Contributors xlv
Preface lxvii

CHAPTER 1

Cell Signaling: Yesterday, Today, and Tomorrow

Ralph A. Bradshaw and Edward A. Dennis

Origins of Cell Signaling
Enter Polypeptide Growth Factors
Cell Signaling at the Molecular Level
Lipid Signaling
Cell Signaling Tomorrow
References

PART I

INITIATION: EXTRACELLULAR AND MEMBRANE EVENTS

James Wells, Editor

Section A: Molecular Recognition

Ian Wilson, Editor

CHAPTER 2

Structural and Energetic Basis of Molecular Recognition

Emil Alexov and Barry Honig

Introduction
Principles of Binding
Nonspecific Association with Membrane Surfaces
Protein–Protein Interactions

Prospects
References

CHAPTER 3

Computational Genomics: Prediction of Protein Functional Linkages and Networks

15

Todd O. Yeates and Michael J. Thompson

Introduction
Approaches to Analyzing Protein Functions on a Genome-Wide Scale
Current Issues and Future Prospects for Computing Functional Interactions
References

CHAPTER 4

Molecular Sociology

21

Irene M. A. Nooren and Janet M. Thornton

Transmembrane Signaling Paradigms
Structural Basis of Protein–Protein Recognition
Conclusion
References

CHAPTER 5

Free Energy Landscapes in Protein–Protein Interactions

27

Jacob Piehler and Gideon Schreiber

Introduction
Thermodynamics of Protein–Protein Interactions
Interaction Kinetics
The Transition State
Association of a Protein Complex
Dissociation of a Protein Complex
Summary
References

11

<u>CHAPTER 6</u>		
Antibody–Antigen Recognition and Conformational Changes	33	
Robyn L. Stanfield and Ian A. Wilson		
Introduction		
Antibody Architecture		
Conformational Changes		
Conclusion		
References		
<u>CHAPTER 7</u>		
Binding Energetics in Antigen–Antibody Interfaces	39	
Roy A. Mariuzza		
Introduction		
Thermodynamic Mapping of Antigen–Antibody Interfaces		
Conclusions		
References		
<u>CHAPTER 8</u>		
Immunoglobulin–Fc Receptor Interactions	45	
Brian J. Sutton, Rebecca L. Beavil, and Andrew J. Beavil		
Introduction		
IgG–Receptor Interactions		
IgE–Receptor Interactions		
Summary		
References		
<u>CHAPTER 9</u>		
Plasticity of Fc Recognition	51	
Warren L. DeLano		
Introduction		
Structures of the Natural Fc Binding Domains		
The Consensus Binding Site on Fc		
Evolution of an Fc Binding Peptide		
Factors Promoting Plasticity		
Conserved and Functionally Important Molecular Interactions		
Conclusion		
References		
<u>CHAPTER 10</u>		
Ig-Superfold and Its Variable Uses in Molecular Recognition	57	
Nathan R. Zaccai and E. Yvonne Jones		
Introduction		
The Immunoglobulin Superfamily		
Ig-Superfold-Mediated Recognition		
References		
<u>CHAPTER 11</u>		
T-Cell Receptor/pMHC Complexes	63	
Markus G. Rudolph and Ian A. Wilson		
TCR Generation and Architecture		
Peptide Binding to MHC Class I and II		
TCR/pMHC Interaction		
Conclusions and Future Perspectives		
References		
<u>CHAPTER 12</u>		
Mechanistic Features of Cell-Surface Adhesion Receptors	74	
Steven C. Almo, Anne R. Bresnick, and Xuewu Zhang		
Mechanosensory Mechanisms		
Cell–Cell Adhesions/Adherens Junctions		
T-Cell Costimulation		
Axon Guidance and Neural Development		
Conclusions		
References		
<u>CHAPTER 13</u>		
The Immunological Synapse	79	
Michael L. Dustin		
Introduction		
Migration and the Immunological Synapse		
The Cytoskeleton and the Immunological Synapse		
The Role of Self MHCp in T-Cell Sensitivity to Foreign MHCp		
Integration of Adaptive and Innate Responses		
Summary		
References		
<u>CHAPTER 14</u>		
NK Receptors	83	
Roland K. Strong		
Introduction		
Immunoreceptors		
Natural Killer Cells		
Ig-Type NK Receptors: KIR		
C-Type Lectin-Like NK Receptors: Ly49A		
C-Type Lectin-Like NK Receptors: NKG2D		
References		
<u>CHAPTER 15</u>		
Carbohydrate Recognition and Signaling	87	
James M. Rini and Hakon Leffler		
Introduction		
Biological Roles of Carbohydrate Recognition		
Carbohydrate Structure and Diversity		
Lectins and Carbohydrate Recognition		
Carbohydrate-Mediated Signaling		
Conclusions		
References		

<u>CHAPTER 16</u>		
Rhinovirus–Receptor Interactions	95	Concluding Remarks
Elizabeth Hewat		References
References		
<u>CHAPTER 17</u>		<u>CHAPTER 22</u>
HIV-1 Receptor Interactions	99	Structures of Heterotrimeric G Proteins and Their Complexes
Peter D. Kwong		127
Molecular Interactions		Stephen R. Sprang
Atomic Details		Introduction
Recognition in the Context of a Humoral Immune Response		G α Subunits
References		G α -Effector Interactions
		GTP Hydrolysis by G α and Its Regulation by RGS Proteins
		G $\beta\gamma$ Dimers
		GPR/GoLoco Motifs
		G α -GPCR Interactions
		References
<u>CHAPTER 18</u>		
Influenza Virus Neuraminidase Inhibitors	105	<i>Section B: Vertical Receptors</i>
Garry L. Taylor		Henry Bourne, Editor
Introduction		
Flu Virus: Role of NA		<u>CHAPTER 23</u>
Structure of NA		Structure and Function of G-Protein-Coupled Receptors: Lessons from the Crystal Structure of Rhodopsin
Active Site		139
Inhibitor Development		Thomas P. Sakmar
Conclusion		Introduction
References		Introduction to Rhodopsin: a Prototypical G-Protein-Coupled Receptor
		Molecular Structure of Rhodopsin
		Molecular Mechanism of Receptor Activation
		References
<u>CHAPTER 19</u>		<u>CHAPTER 24</u>
Signal Transduction and Integral Membrane Proteins	115	Human Olfactory Receptors
Geoffrey Chang and Christopher B. Roth		145
Introduction		Orna Man, Tsviya Olender, and Doran Lancet
Electrophysiology: Rapid Signal Transduction		References
Mechanosensation: How Do We Feel?		
Active Transporters: Rapid Response and Energy Management		<u>CHAPTER 25</u>
Receptors: Gate Keepers for Cell Signaling		Chemokines and Chemokine Receptors: Structure and Function
References		149
		Carol J. Raport and Patrick W. Gray
<u>CHAPTER 20</u>		Introduction
Structural Basis of Signaling Events Involving Fibrinogen and Fibrin	119	Chemokine Structure and Function
Russell F. Doolittle		Chemokine Receptors
References		References
		<u>CHAPTER 26</u>
<u>CHAPTER 21</u>		The Binding Pocket of G-Protein-Coupled Receptors for Biogenic Amines, Retinal, and Other Ligands
Structural Basis of Integrin Signaling	123	155
Robert C. Liddington		Lei Shi and Jonathan A. Javitch
Introduction		Introduction
Structure		
Quaternary Changes		
Tertiary Changes		
Tail Interactions		

The Binding Pocket of GPCRs A Role of the Second Extracellular Loop in Ligand Binding References		
<u>CHAPTER 27</u> Glycoprotein Hormone Receptors: A Unique Paradigm for Ligand Binding and GPCR Activation	161	
Gilbert Vassart, Marco Bonomi, Sylvie Claeysen, Cedric Govaerts, Su-Chin Ho, Leonardo Pardo, Guillaume Smits, Virginie Vlaeminck, and Sabine Costagliola		
Introduction Molecular Pathophysiology Structure Function Relationships of the Glycoprotein Hormone Receptors Conclusions and Perspectives References		
<u>CHAPTER 28</u> Protease-Activated Receptors	167	
Shaun R. Coughlin		
Introduction Mechanisms of Activation Protease-Activated Receptor Family Roles of PARs <i>In Vivo</i> References		
<u>CHAPTER 29</u> Constitutive and Regulated Signaling in Virus-Encoded 7TM Receptors	173	
Thue Schwartz		
Virus-Encoded Proteins Are Developed through Targeted Evolution <i>In Vivo</i> The Redundant Chemokine System Is an Optimal Target for Viral Exploitation Multiple Virus-Encoded 7TM Receptors Constitutive Signaling through Altered Pathways Viral Receptors Recognize Multiple Ligands with Variable Function Attempts to Identify the Function of Virus-Encoded Receptors <i>In Vivo</i> References		
<u>CHAPTER 30</u> Frizzleds as G-Protein-Coupled Receptors for Wnt Ligands	177	
Sarah H. Louie, Craig C. Malbon, Randall T. Moon		
Introduction Wnt Signaling Evidence for Frizzleds as G-Protein- Coupled Receptors Perspective References		
<u>CHAPTER 31</u> Agonist-Induced Desensitization and Endocytosis of G-Protein- Coupled Receptors	181	
Mark von Zastrow		
Introduction General Processes of GPCR Regulation Mechanisms of GPCR Desensitization and Endocytosis Functional Consequences of GPCR Endocytosis References		
<u>CHAPTER 32</u> Functional Role(s) of Dimeric Complexes Formed from G-Protein- Coupled Receptors	187	
Marta Margeta-Mitrovic and Lily Yuh Jan		
References		
<u>CHAPTER 33</u> The Role of Chemokine Receptors in HIV Infection of Host Cells	191	
Jacqueline D. Reeves and Robert W. Doms		
Introduction HIV Entry Coreceptor Use <i>In Vivo</i> Env Domains Involved in Coreceptor Interactions Coreceptor Domains Involved in HIV Infection Receptor Presentation and Processing Role of Signaling in HIV Infection Summary References		
<u>CHAPTER 34</u> Chemotaxis Receptor in Bacteria: Transmembrane Signaling, Sensitivity, Adaptation, and Receptor Clustering	197	
Weiru Wang and Sung-Hou Kim		
Signaling at Periplasmic Ligand Binding Domain Signaling at the Cytoplasmic Domain Adaptation Clustering of the Chemoreceptor and Sensitivity Future Studies References		
<u>CHAPTER 35</u> Overview: Function and Three- Dimensional Structures of Ion Channels	203	
Daniel L. Minor, Jr.		
Introduction Studies of Full-Length Ion Channels General Pore Features Revealed by Bacterial Channels		

Pore Helices: Electrostatic Aids to Permeation
Open Channels
Eukaryotic Ion Channels at High Resolution:
Divide and Conquer
Ion Channel Accessory Subunits: Soluble
and Transmembrane
The Future: Ion Channels as Electrosomes
References

CHAPTER 36

How Do Voltage-Gated Channels Sense the Membrane Potential? 209

Chris S. Gandhi and Ehud Y. Isacoff

Introduction
The Voltage-Sensing Gating Particle
S4 Is the Primary Voltage Sensor
Physical Models of Activation: Turning a Screw
through a Bolt
Coupling Gating to S4 Voltage-Sensing Motions
References

CHAPTER 37

Ion Permeation: Mechanisms of Ion Selectivity and Block 215

Bertil Hille

Aqueous Pore
Ion Selectivity
Block
References

CHAPTER 38

Agonist Binding Domains of Glutamate Receptors: Structure and Function 219

Mark L. Mayer

References

CHAPTER 39

Nicotinic Acetylcholine Receptors 223

Arthur Karlin

Function
Structure
References

CHAPTER 40

Small Conductance Ca²⁺-Activated K⁺ Channels: Mechanism of Ca²⁺ Gating 227

John P. Adelman

Introduction
Clones Encoding SK Channels
Biophysical and Pharmacological Profiles
Mechanisms of Ca²⁺-gating
Pantophobia After All
References

CHAPTER 41

Regulation of Ion Channels by Direct Binding of Cyclic Nucleotides 233

Edgar C. Young and Steven A. Siegelbaum

Introduction
The Cyclic Nucleotide-Gated Channels
Other Channels Directly Regulated by
Cyclic Nucleotides
References

Section C: Horizontal Receptors

Robert Stroud, Editor

CHAPTER 42

Overview of Cytokine Receptors 239

Robert M. Stroud

CHAPTER 43

Growth Hormone and IL-4 Families of Hormones and Receptors: The Structural Basis for Receptor Activation and Regulation 241

Anthony A. Kossiakoff

Introduction
The Growth Hormone Family of Hormones
and Receptors
Structural Basis for Receptor Homodimerization
Hormone Specificity and Cross-Reactivity Determine
Physiological Roles
Hormone-Receptor Binding Sites
Receptor-Receptor Interactions
Hormone-Receptor Binding Energetics
Biological Implications of Transient
Receptor Dimerization
A High-Affinity Variant of hGH (hGH_v) Reveals an
Altered Mode for Receptor Homodimerization
Site1 and Site2 Are Structurally and
Functionally Coupled
IL-4 Hormone-Induced Receptor Activation
IL-4- α -Chain Receptor Interface
Binding of the γ -Chain Receptor
Comparisons of IL-4 with GH(PRL)
Concluding Remarks
References

CHAPTER 44

Erythropoietin Receptor as a Paradigm for Cytokine Signaling 251

Deborah J. Stauber, Minmin Yu, and Ian A. Wilson

Introduction
Biochemical Studies Supporting Preformed Dimers

Other Cytokine Receptor Superfamily Members
 Conclusions
 References

CHAPTER 45

A New Paradigm of Cytokine Action Revealed by Viral IL-6 Complexed to gp130: Implications for GCSF Interaction with GCSFR

Dar-chone Chow, Lena Brevnova, Xiao-lin He, and K. Christopher Garcia

Introduction
 Receptor/Ligand Interactions
 The gp130 System
 Viral Interleukin-6
 GCSF and GCSFR
 Structure of the Viral IL-6–gp130 Complex Site 1
 The Site 2 Interface
 The Site 3 Interface
 Implications of the vIL-6–gp130 Tetramer
 Structure for the Active GCSF–GCSFR
 Extracellular Signaling Complex
 References

CHAPTER 46

The Fibroblast Growth Factor (FGF) Signaling Complex

Fen Wang and Wallace L. McKeehan

Introduction
 FGF Polypeptides
 FGFR Tyrosine Kinases
 Heparan Sulfate
 Oligomeric FGF–FGFR–HS Signaling Complex
 Intracellular Signal Transduction by the FGFR Complex
 References

CHAPTER 47

Structure of IFN- γ and Its Receptors

Mark R. Walter

References

CHAPTER 48

Structure and Function of Tumor Necrosis Factor at the Cell Surface

Stephen R. Sprang

Introduction
 Structure of Tumor Necrosis Factor
 TNF Receptors
 Extracellular (Ligand Binding) Domains of TNF Family Receptors

Ligand–Receptor Complexes
 Consequences of Ligand–Receptor Complex Formation
 Receptor Preassociation
 Conclusion
 References

CHAPTER 49

The Mechanism of NGF Suggested by the NGF–TrkA–D5 Complex

Abraham M. de Vos and Christian Wiesmann

Introduction
 Neurotrophins
 Trks
 NGF–TrkA–D5 Complex
 p75^{NTR}
 References

CHAPTER 50

The Mechanism of VEGFR Activation Suggested by the Complex of VEGF–flt1–D2

Christian Wiesmann and Abraham M. de Vos

Introduction
 Heparin-Binding Domain of VEGF
 Receptor-Binding Domain VEGF
 VEGF Receptors
 VEGF–flt1–D2 Complex
 References

CHAPTER 51

Receptor–Ligand Recognition in the TGF β Family as Suggested by the Crystal Structures of BMP-2–BR-IA_{ec} and TGF β 3–TR-II_{ec}

Matthias K. Dreyer

Introduction
 Ligand and Receptor Structures
 Receptor–Ligand Complexes
 BMP-2–BR-IA_{ec} Complex
 Complex Formation with TGF β Is Different than for BMP-2
 References

CHAPTER 52

Insulin Receptor Complex and Signaling by Insulin

Lindsay G. Sparrow and S. Lance Macaulay

Introduction
 Insulin Receptor Domain Structure
 Binding Determinants of the IR
 Insulin Signaling to Glucose Transport
 References

259

281

265

271

275

285

289

293

STAT Structure and Function
 Inhibition of Cytokine Signaling
 Summary
 References

CHAPTER 63

Organization of Photoreceptor Signaling Complexes 349

Susan Tsunoda

INAD Organizes Signaling Complexes
 INAD-Signaling Complexes in Phototransduction
 Assembly, Targeting, and Anchoring of Signaling
 Complexes
 Signaling Complexes in Vertebrate Photoreceptors
 References

CHAPTER 64

Protein Localization in Negative Signaling 355

Jackson G. Egen and James P. Allison

Introduction
 The Role of CD28 and CTLA-4 in T-Cell Activation
 Expression and Localization of CTLA-4 and CD28:
 Consequences for Receptor Function
 Mechanisms of CTLA-4-Mediated Negative Signaling
 Conclusions
 References

CHAPTER 65

Transmembrane Receptor Oligomerization 361

Darren Tyson and Ralph A. Bradshaw

Introduction
 Tyrosine Kinase-Containing Receptors
 Cytokine Receptors
 Guanylyl Cyclase-Containing Receptors
 Serine/Threonine Kinase-Containing Receptors
 Tumor Necrosis Factor Receptors
 Heptahelical Receptors
 (G-Protein-Coupled Receptors)
 Concluding Remarks
 References

PART II

TRANSMISSION: EFFECTORS AND CYTOSOLIC EVENTS

Tony Hunter, Editor

PART II

Introduction 369

Tony Hunter, Editor

Section A: Protein Phosphorylation

Tony Pawson

CHAPTER 66

Eukaryotic Kinomes: Genomic Cataloguing of Protein Kinases and Their Evolution 373

Tony Hunter and Gerard Manning

Introduction
 The Yeasts: *Saccharomyces cerevisiae* and
Schizosaccharomyces pombe
 Nematodes: *Caenorhabditis elegans*
 Insects: *Drosophila melanogaster*
 Vertebrates: *Homo sapiens*
 Comparative Kinomics
 Coda
 References

CHAPTER 67

Modular Protein Interaction Domains in Cellular Communication 379

Tony Pawson and Piers Nash

Introduction
 Phosphotyrosine-Dependent Protein–
 Protein Interactions
 Interaction Domains: A Common Theme
 in Signaling
 Adaptors, Pathways, and Networks
 Evolution of a Phospho-Dependent Docking Protein
 Multisite Phosphorylation, Ubiquitination, and
 Switch-Like Responses
 Summary
 References

CHAPTER 68

Structures of Serine/Threonine and Tyrosine Kinases 387

Matthew A. Young and John Kuriyan

Introduction
 Structures of Protein Kinases
 Structures of Inactive Protein Kinases
 Summary
 References

CHAPTER 69

Protein Tyrosine Kinase Receptor Signaling Overview 391

Carl-Henrik Heldin

Introduction
 PTK Subfamilies
 Mechanism of Activation
 Control of PTK Receptor Activity
 Cross-Talk Between Signaling Pathways

PTK Receptors and Disease
References

CHAPTER 70

Signaling by the Platelet-Derived Growth Factor Receptor Family

M. V. Kovalenko and Andrius Kazlauskas

Introduction

Platelet-Derived Growth Factors, Their Receptors, and Assembly of the PDGF Receptor Signaling Complex

Some Aspects of Regulation of the PDGF Receptor-Initiated Signaling

References

CHAPTER 71

EGF Receptor Family

Mina D. Marmor and Yosef Yarden

Introduction

Domain Structure of ErbBs

Subcellular Localization of ErbB Proteins

ErbB-Induced Signaling Pathways

Negative Regulatory Pathways

Specificity of Signaling Through the ErbB Network

ErbB Proteins and Pathological Conditions

References

CHAPTER 72

IRS-Protein Scaffolds and Insulin/IGF Action

Morris F. White

IRS-Proteins: The Beginnings

IRS-Proteins and Insulin Signaling

IRS-Protein Structure and Function

IRS-Protein Signaling in Growth, Nutrition, and Longevity

Interleukin-4 and IRS2 Signaling

Heterologous Regulation of IRS-Protein Signals

IRS2 and Pancreatic β -Cells

Summary

References

CHAPTER 73

Eph Receptors

Rüdiger Klein

Introduction

Ephs and Ephrins

Eph Receptor Signaling Via Cytoplasmic Protein Tyrosine Kinases

Eph Receptor Signaling Via Rho Family GTPases

Effects on Cell Proliferation

Eph Receptor Signaling through PDZ-Domain-Containing Proteins

397

Eph Receptors and Cell Adhesion

Ephrin Reverse Signaling

EphrinB Reverse Signaling Via Phosphotyrosine

EphrinB Reverse Signaling Via PDZ

Domain Interactions

Summary

References

CHAPTER 74

Cytokine Receptor Superfamily Signaling

James N. Ihle

Cytokine Receptor Superfamily Signaling

References

427

CHAPTER 75

Negative Regulation of the JAK/STAT Signaling Pathway

Joanne L. Eyles and Douglas J. Hilton

Introduction

The Phosphatases

STAT Phosphatases

PIAS (Protein Inhibitors of Activated STATs)

SOCS (Suppressors of Cytokine Signaling) Family

Concluding Comments

References

431

CHAPTER 76

Activation of Oncogenic Protein Kinases

G. Steven Martin

Introduction

Physiological Regulation of Protein Kinases

Activation of Protein Kinases by Retroviruses

Activation of Protein Kinases in Human Cancer

Oncogenic Protein Kinases as Targets for Therapy

References

441

CHAPTER 77

Protein Kinase Inhibitors

Alexander Levitzki

Signal Transduction Therapy

Protein Tyrosine Kinase Inhibitors

SER/THR Kinase Inhibitors

References

451

CHAPTER 78

Integrin Signaling: Cell Migration, Proliferation, and Survival

J. Thomas Parsons, Jill K. Slack-Davis, and

Karen H. Martin

Introduction

Integrins Nucleate the Formation of Multi-Protein Complexes

463

Cell Migration: A Paradigm for Studying Integrin Signaling Integrin Regulation of Cell Proliferation and Survival: Links to Cancer Concluding Remarks References			
CHAPTER 79 Downstream Signaling Pathways: Modular Interactions	471		
Bruce J. Mayer Introduction General Properties of Interaction Modules Roles in Signaling Prospects References			
CHAPTER 80 Non-Receptor Protein Tyrosine Kinases in T-Cell Antigen Receptor Function	475		
Kiminori Hasegawa, Shin W. Kang, Chris Chiu and Andrew C. Chan Introduction T-Cell Antigen Receptor Structure Src PTKs Csk (c-Src PTK) ZAP-70/Syk PTKs Tec PTKs Summary References			
CHAPTER 81 Cbl: A Physiological PTK Regulator	483		
Wallace Y. Langdon Introduction Domains of Cbl Proteins Sli-1: A Negative Regulator of RPTKs PTK Downregulation by Polyubiquitylation Cbl-Deficient Mice Future Directions References			
CHAPTER 82 TGFβ Signal Transduction	487		
Jeffrey L. Wrana Introduction The Smad Pathway Smads and the Ubiquitin-Proteasome System Smad-Independent Signaling Pathways Other Receptor Interaction Proteins References			
CHAPTER 83 MAP Kinases			493
James R. Woodgett Introduction The ERK Module Stress-Activated MAPKs, Part 1: SAPK/JNKs Stress-Activated MAPKs, Part 2: p38 MAPKs MAPKKs MAPKKKs MAPKKKKs Summary References			
CHAPTER 84 Cytoskeletal Regulation: Small G-Protein-Kinase Interactions			499
Ed Manser Introduction P21-Activated Kinases Myotonic Dystrophy Kinase-Related Cdc42- Binding Kinase Rho-Associated Kinase (ROK) References			
CHAPTER 85 Recognition of Phospho- Serine/Threonine Phosphorylated Proteins			505
Stephen J. Smerdon and Michael B. Yaffe Introduction 14-3-3 Proteins FHA Domains WW Domains Leucine-Rich Repeats and WD40 Domains Concluding Remarks References			
CHAPTER 86 Role of PDK1 in Activating AGC Protein Kinase			513
Dario R. Alessi Introduction Mechanisms of Activation of PKB PKB Is Activated by PDK1 Activation of Other Kinases by PDK1 Phenotype of PDK1 PKB- and S6K-Deficient Mice and Model Organisms Hydrophobic Motif of AGC Kinases Mechanisms of Regulation of PDK1 Activity Structure of the PDK1 Catalytic Domain Concluding Remarks References			

<u>CHAPTER 87</u>		<u>CHAPTER 92</u>	
Regulation of Cell Growth and Proliferation in Metazoans by mTOR and the p70 S6 Kinase	523	Protein Kinase C: Relaying Signals from Lipid Hydrolysis to Protein Phosphorylation	551
Joseph Avruch		Alexandra C. Newton	
Introduction		Introduction	
Functions of TOR		Protein Kinase C Family	
Signaling from TOR		Regulation of Protein Kinase C	
Regulation of mTOR Activity		Function of Protein Kinase C	
References		Summary	
		References	
<u>CHAPTER 88</u>		<u>CHAPTER 93</u>	
AMP-Activated Protein Kinase	535	The PIKK Family of Protein Kinases	557
D. Grahame Hardie		Graeme C. M. Smith and Stephen P. Jackson	
Introduction		Introduction	
Structure of the AMPK Complex		Overview of PIKK Family Members	
Regulation of the AMPK Complex		Overall Architecture of PIKK Family Proteins	
Regulation in Intact Cells and Physiological Targets		MTOR: A Key Regulator of Cell Growth	
Medical Implications of the AMPK System		DNA-Pkes: At the Heart of the DNA	
References		Nonhomologous End-Joining Machinery

Jack E. Dixon, Editor

CHAPTER 99**Overview of Protein Dephosphorylation 591**

Jack E. Dixon

CHAPTER 100**Protein Serine/Threonine Phosphatases and the PPP Family 593**

Patricia T. W. Cohen

Current Classification of Protein Serine/Threonine Phosphatases

Background

Evolution and Conserved Features of the PPP Family

Catalytic Activities of the PPP Family Members

Eukaryotic PPP Subfamilies

Domain and Subunit Structure of PPP Family Members

Medical Importance of the PPP Family

References

CHAPTER 101**The Structure and Topology of Protein Serine/Threonine Phosphatases 601**

David Barford

Introduction

Protein Serine/Threonine Phosphatases of the PPP Family

Protein Serine/Threonine Phosphatases of the PPM Family

Conclusions

References

CHAPTER 102**Naturally Occurring Inhibitors of Protein Serine/Threonine Phosphatases 607**

Carol MacKintosh and Julie Diplexcito

Introduction

Effects of Inhibitors in Cell-Based Experiments
The Toxins Bind to the Active Sites of Protein PhosphatasesChemical Synthesis of Protein Phosphatase Inhibitors
Microcystin Affinity Chromatography and Affinity TaggingAvoiding the Menace of Toxins in the Real World
Outside the Laboratory

References

CHAPTER 103**Protein Phosphatase 1 Binding Proteins 613**

Anna A. Depaoli-Roach

Introduction

Protein Phosphatase 1 (PP1)

PP1 Regulatory or Targeting Subunits

Conclusions

References

CHAPTER 104**Role of PP2A in Cancer and Signal Transduction 621**

Gernot Walter

Introduction

Structure of PP2A

Subunit Interaction

Association of PP2A with Cellular Proteins
Alteration or Inhibition of PP2A Is Essential in Human Cancer DevelopmentMutation of A α and A β Isoforms in Human CancerDifferences between A α and A β Subunits

PP2A and Wnt Signaling

PP2A and MAP Kinase Pathway

Summary

References

CHAPTER 105**Serine/Threonine Phosphatase Inhibitor Proteins**

627

Shirish Shenolikar

Introduction
 Protein Phosphatase 1 (PP1) Inhibitors
 I-1, DARPP-32, and Other Phosphorylation-Dependent Phosphatase Inhibitors
 Latent Phosphatase Complexes Activated by Inhibitor Phosphorylation
 Inhibitors of Type-2 Serine/Threonine Phosphatases
 Conclusions
 References

CHAPTER 106**Calcineurin**

631

Claude B. Klee and Seun-Ah Yang

Introduction
 Enzymatic Properties
 Structure
 Regulation
 Distribution and Isoforms
 Functions
 Muscle Differentiation
 Conclusion
 References

CHAPTER 107**Protein Serine/Threonine-Phosphatase 2C (PP2C)**

637

Hisashi Tatabe and Kazuhiro Shiozaki

Introduction
 Regulation of the Stress-Activated MAP Kinase Cascades
 Control of the CFTR Chloride Channel by PP2C
 Plant Hormone Abscisic Acid Signaling
 Fem-2: A Sex-Determining PP2C in Nematode
 Stress-Responsive PP2Cs in *Bacillus subtilis*

CHAPTER 224		
Specificity of G Protein $\beta\gamma$ Dimer Signaling	623	
Janet D. Robishaw, William F. Schwindinger, and Carl A. Hansen		
Introduction		
Diversity of the β and γ Gene Families		
Assembly of the $\beta\gamma$ Dimer		
Specificity of G Protein $\beta\gamma$ Dimer Signaling		

Conclusion

References

CHAPTER 225

The RGS Protein Superfamily

631

David P. Siderovski and T. Kendall Harden

Introduction

The Signature RGS-Box as a $G\alpha$ GAP

$G\alpha$ GAP and Other Signaling Regulatory Activities of RGS Family Members

References

CHAPTER 226

Mechanism of $\beta\gamma$ Effector Interaction

639

Tohru Kozasa

Introduction

Effectors Interacting with $\beta\gamma$ Subunits

Specificity of the Interaction between $\beta\gamma$ Subunit and Effectors

References

CHAPTER 227

$\beta\gamma$ Signaling in Chemotaxis

645

Carol L. Manahan and Peter N. Devreotes

Introduction

Evidence that G Proteins Are Involved in Chemotaxis
PI3Ks — Role in Chemotaxis?

Lipid Phosphatases, PTEN and SHIP

References

CHAPTER 228

Reversible Palmitoylation in G-Protein Signaling

651

Philip Wedegaertner

Introduction

Sites of Palmitoylation in $G\alpha$ and RGS Proteins

Activation-Regulated Palmitoylation of $G\alpha$

Mechanisms of Reversible Palmitoylation

Functions of Reversible Palmitoylation

Conclusion

References

CHAPTER 229

G Proteins Mediating Taste Transduction

657

Sami Damak and Robert F. Margolskee

Introduction

α -Gustducin

α -Transducin

Other G Protein α Subunits

$\beta\gamma$ Subunits

G-Protein-Coupled Receptors

Second Messenger Pathways

Conclusion

CHAPTER 232

Ras and Cancer

671

Frank McCormick

Introduction: Ras Activation in Cancer

Pathways Downstream of Ras

Mouse Models of Cancer

Prospects for Cancer Therapy Based on Ras

References

CHAPTER 233

The Influence of Cellular Location on Ras Function

675

Janice E. Buss, Michelle A. Booden, and John T. Stickney

Cytosolic Ras Is not Functional

After Modifications by Endomembrane Enzymes, Ras Proteins Move Toward the Cell Surface

Destination-Cell Surface: Ras Proteins Distribute Among Several Plasma Membrane Domains

Ras Proteins Finally Become Active at the Plasma Membrane

Endocytosis — A New Stage for Ras Signaling

Drugs that Affect Ras Membrane Binding

References

CHAPTER 234**Role of R-Ras in Cell Growth**

Gretchen A. Murphy, Adrienne D. Cox, and Channing J. Der

Introduction

General Properties of R-Ras Proteins:

Variations on Ras

R-Ras

TC21/R-Ras-2

M-Ras/R-Ras-3

Conclusions

References

CHAPTER 235**Molecular and Structural Organization of Rab GTPase Trafficking Networks**

Christelle Alory and William E. Balch

Introduction

Rab Proteins are Recycling GTPases

Rab Proteins: An Evolutionary Conserved Family

Structural Organization of the Rab Proteins

Posttranslational Modification and Localization

Effector Molecules: REP/CHM, GEF, Effectors

(Motors/Tethers/Fusogens), GAP, and GDI

Rab Dysfunction and Disease

Perspective

References

CHAPTER 236**Cellular Roles of the Ran GTPase**

Jomon Joseph and Mary Dasso

Introduction

Introduction to the Ran Pathway

Structural Analysis of Ran Pathway Components

Ran's Role in Nuclear Transport

Ran's Function in Mitotic Progression

Ran's Function in Spindle Assembly

Ran's Role in Postmitotic Nuclear Assembly

Conclusions

References

CHAPTER 237**Rho Proteins and Their Effects on the Actin Cytoskeleton**

Anja Schmidt and Alan Hall

Introduction

Effects of Rho GTPases on the Actin Cytoskeleton

Signaling from Rho GTPases to the Actin

Cytoskeleton

Conclusions

References

681

CHAPTER 238**Regulation of the NADPH Oxidase by Rac GTPase**

Becky A. Diebold and Gary M. Bokoch

Components and Regulation of the NADPH Oxidase

The Role of Rac in NADPH Oxidase Regulation

Current Models of Rac Function in NADPH Oxidase

Regulation

Rac GTPase—A More General Role in Regulating

Oxidant-Bases Signaling?

References

705

CHAPTER 239**The Role of Rac and Rho in Cell Cycle Progression**

Laura J. Taylor and Dafna Bar-Sagi

Introduction

Regulation of G1 Progression

The Function of Rac and Rho in Cell Cycle

Progression and Transformation

Cell Cycle Targets of Rac and Rho

Future Perspectives

References

711

CHAPTER 240**Cdc42 and Its Cellular Functions**

Wannian Yang and Richard A. Cerione

Introduction

Biological Effects of Cdc42

Cell Adhesion and Migration

Cell Polarity

Molecular Mechanisms Underlying the Biological

Activities of Cdc42

Conclusions

References

715

CHAPTER 241**Tissue Transglutaminase: A Unique GTP-Binding/GTPase**

Richard A. Cerione

Introduction

TGase as a GTP-Binding/GTPase

New Links to Biological Function

Future Directions

PART III

NUCLEAR AND CYTOPLASMIC EVENTS: TRANSCRIPTIONAL AND POST-TRANSCRIPTIONAL REGULATION

Michael Karin, Editor

PART III

Introduction

Michael Karin

Section A: Nuclear Receptors

Michael G. Rosenfeld, Editor

CHAPTER 270

History of Nuclear Receptors

7

Elwood V. Jensen

Introduction

Discovery of Receptors and Shift in Research Direction

Receptor Forms and Physiological Action

Subsequent Discoveries Relevant to Receptor

Structure and Function

References

CHAPTER 271

Regulation of Basal Transcription by RNA Polymerase II

11

Sohail Malik and Robert G. Roeder

Introduction

The Preinitiation Complex

Global Mechanisms of PIC Function

Gene-Specific Regulation of PIC Function by

Transcriptional Activators

Conclusion

References

CHAPTER 272

Structural Mechanisms of Ligand-Mediated Signaling by Nuclear Receptors

21

H. Eric Xu and Millard H. Lambert

Introduction

Overall Structure of the LBD

Ligand-Binding Pockets

Ligand-Mediated Activation: Mouse Trap versus

Charged Clamp

Ligand-Mediated Repression

Dimerization

Summary

CHAPTER 276

PPAR γ Signaling in Adipose Tissue Development

39

Robert Walczak and Peter Tontonoz

Introduction

PPAR γ : A Dominant Regulator of Adipose Tissue
Development

Analysis of PPAR γ Function in Animal Models

Transcriptional Networks in Adipose Tissue Development

Negative Regulation of Adipocyte Differentiation

PPAR γ , TNF- α Signaling Antagonism and Insulin
Resistance

PPAR γ and Cell Cycle Regulation

References

CHAPTER 277**Orphan Nuclear Receptors**

Barry Marc Forman

Classical Receptors versus Orphan Receptors
 Orphan Receptors and Metabolite-Derived Signals
 Orphan Receptors and Xenobiotic Signals
 Future Directions
 References

CHAPTER 278**Identification of Ligands for Orphan Nuclear Receptors**

Steven A. Kliewer and Timothy M. Willson

Introduction
 PPARs: Fatty Acid Sensors
 LXRs: Cholesterol Sensors
 FXR: Bile Acid Sensor
 PXR and CAR: Xenobiotic Sensors
 Ligands for Other Orphan Nuclear Receptors
 Conclusion
 References

CHAPTER 279**Orphan Receptor COUP-TFII and Vascular Development**

Fabrice G. Petit, Sophia Y. Tsai, and Ming-Jer Tsai

Introduction
 Vascular Development
 PPAR γ : Inhibitor of Angiogenesis
 COUP-TFII: Positive Effector in Angiogenesis
 Conclusion
 References

CHAPTER 280**Cross-Talk between Nuclear Receptors and Other Transcription Factors**

Peter Herrlich

Introduction
 Proliferation and Proinflammatory Pathways
 Nuclear Receptors
 Induced Expression of Inhibitory Molecules
 Immediate Hormone Responses
 Direct Modulation of Transcription Factors
 Conclusion
 References

CHAPTER 281***Drosophila* Nuclear Receptors**

Kirst King-Jones and Carl S. Thummel

Introduction
 Nuclear Receptors and Embryonic Pattern Formation
 Ecdysone Regulatory Hierarchies

The Neuronal Connection

Cell Signaling: Yesterday, Today, and Tomorrow

Ralph A. Bradshaw and Edward A. Dennis

Cell signaling, which is also often referred to as signal transduction or transmembrane signaling, is the process by which cells communicate with their environment and respond temporally to external cues that they sense there. All cells have the capacity to achieve this to some degree, albeit with a wide variation in purpose, mechanism, and response. At the same time, there is a remarkable degree of similarity over quite a range of species, particularly in the eukaryotic kingdom, and comparative physiology has been a useful tool in the development of this field. The central importance of this general phenomenon (sensing of external stimuli by cells) has been appreciated for a long time, but it has truly become a dominant part of cell and molecular biology research in the past ten years, in part because a description of the dynamic responses of cells to external stimuli is in essence a description of the life process itself. This approach lies at the core of the new field of proteomics, and its importance to human and animal health is already plainly evident. Here, we briefly consider the origins of cell signaling, broadly summarize the current state of the art, and speculate on future directions with an eye toward what questions must be answered and which ones likely will be answered in the near future.

Origins of Cell Signaling

Although cells from polycellular organisms derive substantial information from interactions with other cells and extracellular structural components, it was humoral components that first were appreciated to be intracellular messengers. This idea was certainly inherent in the “internal secretions” initially described by Claude Bernard in 1855 and thereafter, as it became understood that ductless glands, such as the

spleen, thyroid, and adrenals, secreted material into the bloodstream. However, Bernard did not directly identify hormones as such. This was left to Bayliss and Starling and their description of secretin in 1902 [1].

Recognizing that it was likely representative of a larger group of chemical messengers, the term *hormone* was introduced by Starling in a Croonian Lecture presented in 1905. The word, derived from the Greek word meaning “I excite or arouse,” was apparently proposed by a colleague, W. B. Hardy, and was adopted, even though it did not particularly connote the messenger role but rather emphasized the positive effects exerted on target organs via cell signaling (see Wright [2] for a general description of these events). The realization that these substances could also produce inhibitory effects, gave rise to a second designation, “chalones”, introduced by Schaefer in 1913 (see Schaefer [3]), for the inhibitory elements of these glandular secretions. The word *autocoid* was similarly coined for the group as a whole (hormones and chalones). Although the designation chalone is occasionally applied to some growth factors with respect to certain of their activities (e.g., transforming growth factor β), autocoid has essentially disappeared. Thus, if the description of secretin and the introduction of the term *hormone* are taken to mark the beginnings of molecular endocrinology and the eventual development of cell signaling, then we are at or near the 100th anniversary of this field.

The origins of endocrinology, as the study of the glands that elaborate hormones and the effect of these entities on target cells, naturally gave rise to a definition of hormones as substances produced in one tissue type that traveled systemically to another tissue type to exert a characteristic response. Of course, initially these responses were couched in organ and whole animal responses, although they increasingly

were defined in terms of metabolic and other chemical changes at the cellular level. The early days of endocrinology were marked by many important discoveries, such as the discovery of insulin [4], to name one, that solidified the definition, and a well-established list of hormones, composed primarily of three chemical classes (polypeptides, steroids, and amino acid derivatives), was eventually developed. Of course, it was appreciated even early on that the responses in the different targets were not the same, particularly with respect to time. For example, adrenalin was known to act very rapidly while growth hormone required much longer time frames to exert its full range of effects. However, in the absence of any molecular details of mechanism, the emphasis remained on the distinct nature of the cells of origin versus those responding and on the systemic nature of transport, and this remained the case well into the 1970s. An important shift in endocrinological thinking had its seeds well before that, however, even though it took about 25 years for these “new” ideas that greatly expanded endocrinology to be enunciated clearly.

Enter Polypeptide Growth Factors

Although the discovery of polypeptide growth factors as a new group of biological regulators is generally associated with nerve growth factor (NGF), it can certainly be argued that other members of this broad category were known before NGF. However, NGF was the source of the name *growth factor* and has been in many important respects a Rosetta stone for establishing many of the principles that are now known to underpin much of signal transduction. Thus, its role as the progenitor of the field and the entity that keyed the expansion of endocrinology, and with it the field of cell signaling, is quite appropriate. There are numerous accounts of the discovery of NGF [5–8] and how this led directly to identification of epidermal growth factor (EGF), another regulator that has been equally important in providing novel insights into molecular endocrinology and signal transduction. However, it was not till the sequences of NGF and EGF were determined [9,10] that the molecular phase of growth factor research truly began. Of particular importance was the suggestion that NGF and insulin were related entities [11], which suggested a similar molecular action (which, indeed, turned out to be remarkably clairvoyant) and was the first indication that the identified growth factors, which at that time were quite limited in number, were hormonal like. This hypothesis led quickly to the identification of receptors for NGF on target neurons, using the tracer binding technology of the time (see Raffioni *et al.* [12] for a summary of these contributions), which further confirmed their hormonal status. Over the next several years, similar observations were recorded for a number of other growth factors that in turn led to the redefinition of endocrine mechanisms to include paracrine and autocrine interactions (see Section V Introduction – Bradshaw/Thompson).

Cell Signaling at the Molecular Level

At the same time that the growth factor field was undergoing rapid development, major advances were also occurring in studies on hormonal mechanisms. In particular, Sutherland and colleagues [13] were redefining hormones as messengers and their ability to produce second messengers. This was, of course, based primarily on the identification of cyclic AMP (cAMP) and its production by a number of classical hormones. However, it also became clear that not all hormones produce this second messenger nor was it stimulated by any of the growth factors known at that time. This enigma remained unresolved for quite a long time until tyrosine kinases were identified, and it was shown, first with the EGF receptor [14], that these entities were responsible for the signal transduction for many of those hormones and growth factors that did not stimulate the production of cAMP. Aided by the tools of molecular biology, it was a fairly rapid transition to the cloning of the receptors (for all hormones and growth factors) and the subsequent development of the main classes of signaling mechanisms. These include, in addition to the receptor tyrosine kinases described above, the G-protein receptors (including the receptors that produce cAMP and probably constituting the largest class of cell surface receptors); cytokine receptors, which recruit soluble tyrosine kinases; serine/threonine receptors; the tumor necrosis factor (TNF) (TRAF) receptors that activate nuclear factor kappa B (NFκB), among other pathways; guanyl cyclase receptors and nuclear receptors utilized by steroids; and other signaling entities. Structural biology has not maintained the same pace and there are still both ligands and receptors for which we do not have full three-dimensional information as yet, but this gap is rapidly closing and it may be anticipated that the full catalog of these structures will soon be available. Of particular importance will be the anticipated first structure of a full-length transmembrane receptor with a regular ligand bound. That would certainly provide important insights into signal transmission that currently are lacking.

In parallel with the development of our understanding of ligand/receptor organization, structure, and general mechanism, an equally important advance has occurred in the appreciation of the intracellular events that these various receptor classes initiate. Indeed, the very substantial repertoire of molecules includes effectors (kinases of various types, phospholipases, etc.), scaffolds, adaptors, and regulatory proteins (see Section B and multiple entries therein). Many are quite common and are activated by several types of receptors in a variety of cell types while others are quite narrow in specificity and distribution. That different receptors can cross-activate other receptors and/or signaling systems adds considerably to the complexity of cellular responses and in turn leads to an even broader array of cellular and organ responses. Indeed, today’s endocrinology is a far cry from the simple pathways envisioned by the early physiologists who define this field a century ago. They would be

amazed indeed to read this Handbook and see where their early seminal observations have gone.

Lipid Signaling

The elucidation of cell signaling mechanisms and the variety of molecules that are employed in these myriad of processes is particularly well exemplified by the lipid messengers. Except for the above mentioned steroid hormones, lipids have long been thought to function mainly in energy metabolism and membrane structure. This last decade has culminated in the broad recognition that membrane phospholipids provide many of the important cell signaling molecules via phospholipases and lipid kinases. Key is the role of phospholipase C in hydrolyzing phosphatidylinositol bisphosphate (PIP₂) to release diglyceride that activates protein kinase C (PKC) and inositol triphosphate (IP₃), which mobilizes intracellular Ca²⁺, central to so many regulatory processes (see Section II X-Berridge). The phosphorylation of PIP₂ at the 3-position to produce PIP₃ promotes vesicular trafficking and other cellular processes. Phospholipase D releases phosphatidic acid, and phospholipase A₂ provides arachidonic acid, which is converted into prostaglandins, leukotrienes, and lipoxins; these ligands in turn bind to unique families of receptors as does platelet activating factor (PAF). The more recent recognition of the importance of sphingolipids and ceramide in signaling and the discoveries of the unique lysophosphatidic acid and sphingosine phosphate families of receptors has sparked the search for other new receptors for lipids. It is clear that the search for new lipid second messengers and their receptors and functions will continue unabated into the future.

Cell Signaling Tomorrow

As the humane genome and importantly the genomes of several other key research paradigms reach completion in terms of sequence, interpretation, and full annotation, it will be possible to know, in a general sense, the complete complement of proteins, involved in cell signaling. Of course, this “signaling proteome” will contain a vast number of variants arising from message splicing and posttranslational modification. Appreciating how all of these variants interact as a function of time in response to stimulation will be a mammoth if not an infinite task. But, this level of knowledge will not be required to make considerable advances over what we know at present. Indeed, we can expect that “expression proteomics,” which some really define as

“systems biology,” will provide much insight in the coming years, particularly through the clever applications of advances in separations methodology, mass spectrometry, and hybridization assays. Both protein and nucleic acid arrays have already demonstrated their worth, and much more information will be obtained from these powerful techniques. Of utmost importance will be the application of quantification to all types of measurements so that these data can eventually be accurately modeled to produce a true picture of signal fluxes through cells as they undergo their transcriptional, phenotypic, and ultimately cell and organ responses. Although one cannot accurately predict over the next ten years what discoveries will be made, other than that there will be many and some of them will be quite unexpected, it seems certain that cell signaling will remain one of the primary areas of expanding biological research. It also seems safe to predict that many singularly important findings in terms of human and animal health will be made and that society, at all levels, will be the better for these efforts.

PART I

Initiation: Extracellular and Membrane Events

James A. Wells, Editor

This Page Intentionally Left Blank

Introduction

James A. Wells

Cells within multicellular organisms communicate via extracellular mediators: either through diffusible molecules or by direct cell–cell contact. These extracellular signals are interpreted for the most part by specific membrane receptors that in turn trigger intracellular machinery that directs the cellular response. The past decade has seen an explosion in our understanding of the molecular basis for membrane receptor signaling. Part I in this Handbook surveys the diversity of mechanisms for membrane receptor signaling.

The first section in Part I, edited by Dr. Ian Wilson, deals with molecular recognition properties at extracellular protein–protein interfaces. The first set of chapters shows how molecular recognition can be studied, ranging from theoretical and database analyses to analysis of structures, mutational studies, and thermodynamics. Next, a series of detailed structural studies are presented to reveal specific examples of the molecular recognition within immune complexes. These binding surfaces do not appear to be rigid locks and keys; they are adaptive and capable of flexing to bind, or evolving to bind, one or more ligands. This section concludes with a variety of examples of recognition complexes that bind viruses, fibrin, and integrins that mediate cell–cell adhesion. These fundamental binding events involve protein–protein interactions that are found in virtually all steps of cell signaling.

Sections B and C, edited by Drs. Henry Bourne and Robert Stroud, respectively, deal with the mechanisms of receptor binding and activation. The activated form of all known receptors or receptor complexes contain at least two transmembrane helices, because for signals to be transmitted requires a change in disposition of at least two helical segments. Membrane receptors can be classified broadly into two groups depending on whether they are fully assembled prior to ligand binding (such as ion channels and most G-coupled receptors) or whether they assemble after the ligand binding (such as most growth factor receptors). The former group can be referred to as *vertical* because ligand

binding immediately transduces a signal vertically through the membrane via a conformational change in the receptor that allows it to associate with proteins on the inner membrane leaflet. The latter receptor class can be referred to as *horizontal* because ligand binding first facilitates lateral association (or change in association) of receptor subunits. This causes a change in the juxtaposition of the intracellular domains of the receptor and induces further association with intracellular signaling molecules. These receptor classes have very different evolutionary origins and cellular roles.

The vertical receptors, covered in Section B, contain multiple membrane-crossing segments and are found in all organisms from bacteria to eukaryotes. They tend to be sensors for small molecules (even photons) and peptides, and in higher eukaryotes they can also bind large proteins such as glycopolypeptide hormones and chemokines. Some of these may also undergo lateral association to form higher order complexes with possible roles in signaling. The vertical receptors often promote immediate and reversible changes in pH, membrane polarity, calcium flux etc. that control cellular metabolism or cell migration.

The horizontal receptors, surveyed in Section C, contain a single helical membrane-crossing segment and are found in multicellular eukaryotes. These tend to be sensors for protein signaling ligands such as growth factors and cytokines. Ligand binding promotes the lateral association of accessory receptor subunits or, in some cases, a change in the mode of arrangement of receptor subunits already associated. The horizontal receptors function to cause slower and irreversible changes in the cells such as proliferation, differentiation, or apoptosis.

The final section in Part I, edited by Dr. Tom Alber, reviews what is known about the cellular machinery proximal to the inside of the membrane that responds to the activated receptor complex. Many of the growth factor receptors have intracellular kinase domains that become activated

upon ligand binding and lead to phosphorylation, which seeds growth of larger signaling complexes via adaptor proteins. The receptors for helical cytokines lack a covalently fused kinase domain but recruit specific kinases (JAKs) to the membrane after oligomerization. Still others, such as the trimeric cytokine receptors (e.g., TNF receptor), provide oligomerized scaffolds that directly recruit adaptor proteins to form the intracellular signaling complex. It is also clear that lipids can play a role in concentrating receptors and signaling molecules both by covalent modification and by forming clusters known as lipid rafts. Many of the vertical receptors, such as the G-coupled receptors and photoreceptors,

have proteins on the inner leaflet of the membrane called G proteins with which they interact to send the signal on to the cytosol. Thus, ligand binding to a receptor on the outside of the cell membrane causes even larger changes in protein assemblies just inside the cell membrane.

Membrane receptors have long been known to act as the cellular gatekeepers to the outside world. Work over the past decade has begun to provide insight into the mechanisms by which extracellular signaling molecules transmit information into the cell without actually passing through the membrane. Part I of this handbook is intended to present the state-of-the-art information about initiation of cell signaling.

Molecular Recognition

Ian Wilson, Editor

This Page Intentionally Left Blank

Structural and Energetic Basis of Molecular Recognition

Emil Alexov and Barry Honig

*Department of Biochemistry and Molecular Biophysics,
Howard Hughes Medical Institute, Columbia University, New York*

Introduction

Molecular recognition can be thought of as the process by which two or more molecules bind to one another in a specific geometry. Any binding process requires that the associating molecules prefer to interact with each other rather than the alternative, in which the individual binding interfaces interact with the solvent in which they are found. The forces that drive binding are reasonably well understood in a qualitative sense, although the accurate prediction of binding free energies or the structure of a complex given the structures of the interacting subunits remain largely unsolved problems. This chapter will briefly review the physical chemical principles of binding and summarize what has been learned so far from the analysis of the three-dimensional structures of interacting molecules and their complexes. A number of recent reviews should be consulted for more extensive discussion of the topics covered here (see, for example, references [1–4]).

Principles of Binding

What drives proteins to associate with other molecules? The hydrophobic effect clearly plays a central role, and it is possible that close packing at interfaces may allow stronger van der Waals interactions between molecules than either one undergoes with solvent molecules. Both types of forces, in general, will increase as the interfacial surface area increases, and these contributions to binding are often assumed to be proportional to the surface area of both proteins that is buried upon binding. In general, there will always be some factors

that oppose binding, including the loss of translational and rotational degrees of freedom as two or more species form a complex [5] and the “strain” induced in each monomer as a result of complex formation [6]. This can involve an increase in the conformational energy of each monomer or entropic losses, such as, for example, side chains in the interface that lose some configuration freedom upon binding.

Electrostatic interactions [2] also play an important role in binding; however, the magnitude and even sign of the effect are more difficult to predict. The complication in predicting the role of electrostatic interactions is that they generally reflect a balance between two large and opposing forces. For example, the formation of an ion pair as a result of complex formation requires that both charges be removed from the solvent and be completely or partially buried at an interface. For a completely buried ion pair, the loss of solvation is believed to be a larger effect than the gain of Coulomb energy in the complex so that individual ion pairs and hydrogen bonds are believed to oppose complex formation. However, ion pairs close to the surface can remain partially hydrated while still stabilized by Coulomb interactions. In some cases, these may provide a favorable driving force for association [7].

Even when charge–charge interactions oppose binding in a thermodynamic sense, they play a crucial role in specificity, as it would be extremely unfavorable energetically to remove a charge from the solvent and not to form any compensatory interactions. The requirement that buried charges and hydrogen bonding groups be satisfied upon complex formation is fairly strictly observed in known complexes. In some cases, there appear to be interfaces where networks of hydrogen bonds and ion pairs are formed [7]. These can result in a strong enough favorable interaction to compensate for the

loss of solvation while at the same time placing fairly stringent specificity requirements on the geometry of the complex.

Overall, the binding of proteins to other proteins, nucleic acids, and membranes can be thought of as being driven by hydrophobic interactions (including stacking when nucleic acids are involved), constrained by the need to minimize the desolvation of charged and polar groups while optimizing the favorable interaction of these groups at an interface. Within the context of these constraints, as well as that of shape complementarity, the great flexibility in the design of different interfaces allows for the wide range of regulated and highly specific interactions that characterize signaling pathways.

Nonspecific Association with Membrane Surfaces

The interaction of proteins with membrane surfaces provides an example of how different combinations of hydrophobic and electrostatic interactions are combined to achieve various specificities. Many biological membranes contain acidic phospholipids that produce a negative electrostatic potential that can be used to attract positive charges to the membrane surface [8]. A number of membrane-binding motifs are used to anchor proteins to membrane, and these generally consist of some combination of nonpolar groups and positively charged amino acids. Some proteins such as Src use unstructured regions for membrane binding and, in the case of Src, this binding involves the N-terminal peptide, which contains basic amino acids and a myristate group [8]. Binding is regulated by phosphorylation, which reduces the electrostatic attraction between the basic amino acids and the acidic phospholipids [9]. Other unstructured regions, such as those of MARCKS and caveolin, use different combinations of aromatic and basic amino acids to effect membrane binding [10].

The same principles operate for structured proteins that bind to membrane surfaces. Many proteins involved in interfacial signaling contain a lipophilic modification (e.g., myristate, farnesyl) that contributes to membrane association by partitioning hydrophobically into the membrane interior. In addition, it appears that peripheral membrane proteins often have positively charged surfaces that provide an additional attraction to the surface of acidic phospholipids. In the case of the β,γ heterodimer of G proteins, the effect appears secondary to that of nonpolar penetration [11], while for many C2 domains electrostatics appears to be the dominant interaction [12]. For example, the C2 domain from protein kinase C β (PKC- β) and the C2A domain from synaptotagmin I (SytI) associate peripherally with membranes containing anionic phospholipids driven primarily by electrostatic interactions. In contrast, the C2 domain from cytosolic phospholipase A2 (cPLA2) penetrates into the hydrocarbon core of membranes and prefers electrically neutral, zwitterionic phospholipids. Other C2 domains may use a combination of these effects.

Protein-Protein Interactions

Theoretical calculations of electrostatic interactions can account quantitatively for many of the observed binding properties of peripheral membrane proteins. This is not the case for protein-protein association, in part because the highly specific interactions that characterize protein interfaces place greater demands on the level of theoretical description. In addition, binding is often associated with conformational changes and, possibly, changes in ionization state, and these are extremely difficult to predict. Much of what we know of how protein-protein interfaces are designed has been obtained from the analysis of crystal structures of complexes [13–15]. A somewhat surprising finding has been that protein-protein interfaces are in general very similar in composition to the rest of the protein surface, and they tend to be much less nonpolar than the protein core. Some interfaces may be primarily nonpolar, while others appear to be characterized by a great deal of electrostatic complementarity [16]. Indeed, the two factors may well be anti-correlated, with some interfaces exploiting hydrophobic interactions and incurring a large electrostatic penalty for binding while others appear to be designed so as to optimize electrostatic interactions and to exploit hydrophobic interactions to a much lesser extent [7].

Given the knowledge of the structures of the isolated monomers it would be extremely useful to be able to predict the structure of the complex they form. This problem is known as the docking problem (see Smith and Sternberg [3] and Camacho and Vajda [4] for recent reviews), and it has been widely studied with the goal of predicting the binding modes of small molecules to proteins. The docking problem is frequently divided into two steps. One involves a geometric matching of the interacting molecules and the other involves “scoring” the model complexes generated in the first step. Scoring functions based on the principles discussed above, maximizing surface area and geometric complementarity while optimizing electrostatic interactions, appears to work quite well. Indeed, assuming that one knows the structure of the monomers as they exist in the complex, it generally appears possible to reproduce the correct complex geometry (see, for example, Norel *et al.* [17]). This suggests that the physical basis of binding is reasonably well understood. Of course, the more meaningful problem is to predict the structure of a complex based on the structures of the free monomers; however, this problem is far from being solved due to unknown conformational changes that accompany complex formation. In general, the larger these changes, the less accurate the result.

Prospects

Although the accurate prediction of binding free energies remains an unsolved problem, the current level of understanding of molecular recognition is such that computational methods can be extremely useful in the design and interpretation of experimental results. Moreover, the use of bioinformatics

tools can significantly expand the range of problems that can be addressed. For example, evolutionary information can be used to map regions on a protein surface involved in binding [18,19]. Moreover, once the binding properties of a few members of a protein family have been determined, it should be possible to understand the behavior of many other family members through a combined analysis of sequence, structure, and energetics. Comparing multiple sequence alignments, multiple structure alignments, and the physicochemical properties of protein surfaces can provide a great deal of information as to how binding affinity and specificity are coded onto the three-dimensional structures of proteins.

THE RAPIDLY GROWING GENOMIC SEQUENCE DATABASES ARE CREATING NEW CHALLENGES CONCERNING HOW TO USE GENOMIC DATA TO LEARN ABOUT THE FUNCTIONS OF PROTEINS AND THEIR FUNCTIONAL RELATIONSHIPS WITH EACH OTHER IN THE CELL. A VARIETY OF EXPERIMENTAL AND COMPUTATIONAL APPROACHES ARE EMERGING FOR DECIPHERING WHICH PROTEINS ARE WORKING WITH WHICH OTHERS AS PARTS OF FUNCTIONAL NETWORKS IN THE CELL. HERE, WE REVIEW SOME OF THE VARIOUS NEW COMPUTATIONAL TECHNIQUES THAT ARE ABLE TO DRAW CONNECTIONS BETWEEN DISTINCT BUT FUNCTIONALLY LINKED PROTEINS BASED ON CERTAIN PATTERNS OF OCCURRENCE OR ARRANGEMENT ACROSS MULTIPLE FULLY SEQUENCED GENOMES.

Introduction

In the last few years, advances in genomic and proteomics technologies have produced an explosion of raw data on biological systems at the molecular level. The rapidly growing number of organisms for which the genomes have been completely sequenced serves as a dramatic example. At the time of this writing, the genome sequences of more than 100 organisms are publicly available [1], including a draft sequence of the human genome released last year [2,3]. As a result, the speed with which protein sequences are being acquired has vastly outpaced our ability to assign functions to them directly by experimental (e.g., biochemical and genetic) methods. This growing disparity between known sequences and known functions for these proteins has created a unique challenge. How can we infer the functions of proteins on the genomic scale? A variety of methods have been devised to meet this post-genomic challenge. While some genome-wide analyses are

mainly experimental in nature, others are predominantly computational, and some combine aspects of both approaches. In this chapter, we touch first on experimental approaches to genome-wide analysis (covered in more detail in Chapter II.C) and then focus on computational analyses of whole genomes.

Approaches to Analyzing Protein Functions on a Genome-Wide Scale

One theme emerging from recent work is that consideration of the genomic context of a protein can provide valuable information about the function of a protein, even in the absence of experimental studies. Analyses of various kinds of patterns across the burgeoning genomic databases can provide insight into functional relationships among distinct (nonhomologous) protein sequences. Consequently, this has led to a natural shift from asking *what a particular protein*

does to asking *what other biomolecules that protein interacts with* or, to use a broader phrasing, *is functionally linked to*. This expanded perspective of protein function within the context of pathways and networks forms the basis for many of the recent developments in genomics.

Experimental Data on a Genome-Wide Scale

Some experimental genomic approaches make direct observations of functional linkages, while others require subsequent computational analyses to make statistical inferences about the existence of such linkages. Two techniques for making direct observations of physical protein–protein interactions are the yeast two-hybrid methods [4–6] and mass-spectrometry methods [7,8]. Both approaches are being applied on a genome-wide scale to generate maps of physical protein–protein interactions. Another genome-wide experimental approach, the synthetic genetic array [9], makes observations of functional linkages among proteins at the genetic rather than physical level.

Some genome-wide studies combine experimentation and subsequent computational analysis. One example of this combined approach is the inference of functional linkages from mRNA expression data obtained from DNA microarrays. In these studies, computational analysis of the raw expression data produces functional linkages between genes for which expression patterns vary in correlated ways with respect to changes in variables such as time, growth conditions, or tissue type [10–14].

Functional Linkages from Genome Sequence Data: Nonhomology Methods

The traditional computational method for inferring the function of an uncharacterized protein relies on establishing a statistically significant similarity between the sequence of the uncharacterized protein and that of a protein whose function has already been experimentally determined. The vast majority of entries in the sequence databases have acquired their functional annotations via this technique. Here, we refer to this large family of sequence-based approaches as the *homology method* because they assign functions to proteins based on homology. While this classical approach has played a major role in shaping molecular biology, its limitation is clear. It can only infer relationships between similar sequences. The homology approach does not shed light on functional linkages between different (non-homologous) proteins. In one situation of special interest, typically accounting for a third to half of the open reading frames in a newly sequenced genome, a protein sequence from one genome may have homologs in other genomes, but it may be that none of these proteins has ever been characterized experimentally. Sequence comparison would tell us that these proteins are all evolutionarily related to each other, but nothing more.

A series of recent computational innovations (reviewed in references [15–18]), denoted here as *nonhomology methods*, utilize patterns discovered at the higher level of genomic

organization to infer functional linkages between nonhomologous proteins. Such linkages provide a rich source of functional information, even for the problematic situation of proteins without any characterized homologs. We describe three different nonhomology methods followed by an illustration of their application.

PROTEIN PHYLOGENETIC PROFILES

Two or more proteins that act together in the cell as part of the same complex or pathway should all be present in any organism that uses that complex or pathway. Conversely, it is natural to expect them all to be absent from organisms that do not use that complex or pathway. A protein phylogenetic profile is a vector that describes the presence or absence of a particular protein across a set of genomes. Two or more different (nonhomologous) proteins that share very similar phylogenetic profiles are likely to be functionally coupled. Pellegrini *et al.* [19] developed the phylogenetic profile method to establish functional linkages among proteins on the genomic scale. Related ideas and data structures were also discussed by others [20]. Statistical treatments have improved the original calculations [17], and the profiles have been used in other applications such as predicting the subcellular localization of proteins [21].

THE ROSETTA STONE METHOD

Two proteins, A and B, that are separate entities in one organism are sometimes found fused together in a single larger protein A–B in the genome of another organism. The evolutionary fusion of these two proteins is taken as evidence that they are functionally linked. The fusion protein is dubbed a *Rosetta Stone* because it allows a functional linkage to be drawn between the two separate proteins A and B. This idea was first applied on a genome-wide scale by Marcotte *et al.* [22] and then by others [23].

CONSERVED GENE CLUSTERS

Especially in prokaryotic organisms, functionally linked proteins are sometimes encoded near each other on the chromosome (e.g., as in operons). When two or more proteins tend to be encoded in proximity, especially in relatively divergent microorganisms, this argues strongly for a functional linkage between the proteins. The information embodied in conserved gene order or proximity was first applied on a genome-wide scale to establish possible functional linkages by Overbeek and coworkers [24,25].

AN EXAMPLE RELEVANT TO CELL SIGNALING

To illustrate the ideas here, algorithms based on the three methods discussed above were applied to the genome of *Escherichia coli*, and the results for a well-known cell signaling pathway were investigated. The protein flgE was chosen as a somewhat arbitrary starting point for investigating the bacterial flagellar complex. Using the multiple methods, high confidence links were established for this protein. Subsequently, high confidence links were established to those proteins first connected to flgE. This process was repeated until links of third order from the central protein were included. The results are shown in Fig. 1. Many of the

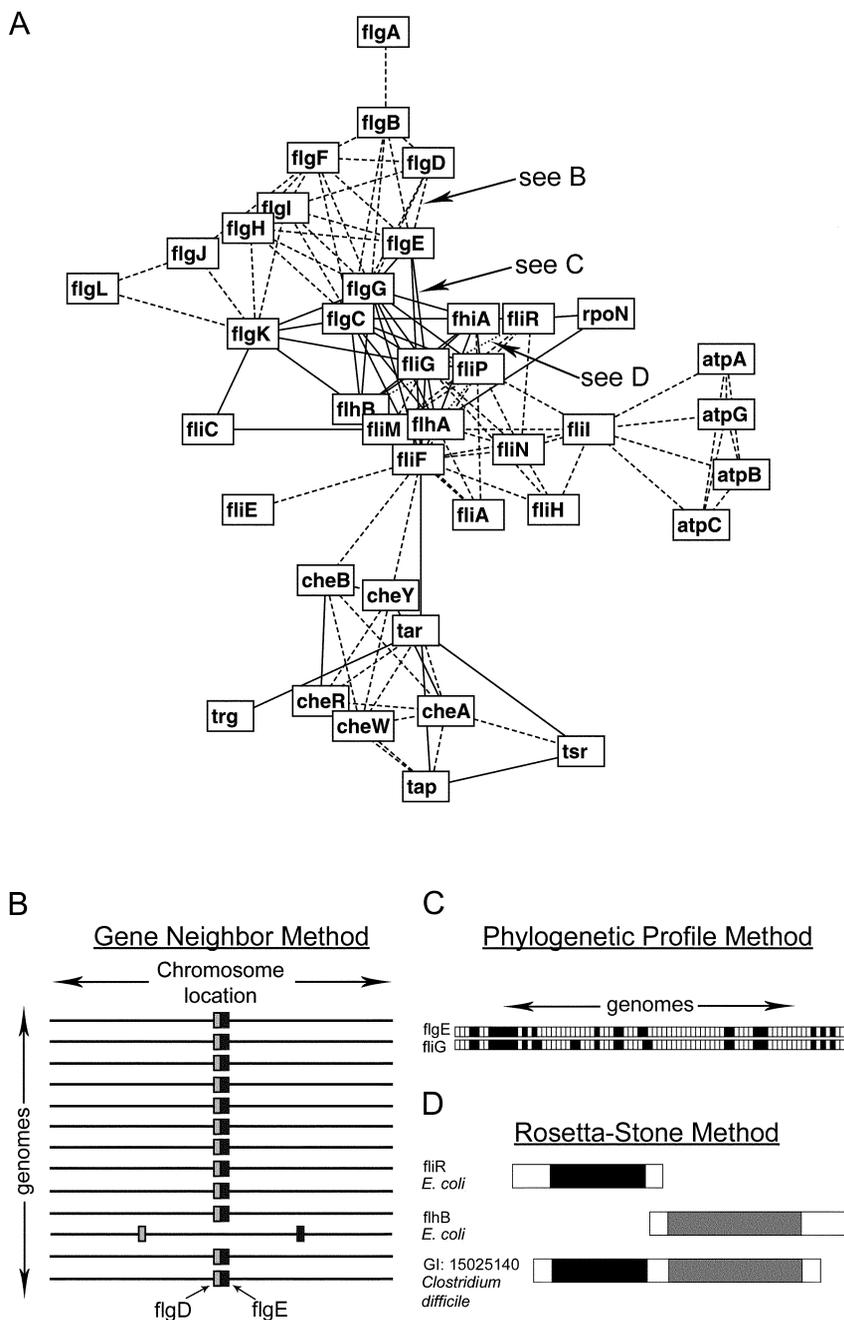

Figure 1 An illustration of functional linkages inferred by computational analysis of genomic data (nonhomology methods). The flagellar protein *flgE* was taken as a query protein. Computational methods were used to predict functional linkages between *flgE* and other proteins in the *E. coli* genome. Subsequent links (of second and third order) were generated from these to others. (A) This procedure produced the network shown, which includes many proteins known to participate in motility and chemotaxis. The computed functional links include proteins involved in various aspects of this biological system, from signal transduction to flagellar assembly and regulation. Each link is coded according to the computational method by which it was inferred. Links from the method of phylogenetic profiles are in solid lines, gene neighbor links are dashed, and Rosetta stone links are dotted. In some instances (not illustrated), multiple methods produced the same link. The three methods are shown at the bottom. Each panel illustrates the pattern in the genomic data that allowed one of the inferences at the top to be made. (B) The gene neighbor method draws a functional linkage between two proteins if they tend to be encoded in adjacent or nearby positions on the chromosomes of multiple organisms [25,26]. (C) In the method of protein phylogenetic profiles [16], the presence or absence of a protein across a set of genomes is analyzed. The two linked proteins shown have profiles for which the similarity is statistically significant. (D) In the Rosetta Stone method, the two separate proteins from one genome are functionally linked because they are found in some other genome as combined parts of a single larger protein [23,24].

proteins involved in flagellar biosynthesis and assembly (flgA, flgB, flgC, flgD, flgE, flgF, flgG, flgH, flgI, flgJ, flgK, flgL, fliA, fliE, fliF, flp, fliR), export (flhA, flhB, fliH), and motor switching (fliG, fliM, fliN) were recovered. Links emanating from these flagellar proteins established connections to the chemosensing proteins (cheA, cheB, cheR, cheY, cheW, tap, tar, trg, tsr) whose signals ultimately drive the flagella, to the transcriptional proteins (fliA, rpoN) that regulate the production of flagellar proteins, and to the ATPase complex (fliI, atpA, atpB, atpC, atpG) that supplies energy for the flagellar motion. The illustration of the chemotaxis system in *E. coli* shows that in favorable cases these computational nonhomology methods not only can recover links among proteins involved in a complex or pathway but also can reveal higher order functional relations among the complexes and pathways.

MISCELLANEOUS METHODS

Other methods for inferring functional linkages have also been explored. For instance, mRNA expression data have been combined with promoter motif detection algorithms to identify regulatory networks [26,27]. In contrast to the analysis of large sets of experimental measurements, another computation approach seeks to distill large volumes of experimental results through the mining of the published literature [28–31]. These methods attempt to ascertain, in an automated fashion, the existence of experimentally established functional relationships among proteins from computational analysis of millions of biomedical literature abstracts. Efforts involving some amount of manual curation have also been conducted. The Database of Interacting Proteins (DIP) [32] is the result of one such effort.

QUALITY CONTROL BY BENCHMARKING

Computational methods like those discussed here provide only circumstantial evidence that various proteins are actually functionally linked in the cell. This makes quality control a particularly important problem. Two complementary approaches to this problem are the development of probabilistic models to evaluate statistical significance and the use of known functional relationships for benchmarking.

Statistical approaches for assessing inferences made by nonhomology methods have only begun to be addressed. One of the statistical difficulties that has not been explored deeply concerns how to handle correlated observations. For example, among the organisms whose genomes have been sequenced, some are much more closely related than others. This complicates the probabilistic treatment of features such as conserved relative positions (or presence versus absence) of proteins across the known genomes. Suppose for example that two (or more) proteins exhibit some genomic pattern that is evident only among very closely related organisms. Such a pattern has not survived over a long evolutionary time scale and so may not indicate a significant functional linkage between the proteins in question.

Regardless of the simplicity or sophistication of the statistical analyses performed, experience has shown that the various

computational methods must be calibrated by examining how well they perform on proteins whose functions are already known. One reasonable benchmarking approach is to measure the fraction of predicted functional linkages that are corroborated by the linked proteins having similar functional categories or keywords in annotated protein databases (e.g., SWISS-PROT, MIPS, KEGG) [33–35]. A related strategy is to use the inferences from one computational method to evaluate another. The general idea of using multiple methods to generate linkages with higher confidence was first applied by Marcotte *et al.* [36]. Multiple sources of experimental measurements have also been used to similar effect [37].

Current Issues and Future Prospects for Computing Functional Interactions

Current and future investigations into the problem of computing functional interactions will address some of the following questions:

- Can probabilistic models be developed to overcome the problem of correlated data in order to give accurate significance scores for inferred linkages?
- Can the methods that work so powerfully on prokaryotic and lower eukaryotic genomes be extended fruitfully to higher organisms? How many eukaryotic genomes must be completed to make this possible?
- How can functional linkages from various methods be combined and visualized in the best way [38]?
- What are the large-scale properties of the biological networks that arise from these computations [39], and how can true pathways be extracted from them?

Solutions to these problems will bring a richer understanding of biological pathways and networks in the coming years.

Acknowledgments

The authors thank Joe Fierro, Matteo Pellegrini, Marco Vasquez, Peter Bowers, Edward Marcotte, Steve Wickert, and David Eisenberg for their valuable contributions to the ideas discussed here.

Transmembrane Signaling Paradigms

The initiation of a cell signaling event relies primarily on interactions between molecules in the extracellular and cell-membrane space. Different types of molecules can serve as extracellular signals (Fig. 1a) [1]: hormones, cytokines, growth factors, and neurotransmitters secreted from distant or neighboring cells; antigens or antibodies free in solution or attached to (migrating) leucocytes or foreign (e.g., virus) cells; small soluble molecules (i.e., <1000 Da; ions, metabolites); and the extracellular matrix. Except for lipid-soluble signaling molecules that can migrate through the lipid bilayer (e.g., steroid hormones and NO gas), transmembrane proteins are involved in transferring the molecular signal into the target cell. Small soluble molecules can be transported across the plasma membrane by channel and carrier proteins or cell–cell GAP junctions, which provide an electrical and metabolic coupling with the extracellular space and neighboring cells, respectively. Larger soluble or tethered molecules, including filaments from the extracellular matrix, require a specific interaction with a transmembrane (co-) receptor for signal transduction across the membrane.

The transmembrane protein undergoes an intramolecular conformational change or change in the quaternary structure (e.g., dimerization) upon binding of the extracellular molecular signal. It is noncovalently or covalently linked either to an ion channel that allows the change of the ion traffic across the membrane or to intracellular membrane-proximal components that are activated to induce an intracellular signaling cascade. In the latter case, the receptor can contain intrinsic enzyme (e.g., phosphorylation) activity, such as the receptor tyrosine kinases; recruit relevant intracellular enzymes; or associate with G proteins, which in turn activate

kinases or ion channels. While the transmembrane signaling process mediated by (ion) channels is immediate and brief, enzyme-linked receptors manifest a slow and more complex molecular mechanism but can achieve a great amplifying signaling effect. Subsequently, gene expression in the nucleus or other cell activities are affected. Recent studies have shown that endocytosis of transmembrane receptor complexes can be used to deliver the complex and affect activities at distant locations in the cell [2].

A careful regulation and coordination of the communication within the molecular signaling society is essential to the initiation of a signaling event, especially in the more complex multicellular organisms. Any molecular interaction, such as that between a receptor or receptor subunits and ligand molecules, is determined by the effective local molecular concentrations and (apparent) dissociation constants. The concentrations of the signaling and receptor molecules can be controlled by various factors at different stages along the path toward an encounter (Fig. 1b). After synthesis or secretion, enzymatic degradation or temporary storage can influence the concentration of the signaling molecule, whereas lateral capping and endocytosis can alter the density of receptor molecules at the membrane surface. A rapid turnover of signals and receptor molecules is required to respond to fast changes in the environment. Signaling molecules may have to travel far (e.g., endocrine signaling) and depend on fluid streams of the vascular system and diffusion to enable an encounter with their target. The gel-like layer of proteoglycans in the extracellular matrix can serve as a selective molecular sieve to regulate the traffic of migrating cells and signaling molecules.

