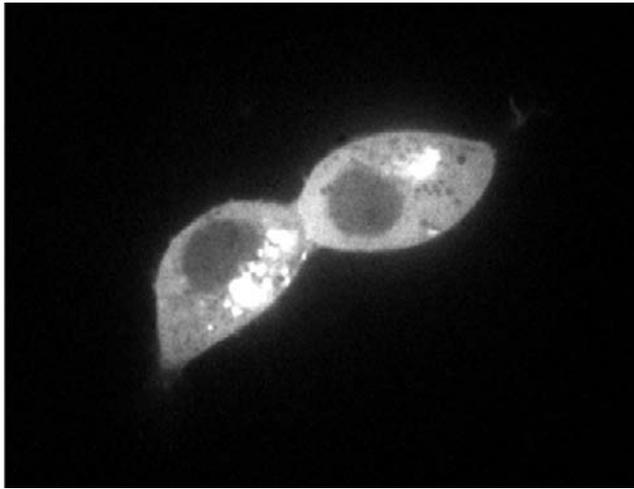

Figure 2 Cellular distribution of SPHK. HEK-293 cells, grown on coverslips, were transiently transfected with SPHK tagged with eGFP (gift from S. Spiegel) and imaged on a confocal microscope ($\times 100$ magnification). Similar to studies using HA-tagged SPHK, or involving SPHK1 antisera, SPHK-eGFP was predominantly cytosolic in location.

sphingosine from a pool of [$\gamma^{32}\text{P}$]-ATP. Such experiments have demonstrated SPHK activity both in cytosolic and membrane fractions [5]. Pretreatment of NIH 3T3 fibroblast cells with PDGF raises the V_{max} of SPHK, with no apparent change in K_m [13], and both cytosolic and membrane forms of SPHK are similarly activated [5]. SPHK activity can also be investigated indirectly by measuring changes in intracellular SPP. In such experiments, cells are pulse-labeled with [^3H]-sphingosine and the resultant [^3H]-SPP extracted. A complicating factor with this method is the lack of equilibrium labeling of [^3H]-sphingosine, hence making substrate availability a potential issue.

Using these methods, a number of extracellular stimuli, which result in Ca^{2+} mobilizing responses, have been shown to stimulate SPHK, hence supporting the possibility that intracellular SPP functions as a Ca^{2+} release mediator. This list of stimuli include PDGF [13], antigen stimulation [14], and a variety of recombinant and endogenous GPCRs (muscarinic M2 and M3 [15], lysophosphatidic acid (LPA), Edg-4 receptor [16]). Although investigating the role of SPP in Ca^{2+} mobilization is complicated by the fact that many of these extracellular stimuli also utilize the $\text{Ins}(1,4,5)\text{P}_3/\text{Ca}^{2+}$ release pathway, this is not always the case. Of particular note here is the $\text{Fc}\gamma$ receptor-I in U937 monocytes. This receptor, which is an integral membrane glycoprotein, undergoes a molecular switching between $\text{Ins}(1,4,5)\text{P}_3$ mediated- and SPHK dependent- Ca^{2+} release according to the differentiation state

of the cell [14], thus changing the temporal profile of the Ca^{2+} response. In addition, our own work in the SH-SY5Y human neuroblastoma cell line indicates an $\text{Ins}(1,4,5)\text{P}_3$ -independent but SPHK-dependent Ca^{2+} mobilizing response to LPA [16,17].

The mechanism by which SPHK, a cytosolic protein, can be activated by cell surface stimuli remains unclear, though there is evidence for a number of possible signaling pathways. PDGF-mediated SPHK activation in TRMP canine kidney epithelial cells (recombinantly expressing PDGF- β receptors) is inhibited by addition of the Ca^{2+} chelator BAPTA [18]. A similar Ca^{2+} -sensitive SPP production has been shown for GPCRs [19]. In addition, receptor-independent increases in intracellular Ca^{2+} levels, either via Ca^{2+} ionophores [18] or voltage-gated Ca^{2+} channels [20], activate SPHK. However, although SPHK binds calmodulin with high affinity in the presence of Ca^{2+} [21], thus supporting a role for Ca^{2+} -mediated SPHK activation, it should be noted that purified SPHK is insensitive to Ca^{2+} in the range 1–100 μM [21]. A second activation pathway involves acidic phospholipids, which despite the lack of a recognized binding domain, increases SPHK activity *in vitro* [22]. In this way, a phospholipase D-mediated increase in phosphatidic acid may be the mechanism through which antigen activation of SPHK and subsequent Ca^{2+} release occurs [14]. Another possibility is that SPHK is activated via protein-protein interactions. Thus, although Ca^{2+} signals were not investigated, activated $\text{TNF}\alpha$ -receptors recruit the adaptor protein TRAF2, which in turn binds to and activates SPHK [23]. Such recruitment of SPHK to protein signaling scaffolds near the plasma membrane may have additional important consequences, as this would bring SPHK into contact with its substrate, sphingosine. It is of interest that antigen [24] and GPCR (unpublished data) stimulation of SPHK also involves recruitment of the kinase to the plasma membrane.

Intracellular Target for SPP-mediated Ca^{2+} Release

Although progress is clearly being made on the signaling pathways leading to SPP production, frustratingly little is known about the intracellular targets responsible for Ca^{2+} release. SPP-mediated Ca^{2+} mobilization was first noted in 1990 by Ghosh and co-workers [7]. Using a permeabilized cell preparation, this group demonstrated that sphingosine and the related compound sphingosylphosphorylcholine (SPC) could release $^{45}\text{Ca}^{2+}$ from the endoplasmic reticulum (ER). As the sphingosine response involved a short time lag, and required the presence of ATP, it was suggested that sphingosine was being converted to SPP, and it was SPP that possessed Ca^{2+} release activity [7,8]. Direct SPP-mediated Ca^{2+} release has now been shown by a number of groups, either in permeabilized cell preparations [8,16,25] or via microinjection [15]. SPP is active over the concentration range 1–100 μM , and although SPP utilizes ostensibly the same intracellular Ca^{2+} pool as $\text{Ins}(1,4,5)\text{P}_3$, there is no requirement for InsP_3 - or ryanodine-receptor activation [17]. Functional studies indicate the presence of both SPHK and the putative release

channel for SPP to be present in the ER [7,8]; however, the identity of the intracellular release channel remains elusive. A putative sphingolipid-mediated Ca^{2+} release channel, termed SCaMPER (sphingolipid Ca^{2+} -release mediating protein of the endoplasmic reticulum), has been cloned [26]. However, a more recent study suggests that SCaMPER is not an ion channel and is not associated with the ER [27]. Indeed it is not clear whether SCaMPER has any sort of interaction with SPP.

Due to the complicating effects of cell surface GPCRs for SPP, and because SPP production often occurs alongside increases in $\text{Ins}(1,4,5)\text{P}_3$, it has been difficult to look at the single cell and subcellular Ca^{2+} signals to SPP. Thus questions concerning the spatial and temporal aspects of SPP responses remain largely unanswered. It is of interest to note that the SPP dependent-, $\text{Ins}(1,4,5)\text{P}_3$ independent-, Ca^{2+} responses to antigen- [15] and LPA- [16] stimulation are similarly transient in nature. To date, there is no evidence that intracellular SPP is capable of producing Ca^{2+} oscillations; however, SPP-mediated Ca^{2+} release can stimulate subcellular Ca^{2+} puffs, presumably by a direct effect of the released Ca^{2+} on InsP_3 receptors [16].

Concluding Remarks

The role of SPP as an intracellular messenger will remain controversial until intracellular targets for SPP are clearly identified. Recent elegant work using a fluorescent bioassay for SPP demonstrates that PDGF-mediated increases in SPHK activity produce detectable increases in extracellular SPP that are capable of activating cell surface Edg-receptors [28]. Furthermore, SPP may itself be produced extracellularly via the extracellular export of SPHK [29], and so great care must be taken when investigating supposedly intracellular actions of SPP. As SCaMPER does not appear to be an appropriate intracellular target, attention needs to be focused on the identification and characterization of the intracellular Ca^{2+} -release channel for SPP. In addition, the use of molecular tools such as the recently described catalytically inactive form of SPHK [30] should allow for greater investigation into the role of SPP in mediating Ca^{2+} signals. Such experiments are essential for fully understanding the significance of SPP as an intracellular mediator for Ca^{2+} release.

Voltage-gated Ca^{2+} Channels

William A. Catterall

*Department of Pharmacology,
University of Washington, Seattle, Washington*

Introduction

Voltage-gated Ca^{2+} channels mediate calcium entry into cells in response to membrane depolarization. Electrophysiological studies reveal different Ca^{2+} currents designated L-, N-, P-, Q-, R-, and T-type. The high-voltage-activated Ca^{2+} channels that have been characterized biochemically are complexes of a pore-forming $\alpha 1$ subunit of about 190 to 250 kDa, a transmembrane, disulfide-linked complex of $\alpha 2$ and δ subunits, an intracellular β subunit, and in some cases a transmembrane γ subunit. Ten $\alpha 1$ subunits, four $\alpha 2\delta$ complexes, four β subunits, and several γ subunits are known. The $\text{Ca}_v 1$ family of $\alpha 1$ subunits conduct L-type Ca^{2+} currents, which initiate muscle contraction, endocrine secretion, sensory transduction, cardiac pacemaking, and gene transcription and are regulated primarily by second messenger-activated protein phosphorylation pathways. The $\text{Ca}_v 2$ family of $\alpha 1$ subunits conduct N-type, P/Q-type, and R-type Ca^{2+} currents, which initiate rapid synaptic transmission and are regulated primarily by direct interaction with G proteins and SNARE proteins and secondarily by protein phosphorylation. The $\text{Ca}_v 3$ family of $\alpha 1$ subunits conduct T-type Ca^{2+} currents, which are activated and inactivated more rapidly and at more negative membrane potentials than other Ca^{2+} channel types. The distinct structures and patterns of regulation of these three families of Ca^{2+} channels provides a flexible array of Ca^{2+} entry pathways in response to changes in membrane potential and a range of possibilities for regulation of Ca^{2+} entry by second messenger pathways and interacting proteins.

Physiological Roles of Voltage-gated Ca^{2+} Channels

Ca^{2+} channels in many different cell types activate upon membrane depolarization and mediate Ca^{2+} influx in response to action potentials and subthreshold depolarizing signals.

Ca^{2+} entering the cell through voltage-gated Ca^{2+} channels serves as the second messenger of electrical signaling, initiating many different cellular events (Fig. 1). In cardiac and smooth muscle cells, activation of Ca^{2+} channels initiates contraction directly by increasing cytosolic Ca^{2+} concentration and indirectly by activating ryanodine-sensitive Ca^{2+} release channels in the sarcoplasmic reticulum [1,2]. In skeletal muscle cells, voltage-gated Ca^{2+} channels in the transverse tubule membranes interact directly with ryanodine-sensitive Ca^{2+} release channels in the sarcoplasmic reticulum and activate them to initiate rapid contraction [3,4]. The same Ca^{2+} channels in the transverse tubules also mediate a slow Ca^{2+} conductance that increases cytosolic concentration and thereby regulates the force of contraction in response to high-frequency trains of nerve impulses. In endocrine cells, voltage-gated Ca^{2+} channels mediate Ca^{2+} entry that initiates secretion of hormones [5]. In neurons, voltage-gated Ca^{2+} channels initiate synaptic transmission [6,7,8]. In many different cell types, Ca^{2+} entering the cytosol via voltage-gated Ca^{2+} channels regulates enzyme activity, gene expression, and other biochemical processes [9,10]. Thus, voltage-gated Ca^{2+} channels are the key signal transducers of electrical excitability, converting the electrical signal of the action potential in the cell surface membrane to an intracellular Ca^{2+} transient. Signal transduction in different cell types involves different molecular subtypes of voltage-gated Ca^{2+} channels, which mediate voltage-gated Ca^{2+} currents with different physiological, pharmacological, and regulatory properties.

Ca^{2+} Current Types Defined by Physiological and Pharmacological Properties

Since the first recordings of Ca^{2+} currents in cardiac myocytes [11,12], it has become apparent that there are multiple types of Ca^{2+} currents as defined by physiological and

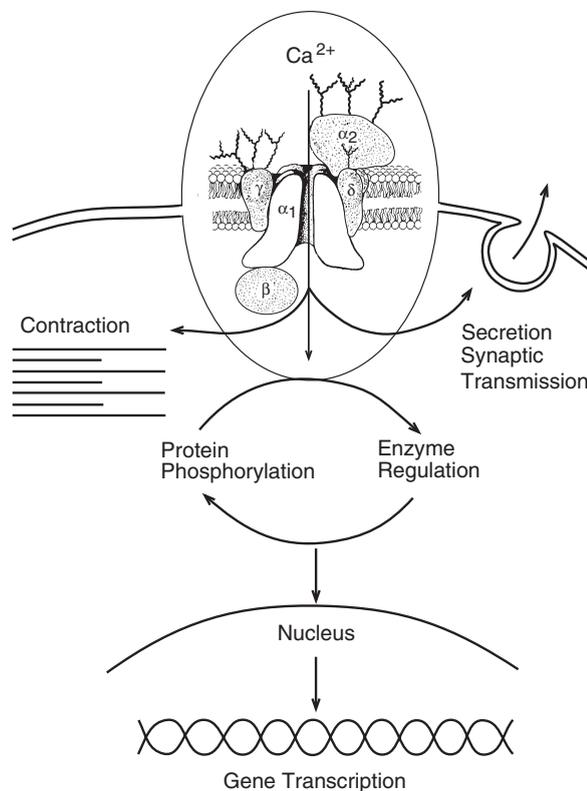

Figure 1 Ca^{2+} channels and signal transduction. Ca^{2+} entering cells initiates numerous intracellular events, including contraction, secretion, synaptic transmission, enzyme regulation, protein phosphorylation-dephosphorylation, and gene transcription. *Inset.* Subunit structure of voltage-gated Ca^{2+} channels. The five-subunit complex that forms high voltage-activated calcium channels is illustrated with a central, pore-forming α_1 subunit, a disulfide-linked dimer of α_2 and δ glycoprotein subunits, an intracellular β subunit, and a transmembrane glycoprotein γ subunit.

pharmacological criteria [6,13–15]. In cardiac, smooth, and skeletal muscle, the major Ca^{2+} currents are distinguished by high voltage of activation, large single channel conductance, slow voltage-dependent inactivation, marked regulation by cAMP-dependent protein phosphorylation pathways, and specific inhibition by Ca^{2+} antagonist drugs, including dihydropyridines, phenylalkylamines, and benzothiazepines [16]. These Ca^{2+} currents have been designated L-type, as they are long-lasting when Ba^{2+} is the current carrier [17]. L-type Ca^{2+} currents are also recorded in endocrine cells, where they initiate release of hormones [18], and in neurons, where they are important in regulation of gene expression and in integration of synaptic inputs [9,10,14].

Voltage clamp studies of Ca^{2+} currents in starfish eggs [19] and recordings of Ca^{2+} action potentials in cerebellar Purkinje neurons [20] first revealed Ca^{2+} currents with different properties from L-type, and these were subsequently characterized in detail in voltage-clamped dorsal root ganglion neurons [17,21–23]. In comparison to L-type, these Ca^{2+} currents activate at much more negative membrane potentials, inactivate rapidly, deactivate slowly, have small single channel conductance, and are insensitive to Ca^{2+} antagonist drugs. They are designated low-voltage-activated Ca^{2+} currents for their

negative voltage dependence [21] or T-type for their transient kinetics [17].

Whole-cell voltage clamp and single-channel recording from dissociated dorsal root ganglion neurons revealed an additional Ca^{2+} current, N-type [17]. In these initial experiments, N-type Ca^{2+} currents were distinguished by their intermediate voltage dependence and rate of inactivation—more negative and faster than L-type but more positive and slower than T-type [17]. They are insensitive to organic L-type Ca^{2+} channel blockers but blocked by the cone snail peptide ω -conotoxin GVIA [6,24]. This pharmacological profile has been the primary method to distinguish N-type Ca^{2+} currents, because the voltage dependence and kinetics of N-type Ca^{2+} currents in different neurons vary considerably.

Analysis of the effects of other peptide toxins revealed three additional Ca^{2+} current types. P-type Ca^{2+} currents, first recorded in Purkinje neurons [25], are distinguished by high sensitivity to the spider toxin ω -agatoxin IVA [26]. Q-type Ca^{2+} currents, first recorded in cerebellar granule neurons [27], are blocked by ω -agatoxin IVA with lower affinity. R-type Ca^{2+} currents in cerebellar granule neurons are resistant to the subtype-specific organic and peptide Ca^{2+} channel blockers [27] and may include multiple channel subtypes [28]. While L-type and T-type Ca^{2+} currents are recorded in a wide range of cell types, N-, P-, Q-, and R-type Ca^{2+} currents are most prominent in neurons.

Molecular Properties of Ca^{2+} Channels

Subunit Structure. Ca^{2+} channels purified from skeletal muscle transverse tubules are complexes of α_1 , β , and γ subunits, and the α_1 and β subunits are substrates for cAMP-dependent protein phosphorylation [29,30]. More detailed biochemical analyses revealed an additional $\alpha_2\delta$ subunit co-migrating with the α_1 subunit [31–34]. Analysis of the biochemical properties, glycosylation, and hydrophobicity of these five subunits led to a model comprising a principal transmembrane α_1 subunit of 190 kDa in association with a disulfide-linked $\alpha_2\delta$ dimer of 170 kDa, an intracellular phosphorylated β subunit of 55 kDa, and a transmembrane γ subunit of 33 kDa (Fig. 1, inset) [31].

The α_1 subunit is a protein of about 2000 amino acid residues with an amino acid sequence and predicted transmembrane structure like the previously characterized, pore-forming α subunit of sodium channels [35] (Fig. 2). The amino acid sequence is organized in four repeated domains (I to IV), each of which contains six transmembrane segments (S1 to S6) and a membrane-associated loop between transmembrane segments S5 and S6. As expected from biochemical analysis [31], the intracellular β subunit has predicted alpha helices but no transmembrane segments [36] (Fig. 2), while the γ subunit is a glycoprotein with four transmembrane segments [37] (Fig. 2). The cloned α_2 subunit has many glycosylation sites and several hydrophobic sequences [38], but biosynthesis studies indicate that it is an extracellular,

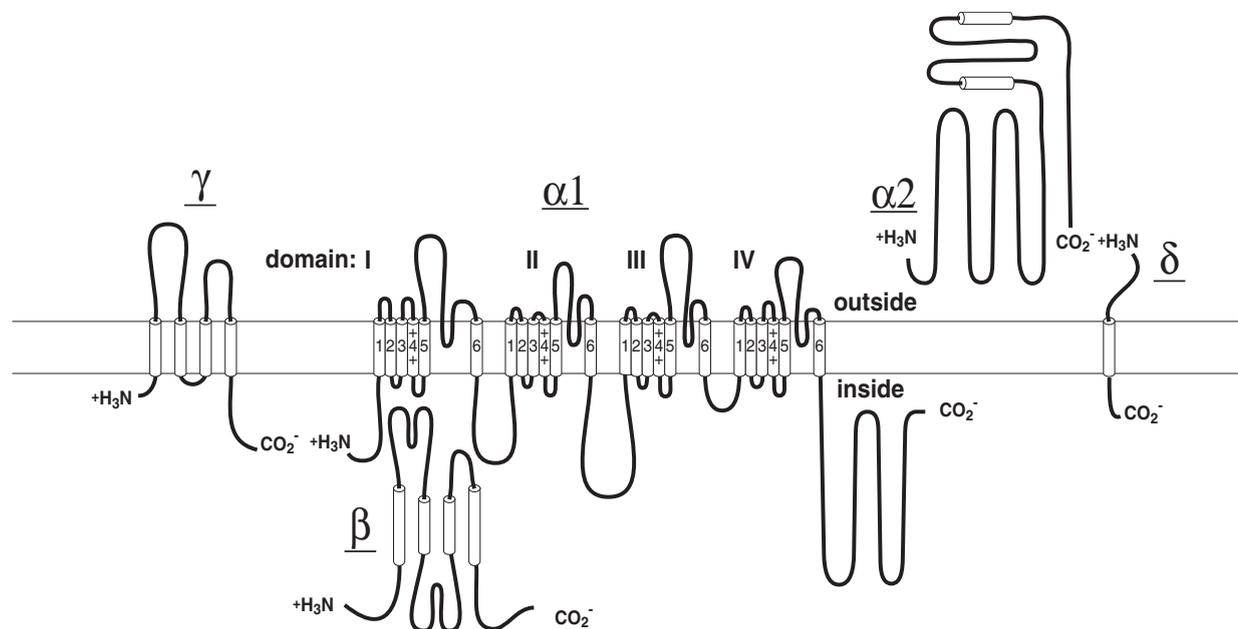

Figure 2 Transmembrane organization of voltage gated Ca^{2+} channels. The primary structures of the subunits of voltage-gated Ca^{2+} are illustrated. *Cylinders* represent probable alpha helical transmembrane segments. *Bold lines* represent the polypeptide chains of each subunit with length approximately proportional to the number of amino acid residues.

extrinsic membrane protein, attached to the membrane through disulfide linkage to the δ subunit [39] (Fig. 2). The δ subunit is encoded by the 3' end of the coding sequence of the same gene as the $\alpha 2$ subunit, and the mature forms of these two subunits are produced by posttranslational proteolytic processing and disulfide linkage [40,41] (Fig. 2).

Purification of cardiac Ca^{2+} channels revealed subunits of the sizes of the $\alpha 1$, $\alpha 2\delta$, β , and γ subunits of skeletal muscle Ca^{2+} channels [42–45], and immunoprecipitation of Ca^{2+} channels from neurons labeled by dihydropyridine Ca^{2+} antagonists revealed $\alpha 1$, $\alpha 2\delta$, and β subunits but no γ subunit [46]. Together, these results suggest a similar subunit composition for L-type Ca^{2+} channels in cardiac and skeletal muscle and in neurons.

Purification and immunoprecipitation of N-type Ca^{2+} channels labeled by ω -conotoxin GVIA from brain membrane preparations revealed $\alpha 1$, $\alpha 2\delta$, and β subunits [47,48]. Similarly, purified P/Q-type Ca^{2+} channels are composed of $\alpha 1$, $\alpha 2\delta$, and β subunits [49–51]. In addition, more recent experiments have unexpectedly revealed a novel γ subunit, which is the target of the *stargazer* mutation in mice [52], and a related series of γ subunits expressed in brain and other tissues [53,54]. These γ -subunit-like proteins can modulate the voltage dependence of P/Q-type Ca^{2+} currents, so they may be associated with these Ca^{2+} channels *in vivo* [52]. If these new γ subunits are indeed associated with all neuronal Ca^{2+} channels, their subunit composition would be identical to that of skeletal muscle Ca^{2+} channels defined in biochemical experiments [31] (Fig. 2).

Functions of Ca^{2+} Channel Subunits. The initial analyses of functional expression of Ca^{2+} channel subunits were carried out with skeletal muscle Ca^{2+} channels. Expression of the

$\alpha 1$ subunit is sufficient to produce functional skeletal muscle Ca^{2+} channels, but with low expression level and abnormal kinetics and voltage dependence of the Ca^{2+} current [55]. Co-expression of the $\alpha 2\delta$ subunit and especially the β subunit enhances the level of expression and confers more normal gating properties [56,57]. As for skeletal muscle Ca^{2+} channels, co-expression of β subunits has a large effect on the level of expression and the voltage dependence and kinetics of gating of cardiac and neuronal Ca^{2+} channels. In general, the level of expression is increased and the voltage dependence of activation and inactivation is shifted to more negative membrane potentials, and the rate of inactivation is increased. However, these effects are different for the individual β subunit isoforms (reviewed in [58,59]). For example, co-expression of the $\beta 2a$ subunit slows inactivation in most subunit combinations. In contrast, co-expression of $\alpha 2\delta$ subunits [58,59] and γ subunits [52] has much smaller functional effects.

Ca^{2+} Channel Diversity. The different types of Ca^{2+} currents are primarily defined by different $\alpha 1$ subunits. The primary structures of ten distinct Ca^{2+} channel $\alpha 1$ subunits have been defined by homology screening, and their function has been characterized by expression in mammalian cells or *Xenopus* oocytes. These subunits can be divided into three structurally and functionally related families (Ca_v1 , Ca_v2 , and Ca_v3) (Table I, [60]). L-type Ca^{2+} currents are mediated by the Ca_v1 type of $\alpha 1$ subunits, which have about 75% amino acid sequence identity among them [35,61,62]. The Ca_v2 type Ca^{2+} channels form a distinct subfamily with less than 40% amino acid sequence identity with Ca_v1 $\alpha 1$ subunits but greater than 70% amino acid sequence identity among themselves. Cloned $\text{Ca}_v2.1$ subunits [63,64] form

Table I Subunit Composition and Function of Ca²⁺ Channel Types

Ca ²⁺ channel type	α_1 subunits	Specific blocker	Principal physiological functions	Inherited diseases
L	Ca _v 1.1	DHPs	Excitation-contraction coupling in skeletal muscle Regulation of transcription	Hypokalemic periodic paralysis
	Ca _v 1.2	DHPs	Excitation-contraction coupling in cardiac and smooth muscle Regulation of enzyme activity Regulation of transcription	
	Ca _v 1.3	DHPs	Endocrine secretion Cardiac pacemaking Auditory transduction	
	Ca _v 1.4	DHPs	Visual transduction	
N	Ca _v 2.1	ω -CTx-GVIA	Neurotransmitter release Dendritic Ca ²⁺ transients	Migraine Cerebellar ataxia Absence seizures (in mice)
P/Q	Ca _v 2.2	ω -Agatoxin	Neurotransmitter release Dendritic Ca ²⁺ transients	
R	Ca _v 2.3	SNX-482	Neurotransmitter release Dendritic Ca ²⁺ transients	
T	Ca _v 3.1	None	Pacemaking and repetitive firing	
	Ca _v 3.2			
	Ca _v 3.3

P- or Q-type Ca²⁺ channels, which are inhibited by ω -agatoxin IVA [65–67]. Ca_v2.2 subunits form N-type Ca²⁺ channels with high affinity for ω -conotoxin GVIA [68,69]. Cloned Ca_v2.3 subunits form R-type Ca²⁺ channels, which are resistant to both organic Ca²⁺ antagonists specific for L-type Ca²⁺ currents and the peptide toxins specific for N-type or P/Q-type Ca²⁺ currents [27,70,71]. T-type Ca²⁺ currents are mediated by the Ca_v3 channels [72]. These α_1 subunits are only distantly related to the other known homologs, with less than 25% amino acid sequence identity. These results reveal a surprising structural dichotomy between the T-type, low-voltage-activated Ca²⁺ channels and the high-voltage-activated Ca²⁺ channels. Evidently, these two lineages of Ca²⁺ channels diverged very early in evolution of multicellular organisms.

The diversity of Ca²⁺ channel structure and function is substantially enhanced by multiple β subunits. Four β subunit genes have been identified, and each is subject to alternative splicing to yield additional isoforms (reviewed in [58,73]). In Ca²⁺ channel preparations isolated from brain, each Ca²⁺ channel α_1 subunit that has been investigated is associated with multiple β subunits, although there is a different rank order in each case [74,75]. The different β subunit isoforms cause different shifts in the kinetics and voltage dependence of gating, so association with different β subunits can substantially alter the physiological function of an α_1 subunit. Genes encoding four $\alpha_2\delta$ subunits have been described [76], but the $\alpha_2\delta$ isoforms produced by these different genes have relatively small functional effects on channel gating and expression. A new family of γ subunits has been recently

described [52–54], which has small, but significant effects on the voltage dependence of Ca²⁺ channel gating.

Molecular Basis for Ca²⁺ Channel Function

Intensive studies of the structure and function of the related pore-forming subunits of Na⁺, Ca²⁺, and K⁺ channels have led to identification of their principal functional components (reviewed in [77–80]). Each domain of the principal subunits consists of six transmembrane alpha helices (S1 through S6) and a membrane-associated loop between S5 and S6 (Fig. 2). The S4 segments of each homologous domain serve as the voltage sensors for activation, moving outward and rotating under the influence of the electric field and initiating a conformational change that opens the pore. The S5 and S6 segments and the membrane-associated pore loop between them form the pore lining of the voltage-gated ion channels. The narrow external pore is lined by the pore loop, which contains a pair of glutamate residues in each domain that are required for Ca²⁺ selectivity. Remarkably, substitution of only three amino acid residues in the pore loops between the S5 and S6 segments in domains II, III, and IV of sodium channels is sufficient to confer Ca²⁺ selectivity [81]. The inner pore is lined by the S6 segments, which form the receptor sites for the pore-blocking Ca²⁺ antagonist drugs specific for L-type Ca²⁺ channels [82–84]. All Ca²⁺ channels share these general structural features, but the amino acid residues that confer high affinity for the organic Ca²⁺ antagonists used in

therapy of cardiovascular diseases are present only in the Ca_v1 family of Ca²⁺ channels, which conduct L-type Ca²⁺ currents.

Ca²⁺ Channel Regulation

The activity of voltage-gated Ca²⁺ channels is tightly regulated by second messenger signal transduction pathways through direct interactions with G proteins and other intracellular signaling proteins and through protein phosphorylation (reviewed in [85]). Regulation of L-type Ca²⁺ currents in cardiac, skeletal, and smooth muscle cells by the β-adrenergic receptor/cAMP pathway involves a signaling complex of the Ca_v1.1 or Ca_v1.2 channels, an A kinase anchoring protein designated AKAP-15 or AKAP-18, and PKA targeted to the channel by AKAP binding via a leucine zipper to a site in the C-terminal domain of the α1 subunit [86–89]. A functionally similar signaling complex in the brain includes the β-adrenergic receptor itself, adenylyl cyclase, the AKAP MAP 250, and PKA [90]. This signaling pathway is also engaged by other G protein-coupled receptors that activate adenylyl cyclase. This pathway regulates beating rate and contractility in the heart, vascular tone, skeletal muscle contractile force, and gene expression in neurons, myocytes, endocrine cells, and other cell types.

The activity of the Ca_v2 family of channels is regulated primarily by direct interaction with G proteins and other signaling proteins and secondarily by protein phosphorylation (reviewed in [8,91]). Many different neurotransmitters and hormones activate G protein-coupled receptors, which release Gβγ subunits that inhibit Ca²⁺ channel activity [92–94]. G protein inhibition can be reversed by strong depolarization, resulting in facilitation of Ca²⁺ channel activity, and by phosphorylation by protein kinase C [8,91,95–98]. In addition, the activity of the Ca_v2 family of channels is regulated by interaction with the SNARE proteins that are required in exocytosis [99–102]. This regulatory mechanism appears designed to focus Ca²⁺ entry on Ca²⁺ channels with exocytotic vesicles docked nearby.

Ca²⁺ itself also regulates the activity of both Ca_v1 and Ca_v2 channels. Low levels of Ca²⁺ entry cause facilitation of Ca²⁺ channel activity, and higher levels cause Ca²⁺-dependent inactivation [103–107]. Both processes involve binding to calmodulin and interaction with specific calmodulin-binding sites in the C-terminal domain of the Ca²⁺ channel. In repetitively firing neurons and in cardiac myocytes, this mechanism allows integration of Ca²⁺ signals as a function of frequency of action potential generation. This mode of regulation also serves to tune the Ca²⁺ entry to the needs of intracellular regulatory processes and prevent inappropriately wide swings in local Ca²⁺ concentration.

Conclusion

Voltage-gated Ca²⁺ channels are essential signal transducers, converting cell surface electrical signals to intracellular

Ca²⁺ transients that initiate many physiological and biochemical events. Recent research has defined their molecular properties, identified many genes that encode their subunits and provide diversity of function, and revealed their complex interaction with cellular regulatory pathways. Further work on this protein family will give essential insights into cellular signaling and its dysfunction in diseases as diverse as epilepsy, migraine, cardiac arrhythmia, hypertension, and diabetes.

Store-operated Ca^{2+} Channels

Capacitative Calcium Entry

Many signaling pathways involve the generation of cytoplasmic Ca^{2+} signals. As reviewed elsewhere in this volume, in many instances these Ca^{2+} signals arise as a result of the Ca^{2+} -mobilizing actions of the intracellular messenger, inositol 1,4,5-trisphosphate (IP_3) (see also [1]). IP_3 binds to specific receptor/channels on the endoplasmic reticulum; the binding of IP_3 results in channel opening and release of stored Ca^{2+} to the cytoplasm. In most cell types, this release of Ca^{2+} from intracellular stores is accompanied by an accelerated entry of Ca^{2+} across the plasma membrane. A variety of mechanisms may be responsible for this entry of Ca^{2+} (reviewed in [2,3]). One mechanism that appears to be ubiquitous in nonexcitable cells, and is found in a number of excitable cell types, is *capacitative calcium entry*, also known as *store-operated calcium entry* [4–6]. The signal for capacitative calcium entry appears to be the fall in the concentration of Ca^{2+} in the endoplasmic reticulum or in a specialized subcompartment of it.

While the physiological mechanism for depleting stores and activating capacitative calcium entry generally involves IP_3 -mediated discharge of Ca^{2+} stores, a number of experimental manipulations can bypass receptor activation to empty Ca^{2+} stores. Inhibitors of sarcoplasmic endoplasmic reticulum Ca^{2+} ATPases, such as thapsigargin, cause passive depletion of Ca^{2+} stores and are thus efficient activators of capacitative calcium entry. In electrophysiological studies, utilizing the patch clamp technique to examine whole-cell store-operated membrane currents, IP_3 can be included in the patch pipet, or Ca^{2+} stores can be depleted simply by high concentrations of a Ca^{2+} chelator. The first store-operated current to be described was the Ca^{2+} release-activated Ca^{2+} current (I_{crac})

characteristically found in hematopoietic cells [7]. Noise analysis indicates that the unitary conductance of single CRAC channels is likely to be too small to measure [8]. However, in other cell types, the electrophysiological profile of store-operated currents appears to differ significantly from I_{crac} , and in some instances single channels have been observed [9–12]. In these instances, the whole cell current resulting from store depletion is always less Ca^{2+} selective than I_{crac} . In some cases the whole cell currents appear to be nonselective cation currents [12–15]. This finding indicates that the molecular composition of store-operated channels differs among cell types, and it is also possible therefore that multiple mechanisms exist for gating these channels.

Store-operated Channels

The leading contenders for molecular components of store-operated channels are members of the *trp* gene superfamily [16]. In *Drosophila*, the *trp* gene encodes a subunit of a cation channel regulated by a light-sensitive phospholipase C [17]. Seven mammalian *trp* genes with 30–40% sequence similarity to *Drosophila trp* have been cloned, and the proteins they encode have been designated TRPC1 ... TRPC7, which fall into four groups based on structural similarities: TRPC1, TRPC2, TRPC3/6/7, TRPC4/5. While the results of transfection experiments sometimes vary from one laboratory to another, there are a gratifying number of instances in which these proteins appear to form or contribute to the formation of store-operated channels (TRPC1 [18,19], TRPC2 [20,21], TRPC3 [22], TRPC4 [23,24]). Generally, the channels formed in these expression studies are not highly calcium selective and thus may be candidates for the less selective channels

found in nonhematopoietic cells. CaT1 (also known as TRPV6), a member of the *trp* superfamily, which is more distantly related to *trp* than the TRPC proteins, was shown in one study to express as a highly Ca²⁺-selective store-operated channel [25]; however, these findings are at present controversial [26].

Mechanism of Activation of Store-operated Channels

There are two distinct proposals for the mechanism coupling Ca²⁺ store depletion to activation of capacitative calcium entry. The earliest idea was that a novel messenger molecule might be released from the endoplasmic reticulum, and this messenger would then diffuse to the plasma membrane and activate the store-operated channels [4]. A number of studies have published evidence for such a messenger, although its structure has not been elucidated [27–31]. The alternative proposal is based on analogy with the mechanism of coupling of L-type Ca²⁺ channels to ryanodine receptors in skeletal muscle. Thus, the conformational coupling model [6,32] proposes that IP₃ receptors in the endoplasmic reticulum interact directly with plasma membrane Ca²⁺ channels, perhaps members of the *trp* family. In support of this idea, TRPC3, when expressed in HEK293 cells, forms channels that are activated in a manner dependent on IP₃ and the IP₃ receptor [33–35]. However, in this expression system, TRPC3 is not a store-operated channel, rather its activation requires agonist activation of phospholipase C and production of IP₃. Also, in DT40 B lymphocytes, when IP₃ receptors were eliminated by gene disruption, store-operated Ca²⁺ entry was unaffected [36]. Expression of TRPC3 in these cells produced a store-operated channel whose activity was only partially reduced in the absence of IP₃ receptors [22]. Thus, conformational coupling may play a role in activation of store-operated channels in some situations, while a second messenger mode of signaling may be involved in others.

Summary

Capacitative calcium entry is a process whereby depletion of Ca²⁺ from intracellular stores leads to the activation of Ca²⁺ channels in the plasma membrane and accelerated entry of Ca²⁺ into the cytoplasm of cells. Current research focuses on the molecular nature of the channels and the mechanism of coupling the channels to Ca²⁺ store depletion. Leading contenders for the store-operated channels are members of the *trp* gene family, although no one gene has been definitively linked to a specific store-operated channel. The mechanism of activation of the channels may involve interactions between the plasma membrane channels and endoplasmic reticulum IP₃ receptors in some instances or a diffusible Ca²⁺ influx factor in others. Continued work is needed to clarify and resolve these important issues.

Arachidonic Acid-regulated Ca²⁺ Channel

Trevor J. Shuttleworth

*Department of Pharmacology and Physiology,
University of Rochester Medical Center,
Rochester, New York*

Introduction

The arachidonic acid-regulated Ca²⁺ (ARC) channel is a recently identified Ca²⁺-selective conductance that is distinct from the store-operated conductances (e.g. CRAC channels) discussed by Putney in the preceding chapter. These ARC channels play a key role in [Ca²⁺]_i signaling in nonexcitable cells in that they appear to provide the predominant pathway for the receptor-activated entry of Ca²⁺ at low, physiologically relevant, agonist concentrations. Under these conditions, [Ca²⁺]_i signals typically take the form of repetitive [Ca²⁺]_i oscillations, and the receptor-activated entry of Ca²⁺ acts to modulate the frequency of these oscillations [1–4]. The realization that during such signals intracellular Ca²⁺ stores are only transiently and/or partially depleted raised the question of whether a sufficient “capacitance signal” to activate the store-operated entry of Ca²⁺ would be generated under these conditions. Subsequent studies revealed that Ca²⁺ entry at these agonist concentrations displayed several features that were inconsistent with the capacitance model [5, 6] (see [6] for details), prompting a search for the basis of this apparent noncapacitance mechanism. The result was that in several different cell types such entry was found to be specifically dependent on the receptor-mediated generation of arachidonic acid [7–10]. Thus, arachidonic acid was shown to be generated by the same low agonist concentrations that induce the noncapacitance entry of Ca²⁺, and inhibition of this arachidonic acid generation specifically and rapidly blocked the associated entry of Ca²⁺. Moreover, the direct application of exogenous arachidonic acid activated an entry of Ca²⁺ (typically measured as Mn²⁺ quench rate) that was independent of any depletion

of agonist-sensitive stores. Especially significant, the use of blockers of arachidonic acid metabolism and/or nonmetabolizable arachidonic acid analogues (e.g. ETYA) indicated that the observed effects reflected the actions of arachidonic acid itself, rather than any of its metabolites [8].

Identification and Characterization of ARC Channels

Although an agonist-activated, arachidonic acid-dependent entry of Ca²⁺ could be demonstrated in a variety of cells, it was unclear whether this involved some kind of “store-independent” activation of the already well-known capacitance Ca²⁺ entry channels (e.g. CRAC channels) or the activation of a novel channel type. This question was resolved by the identification of a novel Ca²⁺-selective current that was specifically activated by low concentrations of arachidonic acid and that was entirely distinct from the endogenous “CRAC-like” store-operated Ca²⁺-selective current recorded in the same cells [11]. This current was named *I*_{ARC} (for *arachidonate-regulated calcium current*), and was first described in HEK293 cells [11], but similar currents have since been observed in mouse parotid cells, HeLa cells, and RBL cells (unpublished observations). When measured in either traditional whole-cell or perforated-patch modes, *I*_{ARC} is seen as a small inward current at negative holding potentials, with a current-voltage relationship displaying marked inward rectification and a reversal potential significantly greater than +30 mV (Fig. 1A) [11]. The current is potently blocked by 50 μM La³⁺ (Fig. 1A) and somewhat less effectively blocked by 50 μM Cd²⁺. Substitution of

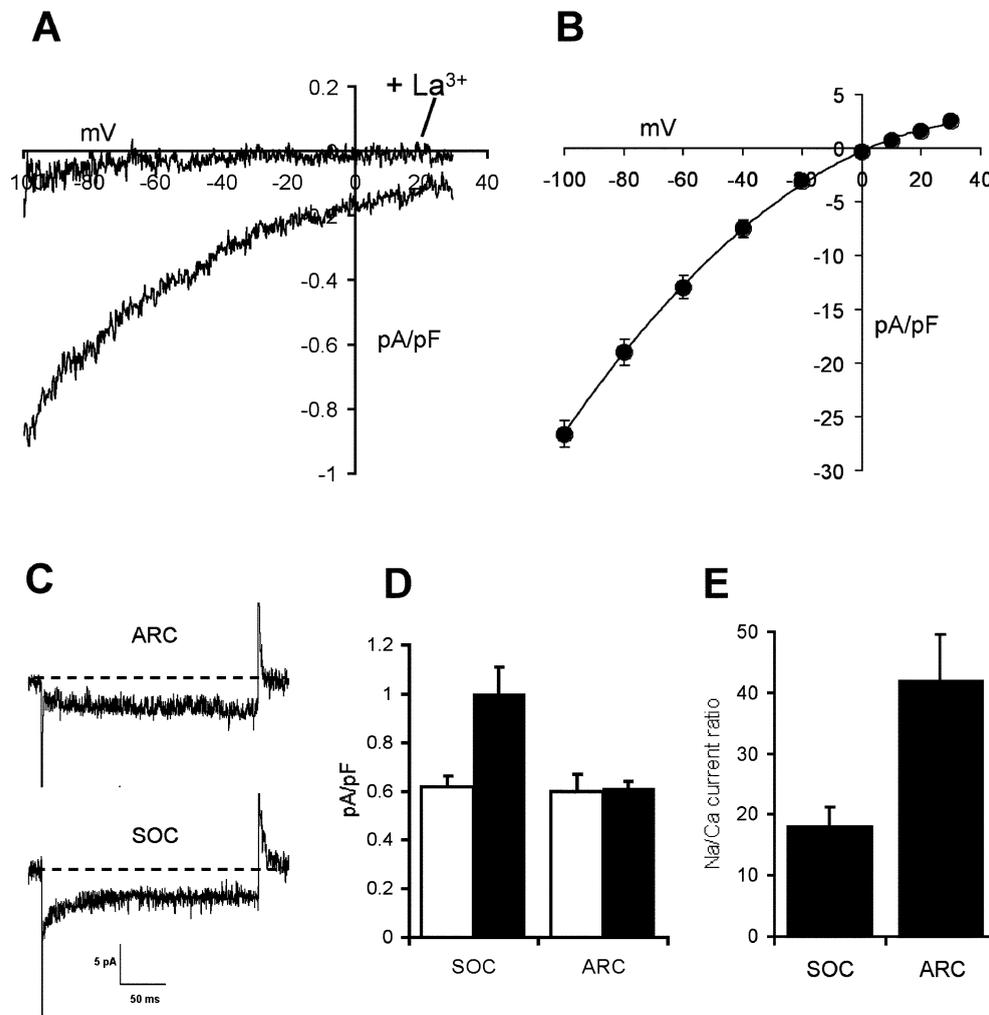

Figure 1 Characteristics of the arachidonic acid-activated current I_{ARC} . (A) Representative I/V curves for macroscopic I_{ARC} in the presence and absence of La^{3+} ($50 \mu M$). I_{ARC} was activated by exogenous addition of $8 \mu M$ arachidonic acid. Current-voltage relationships were recorded using 150 ms voltage ramps from -100 to $+30$ mV. External Ca^{2+} concentration was 20 mM. Adapted from [11]. (B) Mean I/V curve for the arachidonate-activated monovalent current recorded in the nominal absence of extracellular divalent cations. Internal $[Mg^{2+}]$ was 8 mM. ARC currents were activated and measured as described in A. (C) Comparison of fast inactivation in I_{ARC} (activated as described in A) and the endogenous CRAC-like store-operated current (I_{SOC}) in HEK293 cells. I_{SOC} was activated by inclusion of $2 \mu M$ adenophostin in the pipette solution. Representative recordings of the change in the current measured during a 250 ms pulse to -80 mV. Redrawn from [11]. (D) Effect of substituting internal cesium (open columns) with sodium (filled columns) on the magnitude of the endogenous store-operated currents (SOC) and the arachidonic acid-activated currents (ARC) determined at -80 mV. Store-operated and arachidonic acid-activated currents were determined as described. Data from [13]. (E) Sodium to calcium current ratios for store-operated currents (SOC) and arachidonic acid-activated currents (ARC). Maximal sodium current densities were measured at -80 mV by whole-cell patch clamp in the nominal absence of external divalent cations. SOC and ARC currents were activated as described above. Data from [13].

external Na^+ with NMDG $^+$ has negligible effects on the I/V, thus demonstrating that I_{ARC} is highly Ca^{2+} -selective.

Like other highly Ca^{2+} -selective conductances (including voltage-gated Ca^{2+} channels and CRAC channels), the ARC channels become permeable to monovalent cations on removal of external divalent ions (Fig. 1B). All these features of I_{ARC} are very similar to the archetypal store-operated conductance I_{CRAC} and the endogenous store-operated Ca^{2+} -selective current (I_{SOC}) in HEK293 cells. However, further examination revealed marked differences between I_{ARC} and these store-operated conductances. Unlike I_{CRAC} and I_{SOC} , I_{ARC} shows no Ca^{2+} -dependent fast-inactivation (Fig. 1C) and is largely

insensitive to reductions in extracellular pH [11]. I_{ARC} is also insensitive to 2-APB (unpublished observations), which has been shown to potently inhibit I_{CRAC} in a variety of cell types in a manner independent of its originally reported actions on $InsP_3$ receptors [12]. In addition, substitution of the normal Cs^+ -based internal (pipette) solution with a corresponding Na^+ -based solution results in an approximate 70% increase in the magnitude of I_{SOC} [13], whereas similar substitution is without effect on the magnitude of I_{ARC} (Fig. 1D). Differences are also seen when the conductances are recorded in their monovalent-permeable modes in the nominal absence of external divalent cations [14]. For example, the ratio of the recorded

monovalent (Na⁺) currents relative to the normal Ca²⁺-selective currents range from 5 to 20 for I_{CRAC} and I_{SOC} , whereas the corresponding ratio for I_{ARC} is greater than 40 (Fig. 1E). Additional differences are seen in the rates and apparent nature of the spontaneous decline in the monovalent currents [14]. Of course, the fundamental distinction between I_{ARC} and the store-operated conductances is that activation of I_{ARC} is specifically dependent on the generation or addition of arachidonic acid and is entirely independent of store-depletion. Moreover, I_{ARC} and I_{SOC} are additive in the same cell and I_{ARC} can be readily activated in cells whose Ca²⁺ stores have been maximally depleted, e.g. by treatment with thapsigargin or with the high-affinity InsP₃-receptor agonist adenophostin A [11]. Finally, the possibility that arachidonic acid was merely modifying the properties of endogenous store-operated conductances was eliminated by the demonstration that although Ca²⁺-sensitive adenylyl cyclases are uniquely sensitive to Ca²⁺ entering via the capacitative pathway, they fail to respond to Ca²⁺ entering via the ARC channels [15]. Thus, the ARC channels are entirely distinct, both physically and spatially, from the store-operated channels.