The local environment at the cell membrane can play an important role in controlling the receptor–ligand interaction (Fig. 1b). By interacting with the ligands, membrane-associated

molecules can localize and/or immobilize extracellular signals for internalization and degradation or present them for receptor binding (e.g., growth factors and cytokines localized by proteoglycans). The physicochemical and geometrical properties of the molecular interface that determine the (apparent) dissociation constant of the signal binding can be altered by interaction with the local environment. A change

in the physiological condition or binding of an effector molecule from the cytosol, membrane, or extracellular space (e.g., ion, metabolite, other protein) can dramatically change the affinity of a receptor–ligand complex by altering the conformation or electrostatic potential at the signal-binding interface. Individual receptor–ligand interactions may be stabilized or activated by effector binding or multiple

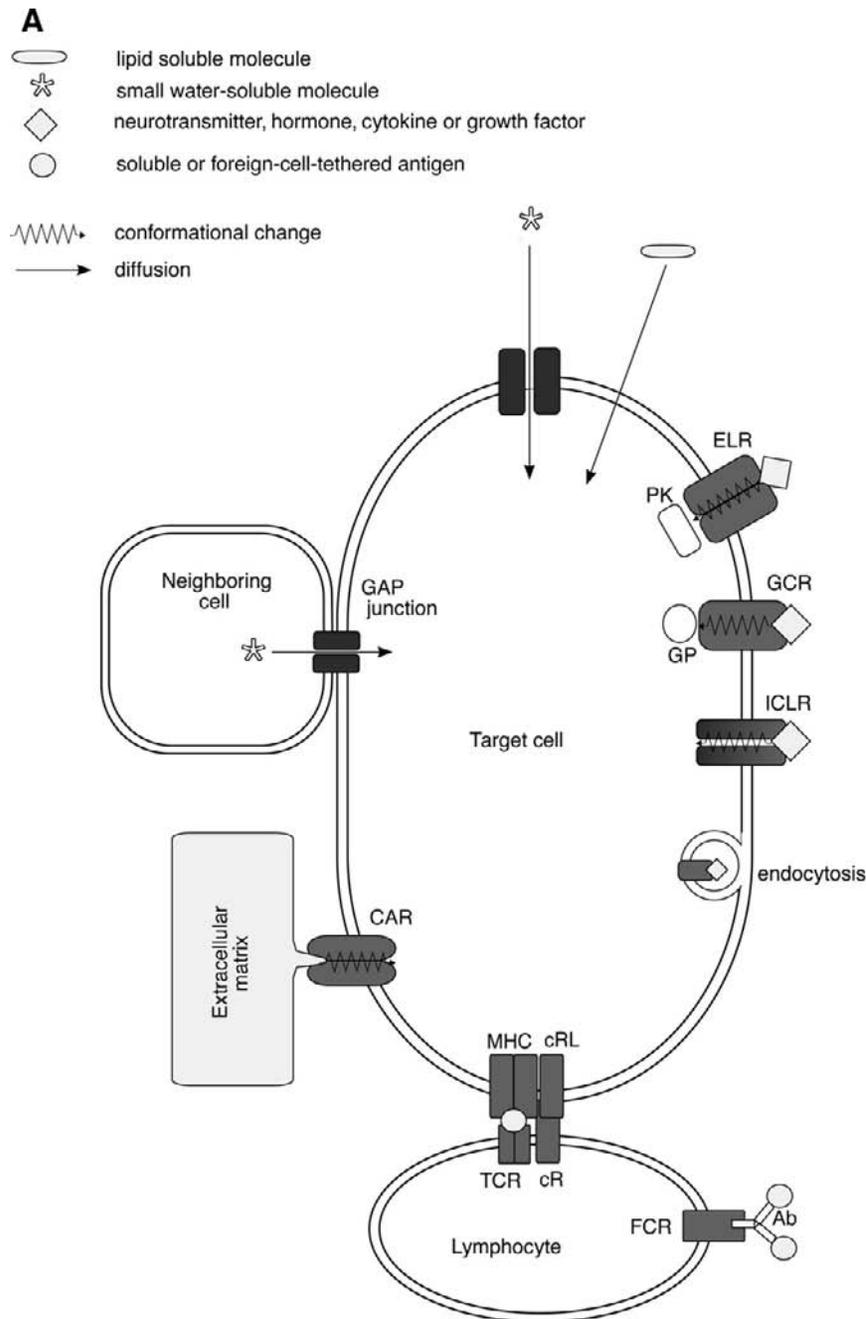

Figure 1 Transmembrane signaling paradigms: (a) molecular interactions and mechanisms, and (b) control of an interaction between a (oligomeric) receptor and (oligomeric) ligand. Extracellular signaling molecules are yellow; channels or carrier proteins and receptors are blue and red, respectively. Lipid soluble molecules comprise hydrophobic or small uncharged polar molecules; small water-soluble molecules comprise inorganic ions, sugars, amino acids, nucleotides, and vitamins. **ELR**=enzyme-linked receptor, **GCR**=G-coupled receptor, **ICLR**=ion-channel-linked receptor, **PK**=protein kinase, **GP**=G protein, **Ab**=antibody, **MHC**=major histocompatibility complex, **TCR**=T cell receptor, **FCR**=Fc receptor, **cR**=coreceptor, **cRL**=coreceptor ligand, **CAR**=cell adhesion receptor.

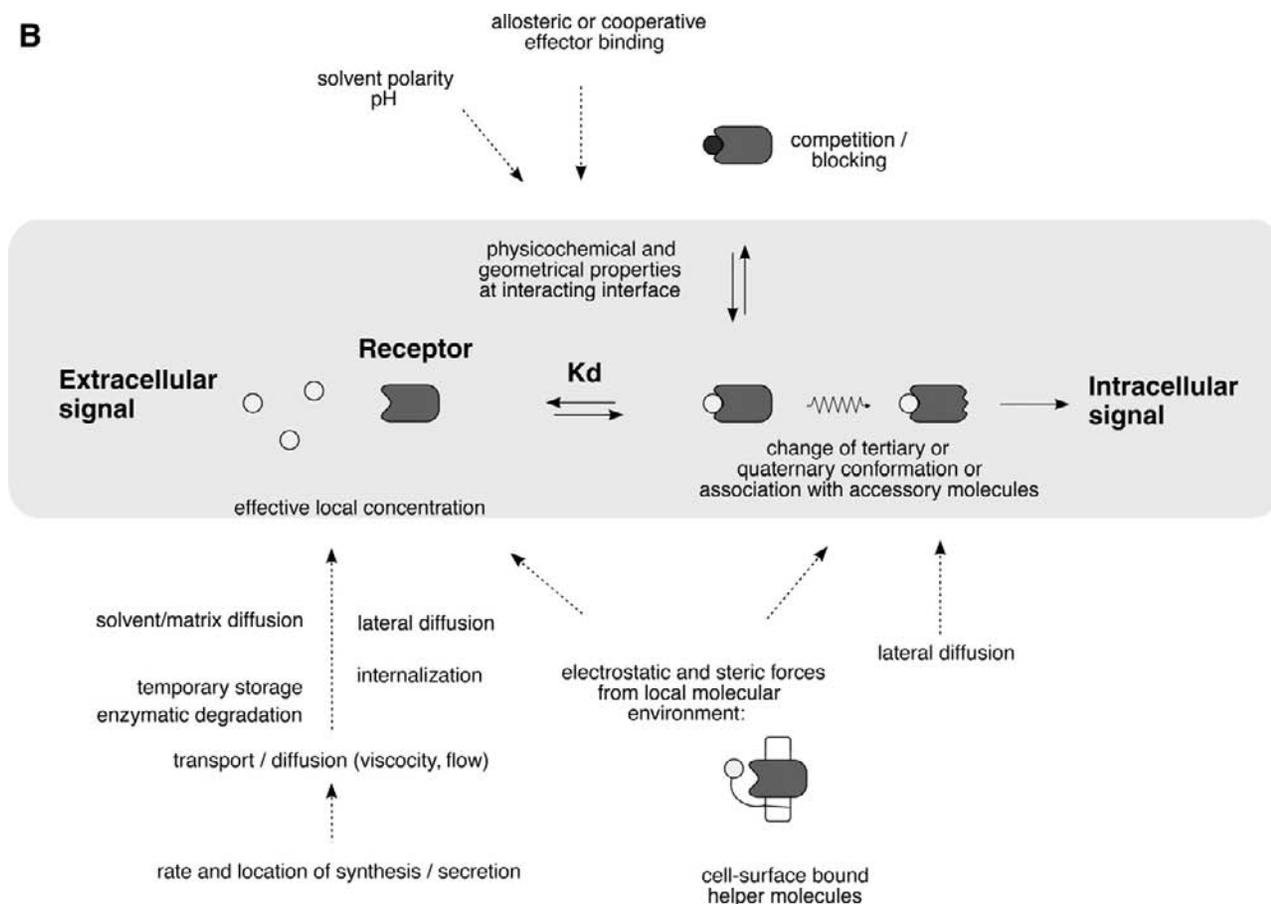

Figure 1 (continued)

interactions, (e.g., clustering of receptor–ligand complexes). Some complexes may be very weak on their own and require accessory proteins or coreceptors for stability or activation; for example, CD4 and CD8 coreceptors in the major histocompatibility complex (MHC) multicomponent complexes help to strengthen the adhesion between a T and antigen-presenting cell. Also, low-affinity antibody–antigen interactions may be amplified by multivalent cross-linking. Furthermore, the apparent affinity for the extracellular signaling ligand can be decreased when another molecule (i.e., antagonist) competes for the same target-binding site. These control mechanisms that regulate the signaling interaction network are similar to those that control other biomolecular interactions such as enzyme–substrate interactions. However, altering the affinity of an assembly by covalent modifications (e.g., phosphorylation) is more common in intracellular signaling, where a large repertoire of modifying enzymes is available.

Structural Basis of Protein–Protein Recognition

A specific interaction between a signaling and membrane receptor molecule is critical to obtain a well-directed signaling event. The molecular recognition process that underlies

a specific interaction is provided by the complementarity of the physicochemical and geometrical properties of the two protein surfaces to obtain an energetically favorable complex. This is determined by the hydrophobic effect, close packing with favorable van der Waals interactions, and the formation of hydrogen and ionic bonds. Computational analyses of atomic structures of protein–protein complexes have identified the structural and physicochemical properties of these interfaces [3–5] (see Kleianthous [6] for reviews). Structures of various extracellular molecular signaling complexes have been elucidated so far: the extracellular domains of receptors complexed with hormones and cytokines, the major histocompatibility complex with diverse peptides (pMHC) in association with the T-cell receptor (TCR), and antibody (Fab fragments)–antigen complexes [6]. For the majority of these complexes, the individual components form homo- or hetero-oligomers by itself or upon ligand binding. Table I summarizes the receptor–ligand complexes and their oligomeric disposition [7].

In general, protein–protein interfaces exhibit a mixture of apolar and polar interactions scattered over the binding surface with the polar residues providing fine specificity. The interfaces of non-obligate complexes (i.e., between molecules that also exist on their own), such as extracellular signalling and enzyme–inhibitor complexes are generally more polar than homodimers (Fig. 2), because of the solubility

Table I Current Receptor–Protein Signaling Complexes in the Protein Data Bank

Protein1	Protein2	pdrcode(s) (resolution in Å)	Oligomeric State ¹		Receptor Activity	Ref.
Growth hormone receptor	Somatotropin (growth hormone)	3hhr (2.8) ³ , 1hwg (2.5)	2:1	Receptor dimerization upon ligand binding	Non-protein kinase, associated jak kinases	12
	Gh antagonist g130r	1hwh (2.9) ³ , 1a22 (2.6) remodeled interface: 1axi (2.1) ³	1:1 1:1			
Prolactin receptor	Somatotropin (growth hormone)	1bp3 (2.9)	1:1		Non-protein kinase, associated JAK kinases	13
	Placental lactogen	1f6f (2.3)	2:1			
Erythropoietin receptor	Erythropoietin	1cn4 (2.8) ³ , 1eer (1.9)	2:1		Non-protein kinase, associated JAK kinases	14
Interleukin-1 receptor	Interleukin-1 receptor antagonist	1ira (2.7)	1:1		Non-protein kinase, associated accessory protein	15
Interleukin-1 receptor	Interleukin-1 beta	1itb (2.5)	1:1		Non-protein kinase, associated accessory protein	16
Interleukin-4 receptor α chain	Interleukin-4	1iar (2.3)	1:1		Non-protein kinase, associates with common γ chain, associated JAK kinase	17
Granulocyte colony-stimulating factor receptor	G-csf	1pgr (3.5) ³ , 1cd9 (2.8)	2:2-I		Non-protein kinase, associated JAK kinases	18
Interleukin-6 receptor GP130 chain	Interleukin-6	1i1r (2.4)	2:2-I		Non-protein kinase, common β chain (e.g., Gp130), associated JAK kinase	19
Trka receptor	Nerve growth factor	1www (2.2)	2:2-II		Tyrosine kinase	20
Bone morphogenetic protein receptor 1a	Bone morphogenetic protein-2	1es7 (2.9)	2:2-II		Serine-threonine kinase	21
Interferon-gamma receptor α	Interferon- γ	1fg9 (2.9) ³ , 1fyh (2.0)	2:2-II		Non-protein kinase, associated JAK kinases	22
Interleukin-10 receptor	Interleukin-10	1j7v (2.9)	2:2-II or 4:4 ²		Non-protein kinase, associated JAK kinases	23
Fibroblast growth factor receptor 1	Fibroblast growth factor-1	1evt (2.8)	2:2-I	Homo-and heterodimerization, interdomain ligand binding; heparin involved	Tyrosine kinase	24
Fibroblast growth factor receptor 1	Fibroblast growth factor-2	1cvs (2.8), 1fq9 (3.0; heparin bound)	2:2-I			
Fibroblast growth factor receptor 2	Fibroblast growth factor-1	1djs (2.4)	2:2-I			
Fibroblast growth factor receptor 2	Fibroblast growth factor-2	1ev2 (2.2)	2:2-I			
	Fibroblast growth factor-2 apert syndrome variant	mutant: 1iil (2.3) ³ , 1ii4(2.7) ³	2:2-I			
Death receptor 5	TRAIL	1d0g (2.4) ³ , 1d4v (2.2)	3:3		Non-protein kinase, associated TRAF	25
Tumor necrosis factor receptor	Tumor necrosis factor β	1tnr (2.9)	3:3;	dimerizes without ligand; trimerizes upon ligand binding	Non-protein kinase, associated TRAF	26

¹There are differences in the literature about the nomenclature used to describe receptor–ligand complexes. Here, we use the stoichiometry of the complex (i.e., the number of protomer chains of the receptor and ligand, respectively, involved in the complex). We identify two types of 2:2 complexes: the 2:2-I type, where each receptor chain contacts both monomeric ligands, and the 2:2-II type, where each receptor chain contacts both protomers of the dimeric ligand.

²The 2:2 complex is thought to form an intermediate receptor–ligand complex, whereas the 4:4 is the active receptor–ligand complex. Structural parameters (Fig. 2) have been computed for the former.

³These entries have not been included in the computational analysis shown in Fig. 2.

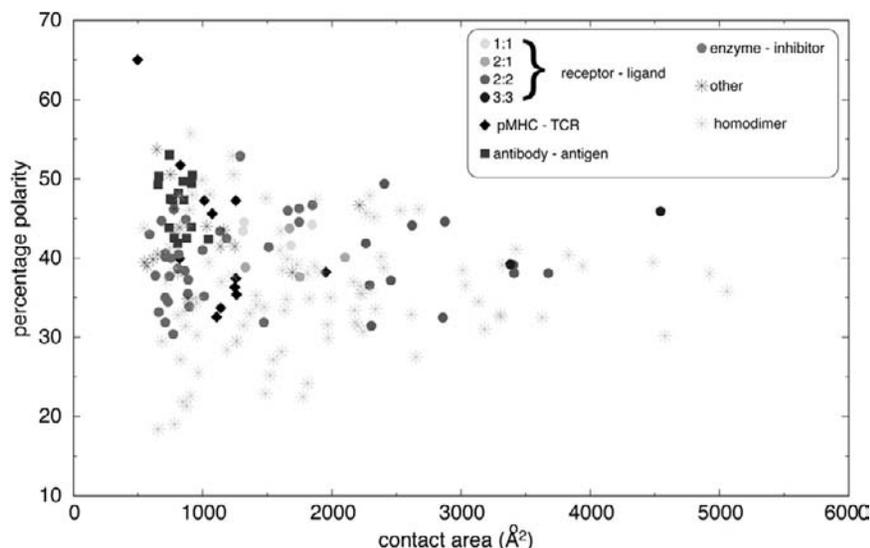

Figure 2 Correlation between the contact area of the interface and the percentage of the contact area that involves polar atoms for extracellular signaling complexes, diverse other nonobligate complexes, and homodimers. Structures used in this analysis are those studied previously [3,5] and more recent solved structures. Parameters have been calculated as described in Jones *et al.* [27]. When one or both of the proteins involved in the complex are multimers, the contact area is summed over all receptor–ligand interfaces to give a total for the complete assembly and the percentage polarity has been averaged respectively.

requirements of the individual molecules. Whereas the percentage of polar atoms in the interface is variable in the receptor–ligand and pMHC–TCR complexes, the antibody–antigen complexes consistently have more than 40% polar atoms in the interface and have a relatively small contact area (i.e., interface smaller than 1500 Å²). The surface area buried in the specific non-obligate protein–protein associations is also highly variable. Large contact areas up to 5000 Å² are found for homodimers and various nonobligate complexes, such as multimeric receptor–ligand and large enzyme–inhibitor complexes (Fig. 2).

Structural rearrangements upon protein–protein association have been identified for many complexes, such as enzyme–inhibitor (e.g., thrombin–hirudin), intracellular signalling (e.g., G_α–G_{βγ} protein) and receptor–ligand (e.g., receptor–human growth factor) complexes. Remarkably, protein–protein complexes that undergo structural rearrangements usually have large interfaces (i.e., >1500 Å²). They involve disorder-to-order transitions, small changes in side-chain conformations (i.e., translational, rotational, and side-chain degrees of freedom), or gross conformational changes such as loop or domain movements. The monomeric human growth factor, for example, shows large helix movements upon binding into a cleft formed by the two subunits of the homodimeric receptor. Conformational changes are expected to play a major role in the transmembrane signalling process. Upon receptor–ligand complexation, side-chain flexibility may facilitate finding the complementary fit [8], whereas larger conformational changes may reveal hydrophobic surfaces or propagate a long-range structural rearrangement of the monomeric or oligomeric transmembrane receptor required for signal transduction. Residue spacing

and molecular flexibility have been demonstrated to be important for protein–carbohydrate recognition in signalling, as well [9].

The structural basis of conformational flexibility is difficult to assess experimentally, as the current available experimental methods in structural determination (i.e., X-ray crystallography, nuclear magnetic resonance spectroscopy, electron microscopy) require a stable structure. Capturing the structures under different conditions (e.g., free and bound) or having thermodynamic and mutagenesis data can help to identify these changes or relate them to signal transduction activity. The current structural data in the Protein Data Bank (PDB) and a computational analysis of these protein–protein complexes in the PDB (Fig. 2) are probably biased toward structures that form stable structures. The atomic structures of many transmembrane domains or proteins have yet to be determined, which leaves the molecular mechanisms responsible for the signal transduction across the membrane still largely unknown.

Conclusion

The biology of signaling features a whole range of interactions, from weak to strong. Dissociation constants are found in the nM to mM range [10]. Both the complementarity of the physicochemical and geometrical properties of the interface and the flexibility of the surfaces of the receptor and signalling molecule contribute to the binding free energy. Structural data and currently available computational methods appear inadequate to estimate the binding energy or specificity of an interaction. The interaction

between molecules has usually been optimized throughout evolution to tune specificity and affinity to function and physiological environment (Fig. 1b). For example, high local concentrations of neurotransmitter can be reached in a chemical synapse that allows a low-affinity receptor–neurotransmitter interaction. Also, adjacent helper molecules or multiple interactions allow reduced affinity of isolated complexes by adding up weak interactions, generating a strong multicomponent complex. In comparison to other (cytosolic) protein–protein complexes, the anchoring of molecules in or at the membrane site is advantageous to localizing target subunits and substrate. In contrast, immune response complexes, such as antigen–antibody assemblies lack an extended period of a selective evolutionary optimization toward their physiological environment. Consequently, they exhibit a poorer shape complementarity than other molecular protein–protein associations [11]. In summary, proteins are versatile and the recognition process is different and unique to each molecular complex. Some of these will be discussed in more detail in the following chapters of this section.

Introduction

Specific protein–protein interactions provide a major part of the basic organization of living cells. Analysis of the structure of the complex provides a high-resolution static picture of the complex, while the affinity allows us to analyze the equilibrium thermodynamics of the interaction. However, understanding biological processes requires information on the nature of the full energy landscape of the complexation reaction. Analysis of the kinetics of association and dissociation allows characterizing the landscape in more detail. In combination with computational methods, the free energy landscape can be reconstructed based on kinetic data, as well as the transition state and intermediates along the pathway. Of special interest in analyzing the free energy landscape are “hot spot” residues, which make an outstandingly large contribution toward binding. The thermodynamics and kinetics of protein–protein interactions and the free energy landscape connecting the free and bound proteins are the subject of this chapter.

Thermodynamics of Protein–Protein Interactions

Specific protein–protein interactions provide a major part of the basic organization of living cells. The structure of a protein complex embeds the information about the relative mutual organization of two proteins in a frozen state; however, it does not intuitively provide information on the affinity between two proteins or the time-dependent process of

complex assembly and dissociation. For a mechanistic understanding of biological processes and for engineering proteins that fulfill specific therapeutic tasks, we require physicochemical observables that describe the pathway of protein–protein interactions in detail. The binding affinity between proteins,

$$K_a = \frac{[AB]}{[A][B]} \quad (1)$$

given by the equilibrium concentrations of the proteins [A] and [B] and the complex [AB], is directly related to the free energy of interaction $\Delta G^\circ = -RT \ln K_a$. Thus, complex formation only takes place if $\Delta G^\circ < 0$. The free energy of the complex formation can readily be analyzed by measuring K_a (Fig. 1); for example, the energetic contributions $\Delta \Delta G_D$ of individual residues can be determined by measuring changes in the K_a upon mutation. According to the Gibbs–Helmholtz relation $\Delta G^\circ = \Delta H^\circ - T\Delta S^\circ$, both the enthalpy ΔH° and the entropy ΔS° of the complex formation contribute to ΔG° . ΔH° reflects the strength of the interactions between two proteins (e.g., van der Waals, hydrogen bonds, salt bridges) relative to those existing with the solvent molecules, which are excluded from the binding interface. ΔS° , on the other hand, mainly reflects two contributions: changes in solvation entropy and changes in conformational entropy. Upon binding, the water released from the binding sites leads to a gain in solvent entropy. This gain is particularly important for hydrophobic patches on the protein surface (*hydrophobic effect*). At the same time, the proteins

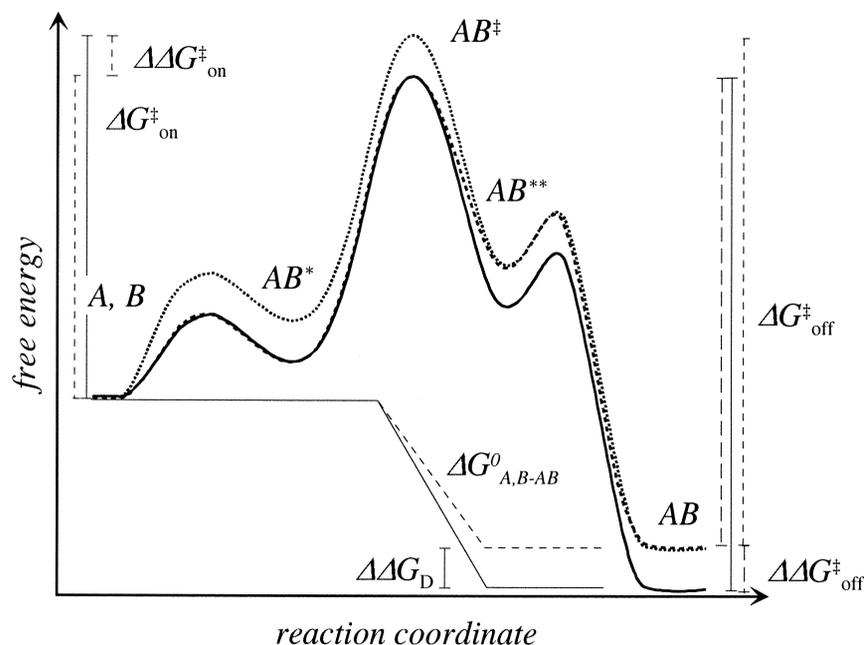

Figure 1 Free energy profile describing the pathway for the formation of a protein–protein complex (AB) from the free proteins A and B via the encounter complex AB^* , the transition state AB^\ddagger , and the intermediate AB^{**} . Comparison of the profiles for the wt proteins (—) with a mutant affecting long-range electrostatic interactions (.....) and a mutant affecting short-range interactions (-----), respectively. The free energies, ΔG , are indicated for both the complex formation ΔG° and the transition state, as well as the changes in free energy of the encounter complex.

and individual residues within the proteins lose conformational freedom, resulting in a negative change in conformational entropy. The loss of conformational freedom was estimated to be on the order of 15 kcal/mol at 25°C, but values between 0 and 30 kcal/mol have been cited as well [1]. What do we know about the contributions toward entropy and enthalpy on the molecular level? Dehydration of non-polar residues during association is always entropically favorable, while that of polar residues is unfavorable. The enthalpies are nevertheless negative, as they represent the energy of interaction of atoms at the interface relative to their interactions with water. As several partially canceling factors contribute toward the entropy and enthalpy of interaction, it is not surprising that for most mutant complexes the difference in free energy of binding is much smaller than the accompanying changes in ΔH° and ΔS° . This has been emphasized by theoretical studies showing that, on forming a cavity in water to accommodate a solvent molecule, the change in the enthalpy of water (solvation) is exactly balanced by the entropy of the cavity; thus, changes in ΔH° and ΔS° cancel out each other in ΔG° [2]. Enthalpy–entropy compensations, then, seem to be a characteristic of weak noncovalent interactions, including protein–protein interactions.

Interaction Kinetics

While analysis of the K_a can provide an extensive thermodynamic picture of the complex, it does not allow any

conclusion about the pathway that leads to the formation of the complex from the individual proteins. This is entirely determined by the shape of the full free energy landscape given by all possible states between the free proteins and the complex, most of which are not accessible experimentally. On this free energy landscape, the reaction itself most likely follows the pathway requiring the least free energy. This pathway is called the *reaction coordinate* and can be studied experimentally through the rates of association and of dissociation. Analysis of these kinetic parameters for several structurally and physicochemically well-defined protein–protein interactions allowed for establishing basic concepts of how proteins form complexes. In the following, we will give an overview about how kinetics can be used for analyzing the interaction pathway through the free energy landscape and how this can be understood on the molecular level.

In a general term, association of a protein complex (AB) from the unbound components (A + B) can be best described using a four state model:

In this scheme, A and B are two proteins in solution, forming the complex AB. The reaction diagram of this interaction (Fig. 1) resembles that of protein folding, with the transition state being the most unstable species along the reaction pathway, which occurs at the highest peak of a reaction coordinate diagram. Two pre-complex states are formed along the reaction pathway. The encounter complex is positioned before the transition state for association (AB^*) and

the intermediate complex (AB^{**}), which is between the transition state and the final complex. In physical terms, the encounter complex tends to dissociate readily (with $k_{-1} \gg k_2$), while the intermediate is already committed to form the final complex (thus, $k_3 \gg k_{-2}$). It has to be emphasized that experimentally one often observes only the transition between $A+B$ to AB and that the equilibrium dissociation constant (K_D) equals $k_{\text{off}}/k_{\text{on}}$. Yet, under certain experimental conditions, the pre-complexes are observable. A good example for such a case is the interaction between Ras and the Ras-binding domain of c-Raf1. Here, a two-step association process was suggested, with an initial rapid equilibrium step followed by an isomerization reaction occurring at the rate of several hundreds per second [3].

The intermediate (AB^{**}) is formed after the rate-limiting step for association, ($k_3 \gg k_{-2}$); therefore, it does not affect the overall rate of association. The intermediate can be envisioned as a partially formed complex that has to reorganize to form the final complex. This reorganization step can be fast, such as for the interaction between cystatin A and papain (230 s^{-1}), or slow, such as for the interaction between lysozyme and HyHEL-10 and HyHEL-26 ($\sim 10^{-3} \text{ s}^{-1}$) [4,5]. A major problem in investigating this intermediate is to find a probe that can monitor independently the formation of the intermediate versus the formation of the final complex.

The Transition State

In the transition state, noncovalent bonds are in the process of being made and broken. At least one encounter complex can be found prior to the transition state, with additional intermediates occupying the energy landscape past the transition state. What is the molecular basis of the transition state for protein–protein interactions? The bound state of two proteins is characterized by local specific interactions (e.g., van der Waals, electrostatic) between widely desolvated binding sites, whereas the unbound state is characterized by complete solvation and higher translational and rotational freedom. During formation of the complex, the proteins have to pass through a free-energy maximum where translational–rotational entropy is reduced and the binding sites are partially desolvated, but short-range interactions and precise structural fitting have not yet been attained. This state is naturally the transition state. The transition state can be approached from the unbound state (association) and from the bound state (dissociation). Yet, by the principle of macro-molecular reversibility, the nature and structure of the transition state should be the same.

The free activation energies required for reaching the transition state from the free proteins, $\Delta G_{\text{on}}^{\ddagger}$, and the complex $\Delta G_{\text{off}}^{\ddagger}$ (Fig. 1) are related to the rate constants of complex formation and complex dissociation, respectively. Thus, experimental information on the nature of the transition state is obtained from the rate constants of the interaction. Absolute values from bimolecular reactions are difficult to

interpret; however, relative values of changes in the rate constants of association k_{on} or dissociation k_{off} upon mutation of individual amino acid residues allow for characterizing the features of the transition state. Mutation studies conducted on many protein interactions have clearly shown that rates of association are mostly affected by mutating charged residues [6]. Moreover, it is possible to introduce charge mutations at the periphery of the binding site that will affect only association, but not dissociation [7]. Mutations, which are neutral in respect to their charge, potentially affect the dissociation rate constants. Masking electrostatic interactions between proteins by increasing the ionic strength has confirmed this observation; while the rate of dissociation is only marginally affected, the effect on the rate of association can be very large and is directly related to the electrostatic energy U of interaction between the two proteins according to Eq. (1):

$$\ln k_{\text{on}} = \ln k_{\text{on}}^0 - \frac{U}{RT} \left(\frac{1}{1 + \kappa a} \right) \quad (2)$$

where $\ln k_{\text{on}}^0$ is the basal rate of association in the absence of electrostatic forces, κ is the inverse Debye length, and a is the minimal distance of approach [6,7].

Direct information on the properties of the transition state could be obtained by double mutant cycle analysis of changes in activation free energies $\Delta\Delta G_{\text{on}}^{\ddagger}$, which are calculated from the association rate constants according to van't Hoff's isotherm:

$$\Delta\Delta G_{\text{on}}^{\ddagger} = RT \ln \frac{k_{\text{on}}^{\text{wt}}}{k_{\text{on}}^{\text{mut}}} \quad (3)$$

$$\Delta\Delta G_{\text{int(on)}}^{\ddagger} = \Delta\Delta G_{\text{on(mut1,mut2)}}^{\ddagger} - \Delta\Delta G_{\text{on(mut1)}}^{\ddagger} - \Delta\Delta G_{\text{on(mut2)}}^{\ddagger} \quad (4)$$

If the $\Delta\Delta G_{\text{on}}^{\ddagger}$ invoked by two individual mutations on each protein are additive, the two residues do not interact during the transition state; however, if the change is less or more than additive, one may assume that these two residues interact at the transition state. Probing the structure of the transition state of barnase/barstar and thrombin/hirudin by this method has shown that only charged residues, which are in close proximity in the final complex, already interact in the transition state. No significant interaction was measured between uncharged residues at this stage [8,9]. A somewhat different approach to probe docking trajectories experimentally uses the analysis of Φ values ($\Phi = \Delta\Delta G_{\text{on}}^{\ddagger} / \Delta\Delta G_{\text{D}}^{\ddagger}$). A Φ value close to one indicates that a specific interaction is formed at the transition state, while a Φ value close to zero indicates that the interaction is formed after the transition state. In a study of the HyHEL-10 Fab complex, multiple replacements were made in two positions, with most of the replacements having Φ values close to zero. This was

interpreted as the transition state being early along the reaction trajectory, before short-range interactions (which have the largest contribution on $\Delta\Delta G_D$) are formed [10]. The notion that short-range interactions affect k_{off} , while long-range electrostatic interactions affect k_{on} , was directly tested by introducing charged mutations at the vicinity, but outside the binding site of TEM1-BLIP. These mutations did increase specifically k_{on} by 250-fold but did not affect k_{off} (thus, the increase in k_{on} equals the increase in K_D and $\Phi=1$) [7]. These data suggest that long-range electrostatic interactions increase the rate of association by lowering the free energy of the transition state by the same magnitude as the equilibrium constant (see Fig. 1). While mutations of non-charged residues do not significantly affect the transition state for association, they can significantly alter k_{off} and K_D . These data imply that the transition state is stabilized by electrostatic interactions and its structure already resembles that of the final complex, but the proteins are not yet close and oriented enough for short-range interactions.

Association of a Protein Complex

While the major part of the activation free energy is required for desolvation of the binding interface as a prerequisite for the formation of specific short-range interactions, further intermediate states are postulated to occur on the pathway of complex formation (Fig. 1). Prior to the transition state, the two proteins diffuse in solution statistically until they enter a steering region, in which the progression along the association pathway is actively steered toward complex formation (Fig. 2). The forces important within this region are mainly electrostatic in nature, with nonspecific hydrophobic interactions contributing as well to steer association. Analysis of the contribution of electrostatic forces to the rate of association clearly indicates that their contribution

stems from guiding the two proteins toward the transition state; from stabilizing the pre-transition-state encounter complex, in which the binding interface is still largely solvated; and from lowering the free energy of the transition state. Calculations of a three-dimensional energy landscape of these forces shows electrostatic steering by charged residues, which provides an energy funnel directed toward formation of the final complex [6]. At physiological salt concentrations this funnel extends to less than 20 Å of inter-protein distance and fades rapidly upon rotation (at 60° rotation from the bound conformation, all electrostatic steering is lost; see Fig. 2). It was shown that charged “hot spot” residues have the largest effect on the size and depth of these energy funnels. Potential “hot spot” residues can now be identified computationally, making it possible to engineer pairs of proteins with much higher rates of association and affinity.

A second mechanism that potentially steers association is a partial desolvation of inter-protein hydrophobic surfaces. This effect plays a significant role in all association processes, but becomes particularly dominant for complexes, in which one of the reactants is neutral or weakly charged. The interaction provides a slowly varying attractive force over a small but significant region of the molecular surface. In complexes with no strong charge complementarity, this region surrounds the binding site, and the orientation of the ligand in the encounter conformation with the lowest desolvation free energy is presented in a conformation similar to the formed complex. While the electrostatic contribution toward faster association can be easily verified from mutational studies and the effect of the ionic strength on k_{on} , the contribution of desolvation effects can be assessed only from theoretical calculations [11]. The reason that mutation studies rarely identify noncharged residues, which significantly contribute to k_{on} , may be attributed to the small contribution of individual side chains to desolvation-induced association, as this is more of a global effect of the protein.

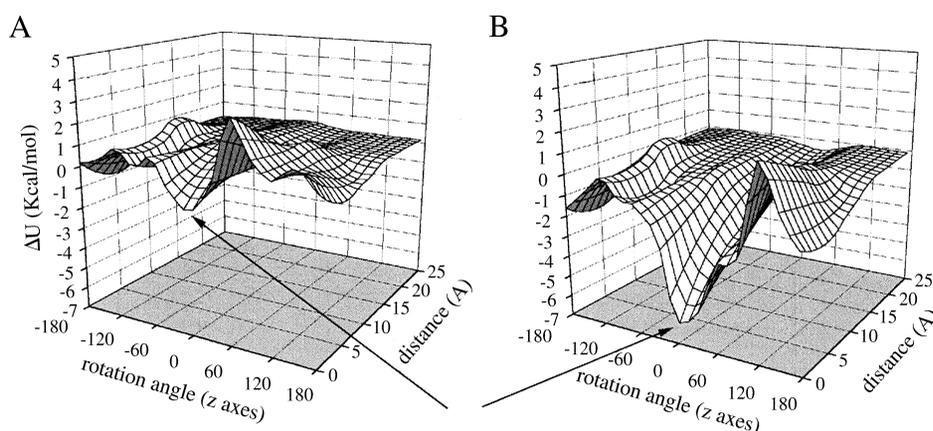

Figure 2 Three-dimensional energy landscape of the association between wt TEM1- β -lactamase with wt BLIP (A) and a much faster binding mutant (B). For demonstration, only the z-angle rotation is shown. The magnitude of the Debye-Hückel energy of interaction (ΔU) is plotted in three dimensions versus the distance and the relative rotation angle between the proteins. The arrows point at the 0° rotation angle, which is the X-ray crystallographic structure of the TEM1/BLIP complex. For details on the calculations employed, see Selzer and Schreiber [6].

Dissociation of a Protein Complex

Dissociation is a first-order reaction, the rate of which is independent of the concentration of the proteins. While the rate of association is a function of a fixed basal rate and a variable contribution of electrostatic nature, the rate of dissociation depends on the simultaneous breaking of many short-range interactions forming the protein–protein interface. These include hydrophobic and van der Waals interactions, H bonds, and salt bridges. The importance of the different interactions toward stabilizing the bound conformation depends on the location within the interface and its specific environment. Thus, individual charge–charge interactions seem to contribute little, as the gained interactions only barely compensate the free energy required for desolvation of the charged groups. However, if a network of charge–charge interactions is formed, a positive contribution toward binding is regained. H bonds seem to have a relatively small, but constant, contribution toward binding [12,13]. The effect of hydrophobic and van der Waals interactions was estimated from the buried surface area (nonpolar and total). However, no good absolute estimations have been obtained. The most intriguing question relates to the nature of “hot spots,” which are residues that, upon mutation, cause a large shift in complex stability (reducing binding affinity by up to 10,000-fold). While no clear physical definition for “hot spot” residues has been formulated, they seem to be located at positions that are not water accessible [14,15]. Thus, the interface can be crudely divided into an outer ring of residues, which form some kind of a seal, and inner residues, which are fully stripped from solvent molecules. However, only a few of these fully buried residues are “hot spots,” and the structural and energetic bases of “hot spot” residues are not yet clear.

Summary

This chapter discusses the energy landscape separating the unbound from the bound state of protein–protein interactions. Along the association pathway, an unstable diffusion encounter complex is formed prior to the transition state. Long-range electrostatic forces play a major role in stabilizing both the encounter complex and the transition state, thereby effectively steering the association process. In the transition state, the two proteins are correctly orientated toward each other and the interface is just being desolvated, so that subsequent short-range interactions can be formed to stabilize the complex. Accordingly, the free activation

energy required to reach the transition state mostly stems from the energetically costly process of surface desolvation (especially of charged residues). Additional intermediates are located past the transition state. For these intermediates, part of the protein–protein interface is already formed, and the proteins are committed to evolving into the final complex. These pre-complexes are often difficult to track experimentally, thus it is reasonable to assume that they are more abundant than what has been reported so far.

Introduction

Our understanding of the structural aspects of the recognition of antigens by antibodies has grown rapidly since the first structure of an antibody Fab fragment was determined in 1973 [1]. As of January, 2003, the Brookhaven Protein Data Bank [2] had 384 entries for X-ray or nuclear magnetic resonance (NMR) structures of antibodies, Fab, Fv, V_L , or V_H fragments. Of these entries, 197 are for Fab or Fv fragments bound to their antigens, and 43 of the Fab or Fv structures are available in both their free and antigen-bound forms. Five structures are now available for intact immunoglobulins [3–7], two of which contain visible electron density for the highly flexible hinge region [6,7]. Structures have been determined for antibodies derived from humans, mice, rats, camels, and llamas, as well as for genetically modified antibody fragments that have been “humanized,” “camelized,” or engineered as single-chain Fv fragments. The antigens recognized by these antibodies include small haptens, peptides, DNA, carbohydrate, and protein. Some of these antibodies are of chemical or medical importance, such as those that catalyze chemical reactions [8–11], neutralize viruses [7,12–24], or recognize tumors [25–31]. This wealth of structural information has proven invaluable in the fields of antibody engineering and catalytic antibody generation and in the development of effective antibody-based drug therapies.

Antibody Architecture

Antibodies can be rapidly tailored to accommodate almost any foreign antigen by a remarkable process whereby a very

large number of different light and heavy chains are formed and then paired to generate the intact antibody. The antibody heavy-chain genes are created by V(D)J recombination [32], where the gene is generated by the recombination of the variable (V_H), diversity (D), and joining (J_H) segments. Extra nucleotides (N and P) can also be added at each recombination site. The light-chain genes are assembled in a similar fashion from a V_L and a J_L segment, with further N additions. For humans, there are 51 V_H [33,34], 6 J_H [35], and 27 D [36,37] segments, resulting in over 8000 different possible heavy-chain gene combinations. There are 40 V_K [38], 5 J_K [39], 30 V_L [37], and 4 J_L [40] genes, plus N additions, that can be combined for at least 200 κ and 120 λ chain combinations. These heavy and light chains can then be further modified by somatic mutations. The immunoglobulin G (IgG) class of antibodies is the best studied structurally of all the different antibody classes, although IgA and IgM Fab fragments have also been structurally elucidated.

In the IgG antibody, the light (~25,000 kDa) and heavy (~50,000 kDa) chains pair to form three distinct protein domains: the Fc fragment and two Fab fragments (Fig. 1). There is a high degree of mobility between these three modules, which has led to some difficulty in the crystallization of intact antibodies, although, as discussed previously, some progress has been made in the crystallization of these molecules. Most of the structures currently available are for Fab or Fv fragments. Within the Fab fragment, mobility is also possible between the variable (V_L – V_H) and the constant (C_L – C_H1) domains around the “elbow angle.” This angle can vary between at least 127° and 224° [41]. There can also be some variability in how the V_L and V_H domains pair with each other [41]. The constant domain region of

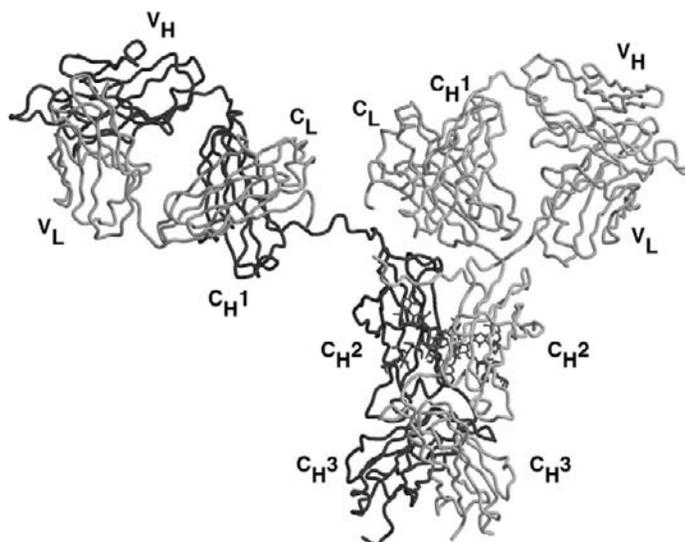

Figure 1 Crystal structure for the intact, HIV-1 neutralizing, human antibody b12 [7] (PDB code 1HZH). The two light chains are colored cyan, and the two heavy chains are colored blue and yellow; carbohydrate in the Fc portion is colored red. The two Fab domains are shown at the top of the figure (V_L , V_H , C_L , C_H1), connected to the Fc domain (C_H2 , C_H3 dimer) by flexible protein linkers that allow the two Fab arms a great deal of flexibility with respect to each other and the Fc domain. All figures were prepared with MOLSCRIPT [70] and rendered with Raster3D [71,72]. For color figures, see CD-ROM version of *Handbook of Cell Signaling*.

the Fab fragment is fairly rigid, but the Fc fragments can show intra-fragment mobility (see Chapter 8). The Fab fragment is the portion of the antibody that recognizes antigen, and it does this via six loops termed the *hypervariable* or *complementarity-determining region* (CDR) loops. These loops can vary in sequence and length in order to optimize their specificity and affinity for antigen. Some studies have suggested that different size antigens may be recognized preferentially by distinct combinations of CDR loops that result in different binding site topologies [42,43]. For example, small haptens are frequently bound into deep pockets, peptides are bound in grooves, and large proteins usually bind a relatively flat binding site, but many examples exist that are exceptions to these broad generalizations. Although the CDR loops are the most variable portion of the Fab fragment, the structures of the L1, L2, L3, H1, and H2 loops have been classified into a limited number of defined or canonical conformations that can be predicted by the occurrence of particular amino acids at key structural positions [44–47]. The conformation of the base of the H3 loop can also be predicted with some reliability [46,48]; however, the portion of H3 that extends beyond the framework region of the Fab is too variable in sequence and structure to be predicted yet.

Conformational Changes

Examination of Fab or Fv structures in both the bound and free forms shows that, in some but not all antibodies, conformational changes accompany antigen binding. It is

not known for certain whether these changes are always induced by antigen binding, or whether the unliganded Fab fragment can exist in multiple conformations in solution, with the binding of antigen stabilizing one of these already preferred conformations. Kinetic stopped-flow fluorescence experiments support the theory of a flexible antigen combining site [49], although no evidence for multiple conformations of unliganded antibodies has been observed yet in crystal structure analyses. The conformational changes can consist of side-chain rearrangements, CDR main-chain rearrangements, segmental movements of the CDR loops, changes in the relative orientation of the V_L – V_H domains, and combinations of some or all of the above.

Side-Chain Rearrangements

An interesting example of a side-chain rearrangement is seen in the anti-progesterone Fab DB3 [50–52]. In this antibody, the Trp^{H100} side chain occupies the antigen-binding site in the unliganded Fab and then moves out of the way in order to allow progesterone to bind (Fig. 2a). Here, this Trp side chain acts as a “surrogate” ligand for this antibody in the absence of progesterone, and its movement completely alters the shape of the binding site when comparing the free and bound forms (Fig. 3).

Main-Chain Rearrangements and Segmental Shifts

Main-chain CDR movements have been seen in all CDR loops with the exception of L2. These main-chain movements

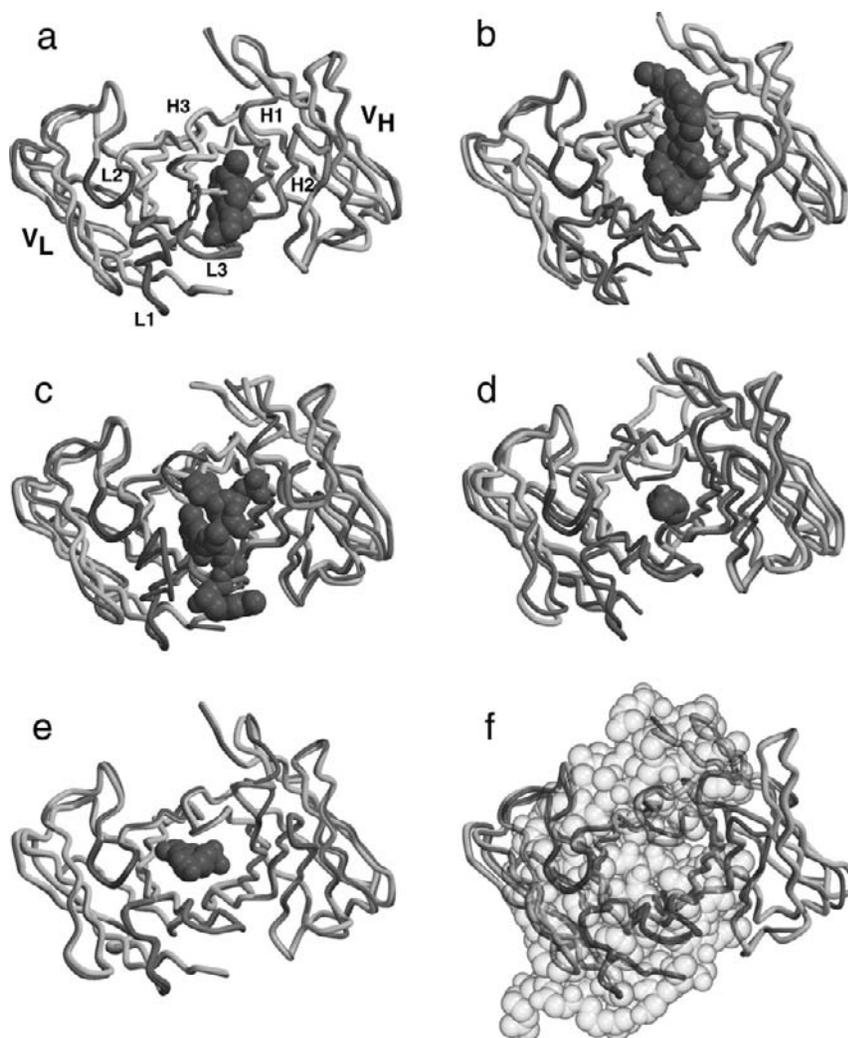

Figure 2 Side-chain and main-chain conformational changes in antibodies. (a) Superposition of the native and antigen-bound coordinates for the anti-progesterone Fab DB3 [50–52] (PDB codes 1DBA, 1DBB). The view is looking down into the antigen-binding site, with the Fab light chain on the left, the unliganded DB3 in light gray, and the liganded DB3 in darker gray. The CDR loops for the antigen-bound Fab are colored in red, while the CDR loops for the unliganded Fab are colored by CDR, with CDR L1, L2, L3, H1, H2, and H3 being colored blue, purple, green, cyan, pink, and yellow, respectively. The progesterone antigen is shown in a red CPK rendering. In DB3, there are no significant main-chain movements upon antigen binding; however, Trp^{H100} is located in the binding site in the unliganded Fab (yellow), while it rotates out of the binding site when progesterone is bound (red). (b) Superposition of the native and antigen-bound coordinates for the anti-tumor Fab BR96 [28,30] (PDB codes 1UCB, 1CLY). The view and coloring for this and all the panels are as for (a). The bound antigen (red CPK) is the Lewis Y nonoate methyl ester. BR96 shows large conformational changes in both the L1 (blue) and L3 (green) CDR loops. (c) Superposition of the native and antigen-bound coordinates for the anti-ssDNA Fab BV04-01 [55] (PDB codes 1NBV, 1CBV). The bound antigen (red CPK) is tri-thymidine. BV04-01 shows large conformational changes in the L1 (blue) and H3 (yellow) CDR loops. (d) Superposition of the native and antigen-bound coordinates for the catalytic antibody CNJ206 with antigen para-nitrophenyl methyl-phosphonate [59,65] (PDB codes 2GFB, 1KNO). This Fab shows large conformational changes in CDRs L3 (green) and H3 (yellow). (e) Superposition of the native and antigen-bound coordinates for the mature catalytic antibody 48G7 [60] (PDB codes 1AJ7, 2RCS). The bound antigen (red CPK) is 5-(para-nitrophenyl-phosphonate)-pentanoic acid. H2 (pink) undergoes large conformational changes. (f) Superposition of the native and antigen-bound coordinates for the anti-lysozyme antibody HyHEL-63 [64] (PDB codes 1DQQ, 1DQJ). The lysozyme antigen is shown as a transparent CPK model in order to see the footprint of the protein on the CDR loops underneath. This Fab has conformational changes in the H2 (pink) and H3 (yellow) loops.

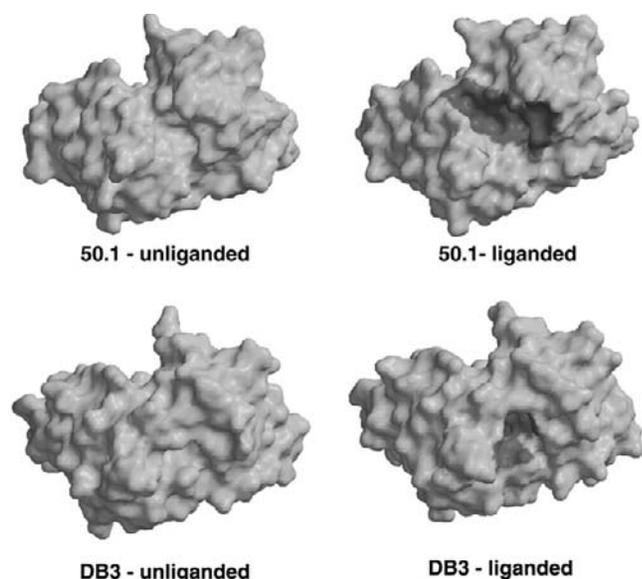

Figure 3 Topographical changes in antigen binding sites due to conformational changes. Fab 50.1 (top panel) is shown before (left) and after (right) antigen binding. The view is that looking down into the antigen binding site, as in Fig. 2. The peptide binding site is highlighted in purple on the liganded antibody surface, with peptide antigen omitted from the figure for clarity. The combination of an H3 rearrangement and a large V_H - V_L domain rearrangement have combined to substantially lengthen and widen the groove for peptide binding. Fab DB3 (bottom panel) is shown before (left) and after (right) antigen binding. The approximate binding site for progesterone is highlighted in purple. The structural change required for its small hapten to bind is the opening of a small pocket for the binding of steroids such as progesterone. This change is mainly due to a tryptophan residue that fills the pocket in the unliganded Fab but then moves out of the way to allow steroids to bind. Solid surfaces were calculated with GRASP [73].

can either consist of a rearrangement of CDR conformation, or a simple rigid-body, segmental shift of the CDR loop. The largest conformational changes in L1 are seen for BR96 [28,30], where the L1 CDR loop moves as much as 10 Å at the tip as it folds toward the antigen (Fig. 2b). Other Fabs showing L1 CDR loop movements upon antigen binding include the anti-hemagglutinin peptide antibody 17/9 [53,54], the anti-DNA antibody BV04-01 [55] (Fig. 2c), the anti-myohemerythrin peptide antibody B1312 [56], the anti-HIV protease antibody F11.2.32 [57], and the anti-rhinovirus antibody 17-IA [18]. These antibodies all have rather long L1 CDRs (inserts after residue 27 of 4–6 residues), with the exception of 17-IA, which has no inserted residues. Small changes have been seen in the L3 CDR loops, where again BR96 shows the largest movement (up to 2.6 Å for the main chain; Fig. 2b), with the anti-hapten B1-8 [58] and catalytic antibody CNJ206 [59] (Fig. 2d) also showing conformational changes here. The largest changes in the H1 CDR loops are observed in the catalytic antibody 48g7 [60] in both its germline and mature forms (Fig. 2e), and also in the anti-HIV-1-peptide antibody 50.1 [61] (Fig. 4). The largest H2 changes are seen for the germline catalytic antibody AZ-28 [62], the anti-lysozyme antibodies HuLys11 [63] and HyHEL63 [64] (Fig. 2f), and the feline peritonitis virus antibody 409.5.3 [13]. The largest and

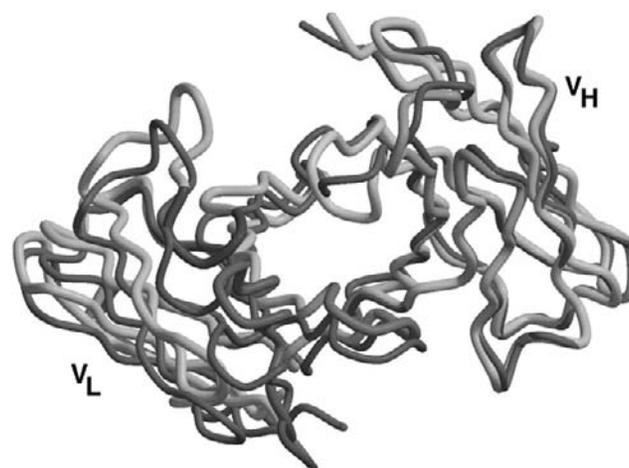

Figure 4 Conformational changes in Fab 50.1 [20,61] (PDB codes 1GGI, 1GGB). The unliganded and liganded Fab 50.1 structures are superimposed using V_H framework residues. The view is looking down into the antigen-binding site, with the Fab light chain on the left and the unliganded and liganded V_H domains in light and dark gray, respectively. CDR loops for the V_H domain are colored by CDR as in Fig. 2. The V_L domains from the liganded and unliganded Fabs are colored blue and cyan, respectively. The V_L domains differ in their relative orientation to the V_H domain by about 15°. Large conformational changes in the H3 CDR loop (yellow and red) are also visible. These combined conformational changes serve to widen and lengthen the binding groove for the peptide antigen.

most frequent CDR conformational changes are found in CDR H3. In an analysis of the 36 Fab or Fv fragments that exist in both free and bound forms, out of 115 total comparisons (some Fabs or Fvs have more than one molecule in the crystallographic asymmetric unit or have been solved in multiple crystal forms) 13, 5, 9, 13, and 38 pairs of structures were shown to have significant conformational changes (total rmsd for CDR residues >1.0 Å) in CDR loops L1, L3, H1, H2, and H3, respectively. The largest H3 movement seen thus far is for the catalytic antibody CNJ206 [65], where the tip of the H3 loop has a main-chain rearrangement of about 16 Å. Catalytic antibody 5C8 [66] and the anti-HIV-1-peptide antibody 50.1 [61] also show large changes in this CDR loop. The H3 CDR loops of CNJ206, 5C8, and 50.1 are not long; CNJ206 and 5C8 both have only two amino-acid inserts after residue H100, while 50.1 has a three amino-acid deletion in this region.

V_L - V_H Rearrangements

Rearrangements are also observed in the relative orientation of the V_L to the V_H domains upon antigen binding. The largest seen thus far is for Fab 50.1 [61], with a change of around 15° (Fig. 4). Other large changes are seen for CNJ206 (6.8°) [65], BV04-01 (7.5°) [55], and 13B5 (8.1°) [67]. The domain rearrangements, in combination with the changes in CDR conformation discussed in the previous section, can combine to create changes in the size and shape of the antigen-binding site (Fig. 3). These changes can be small, such as the creation of a small binding pocket for progesterone in DB3 [50–52], or larger, such as the elongation and widening of a binding groove for the HIV-1 V3 loop peptide in 50.1 [20, 61].

Conclusion

Antibodies are wonderfully malleable molecules that can vary in both their sequence and structure in order to recognize an infinite number of potential antigens. The extensive diversity of the V(D)J recombination along with the fixed pool of variable genes leads to a sufficient number of different specificities to bind almost any antigen with high affinity. Structural studies of these molecules have led to a better understanding of their mechanism of action and allowed for improvements in their natural design in order to produce antibodies that are useful in many fields, such as catalytic antibody production. Catalytic antibodies are now available to carry out many different chemical reactions, some of which have no naturally occurring enzyme catalyst and are being used more and more widely as tools by synthetic chemists [8–10,68,69].

Introduction

Antibodies may be regarded as the products of a protein engineering system developed by nature for generating a virtually unlimited repertoire of complementary molecular surfaces and, as such, constitute an excellent model for elucidating the principles governing macromolecular recognition. We have used X-ray crystallography and site-directed mutagenesis to understand how structural features contribute to the affinity and specificity of antigen–antibody binding reactions.

Antibody molecules are composed of two identical polypeptide chains of approximately 450 amino acids (the heavy, or H, chains) covalently linked through disulfide bridges to two identical polypeptide chains of about 250 residues (the light, or L, chains). Based on amino-acid sequence comparisons, the H and L chains may be divided into N-terminal-variable (V) and C-terminal-constant (C) portions. Each H chain contains four domains (V_H , C_{H1} , C_{H2} , C_{H3}), each of which contains two anti-parallel β -sheets connected by a disulfide, while each L chain consists of two such domains (V_L , C_L). These β -sheet domains are structurally very similar and hence have been termed the *immunoglobulin fold* [1]. The V_H and V_L domains each contain three segments, or loops, which connect the β -strands and are highly variable in length and sequence among different antibodies. These so-called complementarity-determining regions (CDRs) lie in close spatial proximity on the surface of the V domains and determine the precise conformation of the combining site. In this way, the CDRs confer specific binding activity to the antibody molecule. The central paradigm of antigen–antibody recognition is that the

three-dimensional structure formed by the six CDRs recognizes and binds a complementary surface, or epitope, on the antigen.

X-ray crystallographic studies of over 30 antigen–antibody complexes involving protein antigens [2–12] have provided much valuable information on the molecular architecture of protein–protein interfaces, including the identity of contacting residues, the amount of buried surface area, the number and type of hydrogen bonds, and the magnitude of conformational changes associated with complex formation. However, the basic principles governing antigen–antibody and protein–protein interactions have remained elusive [13–20], with important fundamental problems relating to the recognition process still to be solved: What are the relative contributions of hydrophobicity, surface complementarity, and hydrogen bonding to the energetics and mechanism of binding? To what extent do the strengths of individual bonding interactions depend on their local environment and overall location in the interface? What is the role of solvent in complex stabilization? What is the contribution of conformational flexibility, or structural plasticity, in antigen–antibody recognition? Is productive binding mediated by a distinct subset of combining site residues, or are complex cooperative interactions involving both contacting and non-contacting residues responsible for the observed affinities? What determines whether an interface residue is a so-called “hot spot” for ligand binding (i.e., a residue that contributes a disproportionately large fraction of the binding free energy)? How are potentially disruptive amino-acid changes in the interface (for example, ones that create “holes”) accommodated?

What is the structural basis of affinity maturation, whereby somatic mutations in antibody genes that confer increased affinity for antigen are selected? Finally, is it possible to predict *ab initio* the effects of a given amino acid substitution on antibody affinity and specificity? In this review, we describe recent attempts to construct energetic maps of antigen–antibody interfaces using X-ray crystallography coupled with site-directed mutagenesis.

Thermodynamic Mapping of Antigen–Antibody Interfaces

In contrast to the wealth of structural information on antigen–antibody and other protein–protein interfaces, the available data on the thermodynamics of the association reactions are far more limited. Indeed, our current view of the energetics of protein–protein association is largely based on detailed mutagenesis and binding studies of only a few complexes [15]. We have studied the binding of monoclonal antibody D1.3 to two structurally distinct ligands: its cognate antigen, hen egg white lysozyme (HEL), and the anti-D1.3 antibody E5.2. The crystal structure of the complex formed by D1.3 with HEL has been determined to a nominal resolution of 1.8 Å [21]. In addition, the structure of the complex between D1.3 and E5.2 is known to 1.9-Å resolution [12]. Surprisingly, D1.3 contacts HEL and E5.2 through essentially the same set of combining site residues (and most of the same atoms). Thus, of the 18 D1.3 residues that contact E5.2 and the 17 that contact HEL, 14 are in contact with both E5.2 and HEL. In this review, we will focus on the D1.3–HEL and D1.3–E5.2 complexes, as these currently represent the most extensively studied models for antigen–antibody recognition.

To evaluate the relative contribution of individual residues to stabilization in the D1.3–HEL and D1.3–E5.2 complexes, alanine-scanning mutagenesis was performed in the D1.3 combining site. In total, 16 single alanine substitutions were introduced and their effects on affinity for HEL and for E5.2 were measured using surface plasmon resonance detection, fluorescence quench titration, or sedimentation equilibrium [22]. Mutagenesis of D1.3 residues in contact with HEL in the crystal structure of the D1.3–HEL complex revealed that residues in V_LCDR1 and V_HCDR3 contribute more to binding than residues in V_LCDR2, V_LCDR3, V_HCDR1, and V_HCDR2. By far the greatest reductions in affinity ($\Delta G_{\text{mutant}} - \Delta G_{\text{wild type}} > 2.5$ kcal/mol) occurred on substituting three residues: V_LTrp92, V_HAsp100, and V_HTyr101. By replacing V_LTrp92 with residues bearing increasingly smaller side chains and determining the crystal structures and thermodynamic parameters of binding for each of the resulting mutant D1.3–HEL complexes, we demonstrated a correlation between the binding free energy and the apolar surface area that corresponds to 21 cal mol⁻¹ Å⁻² [23]. This estimate of the hydrophobic effect in a protein–protein interface is in excellent agreement with predictions based on transfer free-energy values for small hydrophobic solutes.

Significant effects on HEL binding (1.0 to 2.0 kcal/mol) were also seen for substitutions at D1.3 positions V_LTyr32 and V_HGlu98, even though the latter is not involved in direct contacts with HEL. Mutations at nine other contact positions (V_LHis30, V_LTyr49, V_LTyr50, V_LSer93, V_HTyr32, V_HTrp52, V_HAsp54, V_HAsp58, and V_HArg99) had little or no effect (<1.0 kcal/mol). Therefore, the binding of HEL by D1.3 is largely mediated by only 5 of the 14 residues tested.

For the interaction of D1.3 with E5.2, affinity measurements showed that V_HCDR2, V_HCDR3, and V_LCDR1 of D1.3 are more important for binding E5.2 than V_HCDR1, V_LCDR2, and V_LCDR3 [22]. Overall, D1.3 V_H residues appear to contribute more to the free energy of binding than V_L residues, as the most destabilizing alanine substitutions (>2.5 kcal/mol) are located in V_HCDR2 (Trp52Ala and Asp54Ala) and V_HCDR3 (Glu98Ala, Asp100Ala, and Tyr101Ala). Significant effects (1.0 to 2.0 kcal/mol) were also observed for the following contact residues: His30 and Tyr32 in V_LCDR1, Tyr49 in V_LCDR2, Tyr32 in V_HCDR1, Asn56 and Asp58 in V_HCDR2, and Aeg99 in V_HCDR3. Mutations at positions V_LTyr50, V_LTrp92, and V_HThr30 had little or no effect (<1.0 kcal/mol). Thus, of the 15 contact residues tested, 12 make significant contributions to binding E5.2.

On the basis of extensive mutational analysis of the complex between human growth hormone and its receptor, Wells and colleagues [24–26] proposed that the formation of specific protein–protein complexes is mediated by only a few productive interactions or “hot spots” that dominate the energetics of association. Consistent with this idea, our analysis of the D1.3–HEL interaction revealed that only a small subset of the total combining site residues of D1.3 appears to account for a large proportion of the binding energy; most residues (9 of 14) make little or no apparent net contribution (<1.0 kcal/mol). This contrasts with the interaction of D1.3 with E5.2 in which nearly all the contacting residues play a demonstrable role in binding ligand (>1.0 kcal/mol), even though a number of hot spots ($\Delta\Delta G > 2.5$ kcal/mol) are clearly present. Therefore, stabilization of the D1.3–E5.2 complex is achieved by the accumulation of many productive interactions of varying strengths over the entire interface between the two proteins.

The functional surfaces of D1.3 involved in binding HEL and E5.2 mapped onto its three-dimensional structure are shown in Figs. 1A and 1B, respectively. With the exception of V_LTrp92, which lies at the periphery, the residues of D1.3 most important for binding HEL (V_HTyr101, V_HAsp100, V_LTyr32, and V_HGlu98) are located in a contiguous patch at the center of the combining site. Residues at the periphery make only minor contributions to the binding energy. A similar pattern is observed for the D1.3–E5.2 complex, with the most important residues (V_LTyr32, V_HTrp52, V_HAsp54, V_HGlu98, V_HAsp100, and V_HTyr101) forming a central band of key contacts. For the most part, however, the hot spots for the two interactions do not overlap. For instance, alanine substitution at position V_LTrp92 of D1.3 produces a 100-fold decrease in affinity for HEL but does not appreciably affect binding to E5.2. Conversely, the V_HTrp52Ala

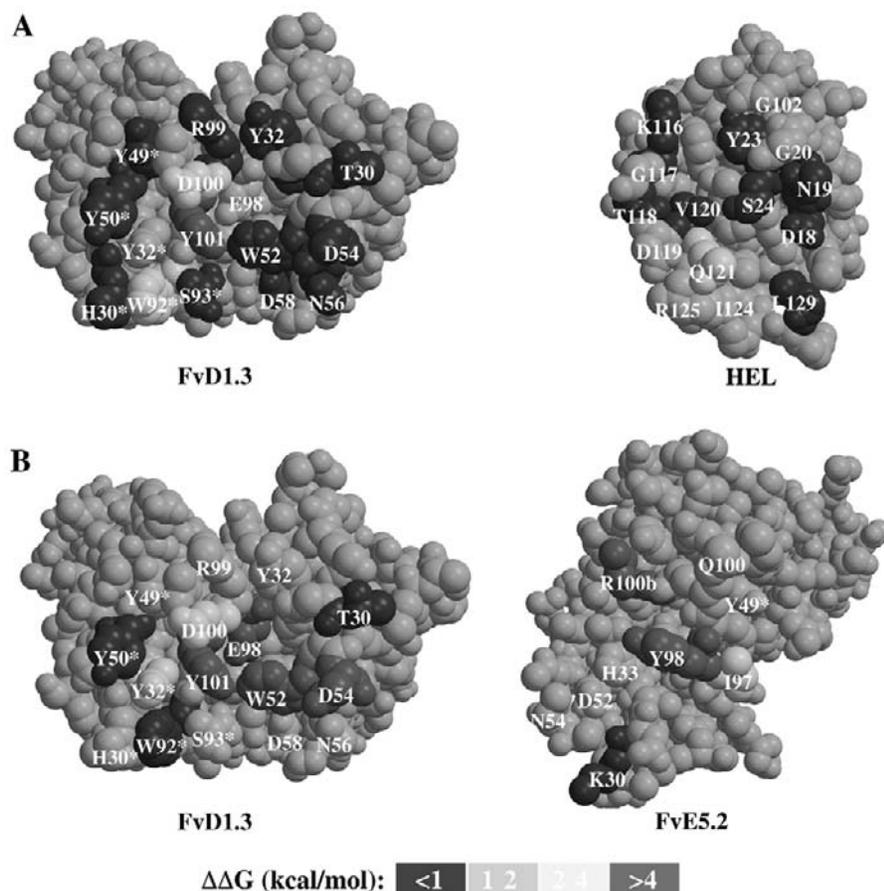

Figure 1 Energetic maps of antigen–antibody interfaces. (A) Space-filling model of the surface of D1.3 (left) in contact with HEL and of the surface of HEL (right) in contact with D1.3. V_L residues are marked with asterisks. The two proteins are oriented such that they may be docked by folding the page along a vertical axis between the components. Residues are color-coded according to the loss of binding free energy upon alanine substitution. (B) Model of the surface of D1.3 (left) in contact with E5.2 and of the surface of E5.2 (right) in contact with D1.3. Residues are colored as in (A).

substitution decreases affinity for E5.2 1000-fold but has virtually no effect on binding to HEL. Only substitutions V_HAsp100Ala and V_HTyr101Ala greatly affect the binding to both HEL and E5.2. We therefore conclude that a single set of contact residues on D1.3 binds HEL and FvE5.2 in energetically different ways. Thus, although D1.3 recognizes these two proteins in ways that are structurally very similar, this similarity extends only partially to the functional epitopes.

To probe the relative contribution to binding of HEL residues in contact with D1.3 in the crystal structure of the FvD1.3–HEL complex, 12 non-glycine HEL residues were individually mutated to alanine and their affinities for wild-type D1.3 measured [27]. Significant decreases in binding ($\Delta\Delta G > 1$ kcal/mol) were only observed for substitutions at four contact positions: Gln121, Ile124, Arg125, and Asp119. The most destabilizing mutation was at position Gln121 ($\Delta\Delta G = 2.9$ kcal/mol). In the wild-type structure, Gln121 penetrates a hydrophobic pocket, where it is surrounded by the aromatic side chains of V_LTyr32, V_LTrp92, and V_HTyr101 [16].

Mutations at the remaining eight contact positions (Asp18, Asn19, Tyr23, Ser24, Lys116, Thr118, Val120, and Leu129) had little or no effect ($\Delta\Delta G < 1$ kcal/mol). Therefore, for both the D1.3 and HEL sides of this interface, only small subsets of the total contacting residues appear to account for a large portion of the binding energy.

As shown in Fig. 1A, the residues of HEL most important for binding D1.3 (Asp119, Gln121, Ile124, and Arg125) form a contiguous patch located at the periphery of the surface contacted by the antibody [27]. Hot spot residues on the D1.3 side of the interface generally correspond to hot spot positions on the HEL side. For example, HEL hot spot residues Gln121 ($\Delta\Delta G = 2.9$ kcal/mol) and Arg125 (1.8 kcal/mol) contact D1.3 hot spot residue V_LTrp92 (3.3 kcal/mol); in addition, Gln121_{HEL} contacts V_LTyr32 (1.7 kcal/mol) and V_HTyr101 (> 4.0 kcal/mol). Similarly, functionally less important D1.3 and HEL residues tend to be juxtaposed in the antigen–antibody interface: Asp18_{HEL} ($\Delta\Delta G = 0.3$ kcal/mol) and Thr118 (0.8 kcal/mol) interact with D1.3 V_LTyr50 (0.5 kcal/mol) and V_HTrp52 (0.9 kcal/mol), respectively.

To investigate the apparent contribution of E5.2 residues to stabilization of the D1.3–E5.2 complex, single alanine substitutions were introduced at 9 of 21 positions in the combining site of E5.2 involved in contacts with D1.3, and the affinity of the mutants for wild-type D1.3 [28] was measured. The most destabilizing substitutions are located at positions V_H Tyr98 and V_H Arg100b ($\Delta\Delta G > 4.0$ kcal/mol). Substitutions at the other 7 positions tested (V_L Tyr49, V_H Lys30, V_H His33, V_H Asp52, V_H Asn54, V_H Ile97, and V_H Gln100) also resulted in significant effects on binding (1.2 to 2.8 kcal/mol). When the residues of D1.3 and E5.2 important in complex stabilization were mapped onto the three-dimensional structure of each antibody, we observed that hot spot positions on the E5.2 side of the interface generally corresponded to hot spots on the D1.3 side (Fig. 1B), as in the D1.3–HEL interface (Fig. 1A). This complementarity of functional epitopes is in agreement with the observation that energetically critical regions on human growth hormone match those on its corresponding receptor [24–26]. In the hormone receptor case, however, the functional epitopes pack together to form a hydrophobic core surrounded by hydrophilic residues, with substantial reductions in affinity occurring only on substitution of the nonpolar ones. In contrast, our analysis of the D1.3–E5.2 and D1.3–HEL systems shows that both polar (e.g., D1.3 residues V_H Asp54, V_H Glu98, and V_H Asp100) and nonpolar residues (e.g., D1.3 residues V_L Trp92 and V_H Trp52) play a prominent role in complex stabilization and that there is not a clear segregation of polar residues at the periphery of the interface and nonpolar ones at the core (Fig. 1).

Conclusions

On the basis of these, and related [15,17,20], studies, two broad categories of protein–protein interfaces may be defined: (1) ones in which ligand binding is mediated by a small subset of contact residues, and (2) ones in which the free energy of binding arises from many productive interactions distributed over the entire protein–protein interface. In addition, each of these categories may be further subdivided into: (1) ones that resemble cross-sections through folded proteins in which hydrophobic residues are in the interior and hydrophilic ones at the periphery and in which productive binding is mediated largely by the former, and (2) ones in which polar and nonpolar residues are evenly distributed throughout the interface and in which both residue types make comparable contributions to complex stabilization.

These results demonstrate that considerable caution should be exercised when attempting to estimate the strengths of specific interactions in an antigen–antibody (or other) protein–protein interface on the basis of three-dimensional structures alone. The simple fact that two residues make direct contacts in a protein–protein interface does not necessarily imply that there exists a net productive interaction between them. Rather, the majority of such contacts may be energetically neutral, as in the D1.3–HEL complex. Although recent

computational methods for predicting the strengths of these interactions appear promising [20,29–32], information on the relative contribution of individual residues to complex stabilization can only be reliably obtained at the present time through actual affinity measurements of site-directed mutants of the interacting species.

Introduction

Antibodies are multifunctional protein molecules capable not only of recognizing and binding to foreign antigens but also activating a range of molecular and cellular responses in the host that lead to neutralization or destruction of the invading organism or foreign material. Antibodies, or immunoglobulins, are built upon a common four-chain structure of two heavy and two light chains, as exemplified by immunoglobulin G (IgG) (Fig. 1A), each chain consisting of a tandem array of domains. Antigen binding occurs at the V (variable) domains, which determine the specificity of the antibody for antigen, but the C (constant) domains of the heavy chain (in the Fc region; Fig. 1A) are responsible for the subsequent effector functions of the antibody.