Consistent with the previously observed arachidonic acid-dependent activation of noncapacitative Ca²⁺ entry, significant activation of I_{ARC} is detectable at concentrations of exogenous arachidonic acid as low as 2–3 μM. Such concentrations are likely to be physiologically meaningful as they lie within the typical range of the Km for the intracellular cyclo-oxygenases and lipoxygenases responsible for metabolizing arachidonic acid. It is important that use of higher concentrations be avoided, as it is clear that fatty acids such as arachidonic acid can have a variety of nonspecific effects (e.g. on membrane fluidity) at such concentrations. As demonstrated earlier for the arachidonic acid-dependent noncapacitative entry of Ca²⁺ (see above), experiments using the nonmetabolizable arachidonic acid analogue ETYA indicate that the activation of I_{ARC} is dependent on the fatty acid itself rather than any metabolite. Other poly-unsaturated fatty acids (e.g. linoleic acid) are also able to activate I_{ARC} , but none are as effective as arachidonic acid. Saturated (e.g. palmitic), and mono-unsaturated (e.g. oleic) fatty acids are completely without effect. Finally, the diacylglycerol analogue OAG fails to activate I_{ARC} even at concentrations as high as 100 μM (unpublished observations).

Specific Activation of ARC Channels by Low Agonist Concentrations

Together, the biophysical, biochemical, and pharmacological data demonstrate that the ARC channels represent a novel Ca²⁺ entry pathway entirely distinct from those activated by store depletion, and suggest that they are likely to be responsible for the arachidonic acid-dependent noncapacitative entry of Ca²⁺ seen in a variety of cells at low agonist concentrations. This suggestion was confirmed by the demonstration of the specific activation of I_{ARC} by the same low concentrations of agonists that had been shown to activate the noncapacitative

entry of Ca²⁺. Activation was achieved by using HEK 293 cells stably transfected with the m3 muscarinic receptor and a protocol based on the previous demonstration of the additive nature of the two Ca²⁺-selective conductances (I_{ARC} and I_{SOC}) in the same cell [13]. Application of a low concentration (0.5 μM) of the muscarinic agonist carbachol to cells in which I_{SOC} had been maximally activated (using adenophostin A in the pipette solution) resulted in the development of an additional inward current at –80 mV (Fig. 2A). The I/V curve of this carbachol-activated current (after subtraction of the underlying I_{SOC}) showed marked inward rectification and a positive reversal potential (> +30 mV) (Fig. 2B). Development of the current was blocked by atropine and reversibly blocked by isotetrandrine, an inhibitor of the receptor-activation of arachidonic acid generation that does not affect the simultaneous stimulation of phospholipase C [8]. Thus, the current activated by carbachol under these conditions was dependent on the muscarinic receptor-mediated generation of arachidonic acid and was therefore likely to be I_{ARC} . This was confirmed by demonstrating that the carbachol-activated current showed no fast-inactivation, was unaffected by substituting Na⁺ for Cs⁺ in the pipette solution, and displayed a monovalent (Na⁺) current in the nominal absence of external divalent ions that was more than 45 times larger than the corresponding normal Ca²⁺-selective current [13]. As discussed above, these features are uniquely characteristic of I_{ARC} , confirming that the additional current activated by low concentrations of carbachol specifically reflects the activity of the ARC channels.

Activation of I_{ARC} by carbachol was measurable at concentrations that were just sufficient to initiate detectable [Ca²⁺]_i signals in the same cells (0.2 μM) and reached a maximum at 1 μM (Fig. 2C) [13]. [Ca²⁺]_i signals within this concentration range are typically oscillatory in nature, and previous evidence had indicated that the associated entry of Ca²⁺ is both noncapacitative and entirely dependent on the generation of arachidonic acid [8]. Thus, the data demonstrated that stimulation with low agonist concentrations results in the specific activation of I_{ARC} , which provides the predominant route for Ca²⁺ entry under these conditions.

Roles of ARC Channels and SOC/CRAC Channels in [Ca²⁺]_i Signals: “Reciprocal Regulation”

Although the ARC channels provide the major route for Ca²⁺ entry at low agonist concentrations, the additive nature of the two conductances I_{ARC} and I_{SOC} would lead to the prediction that entry at high agonist concentrations should be via a combination of both ARC and SOC channels. However, this is inconsistent with earlier evidence indicating that addition of an agonist to cells whose store-operated entry had been maximally activated by treatment with thapsigargin fails to induce any obvious increase in [Ca²⁺]_i [16]. Indeed, such data were widely used to support the proposition that the capacitative pathway was the sole mechanism responsible for the agonist-induced increase in the entry of Ca²⁺ in nonexcitable cells. Examination of the rate of Ca²⁺ entry at

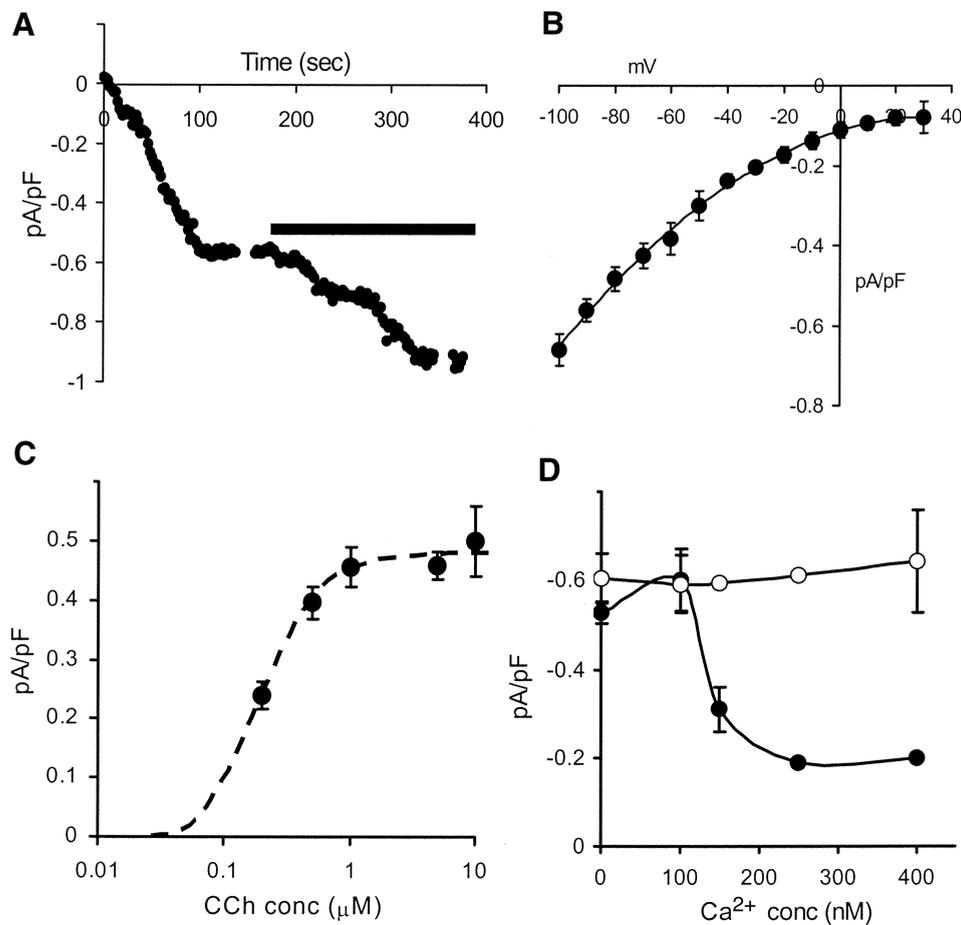

Figure 2 Activation of ARC currents by carbachol in m3-HEK cells. (A) Representative trace showing the activation of an additional inward current measured at -80 mV on addition of low concentrations of carbachol after maximal activation of store-operated currents. On going whole-cell (at time zero), inclusion of adenopostin A ($2 \mu\text{M}$) in the pipette solution rapidly depletes internal Ca^{2+} stores and maximally activates the endogenous store-operated current, I_{SOC} . Subsequent addition of carbachol (CCh, $0.5 \mu\text{M}$, black bar) results in the development of additional inward current. Data taken from [13]. (B) Mean I/V curve for the current activated by carbachol ($0.5 \mu\text{M}$). Individual curves were obtained from voltage ramps after subtraction of the corresponding I/V curve for maximally activated I_{SOC} in the same cell. Taken from [13]. (C) The magnitude of the ARC current activated by different carbachol concentrations. Carbachol-activated ARC currents were measured after maximal activation of store-operated currents as described in B. Taken from [13]. (D) Effects of different buffered internal Ca^{2+} concentrations on the magnitude of SOC (maximally activated with $2 \mu\text{M}$ adenopostin A, open circles) and ARC currents (activated by $8 \mu\text{M}$ arachidonic acid, filled circles). Currents were measured at -80 mV. Taken from [13].

high agonist concentrations (using Mn^{2+} quench) confirmed that this was essentially entirely via the capacitative pathway and no significant arachidonic acid-dependent contribution could be detected, despite an increasing generation of arachidonic acid over the same agonist concentration range [13]. This apparent contradiction was resolved when it was revealed that I_{ARC} is potently inhibited by sustained increases in $[\text{Ca}^{2+}]_i$ above resting values [13] such as would be induced in cells stimulated with high agonist concentrations (Fig. 2D). As yet, the precise mechanism for this Ca^{2+} -dependent inhibition of I_{ARC} is unknown, but it is clear that it does not involve any action of Ca^{2+} entering through the channel itself as inhibition is seen even when I_{ARC} is carrying only monovalent cations (i.e. in the nominal absence of external divalent ions) [13]. Instead, it seems to reflect an effect of the general or global cytosolic Ca^{2+} concentration.

This inhibition of the ARC channels by elevations in $[\text{Ca}^{2+}]_i$ develops only slowly, taking some two minutes to reach completion [13]. This means that the transient increases in $[\text{Ca}^{2+}]_i$ associated with oscillatory Ca^{2+} signals (each typically lasting only a few seconds) would have a negligible effect on the activity of I_{ARC} and would not impair the role of the ARC channels in the entry of Ca^{2+} under these conditions. Only with a prolonged elevation of $[\text{Ca}^{2+}]_i$, such as seen following the sustained depletion of the intracellular stores and activation of I_{CRAC} (or I_{SOC}), will I_{ARC} be significantly inhibited.

These findings lead to the interesting conclusion that the two coexisting, but independent, modes of receptor-stimulated Ca^{2+} entry, via the ARC channels and the SOC/CRAC channels, are regulated in a unique manner by increasing agonist concentrations—a process we have termed “reciprocal regulation” [13]. This is illustrated in Fig. 3. Low concentrations of

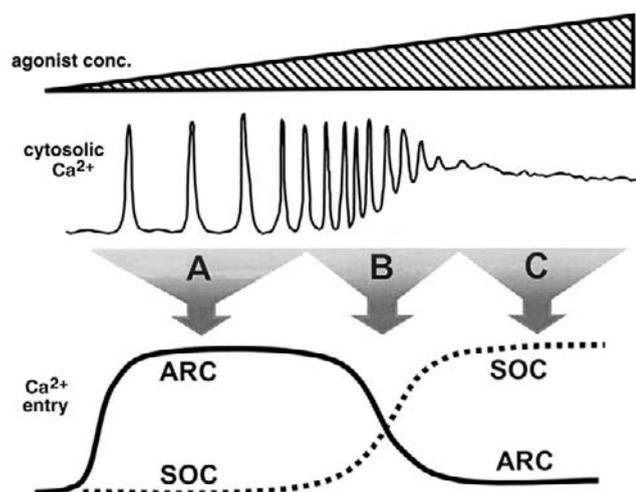

Figure 3 Reciprocal regulation of ARC and SOC channels. Diagram representing the regulation of I_{ARC} and I_{SOC} at different agonist concentrations and the corresponding changes in the nature of the resulting $[\text{Ca}^{2+}]_i$ signal (see text for details). Adapted from [13].

agonist result in the specific activation of the ARC channels which provide the main mode of Ca^{2+} entry under these conditions (see “A” in Fig. 3). This, together with the generation of low levels of InsP_3 , initiates and modulates the cyclical transient discharge and refilling of intracellular Ca^{2+} stores resulting in the generation of the characteristic oscillatory $[\text{Ca}^{2+}]_i$ signals. SOC/CRAC channels fail to activate under these conditions because the transient and/or partial discharge of the intracellular Ca^{2+} stores is not able to generate an adequate “capacitative signal”. As agonist concentrations increase, increasing levels of InsP_3 in the cytosol cause the discharge of the stores to become more complete and sustained, resulting in the activation of the SOC/CRAC channels and the development of a maintained elevated level of $[\text{Ca}^{2+}]_i$ (“C” in Fig. 3). This, in turn, inhibits the activity of the ARC channels. Thus, the transition from an oscillatory $[\text{Ca}^{2+}]_i$ signal to a sustained $[\text{Ca}^{2+}]_i$ signal (“B” in Fig. 3) is associated with a progressive switch in the predominant mode of Ca^{2+} entry from the ARC channels at low agonist concentrations to the SOC/CRAC channels at high (\approx maximal) concentrations.

Conclusions and Implications

The demonstration that ARC channels represent a Ca^{2+} entry pathway that is spatially distinct from those activated by store depletion immediately raises the potential for the specific activation of different targets within the cell, as has already been demonstrated for the SOC channels and certain adenylyl cyclases [15]. Moreover, the fact that these pathways are independently activated at different agonist concentrations adds a new level of complexity to cellular Ca^{2+} signaling. Thus, the appropriate targeting of downstream Ca^{2+} -sensitive effectors to sites in close proximity to either ARC or SOC/CRAC channels may result in the specific selective regulation of these effectors at different agonist concentrations

independent of any obvious overall changes in the spatial and/or temporal features of the induced $[\text{Ca}^{2+}]_i$ changes.

Obviously, the study of ARC channels is still only in its infancy and much remains to be discovered about their properties, regulation, and functions. Undoubtedly, as this novel Ca^{2+} entry pathway begins to receive more attention from researchers, a more complete picture of its distribution and specific roles will be revealed. Critical to this will be the identification of the molecular identity of the channels, which, to date, remains unknown. However, the demonstration that these channels provide the primary route for the receptor-activated entry of Ca^{2+} at physiologically relevant levels of stimulation [13] is of paramount significance, and the recent identification of currents identical to I_{ARC} in several different cell types suggests that this is a widespread phenomenon. Given this, it seems likely that the identification of this unique and specific function of the ARC channels will result in this channel becoming a prime target for possible pharmacological manipulation in any potential therapeutic strategies aimed at this key signaling system.

IP₃ Receptors

Colin W. Taylor

*Department of Pharmacology,
University of Cambridge, Cambridge,
United Kingdom*

Introduction

Inositol 1,4,5-trisphosphate (IP₃) receptors are large proteins: the native receptor is some 20 nm across, extends more than 10 nm from the membrane of the endoplasmic reticulum (ER), and each of its four subunits comprises about 2,700 residues. Their close relatives, ryanodine receptors, are even bigger. Size is important for these intracellular Ca²⁺ channels because it allows opening of the channel to be controlled by many different intracellular stimuli and it allows IP₃ and ryanodine receptors to interact directly with proteins in other membranes, including Ca²⁺ channels in the plasma membrane. IP₃ receptors, for example, may interact directly with the trp channels that are thought to mediate store-regulated Ca²⁺ entry [1]. This role for IP₃ receptors remains controversial, but an essential role in linking receptors that stimulate IP₃ formation to release of Ca²⁺ from intracellular stores is accepted [2].

IP₃ receptors are expressed in most eucaryotic cells, with three genes encoding closely related subtypes in mammals and birds, but only a single subtype in each of *Xenopus*, *Drosophila*, and *C. elegans* [3]. At least two of the mammalian subtypes are also alternatively spliced [4]. Because the functional channel is a tetramer, which can assemble from the same or different subunits, and most mammalian cells express more than one receptor subtype, there is considerable scope for IP₃ receptor diversity [3]. The different subtypes and their splice variants are differentially expressed, respond differently to chronic stimulation, and their assembly into heterotetramers is itself regulated, but the physiological significance of IP₃ receptor heterogeneity is unclear. There are subtle differences in the affinities of the subtypes for IP₃ and in their modulation by various intracellular stimuli [5], but more striking than the differences are the properties shared by all IP₃ receptors. All are

tetrameric intracellular Ca²⁺ channels with large conductances, they have similar primary structures, Ca²⁺ and IP₃ control their opening, and they are modulated by many additional intracellular signals.

Key structural features of the type 1 IP₃ receptor are shown in Fig. 1. Each subunit has an IP₃-binding site formed by two distinct domains lying close to the amino terminal and linked to each other by a short stretch of residues that includes the S1 splice site. Several conserved, positively charged residues are particularly important for recognition of IP₃; they probably interact with its phosphate groups. The core IP₃-binding region of just 350 residues, which can be expressed as a soluble protein with very high affinity for IP₃, has been used as an “IP₃-sponge” to define the role of IP₃ in intact cells [6]. This is a useful tool because the only other antagonists of IP₃ receptors, heparin, Xestospongine and 2-aminoethyl-diphenylborane, are notorious for their side effects.

Toward the carboxy terminal of each subunit there are six membrane-spanning regions, the last two of which together with an intervening loop (the P-loop) line the pore of the channel [7]. In keeping with the similar ion permeation properties of the IP₃ receptor subtypes, the sequences within this pore region are conserved and are also similar in ryanodine receptors [8]. Although almost 1,700 residues separate the IP₃-binding site from the pore, the two regions are associated in the native receptor, with the IP₃-binding region of one subunit perhaps interacting directly with the pore region of a neighboring subunit to control its opening [9]. The long stretch of residues separating the IP₃-binding region from the pore has been described as the “modulatory domain”: it certainly includes at least some of the sites through which channel opening is modulated by phosphorylation or binding of small molecules and proteins [4,10] (Fig. 1).

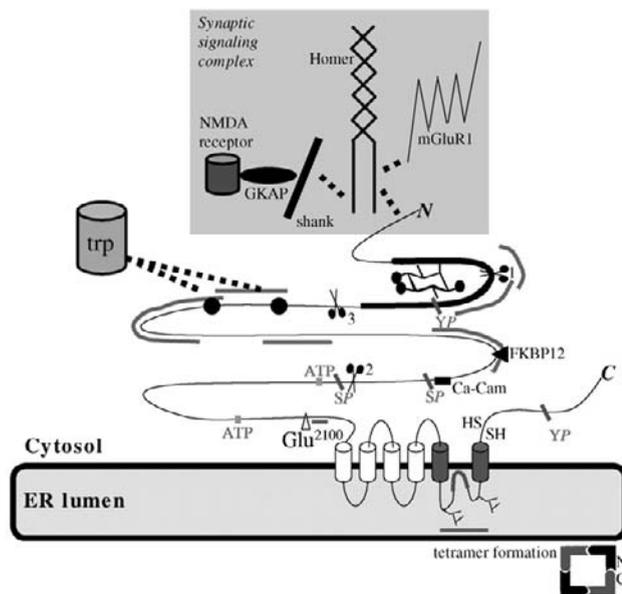

Figure 1 Structure of type 1 IP_3 receptor. The large cytosolic head of the receptor includes the IP_3 -binding domain; seven regions (bold lines) to which Ca^{2+} has been shown to bind; the glutamate²¹⁰⁰ residue shown to affect Ca^{2+} -sensitization; sites phosphorylated by PKA (SP) or tyrosine kinases (YP); the ATP-binding sites; the sites to which FKBP and trp are proposed to bind; and the three alternative splice sites (scissors). The pore is formed by the last two membrane-spanning regions together with part of the intervening loop. The loop also includes two glycosylation sites and a luminal Ca^{2+} -binding site. The C-terminal tail includes conserved cysteine residues and another tyrosine kinase phosphorylation site. Assembly of the subunits into tetramers, which places the N-terminal of one subunit in close proximity to the channel region of another, requires residues downstream of the fourth membrane-spanning region. The box illustrates how Homer might function to link IP_3 receptors to various components of the synaptic signaling complex.

Despite controversy, it seems likely that all IP_3 receptors are biphasically regulated by cytosolic Ca^{2+} . Luminal Ca^{2+} has also been proposed to regulate channel opening, but it is difficult, for both ryanodine and IP_3 receptors [8], to resolve whether this really results from Ca^{2+} stimulating the receptor at its luminal surface or at its cytosolic surface after the Ca^{2+} has passed through the channel. There is a Ca^{2+} -binding site within a luminal loop of the type 1 IP_3 receptor (Fig. 1) and Ca^{2+} -binding proteins within the lumen of IP_3 -sensitive organelles (calreticulin in ER; chromogranin in secretory vesicles) associate with IP_3 receptors [10], but none of these Ca^{2+} -binding sites has been shown to allow luminal Ca^{2+} to regulate channel opening.

Regulation of IP_3 receptors by luminal Ca^{2+} may be unresolved, but there is no such uncertainty about their regulation by cytosolic Ca^{2+} : all IP_3 receptors are stimulated by cytosolic Ca^{2+} and most (possibly all) can also be inhibited by cytosolic Ca^{2+} [5,11]. The details of how this biphasic regulation by cytosolic Ca^{2+} occurs have not been resolved; they are probably different for different receptor subtypes. It is accepted that IP_3 and Ca^{2+} must both bind to the IP_3 receptor before the channel can open and that binding of IP_3 regulates Ca^{2+} binding. IP_3 , in other words, tunes the Ca^{2+} sensitivity of

the IP_3 receptor. One scheme suggests that the major effect of IP_3 is to relieve Ca^{2+} inhibition by decreasing the affinity of an inhibitory Ca^{2+} -binding site [12], while another suggests that IP_3 binding reciprocally regulates two Ca^{2+} -binding sites, causing a stimulatory Ca^{2+} -binding site to be exposed and an inhibitory Ca^{2+} -binding site to be concealed [13]. It is not clear whether these Ca^{2+} -binding sites reside on the IP_3 receptor itself—it certainly has many cytosolic Ca^{2+} -binding sites (Fig. 1)—or on proteins associated with the receptor. A glutamate residue lying close to the C-terminal end of the modulatory domain (Fig. 1), and conserved within all IP_3 and ryanodine receptors, may be important in mediating the stimulatory effect of cytosolic Ca^{2+} [14]. The evidence that it is also involved in Ca^{2+} inhibition is less convincing [14] and difficult to reconcile with evidence suggesting that accessory proteins mediate Ca^{2+} inhibition [11]. Whether calmodulin is required for Ca^{2+} inhibition is hotly contested [15]. In summary, it seems likely that both IP_3 and Ca^{2+} must bind directly to the receptor for the channel to open, and that Ca^{2+} inhibition is via an accessory protein, whose binding to the receptor is probably regulated by IP_3 . Both the regulation of IP_3 receptors by cytosolic Ca^{2+} and the ways in which different subtypes fine-tune that regulation are important in determining the complex spatio-temporal patterns of IP_3 -evoked Ca^{2+} release in intact cells [16].

Besides Ca^{2+} and IP_3 , there are many other modulators of IP_3 receptors. ATP binds to sites within the modulatory domain and increases IP_3 sensitivity [5]. Chemicals that modify sulphhydryl groups, including reactive oxygen species, also increase IP_3 sensitivity, possibly by modifying conserved cysteine residues toward the C-terminal. These residues may thereby link the redox state of the cell to its IP_3 sensitivity. IP_3 receptors are phosphorylated by PKA, PKC, Ca^{2+} -calmodulin-dependent protein kinase II, and PKG [4,10]. The latter also phosphorylates a protein that is tightly associated with the IP_3 receptor (IRAG), causing inhibition of IP_3 -evoked Ca^{2+} release [17]. Phosphorylation of tyrosine residues on IP_3 receptors can also set their sensitivity to IP_3 [18]. The immunophilin FKBP12, which certainly regulates ryanodine receptors, may regulate IP_3 receptors both directly and by anchoring the protein phosphatase, calcineurin, to them.

Most IP_3 receptors are found in the membranes of the ER, but they also occur in the Golgi, secretory vesicles, nuclear envelope, and plasma membrane. Even within the ER, the distribution of IP_3 receptors is far from uniform. On a molecular scale, IP_3 receptors occur in clusters [19], allowing the Ca^{2+} released by one receptor to rapidly influence its neighbors [16]. At a cellular level, they can be concentrated in discrete areas of ER: at the apical pole of pancreatic acinar cells, for example. There are also important functional associations between IP_3 receptors in the ER and other membranes: the possible link between IP_3 receptors and trp channels in the plasma membrane was mentioned earlier (Fig. 1), and there are many examples of IP_3 receptors in close association with mitochondria [20]. We are only just beginning to unravel the mechanisms responsible for putting IP_3 receptors into the right places, but scaffolding proteins are likely to be important.

An example illustrates the likely complexity of the interactions between scaffold proteins and IP₃ receptors. The Homer proteins are a family of dimeric scaffold proteins that assemble signaling proteins at excitatory synapses. The N-terminal of Homer binds to IP₃ receptors, type 1 metabotropic glutamate receptors, and to Shank, another scaffold protein that is targeted by its PDZ domain to the postsynaptic density and that itself binds further signaling proteins [21]. This chain of protein-protein interactions both targets IP₃ receptors to the dendritic spines of hippocampal neurones and brings them into intimate association with other signaling proteins, including receptors that stimulate IP₃ formation and channels that mediate Ca²⁺ entry (Fig. 1).

Function and Structure

The store from which signal Ca^{2+} is derived is either the extracellular space or the luminal space of intracellular organelles, the source depending on the specialization of the cell. In muscle, Ca^{2+} is the major signaling molecule for excitation-contraction coupling, the process involving release of Ca^{2+} from the sarcoplasmic reticulum (SR) in response to depolarization of the sarcolemma and transverse tubules, and the subsequent activation of muscle contraction by the binding of Ca^{2+} to troponin, a component of the contractile apparatus. In highly specialized skeletal muscle, signal Ca^{2+} is released almost exclusively from a store located in the lumen of the SR by the activation of a class of Ca^{2+} release channels referred to as ryanodine receptors (RyR). In cardiac muscle, more than two-thirds of signal Ca^{2+} is derived from the SR, the remainder coming from extracellular spaces [1]. Ryanodine receptors are also expressed in other excitable and nonexcitable cells where their contributions to signal transduction may be less pronounced.

Three RyR isoforms have been characterized: RyR1, associated with skeletal muscle; RyR2, associated with cardiac muscle; and RyR3, which is expressed more ubiquitously. Isolated RyR type Ca^{2+} release channels have a high single channel conductance of 80 to 100 pS for Ca^{2+} and 400 to 800 pS for monovalent cations [2,3]. They are activated by micromolar Ca^{2+} and millimolar adenine nucleotides and inhibited by millimolar Ca^{2+} and Mg^{2+} . They are also modulated by calmodulin and cyclic ADP ribose. Pharmaceutical agents that open the channels include caffeine, 4-chloro-*m*-cresol, and halothane, which is a trigger for malignant hyperthermia (MH). Ryanodine binds to the open channel, converting the open state to a partially open subconductance state. Dantrolene, an antidote for MH, blocks the channel.

All three RyR isoforms are homotetramers formed from subunits of about 5000 amino acids, with subunit masses of about 565,000 Da [4,5]. Electron microscopic reconstruction of the tetrameric RyR1 molecule at about 30 Å resolution shows a cytoplasmic component with a square prism shape with dimensions of 28×28×12 nm and a square transmembrane domain with an edge measuring 12 nm at the point of attachment to the cytoplasmic region and a depth of about 7 nm perpendicular to the membrane [6,7] (Fig. 1). Structures of these dimensions are observed in the junctional terminal cisternae of the SR and in corbular SR in cardiac muscle but are absent from *RYR1* null mice [8]. The N-terminal 85% of the molecule is predicted to form cytosolic domains, while 6 to 8 segments of the remaining C-terminal sequences contribute to the formation of the channel pore [4,5,5a].

The cytoplasmic component appears as a scaffold-like structure composed of at least 10 arbitrarily numbered, interconnected, globular domains, and provides a physical linkage between the SR and the transverse tubule while facilitating flow of Ca^{2+} from a central channel to the periphery (Fig. 1). This structure provides a framework for the identification of binding sites for specific regulatory proteins such as calmodulin (CaM) and FK506 binding protein (FKBP) [9]. CaM binds to an amino acid sequence containing residues 3614–3643 of the ryanodine receptor [10] and FKBP12 to Val²⁴⁶¹ [11].

The structures of channels, closed in the absence of Ca^{2+} or opened in the presence of Ca^{2+} and other ligands, have been compared [12]. A small, central-axis opening with a diameter of 7 Å is revealed in transiently open channels and this opens to 18 Å in the ryanodine-modified channel. The channel runs through the whole transmembrane structure along a four-fold axis opening into the lumen. The process of opening is comparable to the opening of a camera diaphragm. In open channels, the clamp-shaped subdomains at the four

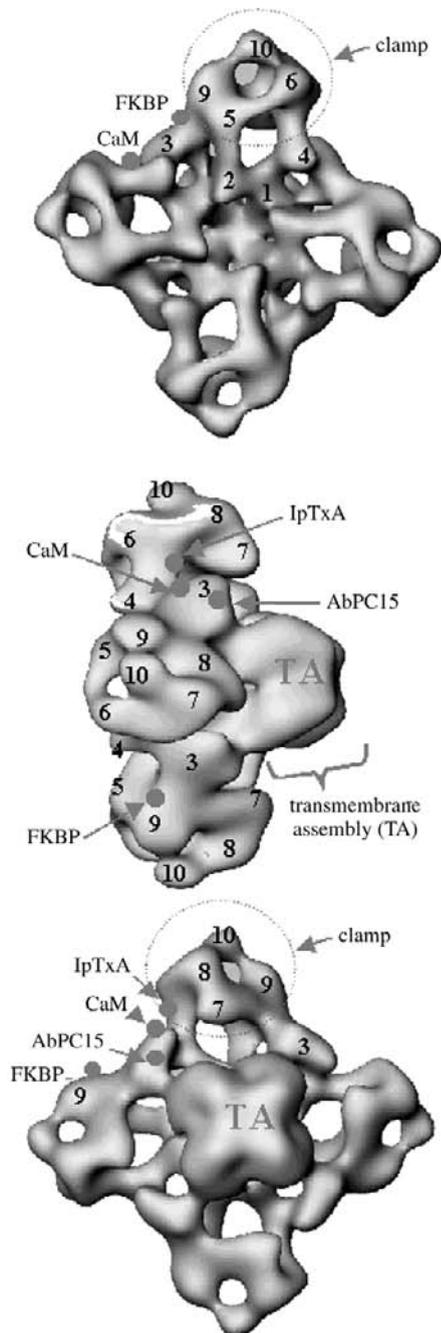

Figure 1 Solid body representation of a 3D reconstruction of RyR1 [7]. The numbers indicate distinct globular structures that correspond to structural domains, all of which are located in cytoplasmic regions of the protein. The filled circles indicate the locations of ligands as determined by reconstruction of RyR-ligand complexes. Abbreviations: CaM, calmodulin; FKBP, FK506-binding protein; IpTxA, imperatoxin A; AbPC15, monoclonal antibody against RyR residues 4425–4621; TA, transmembrane assembly. corners most distal from the membrane sector are in an open conformation and are slightly straightened toward the surface of the T-tubule membrane [13]. This feature supports the postulate that the four corners of the molecule interact with a specific protein in the transverse tubule. The N-terminus of RyR3 is located in the clamp region [14].

Activation of Ryanodine Receptor Ca^{2+} Release Channels

The location of RyR1 cytoplasmic domains in the junctional terminal cisternae of skeletal muscle SR suggests that they interact directly with the $\alpha 1$ -subunit of the voltage-sensitive, dihydropyridine-modulated, slow or L-type Ca^{2+} channels (DHPR) located in closely apposed transverse tubules or plasma membranes [15]. A cluster of four DHPR molecules in the transverse tubule of skeletal muscle directly apposes every other ryanodine receptor molecule, with an individual DHPR molecule overlying an individual RyR1 subunit. Biochemical, physiological, and molecular genetic studies show that physical interactions occur between skeletal muscle RyR1 and DHPR isoforms, leading to both activation of the Ca^{2+} release channel (orthograde interaction) and modulation of the slow Ca^{2+} channel (retrograde interaction) [16]. The exact site of RyR/DHPR interaction is not clear [17]. Presumably, those Ca^{2+} release channels not opened by direct physical interaction are opened by Ca^{2+} -induced Ca^{2+} release. By contrast, there is no indication that direct physical interactions between cardiac RyR2 and DHPR $\alpha 1$ -subunits lead to opening of the cardiac Ca^{2+} release channel [18]. In this case, entry of extracellular Ca^{2+} through the DHPR $\alpha 1$ -subunit induces activation of RyR2 by Ca^{2+} -induced Ca^{2+} release.

Since no high-resolution structure is available and since it has proven difficult to carry out structure-function analysis of RyR molecules, evidence for a coherent mechanism of action is sketchy. If the ion pore corresponds to the model for a K^{+} channel [19], then each of the four RyR subunits must contribute a hairpin-like structure with two transmembrane helices separated by an ion-selective pore-forming unit. In such a model, M8 and M10 [5] are the best candidates for the hairpin, while M9 is the best candidate for the selectivity filter [20]. M5 and M6 and possibly additional hairpin helices, such as M7a and M7b, may contribute to the periphery of the pore structure [5a]. Although interactions among the triggers that open and close this pore must be very complex [8], two triggers stand out as being of special significance [21]. In skeletal muscle, voltage-induced changes in the conformation of the “voltage sensor” DHPR $\alpha 1$ -subunit undoubtedly drive conformational changes in the cytoplasmic segment of RyR1 that are transmitted over long ranges to activate Ca^{2+} release. In most tissues, and even in skeletal muscle, elevations in cytosolic Ca^{2+} trigger Ca^{2+} induced Ca^{2+} release. Indeed, Ca^{2+} may be the master trigger and the ability of all other agents, including protein-protein interactions, to activate the Ca^{2+} release channel may simply reflect an agonist-induced increase in the affinity of an RyR molecule for binding of Ca^{2+} to its trigger sites. A strong candidate for the site for binding of trigger Ca^{2+} is the “ Ca^{2+} sensor” amino acid, Glu⁴⁰³² (Glu³⁸⁸⁵ in RyR3), located within a hydrophobic sequence predicted earlier to form transmembrane helix M2 [22]. Other sites for Ca^{2+} binding might be located elsewhere [23].

ATP is a potent activator of the Ca^{2+} release channel in the presence of Ca^{2+} [3], but since cellular ATP concentrations

are rather constant, ATP is not likely to play a major regulatory role. The site of ATP binding is not defined. A transmembrane redox sensor exists within the RyR1 channel complex that confers tight regulation of channel activity in response to changes in transmembrane redox potential [24]. PO₂ dynamically controls the redox state of several thiols in each RyR1 subunit and thereby tunes its response to NO [25]. At physiological pO₂, nanomolar NO activates the channel by S-nitrosylating a single cysteine residue. S-nitrosylation is specific to RyR1 and its effect on the channel is CaM-dependent.

Caffeine activates Ca²⁺ release but appears to do so by increasing Ca²⁺ sensitivity [26]; ryanodine can drive the channel into an open subconductance state, but this state is Ca²⁺ dependent, with an exceptionally high Ca²⁺ affinity [27,28]. While ryanodine binds to C-terminal sequences [29], the binding site for caffeine is unknown. Most MH mutations alter the apparent affinity of the channel for caffeine and halothane [30], but these mutations are dispersed throughout two “hot spots” in the cytosolic domain [31] and one in the C-terminus [32]. The binding site for dantrolene, which closes the channel, is also not well defined [33].

FKBP [34], triadin [35], junctin [36], CaM [37], sorcin [38], and various protein kinases [39,40] may also regulate the function of ryanodine receptors. The interaction of FKBP with RyR increases channels to full conductance, decreases open probability after caffeine activation, increases mean open time, and coordinates opening of clusters of channels [11]. These observations, together with the 1:1 stoichiometry of FKBP12 with RyR1, suggest that FKBP is an RyR subunit. CaM is both an inhibitor and an activator of Ca²⁺ channel activity [37]. Triadin and junctin, which have single transmembrane sequences and positively charged luminal sequences, form links to the luminal, negatively charged Ca²⁺ buffering protein calsequestrin, so that RyR1, triadin, junctin, and calsequestrin form a quaternary complex that may be required for normal Ca²⁺ release. Sorcin acts as an inhibitor of RyR function. Phosphorylation of RyR1 at Ser²⁸⁴³ enhances open probability by increasing the sensitivity to Ca²⁺ and ATP [41]. Phosphorylation of Ser²⁸⁰⁹ in RyR2 by CaM kinase II reverses inhibition by CaM and restores prolonged channel opening [42]. Thus the RyR can be viewed as a massive protein with multiple protein and ligand binding sites that is designed to integrate complex signals for activation and inactivation from many different sites in the molecule [8].

Molecular Biology of Ryanodine Receptors

Three ryanodine receptors (*RYR*) genes have been identified: *RYR1* on human chromosome 19q13.1; *RYR2* on 1q42.1-43; and *RYR3* on 15q14-15 [31]. *RYR1* is expressed predominantly in fast and slow-twitch skeletal muscle and also in the esophagus and in cerebellar Purkinje cells in the brain. *RYR2* is the predominant isoform in cardiac muscle and brain. Its expression in the brain, brain stem, and spinal cord is widespread, but it is absent from the pituitary. *RYR3* is

differentially expressed in the brain, T-lymphocytes, vas deferens, uterus, and testes [43]. It accounts for a small percentage of total *RYR* expression in mammalian skeletal muscle but is highly expressed in avian and amphibian skeletal muscles. RyR3 may flank RyR1 in the junctional terminal cisternae [44].

The disruption of *RYR1* is neonatally lethal [45]. The mutant mice resemble the mouse mutant *mdg*, which results from disruption in the DHPR α 1-subunit gene *CACNA1S*, in that both disruptions lead to failure of excitation-contraction coupling in skeletal muscle [46]. The disruption of *RYR2* is lethal at embryonic day 10, with morphological abnormalities in the heart tube [47]. The disruption of *RYR3* does not cause gross abnormalities in mice, although *RYR3*-null mice have abnormal locomotor activity [48].

Mutations in *RYR1* cause MH, an autosomal dominant genetic abnormality in which susceptible individuals respond to potent inhalational anesthetics and depolarizing skeletal muscle relaxants with hypermetabolism, skeletal muscle rigidity, fever, and muscle cell damage [31]. Mutations in *RYR1* also cause central core disease (CCD), an autosomal dominant myopathy characterized by hypotonia and proximal muscle weakness. Central cores of skeletal muscle fibers lack oxidative or phosphorylase activity, and electron microscopy of the cores shows disintegration of the contractile apparatus and streaming of the Z lines, an increase in content of the sarcotubular system and depletion of mitochondria. CCD is usually closely associated with MH, but an exception has been found [49].

MH and CCD mutations are clustered in *RYR1* exons 2 to 17 (region 1), 34–46 (region 2), and 91–102 (region 3) [31,32]. The ratio of MH to CCD mutations in region 1 is 5 : 1, in region 2, 8 : 1, and in region 3, 1 : 8. MH mutations are more sensitive to caffeine and halothane activation than wild-type and are more “leaky”: CCD mutant proteins are even more leaky than MH mutations [50,51]. CCD mutations may cause a more severe imbalance in Ca²⁺ regulation than those that cause MH. Elevation of resting Ca²⁺ by a very leaky CCD mutant channel may trigger the series of degenerative and compensatory events that lead to core formation in the center of the fiber without affecting the periphery of the muscle cell where Ca²⁺ homeostasis can be achieved through the intervention of plasma membrane Ca²⁺ pumps and exchangers. However, at least one CCD mutation is not leaky but, rather, uncouples excitation-contraction coupling by disrupting orthograde signaling between the DHPR and RyR1 proteins without disrupting retrograde signaling between these two proteins [52]. Mutations in the *CACNA1S* gene encoding the α 1-subunit of the skeletal muscle DHPR have also been linked to MH, providing further support for strong functional interactions between these two proteins [53].

Mutations in *RYR2* have been linked to two autosomal dominant cardiac diseases [54,55]: catecholaminergic polymorphic ventricular tachycardia (CPVT), which occurs in response to stress and in the absence of either structural heart disease or prolonged QT interval; and arrhythmogenic right ventricular cardiomyopathy type 2 (ARVD2), which is

characterized by partial degeneration of the myocardium of the right ventricle, electrical instability, and sudden death. The mutations are located in regions of the gene that correspond to MH regions 1 and 2 in *RYR1*. Since *RYR2* is not expressed in skeletal muscle, neither MH nor CCD manifest in these diseases. As a corollary, cardiac disease is not associated with MH or CCD mutations, since *RYR1* is not expressed in the heart. It is probable that CPVT and ARVD2, like MH and CCD, are differentiated on the basis of the severity of the alteration in RyR2 channel function.

The “Calcium Signaling Toolkit” and Calcium Homeostasis

Calcium (Ca^{2+}) is a ubiquitous intracellular messenger that controls a diverse range of cellular processes, such as gene transcription, muscle contraction, and cell proliferation. The ability of Ca^{2+} to play a pivotal role in cell biology results from the facility that cells have to shape Ca^{2+} signals in the dimensions of space, time, and amplitude. To generate and interpret the variety of observed Ca^{2+} signals, different cell types employ components selected from a “ Ca^{2+} signaling toolkit,” which comprises an array of homeostatic and sensory mechanisms (reviewed in [1]). Since many of the molecular components of this toolkit have multiple isoforms with subtly different properties, each specific cell type can exploit this large repertoire to construct highly versatile Ca^{2+} signaling networks. Thus by mixing and matching components from the toolkit, cells can obtain Ca^{2+} signals that suit their physiology.

In most cells, Ca^{2+} has its major signaling function when it is elevated in the cytosolic compartment. From there it can also diffuse into organelles such as mitochondria and the nucleus. The Ca^{2+} concentration inside cells is regulated by the simultaneous interplay of multiple counteracting processes, which can be divided into Ca^{2+} “on” and “off” mechanisms depending on whether they serve to increase or decrease cytosolic Ca^{2+} (reviewed in [2–4]) (Fig. 1).

The Ca^{2+} “on” mechanisms include channels located at the plasma membrane that regulate the supply of Ca^{2+} from the extracellular space, and channels on the endoplasmic reticulum/sarcoplasmic reticulum (ER/SR, respectively), Golgi, secretory granules, and acidic stores (e.g. lysosomes),

which release the finite intracellular Ca^{2+} stores. The “off” mechanisms include Ca^{2+} ATPases on the plasma membrane and ER/SR, and exchangers that utilize the electrochemical Na^+ gradient to provide the energy to transport Ca^{2+} out of the cell. Occasionally, some of the “off” mechanisms contribute to cytosolic Ca^{2+} increases; examples are “slippage” of Ca^{2+} through Ca^{2+} ATPases and reverse-mode $\text{Na}^+/\text{Ca}^{2+}$ exchange.

When cells are at rest, the balance lies in favour of the ‘off’ mechanisms, thus yielding an intracellular Ca^{2+} concentration of ~ 100 nM. However, when cells are stimulated by various means, e.g. depolarisation, mechanical deformation or hormones, the ‘on’ mechanisms are activated and the cytosolic Ca^{2+} concentration increases to levels of $1 \mu\text{M}$ or more.

As mentioned above, Ca^{2+} signals can be modulated in their temporal, amplitude, and spatial dimensions. Furthermore, Ca^{2+} signals can arise from different cellular sources, which appear to be regulated by a growing number of messengers (reviewed in [5]). The following sections describe the currently known messengers and channels and present examples of the versatility of Ca^{2+} signals.

Multiple Channels and Messengers Underlie Ca^{2+} Increases

Ca^{2+} Influx Channels

Cells utilize several different types of Ca^{2+} influx channels, which can be grouped on the basis of their activation mechanisms (reviewed in [2]). *Voltage-operated Ca^{2+} channels* (VOCs) are employed largely by excitable cell types such as muscle and neuronal cells, where they are activated by depolarization of the plasma membrane. Different types of VOCs,

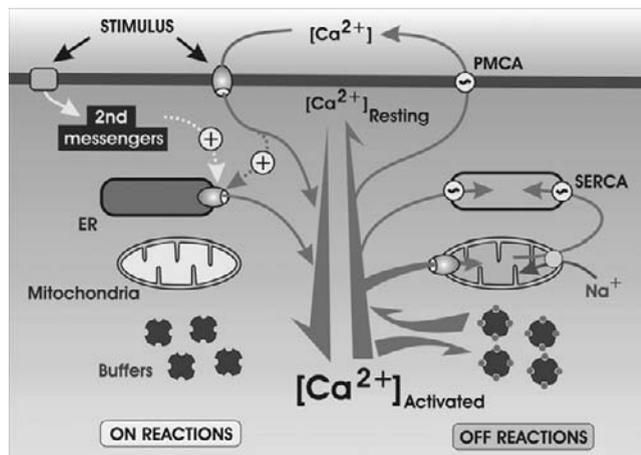

Figure 1 Calcium “on” and “off” mechanisms in cellular signaling and homeostasis. The figure illustrates various pathways and mechanisms by which cytosolic Ca^{2+} levels can increase or decline. At rest, cells generally have a free cytosolic Ca^{2+} concentration of around 100 nM. This can be increased by activation of channels at the plasma membrane and release from internal stores (denoted “ER”). Cytosolic Ca^{2+} signals are attenuated by passive Ca^{2+} buffering and actively reversed by mitochondria and Ca^{2+} ATPases on the ER and plasma membrane.

which are expressed in a tissue-specific manner, have been characterized on the basis of their gating characteristics and pharmacology. *Receptor-operated Ca^{2+} channels* (ROCs) comprise a range of structurally and functionally diverse channels that are particularly prevalent on secretory cells and at nerve terminals. Well-known ROCs include the nicotinic acetylcholine receptor and the N-methyl-D-aspartate (NMDA) receptor. ROCs are activated by the binding of an agonist to the extracellular domain of the channel. The different ROCs are activated by a wide variety of agonists, e.g. ATP, serotonin, glutamate, and acetylcholine. *Mechanically activated Ca^{2+} channels* are present on many cell types and respond to cell deformation. Such channels convey information into the cell concerning the stress/shape changes that a cell is experiencing. A particularly nice example of mechanically induced Ca^{2+} signaling was observed in epithelial cells from the trachea, where deformation of a single cell led to a radial Ca^{2+} wave that synchronized the Ca^{2+} -sensitive beating of cilia on many neighboring cells [6], which may serve to aid clearance of mucous or particles from the lungs. *Store-operated Ca^{2+} channels* (SOCs) are activated in response to depletion of the intracellular Ca^{2+} store. The mechanism by which the SOCs “sense” the filling status of the intracellular pool is unknown. At present, the best candidate for the molecular identity of SOCs are homologues of a protein named TRP (transient receptor potential) that functions in *Drosophila* photoreception. Several mammalian TRP homologues have been identified and found to be expressed in almost all tissues (reviewed in [7]).

Ca^{2+} Release Channels

Inositol 1,4,5-trisphosphate Receptors (InsP₃Rs). The binding of many hormones and growth factors to specific

receptors on the plasma membrane leads to the activation of an enzyme that catalyzes the hydrolysis of phospholipids to produce the intracellular messenger inositol 1,4,5-trisphosphate (InsP₃). InsP₃ is water-soluble and diffuses into the cell interior where it can engage InsP₃Rs on the ER/SR, allowing the Ca^{2+} stored at high concentrations to enter the cytoplasm. Three different isoforms of InsP₃Rs have been found, which appear to subtly differ in their characteristics, such as affinity for InsP₃. An important feature of InsP₃Rs is that they are actually co-regulated by InsP₃ and Ca^{2+} . Indeed, it seems that InsP₃ may simply serve to make InsP₃Rs responsive to an activating Ca^{2+} signal. InsP₃R opening is biphasically regulated by Ca^{2+} ; 0.1–0.5 μM Ca^{2+} increases channel activity, whereas greater Ca^{2+} concentrations inhibit their gating (reviewed in [8,9]). This dependence of InsP₃R activity on cytosolic Ca^{2+} is crucial in the generation of the complex patterns of Ca^{2+} signals seen in many cells.