The five classes of antibody (IgA, IgD, IgE, IgG, and IgM) are distinguished by the C domain sequences of their heavy chains (α , δ , ϵ , γ , and μ), each with a distinct range of effector functions and a specialized role in the body's immune system. Many of the cell-surface receptors for the Fc regions of these antibodies have been identified, but here we shall be concerned only with those for which the three-dimensional structures and their complexes with the antibody Fc are known, namely IgG- and IgE-receptor interactions. IgE, the antibody responsible for antiparasitic responses but nowadays better known for its association with allergic disease, differs from IgG, the principal serum antibody responsible for the secondary immune response to infection, in having an additional pair of domains in its

Fc region in place of the flexible hinge region of IgG (Fig. 1B). The Fc regions of IgA and IgM, which can form dimers and pentamers, respectively, of the basic four-chain unit (and are stabilized by additional polypeptide chains), are more complex still, but the three-dimensional structures of these uncomplexed antibody Fc regions are still unknown.

To date, structural information is available for three distinct types of cell-surface Fc receptors. The first of these is the family consisting of the IgG Fc receptors, Fc γ RI, II (a and b), and III (a and b), as well as the IgE receptor Fc ϵ RI and IgA receptor Fc α RI. All consist of an α -chain with two (three for Fc γ RI) extracellular, Ig-like, ligand-binding domains, either alone (Fc γ RIIIa and b, IIIb) or associated with β and/or a pair of γ -chains (Fc γ RI, IIIa, Fc ϵ RI and Fc α RI). (For reviews, see references [1–4].) The single-chain Fc γ RIIIb and four-chain Fc ϵ RI (the two for which crystal structures of their extracellular domains complexed with Fc are known) are shown schematically in Figs. 1C and D. Distinct from this family of receptors, however, are the neonatal IgG Fc receptor, FcRn, which is responsible for the transport of IgG across the placenta, and the low-affinity receptor for IgE, Fc ϵ R2 (or CD23), which is involved in both allergen uptake by antigen-presenting cells and regulation of IgE synthesis by B cells. Whereas FcRn belongs to the class I major histocompatibility complex (MHC) family (Fig. 1E) [5], Fc ϵ R2 is a trimeric C-type lectin with a wholly different molecular architecture and oligomeric structure (Fig. 1F) [6]. The nature of the interactions between these three different types of receptor and

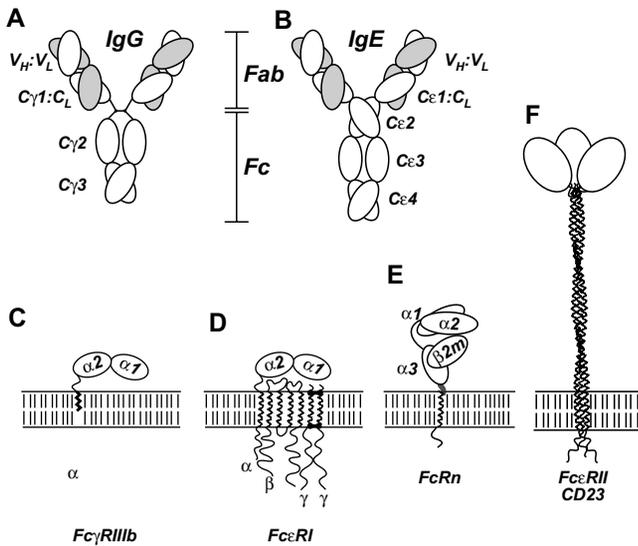

Figure 1 Schematic representations, drawn to scale, of the domain structures of: (A) IgG; (B) IgE; (C) GPI-anchored, low-affinity IgG receptor Fc γ RIIb; (D) high-affinity IgE receptor Fc ϵ RI; (E) neonatal IgE receptor FcRn; and (F) low-affinity IgE receptor Fc ϵ RII (CD23). Molecules A through D consist of Ig or Ig-like domains, FcRn is class I MHC-like, and Fc ϵ RII consists of C-type lectin domains linked to the membrane and trimerised through an α -helical coiled-coil stalk.

Fc will be discussed first for the IgG and then for the IgE receptors.

IgG–Receptor Interactions

Fc γ R

Several crystal structures are now available for the extracellular domains of Fc γ RII [7–9] and Fc γ RIII [10,11], which show (together with Fc ϵ RI [12,13]) that they are all remarkably similar, as expected from their highly homologous sequences. There is an acute angle between the two Ig-like domains, which pack against each other around a hydrophobic interface. In the structure of the complex between Fc γ RIII and IgG Fc, first determined by Sondermann *et al.* in 2000 [10], loops from the α 2 domain and part of the linker region between the two domains of the receptor protrude into the space between the two C γ 2 domains of the Fc just below the hinge region. Thus, there are two distinct regions of interaction, one on each of the heavy chains, which involve residues of the lower hinge and C γ 2 domains (Fig. 2A). Upon binding, the IgG Fc opens up slightly and the C γ 2 domains move apart compared with uncomplexed IgG Fc; at the same time, the angle between the two receptor domains increases (from 70 to 80°), compared with the free receptor structures [10]. The uncomplexed IgG Fc was initially two-fold symmetric and thus in principle might have been expected to bind to two receptors, but the distortion of this symmetry upon binding to the receptor, and the fact that the receptor lies on the approximate two-fold axis of the complex (Fig. 2A), ensures a stoichiometry of 1:1. This is essential if free IgG is not to cross-link receptor in the

absence of antigen [14]. The orientation of the IgG Fc bound to the receptor clearly implies that the Fab arms of the IgG molecule must be bent at the hinge; the overall topology is depicted in Fig. 2A.

The structure of the Fc γ RIII/IgG Fc complex has subsequently been determined by others in a different crystal form [15], and the structure is virtually identical. In neither structure do the two N-linked oligosaccharide chains (at Asn297 in each C γ 2 domain) contribute directly to receptor binding, but they probably serve to stabilize the Fc domains in the binding region, as removal of carbohydrate from IgG Fc severely reduces its receptor binding capacity [16,17].

Because the extracellular Fc-binding domains of the Fc γ RI and Fc γ RII are so similar, (as are the Fc regions of the different subclasses of human IgG), the Fc γ R/IgG Fc complexes are all likely to be essentially similar in structure [9]. There are however, differences in affinity and binding kinetics between the different Fc γ R and the various human subclasses of IgG [1,2,18], and these presumably result from minor differences in the nature of the residues at the interface [9]. More intriguing is the striking difference between the affinity and kinetics of binding of IgE to Fc ϵ RI compared with IgG to its receptors; we shall return to this issue later.

FcRn

The neonatal Fc receptor closely resembles a class I MHC molecule, complete with a β 2-microglobulin chain (β 2-m), but the peptide-binding groove formed between the α 1 and α 2 domains is too narrow and is nonfunctional [5]. In the complex with IgG Fc, recently determined at higher resolution [19] following an earlier low-resolution study [20], FcRn interacts through residues of the α 2 domain, with some contacts from β 2-m. The region on Fc to which it binds is the cleft between the C γ 2 and C γ 3, distant from the Fc γ R binding site (Fig. 2B). IgG binds to FcRn with nanomolar affinity at acidic pH (in transport vesicles), but releases it at neutral pH (in the blood). The binding interface accounts for these properties, as it is both very extensive (1870 Å²) and includes four salt bridges, three of which involve histidine residues on Fc and either aspartic or glutamic residues on FcRn. At pH \leq 6.5, the histidines are protonated and form salt bridges, whereas at pH \geq 7.0 they are neutral and the salt bridges are lost. The crystal structure also appears to show that quaternary structural differences resulting from binding to one Fc heavy chain alter the binding site on the other chain, thus accounting for the observed negative cooperativity in binding a second IgG molecule to the receptor. A common feature of IgG binding to both Fc γ R and FcRn, therefore, is a distortion of the two-fold symmetry inherent in the Fc region of the free antibody molecule, resulting in either a partial (FcRn) or total loss of Fc binding at the second site. Another similarity is the orientation of the Fc relative to the membrane (Fig. 2B), again implying a bend between the Fc and the Fab arms of the antibody.

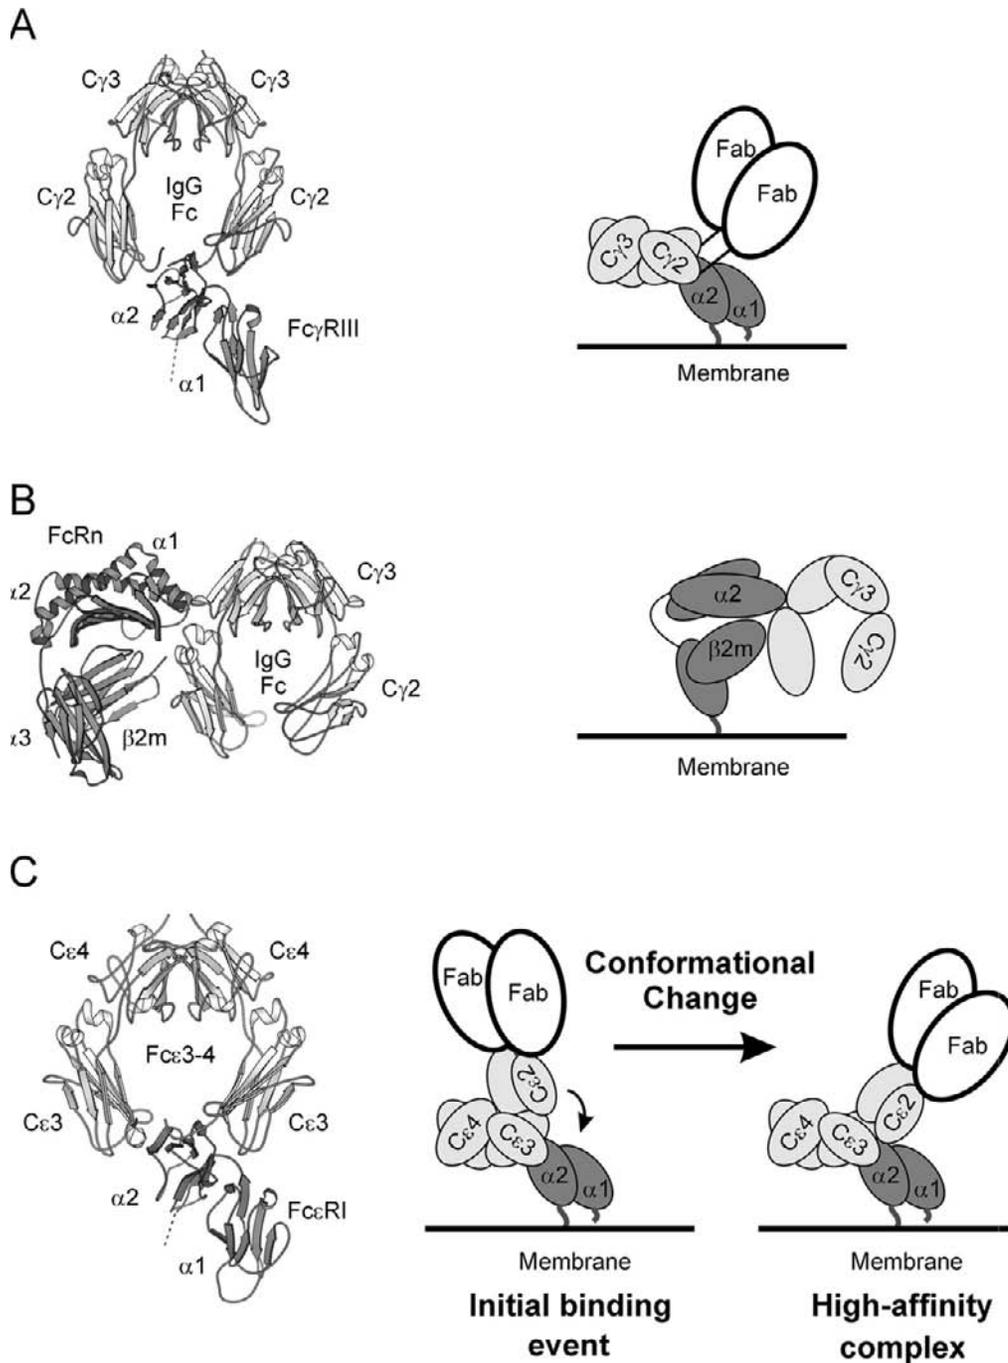

Figure 2 (A) IgG Fc/sFcγRIII complex (PDB code 1E4K) and schematic (rotated view) to show the disposition of the IgG molecule and its Fab arms relative to the membrane. (B) IgG Fc/FcRn complex (PDB code 1I1A) and schematic (same orientation) to show the disposition of the Fc relative to the membrane, again implying that the IgG must be bent. (C) IgE Fcε3-4/sFcεRIα complex (PDB code 1F6A) and schematic (rotated view) to show the complete Fc (with Cε2 domains), the Fab arms, and the conformational change that is proposed to lead to high-affinity binding.

IgE–Receptor Interactions

FcεRI

The crystal structure of the complex between the two extracellular domains of FcεRI α-chain and a subfragment of IgE Fc consisting of the Cε3 and Cε4 domains [21]

(termed here Fcε3-4 to distinguish it from the whole Fc that includes the Cε2 domains) showed essentially the same topology of interaction (Fig. 2C) as seen for the IgG Fc/FcγRIII complex. The Cε3 domains of Fc open up upon binding to the receptor, compared to the uncomplexed state [22,23], but there is little change in the angle between the two receptor domains (refer to previous description of FcγRIII).

However, there is movement in one of the β -strands at the edge of the $\alpha 2$ domain, which moves over from one β -sheet (as a D strand alongside E) in structures of the free receptor [12,13,23] to the other (as a C' strand alongside C) in the complex.

As in the IgG Fc complex, there are two subsites of interaction, one on each heavy chain, and the total buried surface area is extensive (1850 Å²). However, indirect evidence from kinetic studies comparing the binding of Fc ϵ 3-4 and whole Fc to Fc ϵ RI [24,25] and direct evidence from nuclear magnetic resonance (NMR) [26] indicate that the C ϵ 2 domains also contribute to receptor binding. The structure of the complete IgE Fc has recently been solved [27], revealing that the C ϵ 2 domains are not only bent back onto the C ϵ 3 domains, away from the receptor binding region, but also prevent access to one of the two C ϵ 3 subsites required for receptor binding. The clear inference from this structure and modelling of the complex between the complete Fc and Fc ϵ RI (based upon the crystal structure of the Fc ϵ 3-4/Fc ϵ RI complex) is that a substantial conformational change in Fc involving both C ϵ 2 and C ϵ 3 domains, together with the change in the CC' region of the receptor, must accompany receptor binding (shown schematically in Fig. 2C) [27]. It is these conformational changes, more extensive than those accompanying IgG Fc binding to its receptor, together with the additional receptor contacts provided by C ϵ 2, which may account for the significantly enhanced affinity (by several orders of magnitude) and reduced dissociation rate of IgE compared to IgG (IgG binding to Fc γ RIII: $K_a=5 \times 10^5 M^{-1}$ and $k_d=1 s^{-1}$ [18]; IgE binding to Fc ϵ RI: $K_a=1 \times 10^9 M^{-1}$ and $k_d=2 \times 10^{-4} s^{-1}$ [26]). A feature in common with the IgG-receptor interaction, however, is the asymmetry induced in IgE Fc which, together with steric inhibition across the approximate local two-fold axis of the Fc, prevents free IgE molecules from activating mast cells by cross-linking receptors and triggering an immediate allergic reaction.

Fc ϵ RII/CD23

No crystal structure is yet available for Fc ϵ RII, but homology models have been built for the trimer of C-type lectin domains, based upon crystal structures of highly homologous members of this family [28–30]. The interaction site on IgE Fc is contained within C ϵ 3, but, despite the fact that this domain is glycosylated and binds to the lectin-like domain of Fc ϵ RII, carbohydrate is not involved [31]. The site in C ϵ 3 is distinct from that of Fc ϵ RI, and the stoichiometry of binding is 2:1 (sFc ϵ RII:IgE Fc) [32]. It may be that when an IgE molecule binds to the Fc ϵ RII trimer at the cell surface it simultaneously contacts two domains, as thermodynamic analysis of the binding identified two distinct interactions [32], and oligomerization of Fc ϵ RII enhances its affinity for IgE tenfold [33,34]. Furthermore, IgE Fc (with a valency of two) can in principle cross-link Fc ϵ RII (with a potential valency of three) at the cell surface, and it may be that receptor aggregation contributes to the mechanism of IgE homeostasis, as membrane-bound Fc ϵ RII is known to deliver a downregulatory signal for IgE synthesis [35].

Intriguingly, a soluble form of Fc ϵ RII consisting of the lectin heads and a part of the α -helical coiled-coil stalk (refer to Fig. 1F) can upregulate IgE synthesis, presumably by interacting with surface IgE on B cells committed to IgE synthesis, in a reversal of the conventional orientation in which IgE is the soluble ligand (soluble forms of the Fc γ R also exist, but their functions are not known) [35].

Summary

The IgG/Fc γ RIII and IgE/Fc ϵ RI crystal structures reveal homologous interactions, and it is likely that the other IgG receptors, and perhaps also the homologous IgA receptor, will interact in a similar manner. Within this similar topology however, the kinetics and affinity of binding can vary over several orders of magnitude, although the exceptionally slow dissociation rate of IgE from Fc ϵ RI is due in part to additional interactions from the C ϵ 2 domain which has no counterpart in IgG. Thus, IgE bound to mast cells in the tissue has a half-life of the order of weeks and accounts for the persistent sensitization that is characteristic of allergic hypersensitivity; the half-life of IgG bound to its receptors, in contrast, is of the order of minutes. However, the stoichiometry of both of these interactions is 1:1, thus the trigger for receptor signaling is cross-linking of the antibody-receptor complex—for example, by a multivalent or aggregated antigen in an immune complex.

The IgG/FcRn complex presents a different binding topology with a potential stoichiometry of 2:1, although the induced conformational change may limit this to 1:1. However, the role of this receptor is to transport monomeric IgG as ligand, and there may be no requirement for receptor aggregation. The location of the receptor binding site in IgG Fc, between the C γ 2 and C γ 3 domains, overlaps remarkably with the binding sites for a number of other proteins, including the bacterial Fc-binding proteins A and G, and human rheumatoid factor autoantibodies (which as surface IgM are in effect B-cell antigen receptors with specificity for IgG Fc). The crystal structures of these three complexes are known [36–38], and all display 2:1 stoichiometry; a fourth Fc-binding protein, the membrane glycoprotein Fc receptor from herpes simplex virus, binds to this same region but with 1:1 stoichiometry [39]. It has therefore been proposed that this binding cleft has particular physicochemical characteristics that render it such an attractive site [40], and apparently bacteria and viruses have evolved Fc-binding proteins directed at this region in order to interfere with antibody-mediated clearance mechanisms.

Finally, Fc ϵ RII offers yet another topology in which receptor oligomerization in the absence of ligand enhances affinity through an avidity effect, and multivalency in both ligand (bivalency) and receptor (trivalency) may lead to receptor aggregation as the trigger for transmembrane signalling.

Plasticity of Fc Recognition

Warren L. DeLano

Sunesis Pharmaceuticals, Inc., South San Francisco, California

THE HINGE REGION BINDING SITE ON THE IMMUNOGLOBULIN G CONSTANT FRAGMENT (Fc) DEMONSTRATES THE REMARKABLE PLASTICITY THAT SOME PROTEIN SURFACES CAN EXHIBIT IN THEIR MOLECULAR INTERACTIONS. LOCATED AT THE INTERFACE BETWEEN TWO β -SANDWICH DOMAINS (C_{H2} AND C_{H3}), THIS BINDING SITE CLOSELY RESEMBLES THOSE FOUND ON MANY EXTRACELLULAR HEMATOPOIETIC CYTOKINE RECEPTORS; HOWEVER, IT IS DISTINGUISHED BY THE LARGE VARIETY OF UNIQUE PROTEIN FOLDS THAT HAVE EVOLVED TO INTERACT WITH IT. RANDOM DISULFIDE-CONSTRAINED PEPTIDES SELECTED FROM A PHAGE DISPLAY LIBRARY FOR BINDING TO Fc ALSO SPECIFICALLY SEEK OUT INTERACTIONS IN THIS REGION. THIS INDICATES THAT THE MECHANISM BEHIND SUCH CROSS-REACTIVE BINDING IS PHYSIOCHEMICAL IN NATURE AND NOT MERELY A REFLECTION OF THE BIOLOGICAL ROLE OF THE SITE. ANALYSIS OF THE AVAILABLE Fc CO-COMPLEX CRYSTAL STRUCTURES PROVIDES CIRCUMSTANTIAL EVIDENCE THAT CONVERGENT EVOLUTION IN BINDING TO THE HINGE REGION IS FACILITATED BY ITS HYDROPHOBIC, ACCESSIBLE, AND ADAPTIVE NATURE. SUCH FEATURES MAY BE GENERAL INDICATORS OF A POTENTIAL FOR PLASTIC BINDING ON PROTEIN SURFACES.

Introduction

Immunoglobulins play an essential role in targeting the response of the mammalian immune system to foreign matter. Free antibodies, such as immunoglobulin G (IgG), possess a variety of binding sites on their surfaces that directly link molecular recognition events to specific biological consequences (Fig. 1a) [1]. Most well studied are the antigen binding sites located within the variable complementarity determining regions (CDR) present in each Fab fragment. No less important are the binding sites for complement and effector activation, which are located on the N-terminal region of the C_{H2} domain of Fc [2,3].

Here, we focus on a third binding site on IgG, the recognition site for the neonatal Fc receptor (FcRn), which is located at the C_{H2}/C_{H3} hinge region of the Fc fragment (Fig. 1a) [4,5]. Named for its discovery in neonatal tissues, FcRn plays an important role in the shuttling of IgGs from mother to child in development of the immune system. However, the "neonatal" classification for FcRn now appears overly narrow, as it has been implicated in immune system functions

beyond the fetal stage [6], including being a contributor to the unusually long serum half life of IgG [7].

Our primary interest in the FcRn binding site, however, arises not from its biological role, but rather from the great diversity of other natural molecules that have evolved to recognize this same region [8]. Specifically, three other genetically and structurally unrelated protein domains have arisen independently to interact with this shared surface on Fc. Two of these are small bacterial binding domains, and the third is an autoimmune antibody involved in rheumatoid arthritis.

The C_{H2}/C_{H3} hinge region on Fc is also particularly interesting from a cell signaling standpoint because of its structural similarity to a variety of extracellular cytokine receptors (Fig. 1b), wherein the intra-strand loops of two Ig-superfamily β -sandwich domains [9] comprise a protein-binding site. Though there is no close sequence homology between the fibronectin type III domains found in these receptors and the Ig constant domains found in Fc, the similarity in their three-dimensional architectures is quite apparent. Thus, the mechanism of plasticity in Fc may be

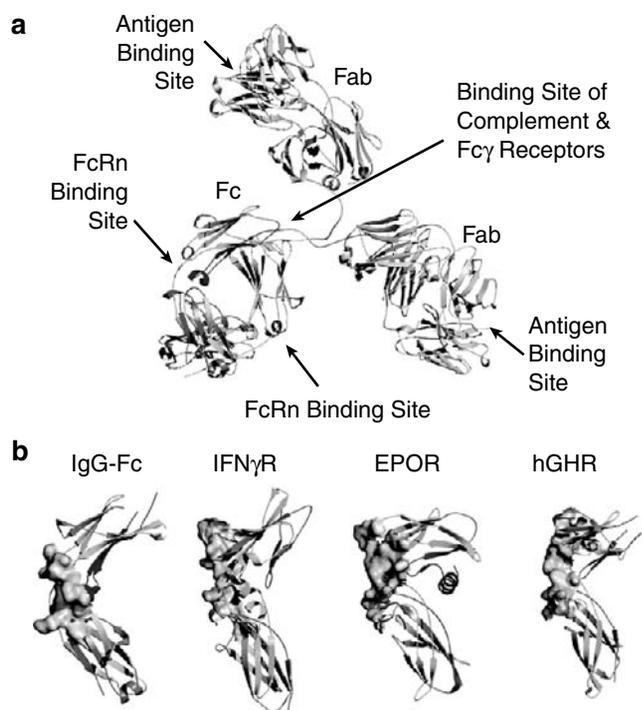

Figure 1 The structure of immunoglobulin G (a) contains several biologically important binding sites on its surface [26]. The neonatal Fc receptor (FcRn) binding site, located at the hinge region of two β -sandwich domains, is structurally analogous to binding sites found on extracellular hematopoietic cytokine receptors (b) in that many of these receptors use loops from two adjacent β -sandwich domains to create a binding site. Several of these receptors surfaces are known to exhibit binding plasticity, through binding of symmetric receptors to asymmetric hormones [27,28], through hormone cross-reactivity [10], or through binding to low-molecular-weight protein mimetics at the hormone binding site [29].

informative and helpful in understanding the cross-reactive binding behavior of certain cytokine receptors [10].

Structures of the Natural Fc Binding Domains

Although FcRn is a homolog of major histocompatibility complex (MHC) class I, the FcRn binding site for IgG is unrelated to the MHC peptide binding groove. Instead, FcRn uses a set of loops displayed from its two structural domains to contact Fc (Fig. 2a). Rheumatoid factors, which are autoantibodies associated with rheumatoid arthritis, also use loop regions to interact with Fc and often target the C_{H2}/C_{H3} hinge region [11]. However, as revealed by the structure of one such antibody in complex with Fc (Fig. 2c) [12], rheumatoid factor CDR loops do not resemble the Fc binding loops found in FcRn. Also unlike FcRn, rheumatoid factors are not known to have any beneficial role, but are instead thought to arise as part of the disease pathology [13].

A variety of infectious organisms have also been found to express proteins capable of binding human immunoglobulins [14–16]. However, only two such proteins, protein A and protein G, have been characterized by X-ray crystallography. Protein A is found on *Staphylococcus aureus* [17],

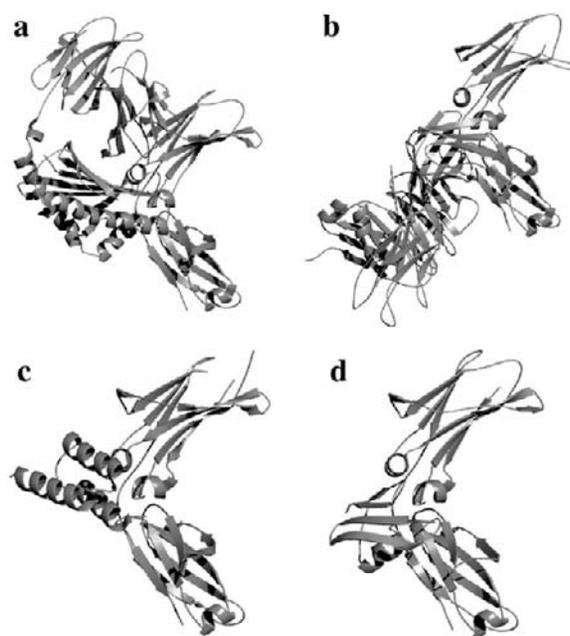

Figure 2 Natural IgG-Fc binding proteins that interact with the Fc C_{H2}/C_{H3} hinge-region binding site include: (a) FcRn [5], (b) rheumatoid factor [12], (c) protein A [19], and (d) protein G [20]. (Adapted from DeLano *et al.*, *Science*, 287, 1279–1283, 2000. With permission.)

whereas protein G is an analogous but structurally unrelated protein expressed by *Streptococcus* G148 [18]. Both proteins contain a series of small, repeated protein binding domains, each capable of binding immunoglobulins. Here, we focus on domain B1 of protein A and domain C2 of protein G, both of which exhibit binding affinity for the Fc fragment of IgG. The structures of the complexes are shown in Figs. 2c and 2d [19,20]. The Fc binding domain of protein A consists of three helices, two of which make direct contact with Fc. In contrast, the protein G binding domain utilizes a single helix and two strands of a β -sheet to make such contacts. Neither protein domain shows structural homology to the Fc binding region of either FcRn or rheumatoid factor.

With these four Fc co-complexes in mind, it is apparent that nature has independently solved the same molecular recognition problem four times and in four different ways. Other natural solutions are also believed to exist [21] but have yet to be resolved by X-ray crystallography. Such profound cases of evolutionary convergence are rare at the molecular level, and they provide a unique opportunity to study the properties that promote binding on protein surfaces.

The Consensus Binding Site on Fc

Superposition of the binding site footprints of the four natural IgG-Fc binding domains reveals the presence of a common surface patch on the Fc surface (Fig. 3a). Just six side chains are involved in forming this saddle-shaped consensus site between the 250's loop of the C_{H2} domain and the 430's loop of the C_{H3} domain. Together these side chains

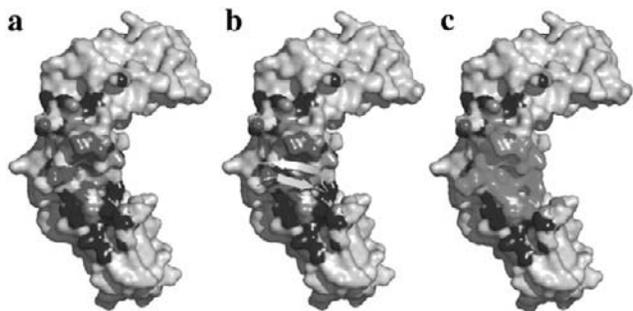

Figure 3 Superposition of the binding site footprints on IgG–Fc for the natural Fc binding proteins (a). Surface atoms are colored red, yellow, light blue, and dark blue, reflecting their participation in four, three, two, or one of these protein interfaces, respectively. Atoms in residues 252 to 254 and 434 to 436 form a nearly contiguous patch of the Fc surface that is common to all of the crystallographically characterized interactions. The crystal structure of an Fc-binding peptide (white) is shown in (b), and atoms in the solvent-protected footprint of the peptide are shown in (c). The peptide covers the same consensus set of atoms as the natural binding domains. (Adapted from DeLano *et al.*, *Science*, 287, 1279–1283, 2000. With permission.)

account for a contiguous surface patch of approximately 500 \AA^2 .

What is the driving force that has led nature to target this binding site repeatedly with so many diverse molecules? A trivial explanation would be that an important biological function of IgG, such as binding of the neonatal Fc receptor, is innately coupled to these residues. If disruption of this particular function is somehow beneficial to bacterial infection, then this hypothesis would explain why protein A and protein G binding domains have co-evolved to bind this site; however, it would not explain why rheumatoid factors are also specifically attracted to the hinge region.

An alternative hypothesis is that the innate physiochemical composition of this site is inherently “sticky” and promotes binding as well as antigenicity. If the biological role for protein A and G is primarily to localize IgGs to the bacterial surface, perhaps to evade immune system surveillance, then it might simply be the case that the C_{H2}/C_{H3} hinge region was the most evolutionarily efficient IgG surface to target for binding. Likewise, if this region is an innately attractive part of the protein surface, then that would explain the frequent emergence of autoimmune rheumatoid factors targeting Fc. We chose to evaluate this hypothesis by evolving novel IgG–Fc binding domains in the laboratory to discover if molecules selected purely for binding would indeed target the C_{H2}/C_{H3} hinge region.

Evolution of an Fc Binding Peptide

Phage display of small peptide libraries is a powerful technique for developing novel binding partners to proteins of interest [22]. We began with a library of approximately 4 billion random, 20-amino-acid, disulfide-constrained peptides displayed in a multivalent fashion on the surface of M13 bacteriophage [23]. This library was screened for

binding to an immobilized Fc fragment. After several rounds of selection and amplification, a dominant peptide, ETQRCTWHMGELVWCEREHN, emerged from the library. Repetition of the experiment gave the original peptide and another with a closely related sequence KEASCSYWL-GELVWCVAGVE. Both of these peptides were synthesized and shown to compete with a protein A binding domain for binding to Fc with dissociation constants of about $5 \mu\text{M}$ [8].

Two subsequent rounds of monovalent phage-display optimization, sequence analysis, and manual truncation led us to identify a smaller 13-amino-acid peptide, DCAWHLGELVWCT, which bound Fc with a dissociation constant of approximately 25 nM and retained competitive binding activity with protein A [8]. Because this peptide shared a highly conserved $-C\text{---}GELVWC-$ sequence pattern with the original peptides, all three peptides were assumed to bind in a related manner.

We solved the X-ray crystal structure of this 13-mer peptide in complex with Fc (Fig. 3b) [8]. The structure confirmed that it interacts with the same hinge region binding site of Fc as the other proteins, and the β -hairpin conformation of the peptide itself provides a fifth example of a unique protein fold capable of binding to the Fc hinge. Remarkably, the footprint of this small peptide on the surface of Fc covers virtually all of the consensus atoms derived from the much larger proteins domains (Fig. 3c). This result supports the hypothesis that the Fc hinge is attractive and that molecules in search of productive binding interactions will be drawn to this region, even in the absence of a specific biological function.

Factors Promoting Plasticity

What is the physiochemical basis for the attractiveness of this site, and how is it that so many diverse scaffolds are able to find productive interactions with it? Several characteristics stand out about this region of the Fc molecule. First, this binding site is located at an adaptive hinge region between two protein domains which are apparently free to move relative to one another, as there are no direct contacts between the protein components of the C_{H2} domains observed in crystal structures of the Fc dimer. Relative rotations of up to 11 degrees between the C_{H2} and C_{H3} domains can be seen across the various structures. Such flexibility makes it possible for main-chain atoms on one hinge loop to move through a distance of over 2.5 \AA relative to the other hinge loop, and this intrinsic adaptability presumably facilitates formation of complementary surfaces with several diverse partners.

A second notable feature is the highly exposed nature of the residues in this consensus site. The 250's and 430's loops protrude from the protein surface, and the side chains of Ile253, Ser254, and Asn434 all point outward, making few intramolecular contacts with other side-chain or main-chain atoms. Thus, they are highly available to form productive intermolecular interactions. Indeed, several binding partners

possess concave pockets on their binding surfaces which engulf these convex features.

A third aspect is the hydrophobic nature of the C_H2/C_H3 hinge. Quantitative surface patch analysis of the Fc surface has shown that this region is one of very few highly accessible hydrophobic regions on the Fc binding site surface [8,24]. Interestingly, one of the other large accessible, hydrophobic surfaces patches is the shared binding site for the family of Fcγ receptors and for C1q, which lead to effector and complement activation after antigen binding has occurred [1].

Conserved and Functionally Important Molecular Interactions

Although the Fc hinge region binding proteins are unrelated at the secondary and tertiary structural levels, patterns do emerge when one compares the detailed atomic interactions made by these molecules. Superposition of the available crystal structures enables identification of a set of conserved molecular interaction sites in the consensus region (Fig. 4). Although the overall folds of each of these Fc binding domains are distinct, there are numerous similarities in the geometric arrangements of the specific functional groups presented by each partner (Fig. 5).

Mutagenesis experiments with the Fc binding partners also support the notion that the consensus binding site serves as a shared “affinity handle” across the different receptors. FcRn binding can be disrupted by alanine substitutions at positions 252, 253, 435, and 436 [2]. Likewise, the

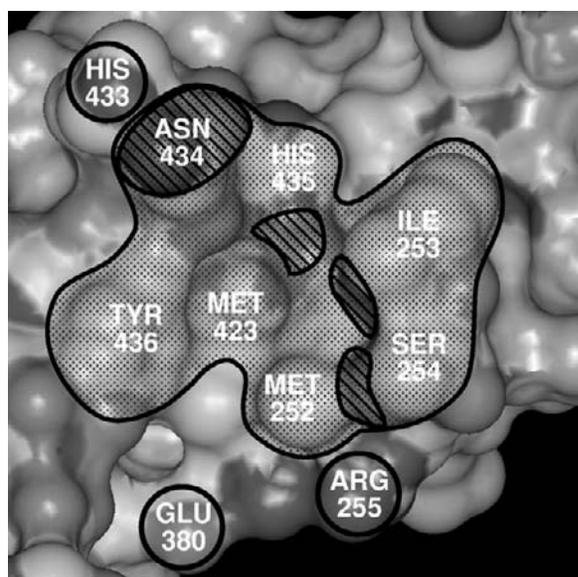

Figure 4 Topology of conserved interaction sites in consensus binding region on Fc. The predominantly hydrophobic consensus region is shaded. The hydrogen bonding sites are shown with diagonal lines, and salt bridging locations are denoted by open circles. Nitrogen and oxygen are colored blue or red, respectively, and carbon and sulfur atoms are colored green. Hydrogens are not shown. (Adapted from DeLano *et al.*, *Science*, 287, 1279–1283, 2000. With permission.)

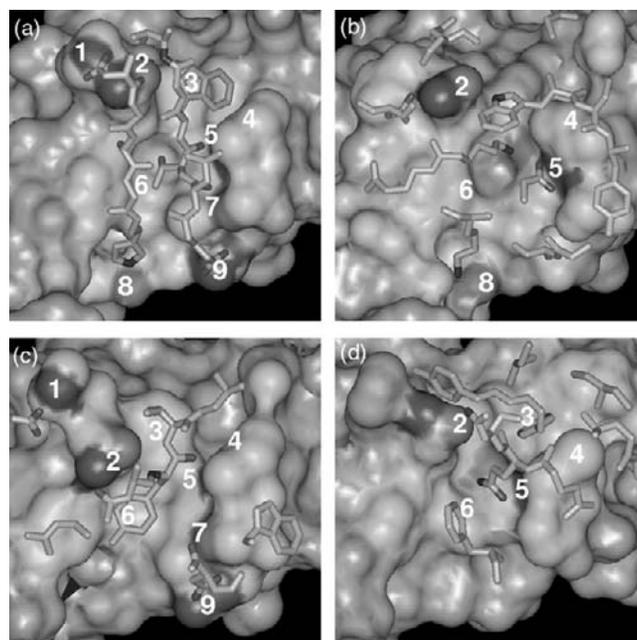

Figure 5 Comparison of the Fc binding interactions of (a) the Fc binding peptide, (b) domain C2 from protein G, (c) rheumatoid factor, and (d) domain B1 of protein A. Numbers indicate the following conserved interactions: (1) salt bridges with His433, (2) hydrogen bonding to Asn434, (3) hydrophobic packing onto His435, (4) burial of the hydrophobic “knob” formed by Ile253 and Ser254, (5) hydrogen bonding to main chain (N-H) of Ile253, (6) hydrogen packing onto Met252 and Tyr436, (7) hydrogen bonding to Ser254, (8) salt bridges with Glu380, and (9) salt bridges with Arg255. For clarity, only interfacial atoms are shown, and only nitrogen and oxygen atoms involved in conserved polar interactions are colored blue or red, respectively. The remaining contacts are colored yellow and green. (Adapted from DeLano *et al.*, *Science*, 287, 1279–1283, 2000. With permission.)

binding of many rheumatoid factors is sensitive to truncation of the side-chain atoms in the consensus binding region [11,25]. Binding of protein A is disrupted by alanine substitutions at positions 253 and 435, and the Fc binding peptide can be blocked by alanine substitutions at 434, 435, or 436 [8]. In each case, there are functionally important binding interactions in the consensus region, though the relative importance of individual residues appears to be non-uniform.

Conclusion

From studying the consensus binding site on Fc, it is evermore apparent that the complementary “lock-and-key” model for specific binding events does not apply to protein–protein interactions in the way it does to interactions between an enzyme and its substrate. The Fc hinge region teaches us that there may be many solutions to binding to a protein surface and that vastly different protein scaffolds can apparently give rise to equivalent sets of molecular interactions. Given that small peptides can be evolved to bind such a site, it seems reasonable to think that small drug-like organic compounds might also be able to bind adaptive protein–protein interaction surfaces and give rise to new classes of therapeutics capable of modulating cellular signaling.

Introduction

The immunoglobulin (Ig)-superfold is one of the most common structural motifs in the proteins of multicellular organisms. Typically, this fold mediates specific protein–protein interactions within the extracellular environment. As such, it is a hallmark of molecular structures that perform recognition and signaling functions. In this chapter, the standard features and variants of the basic Ig-fold are briefly detailed, and the ways in which this motif is incorporated into the overall molecular architecture of monomeric and multimeric proteins are discussed. The available three-dimensional structural information is surveyed for complexes involving Ig-fold interactions, and various examples are compared and contrasted. These complex structures illustrate the diversity of the interaction modes by which the Ig-fold can participate in functional recognition.

The Immunoglobulin Superfamily

The β -sandwich topology, first identified in the domains of immunoglobulin (Ig) structures and hence termed the Ig-fold, is one of the most common structural motifs in the proteins of multicellular organisms. The immunoglobulin superfamily (IgSF) is comprised of proteins that contain at least one Ig domain. This motif characteristically occurs within the extracellular portions of proteins and frequently mediates recognition events. Indeed, the evolution of IgSF proteins appears to be linked to the development of multicellular organisms.

A dramatic increase in the number of IgSF genes is observed in vertebrates (for example, more than 750 in the human genome) when compared to the numbers in flies (140 genes) and in worms (64 genes) [1].

Ig-Superfold Structures and Assemblies

THE IG-SUPERFOLD

The Ig-superfold is characterized by a primary sequence motif that spans some 100 amino acids. In three dimensions, this sequence motif translates into a compact domain structure that comprised of two anti-parallel β -sheets packed face to face (Fig. 1). Although there is a defined topology and connectivity for the Ig-superfold, the number of β -strands is variable. To take account of this variability Ig-like domains have been classified into different sets, according to the number and arrangement of the β -strands [2, 3]. The nomenclature is standardized with the β -strands labeled sequentially from A to G, and structurally equivalent β -strands in different sets retain the same letter. The I set is defined as having strands ABED in one β -sheet and A'GFCC' in the other. The V set has an extra C'' strand in the latter β -sheet, while sets C1 and C2 lack strands A', and A' and D, respectively. For all of the sets, primarily hydrophobic residues form the core of the β -sheet sandwich, and there is commonly an inter-sheet disulfide bond present (usually between β -strands B and F) to add extra stability to the fold. Additional disulfide bonds can also be present both within an Ig-like domain and between Ig-like domains.

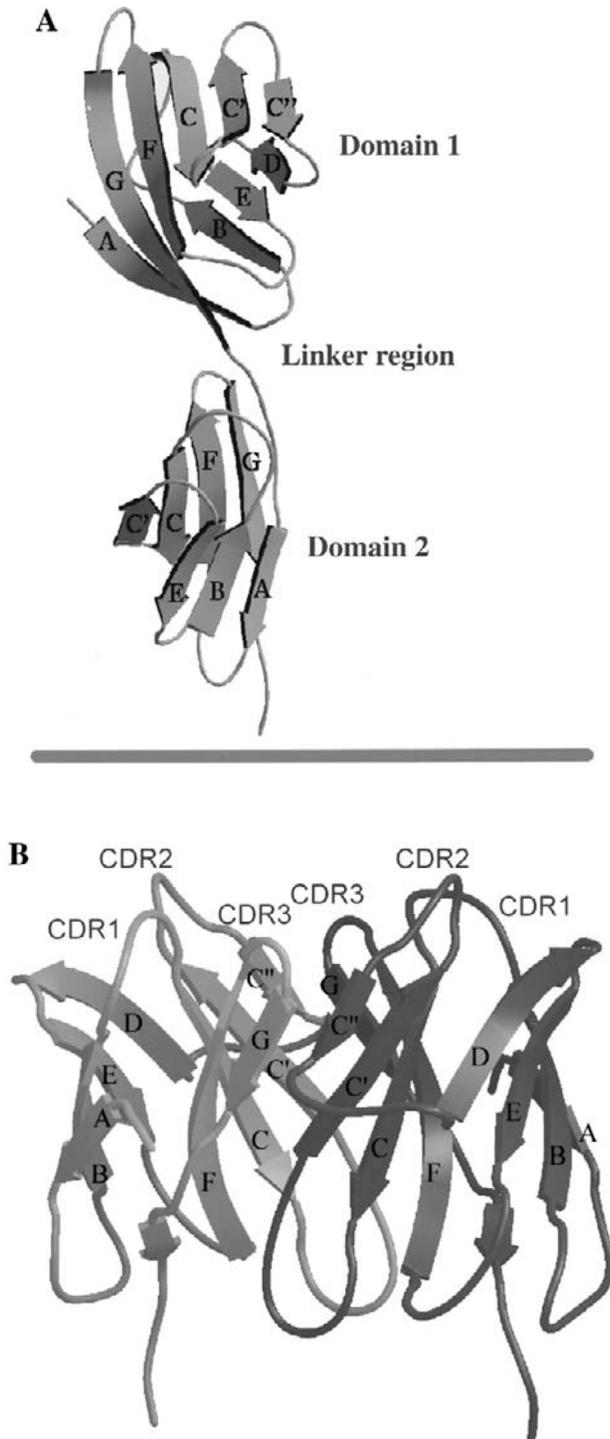

Figure 1 (a) CD2 structure. An example of the “beads on a string” IgSF architecture. (PDB code 1HNF [8]), and (b) CD8 structure. An example of a dimeric IgSF molecule (PDB code 1CD8 [12]).

OTHER TOPOLOGICALLY RELATED FOLDS

Several separately cataloged types of structural motif have a β -sheet sandwich topology similar to that of the Ig-superfold. These will not be discussed in this chapter, as phylogenetically they do not appear to be related to the IgSF, but rather to be the result of different evolutionary paths converging to the same stable fold topology. They include the motif

characterized by the type III domains of fibronectin (FnIII), the bacterial C3 subset, and the actinoxanthine-like C4 subset [4].

MULTIPLE IG-LIKE DOMAIN ASSEMBLIES IN MOLECULAR ARCHITECTURE

IgSF proteins are typically multi-domain structures, and these domains may or may not be exclusively Ig like. Multiple copies of the Ig-superfold can occur sequentially within the same polypeptide chain, resulting in a “beads on a string” type of linear arrangement of the domains (Fig. 1a); an extreme example of this molecular architecture is exhibited by the giant, multidomain muscle protein titin [5]. At the cell surface, the longest of the linear-type IgSF proteins identified to date is sialoadhesin (siglec-1), with an extracellular region consisting of 17 Ig-like domains [6]. More typically, the extracellular regions of IgSF proteins contain 1 to 4 Ig-like domains, often intermingled with fibronectin type III domains [7]. The linker regions between domains in the “beads on a string” type of structures can be short and relatively rigid (for example, between the two Ig-like domains of CD2 [8]) or longer, introducing more degrees of freedom at certain points in the molecular structure, as in the link between domains 2 and 3 of CD4 [9].

For a subset of IgSF cell adhesion molecules, such as axonin/TAG-1 and hemolin, an extended linker region allows the molecule to double back on itself, pairing Ig domains to create an overall horseshoe or U-shaped type of architecture [10,11]. A pair-wise packing of Ig domains is reminiscent of the archetypal immunoglobulin structure, and, more generally, within the IgSF two separate polypeptide chains bearing Ig-like domains homo- or heterodimerize (Fig. 1b) to form the stable molecular structure—for example, CD8 [12].

The size of IgSF molecules, their flexibility, the positioning of the Ig-like domain(s) within the overall structures, and the formation or absence of pairwise domain interactions within the molecules all contribute to the mode of function of the Ig-superfold in each particular case.

Ig-Superfold-Mediated Recognition

The Ig-superfold provides a stable platform that can be adapted to mediate a myriad of specific homophilic and heterophilic interactions ranging from small molecule recognition through to recognition of proteins and glycans. For cell-cell type interactions, the functional capacity of the Ig-like domain is frequently modulated by its position within the overall molecular architecture, as well as within any supra-molecular assemblies at the cell surface.

Modes of Ig-Superfold Interaction

The archetypal Ig-superfold in immunoglobulins mediates specific recognition through the complementarity-determining region (CDR) loops at one end of the variable

domain β -sandwich. However, subsequent IgSF structures and functional studies have highlighted the diversity of potentially functional surfaces on the Ig-superfold. Ig-like domains can interact with a ligand via their β -sheets, via their loop regions, or via a combination of both. A single Ig-like domain may be functional in isolation or two or more may be required, either as consecutive domains of the “beads on a string” molecular architecture or as homo- or heterodimers. Finally, the combination of protein–protein contacts mediated by a single IgSF molecule can result in the formation of extended interaction arrays at and between cell surfaces.

THE CLASSICAL IMMUNOGLOBULIN TYPE OF IG-SUPERFOLD INTERACTION

Several IgSF molecules that act as cell-surface receptors or coreceptors in the immune system employ interaction modes similar to those used by immunoglobulins for antigen recognition. One obvious example is the T-cell receptor, an IgSF molecule that is discussed in detail elsewhere in this handbook (see Chapter 11). A second, closely related example is provided by the cytotoxic T-cell coreceptor CD8. Like the T-cell receptor, CD8 interacts with major histocompatibility complex (MHC) class I molecules. Both TCR and CD8 have an MHC class I binding surface composed of the two sets of CDR-like loops (BC, C’C”, and FG) from a dimer of variable domains. The structure of the CD8 $\alpha\alpha$ –MHC class I complex (Fig. 2) for both human and murine molecules reveals CD8 binds one MHC class I molecule, interfacing with the MHC α_2 and α_3 domains as well as contacting β_2 -microglobulin [13,14]. The focal point of the interaction is the DE loop of the MHC class I α_3 Ig-like domain, which is clamped between the CDR-like loops of the two CD8 subunits. This mode of interaction is analogous to that used by

immunoglobulins when binding to antigenic surfaces containing a single prominent loop.

HETEROTYPIC IG-SUPERFOLD INTERACTIONS

Monomeric IgSF cell-surface molecules mediate interactions with a broad spectrum of ligand types, many discussed in detail elsewhere in this handbook. The diversity of ligands is matched by the diversity of interaction modes. For completeness, three of the most distinctive interaction mechanisms are briefly reviewed here.

At present, there is no complex structure to illustrate definitively the mode of interaction of IgSF members such as ICAM1 and ICAM2, VCAM, and MadCAM with integrins; however, the key contribution of an aspartic acid residue that is prominently exposed on a loop in the N-terminal Ig-like domain of these molecules is well established [15–20]. It is believed that this acidic residue may contribute to the coordination of a divalent cation within the integrin structure [21].

Several Ig-superfold-mediated protein–protein interactions involve contributions from the linker region between two sequential Ig-like domains within a receptor structure. This mode provides a common theme for the otherwise diverse interactions of the FGF receptor to the cytokine FGF [22–24] and the KIR family of natural killer (NK) cell receptors to MHC class I molecules [25,26]. Both families of interaction have been characterized by crystal structures of representative complexes and are discussed in detail in subsequent chapters.

In addition to mediating protein–protein interactions, the Ig-superfold can adapt to function in glycan recognition. This property is exemplified by cell-surface receptors of the siglec (sialic acid binding IgSF lectin) family [27]. Members of this IgSF subgroup are characterized by the sialic acid binding function of their N-terminal, V-set, Ig-like domain. The key features of the siglec-style binding site for sialic acid have been revealed by the crystal structure of the N-terminal domain of sialoadhesin (siglec-1) in complex with 3’ sialyl-lactose [28]. The binding is centered on the N-terminal portion of β -strand G at the edge of the β -sandwich (Fig. 3) and utilizes interactions with side chains from three residues (an arginine and two tryptophans) that are conserved across the siglec family.

HOMOTYPIC IG-SUPERFOLD INTERACTIONS

trans Interactions Mediating Cell-to-Cell Contacts
Many of the cell adhesion molecules responsible for cell-to-cell interactions conform to the “beads on a string” type structure with Ig-like domains arrayed in a linear fashion in the N-terminal extra-cellular region prior to a single membrane spanning section. For such structures, the functional Ig-like domains are frequently those most distal to the cell surface (i.e., the N-terminal domains). Domain 1 of such molecules usually belongs to the I-set or V-set class of Ig-superfold and the functional interactive surface commonly encompasses part of the A’GFCC’(C”) β -sheet. This in particular holds for interactions involving IgSF ligands. Examples of crystal structures for recognition complexes of this type

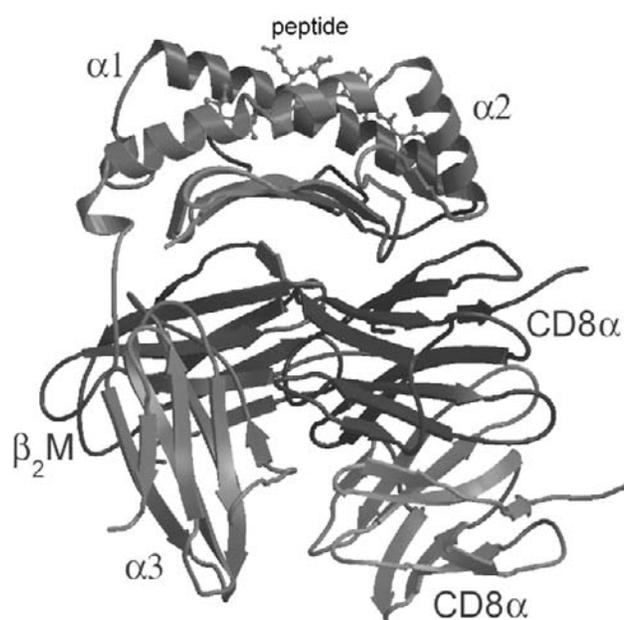

Figure 2 The MHC class I–CD8 $\alpha\alpha$ complex (PDB code 1AKJ [13]).

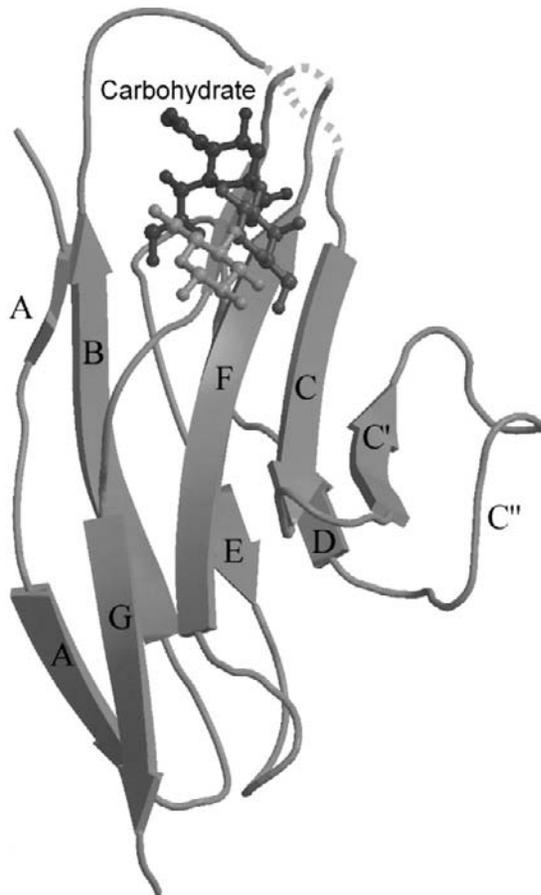

Figure 3 The N-terminal Ig-like domain of sialodhesin in complex with the carbohydrate 3' sialyllactose (PDB code 1QFO [28]).

include P0–P0 (where molecular contacts within the crystal lattice are representative of homophilic IgSF–IgSF interactions [29]) and the structures of CD2–CD58 and B7-1–CTLA4 (representative of heterophilic IgSF–IgSF interactions [30,31]).

The homophilic interactions of the neural cell adhesion molecules show some variations on the above theme. A crystal structure of the first two N-terminal Ig-like domains of NCAM revealed a propensity for this molecular fragment to interact as a cross-shaped antiparallel dimer with residues from the B and E β -strands of domain 1 in molecule 1 interacting with those of the FG loop in domain 2 of the second molecule [32]. Functional data suggest that interactions mediated by domains 1 and 2 may not represent the whole story, but this dimer structure does provide a compelling mechanism for one mode of NCAM-mediated cell–cell adhesion. The four N-terminal Ig-like domains of chicken axonin-1 [10], and the distantly related insect protein hemolin [11], form a U-shaped structure due to intramolecular contacts between domains 1 and 4 and domains 2 and 3 that acts as the functional interactive unit. Lattice contacts within the axonin-1 crystals suggest that these U-shaped units mediate cell–cell interaction via an edge-to-face type of packing involving the CE loop in domain 3 and the FG loop in domain 2.

cis Interactions Modulating Avidity In general, cell adhesion molecule interactions are individually low affinity interactions. However, several crystal structures have provided significant evidence for the occurrence of homophilic *cis* interactions between IgSF molecules, interactions that could mediate the formation of stable, zipper-like arrays in the context of a cell–cell interface. The crystal structure of P0, the major structural protein of peripheral nerve myelin, provided one of the first such examples, with crystal lattice contacts suggesting that *cis* interactions mediate formation of P0 tetramers that in turn mediate an array of *trans* interactions to clusters of tetramers on the opposed membrane [29]. Array-wise interactions have also been proposed for the neural cell adhesion molecules exemplified by axonin-1 [10]. Heterophilic examples include the dimerization of B7-1 [33], which, when combined with the dimeric molecular structure of its IgSF ligand CTLA-4, could result in the formation of extended arrays between T cells and antigen-presenting cells in the immune system [31,33,34] (Fig. 4).

IgSF Molecular Architecture and Interactions in the Context of Function

The Ig-superfold appears to provide a stable structural platform capable of supporting many variations on the theme of specific ligand recognition. The interactions it mediates can be high affinity (nanomolar range, as in cytokine receptor interactions, such as between FGF and FGF receptor), medium affinity (micromolar to nanomolar range, as immunoglobulin–antigen complexes), or weak affinity (millimolar range, as exemplified by many of the cell adhesion molecule interactions), but always a high degree of specificity is retained. For the cell adhesion type of interaction, it has been proposed that a predominance of electrostatic, in particular hydrogen-bond-based, binding provides the mechanism for generating only low affinity while maintaining specificity [35]. In each case, the binding affinities, kinetics, and avidity are matched to the requisite functional role of the interaction.

In addition to the adaptability of the interaction surface it can provide, the modular nature of the Ig-superfold also lends itself well to the formation of large multi-domain or multi-molecular assemblies. Such assemblies provide additional mechanisms by which to modulate function. For example, the 17 Ig-domain extracellular region of sialoadhesin may serve to present the sialic acid binding N-terminal domain at sufficient distance above the cell surface that it avoids any *cis*-type interactions with glycan ligands on the same cell surface [6]. Conversely, the closely matched sizes of interaction complexes such as CD2–CD58, B7-1–CTLA4, and MHC–TCR may be integral to the formation of supra-molecular assemblies between cells [36,37]—for example, the immunological synapse. Such assemblies increasingly are perceived as the deciding factor in the biological outcome of a cell–cell recognition event.

TCR Generation and Architecture

T cells bearing clonotypic T-cell receptors (TCRs) are generated from a pool of naïve progenitor cells by a two-stage process of positive and negative selection. The TCRs on these cells must recognize self peptides bound to self, or syngeneic, major histocompatibility complexes (MHCs) before they can differentiate from “double positives” into CD4⁺- or CD8⁺-expressing “single positives.” However, positively selected T cells that are reactive against self-pMHCs are destroyed by negative selection. Positive selection establishes two subclasses of TCRs that associate with either of the two coreceptors CD8 (Fig. 1), and CD4:CD8⁺ T cells recognize pMHC class I molecules, while CD4⁺ T cells are activated by peptides bound to MHC class II.

$\alpha\beta$ TCRs are heterodimeric cell-surface glycoproteins that consist of disulfide-linked α and β chains and have a domain organization similar to antibodies (Fig. 2). Each chain is composed of an immunoglobulin (Ig)-like variable (V) and constant (C) domain, a transmembrane region, and a short cytoplasmic tail. The C domains serve to anchor the TCR in the membrane of the T cell and to interact with accessory signaling molecules such as CD3. The variable domains carry the complementarity-determining regions (CDRs), with which the TCR binds pMHC antigen with a generally low affinity, but moderate specificity.

Peptide Binding to MHC Class I and II

In the cellular immune response, peptides are displayed to T cells in complex with class I or class II MHC molecules. Both classes of MHC are heterodimers of similar structures; they are composed of three domains, two Ig-like and one α/β domain (MHC fold) that forms the peptide binding site.

Whereas in class I MHC molecules, the peptide binding site is constructed from the heavy chain only, in class II MHC, it is formed by both chains. A β -pleated sheet forms the floor of the binding groove, which is flanked by α -helices (Fig. 2). Polymorphic residues in the α -helices and β -sheet floor cluster at the center of the binding groove and change its shape and chemical properties, thus accounting for the peptide-specific motifs that have been identified for each MHC allele [1–3].

Class I MHC molecules bind peptides in an extended conformation with the C terminus and the other main anchor residues buried in allele-specific pockets, leaving the upward-pointing peptide side chains available for direct interaction with the TCRs. Thus, the peptide lengths are usually 8 to 10 residues [4,5]; substantially longer peptides can bind but, due to the fixing of their N and C termini, they must bulge out of the binding groove [6].

In class II MHC, the peptide termini are not fixed, and the bound peptides can be significantly longer than in class I MHC; the peptide backbone is confined to repeating polyproline type II, helical, ribbon-like conformations [7]. The peptides also lie slightly deeper in the binding groove. Thus, the peptide has the potential to dominate the TCR/pMHC interface more in class I due to the ability to bulge out of the groove depending on the length of the peptide and the pMHC [6]. Additionally, extensive ridges in some MHCs force the peptide to bulge even higher out of the groove and provide more intimate contact with the TCR [8,9].

TCR/pMHC Interaction

Whereas in humoral immunity antibodies identify antigenic molecules as distinct entities, in the cellular response TCRs recognize antigenic peptide fragments only when presented by an appropriate MHC molecule. A fundamental

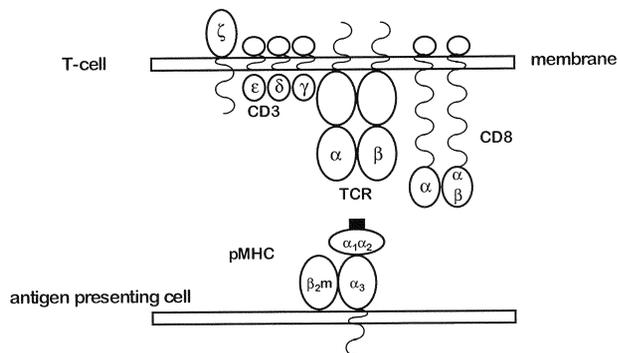

Figure 1 Schematic representation of the components in a class I TCR/pMHC/CD8/CD3 signaling complex. The heavy chain consists of the α_1 - α_3 domains, to which the light chain β_2 -microglobulin (β_{2m}) is noncovalently attached. The peptide-MHC (pMHC) complex is anchored to the plasma membrane of the antigen-presenting cell via its α_3 domain while the $\alpha_1\alpha_2$ super-domain binds the peptide (\square). The CDR loops of the $\alpha\beta$ TCRs recognize the pMHC complex, while the coreceptor CD8 binds simultaneously to the α_3 domain either as an $\alpha\alpha$ homodimer or an $\alpha\beta$ heterodimer. The signal from the pMHC complex (if any) is then transmitted through the T-cell plasma membrane by the CD3 signaling modules. Phosphorylation of the CD3 ζ chain by the ZAP70 kinase (not shown) is an early step in this signal transduction cascade.

difference between antibody/antigen and TCR/pMHC recognition is that the specificity of the former is dependent on high affinity (K_d is nanomolar) for the free antigen, whereas in the latter low affinities predominate (K_d is ~ 0.1 – $500 \mu M$); thus, specificity must be ensured by a different mechanism. Possible mechanisms are outlined in the following sections.

Orientation of the TCR in TCR/pMHC Complexes

The seven independent TCR/pMHC complexes determined to date (reviewed in references [10] to [12]; Table 1) confirm that the TCR heterodimer is oriented approximately diagonally relative to the long axis of the MHC peptide-binding groove [13,14]. The $V\alpha$ domain is located above the N-terminal half of the peptide, while the $V\beta$ domain can contact the C-terminal portion of the peptide (Fig. 2). The fluctuation in the TCR orientation has been described generally as diagonal [13,14] and, in one case, orthogonal [15], but it appears that the TCR orientation, or twist, on MHC class I and class II shows a relatively restricted spread of about 35° (Fig. 3). However, the TCR deviates not only in its twist, but also in its roll and tilt, which can be gleaned from the angle of the pseudo two-fold axis between the TCR $V\alpha$ and $V\beta$ domains and the MHC β -sheet floor (Fig. 3). In addition, the TCRs can differ in their $\alpha\beta$ chain pairings, such that the pseudo- $V\alpha/V\beta$ two-fold angle can also contribute to the variation in TCR orientation on the pMHC. As a result of the various TCR orientations, the buried surface for the TCR/pMHC complex can vary extensively between 1240 and 1930 \AA^2 , with the peptide contributing a relatively restricted range of 21 to 34% to the pMHC side of that interface. $V\alpha$ can contribute from 37 to 74% (average 57%) and $V\beta$ from 26 to 63% (average 43%) of the TCR buried

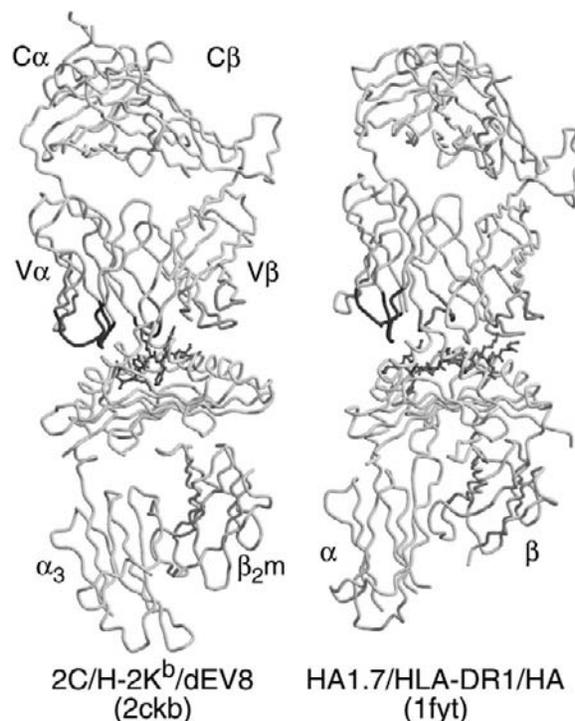

Figure 2 Similar structural architecture of class I and class II TCR/pMHC complexes. The $C\alpha$ traces of the TCRs [34,51] are shown on top with the colored CDR loops contacting the pMHC at the complex interfaces. The $V\alpha$ and $V\beta$ domains are positioned over the N-terminal and C-terminal halves of the peptide, respectively. The peptides are drawn as red ball-and-stick representations and have fixed termini in class I MHC but can extend out of the binding groove in class II MHC. The CDR loops are colored as follows: CDR1 α (residues 24–31): dark blue, CDR2 α (48–55): magenta, CDR3 α (93–104): green, CDR1 β (26–31): cyan, CDR2 β (48–55): pink, CDR3 β (95–107): yellow, and HV4 (69–74): orange.

surface. This bias in chain usage has also been noted for antibodies, where V_H usually provides a larger contribution to the antibody-antigen interface [16].

Peptide Recognition by the TCR CDR Loops

The suggestion that only a few up-pointing peptide side chains contribute to the specificity of the TCR/pMHC interaction [17] was confirmed by TCR/pMHC crystal structures. In class I, these interactions are dominated by the peptide residues that extend or bulge most out of the groove and, hence, represent functional hotspots [18] in the TCR/pMHC interface. For nonamer and octamer peptides, these represent residues P5, P7, and P8 and P4, P6, and P7, respectively. For class II peptides, the key side-chain contributions are more uniformly dispersed (P1, P2, P3, P5, P8). On the other hand, the contribution of the peptide backbone to TCR interaction is very modest for both class I and class II, where none to only a handful of contacts are made. The only exception so far is for the HLA-A2/Tax complex, where the large P4–P5 bulge includes a glycine at P4 that enables the TCR to access the peptide backbone [14,19].

Analysis of the number of contacts reveals that CDR1 β and CDR2 β often make minimal contact with the pMHC

Table 1 Overview of TCR/pMHC Complex Structures (1996–2002)

Complex	PDB ID	Peptide activity	Constructs and expression systems	Ref.
2C/H-2K ^b /dEV8	2ckb	Weak agonist	<i>D. melanogaster</i> , acidic/basic leucine zipper for specific TCR chain pairing	13, 34
2C/H-2K ^b /SIYR	1g6r	Superagonist ^a	—	18
2C/H-2K ^{bm3} /dEV8	1jtr	Weak agonist	—	39
scBM3.3/H-2K ^b /pBM1	1fo0	Agonist	Myeloma cells for TCR, <i>E. coli</i> for MHC (refolded from inclusion bodies)	30
B7/HLA-A2/Tax	1bd2	Strong agonist [†]	<i>E. coli</i> , refolded from inclusion bodies	19
A6/HLA-A2/Tax	1ao7	Strong agonist [†]	<i>E. coli</i> , refolded from inclusion bodies	14
A6/HLA-A2/TaxP6A	1qrn	Weak antagonist	—	21
A6/HLA-A2/TaxV7R	1qse	Weak agonist	—	21
A6/HLA-A2/TaxY8A	1qsf	Weak antagonist	—	21
KB5-C20/H-2K ^b /pKB1	1kj2	Agonist	Myeloma cells for TCR, <i>E. coli</i> for MHC (refolded from inclusion bodies)	12
scD10/I-A ^k /CA	1d9k	Agonist	<i>E. coli</i> for TCR, refolded from inclusion bodies; CHO cells for MHC; peptide covalently connected to the MHC	15
HA1.7/HLA-DR1/HA	1fyt	Agonist	<i>E. coli</i> for TCR, refolded from inclusion bodies; <i>D. melanogaster</i> for MHC; peptide covalently connected to the TCR	51
HA1.7/HLA-DR4/HA	1j8h	Agonist	—	38

^aThe nomenclature *superagonist* or *strong agonist* is equivalent in these instances. Class I and class II complexes are separated by the horizontal line; sc: single-chain Fv fragment of the TCR. (Adapted from Rudolph, M. G. and Wilson, I. A., *Curr. Opin. Immunol.*, 14, 52–65, 2002.)

compared to CDR3 β . In V α , CDR2 α tends to have fewer contacts with the pMHC than CDR3 α , although an exception is found in the allogeneic BM3.3 complex, where CDR3 α has almost no contacts (see above). However, in most cases, peptide contacts are made primarily through the central CDR3 loops, which also exhibit the greatest degree of genetic variability. In contrast, the majority of conserved MHC contacts are mediated by the CDR1 and CDR2 loops [20], particularly in V α .

Discrepancy Between Magnitude of Structural Changes and Biological Outcomes

ALTERED PEPTIDE LIGANDS: ANTAGONISM AND SUPERAGONISM

So far, no dramatic structural changes that could account for the magnitude of the different signaling outcomes of various altered peptide ligands (APLs) have been observed in the TCR/pMHC structures, when strong agonist, weak agonist, and antagonist peptides are presented by the same MHC to the same TCR [18,21]. Only slight readjustments occur in the TCR/pMHC interface to accommodate different up-pointing peptide side chains. In the A6 system, the number of peptide–TCR contacts does not correlate with the degree of agonism and antagonism [14,21]. Similarly, in the 2C system, the buried surface does not change much when weak and strong agonists are compared, but the complementarity [18] and the number of TCR/pMHC contacts increases despite the

relatively minor substitution of an arginine (strong agonist) for a lysine (weak agonist) at P4. Again, no gross conformational changes in the TCR or pMHC are observed, but slight rearrangements in the CDR loops accommodate the different peptides [18].

The correlation of complex half life [22] with the degree of agonism or antagonism is also not clear cut. In both 2C and A6, the strong agonists (SIYR and Tax) have a longer half life (9.2 and 7.5 s) than do weak agonists (3.7 s for H-2K^b-dEV8 and 1.5 s for HLA-A2-V7R). However, by using surface plasmon resonance, agonists have been found in the A6 system that have shorter half lives than do antagonists [23]. An antagonist was converted to an agonist by stepwise filling of a cavity in the TCR/pMHC interface and the biological activity paralleled the TCR/pMHC affinity, not the half life of the complex [23]. Half-lives of TCR/pMHC complexes on the cell surface could be extended by interaction with the coreceptors CD4 and CD8 [24]. Lateral interactions among the TCR/pMHC signaling complexes or interactions with other costimulatory or inhibitory receptors, as in the immunological synapse, may thus form above a certain threshold of TCR/pMHC complex half life [25].

TCR CONFORMATIONAL VARIATION AND CHANGES

Sufficient numbers of TCR structures are now available to assess the extent of conformational variation that arises in their antigen combining sites. As expected, the four TCR outer CDRs 1 and 2 adopt canonical conformations [26],

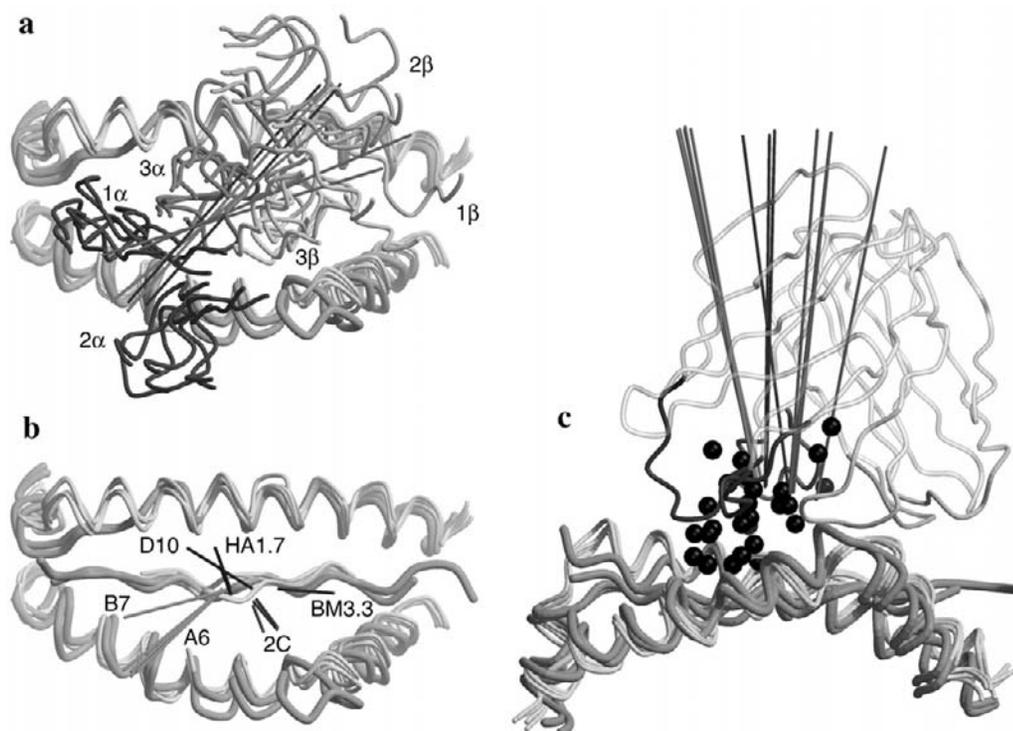

Figure 3 Relative orientation of the TCR on top of the MHC and comparison of peptide conformations in class I and class II TCR/pMHC complexes. The MHC helices are shown as light and dark gray tubes for class I and class II, respectively. The CDR loops are colored as in Fig. 2. Lines and axes are colored blue for class II TCRs and orange and red for human and mouse class I TCRs, respectively. (a) Variation in the diagonal (twist) orientation of the six independent TCR/pMHC complexes. The projection of a linear least-squares fit through the centers of gravity of the CDR loops is shown for the six different TCRs. (b) and (c) Variation in the tilt and roll of TCR/pMHC complexes. The pseudo two-fold axes that relate the V α and V β domains of the TCRs to each other are shown for 12 TCR/pMHC structures. This gives a good estimate of the inclination (roll, tilt) of the TCR on top of the MHC, which is a function of the TCR, not the pMHC ligand. One extreme case is the allogeneic BM3.3 TCR, which is shown as a transparent C α trace. Water molecules filling a large cavity between the TCR and pMHC in this complex are shown as black spheres. (Adapted from Rudolph, M. G. and Wilson, I. A., *Curr. Opin. Immunol.*, 14, 52–65, 2002.)

as first described for antibodies [27,28]. A small number of discrete canonical conformations may be able to describe most of the known sequences of the α 1,2 and β 1,2 loops. At present, three to four canonical structures have been defined for each of these loops [26]. What makes the TCR different from antibodies is the enormous variation seen in both of the central CDR3s (Fig. 3). In antibodies, CDR L3 adopts a well-defined set of canonical structures, but the equivalent CDR3 α loop is highly variable in the current set of TCR structures, as well as the CDR3 β loop [12]. Thus, the prediction [29] that these CDRs would be most variable and adapt to the pMHC primarily (but not exclusively [30]) through contact with the peptide has been borne out.

Two examples are available to assess the extent of conformational variation in the CDR loops in the presence of APL. For TCR 2C, only small variations are seen in CDR3 β but, for TCR A6, these conformational rearrangements are much larger. Evidence for flexibility in the TCR has also been derived from kinetic and thermodynamic studies [31–33]. Whether these data support a model in which flexible CDRs stabilize or rearrange upon pMHC binding remains an unanswered question. What is consistent so far in both

the structural and kinetic/thermodynamic experiments is that conformational rearrangements of the CDRs can provide better complementarity of the TCR to both the MHC [34] and the peptide [18,21].

ALLOREACTIVITY

Alloreactivity is the phenomenon in which a strong immune response can be generated against foreign pMHC molecules to which one's T cells have not been previously exposed [35,36]. Thus, an important practical corollary in defining the structural rules of T cell recognition is to explain alloreactivity [37]. So far, three complexes have addressed this issue [30,38,39]. The complex of the BM3.3 TCR with the allogeneic MHC H-2K^b is perhaps the most structurally distinct so far, but the corresponding syngeneic complex is currently not known. The BM3.3 TCR tilts substantially towards the β -chain side (Fig. 3), with the α -chain making few direct contacts with the MHC. In fact, the long central CDR3 α is flared back such that it makes no contacts with the peptide and only two with the MHC. The majority of the interactions are with the β -chain, consistent with that proposed for the interaction of H-2L^d with TCR 2C, where an extreme bulge in the C-terminal half of the peptide is

likely to increase its interaction with the TCR β -chain [9]. Two recent studies [38,39] suggest that subtle changes in allogeneic MHCs can alter the peptide conformation and location such that the same peptide is presented differently to the TCR. Thus, these structural studies conclude that TCR interaction with the bound peptide strongly affects the alloresponse.

Role of Bound Water in TCR/pMHC Recognition

Several TCR/pMHC complexes contain bound water molecules in their TCR/pMHC interfaces. The ability of water molecules to provide additional complementarity by filling of cavities in the interface is well documented for antibodies [40]. The highest resolution TCR/pMHC complexes (2.4–2.5 Å) contain 17 (2C/H-2K^{bm3}/dEV8 [39]), 39 (BM3.3/H-2K^b/pBM1 [30]), and 15 (HA1.7/HLA-DR4/HA [38]) waters in their interface with 6, 12, and 6, respectively, mediating contact between the TCR and pMHC. Thus, these recent higher resolution TCR/pMHC structures indicate a strong involvement of bound water to provide complementarity and specificity to the recognition process. Yet, no specific waters are conserved among these structures, indicating that their presence is dependent on the individual sequences of both the TCR and pMHC. In the allogeneic BM3.3 complex, about 30 interfacial waters are sequestered in a cavity between the V α and the pMHC, as a result of the TCR V α domain lifting up from the pMHC surface [30].

Water molecules can also improve complementarity to (and, thus, stability of) pMHC interactions. Small sequence and structure changes in either the peptide (APLs) or the MHC (as in alloreactive complexes) can be amplified on the pMHC surface by redistribution or acquisition of bound waters in the TCR/pMHC interface. A good example is the allogeneic H-2K^{bm8} complex, where water can partially substitute for the loss of buried side-chain functional groups [41]. In addition, such buried MHC substitutions, which occur frequently in allogeneic MHC, can transmit their effects by altering the water structure and the electrostatic properties on the surface, even though their mutated residues are not directly “seen” by the TCR [39].

Conclusions and Future Perspectives

The evolution of a common docking mode that enables the $\alpha\beta$ TCR to survey the contents of the MHC binding groove is remarkable. However, the seven independent complex structures determined so far have not yet revealed the basis for this conserved orientation. No absolutely conserved pairs of interactions are apparent in these different TCR/pMHC complex interfaces that would account for their relatively fixed docking orientations. The variability in the tilt, twist, and roll of the TCR indicates that the docking problem is solved in detail differently in each case to provide sufficient complementarity for binding (K_d in the micromolar range). With the exception of the alloreactive

BM3.3 TCR, where most of the interactions with pMHC are due to the β -chain, the TCR V α interactions with the pMHC seem to predominate, providing some basis for a conserved orientation. Additionally, glycosylation may play a role in facilitating docking, as both the TCR and MHC are highly glycosylated and, hence, could sterically restrict the range of possible orientations [42,43].

Another major unresolved issue is how the exceedingly small changes in the TCR/pMHC interface in response to different APLs can lead to such drastically different biological outcomes. Complementarity, buried surface area, or number of contacts in agonist versus antagonist complexes are very similar and are difficult to reconcile with the substantial differences in T-cell responses. Therefore, differentiation of strong from weak agonists, or agonists from antagonists, by visual inspection of the crystal structures seems impossible. Similarly, while the trend of increased half life for agonist versus antagonist TCR/pMHC complexes is so far maintained, exceptions have been found that belie this as a general rule.

In order to extract all of the general principles that govern TCR/pMHC recognition, further TCR/pMHC complex structures are needed. Although models of the TCR/pMHC/coreceptor(CD4/CD8) complex can be assembled from the component pieces [42] that include the distal globular domains of CD8/pMHC class I complexes [44,45], the recent low-resolution CD4/pMHC class I complex [46], and the CD3 $\epsilon\gamma$ NMR structure [47], perhaps the most important breakthrough would be the determination of a complete $\alpha\beta$ TCR signaling complex, that includes the $\alpha\beta$ TCR, CD3 $\gamma\delta\epsilon\zeta$, pMHC, and CD4 or CD8. This more complex assembly would lay open any global changes that may influence TCR signaling events. However, the lack of the membrane-anchoring domains in the constructs used for the current structure determinations will remain a problem until intact membrane proteins can be routinely crystallized. Future studies will also reveal how bulky ligands, such as bulged peptides [6], glycopeptides [48,49], or glycolipids in the case of CD1 [50] can be accommodated in the TCR/pMHC interface.

Living cells constantly interact with their environment. As a consequence, a number of sensory systems have evolved for the collection, processing, and integration of a remarkable range of environmental stimuli arising from cell–cell and cell–substrate interactions. For instance, developmental and morphological processes in higher eukaryotes rely on the orchestrated migration of cells in response to specific physical and chemical cues; T-cell activation relies on the localization and compartmentalization of cell-adhesion and signaling molecules; and adherent cells must respond to a variety of intracellular and extracellular mechanical forces. All of these processes rely on the engagement of specific cell-surface receptors with the appropriate extracellular ligand to report on the immediate physical environment by transducing extracellular signals across the plasma membrane. This review examines the diversity of mechanisms thought to be involved in adhesion and signaling and highlights some of the shared principles that must be considered for all signaling pathways utilizing cell-surface receptors.

Mechanosensory Mechanisms

The ability to detect and respond to alterations in applied mechanical force is required for a number of cellular and developmental functions. This is particularly critical for adherent cells that directly contact the extracellular matrix (ECM) and are subject to considerable physical deformation. For example, sheer forces associated with blood flow are major determinants of arterial tone and vascular reorganization. At the cellular level, morphology and orientation are optimized to minimize mechanical stress and damage associated

with variations in flow-related forces (see, for example, references [1] to [3]). Similarly, fibroblasts must be highly responsive to the mechanical forces associated with alterations in the ECM (reviewed in Schwartz and Ginsberg [4]).

Considerable evidence points to focal adhesions, the sites of cell–substrate contact, as the sensors of mechanical force. Central to focal adhesion assembly and function are the integrins, a family of α – β heterodimeric transmembrane glycoproteins that provide essential adhesive functions for cell migration and the establishment and maintenance of normal tissue architecture. At least 18 α and 8 β chains allow for the formation of multiple integrin heterodimers that are able to display a spectrum of specificities for cell-surface adhesion molecules and for a range of ECM components, including laminin, collagen, and fibronectin. The integrin cytoplasmic domains bind a variety of scaffolding and actin regulatory proteins, which in turn recruit a large number of adaptor and signaling molecules. These physical links couple the integrins to the downstream activation of numerous signaling molecules, including MAP kinase, focal adhesion kinase, Src, and PI3-kinase (see, for example, references [4] and [5]). Furthermore, integrin affinity is modulated by the activation state of the particular cell in question, and this “inside-out” signaling is thought to control the tertiary and quaternary structural rearrangements required for high-affinity ligand binding. The focal adhesion may thus be viewed as a highly dynamic sensory organelle that exploits the direct linkage between the ECM and actin cytoskeleton to respond to mechanical force through a wide range of signaling pathways.

The mechanisms underlying integrin-associated signaling rely on the determinants of mechanical strain, including tension provided by cytoskeletal motor proteins, such as myosin-II,

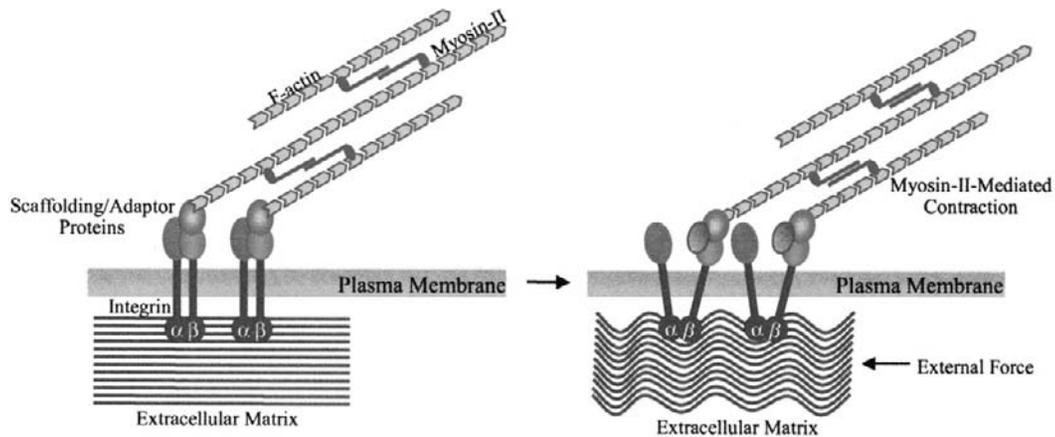

Figure 1 Model for the mechanochemical signaling mechanism of integrins at focal adhesions. The extracellular domain of integrin binds ECM components, such as collagen and fibronectin. The cytoplasmic domain of integrin contacts a series of scaffolding proteins and cytoskeletal regulatory proteins (pink ellipse), including talin and paxillin, which provides a direct physical linkage between the ECM and the actomyosin cytoskeleton. Alterations in the ECM generate tension that may result in tertiary and quaternary structural changes (illustrated here as a scissor-like motion between the α - and β -integrin chains). These structural changes are propagated to the cytoplasm, which may uncover cryptic binding and recruitment sites for additional signaling molecules (blue ellipse). The ability to couple force generation to alterations in the composition of integrin-associated focal adhesion molecules provides a direct mechanism for mechanochemical signaling.

and the intrinsic mechanical properties of the underlying ECM (Fig. 1). For example, the growth of cells on soft, or pliable, surfaces does not support integrin signaling nor the formation of focal adhesions [6], while “stretching” of these substrates supports both focal adhesion formation and integrin signaling [7,8], presumably by allowing for a sufficient level of tension to be achieved. At the molecular level, mechanical force may be transduced into a cytoplasmic signal through a number of possible mechanisms. The application of force may disrupt or distort various intermolecular binding interfaces, resulting in the reorganization of focal adhesions by enhancing the entry or exit of specific signaling molecules through either free or facilitated diffusion. A related potential mechanism is the force-induced conformational reorganization of integrin-associated focal adhesion molecules, which may uncover cryptic binding and recruitment sites for additional signaling molecules. This notion is consistent with the fact that a number of focal adhesion components, including vinculin and ERM proteins, exist in multiple conformations (see references [9] and [10] and references therein). Of special note are a series of structural [11–15] and biochemical studies (reviewed in references [12,13,16]) describing the localized ligand-induced conformational rearrangements and a model for integrin activation [12,13]. This model suggests that a large-scale conformational reorganization, including a scissor-like motion, may be required for high-affinity ligand binding. Some aspects of this conformational plasticity may also play a role in transducing mechanical force into cytoplasmic signals. These mechanisms, whether affecting the dynamic assembly/disassembly properties of the focal adhesion as a whole or directing conformational reorganization of a specific focal adhesion protein, can provide a direct linkage between cell surface–ECM adhesive interactions,

focal adhesion composition, and cytoplasmic signaling. Furthermore, recent studies demonstrate a complex relationship between valency and geometric organization of the ligand and the strength of integrin-associated signaling [17], suggesting some mechanistic similarities with the c described below. Thus, integrin-associated signaling provides one of the clearest couplings of signaling and the adhesive properties of a receptor–ligand pair.

Cell–Cell Adhesions/Adherens Junctions

The cadherins are a family of cell-surface receptors that form calcium-dependent homophilic interactions between the surfaces of adjacent cells. These interactions result in the formation of intercellular adhesions, adherens junctions, which play essential roles in the establishment and maintenance of cell polarity and tissue architecture and in the recognition and migratory events associated with developmental and morphological processes. These adhesive interactions are supported by a catenin-mediated linkage to the underlying actin cytoskeleton, as the carboxy-terminal cytoplasmic tail of cadherin binds β -catenin, and via an interaction with α -catenin is linked to the cortical actin network (Fig. 2) (see Conacci-Sorrell *et al.* [18] and references therein). The importance of this cytoskeletal connection is highlighted by the observation that disruption of normal catenin function prevents the formation of mature adherens junctions and is associated with increased motility and invasiveness of tumor cells (reviewed in Okegawa *et al.* [19]).

β -Catenin plays a dual role in cell physiology, as in addition to being an essential structural component of the adherens junction it serves as a transcriptional activator of several genes involved in cellular proliferation and

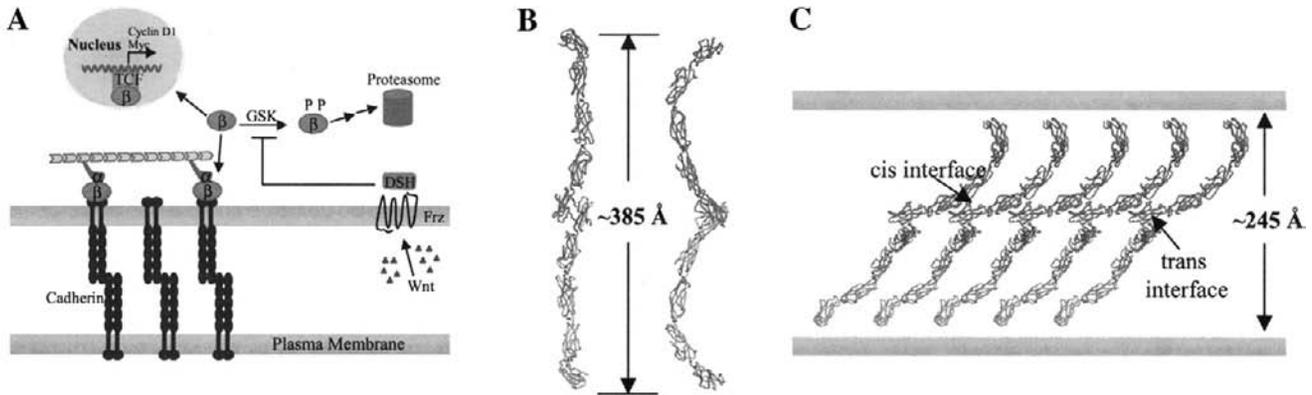

Figure 2 Adherens junctions and cadherin function. (A) Schematic of adherens junction organization and associated signaling pathways. The catenins provide a direct physical linkage between the homophilic cadherin-mediated cell–cell contacts and the underlying actin cytoskeleton and support the integrity of the adherens junctions. In turn, the actin cytoskeleton provides β -catenin docking sites that serve to modulate β -catenin signaling by buffering the soluble concentration of β -catenin. (Adapted from Conacci-Sorrell, M. *et al.*, *J. Clin. Invest.* **109**, 987–991, 2002.) (B) Structure of C-cadherin showing the arched arrangement formed by the five individual cadherin domains (EC1–EC5) and a model for the *trans* (cell–cell) interaction from abutting EC1 domains. Two orthogonal views are shown, with the arched nature of the structure evident in the right figure. (C) A model of the *trans* and *cis* interactions at the adherens junction based on contacts present in the C-cadherin crystal structure. In this model, the individual cadherin molecules in the adherens junction are tilted by $\sim 45^\circ$ with respect to the plasma membrane, implying an intermembrane separation of ~ 245 Å.

invasion, including Myc, cyclin D1, metalloproteinases, and fibronectin [18]. A number of regulatory mechanisms modulate β -catenin signaling. In the absence of Wnt signaling, cytoplasmically disposed soluble β -catenin is a substrate for phosphorylation by glycogen synthase phosphorylase, which serves to mark it for degradation by the 26S proteasome; however, activation of the Wnt pathway inhibits this phosphorylation and β -catenin is shunted to the nucleus, where it forms a complex with the T-cell factor (TCF) to activate selected genes. The formation of normal adherens junctions appears critical for control of β -catenin signaling, as a loss of cadherin expression correlates with increased nuclear β -catenin. Thus, there appears to be a close linkage between cadherin-mediated adhesion and β -catenin-mediated signaling pathways, with the adherens junction acting as a buffer of soluble β -catenin (Fig. 2) [20].

Structural studies have suggested several models for the homophilic adhesive interactions formed by the cadherins at adherens junctions. The recent report of the structure of the entire extracellular domain of C-cadherin by Boggon, *et al.*²¹ provides new insights into both the *cis* (intracellular) and *trans* (intercellular) interactions that are essential for the formation and maintenance of adherens junctions (Fig. 2). The structure shows that the five extracellular cadherin domains (EC1–EC5) form an arched structure, and the abutment of two N-terminal EC1 domains in the crystal provides a model for the *trans* adhesive interaction. Additional crystal contacts suggest a model of the *cis* contact, and together the interactions observed in the crystalline state provide a detailed model for the periodic organization of cadherin molecules within the adherens junction. Of particular note is the suggestion that the cadherin molecules in the adherens junction are tilted by $\sim 45^\circ$ with respect to the plasma membrane, implying an intermembrane separation of ~ 245 Å. This feature of the model is particularly noteworthy, as there is a strong bias to view intrinsic membrane proteins as

projecting perpendicular to the plane of the plasma membrane; *a priori* there is no fundamental reason for this assumption.

T-Cell Costimulation

An optimal T-cell response requires the integration of a number of distinct extracellular signaling and adhesive events at the T-cell–antigen-presenting cell (APC) interface, which has been termed the *immunological synapse*. Engagement of T-cell receptors (TCRs) on the surfaces of T cells with major histocompatibility complex (MHC)/peptide complexes displayed on the surfaces of APCs is essential, but not sufficient, for complete T-cell activation [22]. The subsequent engagement of a series of costimulatory receptor–ligand pairs provides the additional signals needed for efficient T-cell activation, as well as the negative signals required to attenuate the immune response (Fig. 3) [23–25]. The most extensively characterized T-cell costimulatory receptors are CD28 and CTLA-4, which share $\sim 30\%$ identity and bind the B7-1 and B7-2 ligands presented on APCs. Together with signaling through the TCR, the engagement of CD28 by the B7 ligands leads to optimal T-cell activation [22], while the interaction of B7 with CTLA-4 provides inhibitory signals required for downregulation of the response.

Initial TCR engagement is followed by a remarkable reorganization and compartmentalization of signaling and adhesive molecules at the immunological synapse. The central zone of the synapse contains the receptor–ligand pairs, including the TCR–CD3/MHC–peptide complex, CD28/B7 costimulatory complex, and CD2/CD58 complexes, as well as noncovalently associated intracellular signaling molecules, such as fyn, lck, and PKC-theta [26]. The central zone is bordered by the peripheral zone, which is composed of large adhesion molecules, including LFA-1 and ICAM-1,

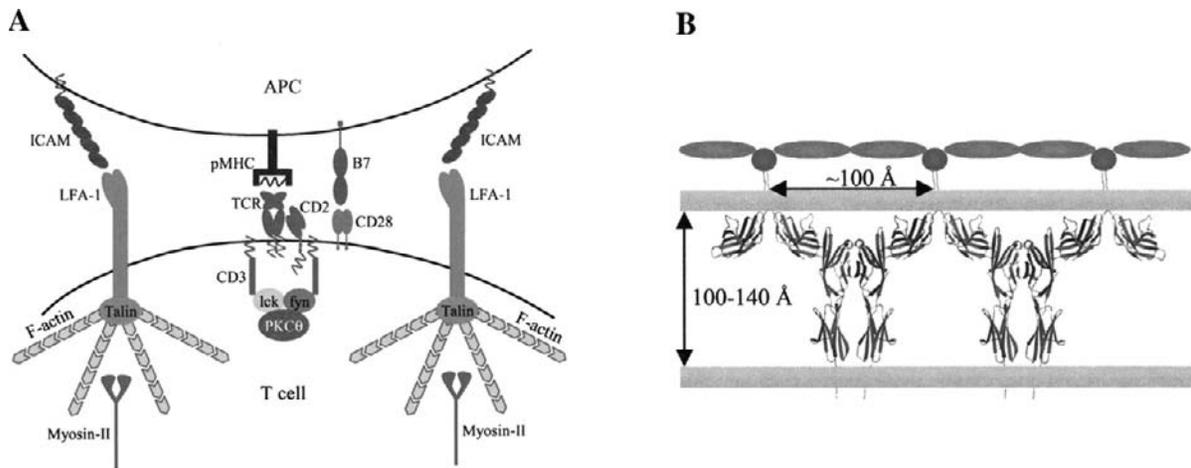

Figure 3 T-cell activation and the immunological synapse. (A) Schematic of the immunological synapse highlighting the compartmentalization of specific signaling components into discrete zones. The central zone is enriched in cell-surface signaling molecules (i.e., TCR, MHC/peptide complex, and costimulatory receptors and ligands) and cytoplasmically associated scaffolding and signaling proteins (i.e., Src family kinases, etc.). Surrounding this signaling complex is the peripheral zone, which is composed of large adhesion molecules and cytoplasmically associated cytoskeletal components required for the observed pattern of localization. (B) Model for the costimulatory signaling network at the T-cell–APC interface. The disulfide-linked CTLA-4 dimers are shown in red, while the noncovalent B7-1 dimers are blue. The interactions between these two dimeric bivalent molecules in the crystal result in a periodic array of CTLA-4 and B7 homodimers with a characteristic spacing of ~ 100 Å. This periodicity may result in the organized recruitment of signaling molecules (pink and red) and may in some circumstances provide further adhesive interactions required for productive signaling.

and components of the actin cytoskeleton (Fig. 3) [26]. This organization appears to be dependent on an uncompromised actomyosin cytoskeleton, thus providing another example of the intimate involvement of the actin-based cytoskeleton in a fundamental signaling pathway. A number of potential functions have been proposed for the molecular organization in the synapse, including the polarized secretion of cytokines, TCR recycling, and the promotion of costimulatory receptor–ligand engagement [27,28]. In addition, the B7 ligands appear to control APC function, as crosslinking the B7 isoforms modulates both B-cell proliferation and antibody production [22,29–31]. Thus, engagement of the costimulatory receptor–ligand pairs represents an outstanding example of bidirectional signaling.

Of particular note are the recent structural descriptions of the CTLA-4/B7 receptor–ligand complexes, which exhibit an alternating arrangement of bivalent CTLA-4 and B7 dimers (Fig. 3) [32,33]. The observation of this linear periodic array suggests a model for the organization of these cell-surface molecules at the immunological synapse. Importantly, the observed spacing between the extracellular receptor domains is also imposed on any cytoplasmically associated signaling molecules, and suggests that the oligomerization of multiple (i.e., at least two) CTLA-4 dimers may be required to afford a biologically optimal organization and local concentration of intracellular signaling molecules.

In considering the types of assemblies that are formed *in vivo* by multivalent receptor–ligand pairs, it is essential to bear in mind the relative concentrations of the binding partners (Fig. 4). For example, a large excess of either receptor or ligand will favor the formation of “isolated” signaling complexes. In the case of limiting ligand, a cell-surface complex composed of two receptor dimers (e.g., CTLA-4)

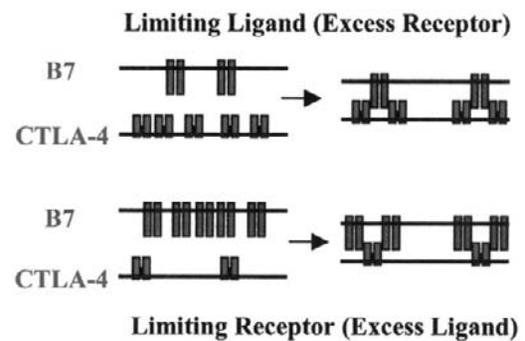

Figure 4 Effect of stoichiometry on the signaling complexes formed by multivalent receptor–ligand pairs. (Top) Limiting ligand will favor the formation of cell-surface complexes composed of two receptor dimers (e.g., CTLA-4) linked by a single ligand dimer (e.g., B7-1). This assembly would impose a constraint between the two adjacent receptors and any associated cytoplasmic signaling molecules (i.e., ~ 100 Å in the case of the CTLA-4/B7 complex). (Bottom) Excess ligand would favor complexes composed of a single receptor linking two independent ligand dimers. This association would not enforce any specific spatial relationship between individual receptor molecules but would still direct the localization of the receptor and ligand to the immunological synapse and could result in a sufficiently high local concentration of individual receptor dimers to support signaling.

linked by a single ligand dimer (e.g., B7-1) would be favored, and such an assembly would impose an ~ 100 -Å constraint between the two adjacent receptors and any associated cytoplasmic signaling molecules. In contrast, the presence of excess ligand would favor complexes composed of a single receptor linking two independent ligand dimers. This association would not enforce any specific spatial relationship between individual receptor molecules but would still direct the localization of the receptor and ligand to the

immunological synapse and could result in a sufficiently high local concentration of individual CTLA-4 dimers to support signaling. Finally, equivalent amounts of receptor and ligand at a cell–cell interface would favor the formation of more extensive periodic networks. Importantly, this is a general consideration relevant to all multivalent receptor–ligand pairs.

In addition to playing a direct role in signaling, cell-surface receptor–ligand engagement constrains the approach of the adjacent plasma membranes (as in the case of the adherens junction discussed above) and may play a role in directing the organization of molecules at the cell–cell or cell–ECM interface. The maximal dimension of the CTLA-4/B7 complexes (~100–140 Å) is compatible with those of other receptor–ligand pairs present in the central zone of the synapse (i.e., MHC/TCR [34,35] and CD2/CD58 [36]). In contrast, the adhesive complexes present in the peripheral zone (e.g., the LFA-1/ICAM-1 complex) are significantly larger in maximal extent, and this difference has led to the suggestion that the compartmentalization observed in the immunological synapse is the consequence of a mechanical sorting mechanism based on relative molecular dimension [37,38]. While this is an appealing hypothesis, it is based on the assumption that intrinsic membrane proteins extend perpendicular to the plasma membrane and ignores the possibility that a molecule of large extent can be accommodated within the central zone by tilting with respect to the plasma membrane, as was suggested in the model of C-cadherin in the adherens junction (Fig. 2).

While the adhesive functions of ICAM and LFA-1 are essential to synapse formation and T-cell function, engagement of these molecules is also likely to play a direct signaling role in T-cell activation and function. Recent studies have shown that ICAM-1 binding is associated with LFA-1 clustering, enhanced actin polymerization, and F-actin bundling within T cells [39]. Conversely, crosslinking of ICAM-1 in lymphocytes stimulates calcium signaling and PKC activity, which results in cytoskeletal rearrangements associated with migration [40]. These observations indicate a strong coupling between adhesive and signaling functions and suggest that reciprocal bidirectional signaling may be associated with ICAM/LFA-1 adhesive interactions (see, for example, Lupher *et al.* [41]).

As the localization of adhesive partners at cell–cell and cell–ECM interfaces necessarily results in the localization of cytoplasmically associated species, it is relevant to ask whether situations exist in which adhesive functions are fully uncoupled from signaling events. For instance, the one-dimensional lattice observed in the CTLA-4/B7 crystal structures exhibits considerable similarities to the adhesive assembly formed by the cadherins (Fig. 2), and on this basis it is tempting to suggest that costimulatory receptor–ligand engagement might also provide adhesive interactions required for efficient T-cell function. Although no data bear directly on the adhesive properties of CTLA-4, recent studies indicate that CD28 does not make any significant contributions to the adhesive properties of naïve T cells [37].

These results differ from earlier studies indicating that the CD28/B7 interaction significantly enhanced adhesion. However, these earlier studies utilized systems in which either receptor or ligand was overexpressed [42,43], again stressing the importance of accurately knowing the cell surface densities of the binding partners in order to correctly predict mechanism. These recent studies also indicated that only ~30% of the CD28 molecules exhibited free lateral diffusion in the plasma membrane [37], implying that only a fraction of the total population may be available to bind B7 at the immunological synapse. While no evidence supports limited diffusional freedom as a general feature of cell-surface proteins, these studies nonetheless stress the potential importance of considering the “available” receptor and ligand concentrations, as opposed to total cellular concentrations.

Axon Guidance and Neural Development

The Eph family of receptor tyrosine kinases and their associated ephrin ligands play a central role in neural development by providing repulsive guidance cues that direct axonal targeting. Specifically, a migrating growth cone expressing a given Eph receptor will turn away from cells expressing cognate ephrin ligands, as a result of the disassembly or redistribution of filamentous actin networks at the leading edge [44]. Two classes of ephrins are defined on the basis of their mode of cell surface attachment. The ephrin A ligands utilize a glycosylphosphatidylinositol (GPI) linkage for cell-surface attachment and bind the EphA receptors, while ephrinB ligands are transmembrane proteins that bind EphB receptors.

Recent structural characterization of the ephrin-B2/EphB2 receptor complex provides new insights into the potential signaling mechanisms utilized (Fig. 5) [45]. This structure provides details of the receptor–ligand binding site and of a “circular” 2:2 receptor–ligand complex that is thought to be relevant to signaling. The organization observed in the crystal structure is consistent with ligand-induced clustering of the EphB2 receptor, resulting in the *trans*-autophosphorylation required for activation and subsequent recruitment of signaling molecules, including src family kinases and GTP-activating proteins (GAPS) [46]. Engagement also results in clustering of the ephrin ligand, providing another example of bidirectional signaling, as the cytoplasmic domain of ephrin-B2 is required for normal angiogenesis and vascular morphogenesis [46]. Furthermore, consistent with the propensity to form higher order oligomers, the crystal structure suggests the formation of an extended two-dimensional signaling complex (super-cluster) of receptors and ligands at the cell–cell interface (in contrast to the one-dimensional array proposed for the CTLA-4/B7 complexes), which might afford enhanced signaling.

The proposed long-range organization suggests that, in addition to a direct role in signaling, engagement of the Eph

Figure 5 Structure of the ephrin-B2/EphB2 receptor complex. (A) Circular tetramer formed by the interaction of two EphB2 receptors (green) with two ephrinB2 ligands (yellow) thought to represent the favored receptor–ligand organization *in vivo*. Note that each ligand contacts two receptor molecules, but there are no ligand–ligand or receptor–receptor contacts. (B) Crystal packing results in another tetramer (elliptical), in which an extensive interface is formed between two receptor molecules. The physiological relevance of this binding interaction remains to be proven but may be consistent with the propensity of Eph/ephrin molecules to form higher order oligomers. (C) A “layer” from the ephrin-B2/EphB2 receptor complex crystal structure showing the long-range, two-dimensional ordered array formed by the combination of both the circular (highlighted in red) and elliptical (highlighted in blue) tetramers. Such an organized network could potentially play roles in signaling and/or adhesion.

receptor–ligand pairs may also provide essential adhesive functions. The first evidence supporting this notion came from the observation that ~17% of mice defective in ephrinA5 exhibit neural tube defects, which is not consistent with the classical repulsive effects attributed to ephrin/Eph receptor function [48]. These studies also revealed that the expression of splice variants of an ephrinA5 receptor (i.e., EphA7) which lack the intracellular kinase domain support direct adhesive interactions with ephrinA5-expressing cells⁴⁸. This provides yet another example of the close linkage between signaling and adhesive interactions.

Conclusions

As illustrated, biology depends on a vast array of information processing activities that are coordinated by diverse cell-surface adhesion receptors and their cognate ligands. Though these receptor–ligand pairs differ in chemical and structural terms, there are common principles that must be carefully considered in order to construct viable molecular and atomic mechanisms for signaling. The engagement of receptor–ligand pairs leads to an increase in their local density/concentration at cell–cell and cell–ECM interfaces, and in many cases may support a natural coupling between signaling and adhesive function. Of particular importance is the quantitative understanding of both cell-surface oligomeric state and the available concentration of receptor and ligand on their cell surfaces, as they dictate the relative stoichiometries and the type of signaling complexes that can be formed at cell–cell and cell–ECM interfaces. Finally, as a general cautionary note, while direct structural information, in the form of X-ray and nuclear magnetic resonance (NMR) structures, may provide enormous insights into function and mechanism, in the absence of confirmatory biochemical data great care should be exercised in extrapolating intermolecular contacts observed in crystal structures to physiologically relevant protein–protein interfaces.

Introduction

The immunological synapse (IS) is a specialized cell–cell junction between a thymus-derived lymphocyte (T cell) and an antigen presenting cell (APC) [1,2]. Activation of T cells is based on the interaction between T cell receptors (TCRs) and major histocompatibility complex proteins that have bound antigenic peptides (MHCp) [3,4]. Because the TCR and MHCp are attached to the surface of the T cell and antigen-presenting cell (APC), respectively, the initiation of an immune response requires a molecular grasp between the T cell and APC—a synapse. A current focus of research on the IS is to determine how this supramolecular structure contributes to T-cell sensitivity and the fidelity of the T-cell response. Four areas in which the IS concept is contributing to our understanding of T-cell activation are (1) coordination of antigen recognition and T-cell migration, (2) role of the cytoskeleton in T-cell activation, (3) mechanism of sensitive antigen recognition by T cells, and (4) integration of the adaptive and innate immune responses.

Migration and the Immunological Synapse

T-cell activation requires a sustained signal. The duration of signaling required to initiate proliferation of T cells is a minimum of 2 hr [5–7], but it may be much longer to achieve appropriate helper T-cell differentiation [8]. T cells migrate continually between the blood and the secondary lymphoid tissues where they encounter APCs. In the absence of an immune response, the T cell completes this cycle about once a day. During the initiation of an immune response, the T cells are held in the antigen-exposed lymph nodes or the spleen for 2 to 3 days, and then effector cells are released

after the third day. *In vitro* T-cell recognition of agonist MHCp in the context of the adhesion molecule ICAM-1 delivers a stop signal to migrating T cells [9]. This stop signal is the first stage in forming an IS [2]. The signaling pathways required for the stop signal may include the adapter protein ADAP [10,11]. The environment of the T-cell/APC interaction regulates the stop signal. One example of this is that APCs with agonist MHCp do not stop T cells in three-dimensional collagen gels *in vitro* [12]. The mechanism of this effect is not known but may involve chemokine gradients [13] or interactions with extracellular matrix that prevent T-cell polarization toward the APCs. In lymph nodes, however, T cells are not exposed to extracellular matrix, which is sequestered in reticular fibers [14]. This non-adhesive reticular scaffold is decorated with APCs and defines corridors through which the T cells migrate. Based on the lymph node environment and *in vitro* data, it is most likely that the IS coordinates T-cell migration and the antigen-recognition process to allow full activation of T cells by small numbers of APCs that express the appropriate MHCp. Having the APCs with agonist MHCp stop the T cell is more efficient than the movement of the T cell from APC to APC when the number of APCs with agonist MHCp is small because the interactions with irrelevant APCs are minimized in the former. This view is supported by *in vivo* data demonstrating clustering of polarized T cells around dendritic cells [15,16].

The Cytoskeleton and the Immunological Synapse

Our expectations about molecular interaction in the IS have been shaped by early molecular definition of the molecules involved in this process [17]. The complex of the LFA-1

with ICAM-1 (~48 nm) is larger than the complex of the TCR with MHCp (~15 nm) by over threefold [18–20]. Therefore, the LFA-1/ICAM-1 and TCR/MHC interactions segregate into different compartments within the contact area [21]. This receptor segregation forms receptor aggregates with the size and organization determined by the rigidity of the membrane, the kinetics of the interactions, and the degree of differences in molecular size of the participating receptor–ligand pairs [22]. This immediate segregation may be the initial trigger of receptor clustering and signaling in the nascent IS [23]. These events happen in seconds and set the stage for mature synapse formation.

The formation of the IS has been followed over time in live T cells [2] and studied at specific time points in fixed cell–cell conjugates [24]. The T cell forms an adhesion zone with the antigen-presenting bilayer, which is then surrounded by areas of close contact where TCR can reach the MHCp. If the TCR engagement exceeds a threshold rate and level, the T cell stops migrating and forms a ring of engaged TCR at the periphery of the nascent IS (Fig. 1A). This pattern takes about 30 sec to form and corresponds to the peak of TCR-associated tyrosine phosphorylation and Ca^{2+} mobilization. Within a few minutes, the sites of TCR engagement move from the periphery of the contact area to the center of the contact area to form the mature IS (Fig. 1B). During this time, the disk-like region of LFA-1/ICAM-1 interaction appears to give way to the centrally moving TCR, but the LFA-1/ICAM-1 interactions maintain the contact area and evolve into a ring of ~5- μ m outer diameter (Fig. 1C). This last pattern can be stable for hours. The central region of TCR engagement is defined by Kupfer *et al.* [24] as a central supramolecular activation cluster (cSMAC) and the ring of LFA-1 engagement

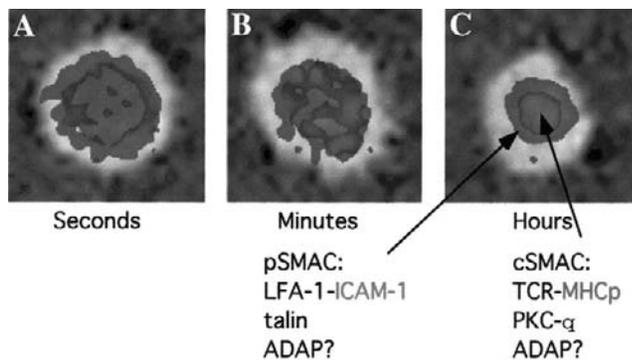

Figure 1 Development of the immunological synapse. Images are based on fluorescence microscope images of T-cell interaction with agonist MHC–peptide complexes (green) and ICAM-1 (red) in a supported planar bilayer with a T cell. The accumulation of fluorescence represents interactions in different time frames. Within seconds the T cell attaches to the substrate using LFA-1/ICAM-1 interactions in the center based on TCR signaling triggered at the periphery of the contact area (A). Over a period of minutes, the engaged TCRs are translocated to the center of the contact area (B). The final pattern with a central cluster of engaged TCR surrounded by a ring of engaged LFA-1 is stable for hours (C). Molecular markers for the cSMAC and pSMAC are indicated. For scale, the pSMAC is ~5 μ m across. (Adapted from Grakoui, A. *et al.*, *Science*, **285**, 221–227, 1999.)

is defined as a peripheral supramolecular activation cluster (pSMAC). The other defining marker for the cSMAC is protein kinase C- θ , and an additional defining marker for the pSMAC is the cytoskeletal protein talin. The adapter protein ADAP links TCR signaling to LFA-1 activation so it may be expected to span these structures, but its physical location in the IS is not currently known. It is not clear if the same TCRs move from the outside to the center or if new TCRs are continually recruited. The interaction of the TCRs with agonist MHC–peptide complexes has a short half life (~5 sec) [25], and it is known that TCRs are degraded following effective engagement [26]. However, at some point in IS formation the interaction of the TCRs and the MHC–peptide complexes changes so they no longer dissociate. Thus, while serial engagement might dominate in the nascent IS, parallel engagement of at least 50 TCRs is a characteristic of the center of the mature IS. These observations have emphasized the concept that biochemical reactions are highly compartmentalized in the IS such that the location of receptor and signaling molecules must be considered to understand the biochemical basis of T-cell activation [27].

The formation of the synapse is highly active and depends on an intact actin cytoskeleton. The formation of the central cluster of TCR has a superficial similarity to antibody-mediated capping in that it requires an intact actin–myosin cytoskeleton. A plausible model based on this similarity has been proposed and initial results support some aspects of the model [28]. However, the IS has many elements that are completely absent in capping of cross-linked antigen receptors. For example, capping is based on a network of bivalent interactions on a cell surface that leads to extensive crosslinking, whereas receptor aggregation in a cell–cell contact is more likely to result from membrane fluctuations, receptor–ligand size differences, and interaction kinetics. These components have been incorporated in a physical model by Chakraborty and colleagues [22]. The predictions of this model are remarkably similar to the observations on the formation of the IS. This more physical view is compatible with an active role for the cortical cytoskeleton, because signaling-induced changes in cytoskeletal dynamics in activated T cells will profoundly regulate the Brownian bending movements of the membrane that are required for movement of the receptor interactions. This model could be described as a physical and mathematical elaboration on the kinetic-segregation model [23]. Thus, the early signals from the TCR that trigger increased actin polymerization may induce the membrane fluctuations that drive the maturation of the IS. Both the capping and the kinetic-segregation models predict that cytoskeletal dynamics are critical for IS formation.

The Role of Self MHCp in T-Cell Sensitivity to Foreign MHCp

Any single TCR interacts with a degenerate spectrum of MHCp. One way to study this spectrum is through altered peptide ligands in which an agonist peptide is mutated and

tested for biological activity: Null MHCp alone do not activate T cells, and agonist MHCp, the model foreign MHCp, induce full T-cell activation. Weak agonists induce a subset of T-cell responses, and antagonists interfere with T-cell responses to agonists. Approximately half of the TCR/MHCp binding energy comes from the TCR contacts with the MHC molecule [29]. Thus, the remaining peptides can be further divided. Naught peptides actively interfere with the TCR interactions and thus allow no interaction of the TCRs with MHC, while null peptides are neutral and allow the TCRs to interact with MHC. The interaction of null MHCp is too fast to induce a response in mature T cells [30]. Self MHCp that are agonists, weak agonists, or antagonists all induce apoptosis of immature T cells *in vivo* [30]. In contrast, null MHCp enhance positive selection. Thus, most mature T cells face APCs that are loaded with a mixture of null peptides (self). These mature T cells are triggered by APCs bearing a few agonist/weak agonist MHCp mixed with diverse null MHCp. Naïve T cells respond to approximately 300 agonist MHCp on APCs, while memory T cells require only 50 agonist MHCp [31]. A single agonist MHCp is sufficient to trigger cytotoxic T-cell killing [32].

How is the high sensitivity of immune recognition achieved? Can a single agonist MHCp achieve T-cell activation, or do other MHCp promote this process? Wülfing *et al.* tested the hypothesis that null (self) MHCp contribute to T-cell activation through analysis of proliferation and formation of the IS [33]. They demonstrated that null MHCp with a lysine-to-alanine mutation at a key TCR contact contributes to IS formation and T-cell activation triggered by subthreshold amounts of agonist MHCp. It was demonstrated that fluorescently labeled null MHCp were accumulated in the center of the IS and synergized with trace levels of agonist MHCp for T-cell activation. This was not true of all null MHCp, as a similar peptide with a lysine-to-glutamate mutation at the same TCR contact, most likely precluding TCR approach to the MHCp, did not have this coagonist activity. Therefore, the “null” classification of altered peptide ligands can be divided into coagonists, which synergize with agonist MHCp, and null peptides, which have no activity. Based on this result it can be proposed that agonist MHCp do not have to go it alone; they may be substantially helped by coagonist MHCp in the self peptide repertoire. The degree of help may vary with the specific TCR and MHC molecules and may have a role in autoimmune diseases. Help from coagonist MHCp may account for the remarkable sensitivity of T cells to agonist MHCp.

Integration of Adaptive and Innate Responses

The IS is not limited to adhesion molecules and MHC–peptide complexes. The process of naïve T-cell activation involves a system of checks and balances that are integrated to make activation decisions. An important aspect of this integration is that T cells test both the MHC–peptide complex and the status of the innate immune response in the APC.

In response to evolutionarily conserved microbial products such as lipopolysaccharide, the APC is activated. This increases expression of a number of molecules including the MHCp, adhesion molecules, and ligands for costimulatory receptors. Ligands for costimulatory receptors include CD80 and B7-DC (also known as PDL2) [34]. CD28 is the receptor for CD80 and by binding CD80 it indirectly transduces an innate immune system signal that can be integrated with the TCR signal. CD28/CD80 interactions are very inefficient due to the low density of CD28 and its low lateral mobility on naïve T cells [35]. Upon immunological synapse formation CD28/CD80 interactions are facilitated and focused in the central region of the immunological synapse, very close to the site of TCR engagement. However, CD28/CD80 interaction does not help the TCR/MHCp interaction, which sets it apart from adhesion molecules such as LFA-1 and CD2 [35]. This suggests a sequential model for T-cell response to TCR and innate signals. The formation of the IS corresponds to the antigen signal. It is only when this signal is received that the T cell becomes competent to receive the signal through CD28. This is the first analysis of receptor interactions in adaptive–innate signal integration in the IS. It will be important to determine if other secondary signals are dependent on IS formation.

Summary

In summary, the IS concept provides a number of insights into the T-cell activation process. First, it provides a stop signal that coordinates antigen recognition and T-cell migration. Second, the essential role of the actin cytoskeleton in T-cell activation is related to the role of actin in IS formation. Third, the sensitivity of T cells to agonist MHCp is related to the role of weakly interacting, but probably more abundant, self MHCp in promoting IS formation. Finally, the IS provides a framework for orderly integration of the TCR and innate immune signals, such as in the case of CD28/CD80 interaction.

Acknowledgments

I thank my colleagues at Washington University and Stanford University for contributions to prepublication work described in this chapter. I also thank S. Alzabin and E. Block for critical reading of this chapter and R. Barrett for preparation of the manuscript.

NK Receptors

Roland K. Strong

*Division of Basic Sciences,
Fred Hutchinson Cancer Research Center,
Seattle, Washington*

Introduction

Analogous to T cell receptors (TCRs) on the surface of T lymphocytes, natural killer (NK) cells function through cell-surface receptors (NCRs) that, unlike TCRs, can be any of a diverse array of molecules, either immunoglobulin-like or C-type lectin-like in structure. NCRs specific for classical and nonclassical major histocompatibility complex (MHC) class I proteins, expressed in complex patterns of inhibitory and activating isoforms on overlapping but distinct subsets of NK cells, play an important role in immunosurveillance against cells that have reduced MHC class I expression as a result of infection or transformation. Another NCR, NKG2D, an activating NCR first identified on NK cells but subsequently found on macrophages and a variety of T-cell types, is implicated in direct, antiviral, and antitumor immune responses. Recent crystallographic analyses of NCRs and NCR/ligand complexes reveal a range of recognition mechanisms that can be either similar to or quite distinct from TCR-mediated events.

Immunoreceptors

Recognition events between $\alpha\beta$ T cell receptors (TCRs), expressed on the surface of T cells, and processed peptide fragments of endogenous proteins, presented on target cell surfaces as complexes with major histocompatibility complex (MHC) class I proteins, ultimately mediate activation of T-cell cytotoxic responses by the cellular arm of the adaptive immune system [1]. MHC class I proteins are integral-membrane, heterodimeric proteins with ectodomains consisting of a polymorphic heavy chain, comprising three extracellular domains ($\alpha 1$, $\alpha 2$, and $\alpha 3$), associated with a non-polymorphic light chain, β_2 -microglobulin (β_2 -m) [2].

The $\alpha 1$ and $\alpha 2$ domains together comprise the peptide- and TCR-binding “platform” domain; the $\alpha 3$ and β_2 -m domains have C-type immunoglobulin (Ig) folds. Crystal structures of TCR/MHC complexes show that the TCR variable domains sit diagonally on the MHC platform domain, making contact with the peptide and the MHC $\alpha 1$ and $\alpha 2$ domains [3] (see Fig. 1). Binding studies show that the dissociation constants for these interactions range from one to tens of micromolar (see Table 1). Analysis of the kinetics of binding suggest that TCR/MHC binding is accompanied by a reduction in flexibility at the receptor/ligand interface [4].

Natural Killer Cells

Surveillance against cells undergoing tumorigenesis [5–9] or infection by viruses [10,11] or internal pathogens [12,13] is provided by natural killer (NK) cells, components of the innate immune system, thus helping to provide “covering fire” during the period that responses by the adaptive immune system are gearing up [14]. NK cells also act to regulate innate and acquired immune responses through the release of various immune modulators, chemokines, and cytokines, such as tumor necrosis factor α , interferon γ , MIP-1, and RANTES. Unlike T cells, NK cells function through a diverse array of cell-surface inhibitory and activating receptors.

Many NK cell surface receptors (NCRs) are specific for classical (such as HLA-A, -B, and -C in humans) and nonclassical (such as HLA-E in humans) MHC class I proteins and occur in paired activating and inhibitory isoforms [15–17]. Different NCRs, with different MHC class I specificities, are expressed on overlapping, but distinct, subsets of NK cells in variegated patterns—where the strength of the inhibitory signals may be stronger than stimulatory signals.

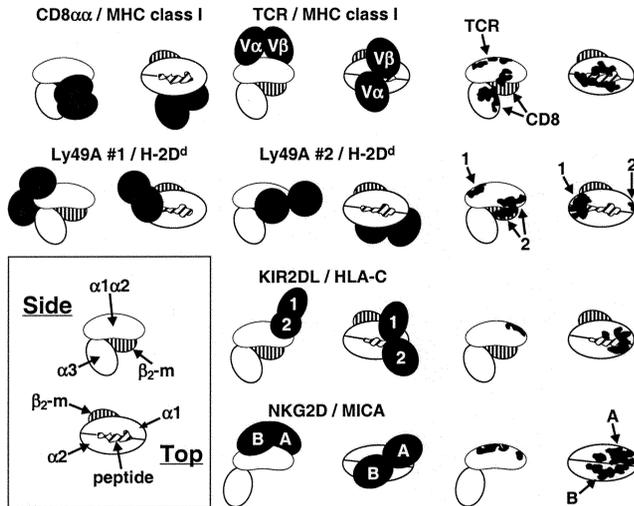

Figure 1 Schematic representations of structurally characterized NK receptor–ligand complexes. Each row shows two views of a receptor–ligand complex, first showing the organization of domains in the complex (receptor domains in black, labeled where a distinction between domains is significant; MHC class I ligand heavy chains in white and β_2 -m in vertical stripes). The arrangement of domains in the ligands is detailed in the inset; the approximate solvent-accessible surface area of the bound peptide, if present, is shown as a cross-hatched area. The right-most columns show approximate footprints of receptors and coreceptors on the ligands as black patches, labeled by receptor component, subsite, or domain, as appropriate.

Thus, NK cell effector functions are regulated by integrating signals across the array of stimulatory and inhibitory NCRs engaged upon interaction with target cell surface NCR ligands [16,17], resulting in the elimination of cells with reduced MHC class I expression, a common consequence of infection or transformation [18]. Other NCRs, such as human and murine NKG2D, recognize divergent MHC class I homologs (ULBPs [19], MICA, and MICB in humans [20], and RAE-1 and H60 in mice [21,22] not involved in conventional peptide antigen presentation. Inhibitory receptors transduce signals through recruitment of tyrosine phosphatases, such as SHP-1 and SHP-2, and contain immunoreceptor tyrosine-based inhibitory motifs (ITIMs) in their cytoplasmic domains [23,24]. Activating receptors associate with immunoreceptor tyrosine-based activation motif (ITAM)-bearing adaptor proteins, either DAP12 [25] or DAP10 [26,27], through a basic residue in their transmembrane domain.

Natural killer cell surface receptors can be divided into two groups based on structural homologies [28,29]. The first group includes the killer cell Ig receptors (KIRs) and consists of type I transmembrane glycoproteins with ectodomains containing tandem Ig domains. The second group, including the rodent Ly49 receptor family and the CD94/NKG2 and NKG2D receptor families found in primates and rodents, comprises homo- and heterodimeric type II transmembrane glycoproteins containing C-type lectin-like NK receptor domains (NKDs) [30]. NCR/ligand dissociation constants range from a hundred micromolar to tens of nanomolar (see Table 1). A series of recent results from X-ray crystallographic analyses detail the interactions for a number of NCR/ligand complexes.

Table I Immunoreceptor Affinities

Receptor	Ligand	K_D (μ M)	Ref.
TCR	MHC class I	1–90	4,36
NKG2A–CD94	HLA-E	11.23	37
KIR	MHC class I	~10	38
huNKG2D	MICA	0.3	34
muNKG2D	H60	0.0189	39
muNKG2D	RAE-1 α , β , γ , δ	0.345–0.726	39

Ig-Type NK Receptors: KIR

Two crystal structures of complexes between inhibitory KIR family NCRs and their MHC class I ligands, KIR2DL2/HLA-Cw3 [31] and KIR2DL1/HLA-Cw4 [32], show that the receptor binds in a 1:1 complex with HLA-C, making contact with both the $\alpha 1$ and $\alpha 2$ platform domains and the carboxy-terminal end of the bound peptide (see Fig. 1). (KIR receptor nomenclature identifies the number of Ig domains [2D(omains) or 3D, specific for HLA-C or HLA-B respectively], and whether the receptor is a long [L] form, containing ITIM repeats, or a short [S] form, interacting with ITAM-containing adaptor proteins.) Both complexes have interfaces showing both significant shape and charge complementarity, with the N-terminal KIR domains interacting primarily with the $\alpha 1$ domains of HLA-C, the C-terminal KIR domains contacting the $\alpha 2$ domains, and additional contacts provided by the interdomain KIR linker peptides (the “elbow”). The kinetics of binding, rapid on and off rates, are consistent with interactions dominated by charge–charge interactions.

Despite a high degree of conservation of binding surface residues between both KIR2DL2 and KIR2DL1, and HLA-Cw3 and -Cw4, few actual intermolecular interactions are conserved. This recognition flexibility is accomplished through altered side-chain conformations. KIR2D receptors distinguish between HLA-C allotypes on the basis of the residue at position 80; KIR2DL1 recognizes lysine and KIR2DL2 recognizes asparagine, and this specificity is conferred by the identity of the residue at position 44 in the receptor. In KIR2DL1, Lys80 is shape and charge matched to a distinct pocket on the surface of the receptor; while Asn80 is sensed through a direct hydrogen bond in the KIR2DL2 complex.

C-Type Lectin-Like NK Receptors: Ly49A

Ly49A is a disulfide-linked, symmetric, homodimeric, NKD-type NCR that is specific for the murine MHC class I protein H-2D^d (the human ortholog is nonfunctional). The crystal structure of the D^d/Ly49A complex [33] shows D^d homodimers binding to two distinct sites on the MHC protein (see Fig. 1). The first binding site positions Ly49A on the D^d platform domain, contacting both $\alpha 1$ and $\alpha 2$ and the

N-terminal end of the bound peptide—the opposite end from where KIR2D binds. The second binding site positions Ly49A in the cleft between the underside of the platform domain (the top being the peptide and TCR binding surface), the $\alpha 3$ domain and β_2 -m. The second site is considerably more extensive than the first site, though less shape complementary and less dominated by charge–charge interactions, and is likely to be the immunologically relevant interaction on the basis of subsequent mutagenesis studies. The second site also overlaps the CD8 binding site on MHC class I proteins. As predicted, Ly49A clearly displays a C-type lectin-like fold, though failing to retain any remnant of the divalent cation or carbohydrate binding sites conserved in true C-type lectins. While the simplest binding mode for a symmetric homodimer is to interact with two monomeric ligands through two identical binding sites, each Ly49A interaction with D^d is with a single monomer because binding of ligand at one site sterically blocks binding at the second, homodimer-related site.

C-Type Lectin-Like NK Receptors: NKG2D

NKG2D is an activating, symmetric, homodimeric, NKD-type NCR. While highly conserved between primates and rodents, its ligands include very different molecules, both in humans and rodents. Crystal structures of two complexes, human NKG2D/MICA [34] and murine NKG2D/RAE-1 [35], show that NKG2D interacts with its MHC class I homologous ligands in a manner very similar to the way in which TCRs interact with classical MHC class I proteins (see Fig. 1), even though NKG2D contains NKDs while TCRs contain Ig domains. NKG2D retains the C-type lectin-like fold seen in Ly49A, with few variations, although the binding surface of NKG2D is much more curved than in Ly49A, matching the more curved surface of its ligands (which do not bind peptides), where the Ly49A and NKG2D binding surfaces encompass overlapping surfaces on the receptors. The interaction surfaces bury considerable solvent-accessible surface area and are highly shape complementary, but the human NKG2D/MICA interaction is markedly more so than the murine NKG2D/RAE-1 interaction. The reason that the human complex does not bind considerably more tightly than the murine complex (see Table 1) is likely due to the necessity of ordering a large loop on the surface of MICA concurrent with complex formation, reflected in the unusually slow on-rate for the human complex. Unlike KIR and Ly49A interactions at the first site, the NKG2D binding sites are much less dominated by charge–charge interactions. The stoichiometries of the NKG2D complexes are one homodimer binding to one monomeric ligand; however, unlike Ly49A, both homodimer-related binding sites on NKG2D contribute approximately equally to the interactions in both complexes, reflecting a binding site that has evolved to bind multiple target sites without the degree of side-change rearrangements seen in the KIR interactions. It has also been proposed that the NKG2D/MICA complex is likely a good model for the CD94/NKG2A/HLA-E complex.

Introduction

The recognition of extracellular and cell surface carbohydrates by specific carbohydrate-binding proteins, or lectins, is an important component of many biological processes. Here, we review the main principles of protein-carbohydrate recognition with particular reference to examples where structural data are available and signaling is known to be important. In conclusion, we explore the suggestion that carbohydrate-mediated interactions provide unique cell-signaling mechanisms.

Biological Roles of Carbohydrate Recognition

Carbohydrates, in the form of oligosaccharides or glycoconjugates, are found on the cell surfaces and extracellular proteins of virtually all living organisms. Although roles for carbohydrates in endogenous physiological interactions had long been suspected, it was not until the 1970s, with the discovery of the hepatic asialoglycoprotein receptor and Man-6-phosphate-mediated intracellular protein targeting, that firm evidence for such roles began to emerge. Since then, a number of animal lectin families have been identified [1,2] and their functions, in processes ranging from protein folding and quality control to leukocyte homing, have been the subject of considerable study.

The cloning of glycosyltransferases and the generation of null-mutant mice have also provided further clear evidence

of roles for endogenous carbohydrate recognition in the development and functioning of the immune and nervous systems [3–5]. In addition, mutations affecting the elaboration of complex carbohydrates are now known to be the basis for a growing number of human diseases collectively known as the congenital disorders of glycosylation (CDGs) [6]. The discovery that aberrant glycosylation of dystroglycan results in various forms of muscular dystrophy provides the most recent example [7–9].

Perhaps most surprising has been the finding that carbohydrates are also involved in the regulation of a number of signaling pathways. Fringe, for example, is a β 1,3 *N*-acetylglucosaminyltransferase [10,11] whose action modulates the interaction of the Notch receptor with its ligands, and mutations in Brainiac, a glycolipid-specific β 1,3 *N*-acetylglucosaminyltransferase [12,13], effect oogenesis. Genetic studies have also shown that proteoglycans/glycosaminylglycans play key roles in development, and, in *Drosophila* and *Caenorhabditis elegans*, they have been shown to be involved in regulating the fibroblast growth factor, Wnt, transforming growth factor- β , and Hedgehog signaling pathways [14].

Carbohydrate Structure and Diversity

The structural diversity characteristic of the oligosaccharides found in nature stem principally from three sources: (1) a large number of monosaccharide types, (2) the multiple ways in which the monosaccharides can be linked

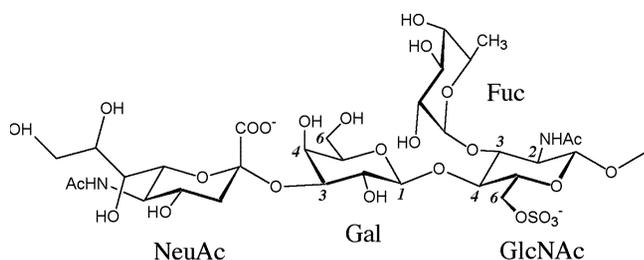

Figure 1 Structural representation of the sulfated sialyl Lewis x tetrasaccharide, NeuAc α 2-3Gal β 1-4[Fuc α 1-3](6-sulfo)GlcNAc. NeuAc, Gal, GlcNAc, and Fuc label the monosaccharide moieties *N*-acetylneuraminic acid, galactose, *N*-acetylglucosamine, and fucose, respectively.

together, and (3) the fact that oligosaccharides can be further modified chemically (e.g., sulfate, phosphate, and acetyl). The basic themes are illustrated in Fig. 1, which shows the structure of sulfated sialyl Lewis x, a tetrasaccharide important in selectin-mediated recognition. Because most monosaccharides have more than one hydroxyl group available for glycosidic bond formation, oligosaccharides, unlike their peptide counterparts, can form branched structures. The oligosaccharide structures linked to lipid or to protein, through Ser/Thr (O-linked) or Asn (N-linked), typically contain between 1 and 20 monosaccharide moieties and may be branched or linear. The much longer linear glycosaminylglycans, either in isolation or as the oligosaccharide chains of proteoglycans, are found on cell surfaces and in the extracellular matrix.

In vivo, oligosaccharides are synthesized by glycosyltransferases, each of which typically has a unique donor, acceptor, and linkage specificity. As such, a very large number of glycosyltransferases and related enzymes are required to generate the oligosaccharide diversity seen in nature. Although the basis for this diversity is not fully understood, general themes are beginning to emerge. The so-called terminal elaborations (e.g., sialic acid, galactose, and sulfate) typical of the N-linked oligosaccharides of multicellular organisms, for example, seem to have appeared as part of the machinery required to mediate cell–cell and cell–matrix interactions [15]. In addition, it seems likely that oligosaccharide diversity has also been driven by evolutionary pressures arising from the need to differentiate self from nonself [16].

Lectins and Carbohydrate Recognition

Carbohydrate-binding proteins or lectins, like their saccharide counterparts, are also found in organisms ranging from microbes to humans [1]. The canonical carbohydrate recognition domain (CRD), characteristic of a given lectin type, can be found either in isolation or in conjunction with other protein domains, including coiled-coil domains and membrane-spanning motifs. Although many of the known CRD types are completely unrelated at the protein structural level [17–19], they can be grouped into two broad classes [20]. The type I CRDs are typified by the bacterial carbohydrate

transporters and are characterized by deep carbohydrate-binding sites that essentially envelop their small saccharide ligands. In type II CRDs, the carbohydrate-binding sites are more shallow in nature and the saccharide remains relatively exposed to solvent, even when bound to the CRD. As a result, the dissociation constants (K_d) for small mono- or disaccharides can approach 0.1 μ M for the type I CRDs, while the type II CRDs tend to bind small saccharides with K_d in the range of 0.1 to 1.0 mM.

Despite their relatively weak affinities for small saccharides, type II CRDs often show a strict mono- or disaccharide binding specificity. From a structural standpoint, this is achieved by a complementarity of fit between the CRD and the saccharide moiety which includes both hydrogen bond and van der Waals interactions. The structural and thermodynamic basis for this specificity has, in fact, been well studied and reviewed in detail elsewhere [17–23].

Given that the type II CRDs bind small saccharides relatively weakly, most of these lectin types have employed multivalency as a means of conferring additional affinity and specificity on their binding interactions with larger oligosaccharides [17]. In addition to the monosaccharide in the primary site, the CRD may possess subsites for interaction with other monosaccharides of the oligosaccharide. Alternately, many lectins cluster their CRDs as a means of making multivalent interactions with larger oligosaccharides or other extended structures such as cell surfaces. Members of the C-type lectin family, for example, are known to form monomers, trimers, tetramers, pentamers, and hexamers, as well as higher order oligomers, and in some cases a single polypeptide chain will possess more than one canonical CRD.

Carbohydrate-Mediated Signaling

Lectins as Receptors

Most of the current evidence for the biological roles of complex carbohydrates comes from systems where they act as ligands for membrane-bound receptors that are lectins. Typically, these receptors have one or more extracellular CRDs, a single transmembrane-spanning region, and a relatively short cytosolic tail. In most cases, they are probably activated by receptor cross-linking mechanisms.

L-, P-, and E-selectin are cell-surface, C-type lectins responsible for leukocyte homing [24]. Unlike other members of the family, they do not possess a monosaccharide binding specificity. They require at least a tetrasaccharide, sialyl Lewis x (Fig. 1) for binding, and specific sulfation further enhances binding to L- and P-selectin [25]. The crystal structures of P- and E-selectin, in complex with oligosaccharide/glycopeptide ligands, have shown the importance of electrostatics in these interactions, a factor thought to be important in the rapid binding kinetics required for leukocyte rolling [26]. Moreover, the structures have provided a rationalization for the specificity differences that ensure that lymphocytes target to lymph nodes and neutrophils reach sites

of inflammation. Although the selectins are not known to form oligomers, E-selectin-mediated clustering at contact points between interacting cells has been shown to activate the ERK1/2 signaling pathway [27].

DC-SIGN and DC-SIGNR are also C-type lectins, but in this case they are involved in dendritic cell/T-cell interactions [28], as well as the promotion of HIV-1 infection [29]. These lectins possess a mannose-binding specificity, but in addition show a marked increase in affinity for high mannose oligosaccharides [30]. The crystal structures of their CRDs in complex with a mannopentasaccharide show that the increased affinity arises from a further set of interactions in addition to those made with the mannose in the primary binding site [31]. Because these lectins also possess α -helical tetramerization domains, it seems likely that they would be capable of making high-affinity interactions with ICAM-3 and HIV gp120, two of their natural ligands. In fact, it has been suggested that the cross-linking of DC-SIGN tetramers, by the highly multivalent high mannose oligosaccharide containing HIV virus, provides the signal required to promote transport of HIV from the periphery to the T-cell-containing lymph nodes [29].

The hepatic asialoglycoprotein receptor, a member of the C-type lectin family, provides a well-characterized example of the interplay between structure, specificity, and receptor cross-linking. Although an isolated CRD of this receptor binds galactose with a K_d in the millimolar concentration range, the cell-surface form of the receptor can bind the appropriate triantennary N-linked oligosaccharide with nanomolar affinity. Cross-linking studies have shown that the HL-1 subunit forms trimers on the cell surface and that recruitment of an additional HL-2 subunit(s) generates the high-affinity receptor. The galactose termini of the triantennary oligosaccharides (separated by 15 to 25 Å) are found to interact with both the HL-1 and HL-2 subunits [32]. Linking receptor specificity to receptor cross-linking in this way may be important for both receptor uptake and signal transduction [33].

The targeting of lysosomal enzymes is also dependent on receptor-mediated endocytosis. In this case, the cation-dependent mannose 6-phosphate receptor (CD-MPR) and the insulin-like growth factor II/cation-independent mannose 6-phosphate receptor (IGF-II/CI-MPR) specifically recognize the mannose-6-phosphate moiety on acid hydrolases destined for lysosomes [34]. Again, multivalency is important; CD-MPR binds mannose 6-phosphate with a dissociation constant in the micromolar concentration range, while the dimeric receptor binds tetrameric β -glucuronidase with nanomolar affinity. Both dimeric and tetrameric forms of the receptor are found in the Golgi membrane, and, based on the crystal structure of the dimeric CD-MPR, a model for its high-affinity interaction with β -glucuronidase has been proposed [35]. The IGF-II/CI-MPR receptor contains two canonical CRDs presumably capable of promoting high-affinity interactions with multivalent lysosomal enzymes, and together with CD-MPR these receptors are responsible for targeting over 50 structurally distinct lysosomal enzymes. Dimerization of the IGF-II/CI-MPR receptor by

β -glucuronidase binding increases receptor internalization at the cell surface [36].

The siglecs are a family of sialic acid binding lectins whose canonical CRD is a member of the immunoglobulin (Ig) superfamily. They are particularly important in the immune system, where they function in processes ranging from leukocyte adhesion to hemopoiesis [37]. Members of the family show specificity differences for α 2,3- versus α 2,6-linked sialic acids, as well as for sialic acids modified with respect to *O*-acetylation. The crystal structure of the CRD of sialoadhesin in complex with 3' sialylactose shows that interactions with the bound oligosaccharide are mediated primarily with the terminal sialic acid moiety [38]. Of particular interest are the roles played by *cis* interactions. CD22 (Siglec-2), for example, is a B-cell-specific receptor which, through interaction with α 2,6-linked sialic acid containing glycoproteins on its own cell surface, inhibits B-cell receptor signaling. This stable inhibition can be broken by the addition of external competing saccharide and *in vivo* may be controlled by the regulation of sialyltransferases and/or sialidase expression levels [39]. The cloning of several CD33-related receptors expressed on myeloid cell progenitors suggests new insight into the significance of their sialic acid binding properties. In all cases, these receptors possess cytoplasmic immunoreceptor tyrosine-based inhibitory motifs (ITIMs), elements now known to be hallmarks of inhibitory receptors central to the initiation, amplification, and termination of immune responses [40]. Through interactions with sialic acid containing self determinants, these receptors may play roles in the control of innate immunity [41].

Serum mannose binding protein (MBP), a component of the vertebrate innate immune system, is also a C-type lectin. Although not membrane bound, it signals activation of the complement cascade through a conformational change initiated by binding the cell surface of a foreign pathogen [42]. Like the asialoglycoprotein receptor, the CRD of MBP also recognizes only a terminal monosaccharide moiety, in this case mannose. The CRDs are also found to form trimers; however, in MBP they are mediated by long, triple-helical, coiled-coil domains that in addition promote the formation of trimer clusters containing 18 CRDs in total [43]. The crystal structures of truncated forms of the trimer show that the mannose binding sites are separated by 45 and 53 Å, respectively, in human [44] and rat [45] MBP. Thus, unlike the asialoglycoprotein receptor, which is designed to recognize the closely spaced galactose determinants of a single N-linked oligosaccharide, MBP is designed to bind the widely spaced mannose determinants typical of the cell surfaces of pathogenic microorganisms [46].

Glycoproteins as Receptors

It has long been known that certain multivalent, soluble plant lectins (e.g., PHA and Con A) can induce mitosis in lymphocytes and oxidative burst in neutrophils. The mechanism for initiation of these signals has generally been assumed to result from the cross-linking of cell-surface glycoproteins.

More recently, soluble animal lectins of the galectin type have also been found to induce a variety of signals, including, among others, apoptosis, oxidative burst, cytokine release, and chemotaxis in immune cells [47]. In structural terms, the galectins are either dimeric or contain more than one CRD on a single polypeptide chain and as such they are capable of cross-linking receptors [48]. Recent studies aimed at understanding T-cell homeostasis have suggested that CD45, CD43, CD7 [49], and the TCR-CD3 complex [50] are physiologically relevant cell-surface receptors for galectins-1 and -3, respectively.

Glycolipids as Receptors

The role of glycolipids as receptors for microbial lectins has been well studied. Bacterial AB₅ toxins possess a pentameric arrangement of B-subunit lectins which, through multivalent interactions, promote high-affinity binding with host cell-surface gangliosides [51]. In the case of cholera toxin, binding to G_{M1} on the cell surface is followed by retrograde transport and translocation across the ER membrane [52]. Once in the cytosol, the A1 fragment of the A subunit catalyzes the ADP ribosylation of the heterotrimeric G α s protein, leading to the characteristic chloride and water efflux. In what is a fundamentally different type of interaction, the lectin subunits of the *Escherichia coli* P-fimbriae bind glycolipids in uroepithelial cells leading to ceramide release, activation of ceramide signaling pathways, and ultimately cytokine release through a process that also appears to involve activation of the TLR-4 receptor pathway [53–55]. Although not yet fully characterized, the interactions of glycosphingolipids with various adhesion and signaling receptors found in cell-surface microdomains are being found to mediate signaling events important in cell–cell interactions [56].

Proteoglycans and Glycosaminoglycans

Proteoglycans contain long linear oligosaccharide chains (glycosaminoglycans) made up of disaccharide repeats containing acidic monosaccharides and variable degrees of sulfation. They are found at the cell surface and in the extracellular matrix, where they interact with a wide variety of molecules, including, among others, signaling receptors, growth factors, chemokines, and various enzymes [57–59]. In the well-characterized fibroblast growth factor (FGF)–fibroblast growth factor receptor (FGFR) interaction, heparin/heparan sulfate serves as coreceptor. Two recent crystal structures of ternary complexes have begun to shed light on how the intrinsically multivalent oligosaccharide serves to promote receptor cross-linking in this system [60,61]. Recent evidence from studies on hepatocyte growth factor/scatter factor suggests that heparan and dermatan sulfate binding serves to promote a conformational change in the growth factor that promotes receptor binding [62]. In some cases, specific sulfation patterns appear to be important determinants of specificity [58,63]. The syndecans are cell-surface proteoglycans whose core proteins contain

cytoplasmic signaling motifs. They have been implicated in the formation of focal adhesions, where interactions with heparin binding domains and other receptors are proposed to lead to adhesion, cross-linking, and signal transduction [64].

Small Soluble Saccharides

Small nutrient saccharides are often sensed by the receiving cells after entry through a transporter. In mammals, for example, glucose is sensed by an alteration in the adenosine triphosphate (ATP)/adenosine diphosphate (ADP) ratio resulting from glucokinase-initiated glucose metabolism. In microbes, small saccharides are often sensed by specific, non-enzyme cytosolic binding proteins that in turn regulate gene expression (e.g., the Lac-repressor of *E. coli*). In plants, nutrient sugars are also known to be important mediators of signal transduction [65], and the recognition of small soluble oligosaccharides by membrane and cytoplasmic receptors is important in plant host defense [66]. Although these examples are beyond the scope of this review, it is worth noting that these carbohydrate-mediated signaling mechanisms may be operative in systems yet to be characterized.

Carbohydrates and Lectins in the Nucleocytosolic Compartment

The O-linked glycosylation of serine and threonine residues of nuclear and cytoplasmic proteins by *N*-acetylglucosamine (O-GlcNAc) is involved in signal transduction in multicellular organisms [67]. This dynamic modification occurs at sites of protein phosphorylation and may serve to transiently block sites of phosphorylation. Although its roles are not yet fully characterized, O-GlcNAc has been found to modulate a wide range of cellular functions, including transcription, translation, nuclear transport, and cytoskeletal assembly [68].

Galectins are also cytosolic and nuclear proteins, but they are not known to bind carbohydrates in these compartments; however, galectins 1 and 3 have been implicated in pre-mRNA splicing, a process inhibited by oligosaccharide binding [69]. The galectins are also secreted from the cytoplasm (by non-classical pathways), and it is at the cell surface that they perform the carbohydrate-mediated processes discussed previously.

For the sake of completeness it is worth noting that well-known second messengers such as cyclic AMP, GDP, GTP, etc. are ribose-containing glycoconjugates and that even more complex saccharide second messengers may be operative in insulin signaling [70].

Conclusions

The interactions between lectins and carbohydrates are relatively weak in nature and, as such, carbohydrate-mediated interactions may play important roles where weak interactions are required—the leukocyte rolling phenomenon perhaps providing a good example. In many cases, however, type II lectins have employed multivalency as a means of conferring

increased affinity and specificity on their binding interactions. The structures of the asialglycoprotein receptor and MBP provide important examples of this principle. Because receptor cross-linking or clustering is a natural outcome of such multivalent interactions, it is clear that lectin–oligosaccharide interactions are inherently well suited to mediating signal transduction by the so-called horizontal mechanisms. In contrast, the higher affinity type-I lectins, typified by the bacterial transport/chemosensory receptors, appear to employ a mechanism more akin to vertical signaling where ligand-induced conformational changes in the receptor lead to signal transduction [71]. Interestingly, the affinity of these receptors for their carbohydrate ligands is close to the minimum affinity ($K_d \sim 10^{-8} M$) thought to be required for vertical signaling through 7TM receptors.

Although similar in some ways, it is clear that protein–carbohydrate interactions differ from protein–protein interactions in ways that might confer on them unique signaling roles or properties. Because glycosylation is a posttranslational modification capable of modifying any molecule with the appropriate acceptor, the subsequent recognition of carbohydrate determinants differs fundamentally from that involving specific protein–protein interactions. The galectins and siglecs, for example, bind β -galactosides and sialic-acid-containing ligands, respectively, and either of them might be expected to interact with more than one receptor type. As such, carbohydrate-mediated interactions may enable the activation of multiple signaling pathways or networks, as described by Bhalla and Iyengar [72]. Alternately, if carbohydrate-mediated interactions lead to heterogeneous cross-linked receptor arrays, this might result in spatial/geometric associations, where the triggering of one receptor type leads to the activation of another [73,74]. Brewer and colleagues [75] have also provided evidence for the ability of multivalent lectins to form homogeneous cross-linked arrays or lattices, even in the presence of competing ligands. In fact, in recent *in vivo* studies they have shown that galectin-1-induced apoptosis is accompanied by the redistribution and segregation of CD45 and CD43 on T-cell surfaces. Galectin-3-mediated cross-linked arrays have also been recently invoked in a model for T-cell receptor activation [50]. In a similar vein, it seems likely that the highly multivalent proteoglycans provide scaffolds upon which interacting molecules can be assembled and organized.

In addition to the potential for triggering signaling events, the formation of carbohydrate-mediated cross-linked arrays may also be important in receptor turnover, one way in which signaling events are modulated [76]. In fact, evidence already exists for the ability of galectin-3 to both accelerate [77] and retard the turnover of cell surface receptors (J. Dennis, personal communication). In what might be a variation on this theme, the priming of neutrophil leukocytes with lipopolysaccharide (LPS) leads to galectin responsiveness by inducing the transfer of receptor-containing vesicles to the cell surface [78,79].

Our knowledge of lectin and glycoprotein structures shows that multivalent interactions are a recurring theme.