Ryanodine Receptors (RyRs) These receptors are structurally and functionally analogous to InsP₃Rs, although they have approximately twice the conductance and molecular mass of InsP₃Rs. Another property that RyRs share with InsP₃Rs is their sensitivity to cytosolic Ca^{2+} concentrations, although they are generally activated and inhibited by higher concentrations (activation at 1–10 μM ; inhibition at >10 μM). In contrast to InsP₃Rs, which are almost ubiquitously expressed in mammalian tissues, RyRs are largely present in excitable cell types, such as muscle and neurons. As with InsP₃Rs, RyR subunits are encoded by three genes. However, these genes do not appear to have the same functional redundancy as observed with the InsP₃R isoforms. Instead, the different RyR proteins are often used for specific functions. For example, only type-1 RyRs are employed in triggering excitation of skeletal muscle, whereas only type-2 RyRs fulfil this role in cardiac muscle (reviewed in [1,10]).

Multiple Messengers

A wide range of messengers has been shown to mediate the activation of Ca^{2+} entry and Ca^{2+} release channels (reviewed in [5]). These messengers include InsP₃, cyclic adenosine 5'-diphosphoribose (cADPR), nitric oxide (NO), $\text{H}_2\text{O}_2/\text{O}_2^-$, nicotinic acid adenine dinucleotide phosphate (NAADP), diacylglycerol, arachidonic acid, sphingosine, sphingosine-1-phosphate (S-1-P), leukotrienes, and Ca^{2+} itself. From the specificities of the Ca^{2+} -releasing messengers we know that there must be several different types of intracellular Ca^{2+} release channel, although at present only InsP₃ receptors (InsP₃Rs) and ryanodine receptors (RyRs) have been characterized in detail. Exactly which messengers act in particular cells is far from clear. However, it is becoming apparent that Ca^{2+} signals can be activated by the simultaneous interplay of several factors. In pancreatic acinar cells, for example, the combined action of InsP₃, cADPR, and NAADP underlies the Ca^{2+} signals generated by physiological stimuli [11].

Temporal Regulation of Ca²⁺ Signals

Since prolonged elevation of cytoplasmic Ca²⁺ levels can be toxic, most cells do not usually respond with sustained Ca²⁺ signals. Rather, Ca²⁺ is commonly presented in a pulsatile manner [12,13]. A well-known example of such repetitive Ca²⁺ increases is the response of hepatocytes to stimulation with various hormones that, for example, regulate glycogen metabolism and mitochondrial respiration [14]. The Ca²⁺ increases that occur in hepatocytes during such stimulations are transient spikes, which arise from the cyclical activation of InsP₃Rs (see below). The frequency of the Ca²⁺ spikes is directly proportional to the concentration of hormone applied to the cells, and they can persist for the duration of agonist application. These Ca²⁺ spikes are therefore essentially a frequency-modulated digital read-out of cell stimulation.

Another system in which pulsatile Ca²⁺ increases are critical is excitation-contraction coupling in striated muscle cells. The mechanism and channels underlying these signals are very different from those in hepatocytes. In cardiac muscle, for example, type 2 RyRs are activated following depolarization of the sarcolemma. The Ca²⁺ that enters the cell following voltage-operated Ca²⁺ channel activation triggers release of Ca²⁺ from ryanodine receptors (RyRs) by a process known as Ca²⁺-induced Ca²⁺ release (CICR) [1]. This Ca²⁺ can then globally diffuse to the myofibrils and promote the interaction between actin and myosin that leads to contraction.

Although the Ca²⁺ signals observed in both hormonally stimulated hepatocytes and cardiomyocytes are repetitive Ca²⁺ transients, the periodicity and kinetics of these signals are very different. The Ca²⁺ spikes in hepatocytes (and many other nonelectrically excitable cells) typically have frequencies in the range of 0.1–0.01 Hz, a time-to-peak amplitude of several seconds, and a recovery phase lasting tens of seconds [15]. In contrast, cardiac Ca²⁺ signals are triggered at frequencies in the 1–10 Hz range (depending on the species of animal), reach peak within a few tens of milliseconds, and persist for only a few hundred milliseconds [16]. The distinct timescales of these Ca²⁺ responses reflect the very different mechanisms by which they are generated.

Pulsatile Ca²⁺ increases, such as those observed in hepatocytes, are generally considered to have a much higher fidelity of information transfer than simple tonic changes in Ca²⁺ concentrations, since they are much less prone to noisy fluctuations. The major sensors for these Ca²⁺ spikes are Ca²⁺ binding proteins such as calmodulin (reviewed in [17]). This ubiquitous protein is one of a family of proteins bearing structural Ca²⁺-binding motifs known as EF-hands. The binding of Ca²⁺ to calmodulin has a K_d around 1 μM, making it an ideal receiver for the rapid transient Ca²⁺ increases seen with each spike. One of the best-known enzymes that uses calmodulin to help it “count” Ca²⁺ spikes is calmodulin-dependent protein kinase II, which can activate other proteins via phosphorylation. This enzyme is composed of many subunits that undergo variable degrees of activation depending on

the frequency of Ca²⁺ spikes. Essentially, increasing the frequency or duration of Ca²⁺ spikes maintains this enzyme in an active state by trapping calmodulin and causing autophosphorylation [18,19].

There are many examples of cellular activities being modulated by the frequency of Ca²⁺ signals. The transcription of Ca²⁺-regulated genes was sensitive to the frequency at which Ca²⁺ spikes occurred. Indeed, it appears that alternative transcription factors are tuned to distinct frequencies of Ca²⁺ spikes. Thus temporal modulation of Ca²⁺ signaling can underlie differential gene transcription [20].

Spatial Regulation of Ca²⁺ Signals

All Ca²⁺ signals derive initially from local sources such as the activation of Ca²⁺ channels. Both Ca²⁺ entry and Ca²⁺ release channels can give rise to brief pulses of Ca²⁺ that form a small plume around the mouth of the channel before diffusing into the cytoplasm (reviewed in [21]). In many situations, these local sources provoke global signals through regenerative CICR as described for cardiomyocytes above. However, there are numerous instances in which the spread of Ca²⁺ is constrained to a specific subcellular region. Such spatial regulation of Ca²⁺ provides perhaps the most elegant examples of how cells subtly modulate Ca²⁺ signals to control multiple, sometimes opposing, processes.

Nonelectrically Excitable Cells

A few different types of localized Ca²⁺ signals have been observed in various nonelectrically excitable cell types [22]. Probably the best known examples are “Ca²⁺ puffs” and the apical Ca²⁺ signals that occur in secretory cells (reviewed in [3]). Ca²⁺ puffs are local signals that derive from the activation of a cluster of InsP₃Rs. Typically Ca²⁺ puffs give a modest elevation of cytosolic Ca²⁺ (~50–600 nM) with a limited spatial spread (~2–6 μm) and are transient (duration of ~1 second) [23]. Such events were first observed in *Xenopus* oocytes [e.g. 24] but have subsequently been observed in many other cell types. The temporally and spatially coordinated recruitment of Ca²⁺ puffs is responsible for the generation of repetitive Ca²⁺ waves and oscillations observed during hormonal stimulation. Essentially Ca²⁺ waves reflect the progressive release of Ca²⁺ by Ca²⁺ puff sites distributed along the ER/SR. Ca²⁺ released by one puff site can diffuse to a neighboring site and activate it (providing InsP₃ is bound to the channels). Successive rounds of Ca²⁺ release and diffusion allow the initially local Ca²⁺ puffs to trigger global Ca²⁺ waves and oscillations (reviewed in [3,25]).

It is interesting that in HeLa cells [26] and *Xenopus* oocytes [27], it has been demonstrated that Ca²⁺ puff sites expressing a higher sensitivity to InsP₃ consistently trigger Ca²⁺ waves. What gives these pacemaking Ca²⁺ puff sites their enhanced sensitivity is unclear. In the case of somatic cells, the pacemaker sites tend to be distributed in a perinuclear region [28], thus raising the possibility that they can

send signals specifically into the nucleus. In *Xenopus* oocytes, it has been shown that mitochondria can constrain the activity of Ca^{2+} puffs, and locations lacking these organelles may thus define pacemaking sites [29].

Another well-known local Ca^{2+} signal occurs in the apical region of secretory cells such as pancreatic acinar cells (reviewed in [30]). Similar to the pacemaker Ca^{2+} puffs (see above), the InsP_3 Rs that underlie the apical Ca^{2+} spikes are distinguished by a heightened sensitivity to InsP_3 . Also like Ca^{2+} puffs, such apical Ca^{2+} spikes probably arise from the coordinated Ca^{2+} release from multiple Ca^{2+} release channels. Recent evidence has pointed to the apical spikes arising from a stimulus-dependent hierarchical activation of different types of Ca^{2+} release channel [11]. With low levels of cell stimulation, the Ca^{2+} spikes stay restricted to the apical pole of the acinar cells, where they can activate ion channels and trigger limited secretion. Greater stimulation causes the Ca^{2+} spikes to trigger Ca^{2+} waves that propagate toward the basal pole. It appears that the restriction of the Ca^{2+} signal in the apical pole is due in part to a “firewall” of mitochondria that buffer Ca^{2+} as it diffuses from the apical pole and prevent the activation of RyRs in the basal pole [31,32].

Electrically Excitable Cells

Spatial regulation of Ca^{2+} signaling is the forte of electrically excitable cells. For more detailed discussions, the reader is referred to recent reviews [3,33–35].

One of the best-known examples in which spatial regulation of Ca^{2+} signals can have diametrically opposing effects in the same cell is in the regulation of smooth muscle tone (reviewed in [35]). In these cells, global responses induce contraction by the activation of Ca^{2+} /calmodulin-dependent enzymes, whereas local subsarcolemmal Ca^{2+} signals promote relaxation by activating Ca^{2+} -dependent plasma membrane ion channels [36]. The subsarcolemmal Ca^{2+} signals are known as Ca^{2+} sparks; they are analogous to the Ca^{2+} puffs observed in nonelectrically excitable cells, but they arise from the activation of a cluster of RyRs. Ca^{2+} sparks are generally faster in onset and decline than Ca^{2+} puffs and have usually a more restricted spread ($\sim 1\text{--}3\ \mu\text{m}$).

In smooth muscle, the subsarcolemmal Ca^{2+} sparks activate K^+ and Cl^- conductances, giving rise to brief currents known as STOCs (spontaneous transient outward currents; K^+ current), STICs (spontaneous transient inward current; Cl^- current) and STOICs (mixed K^+ and Cl^- currents). STOCs have been measured in a wide variety of smooth muscle cell types and serve to hyperpolarize the cell membrane by $\sim 20\text{ mV}$, thus causing the muscle to relax. STOCs primarily arise due to the activation of large conductance Ca^{2+} -activated K^+ channels (BK channels). These Ca^{2+} -activated channels have a low sensitivity to cytosolic Ca^{2+} , requiring concentrations $>1\ \mu\text{M}$ for significant activity. It has been proposed that the BK channels sit in close apposition to Ca^{2+} spark sites and sense rapid step-like Ca^{2+} changes during RyR activation [37].

Spatio-temporal recruitment of Ca^{2+} sparks also underlies the global Ca^{2+} signals that activate skeletal and cardiac myocyte contraction. When the sarcolemma of these cells is depolarized by an action potential, VOCs open and allow a small influx of Ca^{2+} [38]. Through the process of CICR, this trigger Ca^{2+} signal is greatly amplified by clusters of closely apposed RyRs, thereby activating Ca^{2+} spark sites throughout the cell. The spatial overlap and temporal summation of the Ca^{2+} sparks gives rise to the global responses that ensure synchronized contraction in the muscle (reviewed in [3,34]).

The intricate morphologies of neurons means that these cells are well-suited to producing spatially regulated Ca^{2+} signals. Local Ca^{2+} changes in dendritic spines can underlie processes such as synaptic plasticity and neurite outgrowth, whereas more global Ca^{2+} signals can cause gene transcription and neuronal maturation within the brain (reviewed in [39–41]). An example of the necessity for precise spatial regulation of neuronal Ca^{2+} signals can be seen in the effects of activating synaptic versus nonsynaptic glutamate receptors on hippocampal neurons. At synaptic junctions, hippocampal neurons respond to the release of the neurotransmitter glutamate by activation of NMDA receptors. These ROCs are ligand-gated ion channels that allow the influx of Ca^{2+} . The Ca^{2+} that enters neurons through the synaptic NMDARs causes local activation of ERK1/2 [42] and promotes cell survival. When neurons and glia become anoxic, the glutamate released at synaptic terminals can diffuse to nonsynaptic NMDARs and cause Ca^{2+} signals that lead to cell death [43]. The drastically different effects of stimulating synaptic or nonsynaptic NMDARs explains the paradox that glutamate can be a physiological neurotransmitter, yet bath application of glutamate kills cultured neurons. Essentially, the spatial location of the Ca^{2+} signals determines which biochemical pathways will become activated and can switch cells from life to death.

Modulation of Ca^{2+} Signal Amplitude

Although many cell types can grade the amplitude of their Ca^{2+} signals, most control of Ca^{2+} signaling occurs through the types of spatial and temporal regulation described above. Consequently, there are only a few situations in which such modulation has been shown to have a physiological relevance. One well-known example is in muscle, where the amplitude of Ca^{2+} signals governs the force of contraction. In the case of cardiac muscle, inotropic agents (e.g. adrenaline) can alter the influx of Ca^{2+} through VOCs or Ca^{2+} release from RyRs, thus altering the capacity of the heart for pumping blood.

Since large, rapid increases in Ca^{2+} are easier to detect than small, graded changes, Ca^{2+} signals based on frequency modulation are believed to have greater fidelity than those occurring through amplitude modulation. However, it has been shown that cells may interpret modest changes in cytoplasmic concentration. For example, differential gene activation may occur by varying the amplitude of Ca^{2+} signals [44].

Ca²⁺ as a Signal within Organelles and in the Extracellular Space

The discussion above has largely considered the regulation of Ca²⁺ signals within the cytoplasm. However, it is important to point out that Ca²⁺ has crucial functions within organelles. Mitochondrial Ca²⁺ signals can enhance mitochondria respiration by activation enzymes of the citric acid cycle to stimulate production of NADH [45]. Elevation of nuclear Ca²⁺ appears to be important for transcription of specific genes [46]. Ca²⁺ has a diverse range of functions within the lumen of the ER. Depletion of ER Ca²⁺ leads to incorrect folding of nascent proteins and a stress response culminating in cell death [47].

Many cell types express receptors for Ca²⁺ on their surface, allowing them to sense changes in extracellular Ca²⁺ concentration (reviewed in [48]). These receptors can activate InsP₃ production to evoke intracellular Ca²⁺ changes. Through the action of such Ca²⁺-sensing receptors, the Ca²⁺ that is extruded from a cell at the termination of a cytosolic signal can become an agonist for its neighbors [49], perhaps serving to coordinate the activity of adjacent cells.

Calcium Pumps

Introduction

The plasma membrane controls the exchange of calcium between the intracellular and extracellular environments [1,2]. A limited and strictly controlled amount of Ca^{2+} is allowed to penetrate into the cells through a number of specific channels to trigger important cellular events, including the massive liberation of Ca^{2+} from membrane enclosed stores. An equivalent amount of Ca^{2+} must then be ejected to the extracellular spaces. Two systems preside over this function in animal cells: a large system that is particularly active in excitable cells exchanges electrogenically Na^+ for Ca^{2+} interacting with Ca^{2+} with low affinity. The other system is an ATPase (the PMCA pump [3]), which interacts instead with Ca^{2+} with high affinity but has low Ca^{2+} ejecting capacity: it is thus normally considered as the fine-tuner of cellular Ca^{2+} . Calcium is also exchanged between the cytoplasm and the internal space of the organelles, chiefly the mitochondria and the endo(sarco)plasmic reticulum (ER/SR). The latter contains an ATPase (the SERCA pump, [4]), which is similar in mechanism to the PMCA pump. The total Ca^{2+} transporting capacity of the reticulum depends on the amount of pump it contains, which is high in heart and skeletal muscle and low in nonmuscle tissues. The SERCA pump works in concert with channels in the ER/SR membrane that are activated by second messengers and return to the cytoplasm the calcium that the pump had transported to the ER/SR lumen. Since the ER/SR is located in close proximity to the mitochondria, the released calcium creates an ambient of high calcium concentration adequate to activate the low affinity electrophoretic uptake uniporter of the inner mitochondrial membrane [5]. Ca^{2+} accumulated in the mitochondrial matrix is released to the cytoplasm via two systems, a well-characterized $\text{Na}^+/\text{Ca}^{2+}$ exchanger [6] and a less well-characterized $\text{Ca}^{2+}/\text{H}^+$ antiporter.

Ca^{2+} pumps have also been described in lower eukaryotes. In yeasts, two pumps termed PMR1 and PMC1 [7–9] have been described in the Golgi complex [10] and the vacuoles [9], respectively. Their degree of sequence homology to the SERCA and PMCA pump does not exceed 40–50%, and in particular, the PMC1 pump does not contain the calmodulin binding domain that characterizes the PMCA pumps. Most bacteria extrude calcium via $\text{Ca}^{2+}/\text{H}^+$ or $\text{Ca}^{2+}/\text{Na}^+$ antiporters [11], but bona fide Ca^{2+} ATPases have also been described, e.g. in *Flavobacterium odoratum* [12] and in a cyanobacterium [13].

Reaction Cycle of the SERCA and PMCA Pumps

The basic enzyme cycle of the two calcium pumps is essentially the same [14] (Fig. 1). Ca^{2+} is bound on one side of the membrane in a reaction that does not require ATP, since Ca^{2+} binding can be measured in its absence. ATP is then bound and split to form an acyl-phosphate intermediate on an aspartic residue [15]. The formation of a phosphorylated intermediate has suggested the nomenclature of “P type” pumps [16,17]. After phosphorylation, the pump undergoes a conformational transition from a state termed E1 to one termed E2. In the E1 conformation the pump binds Ca^{2+} with high affinity to sites exposed to the cytosolic site, whereas in the E2 conformation the Ca^{2+} binding sites have lower affinity and are exposed to the ER/SR lumen or to the extracellular space. Ca^{2+} can thus be released. After releasing ATP and Ca^{2+} the enzyme becomes slowly dephosphorylated and returns to the E1 state. The SERCA and PMCA pumps differ in the $\text{Ca}^{2+}/\text{ATP}$ transport stoichiometry, which is 2 in the former and 1 in the latter. Powerful inhibitors have been described. Lanthanum inhibits both pumps but with interesting differences. In the SERCA pump it decreases the steady state level of

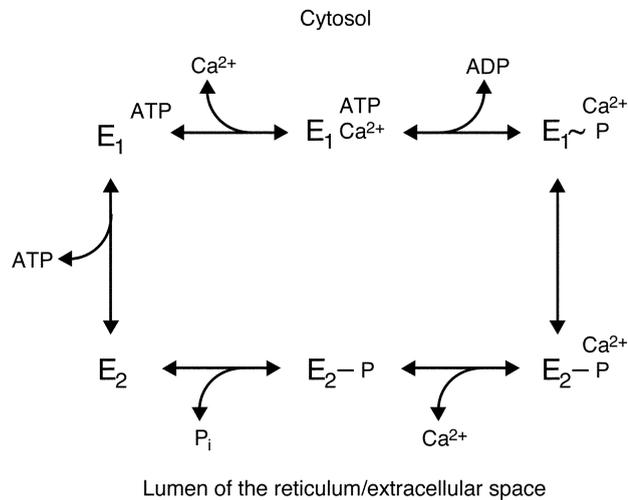

Figure 1 A simplified scheme of the reaction mechanism of calcium pumps. The pump, symbolized by E, is assumed to exist in two different conformations, E1 and E2. E1 binds calcium with high affinity at the cytoplasmic site of the membrane; E2 has lower affinity for calcium and releases it to the opposite site. Molecular details on the uptake and release path for calcium are discussed in the text. The energy of ATP is momentarily conserved in the enzyme as a phosphorylated intermediate (an aspartyl phosphate) that is formed prior to the translocation of calcium. The scheme shows a 1 to 1 stoichiometry between hydrolyzed ATP and transported calcium, which is that of the PMCA pump. The SERCA pump transports instead two Ca^{2+} per ATP hydrolyzed. See text for details.

the phosphorylated intermediate, whereas in the PMCA pump it greatly stimulates it. The phosphate analogue orthovanadate ($[\text{VO}_3(\text{OH})]^{2-}$) inhibits both pumps with presumably identical mechanisms, whereas the inhibitors thapsigargin and thapsigargin [18] and cyclopiazonic acid [19] only act on the SERCA pump by interacting with it with high affinity (K_d in the sub-nM range) [20].

The SERCA Pump

An enzyme that couples the hydrolysis of ATP to the transport of Ca^{2+} across the membrane of SR had been postulated about 40 years ago by Ebashi and Lipmann [21] and Hasselbach and Makinose [22]. Later work has identified the pump in the ER of nonmuscle cells as well. The ATPase, later termed the SERCA pump, was purified by MacLennan in 1970 [4] as a protein of about 100 kDa and cloned 15 years later [23]. The enzyme was predicted to be organized in the membrane of the reticulum with ten transmembrane domains and to protrude into the cytosol with three large units. The ATP binding domain and the catalytic aspartic acid are located in the cytosolic unit that protrudes between the fourth and the fifth transmembrane domains. The pump is the product of a multigene family: three basic gene products have so far been described with peculiar tissue distribution, additional isoform diversity being generated by alternative splicing of primary transcripts. SERCA1a is the major isoform of adult fast twitch muscle, whereas the transcripts of SERCA1b are detected in large amounts in neonatal fast twitch muscle.

The SERCA2 gene transcript is spliced to generate SERCA2a, which is found in slow twitch and heart muscles, whereas SERCA2b is found in smooth muscle and most nonmuscle cells. The SERCA2b protein is of particular interest because it replaces the last four residues of the SERCA2a isoform with a 49 amino acid stretch [24] that contains a hydrophobic sequence predicted to be the eleventh transmembrane domain [25]. Thus, the C-terminus of the SERCA2b isoform protrudes into the ER lumen. SERCA3 is only expressed in a limited range of nonmuscle cells [26].

Striking advances on the structure of the SERCA pump have recently extended our understanding of the molecular mechanism by which the enzyme couples the hydrolysis of ATP to the transport of Ca^{2+} across the protein. The pump has been crystallized in the Ca^{2+} bound E1 state by Toyoshima *et al.* [27] (Fig. 2). Its structure has been solved at 2.6 Å resolution, validating a number of previous suggestions on membrane topography and Ca^{2+} binding and transport. Specifically, the structure has confirmed that the number of transmembrane domains is 10 and has shown that the three large cytosolic domains (N for nucleotide binding; P, which contains the catalytic aspartic acid; and A, termed actuator or N anchoring domain) undergo large movements during ATP energized Ca^{2+} translocation. The movement of the three cytosolic units has been predicted by fitting the atomic structure to a low resolution structure (8 Å) derived from tubular crystals of the pump in the vanadate inhibited Ca^{2+} free (E2) conformation. The cytoplasmic portion of the E2 pump is more compact, suggesting that Ca^{2+} loosens the interactions between the cytosolic units. The N and P domains come close to each other whereas the A domain rotates by about 90° to bring a conserved, critically important sequence (TGES) next to the catalytic aspartic acid. The structure has also validated previous mutagenesis experiments [28] that had led to the conclusion that a number of residues in transmembrane domains 4, 5, 6, and 8 would form the two Ca^{2+} binding sites and the path of Ca^{2+} across the protein. The atomic structure has shown that transmembrane domain 5 is straight and extends to the center of the P domain, whereas transmembrane domains 4 and 6 are unwound in the middle to optimize Ca^{2+} coordination geometry. The two Ca^{2+} binding sites are separated by a distance of 5.7 Å, site I being formed essentially by transmembrane domains 5 and 6 (with a contribution of transmembrane domain 8) and site II by transmembrane domains 4 and 6. The two Ca^{2+} binding sites are stabilized by H bridges between coordinating residues and to residues on other transmembrane helices. The structure has also suggested the path for Ca^{2+} to the binding sites and from them to the lumenal space. The path to the sites may be a cavity opened to the cytoplasm formed by transmembrane domains 2, 4, and 6. Ca^{2+} would move along a row of hydrophilic carbonyl oxygens and would exit to the lumen of the ER through a zone ringed by hydrophilic oxygens surrounded by transmembrane domains 3, 4, and 5.

The SERCA pump is regulated by interaction with phospholamban (PLN, [29]), a small hydrophobic protein that has a strong tendency to form pentamers but that is active in

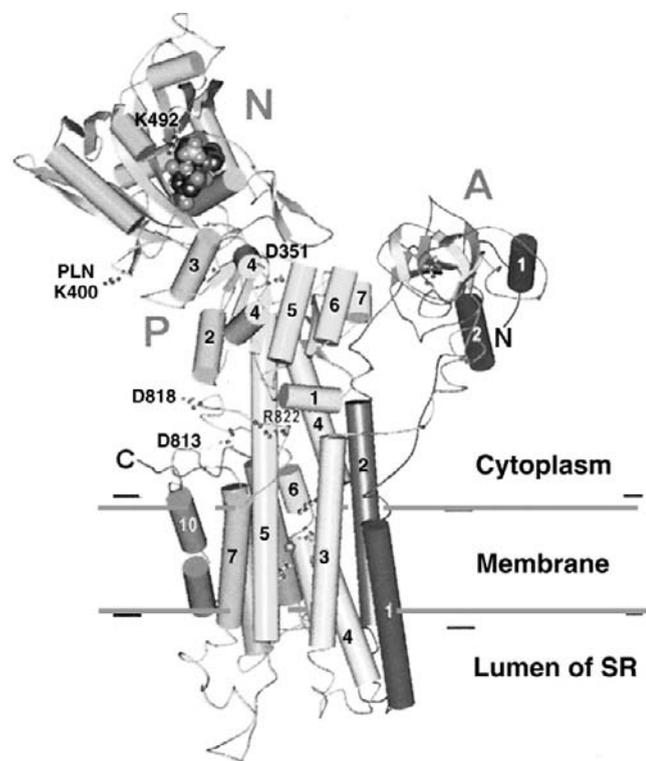

Figure 2 Crystal structure of the calcium bound (E1 form) of the SERCA pump [27]. The structure shows the predicted ten transmembrane domains and three units protruding into the cytoplasm, termed N (nucleotide binding), P (phosphorylation), and A (actuator, or N anchoring domain). Some residues important to the function of the pump are indicated, including K400, which is part of a loop that binds the cytosolic portion of phospholamban. Additional details of the structure and on the predicted motions of the cytosolic domains of the pump in the E1 to E2 conformational transition are discussed in the text.

the monomeric state [30]. Since PLN is only expressed in slow-twitch, heart, and smooth muscles, it only regulates the activity of the SERCA pump in these tissues. PLN is the substrate of two protein kinases, protein kinase A and a calmodulin-dependent kinase (protein kinase G may also phosphorylate it). In the unphosphorylated state it interacts with a cytosolic loop around Lys 400 [31], maintaining the pump inhibited. When phosphorylated on Ser16 and/or Thr17, PLN becomes detached from the binding loop freeing the pump from inhibition. Mutagenesis studies [32] have indicated that PLN also interacts with the intramembrane sector of the pump, specifically, with transmembrane domain 6. This indication has been recently supported by molecular modeling studies of the interaction of PLN [33] with the pump, based on the structure of the latter in the vanadate inhibited state and on the recently solved tertiary structure of PLN [34].

The PMCA Pump

The PMCA pump had been discovered by Schatzmann in 1966 as a system that ejected calcium from erythrocytes.

The pump was purified in 1979 as a protein of about 135 kDa by Niggli *et al.* [35], and was cloned ten years later by Shull and Greb [36] and Verma *et al.* [37]. The membrane architecture of the protein resembles that of the SERCA pump, i.e., it is predicted to contain ten transmembrane domains and three large hydrophilic units protruding into the cytoplasm. One important difference with respect to the SERCA pump is the long C-terminal tail, which contains a calmodulin-binding domain [38]. Calmodulin is the most important regulator of the PMCA pump, although polyunsaturated fatty acids, acidic phospholipids, phosphorylation steps involving the C-terminal tail by protein kinase A, or protein kinase C may also activate the pump by lowering its K_m for calcium. Activation is also brought about by a dimerization process that occurs through the calmodulin-binding domain and by the proteolytic removal (e.g. by calpain) of most of the C-terminal tail of the pump [39]. At variance with the SERCA pump, the reaction cycle of the PMCA pump is not regulated by PLN but by a mechanism that has striking similarities to that of the SERCA pump. Specifically, the calmodulin-binding domain interacts in the resting state with two sites in the cytoplasmic portion of the pump, keeping it inhibited [40,41]. Calmodulin removes the binding domain from its “receptors” in the cytosolic portion of the pump, relieving the inhibition. Although in this case phosphorylation is not involved, the similarity to the reversible mechanism of inhibition of the SERCA pump by PLN is even more striking. The phosphorylation of the calmodulin-binding domain of the PMCA pump by protein kinase C impairs its ability to bind to the cytosolic portion of the pump [42,43].

The PMCA pump is the product of a multigene family, with four basic gene products. As in the case for the SERCA pump the number of isoforms is increased by the alternative splicing of primary transcripts. Two of the four basic isoforms (PMCA1 and 4) are expressed in all tissues, whereas PMCA2 and 3 are expressed in significant amounts only in neurons and in cells somehow related to them, e.g. the outer hair cells of the organ of Corti. Alternative splicing occurs at two sites. Site A is located upstream of the third transmembrane domain, next to a site that mediates the sensitivity of the pump to acidic phospholipids, site C within the calmodulin-binding domain itself. Information on the differential functional properties of the PMCA isoforms is very scarce, but it is known that PMCA2 has the highest sensitivity to calmodulin. The proximity of the splicing sites to domains that are important in regulation suggests different regulatory properties of the spliced isoforms. C-spliced variants of the pump may indeed interact with calmodulin with peculiar pH sensitivity [44], whereas a variant of the pump truncated C-terminally as a result of the insertion of a 154 bp hexon at site C [45] has decreased affinity for calmodulin.

An interesting development in the regulation of the PMCA pump has been the finding that its genes are transcriptionally regulated by Ca^{2+} itself [46,47]. The discovery has been made on maturing cultured cerebellar granular neurons, and reflect the regulation of PMCA gene expression within the cerebellum. The cultured granular neurons require a modest

increase in cytosolic calcium (about three-fold) to switch off the apoptotic programs that would otherwise kill them in 3–5 days, and do so by rearranging the expression of PMCA isoforms to accommodate the changing requirements of calcium homeostasis necessary to set cell calcium at a higher level. Under these conditions, PMCA2 and 3 become strongly upregulated within days after the beginning of culture; PMCA1 experiences instead a splicing switch that favors a C-terminally truncated variant. PMCA4, by contrast, becomes rapidly and dramatically downregulated in a process that is mediated by the Ca^{2+} -dependent protein phosphatase calcineurin.

Genetic Diseases Evolving Defects of Calcium Pumps

Pathological phenotypes linked to genetic defects in the genes of both the SERCA and PMCA pumps have been described. In agreement with the distinct brain distribution of PMCA2, which appears to be specifically expressed in cerebellar Purkinje cells and in the outer hair cells of the inner ear, mice with defects in the gene of PMCA2 have been described that display vestibular/motor imbalance and are deaf [48,49]. A similar phenotype has also been described in PMCA2 knockout mice [50].

Pathological phenotypes have also been described as a result of inactivating mutations in the SERCA pump genes. Brody's disease, an autosomal recessive disorder of skeletal muscle characterized by muscle cramping and exercise-induced impairment of relaxation, has been traced back to three different mutations in the SERCA1 gene [51,52] that lead to a loss of SERCA1 activity (although not all cases of Brody's disease are linked to SERCA1 gene defects). Darier's disease, an autosomal dominant skin disorder, has been traced back to mutations in the SERCA2a gene. It has been suggested that the SERCA2 pump influences the adhesion between keratinocytes and thus cellular differentiation in the epidermis [53].

Introduction

The plasma membrane (PM) $\text{Na}^+/\text{Ca}^{2+}$ exchanger (NCX) is one of the critical mechanisms involved in Ca^{2+} homeostasis and the regulation of Ca^{2+} signaling in most cells. The PM NCX was discovered about 35 years ago in mammalian cardiac muscle [1] and squid neurons [2]. It uses energy from the Na^+ electrochemical gradient, and not directly from ATP, to transport Ca^{2+} . Therefore, as we shall see, a critical aspect of the exchanger's function is that it may either export or import Ca^{2+} , depending upon the NCX coupling ratio and the prevailing membrane potential and Na^+ concentration gradient. The Na^+ gradient and membrane potential are maintained by the ATP-dependent, ouabain-sensitive Na^+ pump (Na^+ , K^+ -ATPase). A mitochondrial membrane $\text{Na}^+/\text{Ca}^{2+}$ exchanger has also been identified [3] but has been less well characterized than the PM NCX; the mitochondrial exchanger will not be discussed here. Recent, more extensive reviews of NCX structure and function [3,4] should be consulted for details.

Two Families of PM $\text{Na}^+/\text{Ca}^{2+}$ Exchangers

Early measurements suggested that the cardiac and neuronal exchangers both had coupling ratios of $3 \text{Na}^+ : 1 \text{Ca}^{2+}$, and that these two ion species were the only ones translocated by the exchanger [3,5]. Subsequently, a $\text{Na}^+/\text{Ca}^{2+}$ exchanger was identified in the PM of photoreceptor cells. The photoreceptor exchanger was also dependent upon K^+ and appeared to have a coupling ratio of $4\text{Na}^+ : (1\text{Ca}^{2+} + 1\text{K}^+)$ [6,7]. This latter exchanger is therefore designated as the $\text{Na}/(\text{Ca}, \text{K})$ exchanger or NCKX.

Two families of $\text{Na}^+/\text{Ca}^{2+}$ exchanger molecules have been cloned and sequenced [8,9]. One corresponds to the

cardiac/neuronal NCX [8]; three members of this family, designated NCX1, NXC2, and NCX3, have been identified in mammals [10]. Each of these isoforms is the product of a different gene. NCX1 is the most prevalent, but they all have different tissue distributions. The functional significance of these different isoforms is unclear. In addition, there are several tissue-specific splice variants of NCX1; these, too, exhibit different tissue expression [11], but the functional significance has not been resolved.

The membrane topology of NCX1 is illustrated in Fig. 1. NCX has a molecular weight of 108 kDa (excluding glycosylation) and appears to have nine membrane-spanning segments [12]. A large cytoplasmic loop is located between the 5 N-terminal and 4 C-terminal transmembrane segments. This loop includes a calmodulin-like "exchanger inhibitory peptide" (XIP) binding site, a Ca^{2+} binding site that is involved in internal Ca^{2+} -dependent Ca^{2+} entry, and a peptide region that is alternatively spliced in different tissues (Fig. 1). A site that participates in intracellular Na^+ -dependent inactivation may be included within the XIP region. The alpha helix repeat that occurs in helices 2–3 and 7 (gray regions in Fig. 1) has been postulated to participate in the binding and translocation of Na^+ and Ca^{2+} , but the evidence is inconclusive. Part of the second alpha repeat is a P loop-like region between transmembrane segments 7 and 8 that dips into the membrane from the cytoplasmic side but does not traverse the membrane.

Three mammalian members of the second exchanger family, the NCKX family, also have been cloned: NCKX1 is found in rod photoreceptors, NCKX2 is expressed in cones and neurons, and NCKX3 is expressed in the brain and smooth muscles [13,14]. The topology of the deduced NCKX proteins is similar to that of NCX. Nevertheless, the sequence homology of the two families of expressed proteins is limited to two of the putative membrane-spanning domains that

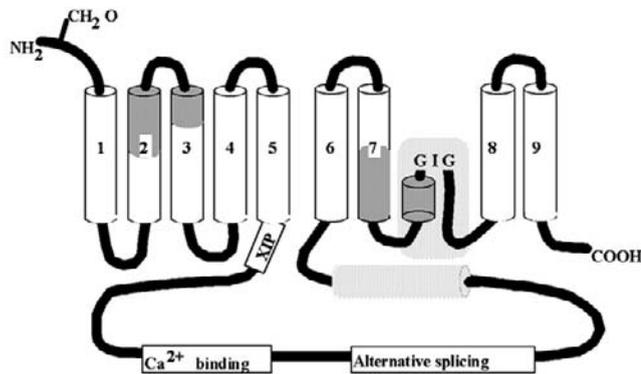

Figure 1 Diagram of $\text{Na}^+/\text{Ca}^{2+}$ exchanger topology. The model shows the dog cardiac NCX1 (938 amino acids), which apparently has 9 transmembrane segments. The glycosylated N terminus is extracellular. The region between transmembrane segments 7 and 8 apparently forms a “P-type” loop that dips into the membrane (shaded area). The grey portions of segments 2–3 and 7 (and part of the P-type loop) are the alpha repeats. The large cytoplasmic loop (which actually contains nearly 550 amino acids) includes the XIP binding region (and internal Na^+ -dependent inactivation site), the Ca^{2+} regulatory site, and the alternative splice site. This cytoplasmic loop also apparently includes a hydrophobic alpha helix region (shaded segment). Reproduced from Philipson and Nicoll [4] with permission.

may be involved in ion binding and translocation. Thus, the NCX and NCKX genes evolved independently.

Modes of Operation of the $\text{Na}^+/\text{Ca}^{2+}$ Exchangers

As diagrammed in Fig. 2, the NCX can mediate electroneutral Na^+/Na^+ exchange and electroneutral $\text{Ca}^{2+}/\text{Ca}^{2+}$ exchange, as well as the Na^+ entry/ Ca^{2+} exit and Na^+ exit/ Ca^{2+} entry exchange modes. The $\text{Ca}^{2+}/\text{Ca}^{2+}$ exchange mode is activated by nontransported alkali metal ions. These partial reactions are consistent with a sequential transport mechanism (Fig. 2) [3] in which either one Ca^{2+} ion or three Na^+ ions are bound at one side of the membrane, translocated to the other side, and dissociated before the ion(s) from that side are bound. The reversal potential, $E_{\text{Na}/\text{Ca}}$, for an NCX with a coupling ratio of $3\text{Na}^+ : 1\text{Ca}^{2+}$ is given by the equation [3]:

$$E_{\text{Na}/\text{Ca}} = 3E_{\text{Na}} - 2E_{\text{Ca}}$$

where $E_{\text{Na}} = (RT/F) \ln ([\text{Na}^+]_o/[\text{Na}^+]_i)$ and $E_{\text{Ca}} = (RT/2F) \ln ([\text{Ca}^{2+}]_o/[\text{Ca}^{2+}]_i)$, and the subscripts “o” and “i” refer to the extracellular and intracellular ion concentrations, respectively; R, T, and F have their usual meanings. If the membrane potential is more negative than $E_{\text{Na}/\text{Ca}}$, the NCX will extrude Ca^{2+} , and if more positive, the NCX will move Ca^{2+} into the cell.

The Na^+ entry/ Ca^{2+} exit and Na^+ exit/ Ca^{2+} entry exchange modes are both rheogenic (i.e., they are associated with net current flow). The exchange of 3Na^+ for 1Ca^{2+} in both of these modes means that one positive charge enters the cells during each Ca^{2+} exit exchange and one positive charge exits the cells during Ca^{2+} entry exchange. Net Ca^{2+} transport mediated by the NCKX also is rheogenic, with one net charge transported per cycle. Consequently, NCX- and

NCKX-mediated Ca^{2+} transport can both be measured electrically as ionic current flow across the plasma membrane in the direction opposite the net Ca^{2+} flux. Furthermore, the coupling ratio indicates that $\text{Na}^+/\text{Ca}^{2+}$ exchange is voltage-sensitive: membrane hyperpolarization promotes Ca^{2+} exit via the exchanger, while depolarization promotes exchanger-mediated Ca^{2+} entry. This is counterintuitive, because hyperpolarization is normally expected to drive Ca^{2+} into cells, while depolarization should slow Ca^{2+} entry.

Regulation of NCX

Several regulatory sites have been identified in the large cytoplasmic loop of NCX. These sites play critical roles in exchanger function. When the cytoplasmic Na^+ concentration ($[\text{Na}^+]_i$) is increased, exchanger-mediated Ca^{2+} entry is increased almost instantly, but only transiently; the exchange then declines in a time- and $[\text{Na}^+]_i$ -dependent manner [15]. This phenomenon, known as Na^+ -dependent inactivation, might be expected to limit exchanger-mediated Ca^{2+} entry. However, binding of cytosolic Ca^{2+} to the activation site on the cytoplasmic loop not only is required to activate exchanger-mediated Ca^{2+} entry, but it also reduces Na^+ -dependent inactivation [16].

Cardiac NCX is activated by phosphatidylinositol-4, 5-bisphosphate (PIP_2), which is generated from membrane-bound phosphatidylinositol by a mechanism that involves ATP hydrolysis [17]. The PIP_2 apparently binds to the XIP binding region of the large cytoplasmic loop [16]. This not only activates the NCX, but also eliminates Na^+ -dependent inactivation.

Inhibition of NCX

NCX is highly selective for Na^+ ; other monovalent cations cannot substitute for Na^+ . While Sr^{2+} and Ba^{2+} can be transported by the NCX, they are very poor substitutes for Ca^{2+} (i.e. maximum transport rates are much lower). Other divalent cations including Ni^{2+} and Cd^{2+} , and La^{3+} and some other lanthanides, inhibit NCX but are nonselective.

NCX inhibitory activity is displayed by various organic molecules. These include some hydrophobic amiloride analogs (e.g. 3,4-dichlorobenzamil), some antiarrhythmic agents (e.g. quinacrine and bepridil), and an isothiourrea derivative (“compound 7943”). Unfortunately, none of these molecules is completely selective.

XIP is a synthetic calmodulin-like peptide that can be used as an experimental tool [16]. When introduced into the cytosol, it binds to the “XIP region” of the large cytoplasmic loop (Fig. 1) and inhibits NCX activity.

Localization of the NCX

The PM NCX functions in parallel with the ATP-driven PM Ca^{2+} pump (PMCA), and both transport systems are

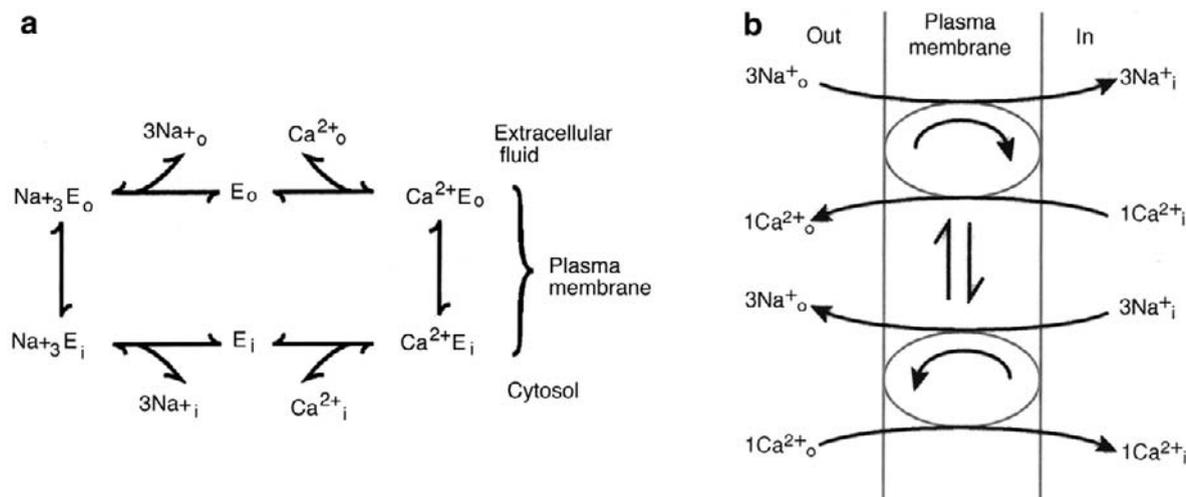

Figure 2 (a) State diagram illustrating the transport reactions mediated by the NCX (“E”). Subscripts “o” and “i” refer to the extracellular fluid or exofacial configuration of the carrier and cytosol or endofacial configuration of the carrier, respectively. Note that the carrier can switch between exofacial and endofacial conformations only when the carrier is loaded (Na_3^+E_o , Na_3^+E_i , Ca^{2+}E_o , or Ca^{2+}E_i); the unloaded carrier does not undergo conformational change (i.e. between E_o and E_i). (b). Diagram of net transport reactions mediated by the $\text{Na}^+/\text{Ca}^{2+}$ exchanger. The exchanger can either move 3Na^+ ions into the cell in exchange for one exiting Ca^{2+} ion (top) or move 3Na^+ ions out of the cell in exchange for one entering Ca^{2+} ion (bottom). Reproduced from Blaustein *et al.* [33] with permission.

present in the PM of most cells. Moreover, the PMCA and NCX have very different kinetic properties—most notably, their affinities for cytosolic Ca^{2+} ($K_{\text{Ca}(\text{cyt})} \approx 0.1 \mu\text{M}$ for PMCA and $\approx 1.0 \mu\text{M}$ for NCX1) and their turnover numbers ($\approx 30 \text{ sec}^{-1}$ for PMCA and $\approx 5,000 \text{ sec}^{-1}$ for NCX1). This implies that they have very different functions.

A further clue to their relative functions is their different distributions in the PM. The PMCA is very widely (uniformly?) distributed in the PM of several cell types, including astroglial cells, neurons, and smooth muscle cells [18,19]. In contrast, the NCX has a very much more limited distribution; indeed, in these same three cell types, NCX1 appears to be confined to microdomains of PM that overlie sub-PM (“junctional”) elements of the endoplasmic or sarcoplasmic reticulum (jER or jSR) [18]. In skeletal muscle, NCX is localized primarily in T-tubule membranes. In cardiac muscle, too, the NCX is concentrated in T-tubule membranes [20,21]. However, there also is evidence (albeit controversial) of high levels of NCX expression in the peripheral PM [22] and some evidence that the NCX does not reside in the PM overlying jSR [21]. NCX is prevalent at presynaptic nerve terminals, but it appears to be excluded from transmitter release sites (“active zones”) where the PMCA is concentrated [23].

Physiological Roles of the NCX

NCX (and NCKX) are expressed at high levels in cells with a large traffic of Ca^{2+} across the PM. Important examples are cardiac myocytes, neurons (especially nerve terminals), photoreceptor cells, and renal distal tubule epithelial cells [3,8,24]. The high level of activity in cardiac myocytes and neurons is consistent with the major role of the NCX in Ca^{2+} extrusion following periods of activity in these cells,

and with the >100-fold difference in turnover number between NCX and PMCA. In the heart, the plateau of the action potential may help to maintain a high $[\text{Ca}^{2+}]_{\text{CYT}}$ during systole by temporarily reducing NCX-mediated Ca^{2+} extrusion. The possibility that NCX-mediated Ca^{2+} entry may contribute to cardiac excitation-contraction coupling has long intrigued investigators but is still controversial.

In the nervous system, the relative distribution of NCX has not yet been directly compared to that of NCKX. The specific roles of these two types of exchangers are not known, nor is it known whether members of both families are expressed in the same cells, but it is noteworthy that the two transporters have different coupling ratios and different reversal potentials.

The NCX is expressed in many epithelia, including gastrointestinal and renal epithelia, and in various endocrine and endocrine secretory cells. In renal distal tubules, the NCX is a key player in the reabsorption of Ca^{2+} and control of Ca^{2+} homeostasis.