Many lectins are oligomeric and/or membrane bound, and many glycoproteins (and certainly proteoglycans) possess multiple glycosylation sites. Their inherent ability to mediate cross-links make it certain that new examples of signaling roles will follow from the study of these complex and diverse molecules.

Rhinovirus–Receptor Interactions

Elizabeth Hewat

*Institut de Biologie Structurale J-P Ebel,
Grenoble, France*

The attachment of a virus to specific cell-surface receptors is a key event in the life cycle of animal viruses. It determines the host range and tropism of infection and initiates delivery of the genome into the cell. Once bound to a receptor, the non-enveloped viruses such as the rhinoviruses must then transfer their genome directly across a membrane into the cytoplasm for reproduction [1].

Human rhinoviruses (HRVs) are a major cause of the common cold. They are small, icosahedral viruses, 300 Å in diameter, and belong to the Picornaviridae family, which includes Rhinovirus, Aphthovirus, Enterovirus, Cardiovirus, etc. Their capsid is composed of 60 copies each of four viral coat proteins, VP1, VP2, VP3, and VP4, on a T=1 (or pseudo T=3) icosahedral lattice [2]. The three major capsid proteins VP1, VP2, and VP3 all have the same basic eight-stranded β-barrel fold and a molecular weight of around 30 kDa. VP4 is a small protein located inside the capsid. The capsid encloses a single positive RNA strand of about 7000 bases. The HRV capsid has a star-shaped dome on each of the five-fold axes surrounded by a shallow depression or “canyon” and a triangular plateau centered on each three-fold axes and around each five-fold axes (Fig. 1).

A distinctive feature of VP1 is that it has a “pocket” or hollow within the β-barrel that is accessible from the exterior of the capsid. This hydrophobic pocket located at the base of the canyon is frequently occupied by a natural *pocket factor*, a fatty-acid-like molecule. This pocket factor is believed to stabilize the virus during its spread from cell to cell [3].

With one exception, HRVs are classified into a major group and a minor group based on their specificity for cell receptors (Fig. 2). The major group HRVs bind to the intercellular adhesion molecule-1 (ICAM-1) [4], which belongs to the

immunoglobulin superfamily. ICAM-1 plays an important role in cell–cell interactions and contains five immunoglobulin-like domains. The minor group HRVs bind to members of the low-density lipoprotein receptor (LDL-R) family [5,6], which internalize LDL particles but also mediate the transport of macromolecules into cells by receptor-mediated endocytosis (Fig. 3). The ligand-binding amino terminus of the LDL receptors all contain various numbers of imperfect repeats of approximately 40 amino acids. These rigid ligand-binding domains are linked by four to five amino acids which confer some flexibility. Both ICAM-1 and the LDL receptors appear to bind their ligands by electrostatic interactions. HRV87 alone uses an unidentified sialoprotein as receptor [7] for which the receptor site is unknown. The major group HRV89 has the capacity to evolve under the pressure of passage *in vitro* to use an alternative receptor and even to infect cells devoid of its normal ICAM-1 receptor [8].

There is a remarkable difference in the location and accessibility of the receptor sites of the two groups of HRV. The major group HRV receptor site lies at the base of a depression or canyon around each five-fold axis [9] (Figs. 1 and 4). In contrast, the minor group HRV receptor binds to the star-shaped dome on the five-fold axis [10] (Figs. 1 and 4). The canyon hypothesis [1] proposed that the major group HRVs protect their receptor sites from immune surveillance by effectively hiding their receptor sites at the base of the canyon. The antibodies, being much larger than the ICAM-1 receptor, were supposed to be unable to reach the base of the narrow canyon. However, it was later shown that key viral amino acid residues involved in binding ICAM-1 are also accessible to antibodies [11]. Effectively, the receptor binding site is indeed accessible to antibodies but is flanked by residues capable of

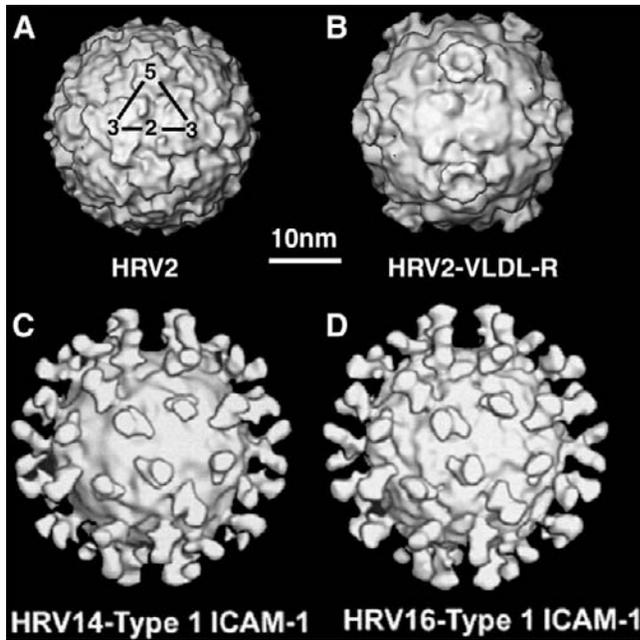

Figure 1 Surface views of the reconstructed cryo-electron microscopy maps of (A) the minor group HRV2 and (B) the complex of HRV2 and a soluble fragment of the VLDL receptor where a “crown” of receptor molecules is seen on each five-fold axis. The icosahedral axes of one asymmetric unit are indicated in (A). Similar views show the major group HRV14 (C) and HRV16 (D) complexed with a soluble fragment of ICAM-1. All reconstructions are viewed down a two-fold axis. (Figures 1A and B are adapted from Hewat, E. A. *et al.*, *EMBO J.*, **19**, 6317–6325, 2000; Figs. 1C and D are reproduced from Kolatkar, P. R. *et al.*, *EMBO J.* **18**, 6249–6259, 1999. With permission.)

mutating to give a viable virus that escapes immune surveillance [12]. This is an interesting example of a highly plausible hypothesis that is not quite correct.

Binding of ICAM-1 to major group HRVs, such as HRV14, initiates rapid uncoating at physiologic temperature without the need of any cellular machinery [13]. In contrast, binding of LDL receptors to minor group HRVs, such as HRV2, does not directly catalyze decapsidation [5], and the subsequent internalization into acidic endosomal compartments is required for the transfer of the viral RNA into the cytosol [14] (Fig. 3).

The difference in the stability of the virus–receptor complexes and in the receptor binding sites of the major and minor group HRVs correlate with differences in their uncoating mechanisms. Rossmann and colleagues [9] have

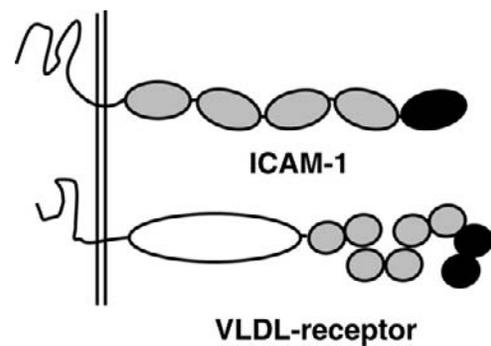

Figure 2 Schematic representation of the two proteins known to act as rhinovirus receptors. ICAM-1 contains five immunoglobulin-like domains and attaches to the major group HRVs by the N-terminal domain depicted in black. The ligand-binding amino terminus of the VLDL receptor (one of the LDL receptor family) contains eight imperfect repeats; two of these repeats bind to the minor group HRV2.

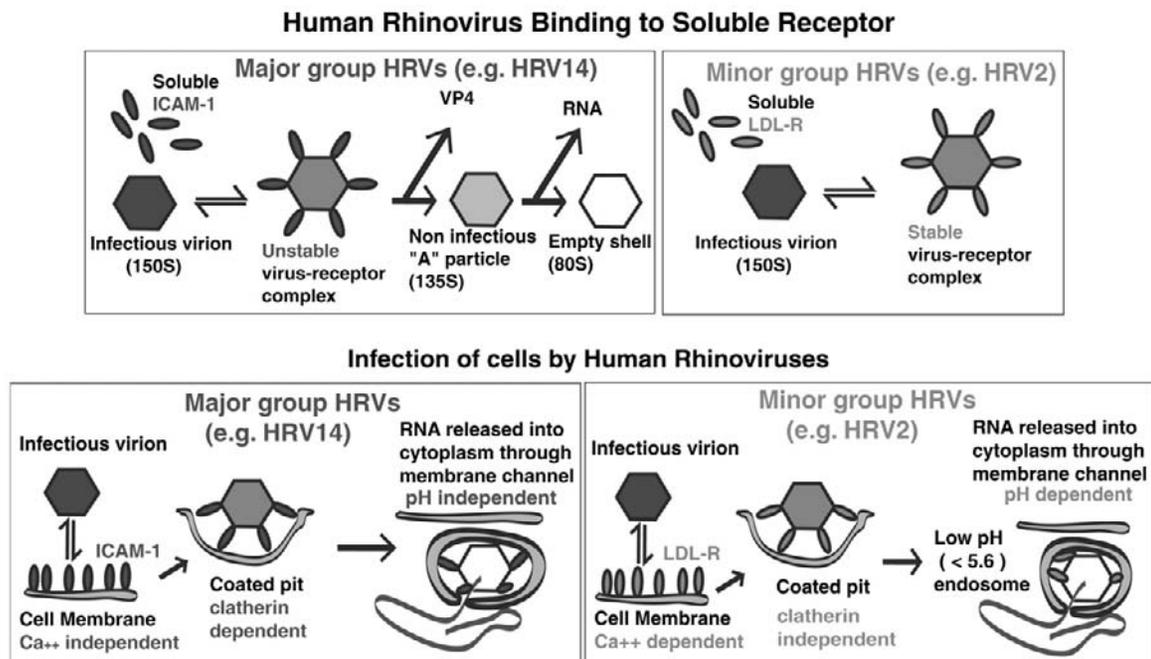

Figure 3 Schemas for attachment of soluble receptors to major and minor group HRVs and for the infection of cells by HRVs.

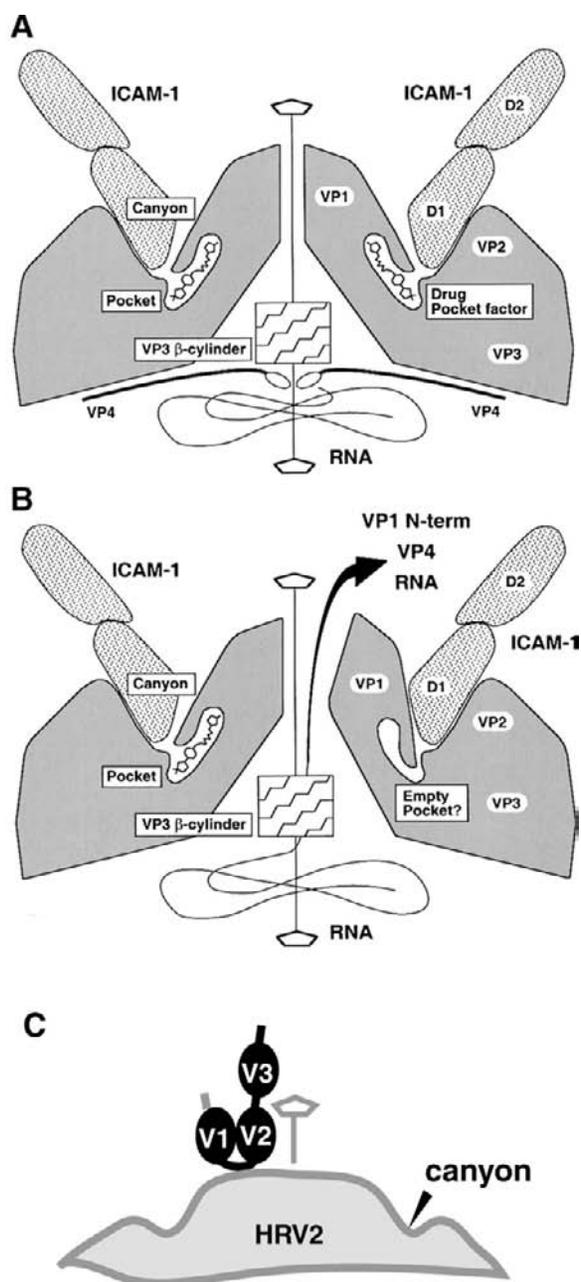

Figure 4 Schematic representation of the two step binding mechanism between ICAM-1 and the major group HRVs proposed by Kolatkar *et al.* [9]. See the text for a description of the first step shown in (A) and the second step in (B). Only two of the five ICAM-1 domains are shown. Part (C) shows how the VLDL receptor attaches to the minor group HRV2. Only three of the VLDL-R domains are shown. (Figures 4A and B are reproduced from Kolatkar, P. R. *et al.*, *EMBO J.*, **18**, 6249–6259, 1999; Fig. 4C is adapted from Hewat, E. A. *et al.*, *EMBO J.*, **19**, 6317–6325, 2000. With permission.)

proposed that ICAM-1 binds to the major group HRVs in a two-step process, as shown in Fig. 4. In the first step, ICAM-1 binds essentially to the base and one side of the canyon in the conformation as observed in cryo-electron microscopy reconstructions. The second step would then consist of expulsion of the natural pocket factor, as the ICAM-1 molecule binds to the other side of the canyon. This would induce

the VP1 to flex at the canyon, moving away from the five-fold axis and thus opening the pentameric vertex. Because the binding site of the HRV2 receptor lies entirely on the dome on the five-fold axis and does not overlap the canyon or the pocket in the canyon at all, the mechanism must be quite different. The binding of VLDL-R to HRV2 as seen by cryo-electron microscopy is probably also the first step in a two step process [10]. The first step of receptor binding simply ensures that the HRVs are anchored to the membrane. The second step (i.e., expulsion of the pocket factor and flexing of VP1 to open a passage for the exit of the molecule of RNA) is then triggered by the low pH (5.6) in the endosome (Fig. 4). It is generally believed that the RNA exits along one of the five-fold axes. As the capsid opens, the VP4 and the N-terminus of VP1 are externalized. It has been hypothesized that both VP4 and the N-terminus of VP1 are inserted into the membrane in order to facilitate passage of the RNA across the membrane [1].

Antiviral compounds, such as the “WIN compounds” produced by the former Sterling Winthrop Research Institute, bind in the VP1 pocket. In many major group viruses, this induces a deformation of the canyon which causes a loss of receptor binding. It also stabilizes the capsid; however, in minor group viruses these antivirals do not affect receptor binding [15], and their antiviral effect is based on their stabilizing effect only. This behavior is in accord with the fact that the binding site of LDL-R on minor group viruses does not overlap the pocket at the base of the canyon.

HIV-1 Receptor Interactions

Peter D. Kwong

*Vaccine Research Center, NIAID,
National Institutes of Health,
Bethesda, Maryland*

Viral recognition of host receptors forms a special subset of molecular recognition. Unusual properties arise from the exceptional constraints that viruses encounter during infection. Although each virus is unique, examination of the human immunodeficiency virus type 1 (HIV-1) illustrates some of these special viral features.

Molecular Interactions

Human immunodeficiency virus type 1 is an enveloped retrovirus that infects CD4⁺ T lymphocytes [1,2]. T lymphocytes are mobile and, once infected, live only a few days [3]. Thus, HIV must not only find the proper cell, but it must do so repeatedly over the hundreds of cycles of lymphocyte turnover that typify its persistent infection. The combined function of finding host cells and of properly initiating the viral fusion machinery is accomplished by the HIV-1 gp120 exterior envelope glycoprotein (reviewed by Wyatt and Sodroski [4]). The gp120 glycoprotein is initially synthesized as part of a trimeric gp160 glycoprotein, which is cleaved by cellular proteases into gp120 (N-terminal portion, roughly 500 amino acids, highly glycosylated) and gp41 (C-terminal portion, roughly 350 amino acids, transmembrane spanning) components. Noncovalent interactions keep this trimer of heterodimers associated as the biologically active viral spike.

The gp120 glycoprotein binds to the N-terminal membrane distal domain of the cellular CD4 receptor [5–8]. This interaction triggers conformational changes in gp120 that induce the formation of a binding site for the coreceptor, a member of the chemokine receptor family, either CCR5 or CXCR4 [9,10]. Binding by coreceptor initiates additional conformational changes that trigger the gp41 fusion machinery, leading to a fusion of the viral and cellular membranes and entry of the HIV-1 genome into the host cytoplasm (Fig. 1).

Although the small size of the virion (approximately 1000 Å in diameter) enhances diffusion, HIV virions are cleared rapidly from serum, and HIV gp120 employs several means to enhance receptor encounters. First, nonspecific electrostatic interactions generate binding to cell-surface polyanions such as heparin sulfate [11,12]. This electrostatic adhesion allows two-dimensional cell-surface scanning, enhancing the probability of gp120/cell-surface CD4 encounters. Second, it abducts innate immune responses on dendritic cells to promote infection in *trans* [13]. The gp120 glycoprotein displays high mannose N-linked glycans that bind to DC-SIGN and other dendritic cell receptors [14]. These receptors are used in innate immunity to scavenge for microbial invaders and to activate immune recognition, but binding to HIV gp120 results in the efficient presentation of the virus to suitable target cells (reviewed by Pohlmann *et al.* [15]).

These molecular interactions highlight several unique features of viral interactions. First, the ingenious manner by which the virus usurps host systems, with a redundancy of mechanisms to ensure viral propagation. Second, virions are not metabolically active, which has several diverse implications: highly specific recognition must occur without metabolic activation or proofreading; viral motion is propelled solely by Brownian forces; and large thermodynamic barriers (such as membrane fusion) must be overcome by using only energy stored in folded proteins. Third, HIV viral proteins function under severe constraints on genome size. The entire HIV genome is only 10 kilobase-pairs. These genome constraints are reflected at the DNA level by overlapping reading frames. On the protein level, they lead to a condensed multifunctionality. While eukaryotic recognition often involves a number of different proteins, each performing a specific task, the entire HIV recognition and entry procedure is accomplished with only two proteins. Multiple functionalities are encoded by different subunits as well as by different conformational states of the same polypeptide (Fig. 1).

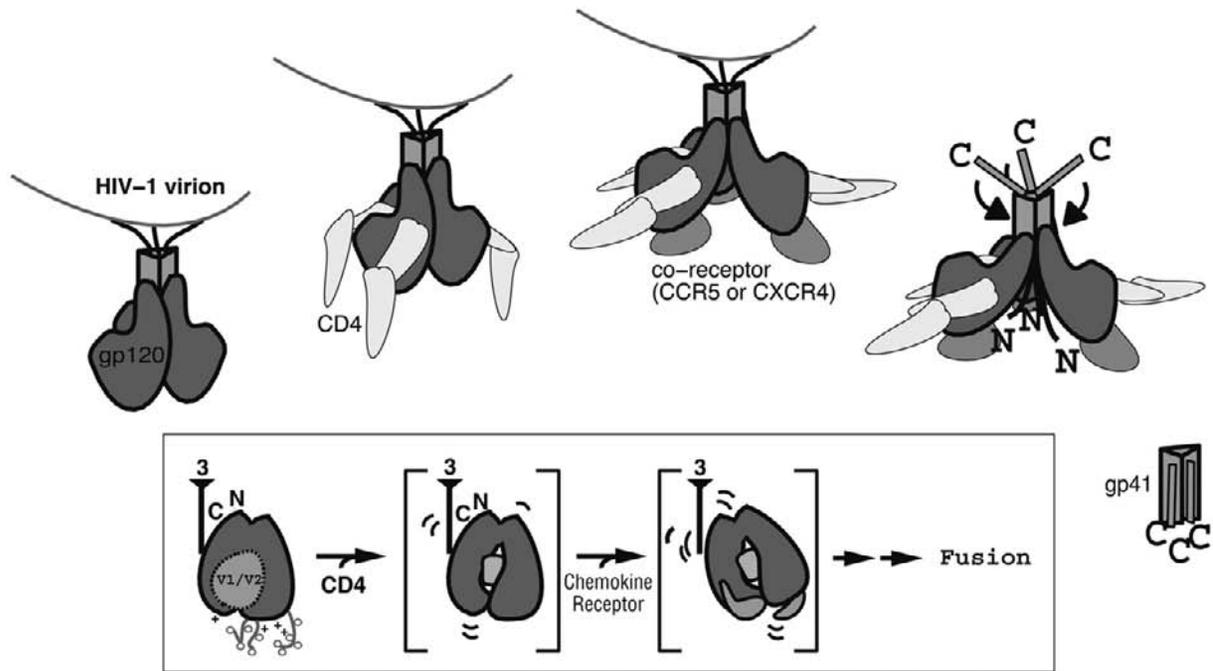

Figure 1 Molecular interactions and conformational states of the HIV-1 envelope glycoproteins. The top panel of figures illustrates the molecular interactions of the HIV-1 envelope glycoproteins. In the leftmost figure, a schematic of the biologically active viral spike is depicted, with gp120 molecules attached to the gp41 ectodomain. The subsequent figures diagram binding of CD4, followed by co-receptor (gray ovals), which initiates the gp41 fusion machinery: the N-terminal fusion peptide of gp41 is thrown into the target cell, and dramatic refolding of gp41 results in a final coiled-coil structure, with gp41 N- and C-ectodomain termini proximal. (For clarity, only the gp41 ectodomain is depicted. Thus the gp41 “C” corresponds to the membrane proximal portion of the gp41 ectodomain.) The boxed panel of figures illustrates these changes in the context of a single gp120 protomer. The leftmost figure shows the quiescent gp120. Basic surfaces (++) and high mannose N-linked glycan (o o) enhance cell-surface attachment and presentation to CD4⁺ lymphocytes. In this quiescent state, the CD4 binding site is occluded by the V1/V2 variable loop, and the co-receptor binding site is not formed. Upon binding to CD4 (second figure), the inner and outer domains reorganize, forming both the Phe-43 cavity (at the center of gp120) and the bridging sheet and partially destabilizing quaternary interactions. Chemokine receptor binding (third figure) to the newly formed bridging sheet and V3 loop (light gray) trigger the gp41 fusion machinery. (Boxed panel adapted from Kwong, P. D. *et al.*, *Nature*, **393**, 648–659, 1998, Fig. 5.)

Atomic Details

The X-ray crystal structure of core gp120 in complex with CD4 and a neutralizing antibody permitted one of these conformations to be examined at the atomic level (Fig. 2) [16,17]. The core gp120 construct used for crystallization contained deletions at the gp41-interactive region (at the gp120 N/C termini) as well as tripeptide substitutions for two loop regions. The crystal structure showed that core gp120 has two domains: an “inner” domain containing the N and C termini and a heavily glycosylated “outer” domain containing approximately 15 sites of N-linked glycosylation. Extensions emanating from β -hairpins of these two domains combine to form a four-stranded “bridging sheet” minidomain. This minidomain rests on hydrophobic residues contributed by the outer surfaces of the underlying inner and outer domains; thus, the integrity of the bridging sheet is intimately dependent on the precise alignment of the underlying domains.

The CD4 receptor binds at the nexus of the inner domain, outer domain, and bridging sheet. A total of $\sim 1600 \text{ \AA}^2$ of surface is buried in the interaction ($\sim 800 \text{ \AA}^2$ from both CD4 and gp120), which is in the range typical for protein–protein

interactions with nanomolar affinity. The interface itself is unusual. Two large interfacial cavities are present, and the gp120 component is contributed by mostly back-bone interactions from six separate sequence stretches. Thermodynamic studies indicate that gp120 undergoes significant conformational change upon binding to CD4. The gp120 glycoprotein appears to fold around CD4, with a coordinated alignment of the inner and outer domains and a reorganization of the bridging sheet [18].

The neutralizing antibody, 17b, captured in the ternary crystal complex binds to the gp120 bridging sheet, to a surface proximal but distinct from that bound by CD4. Sequence analysis shows that this relatively flat surface is highly conserved between different HIV-1 strains, although it appears to be conformationally masked prior to CD4 interaction.

The site of coreceptor binding overlaps with the 17b epitope. Mutational analysis shows that the coreceptor binding surface includes the bridging sheet and part of a variable surface loop, called the *V3 loop* [19]. Thus, the ternary structure provides a snapshot of the constant regions bound by both CD4 and coreceptor.

The bridging sheet is roughly 50 \AA distal from the gp120 N and C termini, which interact with gp41. The manner in which

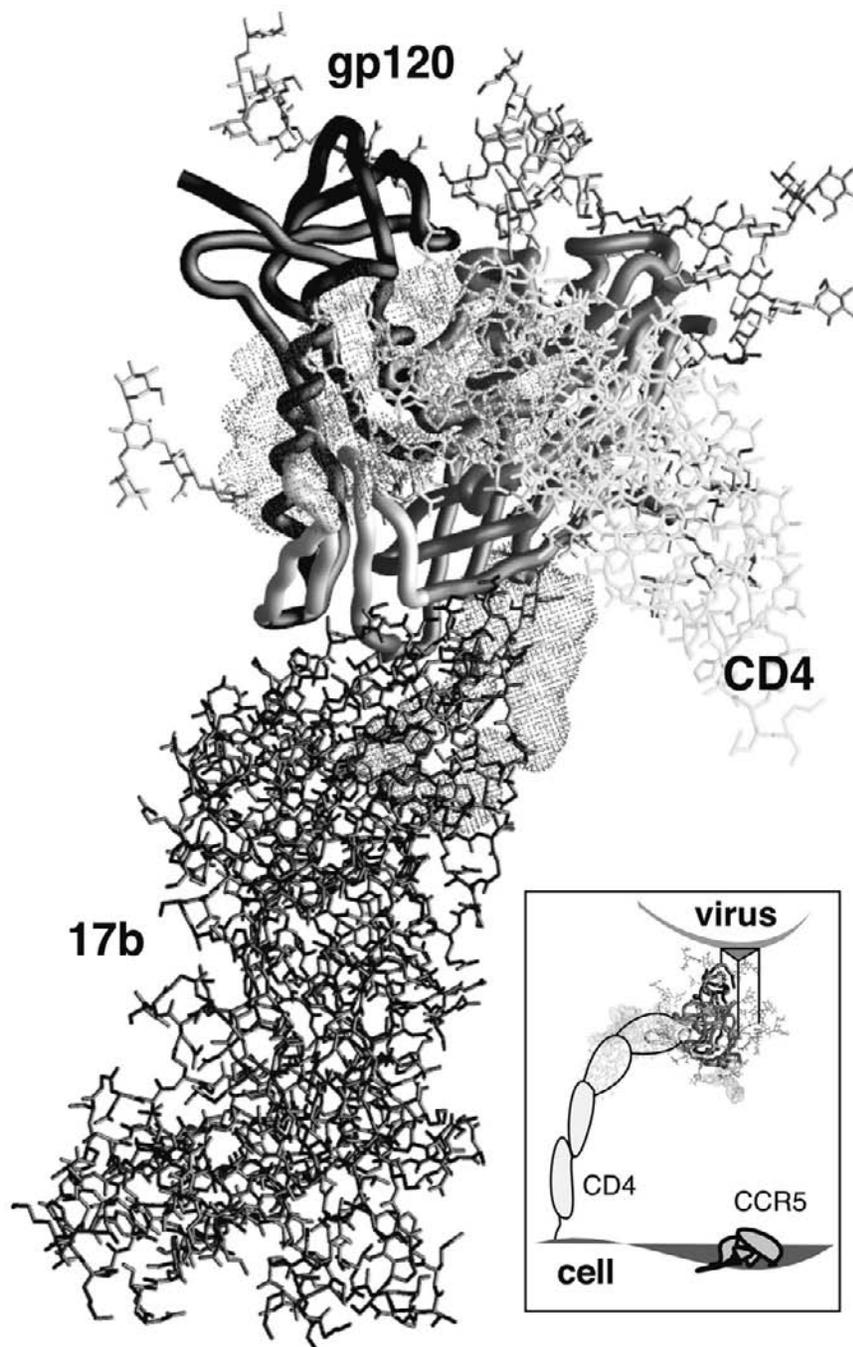

Figure 2 Atomic structure of the ternary complex of core gp120, CD4, and 17b neutralizing antibody. The N-terminal two domains of CD4 are shown in light gray, and the antigen-binding fragment of 17b in dark gray. For the gp120 core of the HXBc2 isolate, a carbon-alpha (Cα) worm representation is shown with inner domain in black, bridging sheet in light gray and outer domain in gray. The protein proximal pentasaccharide for each N-linked glycan is shown in gray all atom representation. The approximate positions of the V1/V2 and V3 variable loops are shown as semi-transparent surfaces. (To aid in orienting the viewer, a small boxed inset is shown which depicts gp120 and CD4 in the context of virus and cell surface, respectively. The orientation of gp120 and CD4 in this insert is related to the larger ribbon/atomic depiction by a 90° rotation about a vertical axis.)

a signal from coreceptor binding at the bridging sheet/V3 loop is transmitted to gp41 to trigger the fusion machinery is unclear. What is clear is that a number of intermediate conformational steps occur, differentiated antigenically and by accessibility

of various neutralizing ligands. While these intermediate structures are currently under investigation, the final fusion-activated, coiled-coil structure of gp41 has been determined at the atomic level by a number of groups (Fig. 1) [20,21].

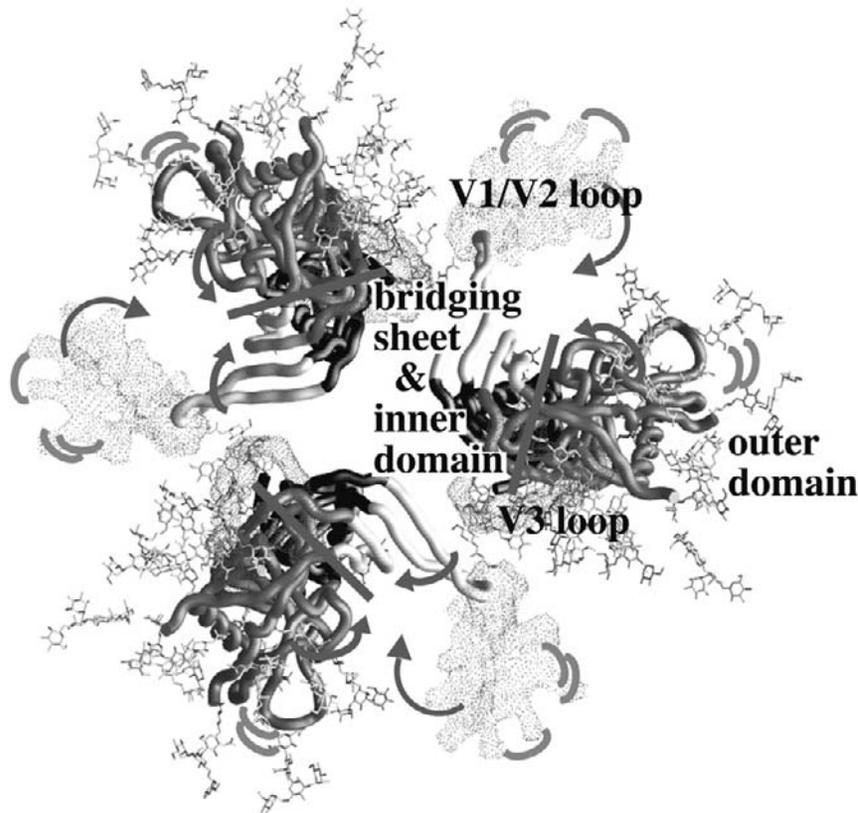

Figure 3 Mechanisms of humoral immune evasion. The trimeric structure of gp120 is depicted in the orientation obtained by optimization of quantifiable surface parameters [26]. The orientation of the right most protomer is related to the orientation of Fig. 2 by a $\sim 90^\circ$ rotation about a horizontal axis. This orientation depicts the trimer from the viewpoint of the target cell membrane. The shading scheme for the core gp120 is the same as in Fig. 2 (black C α worm, inner domain; light gray C α worm, bridging sheet; gray C α worm, outer domain; all atom representation, carbohydrate; and semitransparent surfaces, variable loops). Oligomeric shielding of the inner domain by neighboring protomers is apparent, as is the extensive carbohydrate masking of the outer domain surface. The potential shielding of the CD4 binding site by the V1/V2 variable loop is shown with an arrow. The bridging sheet is not formed until CD4 binds; potential conformational alterations in outer domain and V1/V2 loop are highlighted.

Recognition in the Context of a Humoral Immune Response

An understanding of the parameters governing the HIV-1 receptor interactions would be incomplete without an understanding of the context in which this recognition occurs. While all recognitions pit specific versus non-specific interactions, HIV-1 receptor recognition occurs in the context of a persistent infection. In order to bind to receptor while simultaneously eluding neutralization by the humoral immune system, gp120 has evolved sophisticated strategies of evasion (Fig. 3) [17,22,27].

Three primary mechanisms protect the envelope protein surface not involved in receptor recognition: sequence variation, oligomerization, and carbohydrate masking. The small size of the HIV genome, coupled to high rates of replication error and recombination, facilitates rapid antigenic escape. Oligomerization uses protein–protein interfaces to sterically block access to conserved epitopes. This protects conserved epitopes that are involved in the gp120–gp120 interface as

well as the gp120–gp41 interface. Antibodies directed against these epitopes are usually non-neutralizing and recognize only separate gp120 or gp41 components, not the oligomeric gp120/gp41 viral spike.

Carbohydrate masking involves covering exposed protein surfaces with a dense array of N-linked glycans. Because these glycans are derived from host biochemical pathways, they are interpreted as “self” by the immune system and do not elicit antibodies. In addition, the carbohydrate sterically inhibits access to the underlying protein surfaces. Epitopes protected by carbohydrate masking are thus immunologically “silent.”

In terms of the potentially vulnerable receptor binding surfaces, the virus must recognize receptor, while at the same time eluding an ever-adapting immune response. The surfaces on gp120 that interact with cellular receptors are not only larger than the typical antibody footprint (600 \AA^2), but they also must be functionally conserved and exposed.

HIV-1 receptor surfaces are partially protected by variable loops. These loops have little structural restraint, and sequence variation can occur at a rate roughly 1,000,000 times faster than the human genome [23]. The CD4 binding

site is protected by the V1/V2 variable loop. This loop emanates from the bridging sheet, is approximately 70 amino acids in length, and contains several sites of N-linked glycosylation. Both by steric occlusion and by antigenic variation, the loop shields the CD4 binding site from antibody recognition.

Another highly variable structure, the V3 loop, resides on the other side of the bridging sheet. This loop contains a conserved element at its tip that is required for chemokine receptor binding. The placement of a conserved functionally crucial element amidst a highly variable region allows protection to be conferred by the surrounding antigenic variation. A variation of this anti-“hot spot” mechanism of immune evasion is seen in the CD4 binding site itself. Analysis of a number of tight protein–protein interfaces shows that most have good complementarity of fit, although only a small portion of the binding surface generates most of the binding energy (at an interaction hot spot) [24]. With CD4, the gp120 hot spot of interaction involves residues Phe-43 and Arg-59. The rest of the surface, however, does not show a nice complementarity of fit. A substantial portion of the interactive surface is buffered by a water-filled cavity. Residues on gp120 that contribute to this outer cavity are relatively variable in sequence. Such variation permits gp120 to escape from antibodies directed at the CD4 receptor binding surface. A similar cavity-filled interface is seen in the adenovirus interaction with its receptor, CAR, which like CD4 is a member of the immunoglobulin superfamily [25].

The most conserved exposed surface on gp120 is the bridging sheet, which mutational data show to be part of the chemokine receptor binding surface [19]. HIV hides this surface though another innovative means—conformational change [27]. Thus, this surface is not formed until cellular CD4 induces the appropriate conformational reorganization in gp120. Such conformational masking serves not only to reduce the elicitation of antibodies against the chemokine receptor binding site but also to prevent neutralization. Within the oligomeric viral spike, quaternary interactions oppose the conformational changes induced by CD4. Such opposition decreases the efficiency of both CD4 binding as well as of antibodies against the receptor binding region that require conformational change in order to bind. The degree of opposition is controlled by variable loop elements involved in quaternary contact [16]. Extensive variation within these loops allows this opposition to be modulated. With primary isolates, humoral pressures select the degree of opposition to permit only highly avid binding. Because such avidity is available for cell-surface receptors, but not for most antibodies, conformational masking allows HIV-1 to resist neutralization while simultaneously permitting receptor binding.

Analysis of the HIV-1 receptor interactions illustrates some of the unique features associated with viral receptor recognition. Not only is there the problem of specific binding to receptors, but there is also the complementary problem of avoiding specific recognition by the immune system. Compressed into the 500 amino acids of the HIV-1 gp120

are complex mechanisms of evasion and recognition. HIV-1 receptor recognition thus provides an example of a system driven to an extraordinary level of sophistication by the incredible evolutionary speed of HIV-1 opposed by the equally remarkable adaptive capabilities of the immune system.

Influenza Virus Neuraminidase Inhibitors

Garry Taylor

*Centre for Biomolecular Sciences,
University of St. Andrews, St. Andrews,
Fife, Scotland*

Introduction

Two inhibitors of the influenza virus neuraminidase (NA) are currently licensed as drugs for the treatment of influenza: Relenza[®] (GlaxoSmithKline) and Tamiflu[®] (Roche). Several other companies are developing similar inhibitors. All were developed with the aid of structure-based drug design (SBDD), following elucidation of the X-ray structure of the influenza virus NA in 1983. Here, we will review the development of these compounds which represents one of the successes of SDBB.

Flu Virus: Role of NA

Influenza remains a major cause of mortality and morbidity worldwide. Vaccination affords some protection but must be reformulated each year based on a prediction of the most likely strains circulating in the coming flu season. The antigenic drift and shift characteristic of the virus limits the effectiveness of the vaccine, and some warn of a re-emergence of a catastrophic pandemic strain such as occurred in 1918—the so called Spanish flu [1]. Two antiviral drugs (amantadine and rimantadine) have existed for some time that target the viral ion-channel protein M2 [2], but these are ineffective against the type B influenza virus and cause unwanted side effects. Of the several influenza virus proteins, the surface glycoprotein neuraminidase (NA) has emerged as the most successful target for antiviral development, although other work has been carried out on the hemagglutinin (HA) [3,4] and endonuclease [5].

The influenza virus NA exists as a mushroom-shaped tetramer on the surface of the virus; a typical virus carries around 100 copies of NA and 400 copies of the other surface glycoprotein HA. HA contains domains that recognize sialic acid receptors (Neu5Ac, NANA) (Fig. 1, structure 1), the very sugar that NA hydrolyzes. NA catalyzes the cleavage of the α -ketosidic linkage between sialic acid and the adjacent sugar residue, which lowers membrane viscosity and permits entry of the virus into epithelial cells. NA also destroys the HA receptor on host cells, allowing the emergence of progeny virions from infected cells and presumably also removing sialic acid from the HA and NA of such virions to permit cell-to-cell spread of the virus [6,7]. Inhibitors of NA can therefore reduce this spread of the virus from the site of infection.

The first inhibitors were made in the 1960s through an attempt to understand the catalytic mechanism, which resulted in analogs of 2,3-didehydro-2-deoxy-*N*-acetylneuraminic acid (Neu5Ac2en, DANA) (Fig. 1, structure 2a) [8,9]. These compounds inhibited influenza virus NA with a $K_i \approx 4 \mu M$, as they do most neuraminidases found in nature. Neuraminidases, or sialidases, are found in many pathogenic and nonpathogenic bacteria, where they are largely secreted and provide primarily a nutritional role, although in the case of *Vibrio cholerae*, for example, the enzyme plays a defined role in pathogenesis [10–12]. Animals possess neuraminidases (three are encoded in the human genome) identified by characteristic sequence fingerprints (the so-called bacterial neuraminidase repeats, or BNRs) not found in the viral enzyme [12]. Certain parasites possess the enzyme GPI-linked to their surface, and in the case of *Trypanosoma cruzi* the enzyme

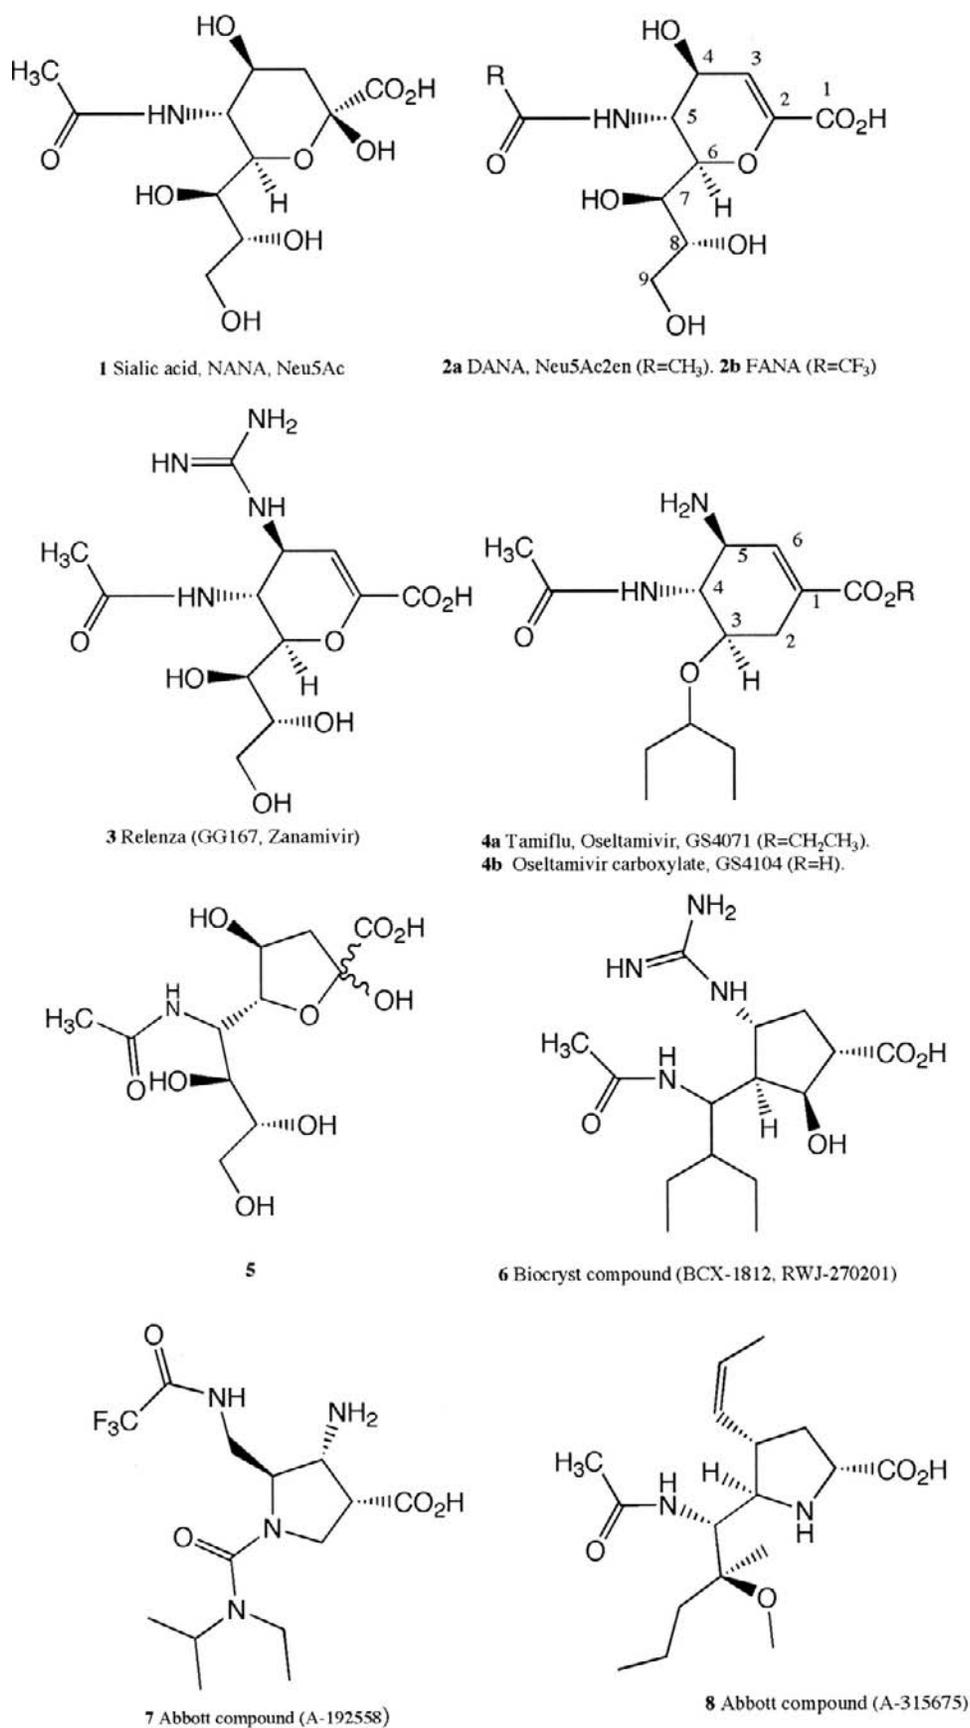

Figure 1 Influenza virus NA ligands.

serves as a more efficient *trans*-sialidase rather than a sialidase [13,14]. Finally, paramyxoviruses possess surface glycoproteins (HNs), which embody the functions of both hemagglutinin and neuraminidase and appear to have a combined, single sialic acid recognition site [15–17]. Any influenza virus inhibitors must therefore avoid inhibiting the endogenous human enzymes which play key roles in modulating cell-surface sialic acid in events from immune response to apoptosis [17,18].

Structure of NA

The tetrameric NA of the influenza virus contains a head of four roughly spherical catalytic domains and a stalk that is anchored in the viral membrane via a hydrophobic N-terminal tail. The crystal structure of the protease-released head region revealed a six-bladed β -propeller structure, and a complex with Neu5Ac2en identified the active site sitting roughly at the center of the propeller (Fig. 2a) [19,20]. There is extensive sequence variation among the various influenza virus NAs, for which nine immunologically distinct subtypes have so far been identified (N1 to N9) for the type A virus, with sequence identities as low as 40%. Even within a subtype, the variation is extensive, as illustrated in Fig. 2b. The residues within and surrounding the active site remain constant, however, and present an Achilles heel of the virus [21].

Active Site

The crystal structure of NA complexed with sialic acid, which is itself a weak inhibitor of influenza NA with a $K_i \approx 1 \text{ mM}$, revealed sialic acid in a strained conformation with its hexose ring in a half-chair rather than a chair conformation (Fig. 3) [22]. Neu5Ac2en represents a transition-state analog, and its interactions with the active site are shown in Fig. 4a. A trifluoroacetyl derivative of Neu5Ac2en, FANA (Fig. 1, structure 2b), was the best inhibitor of the influenza NA for some years, with a $K_i = 0.8 \mu\text{M}$ [9]. Comparison of the several influenza NA structures now available reveal a relatively rigid active site, and so the challenge in inhibitor design has been to exploit the largely immobile features of this site [19,22–24]. The most effective inhibitors that have been developed to date include Relenza[®] (SKB) [25], Tamiflu[®] (Roche), BCX-1812 (Biocryst Pharmaceuticals) [26], and A-315675 (Abbott) [27]. Compound A-192558 from Abbott has been less successful [28], as have derivatives of benzoic acid [29]. Table 1 lists the K_i and IC_{50} of several ligands.

The sialic-acid-binding active site is a deep pocket, mainly acidic in nature, but with a basic side to it (Fig. 3). The four characteristic features of the site are:

1. A basic pocket formed by an arginine triad (Arg118, Arg292, Arg371) that interacts with the carboxylic acid of the ligand; this feature is a key determinant of the

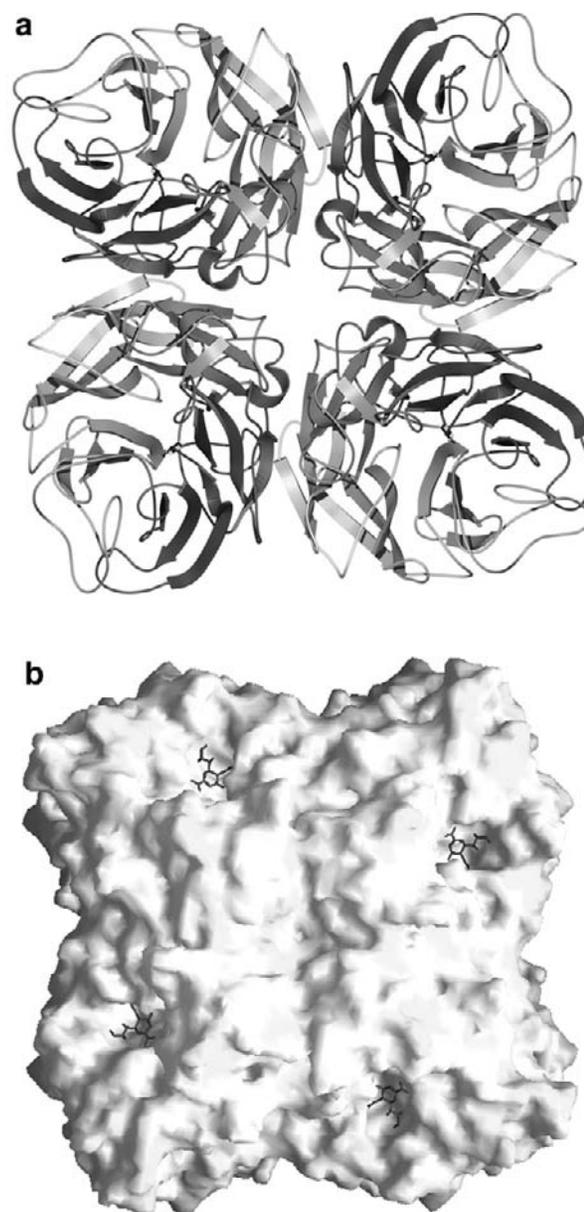

Figure 2 The influenza virus NA. (Top) Schematic drawing of the influenza virus NA tetramer, as if looking down onto the virus surface. Coloring is from blue at the N terminus to red at the C terminus. (Bottom) Surface representation of the same tetramer, showing the location of Neu5Ac2en bound in the active site. The yellow coloring shows amino acids that vary within the N8 subtype, revealing the antigenic drift that the virus undergoes.

binding, and all inhibitors developed to date preserve the carboxyl moiety.

2. An acidic pocket formed by glutamates (Glu276, Glu277); Glu277 forms a strong H-bond with Tyr406, and together these residues are thought to stabilize an oxocarbenium ion intermediate in the reaction [30,31]. Glu276 interacts with O8 and O9 of the glycerol moiety of sialic acid and Neu5Ac2en, and Relenza preserves this interaction. Other inhibitors have placed a hydrophobic moiety at this position to improve the lipophilicity of the compounds, which

Table I Inhibition Parameters for Ligands of Influenza Virus Neuraminidase

	Influenza A Virus		Influenza B Virus		Refs.
	K_i	IC_{50}	K_i	IC_{50}	
Sialic acid	1 mM	—	1 mM	—	9
DANA	4 μ M	0.015 mM	4 μ M	0.015 mM	9
FANA	0.8 μ M	—	20 μ M	—	9
Relenza	0.06–1.3 nM	0.3–2.3 nM	0.09–0.27 nM	1.5–17 nM	46
Tamiflu	0.10–1.3 nM	0.01–2.2 nM	1.1–2.1 nM	5.0–10.4 nM	49
BCX-1812	0.014–1.1 nM	0.1–1.4 nM	0.21–0.96 nM	0.6–11 nM	46
A-192558	—	0.28 μ M	—	8 μ M	27
A-315675	0.024–0.21 nM	0.4–5.9 nM	0.14–0.31 nM	6.7–14.1 nM	49

- subsequent crystal complexes have shown are accommodated by a movement of Glu276 to extend a hydrophobic pocket.
3. A hydrophobic pocket formed by Trp178, Ile222, and the methylene elements of the side chains of Arg152 and Arg224, all residues that are conserved across influenza viruses. This pocket accommodates the methyl group of the acetamido moiety of sialic acid and Neu5Ac2en. The oxygen of the acetamido group hydrogen bonds to the guanidinium group of Arg152, and the acetamido nitrogen hydrogen bonds to a buried water molecule, which in turn interacts with Glu276 and Glu227. Most inhibitors have preserved the acetamido group or a trifluoroacetamido group, such as in FANA and the Abbott A-192558 compound.
 4. An acidic pocket formed from Glu119, Glu227, and Asp151, the latter residue being most likely to be involved in hydrolysis via a water molecule [30]. The two glutamates are conserved, yet play no obvious role in substrate binding or hydrolysis. The O4 hydroxyl of sialic acid and Neu5Ac2en does not hydrogen bond to any of these residues as there is a large cavity around this position. Most successful inhibitors have an amino or guanidino group substituted at this position, except for the Abbott A-315675 compound.

for an NH_3^+ group with a calculated binding energy of -16 kcal/mol in the vicinity of the position normally occupied by the O4 hydroxyl of sialic acid [33]. Using Neu5Ac2en as the scaffold, substitution of O4 with an amino group gained two orders of magnitude of binding over Neu5Ac2en, whereas substitution by a guanidino group (4-guanidino-Neu5Ac2en, Relenza) (Fig. 1, structure 3) gained five orders of magnitude of binding over Neu5Ac2en [33]. In complexes of Relenza with both influenza A [34] (Fig. 4b) and influenza B [35] virus NA (PDB codes 1NNC and 1A4G, respectively), the guanidino group interacts almost ideally with Asp151 and Glu227. Glu119 is also close enough to make a charge-charge interaction, although one study suggests that Glu119 may be neutral in the case of 4-amino-Neu5Ac2en binding [36]. Relenza-resistant mutants have been isolated *in vitro*, with mutations mainly in Glu119 [37–39], and, in one case, one of the catalytic arginines, Arg292 [40]. A resistant mutant has also been isolated *in vivo*, with the mutation of Arg152 \rightarrow Lys [41]. Relenza is a successful inhibitor of influenza A and B virus NA, but its highly polar nature (calculated $\log P$ of -7) has necessitated administration as a powder, requiring an inhaler with all the inherent problems of such use. Replacement of the glycerol group of Relenza by a series of hydrophobic dihydropyranboxamides have provided inhibitors with a binding affinity similar to Relenza for influenza A NA, but with only micromolar inhibition of influenza B NA [35].

Inhibitor Development

Relenza

Relenza was developed through the use of the program GRID [32], which revealed a potentially strong binding site

Tamiflu

The starting point for the development of Tamiflu was replacement of the dihydropyran ring with a cyclohexene, which is chemically more stable and retains the ability to

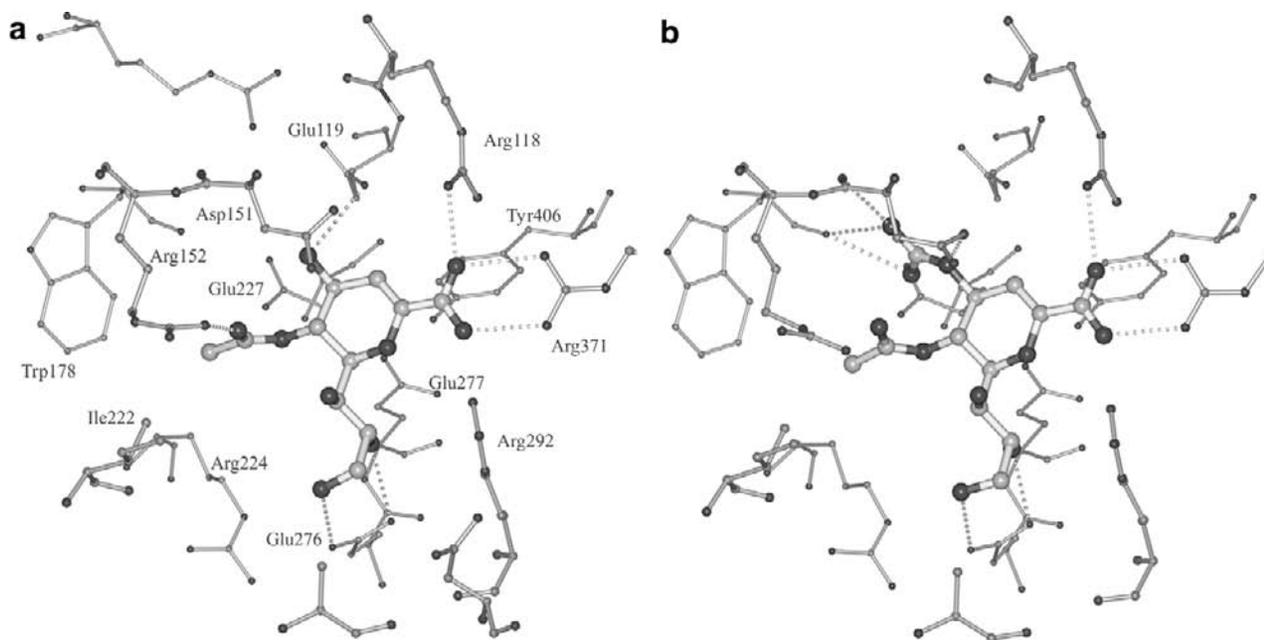

Figure 4 Interactions of the ligands with the active site of the tern N9 influenza virus NA: (a) Neu5Ac2en (PDB code 1F8B); (b) Relenza (PDB code 1NNC); (c) Tamiflu (PDB code 2QWK); and (d) BCX-1812. (e) Stereo view of a superposition of all four ligands reveals a rigid active site with only Glu276 altering position. Neu5Ac2en complex is yellow, Relenza complex is magenta, Tamiflu complex is cyan, and the BCX-1812 complex is green.

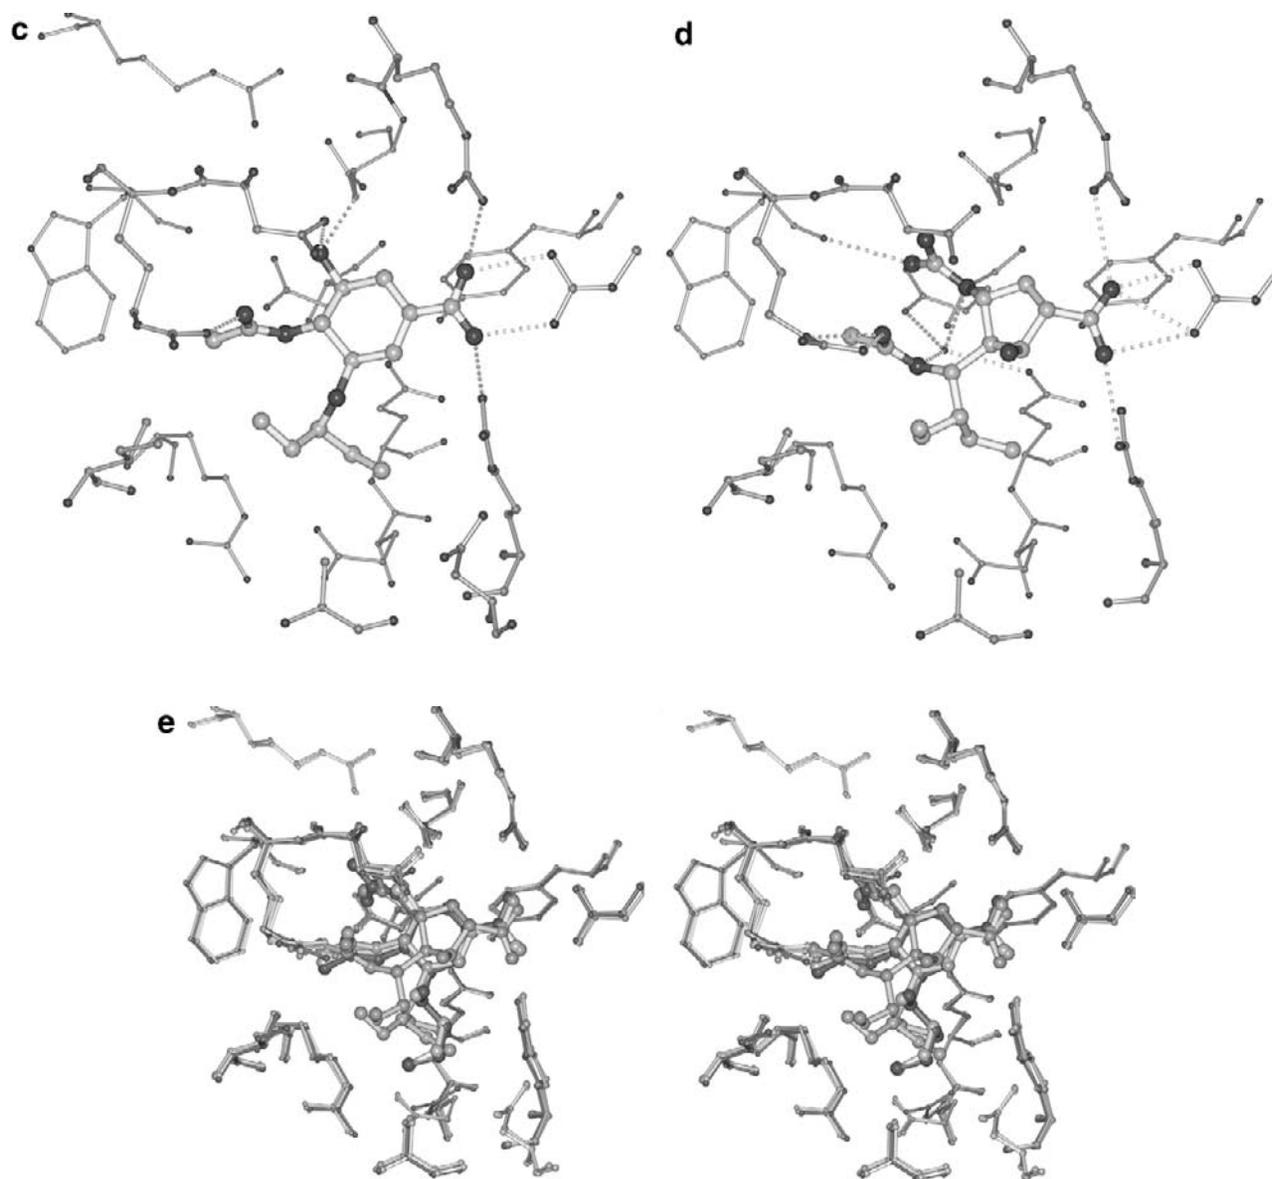

Figure 4 (Continued)

alter the stereochemistry of ring substituents [42]. The best inhibition was obtained with the double bond in the position equivalent to that in Neu5Ac2en, mimicking the carbonium cation intermediate. The carboxylate and acetamido groups were kept at C₁ and C₄, respectively, and an amino group at C₅ in light of the success of the Relenza development. In order to improve the lipophilicity, the glycerol group was substituted by a series of alkyl ethers. There is a remarkable correlation between the length, geometry, and rigidity of the alkyl chains and NA inhibitory activity, suggesting an incremental entropy gain. The crystal structure of the best inhibitor, with a 3-pentyl group (GS4071, later named Tamiflu carboxylate) (Fig. 1, structure 4a), showed that Glu276 is rotated away from the active site to extend the hydrophobic pocket (Fig. 4c). The prodrug of GS4071, an ethyl ester derivative (GS4104, Oseltamivir, Tamiflu) (Fig. 1, structure 2a; Fig. 4b) exhibits good oral efficacy [43].

Biocryst Compound (BCX-1812)

The starting point for the development of BCX-1812 was a furanose-based compound (Fig. 1, structure 5) that had the same ring substituents as sialic acid and Neu5Ac2en and inhibited influenza virus NA with a potency similar to Neu5Ac2en [44]. The structure of a complex of (Fig. 1, structure 5) with N9 influenza NA (Fig. 4d) showed that, although the furanose ring is significantly displaced compared to the pyranose ring of DANA, all of the ring substituents have very similar interactions with the enzyme. This reflects a feature of the active site, namely that there is little interaction with the ring itself. Consequently, a cyclopentane ring was chosen as the scaffold for chemical stability, with a carboxylic acid group placed at C₁. An interesting route in the development was the synthesis of racemic mixtures with a guanadino group at C₄ and an *n*-butyl at C₁, followed by inspection of the high-resolution difference electron density maps to ascertain the

stereochemistry of the active isomer [26]. The *n*-butyl chain bound in two different modes in influenza A and B virus NA, reflecting the slightly different environments around the sialic acid glycerol binding pocket in the two enzymes. Again, Glu 276 moves, and in influenza A NA forms a salt bridge with Arg224 as had been observed in the binding of GS4071 [35]. In order to take advantage of both hydrophobic pockets, BCX-1812 (Fig. 1, structure 6) was developed, again as a racemic mixture, and the active isomer identified crystallographically. An interesting feature of BCX-1812 (Fig. 4d) is that the orientation of the guanidino group in the active site is different from that seen for Relenza (Fig. 4b). This may be why BCX-1812 remains effective against a Relenza-resistant mutant (Glu119→Gly) [45], as is also true for Tamiflu, which has only an amino group at this position. BCX-1812 shows great promise as an oral treatment for influenza [46–48].

Abbott Compounds

Abbott published a series of inhibitors based on a pyrrolidine core, the best of which (A-192558) (Fig. 1, structure 7) had an IC₅₀ of 0.28 μM against influenza A NA [28,49]. One feature of the development of these inhibitors was the creation of focused combinatorial libraries by automated solid-phase synthesis, in one case containing 550 analogs [28]. Recently, a new compound with K_i of between 0.024 and 0.31 nM against a range of influenza virus NAs has been reported [27]. This compound, A-315675 (Fig. 1, structure 8), retains the carboxyl and acetamido groups, but does not have an amino or guanidino group. No details are available as to how this compound binds in the active site, but it is reported that only Glu276 moves in the active site upon binding, as in other complexes of other inhibitors with a hydrophobic moiety in place of the glycerol group [27].

Conclusion

The development of effective nanomolar-binding inhibitors of the influenza virus NA is one of the success stories of structure-based drug design. The active site is remarkably rigid (Fig. 4e), except for one conserved glutamic acid, Glu276, which is free to rotate 90° about χ₂. This creates an extensive hydrophobic pocket in a region normally occupied by the glycerol group of the natural substrate. The most successful inhibitors have exploited this pocket to provide molecules with greater lipophilicity and hence bioavailability so they can be given in tablet form. Analysis of successful influenza virus NA inhibitors reveals the following observations:

1. Interaction with all four sites is required.
2. A scaffold that allows stereoselectivity is essential.
3. The nature of the scaffold is less important, but carbocyclic rings give greater chemical stability.
4. Replacement of the glycerol moiety with a hydrophobic group increases bioavailability.

5. Crystallography is a powerful tool for selecting active isomers for racemic mixtures, as was used in the development of BCX-1812.
6. Focused, diversity-oriented synthesis of side groups has been of some use, especially in conjunction with structural analysis.

An interesting spinoff has been a series of studies that have aimed at predicting binding affinities for inhibitors of the influenza virus NA [36,50,51]. Although these studies obtain good correlation between predicted and observed affinities, their predictive value in developing new inhibitors is unclear.

A disappointing postlude to the story is that, although we now have effective drugs for the control of influenza, their use so far has not been a great success in the clinic. A major problem is that, to be effective, the drugs must be taken within 48 hours of patients showing flu-like symptoms. Unlike Relenza, Tamiflu is also licensed as a prophylactic to stop the spread of the virus within families and close communities and it appears to be preferentially prescribed at this time.

Acknowledgments

I thank Dr. Y. S. Babu of Biocryst Pharmaceuticals for providing the coordinates of the BCX-1812 complex.

Signal Transduction and Integral Membrane Proteins

Geoffrey Chang and Christopher B. Roth

*Department of Molecular Biology,
The Scripps Research Institute, La Jolla, California*

Introduction

Cells need to adapt their behavior continuously in response to a barrage of external stimuli. Integral membrane proteins are the best positioned to interact with outside stimuli and are, therefore, critical components of signal transduction. Ion channels, transporters, and receptors are integral membrane proteins that can mediate signaling across the cellular membrane. The availability of detailed structural information on these proteins has been limited by technical challenges unique to the high-resolution structure determination of membrane proteins by X-ray crystallography. In recent years, however, the X-ray structures of a few of these important proteins have been solved, providing insight into the molecular structural basis of signal transduction across the cell membrane.

Electrophysiology: Rapid Signal Transduction

Ion channels are the fundamental electrical signaling units of neurobiology. As molecular transducers, ion channels are highly sensitive (detectable gating thresholds as low as thermal noise), extremely efficient (ion transport rates up to 10^{-7} ions/sec), and very responsive (microsecond turn-on times). They are essential components of the cellular response to external stimuli and are directly responsible for the transmission of all electrical signaling events for multicellular organisms. For more than 50 years, biophysicists have used sophisticated patch clamping experiments and site-directed mutagenesis to understand the function of ion channels with exquisite detail. A major breakthrough in understanding the wealth of ion channel biochemical data began with the recent

X-ray crystal structures of the K^+ ion channel KcsA from *Streptomyces lividans* [2,10] and a pair of CLC ion channel homologs from *Escherichia coli* (EcCLC) and *Salmonella typhimurium* (StCLC) [3]. These X-ray structures have provided the first clues for the molecular structural basis for the transport of ions involved in the transmission of electrical signals.

The KcsA structure reveals a pore region that is similar in protein sequence to all known K^+ ion channels. The KcsA is arranged as a tetramer of identical subunits creating a cone-shaped structure with the pore selectivity filter on the outer membrane leaflet side. A large water-filled cavity with helix dipoles located on the outer membrane side is uniquely positioned to overcome the electrostatic destabilization energy of a K^+ ion at the center of the bilayer. Selectivity is accomplished by main-chain carbonyl oxygen atoms of the K^+ ion channel signature sequence. The general architecture of KcsA establishes the structural basis underlying the selectivity of K^+ conduction. In contrast to KcsA, the CLC chloride channel overcomes the energetic barrier of ion transport by a different mechanism. The bacterial chloride ion channel is homodimeric in structure, with the selectivity filter formed within each monomer by two opposed membrane-spanning subunits. This anti-parallel arrangement defines a selectivity filter in which chloride ions are stabilized by electrostatic interactions with α -helix dipoles and coordination bonding.

Mechanosensation: How Do We Feel?

What is the molecular basis by which we sense touch? Mechanosensitive (MS) ion channels present an elegant

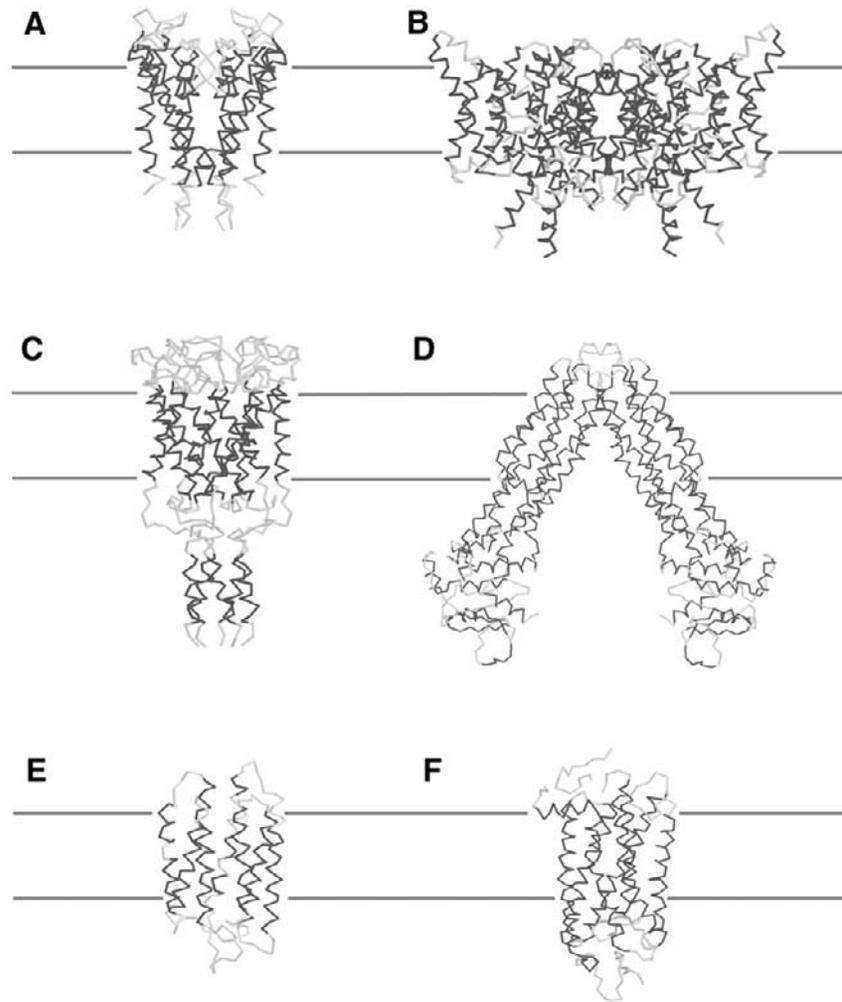

Figure 1 Structure of integral membrane proteins involved in signal transduction. (A) KcsA potassium ion channel structure [2]; (B) chloride CLC ion channel [3]; (C) mechanosensitive ion channel of large conductance (MscL [1]); (D) MsbA multidrug ABC transporter homolog [1], (E) bacteriorhodopsin [6]; and (F) bovine rhodopsin [5]. The α -helices and β -sheets are colored in red and yellow, respectively. The membrane-spanning portion of the molecule is indicated with green lines.

solution to the need for a rapid signaling response to external physical stimuli. MS channels are classified by their ability to alter their opening probability in response to lateral tension in the lipid bilayer. In bacteria, mechanosensitive ion channels help microbes react to hypoosmotic stress by allowing them to expel cytoplasmic solutes such as ions and small molecules into the surrounding medium. The crystal structure of the mechanosensitive ion channel from *Mycobacterium tuberculosis* (TB-MscL) gives some clues as to the structural basis of the cellular response to lateral tension in the lipid bilayer resulting from increased osmotic pressure [1]. TB-MscL is arranged as a homopentamer of 15-kDa subunits. The membrane-spanning domain of the channel consists of ten transmembrane α -helices that are significantly tilted relative to the normal of the cell membrane. The cytoplasmic domain consists of a helix bundle and is likely to be disrupted upon channel opening. MS channels of the MscL family have large conductances on the order of approximately 2.5 nS [8].

Upon channel opening, MscL is thought to form a large pore through the cell membrane with an opening of at least 10 Å.

Some unique features of the TB-MscL structure suggest a general mechanism for channel gating in response to lateral tension in the bilayer. First, the gate or “plug” of TB-MscL is located on the inner membrane leaflet side of the cell membrane. Second, there is a cluster of bulky hydrophobic residues positioned to interact directly with neighboring lipid molecules of the inner membrane leaflet. And, finally, the experimentally determined electron density maps have revealed highly ordered lipid/detergent near these bulky residues, suggesting a strong interaction with lipids of the inner membrane leaflet. These features of TB-MscL suggest that structural changes due to lateral tension could be directly transmitted to the transmembrane α -helices via bound lipid. Rearrangement of the transmembrane α -helices causes the plug to pull apart, allowing ion conduction and enabling bacteria to respond rapidly to changing tonicity.

Active Transporters: Rapid Response and Energy Management

When a cell encounters a new environment, a rapid response is required to take advantage of nutrients in the surrounding media. If useful substrates such as sugars, amino acids, and ions are in relatively low concentration, then highly regulated and efficient transport systems must be activated to uptake substrates through their cell membranes. Likewise, if cells encounter toxins such as antibiotics or anti-cancer drugs, they must be quickly transported out of the cell. Both types of transport are accomplished by a diverse array of energy-dependent pumps located in the cell membrane. The active transport systems of the cell membrane are critical for a rapid cellular response, and cells devote a significant portion of their resources to the maintenance of transporters on the cell surface. For example, transport proteins comprise nearly 5% of the genes encoded in the *E. coli* genome, and nearly half of these transporters belong to the ATP-binding cassette (ABC) transporter super family. ABC transporters are highly conserved from bacteria to human and contain a highly conserved nucleotide binding domain (NBD) that binds and catalyzes the hydrolysis of ATP. ABC transporters are thought to translocate substrate by coupling the energy derived from ATP hydrolysis to structural rearrangements in the portion of the molecule spanning the cell membrane. ABC transporters are involved in the import and export of a wide variety of substrates, including amino acids, peptides, sugars, ions, lipids, and hydrophobic drug molecules. Several ABC members of the multidrug resistance ABC (MDR-ABC) transporter group severely reduce the effectiveness of chemotherapeutics and antibiotics, leading to a failure of treatments for cancer and infectious diseases. The X-ray structure of the MDR-ABC transporter homolog MsbA from *E. coli* sheds light on this type of substrate transport [1].