NCX plays a role in the modulation of Ca^{2+} signaling in many types of cells. Indeed, this is the basis of the cardiotoxic and vasotonic action of cardiotonic steroids [2,25–27]. In some cells, the NCX co-localizes with Na^+ pumps containing $\alpha 2$ or $\alpha 3$ subunits in PM microdomains [18] that are functionally coupled to the underlying jSR or jER [19,24,26]. These units (“PLasmERosomes”), which apparently help regulate Ca^{2+} signaling, contain a tiny diffusion-restricted volume of cytosol wedged between the PM and jSR or jER. Therefore, modulation of the Na^+ pump activity within the PM microdomains by hormones [27] or neurotransmitters [29,30] can alter the local (sub-PM) Na^+ and, via NCX, local Ca^{2+} concentrations. In this way, the Ca^{2+} content of the jSR or jER can be increased or decreased and can thus influence global Ca^{2+} signaling despite minimal change in the bulk $[\text{Na}^+]_i$. This resolves a long-standing dilemma about how low-dose

cardiotonic steroids can exert their cardiotonic effect without altering bulk $[\text{Na}^+]_i$ [31]. Inhibition (by ouabain, for example) of just a small fraction of the total Na^+ pump molecules [26,32] should raise the local (sub-PM) $[\text{Na}^+]_i$. The PLasmERosome structure/function relationships then, in effect, enable the NCX to help translate and amplify the local $[\text{Na}^+]_i$ rise into an augmented global Ca^{2+} signal [26]. In other words, the NCX is not simply a “second” Ca^{2+} extrusion mechanism, even though Ca^{2+} extrusion may be a very important part of its function. In addition, the Na^+ pumps and NCX in the PLasmERosome work together to influence jSR/jER Ca^{2+} content; they thereby modulate Ca^{2+} signaling and all of the downstream consequences.

Ca²⁺ Buffers

Beat Schwaller

*Division of Histology, Department of Medicine,
University of Fribourg, Perolles, Fribourg, Switzerland*

Introduction

In principal, any molecule with several negatively charged groups can act as a chelator for Ca²⁺ ions if the negative charges are spatially distributed in such a manner as to satisfy the necessary geometrical considerations for coordination. In biological systems, these requirements are fulfilled by the carboxylic groups of small molecules such as citrate and more especially by the acidic side chain residues (e.g. glutamate, aspartate) or carbonyl groups of proteins. The possibilities for forming Ca²⁺-binding sites are clearly numerous, and several protein families have been identified that contain different, evolutionarily well-conserved Ca²⁺-binding domains. These include the EF-hand proteins [1], annexins, and C₂ domain proteins, each of which is described in a separate chapter (see Chapters 136, 140, and 141 of this volume). Almost all known proteins described as “Ca²⁺ buffers” belong to the family of EF-hand proteins [1,2]. An analysis of the human genome has revealed 242 proteins with EF-hand domains, which renders this one of the largest groups of proteins sharing a common motif [3]. EF-hand proteins have been somewhat arbitrarily designated as either “buffers” or “sensors” [4], the distinction being made on the basis that “sensors” undergo Ca²⁺-dependant conformational changes, which permit them to interact with specific targets in a Ca²⁺-regulated manner. Typical sensor proteins include calmodulin (see Chapter 137 by Means), some S100 proteins (see Chapter 138 by Heizmann *et al.*), and several others (see Chapter 136 by Bourgoyne and Weiss). Some so-called EF-hand “buffers” [e.g. calretinin (CR) and calbindin D-28k (CB28k)] also display Ca²⁺-dependent conformational changes, but since no specific targets have as yet been identified, they are currently viewed as buffers. Whether an EF-hand protein can contribute to Ca²⁺-buffering in a given cell depends largely upon its intracellular concentration.

Thus, all proteins classified as “sensors” could essentially act as “buffers” if present at sufficiently high levels.

Relevant Parameters for Ca²⁺ Buffers

In order to understand how a buffer will affect Ca²⁺ homeostasis within a cell, one first needs to consider the relevant parameters. These include (a) its cytosolic concentration, (b) its affinity for Ca²⁺ and possibly also for other metal ions, (c) the kinetics of Ca²⁺ binding and release, and (d) its mobility. But for no single protein have all of these parameters been determined with precision *in vivo*. During the past few years, most studies dealing with EF-hand Ca²⁺-binding proteins have focused either on their metal-binding affinities (K_D values) or on elucidating their intracellular localization within specific cell types in a given tissue [1]. Proteins that will be discussed here include CB28k, CR, parvalbumin (PV), calbindin D-9k (CB9k; an S100-family protein), visinin-like protein III, and calmodulin (CaM).

Intracellular Concentration

With the exception of the ubiquitously expressed CaM, each of the aforementioned proteins is characterized by a very restricted pattern of expression within a given tissue, which renders an accurate determination of their intracellular concentrations extremely difficult. The proteins are frequently found in excitable cells (e.g. neurons), whose complex morphologies are prone to yield erroneous estimations of volume. Predictions of concentration in specific neurons usually fall within the range 1–50 μM, but the levels of PV in fast-twitch muscles and of CB9k or CB28k in specific cells of the kidney attain millimolar concentrations.

Metal-Binding Affinities

Two types of Ca^{2+} -binding sites in EF-hand proteins have been identified on the basis of differences in their selectivity and affinity for Ca^{2+} and Mg^{2+} ions [5]. The so-called Ca^{2+} -specific sites predominate, the affinity for this cation being much higher ($K_{\text{Ca}} = 10^{-3}$ – 10^{-7} M) than those for Mg^{2+} ($K_{\text{Mg}} = 10^{-1}$ – 10^{-2} M). Under basal conditions (free intracellular Ca^{2+} concentrations $[\text{Ca}^{2+}]_i = 40$ – 100 nM), the Ca^{2+} -specific sites of most of these proteins are assumed to be essentially vacant of metal ions and thus capable of binding Ca^{2+} rapidly, when $[\text{Ca}^{2+}]_i$ is raised. The second type, the mixed $\text{Ca}^{2+}/\text{Mg}^{2+}$ site binds Ca^{2+} with high and Mg^{2+} with moderate affinity in a competitive manner (dissociation constants: $K_{\text{Ca}} = 10^{-7}$ – 10^{-9} M; $K_{\text{Mg}} = 10^{-3}$ – 10^{-5} M). Under basal conditions, these sites are occupied principally by Mg^{2+} ions, which must dissociate before Ca^{2+} binding can occur. EF-hand proteins have also been shown to contain allosteric effector, Mg^{2+} -specific binding sites, which can influence the affinities of the EF-hand Ca^{2+} binding sites [6]. Most EF-hand domains are paired to form a tandem domain consisting of two helix-loop-helix regions linked by a short stretch of 5–10 amino acid residues. Hence, the majority of these proteins have an even number of EF-hand domains (2, 4, or 6; for details, see Chapter 136). Not only are the tandem domains important for the structural stability of the individual EF-hand domains, but binding of Ca^{2+} ions to one site allosterically affects the affinity and probably also the binding kinetics of the second.

Metal-Binding Kinetics

Under physiological conditions, Ca^{2+} -binding kinetics (on-rates) can vary from $>10^8 \text{ M}^{-1}\text{s}^{-1}$ for proteins with Ca^{2+} -specific sites implicated in very fast biological processes, such as muscle contraction (e.g. troponin C; TnC), down to an apparent on-rate of approximately $3 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$ for the

slow-onset buffer PV. In the absence of Mg^{2+} ions, the on-rate of Ca^{2+} -binding to PV is very rapid ($1.08 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$) [7]. But at the free intracellular concentration of magnesium ions $[\text{Mg}^{2+}]_i$, pertaining within neurons (0.3–0.6 mM) and rat myocytes (0.9 mM) [8,9], the rate for Ca^{2+} -binding, being determined by the rather slow Mg^{2+} off-rate [7,10] (Table I), will consequently be significantly slower.

During muscle contraction, PV does not compete with TnC for the binding of Ca^{2+} but helps increase the initial rate of $[\text{Ca}^{2+}]_i$ decay [11], thereby shortening the relaxation phase following very brief contractions. In this case, Mg^{2+} plays a role of almost equal importance to that of Ca^{2+} ; it not only lowers Ca^{2+} affinity to within the physiological range but also exerts a considerable influence on the kinetics of Ca^{2+} binding to, and its release from, PV. The kinetics of Ca^{2+} binding for “fast” and “slow” buffer proteins are similar to those characterizing the synthetic chelators BAPTA and EGTA (Table I), respectively, which are thus often used experimentally to mimic endogenous buffer proteins. Owing to differences in their Mg^{2+} -buffering capacities, PV and EGTA are comparable only so far as their Ca^{2+} -binding kinetics are concerned—not with respect to the $\text{Ca}^{2+}/\text{Mg}^{2+}$ antagonism (Table I).

Protein Mobility

In the cytosol of *Xenopus laevis* oocytes, only slowly mobile or immobile Ca^{2+} buffers exist. Accordingly, the rate of diffusion for Ca^{2+} ions under basal conditions ($D^* = 13 \mu\text{m}^2/\text{s}$) is much slower than that of another small molecule involved in cellular signaling, IP_3 ($283 \mu\text{m}^2/\text{s}$) [12]. Even when $[\text{Ca}^{2+}]_i$ is raised to $1 \mu\text{M}$, with a view of saturating the immobile buffer sites, the diffusion coefficient remains relatively low ($65 \mu\text{m}^2/\text{s}$). The manner in which a Ca^{2+} transient is affected by the presence of a buffer is also linked to its intracellular localization, that is, whether the buffer is freely

Table I Properties of Ca^{2+} -binding Proteins and Artificial Ca^{2+} Buffers (Adapted from [24])

Buffer	K_D value(s)	$k^+_{\text{Ca}^{2+}} \text{ M}^{-1}\text{s}^{-1}$	$\text{Ca}^{2+}/\text{Mg}^{2+}$ antagonism	No. of EF-hands (functional)	Refs.
PV	4–9 nM ⁽¹⁾ $K_{D,\text{app}} 50 \text{ nM}^{(2)}$ 1 nM–100 nM ⁽³⁾	1.1×10^8 $1\text{--}2 \times 10^7$	strong	3 (2)	[7] [25]
CB	$K_{D1} \approx 180\text{--}240 \text{ nM}^{(4)}$ $K_{D2} \approx 410\text{--}510 \text{ nM}$	$\approx 1.2 \times 10^7$ $\approx 8.2 \times 10^7$	weak	6 (4)	[26]
CR	380–1500 nM	$\geq 10^8$ ⁽⁵⁾	weak	6 (5)	[27,28]
BAPTA	130–800 nM	$10^8\text{--}10^9$	weak		[29,30]
EGTA	$\approx 70 \text{ nM}$	$3 \times 10^6\text{--}1 \times 10^7$	weak		[26]

¹This represents the K_D value in the absence of Mg^{2+} .

²The apparent dissociation constant ($K_{D,\text{app}}$) for Ca^{2+} depends heavily upon $[\text{Mg}^{2+}]_i$. The K_D value of 50 nM was obtained at a $[\text{Mg}^{2+}]_i$ of 0.16 mM. But at a $[\text{Mg}^{2+}]_i$ of 0.3–0.6 mM, which corresponds to the range encountered in neurons, $K_{D,\text{app}}$ lies around 80–150 nM. This will affect the on-rate of Ca^{2+} binding, lowering it to values of approximately $3\text{--}6 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$ (similar to that for EGTA).

³ K_D values ranging from 1–100 nM were obtained under different experimental conditions (pH, ionic strength, etc.).

⁴CB contains two types of binding sites, which differ in their affinity for Ca^{2+} and their Ca^{2+} -binding on-rates.

⁵This is an approximation proposed by Edmonds *et al.* [31]. With its five Ca^{2+} -binding sites, CR would be expected to have different K_D and $k^+_{\text{Ca}^{2+}}$ values, as is the case with CB. The cited on-rate of $10^8 \text{ M}^{-1}\text{s}^{-1}$ most probably represents that of the fastest site(s).

diffusible or is bound to structures such as organelles, the plasma membrane, or cytoskeletal structures. The mobility effect may be further complicated if the buffer relocalizes as a result of changes in [Ca²⁺]_i, as in the case for the Ca²⁺ “sensor” visinin-like protein III [13].

Ca²⁺ Buffers as One Component Contributing to Intracellular Ca²⁺ Homeostasis

Following an influx of Ca²⁺ ions into a cell, the role played by Ca²⁺ buffers is apparently a simple one, namely, to bind this cation and thereby lower [Ca²⁺]_i. However, soluble buffers represent but one component of the intricate system implicated in Ca²⁺ homeostasis. A rise in [Ca²⁺]_i activates also the pumps involved in Ca²⁺ extrusion or Ca²⁺ uptake by organelles, such as the endoplasmic reticulum or mitochondria. These will remain operative until [Ca²⁺]_i has once again attained its steady-state level and the Ca²⁺ buffers have essentially reverted to their Ca²⁺-free form, loading at this point being determined by their *K*_D and by basal [Ca²⁺]_i. It is important to bear in mind that steady-state [Ca²⁺]_i is determined by the balance obtaining between Ca²⁺-fluxes across the membranes surrounding the cytosol; it is not influenced by the presence of buffers *per se*. Neither the addition of a Ca²⁺ buffer such as PV or CB28k [7,14] to cells nor its elimination in knockout mice [11,15] affects basal [Ca²⁺]_i, but rather prolongs the time ensuing until the steady-state level has been reattained (Fig.1). In the simplest case, the reduction in amplitude is inversely correlated to the lengthening of the transient, that is the time integral (the product of amplitude and time constant) remains unchanged by the presence of a Ca²⁺ buffer [16].

Intracellular Ca²⁺ transients are often characterized by highly complex patterns in time and space, since several relevant processes, such as Ca²⁺ entry via different pathways, Ca²⁺ binding to buffers (mobile and immobile), and sequestration by pumps, occur on the same temporal scale [7]. Furthermore, saturation of buffers may occur leading to nonlinear (e.g. supralinear) summation of Ca²⁺ signals as demonstrated in cerebellar Purkinje cells [17]. It is evident that the temporal and spatial aspects of Ca²⁺ signals are governed by an intricate interplay of the participating components. In biological systems, nonlinear summation of these signals is rather the rule than the exception, which makes it difficult to analyze the contribution of individual components [16].

Biological Effects of Ca²⁺ Buffers

CR, CB28k, and PV are three major representatives of EF-hand proteins that are classified as “buffers,” and each is expressed within a specific subpopulation of neurons. The former two proteins possess, respectively, 5 and 4 Ca²⁺-specific sites with presumably fast Ca²⁺-binding kinetics (Table I), whereas PV has two Ca²⁺/Mg²⁺-mixed sites with a slow Ca²⁺-onset rate. In knockout mice for any one of these proteins [11,15,18], the remaining two have been observed to be

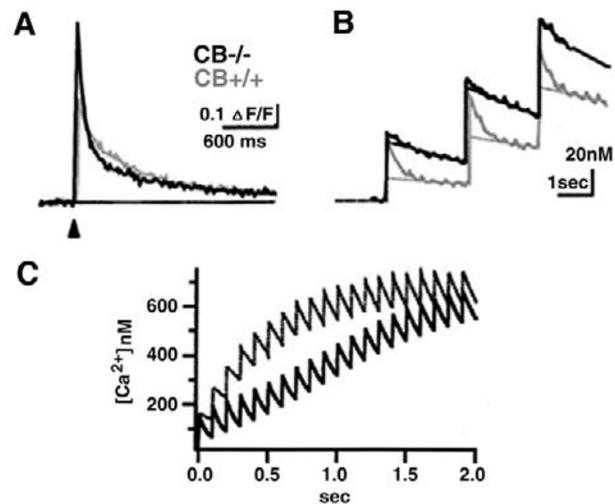

Figure 1 Effect of a fast and a slow buffer on Ca²⁺ transients. (A) Dendritic Ca²⁺ signals in Purkinje cells of CB+/+ (grey trace) and a CB-/- (black trace) mice, elicited by single-shock synaptic stimulation of the climbing fiber (arrowheads; for details, see [15]), CB markedly reduces the amplitude of a Ca²⁺ transient but prolongs the temporal decay of [Ca²⁺]_i. (B) A series of Ca²⁺ transients evoked in a patched chromaffin cell by applying short (20 ms) depolarizing bursts just after break-in (black trace) and after loading with PV via a patch pipette (grey trace, for details, see [7]). PV does not affect the amplitude of the Ca²⁺ transients but increases the initial rate of decay of [Ca²⁺]_i. (C) Simulated Ca²⁺ transients evoked in a neuron by 10 Hz stimulation in the absence (grey trace) or presence (black trace) of 200 μM PV (modified from [7]). Although the build-up of [Ca²⁺]_i is more rapid in the absence of PV, once the protein is Ca²⁺-saturated, steady-state [Ca²⁺]_i is identical under both conditions. Hence, it is the time-course en route to the steady state that is significantly different. From this model, it is likewise evident that it is the metal-binding kinetic parameters that define the frequencies (stimulation intervals) at which a slow-onset buffer is effective in lowering the residual [Ca²⁺]_i between impulses.

neither upregulated nor expressed by any types of neurons other than those expressing them in wild-type animals. Hence, neurons are either incapable of inducing the expression of the other two buffers, or the relevant parameters (binding affinities, kinetics or diffusion) are unsuited to these acting as surrogates for the missing one.

Typical hallmarks of Ca²⁺ transients in excitable cells are their short duration (in the range of 10 to several 100 ms) and often restricted localization, within the axon of neurons, in the subplasmalemmal region of the soma, within parts of the dendrites or even within single spines only. Cytosolic Ca²⁺ buffers have a considerable influence on the spatiotemporal characteristics of such transients. Fast buffers such as CB or CR are able to buffer Ca²⁺ entering via channels from the extracellular space or being released from internal stores with virtually no delay. This reduces the peak amplitude of Ca²⁺ transients but prolongs the decay phase, since proteins such as CB28k or CR act as sources of Ca²⁺ at a later juncture (Fig. 1A). CB28k, on the one hand, is a fast enough buffer to slow down the Ca²⁺-dependent inactivation of a Ca²⁺ channel and thereby even increases the total Ca²⁺ load [19]. PV, on the other hand, is too slow to affect the peak [Ca²⁺]_i in most cases, but it can significantly increase the rate of

$[Ca^{2+}]_i$ decay, as revealed in murine fast-twitch muscle fibers [11] or PV-injected chromaffin cells ([7], Fig. 1B).

In the presynaptic terminals or postsynaptic regions (soma, dendrites, and spines) of neurons, repetitive Ca^{2+} transients occurring at short time intervals are a typical physiological signaling event. Whether a particular Ca^{2+} buffer influences the spatiotemporal characteristics of these transients depends upon its concentration, Ca^{2+} affinity, binding kinetics, and diffusion rate. This is exemplified for PV during repetitive stimulations. At short pulse intervals (30 ms), paired-pulse modulation at the synapse between stellate or basket cells and Purkinje cells shifts from depression (Fig. 2A) to facilitation (Fig. 2B), if PV is absent (for example, in PV $-/-$ mice). This phenomenon is attributable to the higher residual $[Ca^{2+}]_i$ obtained in the absence of PV, which results in the second inhibitory postsynaptic current (IPSC) having a higher amplitude than that of the first (Fig. 2D). Clearly, if the pulses are delivered at longer intervals (300 ms), when residual $[Ca^{2+}]_i$ has decayed to basal levels irrespective of the presence of PV, paired-pulse depression is also observed in PV $-/-$ mice (Fig. 2C). Steady state $[Ca^{2+}]_i$ level during burst-like action potentials (AP) depends upon $\Delta t/\tau$; Δt being the time interval between APs and τ the Ca^{2+} relaxation-time constant of individual Ca^{2+} transients. In the presence of PV, the time course until the equilibrium is reached is delayed, but eventually catches up if all PV molecules are saturated with Ca^{2+} (Fig. 1C; [7]).

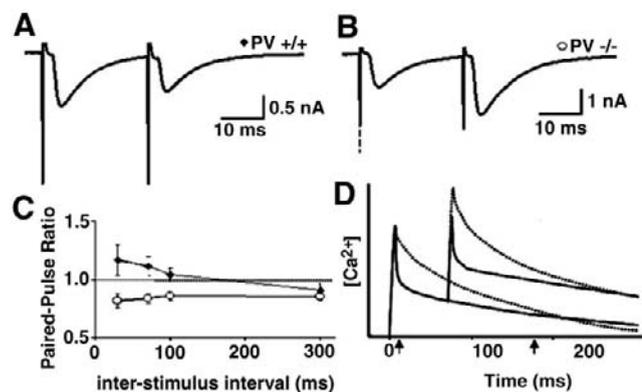

Figure 2 Parvalbumin affects short-term plasticity at the synapse between stellate or basket cells and Purkinje cells in the cerebellum. (A–B) Inhibitory postsynaptic currents (IPSCs) recorded from Purkinje cells during extracellular paired-pulse protocols (at an inter-stimulus interval (ISI) of 30 ms) of GABAergic interneurons. In the presence of PV (i. e. in PV $+/+$ mice), the second IPSC is depressed (A), whereas in its absence (i. e. in PV $-/-$ mice), facilitation occurs (B). (C) The effect of PV on the paired-pulse ratio (IPSC $_2$ /IPSC $_1$) is seen only when the ISI lies between 30 and 100 ms. When the interval is increased to 300 ms, the ratio does not differ between PV $-/-$ and PV $+/+$ mice. (D) Within a presynaptic terminal, the peak $[Ca^{2+}]_i$ attained during the initial pulse is not affected by the absence or presence of PV, but the decay phase is slower in the former case (broken line). Hence, for a certain period of time (arrows), residual $[Ca^{2+}]_i$ will be elevated. If a second pulse is delivered during this period, then the peak $[Ca^{2+}]_i$ attained will be higher than during the first, a result that leads to enhanced facilitation. At the synapse between PV-containing stellate or basket cells and Purkinje cells, the effect of this Ca^{2+} buffer is maximal at a ISI of 30 ms (A, B, C: modified from [23]; D: modified from [24]).

In *Xenopus* oocytes, the injection or overexpression of PV induces elementary Ca^{2+} release events (Ca^{2+} puffs), which are elicited from discrete clusters of inositol 1,4,5 trisphosphate receptors (IP $_3$ R) at low concentrations of IP $_3$ [20]. Ca^{2+} puff activity has also been detected after the injection of low concentrations of EGTA, but not after that of CB28k, which supports the idea that particular buffers are not simply interchangeable. This circumstance indicates that each buffer has distinct functions, which accord with its specific buffering properties. This is further illustrated by the finding that the changes in spine morphology of Purkinje cell dendrites (increased length and volume) observed in CB-deficient mice are not seen in PV-deficient ones [21]. In the fast-twitch muscles of PV-deficient mice, the volume of mitochondria, organelles also involved in Ca^{2+} sequestration helping to decrease $[Ca^{2+}]_i$ after Ca^{2+} transients (see Chapter 14 by Duchen), is almost twice as large as those in wild-type animals [22]. Ca^{2+} buffers thus constitute an integral part of the finely tuned system involved in Ca^{2+} homeostasis and have a profound effect on many aspects of Ca^{2+} signaling. The removal of such a buffer does not apparently trigger the obvious compensation mechanism (that is, the upregulation of another Ca^{2+} buffer), but leads rather to subtle changes in cell morphology or to discrete modulations in Ca^{2+} uptake or release systems. This may represent the cell's attempt to re-establish a "normal" state of Ca^{2+} homeostasis.

Mitochondria and Calcium Signaling, Point and Counterpoint

Michael R. Duchon

*Department of Physiology and UCL Mitochondrial Biology Group,
University College London, London, United Kingdom*

Introduction

Mitochondria can no longer be considered as static structures whose sole function is the unobtrusive manufacture of ATP. It is now clear that they also represent a storeroom for a number of potentially lethal proteins that are unleashed during programmed cell death and that they are significant participants in the detailed intracellular organization of cellular $[Ca^{2+}]_c$ signaling. While the expression in the mitochondrial membrane of Ca^{2+} transporting mechanisms was established years ago, the physiological significance of these pathways has only recently become apparent. There is now no question that mitochondria will take up and accumulate Ca^{2+} in all cells studied during the routine events of cellular $[Ca^{2+}]_c$ signaling, and that the pathway influences both mitochondrial function itself and the spatiotemporal and quantitative characteristics of the cellular $[Ca^{2+}]_c$ signal. As general issues relating to mitochondrial Ca^{2+} handling have recently been widely reviewed (e.g. [1–3]), I propose in this essay to highlight some of the more controversial and novel developments in the field over recent years and some of the mechanistic, quantitative, and comparative questions that remain.

Fundamentals

When energized mitochondria are exposed to raised $[Ca^{2+}]_c$, Ca^{2+} will move into the matrix. The accumulation of Ca^{2+} by mitochondria depends on the electrochemical gradient for Ca^{2+} , defined by the mitochondrial membrane potential, referred to as $\Delta\Psi_m$, and by the intramitochondrial Ca^{2+} concentration ($[Ca^{2+}]_m$), which is kept low under resting conditions largely through the activity of a xNa^+/Ca^{2+}

exchanger (see below). The mitochondrial potential is established and maintained by respiration and so requires a supply of oxygen and carbon substrate—collapse of $\Delta\Psi_m$ due to anoxia, ischemia, damage to the respiratory chain, or the action of biochemical reagents, such as uncouplers, limit mitochondrial Ca^{2+} accumulation. One might ask whether any cell is ever really “at rest” *in situ* in the active organism in contrast to the artificial situation of the cell grown in culture—in which case, what would the normal $[Ca^{2+}]_m$ be in a cell in the living tissue and organism? The closest we get to that information comes from electron probe microanalysis (e.g. see [4]), but multiphoton imaging now holds the promise of being able to study mitochondria within intact tissues.

Machinery of Mitochondrial Ca^{2+} Movement

The Uniporter

Ca^{2+} is taken up through the mitochondrial inner membrane by a uniporter. Remarkably, we do not know the molecular identity or even the precise nature of this pathway. Is it a channel or a carrier? Flux rates are equivalent to those measured for fast gated pores, but rather slower than those seen for channels (see [3] for review). The activity of the uniporter shows little sensitivity to changes in temperature, and it also shows a wide spectrum of cation selectivity, together suggesting that it is a channel rather than a carrier. Ca^{2+} uptake via the uniporter is inhibited by ruthenium red (RuR), a compound that inhibits a variety of cation channels, including L-type plasmalemmal Ca^{2+} channels [5], ryanodine sensitive ER Ca^{2+} release channels [6], and vanilloid receptor operated channels [7], again suggesting that the uniporter may share channel properties.

One of the most interesting features of the uniporter is an apparent gating by $[Ca^{2+}]_c$, identified primarily through studies of the Ca^{2+} sensitivity of RuR-sensitive mitochondrial Ca^{2+} efflux in response to dissipation of $\Delta\psi_m$ [8,9]. Montero *et al.* [9], showed that, while collapse of $\Delta\psi_m$ prevents mitochondrial Ca^{2+} uptake, collapse of $\Delta\psi_m$ after the accumulation of mitochondrial Ca^{2+} inhibited mitochondrial efflux, i.e. all mitochondrial efflux pathways were inhibited by depolarization. Addition of Ca^{2+} to the depolarized Ca^{2+} loaded mitochondria then promoted mitochondrial Ca^{2+} release sensitive to RuR, suggesting release through the uniporter. This is consistent with suggestions that the uniporter is allosterically gated by $[Ca^{2+}]_o$ [8], an observation that may also explain why local $[Ca^{2+}]_c$ needs to be higher than one might expect from the behavior of a conducting Ca^{2+} channel in order to see significant increases in $[Ca^{2+}]_m$.

An uptake pathway with properties distinct from those of the uniporter has also been described [10,11] and dubbed the rapid uptake mode (RaM). This pathway has the capacity to transfer Ca^{2+} very rapidly into the mitochondria during the rising phase of a Ca^{2+} pulse. The properties of the pathway differ in different tissues [11], but in heart the pathway saturates quickly and is slow to reset after activation. Again, the functional significance of the pathway remains to be established.

VDAC

The mitochondrial outer membrane has been assumed to be permeant to small ions and so has been largely neglected in considerations of mitochondrial Ca^{2+} handling. However, the outer membrane may play a more significant role in modulating access of Ca^{2+} to the uniporter through the selectivity filter of the voltage-dependent anion channel (VDAC). It appears that VDAC is Ca^{2+} permeant and is regulated both by $[Ca^{2+}]_c$ and by RuR [12]. This finding raises questions about the extent to which the properties of the uptake pathway are defined by VDAC acting as a first filter. It is also tantalizing that VDAC appears to be part of the mitochondrial permeability transition pore (mPTP; see below), itself regulated by $[Ca^{2+}]_m$, as the mPTP provides a potential efflux pathway for Ca^{2+} , although the physiological relevance of this pathway is debated. Such studies point to the outer membrane as a significant permeability barrier that may itself be regulated.

Mitochondrial xNa^+/Ca^{2+} Exchange

The major route for Ca^{2+} efflux from mitochondria is a xNa^+/Ca^{2+} exchange. Identified about twenty years ago, it has a discrete pharmacology distinct from the plasmalemmal exchanger. The stoichiometry of the exchanger seems still to be controversial. Initially, it was thought to be an electroneutral $2Na^+/Ca^{2+}$ exchanger [13], but this has been questioned, as the exchanger can operate against a $[Ca^{2+}]_c$ gradient whose energy is over twice that of the Na^+ gradient [14]. Jung *et al.* [14] suggested a stoichiometry of $3Na^+/Ca^{2+}$, in which case the operation of the exchanger will be dependent on $\Delta\psi_m$. The inhibition of mitochondrial Ca^{2+} efflux by mitochondrial

depolarization (see above [9], and also [15]) supports this electrogenic stoichiometry. An electrogenic stoichiometry also predicts that Ca^{2+} efflux should be associated with mitochondrial depolarization. To my knowledge, this has not been documented.

The Set Point

Flux studies in isolated mitochondria revealed many years ago that mitochondria will take up Ca^{2+} . With small elevations of $[Ca^{2+}]_o$, the removal of Ca^{2+} from the matrix by the xNa^+/Ca^{2+} exchange may be sufficiently rapid so that net $[Ca^{2+}]_m$ changes little. As $[Ca^{2+}]_o$ rises above ~4–500 nM, the capacity of the exchanger is exceeded and mitochondria show net accumulation of Ca^{2+} . This was termed the “set point” for mitochondrial Ca^{2+} uptake by Nicholls and Crompton [16]. It is worth considering that Ca^{2+} flux into mitochondria is not necessarily synonymous with a net increase in $[Ca^{2+}]_m$, especially given our ignorance of the Ca^{2+} buffering capacity of the matrix. This is not purely semantic, as Ca^{2+} uptake by the uniporter is electrogenic and is therefore associated with small changes in $\Delta\psi_m$. Experimentally, changes in $\Delta\psi_m$ will reflect the rate of Ca^{2+} flux, and may therefore prove a more sensitive measurement of Ca^{2+} movement into mitochondria than measurement of $[Ca^{2+}]_m$. Further, net mitochondrial Ca^{2+} accumulation will be partly set by the activity of the xNa^+/Ca^{2+} exchanger—and we still know little about its regulation.

Many excitable cells respond to depolarization with a rise in $[Ca^{2+}]_c$, which rises rapidly and recovers with an initial rapid phase and a slower second phase that can even form a plateau [17–19]. It has been established in many preparations that the slow recovery phase reflects the redistribution of mitochondrial Ca^{2+} through the activity of the Na^+/Ca^{2+} exchanger, reflecting the set point, typically initiated at a $[Ca^{2+}]_c$ of ~500 nM. The operation of this system has functional consequences at presynaptic terminals, where the $[Ca^{2+}]_c$ plateau that follows repetitive stimulation, maintained by the reequilibration of mitochondrial Ca^{2+} , provides an elevated $[Ca^{2+}]_c$ baseline upon which subsequent stimulation initiates an enhanced synaptic response—the basis for post-tetanic potentiation of synaptic transmission [18,20]. It is also intriguing that the post stimulus plateau phase is not seen in nonexcitable cells following the transmission of $[Ca^{2+}]_c$ signals from ER to mitochondria. Certainly in astrocytes, $[Ca^{2+}]_m$ remains high for a very prolonged period after stimulation [21], suggesting that mitochondrial Ca^{2+} efflux must be very slow and perhaps the activity of the exchanger differs between tissues or cell types.

Quantitative Issues, Microdomains, and the Regulation of $[Ca^{2+}]_c$ Signals

There has been some debate about the quantitative relationships between ambient $[Ca^{2+}]_c$ and mitochondrial uptake.

In HeLa cells transfected with mitochondrially targeted aequorin and then permeabilized, net mitochondrial Ca^{2+} accumulation was only detectable if the added Ca^{2+} reached concentrations higher than $3\ \mu\text{M}$, while $[\text{Ca}^{2+}]_c$ signals evoked by IP_3 mobilizing agonists were far more effective at raising $[\text{Ca}^{2+}]_m$ even though the mean $[\text{Ca}^{2+}]_c$ signal might rise to $<1\ \mu\text{M}$ [22]. This led to the suggestion that mitochondria must be positioned at privileged sites close to the ER Ca^{2+} release sites where they would be exposed to microdomains of high local $[\text{Ca}^{2+}]_c$ sufficient to promote rapid Ca^{2+} uptake.

The proximity of mitochondria to SR or ER Ca^{2+} release sites has been further emphasized through evidence that focal, nonpropagating ER/SR Ca^{2+} release can cause a transient increase in $[\text{Ca}^{2+}]_m$ in mitochondria close to the release site. Thus, we found [23] that mitochondria in cardiomyocytes show spontaneous transient mitochondrial depolarizations that were dependent on local SR Ca^{2+} release and were blocked by inhibition of mitochondrial Ca^{2+} uptake. Hajnoczky *et al.* [24] have since shown that local $[\text{Ca}^{2+}]_c$ sparks may be associated with the direct transfer of Ca^{2+} to mitochondria visualized as transient increases in $[\text{Ca}^{2+}]_m$, which the group termed Ca^{2+} “marks.” Further data from cardiomyocytes [25] strongly suggest that, in cardiomyocytes, mitochondria and SR must show very close coupling, as the transfer of Ca^{2+} to mitochondria in response to SR Ca^{2+} release with caffeine in permeabilized cells was sustained despite Ca^{2+} buffering by BAPTA sufficient to suppress the cytosolic signal. The transfer of Ca^{2+} was prevented by disrupting the cytoskeleton, suggesting that the maintained close apposition of mitochondria to SR was central to this signal.

The proximity of mitochondria to Ca^{2+} release sites has functional consequences for $[\text{Ca}^{2+}]_c$ signaling. Using $[\text{Ca}^{2+}]$ indicators in both mitochondria and ER in permeabilized cells, Csordas *et al.* [26] showed direct transfer of Ca^{2+} from ER to mitochondria and suggested that the proximity must be $\sim 10\text{--}20\ \text{nm}$. This work was extended to show that mitochondrial Ca^{2+} uptake enhances the release of Ca^{2+} from the ER in response to IP_3 by acting as a local buffer [27]. Thus, by removing Ca^{2+} from the microdomain close to the IP_3 Ca^{2+} release channel, mitochondria prevent the Ca^{2+} dependent inactivation of the channel and facilitate ER Ca^{2+} release. This mechanism allows mitochondria to play a significant role in shaping the spatiotemporal patterning of $[\text{Ca}^{2+}]_c$ signals. In *Xenopus* oocytes, energization of mitochondria enhances the propagation and coordination of $[\text{Ca}^{2+}]_c$ waves [28], while in astrocytes, which express primarily IP_3 type 3 receptors, energized mitochondria serve as a spatial buffer that limit the rate and extent of propagation of $[\text{Ca}^{2+}]_c$ waves [21]. Microdomains of $[\text{Ca}^{2+}]_c$ regulated by mitochondria also play a significant role in the regulation of capacitative Ca^{2+} influx [29,30], suggesting that the mitochondria must be positioned close to the plasma membrane. The principle is very much as outlined above for the IP_3 receptor, as the Ca^{2+} influx channel is desensitized by Ca^{2+} . By keeping $[\text{Ca}^{2+}]_c$ low in microdomains close to the channels, mitochondria keep the channels open and facilitate Ca^{2+} influx through the channels.

In the blowfly salivary gland and in pituitary gonadotropes, mitochondrial Ca^{2+} uptake may even play a major role in defining the rates of oscillation of the IP_3 generated $[\text{Ca}^{2+}]_c$ signal [31,32], suggesting that the interplay between mitochondrial Ca^{2+} uptake and ER Ca^{2+} release contribute significantly to the temporal patterning of the $[\text{Ca}^{2+}]_c$ signal.

In pancreatic acinar cells, the mitochondria are concentrated into a band that isolates the secretory pole of these polarized cells, and they seem to act as a “firewall” that limits the spread of $[\text{Ca}^{2+}]_c$ signals from their initiation at the apical pole to the basal pole [33]. Furthermore, mitochondria localized close to the basal pole are more sensitive to local Ca^{2+} influx by capacitative entry, and so it seems that the positions of mitochondria within the cell may have a profound influence on their interaction with cellular $[\text{Ca}^{2+}]_c$ signals [34]. This issue alone is fascinating but unresolved—what dictates the positions mitochondria occupy within cells? Indeed, imaging mitochondria within cells shows that they move, and that the movement is erratic and unpredictable, and, to my knowledge, we have no idea what might be the functional significance of that movement.

Are $[\text{Ca}^{2+}]_c$ microdomains essential for mitochondria to sense changes in $[\text{Ca}^{2+}]_c$ associated with $[\text{Ca}^{2+}]_c$ signals? In permeabilized adrenal glomerulosa cells, Szabadkai *et al.* [35] found that graded additions of buffered external Ca^{2+} caused a graded but nonlinear increase in $[\text{Ca}^{2+}]_m$, showing a response even when the ambient $[\text{Ca}^{2+}]$ was only $\sim 200\text{--}300\ \text{nM}$. Such data suggest that the close juxtaposition of mitochondria to Ca^{2+} sources is not an absolute requirement if they are to respond to $[\text{Ca}^{2+}]_c$ signals. A recent study in HeLa cells [36] also suggests that areas of maximal mitochondrial Ca^{2+} uptake may be divorced from areas of maximal proximity with ER in HELA cells. This study suggested that peripheral mitochondria had larger mitochondrial potentials and that this might provide a mechanism to enhance mitochondrial $[\text{Ca}^{2+}]_c$ accumulation into that mitochondrial population. The notion that mitochondria within a single cell may have different potentials remains contentious and the observation is critically dependent on the behavior of the fluorescent indicators used to measure $\Delta\psi_m$. This is probably not the place for further discussion of this issue, but my own view is that the question remains open and has not been satisfactorily resolved either way.

Impact of Ca^{2+} Uptake on Mitochondrial Function

In teleological terms, it seems that the major functional significance of mitochondrial Ca^{2+} uptake is in the regulation of mitochondrial metabolism. In the early 1990s it was shown that the three major rate-limiting enzymes of the citric acid cycle are all upregulated by Ca^{2+} (for review, see [37]). The question that remained was the functional issue—is mitochondrial Ca^{2+} uptake during physiological signaling sufficient for this mechanism to provide a functional regulation of metabolism? First suggestions that such a system operates in intact cells came from measurements of changes

in mitochondrial redox state, reflected as changes in mitochondrial NADH and flavoprotein autofluorescence, in response to changes in $[Ca^{2+}]_c$ [5,38]. These observations showed clearly that (1) mitochondria must be taking up Ca^{2+} during $[Ca^{2+}]_c$ signals, and (2) that this was sufficient to activate the TCA cycle, causing increased net reduction of the coenzymes. More recently, transfection of cells with firefly luciferase allowed a clear and unequivocal demonstration that mitochondrial Ca^{2+} uptake increases mitochondrial ATP production [39]. The relative importance of this mechanism in the regulation of mitochondrial oxidative phosphorylation over the more traditional model, in which the rate of ATP generation is regulated largely by the ATP/ADP ratio, is not clear. It is very attractive to suggest that the transfer of Ca^{2+} from the cytosol to mitochondria during $[Ca^{2+}]_c$ signals represents a major mechanism to couple ATP supply with demand, as in almost all systems, increases in work are associated with increases in $[Ca^{2+}]_c$. Nevertheless, direct evidence for a significant role in intact systems is limited and there are conflicting data (see e.g. [40,41]).

The time course of the changes in $[Ca^{2+}]_m$ and in activation of the enzyme systems becomes crucial. $[Ca^{2+}]_c$ signals are typically brief, transient phenomena. Typically, it seems that the resultant mitochondrial activation is prolonged with respect to the change in $[Ca^{2+}]_c$ [5,42,43], and this in turn will be a function of the rate of mitochondrial Ca^{2+} efflux and the half-life of the activated states of the enzymes.

A further major question that is important in considering the impact of Ca^{2+} on mitochondrial function is, how high does $[Ca^{2+}]_m$ rise during these signals? There is not space here for a detailed discussion, but experiments using low-affinity variants of aequorin suggest that, at least in some mitochondria in some cells, $[Ca^{2+}]_m$ may rise into the millimolar region [44].

Mitochondrial Ca^{2+} , Disease, and Death

Most important, mitochondrial Ca^{2+} uptake may have profound consequences for mitochondrial function under pathological conditions. A combination of mitochondrial Ca^{2+} loading and oxidative stress and/or ATP depletion may promote opening of the mitochondrial permeability transition pore (mPTP). This appears to reflect a pathological conformation of a group of mitochondrial membrane proteins, notably the adenine nucleotide translocase (ANT) and VDAC, with the association of cyclophilin D, a regulatory protein that confers sensitivity of the complex to cyclosporin A, and a possible association of a number of other proteins, including the antiapoptotic Bcl-2, and the benzodiazepine receptor (see [45,46] for reviews). It is not clear whether the mPTP has any physiological function, but its complete opening under pathological conditions will lead inevitably to energetic collapse and cell death, and has been implicated in Ca^{2+} dependent cell death in reperfusion injury in the heart and in glutamate neurotoxicity in the CNS.

CODA

Our perception of the mitochondrion has changed radically over the last few years. Mitochondrial function is critical for the viability of the cell, mitochondria play an integral role in shaping cell signaling, and the dysfunction of the pathways necessary for these functions may trigger cell death. These are not trivial and peripheral functions but are central to cell life and cell death.

Acknowledgments

Work in my laboratory is supported by the Wellcome Trust, the Medical Research Council, and the Royal Society, whom I thank. I also thank Remi Dumollard, Jake Jacobson, and Laura Canevari for their invaluable discussion and comments on the manuscript. In so short an essay, it is not possible to describe all the fascinating activity in this field, and so I also apologize to those whose work is not cited here.

EF-Hand Proteins and Calcium Sensing: The Neuronal Calcium Sensors

Jamie L. Weiss and Robert D. Burgoyne

*The Physiological Laboratory,
The University of Liverpool,
Liverpool, United Kingdom*

Introduction

EF-hand calcium (Ca^{2+})-binding proteins play many important roles in Ca^{2+} -homeostasis and Ca^{2+} -signaling mechanisms. The EF-hand containing protein calmodulin has been most extensively studied but the EF-hand motif is the most prevalent and widely distributed protein domain in Ca^{2+} signaling. The neuronal Ca^{2+} -sensor (NCS) proteins are a closely-related family of Ca^{2+} -binding proteins whose physiological functions have begun to emerge in recent years.

EF-hand Ca^{2+} -binding proteins fall into two main categories: Ca^{2+} buffers, which act as Ca^{2+} chelators but do not undergo a conformational change, and Ca^{2+} sensors, which upon Ca^{2+} binding undergo a conformational change and transfer the signal to other proteins. This conformational change can alter interactions of EF-hand Ca^{2+} sensing proteins with target proteins or cause a conformation change in proteins already bound to the sensor concurrent with the Ca^{2+} concentration shift. Members of the neuronal Ca^{2+} -sensor (NCS) family (Table I) include proteins expressed only in the retina (e.g. recoverin) and others expressed mainly in neuronal and neuroendocrine cells such as the neurocalcins (*visinin-like proteins* [VILIPs]) and NCS-1 (frequenin). The NCS proteins are ~22 kDa, high-affinity Ca^{2+} -binding proteins, with ~30–70% protein sequence identity to each another, and most members of the family are N-terminally myristoylated. A Ca^{2+} -myristoyl switch mechanism has been proposed

for some members of the family in which the proteins bind membranes in a Ca^{2+} -dependent manner via exposure of the myristoyl-group upon Ca^{2+} binding (Table I). The myristoyl group may also be important for protein-protein interactions. Two recent reviews [1,2] cover the NCS proteins in detail, and this chapter will emphasize recent developments in the field.

Class A. Neuronal Calcium Sensor 1 (Frequenin)

Drosophila mutants overexpressing frequenin were found to have frequency-dependent facilitation of evoked neurotransmission at the neuromuscular junction [3], and overexpression of NCS-1 results in enhancement of evoked exocytosis in neuroendocrine cells via an indirect effect of NCS-1 [4]. It is now known that NCS-1 regulates both voltage-gated (VG) Ca^{2+} channels and potassium (K^+) channels. NCS-1 functions in a G-protein-coupled receptor-mediated pathway of VG Ca^{2+} channel inhibition in chromaffin cells that relies on the activity of a Src-like tyrosine kinase [5,6]. NCS-1 has also been shown to increase the current amplitude for Kv4 (A-type) K^+ channels [7]. In a pathway involving glial-derived neurotrophic factor (GDNF), NCS-1 has been implicated in the facilitation of N-type channels in neuromuscular synapses [8]. NCS-1 knockouts and overexpression mutants in *C. elegans* demonstrate that NCS-1 has a role in learning and memory [9].

Table I General Properties of the NCS Family of Proteins

Protein name	Myristoyl switch mechanism	Structure determined	Ca ²⁺ binding affinity	Tissue/cell localization	Subcellular localization	Pathways/ molecular targets	Possible physiological function(s)
NCS-1	No	Yes	0.3 μM	Brain, adrenal gland, COS cells, mouse inner ear, insulin secreting cells, heart, etc.	Golgi, synapses, dendrites, synaptic-like vesicles	PI4 kinase, calcineurin, ion channels	Control of neurotransmitter release, Ca ²⁺ and K ⁺ channel regulation, learning and memory
Recoverin	Yes	Yes	2.1 μM	Photoreceptors	Photoreceptor membranes	Rhodopsin kinase	Retinal phototransduction
VILIP 1	Yes	No	1 μM	Brain-highest expression in cerebellar granule cells, and hippocampus, retina	Unknown	Actin, tubulin, ds RNA, cGMP	Cytoskeletal regulation, cGMP pathways
VILIP 2	Yes	No	Unknown	Brain-except cerebellum	Unknown	Unknown	Unknown
VILIP 3	Yes	No	Unknown	Highest expression in cerebellar purkinje cells	Unknown	Unknown	Unknown
Neurocalcin δ	Yes	Yes	0.6 μM	Highest expression in cerebellar purkinje cells	Plasma membrane, Golgi complex	Actin, tubulins and clathrin	Cytoskeletal regulation, protein trafficking
Hippocalcin	Yes	No	5 μM	Highest expression in hippocampus	Hippocampal pyramidal neurons-soma and dendrites	PLD, NAIP, Cdc42, MLK2	Apoptosis, MAP kinase pathway
GCAP 1	Yes	No	0.26 μM	Photoreceptors	Photoreceptor membranes	Guanylate cyclase	Retinal phototransduction
GCAP 2	Reversed	Yes	0.25 μM	Photoreceptors	Photoreceptor membranes	Guanylate cyclase	Retinal phototransduction
GCAP 3	Yes	No	0.25 μM	Photoreceptors	Photoreceptor membranes	Guanylate cyclase	Retinal phototransduction
KChIP 1	Unknown	No	Unknown	Brain	Plasma membrane	K ⁺ channels	K ⁺ channel regulation
KChIP 2	No myr. group	No	Unknown	Brain, heart	Plasma membrane	K ⁺ channels	K ⁺ channel regulation
KChIP 3	No myr. group	No	14 μM	Brain, testes	Plasma membrane	K ⁺ channels, DNA, Presenilins	K ⁺ channel regulation, transcriptional repressor for pain modulation
KChIP 4	No myr. group	No	Unknown	Brain	Membranes	K ⁺ channels	K ⁺ channel regulation, KchIP4b abolishes fast inactivation of Kv4 A-type currents.

Further evidence for a role of NCS-1 in learning and memory comes from the observation of an increase in brain NCS-1-mRNA levels following induction of long-term potentiation [10]. It has been demonstrated both biochemically and in cells that myristoylated NCS-1 binds membranes in a Ca^{2+} -independent manner [11,12]. It has also been reported that yeast frequenin does not need Ca^{2+} for interaction with its major target PI-4-kinase [13]. This suggests that NCS-1 does not rely on the Ca^{2+} -myristoyl switch mechanism for binding interactions. NCS-1 has multiple binding partners in adrenal chromaffin cell fractions; some of these interactions are Ca^{2+} -independent and others are Ca^{2+} -dependent [11].

Class B. Neurocalcins (VILIPs) and Hippocalcin

Neurocalcins (VILIPs) are expressed in certain classes of neurons (Table I). Both VILIPs and hippocalcin have been shown to have a classic Ca^{2+} -myristoyl switch mechanism in cells [12]. VILIP1 and neurocalcin δ have been shown to bind actin, tubulins, and, in the case of neurocalcin δ , clathrin as well [14,15]. These interactions appear to link neurocalcins to cytoskeletal regulation and possibly vesicle trafficking mechanisms. VILIP1 has also been shown to interact with double stranded RNA in a Ca^{2+} -dependent manner [16] and also increases cGMP levels in PC12 cells and cerebellar granule neurons [17]. VILIP1 expression promoted cell death, tau phosphorylation, and appeared to have a role in Ca^{2+} -mediated cytotoxicity in PC12 cells [18]. Hippocalcin is predominantly expressed in mammalian hippocampus and has been implicated in interactions with neuronal apoptosis inhibitory protein (NAIP), phospholipase D (PLD)/Cdc42, and mixed lineage kinase 2 (MLK2) [19–21]. These studies link hippocalcin to endocytosis, MAP kinase, and apoptosis pathways.

Class C. Recoverins

Recoverins are the best-studied members of the NCS protein family. The structure of recoverin has been resolved both in the Ca^{2+} -free and Ca^{2+} -bound states. Analysis of its biochemical properties and structure has revealed that recoverin uses the Ca^{2+} -myristoyl switch mechanism. Recoverins are expressed in rod photoreceptors and have an important role in the Ca^{2+} -signaling of retinal phototransduction [22]. Recoverin regulates cGMP levels indirectly via a Ca^{2+} -dependent interaction with rhodopsin kinase inhibiting the kinase in the dark when Ca^{2+} levels are high [22].

Class D. Guanylate Cyclase Activating Proteins

Like recoverins, guanylate cyclase activating proteins (GCAPs) are Ca^{2+} sensors expressed in photoreceptors that play an important role in the signal transduction pathways of

the retina by regulating guanylate cyclase (GC) activity. In the retina Ca^{2+} levels are low in the light. In such low Ca^{2+} conditions the GCAPs activate GC. This allows cGMP levels to be directly increased to allow activation of the cyclic-nucleotide gated channels. GCAP2 and GCAP3 directly activate GC in their Ca^{2+} -free state and at increased levels inhibit GC. GCAP2 is bound to membranes at low Ca^{2+} levels and as Ca^{2+} is elevated it dissociates from membranes [22]. EF-hand 1 in all the NCS family members is unable to bind Ca^{2+} . Recently it was determined that GCAP2 interacts with GC via this EF1 domain [22]. This may be an evolutionarily conserved mechanism in the NCS proteins, whereby the ability of EF1 to bind Ca^{2+} was lost in order to gain a protein interaction domain.

Class E. K^+ Channel Interacting Proteins

K^+ channel interacting proteins (KChIPs) [24,25] regulate A-type K^+ channel currents. KChIP1 is the only member of the KChIP subfamily that is myristoylated. Modulation of Kv4.2 K^+ channels in CHO cells and Kv4.2 and Kv4.3 K^+ channels in *Xenopus* oocytes via arachidonic acid has been shown to be dependent on KChIP1 [26]. KChIP2 also regulates Kv4.2 and Kv4.3 K^+ channels, and KChIP2 knockout mice are highly susceptible to ventricular tachycardia due to the loss of a transient outward K^+ channel current in the heart [27]. KChIP3 is the same protein as calnenilin, which interacts with presenilin-1 and 2. Presenilin-1 mutations are the most common cause of familial Alzheimer's disease, and calnenilin interacts with the endogenous 20 kDa C-terminal fragment of presenilin 2 that is a product of regulated proteolytic cleavage [28]. KChIP3/calnenilin is also the same protein as downstream regulatory element antagonist modulator (DREAM), which is a Ca^{2+} -regulated transcriptional repressor involved in pain modulation [29,30]. An alternative splice variant of KChIP4 (KChIP4a) encodes a protein with a novel N-terminus called the KIS (K-channel inactivation suppressor) domain. The KIS domain appears to be important for the abolishment of fast inactivation of Kv4.3 channels [31].

Future Perspectives for the NCS Protein Family

The NCS proteins are already known to have multiple binding protein partners. More studies are needed to characterize these interactions so that we can place NCS proteins in known pathways. Further *in vivo* knockout and over-expression studies will reveal more about the roles of the NCS proteins and clarify their range of physiological functions in the regulation of neuronal activity.

Calmodulin-Mediated Signaling

Anthony R. Means

*Department of Pharmacology and Cancer Biology,
Duke University Medical Center,
Durham, North Carolina*

Calmodulin (CaM) is a ubiquitous, essential protein that serves as the primary sensor of changes in intracellular Ca^{2+} in all eukaryotic cells [1]. In this way CaM is the Ca^{2+} receptor that orchestrates Ca^{2+} -initiated signal transduction cascades leading to changes in cell function. Some of these cascades are initiated by Ca^{2+} and proceed in a linear fashion that culminate in regulation of the vital cellular response. However, Ca^{2+} /CaM can also influence physiologically important processes indirectly via cross-talk with pathways initiated by other second messengers [2]. These pathways include those regulated by cyclic nucleotides, nitric oxide, and MAP kinases (Fig. 1). Thus, it is with good reason that Ca^{2+} is recognized as the most versatile of the second messengers and CaM as its pivotal receptor.

The exquisite design of CaM allows it to assume an almost limitless number of conformations, each one dictated by the amino acid sequence of the CaM-binding domain of the individual target proteins. Illustrative of the versatility of CaM, over 50 CaM-binding proteins have been described to date [1]. Whereas CaM is generally considered to be a Ca^{2+} -binding protein and binds to many of its targets only in the presence of Ca^{2+} , this is not the only mode of action of CaM in cells. Some physiologically relevant interacting proteins also bind CaM in a Ca^{2+} -independent way. For example, CaM is an integral subunit of phosphorylase kinase (PK). Whereas the subunit association of PK is Ca^{2+} -independent, CaM still serves to sense changes in the concentration of Ca^{2+} as Ca^{2+} can regulate the activity of the enzyme. Alternatively, CaM can bind to a partner in the absence of Ca^{2+} but be released from its binding partner upon Ca^{2+} -binding. CaM-binding proteins of this kind include the unconventional myosins, neurogranin and neuromodulin. However, this review will

focus on the central role of CaM as a transducer of Ca^{2+} signals to Ca^{2+} /CaM-dependent effector proteins. In addition, because of space limitations, references are primarily restricted to other reviews that focus on different aspects of CaM structure and function.

Calmodulin is a 148 amino acid protein in which globular domains, each containing a pair of EF-hand Ca^{2+} -binding motifs, are separated by an 8-turn α -helix. Ca^{2+} binding causes a conformational change in CaM that exposes hydrophobic residues and generates a considerable amount of biochemical energy, which is then used to modify the activity of its targets. It is this remarkable ability to serve as a selective allosteric regulator of so many enzymes that allows CaM to react to both global and transient changes in Ca^{2+} concentration within the dynamic and physiologically relevant range experienced by a cell. A rise in Ca^{2+} markedly increases the affinity of CaM for its target proteins and promotes conformational changes in both CaM and the effector [1].

Although generally considered a soluble protein, almost 95% of the CaM in mammalian cells, such as those in smooth muscle, is immobile [3]. However, in neurons and pancreatic acinar cells CaM has been reported to specifically translocate from plasma membrane to nucleus in response to brief stimuli that result in a localized rise in Ca^{2+} [4,5]. Thus, although CaM may relocate in response to Ca^{2+} signals, it seems to primarily move around in cells by diffusion. Calmodulin is found in all subcellular compartments where CaM-binding proteins characteristic to a given organelle serve to tether the Ca^{2+} receptor in a manner appropriate to facilitate Ca^{2+} /CaM-dependent function [6].

In the absence of Ca^{2+} /CaM, the target enzymes for this protein are inactive. In most cases this is due to intracellular

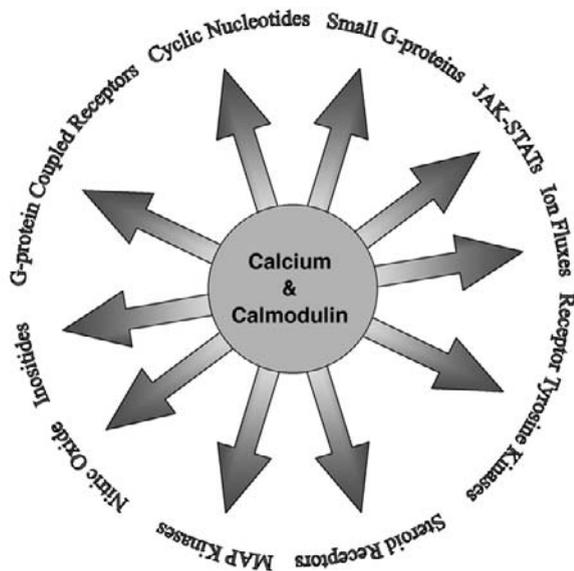

Figure 1 Signaling pathways influenced by $\text{Ca}^{2+}/\text{CaM}$.

autoinhibition in which a portion of the protein is folded in a manner that prevents substrate access to its active site [7]. $\text{Ca}^{2+}/\text{CaM}$ -binding to a region contiguous to the inhibitory segment relieves autoinhibition and thus promotes enzyme activity. Many of the autoinhibitory segments possess sequence similarity to the protein substrate, which led to the idea that autoinhibition was of the “pseudosubstrate” type. This concept has also been confirmed by both biochemical and structural approaches [7]. $\text{Ca}^{2+}/\text{CaM}$ binding to a target enzyme can have one of three consequences. First, binding can activate the enzyme and inactivation follows the termination of the Ca^{2+} signal [1]. Enzymes that behave in this way include myosin light chain kinase, protein phosphatase 2B (calcineurin), CaMKI, and phosphodiesterase. Second, $\text{Ca}^{2+}/\text{CaM}$ can activate the enzyme by promoting intersubunit phosphorylation that results in generation of constitutive activity. CaMKII is the prototypic example of this mode of regulation. As a CaMKII holoenzyme is composed of 10 to 12 subunits, this protein kinase can sense and record incremental increases in the intracellular concentration of Ca^{2+} [8]. Third, $\text{Ca}^{2+}/\text{CaM}$ binding can enable phosphorylation of the target enzyme by an upstream enzyme in a signaling cascade of reactions. CaMKI and CaMKIV are examples of enzymes subject to this type of control. In response to $\text{Ca}^{2+}/\text{CaM}$ binding these enzymes are phosphorylated by a CaMKK in a manner similar to the cascade of reactions that characterize MAPK pathways. This analogy has led to the concept of a CaMK cascade [9]. Like CaMKII, CaMKIV activity is maintained even after termination of the Ca^{2+} signal. The second and third control mechanisms provide means of continuing a Ca^{2+} -initiated reaction even after the Ca^{2+} signal has dissipated. Since in these cases the kinases are inactivated by dephosphorylation, kinase activity can also be terminated in the presence of a high level of intracellular Ca^{2+} , thus uncoupling the maintenance and inactivation of the response from the changes in Ca^{2+} required for its initiation.

One biological system that illustrates the multifaceted modes by which CaM can transduce a Ca^{2+} signal is the T lymphocyte. Stimulation of this cell through the T cell receptor results in a rapid and robust increase in intracellular Ca^{2+} that peaks about 2 min after receptor occupancy. The rise in Ca^{2+} is required for activation of two CaM-dependent pathways involved in expression of the interleukin 2 gene (IL-2) that encodes a mitogen necessary to expand this cohort of T cells. On the one hand, $\text{Ca}^{2+}/\text{CaM}$ activates calcineurin in the cytoplasm. Calcineurin dephosphorylates a subunit of the NF-AT transcription factor, which allows the NF-AT/calcineurin complex to translocate into the nucleus and bind to the IL-2 gene promoter [10]. On the other hand, $\text{Ca}^{2+}/\text{CaM}$ also activates CaMKIV, which resides in the nucleus and is involved in the phosphorylation of CREB [11], which is required for activation of immediate early genes such as those of the Fos and Jun families of transcription factors. Fos and Jun heterodimerize to form the AP1 transcription factor, which collaborates with NF-AT to activate the IL-2 gene promoter [10]. By 5 min after T cell receptor activation, the Ca^{2+} levels have largely decreased but remain elevated in the nucleus at a level about twice that present in resting T cells. This higher sustained Ca^{2+} concentration, which has to be maintained for approximately 2 hours, is required to maintain the activity of calcineurin and keep the NF-AT/calcineurin complexes in the nucleus [10]. However, because once fully activated CaMKIV becomes independent of $\text{Ca}^{2+}/\text{CaM}$, this enzyme is inactivated by dephosphorylation, which is catalyzed by PP2A that is in a complex with CaMKIV [11]. Hence, although a very similar $\text{Ca}^{2+}/\text{CaM}$ -dependent mechanism is used to activate calcineurin and CaMKIV, the characteristics distinct to each enzyme permit maintenance of calcineurin activity and thus continued IL-2 gene transcription but inactivation of CaMKIV and the immediate early genes it regulates in the face of a sustained elevation of intranuclear Ca^{2+} .

Calcium is mandatory for cell proliferation and plays an important role in all cell cycle transitions [12]. In model organisms such as fungi, nematodes, and flies, the single CaM gene is essential for cell growth. It is interesting that the CaM effector proteins shown to be essential in *S. cerevisiae* are unique, as all bind CaM in the absence of Ca^{2+} . However, in the filamentous fungus *Aspergillus nidulans*, several essential CaM targets are Ca^{2+} -dependent and seem to be very similar to those required in mammalian cells. Thus, for the entry of quiescent cells into the cell cycle, both calcineurin and a CaMK are required and function in mid-G1 upstream of the activation of the cyclin/cdk complex that is a prelude to entry into DNA synthesis. In mammalian cells calcineurin is required to maintain stability of cyclin D, whereas the CaMK is required for activation of the cyclin D/cdk4 complex in the nucleus. Progression of *A. nidulans* and mammalian cells from G2 into mitosis requires a second CaMK. Again the CaMK is required prior to the activation of cyclin B/cdc2 and at least one target protein has been suggested to be the cdc25 phosphatase that activates the cdc2 complex. Finally, $\text{Ca}^{2+}/\text{CaM}$ is important for mitosis. Presently available

data suggest that $\text{Ca}^{2+}/\text{CaM}$ is likely to be required for breakdown of the nuclear envelope, the transition from metaphase to anaphase and for cytokinesis. However, the $\text{Ca}^{2+}/\text{CaM}$ -dependent target proteins appear to be different at all three points in mitotic progression, although the details are unclear and under intense investigation [12].

Based on studies in a variety of cell types except *S. cerevisiae*, it seems clear that all roles for CaM in the cell cycle are heralded by transient changes in the intracellular Ca^{2+} concentration, which emphasizes the ubiquitous role of CaM as a Ca^{2+} receptor [13,14]. In addition, at least six different $\text{Ca}^{2+}/\text{CaM}$ -dependent effector proteins have been shown to be essential for cell proliferation. These observations illustrate the pleiotypic ability of CaM to relay Ca^{2+} signals to very different effectors. Thus, Ca^{2+} , CaM, and CaM-dependent target proteins are essential components of signaling cascades that monitor progression through the cell cycle.

The Family of S100 Cell Signaling Proteins

Claus W. Heizmann, Beat W. Schäfer and Günter Fritz

*Department of Pediatrics, Division of Clinical Chemistry and Biochemistry,
University of Zürich, Zürich, Switzerland*

Introduction

S100 proteins attracted great interest in recent years due to their association with various human pathologies and their use in the diagnosis of these diseases. Twenty members have been discovered so far, and altogether S100 proteins represent the largest subgroup within the EF-hand Ca^{2+} -protein family. S100 proteins show a very divergent pattern of cell- and tissue-specific expression and of affinities for Ca^{2+} , Zn^{2+} , and Cu^{2+} , consistent with their pleiotropic intra- and extracellular functions. Several genetically engineered animal models have now been generated to study the roles of S100 proteins under normal and pathological conditions.

Many cellular events are regulated by oscillations of intracellular Ca^{2+} concentrations wherein the signal specificity is obtained through differences in location, duration, and frequency [1]. Participants in most Ca^{2+} -signaling pathways are members of the large family of Ca^{2+} -binding proteins characterized by the EF-hand structural motif [2]. Certain members, notably calbindin D28k and parvalbumin, serve as cytosolic Ca^{2+} buffers/shuttles whereas others such as calmodulin, troponin C, and the S100 proteins are Ca^{2+} -dependent regulatory proteins.

Unlike the ubiquitous calmodulin, most of the 20 members of the S100 protein family show cell- and tissue-specific expression, which is often deregulated in a number of human diseases including cancer, neurodegenerative disorders, inflammations and cardiomyopathy [3]. S100 proteins have a size of 10 to 12 kDa and form homo- and heterodimers. The monomer is composed of two helix-loop-helix (EF-hand) motifs connected by a central hinge region. The C-terminal EF-hand contains the canonical Ca^{2+} -binding loop, common

to all EF-hand proteins. The N-terminal EF-hand consists of 14 amino acids and is characteristic for S100 proteins. Upon Ca^{2+} -binding S100 proteins undergo a conformational change required for target recognition and binding [32]. Generally, the dimeric S100 proteins bind four Ca^{2+} per dimer ($K_d=20\text{--}500\ \mu\text{M}$). Besides Ca^{2+} a number of S100 proteins bind Zn^{2+} with a wide range of affinities ($K_d=0.1\text{--}2000\ \mu\text{M}$). For S100B and S100A5 even Cu^{2+} -binding was reported ($K_d=0.4\text{--}5\ \mu\text{M}$). This suggests that S100 protein target interactions and cellular functions may also be triggered by Zn^{2+} and Cu^{2+} .

Another unique feature is that individual members of S100 proteins are localized within specific cellular compartments from which some of them are able to relocate upon Ca^{2+} or Zn^{2+} activation [4], transducing the signal in a temporal and spatial manner by interacting with different targets specific for each S100 protein. Furthermore, some S100 proteins are even secreted from cells acting in a cytokine-like manner. The individual members seem to utilize distinct pathways (ER-Golgi route, tubulin- or actin-dependent) for their translocation/secretion into the extracellular space [5]. S100B and S100A12 specifically bind to the surface receptor RAGE (receptor for advanced glycation endproduct)—a multiligand member of the immunoglobulin superfamily [6]. The extracellular levels of S100B thereby play a crucial role in that nanomolar concentrations of S100B have trophic effects on cells whereas pathological levels (as found in Alzheimer's patients) induce apoptosis [7].

Unique to the S100 protein family is that most S100 genes are located in a gene cluster on human chromosome 1q21. Within this chromosomal region, several rearrangements and deletions have been reported during tumor development,

probably linked to the deregulated S100 gene expression observed in various tumor types. Genetically manipulated mice (knockout and transgenics for S100 proteins and RAGE) and microarray technologies are now becoming available that will further advance our understanding of the diverse cell signaling activities of S100 proteins.

Protein Structures and Metal-Dependent Interactions with Target Proteins

The amount of detailed structural data for S100 proteins is growing rapidly. With the exception of calbindin D_{9K} all structures of S100 proteins revealed a tight homodimer whereby the dimerization plane is composed of strictly conserved hydrophobic residues, which are missing in the case of calbindin D_{9K} [2,3]. Each S100 monomer consists of two helix-loop-helix Ca^{2+} -binding domains termed EF-hands (Fig. 1). The N-terminal domain consisting of helices H_I and H_{II} connected by loop L_1 is different from the canonical EF-hand motif and is therefore called S100-specific or pseudo EF-hand, whereas the C-terminal domain (H_{III} - L_3 - H_{IV}) contains the canonical EF-hand motif. Upon Ca^{2+} -binding almost all S100 proteins undergo a conformational change exposing a previously covered hydrophobic patch. The Ca^{2+} -dependent conformational change of S100 proteins was characterized by NMR and high-resolution X-ray studies. This conformational change of Ca^{2+} -bound S100 proteins is distinct from Ca^{2+} -dependent changes observed in other EF-hand proteins such as calmodulin or troponin C. In the C-terminal EF-hand (canonical EF-hand) there is a large change in the position of helix H_{III} upon Ca^{2+} -binding. The interhelical angle between helices H_{III} and H_{IV} changes by 90° in S100B compared to the Ca^{2+} -free structure, opening the structure and exposing the residues required for

target recognition and binding. A similar change in conformation is observed for Ca^{2+} -bound S100A6 [30,31]. The crystal structures of Ca^{2+} -bound S100A7 [8], S100A8 [9], S100A11 [10], and S100A12 [11] confirmed the observations made for Ca^{2+} -bound S100B. All four structures revealed an open conformation suitable for target binding. A further interesting phenomenon was observed for S100A10, which is not able to bind Ca^{2+} . The crystal structure of S100A10 showed that the Ca^{2+} -free protein is already in a Ca^{2+} -bound like open conformation that enables S100A10 to interact Ca^{2+} -independently with its target molecule [12]. Recently a hexameric form of S100A12 was described [11]. Three S100A12 dimers assemble as a hexamer that is stabilized by six additional Ca^{2+} ions bound to the interface of two adjacent dimers.

S100A3 is a unique member of the S100 protein family; it has a low affinity for Ca^{2+} but a high affinity for Zn^{2+} ions. The crystal structure of S100A3 (Fig. 1A) [13] allowed the prediction of one putative Zn^{2+} -binding site (distinct from the EF-hand) in the C-terminus of each monomer, thus disturbing the hydrophobic interface of the homodimer.

Target Binding

So far three different S100-target complexes have been characterized: S100B complexed with a peptide of the regulatory domain of p53 [14], S100A10 with a peptide of annexin II, and S100A11 complexed with a peptide of annexin I [10]. All three peptides were located in a cavity formed by helices H_{III} and H_{IV} in the open conformation of the C-terminal canonical EF-hand. The binding of the target peptides with the protein matrix is accomplished by hydrophobic and ionic interactions. Furthermore the stoichiometry of the complex is two target peptides per S100 homodimer. However, the binding

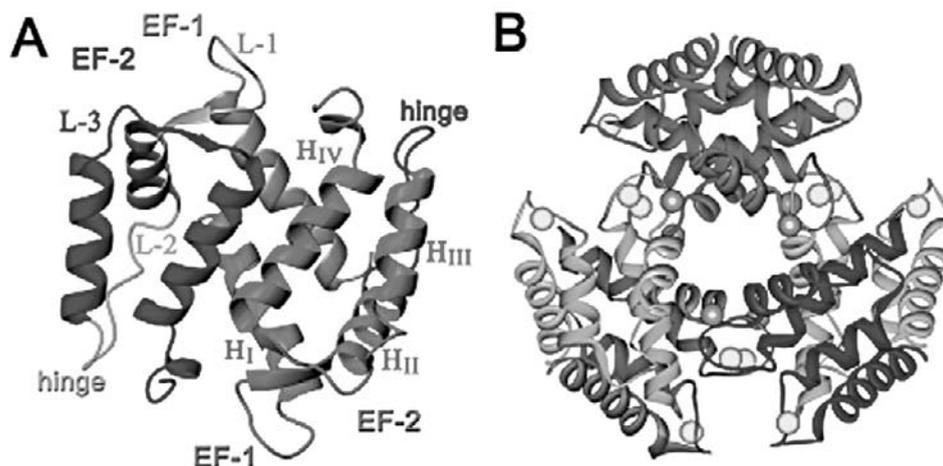

Figure 1 Structure of S100 proteins. (A) Dimeric structure of S100A3. The monomers are depicted in red and blue, respectively. Each monomer consists of two EF-hands connected by a hinge region. (B) Hexameric structure of S100A12 (pdb code 1GQM [11]). Three S100A12 dimers form a hexamer. The Ca^{2+} ions bound to the EF-hands are shown as bright yellow spheres. At the hexamer-forming interface six additional Ca^{2+} ions are located, which are shown as dark yellow spheres. A color representation of this figure is available on the CD version of the *Handbook of Cell Signaling*.

mode of the annexin peptides to S100A10 and S100A11 is strikingly different from that of the p53 peptide to S100B. In contrast to the p53 peptide the annexin peptides interact with both monomers whereby the required residues are located on the helices H_{III} and H_{IV} of one monomer and on helix H_I of the second monomer.

Based on these observations one can suppose that there are further modes of target binding to other S100 proteins. For example, it was proposed [11] that the hexameric form of S100 A12 (Fig. 1B) might interact with three extracellular domains of the RAGE receptor, bringing them together into large trimeric assemblies.

Zn²⁺ Binding

Although a number of S100 proteins bind Zn²⁺ with high affinity, only the structure of Zn²⁺ bound-S100A7 is known so far [8]. The Zn²⁺ binding sites in other S100 proteins, such as S100B, S100A2, S100A3, S100A4, or S100A6, are only preliminarily characterized [15]. The Zn²⁺-binding residues were identified by spectroscopic and mutational analysis mainly as histidine and cysteine residues; however, a common Zn²⁺ binding motif has not yet been recognized in the sequence of these proteins.

Genomic Organization, Chromosomal Localization, and Nomenclature

The structural organization of S100 genes is highly conserved both within an organism and in different species [3]. A typical S100 gene consists of three exons whereby the

first exon carries exclusively 5' untranslated sequences. The second exon contains the ATG and codes for the N-terminal EF-hand, and the third exon encodes the carboxy-terminal canonical EF-hand. Only a few genes, such as S100A4, S100A5, and the newly identified S100A14 [16], are composed of four exons. In these genes, the first two exons can either be alternatively spliced (S100A4) or noncoding (S100A5), leaving the two exon-splitting of the coding region intact. It is interesting that for both S100A11 and S100A14 this region encoding the corresponding proteins is split into three exons. Whether this finding reflects a functional or evolutionarily close relationship between these two members of the S100 family remains to be seen.

Presently 14 bona fide S100 genes are found in a gene cluster on human chromosome 1q21 (Fig. 2), a finding that led to the introduction of the now widely accepted S100 nomenclature (Table I). Four additional S100 genes are found on other human chromosomes, including the newly discovered S100Z [17] likely to be localized on chromosome 5 (the 3-terminal sequence of the S100Z cDNA is part of a human BAC clone on region 5q12-q13). Hence, one can recognize at least four different subgroups of S100 genes located closely together (S100A1–S100A13–S100A14; S100A2 to S100A6; S100A8–S100A9–S100A12; S100A10–S100A11). This finding raises the question of whether each gene is regulated by its own promoter elements or by as yet uncharacterized locus control elements, as has been suggested for the epidermal differentiation genes. The evidence available today would rather suggest an individual regulatory mechanism for most S100 genes. It is striking, however, that for some of these subgroups of genes, similarities in the function of their encoded proteins have been recognized. Furthermore,

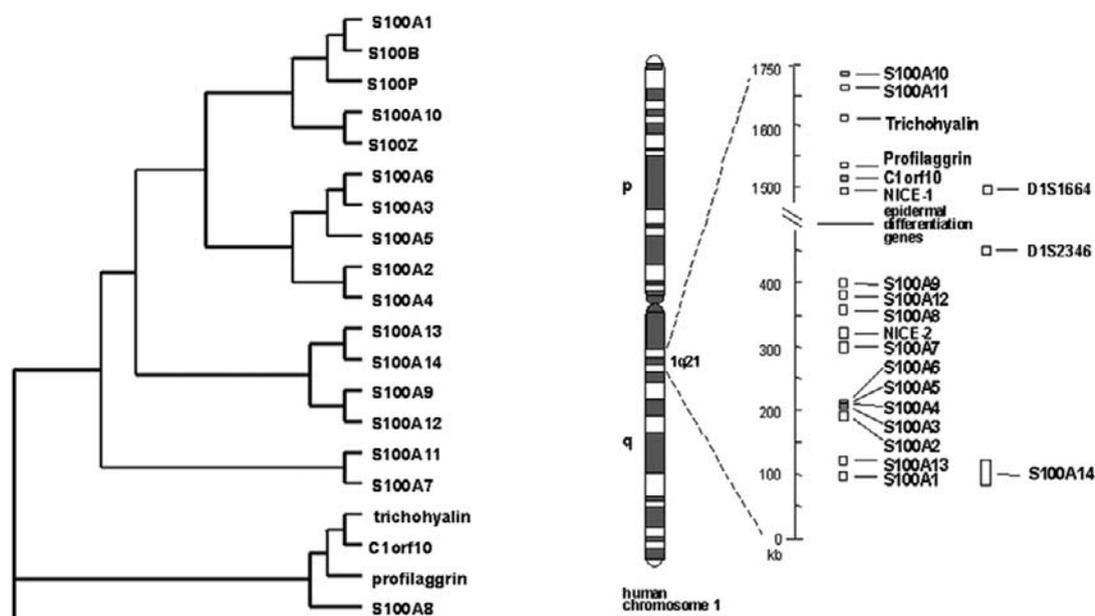

Figure 2 Phylogenetic tree of human S100 proteins in comparison with physical map of the S100 gene cluster on human chromosome 1q21. In the phylogenetic tree each node represents a putative gene duplication. The left-most nodes indicate the earliest gene duplications. Genes lying in the cluster region are indicated as well as two commonly used genomic markers (D1S1664 and D1S2346); p and q represent the long and the short arm of the chromosome, respectively.

Table I Nomenclature for S100 Genes Clustered on Human Chromosome 1q21

New name	Previous symbols/synonyms
S100A1	S100 α
S100A2	S100L, CaN19
S100A3	S100E
S100A4	CAPL, p9ka, pEL98, mts 1, metastasin, calvasculin, murine placental calcium protein, Fsp1, 18A2
S100A5	S100D
S100A6	Calcyclin, CACY, 2A9, PRA, CaBP, 5B10
S100A7	Psoriasis, PSOR1, BDA11, CAAF2
S100A8	Calgranulin A, CAGA, CFAg, MRP8, p8, MAC387, 60B8Ag, L1Ag, CP-10, MIF, NIF, calprotectin
S100A9	Calgranulin B, CAGB, CFAg, MRP-14, p14, MAC 387, 60B8Ag, L1Ag, MIF, NIF, (S100A8/A9 dimer)
S100A10	Calpactin light chain, CAL12, CLP11, p11, p10, 42C
S100A11	Calgizzarin, S100C
S100A12	Calgranulin C, p6, CAAF1, CGRP, corned-associated antigen
S100A13	CAAF2
S100A14	—

Nomenclature for S100 Genes Located on Different Chromosomes

Name	Previous symbols/synonyms	Chromosomal location
Calbindin-D9K	9K CALB3, CaBP9k, I CaBP, Cholecalciferin	Xp22
S100B	S100 β , NEF	21q22
S100P	S100P	4p16
S100Z	—	5

a number of chromosomal abnormalities such as deletions, rearrangements or translocations in this region have been associated with neoplasias, suggesting that the expression of S100 genes might be altered in human cancer. It is also interesting that the clustered organization of the human genes seems to be evolutionarily conserved, at least in the mouse. In other species, S100 genes are less well characterized.

Comparison of a phylogenetic tree constructed on the basis of sequence alignments between the different human S100 proteins revealed a clustering of S100 proteins, which is mirrored in the physical map of the S100 genes on chromosome 1q21 (Fig. 2). For example, S100A2 through to S100A6 cluster tightly together both on the phylogenetic tree and on the chromosome. The small distances on the chromosome and the phylogenetic tree indicate that these S100 proteins most likely originate from late gene duplication events. Similarly, clusters are seen for S100A10 and S100A11, as well as for S100A13 and S100A14. Furthermore, there are three proteins encoded in 1q21 that carry in the N-terminus an S100-like domain, namely Trichohyalin, Profilaggrin, and C1orf10.

Translocation, Secretion, and Biological Functions

S100 proteins are generally involved in a large number of cellular activities such as signal transduction, cell differentiation, regulation of cell motility, transcription, and cell cycle progression (Table II) [3]. S100 proteins are thought to modulate the activity of target proteins in a Ca²⁺- (and possibly also in a Zn²⁺- and Cu²⁺-) dependent manner. During the last decade, a large number of such possible interactions have been described involving enzymes, cytoskeletal elements, and transcription factors.

Apart from these intracellular functions, some S100 proteins, such as S100A8/A9, S100B, S100A4, and probably others, are secreted from cells and exhibit cytokine-like extracellular functions [3]. These include chemotactic activities related to inflammation (S100A8; S100A9 and S100A12), neurotrophic activities (S100B), and a recently described angiogenic affect (S100A4). In all cases, the mechanisms of secretion as well as the nature of high affinity surface receptors remain largely unknown. One candidate receptor to mediate at least some of the described extracellular functions is RAGE, which was shown to be activated upon binding of S100A12 and S100B [6]. It is currently not known whether RAGE is a universal S100 receptor.

Generation of some animal models has been initiated to study the physiological impact of S100 proteins [3]. Ectopic overexpression in the mouse has been described for S100B and S100A4. In the case of S100B, enhanced expression in the brain led to hyperactivity associated with an impairment of hippocampal function. Brains from S100B transgenic mice show a higher density of dendrites in the hippocampus postnatally compared to controls and a loss of dendrites by one year of age. In contrast to this mild phenotype, expression of S100A4 in oncogene-bearing transgenic mice is capable of inducing metastasis of mammary tumors, suggesting that S100A4 has an important role in the acquisition of the metastatic phenotype during tumor progression. While stimulation of angiogenesis might play a role, the exact mechanisms of this function are still under investigation.

Inactivation through homologous recombination in mouse embryonic stem cells has been achieved for S100B and S100A8. While inactivation of S100B has no obvious consequences for life, S100A8 null mice die via early resorption of the mouse embryo, a result that suggests a role for this protein in prevention of maternal rejection of the implanting embryo.

Since S100 proteins can form homo- and also heterodimers and usually more than one S100 protein is found to be expressed in a given cell type, functional redundancy or compensatory mechanisms might explain the lack of phenotype observed in some animal models. Clearly, more animal models inactivating single S100 proteins as well as combinations thereof are needed before their physiological roles can be clarified.

Table II S100 Proteins: Functions and Association with Human Diseases

Protein	Postulated functions	Disease association
S100A1	Regulation of cell motility, muscle contraction, phosphorylation, Ca ²⁺ release channel, transcription	Cardiomyopathies
S100A2	Tumor suppression, nuclear functions, chemotaxis	Cancer, tumor suppression
S100A3	Hair shaft formation, tumor suppression, secretion, and extracellular functions	Hair damage, cancer
S100A4	Regulation of cell motility, secretion and extracellular functions, angiogenesis	Cancer (metastasis)
S100A5	Ca ²⁺ -, Zn ²⁺ -, and Cu ²⁺ -binding protein in the CNS and other tissues; unknown function	Not known
S100A6	Regulation of insulin release, prolactin secretion, Ca ²⁺ homeostasis, tumor progression	Amyotrophic lateral sclerosis
S100A7	S100A7-fatty acid binding protein complex regulates differentiation of keratinocytes	Psoriasis, cancer
S100A8/A9	Chemotactic activities, adhesion of neutrophils, myeloid cell differentiation, apoptosis, fatty acid metabolism	Inflammation, wound healing, cystic fibrosis
S100A10	Inhibition of phospholipase A2, neurotransmitter release, in connection with annexin II regulates membrane traffic, ion currents	Inflammation
S100A11	Organization of early endosomes inhibition of annexin I function, regulation of phosphorylation, physiological role in keratinocyte cornified envelope	Skin diseases, ocular melanoma
S100A12	Host-parasite interaction, differentiation of squamous epithelial cells and extracellular functions	Mooren's ulcer (autoimmune disease), inflammation
S100A13	Regulation of FGF-1 and synaptotagmin-1 release	—
S100A14	—	malignant transformation
S100B	Cell motility, proliferation, inhibition of phosphorylation, inhibition of microtubule assembly transcription, regulation of nuclear kinase, extracellular functions, e.g. neurite extension	Alzheimer's disease, Down's syndrome, melanoma, amyotrophic lateral sclerosis, epilepsy
S100P	Function in the placenta	Cancer
S100Z	Function in spleen and leukocytes	Aberrant in some tumors
Calbindin D _{9k}	Ca ²⁺ buffer and Ca ²⁺ transport	Vitamin D deficiency, abnormal mineralization

Associations with Human Diseases

As listed in Table II, various S100 proteins are closely associated with several human diseases. We will briefly discuss a few examples.

S100 A1 is mainly expressed in the human myocardium. Reduced levels measured in the left ventricles of patients with end stage heart failure may contribute to a reduced contractility [18]. This notion is in agreement with the reported interactions of S100A1 with SR proteins, regulating Ca²⁺-induced Ca²⁺ release [19], and with SERCA2a, phospholamban (own results), and titin [20], modulating Ca²⁺ homeostasis and contractile performance [21]. Therefore, an S100A1 gene transfer to the heart *in vivo* might provide a new therapeutic approach to correct the altered Ca²⁺ signaling pathways that cause abnormal myocardial contractility.

S100A4 has been implicated in invasion and metastasis [22]. The prognostic significance of its selective expression in various cancers has been exploited. Identification of predictive markers of cancer is of major importance to the improvement of clinical management, therapeutic outcome, and survival of patients. In gastric cancer the inverse expression of S100A4 in relation to E-cadherin (a tumor suppressor) was found to be a powerful aid in histological typing and in

evaluating the metastatic potential/prognosis of patients with this type of cancer [23].

Extracellular functions of S100 proteins such as S100A4 have been described. Recently it was demonstrated [24] that S100A4 could act as an angiogenic factor and might induce tumor progression via an extracellular route stimulating angiogenesis. Inhibiting the process of tumor angiogenesis might be possible by either blocking S100A4 secretion or its extracellular function.

A prognostic significance of S100A2 in laryngeal squamous-cell carcinoma has also been found [25], thus allowing discrimination of high- and low-risk patients in the lymph-node negative subgroup to provide better therapy.

Human S100A8 and S100A9 are associated with chronic inflammatory diseases. Both proteins are also involved in wound repair by reorganizing the keratin cytoskeleton in the injured epidermis [26].

S100B and its interacting tau protein are individually affected in Alzheimer's disease (AD). S100B is overexpressed in AD, and hyperphosphorylated tau constitutes the primary component of neurofibrillary tangles. In addition, S100B interacts with other AD-associated proteins such as presenilin (PS1 and PS2) and with the amyloid precursor protein (APP). These interactions are altered by the phosphorylation state

of tau and the overexpression of S100B, a finding that strongly indicates that S100B plays an important role in pathways associated with neurodegeneration [27–29].

Conclusion and Perspectives

S100 proteins have been implicated in pleiotropic Ca^{2+} -dependent cellular events, with specific functions for each of the family members. However, some S100 proteins have also physiologically relevant Zn^{2+} affinities, suggesting that Zn^{2+} rather than Ca^{2+} controls their biological activities. In order to understand how the biological functions of S100 proteins are regulated by Zn^{2+} and Ca^{2+} it will be necessary to determine the three-dimensional structures of the Zn^{2+} loaded S100 proteins and their interactions with target proteins.

S100 proteins are localized in specific cellular compartments from which some of them relocate upon cellular stimulation and even secrete exerting extracellular, cytokine-like activities. This finding suggests that translocation might be a temporal and spatial determinant of their interactions with different partner proteins. Our recent experiments suggest that different S100 proteins utilize distinct translocation pathways, which might lead them to certain subcellular compartments in order to perform their physiological tasks in the same cellular environment.

Some S100 proteins can play a crucial role in physiological responses through their paracrine effects on neighboring cells. The discovery of the surface receptor RAGE for two S100 proteins (S100B and S10012) has shed more light on the extracellular functions of these two proteins. Just how they are secreted and how they interact with RAGE still remains to be investigated. This could be done using animal models with inactivated single S100 proteins or deletion mutants of RAGE. Future research activities will also focus on the deregulated expression of S100 genes, which is a hallmark of a wide range of human diseases.

Acknowledgments

We thank Patricia McLoughlin for critical reading and D. Arévalo for help with the preparation of the manuscript. Structures of C₂-Domains

C₂-domains are widespread protein modules of approximately 130 residues that are defined by a consensus sequence and a common three-dimensional fold [1]. Most C₂-domains bind Ca²⁺ and mediate interactions of their proteins with phospholipids. In the initial analysis of the human genome [2], C₂-domains were the second most abundant Ca²⁺-regulatory domain (123 genes) after EF-hands (242 genes). C₂-domains primarily occur in membrane trafficking proteins such as synaptotagmin 1 and in signal transduction proteins such as protein kinase C (PKC). Although most C₂-domains bind Ca²⁺, a significant number of C₂-domains do not bind Ca²⁺.

As initially revealed in the structure of the synaptotagmin 1 C₂A-domain [3] and confirmed in more than ten C₂-domain structures (see Table I), C₂-domains are composed of a compact β -sandwich containing two β -sheets with four β -strands each. This is illustrated exemplarily for the two C₂-domains for synaptotagmin 1 in Fig. 1. Flexible loops at the top and bottom connect the eight β -strands. The β -strands are conserved between C₂-domains, whereas the loops vary and frequently contain additional secondary structure elements. The eight β -strands in the C₂-domain β -sandwich can be arranged in two distinct topologies. These topologies are circular permutations of each other, and are referred to as type 1 and type 2 (Fig. 2; reviewed in [1]). As a result, the N- and C-termini of the C₂-domains are either on top or at the bottom of the domains. However, C₂-domains with distinct topologies can nevertheless have similar three-dimensional structures. For example, the type 1 C₂A-domain from synaptotagmin 1 [3] and the type 2 C₂-domain from phospholipase

C δ 1 [4] exhibit a root mean square deviation of 1.4 Å for 109 equivalent α -carbons. One reason for the different C₂-domain topologies may be that the topology influences the relative orientation of a C₂-domain and the neighboring domains.

The conserved core β -sandwich of C₂-domains serves as a scaffold for the emergence of variable loops at the top and bottom of the domain. In C₂-domains that bind Ca²⁺ and/or phospholipids, these exclusively bind to sites formed by the top loops. In contrast, the function of the bottom loops is unclear. The distinct Ca²⁺- and phospholipid-binding properties of C₂-domains—as well as other activities—are probably encoded in the variable top and bottom loops which differ in size and sequence. C₂-domains thus are “janus-faced” modules in which a stable β -scaffold supports two variable surfaces: a generally Ca²⁺-dependent top surface and a Ca²⁺-independent bottom surface [5].

C₂-domains can be classified based on structural or functional properties. Structurally, in addition to the assignment of C₂-domains to the two principal types of β -strand topology, C₂-domains can be subdivided into classes that share common sequences. For example, the two C₂-domains of synaptotagmins (referred to as the C₂A- and C₂B-domains) exhibit conserved sequence differences. The fourth bottom loop of all C₂B-domains from synaptotagmins and related proteins forms a α -helix that is absent from all C₂A-domains and other C₂-domains [5]. In addition, the C₂B-domains from synaptotagmins 1, 2, and 8 but not other synaptotagmins include an extra C-terminal α -helix [6]. In contrast to this structural classification, C₂-domains can also be divided into functional classes. Again taking synaptotagmins as an example, synaptotagmins 1 and 2 bind Ca²⁺ but synaptotagmin 8

Table I Atomic Structures of C₂-Domains

Protein/C ₂ -domain	Method ^a	Ca ²⁺ -binding state of structure ^b	Ca ²⁺ -binding sites of C ₂ -domain ^c		References
			Number	Intrinsic affinity (in μM Ca ²⁺)

^bNumber of Ca²⁺-ions in structure.

^cn.d. = not determined; n.a. = not applicable.

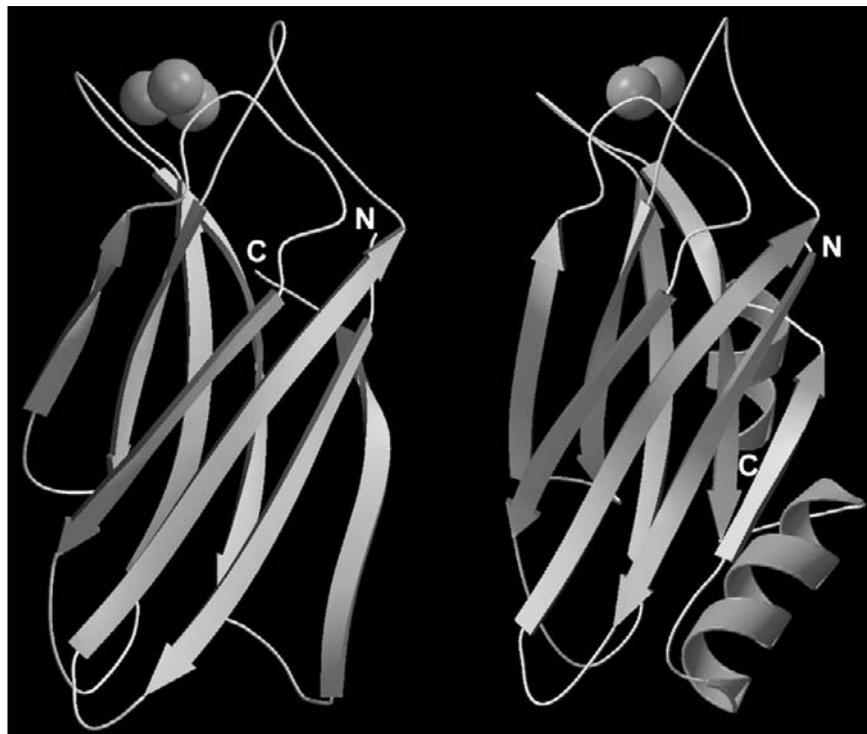

Figure 1 Structures of the synaptotagmin 1 C₂A- and C₂B-domains. Pictures show ribbon diagrams of the synaptotagmin C₂-domains (wide ribbons = β-strands; helices = α-helices; thin light strands = no secondary structure) in the Ca²⁺-bound state. Three Ca²⁺-ions are shown bound to the top loops for the C₂A-domain (left), and two Ca²⁺-ions for the C₂B-domain (right). Note that only the C₂B-domain contains significant α-helices. Positions of N- and C-termini are indicated by N and C.