MsbA is a dimer (≈ 129 kDa) of two identical peptides, each containing a transmembrane domain of six membrane-spanning α -helices and a nucleotide binding domain that hydrolyzes ATP. In the course of the X-ray structure determination, a third domain has been identified that bridges the transmembrane domain and the NBD. This domain is well positioned to scan the head groups of various lipids and could serve as a trigger for initiating the ATP hydrolysis. A prominent feature of Eco-MsbA is a large opening facing the inner membrane leaflet side of the cell membrane. This opening leads into a large chamber that has a polar interior. Structural changes caused by the recruitment of lipid A molecules into the chamber triggers ATP hydrolysis by the NBD. Energy derived from this process closes the chamber, producing a microenvironment that is unfavorable for hydrophobic substrates in the inner membrane leaflet side. At this point, the substrate flips to the energetically more favorable position in the outer leaflet side of the chamber and is then expelled into the outer leaflet of the bilayer. The structure of Eco-MsbA provides a structural basis for the

transport of lipids and a wide variety of hydrophobic cytotoxins across the cell membrane.

Although the structure of MsbA provided the first glimpse of an ABC exporter, the structural basis of transport in the opposite direction across the membrane has, until recently, remained a mystery. Impressive work done by Rees and colleagues [4] has resulted in the first structure of an ABC importer, the vitamin B₁₂ transporter BtuCD. The structure reveals for the first time an ABC transporter with direct contact between the nucleotide-binding domains and in a manner reminiscent of the popular Rad50 ABC dimer. Contact between the nucleotide binding domains could explain the observed cooperative kinetics of ATP hydrolysis during the transport cycle. In addition, the precise point of contact between the ABC cassette and the membrane-spanning domain is seen, providing insight into the coupling of ATP hydrolysis to substrate transport. Generally, most members of the ABC transporter family have been predicted to contain 12 transmembrane segments, as is the case with MsbA. BtuCD is unusual in that it was found to have an astonishing 20 transmembrane helices. One explanation offered for such a dramatic departure from the canonical view could be that a common core structure of membrane-spanning subunits exists, while the surrounding helices vary according to function. The BtuCD structure represents yet another milestone in the understanding of ABC transporter mechanics and provides the first structural evidence that supports the idea of catalytic cooperativity between the ABC cassettes during the transport cycle.

Receptors: Gate Keepers for Cell Signaling

The classic paradigms for signal transduction across the cell membrane are the membrane-bound receptors. Crystal structures of a bacterial ion channels and transporters have been elucidated, and the next frontiers of membrane protein structural biology will likely focus on smaller mammalian targets. One of the most widely studied families of receptors is the G-protein-coupled receptors (GPCRs). GPCRs are not only fascinating from a scientific standpoint but are also pharmaceutically important drug targets. Nearly 60% of all the drugs on the market target GPCRs. All GPCRs are predicted to have seven membrane-spanning α -helices with a NH₂-terminal domain that binds ligand (such as a hormone) and a c-terminal cytoplasmic domain that binds and activates a specific G protein. How does a ligand/drug molecule on the outside of the cell membrane transmit a signal across the cell membrane to initiate a cascade of signals via a cytoplasmic G protein? The answer to this question will surely require a detailed molecular structure. Some initial clues about GPCR function might be derived from the structures of the light-transducing bacteriorhodopsin [6] and bovine rhodopsin [5].

Bacteriorhodopsin is a photon-driven ion pump that shares the same putative 7-TM membrane-spanning topology

as GPCRs. In the bacterium *Halobacterium salinarium*, bacteriorhodopsin converts light energy to a proton gradient that is, in turn, used by the membrane-bound ATP synthase. The process of converting light to useful energy is remarkably efficient, with quantum yields of greater than 60%. Similarly, bovine rhodopsin, which is a member of the GPCR family, is a photoreceptor protein found in the rod cells of vertebrates and is responsible for vision in low light. In both molecules, the conversion of light energy is accomplished by a retinal chromophore called 11-*cis*-retinal, which is a derivative of vitamin A and is covalently linked via a Schiff base bound to the membrane-spanning portion of the molecule. Upon photoisomerization of the chromophore, several intermediates are formed, and an all-*trans* chromophore is generated. This conversion leads to the activation of phosphodiesterase and the closing of cyclic-GMP-gated cationic channels. The resulting hyperpolarization of the channels is transmitted through the photoreceptor cell to the synapsed nerve cells of the optic fiber.

Most classes of GPCRs, although similar to rhodopsin, have a more extensive NH₂-terminal domain that binds ligand. The structures of the NH₂ domains of the Methuselah GPCR from *Drosophila* [9] and the Cholecystokinin-8 receptor have been determined [7]. However, the molecular structural basis of how these NH₂ domains interact with the membrane-spanning portion of the molecule to achieve signal transduction signal is unknown. In addition, the binding and activation interactions between receptors and the G proteins still remains a mystery. The answer to these questions will require molecular detail that can only be provided by a high-resolution structure of a complete GPCR/G-protein complex.

Structural Basis of Signaling Events Involving Fibrinogen and Fibrin

Russell F. Doolittle

*Center for Molecular Genetics,
University of California, San Diego, La Jolla, California*

Fibrinogen is an extracellular protein found in significant concentrations in the blood plasmas of all vertebrate animals. It is a large, multi-domained protein, some portions of which share common ancestry with lectins and other cytotactic proteins found throughout the animal kingdom [1]. Although the principal role of fibrinogen has to do with its polymerization into fibrin clots, the protein also interacts with a number of other extracellular proteins, blood platelets, and a variety of cells. Directly or indirectly, the fibrinogen–fibrin system is involved in hemostasis, inflammation, wound healing, and angiogenesis. Fibrinogen also interacts with various bacteria, especially certain strains of *Staphylococcus*.

Fibrinogen is a covalent dimer composed of two sets of three nonidentical chains ($\alpha_2\beta_2\gamma_2$). The β and γ chains are homologous over their full lengths, but the α chain homology is limited to its amino-terminal third. The molecular weights of vertebrate fibrinogens range from 320,000 to 400,000, the variation invariably being due to differences in the α chains, the carboxyl terminal two-thirds of which are extremely variable from species to species. In contrast, the carboxyl-terminal halves of the β and γ chains are globular and conserved. Together, they constitute bi-lobed macro domains at the extremities of the extended molecule, being connected to a small central domain by three-strands coiled coils made up of all three chains (Fig. 1).

Several regions of the fibrinogen molecule are highly mobile and are not resolvable in crystallographic electron density maps, even at moderately high resolution [2]. The flexible parts include the entire α -chain carboxyl region, which can contain from 300 to 500 amino acid residues, depending on the species (region I in Fig. 1). Additionally, the last 15 residues at the carboxyl terminus of the γ chain have not been pinned

down with any precision [3,4], nor have the amino-terminal segments corresponding to approximately the first 30 residues of the α chain and the first 60 of the β chain (numbering varies slightly from species to species; the numbering here is based on human fibrinogen). Several of these mobile regions figure prominently in interactions with other proteins and with cells.

Apart from the mobile and highly variable carboxyl-terminal domains of the α chains, the general framework of all vertebrate fibrinogens is highly conserved, as evidenced by the ready superposition of the chicken fibrinogen crystal structure on that of a modified bovine fibrinogen [5,6]. The length of the protein is about 45 nm.

The conversion of fibrinogen to fibrin is initiated by thrombin-removing short peptide regions, called *fibrinopeptides*, from the amino-terminal ends of the α and β chains. The consequence of these narrowly specific proteolytic events is the exposure of sets of A and B “knobs” on the α and β chains, respectively, that fit into holes on the terminal globular domains of neighboring fibrinogen molecules. The initial knob-hole interactions position a pair of A knobs (Gly–Pro–Arg is the sequence at the newly exposed α -chain site, residues 17–19) so as to pin together two neighboring molecules by fitting into holes on their γ -chain carboxyl domains. Further propagation results in a noncovalently associated, two-molecule-thick, half-staggered protofibril. Interactions involving the B knob (Gly–His–Arg is the sequence at the newly exposed β -chain site) can fill holes in the β -chain carboxyl domains and, directly or indirectly, lead to lateral growth of the fibrin network. Meanwhile, thrombin-activated factor XIII reinforces the fibrin polymer by introducing γ -glutamyl- ϵ -amino crosslinks, initially between the

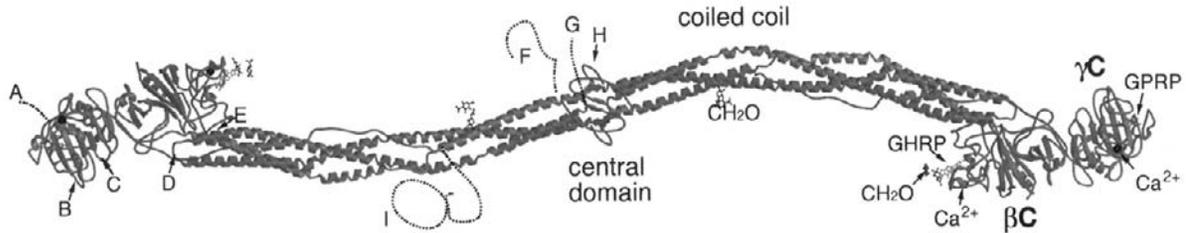

Figure 1 Ribbon model of those portions of fibrinogen for which high-resolution X-ray structures are available. Highly mobile regions of the molecule are not shown fully (broken lines), including the carboxyl-terminal domain of α chains (I) and the last 15 residues of γ chains (A), as well as the amino-terminal segments of α and β chains (G, F). The molecule is a covalent dimer with a pseudo-axis of symmetry running through the central domain. Key structural features are labeled on the right half, and some reported recognition sites are designated on the left half. A, γ -chain carboxyl terminal (platelets, fibroblasts, staphylococcal clumping factors); B, γ -chain 383–395 (α M β 2); C, γ -chain 195–202 (α M β 2); D, γ -chain 117–133 (ICAM-1); E, α -chain 151–158 (t-PA stimulator); F, β -chain 15–42 (angiogenesis, heparin-binding); G, α -chain 17–20 (α M β 2); H, α -chain 15–44 and β -chain 61–72 (thrombin); I, α -chain 240–610 (α M β 2). (Adapted from Yang, Z. *et al.*, *Biochemistry*, 40, 12515–12523, 2001.)

carboxyl-terminal segments of abutting γ chains, but eventually also between carboxyl domains of α chains.

Fibrin can be distinguished from fibrinogen by many recognition systems. Quite apart from sites lost with the removal of the fibrinopeptides and the coincident appearance of the A and B knobs, the mere act of polymerization can mask certain sites. Additionally, conformational changes occur, some of which have been observed in crystal structures of fibrin(ogen) fragments complexed with synthetic knobs [7]. Other more subtle changes may occur during the later stages of polymerization. For example, there is a region of the α chain that has been implicated in the stimulation of tissue plasminogen activator [8] that is wholly inaccessible to solvent in fibrinogen but which somehow becomes accessible as a result of the polymerization process.

Over the years, there have been numerous reports describing regions of fibrinogen or fibrin responsible for binding various macromolecules or cells. The availability of X-ray structures now provides a backdrop for visualizing some of these at atomic resolution (Fig. 1). Among the cells and particles known to bind fibrin(ogen) are platelets, endothelial cells, monocytes, lymphocytes, neutrophils, and fibroblasts, all of which are actively involved in hemostasis, wound healing, inflammation, or angiogenesis. For the most part, studies have utilized fragments of fibrin(ogen), antibodies directed against localized features, site-directed mutagenesis of recombinant fibrinogens, or synthetic peptides corresponding to specific regions.

Some parts of fibrinogen have been implicated in several different events. The carboxyl-terminal segments of γ chains bind platelets [9] and fibroblasts [10]; the same sites bind to certain strains of *Staphylococcus aureus* [11]. The locations of these sites at the tips of the dimeric fibrinogen molecule are well disposed for bridging and clumping cells or platelets. The crosslinking of these segments in fibrin by factor XIII must render the sites inaccessible. Similarly, certain regions of the α -chain carboxyl domain have been implicated in binding to platelets and various leucocytes, and these must also be compromised by becoming crosslinked in the final stages of clot formation.

The flexible amino-terminal segment of the β chain is another targeted region. The bacterium *Staphylococcal epidermis* binds to a peptide segment that includes a bond cleaved by thrombin [12]. Other entities bind in the region of β -chain residues 15 to 42, exposed after thrombin attack, including certain cadherins [13] and heparin [14]. Angiogenesis is also stimulated by this general region [15].

In the main, two kinds of cell surface proteins have been associated with fibrinogen binding: (a) members of the immunoglobulin family such as cadherins [13] and ICAM-1 [16], and (b) heterodimeric integrins. The most commonly implicated integrins are α M β 2 and α χ β 2 [17]. Some findings about the sites of interaction remain uncertain in that the same integrins have been reported to interact with widely differing regions of the fibrinogen molecule for which there are no apparent structural similarities. Final resolution may have to await crystal structures of complexes of fibrin(ogen) fragments with specific integrins or other interactants.

Structural Basis of Integrin Signaling

Robert C. Liddington

Program on Cell Adhesion, The Burnham Institute, La Jolla, California

Introduction

The integrins are a family of proteins that reside in the plasma membrane of most cells of multicellular organisms [1]. They are the primary receptors that recognize the protein components of the extracellular matrix (ECM). Binding to the ECM triggers intracellular signaling pathways that regulate adhesion, migration, growth, and survival [2]. These pathways often intersect with those generated by receptors for soluble factors [3]. However, integrins differ from “classical” signaling receptors in a number of ways. First, because the ECM is static and polyvalent, integrins cluster at the sites of attachment. Second, ligand-bound integrins form connections with the cytoskeleton that regulate cell shape and rigidity, as well as providing platforms for signaling complexes. Third, integrins can also transmit signals from the inside of the cell to the outside. Thus, integrin signaling is a bidirectional process that evolves rapidly in time and space as the cell adapts to its environment, allowing integrins to be sensors and messengers of the surroundings and shape of the cell, as well as the mechanical forces acting upon it [2].

Integrin signaling typically involves conformational changes within the integrin molecule that are propagated across the plasma membrane. Under some circumstances, lateral self-association of integrins (“clustering”) is sufficient for signaling [4,5], and a number of molecules that associate laterally with integrins have also been identified that contribute to signaling [6]. However, the focus of this section is on the conformational changes within individual molecules that control the recognition of extracellular and intracellular binding partners.

Structure

Integrins are $\alpha\beta$ heterodimers, consisting of a head domain from which emerge two legs, one from each subunit, ending in a pair of single-pass transmembrane helices and short cytoplasmic tails (Fig. 1). In the absence of ligand, bonds between the legs and tails are believed to hold the head in an inactive or resting conformation that has low affinity for ligand [7,8]. During outside-in signaling, ECM binding to the head triggers conformational changes that are propagated down the legs and through the plasma membrane, leading to a reorganization of the C-terminal tails that allows them to bind intracellular proteins [3]. During inside-out signaling, cytosolic proteins bind and sequester one or both of the cytoplasmic tails, triggering conformational changes in the head that lead to a high-affinity active integrin.

The integrin “head” is composed of a seven-bladed propeller from the α -subunit that makes an intimate contact with a GTP-ase-like domain of the β -subunit (called either an A or I domain by different authors, and I domain here), in a manner that strongly resembles the heterotrimeric G proteins [9]. Instead of a catalytic center, the I domain contains an invariant ligand binding site called MIDAS (metal ion-dependent adhesion site), in which a metal ion is coordinated by three loops from the I domain, and a glutamic or aspartic acid from the ligand completes an octahedral coordination sphere around the metal. Specificity is provided by ligand contacts to the surface surrounding the MIDAS, which is highly variable among integrin family members, and in some cases by additional contact to the α -subunit propeller. A helix that emanates from one of the MIDAS loops packs against the central axis of the propeller,

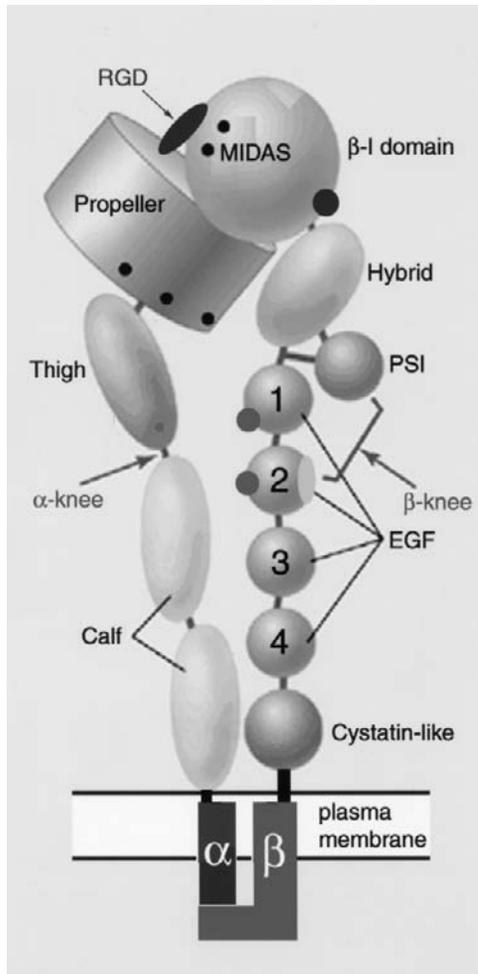

Figure 1 Integrin domain organization. Activation epitopes [13,33] are shown as red, blue, and cyan disks.

thus providing a potential link between ligand binding and the quaternary structure. In certain integrins, an additional I domain (α -I) is inserted into the α -subunit, between two loops on the upper surface of the propeller, where it forms the major ligand binding site. Modeling studies indicate that this domain will form contacts with both the propeller and the β -I domain that regulate the conformation and ligand affinity of the domain, and indeed mutations to the outer surface of the domain can lead to loss- or gain-of-function [10]. The remaining domains of the two subunits form a pair of legs that contact each other along their length, ending at their closely apposed C termini. The legs are followed by a pair of single-pass transmembrane helices and short (except for β 4) cytoplasmic tails, typically 20 to 50 residues in length. These tails lack catalytic activity and transduce signals by binding to intracellular structural and signaling proteins.

Quaternary Changes

Early biophysical and immunochemical studies demonstrated that integrin signaling is associated with large changes in quaternary structure [11]; however, there remains

much controversy over the structure of the resting integrin, as well as the nature of the conformational changes underlying signal transduction [12]. The overall structure of the integrin, based on electromagnetic (EM) images, was expected to have straight legs. However, in the first crystal structure of the entire extracellular portion of an integrin (α V β 3), it is severely bent at the knees [9]. The authors proposed that this bending was likely to be a crystal artifact; they further suggested that the crystallized fragment represents the activated, high-affinity state of the integrin, as it binds ligand with high affinity in solution and is able to bind peptide ligand mimetics in the crystal. However, based on the NMR structure of two domains that were poorly ordered in the crystal structure and on the location of epitopes for activating antibodies within these domains, Springer, Blacklow, and colleagues have suggested that the “knees-bent” or genuflected integrin represents the inactive conformation *in vivo* and that a “switchblade” opening of the integrin is associated with activation [13]. In a third model of quaternary changes in integrins, Hantgan and colleagues [14] have provided evidence, using EM and hydrodynamic studies of peptide-bound integrin, that the α - and β -head segments separate on activation. Such a model would extend the analogy with the heterotrimeric G proteins [15]. In the G proteins, the GTP-ase domain locks onto the propeller domain, regulating ligand binding in two ways: steric blockade of the propeller and allosteric control of the GTP-ase domain. On binding GTP, the GTP-ase domain dissociates from the propeller, enabling both domains to bind their respective ligands. Binding of an RGD-style ligand could play a role analogous to GTP. The G protein model is also consistent with the observations of Mould *et al.* [16], who mapped two distinct binding sites, one on the propeller and the other at the MIDAS motif, for two different regions of fibronectin, separated by ≈ 40 Å. In the crystal structure of α V β 3, the fibronectin binding sites are much closer together, suggesting that the head must separate in order to engage both sites on fibronectin and supporting the notion that the head separates on activation.

Curiously, none of these integrin models is consistent with the assignment of a long-range disulfide in the β -subunit [17], although Yan and Smith [18] have provided evidence that disulfide shuffling occurs in integrin α IIb β 3 and modulates activation, raising the possibility of further, thus far uncharacterized, large-scale quaternary changes underlying activation and signaling.

Tertiary Changes

Crystal structures of recombinant α -I domains with and without ligand have demonstrated a dramatic conformational switch between closed and open states involving a change in the details of metal coordination at the MIDAS motif that is mechanically linked to a 10-Å downward shift of the C-terminal helix (α 7) [19]. Mutational studies of the I domain in the context of the intact integrin have confirmed

that these conformational changes underlie affinity control and that the conformational state of the I domain is regulated by the quaternary organization of the integrin [10,20,21].

The conformation of the β -I domain in the crystal structure is much more similar to the closed (i.e., inactive) conformation of the α -I domain, although Xiong *et al.* have proposed the opposite [9]. Furthermore, the same group recently soaked a short circular RGD peptide that acts as a ligand mimetic into the same crystals [22], and the conformational changes are consistent with those expected for a liganded domain within the context of a closed quaternary structure, in which tertiary changes are in the direction of those observed in the α -I domain but are frustrated by the closed quaternary structure [12]. Indeed, three mutations that suppress activation map to the loops that link one of the MIDAS loops to the C-terminal (α 7) helix [23]. It is conceivable that in the activated integrin, a large shift of α 7, comparable to that observed in the α -I domain, occurs in concert with a hinge-like motion of α -I, allowing it to roll around its N-terminal connector and freeing it from the propeller. The crystal structure of an authentic active integrin–ligand complex is required to test this proposal.

Tail Interactions

Abundant biochemical and genetic data support the notion that interactions between integrin α and β cytoplasmic tails hold the resting integrin in a low-affinity conformation [7,24,25]. For example, a classic study by Ginsberg and colleagues [7] showed that a salt bridge between the α Ib Arg⁹⁹⁵ and β 3 Asp⁷²³ was necessary and sufficient to hold the integrin in its resting state. It is puzzling, therefore, that several nuclear magnetic resonance (NMR) analyses have failed to demonstrate such an interaction directly [26,27]. A recent paper by Vogel and coworkers, however, provides the first direct structural evidence for extensive interactions, albeit with truncated tail fragments [28].

Given this confusion, it has been difficult to develop a definitive model of how reorganization of the cytoplasmic tails propagate through the transmembrane domain to the ligand-binding head. Two simple models are supported by data. The first is a *scissors model*, in which the integrin pivots about some point between its legs, leading to a separation of both the head and tail domains [2,29]. Such a movement is consistent with the EM studies of Hantgan *et al.* [14]. Inside-out signaling is simple to envisage in such a model and would simply require that a cytosolic protein is bound tightly to one or both tails, pulling them apart. An example of such a protein is talin, which activates integrins by binding to an NPxY motif near the center of most β tails via a phosphotyrosine binding (PTB)-like domain in the head region [30]. A second possibility is a *piston model*, in which one or both tails move up and down with respect to the plasma membrane, changing the border of the transmembrane and cytoplasmic domains. Typically, an R or K is positioned 23 hydrophobic amino acid residues carboxy

terminal to the predicted start of the transmembrane domain, followed by four to six hydrophobic residues [24] that also appear to be membrane-imbedded in the resting integrin [31]. It has been proposed that changes in the localization or orientation of the integrin transmembrane domain could occur during physiological integrin activation. For example, the binding site of the β 2 integrin regulatory protein, cytohesin-1, is in the hydrophobic membrane proximal region [32], so that sequestering this region could “pull” on the β -subunit, altering the packing between the α -subunit propeller and the β -I domain.

Concluding Remarks

In spite of major advances in the past 12 months, understanding the structural basis of integrin signaling is far from complete. The major missing data include the structure of a true ligand-bound, active integrin and definitive structural data on the interactions between the cytoplasmic tails and how these are affected by complex formation with cytoplasmic binding partners.

Structures of Heterotrimeric G Proteins and Their Complexes

Stephen R. Sprang

Howard Hughes Medical Institute,
University of Texas Southwestern Medical Center, Dallas, Texas

Introduction

The alpha subunits of heterotrimeric G proteins belong to the superfamily of intracellular GTP hydrolases that use the energy derived from the binding of guanosine triphosphate (GTP) to effect signal transduction. The energy derived from GTP binding is used to stabilize an activated state of the G protein that is able to bind and regulate certain molecules, called *effectors*, in the cell. This capability is diminished or lost when the G protein hydrolyzes GTP. It is regained when a new molecule of GTP is bound, a process that is catalyzed by ligand-activated, seven-transmembrane helical G protein-coupled receptors (GPCRs). Intracellular targets of G protein regulation include a small group of second-message-generating molecules such as potassium and calcium ion channels, phospholipase C β isoforms (PLC β), adenylyl cyclases (ACs), cyclic GMP phosphodiesterase, and regulators of other signaling pathways, such as the p115 Rho guanine nucleotide exchange factor (p115RhoGEF). The sequence of GTP binding, hydrolysis, product release, and reformation of the G protein–GTP complex constitutes a signaling cycle. Steps within this cycle are subject to regulation that shapes the temporal characteristics of the signal, from ligand–receptor recognition to G-protein–effector interaction. The three-dimensional structures of many of the components of this cycle have been described in several functionally relevant states (Table 1). These structures provide insight into the molecular mechanics of G-protein-mediated signal transduction. Here, we briefly describe the three-dimensional structures of G proteins and the molecular processes that constitute the signaling pathway. This area of research has been extensively reviewed [1–4]

and the reader is directed to the primary literature for details.

Heterotrimeric G proteins have two functional components. The alpha subunits ($G\alpha$) are GTP binding proteins which, when bound to GTP, preferentially interact with effectors. Dimers composed of tightly bound β ($G\beta$) and γ ($G\gamma$) chains constitute the second functional unit. $G\beta\gamma$ dimers act both as inhibitors of nucleotide release from $G\alpha$ and as regulators of effector proteins, either independently or coordinately with $G\alpha$.

$G\alpha$ Subunits

$G\alpha$ subunits are members of the Ras superfamily, which also includes translation elongation factors and the components of the signal recognition apparatus. In mammals, the family of $G\alpha$ isoforms is encoded by 16 genes; these can be sorted into four closely related homology groups or classes named for representative members of each class: $G\alpha_s$, $G\alpha_i$, $G\alpha_q$, and $G\alpha_{12}$ (Fig. 1). Two variants of $G\alpha_s$ are generated by alternative mRNA splicing. Each member of the $G\alpha$ family interacts specifically with one effector or effector isoform, although certain effectors are regulated by more than one species of $G\alpha$. Known effectors include all isoforms of AC: $G\alpha_s$, $G\alpha_{olf}$, and $G\alpha_i$ (a negative regulator of types I and V AC) [5]; PDE: $G\alpha_i$; PLC β isoforms: $G\alpha_q$ class members [6]; and p115RhoGEF: $G\alpha_{13}$ [7]. Effectors of certain $G\alpha$ proteins, $G\alpha_o$, and $G\alpha_z$, remain in question.

Ras superfamily proteins are built upon a scaffold of six parallel β -strands, layered on each side by a set of five α -helices (Fig. 2). Unique to the heterotrimeric $G\alpha$ family is an α -helical bundle domain inserted into the loop between

^aGTP γ S—guanosine 5'-[γ -thio]triphosphate.

^bGppNHp—guanosine-5'-($\beta\gamma$ -methylene)triphosphate.

^cG α subunit is a chimera comprising residues 26 to 215 of bovine G α_t , residues 220 to 298 of rat G α_{i1} , and residues 295 to 350 of bovine G α_t .

^dGoLoco motif peptide from RGS14.

^ePDE γ —cyclic GMP phosphodiesterase γ subunit.

^fAC: a complex between the C1 domain of adenylyl cyclase type V and the C2 domain of adenylyl cyclase type II. These domains comprise the catalytic unit. A soluble forskolin derivative is bound at the regulatory site of AC. The domains adopt the open conformation.

^gThis complex contains the ATP analog β -L, 2',5', dideoxy adenosine triphosphate, and two magnesium ions. The domains adopt a closed conformation.

the first and second β strands of the Ras-like domain. G α subunits are modified by N-terminal myristoylation [8] (G α_t) and thioester-linked palmitoylation (G α_s , G α_q , G α_{13}), or both (G α_i , G α_o , G α_z) [9,10]. The latter confers plasma membrane localization upon G α_s and G α_q but may be reversed upon activation [11]. Myristoylation is required in some cases for activity, for example, efficient inhibition of adenylyl cyclase by G α_{i1} [12].

GTP is bound between the helical and Ras-like domains but interacts primarily with conserved sequence motifs within the Ras domain [13–17]. The P-loop, which enfolds the alpha and beta phosphates of the nucleotide, contains a characteristic Walker A sequence motif, G^A_TGESGKST [18], which is permissive for the tight turn required to encompass the phosphate. The lysine residue is a critical β -phosphate ligand and the following serine residue binds the catalytic Mg²⁺ ligand. The connector leading from the helical domain to the Ras-like domain contains a series of residues called Switch I. The arginine residue (178 in G α_{i1}) within this

sequence (...RVXTTG...) is an important catalytic ligand, and the succeeding threonine is the second Mg²⁺ ligand (Fig. 3). The gamma phosphate group of GTP is cradled by a tight turn (...DVGGQ...) which precedes Switch II, an irregular and conformationally mobile helix (α_2). The glutamine residue in this series (204 in G α_{i1}) plays a critical catalytic role in GTP hydrolysis. However, in the structures of G α subunits bound to slowly hydrolyzable GTP analogs, the catalytic glutamine and, in G α_{i1} , the catalytic arginine as well are either poorly ordered or adopt conformations in which they would be incapable of providing catalytic assistance (Fig. 3). A key role of GTP, in league with Mg²⁺, is to maintain the conformational state and structural integrity of the helical Switch II via a set of hydrogen bonds and oxygen-metal interactions that link Mg²⁺•GTP with the P-loop, Switch I, and Switch II. Structural studies of G α_{i1} and G α_t show that, in the guanosine diphosphate (GDP) state, Switch II is either wholly disordered or adopts an alternate conformation. The well-ordered state induced by GTP also

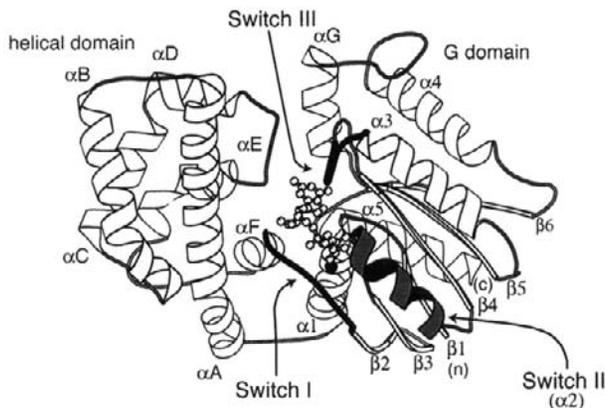

Figure 2 Schematic of the GTP-bound complex of $G\alpha_{11}$ with secondary structure elements (arrows: β -strands, coils: α -helices). GTP is shown as a ball-and-stick model. (From Sprang, S. R., *Annu. Rev. Biochem.*, 66, 639–678, 1997. With permission.)

promotes a set of ionic contacts between Switch II and the β_4 – α_3 loop called Switch III. Upon GTP hydrolysis, the network of interactions between the three switch regions is altered or lost.

The purine ring of the guanine nucleotide is cradled by two conserved loops, β_5 – α_G and β_6 – α_5 (Fig. 2). The aspartate residue within the first sequence (...FLNKKD...) confers specificity towards guanine nucleotides. The second loop acts in a supporting role. A variety of α mutations have been described, some of physiological relevance, that directly affect GTP hydrolysis, nucleotide specificity exchange, and effector coupling. Such mutants are useful for probing or controlling the action of G proteins in cell culture or *in vivo* (Table 2).

G α –Effector Interactions

In the two $G\alpha$ –effector complexes for which structures are known, $G\alpha$ binds the effector in the same manner, even though the structures of the effectors themselves are quite different. The interactions are dependent on the “activated” state of $G\alpha$ that is stabilized by GTP. In the complex

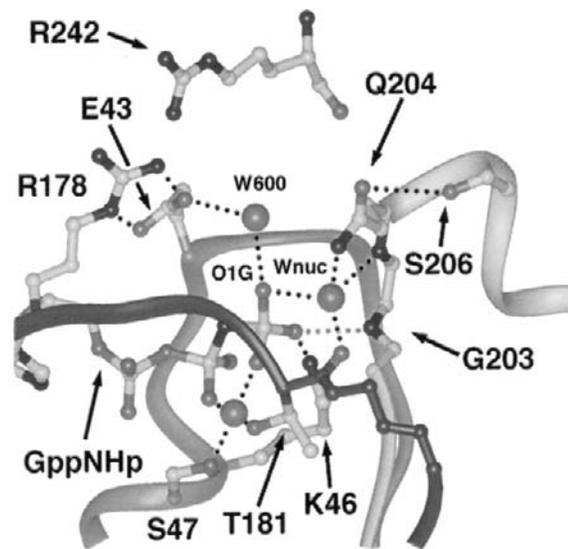

Figure 3 Close-up of the catalytic site of the $G\alpha_{11}\cdot Mg^{2+}\cdot GppNHp$ complex, showing the side chains involved in catalysis and Mg^{2+} binding. Residues of Switch I are blue, the P-loop is green, and Switch II is pale yellow. (Adapted from Coleman, D. E. and Sprang, S. R., *J. Biol. Chem.*, 274, 16669–16672, 1999.)

between $G\alpha_s\cdot GTP\gamma S$ and the catalytic domains of adenylyl cyclase [19] and that between $G\alpha_t\cdot GTP\gamma S$ and the γ subunit of PDE [20], the effector is bound at the cleft between Switch II and the α_3 – β_5 loop of $G\alpha$ (Fig. 4). The effector specificity of $G\alpha$ is conferred both by side chains in the effector binding segments and the conformation of the polypeptide chain within them. For example, $G\alpha_{11}$ inhibits the $G\alpha_s$ -stimulated activity of adenylyl cyclase isoforms I and V, but does not bind to the $G\alpha_a$ activation site [21], possibly interacting at a dyad-related site in the C1 domain instead. The ability of $G\alpha_{11}$ to discriminate its own from the $G\alpha_s$ binding site is unlikely to be entirely due to the amino acid sequence of the Switch II and α_3 – β_5 loops, because all but two amino acids in the adenylyl cyclase contact region are conserved between the two $G\alpha$ subunits. The failure of $G\alpha_{11}$ to act as an activator (or $G\alpha_s$ as an inhibitor) may stem from differences between the two proteins in the spacing and orientation of the α_3 – β_5 loop and the α_4 – β_6 loop that buttresses it [17]. Indeed, the α_4 – β_6 loop had been proposed, on the basis of mutagenesis experiments, to direct the specificity of $G\alpha_{12}$ and $G\alpha_s$ toward their respective binding sites on AC [22], even though the structure of the complex revealed no direct contact with effector. In its interaction with PDE γ , $G\alpha_t$ uses the same structural elements that $G\alpha_s$ employs in contacting AC. Although the chemical basis of certain of the $G\alpha$ –effector interactions are conserved, the amino acid sequence differences between $G\alpha_t$ and other $G\alpha$ subunits are sufficient to ensure specificity. There is structural and biochemical evidence to suggest that $G\alpha_s$ stimulates adenylyl cyclase by controlling the relative orientation of its catalytic domains. $G\alpha_t$ (transducin), on the other hand, sequesters an inhibitory subunit of cyclic GMP phosphodiesterase.

Table II Selected Mutations in G α Subunits

Mutation	G α	Structural element	Effect	Structure	Ref.
G49A	G α_s	P-loop	Reduced GTPase rate	—	[72]
G42V	G α_{i1}	P-loop	Reduced GTPase rate	G α_{i1} , 1AS0, 1AS2, 1AS3	[73]
S54N	G α_s	P-loop; Mg ²⁺ ligand	Weak Mg ²⁺ binding; reduced receptor activation; negative dominant	—	[74]
R201X	G α_{i1} , G α_s	Switch I Catalytic R	Reduced GTPase rate; activating mutant	—	[75,76]
G202T	G α_o	Switch II	Dominant negative	—	
G226L	G α_s	Switch II Catalytic Q	Reduced rate of G $\beta\gamma$ release (prevents activation), loss of Mg ²⁺ affinity	G α_{i1} (G203A), 1GIT, G α_{i1} (G203A) $\beta_1\gamma_2$, 1GG2	[77,78]
Q227L	G α_s , G α_{i1}	Switch II	Abolishes GTPase activity	G α_{i1} (Q204L), 1GIL	[72,79]
D273N	G α_o	Switch II NKXD motif	Switches nucleotide specificity to XTP (in background of Q205L)	—	[80]
A366S	G α_s , G α_{i1}	β 6- α 5 loop	Increases GDP release rate, decreases thermostability	G α_{i1} (A326S), 1BH2	[63,64]
T325A V328A F332A	G α_t	α 5 (C-terminal helix)	Increases GDP release	—	[62]

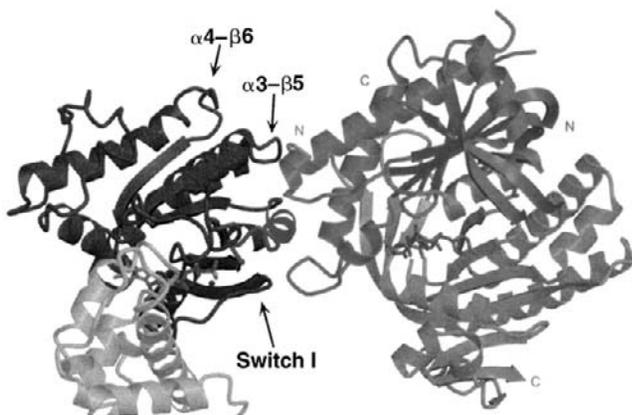

Figure 4 Schematic of G α_s •Mg²⁺•GTP γ S bound to the catalytic domains of adenylyl cyclase. The Ras-like domain of G α_s is rendered in charcoal and Switch II is red. The C1 and C2 domains of type V and type II AC, respectively, are tan and magenta. (Adapted from Tesmer, J. J. G. *et al.*, *Science*, 278, 1907–1916, 1997.)

GTP Hydrolysis by G α and Its Regulation by RGS Proteins

G α proteins hydrolyse GTP with a slow catalytic rate of approximately 0.05 s⁻¹ at physiological temperature. Because G α •GDP binds effectors with less affinity than G α •Mg•GTP, the rate of hydrolysis determines the lifetime of the signal, as measured by the output of activated effector. The origin of the kinetic barrier may be deduced from the structure of the complex between G α bound to GDP and magnesium

fluoroaluminate (Mg²⁺•AlF₄⁻¹) [13]. Fluoroaluminate (AlF₃) and its hydrates mimic the γ phosphate of GTP [23] and in the presence of GDP promote the activated state of G α [24]. Structural studies of G α_{i1} and the G α_t •GDP•Mg•AlF₄⁻¹ complexes demonstrate that AlF₄⁻¹ forms a hexacoordinate complex with a β phosphate oxygen of GDP and a water molecule (the presumptive nucleophile) as axial ligands, thereby approximating the pentacoordinate transition state for phosphorolysis [13,25]. The structures show that, relative to the ground state (Fig. 2) the Switch I arginine and Switch II glutamine must be substantially reoriented in order to stabilize the transition state. It is therefore possible that a conformational rearrangement within the active site corresponds to the kinetic barrier to GTP hydrolysis.

In some cellular contexts (for example, regulation of adenylyl cyclase by G α_s), the rate of signal termination may indeed correspond to the intrinsic GTPase rate of the regulatory G α . However, it is clear that other physiological responses decay much more rapidly following agonist withdrawal (for example, visual recovery after a light flash or deactivation of G protein-regulated K channels.) Rapid signal termination is achieved by RGS (regulator of G protein signaling) proteins, a family of proteins that have in common a homologous stretch of \approx 120 amino acids termed the RGS-box [26]. RGS domains function as GTPase-activating proteins (GAPs) for G α subunits [27,28]. Rate enhancement conferred by RGS ranges from 5- to 10-fold (for RGS9 regulation of G α_t [29]) to well over 50-fold (for RGS4 stimulation of G α_{i1} [30]). RGS proteins show varying degrees of specificity towards their G α substrates [26], and most

$G\alpha$ subunits including $G\alpha_s$ [31] are known to be subject to the action of one or more RGS proteins. Biochemical and crystallographic analysis indicate that RGS domains stabilize a conformation of $G\alpha$ that promotes binding of $GDP\cdot Mg\cdot AlF_4^{-1}$ [32–34]. GAP activity and $G\alpha$ recognition is achieved by specific interactions between the surface of the RGS domain and the three switch segments of $G\alpha$ (Fig. 5). In contrast to certain Ras-family GAPs, RGS proteins do not supply catalytic residues to the catalytic site of $G\alpha$, but rather stabilize the catalytically competent conformation [35].

Effectors may contain domains that exhibit GAP activation toward $G\alpha$. A C-terminal dimerization and binding region within phospholipase C β isoforms comprises part of a domain that expresses this activity [36–38] but is evidently not an RGS domain. A recently discovered effector of $G\alpha_{13}$ [7], p115RhoGEF, contains a domain with remote sequence and strong structural homology to RGS domains [39,40] but requires structural elements outside of the RGS box for GAP activity [41]. Such domains, unique to the p115RhoGEF family, have been termed rgRGS modules.

Although RGS domains bind to $G\alpha$ Switch regions, they do not in general compete with the binding of effectors. PDE γ binding is positively cooperative with that of RGS9 to $G\alpha_t$ [42], whereas it inhibits binding of RGS7 [43]. In their interactions with $G\alpha_{i1}$ and $G\alpha_t$, RGS domains interact with Switch I and the N-terminal half of Switch II; these are adjacent to but do not overlap effector contact surfaces [17]. Small structural changes that accompany formation of the ternary complex between $G\alpha_{i1}$, PGE γ , and the RGS9 suggest a structural basis for cooperative binding [20]. RGS proteins are therefore able to terminate signaling without the requirement for $G\alpha$ -effector dissociation. *In vivo*, tight spatial coupling among $G\alpha$, RGS, effector, and receptor could generate a high steady-state rate of GTPase activity and continual effector activation as long as GPCR agonist is present [26].

$G\beta\gamma$ Dimers

Upon GTP hydrolysis, the affinity of $G\alpha_s$ for AC is reduced about 10-fold [44]. The most potent factor in signal termination may be the high affinity of $G\beta\gamma$ for $G\alpha\cdot GDP$. $G\beta\gamma$ binds to the effector-binding surface of $G\alpha$ but requires a conformation of Switch II that cannot be attained in the GTP-bound state. This nonsignaling state of $G\alpha$ is stable in the presence of GDP and exhibits high affinity for $G\beta\gamma$ [45]. Receptor-catalyzed exchange of GDP for GTP also causes full or partial dissociation from $G\beta\gamma$. When not bound to $G\alpha$, $G\beta\gamma$ subunits are able to regulate other effectors such as inward-rectifying potassium channels [46] and phospholipase C β isoforms [6]. Thus, receptor-activation of a G protein heterotrimer releases two regulatory species that can act independently or coordinately on downstream effectors. Five closely related $G\beta$ subunits have been described, together with 12 isoforms of $G\gamma$.

$G\beta$ subunits are toroidal structures, consisting of seven four-stranded antiparallel β -sheets, each projecting like the

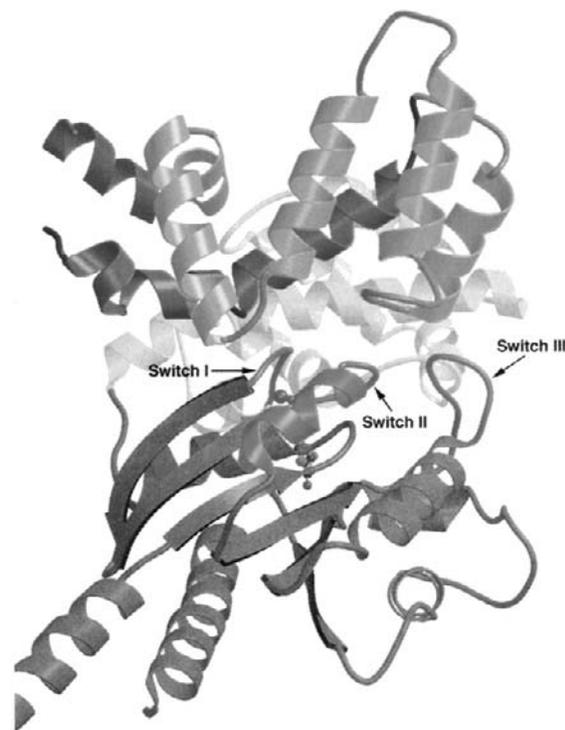

Figure 5 The complex of the RGS domain from RGS4 bound to the Ras-like domain of $GDP\cdot Mg^{2+}\cdot AlF_4^{-1}$ activated $G\alpha_{i1}$. (Adapted from Tesmer, J. J. G. *et al.*, *Cell*, 89, 251–261, 1997.)

blades of a propeller from the central axis of the molecule (Fig. 6) [45,47]. The seven-fold symmetry is reflected in the amino acid sequence of $G\beta$, which is composed of seven so-called WD (or WD40) repeats, represented by the consensus sequence $[GHX_{3-5}\Phi_2X\Phi X\Phi X_{5-6}\Phi(S/T)(G/A)X_3DX_4WD]$, where X is any residue, Φ denotes a hydrophobic residue, and parentheses enclose alternate possibilities [2]. The sequence repeat is staggered with respect to the structural repeat (one propeller “blade”) such that the first β -strand within the WD motif corresponds to the last β strand of the $n-1$ th blade, and the following three β strands of the WD constitute the first three strands of the n th blade. This construction ensures a lap-joint in which the N- and C-terminal strands of the propeller are hydrogen-bonded to each other. The first of the two Asp residues in the motif is invariant and participates in a hydrogen-bonded network with the His, Ser/Thr, and Trp residues in most of the blades. The first ≈ 40 residues of $G\beta$, preceding the seven-bladed propeller, are folded into an α helix. The $G\gamma$ subunit is an extended molecule consisting of three α -helical segments that do not contact each other. $G\gamma$ subunits are farnesylated ($G\gamma_{11}$, $G\gamma_{11}$) or geranylgeranylated (all others) at their C termini, thereby tethering them to the plasma membrane and promoting high-affinity interactions between $G\beta\gamma$ and $G\alpha$ subunits and with effectors (see references in [2]). The N-terminal helix of $G\gamma$ forms a parallel coiled-coil with that of $G\gamma$. The second and third helices lie over the surface of the $G\beta$ torus that is formed by the AB and CD β -strands of each propeller. This surface contains two hydrophobic pockets, located

between successive propellers, that accept nonpolar residues from the end of $G\gamma$ helix 3 and the succeeding loop region [48,49]. The $G\gamma$ binding surface is highly conserved among the five isoforms of $G\beta$. The limited selectivity between $G\beta$ and $G\gamma$ isoforms seems to involve the interaction of hydrophobic residues in helix 2 of $G\gamma$ with its binding surface on $G\beta$. $G\beta 5$ is the most divergent among the five isoforms of $G\beta$. It has recently been shown to interact most strongly with the G-gamma-like domains (GGLs) present in a variety of proteins, most notably the members of the RGS11 family [50,51].

$G\alpha$ binds to the surface of $G\beta$ opposite that to which $G\gamma$ is bound (Fig. 7). $G\alpha$ interacts with $G\beta$ at two distinct and separate surfaces, both of which are required for high-affinity binding. The N-terminal helix of $G\alpha$ contacts the side of the $G\beta$ torus at blade 1. The Ras-like domain of $G\alpha$ binds $G\beta$ at Switch I and Switch II. All of the residues of $G\beta$ that contact $G\alpha$ are conserved among $G\beta$ isoforms. Although the $G\beta$ -binding residues within the Ras domain of $G\alpha$ are well conserved, the N-terminal helix of $G\alpha$ is more variable, and this might confer some degree of conformational specificity to $G\alpha$ - $G\beta$ interactions. The orientation of this helix with respect to $G\beta 1$ differs in complexes with $G\alpha_{i1}$ and $G\alpha_q$. A series of mutagenesis studies have demonstrated that several effectors of $G\beta\gamma$, including PLC $\beta 2$, β -adrenergic receptor kinase, type II adenylyl cyclase, G-protein-regulated inward rectifying potassium channels (GIRK), and the calcium channel $\alpha 1B$ subunit, all contact $G\beta\gamma$ at the same molecular surface to which $G\alpha$ subunits binds [52].

GPR/GoLoco Motifs

Recently, a diverse group of proteins containing 25-30 residue GPR (G-protein regulatory) [53,54], or GoLoco [55]

Figure 6 The complex of $G\beta_1\gamma_2G\beta_1$ is colored yellow, except for the second (from the N-terminus) WD repeat, which is rendered in orange. The four-stranded antiparallel β "blades" that comprise the propeller fold are numbered. Individual strands in one repeat are lettered (a) through (d), in order of sequence. The $G\gamma$ subunit is green. The amino termini of both subunits are labeled.

motifs were shown to inhibit, like $G\beta\gamma$, the dissociation of GDP from $G\alpha_{i1}$ and $G\alpha_o$. GPR/GoLoco motifs bind only to the GDP-bound $G\alpha$ isoforms and also inhibit binding of $G\gamma\beta$ [53,56,57]. The GPR/GoLoco repeat from RGS14 adopts an extended conformation when bound to $G\alpha_{i1}\bullet$ GDP, forming contacts with Switch II and crossing the gap between the Ras-like and helical domains. A conserved arginine residue from GoLoco engages the GDP β -phosphate, thus stabilizing the nucleotide within the catalytic site. GPR-containing molecules provide a mechanism for receptor-independent activation of $G\beta\gamma$ signaling pathways, while inhibiting reactivation of $G\alpha_{i1}$.

$G\alpha$ -GPCR Interactions

Although the mechanism by which receptors activate G proteins is beyond the scope of this review, some mention of $G\alpha$ -GPCR recognition is in order. The structure of one GPCR, rhodopsin, has been reported, in an inverse-agonist-bound (i.e., resting) state [58]. The structural basis of the heterotrimer-receptor interaction is known only from extensive mutagenesis and cross-linking studies [3,59-61], particularly of the rhodopsin- $G\alpha_i$ interface. These studies point to the $\alpha 4$ - $\beta 6$ loop and the C-terminal helix, $\alpha 5$, of $G\alpha_i$. Mutations of residues located at the inward face of the $\alpha 5$ helix of $G\alpha_i$ dramatically increase receptor-independent rates of nucleotide release [62]. Mutation of a conserved alanine residue within the purine-contacting $\alpha 4$ - $\beta 6$ loop

Figure 7 The complex of $G\alpha_{i1}\bullet$ GDP with $G\beta_1\gamma_2$. $G\beta_1$ and $G\gamma_2$ are colored as in Figure 6. The sidechain of tryptophan 99 in $G\beta_1$, shown as a stick model, is prominent in the interface with $G\alpha_{i1}$, which is rendered in charcoal. The switch regions of $G\alpha_{i1}$ are red, and GDP is shown as a ball-and-stick model.

preceding $\alpha 5$ increases the intrinsic nucleotide exchange rate and also reduces the thermostability of $G\alpha_{i1}$ [63,64]. Some residues that affect receptor coupling are located in the $G\alpha$ - $G\beta$ interface but distant from the putative receptor binding surface, suggesting that $G\beta\gamma$ plays a direct role in GPCR-mediated nucleotide exchange.

The mechanism by which GPCRs catalyze nucleotide exchange from $G\alpha$ remains one of the more puzzling mysteries in the structural biology of signaling. Crystal structures of receptors bound to heterotrimeric G proteins, in a spectrum of functional states, will eventually be determined and will provide some, but probably not complete, insight into receptor function. Equally important is the need to understand the organization and dynamic behavior of G protein signaling complexes at the cell membrane. The tools required for such investigations are still being developed (see <http://www.cellularsignaling.org/>).

Structure and Function of G-Protein-Coupled Receptors: Lessons from the Crystal Structure of Rhodopsin

Thomas P. Sakmar

*Laboratory of Molecular Biology and Biochemistry,
Howard Hughes Medical Institute, The Rockefeller University,
New York, New York*

Introduction

The crystal structure of rhodopsin was recently solved at 2.8-Å resolution. As a prototypical seven-helical G-protein-coupled receptor (GPCR), rhodopsin has provided significant insights toward defining structure–activity relationships among other related receptors. In particular, many advances in understanding the molecular mechanism of receptor activation and how an active receptor catalyzes the exchange of guanine nucleotides on heterotrimeric G proteins have been suggested from biochemical and biophysical studies of rhodopsin and expressed rhodopsin mutants. The report of a high-resolution crystal structure of rhodopsin now provides new opportunities to understand how GPCRs work. For example, the ligand-binding pocket of rhodopsin is remarkably compact, and several apparent chromophore–protein interactions were not predicted from extensive mutagenesis or spectroscopic studies. The transmembrane helices are interrupted or kinked at multiple sites. An extensive network of interhelical interactions stabilizes the ground state of the receptor. The helix movement model of receptor activation, which might apply to all GPCRs in the rhodopsin family, is supported by several structural elements that suggest how light-induced conformational changes in the

ligand-binding pocket are transmitted to the cytoplasmic surface. Future high-resolution structural studies of rhodopsin and other GPCRs will form a basis to elucidate the detailed molecular mechanism of GPCR-mediated signal transduction.

Introduction to Rhodopsin: a Prototypical G-Protein-Coupled Receptor

Rhodopsin (Rho) is a highly specialized G-protein-coupled receptor (GPCR) that detects photons in the rod photoreceptor cell. Within the superfamily of GPCRs that couple to heterotrimeric G proteins, Rho defines the so-called family A GPCRs, which share primary structural homology [1–3]. Rho shares a number of structural features with other GPCRs, including seven transmembrane segments (H1 to H7) (Fig. 1). In visual pigments, a Lys residue that acts as the linkage site for the chromophore is conserved within H7 in all pigments, and a carboxylic acid residue that serves as the counterion to the protonated, positively charged Schiff base is conserved within H3. The position analogous to the Schiff base counterion is one helix turn away from the position of an Asp residue conserved in biogenic amine receptors that serves as

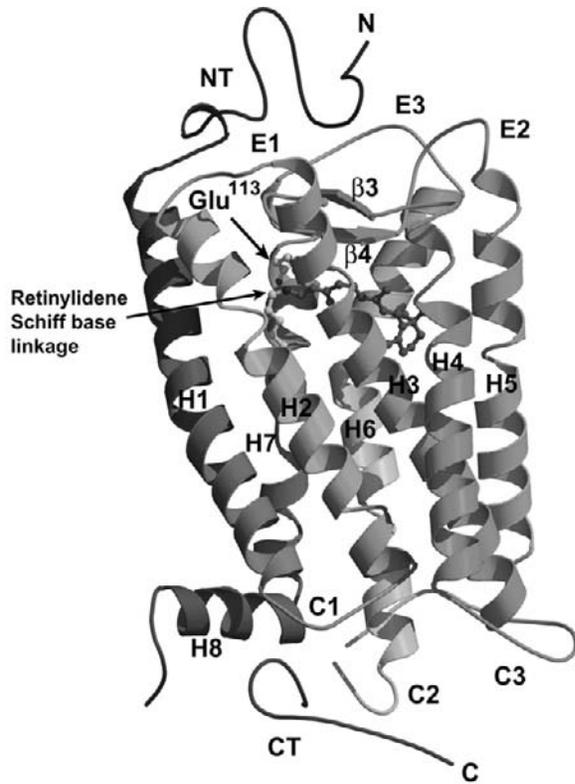

Figure 1 A molecular graphics ribbon diagram of Rho prepared from the 2.8-Å crystal structure coordinates (PDB 1f88). The amino terminus (N) and extracellular surface is toward the top of the figure and the carboxyl terminus (C) and intracellular surface is toward the bottom. Seven transmembrane segments (H1 to H7), which are characteristic of GPCRs, are labeled. The RET chromophore is shown in magenta, and the side chain of Glu-113 and the retinylidene Schiff base linkage are shown to highlight the orientation of the chromophore in the binding pocket. The Schiff base imine nitrogen is labeled. The Rho crystal structure does not resolve a small segment of the C3 loop linking H5 and H6 or a longer segment of the carboxyl-terminal tail distal to H8. The α -helical transmembrane segments are tilted with respect to the presumed plane of the membrane bilayer, and they contain significant kinks and irregularities.

the counterion to the cationic amine ligands. A pair of highly conserved Cys residues is found on the extracellular surface of the receptor and forms a disulfide bond. A Glu(Asp)/Arg/Tyr(Trp) tripeptide sequence is found at the cytoplasmic border of H3. This sequence is conserved in family A GPCRs and has been shown to be involved in G-protein interaction [4,5].

Molecular Structure of Rhodopsin

The extracellular surface domain of Rho is comprised of the amino-terminal tail (NT) and three interhelical loops (E1, E2, and E3) (Fig. 1) [6]. There is significant secondary structure in the extracellular domain and several intra- and inter-domain interactions. The E2 loop is extremely interesting in that it is folded deeply into the core of the membrane-embedded region of Rho. In addition to contacts with

the chromophore (11-*cis*-retinol), E2 forms extensive contacts with other extracellular regions. The $\beta 3$ and $\beta 4$ strands, which arise from E2, run anti-parallel. The $\beta 4$ strand is situated more deeply within the membrane-embedded region of Rho than the $\beta 3$ strand. The $\beta 4$ strand is adjacent to the chromophore and forms the extracellular boundary, or roof, of the ligand-binding pocket. A disulfide bond between Cys-110 and Cys-187, which forms the extracellular end of H3, is highly conserved among all class A GPCRs.

More than one-half of the 348 amino acid residues in Rho make up the seven transmembrane segments (H1 to H7) included in the membrane-embedded domain. The crystal structure of this domain is remarkable for a number of kinks and distortions of the individual transmembrane segments, which are otherwise generally α -helical in secondary structure. Many of these distortions from idealized secondary structure were not accounted for in molecular graphics models of Rho based on projection density maps obtained from cryoelectron microscopy [7]. H7 is the most highly distorted of the seven transmembrane helical segments. There are kinks at two Pro residues, Pro-291 and Pro-303. In addition, the helix is irregular around the region of residue Lys-296, which is the chromophore attachment site. Pro-303 is a part of the highly conserved Asn/Pro/X/X/Tyr motif (Asn-302/Pro-303/Val-304/Ile-305/Tyr-306 in Rho).

The membrane-embedded domain of Rho is also characterized by the presence of several intramolecular interactions that may be important in stabilizing the ground state structure of the receptor. One of the hallmarks of the molecular physiology of Rho is that it is essentially silent biochemically in the dark. The bound chromophore serves as a potent pharmacological inverse agonist to minimize activity. The Rho structure reveals numerous potentially stabilizing intramolecular interactions, some mediated by the chromophore and others arising mainly from interhelical interactions that do not involve the chromophore-binding pocket directly. For example, a complex H-bond network appears to link H6 and H7. The key interaction here is between Met-257 and Asn-302. The precise functional importance of the highly conserved Asn/Pro/X/X/Tyr motif (Asn-302/Pro-303/Val-304/Ile-305/Tyr-306 in Rho) is unclear. However, one key structural role is to mediate several interhelical interactions. The side chains of Asn-302 and Tyr-306 project toward the center of the helical bundle. The hydroxyl group of Tyr-306 is close to Asn-73 (cytoplasmic border of H2), which is also highly conserved. A key structural water molecule may facilitate an H-bond interaction between Asn-302 and Asp-83 (H2). A recent mutagenesis study of the human platelet-activating factor receptor showed that replacement of amino acids at the positions equivalent to Asp-78 and Asn-302 in Rho with residues that could not H bond prevented agonist-dependent receptor internalization and G-protein activation [8].

The 11-*cis*-retinol chromophore is a derivative of vitamin A₁, with a total of 20 carbon atoms (Fig. 2). The binding site of the chromophore lies within the membrane-embedded

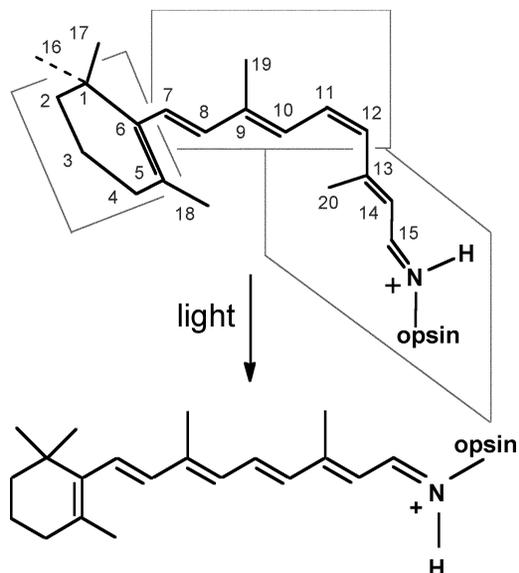

Figure 2 Photoisomerization of the 11-*cis*-retinylidene chromophore (RET) to its 11-*trans* form is the only light-dependent event in vertebrate vision. The RET chromophore is a derivative of vitamin A₁ with a total of 20 carbon atoms. The structure of the chromophore in rhodopsin appears to be 6*s-cis* 11-*cis* 12*s-trans* 15-*anti*-retinylidene protonated Schiff base. The planar surfaces are meant to depict the twists about the C-6–C-7 and C-12–C-13 bonds. Photoisomerization in Rho occurs on an ultrafast time scale, with photorhodopsin as the photoproduct formed on a femtosecond time scale [23]. The photolyzed pigment then proceeds through a number of well-characterized spectral intermediates. As the protein gradually relaxes around 11-*trans* RET, protein–chromophore interactions change and distinct λ_{\max} values are observed. Important photochemical properties of Rho in the rod cell disc membrane include a very high quantum efficiency (≈ 0.67 for Rho versus ≈ 0.20 for RET in solution) and an extremely low rate of thermal isomerization.

domain of the receptor (Fig. 3). All seven transmembrane segments and part of the extracellular domain contribute interactions with the bound chromophore. The chromophore is located closer to the extracellular side of the transmembrane domain of the receptor than to the cytoplasmic side. Glu-113 serves as the counterion for the Schiff base attraction of the chromophore to Lys-296. In all, at least 16 amino acid residues are within 4.5 Å of the chromophore: Glu-113, Ala-117, Thr-118, Gly-121, Glu-122, Glu-181, Ser-186, Tyr-191, Met-207, His-211, Phe-212, Phe-261, Trp-265, Tyr-268, Ala-269, and Ala-292. The most striking feature of the binding pocket is the presence of many polar or polarizable groups to coordinate an essentially hydrophobic ligand.

The cytoplasmic domain of Rho is comprised of three cytoplasmic loops and the carboxyl-terminal tail: C1, C2, C3, and CT. Loops C1 and C2 are resolved in the crystal structure, but only residues 226 to 235 and 240 to 246 are resolved in C3. CT is divided into two structural domains. C4 extends from the cytoplasmic end of H7 at Ile-307 to Gly-324, just beyond two vicinal Cys residues (Cys-322 and Cys-323), which are posttranslationally palmitoylated. The remainder of CT extends from Lys-325 to the carboxyl terminus of Rho at Ala-348. The crystal structure does not resolve residues 328 to 333 in CT.

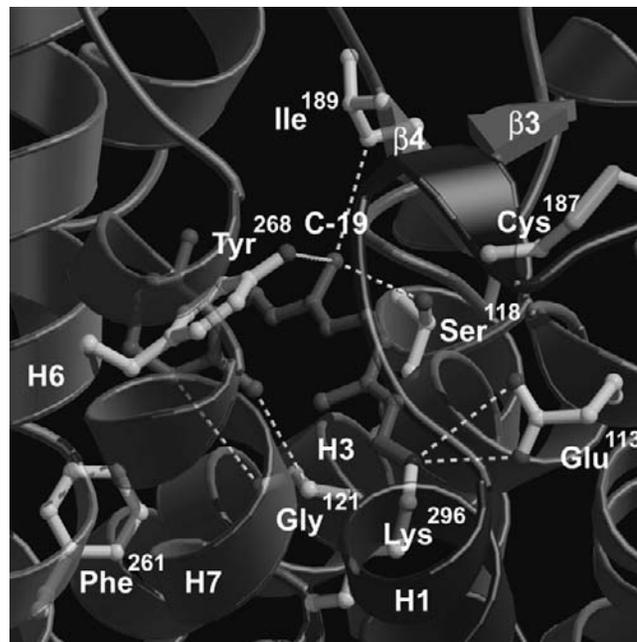

Figure 3 The RET chromophore-binding pocket of bovine Rho. The RET chromophore-binding pocket is shown from slightly above the plane of the membrane bilayer looking between transmembrane segments H1 and H7. Several amino acid residues are labeled, including the Schiff base counterion Glu-113. At least three residues appear to interact with the C-19 methyl group of the chromophore: Ser-118, Ile-189, and Tyr-268. The C-19 methyl group might provide a key ligand anchor that couples chromophore isomerization to protein conformational changes. Some additional key amino acid residues are labeled, including the Cys-187, which forms a highly conserved disulfide bond with Cys-110.

A number of cytoplasmic proteins are known to interact exclusively with the active state of the receptor (R^*). Because the crystal structure depicts the inactive Rho structure that does not interact significantly with cytoplasmic proteins, the structure can provide only indirect information about the relevant R^* state. Perhaps the most extensively studied receptor–G-protein interaction is that of bovine Rho with G_t . Detailed biochemical and biophysical analysis of the R^* – G_t interaction has been aided by mutagenesis of the cytoplasmic domain of bovine Rho. Numerous Rho mutants defective in the ability to activate G_t have been identified. Several of these mutant receptors were studied by flash photolysis [9], light-scattering [10], or proton-uptake assays [11]. The key overall result of these studies is that C2, C3, and H8 are involved in the R^* – G_t interaction.

H8 is a cationic amphipathic helix that may bind a phospholipid molecule, especially a negatively charged phospholipid such as phosphatidylserine. In fact, spectroscopic evidence has been reported to show an interaction between Rho and a lipid molecule that is altered in the transition of Rho to metarhodopsin II, the spectrally defined form of R^* [12]. H8 points away from the center of Rho, and the area of the membrane surface covered by the entire cytoplasmic surface domain appears to be roughly large enough to accommodate G_t in a one-to-one complex.

Molecular Mechanism of Receptor Activation

Although the crystal structure of Rho does not provide direct information about the structure of R* or about the dynamics of the Rho to R* transition, it does provide a wealth of information that should help to design experiments using existing methods to address specific questions regarding the molecular mechanism of Rho activation. An inactive receptor conformation must be capable of changing to an active conformation which catalyzes nucleotide exchange by a G protein. In Rho, the chromophore is in its “off” state, but switches to the “on” state 11-*trans* geometry by photoisomerization, which leads to the R* conformation of the receptor. Recent studies have suggested that steric and/or electrostatic changes in the ligand-binding pocket of Rho may cause changes in the relative disposition of transmembrane (TM) helices within the core of the receptor. These changes may be responsible for transmitting a “signal” from the membrane-embedded binding site to the cytoplasmic surface of the receptor. Trp mutagenesis [13], mutagenesis of conserved amino acid residues on H3 and H6 [14,15], and the introduction of pairs of His residues at the cytoplasmic borders of TM helices to create sites for metal chelation [16] have recently provided insights regarding the functional role of specific helix-helix interactions in Rho. These results indicated a direct coupling of receptor activation to a change in the spatial disposition of H3 and H6. This could occur if movements of H3 and H6 were coupled to changes in the conformation of the connected intracellular loops, which are known to contribute to binding surfaces and tertiary contacts of Rho with G_i.

More direct evidence for changes in interhelical interactions upon receptor activation were provided by extensive site-directed spin labeling and electron paramagnetic resonance (EPR) spectroscopy studies of the transition of Rho to R* in modified, or expressed, mutant pigments. The results suggested a requirement for rigid body motion of transmembrane helices, especially H3 and H6, in the activation of Rho [17]. A slight reorientation of helical segments upon receptor activation is also supported by experiments using polarized attenuated total reflectance infrared difference spectroscopy [18]. Finally, movement of H6 was also detected by site-specific chemical labeling and fluorescence spectroscopy [19]. The structural rearrangement of helices upon activation might not result in an R* structure that is drastically different from that of Rho as an engineered receptor with four disulfide bonds (between the cytoplasmic ends of H1 and H7, and H3 and H5, and the extracellular ends of H3 and H4, and H5 and H6) was still able to activate G_i [20].

Because the arrangement of the seven transmembrane segments is likely to be evolutionarily conserved among the family of GPCRs, the proposed motions of H3 and H6 may be a part of a conserved activation mechanism shared among all receptor subtypes [21,22]. In other class A GPCRs, agonist ligand binding would be coupled to a change in the orientations of H3 and H6.

Human Olfactory Receptors

Orna Man, Tsviya Olender, and Doron Lancet*

*Department of Molecular Genetics, Weizmann Institute of Science,
Rehovot, Israel*

Olfaction, the sense of smell, is a versatile and sensitive mechanism for detecting volatile odorous molecules [1,2]. It is mediated by hundreds of olfactory receptor (OR) proteins in the membrane of the chemosensory neurons, extended by the formation of long cilia. Odorant binding initiates a cascade of signal transduction events that involve a G-protein-dependent elevation of cAMP second messenger and opening of cAMP-gated ion channels [3]. The olfactory system utilizes a combinatorial receptor-coding scheme to discriminate different odorants [4–7]. A specific odor is recognized as a pattern of saturation values, which may be viewed as an “activity vector” generated across an array of ORs. As each sensory neuron expresses only one OR gene (in fact, a single allele thereof) [8], the pattern of receptor activation is faithfully represented in an array of cellular activities, as conveyed to the central nervous system.

In humans, a repertoire of more than 1000 OR genes has been elucidated by cloning and genomic data mining [9–12]. Genes of this “olfactory subgenome”, the largest subgroup within the G-protein-coupled receptor (GPCR) hyperfamily, are disposed in dozens of clusters on most human chromosomes. This genomic disposition is accounted for by an elaborate process of gene and cluster duplication, as well as gene conversion events [13,14]. Approximately two-thirds of all human ORs are pseudogenes that have accumulated up to 27 frame-disrupting mutations [9,15]. Such an observation is consistent with the diminished importance of the sense of smell in primates, including humans. The OR subgenome consists of 17 gene families [16,17], which belong to either class I (fish-like) or class II (tetrapod-specific) receptors. Interestingly, the proportion of intact genes is greater among class I receptors, suggesting they have greater functional importance.

The genetics of ORs has only begun to be elucidated. In humans, it is commonly believed that OR polymorphisms underlie the widespread inter-individual variations in odorant

threshold [18]. This is in line with genetic models developed in other species [19–21]. Providing direct evidence for this notion by genotype–phenotype correlations in humans constitutes an important future challenge that may involve the identification of pseudogenes present only in certain individuals [22].

As is the case for most integral membrane proteins, the three-dimensional structure of ORs has not yet been determined. Therefore, scientists have resorted to alternative methods of structure prediction. These include homology modeling [23,24] based on the structure of bovine rhodopsin, the only GPCR for which crystallographic structural information is available (see Chapter 22). This approach is rendered more valid because both ORs and rhodopsin belong to class A GPCRs [25]. Homology modeling was performed despite the marginal sequence similarity between ORs and rhodopsin ($\approx 21\%$ amino acid identity over most of the protein sequence) and was greatly aided by the occurrence of sequence motifs common to the two sets of proteins (Fig. 1). Such shared features include the overall seven-helix structure, the conserved extracellular cysteine bridge between the first and second extracellular loops, the (D/E)RY motif in the transition zone between the third transmembrane helix and second intracellular loop, the SY motif in transmembrane 5 (TM5), and the NP motif in TM7 [10,26].

Variability analysis identified 17 hypervariable residues which point to a putative odorant binding pocket formed by TM3 to TM6; these residues were proposed to form the complementarity-determining regions (CDRs). The use of enhanced variability as a criterion for functional importance is analogous to an approach originally proposed for immunoglobulins [26]. Additional information on potential functional residues is provided by correlated mutation analysis [27] and by comparisons of variability patterns in orthologous and paralogous sequences ([28]; Man, Gilad, and Lancet, unpublished work).

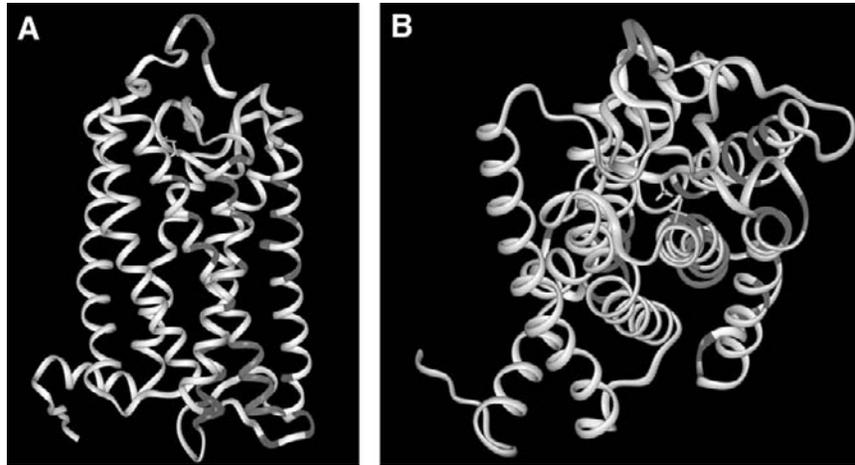

Figure 1 A three-dimensional homology model of an OR protein (OR1E1) using the structure of bovine rhodopsin ([39]; PDB code 1F88). As a template, in side view (A, extracellular at the top), and in a frontal view into the putative binding site from the extracellular side (B). Functionally important features are shaded and include the following: the conserved MAYDRYVAIC motif in the end of TM 3; exceptionally conserved residues in the second and third intracellular loops; the putative disulfide bond between the first and second extracellular loops; the *N*-glycosylation site near the amino terminus; the second extracellular loop that covers the binding site; the 17 putative CDRs [26].

Functionally important residues were also highlighted using sequence conservation analysis (Fig. 1). In particular, ten sequence motifs concentrated in either the extracellular-most or intracellular-most parts of the receptors have been identified [26,29]. It was suggested that these motifs are involved in the interactions of the receptors with their signaling partners upstream (e.g., odorant-binding protein, OBP, [30]) or downstream (olfactory GTP-binding protein [31]). While many GPCRs contain conserved palmitoylation sites in their carboxy-terminal region (such as rhodopsin; see Chapter 22), which anchor them to the membrane, only 26% of intact human ORs contain such sites [10].

The second extracellular loop of ORs has attracted particular attention. It is comparatively long, and, in addition to the cysteine residue conserved in all GPCRs, it contains two conserved cysteines, perhaps forming an internal disulfide bond [10,32]. This loop also has a relatively high variability, and a correlation was found between residues within it and those in the putative binding pocket [27]. This might suggest that the loop acts as an auxiliary recognition domain, reflecting the unique specificity of the odorant-binding pocket [33]. The finding of OR mRNA in the axon terminals of olfactory receptor neurons within their target glomerular synaptic complex [34,35] led to the hypothesis [33] that the second extracellular loop participates in the guidance of olfactory neuronal axons [36].

Functional expression studies have the potential to identify the ligands that activate each receptor. Such studies have been hindered by the apparent failure of the transfected OR proteins to translocate efficiently to the plasma membrane [19]. Solutions to this problem have included *in vivo* infection with OR-containing viral vectors in rat olfactory epithelium [37]; expression of chimeric receptors containing rhodopsin sequences in a heterologous cell system, in conjunction with

a promiscuous G protein [19]; and expression in oocytes [19]. A combination of calcium imaging and single-cell reverse transcription–polymerase chain reaction (RT-PCR) analysis has also been used to identify receptors that recognize specific odorant molecules and to elucidate a combinatorial code [5]. One study led to a relatively comprehensive elucidation of the odorant-binding characteristics of one OR protein, I7 [38]. Comparison of the highly homologous mouse and rat I7 receptors [19] resulted in the identification of a one-residue substitution, V206I, responsible for a shift in ligand binding preference from octanal in rat to heptanal in mouse. This residue resides in the extracellular region of transmembrane segment five in the vicinity of residues previously predicted to confer specificity, but points away from the homology-modeling-based proposed binding site, a point that will require additional scrutiny.

Future studies should involve a considerable augmentation of ligand–receptor relationships in the olfactory system in mammals. This should include improved protein expression methodologies, as well as genetic studies that would link olfactory sensitivity phenotypes to OR genotypes.

Chemokines and Chemokine Receptors: Structure and Function

¹Carol J. Raport and ²Patrick W. Gray

¹ICOS Corporation, Bothell, Washington; ²Macrogenics, Inc., Seattle, Washington

Introduction

The name *chemokine* is derived from “chemotactic cytokine” and the hallmark activity of chemokines is chemotaxis, the ability to induce directed cell movement. Chemokines are encoded by a large gene family with at least 45 members. The receptors for chemokines also belong to a gene family with at least 18 members and all are G-protein-coupled receptors. The sequence similarities found in the chemokine gene family are reflected in their similar three-dimensional structures; however, chemokines display a diverse range of activities. Chemokines were originally identified as potent leukocyte attractants involved in inflammatory disease. More recently, they have been found to play critical roles in the natural development and regulation of the immune system. In addition, chemokines and their receptors have been utilized by pathogens to subvert the host immune system. This review will explore the many functions of this important family of immune modulators.