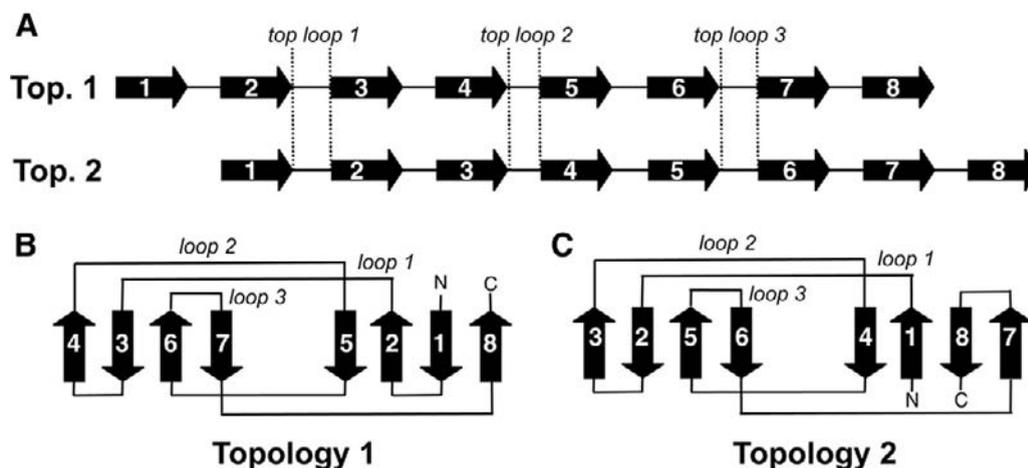

Figure 2 Diagram of the topography of β -strands in various types of C₂-domains. Two types of C₂-domain structures have been described that differ in the arrangement of β -strands; they are circular permutations of each other. In type 1 C₂-domains exemplified by the synaptotagmin C₂-domains (diagrams A and B; see also Fig. 1), N- and C-termini are on top of the C₂-domains, whereas in type 2 C₂-domains exemplified by the phospholipase C δ 1 structure (diagrams A and C; see ref. 4), the N- and C-termini are on the bottom. Note that the position of the top loops changes, but the actual localization of the loops within the three-dimensional structure does not.

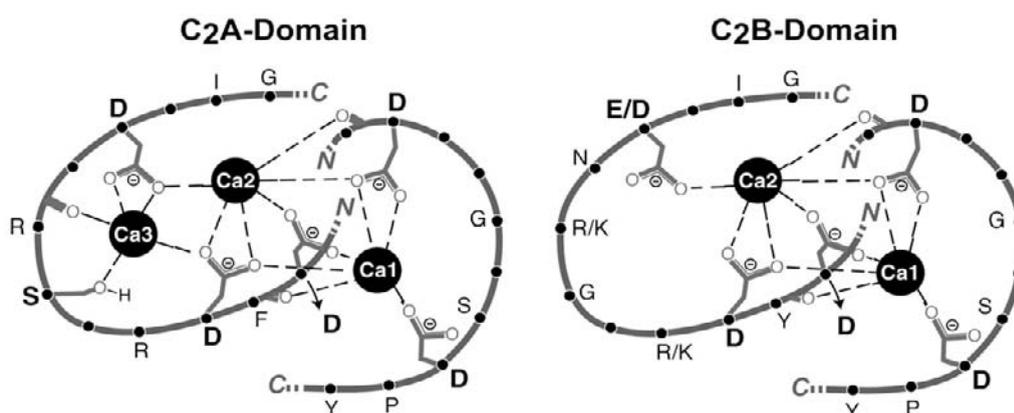

Figure 3 Model of the Ca²⁺-binding sites of synaptotagmin C₂-domains. In both the C₂A- and C₂B-domains, the Ca²⁺-binding sites are primarily formed by negatively charged residues located on top loops 1 and 3 (loop 2 is not shown). Most of the Ca²⁺-coordinating negatively charged residues are multidentate ligands for the Ca²⁺-ions. The sequences shown for the top loops are consensus sequences present in most but not all synaptotagmins (modified from [40]).

does not, in spite of the fact that the C₂B-domains from these three synaptotagmins share the same extra C-terminal α -helix, which is absent from other C₂B-domains [6,7]. Thus structural and functional classifications do not necessarily overlap.

Ca²⁺-Binding Mode of C₂-Domains

In all Ca²⁺-binding C₂-domains, Ca²⁺ binds exclusively to the top loops [3–6,8–17]. C₂-domains usually bind either two or three Ca²⁺-ions at closely spaced sites that are primarily formed by aspartate residues, as illustrated in Fig. 3 for the two C₂-domains of synaptotagmin 1. The residues that form the Ca²⁺-binding sites are widely separated in the primary sequences. The Ca²⁺-binding residues often serve as

bidentate ligands for multiple Ca²⁺-ions [8,11,12]. The coordination spheres of the bound Ca²⁺ ions in the C₂-domain are incomplete in many C₂-domains, resulting in low intrinsic Ca²⁺-affinities (e.g. the synaptotagmin 1 C₂A-domain exhibits an affinity of >1.0 mM for complete Ca²⁺-binding; [18]). As a result of this design, multiple Ca²⁺-ions are concentrated in a small region on top of the C₂-domains and contain unsatisfied coordination sites that remain available for interaction with target molecules (see model in Fig. 3). Other C₂-domains, however, exhibit a much higher intrinsic Ca²⁺-affinity (e.g. in the rabphilin C₂B-domain the two Ca²⁺-ions bind with intrinsic affinities of 7 and 11 μ M; [5]), and may have complete Ca²⁺-coordination spheres.

The detailed characterization of the Ca²⁺-binding sites for several C₂-domains, especially the C₂A-domain of

synaptotagmin 1 [8–11,18] and the C₂-domain of phospholipase C δ [4,12], revealed that the Ca²⁺-binding sites are very similar, allowing a reasonably reliable prediction of whether a given C₂-domain is likely to bind Ca²⁺. The aspartate residues involved in Ca²⁺ binding in the synaptotagmin I C₂A-domain are conserved in many C₂-domains, and the conserved Ca²⁺-binding sequence that they form is referred to as the C₂-motif [8]. However, it has been difficult to predict the precise Ca²⁺-binding properties of C₂-domains—for example their phospholipid specificities and apparent Ca²⁺-affinities—presumably because they are determined by the variable sequences of their top loops that do not have defined conformations.

In all C₂-domains studied so far except for the piccolo C₂A-domain [19], Ca²⁺-binding does not induce a substantial conformational change. For example, comparison of the Ca²⁺-free and Ca²⁺-bound forms of the synaptotagmin I C₂A-domain demonstrated that Ca²⁺ binding involves rotations of some side chains but causes no substantial backbone rearrangements [10]. The Ca²⁺-binding region appears to be flexible in the absence of Ca²⁺, and is stabilized after Ca²⁺ binding. Similar findings have been obtained for the C₂B-domain of synaptotagmin 1 [6] and the C₂-domain of phospholipase C δ [4,12]. These results suggest that in most C₂-domains, Ca²⁺-binding to a small patch on the top surface causes only a local effect that transduces the Ca²⁺-binding signal. The nature of this effect probably depends on an electrostatic switch, since Ca²⁺-binding causes a major change in the electrostatic potential of the top surface of the synaptotagmin 1 C₂A-domain [9].

The only C₂-domain that has been shown to undergo a major conformational change in response to Ca²⁺-binding is the C₂A-domain of piccolo/aczonin [19]. Although this C₂-domain probably has “standard” C₂-domain Ca²⁺-binding sites, Ca²⁺-binding appears to induce a rearrangement of β -strands. The fact that a C₂-domain can undergo such a conformational change in response to Ca²⁺ indicates that C₂-domains are more versatile than suggested by the characterization of the initial C₂-domain structures.

Phospholipid Binding Mechanism of C₂-Domains

As first described for the Ca²⁺-dependent binding of the synaptotagmin 1 C₂A-domain to phospholipids [20], the most common property of C₂-domains is phospholipid binding. This is true even for C₂-domains that do not bind Ca²⁺; in fact, the function of most Ca²⁺-independent C₂-domains appears to be to attach their resident proteins to phospholipid membranes [21–24]. Ca²⁺-independent phospholipid binding is possibly best illustrated by the C₂-domain of PTEN, a tumor suppressor gene that is a phosphatase for the lipid phosphatidylinositol 3,4,5-trisphosphate [21,22]. The C₂-domain of PTEN positions its catalytic domain on top of the substrate. The C₂-domain not only recruits PTEN to the membrane, it also orients the catalytic domain with respect

to the membrane substrate. Similar functions have been ascribed to the N-terminal C₂-domains of novel PKCs whose structures have been solved [23,24]. However, although significant evidence exists that phospholipid binding may be an even more general property of C₂-domains than Ca²⁺-binding, it seems likely that not all C₂-domains bind phospholipids.

In all phospholipid-binding C₂-domains, phospholipids bind exclusively to the top loops similar to Ca²⁺-binding. In spite of this similarity, however, the mechanism of phospholipid binding and the phospholipid specificity vary greatly among C₂-domains. Some C₂-domains (such as both C₂-domains of synaptotagmin 1) bind promiscuously negatively charged residues [6,20], whereas other (such as the C₂-domain of cytoplasmic phospholipase A2) bind neutral lipids [25]. Both hydrophobic and electrostatic interactions contribute to phospholipid binding but to different degrees in the various C₂-domains (see e.g. [25,26]). The contribution of different types of interactions has been described in detail for the double C₂-domain fragment of synaptotagmin 1 in which both C₂-domains contribute to the overall interaction [27,28]. Here, each C₂-domain separately participates in three types of interactions with the phospholipid bilayer, Ca²⁺-mediated binding, hydrophobic attachment, and electrostatic interactions via positively charged residues.

Ca²⁺-ions serve as a bridge that connect the C₂-domains to the phospholipid headgroups. The bound Ca²⁺-ions are incompletely coordinated by the top loops of the C₂-domains. When phospholipids bind, they probably fill unsatisfied coordination sites on the bound Ca²⁺ ions. This results in a 100 to 1,000-fold increase in the apparent Ca²⁺-affinity of the C₂-domains, and converts noncooperative intrinsic Ca²⁺-binding into highly cooperative Ca²⁺-binding by the C₂-domain/phospholipid complex [17,18,29]. In fact, at least for synaptotagmin 1, intrinsic Ca²⁺-binding has an unphysiologically low affinity and probably never occurs in the absence of phospholipids, suggesting that the true signaling structure for synaptotagmins is the C₂-domain/phospholipid complex [18].

In addition to Ca²⁺-ions, the synaptotagmin 1 C₂-domains are connected to the phospholipids by hydrophobic residues that insert into the bilayer [30,31] and by positively charged residues that form electrostatic interactions with negatively charged phospholipid headgroups [18,29]. All three forces contribute; in fact, the hydrophobic interactions, although constitutive, are essential for Ca²⁺-triggered phospholipid binding [31]. Because the two C₂-domains are so closely spaced, the C₂-domains cooperate, resulting in a higher apparent Ca²⁺-affinity of the double C₂-domain fragment than for the individual C₂-domains [28,32]. Furthermore, mutations that induce dramatic changes in the properties of isolated C₂-domains have unpredictable effects on the double C₂-domain fragment: Whereas some mutations induce the same change in the double C₂-domain fragment [18], others cause no change at all [32].

It seems likely that other C₂-domains, such as that of PKC α [17], bind phospholipids by a similar mechanism,

although the contribution of the various types of interactions vary dramatically among C₂-domains [25]. In C₂-domains that bind phospholipids Ca²⁺ independently, the two Ca²⁺-independent types of interactions are presumably sufficient to mediate constitutive binding. Such interactions could easily be modulated by other signaling pathways; for example, phosphorylation as shown for a C₂-domain from *Aplysia* PKC [33]. It would not be surprising if in Ca²⁺-dependent and Ca²⁺-independent C₂-domains membrane binding was further modulated by additional mechanisms.

Other Ligands of C₂-Domains

In addition to phospholipids, various C₂-domains have been reported to bind to many other molecules, primarily proteins (reviewed in [1]). Like all protein-protein interactions, the *in vivo* importance of these *in vitro* interactions is difficult to assess, and all of these interactions remain to be validated. Nevertheless, indirect evidence indicates that at least some of these interactions are important. First, some C₂-domains apparently do not bind to either phospholipids or Ca²⁺. Although this finding does not exclude the possibility that the right lipids have not yet been tested, some of these C₂-domains strongly bind to other ligands that may mediate their functions. For example, the C₂B-domain of the active zone protein RIM does not bind Ca²⁺ or phospholipids but strongly interacts with proteins called α -liprins [34], suggesting that some C₂-domains might function as standard protein-protein interaction domains. Second, as janus-faced modules, C₂-domains have conserved sequence elements on their bottom surfaces that have no role in either Ca²⁺ or phospholipid binding [5]. It stands to reason that these sequences perform a function, although the nature of this activity remains obscure.

Function of C₂-domains

As is evident from their properties, the function of most C₂-domains is to attach their resident proteins to phospholipid membranes, although C₂-domains probably also connect their resident proteins to other ligands. The membrane-attachment function of C₂-domains may differ between trafficking and signal transduction proteins, the two classes that contain most of the C₂-domains in the genome. Signal transduction proteins usually contain a single C₂-domain that serves to position the catalytic domain of these proteins close to their substrates in the membrane. This is most obvious for enzymes that act on lipids such as phospholipase A2 and PTEN, where the C₂-domain is essential for placing the catalytic domain close to the phospholipid substrate either in a Ca²⁺-dependent or constitutive manner [21,22,35,36]. However, this is also true for enzymes such as ras-GAP and PKC, where the C₂-domain brings the enzyme into proximity with membrane-bound ras (for ras-GAP) or diacylglycerol (for PKC) [37,38].

In contrast to signal transduction proteins, membrane trafficking proteins usually contain tandem C₂-domains

(e.g. synaptotagmins), but some proteins include as many as six C₂-domains (e.g. ferlins; [39]). The properties of the tandem C₂-domain architecture has only been worked out for synaptotagmin 1 (reviewed in [40]). Here both C₂-domains bind Ca²⁺ and phospholipids, and both are essential for the function of the protein. Since synaptotagmins are intrinsic membrane proteins, their C₂-domains do not function to recruit these proteins to the membrane. The precise need for two C₂-domains is unknown, but a possible function of this configuration is to effect a physicochemical change in the target membranes to which they bind. For example, the role of synaptotagmin 1 in fast Ca²⁺-triggered exocytosis may be mediated by a rapid Ca²⁺-induced rearrangement of phospholipids during the fusion reaction, thereby opening the fusion pore that lets the transmitters escape. Although this is a plausible hypothesis for the need for two C₂-domains in synaptotagmin 1, it does not explain why so many other membrane trafficking proteins also contain two C₂-domains, even membrane proteins such as RIMs in which the C₂-domains do not appear to bind Ca²⁺ and/or phospholipids.

In the emerging universe of protein modules that are used to construct many of the eukaryotic signaling pathways, C₂-domains are remarkable for several reasons. A rigid core composed of a relatively invariant β -sandwich is used as a scaffold to form variable binding surfaces on the top and bottom of the module. The Ca²⁺-binding sites formed in most C₂-domains are unusual because these sites are built from residues that are widely separated in the primary sequence and because Ca²⁺-binding does not generally cause a conformational change but induces an electrostatic switch.

Although the progress in understanding C₂-domains has been significant over the last ten years, many questions remain to be addressed. For example, the mechanism and validity of the protein-protein interactions mediated by C₂-domains needs to be examined, the function of the bottom surface of C₂-domains needs to be elucidated, and the molecular basis for the Ca²⁺-affinity and phospholipid-binding specificity of C₂-domains needs to be clarified. Before these important goals are realized, it will be difficult to postulate general conclusions about the functions of these domains.

Annexins and Calcium Signaling

Stephen E. Moss

London, United Kingdom*

Introduction

The vertebrate family of annexins comprises 12 calcium-binding proteins encoded by distinct genes. Although the functions of annexins are not yet fully elucidated, there is growing evidence that certain members of this family are involved in the homeostatic regulation of intracellular calcium ion concentration [1]. Annexins have a lower affinity for Ca^{2+} than E-F hand proteins, but this affinity is increased in the presence of negatively charged phospholipids. This defining biochemical property forms the basis of a generalized paradigm for annexin function in which elevation of intracellular Ca^{2+} concentration during cell stimulation is accompanied by translocation of annexins from the cytosol to the inner face of the plasma membrane. Ca^{2+} -dependent spatiotemporal regulation of subcellular localization is therefore likely to be a key aspect of annexin function, enabling annexins to influence the activities of other peripherally bound or integral membrane proteins in response to transient increases in cytosolic Ca^{2+} concentration. The precise question of what annexins do once membrane-bound has not been clearly answered, but it is probable that annexins are involved in membrane-associated events such as phospholipid clustering in lipid rafts, control of membrane fluidity, and structural changes to the membrane-cytoskeleton during endocytosis or phagocytosis (for review see [2]). Another possible role for membrane-bound annexins is in the generation and regulation of intracellular Ca^{2+} fluxes, and it is this topic that forms the focus of this chapter.

Annexins as Ca^{2+} Channels

The notion that annexins could function as Ca^{2+} channels first emerged in 1987, with the observation that purified annexin 7 (synexin) displays the properties of a voltage-gated Ca^{2+}

channel when added to synthetic phospholipid bilayers [3]. Subsequent studies on the *in vitro* channel activities of various annexins, often supported by parallel structural analyses, have revealed this to be a general property of most members of the family. Annexin 5, which has been most extensively investigated with regard to the relationship between structure and Ca^{2+} channel activity, is approximately doughnut shaped with a slightly convex upper surface on which the Ca^{2+} -binding loops are located, and a slightly concave lower surface [4]. The proposed ion conductance pathway is lined with acidic residues, some of which have been demonstrated by mutagenesis studies to function as ion selectivity filter and voltage sensor [5,6]. Structural analysis of many other annexins has revealed almost superimposable tertiary architectures, and it is unsurprisingly that most family members exhibit Ca^{2+} channel activity *in vitro*.

The convincing structural basis for the Ca^{2+} channel activities of annexins is supported by electrophysiological and pharmacological correlates between the properties of putative annexin channels and as yet uncharacterized Ca^{2+} channels in mammalian cells [7–9]. For example, annexin 5 exhibits the properties of a classic voltage-gated Ca^{2+} channel, with unitary channel conductance values in the 10–20 pS range at both depolarizing and hyperpolarizing membrane potentials. The annexin 5 Ca^{2+} channel activity is inhibited by La^{3+} , which is known to block Ca^{2+} influx in most nonexcitable cells, whereas blockers of the L-, N-, P-, and T-type Ca^{2+} channels, such as nifedipine and Cd^{2+} , are without effect on the annexin 5 channel. Perhaps the most interesting pharmacological antagonist of annexin 5 is a cardioprotective benzothiazepine named K201, which exerts its effect by inhibiting Ca^{2+} influx into cardiomyocytes following ischemia-reperfusion injury [10]. Co-crystallization studies of K201 in complex with annexin 5 revealed the inhibitor to be tightly bound in a cleft at the proposed exit site of the Ca^{2+} conductance pathway [11].

Despite the weight of the structural, pharmacological, and electrophysiological evidence, the consensus view that annexins are either cytosolic or peripheral membrane-binding proteins presents a conceptual obstacle to the idea that such proteins could function as ion channels. There are few studies that have directly addressed this point, but investigations using bone-derived matrix vesicles [12] and chick DT40 cells containing a targeted disruption of the annexin 5 gene [13] add credibility to this theory. Mineralizing chondrocytes shed vesicles rich in phosphatidylserine and annexin 5 and take up Ca^{2+} , which forms crystals that embed in the collagen matrix during *de novo* bone deposition. The Ca^{2+} entry pathway in matrix vesicles was shown to be inhibited by Zn^{2+} and GTP, and increased by ATP. These characteristics mirror those observed in phospholipid vesicles containing annexin 5, suggesting that annexin 5 may be directly responsible for Ca^{2+} influx in mineralizing matrix vesicles. In annexin 5 null-mutant DT40 cells, Ca^{2+} signals elicited by both thapsigargin and activation of the B-cell receptor are normal, whereas the Ca^{2+} influx component of the biphasic response to hydrogen peroxide is absent. Cells lacking annexin 2 were normal with regard to peroxide-induced Ca^{2+} fluxes, showing that although both annexins exhibit Ca^{2+} channel activity *in vitro* [14], only annexin 5 seems to be involved in Ca^{2+} signaling *in vivo*. These data show that annexin 5 functions either as a Ca^{2+} channel, Ca^{2+} channel subunit, or signaling intermediate in the peroxide-activated Ca^{2+} influx pathway. Although the case for annexin 5 having a role as a Ca^{2+} channel is not yet proven, it would be a curious denouement if a protein that possesses so many of the structural and biophysical characteristics of a bona fide Ca^{2+} channel were to be shown to function as a Ca^{2+} channel regulator *in vivo*.

Annexins as Ca^{2+} Channel Regulators

A more readily acceptable *modus operandi* for annexins is in the regulation of intracellular Ca^{2+} fluxes. Annexins could influence Ca^{2+} signals by direct interaction with the cytoplasmic domains of proteins involved either in Ca^{2+} extrusion or in release of Ca^{2+} from the endoplasmic reticulum (ER) or sarcoplasmic reticulum (SR) Ca^{2+} stores. The first evidence for such roles came from studies in which annexin 6 was shown to increase the mean open time and opening probability of SR ryanodine-sensitive Ca^{2+} release channels in isolated membrane preparations [15]. However, annexin 6 was shown to exert this effect only when added to the luminal side of the vesicles, and annexin 6 is generally considered to be a cytosolic protein. Also, these experiments were performed before it was known that annexin 6 itself has Ca^{2+} channel activity [16], raising the possibility that the changes observed in Ca^{2+} conductance may have been directly due to annexin 6. In A431 squamous epithelial carcinoma cells (which normally lack annexin 6), ectopic expression of annexin 6 was found to attenuate the sustained phase of the Ca^{2+} response to epidermal growth factor [17]. Other responses, such as to thapsigargin, were unaffected by annexin 6. An interesting

finding is that only the larger of the two splice forms of annexin 6 exhibited this effect, which correlated with slower proliferative rate and tumor growth in nude mice [18].

Further studies in transgenic mice showed that targeted overexpression of an annexin 6 transgene in the heart led to cardiomyopathy, acute myocarditis, and fibrosis [19]. Experiments on isolated cardiomyocytes from these animals revealed lower resting Ca^{2+} levels, decreased amplitude of electrically evoked Ca^{2+} spikes, and impaired contractility. Similar studies on cardiomyocytes from annexin 6 knockout mice failed to identify any changes in resting cytosolic Ca^{2+} levels, but the contractile properties of these cells were significantly enhanced with regard to rate of contraction, extent of contraction, and rate of relaxation [20]. These mechanical changes correlated with accelerated diastolic clearance of Ca^{2+} from the cytosol, perhaps through enhanced activity of either the SR Ca^{2+} ATPase or the $\text{Na}^+/\text{Ca}^{2+}$ exchanger. It is interesting to note that in humans with end-stage heart failure annexin 6 is downregulated [21]. Based on the studies of transgenic and null mutant mice, this would be predicted to enhance cardiomyocyte contractility, suggesting a negative inotropic role for annexin 6 in cardiomyocyte function.

Similar changes in cardiomyocyte function have been reported in mice lacking annexin 7 [22]. In normal mice, the degree of cell shortening increases with increasing frequency of stimulation, but this was not the case in the annexin 7 KO mice. In a separate study, targeted disruption of the annexin 7 gene in mice was reported to be lethal, and the heterozygous mice exhibited severe defects in insulin secretion that were apparently due to abnormally low expression of the inositol trisphosphate (IP_3) receptor [23]. Although these observations suggest a functional link between annexin 7 and IP_3 receptor expression, it is not clear why loss of a single annexin 7 allele should have such a striking effect on the expression of the IP_3 receptor.

Conclusions

The evidence that certain members of the annexin family have roles in Ca^{2+} signaling continues to grow. Most of the studies in this area have focused on annexins 5 and 6, and a combination of structural, electrophysiological, pharmacological, and genetic evidence tends to support the idea that annexin 5 functions as a Ca^{2+} channel. If this is indeed a physiological role of annexin 5, how does one account for the ability of a resident cytosolic protein to channel calcium ions? One study based on theoretical calculations predicted that membrane binding by annexin 5 would lead to foci of increased ion permeability caused by electrostatic destabilization of the lipid bilayer [24]. An alternative mechanism emerged from spin-labeling studies on annexin B12, which suggested that under certain conditions structural changes could occur that would lead to membrane insertion [25]. The availability of annexin null mutant cells and animals provides the opportunity to test these and other models of annexin function *in vivo*. Studies of this type should refine

our understanding of the increasingly firm link between calcium signaling and annexin function.

Introduction

Four decades of study have provided much understanding of the calpain family of intracellular cysteine proteases [1]. Due to the limitations of investigative tools, earlier work focused on *in vitro* regulation and activities of these proteases, primarily the two ubiquitous isoforms μ - (calpain I) and m-calpain (calpain II) [2]. Structure-function studies have culminated in elucidating the molecular structure of the two ubiquitous calpains and deciphering how these enzymes might be activated and modulated. More recently, investigators have focused on connecting calpain function to physiology and pathology, particularly in regard to motility during wound repair [3,4], injury-mediated apoptosis in stroke and ischemia [5], protein degradation in muscular dystrophies [6], and susceptibility for non-insulin dependent diabetes mellitus [7,8].

Calpain Family

Thirteen distinct mammalian calpain gene products comprise the calpain gene family. The general structure is of a large subunit complexed to a single 30 kDa small subunit [6,9]. These isoforms differ in the length of N-terminal sequences, regulatory domain structures, and presence of calcium-binding domains. Ten calpain isoforms have been studied; most of these appear to be relatively selective for or enriched in cell and tissue types. The two ubiquitous calpains, μ - and m-calpain, are the best understood due to their high level of expression and primacy of discovery. These two isoforms were named according to their relative requirement for calcium *in vitro*, with μ -calpain requiring micromolar concentrations and m-calpain requiring near

millimolar levels of calcium to elicit proteolytic activity *in vitro*.

Two other calpains, p94 calpain III and calpain X, also have a high level of interest due to their potential involvement in pathologies. The muscle-specific calpain III is characterized by two inserts, one within domain II and the other between domains III and IV [6]. It is interesting that p94 calpain appears to be independent of high calcium for activation but demonstrates low-level constitutive activity across a wide range of calcium concentrations. Calpain X has recently gained attention because of its identification in a linkage analysis study for type II or non-insulin-dependent diabetes [7,8]. This calpain is present in the β -cells of islets as well as in muscle and liver. Its structure is similar to that of the ubiquitous calpains.

Structure

The calpain molecule can be divided into five domains, initially described in protein structure-function studies and now by the crystal structure [10,11] (Fig. 1). Domain I contains a short 19 amino acid N-terminal sequence that is cleaved during autoproteolysis. The catalytic domain is divided into two parts, with the active site forming in the cleft between them. Domain III is a regulatory domain that has been shown to contain sites for attenuative phosphorylation [12] and a potential phospholipid-binding domain [13]. The fourth domain contains four calcium-binding EF-hand domains.

The crystal structure of calpain provides for the mechanism of activation. Unlike papains, the N-terminal domain is not a prodomain residing in the active site, a finding that confirms that autolysis of the N-terminal is not required for activation [14,15]. The most intriguing aspect is the active site itself.

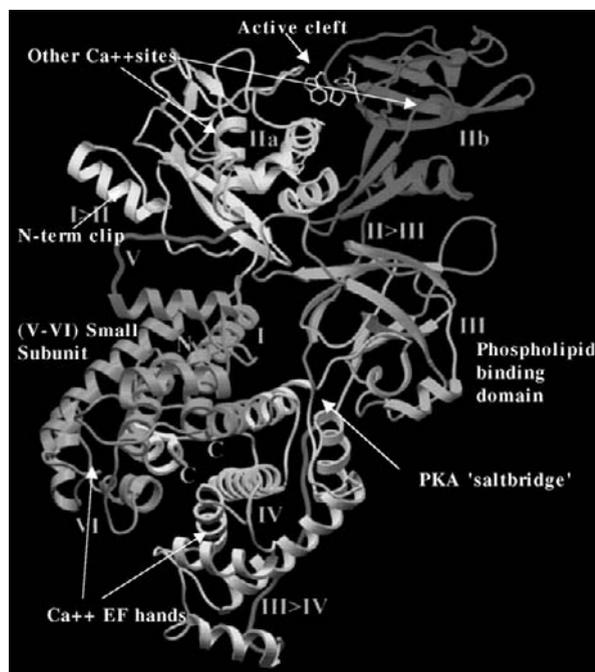

Figure 1 Structural domains of human m-calpain. Ribbon diagram of the crystal structure in the absence of calcium (domain V of the small subunit is absent) [10]. Denoted are sites of calcium binding in domains V and VI and in the active sites. Also noted are potential regulatory sites of phospholipid binding (the C2-like domain III), autoproteolysis of the N-terminal leader, and negative attenuation by PKA phosphorylation at serine/threonine 369/370. Adapted from [3,10].

In the inactive state, the catalytic residues (Cys105, His262, Asn286) are misaligned and too far apart to form a catalytic center [11,16]. Therefore, activating processes such as calcium binding, phospholipid binding, intramolecular cleavage, or phosphorylation must effect a realignment of these domains. Recent crystallography demonstrates that calcium loading at supraphysiological levels can accomplish such a shift. However, how these activating reorganization are effected *in vivo* remains a major challenge.

Modes of Regulation

An intricate strategy for the temporal and spatial regulation of calpain activity is necessary because calpain, which is abundant in the cytoplasm, cleaves many intracellular signaling and structural proteins. However, controversy still exists about how calpain activity is regulated *in vivo*. The lack of progress in this arena stems from many of the earlier studies having focused on calpain behavior *in vitro*. Whatever mechanisms are used to form an active site, the upstream signals triggering this activation and the downstream targets are critical in understanding the physiological roles of calpain. Furthermore, the ways that calpains are activated might vary not only by isoform, but also by subcellular localization as the ubiquitous isoforms are found throughout the cell, including in the nucleus. Therefore, multiple, potentially alternative or complementary mechanisms of activation have been proposed (Table I).

Table I Possible Mechanisms of Modulation

Activation	Inhibition
Calcium fluxes	Endogenous inhibitor Calpastatin
Phosphorylation	Phosphorylation
Proteolysis-limited	Proteolysis-extended
Phospholipids	
Protein cofactors	
DNA	

Calcium

Based on *in vitro* findings, calpains were proposed to be activated by intracellular calcium fluxes. That calcium can activate calpains is well supported *in vitro* [10,16]. *In vivo*, calcium chelation blocks activation of μ -calpain in response to chemokines in keratinocytes [17]. However, the need for seemingly supraphysiological levels of calcium has instigated searches for other modes of activation. Recent advances in calcium imaging suggest that levels high enough for μ -calpain activation could be achieved in highly localized calcium puffs (up to ~600 nM in nonexcitable cells) or sparks (excitable cells)[18]. During traumatic or ischemic compromise of the plasma membrane, calcium influx may reach levels that activate both μ - and m-calpain; but this level of calcium is not compatible with cell survival. Thus, the *in vitro* calcium levels required for m-calpain cannot be attained for other physiological responses. Therefore, a number of mechanisms have been suggested to lower the calcium requirement, even down to ambient cytosolic levels.

Phosphorylation

Most recently, an old standby of signal transduction cascades has been shown to regulate m-calpain. Early studies reported calpains not to be phosphorylated *in vivo* as determined by autoradiography due to the long half-life of calpains in unstimulated cells [19]. However, both m- and μ -calpain have been shown to be phosphorylated *in vivo* [20]. Under unstimulated conditions, there are three sites each of phosphotyrosine, phospho-serine, and phospho-threonine phosphorylation, with the isolated calpains demonstrating varied sub-stoichiometric phosphorylation. Growth factors activate m-calpain downstream of ERK MAP kinase [21]; this is likely to occur by direct phosphorylation at amino acid S50 [22]. This is an intriguing finding, as p94 calpain III, which is considered constitutively active [23], presents a glutamic acid at this site.

Accessory Molecules

Mechanisms to reduce the requirement for calcium to the physiological range have been proposed. These include phospholipid binding, release of calpain from its inhibitor calpastatin, and binding of activator proteins. Phospholipids decrease

the calcium requirement *in vitro* [24,25]. Calpain translocates to the plasma membrane in the presence of calcium, where it associates with phosphatidylinositol bis-phosphate [26]. Of particular interest, there is a putative phospholipid-binding activity in the regulatory domain III [13]. What is especially intriguing, DNA has been reported to lessen the requirement of m-calpain for select nucleoproteins [27], which may provide a mode of activation for the nuclear-localized pool of this protease.

A ubiquitous, endogenous inhibitor of calpains, calpastatin, provided hope that dissociation/re-association would be the mainstay of calpain regulation. Calpastatin binds and inactivates calpains through each of its four repetitive inhibitory domains. However, release of calpain from calpastatin, although it correlates with activity, is insufficient for activation. Furthermore, calpastatin is neither always present in excess molar levels, nor always co-localized with calpain. Calcium fluxes actually enhance calpastatin inhibition of calpains, suggesting that calpastatin might attenuate activated calpains rather than prevent activation [28,29]. Despite the conflicting evidence of physiological relevance, overexpression of this molecule can be employed to prevent calpain activation.

Other protein-protein interactions have been proposed to activate calpain. Select proteins co-purify with active calpains from many cell types. In rat skeletal muscle, bovine brain, and rat brain, activator proteins were found that increased autolysis and lowered the calcium requirement of μ -calpain [30–32]. Acyl-CoA-binding protein has been proposed as an activator for m-calpain [33]. Unfortunately, the association and activation of calpain *in vivo* by these proteins has not been demonstrated, and the mechanism by which these proteins would activate calpains remains unclear.

Inactivation

Key to all enzymes, especially those that cause irreversible signaling such as proteolytic cleavage, is an efficient system to prevent unintended activity. Calpain activity appears to be kept at minimal levels until signaled. How this occurs is still unknown, in part because the activation mechanisms are similarly unclear.

Calpain autoproteolysis and degradation rapidly remove active enzyme. The half-life of active calpain I or calpain II is shortened from almost a week [34] to just hours [21]. This autolysis was thought to activate calpain [35,36], since the N-terminal clipped intermediaries display increased activity. However, as intact calpain can be equally active [15,37,38], these are now considered just steps on the way to degradative removal.

Calpastatin can inhibit calpain activity by acting through each of four repeated domains. Expression of exogenously encoded calpastatin has been used successfully to block calpain activation [39,40]. Still, this does not address whether this endogenous protein acts as such *in vivo*. In fact, the reported discrepancies in subcellular localization [41] argue against this being the only inhibitory mechanism for preventing

calpain activity. However, it is possible that calpastatin serves to attenuate activated calpain [42], whereas low calpain activity levels are maintained through lack of positive signals.

Phosphorylation of calpains may serve to either prevent activation or attenuate triggered enzyme. PKA phosphorylation of at least m-calpain limits the ability of growth factors to activate this isoform [12,43]. Whether this mechanism is operative in other isoforms is still an open question. The target serine at amino acid 369 is present in some of the other isoforms, but the recipient residues of the putative ensuing salt-bridge is lacking in μ -calpain.

Calpain as a Signaling Intermediate: Potential Targets

Evidence supports a critical role for calpain as a signaling intermediate downstream of both integrin and growth factor signaling pathways. The role for calcium, phospholipids, and phosphorylation in calpain regulation supports a central role for calpain in basic signal transduction mechanisms. However, the key question for understanding calpain function remains frustratingly unsolved—what are the operative targets of calpains? Cell behaviors dependent on calpain have provided hints as to what these targets might be, and many substrates have been identified both *in vitro* and *in vivo* (Table II). However, establishing whether proteolysis of these targets is either sufficient or required for the cellular responses has remained challenging due to the difficulties in generating calpain-resistant functional target molecules. The structure, primary or tertiary, of the proteolytic sites remains unknown, a fact that has confounded attempts to identify key target molecules or negative calpain cleavage of putative targets to allow assessment of functional role. Originally, calpain was proposed to cleave downstream of PEST sequences [9]; although further identification of targets demonstrated that the presence of a PEST sequence was not required [10].

The limited proteolysis of calpain suggests that it functions as an irreversible step in signaling cascades, generating constitutively active or dominant-negative versions of signaling proteins, rather than serving a degradative function. A number of structural and signaling molecules have been

Table II Potential Targets of m- and μ -Calpain

Signaling	Adhesion	Proliferation/ survival	Cytoskeletal components
EGF receptor	β -integrins	cyclin D1	spectrin
Protein kinase C	ezrin	caspases	MAP2
Src	talin	p53	filamin
Rho A	paxillin	p35	fodrin
Myosin light chain kinase	vinculin		tau
Focal adhesion kinase	α -actinin		

identified *in vitro* and in cells as targets of calpain. An early identified target of calpain was the EGF receptor, wherein calpain removes most of the carboxy-terminal domain that serves both as an autoinhibitory and a docking domain. Thus, it is not obvious whether calpain cleavage would increase or decrease EGF signaling or generate a signaling-restricted EGFR. Many of the other targets of the ubiquitous calpains are involved in cell adhesion and motility, being linked to the cytoskeletal machinery. These include FAK, ezrin, talin, paxillin, src, MLCK, RhoA, and the cytosolic tails of some of the β -integrins [3]. Recent studies with calpain-deficient embryonic fibroblasts adherent to fibronectin substrata demonstrate *in vivo* cleavage of talin but not FAK, paxillin, α -actinin, or vinculin, suggesting that talin may be a critical calpain substrate *in vivo* [44]. In accordance with previously published reports [45], *Capn4*^{-/-} embryonic fibroblasts have reduced stress fibers, thus implicating a role for calpain in the formation of Rho-mediated stress fibers [44]. It must be mentioned that various investigators report different spectra of cellular targets in very similar systems, thereby suggesting that calpain targeting is likely to be plastic and redundant and possibly dependent on the mode of activation and analysis.

Functional Roles

Selective inhibitors for calpain have provided functional indications of calpain's roles in a wide range of physiological processes, including cell motility, cell proliferation, and apoptosis. However, confusion and controversy have existed regarding calpain's functional role, to a large extent, because of a lack of specificity of many of the cell-permeable inhibitors. More recent studies using calpain-deficient embryonic fibroblasts or ectopic expression of the endogenous calpain inhibitor calpastatin have helped clarify calpain's physiological role; however, the current efforts are also not isoform specific but target both m- and μ -calpain. These studies support a critical role for calpain in regulating the actin cytoskeleton and cell migration [44] but have called into question its role in other processes such as cell proliferation [24]. However, part of calpain's widespread functional profile is likely to be due to the various calpain isoforms and their cell-specific functions. In many cases these various functions of calpain can be seen in the same cell system, thus suggesting that these different functions may also be subserved by the different localized pools of calpain that exist throughout a cell.

The critical importance of ubiquitous m- and μ -calpain for normal development has been demonstrated by transgenic mice deficient in the regulatory subunit that eliminates detectable calpain activity [24]. These mice die during embryonic development with vascular defects, thus supporting a role for calpain in blood vessel formation.

Platelet Activation

Initial studies of the role of calpain were conducted in platelets, an interesting system in which calpain clearly

plays a role in secretion, adhesion, and aggregation. Inhibition of calpain via overexpression of calpastatin prevents α -granule secretion, platelet aggregation, and spreading on glass surfaces [46]. Platelets uniquely express predominantly μ -calpain and have negligible levels of M-calpain. Therefore, molecular inhibition of μ -calpain is sufficient to down-regulate all detectable calpain activity, and antibodies to the autolyzed form of μ -calpain can yield meaningful results.

In this context, calpain was shown to be part of the signal transduction apparatus. Calpain is activated following signaling by the platelet integrin α IIB β 3 [47,48]. Calpain associates with focal adhesion proteins in platelets, regulates the attachment of α IIB β 3 to the cytoskeleton, and relaxes the retraction of fibrin clots. Activation of calpain by ionophore A23187 increased the proteolysis of pp60c-src and PTP-1B, which then dissociated from the cytoskeleton, thereby inactivating these proteins. This correlated with the inhibition of fibrin clot retraction observed in aggregated platelets in the presence of calcium. Calpain inhibition also blocked the cleavage of the actin-binding protein talin, whereas calpain activation caused the movement of both cleaved talin and integrin α IIB β 3 from the Triton X-100 insoluble fraction (cytoskeleton) to the Triton X-100 soluble fraction [49]. Calpain therefore functions as a signaling molecule in platelets by coordinating the cellular response of aggregation and clot formation.

Adhesion Modulation—Spreading and Motility

Calpains regulate cell adhesion to the substratum and thereby affect spreading and motility of many cell types. Cell spreading requires active remodeling and turnover of adhesion sites to enable cells to extend processes subsequent to attachment. It is also considered to be similar to forward protrusion during active cell locomotion. In bovine aortic endothelial cells, calpain enables spreading by allowing formation of Rac-induced adhesions under the extended lamellae [45,50]. Inhibition of calpain caused a marked reduction in cell spreading and adhesion formation, without affecting initial attachment. Calpain acting to enable new supramolecular assembly is also noted in T cells, in which integrin ligation activates calpain to promote integrin diffusion to form focal complexes and ultimately cell spreading [51,52]. Calpain inhibition may have very different effects on cell spreading in different cellular contexts. For example, enhanced membrane protrusion and filopodia formation is observed in calpain deficient embryonic fibroblasts ([44]; A. Huttenlocher, unpublished).

Calpain-mediated regulation of cell/substratum adhesion is critical not only during spreading and forward protrusion but also in rear release during productive motility [40,53]. Haptokinetic motility, signaled by adhesion receptors, primarily integrins, is calpain dependent. β 1 and β 3 integrin-mediated CHO cell migration is sensitive to calpain inhibition [40]. Calpain inhibition stabilized peripheral focal adhesions and decreased the detachment rate. If the effect of

calpain was to alter adhesion to the substratum, one would predict a varied effect dependent on substrate density, with calpain being required most for migration over highly adhesive surfaces but only minimally involved for low adhesive regimens [40,54]. That calpain modulated cell motility dependent on adhesive strength identically to alterations in integrin affinity for fibronectin [54] indicates that calpain is acting effectively as a physiologic rheostat for adhesion.

Although the calpain isoform that functions downstream of integrin-mediated adhesion and migration has not been clearly identified, some evidence supports a role for μ -calpain in this regulation, most specifically during endothelial cell and platelet spreading. A growing body of evidence suggests that m-calpain may be involved in growth factor motility [53]. Growth factor-induced chemokinesis also requires de-adhesion [55], dependent on calpain [21]. It is interesting that this de-adhesion and motility occurs via ERK MAP kinase phosphorylating and enabling activation of m- but not μ -calpain in the absence of a calcium flux ([21]; A. Glading, unpublished). The site of phosphorylation appears to be S50, which is absent in μ -calpain. This finding provides an imposed rationale for the evolutionary duplication of the ubiquitous isoforms.

Calpain in Muscular Dystrophy

Calpain 3 is the skeletal muscle-specific calpain isoform. Defects in the human calpain 3 gene are responsible for a form of muscular dystrophy, limb girdle muscular dystrophy type 2A [56]. A calpain 3-deficient mouse model also shows a progressive muscular dystrophy with perturbations in membrane architecture and apoptosis-associated regulation of the I κ B pathway [57]. It is interesting that in the mouse model of Duchenne's muscular dystrophy there is an increase in the expression and activity of the ubiquitous calpain isoforms, suggesting that perturbation of the muscle calpains, and not just enhanced proteolysis, may contribute to the pathogenesis of muscular dystrophy.

Apoptosis

Calpain has been implicated in necrotic and apoptotic cell death [58]. Previous reports have shown that calpain inhibitors have protective effects in *in vivo* models of CNS [58] and cardiac ischemia [59]. The combined treatment of neurons with both calpain and caspase inhibitors may have an additive protective effect against neuronal apoptosis [58]. These studies support the intriguing potential of calpain inhibitors as a therapeutic target to treat cerebral or cardiac ischemia. How calpain inhibitors exert anti-necrotic and anti-apoptotic effects remain unclear. During ischemic compromise, calcium influx may reach levels that activate both μ - and m-calpain. Under these conditions, calpain may cleave multiple substrates, including signaling, cytoskeletal proteins, and transcription factors. It is likely that calpain-mediated cleavage of focal adhesion and cytoskeletal proteins contributes to cell rounding and loss of focal adhesions during

apoptosis and necrotic cell death. However, a direct modulation of apoptotic signaling pathways, i.e. by the cleavage and regulation of caspase activity, for example, may also contribute to calpain's role during apoptosis [60].

Proliferation

Substantial controversy exists about calpain's role during cell proliferation and cell cycle progression. Capn4-/- embryonic fibroblasts exhibit normal proliferation rates. However, ectopic expression of calpastatin reduces CHO cell proliferation [61] and Src-mediated transformation [62]. The calpastatin-induced inhibition of cell cycle progression in Src-transformed cells is associated with a decrease in pRb phosphorylation and reduced levels of cyclin A and D. However, although calpain may cleave cell cycle proteins such as cyclin D1 [40], a substrate for calpain's effects on cell cycle progression has not been identified. Defining calpain's role during cell cycle progression will be an important challenge for future investigation.

Future Considerations

Much is known about this ubiquitous family of limited intracellular proteases. Many investigators have defined the extended family and begun to establish structural bases of calpain activation and regulation. In addition, a number of functional roles have been established by calpain family-selective inhibitors, which in turn have provided potential target proteins. However, much remains to be learned about this complex family of enzymes.

A glaring gap in our knowledge is what precise roles the various members serve in cells, and how the different calpain localizations contribute to these cellular responses. For instance, if membrane-associated μ - and m-calpain contribute to rear detachment during motility [3,12,40], what do the majority of cytosolic and nuclear μ - and m-calpains do? Only by linking the function of isoform pools of calpain to specific cellular behaviors will we be able to understand the key targets of calpains and whether calpain clipping results in an active or dead molecule. To achieve this level of understanding will require significant advances in our tool sets. First, isoform-specific inhibitors have been attempted without widespread adoption. Second, calpain activity or activation needs to be imaged within subcellular compartments; the ubiquitous nature of calpain distribution throughout the cell renders simple localization and colocalization data of limited utility. That these advances will occur is ever more likely due to the increased realization that calpains function in motility during wound repair and tumor progression, in ischemia-induced apoptosis that aggravates stroke and myocardial infarction, and in myosin degradation of muscle-wasting syndromes. That calpain may prove a target for intervention in these major medical conditions ensures a burgeoning body of work on these fascinating molecules.

Introduction

H₂O₂ production, as a result of normal metabolism, environmental factors, and ligand-receptor interactions, is generally associated with an increase in cytoplasmic Ca²⁺ concentration. This Ca²⁺ increase can be attributed partly to the fact that H₂O₂ causes selective oxidization of certain reactive cysteine residues of the ryanodine receptor and the inositol(1,4,5)P₃ receptor, leading to enhanced Ca²⁺ channel activity of these two receptors. The Ca²⁺ elevation may also arise indirectly from inactivation of protein tyrosine phosphatase and PTEN, both of which contain an essential cysteine residue that is especially sensitive to H₂O₂-dependent oxidation.

Sources and Chemical Properties of ROS

Incomplete reduction of O₂ during respiration produces superoxide anion (O₂^{•-}), which is spontaneously or enzymatically dismutated to H₂O₂. H₂O₂ can be reduced further to hydroxyl radicals (HO[•]) in the presence of catalytic amounts of iron and electron donor molecules such as thiols and ascorbic acid (reviewed in [1,2]). These reactive oxygen species (ROS), O₂^{•-}, H₂O₂, and HO[•], are also produced in response to environmental factors such as inflammation and UV radiation. Furthermore, substantial evidence suggests that O₂^{•-} and H₂O₂ are generated transiently upon interaction of various ligand-cell surface receptor pairs and function as intracellular messengers (reviewed in [3]). Therefore, O₂^{•-} and

H₂O₂ are not merely damage-causing agents but are also mediators of physiological functions.

Calcium homeostasis is controlled by (1) Ca²⁺ channels such as the ryanodine receptor (RyR), inositol(1,4,5)P₃ receptor (IP₃R), dihydropyridine receptor (DHPR), and L-type voltage-sensitive channels, (2) Ca²⁺ pumps such as the sarcoplasmic reticulum Ca²⁺ATPase (SERCA pump) and sarcolemmal Ca²⁺ATPase, and (3) Na⁺/Ca²⁺ exchangers [4]. A shift in the cellular redox status to a more oxidized state generally causes a rapid increase in the concentration of intracellular calcium ([Ca²⁺]_i) (reviewed in [5–9]). The effect of ROS on [Ca²⁺]_i, however, is variable, depending on the cell type, the type of ROS, the level of ROS production, and the duration of exposure to ROS. The effects of ROS on Ca²⁺ homeostasis have been studied extensively in vascular endothelial cells, smooth muscle cells, cardiomyocytes, and neuronal cells because of the pathophysiologic role of oxidative injury in myocardial ischemia-reperfusion, atherosclerotic lesion formation, and trauma. Despite abundant studies, the target molecules on which ROS act and the chemical nature of ROS-induced modification are largely unknown. Considerable differences in the chemical reactivity of O₂^{•-}, H₂O₂, and HO[•] also add complexity to such studies.

Hydroxyl radicals are extremely reactive, with a lifetime of several nanoseconds in the cellular milieu, and inflict indiscriminate damage on proteins, DNA, and lipids. Oxidation of membrane lipids by HO[•] alters the physical properties of membranes and membrane-associated proteins, leading to nonspecific ion leakage. It is therefore unlikely that HO[•] functions as a specific mediator of redox regulation.

$O_2^{\bullet-}$ and H_2O_2 are less reactive species that are known to display selective oxidation of particular target molecules. H_2O_2 is a mild oxidant that can oxidize the sulfur atom of methionine and cysteine residues in proteins. Cysteine is oxidized to cysteine sulfenic acid or disulfide, both of which are readily reduced back to cysteine by various cellular reductants. The pK_a (where K_a is the acid constant) of the sulfhydryl group (Cys-SH) of most cysteine residues is ~ 8.5 . Because Cys-SH is less readily oxidized by H_2O_2 than is the cysteine thiolate anion (Cys-S⁻), few proteins might be expected to possess a cysteine residue that is vulnerable to oxidation by H_2O_2 in cells [10]. However, certain protein cysteine residues have low pK_a values and exist as thiolate anions at neutral pH because of nearby positively charged amino acid residues that are available for interaction with the negatively charged thiolate. Proteins with low- pK_a cysteine residues can be the targets of specific oxidation by H_2O_2 , and such oxidation can be reversed by thiol donors such as glutathione and thioredoxin. Methionine (Met) is more susceptible to oxidation by H_2O_2 and is converted to Met sulfoxide, which is reduced back to Met by specific enzymes called Met sulfoxide reductases (reviewed in [11]). Furthermore, reversible oxidation of Met residues can serve as a control switch for the regulation of protein function, as exemplified by calmodulin, which loses the ability to activate plasma membrane Ca^{2+} ATPases when its COOH-terminal Met residues are oxidized [12]. However, it is not known if H_2O_2 can effect selective oxidation of specific Met residues among many solvent-exposed Met residues.

Although $O_2^{\bullet-}$ is a poorer oxidant than H_2O_2 , it specifically oxidizes certain metal ions bound to proteins and consequently modifies the function of these proteins (e.g. inactivation of calcineurin due to oxidation of its Fe-Zn center [13]). It seems that $O_2^{\bullet-}$ is also able to react selectively with certain proteins as the result of electrostatic attraction between the negatively charged $O_2^{\bullet-}$ molecules and positively charged amino acid residues of the targeted proteins. One such example is the vascular smooth muscle SR Ca^{2+} ATPase, which is inactivated by $O_2^{\bullet-}$ but not by H_2O_2 [14]. However, the amino acid residues affected by $O_2^{\bullet-}$ have not been identified in this case. Furthermore, the cardiac muscle SR isoform, which shares 90% homology with the smooth muscle isoform, is insensitive to $O_2^{\bullet-}$.

Activation of Ryanodine and IP₃ Receptor Ca^{2+} Release Channels by H_2O_2

At the present time, H_2O_2 -mediated oxidation of Cys residues residing within special microenvironments appears to provide the most well defined mechanism underlying the reversible and specific effects of ROS [3]. Good examples of this phenomenon are RyR and IP₃R, both of which are activated when specific Cys residues are oxidized. RyRs, which are involved in Ca^{2+} release from the SR in skeletal and cardiac muscles, are composed of four subunits and form a complex with triadin. RyR contains about 21 cysteine residues

per subunit. Some of the 21 cysteine residues have higher reactivity than others toward H_2O_2 and various sulfhydryl reagents, but these have not been mapped precisely (reviewed in [7,15]). Oxidation by H_2O_2 or modification by sulfhydryl reagents of the reactive Cys-SH residues decreases the K_d for ryanodine as well as the EC_{50} for Ca^{2+} activation [16]. Single-channel reconstitution experiments indicate that H_2O_2 , at submicromolar concentrations, enhances the Ca^{2+} release that follows fusion of SR vesicles to planar lipid membranes [16,17]. Cysteine oxidation also contributes to the stabilization of a RyR/triadin complex during channel activation, probably through intermolecular disulfide bonding. The stimulatory effects of peroxide are reversed by thiol-reducing agents such as dithiothreitol and glutathione (GSH). Increased oxidative stress produced by ROS and nitric oxide is generally reflected by an increased ratio of GSSG to GSH in cells. GSSG is capable of forming a mixed disulfide with a reactive cysteine or converting two neighboring cysteines to a disulfide. In accordance with this capacity, GSSG, like H_2O_2 , has been demonstrated to enhance the binding affinity of RyR to ryanodine and enhance its reconstituted single channel Ca^{2+} release [18].

Sensitivity to sulfhydryl oxidation also appears to be a property of the endoplasmic reticulum (ER) Ca^{2+} channel IP₃R. H_2O_2 and GSSG were shown to cause spontaneous release and oscillation of Ca^{2+} by sensitizing IP₃R to endogenous IP₃ [19–22]. Recent reports suggest that H_2O_2 generated intracellularly as the result of ligation of cell surface receptors also contributes to Ca^{2+} mobilization. For example, histamine produces H_2O_2 through activation of NADPH oxidase in endothelial cells, and the NADPH oxidase-derived H_2O_2 is critical for the generation of Ca^{2+} oscillations during histamine stimulation [23]. Many other agonists induce Ca^{2+} oscillations as well as H_2O_2 production. Therefore, receptor-mediated H_2O_2 production is likely to be a key process affecting Ca^{2+} signaling. However, care should be taken not to attribute the H_2O_2 effect entirely to the oxidation of IP₃R, as H_2O_2 is also known to cause the production of IP₃ (see below).

Many studies on other Ca^{2+} channels (dihydropyridine receptors, L-type voltage-sensitive channels), Ca^{2+} ATPases, and Na^+/Ca^{2+} exchangers also suggest that H_2O_2 affects their activity through cysteine oxidation (reviewed in [4]). However, the results remain inconclusive and, at times, controversial.

Enhancement of $[Ca^{2+}]_i$ through H_2O_2 -mediated Inactivation of Protein Tyrosine Phosphatase and PTEN

The changes in Ca^{2+} homeostasis need not be entirely due to the modification of Ca^{2+} transporters (channels, pumps, and exchangers) but may also arise indirectly from the modification of other proteins. Candidates for such modification include protein tyrosine phosphatases (PTPs) and PTEN. All PTPs contain an essential cysteine residue (pK_a , 4.7 to 5.4) in the signature active site motif HCXXGXXRS/T (where X is any amino acid residue) that exists as a thiolate anion at

neutral pH [24]. This active site cysteine is the target of specific oxidation by H_2O_2 , and the ability of intracellularly produced H_2O_2 to inhibit PTP activity has been demonstrated in cells stimulated with EGF, PDGF, and insulin [25–27]. Furthermore, EGF- and PDGF-induced protein tyrosine phosphorylation of cellular proteins, including their respective receptor protein tyrosine kinases (RPTKs) and PLC-gamma, requires H_2O_2 production [28,29]. These results indicate that the activation of an RPTK *per se* by binding of the corresponding growth factor may not be sufficient to increase the steady state level of protein tyrosine phosphorylation in cells. Rather, the concurrent inhibition of PTPs by H_2O_2 may also be required. As such, H_2O_2 plays a major messenger role in the activation (tyrosine phosphorylation) of PLC-gamma and subsequent production of IP_3 in cells stimulated with PDGF and EGF. Exogenous H_2O_2 alone, in the absence of a growth factor, induces tyrosine phosphorylation of various cellular proteins including PLC-gamma and elicits IP_3 production [30]. This probably reflects the background activity of various protein tyrosine kinases, which is apparently sufficient to enhance the level of protein tyrosine phosphorylation when the activity of most PTPs is suppressed by H_2O_2 .

PTEN is a member of the PTP family and reverses the action of phosphoinositide (PI) 3-kinase by catalyzing the removal of the 3'-phosphate of $PI(3,4,5)P_3$. H_2O_2 induces reversible inactivation of PTEN through specific oxidation of the catalytic site cysteine [31]. As with protein tyrosine phosphorylation, it is likely that the activation of PI 3-kinase in receptor-stimulated cells may not be sufficient to achieve the accumulation of $PI(3,4,5)P_3$ because of the opposing activity of PTEN; the concomitant inactivation of PTEN by H_2O_2 might thus be necessary to increase the abundance of $PI(3,4,5)P_3$ sufficiently to trigger downstream signaling events. However, production of $PI(3,4,5)P_3$ was shown to be necessary for PDGF-induced H_2O_2 production [32]. This is probably because $PI(3,4,5)P_3$ activates Rac, an essential component of the activated NADPH oxidase complex, by binding to the pleckstrin homology domains of the Rac guanine nucleotide exchange factors [33]. Thus, through its effect on the concentration of $PI(3,4,5)P_3$, the oxidation of PTEN by H_2O_2 constitutes a positive feedback loop that increases the production of H_2O_2 . This positive feedback loop is expected to result in a rapid increase in Ca^{2+} concentration. Because many inositol polyphosphate phosphatases also contain a cysteine at their active site [34], degradation of IP_3 might be inhibited by H_2O_2 . There are observations that support this possibility.

In all likelihood, PTPs and PTEN represent the first examples among many more proteins that connect H_2O_2 and Ca^{2+} signaling. Hence, we are merely taking our first steps in understanding how oxidants modulate Ca^{2+} signaling.

Historical Overview: Protein Kinase C, Phorbol Ester, and Lipid Mediators

Yasutomi Nishizuka and Ushio Kikkawa

Biosignal Research Center, Kobe University, Kobe, Japan

Retrospectives of Phospholipid Research

Nearly 200 years ago, a French chemist, L. N. Vauquelin, found phosphorus in the brain material extracted with hot alcohol. This material was probably a mixture of crude phospholipids. Thirty years later, choline-containing phospholipid was obtained from the brain by F. Fremy (oleophosphoric acid) and from the egg yolk by M. Gobley (lecithin). Since then, during a period of more than 100 years, several phospholipids were isolated and structurally identified. The existence of inositol in plants was known in the nineteenth century but was unknown in animal tissues until 1941, when D. W. Woolley found it in the mammalian brain. In the next year, J. Folch and Woolley at Rockefeller Institute in New York fractionated several phospholipids and identified the chemical structure of inositol phospholipid. In the late 1940s Folch, then at Harvard University, noticed that additional phosphate was attached to the inositol moiety.

In the subsequent years many efforts were made to clarify the metabolic and synthetic pathways of various lipids, including inositol phospholipids. In parallel with these investigations, in the decade of 1960s, phospholipids were shown to be cofactors essential to the catalytic activity of enzymes such as β -hydroxybutyrate dehydrogenase (D. E. Green), Na^+/K^+ ATPase (T. Tanaka), NADH-cytochrome C reductase (S. J. Wakil), and many others. Nevertheless, with some exceptions such as the production of platelet-activating factor (D. J. Hanahan) and eicosanoid (S. K. Bergström and B. I. Samuelsson), membrane phospholipids were generally

viewed as a biologically inert entity that provide a semipermeable barrier between exterior and interior compartments within and between cells.

In the early 1950s, with radioactive orthophosphate, Hokin and Hokin [1] observed that acetylcholine induced rapid labeling of acid-precipitable materials of some exocrine tissues such as pancreas. It became evident soon that the materials were inositol phospholipid and phosphatidic acid. Namely, the rapid labeling of these lipids resulted from the enhanced breakdown and resynthesis of inositol phospholipid, but its biological significance remained to be clarified for many years. In 1975, Michell postulated that this phospholipid hydrolysis may open the Ca^{2+} gate [2].

Protein Kinase C and Diacylglycerol

In 1977, when protein kinase C (PKC) was first found as an undefined protein kinase present in many mammalian tissues, the enzyme was activated by limited proteolysis with Ca^{2+} -dependent protease, and no obvious evidence was available for its role in signal transduction. Before long it became clear that without proteolysis the enzyme could be activated by a membrane factor in the presence of Ca^{2+} . The membrane factor was identified as anionic phospholipids, particularly phosphatidylserine. Curiously, crude phospholipids extracted from brain membranes could activate the enzyme in the absence of added Ca^{2+} , whereas pure phospholipids obtained from erythrocyte membranes could not

produce any enzyme activation unless a higher concentration of Ca^{2+} was added to the reaction mixture. Analysis of the lipid impurities on a silicic acid column led us to conclude that diacylglycerol is an essential activator.

To explore the link of PKC activation to inositol phospholipid hydrolysis, we developed a procedure to activate this enzyme in intact cells by applying membrane-permeant diacylglycerols. Diacylglycerols having two long fatty acyl moieties could not be readily intercalated into the cell membrane. If, however, one of the fatty acids is replaced with a short chain, the resulting diacylglycerols, such as 1-oleoyl-2-acetyl-glycerol (OAG), obtain detergent-like properties and could be dispersed into the phospholipid bilayer and activate PKC directly. In the initial studies, human platelets were employed. Thrombin and collagen induce release of serotonin with the concomitant hydrolysis of inositol phospholipid and phosphorylation of two endogenous proteins with 20 and 47 kDa molecular size. It was already known that the 20 kDa protein is myosin light chain, and a specific calmodulin-dependent kinase is responsible for its phosphorylation. Before long we knew that the 47 kDa protein, pleckstrin we call it today, was a substrate specific to PKC. Thus, the phosphorylation of these two proteins served as excellent markers for the increase of Ca^{2+} and diacylglycerol-dependent activation of PKC, respectively. In 1980, we were able to show that both Ca^{2+} increase and PKC activation were essential and acted synergistically to elicit full activation of platelets and release of serotonin. Similarly, it was possible to show unequivocally that PKC activation is indispensable for neutrophil release reaction and T-cell activation, thus establishing the biological role of PKC in cellular responses. In 1983, Berridge and his colleagues announced at Cambridge the important inositol 1,4,5-trisphosphate story [3].

Phorbol Ester and Cell Signaling

In the summer of 1981, M. Castagna visited our laboratory from Villejuif, France. We discussed a possible role of tumor-promoting phorbol ester in the PKC signaling pathway. It was already known that phorbol ester shows pleiotropic activities by mimicking hormone actions. When platelets were stimulated by 12-*O*-tetradecanoylphorbol-13-acetate (TPA), the 47 kDa protein was remarkably phosphorylated, but against our expectation diacylglycerol was not produced. It was extremely disappointing to us because this meant that our idea that diacylglycerol is the mediator for PKC activation was not correct. A few days later, however, an idea flashed: What would happen if TPA could activate PKC directly because the phorbol ester contains a diacylglycerol-like structure very similar to the membrane-permeant lipid molecule OAG that we had used? This insight occurred near the end of August. The following year several groups of investigators showed that PKC is the major target of phorbol ester. It was also shown that phorbol ester could cause translocation of PKC from the cytosol to the membrane. As a result, the traditional concept of tumor promotion originally proposed by

I. Berenblum at Oxford in 1941 was replaced by an explicit biochemical explanation providing for an understanding the role of PKC. Along this line of study, phorbol esters and membrane-permeant diacylglycerols have since then been used as crucial tools for the manipulation of PKC in intact cells, and have allowed the determination of the wide range of cellular processes regulated by this enzyme [4]. It was realized much later, however, that phorbol ester can bind to other cellular proteins, such as chimaerin and RasGRP [5], and potentially affect cell functions through additional targets.

Structural Heterogeneity and Mode of Activation

Although PKC was once considered as a single entity, molecular cloning and enzymological studies in the mid 1980s revealed the existence of multiple isoforms of PKC. The mammalian PKC family consists of at least ten isoforms encoded by nine genes. These isoforms are divided into three subgroups based on their primary structures and biochemical properties: classical PKC isoforms (cPKC), novel PKC isoforms (nPKC), and atypical PKC isoforms (aPKC) [6]. The PKC isoforms are conserved in a variety of species, including yeast, nematoda, fly, fish, and frog. On the one hand, the serine-threonine protein kinase region that is located in the C-terminal half does not show much difference and exhibits similar enzymatic properties when tested in *in vitro* systems. On the other hand, the N-terminal half of the enzyme molecule contains multiple characteristic functional domains, such as the C1 domain, which binds diacylglycerol or phorbol ester; the C2 domain, which binds phospholipid in the presence of Ca^{2+} ; and the OPR (octacosapeptide repeat) domain, which is involved in protein-protein interaction. The structural feature and multiple functional domains of the PKC isoforms are well investigated, as documented in excellent reviews [7,8]. In addition, several protein kinases that share kinase regions closely related to the PKC family are isolated and characterized [9]. These include protein kinase N (PKN or PRK), protein kinase D (PKD or PKC μ), and protein kinase B (PKB, Akt or rac-PK). The N-terminal regions of these enzymes contain multiple distinct functional domains such as PH and HR1 domains.

Structural analysis also made it clear that the mode of activation of the PKC family is far more complicated than we initially had thought. Newton [8] has shown that the newly synthesized kinase is catalytically inert and is regulated by phosphorylation by itself and also by other kinases, including PDK1 and related enzymes. A unique cross-talk thus emerged between the PKC signal pathway and one branch of the inositol phospholipid 3-kinase pathway that was described first by L. Cantley in the mid-1980s [10]. Another cross-talk with tyrosine kinase pathway for the activation of PKC is becoming clearer. PKC was initially recognized as an enzyme that can be activated by limited proteolysis, but later this proteolysis was recognized as a process of downregulation. More recently, however, the PKC δ -isoform is proposed to be a target of caspase 3 for its activation during apoptosis.

Translocation and Multiple Lipid Mediators

The specific functions of individual PKC isoform have been studied for many years, but whether the isoforms exert functional redundancy or functional specialization remains unclear, although some of them obviously play unique specific roles (see PKC minireview series, isoform-specific functions, *J. Biochem.* 2002–2003).

In addition to phospholipase C, phospholipase A2, phospholipase D, and sphingomyelinase appear to be indispensable players in signal transduction. In fact, it becomes increasingly clear that fatty acids, lysophospholipids, ceramide, and other lipid products may play roles in cell signaling, as described elsewhere [6] and in this chapter. In addition, the products of phosphatidylinositol 3-kinases play key roles in the transmembrane control of cellular processes as proposed by Toker and Cantley [10]. Multiple lipid mediators produced in membranes may recruit various protein kinases and other signal molecules to “lipid rafts” through lipid-lipid, lipid-protein, and protein-protein interactions. The lipid-mediated translocation of protein kinases to selective intracellular compartments such as plasma membrane, Golgi complex, and cell nucleus represents an essential step for stable access to their substrate proteins. It is attractive to surmise, then, that the N-terminal half of the enzyme molecule with multiple membrane-binding domains governs the enzymatic activity as well as the functional specificity of the C-terminal half. It is curious that such lipid-mediated translocation of PKC isoforms to membranes sometimes shows oscillation back and forth from the cytosol to the membrane. The mechanism of this oscillation is not clear, but lipid mediators appear to oscillate after receptor stimulation, presumably due to a repetitive feedback mechanism. The destination and reversibility of such translocation appear to differ with the isoform, lipid mediator, and cell type. The dynamic behavior of the PKC isoforms and related kinases can be visualized with the enzymes fused to green fluorescence protein.

Conclusion

In the last decade, our knowledge of the PKC family and related enzymes as well as the lipid mediators derived from membrane phospholipids has expanded enormously. It appears that the enzymes anchor to specific protein complexes through interaction with some adapter proteins, as directed by multiple lipid mediators. Such interactions may be essential for the function of each protein kinase at selective intracellular compartments. Further exploration of the dynamic aspects of such lipid mediators and identification of interacting proteins may unveil more of the transmembrane control of physiological and pathological cellular processes.

Type I Phosphatidylinositol 4-phosphate 5-kinases (PI4P 5-kinases)

K. A. Hinchliffe and R. F. Irvine

*Department of Pharmacology
University of Cambridge,
Cambridge, United Kingdom*

Introduction

Type I phosphatidylinositol 4-phosphate 5-kinases (PI4P5Ks) phosphorylate phosphatidylinositol 4-phosphate (PI4P) in the 5-position to form phosphatidylinositol 4,5-bisphosphate (PI4,5P₂). Because metabolic evidence suggests that *in vivo* the major route of synthesis of PI4,5P₂ in animal cells is by the 5-phosphorylation of PI4P, both in the plasma membrane [1,2] and the nucleus [3], type I PI4P5Ks are obviously the enzymes primarily responsible for regulating levels of this multifunctional lipid. In the test tube type I PI4P5Ks have been reported to catalyze other reactions. For example, both I α and I β isoforms can convert PI into PI5P [4], and PI3P into PI3,4P₂ [4, 5] or PI3,5P₂ [4], or even eventually PI3,4,5P₃ [4,5]. A PI4P5K from *Arabidopsis* shows a similar flexibility when expressed in insect cells [6]. However, the 5-phosphorylation of PI4P is the major activity of the Type I enzymes, and the physiological significance (or even natural occurrence) of these other reactions remains unclear. The exception is the demonstration that an endogenous type I PI4P5K (isoform unknown) makes a physiologically significant contribution to the synthesis of PI3,4,5P₃ from PI3,4P₂ in response to cell stress [7].

Several fuller reviews have discussed these enzymes directly or indirectly (e.g. [8–10]).

Basic Properties

Cloning

Our current understanding of type I PI4P5Ks is that there are three distinct mammalian isoforms, and no other obvious candidate emerges from a scan of the current human genome database. Nomenclature is rather confusing, as the type I β cloned from mouse [11] and the human isoform called type I α cloned shortly afterwards by Loijens and Anderson [12] are exact orthologues (and similarly, mouse type I α and human type I β). As the type I γ [13] has come from the same species (mouse) and lab as the original cloning of the I α and I β , we have in Fig. 1 used the mouse nomenclature. The isoform that Carvajal *et al.* [14] identified as the STM7 gene, mapping close to the Friedrich's ataxia gene (X25), is the human type I β isoform.

Loijens and Anderson [12] reported two splice variants of the human type I α and one of the type I β , and the mouse type I γ also has at least two splice variants [13].

Structure

The lineup in Fig. 1 tells a superficially simple story of a highly conserved central core, which consists of the catalytic

Figure 1 The sequences of the mouse type I PI4P5Ks are shown (Genebank accession numbers: Iβ, NM_008847; Iγ, NM_008844; Iα, NM_008846).

site interspersed with some loops of significant variation between isoforms, and then virtually no sequence similarity whatsoever between the isoforms at the C- and N-termini. The latter, in turn, implies diverse isoform-specific regulation, which has implications in the discussions about regulation, below.

There is also a close similarity in the catalytic “core” with the yeast gene *Mss4* [11,15], but again no similarity in other parts of the sequence between the yeast and the mammalian enzymes. There is a limited amount of similarity with the members of the *Fab1* family, both yeast and mammalian; these are PI3P 5-kinases, now given the name type III PIP kinases. Also, there is similarity in the catalytic core with the type II PI5P4Ks, and from this, and from the x-ray structure of the type IIβ PI5P4K [16], some deductions can be made about probable crucial residues for catalytic activity in

the type I enzymes. Ishihara *et al.* showed that lysine 138 of the type Iα PI4P 5K, which they identified as being in the putative ATP-binding site, is essential for catalytic activity [13].

Substrate Specificity

Kunz *et al.* [17] have shown that the substrate specificity of the type I and II PIP kinases is dictated largely by their “activation loop,” that is, transferring the activation loop from type IIβ PIPK into type Iβ (human) converted the type I enzyme into a PI5P4K activity (the activation loop of the orthologous mouse type Iα is residues 347–387 in Fig. 1). The converse (converting a type II PIPK into a PI4P5K activity by inserting a type I loop) was also observed. These observations have recently been taken a stage further by some elegant site-directed changes in this loop [18].

A remarkable finding is that changing a single residue, glutamate 362 in human type I β (equivalent to E362 in murine I α , see Fig. 1), to an alanine transformed its substrate specificity to that resembling a type II activity in that it would use PI5P as a substrate (though its activity against PI4P was diminished rather than lost). Kunz *et al.* have suggested that the activation loop might fold into an α -helix *in vivo* [18]. The structure of type II β PI5P4K [16] suggests how the activation loop might lie adjacent to the presumed active site where the PI5P substrate head-group binds. Although the activation loop did not crystallize [16], it seems likely that it will influence the orientation of two loops that link contiguous β strands; both of these loops contribute residues that interact with the inositol 1,5 bisphosphate moiety of the substrate [16].

Localization

These latter studies on substrate specificity [18] have implications also for the localization of the type I enzymes. So far, localization studies have suggested that they are all primarily in the plasma membrane (though see below for some possible regulation of this). The combined data of the two papers on the influence of the activation loop [17,18] demonstrated that changing the substrate specificity from favoring PI4P to PI5P also changes the localization of the type I β enzyme from plasma membrane to cytosol. This in turn implies that the plasma membrane localization is governed primarily by interaction with the PI4P substrate. This conclusion is subject to the caveat that these studies use transfection, which might saturate endogenous (protein) binding sites in locations other than the plasma membrane, and it is then the “excess” that is being visualized, bound to its substrate.

Chatah and Abrams have reported a different localization of human type I β PI4P5K, that is, perinuclear, with a translocation to the plasma membrane after prolonged activation of the cells [19]. Our own experience is that there is some variation in subcellular localization of transfected type I PI4P5Ks between cell types, and also some dependence on culture conditions and length of transfection time. There is still a lot to learn about the localization *in vivo* of endogenous type I PI4P5Ks and how it is controlled.

Regulation

Given their self-evident role in cell regulation, it is not surprising that type I PI4P5Ks have been found to be subject to a variety of regulatory influences. Only a brief summary of the literature to the end of 2001 is possible here.

Phosphatidic Acid

This lipid has long been known to be a potent stimulator of type I (but not type II) PIPKs [20]. Under some circumstances it can be essential—for example, Honda *et al.* could only see the effects of Arf-6 (below) if PA was supplied [21]. Jones *et al.* [22] have produced evidence that endogenous PA may be a significant regulator of type I PI4P5Ks *in vivo*.

PA is of course the product of PLD, itself an enzyme frequently tied in with PI45P₂ and with type I PI4P5Ks (e.g. [23]), and it may be that the two enzymes have a complex interregulatory relationship.

Monomeric G Proteins

There is abundant evidence that members of the Rho and Arf family can regulate type I PI4P5Ks, though to a significant degree we do not know the physiological veracity of these events, nor the isoform involved. The clear difference between the three isoforms (Fig. 1) raises the possibility that *in vivo* there may be significant specificity in the G-protein-PI4P5K interaction.

Arguably the strongest evidence supports regulation by members of the Arf family. For example, Honda *et al.* [21] purified from brain cytosol the major GTP γ S-dependent activator of murine type I α PI4P5K, and found it to be Arf-1. They went on to show that its localization in HeLa cells was not consistent with its being a natural regulator of type I α PI4P5K (Arf-1 being predominantly in the Golgi in these cells), but rather that Arf-6 fitted the bill under all the criteria they addressed. Martin *et al.* [24] also thought that Arf and not Rho (see below) was the endogenous regulator of a type I PI4P5K (isoform unknown). Brown *et al.* [25] have implicated Arf-6 in endosome formation, and showed that human Type I α PI4P5K can mimic the effects of a constitutively active Arf-6 (though again the endogenous Type I PI4P5K is unknown). Arf-1 may regulate PI45P₂ synthesis in the Golgi, though in these experiments it most likely recruited the type I PI4P5K from the cytosol [26,27].

There is also a reasonable case for type I PI4P5K activation by Rho family members, though it is sometimes confusing. Thus using the Rho-specific C3 *Botulinum* toxin, Chong *et al.* [28] implied that Rho regulates a type I PI4P5K activity in fibroblasts, whereas others have failed to see a Rho-type I PI4P5K interaction in experiments where it did interact directly with Rac [29]. Rac interaction with type I PI4P5Ks has been suggested in other experiments [30,31], and there are convincing data placing type I α or I β PI4P5Ks in the signaling pathway from the thrombin receptor, *via* Rac, to actin polymerization [32]. For the most part the evidence for Rho involvement still remains indirect [33]. Some of these simplistic contradictions may be due to differences in isoforms, though Honda *et al.* [21] stated that this was unlikely to be the reason they could not see an effect of Rho in their experiments. An interaction with RhoGDI has also been reported [31], and we think that a fair summary of the state of play is that the involvement of monomeric G-proteins in regulation of type I PI4P5Ks is real, and important, but incompletely understood.

Phosphorylation

Several protein kinases have been reported to associate with or regulate type I PI4P5Ks; for example, casein kinase I in *S. pombe* [34], Rho-kinase [35] (which might explain some of the contradictions about Rho, though see ref [33]),

and PKC μ (a.k.a. PKD) [36]. Also, Park *et al.* [37] showed that all three type I PI4P5Ks can be negatively regulated by PKA, and also suggested that receptor activation led to a dephosphorylation (and thus activation) by an uncharacterized mechanism that may involve PKC. Wenk *et al.* [38] have shown a stimulation-dependent dephosphorylation of type I γ PI4P5K in synapses (where it is the major type I isoform). Another intriguing possible regulatory mechanism has been suggested by Itoh *et al.* [39]. All three isoforms of type I PI4P5K are capable of autophosphorylation, an activity that is stimulated by PI and that leads to an inhibition of the enzyme's activity against PI4P. The physiological relevance of this awaits further study, as does the even more intriguing (and as yet untested) possibility that, like some of the type I PI3Ks [40], type I PI4P5Ks might phosphorylate other proteins.

Other Regulation Mechanisms

Mejillano *et al.* [41] have suggested that human type I α PI4P5K is cleaved by caspase during apoptosis, an event that, because they also suggest PI45P₂ to be anti-apoptotic, serves as part of the amplification of the apoptotic process once it has started. Recently, Barbieri *et al.* have shown an isomeric specificity for the involvement of type I PI4P5Ks in EGF receptor-mediated endocytosis [42], in that the mouse type I β PI4P5K was required but the type I α was not. How the type I β is regulated in this process is an intriguing question for further exploration.

Function

The physiological role of type I PI4P 5Ks is self-evidently well established (in contrast with the more enigmatic type II PI5P 4-kinases; see the next chapter by Rameh), because their primary function is to synthesize PI45P₂. Thus the question, what is the function of type I PI4P 5Ks, is essentially the same as the question, what is the function of PI45P₂. This is now a huge topic, with upwards of 20 suggested physiological functions (e.g. see [8,10] for reviews) and therefore is outside the scope of this short review.

Type 2 PIP4-Kinases

Lucia Rameh

*Boston Biomedical Research Institute,
Watertown, Massachusetts*

Introduction

The type 2 PIP4-kinase family of enzymes appeared relatively late in the evolution of eukaryotes. Homologous to the type 1 PIP5-kinases, they also catalyze the synthesis of phosphatidylinositol-4,5-bisphosphate (PtdIns-4,5-P₂). However, the type 2 PIP4-kinases are 4-kinases that use phosphatidylinositol-5-phosphate (PtdIns-5-P) as substrate, while the type 1 are 5-kinases that use phosphatidylinositol-4-phosphate (PtdIns-4-P) as substrate. Unlike type 1 PIP5-kinases, type 2 PIP4-kinases are not found in yeast (*S. cerevisiae* and *S. pombe*), but they are present in lower multicellular eukaryotes (such as *C. elegans*). Thus, the type 2 PIP4-kinases probably diverged from the type 1 PIP5-kinase to fulfill a specialized but essential function in multicellular organisms. Despite the fact that the type 2 PIP4-kinases were the first phosphoinositide kinases to be isolated, cloned, and crystallized, their purpose in cells still remains elusive. Type 2 PIP4-kinases appear to be regulated by extracellular factors, which suggests a role for these enzymes in cell-cell signaling. Here I review the history of the type 2 PIP4-kinases along with their structure and regulation. I present their potential roles in phosphoinositide metabolism and in the transduction of extracellular signals.

History

The kinases capable of synthesizing PtdIns-4,5-P₂ were first purified from erythrocytes in the late 1980s [1]. Two distinct activities, type 1 and type 2, were separated and initially distinguished from each other based on biochemical and immunogenic characteristics [2]. In the literature prior to 1997, type 1 and type 2 PIP-kinases were assumed to carry out the same reaction-conversion of PtdIns-4-P to PtdIns-4,5-P₂. In fact, they were first named PtdIns-4-P 5-kinases.

In 1997, a surprising observation led to the realization that the type 2 PIP-kinases actually produce PtdIns-4,5-P₂ by phosphorylating the 4 position of PtdIns-5-P (a contaminant in commercial PtdIns-4-P) [3]. This observation demonstrated that PtdIns-4,5-P₂ can be synthesized through two independent pathways. The pathway catalyzed by the type 1 PIP5-kinase uses PtdIns-4-P as intermediate and is referred to as the canonical pathway for PtdIns-4,5-P₂ synthesis. The pathway catalyzed by the type 2 PIP4-kinase uses PtdIns-5-P as intermediate and is referred to as the alternative pathway for PtdIns-4,5-P₂ synthesis, because it accounts for only a fraction of the total PtdIns-4,5-P₂ in cells. PtdIns-5-P levels in cells are very small when compared to PtdIns-4-P and cannot be easily detected via conventional HPLC separation protocols [3]. For this reason, PtdIns-5-P was not known to exist *in vivo* prior to this discovery. *In vitro*, the type 2 PIP4-kinases can also convert PtdIns-3-P to PtdIns-3,4-P₂, but PtdIns-5-P is the preferred substrate (50-fold better) [3]. In summary, it is now clear that the type 1 and 2 PIP-kinases have different biological and metabolic functions in cells, even though they both synthesize the same lipid product.

Structure

The domain structure of the type 2 PIP4-kinase protein is fairly simple (Fig. 1). Its predicted molecular weight is approximately 47 kDa, but the α and β isoforms migrate with apparent molecular weight of 55 kDa in SDS-polyacrylamide gels. The kinase domain is located in the carboxy-terminal portion of the protein and accounts for most of the protein. The amino-terminal portion of the protein is involved in dimerization. Crystals of the type 2 β PIP4-kinase revealed that these enzymes have structures similar to protein kinases. The homodimer forms an elongated disc shape and a large flat surface containing the two catalytic pockets of the subunits [4].

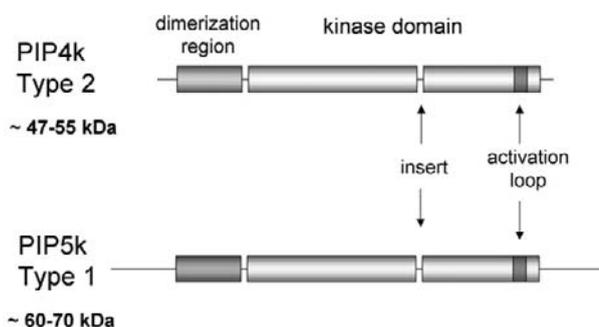

Figure 1 Structure of the type 2 and type 1 PIP-kinases.

A high concentration of positive residues on this flat surface suggests that this region is involved in membrane interaction through electrostatic forces. The substrate pocket is not as deep as protein kinase's substrate pocket, suggesting that the homodimer can float across the surface of membranes and phosphorylate PtdIns-5-P without a necessity for the lipid to significantly protrude from the membrane [4].

The kinase domain of the type 1 and the type 2 PIP-kinases are both interrupted by an insert that does not resolve in the type 2 crystal structure. The type 1 and type 2 are 35 percent identical at the kinase domain. However, the sequence of the type 1 and type 2 PIP-kinases are significantly divergent at a stretch of about 25 amino acids in the region of the kinase domain that corresponds to the activation loop of protein kinases. This region is highly conserved between the different isoforms of a given isotype. Anderson and collaborators showed that this activation loop region is sufficient to determine substrate specificity to the type 1 and type 2 PIP-kinases [5]. When the activation loop of the type 1 PIP5-kinase was swapped with the activation loop of the type 2, the chimeric enzymes lost their original substrate specificity and acquired the catalytic properties of the donor enzyme.

Type 2 PIP4-Kinase Isoforms

There are three isoforms of the type 2 PIP4-kinase in mammalian cells, namely the α , β , and γ isoforms [6–8]. At the protein level, the α and β isoforms are 83 percent identical and the γ isoform is about 60 percent identical to either one of them. All isoforms are ubiquitously expressed, but the α isoform is predominantly found in brain and platelets, the β isoform in brain and muscle, and the γ isoform in brain and kidney. Type 2 PIP4-kinase orthologs are present in the *C. elegans* (F535H12.4) and *Drosophila* (CG17471) genomes. Even though the biochemical properties of the products of the *C. elegans* and *Drosophila* genes have not yet been demonstrated, they are likely to be enzymatically active, based on conservation of critical residues in the active site. Because this gene family has been conserved from worms to humans, it is likely that the type 2 enzymes serve an important function in multicellular organisms. Similarities between the type 1 and type 2 PIP-kinases suggest that they have a common ancestor.

Regulation

The levels of PtdIns-4,5-P₂ in cells can be affected by extracellular signals, thereby suggesting that the activity of PIPkinases may be regulated [9–11]. Although the mechanisms by which the type 2 PIP4-kinases are regulated in cells are not completely clear, the existing data suggest that subcellular localization, interaction with membrane receptors, phosphorylation, and substrate availability are important factors.

Subcellular Localization

The first indication that the type 2 PIP4-kinases respond to extracellular factors came from studies in platelets. Thrombin-stimulated aggregation of platelets induced the redistribution of type 2 PIP4-kinase to the cytoskeleton [12]. This phenomenon correlated with increased cytoskeleton-associated PIP-kinase activity and increased levels of cytoskeleton-associated PtdIns-4,5-P₂. This thrombin-stimulated PIP4-kinase re-localization to the cytoskeleton was mediated by integrins, and the results suggested a role for this enzyme in controlling cell morphology and adhesion.

The subcellular localization of the type 2 PIP4-kinases (α and β) was also examined in fibroblasts by immunofluorescence and by expression of GFP-tagged fusion proteins. A surprising finding was that a fraction of these enzymes, together with the type 1 PIP5-kinases, was present in the nucleus, in structures that appear as nuclear speckles and contain pre-mRNA processing factors [13]. In a different study, the type 2 β was found in the nucleus and cytosol, but the α was found exclusively in the cytosol [14,15]. Mutations in the β isoform revealed that α helix-7 of type 2 β is necessary for its nuclear localization. The function of the type 2 PIP4-kinase in the nucleus remains to be determined. Nonetheless, many studies have indicated that phosphoinositide metabolism in the nucleus is an active process.

Interaction with Membrane Receptors

The type 2 β isoform was first cloned from a yeast two-hybrid screen by using the p55/tumor necrosis factor (TNF) receptor as bait [7]. Later, it was also shown to associate with the EGF receptor and with ErbB2 [16]. Association with the TNF receptor is specific for the p55 subunit and involves the juxta-membrane region of the receptor. Very little is known about how these interactions affect type 2 PIP4-kinase activity. It is possible that association with receptors may bring PIP4-kinase in close proximity with its substrate or with other regulatory proteins. Association with receptors is independent of ligand stimulation, thus it is not clear whether PIP4-kinase can be regulated by TNF α , EGF, or neuregulin stimulation or whether it participates in signaling by these growth factors.

More recently, the type 2 α PIP4-kinase was shown to be present in bovine photoreceptor rod outer segments (ROS), a compartment of retinal photoreceptor cells in which

phosphoinositide metabolism is active and responsive to light stimuli [17]. It is interesting that in tyrosine-phosphorylated ROS, the type 2 enzyme can be precipitated with anti-phosphotyrosine antibodies. The type 2 protein itself does not seem to be phosphorylated in these preparations, indicating rather that it associates with phosphotyrosine-containing proteins. These results suggest that receptor tyrosine kinases may regulate type 2 PIP4-kinase activity, although the phosphotyrosine containing partner of the type 2 PIP4-kinase has not been identified in these studies. Furthermore, these studies indicate that the type 2 enzymes may have a role in the transduction of signals initiated by light. Further analysis will be necessary to confirm these hypotheses.

Phosphorylation

The type 2 α PIP4-kinase present in platelets was shown to be phosphorylated on serine and threonine residues [18]. Unlike other lipid kinases, such as the type 1 PIP5-kinase and PI3-kinases, the type 2 PIP4-kinase is not autophosphorylated [19]. The protein kinase CK2 was identified as a PIP4-kinase kinase and shown to phosphorylate Serine 304 (S304), a residue that is not conserved in the β and γ isoforms [20]. The phosphorylation state of S304 in resting versus activated platelets has not been determined. Since CK2 is a constitutively active kinase in cells, it is not clear whether S304 is involved in PIP4-kinase regulation in response to extracellular factors.

The type 2 γ isoform was also found to be phosphorylated [8]. In polyacrylamide gels, this isoform migrates as a doublet, and the upper band was shown to be phosphatase-sensitive. *In vivo* labeling of cells with [32 P]-phosphate demonstrated that this enzyme is phosphorylated on serine and threonine but not on tyrosine. The phosphorylation state of the type 2 γ changes in response to various signals, including EGF and serum. This is strong evidence that the type 2 PIP4-kinases may be regulated by extracellular signals. However, the exact role of phosphorylation on the type 2 γ activity in cells remains to be determined.

Substrate Availability

The levels of PtdIns-5-P in cells are comparable to the levels of 3'-phosphorylated phosphoinositides, such as PtdIns-3-P, but are much lower than the levels of PtdIns-4-P [3]. This suggests that the availability of PtdIns-5-P substrate may be the limiting step in the production of PtdIns-4,5-P₂ by the type 2 PIP4-kinases. Although the type 2 PIP4-kinases are subject to posttranslational modifications and protein-protein interactions, no direct effect on kinase activity was reported, as discussed above. In addition, expression of these PIP4-kinases in bacteria results in active enzymes (except for the type 2 γ isoform) and indicates that the type 2 α and β may be constitutively active in cells. Therefore, it is possible that the local and temporal activation of the alternative pathway for PtdIns-4,5-P₂ synthesis is dependent upon PtdIns-5-P synthesis and the co-localization of type 2 enzyme

with this substrate. PtdIns-5-P levels in cells were shown to be regulated by thrombin, by cell cycle progression, and by serum stimulation ([21,22] and personal unpublished data). However, the pathways for PtdIns-5-P synthesis *in vivo* have not been determined. *In vitro* PtdIns-5-P can be generated through phosphorylation of PtdIns by 5'-kinases, such as the type 1 PIP5kinase [23] and PIKfyve [24], or by dephosphorylation of PtdIns-4,5-P₂ by SHIP [3].

Putative Models for the Function of the Type 2 PIP-Kinases

Despite more than a decade of research on type 2 PIP4-kinases, the biological role of the alternative pathway for PtdIns-4,5-P₂ synthesis is not clear. Nevertheless, it is clear that the type 1 and the type 2 PIP-kinases have nonoverlapping biological functions. For example, overexpression of the type 1 PIP5-kinase, but not the type 2, leads to a dramatic reorganization of actin cytoskeleton [25].

Pulse labeling of phosphoinositides in cultured cells has indicated that the phosphate at the 5' position of the inositol ring is incorporated last in the majority of PtdIns-4,5-P₂ synthesized *in vivo* [26]. Therefore, the type 2 PIP-kinase is not involved in maintaining the bulk of the PtdIns-4,5-P₂ in cells. At this point we can only speculate on the roles for this enzyme in phosphoinositide metabolism and cell signaling. Here are a few possibilities:

Model 1: to Regulate the Synthesis of Specific Pools of PtdIns-4,5-P₂ in Cells. One possibility is that the type 2 PIP4-kinases may contribute to PtdIns-4,5-P₂ synthesis in specific subcellular compartments where PtdIns-5-P is present (model 1, Fig. 2). This would permit the regulation of local synthesis of PtdIns-4,5-P₂ independent of the bulk of PtdIns-4,5-P₂ synthesis. Even though total PtdIns-4,5-P₂ levels in cells are high, there are reports that demonstrate that a large fraction of cellular PtdIns-4,5-P₂ is unavailable [27]. For instance, the PtdIns-4,5-P₂ synthesized through the alternative pathway could be the main source of substrate for the

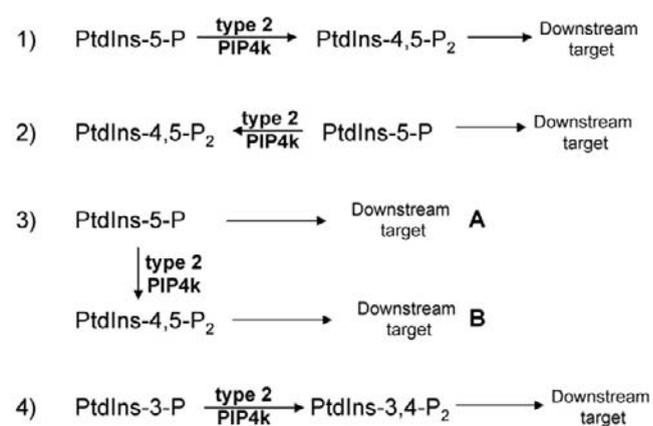

Figure 2 Putative models for the type 2 PIP4-kinase function in cells.

enzyme PLC γ to generate IP $_3$ and diacylglycerol, despite the availability of PtdIns-4,5-P $_2$ in the cell.

Model 2: to Regulate the Levels of PtdIns-5-P in Cells. As discussed above, PtdIns-5-P levels in cells are small and comparable to the levels of other signaling phosphoinositides. This observation raises the possibility that the important function of the type 2 PIP4-kinases is to get rid of PtdIns-5-P rather than generate PtdIns-4,5-P $_2$. This implies that PtdIns-5-P has a specific role in cells that may not be related to its role as an intermediate for PtdIns-4,5-P $_2$ synthesis. PtdIns-5-P could be a signaling molecule with specific downstream targets or a substrate for other enzymes such as PI 3-kinases. In this case, the function of the type 2 PIP4-kinase could be to assure that the levels of PtdIns-5-P are kept low and tightly regulated (model 2, Fig. 2). New data showing that PtdIns-5-P can be regulated by extracellular factors make this an attractive model.

Model 3: to Coordinate PtdIns-5-P Consumption with PtdIns-4,5-P $_2$ Synthesis. Models 1 and 2 are not mutually exclusive and it is possible that PtdIns-5-P and PtdIns-4,5-P $_2$ generated through PtdIns-5-P can trigger opposite cellular responses. In this model, the type 2 PIP4-kinase could serve as a switch between these two modes of signaling, necessary to assure that the termination of the signal generated by PtdIns-5-P is coupled to the initiation of the PtdIns-4,5-P $_2$ signal (model 3, Fig. 2).

Model 4: to Regulate the Synthesis of PtdIns-3,4-P $_2$ in Cells. The type 2 PIP-kinase could possibly be responsible for PtdIns-3,4-P $_2$ synthesis in cells, independent of PtdIns-3,4,5-P $_3$ (model 4, Fig. 2). In this case, PtdIns-3-P would be the major substrate for type 2 PIP4-kinases. This model is unlikely, based on the strong preference that these enzymes have for PtdIns-5-P.