Chemokine Structure and Function

Although their discovery has been relatively recent (mostly within the past 15 years), chemokines and their receptors have rapidly become appreciated for their impact on health and disease. They are involved in a broad variety of natural biological processes, including development, inflammation, immunity, and angiogenesis. In addition, these sequences have been corrupted by pathogens to subvert the innate and adaptive immune responses. This review provides a brief introduction to chemokine structure and activities. More detailed reviews can be found in the reference section [1–4].

Over 45 human chemokines have been characterized. The first chemokines to be identified were associated with inflammatory disease, but their discrete biologic activities were not known. Once interleukin-8 (IL-8), monocyte chemoattractant protein-1 (MCP-1), and others were shown to attract leukocytes, other proteins with similar structure were also identified with leukocyte chemotactic activity [5–8]. The earliest identified chemokines were isolated by standard protein purification techniques, including heparin affinity chromatography. Others were soon identified as induced sequences in cDNA libraries that encoded similar protein structures [9–11]. Most of the newer chemokines were found in expressed sequence tag (EST) cDNA libraries by sequence similarity, while others have been discovered in the course of sequencing the human genome. Because many laboratories and many methods have been responsible for chemokine discovery, the original chemokine nomenclature is confusing. Recently a more comprehensive nomenclature has been developed [12]. This is presented in Table 1, along with the receptors and cell types with which they interact.

Chemokines are 8- to 10-kDa proteins that share significant homology in their amino acid sequences. Chemokines share between 20 and 80% identity and are found as gene families in all species of vertebrates. The four families of chemokines have been distinguished on the basis of the relative position of their cysteine residues. The α and β chemokines contain four cysteines (sometimes six) and are the largest families. One amino acid separates the first two cysteine residues (cysteine–X amino acid–cysteine, or CXC) in the α chemokines. In the β chemokines, the first two cysteine residues are adjacent to each other (cysteine–cysteine, or CC). The other two families of chemokines contain a single member each: lymphotactin, with only two cysteines [13],

Table I Chemokine Receptors and Ligands

Receptor	Expression	Ligands
CXCR1	Neutrophils	CXCL8 (IL-8)
CXCR2	Neutrophils	CXCL8 (IL-8), CXCL1–3 (gro- $\alpha/\beta/\gamma$), CXCL5 (ENA-78), CXCL6 (GCP-2), CXCL7 (NAP-2)
CXCR3	Activated T cells (Th1)	CXCL9 (mig), CXCL10 (IP-10), CXCL11 (ITAC)
CXCR4	T cells and other leukocytes	CXCL12 (SDF-1)
CXCR5	B cells	CXCL13 (BLC, BCA-1)
CXCR6	Activated T cells	CXCL16
CCR1	Monocytes, activated T cells	CCL3 (MIP-1 α), CCL5 (RANTES), CCL7 (MCP-3), CCL 14–16 (HCC 1, 2, 4), CCL23 (MPIF-1)
CCR2	Monocytes, activated T cells	CCL2 (MCP-1), CCL8 (MCP-2), CCL7 (MCP-3), CCL13 (MCP-4)
CCR3	Eosinophils, basophils	CCL11 (Eotaxin), CCL24 (Eotaxin-2), CCL26 (Eotaxin-3), CCL5 (RANTES)
CCR4	T cells (Th2)	CCL22 (MDC), CCL17 (TARC)
CCR5	Macrophages, Th1 cells	CCL3 (MIP-1 α), CCL4 (MIP-1 β), CCL5 (RANTES)
CCR6	Activated T cells, dendritic cells	CCL20 (LARC, MIP-3a)
CCR7	Naïve lymphocytes, mature dendritic cells	CCL19 (ELC, MIP-3b), CCL21 (SLC, 6CKine)
CCR8	T cells (Th2)	CCL1 (I-309)
CCR9	Gut homing $\alpha 4\beta 7+$ T cells	CCL25 (TECK)
CCR10	Skin homing CLA+ T cells	CCL27(CTACK), CCL28 (MEC)
CX ₃ CR1	Monocytes, microglia, T cells	CX3CL1 (Fractalkine)
XCR1	Lymphocytes	XCL1 (Lymphotactin)

and fractalkine, in which the first two cysteine residues are separated by three amino acids (CXXXC) and the chemokine domain is at the amino terminus of a membrane-bound glycoprotein (fractalkine is also unusual in its size, 95 kDa) [14].

The three-dimensional structures of many chemokines have been determined by either X-ray crystallography or nuclear magnetic resonance (NMR) (reviewed in Clore and Gronenborn [15] and Rojo *et al.* [16]). Because of their multiple cysteine residues, the structures are confined by disulfide bridges. The first amino terminal cysteine forms a disulfide bond with the third, and the second cysteine with the fourth. Because of the disulfide constraints and relatively high sequence similarity, different chemokines share quite similar structural features. As also shown by structural studies, chemokines are isolated as dimers; however, dimerization does not appear to be necessary for receptor binding and may occur most frequently at the high concentrations used for the structural studies.

The structures of chemokines are critical for function. Alteration of a single residue, especially near the amino terminus, can greatly affect activity. For example, amino-terminal modification of RANTES results in a potent receptor antagonist [17]. Several chemokines undergo natural amino-terminal proteolytic processing after secretion which can alter their activity. Platelet basic protein is inactive until processed at its amino-terminal end by monocyte proteases to form neutrophil-activating peptide 2, a potent neutrophil chemoattractant [18]. The protease CD26 removes two

amino acids from macrophage-derived chemokine (MDC) [19]; this destroys its activity on CCR4 but enhances its binding to CCR5, enabling it to inhibit HIV entry. HCC-1 is found in serum at relatively high concentrations, but it is inactive until its amino-terminal end is cleaved off [20]. Limited proteolysis may be a general mechanism that allows local factors to regulate chemokine activity.

The α chemokines (with 16 human members thus far) can be divided into two functional groups. The CXC chemokines that contain the sequence glutamic acid–leucine–arginine (ELR) preceding the CXC sequence are chemotactic for neutrophils [21]. Such chemokines play an important role in acute inflammatory diseases. The other (non-ELR) group of CXC chemokines tend to act on lymphocytes. For example, IP-10 and MIG (monokine induced by interferon- γ) attract activated T cells [22], and stromal-cell-derived factor 1 (SDF-1) acts on resting lymphocytes [23]; SDF-1 also plays a critical role in cardiac and neuronal development [24,25].

There are at least 28 human β chemokines. In general, these CC chemokines attract monocytes, eosinophils, basophils, and lymphocytes with variable selectivity, but they do not attract neutrophils. The four monocyte chemoattractant proteins and eotaxin form a subfamily for which the members are approximately 65% identical to each other [26]. As with the CXC family, the amino-terminal amino acids preceding the CC residues of β chemokines are critical for biologic activity and leukocyte selectivity [27].

Chemokines can be divided into two general classes based on whether they are induced by pro-inflammatory cytokines

or are constitutively expressed [4]. The induced chemokines are upregulated very quickly at sites of infection or trauma and control the recruitment of leukocytes to the affected area. The constitutive chemokines are generally more involved in controlling migration of leukocytes through various tissues. This allows for naïve T and B cells to encounter antigen in secondary lymphoid organs and results in their subsequent activation and differentiation. In addition, the migration of T cells in the thymus is regulated by chemokines as thymocytes proceed through development [28].

Chemokine Receptors

Chemokines induce cell migration and activation through interactions with a family of cell-surface receptors containing seven transmembrane regions [2]. Typical of all heptahelical receptors, ligand binding induces a cascade of intracellular events mediated by activation of G proteins. Early studies showed that chemokine responses were sensitive to inhibition by pertussis toxin, confirming coupling of these receptors through the G_i family of G proteins [29]. A key result of chemokine binding is the activation of phospholipase C, producing inositol-1,4,5-trisphosphate (IP₃) and diacylglycerol [30]. Elevation of these products leads to release of Ca⁺⁺ from intracellular stores and activation of protein kinase C. Chemokine receptor engagement can also lead to stimulation of other intracellular enzymes such as phosphatidylinositol 3-kinase [31,32], mitogen-activated protein kinase, and the ras family of GTP binding proteins [33,34,35]. These signaling events are key mediators of the ultimate cellular responses to chemokines, most notably cell migration. Different chemokines may participate in alternative downstream signaling pathways. For example, chemokines that have acute inflammatory properties ultimately activate nuclear factor κB (NF-κB) and modulate transcription of inflammatory cytokines. Other chemokines are involved in alternative signaling cascades responsible for cellular differentiation or angiogenesis [36].

The first chemokine receptors identified were the IL-8 receptors in 1991 [37,38]. Since then, a total of 18 chemokine receptors have been identified. They are divided into several classes, depending on the type of chemokine they bind (see Table 1). Six CXC receptors (CXCRs) that interact with one or more of the CXC chemokines have been identified. In addition, ten CCRs bind only CC chemokines. There are also single members in the CX3CR and XCR classes. Most of the CXCRs and CCRs interact with multiple chemokines, resulting in considerable apparent redundancy of chemokine function [1,2].

Chemokine receptors contain conserved motifs found in all members of the family of chemoattractant receptors. Certain regions in the extracellular domains have been implicated in chemokine ligand binding. The amino terminus of the receptors was found to be necessary and to confer specificity for binding to their cognate ligands. However, a region of the third extracellular loop, extending into the

transmembrane domain, was also determined to be involved in high-affinity ligand binding and receptor signaling [39,40]. Most chemokine receptors have two disulfide bonds in their extracellular domains that are necessary for chemokine binding, while the majority of GPCRs have a single disulfide bridge [41]. Regions in the third intracellular loop and carboxy terminus have been shown to interact with G proteins, similar to other G-protein-coupled receptors [42]. The carboxy terminus is also rich in serine and threonine residues, which are thought to be phosphorylated, leading to interaction with arrestin to turn off the receptor signal [43]. Posttranslational modifications of the chemokine receptors include glycosylation (residues in the amino terminus and third extracellular domain) and sulfation (tyrosine residues in the amino terminus), which are necessary for high-affinity interactions with chemokine ligands [44].

Each chemokine receptor is expressed on a subset of cells and confers responsiveness of those cells to particular chemokines. Some receptors are restricted to a particular leukocyte. For example, CXCR1 is found almost exclusively on neutrophils [38]. Others are more broadly expressed, such as CXCR4. Other chemokine receptors are expressed only by a subset of cells in a certain activation state. CXCR3 for example is expressed only on activated T cells of the Th1 subtype. T cells especially seem to regulate their expression of many chemokine receptors in response to activating cytokines and other external stimuli [22]. Receptor regulation with cell activation allows for a selective amplified response to a particular antigen.

In addition to their role in cell migration, chemokine receptors are utilized by various pathogens to gain access to host cells [45]. The most striking example is HIV, which can interact with CXCR4 and CCR5, along with CD4, to infect T cells and macrophages (reviewed in Clapham and McKnight [46]). This discovery, made in the mid-1990s, has inspired great efforts to produce inhibitors of the HIV/receptor interaction as a treatment for AIDS.

While chemokines are necessary for coordinating leukocyte defense against external invaders, inflammation often occurs inappropriately and can lead to a variety of diseases [47]. Over-expression of chemokines and chemokine receptors has been reported in many conditions, leading to leukocyte accumulations in tissues. These include rheumatoid arthritis, multiple sclerosis, psoriasis, ulcerative colitis, asthma, and arteriosclerosis. In animal models for many of these diseases, chemokine inhibitors (generally blocking antibodies) have been found to prevent development of inflammatory lesions. Chemokines and their receptors have also been implicated in carcinogenesis [48].

Small molecule inhibitors of chemokine/receptor interactions are being developed for treatment of many human inflammatory diseases [49,50]. GPCRs have historically been very good targets for drug development and hold promise for success in the chemokine area. Some chemokine inhibitors that have reached human clinical trials target CCR1, CCR5, and CXCR4. Others that are in preclinical development include inhibitors of CCR2, CCR3, CCR4, CCR6, CXCR2,

and CXCR3. By targeting specific receptors, the hope is that only subsets of leukocytes involved in disease will be affected while general immune functions can still occur. The future of chemokine inhibitors looks bright, and we should soon have clinical data to confirm the potential for utilizing these inhibitors for treating disease.

Introduction

G-protein-coupled receptors (GPCRs) represent a very large superfamily of receptors that are critical for signaling of a diverse group of ligands to heterotrimeric G proteins [1]. At least 30% of predicted potential drug targets are GPCRs [2]. Ligands for these receptors include light, odorants, tastes, small-molecule neurotransmitters, peptides, glycoprotein hormones, proteases, and others. GPCRs are composed of seven transmembrane segments, with an extracellular amino terminus and a cytoplasmic carboxy terminus. In the class A, rhodopsin-like GPCRs, the binding pocket is formed among the transmembrane segments and/or extracellular loops. The role of these receptors, as for all GPCRs, is to transmit a conformational change induced by extracellular signaling molecules from the ligand-binding pocket via the transmembrane segments to the cytoplasmic surface of the receptor and subsequently to the G protein. The conformational change produced by agonist binding facilitates the interaction of the receptor with G protein and the subsequent exchange of guanosine diphosphate (GDP) for guanosine triphosphate (GTP), which results in dissociation of the G-protein heterotrimer to form activated G α and G $\beta\gamma$.

Despite an enormous amount of research on the structure and function of these receptors, until very recently no high-resolution structure of any GPCR was available. In 2000, the crystal structure of bovine rhodopsin was determined to 2.8 Å [3]. Based on an analysis of the consistency of previous data from a number of different GPCRs with the structure of rhodopsin, we have inferred that the overall structures of rhodopsin and of class A receptors are very similar, although we also identified localized regions where the structure of these receptors may diverge [4]. We further proposed that several of the unusual bends and twists in the transmembrane segments (TMs) of rhodopsin are also present in other GPCRs, despite the absence of amino acids that might have been thought to be critical to the adoption of these features. Thus, different amino acids or alternative microdomains can support similar deviations from regular α -helical structure, thereby resulting in similar tertiary structure. Such structural mimicry may be a mechanism by which a common ancestor could diverge sufficiently to develop the selectivity necessary to interact with diverse signals, while still maintaining a similar overall fold. The shared three-dimensional architecture of different class A GPCRs suggests that they may also share the basic mechanisms of ligand-induced conformational change. Thus, although there is no logical necessity

that all GPCRs use the same cognate amino acid positions to bind ligand [5], as discussed below, it seems likely that many indeed do so.

With hundreds of class A receptors and more than 700 GPCRs in the human genome alone, it is important to develop a language and nomenclature that can allow scientists studying different receptors to communicate. To facilitate the comparison of aligned residues in different GPCRs, we use and advocate the indexing method introduced by Ballesteros and Weinstein [6], in which the most conserved residue in each transmembrane segment (TM) is given the index number 50. Thus, for example, the Arg in the highly conserved (E/D)RY sequence at the cytoplasmic end of TM3 is Arg^{3.50}, and the other residues in TM3 are indexed relative to this position, with the preceding Asp^{3.49} and the subsequent Tyr^{3.51}. This method, which counts from the most conserved position rather than from inexact inferences of the beginning of the TMs, facilitates comparison among different GPCRs. Arg^{3.50} now takes on significant meaning in any GPCR, and Arg131^{3.50} in the β 2-adrenergic receptor (AR) identifies not only the absolute residue number in the β 2-AR sequence but also the position of the aligned residue in other GPCRs. In contrast, unless one's research focuses on these receptors, for example, Arg131 in the human

β 2-AR or Arg135 in bovine rhodopsin or Arg519 in the human thyrotropin receptor are meaningless residue numbers without reference to a multiple alignment and much counting of residues. The index residues in each of the TMs of bovine rhodopsin are Asn55^{1.50}, Asp83^{2.50}, Arg135^{3.50}, Trp161^{4.50}, Pro215^{5.50}, Pro267^{6.50}, and Pro303^{7.50} (Fig. 1). All of these are highly conserved in aminergic receptors and rhodopsins and therefore allow unambiguous alignment of the TMs of these receptors.

The Binding Pocket of GPCRs

In this chapter, we compare the binding sites of aminergic GPCRs and the retinal-contact residues in rhodopsin. Other than rhodopsin itself, the aminergic GPCRs have been the most exhaustively studied GPCRs, although the comparison is probably relevant to many other class A receptors as well. The results of a solvent-accessible surface area (SASA) analysis of the high-resolution structure of rhodopsin in the presence and absence of retinal are shown in Table 1. The difference between these two calculated surfaces represents the surface of the binding-site crevice in rhodopsin that is protected from water by retinal. It is important to

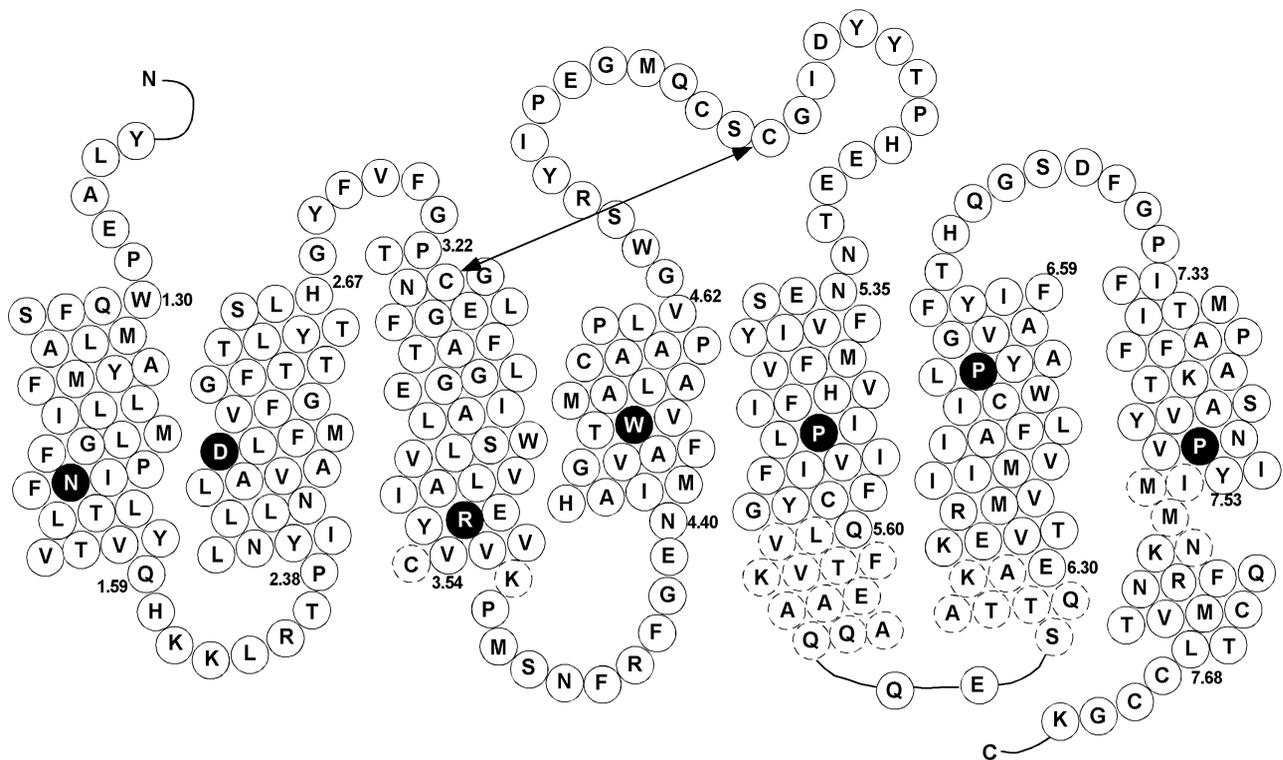

Figure 1 Helical net representation depicting the relative positions of the residues in the transmembrane domain of rhodopsin and the indexing system. The helix ends are shown as per the rhodopsin structure. TM1 is from index 1.30 (rhodopsin residue 35) to 1.59 (64), TM2 is from 2.38 (71) to 2.67 (100), TM3 is from 3.22 (107) to 3.54 (139), TM4 is from 4.38 (149) to 4.62 (173), TM5 is from 5.35 (200) to 5.60 (225), TM6 is from 6.30 (247) to 6.60 (277), and TM7 is from 7.33 (286) to 7.54 (307). The most conserved residue in each TM is Asn55^{1.50}, Asp83^{2.50}, Arg135^{3.50}, Trp161^{4.50}, Pro215^{5.50}, Pro267^{6.50}, and Pro303^{7.50}. Their single letter codes are shown in white on filled black circles. Residues at the cytoplasmic ends of TM5, TM6, and TM7 predicted by spin-labeling studies to be in an α -helical conformation but which are not in an α -helical conformation in the rhodopsin structure are shown with dotted circles (4).

Table I Residues in Bovine Rhodopsin Found in SASA Calculations To Be Protected by Retinal and Representative Receptors in Which the Aligned Residue Has Been Implicated in Ligand Binding

Residue	SASA(Å ²) ^a			Representative receptors
	NR	WR	Δ

Note: Receptor names are abbreviated according to their SWISS-PROT Annotated Protein Sequence Database entry names: <http://www.expasy.ch/cgi-bin/lists?7tmrlist.text>. Ser186–Ile189 forms β4 in E2 (see text).

Residue indexing: To facilitate comparison of aligned residues in related GPCRs, the most conserved residue in TMX is given the index number X.50, and residues within a given TM are then indexed relative to the “50” position [6]. The most highly conserved residues in this family are indicated in Fig. 3 in an alignment of rhodopsin with a selected group of class A GPCRs. (Note that the “50” position does not require the residue to be in the middle of the TM; for example, the highly conserved Arg^{3.50} is at the cytoplasmic end of TM3 in the conserved E/D–R–Y sequence.)

^aThe calculation is based on chain A of the refined bovine rhodopsin structure (PDB code 1HZX). NR, the SASA is calculated without retinal; WR, the SASA is calculated with retinal; Δ, the difference between NR and WR. The values shown are the surface area of each residue that is exposed to solvent.

^bProtected residues in D₂ receptor SCAM experiments [14,23–26].

^cAccessible but protection not tested due to small effect size [26].

Source: Adapted from Table 3 of Ballesteros, J. *et al.*, *Mol. Pharmacol.* 60, 1–19, 2001, which contains the references for the studies in the representative receptors, except for 3.40 [27,28] and 4.56 [29,30].

note that, in the dark, retinal is an inverse agonist, a particular type of antagonist that stabilizes the inactive state of the receptor and contributes to the very low constitutive activity of rhodopsin in the dark (see Chapter 22). Upon photoisomerization by light, retinal adopts a different configuration in the binding pocket and becomes an agonist. The high-resolution rhodopsin structure was obtained in the dark in an inactive state, and because there is no high-resolution active structure, the conformational changes involved in receptor activation have been studied using indirect methods.

The residues identified by the SASA analysis in rhodopsin are highlighted in Figs. 2 and 3A, in which retinal is shown within the binding-site crevice formed by the retinal-protected residues. The positions of these residues are remarkably consistent with those of previously identified ligand–receptor contact sites for aminergic GPCRs (Table 1), as well as with our substituted-cysteine accessibility method (SCAM) studies of the dopamine D₂ receptor (reviewed in Ballesteros *et al.* [4]). Figure 3B illustrates this agreement with the backbone of the rhodopsin structure and the side chains of the β2-AR that have been shown to interact

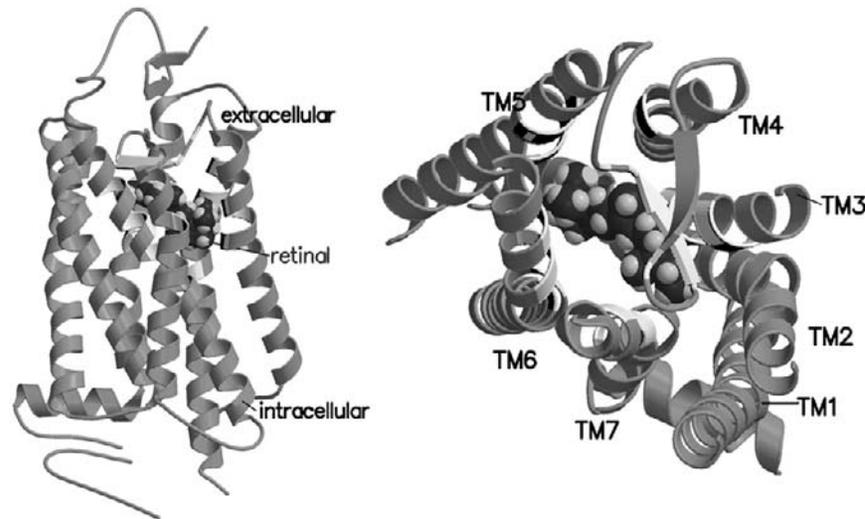

Figure 2 Schematic three-dimensional representations of the bovine rhodopsin structure. The 7 α -helical TMs are shown as green ribbons. The β -strands in the extracellular domain are indicated by large strand arrows. The positions of the residues that are in direct contact with the ligand retinal are colored yellow. The left panel shows a side view, and the right panel shows an extracellular view of the 7 α -helical TMs and E2, but with the amino terminus, E1, and E3 removed.

directly with catecholamine agonists. These residues include Asp113^{3,32}, which interacts with the protonated amine of biogenic amines; Ser203^{5,42}, Ser204^{5,43}, and Ser207^{5,46}, which interact with the *meta*-OH and *para*-OH of catecholamines; Asn293^{6,55}, which interacts with the β -OH of epinephrine; and Phe208^{5,47}, Trp286^{6,48}, Phe289^{6,51}, and Phe290^{6,52}, which form a cluster of aromatic residues in TM5 and TM6 that interact with the aromatic ring of ligands. Even without modification of the rhodopsin backbone, it is clear that epinephrine fits remarkably well within the binding site formed by these critical residues.

In Fig. 3C, we illustrate a β 2-AR antagonist affinity label, docked within the TMs of the rhodopsin structure, with all the residues from Table 1 mutated to the aligned β 2-AR residues. Again, the ligand is bound to essentially an overlapping set of the residues that contact retinal in rhodopsin. It is important to note that, although some of the residues in the binding-site crevice of these receptors are conserved, most are not. Thus, these residues have apparently evolved to impart specificity within a certain receptor. Consequently, what is “conserved” among these receptors are the positions of the residues involved in ligand binding and thus the particular surface that serves the role of ligand binding.

It seems likely that many, although certainly not all, GPCRs will share similar locations of their binding pockets. Indeed, although peptide ligands bind to extracellular loops, at least in certain cases, there is also evidence that parts of peptides dip down into the transmembrane domain and contact some of the same positions found to be critical for binding to rhodopsin and the aminergic GPCRs [7–9]. It is likely, however, that structurally dissimilar ligands bind to some extent in different orientations, and these modes of binding can be extremely difficult to predict [10].

A Role of the Second Extracellular Loop in Ligand Binding

A surprising feature of bovine rhodopsin is the highly structured extracellular N terminus and extracellular loops [3]. In particular, the second extracellular loop (E2), which connects TM4 and TM5, dives down into the transmembrane domain and forms a “plug” that contacts retinal (Table 1 and Fig. 2). This loop also contains a highly conserved Cys that is disulfide-bonded to another highly conserved Cys at the top of TM3 [11]. E2 contains two stretches of β -strand, one of which, β 4, lies directly over retinal [3]. E2 thus forms a lid over retinal and protects it from the extracellular milieu. Given the high degree of conservation of the amino acids in the β 4 strand in vertebrate opsins, and the variability within this region in other class A receptors, the prevailing view was that the β 4 strand might serve specifically to define the retinal-binding pocket in vertebrate opsins and not other GPCRs [12,13]. We suggest that this response is at least partly wrong, for a number of reasons discussed below.

We do not yet know of any structural similarity of E2 between rhodopsin and other class A receptors beyond the shared disulfide bond, but the sequence at the extracellular end of TM4 and the beginning of E2 is highly conserved among functionally related receptors and among species variants of these receptors, despite the fact that the sequence of E2 is highly variable across class A receptors [14]. In addition, this region has been identified as the site of covalent attachment of photoaffinity derivatives of agonist and antagonist ligands of the α 2-AR [15], and mutations in this region have ligand-specific effects (reviewed in Javitch *et al.* [14]). Moreover, known ligand binding sites in other TMs are predicted to be in spatial proximity to this region. It is likely, therefore, that this region plays a functional role, and it

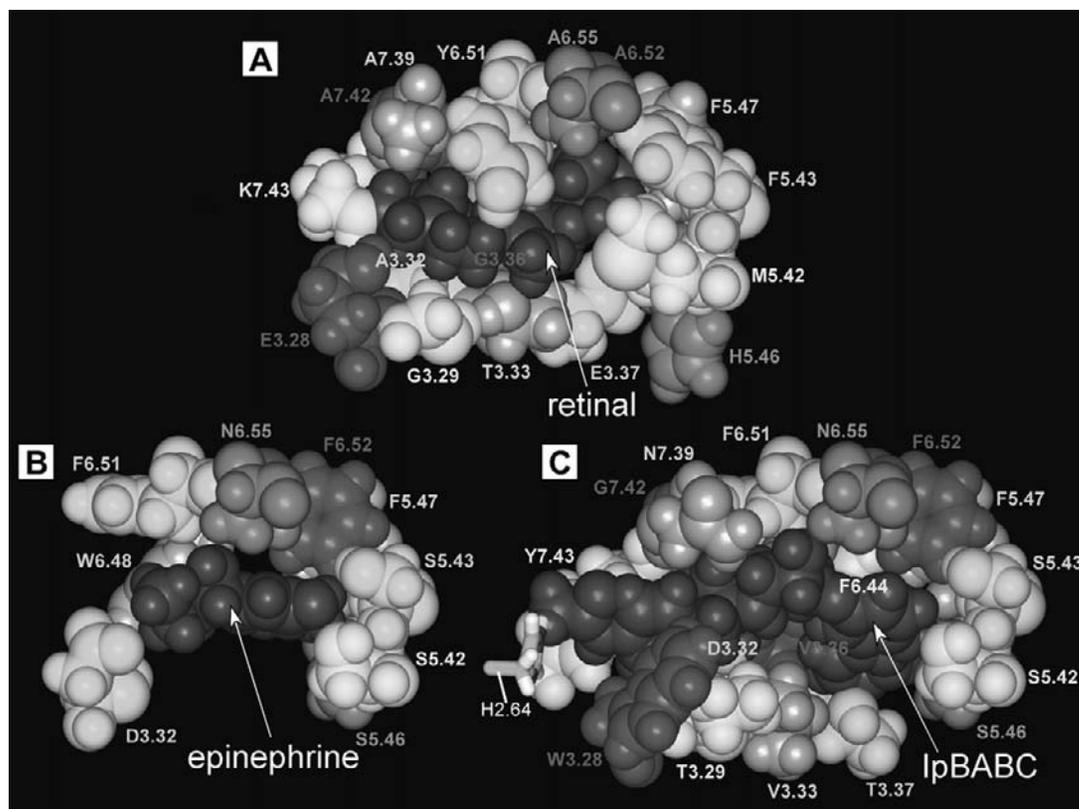

Figure 3 Ligand binding crevice. In (A), the residues in the TMs that were identified from the SASA analysis (see text, Table 1, and Fig. 2) are shown in van der Waals representation, with retinal bound within the surface created by these residues. In (B), the side chains of residues from the β 2-adrenergic receptor are shown on the backbone of the rhodopsin structure. These residues have been experimentally determined to interact with catecholamine ligands, and include Asp113^{3,32}, Ser203^{5,42}, Ser204^{5,43}, Ser207^{5,46}, Phe208^{5,47}, Trp286^{6,48}, Phe289^{6,51}, Phe290^{6,52}, and Asn293^{6,55}, a subset of the positions shown in (A). In (C), IpBABC (p-(bromoacetamido) benzyl-1-[¹²⁵I]iodocarazolol), an affinity label derivative of pindolol, is docked within the TMs of the rhodopsin structure with the TM residues from Table 1 mutated to the aligned β 2-adrenergic receptor residues. IpBABC is shown covalently attached to His93^{2,64} in TM2. Residues with the same index number are shown in the same color in all three panels. The residues displayed next to each other are shown in different colors. (From Ballesteros, J. *et al.*, *Mol. Pharmacol.* 60, 1–19, 2001. With permission.) A color representation of this figure is available on the CD version of the *Handbook of Cell Signaling*.

is possible that an orientation of E2 similar to that in rhodopsin may explain these findings.

Several reports implicate E2 in ligand specificity in a number of small molecule-ligand GPCRs. Perez and colleagues found that substitution of three consecutive residues in E2 changed the ligand specificity for particular antagonists from that of α_{1B} AR to that of α_{1A} AR, and vice versa [16]. Similarly, substitution of E2 and TM5 altered the subtype specificity of the 5-HT_{1D} receptor to that of the 5-HT_{1B} receptor and vice versa [17], and substitution of a single residue in E2 was also sufficient to interconvert the pharmacological specificity of canine 5-HT_{1D} and human 5-HT_{1D} receptor [18]. In adenosine receptor, in which the binding site is also formed in the transmembrane domain [18], several glutamate residues in E2 are critical for ligand recognition [20,21]. Although it is currently difficult to envision the entrance route of ligands into the binding-site crevice and the potential associated conformational rearrangements of E2, these data nonetheless suggest a direct role of residues in E2 in ligand binding in other class A receptors [22].

Acknowledgments

We are grateful to all our current and former colleagues and collaborators, and especially to Myles Akabas, Juan Ballesteros, Arthur Karlin, and Harel Weinstein for much helpful discussion, and to NIMH grants 57324 and 54137, the Lebovitz Foundation, and the Lieber Center for support.

Introduction

The glycoprotein hormones (GPHs) and their receptors (GPHrs) constitute an interesting paradigm of agonist–receptor coevolution. The hormones of pituitary or placental origin, lutropin (LH), chorionic gonadotropin (CG, with lutropin activity), follitropin (FSH), and thyrotropin (TSH), are dimeric glycoproteins of about 30 kDa made of a common alpha subunit and a specific beta subunit endowed with the functional and binding specificity. In all vertebrates, beta subunits are encoded by paralogous genes. The tridimensional structures of CG and FSH have been solved at 2.6- and 3-Å resolution, respectively [1,2]. To these three different hormone activities correspond the three GPHrs, namely the LH/CGr [3], FSHr [4], and TSHr [5,6]. The GPHrs have a bipartite structure reflecting a dual evolutionary origin; they are made of a serpentine portion with seven transmembrane alpha helices, typical of rhodopsin-like G-protein-coupled receptors (GPCRs), and a large (350 to 400 residues) amino-terminal extracellular domain containing nine motifs characteristic of the family of leucine-rich repeat (LRR) proteins.

All three receptors are preferentially coupled to Gs, although at high agonist concentrations they also couple to Gq [3,4,7]. Mining of genomes and low-stringency PCRs have revealed additional GPCRs with a similar structural organization; these will not be dealt with further here [8].

Molecular Pathophysiology

Amino acid substitutions at each of 20 separate positions cause constitutive activation of TSH or LH/CG receptors [9]. The TSH receptor has been particularly fertile in activating mutations because of the fact that somatic mutations leading to activation of the TSHr cause a readily detectable thyroid phenotype (i.e., autonomous toxic adenomas) [10]. Much less frequent are germline mutations with similar activating effects. When affecting the TSHr or LH/CGr, they cause autosomal dominant hyperthyroidism or pseudo precocious puberty of the male, respectively [3,9]. Except for a single anecdotal case, no disease has been associated with activating mutations of the FSHr [4].

Structure Function Relationships of the Glycoprotein Hormone Receptors

The particularly wide spectrum of activating mutations identified in the TSHr correlates with the observation that wild-type TSHr displays readily detectable basal activity [10,11], whereas gonadotropin receptors are virtually silent in the absence of their ligands [12]. Another peculiarity of the TSHr is the spontaneous cleavage of a proportion of the molecules present at the cell surface into two subunits that remain linked by disulfide bridges [6].

The GPHrs show clear structural dichotomy between the ligand-recognizing amino-terminal ectodomain and the serpentine rhodopsin-like portion that transmits the signal to the G protein. How does binding of the hormone to the

ectodomain result in the activation of the serpentine domain? We will summarize the three key steps in this process: recognition and binding of the hormones, activation of the serpentine portion of the receptors, and intramolecular transduction of the activation signal between the ectodomain and the serpentine portion.

Structure and Function of the Ectodomain of Glycoprotein Hormone Receptors

The ectodomain of all three receptors is made of nine leucine-rich repeats (LRRs), each ≈ 25 amino acids, flanked by two-cysteine containing domains (Fig. 1A,B). LRR-containing proteins constitute a large family of both intra- and extracellular molecules specialized in protein-protein

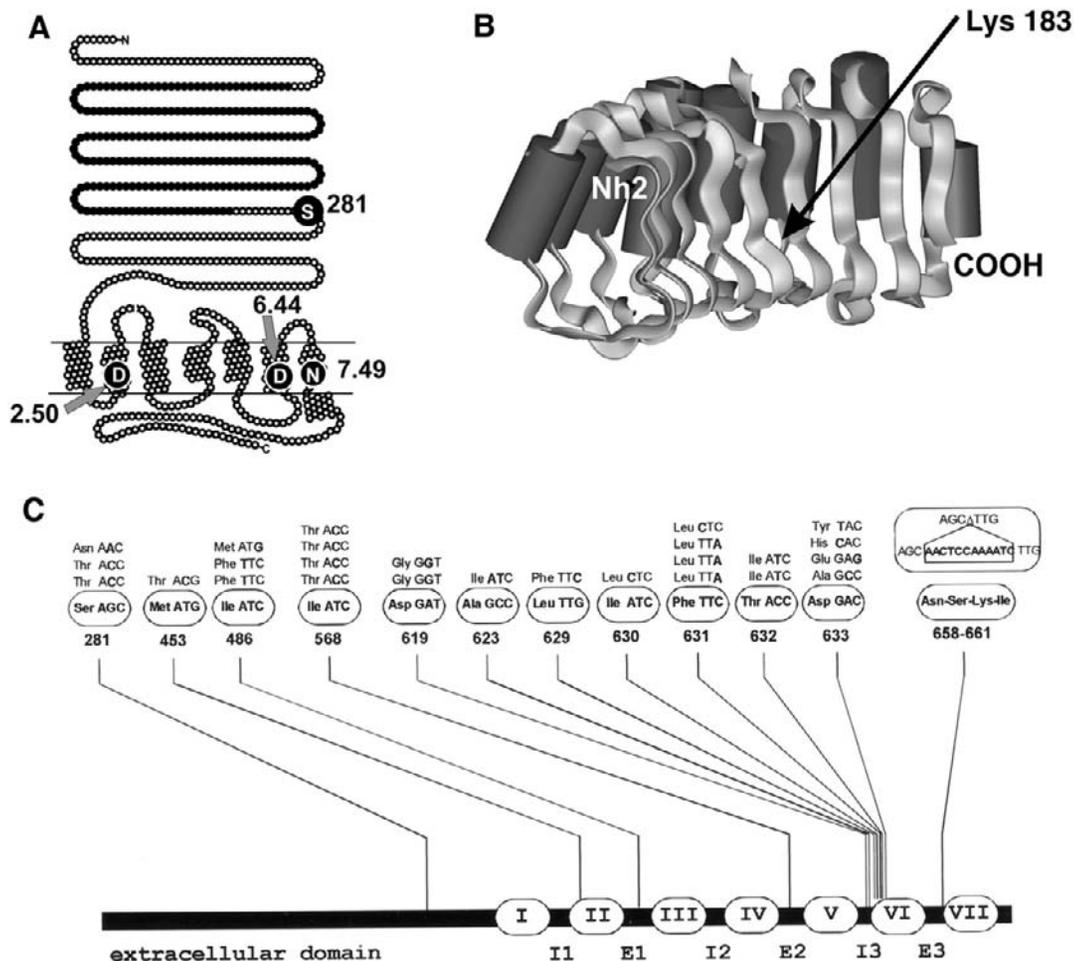

Figure 1 Schematic representation of the TSH receptor (A), ribbon representation of the model of the leucine rich repeats region (B), and illustration of the position of a series of activating mutations (C). (A) The seven transmembrane helices are drawn as helical nets, respecting the helice ends as observed in the crystal structure of rhodopsin [51]. Closed circles in the N-terminal extension represent the portion of the domain modeled by Kajava *et al.* [14], comprising residues 54 to 254. Some of the key residues discussed in the text are indicated as black circles with an indication of the amino acid and the position (numbering system of Ballesteros *et al.* [50]) (B) The α -helices are drawn as solid tubes. The “horseshoe” curvature is clearly visible, and the position of the residue mutated in pregnancy hyperthyroidism (Lys 183) is indicated. (C) The TSH receptor is represented linearly, with the transmembrane helices indicated in Roman numerals. The positions of a series of activating mutations are indicated with the nature of the amino acid substitutions. The numbering is TSHr specific (e.g., D633 corresponds to D6.44). (Adapted from Smits, G. *et al.*, *Mol. Endocrinol.*, 16, 722–735, 2002; Parma, J. *et al.*, *J. Clin. Endocrinol. Metab.*, 82, 2695–2701, 1997. With permission.)

interactions [13]. Structural models for the ectodomains of the TSHr and LH/CGr were elaborated on the basis of the three-dimensional structure of an LRR protein, ribonuclease inhibitor [14,15]. The models predict that the LRR portion of the ectodomains of the receptors would adopt a horseshoe (or segment of doughnut) shape, with alpha helices and beta sheets making the convex and concave surfaces of the structure, respectively (Fig. 1B). For the ribonuclease inhibitor, direct crystallographic evidence indicated that the concave surface was responsible for the majority of the binding interactions with the ligand (ribonuclease) [16]. The pertinence of this model has been tested for the LH/CGr, essentially by means of loss-of-function mutations [15,17,18]. In the case of the TSHr, a gain-of-function mutation was identified in a family presenting with pregnancy-dependent hyperthyroidism due to a K183R amino acid substitution, located in the middle of the LRR portion of the ectodomain of the receptor (Fig. 1B), predicted to face inside the putative hormone binding domain [19]. Functional studies in transfected C cells show that the K183R mutant becomes abnormally sensitive to the pregnancy hormone hCG [19]. The gain of function, though modest, is enough to cause disease because of the extremely high concentration of hCG achieved during the first trimester of pregnancy. Extensive site-directed mutagenesis based on the putative structural model suggested that the gain of function was due to the unmasking of the negative charge of glutamic acid in position 157 from a salt bridge with lysine 183, not achieved with the arginine replacement [20]. Any amino acid substitution in position 183 causes a gain of function similar to that of K183R. Definitive validation of the model of the TSHr based on the structure of the ribonuclease inhibitor has been obtained very recently. Conversion of eight carefully selected residues of the putative binding surface of the TSHr to their LH/CGr homologs yields a TSHr mutant displaying a sensitivity to hCG comparable to that of wild-type LH/CGr (G. Smits *et al.*, in preparation).

A posttranslational modification with important functional significance has recently been identified in all three GPHrs. Close to the border between the ectodomain and the first transmembrane segment of the serpentine, the three receptors harbor a motif that undergoes tyrosine sulfation just before insertion of the molecule into the plasma membrane [21]. The sulfated tyrosines are an important component of the binding surface, as mutant receptors unable to become sulfated lose sensitivity to their hormones by one order of magnitude [21]. This identifies the sulfated tyrosines as an important participant in the known ionic interactions between GPH and their receptors [22].

Activation of the Serpentine Portion

The GPHr and, in particular, the TSHr can be activated by a wide spectrum of amino acid substitutions or deletions affecting mainly but not exclusively the serpentine domain (Fig. 1C) [9]. Some of these are homologous to activating mutations identified initially in adrenergic receptors [23,24].

Others involve residues specific to the GPHr subfamily. Despite their high sequence similarity, the three receptors display great differences in the propensity to be activated by mutations, with the TSHr being more prone to activation than the LH/CGr and the FSHr being particularly refractory [25]. The structural bases for these differences are still unknown. Among the spontaneous gain of function mutations, those affecting residue D6.44, in the sixth transmembrane segment (numbering system of Ballesteros *et al.* [26]) deserve special attention. This residue is part of one of the sequence signatures specific to the GPHr in transmembrane VI [27]. D6.44 (D633 or D578 in the TSHr- or LH/CGr-specific numbering systems, respectively) is one of the residues most frequently mutated in precocious puberty of the male and toxic thyroid adenomas.

Experiments performed with the TSHr were driven by the observation that in LGR1 (a glycoprotein hormone receptor homolog of *Drosophila*) [28] Asp and Asn residues were naturally exchanged between 6.44 and 7.49, suggesting that these residues of transmembrane segments VI and VII interact with each other. Functional studies of single and double mutants transfected in COS cells led to the following model: In the inactive state of the receptor, D6.44 and N7.49 interact; release of the side chain of N7.49 from this interaction, caused by mutation of D6.44 (e.g., D6.44A), would make it available for interactions involved in stabilization of an active state of the receptor [29]. This conclusion is also drawn from the observation that the N7.49A mutant loses the ability to be stimulated by TSH. Addition of the N7.49A mutation to constitutively active TSHr mutants dramatically reduces their activity, to the level of the wt receptor or below [30]. These results are in agreement with others that point to N7.49, one of the most conserved residues in rhodopsin-like GPCRs, as a key residue involved in stabilizing both the inactive and the active conformations (see discussion in Meng and Bourne [31] and Lu *et al.* [32]). The partner(s) of N7.49 in the active conformation is (are) still subject to intense investigation; in several other GPCRs, experimental evidence points to D2.50 [33–36]. It is likely that a complex network of interactions implicating N7.49 and D2.50, but also other residues (e.g., N1.50), stabilizes the active conformation [31,32].

Intramolecular Signal Transduction Between the Ectodomain and the Serpentine Domain

The observation that ectodomains of the GPHr can bind their agonists with high affinity in the absence of the serpentine domain [1,37,38] is compatible with two models for the activation of the receptors. According to the first, high-affinity binding of the agonist would position the hormone for a low-affinity interaction with the extracellular loops (and/or crevice) of the serpentine, leading to activation. A candidate for this activating interaction is the alpha subunit common to the three hormones. Experimental support for this model has been provided by site-directed mutagenesis experiments introducing reciprocal mutations in the LH/CGr and hCG and by affinity labeling [39,40].

The above model, however, does not account for the capacity of the three receptors to be fully activated by point mutations in their ectodomain. A serine in position 281 of the TSHr was found mutated to threonine, asparagine, or isoleucine in autonomous thyroid adenomas [41–43]. Subsequently, it was found that mutations introduced at homologous positions in the LH/CGr (S277) and FSHr (S273) were similarly active [44]. This led to the notion that the ectodomain normally exerts a silencing effect on the serpentine domain and that activation of the GPHr results from the release of this inhibitory interaction. Direct evidence for this silencing role of the ectodomain was obtained in two types of experiments. In the first, constructs containing only the serpentine domain of the TSHr were shown to increase basal cAMP levels when expressed in transfected cells [45,46]. In the second, chimeric molecules were made containing segments of LGR2 [47] (a *Drosophila* homolog of the GPHr with a high basal activity) and the LH/CGr (which is virtually devoid of basal activity). The results indicated the establishment of silencing interactions between a segment of the ectodomain (containing serine 277 of LH/CGr, see above) and the second extracellular loop of the transmembrane domain, provided they both originate from the LH/CGr [8]. From these experiments, one could propose that activation

of GPHrs by their agonists results from the release of a silencing effect exerted by the unliganded ectodomain on an intrinsically active serpentine.

Whereas this would be in agreement *qualitatively* with the above experiments, it does not account for the observation that, when normalized to the level of receptor expression at the cell surface, the basal activity of serpentine-alone TSHr constructs is much lower than the maximal activity achieved after stimulation by saturating concentrations of the hormone, or in the most active serine 281 mutants [45]. In an attempt to integrate available information, we have proposed a model for the activation of the TSHr in which the ectodomain would act as a molecular switch (Fig. 2) [45]. In the “off” position, in the absence of hormone, the ecto domain acts as a tethered inverse agonist of the serpentine domain, minimizing basal activity. Binding of the hormone to the receptor stabilizes the “on” position, in which the ectodomain now behaves as a tethered full agonist. Mutations affecting serine 281 of the ectodomain similarly puts the switch in the “on” position. The relative potency of individual amino acid substitutions at S281 indicates a direct relation between the destructuring effects of the mutations and constitutive activity [44,48], suggesting that the gain of function results from a local loss of structure in the ectodomain.

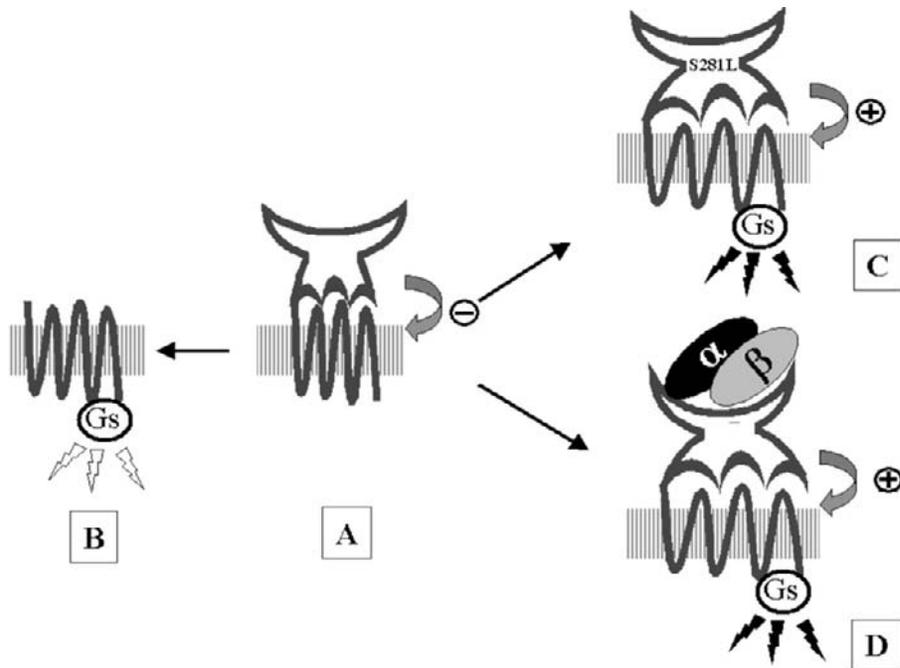

Figure 2 Putative model of the intramolecular interactions involved in the activation of the TSH receptor. (A) The basal state of the receptor is characterized by an inhibitory interaction between the ectodomain and the serpentine domain; the ectodomain would function as a tethered inverse agonist. (B) Removal of the ectodomain releases the serpentine domain from the inhibitory interaction, resulting in partial activation. (C) Mutation of Ser281 into Leu switches the ectodomain from an inverse agonist into a full agonist of the serpentine domain. (D) Binding of TSH to the ectodomain is proposed to have a similar effect, converting it into a full agonist of the serpentine portion. It must be stressed that the scheme is purely illustrative. It emphasizes that, according to the model, activation does not require a direct interaction between the hormone and the serpentine domain. Such an interaction, however, is by no means excluded. (Adapted from Vlaeminck, V. *et al.*, Activation of the cAMP pathway by the TSH receptor involves switching of the ectodomain from a tethered inverse agonist to an agonist. *Mol. Endocrinol.*, 16, 736–746, 2002.)

A last set of experiments suggests that the molecular switch controlling activation of the serpentine domain must be a composite structure combining a portion of the ectodomain and the extracellular loops of the serpentine. A spectrum of well-defined activating mutations of the TSHr were engineered, either on a holoreceptor background or in serpentine-alone constructs. Whereas the mutations in the transmembrane segments or intracellular loops were equally effective on both backgrounds, mutations of the extracellular loops with a strong effect on the holoreceptor were totally ineffective on the serpentine-alone constructs [45]. This model does not rule out that activation of GPHr involves a direct interaction between the hormones and the serpentine portion of the receptors, but it indicates that such an interaction is not required to account for most observations. In the case of the TSHr, it also provides a rationale for the activation of the receptor by autoantibodies present in the plasma of patients with Graves' disease [6]. According to this model, stimulating autoantibodies would only need to have a "destructuring" effect on a segment of the ectosomain controlling the molecular switch.

Conclusions and Perspectives

With their bipartite structure already present in primitive marine invertebrates [49], the GPHr have evolved a specific way to become activated after binding of their hormones to the ectodomain. On the other hand, their membership in the rhodopsin-like family of GPCRs implies that basic molecular mechanisms implicated in the activation of their serpentine domain must be shared with this protein family. We believe that these peculiarities provide a unique opportunity to dissect the molecular steps of activation of type I GPCRs. The particularly wide spectrum of activating mutations in GPHr are expected to mimic (and allow us to explore) the sequential conformational changes that begin after binding of agonists and terminate with activation of the G protein.

Protease-Activated Receptors

University of California, San Francisco,
San Francisco, California*

Introduction

G-protein-coupled receptors have evolved a variety of mechanisms to acquire information about the environment of a cell. They sense light, odorants, ions, lipids, nucleotides, amino acids and their derivatives, small peptides, polypeptides, and large glycoprotein hormones. This chapter describes a sub-family of heptahelical receptors known as protease-activated receptors (PARs), which have evolved to sense proteases [1–8]. PAR1, the prototype for the PAR family, was identified in the context of an effort to understand how the coagulation protease thrombin activates platelets and other cells. Thrombin is a multifunctional serine protease generated at sites of tissue injury. In addition to cleaving fibrinogen, thrombin triggers a variety of cellular responses from platelet aggregation to endothelial display of adhesion molecules to fibroblast proliferation. These actions of thrombin raised the question of how a protease can function like a hormone to regulate cell behavior. PARs provide an answer.

Mechanism of Activation

Thrombin activates PAR1 by binding to and cleaving its amino terminal exodomain (Fig. 1). This cleavage event is both necessary and sufficient for receptor activation. Mutation of the cleavage site ablates receptor signaling, and substitution of cleavage recognition sites for another protease for the thrombin site confers signaling in response to that protease. Thus, the essential role of the protease in activating PARs is cleavage of the receptor at a single site within its amino-terminal exodomain. How does cleavage of this apparently flexible, unstructured domain send information across the cell membrane? The synthetic peptide SFLLRN,

which mimics the first six amino acids of the new amino terminus unmasked by receptor cleavage, functions as an agonist for PAR1 and activates the receptor independent of thrombin and proteolysis. Moreover, removal of the amino terminal exodomain of the receptor yields a receptor that responds to SFLLRN but not to thrombin. These and other data support a model in which receptor cleavage serves to unmask a new amino terminus that then functions as a tethered peptide ligand and binds to the heptahelical segment of the receptor to effect transmembrane signaling and G-protein activation. Thus, PAR1 is in essence a peptide receptor that carries its own ligand, and this ligand remains hidden until revealed by selective cleavage of the amino terminal exodomain of PAR1. This mechanism raises several interesting questions, addressed below.

How is it that the PAR1 tethered ligand remains inactive in the uncleaved receptor and is activated by cleavage? Addition of even one amino acid to the N terminus of the SFLLRN agonist peptide ablates agonist activity, as does removal of its N-terminal protonated amino group. In the uncleaved receptor, the cognate nitrogen atom is part of the peptide bond between Arg41 and Ser42, the P1 and P1' amino acids of the thrombin cleavage site. Ser42 is also the N-terminal amino acid of the tethered ligand. Thus, the proteolytic switch that activates the cryptic peptide ligand appears to involve removal of amino terminal sequence that sterically hinders ligand function as well as generation of a new and functionally important protonated amino group at the N terminus of the ligand (Fig. 2). Parallels with zymogen activation of serine proteases are apparent. In conversion of trypsinogen to trypsin, precise proteolytic cleavage generates a new amino terminus that bears a new protonated amino group; this then docks intramolecularly to trap the protease in its active conformation.

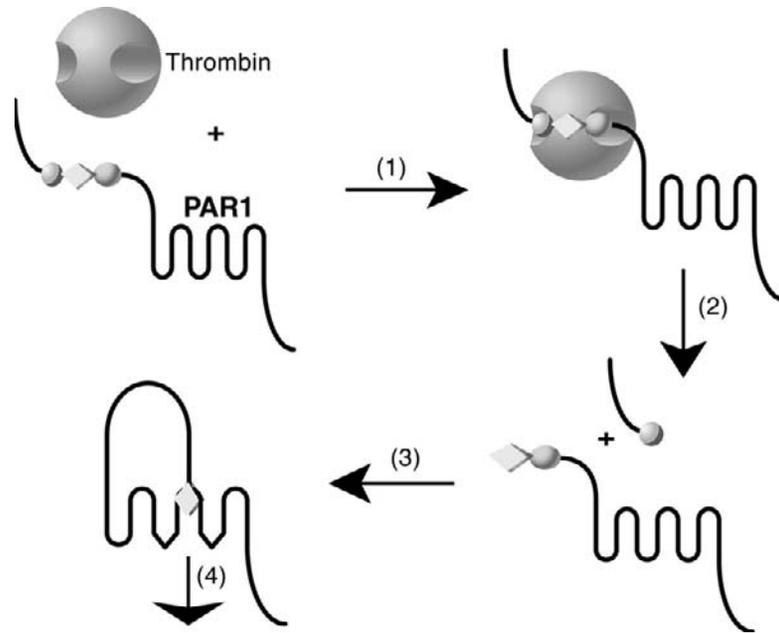

Figure 1 Model for proteolytic mechanism of PAR activation. (1) Thrombin, the green sphere, binds to the amino-terminal exodomain of PAR1. Receptor amino acids L³⁸DPR⁴¹ (small blue sphere) interact with the active center of thrombin, and receptor amino acids D⁵⁰KYEPF⁵⁵, the so-called hirudin-like domain (pink oval), interact with exosite 1 of thrombin. (2) After binding, thrombin cleaves the receptor between R⁴¹ and S⁴² to create a new amino terminus beginning with the sequence S⁴²FLLRN (yellow diamond). (3) Once unmasked, SFLLRN serves as a tethered peptide ligand that binds to the heptahelical domain to effect transmembrane signaling and G-protein activation (4).

Does the tethered ligand bind intramolecularly? Where does it bind and how does such binding yield G-protein activation? These questions are both basic and practical. One strategy for blocking PAR1 function is to block binding of the tethered ligand, and the SFLLRN tethered-ligand peptide has served as a pharmacophore for antagonist development.

Intramolecular binding of the ligand to the receptor to which it is tethered would clearly be favored unless prevented by specific structural constraints. Assuming an ≈ 50 -amino-acid tether localized the ligand to a hemisphere of radius ≈ 100 Å, the effective concentration of the tethered ligand would be on the order of 1 mM; micromolar concentrations of SFLLRN peptide in solution suffice to activate PAR1. Structure–function studies indeed suggest that intramolecular ligation is the predominant mode for PAR activation, and the relative ineffectiveness of PAR1 antagonists at blocking cellular responses to thrombin versus SFLLRN is consistent with favored, intramolecular binding of the tethered ligand. Intermolecular ligation of PARs can be demonstrated in certain settings. It is worth noting that intermolecular ligation of receptors in stable dimeric or oligomeric complexes would not be readily distinguished from intramolecular ligation of monomers, but there is as yet no compelling evidence that PARs form such complexes.

Studies with chimeric receptors, receptor mutations that complement loss of function substitutions in agonist peptide, and blocking antibodies all point to the exofacial domain of PAR1 as being critical for recognition of agonist peptides.

Such studies also suggested that PAR exofacial domains interact to form a structure necessary for receptor function. The crystal structure of rhodopsin reveals that the N-terminal exodomain and extracellular loops of rhodopsin interact to form a cap over the heptahelical core of the receptor. Thus, the exofacial domain of PAR1 might be the binding site for the tethered ligand or, alternatively, might function as a kind of template or keyhole that determines access of the tethered ligand to a site deeper in the heptahelical core. A satisfying answer will await a crystal structure.

The mechanism of PAR1 activation is strikingly irreversible. Cleavage of PAR1 by thrombin is irrevocable, and the tethered ligand generated cannot diffuse away from the receptor. How then is PAR1 shut off? Activated PAR1 is rapidly phosphorylated and uncoupled from signaling, then internalized and degraded in lysosomes—a disposable receptor. In fibroblasts and endothelial cells, an intracellular pool of naïve receptors can refresh the cell surface without need for new receptor synthesis. These observations suggest a plausible answer to another question raised by the fact that thrombin functions like a hormone. Because thrombin is an enzyme, one molecule of thrombin should be able to activate more than one receptor; in the limiting case, one thrombin molecule might eventually activate all molecules of PAR1 on a cell. How, then, does PAR1 mediate graded responses that are proportional to thrombin concentration? Because each activated PAR1 signals only transiently (and because the second messengers formed are themselves

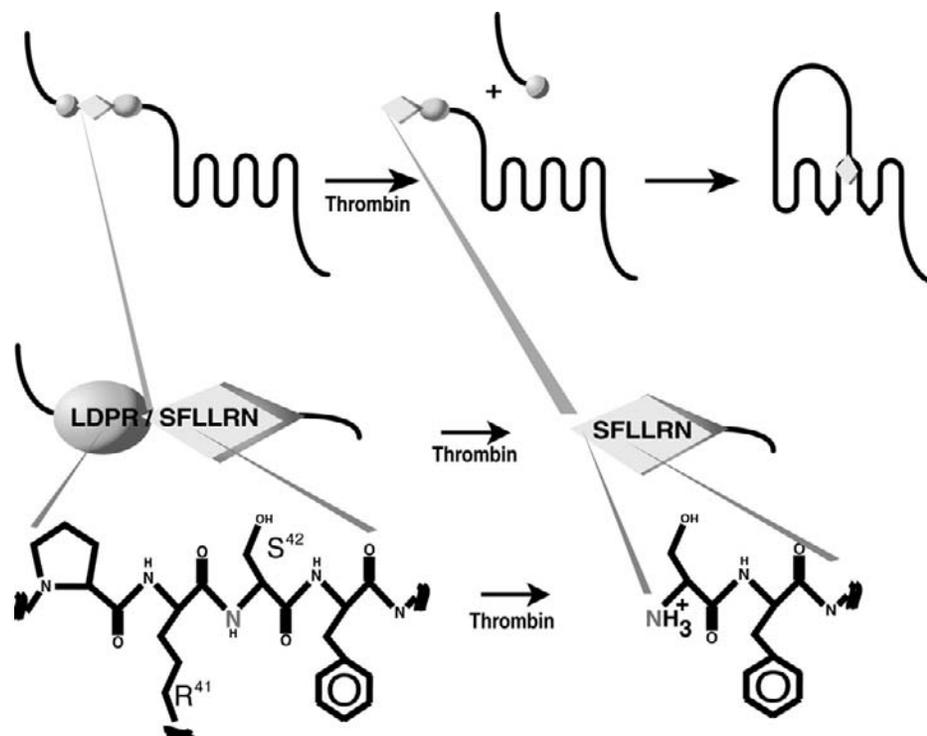

Figure 2 Details of the PAR1 proteolytic switch. A synthetic peptide of sequence SFLLRN (the tethered ligand sequence) can activate PAR1 independent of thrombin and receptor cleavage. Adding a single amino acid to the N terminal of SFLLRN or removing its N-terminal protonated amino group inhibits agonist activity. This suggests that cleavage of PAR1 between R⁴¹ and S⁴² accomplishes two things to switch on the cryptic ligand; it removes an activation peptide that sterically inhibits SFLLRN and creates a new protonated amino group (red N) that is important for agonist function.

short lived), the magnitude of the response is related to the rate of receptor cleavage and activation and hence to thrombin concentration. The existence of different PARs that are cleaved more or less efficiently by thrombin may also contribute to differential responses over a range of thrombin concentrations.

Protease-Activated Receptor Family

Four PARs are now known (Table 1). PAR1, PAR3, and PAR4 can be activated by thrombin. PAR2 can be activated by trypsin, mast cell tryptase, tissue factor/VIIa complex, factor Xa, and membrane-tethered serine protease-1, but not by thrombin. PAR1 and human PAR3 have a recognizable thrombin binding sequence and respond to thrombin at subnanomolar concentrations. PAR4 requires higher but probably still physiological levels of thrombin for activation, perhaps because it lacks the hirudin-like thrombin binding sequence that is present in PAR1 and PAR3. It is very likely that PAR1, PAR3, and PAR4 are activated by thrombin *in vivo*. Indeed, these receptors seem to account in large part for the ability of thrombin to activate platelets, and recent knockout studies suggest an important role in hemostasis and thrombosis. It is possible that other proteases are also physiological activators of PAR1, PAR3, and PAR4. Similarly, it is certainly possible that one or more of the

PAR2-activating proteases listed above are its physiological activators, but this remains to be established.

PAR1 can activate members of the G_{12/13}, G_q, and G_i protein families, consistent with the pleiotropic effects of PAR1 in platelets and other cells which include cytoskeletal reorganization, secretion of granule contents, mobilization of transmembrane adhesion proteins to the cell surface, and metabolic and transcriptional responses. PAR4 couples to G_q and probably G_{12/13}, but not to G_i. PAR2 and human PAR3 couple to G_q; their ability to activate other G proteins remains to be explored (Table 1).

Roles of PARs *In Vivo*

Because of the importance of platelet activation in myocardial infarction and stroke, defining the role of PARs in platelet activation by thrombin and the relative importance of this pathway in hemostasis and thrombosis has been a priority. A useful working model is in place. In human platelets, PAR1 appears to be the main thrombin receptor and mediates platelet activation at low concentrations of thrombin. In the absence of PAR1 function, PAR4 can mediate platelet activation, but relatively higher concentrations of thrombin are required. In addition to being activated by thrombin, PAR4 can be activated by the neutrophil granzyme cathepsin G, and PAR4 signaling is shut off more slowly than that of PAR1.

Table I Properties of Human PARs

Receptor	Chromosome	Activated by	Coupled to			Rapid agonist-triggered phosphorylation, internalization, and degradation	Expressed by	Possible roles <i>in vivo</i>
			G _{12,13}	G _q	G _i			
hPAR1	5q13	Thrombin, trypsin, Xa	Yes	Yes	Yes	Yes	Platelets, megakaryocytes, endothelial cells, mast cells, vascular smooth muscle, glia, fibroblasts, T cells, cardiac myocytes, skeletal myoblasts, etc.	Hemostasis—platelet secretion, aggregation, ? procoagulant activity Inflammation— leukocyte and platelet recruitment, increased permeability Inflammation— degranulation Inflammation—neurogenic inflammation and pain perception ? Contraction and repair ? Repair ? Repair Unknown
hPAR2	5q13	Trypsin, mast cell tryptase, TF/VIIa, Xa, TF/VIIa/Xa, MTSP1	?	Yes	Probably	Yes	Most epithelial cells including intestine, vascular endothelial cells, neurons, mast cells	Possible cytoprotective role Inflammation—leukocyte and platelet recruitment, ? increased permeability Inflammatory—neurogenic inflammation and pain perception Inflammation—degranulation
hPAR3	5q13	Thrombin, Xa	?	Yes	?	?	Multiple organs northern blot	Unknown (not yet shown to be a major contributor to thrombin signalling)
hPAR4	19p12	Thrombin, cathepsin G	Probably	Yes	No	No (shutoff of signalling is slow)	Platelets, megakaryocytes endothelial cells under some conditions	Hemostasis—platelet secretion, aggregation, procoagulant activity unknown

Note: The genes encoding PAR1, PAR2, and PAR3 are located in tandem on chromosome 5; the PAR4 gene is on chromosome 19. A partial list of proteases capable of activating the different PARs is shown. Thrombin is capitalized to indicate that there is good evidence that it is a physiological activator. TF/VIIa, tissue factor/factor VIIa complex; TF/VIIa/Xa, the cognate ternary complex. The G-protein families activated by each PAR and their shutoff properties are listed along with a partial description of expression patterns and probable *in vivo* roles. The latter description is by no means complete and focuses responses relevant to tissue injury. Roles in normal embryonic development and homeostasis are emerging.

It is not known whether these differences between PAR1 and PAR4 are important *in vivo*; PAR4 might simply be redundant and/or provide robustness in an important system.

In contrast to human platelets, mouse platelets utilize PAR3 and PAR4 to mediate thrombin signaling. Interestingly, the mouse homolog of PAR3 appears incapable of mediating transmembrane signaling by itself. Instead, it functions as a cofactor to promote cleavage and activation of PAR4 at low thrombin concentrations. There is as yet no evidence that PAR3/PAR4 heterodimers are required for the cofactoring activity of PAR3, and available data are consistent with PAR3 simply localizing thrombin to the cell surface. This paradigm is not novel from the perspective of the coagulation cascade, which is replete with examples of cofactors that localize proteases to the plasma membrane and/or bring protease and substrate together. It does, however, represent an interesting mode of interaction among heptahelical receptors in which one receptor localizes ligand to the cell surface for the ultimate ligation of another.

The model of thrombin signaling in mouse platelets predicts that platelets from PAR4-deficient mice should be unresponsive to thrombin. This was indeed the case, and mice lacking PAR4, while grossly normal, had markedly prolonged bleeding times and were protected from thrombosis—strong genetic evidence that, despite the existence of multiple redundant mechanisms for platelet activation, platelet activation by thrombin appears to be necessary for normal hemostasis and important in at least one model of thrombosis [9].

Recent studies suggest interesting roles for PARs in other cell types. For example, activation of endothelial PARs may help trigger recruitment of platelets and leukocytes in response to vascular injury. Activation of PARs on sensory neurons may contribute to neurogenic inflammation and edema and modulate sensitivity to painful stimuli [10,11]. Like the role for PARs in hemostasis, these roles are consistent with the general view that PARs mediate cellular responses to tissue injury. Roles in other settings, such as blood vessel development during embryogenesis, are emerging [12].

Constitutive and Regulated Signaling in Virus-Encoded 7TM Receptors

Mette M. Rosenkilde and Thue W. Schwartz

Laboratory for Molecular Pharmacology, University of Copenhagen, Copenhagen, Denmark

Virus-Encoded Proteins Are Developed through Targeted Evolution *In Vivo*

Large DNA viruses, in particular herpes- and poxviruses, have evolved a number of proteins that function as mimics of or as decoys for endogenous proteins of the host organism. Often the virus uses such proteins to evade key components of the immune system. The virus-encoded proteins are elegant examples of targeted evolution, where the virus has captured a gene from its host and through “combinatorial chemistry” varied its structure and thereby its function randomly through mutagenesis. Unlike biotech entrepreneurs, the virus has the advantage of being able to select the mutant protein with the optimal pharmacological property through *in vivo* screening in the intact organism. The virus with the most useful protein—for example, the most potent or broad-spectrum antagonist—will prevail. One example is the vMIP-II chemokine of human herpesvirus 8, which acts as an efficient blocker of a surprisingly large number of structurally different chemokine receptors. The chemokine system in general is a favored target for virus-encoded proteins. Many chemokine receptors have been hijacked by viruses and optimized for ligand recognition and signaling properties (Fig. 1A).

The Redundant Chemokine System Is an Optimal Target for Viral Exploitation

Chemokines are chemotactic cytokines, which primarily control the migration but also the activation and differentiation

of all subsets of leukocytes and play important roles in angiogenesis, organogenesis, and carcinogenesis [1]. Chemokines act through a large family of G-protein-coupled receptors, which are divided into subfamilies of CXC, CC, and CX3C receptors. This nomenclature refers to a fingerprint sequence in the ligands where the first two Cys residues are either neighbors (CC) or separated by one (CXC) or three (CX3C) residues. Although a few chemokine receptors are regulated by only a single chemokine protein, the system is generally characterized by a high degree of redundancy, in which a given chemokine receptor is activated by more than one ligand and a given chemokine acts through more than one receptor within a chemokine subfamily. Thus, the chemokine system is not only the key to the control of the immune system, but it is also an optimal target for viral exploitation, due to the redundancy among multiple endogenous proteins.

The endogenous chemokine receptors all signal rather similarly via the pertussis toxin sensitive G_i pathway. Calcium mobilization mediated mainly by the $\beta\gamma$ subunit of the heterotrimeric G protein is a generally used, robust readout. In fact, non-chemokine receptors, that signal through G_i can also mediate cell migration when expressed in chemotactic cells. Surprisingly, the chemokine receptors are distributed uniformly in the membrane of the migratory cell, and the directional migration apparently depends on an asymmetric distribution of effector molecules downstream to the G proteins. Some chemokine receptors in addition activate $G\alpha_q$ and $G\alpha_{16}$. The downstream signaling events involve various kinases, including MAP kinases such as p38, which appears to be important for chemotaxis, as well as PI3-K γ

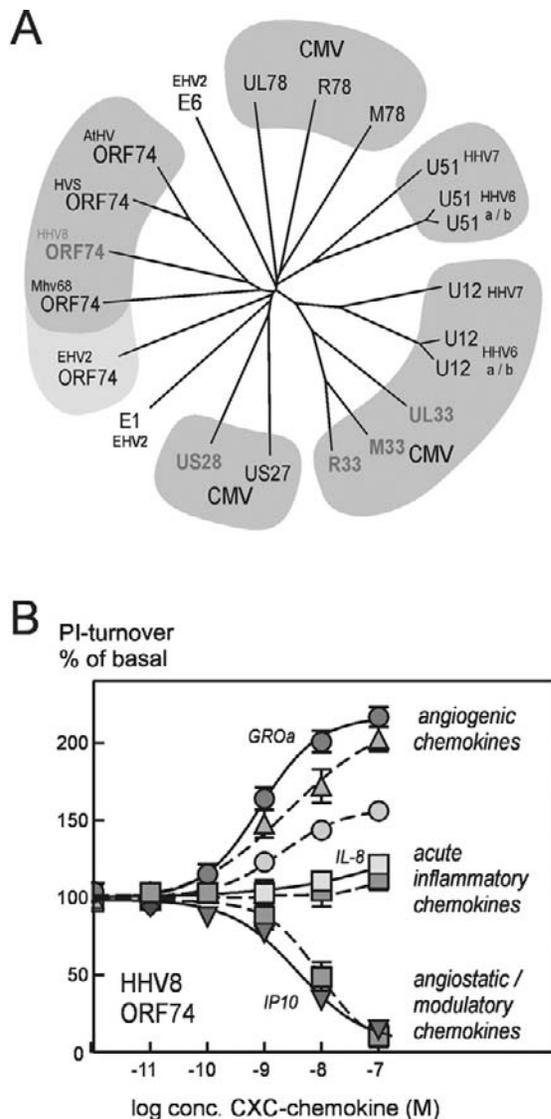

Figure 1 Structural relationship between herpesvirus-encoded chemokine receptors (A) and highly constitutive but regulated signaling of the prototype virus-encoded receptor ORF74 (B). In the dendrogram of herpesvirus-encoded chemokine receptors structural groupings are marked with shaded areas and receptors with known constitutive activity are highlighted. Panel (B) shows how the high constitutive signaling of the most well-characterized virally encoded receptor, ORF-74 from HHV8 (Kaposi's sarcoma-associated herpesvirus), is tuned by angiogenic chemokines acting as agonists and by angiostatic/angiomodulatory chemokines acting as inverse agonists.

and tyrosine kinases, which link the receptors to activation of small GTP-ases [2].

Endogenous chemokine receptors are strictly ligand regulated and normally do not display constitutive signaling activity. This is in accordance with the fact that the receptors are involved in directional migration (i.e., chemotaxis), controlled by a chemokine gradient built in the interstitial tissue through attachment of the secreted chemokines to glycosaminoglycans. Constitutive signaling of a chemokine receptor in a migratory cell would conceivably lead to chemokinesis (i.e., undirected cell movement), which perhaps

in conjunction with binding to cell adhesion molecules could be useful in the extravasation process.

Multiple Virus-Encoded 7TM Receptors

More than 20 G-protein-coupled receptors have been identified in various herpes- and poxviruses (Table 1 and Fig. 1A). Most of these receptors display key structural elements, that identify them as belonging to the family of chemokine receptors. In general, however, it is impossible to identify a specific endogenous chemokine receptor as the original scaffold hijacked by the virus. The extensive subsequent mutational effort performed by the virus which has generated the desired pharmacological profile has at the same time significantly altered the primary structure of the receptor. Conceivably a multitude of more or less silent mutations have accompanied the functionally important substitutions that produced the useful property of the viral receptor. A few chemokine-like virus-encoded receptors nonetheless have been convincingly de-orphanized. That is, their endogenous chemokine ligand has been identified. The best examples are US28, a broad-spectrum CC and CX3C chemokine receptor from human cytomegalovirus (CMV), and ORF74, a broad-spectrum CXC chemokine receptor from human herpesvirus 8.

Constitutive Signaling through Altered Pathways

The virus-encoded receptors have often chosen G proteins and downstream effector molecules different from those of the endogenous chemokine receptors. Moreover, whereas most endogenous chemokine receptors are rather silent in the absence of agonist, the virus-encoded receptors often display clear constitutive signaling activity, which may or may not be subject to further fine-tuning or regulation by endogenous ligands.