Conclusion

Despite new biochemical, genetic, and structural information that has been acquired in recent years, the type 2 PIP4-kinase family remains a mystery to cell biologists who are trying to identify the physiologic role for the alternative pathway for PtdIns-4,5-P $_2$ synthesis, catalyzed by these lipid kinases. Future experiments involving inactivation or suppression of the type 2 activity in cell or animal models are likely to shed a light on this intriguing question.

Introduction

Engagement of a great variety of cell surface receptors triggers the activation of phosphoinositide 3-kinase (PI3K). The lipid products of PI3K serve as second messengers by interacting with phosphoinositide-binding domains in certain cytoplasmic proteins, thereby recruiting these “PI3K effectors” to specific sites in cellular membranes. PI3K and its effectors have been implicated in diverse cellular functions, including vesicle trafficking, cell proliferation, survival, cytoskeletal remodeling, migration, and glucose uptake. The importance of PI3K signaling in cellular and organismal function has been illustrated by the striking phenotypes of animals with genetic perturbations of PI3K signaling.

This chapter is intended to provide a brief summary of PI3K signaling with an emphasis on recent advances. The reader is referred in the text to several excellent reviews that provide more detail on specific topics.

The Enzymes

Phosphoinositide 3-kinase (PI3K) isoforms have been divided into three classes that differ in subunit structure, substrate selectivity, and regulation [1,2]. Class I PI3Ks exist as heterodimers with a tightly bound regulatory subunit (Fig. 1). In addition to the kinase domain, each class I catalytic subunit possesses a Ras-binding domain, a C2 domain for interaction with phospholipid membranes, and a helical “PIK” domain that is also conserved in PtdIns-4-kinases. In a landmark paper describing the crystal structure of the p110 γ isoform, Walker and colleagues showed that the helical domain acts as a scaffold or spine on which the other

three functional domains are organized [3]. This report also confirmed that the kinase domain is similar in structure to protein kinases, as predicted from primary sequence comparison and limited protein kinase activity of PI3K enzymes. The shape of the substrate binding pocket helped explain the selectivity for phosphoinositide recognition and the likely basis for differential recognition of single and multiply phosphorylated substrates by different PI3K classes. Subsequent structural work from this group has clarified the mode of binding of various PI3K inhibitors to the active site of p110 γ and has provided evidence for allosteric activation by Ras [4,5].

Class I PI3Ks are further subdivided by their modes of regulation. The class I_A subgroup (p110 α , p110 β , and p110 δ) associates with regulatory subunits (p85 α , p55 α , p50 α , p85 β , or p55 γ) that have multiple modular protein-protein interaction domains (Fig. 1). Class I_A PI3Ks function downstream of receptors with intrinsic or associated tyrosine kinase activity. Full activation of class I_A PI3K is thought to require occupancy of both Src-homology 2 (SH2) domains of the regulatory subunit by tyrosine phosphopeptides, along with the binding of catalytic subunit to Ras-GTP [6]. This normally occurs only in proximity with membrane-associated tyrosine kinases that also activate Ras. Other domains of the regulatory subunits may also contribute to activation or localization [1]. The class I_B enzyme (p110 γ) interacts with a distinct regulatory subunit, p101, with no significant homology to other known proteins (Fig. 1). The class I_B enzyme is activated by $\beta\gamma$ subunits of heterotrimeric G proteins [1,2] following engagement of G-protein-coupled receptors (GPCRs). The presence of a Ras binding domain within p110 γ suggests that this isoform also integrates signals from tyrosine kinase pathways.

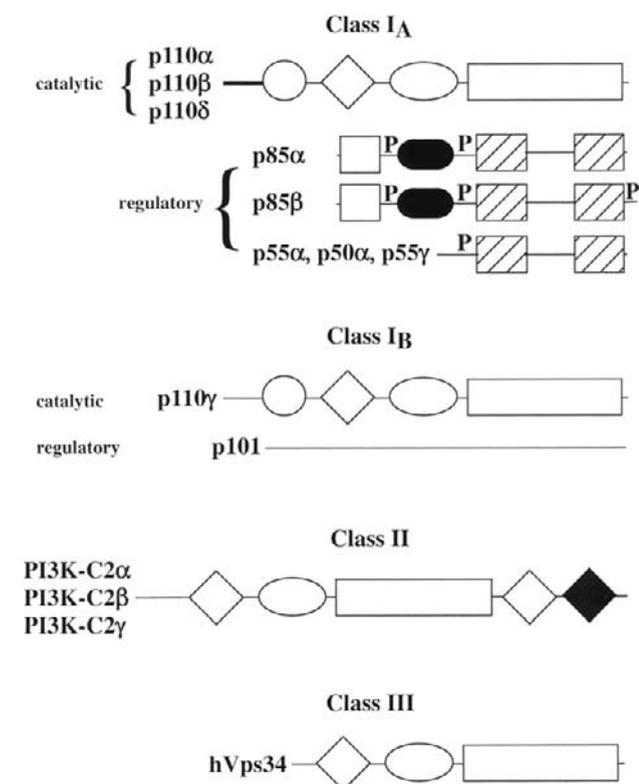

Figure 1 Schematic diagram of the domain structure of mammalian PI3Ks. The common names of the proteins are listed at the left of each structure (hVps34=human homolog of class III PI3K [Vps34] first cloned from *S. cerevisiae*). The three class I_A catalytic subunits associate with each of the five regulatory subunits without any apparent preference. p85 α , p55 α , and p50 α are alternative transcripts of a single gene. Open boxes, kinase domain; open ovals, PIK domain; open diamond, C2 domain; open circle, Ras-binding domain; open square, SH3 domain; hatched rectangle, SH2 domain; closed oval, RhoGAP-homology domain; closed diamond, PX domain; P, proline-rich motif.

Class II PI3Ks are distinguished by the presence of an additional C-terminal C2 domain and a PX domain (Fig. 1). Although comparatively little is known about class II PI3K regulation, there is growing evidence that these enzymes can be activated by extracellular signals [2]. Genes for class I and class II enzymes have been found in all multicellular animals. Class III PI3Ks are found in all eukaryotes from yeast to humans. These enzymes appear to have a housekeeping function related to vesicular transport and protein sorting [1,2]. They interact with an associated serine kinase in both yeast (vps15p) and humans (p150).

The Products

PI3Ks phosphorylate the 3'-hydroxyl of the D-*myo*-inositol ring of phosphatidylinositol (PtdIns) (Fig. 2A). Four D-3 phosphoinositides exist in mammalian cells: PtdIns(3)P, PtdIns(3,4)P₂, PtdIns(3,5)P₂, and PtdIns(3,4,5)P₃. The pathways of synthesis and degradation of these lipids have been reviewed recently in detail [2,7] and are summarized in Fig. 2B. PtdIns(3,4,5)P₃ is produced only by class I PI3Ks with PtdIns(4,5)P₂

as a substrate. PtdIns(3,4)P₂ can be generated from PtdIns(4)P by class I or class II PI3Ks, or by 5'-phosphatase action on PtdIns(3,4,5)P₃, or by a PtdIns(3) P-4-kinase. The signaling functions of PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ are well studied and will be discussed further below. Although PtdIns(3)P can be produced by all PI3Ks *in vitro*, the majority of PtdIns(3)P in cells appears to be made by class III PI3Ks and is detected primarily in endosomal vesicles [8]. PtdIns(3,5)P₂ is generated *in vivo* probably by a PtdIns(3)P-5-kinase and like PtdIns(3)P may be involved in vesicle trafficking.

Lipid-Binding Domains

Pleckstrin homology (PH) domains are small (~60aa) protein modules that mediate protein-lipid and protein-protein interactions. There is a growing list of PH domains shown to bind selectively to D-3 phosphoinositides [2,9]. It is important to note that PtdIns(4)P and PtdIns(4,5)P₂ are much more abundant in cellular membranes compared to D-3 phosphoinositides; thus, for a PH domain to be considered D-3-specific, the binding affinity for D-3 lipids must be considerably higher than the affinity for PtdIns(4)P or PtdIns(4,5)P₂. Subgroups have been identified that show greater affinity for either PtdIns(3,4,5)P₃ or PtdIns(3,4)P₂, with others that bind these lipids comparably [2,9]. A combination of biochemical and structural approaches has helped define features of PH domain primary sequence that determine selectivity for different D-3 phosphoinositides [2,10,11]. D-3-selective PH domains are found in a variety of proteins involved in signal transduction, some of which are discussed below.

PX domains are found in a diverse list of proteins involved in vesicle trafficking, protein sorting, and signal transduction [12,13]. Like PH domains, different PX domains exhibit selectivity for different phosphoinositides. Two components of the oxidative burst complex in phagocytes, p40phox and p47phox, possess PX domains that bind preferentially to PtdIns(3)P and PtdIns(3,4)P₂, respectively [14,15]. These interactions are thought to be important for targeting the cytosolic components of the NADPH oxidase complex to the phagolysosome, where they meet with the membrane-bound components p22phox and gp91phox to initiate the oxidative burst. The PX domain of class II PI3K (Fig. 1) binds selectively to PtdIns(4,5)P₂ [16]. The PX domain of cytokine-independent survival kinase (CISK) binds both PtdIns(3,5)P₂ and PtdIns(3,4,5)P₃ [17]. The crystal structure of the PX domain of p40phox bound to PtdIns(3)P shows that the lipid binds in a positively charged pocket and suggests how phosphoinositide binding specificity is determined [18].

The FYVE domain, originally identified in several yeast proteins, is a protein module that binds selectively to PtdIns(3)P. The structure of FYVE domains and their binding to PtdIns(3)P are distinct from the PH domain/D-3 lipid interaction [2,19]. Although some mammalian FYVE domain-containing proteins are involved in signal transduction,

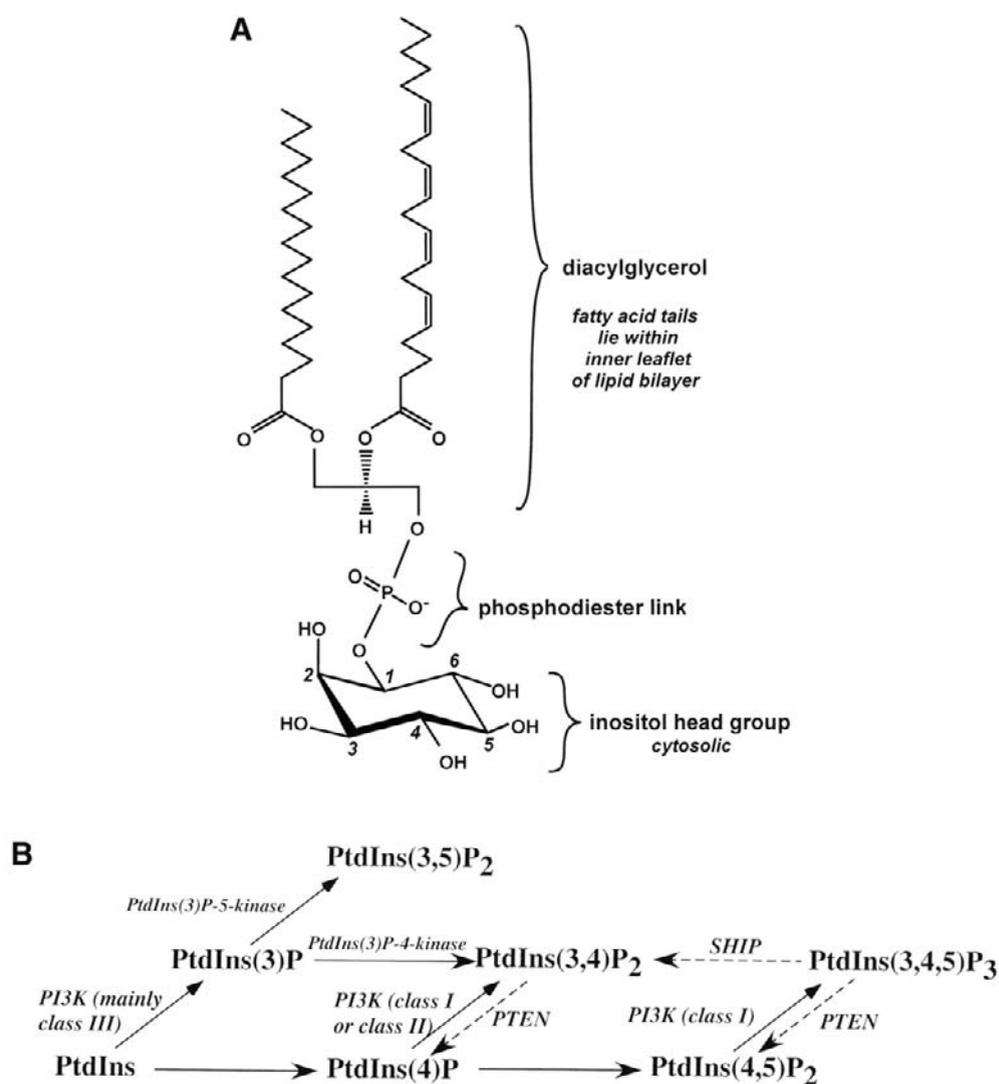

Figure 2 (A) Structure of *D-myo*-phosphatidylinositol (PtdIns). Note that the head group is positioned to interact with cytoplasmic molecules. Although free hydroxyls exist at positions 2–6, phosphorylation *in vivo* has only been detected at positions 3, 4, and 5. Reprinted with permission from the *Annual Review of Biochemistry*, Volume 70 ©2001 by Annual Reviews www.AnnualReviews.org. (B) Pathways of synthesis and degradation of *D-3* phosphoinositides. The major enzymes responsible for particular reactions are indicated. For simplicity, many of the enzymes involved in metabolism of other phosphoinositides are omitted.

the primary role of most mammalian and all yeast proteins with this module is in membrane trafficking.

A recent study described the use of phosphoinositide affinity matrices to purify and clone a number of *D-3* lipid-binding proteins [20]. Many of these were known proteins with PH or FYVE domains previously shown to bind to PI3K products, helping to validate the method. A novel protein with five PH domains, termed ARAP3, was found to possess distinct domains with GAP activity for Arf and Rho family G proteins. The ARAP family, along with other regulators of Arf and Rho function [2], may thus play an integral role in PI3K-regulated cytoskeletal changes (Fig. 3). This study also identified the Sec14 homology domain, originally identified in the yeast PtdIns transfer protein Sec14p, as a putative phosphoinositide-binding module.

Effectors and Responses

PI3K activation has been linked to distinct cellular responses downstream of different receptors. For example, PI3K is required for proliferation induced by numerous growth factors and cytokines, for glucose uptake triggered by insulin, and for cell migration in response to chemoattractants [1,2]. A major challenge in PI3K research has been to determine how specificity in signaling is achieved. With all the factors that can trigger increases in *D-3* phosphoinositides, how is it that different stimuli evoke distinct responses through PI3K?

There are several answers to this puzzle. One level of specificity is conferred by differential expression of PI3K isoforms in distinct tissues and cell types. For example, the p110 δ isoform is leukocyte specific, and antibody-blocking

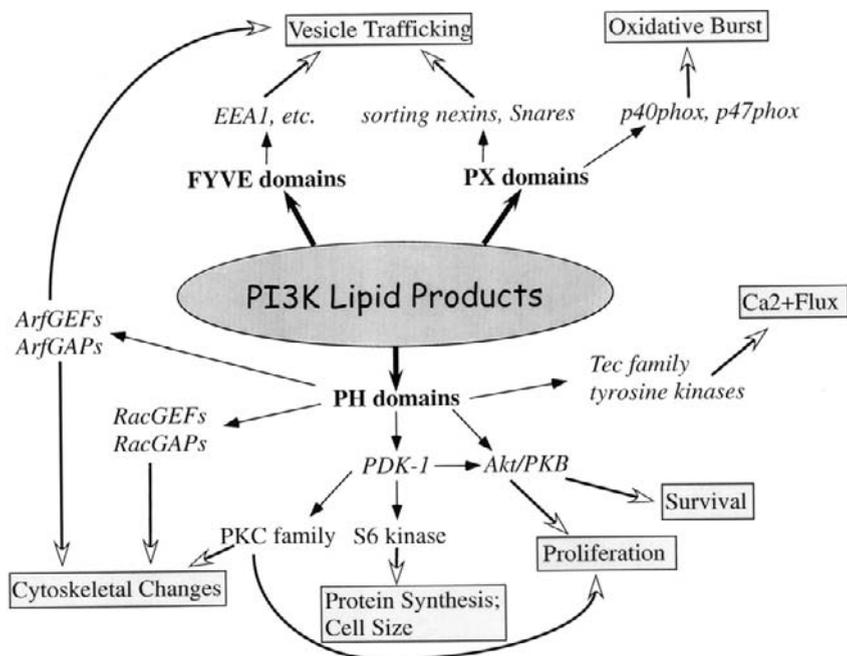

Figure 3 Overview of the effector proteins and signaling pathways regulated by PI3K lipid products. D-3 lipid-binding modules are in bold print. Functional responses are in boxes. The diagram shows selected effector proteins (in italics) whose lipid-binding domains have been well studied and whose activation has been linked to particular responses. GEF, guanine nucleotide exchange factor; GAP, GTPase-activating protein.

experiments suggest that in macrophages p110 δ is required for migration whereas p110 α is required for proliferation triggered by the CSF-1 receptor [21]. The regulatory isoform p50 α is expressed at highest levels in the liver, and loss of p50 α is associated with hepatocellular necrosis [22]. Similarly, some PI3K effectors are differentially expressed. An example is Btk, a PH domain-containing tyrosine kinase expressed primarily in B lymphocytes and mast cells. Mice lacking either Btk or the predominant class I_A regulatory isoform, p85 α , exhibit similar defects in B cell development and function [23, 24]. Another factor in signaling specificity could be the compartmentalization of PI3K activation. In other words, distinct localization of receptors in membrane subdomains affects the pool of PI3K substrates and effectors utilized. D-3 lipids accumulate at the leading edge of cells migrating in response to chemoattractants, thus resulting in localized activation of PI3K effectors [25,26]. Finally, full activation of a given PI3K effector may require synergy with other signals, which may be differentially provided by distinct receptors. For example, full activation of Btk requires phosphorylation by Src family tyrosine kinases that are also activated by B cell antigen receptors [27].

Figure 3 summarizes current knowledge of the linkage of certain PI3K effectors to distinct responses. It is important to note that this diagram is simplified for clarity, and some effectors have been linked to additional functions. A central player in many responses to PI3K activation is phosphoinositide-dependent kinase-1 (PDK-1) [28]. This serine/threonine kinase has a PH domain that binds both PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂. Current evidence suggests

that PDK-1 is constitutively active but only gains access to substrates upon binding D-3 lipids. Phosphorylation by PDK-1 contributes to the activation of many downstream kinases, including Akt/PKB, S6kinase, and some protein kinase C isoforms.

Phosphatases

The membrane-targeting signal provided by D-3 phosphoinositides can be modulated by the action of phosphoinositide phosphatases (PPases). PTEN (phosphatase and *tensin* homology deleted on chromosome 10) hydrolyzes the 3'-phosphate of PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂, effectively reversing the action of PI3K (Fig. 2A) [2,29]. Although the importance of PTEN is well established (see next section), it is not yet clear how PTEN is regulated or recruited to sites of PI3K activation. SHIP1 and SHIP2 are related 5'-PPases that contain N-terminal SH2 domains (SH2-containing Inositol polyphosphate 5-phosphatase). SHIPs can remove the 5'-phosphate from PtdIns(3,4,5)P₃ to produce PtdIns(3,4)P₂ (Fig. 2A) [2,30]. Hence, these enzymes may alter the spectrum of PI3K effectors recruited to the membrane rather than simply turning the signal off. The SH2 domains of SHIP1 and SHIP2 are selective for phosphotyrosines within a particular sequence context known as the immunoreceptor tyrosine-based inhibitory motif (ITIM). ITIMs are found in a number of receptors (for example, Fc γ RIIB) whose ligation attenuates signaling through antigen receptors [30].

Genetics

Pharmacological inhibitors of PI3K enzyme activity impair proliferation in a variety of cell systems [1,2]. Natural and engineered mutations in PI3Ks and lipid phosphatases have further established the fundamental role of PI3K signaling in promoting growth of normal and transformed cells. The transforming oncogene of an avian sarcoma virus, ASV16, encodes a membrane-targeted variant of p110 whose expression in cells causes accumulation of D-3 phosphoinositides [31]. A truncated variant of p85 α (termed p65), first isolated from a T-cell lymphoma, increases basal activity of class I_A catalytic subunits and promotes lymphoproliferation when expressed as a transgene in the T lineage [32,33]. Mice heterozygous for a disrupted PTEN gene exhibit a similar lymphoproliferative disorder [34,35]. Mice with homozygous loss of PTEN specifically in the T lineage develop autoimmune symptoms associated with spontaneously activated T cells that are resistant to apoptosis [36]. Inherited mutations in PTEN are the cause of three autosomal dominant cancer syndromes in humans: Cowden's disease, Lhermitte-Duclos disease, and Bannayan-Zonana syndrome [29]. Moreover, loss of PTEN function is seen in a large fraction of sporadic human cancers, especially glial, prostate, and endometrial tumors [29]. Mice lacking SHIP1 develop a myeloproliferative disorder and have lower activation thresholds for a variety of immune cell stimuli [30]. In addition to these examples of increased PI3K signaling promoting proliferation and tumorigenesis, there are also examples of decreased PI3K signaling causing impaired proliferation. Forced expression of PTEN in PTEN-deficient embryonic fibroblasts and tumor cells impairs growth by inducing cell cycle arrest and/or apoptosis [29]. Loss of the class I_A regulatory isoform p85 α in mice abrogates B lymphocyte proliferation in response to antigen receptor engagement, diminishes interleukin-4-mediated B cell survival, and reduces stem cell factor-driven mast cell growth [23,24,37,38]. These mice show impaired immune responses to T-cell-independent antigens, bacteria, and parasitic worms [24,38].

Genetic studies have also implicated PI3K signaling in responses to insulin and insulin-like growth factors. In *C. elegans*, a class I PI3K functions downstream of the insulin receptor homolog in a pathway that regulates both dauer entry and lifespan [39]. This pathway involves the worm orthologs of PDK-1 and Akt and is antagonized by PTEN. In mice, SHIP2 phosphatase is a critical modulator of insulin signaling as SHIP2-deficient mice show increased insulin sensitivity [40]. Based on these findings and a wealth of cell culture experiments, it was expected that mice deficient in class I_A PI3K would show insulin resistance. However, in every case examined, the opposite result has been observed. Mice lacking p85 α alone, or all p85 α gene products (including p55 α and p50 α), exhibit hypoglycemia and decreased glucose tolerance [41,42]. Mice lacking p85 α alone or p85 β also show increased insulin sensitivity [41,43]. Fibroblast experiments suggest that class I_A regulatory isoforms are expressed in excess of catalytic subunits, producing a "buffer" effect that

is overcome when regulatory subunit expression is reduced genetically [44]. However, it is not yet known whether this mechanism explains altered insulin sensitivity *in vivo*. Deletion of the mouse class I_A catalytic isoform p110 α causes early embryonic lethality, preventing the analysis of insulin signaling in these animals [45].

In *Drosophila*, class I PI3K acts downstream of the insulin receptor ortholog in a pathway that controls cell size [2,46]. Overexpression of class I PI3K in wing imaginal discs increases cell size and yields enlarged wings in the adult fly. Mutation of *Drosophila* PTEN has a similar effect. Conversely, mutation of class I PI3K genes or expression of dominant-negative PI3K reduces cell and wing size. PI3K signaling was also shown to regulate the size of mouse cardiac myocytes [47]. The critical downstream effectors of PI3K in the *Drosophila* system are Akt and S6K, a serine/threonine kinase that regulates protein synthesis [2,46]. These kinases are also regulated by PI3K signaling in mammalian cells (Fig. 3), but their role in controlling the size of cardiac myocytes or other cells has not yet been reported.

p110 γ , the class I_B isoform, is expressed primarily in leukocytes. Disruption of the mouse p110 γ gene causes defects in inflammatory responses that correlate with defective chemotaxis to GPCR ligands such as f-Met-Leu-Phe and C5a [48–50].

Summary

Signaling through PI3K is an evolutionarily conserved process that enables reversible membrane localization of cytoplasmic proteins. Three modular domains (PH, PX, and FYVE) that interact with D-3 phosphoinositides are broadly distributed among proteins of different function. The recruitment and activation of specific subsets of PI3K effectors in a receptor-specific and cell type-specific manner allows PI3K activation to be linked to different functional responses. Given the pleiotropic effects of pharmacological PI3K inhibitors, therapeutic modulation of PI3K signaling is likely to require targeting of specific effectors that govern particular responses.

Note Added in Proof

Since submission of this chapter, new mouse genetic models have yielded a number of important advances in the PI3K field. Of particular interest are studies demonstrating lymphocyte defects in mice lacking functional p110 δ [51–53], analysis of more tissue-specific PTEN knockouts (reviewed in ref. [54], also see [55]), studies showing a role for Akt and S6 kinase in regulation of mammalian cell and organ size [56,57], and a study establishing a role for GPCR signaling through the p110 γ isoform in cardiac muscle contractility [58].

PTEN

Introduction

PTEN (phosphatase and *tensin* homolog deleted on chromosome 10) was first identified as a tumor suppressor gene localized on chromosome 10q23. *PTEN* mutations are found at high frequencies in certain tumors, including endometrial carcinomas, gliomas, and breast and prostate cancers. Furthermore, germline mutations in the *PTEN* gene are found in the related autosomal disorders Cowden disease and Lhermitte-Duclos and Bannayan-Zonana syndromes. Biochemical and genetic analyses of *PTEN* and its role in these diseases have placed it in a group of gatekeeper genes essential for controlling cell growth and development [1–3].

Activity and Function

PTEN is a member of the protein tyrosine phosphatase (PTP) superfamily of enzymes characterized by the invariant Cys-x₅-Arg (Cx₅R) active site motif (Table I). However, unlike other PTP superfamily enzymes, *PTEN* utilizes the lipid second messenger phosphatidylinositol 3,4,5-trisphosphate (PIP₃) as its substrate [4]. This places *PTEN* as a negative regulator of phosphatidylinositol 3-kinase (PI3K) signaling [5]. *PTEN* has been reported to regulate signaling through Akt/PKB, PDK1, SGK1, and Rho GTPases and therefore as a modulator of a broad range of cellular processes [6,7]. Loss of

PTEN function can lead to tumor development through defects in cell cycle regulation, apoptosis, or angiogenesis.

Homozygous *PTEN*^{-/-} mice die before birth, and embryos display regions of increased proliferation and disturbed developmental patterning. Heterozygous *PTEN*^{+/-} mice are viable but spontaneously develop various types of tumors [3]. Cells from both *PTEN*^{-/-} mice and *PTEN*^{+/-} have constitutively activated Akt and are resistant to apoptotic stimuli. A direct role of *PTEN* and its lipid phosphatase activity in the regulation of Akt has been demonstrated in several tumor cell lines [2,3]. Furthermore, *PTEN*^{+/-} mice have a tendency of developing both T-cell lymphomas and autoimmune disorders. A role for *PTEN* in this postulated link between autoimmune disorders and cancers are further supported by studies of mice where *PTEN* is conditionally targeted in T cells [8].

Mice in which *PTEN* is conditionally deleted in neuronal brain cells develop macrocephaly as a result of increased cell numbers, decreased cell death, and enlarged soma size [9,10]. Targeted deletion early in brain development suggests a role for *PTEN* in controlling the proliferation and potency of stem cells, whereas restricted deletion of *PTEN* in postmitotic neurons does not result in increased cell proliferation, but rather causes a progressive enlargement of soma size resulting in enlarged cerebellum and seizures. It is of note that the abnormal phenotype of these mice resembles that of Lhermitte-Duclos disease, suggesting that loss of *PTEN* function is sufficient to cause this disease in humans.

Table I PTEN and Myotubularin-Related Genes in Human.

Name	Active site	C-terminal domains	Length (aa)	Chromosome	Disease
PTEN	IHC R AG K GG R ET	PDZ-binding	403	10q23.3	Multiple cancers, Cowden and Lhermitte-Duclos

Length of predicted protein products (amino acids) and chromosomal localization are listed for each gene. Conserved amino acids within predicted active site sequences are presented, including the catalytic cysteine (yellow) and arginine (light-blue), and non-catalytic basic (blue) and acidic (red) residues. Non-catalytic domains predicted for carboxy-terminal regions as well as related diseases are also listed.

A conserved role for PTEN as a PIP₃ phosphatase and negative regulator of PI3K signaling has also been demonstrated by genetic studies of *D. melanogaster* (dPTEN) and *C. elegans* (Daf-18). By balancing signals from the insulin receptor, dPTEN controls cell size and number in flies, whereas Daf-18 regulates metabolism and longevity in worms [11,12].

The crystal structure of PTEN has revealed several features that contribute to its unique substrate specificity [13]. A 4-residue insertion in one loop of the PTP domain results in the widening and extension of the catalytic pocket and enough space for the bulky PIP₃ headgroup. In addition, the two lysines (Lys125 and Lys128) within the Cx₅R active site sequence, as well as an upstream histidine (His93), coordinate the D1 and D5 phosphate groups of the inositol ring. Hence, the specificity of PTEN toward PIP₃ is generated by a larger active site pocket combined with the conserved residues within the Cx₅R active site. C-terminal to the PTP catalytic domain PTEN contains a Ca²⁺ independent C2 domain, two PEST sequences, and a PDZ-binding motif (Fig. 1). These domains are likely to play important roles in PTEN regulation (see below).

The human genome contains several PTEN-related genes, but so far little is known about their function. Most of these genes exhibit restricted expression pattern and/or sub-cellular localization different from PTEN and do not appear to regulate Akt phosphorylation. In that respect it is interesting

to note that these genes have a different active site sequence, which might suggest a different substrate specificity [14,15].

Regulation

The crystal structure of PTEN revealed an extensive interface between its PTP-domain and C2-domain, suggesting that membrane targeting and lipid phosphatase activity are interdependent [13]. This is further supported by the observation that mutations affecting this interface are frequently found in cancers [3]. *In vitro*, the C2-domain of PTEN binds phospholipids independent of Ca²⁺ and its structural characteristics predict a direct membrane association. Mutations in critical lipid binding residues inhibit the ability of PTEN to function as a tumor suppressor and cannot be rescued by artificial membrane targeting. Hence, both structural and functional analysis suggests that the C2-domain play a dual role of both membrane recruitment and positioning of the PTP-domain.

The extreme C-terminus of PTEN contains tandem PEST sequences and a consensus PDZ-binding domain. Whereas the regulatory role of the PEST sequences remain elusive, the PDZ-binding motif has been demonstrated to associate with several PDZ-domain containing proteins [3,16]. The identification of phosphorylation sites in the C-terminal tail of PTEN regulating PDZ-binding and

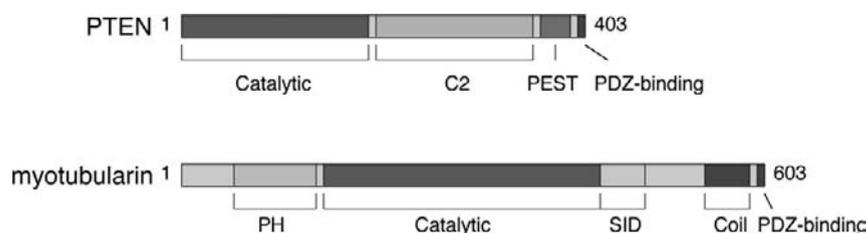

Figure 1 Structural features of PTEN and myotubularin phosphoinositide phosphatases. PTEN and myotubularin contain a catalytic domain that encompasses the CX_5R active site motif of PTP. In addition, both proteins possess several other domains/motifs that are likely to facilitate membrane association and protein-protein interactions. The C2 domain of PTEN is required for binding to lipid vesicles, whereas the carboxy-terminal PDZ-binding motif mediates interaction with PDZ-containing proteins. Phosphorylation in this region inhibits PDZ binding. Myotubularin contains a PH domain that may function to regulate membrane association. Furthermore, myotubularin contains a coiled coil motif as well as a putative PDZ-binding motif.

complex formation (Fig. 1) suggests additional levels of PTEN regulation [3,16].

Finally, several regulatory elements have recently been identified in the PTEN promoter, including binding sites for the tumor suppressors p53, early growth response-1 (Egr-1), and the peroxisome proliferator-activator receptor γ (PPAR γ) [17–19]. The inducible transactivation of PTEN by these genes leads to reduced Akt activity and increased cell survival.

Myotubularin: a Novel Family of Phosphatidylinositol Phosphatases

Myotubularin-related proteins constitute one of the largest and most highly conserved protein tyrosine phosphatase (PTP) subfamilies in eukaryotes [14,19]. The MTM family includes at least eight catalytically active proteins as well as five catalytically inactive proteins in human [14,20]. Phylogenetic analysis of MTM family proteins allow a division of myotubularin family onto six subgroups, which include the catalytically active MTM1/MTMR1/MTMR2, MTMR3/MTMR4, and MTMR6/MTMR7/MTMR8 enzymes, as well as MTMR5 (Sbf1), MTMR9 (LIP-STYX), and MTMR10/MTMR11/MTMR12 (3-PAP) inactive forms [14,20]. One gene from *D. melanogaster* and *C. elegans* corresponding to each of these subfamilies has been identified [14].

Phosphatase Activity

Myotubularin (MTM1), the first characterized member of this novel family, utilizes the lipid second messenger phosphatidylinositol 3-phosphate (PI(3)P) as a physiological substrate [21,22]. In addition, recent findings demonstrate that other MTM-related phosphatases MTMR1, MTMR2, MTMR3, MTMR4, and MTMR6 also dephosphorylate PI(3)P, a finding that suggests that activity toward this substrate is common to all active myotubularin family enzymes [23,24].

The consensus CX_5R active site motif of PTP/DSP (dual specificity protein phosphatase) is found in the myotubularin family proteins, and the sequence “CSDGWDR” is invariant

within all members of the active phosphatase subgroups. Unlike PTEN, in which two lysine residues within its active site (CKAGKGR) contribute to substrate specificity by interacting with the D1 and D5 phosphates of PIP₃, two aspartic acid residues are found in myotubularin family phosphatases. It is possible that interactions between the active site aspartic acid residues and phosphoryl groups at either the D4 or D5 position of the inositol ring may contribute to the high degree of specificity for PI(3)P found in MTM family enzymes.

One of the most notable characteristics of the human MTM family is the existence of at least five catalytically inactive forms, which contain germline substitution in catalytically essential residues within the PTP active site motif (Table I). Myotubularin-related inactive forms may function to regulate PI(3)P levels by opposing the actions of myotubularin phosphatases or directly affect the activity and/or subcellular localization of their active MTM counterparts [25].

Myotubularin Family and Human Diseases

To date, two myotubularin-related proteins have been associated with human disease. The myotubularin gene on chromosome Xq28, *MTM1*, is mutated in X-linked myotubular myopathy (XLMTM), a severe congenital muscular disorder characterized by hypotonia and generalized muscle weakness in newborn males [26]. Myogenesis in affected individuals is arrested at a late stage of differentiation/maturation following myotube formation, and the muscle cells have a characteristically large centrally located nuclei [26].

Mutations in a second MTM family member, *MTMR2* on chromosome 11q22, have recently been shown to cause the neurodegenerative disorder, type 4B Charcot-Marie-Tooth disease (CMT4B) [27]. CMT4B is an autosomal recessive demyelinating neuropathy characterized by abnormally folded myelin sheaths and Schwann cell proliferation in peripheral nerves.

Because these two highly similar genes, *MTM1* and *MTMR2* (64 percent identity, 76 percent similarity) utilize the same physiologic substrate, have a ubiquitous expression pattern, and are mutated in diseases with different target tissues and pathological characteristics, myotubularin and

MTMR2 may be subjected to differential regulatory mechanisms that preclude functional redundancy. Although their specific physiological roles are not known, a recent study has shown that developmental expression and subcellular localization of myotubularin and MTMR2 are differentially regulated, resulting in their utilization of specific cellular pools of PI(3)P [23].

Structural Features

In addition to the phosphatase domain, myotubularin-related proteins possess several motifs known to mediate protein-protein interactions and lipid binding. A PH domain, which was previously defined as a GRAM domain in myotubularin, is present in the N-terminal region of all myotubularin family members, including the catalytically inactive MTMs (Fig. 1). Although the physiologic relevance of this domain is not known, its presence in the myotubularin family lipid phosphatases suggests a role in membrane targeting of these proteins. A coiled coil motif is also present in all family members (Fig. 1) and may play a role in the regulation of MTM proteins through interactions with protein effectors and/or subcellular location. Some myotubularin family members have additional lipid-binding domains. For example, MTMR3 and MTMR4 contain a FYVE domain, and MTMR5 has an additional PH domain in its C-terminal region (Table I).

Although the role of the PH and FYVE domains in MTM function has yet to be determined, it is possible that they serve as targeting motifs to direct the lipid phosphatase domains to specific subcellular environments where PI(3)P is abundant. The physiologic function of myotubularin and related proteins in cell development and signaling processes remains unknown. Studies directed toward clarifying the regulation of myotubularin-related enzymes, as well as identifying downstream effectors, will be of significant value in understanding their roles in cell signaling and development.

SHIP Inositol Phosphate Phosphatases

Larry R. Rohrschneider

*Fred Hutchinson Cancer Research Center,
Division of Basic Sciences,
Seattle, Washington*

Introduction

The SHIP (*SH2* domain-containing inositol 5-phosphatase) class of cytoplasmic signaling proteins in higher eucaryotes currently includes a pair of distinct gene products, each encoding an N-terminal SH2 domain, a central amino acid region with inositol 5-phosphatase enzymatic activity, and a C-terminal tail region. The two proteins, named SHIP1 and SHIP2, designating their domain structure and sequence of discovery (gene symbols INPP5D and INPPL1, respectively), are currently the only known members of this family. However, extended family members include many more proteins with inositol phosphatase activity (such as PTEN, type II IP5P, OCRL, and the synaptojanins). A search of the human genome yields only a single orthologue for SHIP2 (Ch. 11q13.3, contig. NT_030106.2) whereas the human genomic sequence for SHIP1 (Ch. 2q37, contig. NT_030597.1) is still incomplete. This review will focus on the principal structural, biochemical, and biological features and familial relationships of the two, so far identified, SHIP proteins. Additional details can be found in recent reviews [1–3].

SHIP1 Structure, Expression, and Function

The 27 exons encoding the SHIP1 protein stretch along an approximately 100 kb region of the murine genome (Ch1, 57.0 CM, C4 to band C5), and are spliced into an approximately 5 kb mRNA as shown in Fig. 1 [4]. The largest SHIP1 protein product, encoded by the co-linear expression of all

genomic exons, results in a 1190-amino acid protein termed SHIP1 α . This prototypical product contains an N-terminal SH2 domain, an ~450 amino acid inositol 5-phosphatase enzymatic domain, and a C-terminal tail containing multiple motifs for binding potential effector proteins with PTB, SH2, and/or SH3 domains. The SH2 domain has binding specificity for the Y-phosphorylated YxxL motif [3], and the 5'-phosphatase enzymatic activity of the central domain converts PtdIns 3,4,5-P3 to PtdIns 3,4-P2 [5,6]. Either inositol 1,3,4,5-P4 or phosphatidylinositol 3,4,5-P3 can serve as substrate but must contain phosphate at the 3' position, suggesting that the substrate for SHIP1 is the end product of PI3K activity. Within the C-tail region, notable are the two NPXY motifs, which, when tyrosine phosphorylated, interact with the PTB domain of Shc [6,7]. The NPNY motif also interacts with p85/PI3K, and the Y within this motif plus the three adjacent amino acids comprise the canonical YIGM, which binds the C-terminal SH2 domain of the p85 most avidly [8,9]. The adapter protein, Grb2, contains two SH3 domains, and at least one interacts avidly with SHIP1, probably via one of the "PxxP" motifs in the C-terminal tail region [5,10].

The apparent molecular mass of SHIP1 α on SDS acrylamide gel electrophoresis is 145 kDa; however, a large number of additional SHIP-related proteins are detectable (by immunoprecipitation, for example). These additional proteins may be ascribed to spliced isoforms [3], usage of an alternative internal SHIP promoter [11], and C-terminal proteolysis, which affects each of the above protein products [12].

Three SHIP1 α isoforms result from three distinct splicing reactions (see Fig. 1), and two complete cDNAs and their

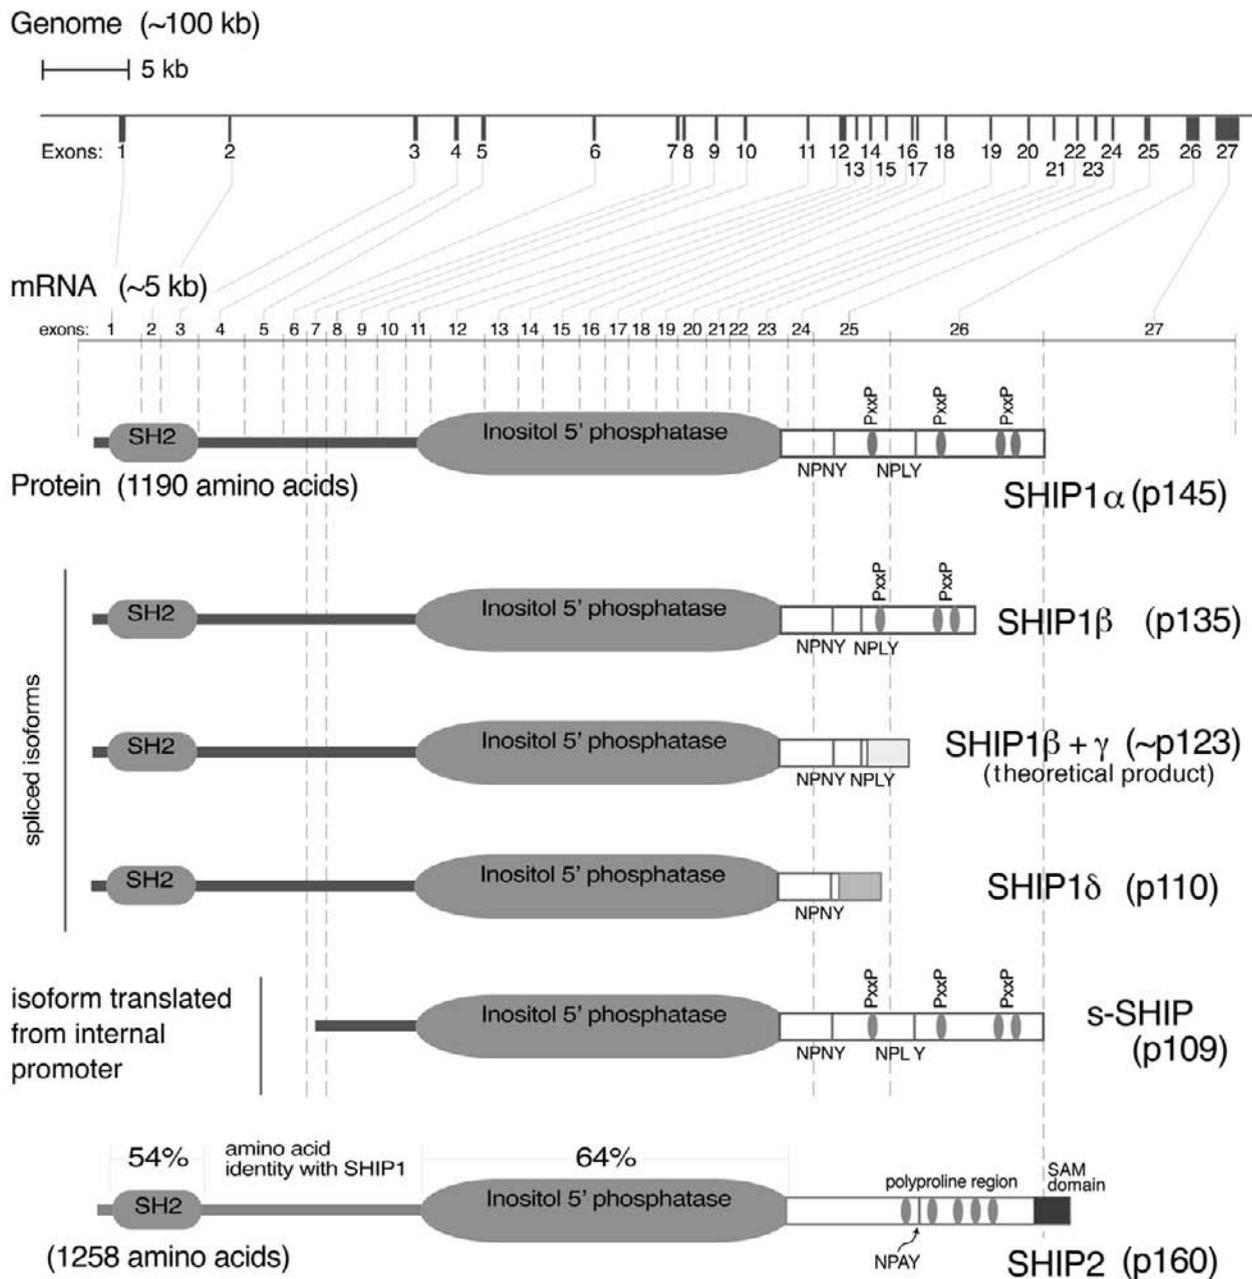

Figure 1 SHIP1 and SHIP2 proteins. The genomic organization of *ship1* is at the top with the mRNA and protein isoforms diagrammed below. At the bottom is the single known protein for SHIP2. See text for details.

protein products have been described for two of the spliced products (the β and δ isoforms) [4,9]. These splicing events, outlined in detail elsewhere [3], in general result in removal of one or several of the C-tail motifs required for binding PTB-, SH2-, or SH3-domain containing proteins. The splice within the $\beta + \gamma$ and δ isoforms results in addition of new amino acid sequences at the C-terminal end. The biological function of each shorter isoform is not completely understood.

Recent experiments have established the existence of an SH2-less form of SHIP1 [11]; this isoform is termed s-SHIP (GenBank AF184912) for stem- or short-SHIP. This protein probably results from the usage of a potential promoter region within intron 5 [11]. Transcription of s-SHIP originates at

least 44 nucleotides upstream of exon 6 and includes all downstream exons. Translation would probably not begin until exon 7, where the first ATG in the appropriate Kozak motifs is found. The β spliced product has been observed in s-SHIP (GenBank AF184913). In ES cells grown in LIF, s-SHIP is not tyrosine phosphorylated and is not associated with Shc. s-SHIP does, however, form a constitutive complex with Grb2 and is found in the membrane fraction of ES cells. The structure and expression (see below) of s-SHIP suggests it may have a function different from SHIP1 expressed in growth factor stimulated mature cells.

SHIP1 is expressed throughout hematopoietic cell development and tyrosine phosphorylated by a broad range

of cytokines and growth factors of blood cells [3,13,14]. Adult uterus and kidney express SHIP1 detectable by RT-PCR [4], and immunohistochemistry shows strong testis expression [14]. SHIP1 is located within the seminiferous tubules of the testis and exhibits an interesting expressional relationship to both SHIP2, also in these structures of the testis, and the well-defined sequence for spermatozoa development in this organ (discussed in the SHIP2 section). Within the hematopoietic program for blood cell development, the largest SHIP1 α product is found in more mature cells [9,13], especially in cell lines, and although numerous spliced isoforms are produced from the SHIP gene, their function and the cellular cues for their production are not understood. Some evidence suggests a developmental role [13]. The s-SHIP product is an exception, as good evidence exists for a function in primitive or stem cells of the blood [11]. s-SHIP is expressed only in very early progenitor or stem cells of the bone marrow and vanishes as cells mature. s-SHIP is also expressed in embryonic stem cell lines. The cDNA for s-SHIP predicts a “stem cell” promoter within intron 5 (see Fig. 1), and the correct size mRNA and protein are expressed in stem or progenitor cells. The exact function of s-SHIP in these cells is not known.