ORF74, also named KSHV-GPCR (i.e., Kaposi's sarcoma-associated herpesvirus GPCR), is the prototype of a constitutively active, virus-encoded receptor. Multiple signal transduction pathways have been demonstrated for this receptor, involving a variety of G proteins, with G_q signaling dominating, in contrast to the G_i signaling of endogenous receptors. Small GTPases, kinases including MAP kinases, and many transcription factors are also involved in ORF74 signaling (Fig. 2). The receptor activates NF κ B, for instance, via $G_{i/o}$, G_{a13} RhoA pathway, G_q , $\beta\gamma$ subunits, and P13-K γ . VEGF secretion, possibly regulated by a transcription factor (HIF-1 α) controlled by MAP kinases, may mediate ORF74's ability to induce angiogenic lesions *in vivo*. The constitutive activity of other transcription factors (CREB and NFAT) downstream of ORF74 could be important for lytic replication of the virus, as both pathways have been shown to contribute to HHV8 reactivation. ORF74 also promotes cell survival through activation of PKB/Akt and NF κ B.

US28, from human cytomegalovirus, is another highly constitutively active, virus-encoded receptor. In contrast to ORF74,

Table I Properties of Known Herpes and Poxvirus-Encoded Chemokine Receptors. Constitutive and Regulated Activities are Listed Together with the Proposed Functions in Virus Life-Cycle

Virus class and name	Receptor name	Constitutive activity	Regulated activity	Function in virus life-cycle
β-Herpesvirus				
Human CMV	US27	–	–	–
	US28	PLC, Erk2, NFκB, CREB and NFAT activation	Sparse regulation of constitutive activity by chemokines	Chemokine sequestration, cell programming, migration of smc
	UL33 UL78	PLC and CREB activation –	no described ligand –	
HHV6A and B	U12	–	Ca ²⁺ release by CCLs	Viral replication and survival
	U51	–	Binding of various CCLs ^a	Viral replication and survival
HHV7	U12	–	–	–
	U51	–	–	–
Murine CMV	M33	CREB and NFκB activation ^b	no described chemokine ligand	Viral replication, survival and targeting to salivary glands
	M78	–	–	Viral replication and survival
Rat CMV	R33	PLC activation. CREB, NFκB activation	no described chemokine ligand	Viral replication, survival and targeting to salivary glands
	R78	–	–	Viral replication and survival
γ-Herpesvirus				
HHV8	ORF74	see Fig. 2	Regulation of constitutive activity by CXCLs ^c (Fig. 1B and 2)	Angiogenesis, cell-survival, reactivation of viral replication
EHV-2	E1	–	Ca ²⁺ release by CCL11	
	E6	–	–	
	ORF74	–	–	
HVS	ORF74	–	Ca ²⁺ release by ELR+CXCLs	
AtHV	ORF74	–	–	
Mhv68	ORF74	–	–	
Poxvirus				
Swinepox	K2R	–	–	
Capripox	Q2/3L	–	–	

^aVarious CC-chemokines bind to U51 (HHV6B) transfected cells, but no signaling has ever been shown.

^bUnpublished data about activity by M. Waldhoer.

^cCREB and NFAT activation are unpublished data from K. McLean, P. Holst, MMR and TWS.

^dAbbreviations: CMV, cytomegalovirus, HHV, human herpesvirus; Mhv68, Murine γ-herpesvirus 68; EHV2, Equine Herpesvirus-2; HVS, Herpesvirus Saimiri; AtHV, Ateles Herpesvirus; ORF74, open reading frame 74; PLC, phospholipase C; AC, adenylate cyclase; PI3K-phosphatidylinositol 3 kinase; RAFTK, Related Adhesion Focal Tyrosine Kinase/or Proline-rich Tyrosine Kinase 2; DAG, Diacylglycerol; IP3, Inositol-3-phosphat; PKA/B/C, protein kinase A/B/C; MAPK-mitogen activated protein kinase; Erk, extracellular regulated kinase; JNK/SAPK, Jun N-terminal kinase/stress activated protein kinase; CREB, cAMP responsive element-binding protein; NFAT, Nuclear Factor of Activated T-cells; NFκB, Nuclear Factor κB; AP-1 (Fos-Jun); HIF-1a, Hypoxia inducible factor 1a; VEGF, vascular endothelial growth factor; Smc, smooth muscle cell.

this receptor is constitutively internalized and accumulates mainly in the late endocytotic pathway in multivesicular bodies. Other CMV-encoded receptors such as US27 and UL33 also accumulate in multivesicular bodies, a location where the virus is believed to pick up its envelope. Accordingly, these receptors are found on the virions and may be transferred to the target cell during the initial fusion phase of infection [3].

Viral Receptors Recognize Multiple Ligands with Variable Function

The constitutive signaling of ORF74 from HHV8 is fine-tuned by a number of endogenous CXC-chemokines. Thus,

ORF74 responds to certain angiogenic CXC ligands (called ELR+CXCLs) as agonists and angiostatic ELR–CXCLs as inverse agonists (ELR refers to the conserved amino acids located just prior to the first Cys in the protein). CXC chemokines that are involved especially in acute inflammatory reactions (for example, IL-8) do not affect the high level of constitutive signaling (Fig. 1B). Interestingly, ORF74 in fact *binds* basically all human CXC chemokines, including IL-8, with high affinity. Competition binding experiments with multiple radiolabeled ligands have revealed different active and inactive conformations that apparently do not readily interchange. The constitutive activity per se as well as the regulated activity are important functions for oncogenesis [4,5].

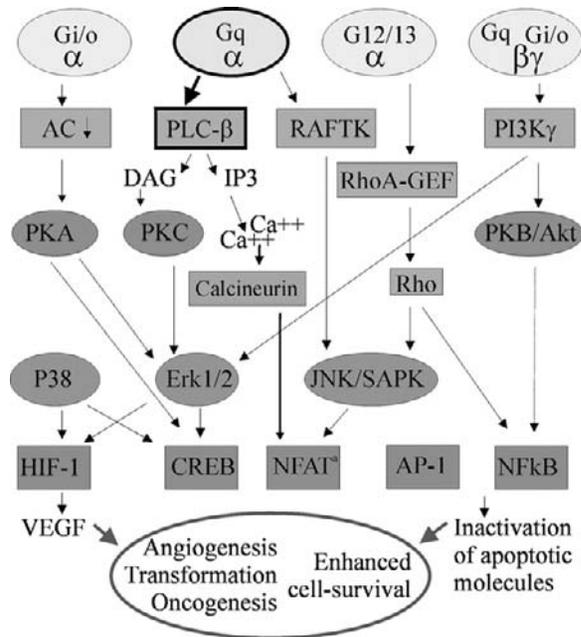

Figure 2 Multiple downstream signaling pathways are activated by ORF74 from HHV8. Several levels of effector molecules have been implicated as being part of the signaling cascade elicited by ORF74 from the G-protein activation (yellow) over a variety of signaling molecules to gene transcription regulation through control of at least five different transcription factors (orange) in the cell nucleus. The diagram is grossly simplified, and several suggested cross-regulations between the depicted enzymes have been excluded. For abbreviations, see footnote for Table 1.

Although US28 binds all human CC chemokines with nanomolar affinity, *none* of the ligands appears to affect signaling by the receptor. It has been suggested that the receptor could function as a scavenger, picking up the CC chemokines from around the infected cell and rapidly inactivating them through internalization. The favored ligand for US28, however, is membrane-bound CX3C chemokine fractalkine, which acts as a partial inverse agonist. Surprisingly, the fractalkine binding cannot be blocked by the otherwise high-affinity binding of CC chemokines. The membrane-anchored fractalkine may serve as a cell-entry gateway for human CMV via interaction with US28 expressed on the surface of infected cells and the virion [6].

Attempts To Identify the Function of Virus-Encoded Receptors *In Vivo*

None of the virus-encoded 7TM receptors is essential for viral replication in cell cultures. *In vivo* studies with rodent CMV, however, consistently demonstrated decreased virulence of viruses in which R33, M33, R78, or M78 receptors had been selectively knocked out. In the cases of R33

and M33, the receptor-deleted virus replicated normally in the bone marrow, but not in salivary glands. This could indicate that the M33/R33 receptor is essential either for targeting of the virus to the salivary gland (a “taxi” function where the receptor provides the infected cell with a new homing address) or for viral replication in this tissue, which would be crucial for the spread of the virus between animals.

Transgenic expression of ORF74 from HHV8 under the CD2 promoter in mice resulted in a phenotype with striking similarities to Kaposi’s sarcoma, in regard to both location and histopathology of the highly vascularized lesions [7]. By selectively eliminating either the high constitutive activity of the receptor or the ability of the receptor to be controlled by ligands it was demonstrated that both these properties were required in order to obtain the angiogenic lesions [5]. This is especially interesting, because the virus apparently has optimized the ORF74 receptor to be regulated positively by endogenous angiogenic chemokines—as agonists—and negatively by angiostatic or angiomodulatory chemokines—as inverse agonists (Fig. 1B).

In summary, virally encoded chemokines and receptors have evolved through a massive *in vivo* selection process performed by opportunistic organisms trying to exploit our endogenous cellular communication systems. Consequently, each of these molecules is an interesting pointer or showcase for key aspects of signal transduction by 7TM receptors.

Introduction

The *frizzled* (*fz*) gene family encodes predicted seven-transmembrane proteins that serve as receptors for the Wnt family of secreted glycoprotein ligands [1–3]. Together, Wnts and Fzs stimulate signaling pathways integral to development and implicated in disease. A persistent problem in Wnt and Fz signaling, until recently, has been the identity of intracellular signaling molecules activated directly by Fz [2]. In one pathway, intracellular signaling by Fz requires the cytoplasmic phosphoprotein Dishevelled (Dsh), shown genetically to be the most immediate cytoplasmic protein involved in Fz signaling. Fz and Dsh have never been shown to interact biochemically, however, leaving a gap in this important signaling pathway. Although the sequence of Fz does not fit the classical G-protein-coupled receptor (GPCR) mold [4–6], it has for some time been attractive to imagine that the Fz family of proteins may indeed be GPCRs. An abundance of recent evidence has now demonstrated that Fzs require G proteins in two Wnt/Fz signaling pathways (discussed below). Fzs are therefore now known as GPCRs for Wnt ligands, which begins to explain how Fzs activate downstream signaling molecules such as Dsh. Here, after a brief overview of Wnt signaling pathways, we will review the lines of evidence supporting the characterization of Fzs as GPCRs.

Wnt Signaling

Fzs bind and synergize with Wnts to activate two signaling pathways in vertebrates referred to as the Wnt/ β -catenin

and Wnt/calcium pathways [2,7]. The canonical or Wnt/ β -catenin pathway (Fig. 1A) promotes the interaction between β -catenin and the Lef/Tcf family of transcription factors [1] to regulate cell proliferation and cell fate determination. Upon binding Wnt, Fz signals to Dishevelled (Dsh), which inhibits the “destruction complex” [2]. The destruction complex is composed of a large assembly of proteins, including Axin, APC, PP2A, and GSK-3 that continually promotes the ubiquitination and proteosomal degradation of β -catenin in the absence of active Wnt signaling. Once Dsh has inactivated this complex, β -catenin accumulates and interacts with the Lef/Tcf family of transcription factors to activate transcription of Wnt-responsive genes. In *Xenopus* and mammalian cells, strong evidence shows that Fz signaling to Lef/Tcf occurs via G-protein subunits (discussed below). A lack of biochemical data showing how G proteins might then regulate the function of Dsh and ultimately Lef/Tcf transcription factors represents a significant gap in our knowledge of Wnt/ β -catenin signaling. (Detailed maps of this pathway can be found at <http://www.ana.ed.ac.uk/rnusse/pathways/cell2.html> and http://stke.sciencemag.org/cgi/cm/CMP_5533.)

Although the net effect of activation of the Wnt/ Ca^{++} pathway (Fig. 1B) is poorly understood, at a minimum it regulates cell behavior and some cell fates [7]. Activation of this pathway has also been reported to oppose the effects of Wnt/ β -catenin pathway activation. Fz stimulates G proteins, which activate phospholipase C to turn on Ca^{++} signaling. Wnts and Fzs increase the release of Ca^{++} from intracellular stores and activation of the Ca^{++} -sensitive

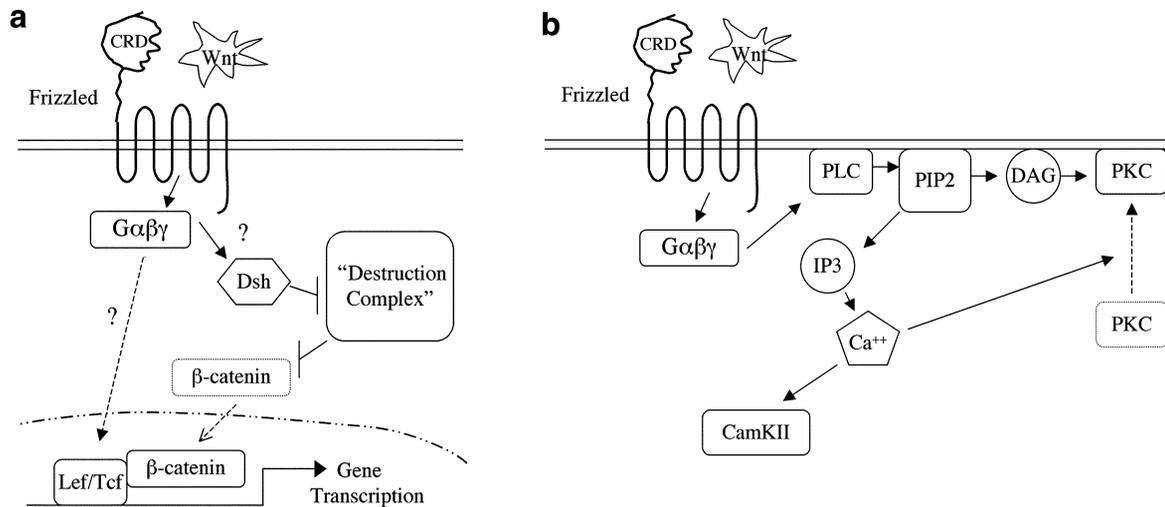

Figure 1 The two vertebrate Wnt signaling pathways are discussed in detail in the text. *Abbreviations:* cysteine-rich domain (CRD); Dishevelled (Dsh), phospholipase C (PLC), phosphatidylinositol 4,5-bisphosphate (PIP2), diacylglycerol (DAG), inositol 1,4,5-triphosphate (IP3), protein kinase C (PKC), and calcium-/calmodulin-dependent protein kinase II (CaMKII).

protein kinase C (PKC) and calcium-/calmodulin-dependent kinase II (CaMKII).

Evidence for Frizzleds as G-Protein-Coupled Receptors

Structural comparison to GPCRs and interesting experimental findings argue that Frizzleds signal through heterotrimeric G proteins. The seven hydrophobic domains of the predicted Fz protein, the predicted NH₂-terminal signal sequence, and the potential signal peptidase cleavage site suggest topological homology to all known GPCRs [8,9]. Phylogenetically, *fz* is most closely related to *smoothened* (*smo*) [5], which was recently reported to signal through G proteins [10]. Some reports have noted that *fz* has no amino acid sequence similarity to the *rhodopsin* superfamily of GPCRs [4,5,11,12]. However, reevaluation of Fz predicted protein sequences reveals that Fzs share more characteristics with established GPCR families than was previously thought (Table 1) [4,11,13]. Because Fzs are phylogenetically linked to a known GPCR, *Smo*, and Fzs contain several GPCR sequence motifs, Fzs might also share with GPCRs a mechanism of conformational change that can activate G proteins.

Fzs not only resemble GPCRs but experimental evidence also argues that Fzs rely upon G proteins for signaling. Recent work examined Fzs as GPCRs using rat Fz-2 signaling in the Wnt/Ca⁺⁺ pathway and rat Fz-1 signaling in the Wnt/β-catenin pathway. The first report showing a requirement for G proteins by Fz came from the analysis of intracellular calcium in zebrafish [14]. An increase in the frequency of intracellular calcium transients was measured in zebrafish embryos over-expressing Wnt-5A or rat Fz-2. Whether G proteins were required for this phenomenon was tested by treating embryos expressing rat Fz-2 with several G-protein inhibitors.

The elevation of Ca⁺⁺ stimulated by rat Fz-2 was blocked by the G-protein inhibitors GDPβS, which prevents G-protein activation; pertussis toxin, which adenosine diphosphate (ADP) ribosylates and which specifically inhibits guanosine diphosphate (GDP)–guanosine triphosphate (GTP) exchange on G_{oi}, G_{oo}, and G_{ot}; and α-transducin, which sequesters βγ subunits. Subsequent studies in *Xenopus* embryos found that rat Fz-2 requires G proteins to activate two Ca⁺⁺-sensitive enzymes, PKC [15] and CaMKII [16]. Activation of both these enzymes by rat Fz-2 was also inhibited by pertussis toxin and α-transducin, confirming that Wnt/Ca⁺⁺ signaling by rat Fz-2 is mediated, directly or indirectly, by G proteins.

In order to determine whether G proteins mediate Fz signaling directly, chimeric receptors were constructed to control the activation state of Fz. The intracellular loops of rat Fz-1 and -2 were substituted for the cognate loops of the

Table 1 Conserved Sequence Characteristics in the G-Protein-Coupled Receptors of the Rhodopsin (Rho) and Smoothened (Smo) Families and Frizzleds (Fz)

Conserved sequence characteristic	Rho	Smo	Fz
Putative signal peptide	Y	Y	Y

^aInhibition of these G-protein subunits interfered with Fz signaling.

β2-adrenergic receptor (β2-AR), so that Fz signaling domains could be kept in an inactive state using a β2-AR antagonist and quickly activated by a β2-AR agonist [17,18]. Stimulation of the β2-AR/rat Fz-2 chimera activated CaMKII within just 10 minutes, and that effect was inhibited by treatment with pertussis toxin [16]. The dependence on G proteins for such a rapid response to Fz signaling indicated that G proteins must be integral to Fz signaling. Actual binding of G proteins to Fz has not been reported but can be inferred from the observation of a shift in agonist affinity of the β2-AR/rat Fz chimeras in the presence of a nonhydrolyzable GTP analog. The presence of GTP causes a reduction in the affinity of most GPCRs for their agonists; the decrease correlates with dissociation of the GPCR from the G protein. The β2-AR/rat Fz chimeras exhibit this classic affinity shift, suggesting that intracellular residues of rat Fz-1 [17] and rat Fz-2 [19] directly bind G proteins also. Together, these experiments suggest that Fzs interact directly with G proteins to activate cytoplasmic signaling molecules.

Additional work aimed to show that Fzs require G proteins to mediate cellular and physiological processes. First, it was observed that a GPCR known to stimulate Ca⁺⁺ signaling, 5-HT_{1c}, and Xwnt-5A produce the same over-expression phenotype in *Xenopus* embryos [20]. It was then shown that Wnts require G proteins to produce the classic duplicated-axis over-expression phenotype. The regulator of G-protein signaling (RGS4), which enhances the intrinsic GTPase activity of G_{αi} and G_{αq} subunits blocked the ability of Wnt, but not Dsh, to induce duplicated axes in *Xenopus* embryos [21]. This observation placed G proteins between Fz and Dsh for the first time. In cultured mammalian F9 cells, pertussis toxin and oligonucleotides antisense to specific G proteins inhibited both induction of primitive endoderm by rat Fz-1 [22] and the β2-AR/rat Fz-2 chimera [18] and activation of a Lef/Tcf specific reporter gene by rat Fz-1. This result was confirmed in *Xenopus* embryos where pertussis toxin blocked activation of Wnt-responsive genes by rat Fz-1 [17]. Recently it has been shown that activation of Frizzled-2 in mouse totipotent F9 cells involves activation of cyclic GMP phosphodiesterase and a sharp decline in the intracellular concentration of cyclic GMP [23].

Inhibitors of cyclic GMP phosphodiesterases block aspects of Frizzled-2 signaling in the F9 cells as well as in zebrafish oocytes. Wnt-5A and G-protein signaling are required also for collagen-induced DDR1 receptor activation and normal cell adhesion [24]. Taken together, these studies indicate that Fzs not only require G proteins to activate intracellular signaling enzymes, but also couple to G proteins to regulate physiologically relevant events.

Perspective

Understanding basic development and human disease requires better understanding of Fz signal transduction. Recent work demonstrates that G proteins are directly required for Fz signaling, supporting the inclusion of the Fz family within the greater GPCR superfamily. Rat Fz-1 and rat Fz-2 were used as model Fzs and demonstrated different but overlapping G-protein requirements (Table 2). Because these studies relied upon inhibiting effects of Wnts or involved over-expression of Fzs and not endogenous cellular processes, it remains to be seen specifically which Fzs couple to which G proteins during endogenous signaling events. The identification of Fz coreceptors combined with the large number of Wnts, Fzs, and G proteins, which are often expressed in tissue-specific patterns, increases the complexity of defining these important signaling pathways.

University of California, San Francisco, California*

Introduction

Multiple mechanisms contribute to the physiological regulation of G-protein-coupled receptors (GPCRs). Early studies delineated the existence of distinct functional processes of receptor regulation in natively expressing cells and tissues [1,2]. More recent studies have led to an explosion of new information regarding cellular and molecular mechanisms of receptor regulation [3–5]. We begin this chapter by reviewing some functional processes of GPCR regulation defined in early studies, followed by a review of our current understanding of some specific mechanisms that mediate (or contribute to) these processes of regulation. In doing so, we focus on relatively well-characterized mechanisms of desensitization and endocytosis that are relevant to the regulation of a large number of GPCRs. Finally, we briefly mention insights from recent studies suggesting some previously unanticipated features of GPCR desensitization and endocytosis.

General Processes of GPCR Regulation

Desensitization and Resensitization: Rapid Regulation of the Functional Activity of Receptors

Many GPCRs are regulated very rapidly after agonist-induced activation, a process that has been characterized in considerable detail in studies of the β_2 adrenergic receptor

(β_2 -AR) [3–5]. Upon binding of agonist the β_2 -AR promotes guanine nucleotide exchange on its cognate heterotrimeric G protein (G_s), which thereby activates downstream effectors such as adenylyl cyclase. Receptor-mediated signaling via this pathway occurs within seconds after the initial addition of agonist to cells or tissues. Within several minutes the ability of the same concentration of the same agonist to stimulate adenylyl cyclase diminishes greatly. This process of *rapid desensitization* can make the tissue refractory to even high concentrations of agonist. In some cases, the physiological responsiveness of the tissue can return quite rapidly (within several minutes) after agonist washout, allowing the cell or tissue to respond again when rechallenged with the same agonist. This recovery of signaling potential from the desensitized state is called *resensitization*. Rapid desensitization of β_2 -AR-mediated signaling can occur without significant effects on other signaling pathways and without any detectable change in the total number of receptors present in cells or tissues. These processes of desensitization and resensitization were therefore proposed to reflect primarily changes in the *functional activity* of receptors.

Sequestration: Rapid Regulation of the Subcellular Localization of Receptors

Agonists can also cause a pronounced decrease in the number of receptors present in the plasma membrane, usually within several minutes after the onset of rapid desensitization.

This process, called *sequestration*, was defined originally by pharmacological studies investigating the number of receptor sites accessible to membrane-impermeant radioligands in intact cells. In general, sequestration occurs without any change in the total number of receptors present in cells or tissues, as detected using membrane-permeant radioligands or disrupted membrane preparations [6]. Therefore, it was proposed that sequestration represents primarily a change in the subcellular *localization* of GPCRs.

Downregulation and Upregulation: Slower Modulation of the Total Number of Receptors

The term *downregulation* refers to a distinct process associated with reduced responsiveness of cells or tissues that occurs much more slowly than the process of rapid desensitization. Instead of occurring in seconds or minutes, downregulation is often observed hours or even days after exposure of cells or tissues to ligands. The process of downregulation is characterized pharmacologically by a decrease in total number of receptor sites (B_{\max}), detected in radioligand binding assays using membrane-permeant compounds or disrupted membrane preparations, and is not associated with a change in ligand binding affinity (K_d) [1,7]. Recovery of receptor number (and signaling responsiveness) after downregulation is a slow process that requires biosynthesis of new receptor protein. Some ligands (typically antagonists) can induce the opposite process, *upregulation*, which refers to a gradual increase in the B_{\max} detected by radioligand binding [8]. Thus, downregulation and upregulation primarily reflect changes in the total *number* of GPCRs.

Mechanisms of GPCR Desensitization and Endocytosis

Functional Uncoupling of GPCRs from Heterotrimeric G Proteins Mediated by Receptor Phosphorylation

Extensive studies of certain GPCRs, such as rhodopsin (a light-activated GPCR) and β 2-AR (a ligand-activated GPCR), established a highly conserved mechanism that regulates the functional activity of many GPCRs [3–5,9]. This mechanism involves the phosphorylation of receptors by a specific family of G-protein-coupled receptor kinases (GRKs) followed by the interaction of phosphorylated receptors with cytoplasmic accessory proteins called *arrestins*. Arrestin-bound receptors are unable to couple to heterotrimeric G proteins and disrupt the pathway of GPCR-mediated signal transduction at the earliest stage (Fig. 1A and B).

Biochemical studies of signal transduction in isolated rod outer segment preparations identified a protein, *rhodopsin kinase* (or GRK1), that inhibited the ability of light-activated rhodopsin to activate transducin. Light-activated rhodopsin is a good substrate for phosphorylation by rhodopsin kinase,

whereas rhodopsin that has not been activated by light is a poor substrate [10]. Phosphorylated rhodopsin was only partially inhibited in activating transducin. A second protein, *visual arrestin*, was identified from cytoplasmic fractions of rod cells according to its ability to completely inhibit, or arrest, activation of transducin by phosphorylated rhodopsin [11].

Studies using functional reconstitution of β 2-AR-mediated activation of adenylyl cyclase provided strong evidence for a role of phosphorylation in mediating rapid desensitization of a ligand-activated GPCR [12]. Biochemical purification of the cytoplasmic activity responsible identified a protein called β adrenergic receptor kinase (BARK, or GRK2), which preferentially phosphorylates agonist-occupied receptors [13] and is similar in structure to rhodopsin kinase [14]. Biochemical reconstitution studies indicated that increasingly purified fractions of BARK exhibited reduced ability to attenuate β 2-AR-mediated signal transduction in reconstituted membrane preparations. Further analysis of this effect led to the identification of a distinct protein component that was lost in increasingly purified fractions and which increased functional desensitization when added back to highly purified fractions of BARK [15,16]. This protein cofactor turned out to be a protein similar to visual arrestin and was therefore named *nonvisual arrestin*, or β arrestin (β Arr). cDNA cloning has identified a family of arrestins involved in regulating the function of phosphorylated GPCRs [5].

It turns out that agonists regulate not only phosphorylation of GPCRs by GRKs but also the affinity with which phosphorylated receptors bind to arrestins [17]. Such dual control by agonist of a single regulatory mechanism is an example of coincidence detection, an important principle guiding many other signaling processes. One role of coincidence detection in GRK/arrestin-mediated regulation may be to assure definitively that only those receptors actually activated by agonist are desensitized. In this way, other receptors that are not activated (including coexpressed GPCRs that recognize other ligands but are potentially upregulated by the same desensitization mechanism) are not affected. Indeed, GRK-mediated phosphorylation and subsequent binding of arrestins is generally considered to be a paradigm for *homologous desensitization*, a form of desensitization that is specific only to the activated GPCR at hand and is not influenced by (or extended to) activation of other receptors in the same cell [13]. Coincidence detection may serve other important functions in GPCR regulation. For example, one might imagine that transient or low-frequency activation of GPCRs could promote GRK-mediated phosphorylation of receptors without much binding of arrestins, thus causing only partial desensitization of receptors (because phosphorylated receptors can still interact weakly with heterotrimeric G proteins). More prolonged or higher frequency activation of receptors by strongly promoting both phosphorylation of receptors and arrestin binding (which essentially blocks receptor–G protein coupling), could lead to a more profound desensitization of signal

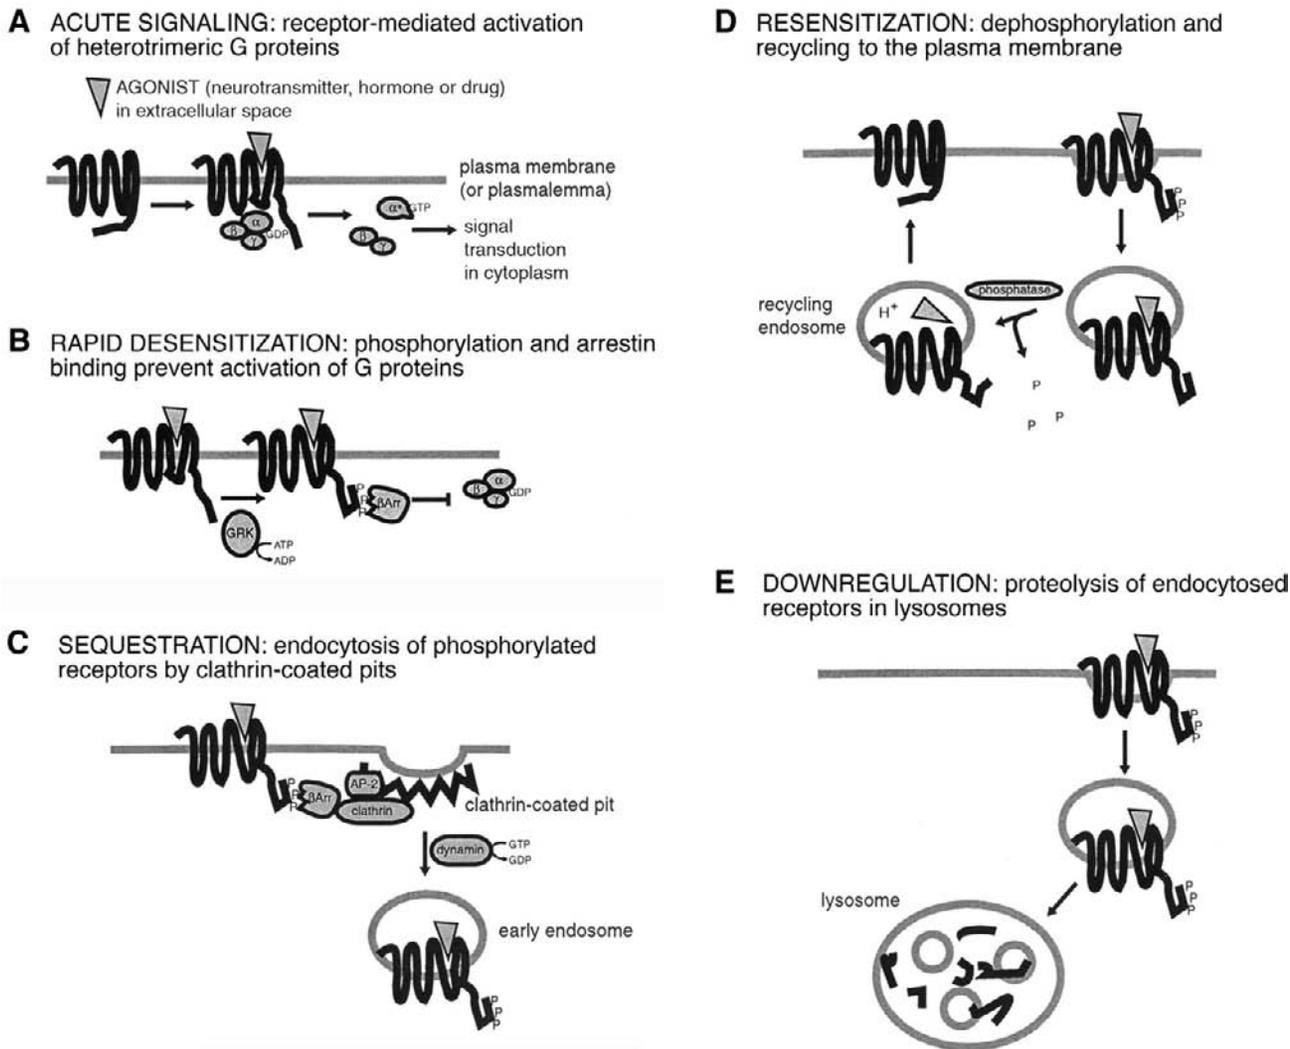

Figure 1 Major mechanisms of GPCR desensitization and endocytosis. (A) Classical pathway of GPCR signaling via receptor-mediated activation of heterotrimeric G proteins. (B) Rapid desensitization (functional uncoupling) of GPCRs mediated by GRKs and arrestins. (C) Role of GRKs and non-visual (beta-) arrestins (β Arr) in promoting endocytosis of GPCRs via clathrin-coated pits. (D) Role of endocytosis in mediating resensitization of GPCRs. (E) Role of endocytosis in mediating downregulation of GPCRs by proteolysis in lysosomes.

transduction. In this way, functional desensitization could be modulated both by the strength and kinetics of receptor activation.

Desensitization of GPCRs by Other Kinases: Example of a Mechanism Mediating Heterologous Desensitization

Other kinases, such as the so-called second-messenger-regulated kinases, are also implicated in mediating desensitization of GPCRs. For example, the β 2-AR can be phosphorylated by cyclic-AMP-dependent protein kinase (PKA). PKA-mediated phosphorylation of a single residue located in the third intracellular loop of the β 2-AR impairs the ability of the receptor to couple to G_s and thereby attenuates receptor-mediated activation of adenylyl cyclase [18–20]. Phosphorylation of this residue is thought to impair

receptor–G protein coupling directly, without requiring any known protein cofactor such as an arrestin. An important feature of PKA is that this kinase can phosphorylate β 2-ARs whether or not they have been activated by ligand, in contrast to the preferential phosphorylation of agonist-activated receptors by GRKs. Because PKA is activated by cyclic AMP (a signaling intermediate produced as a result of β 2-AR activation), PKA-mediated phosphorylation of the β 2-AR is an example of feedback inhibition by a second messenger. In addition, because activation of any other receptor that stimulates adenylyl cyclase can also activate PKA, phosphorylation of the β 2-AR by PKA is generally considered to be a paradigm for *heterologous desensitization*—that is, desensitization of one type of GPCR that is induced by activation of another (heterologous) receptor. Heterologous desensitization of GPCRs by kinases such as PKA, in contrast to homologous desensitization mediated by GRKs, is thought to play

important roles in integrating and controlling “cross-talk” between diverse signaling pathways in the same cell.

Agonist-Induced Endocytosis of GPCRs

Pharmacological studies of the process of sequestration led to the hypothesis that certain GPCRs are removed from the plasma membrane within minutes after agonist-induced activation [6,21]. Biochemical and immunochemical methods have demonstrated that this is indeed the case, both in cultured cells and certain native tissues [22–24]. Rapid endocytosis of the β 2-AR is mediated by an agonist-dependent lateral redistribution into clathrin-coated pits [25]. Coated pits then pinch off from the plasma membrane to form endocytic vesicles, a process dependent on the cytoplasmic GTPase *dynamain* [26–29]. Subsequent studies have demonstrated that regulated endocytosis of several other GPCRs is also mediated by a dynamain-dependent mechanism, suggesting a conserved role of clathrin-coated pits in mediating endocytosis of many GPCRs.

Clathrin-coated pits play a general role in mediating rapid endocytosis of a large number of cell-surface components besides signaling receptors, many of which are endocytosed constitutively (i.e., in a ligand-independent manner). This has raised the question of how GPCR endocytosis is regulated by ligands. It turns out that GRKs and arrestins, in addition to their previously established role in mediating functional uncoupling of receptors from heterotrimeric G proteins, also play an important role in regulating endocytosis of certain GPCRs. In particular, nonvisual (or β -) arrestins can promote the concentration of phosphorylated receptors in coated pits by binding simultaneously, via distinct protein interaction domains, to both receptors and the clathrin-containing lattice structure, thereby functioning as adapters linking specific GPCRs to endocytic membranes [30,31] (Fig. 1C). Despite the highly conserved nature of this endocytic mechanism, there are also examples of GPCRs that either are not rapidly endocytosed or are endocytosed by a different mechanism [32]. This diversity of GPCR membrane trafficking, although not yet understood at the mechanistic level, has important implications for the physiological regulation of distinct GPCRs [33].

Functional Consequences of GPCR Endocytosis

Role in Rapid Desensitization of GPCRs

In many cases, endocytosis is not thought to play a primary role in mediating rapid desensitization of many GPCRs, although the precise role of endocytosis in this process may depend on receptor expression level. Endocytosis of μ -opioid receptors does not contribute significantly to functional desensitization in cells expressing relatively high levels of receptor protein but does appear to cause desensitization in cells expressing lower levels of receptor [34]. Studies of the β 2-AR emphasize that GRK- and arrestin-dependent uncoupling of

receptor from G protein (Fig. 1B) occurs in the plasma membrane before endocytosis begins, and desensitization of the β 2-AR is not affected by blockade of receptor endocytosis [35].

Role in Resensitization of GPCRs

In contrast to its limited role in mediating rapid desensitization, endocytosis of certain GPCRs is thought to play a major role in mediating the distinct process of receptor resensitization [4,36,37]. It is believed that the reason for this is that endocytosis brings receptors in close proximity to an endosome-associated phosphatase, which dephosphorylates receptors that were previously phosphorylated (hence, *desensitized*) at the cell surface. Dephosphorylated receptors are then recycled back to the plasma membrane in a “resensitized” state, which is fully functional to mediate subsequent rounds of signal transduction upon re-exposure to agonist [35,38]. This proposed mechanism of GPCR resensitization is shown in Fig. 1D.

Role in Mediating Proteolytic Downregulation of GPCRs

Endocytosis is also thought to play an important role in mediating downregulation of many GPCRs by promoting proteolysis of receptors. The best characterized pathway mediating proteolytic downregulation of GPCRs involves endocytosis of receptors followed by membrane trafficking to lysosomes (Fig. 1E). Additional proteolytic machinery, such as proteasomes or cell-associated endoproteases, are also implicated in mediating downregulation of certain GPCRs [39]. GPCRs may be targeted to lysosomes after initial endocytosis by clathrin-coated pits or may follow a distinct membrane pathway involving alternate mechanism(s) of endocytosis [7,39]. In some cases it is clear that receptors endocytosed by clathrin-coated pits can be targeted to a rapid recycling pathway mediating resensitization of receptors as well as to a degradative pathway mediating receptor trafficking to lysosomes. Furthermore, distinct GPCRs differ in their sorting between divergent membrane pathways when coexpressed in the same cells [40,41]. Recent studies have identified cytoplasmic sequences present in certain GPCRs that promote sorting of internalized receptors to lysosomes [42], as well as sequences that promote [43] or prevent [44] rapid recycling of receptors from endocytic vesicles to the plasma membrane. It is likely that there exist multiple biochemical mechanisms which distinguish the post-endocytic sorting of specific GPCRs and that these distinct mechanisms play critical roles in determining the precise functional consequences of agonist-induced endocytosis.

Role in Controlling the Specificity of Signal Transduction

Endocytosis of GPCRs may also control the specificity with which receptors signal to or via certain downstream effectors, such as mitogen-activated protein (MAP) kinase

modules, although the physiological significance of this regulation has not yet been established. A number of mechanisms have been proposed, generally involving the formation on endosome membranes of a protein complex including internalized GPCRs and signal-transducing kinases (such as c-Src) recruited from the cytoplasm [45,46] or receptor tyrosine kinases (such as epidermal growth factor receptors) co-endocytosed from the plasma membrane [47].

G-protein-coupled receptors (GPCRs) form the largest known gene superfamily and are involved in the regulation of numerous physiological processes, including hormonal signaling, neurotransmission, and reception of sensory stimuli; not surprisingly, these receptors are targets for the large majority ($\approx 90\%$) of clinically used drugs. All GPCRs share the same basic topology (an extracellular N terminus, seven transmembrane domains, and an intracellular C terminus) and are classified into six large families, A through F, based on sequence homology. Classically, GPCRs were thought to function as monomers; however, higher molecular weight complexes were often observed on protein electrophoretic gels, suggesting the existence of dimeric or higher order macromolecular complexes. The presence of receptor homo- and heterodimers in living cells was recently confirmed for many different GPCRs using novel experimental approaches such as fluorescence resonance energy transfer (FRET), bioluminescence resonance energy transfer (BRET), functional complementation assays, and studies of receptor trafficking. However, questions remain as to whether dimerization is constitutive or ligand induced for various GPCRs and what its functional significance may be. Table 1 classifies the types and functions of GPCR oligomers that have been documented.

The best examples of constitutive GPCR dimerization are found in the GPCR family C, which includes metabotropic glutamate receptors (mGluRs), GABA_B receptors, extracellular Ca²⁺-sensing receptor (CaR), and some pheromone and taste receptors. mGluR1, mGluR5, and CaR are known to

form constitutive homodimers, and it was recently shown that CaR dimers represent a true signaling unit [1]. For both mGluRs and CaR, dimerization is mediated by both noncovalent and covalent interactions of the extracellular N-terminal domains [2–7]. In contrast, GABA_B receptors are obligate heterodimers [8–11], and individual receptor subunits do not form functional receptors even if expressed on the plasma membrane [12–14]. The known GABA_B receptor subunit interactions include the C-terminal coiled-coil interaction, important for the regulation of assembly-dependent receptor trafficking [12,14], and N-terminal domain interactions, important for ligand binding and intramolecular signaling [15,16]. Similar obligate heterodimerization has recently been reported for T1R2/T1R3 sweet taste receptors, which also belong to family C [17]. The importance of dimerization for family C GPCRs is underscored by crystallographic analysis of the mGluR1 N-terminal ligand-binding domain; this domain, homologous to bacterial periplasmic amino acid binding proteins and conserved among family C GPCRs, was shown to exist in the dimeric form even in the absence of ligand [18]. Taken together, these findings suggest that family C GPCRs are expressed on the plasma membrane as preformed constitutive dimers and that dimerization is a prerequisite for signaling in this receptor family.

What about non-family C GPCRs? Basal homodimerization was demonstrated for yeast α -factor receptors using FRET [19], β 2-adrenergic [20] and thyrotropin-releasing hormone receptors [21] using BRET, and δ opioid receptors

Table I GPCR Oligomers

Type of GPCR oligomerization and its potential functions	Examples with references
<i>Constitutive homomerization:</i> A role in receptor/G-protein coupling?	<i>Energy transfer experiments:</i> Yeast α -factor receptor [19] β 2-Adrenergic receptor [20] δ Opioid receptor [22] Thyrotropin-releasing hormone receptor [21] <i>Dominant-negative trafficking effect experiments:</i> D2 dopamine receptor [23] V2 vasopressin receptor [24] Platelet-activating factor receptor [26]
<i>Ligand-induced homomerization:</i> A role in receptor maturation and trafficking?	<i>Energy transfer experiments:</i> Gonadotropin-releasing hormone receptor [28] SSTR5 somatostatin receptor [29] <i>Coimmunoprecipitation experiments:</i> B2 bradykinin receptor [27]
<i>Heteromerization:</i> Receptor synergy Novel agonist selectivity Novel signaling properties Novel trafficking properties	<i>Constitutive (coimmunoprecipitation experiments):</i> κ/δ opioid receptors [35] μ/δ opioid receptors [37,39] δ opioid/ β 2-adrenergic receptors [40] κ opioid/ β 2-adrenergic receptors [40] Angiotensin AT1/bradykinin B2 receptors [36] Dopamine D1/adenosine A1 receptors [38] Purinergic P2Y/adenosine A1 receptors [41] <i>Ligand-induced (energy transfer experiments):</i> SSTR5/SSTR1 somatostatin receptors [29] Somatostatin SSTR5/dopamine D2 receptors [42] δ Opioid/ β 2-adrenergic receptors [22]
<i>A special case—family C GPCRs:</i> Constitutive homo- or heterodimerization of individually nonfunctional subunits results in signaling-competent receptors	mGluR1 metabotropic glutamate receptor [4,5] mGluR5 metabotropic glutamate receptor [2,6] Ca ²⁺ -sensing receptor [1,3,7] GABA _B GABA-ergic receptor [8–16,33] T1R2/T1R3 sweet taste receptor [17]

using both BRET and time-resolved FRET [22]. In addition, for dopamine D2 receptors [23], vasopressin V2 receptors [24], chemokine CCR5 receptors [25], and platelet-activating factor receptors [26], it was shown that plasma membrane expression of wild-type receptors can be suppressed by co-expression of mutant receptors, suggesting ligand-independent, constitutive dimerization in the endoplasmic reticulum. In contrast, ligand-induced rather than constitutive homodimerization was observed for bradykinin B2 receptors using coimmunoprecipitation [27] and for gonadotropin-releasing hormone (GnRH) receptors [28] and somatostatin SSTR5 receptors [29] using FRET. The reason for these apparent differences among different GPCRs is not clear. However, it is worth noting that, at least for B2 and GnRH receptors, this agonist-induced homooligomerization was not related to receptor activation and may thus not be relevant for receptor signaling. For example, N-terminal truncation of B2 receptors eliminates bradykinin-induced receptor dimerization as well as receptor phosphorylation and downregulation, without affecting receptor function [27]. Similarly, agonist-exposed GnRH receptors exhibit slow and long-lasting microaggregation [28] not clearly related to receptor signaling. It is also worth noting that the efficiency of energy transfer

depends on both the distance and the orientation of the two fluorophores; absence of FRET or BRET does not necessarily indicate absence of dimerization. The available data are thus consistent with the possibility that GPCRs constitutively dimerize, probably while still in the endoplasmic reticulum. Interestingly, in all known cases, except for the two family C examples, these preformed dimers are homomeric in nature.

What might be the functional significance of constitutive dimerization? The surface area of a GPCR monomer is barely large enough to contact the α and $\beta\gamma$ subunits of the trimeric G protein simultaneously, and it was suggested that a receptor dimer might be necessary for G protein activation [30–32]. For GABA_B receptors, it was demonstrated that while the intracellular segments of GB2 subunit were required for the G protein activation, the GB1 C terminus could be deleted and GB1 intracellular loops could be replaced with those of G_I- or G_q-coupled family C receptors without impairing function [33]. These data suggest that a single GPCR may provide all the specific G protein contacts. However, it remains to be determined whether the other subunit in a dimer provides nonspecific contacts for the $\beta\gamma$ and/or the conserved part of the α subunit, or whether it

does not participate in G-protein activation. In addition to this potential role in G-protein coupling, constitutive GPCR dimerization may be important in receptor maturation and/or trafficking (reviewed in Bouvier [30] and Milligan [34]).

What about GPCR heterodimerization? Aside from family C receptors, the evidence for constitutive heterodimerization is based mainly on coimmunoprecipitation experiments [35–41]. Notably, no constitutive and only ligand-induced dimerization was reported for somatostatin receptor SSTR5/SSTR1 [29], SSTR5/dopamine D2R [42], and δ opioid/ β 2-AR complexes [22] using energy transfer approaches. Interestingly, ligand-induced δ / β 2 receptor heterodimerization was observed using BRET but not the time-resolved FRET (which detects only the plasma membrane receptors). These data suggest that, at least in this case, ligand-induced oligomerization might underlie not the signaling but the trafficking events, or that ligand binding induces conformational changes that alter the efficiency of energy transfer [22]. An interesting possibility is that preformed GPCR (homo)dimers might form ligand-regulated heterooligomeric complexes on the plasma membrane, resulting in novel signaling and/or trafficking properties. This possibility is supported by several recent studies that explored the functional consequences of heterooligomerization between GPCRs that form functional monomeric or homomultimeric receptors. Receptor synergy, where application of one agonist resulted in the leftward shift of the dose–response curve for the other agonist, was reported for heterooligomers of dopamine D2R and somatostatin SSTR5 receptors [42], opioid μ and δ receptors [39], opioid κ and δ receptors [35], and angiotensin AT1 and bradykinin B2 receptors [36]. The formation of receptors with novel agonist selectivity and/or signaling properties was reported for opioid κ / δ [35] and μ / δ heterooligomers [37], as well as for heterooligomers of adenosine A1 receptors with ATP P2Y1 receptors [41] or dopamine D1 receptors [38]. These findings are particularly interesting in light of some long-standing discrepancies between pharmacologically and structurally defined receptor subtypes. For example, pharmacological properties of κ / δ heterooligomers are identical to the previously reported κ 2 subtype [35]. Finally, changes in trafficking were observed with AT1/B2 [36], SSTR5/SSTR1 [29], D1/A1 [38], and β 2/ δ and β 2/ κ receptor heterodimers [40].

In summary, it is clear that many GPCRs constitutively dimerize early in the synthetic pathway. In addition, it appears that ligand application can result in the formation of higher order heterooligomeric complexes with novel signaling and/or trafficking properties. It is hoped that future studies will elucidate whether these findings apply to all GPCRs or whether qualitative differences exist between different GPCRs with respect to their oligomerization.

The Role of Chemokine Receptors in HIV Infection of Host Cells

Jacqueline D. Reeves and Robert W. Doms

*Department of Microbiology, University of Pennsylvania,
Philadelphia, Pennsylvania*

Introduction

For retroviruses to infect cells, they must transfer their genetic material across two membranes: the envelope that surrounds the virus, and the membrane of the cell. To accomplish this, retroviruses encode an integral membrane envelope (Env) protein that not only attaches virus to the cell surface but also mediates membrane fusion. The human immunodeficiency virus (HIV) Env protein attaches viruses to the surface of CD4-positive T cells and cells of the monocyte/macrophage lineage by binding directly to CD4. However, CD4 binding by itself does not trigger the fusion activity of Env. Surprisingly, the seven-transmembrane (7TM) chemokine receptors CCR5 and CXCR4 hold the key to unlocking the fusion potential of Env; sequential binding of CD4 and one of these chemokine coreceptors by the viral Env protein leads to a series of conformational changes that ultimately result in membrane fusion, virus entry, and replication. This entry pathway provides new targets for antiviral approaches and helps to explain viral tropism and pathogenesis. In addition, use of the CCR5 and CXCR4 7TM receptors by HIV raises the possibility that virus-induced signaling could impact virus infection. In this chapter, we provide an overview of 7TM coreceptor use for HIV entry, summarize what is known about the structural basis for envelope-coreceptor interactions, and indicate how signaling via 7TM receptors may influence HIV infection.

HIV Entry

Human immunodeficiency virus type 1 and 2 (HIV-1/HIV-2) are members of the lentivirus genus of the Retroviridae

family and are the causative agents of acquired immune deficiency syndrome (AIDS) [1,2]. While all HIV strains infect primary CD4⁺ T-cells, they can differ in their relative tropism for macrophages and human T-cell lines, both of which also express CD4. Some HIV strains can infect T-cell lines but not macrophages, some can infect macrophages but not T-cell lines, and others can infect both cell types. With some exceptions, HIV tropism is largely explained by the differential expression of CCR5 and CXCR4 on these CD4⁺ cell types, coupled with the fact that some HIV strains use CCR5 (R5 strains), some use CXCR4 (X4 strains), and others can utilize both molecules after binding to CD4 to enter cells (R5X4 strains) [3]. That tropism can be controlled merely by the presence of the correct viral coreceptor can be demonstrated with T-cell lines that typically express CXCR4 but not CCR5. Expression of CCR5 in T-cell lines makes them permissive to infection by R5 virus strains. Likewise, introduction of CXCR4 into a CD4⁺ cell that otherwise lacks this coreceptor confers susceptibility to infection by X4 virus strains.

How does HIV use CD4 and a coreceptor to enter a cell? The viral Env protein on the surface of virions can be triggered to undergo a dramatic conformational change that allows it to fuse the virus membrane with that of a cell. Triggering is caused by receptor engagement, which explains why the presence or absence of CCR5 or CXCR4 along with CD4 governs the susceptibility of a cell to HIV infection.

The HIV Env protein is first synthesized as a 160-kDa precursor glycoprotein (gp160) in the endoplasmic reticulum. Like many other viral membrane proteins, including those of other retroviruses, Env assembles into homotrimers after which each subunit is cleaved by a host protease into

two parts, which in the case of HIV are termed gp120 and gp41. The gp120 subunit is external to the viral membrane and is noncovalently associated with the gp41 subunit, which traverses the virus membrane. This cleavage event is essential to render Env fusion active [4]; in the absence of cleavage, Env is expressed on the cell surface, is incorporated into virus particles, and can bind to its receptors; however, it cannot cause membrane fusion. The reason is that the cleavage liberates what is now the N-terminus of the gp41 subunit. The hydrophobic N-terminal domain of gp41 acts as a fusion peptide that functions much like a harpoon, ultimately spearing the membrane of the cell during the fusion process. Many other membrane-bound viruses express proteins that, like Env, are cleaved by a host cell protease in a manner that liberates a hydrophobic fusion peptide, suggesting a common membrane fusion mechanism.

How does the fusion peptide actually cause membrane fusion? It is thought that this hydrophobic domain is hidden in the native Env protein. During virus entry, the gp120 subunit of Env interacts with CD4. This induces conformational changes within Env that then enable an interaction with either CCR5 or CXCR4. Coreceptor binding is thought to be the final trigger that induces further conformational changes in Env that result in exposure of the hydrophobic fusion peptide in gp41. The fusion peptide is then thought to insert into the membrane of the host cell, making gp41 an integral component of two membranes: the viral membrane in which it is lodged and the cellular membrane it has speared. To actually cause membrane fusion, the lipids in both membranes must be brought together. This, too, is accomplished by gp41, which folds back on itself, much like closing a jackknife. This final conformational change is associated with a significant change in free energy that likely provides the force required to elicit a fusion pore [5]. A model for HIV entry is depicted in Fig. 1.

Coreceptor Use *In Vivo*

Regulating expression of CD4, CCR5, and CXCR4 on cell lines *in vitro* controls whether or not a cell can be infected

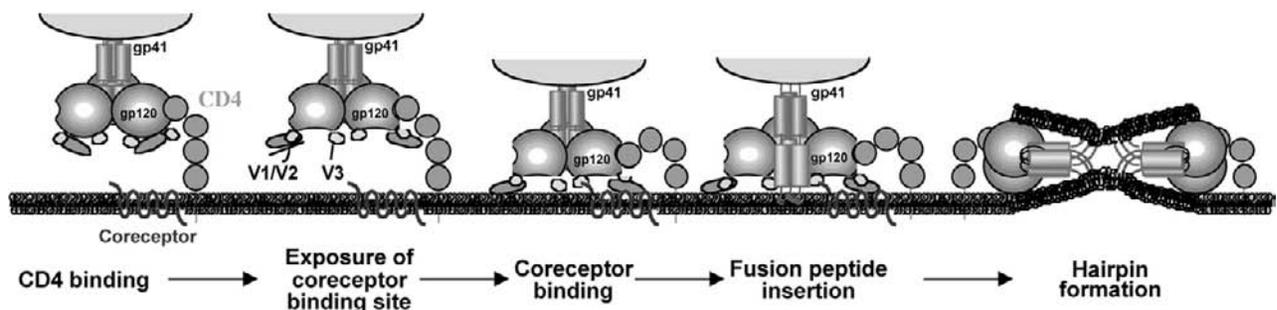

Figure 1 Model of HIV entry. The interaction of gp120 with CD4 at the cell surface induces conformational changes in Env that result in the exposure of a coreceptor binding site. Binding to a 7TM-coreceptor molecule induces further conformational changes that may involve fusion peptide insertion into the target cell membrane. The ectodomain of gp41 is then likely to fold back upon itself to form a coiled-coil bundle, causing apposition then fusion of viral and cellular membranes. (Adapted from Doms, R. W., *Virology*, 276, 229–237, 2000.)

by HIV. Receptor expression, as well as virus tropism, also regulates virus infection *in vivo*. For HIV-1, R5 viruses are predominantly transmitted, are the major virus population in asymptomatic individuals [6,7], and usually remain present throughout the course of infection [8–10]. R5X4 viruses may precede the evolution to X4 tropism, which occurs in less than 50% of AIDS patients [6,11]. A broadening of coreceptor specificity and the development of X4 tropic strains is linked with disease progression in HIV-1 infection [6]. The importance of CCR5 in transmission of HIV-1 was revealed with the discovery of a 32-bp deletion in the CCR5 gene ($\Delta 32$ CCR5) that ablates cell-surface expression [12–14]. Approximately 1% of the Caucasian population are homozygous for this deletion, and these CCR5-negative individuals are highly resistant to HIV infection [7,12–14]. Only a few cases of HIV infection in $\Delta 32/\Delta 32$ CCR5 individuals have been reported resulting from heterosexual, homosexual, and blood transfusion transmission routes, with X4 tropic viruses being transmitted where characterized [15–20]. Heterozygosity for $\Delta 32$ CCR5 may confer very modest protection against HIV-1 transmission [14,21,22] but is clearly associated with delayed progression to AIDS [12,23–25].

Env Domains Involved in Coreceptor Interactions

The gp120 subunit of Env binds to both CD4 and CCR5/CXCR4. It contains five variable regions (V1–V5) interspersed between five conserved domains (C1–C5), and is very heavily glycosylated. The third variable region, or V3-loop, plays a major role in governing whether Env interacts with CXCR4, CCR5, or both coreceptors. The first and second variable loops, termed the V1/V2 region, play a more subsidiary role. Amino acid changes in the V3 loop can result in a coreceptor switch, while changes in V1/V2 do so less commonly [26–29]. Other regions of gp120 are also involved in coreceptor binding as revealed by the crystal structure of a core of HIV-1_{HXBc2} gp120 glycoprotein coupled with site-directed mutagenesis (see Fig. 2) [30,31].

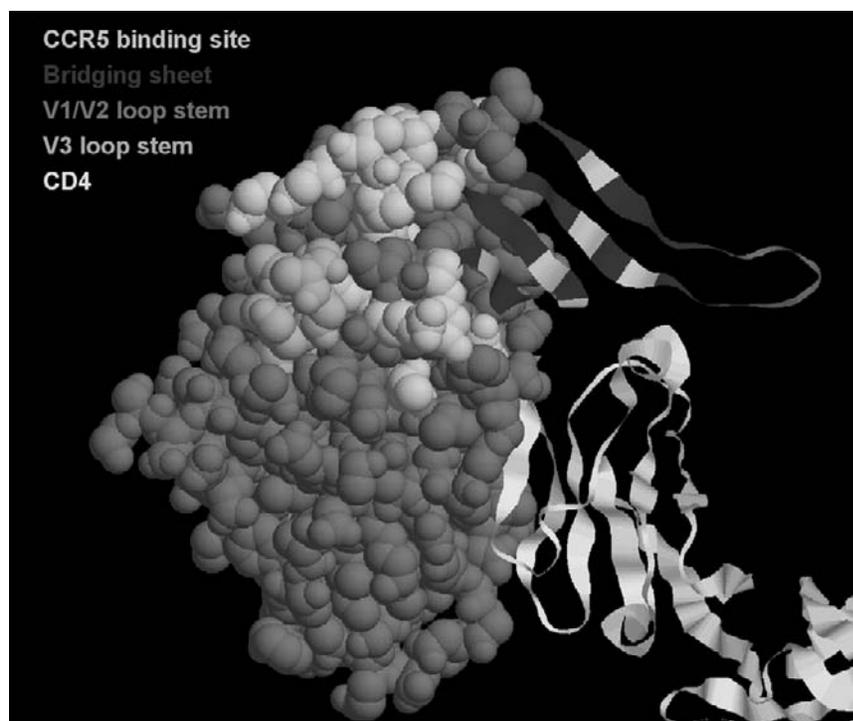

Figure 2 CCR5 binding site on gp120. Space-filling model of gp120 with the conserved bridging sheet domain and two-domain sCD4 in ribbon format. Residues involved in CCR5 binding are indicated, as are the V1/V2 and V3 loop stems. Model was rendered with RasMol 2.7.1 from the Protein Databank file 1GC1.PDB, gp120 crystal structure [30].

To aid in crystallization, the gp120 was deglycosylated, the V3 and V1/V2 loops were genetically deleted, and the protein was cocrystallized with a two-domain soluble CD4 molecule and a Fab fragment of a monoclonal antibody that binds to an epitope in gp120 that is induced by CD4 binding (Fig. 2). The epitope recognized by this antibody is highly conserved across different virus strains and is located between the base of the V3 loop and the base of the V1/V2 region, near or within the bridging sheet domain (Fig. 2). Interestingly, mutations in this conserved domain diminish the ability of gp120 to bind to CCR5 [31]. The model that logically follows is that CD4 binding results in the exposure or generation of this highly conserved portion of gp120, perhaps as the result of repositioning of the V2 and V3 loops [30,32]. This conserved domain and V3 together form a CCR5 receptor-binding domain. This is in some ways reminiscent of how chemokines bind to their receptors, which is thought to likewise involve two regions of the chemokine.

Coreceptor Domains Involved in HIV Infection

The structure of rhodopsin and the presence of conserved Cys residues in each of the extracellular domains of CCR5 and CXCR4 suggest that the four extracellular regions interact closely with each other [33]. All extracellular domains of CCR5 (N terminus [Nt]; extracellular regions 1 [E1], 2 [E2], and 3 [E3]) have been implicated in mediating infection of various R5 tropic HIV strains, with Nt and E2 being required

by the majority [34–38]. Additionally, HIV-1 strains that use both CCR5 and CXCR4 have been found to interact differently with CCR5 compared to R5 viruses [37]. CCR5-restricted viruses may evolve to become R5X4 tropic by acquiring the ability to interact with the extracellular loops of CXCR4 while retaining the ability to interact with the Nt of CCR5 [39]. The involvement of multiple coreceptor domains in Env binding is perhaps therefore not surprising. As for CCR5, multiple regions of CXCR4 are important for coreceptor activity, with the E2 loop being particularly important [39–43]. The surface of CXCR4, and particularly E2, has a greater negative charge than that of CCR5, perhaps explaining why X4 tropic V3 loops are more positively charged than those of R5 viruses.

Receptor Presentation and Processing

The expression of receptors on a particular cell type does not necessarily indicate susceptibility to infection. As for other enveloped viruses, fusion mediated by the HIV Env protein is likely to require several Env trimers, each in turn triggered by independent receptor binding events (reviewed in Doms [44]). Thus, receptor density is clearly a factor that impacts the efficiency of virus infection. The fact that $\Delta 32$ -CCR5 heterozygotes exhibit delayed progression to AIDS despite only a modest reduction in CCR5 expression levels indicates that coreceptor expression can be limiting for virus infection *in vivo*. Thus, cells that express higher levels

of coreceptor may be more susceptible to virus infection. The requirement for multiple coreceptor binding events may in part explain why some viruses that bind to CXCR4 with low affinity cannot infect macrophages, which express low levels of CXCR4. If CXCR4 expression is increased, infection of macrophages by these viruses can occur [45]. Thus, the ability of some primary X4 virus strains to infect macrophages may be due to their increased affinity for this coreceptor relative to TCLA virus strains [46–48]. Finally, in addition to receptor density, receptor conformation and processing may influence virus infection. Both CCR5 and CXCR4 have been shown to exist in antigenically distinct conformations, not all of which may function equally well as virus coreceptors [49,50]. Posttranslational modifications of CCR5 and CXCR4 can also impact their coreceptor activity. There are two N-linked glycosylation sites in Nt and E2 of CXCR4, and mutation of these sites can enhance HIV fusion and infection several-fold [40–42]. The N-terminal domain of CCR5 contains tyrosine residues that are sulfated, and sulfation contributes substantially to infection by HIV-1 [51].

Role of Signaling in HIV Infection

Env protein binding to CCR5 and CXCR4 can trigger signaling via these receptors, though the importance of this for virus infection is not known. Several studies have shown conclusively, through the expression of signaling-deficient receptors, that receptor internalization or intracellular signaling through inhibitory guanine nucleotide-binding regulatory (G_i)-proteins is not required for viral entry of cell lines [34,39,42,52,53]. However, a number of studies indicate that signaling may facilitate HIV infection of primary cells and may be especially important for post-entry viral events (reviewed in Kinter *et al.* [54]). These inferences are not definitive due to their reliance on signaling inhibitors that can exert their effects by other means.

Signaling mediated by chemokines may also impact virus replication, though these effects can be double-edged. Chemokines that bind to CCR5 or CXCR4 can block virus infection by preventing Env-coreceptor interactions. However, these same chemokines may also be able to enhance HIV infection and replication in T cells, in part by activation of signal transduction pathways [55–58]. The mechanisms of this enhancement have been reported to involve either tyrosine kinase or G_i protein-dependent signaling cascades, to increase viral attachment via glycosaminoglycans, to enhance CXCR4 transcription and thus viral attachment, or to enhance CD4: CXCR4 colocalization. The mechanisms by which HIV or chemokines induce receptor signaling, the signaling pathways that are activated, and their effects on different steps in the virus life cycle clearly must be examined in more detail, as this may help explain the post-entry restriction of some viruses that fail to replicate in macrophages [59–62] as well as lead to the development of new therapeutics.

Summary

The discovery that HIV uses the chemokine receptors CCR5 and CXCR4 in conjunction with CD4 to infect cells helped explain viral tropism and pathogenesis. The expression pattern of CCR5 and CXCR4 coupled with their differential use by diverse virus strains largely explains HIV tropism, at least at the level of entry. Their discovery led directly to the identification of receptor-related polymorphisms that determine the genetic basis for the resistance to infection exhibited by some individuals and help explain the variable progression rates to AIDS of others. Subsequent structural studies have revealed the presence of highly conserved domains in the viral Env protein that are responsible for receptor binding and membrane fusion and that are real or potential targets for antiviral agents and neutralizing antibodies. The Env protein can also induce signaling via either CCR5 or CXCR4. While receptor signaling is not required for virus replication in transformed cell lines, it may modulate virus infection of primary cell types. The utilization of CCR5 and CXCR4 for the membrane fusion reaction is clear, but the role of signaling in the infection of primary cells is not and is clearly an area that requires further investigation.

Acknowledgments

We thank Mark Biscone for modeling the CCR5 binding site on gp120. Our work is supported by grants from the NIH (AI35383, AI40880, AI45378) and an Elizabeth Glaser Pediatric Scientist Award to R.D.

Chemotaxis Receptor in Bacteria: Transmembrane Signaling, Sensitivity, Adaptation, and Receptor Clustering

Weiru Wang and Sung-Hou Kim

*Department of Chemistry and Lawrence Berkeley National Laboratory,
University of California, Berkeley, California*

While the chemotactic signaling pathway of bacteria has been established [1,2] well enough to enable accurate computer simulation of the migration of virtual bacteria [3], detailed molecular mechanisms underlying ligand-mediated transmembrane signaling, high receptor sensitivity, receptor adaptation, and one broad dynamic range of sensitivity to attractants remain to be elucidated.

Bacteria rapidly respond to changes in concentrations of critical chemicals in their environment by chemotaxis—that is, a swimming pattern biased toward or away from particular stimuli [4]. The chemotaxis pathway includes chemosensory receptors and a phosphotransfer system known as the two-component signal transduction pathway [5–8]. It is well established that bacteria sense their environmental changes over time [9]. Like many other sensory perception processes, bacterial chemotaxis has high sensitivity and broad dynamic range [10–12]. The sensitivity allows the binding of attractants to less than 1% of the receptors to induce increased swimming motion of *Escherichia coli* [13]; this high sensitivity does not appear to be due to a signal amplification step downstream of the receptor [14]. As for the dynamic range, bacteria can detect the gradient of attractants such as aspartate under background concentrations (from nanomolar to millimolar) spanning five to six orders of magnitude [13,15,16].

Most bacterial chemoreceptors belong to a family of transmembrane methyl-accepting chemotaxis proteins (MCPs). MCPs can be divided into at least four subfamilies on the

basis of the disposition of hydrophobic regions that are predicted to be transmembrane helices by hydrophathy analysis [17]. Family A includes two transmembrane helices separated by a substantial periplasmic domain (Fig. 1). Whereas the other families possess less periplasmic and less transmembrane components (for a recent review, see Falke and Kim [18]). Family A also includes the chemoreceptors for aspartate, serine, ribose and galactose, peptide, citrate, and osmolarity [19,20]. The architectures of selected family chemoreceptors are well understood and are likely to represent many other members of family A. The folding unit of the chemoreceptor is a stable homodimer [21]. Each receptor monomer consists of a ligand binding region (periplasmic sensory domain) made up by an anti-parallel, four-helix bundle ($\alpha 1$, $\alpha 2$, $\alpha 3$, and $\alpha 4$), an antiparallel two-helix (TM1, TM2) transmembrane region, and a long two-helix hairpin region (cytoplasmic signaling domain) (Fig. 1). The receptor dimer is thus an elongated helical bundle thought to be oriented normal to the membrane plane [22–27]. The length of one *E. coli* serine receptor model spans ≈ 380 Å from one end to the other [27]. The incoming signal propagates through the cytoplasmic domain, which is coupled by a scaffolding protein CheW to the signaling kinase CheA [8,28]. CheA in turn regulates two response regulators: CheY (in the phosphosignaling branch of the pathway) and CheB (in the adaptation branch). Attractant binding attenuates CheA activity and, ultimately, via the phosphosignaling branch, reduces the overall frequency of tumbling (by clockwise rotation of flagella) (Fig. 2) [8].

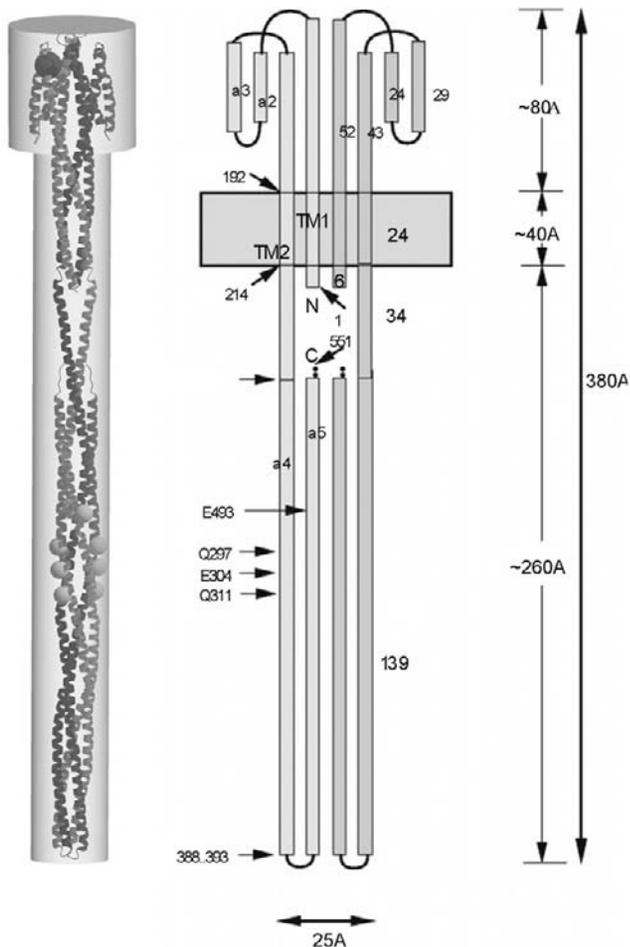

Figure 1 A model of intact *E. coli* Tsr chemotaxis receptor dimer [27]: one monomer is blue, the other pink. The presumed membrane bilayer is represented by a gray horizontal band. The model is about 380 Å long and consists of about 80-Å-long ligand binding domains, an about 40-Å long transmembrane domain, and an about 260-Å long cytoplasmic domain. The length of each domain is shown. (Left) Ribbon diagram of the intact Tsr dimer model viewed perpendicular to the non-crystallographic two-fold symmetry axis. The dimensions are scaled to match those of the schematic figure at right. One monomer is purple, the other cyan. Methylation sites are marked by yellow balls in one monomer and orange balls in the other, and the ligand serine is red (partially hidden at upper left corner). Some landmark residues are shown.

Signaling at Periplasmic Ligand Binding Domain

In contrast to many other receptors, such as growth hormone receptors, bacterial chemotaxis receptors do not signal by horizontal aggregation of the receptor monomers; instead, ligand binding induces small conformational changes, which are assumed to be transmitted through the transmembrane helices to the cytoplasmic domain and to affect the phosphorylation rate of the bound histidine kinase (recently reviewed by Falke and Hazelbauer [29]). Crystal structures of the ligand binding domain of a *Salmonella tryphimurium* aspartate receptor (Tar) mutant [22] in apo and liganded (Asp bound) forms and of the wild-type Tar of apo and liganded forms [30] revealed one Asp bound per dimeric receptor, which was also shown to be true in solution [31]. The difference distance matrix method of comparing apo and Asp bound forms

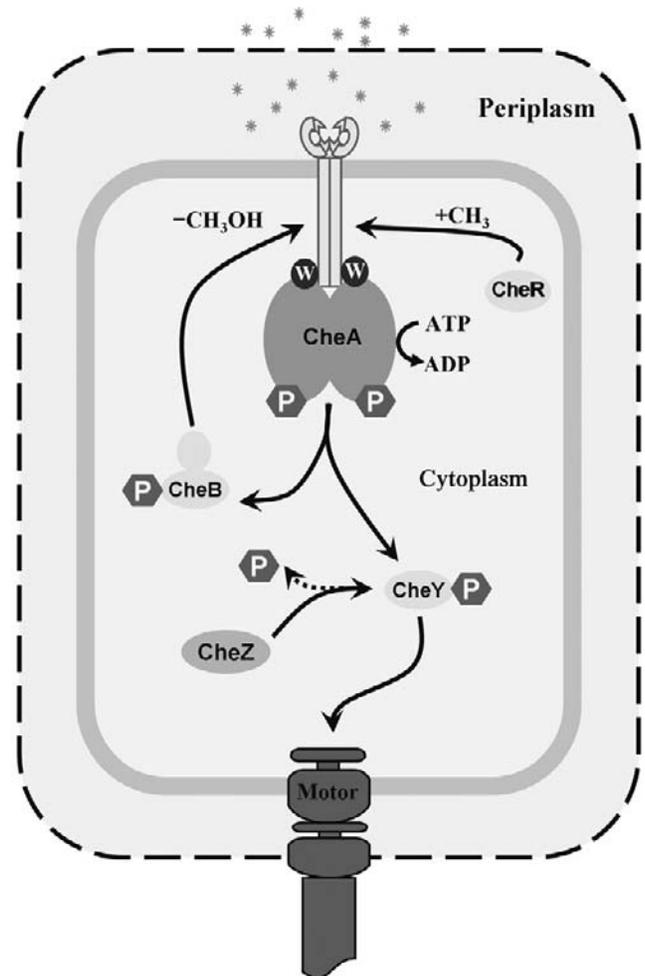

Figure 2 A schematic presentation of the chemotaxis pathway. The chemotaxis receptors are coupled to the histidine kinase CheA by CheW. Binding of attractant at the periplasmic domain of the receptor downregulates the phosphorylation rate of CheA. CheA is phosphorylated by hydrolyzing adenosine triphosphate (ATP). The phosphorylated CheA activates two response regulators CheB and CheY. Phosphorylation of CheB activates its effector domain, which demethylates four glutamate sites of the receptor cytoplasmic domain, while a methyltransferase CheR constitutively methylates these sites. Phosphorylation of CheY modulates the flagella motor. Phosphorylated CheY docks the motor switch apparatus and controls the direction of motor rotation (clockwise rotation of flagella causing tumbling behavior of bacteria). Both CheY and CheB catalyze autodephosphorylation. CheZ, a phosphatase, enhances the dephosphorylation rate of CheY.

suggested a small but significant intersubunit conformational change ($\alpha 1$ with respect to $\alpha 1'$) [30] and even smaller intrasubunit conformational changes ($\alpha 1$ with respect to $\alpha 4$) [32]. The main difference between structures of the apo and complex forms of the periplasmic domain is a small, approximately 4°, rigid-body rotation of one monomer subunit with respect to the other in the dimeric domain [22,30,33]. The crystal structures of *E. coli* Tar periplasmic domain in true apo and pseudoligand-bound forms [34] provided further evidence in favor of dimeric signaling models [32,35] involving intersubunit motion. Because the apo and Asp bound domains are in two different crystalline environment, it is not clear whether these small conformational changes are functionally relevant or caused by differences in crystal packing.

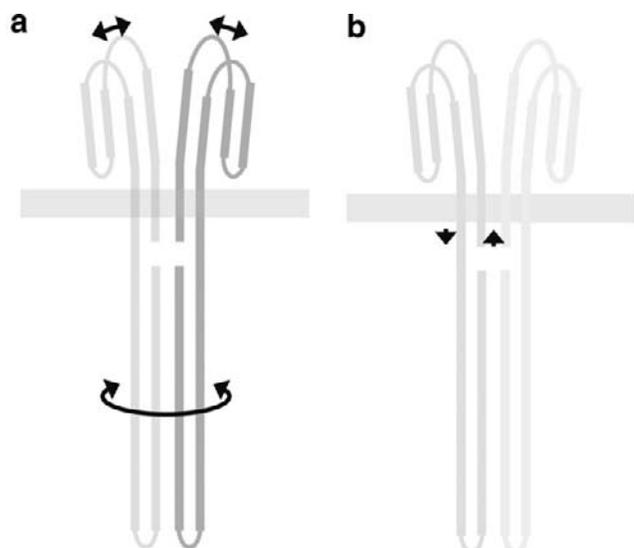

Figure 3 Two models of transmembrane signaling mechanism. (a) Dimeric signaling model; (b) monomeric signaling model.

In contrast to crystallographic data, biochemical and other biophysical studies provided information that led to monomeric signaling models of transmembrane mechanism. Results from site-directed disulfide chemistry [24,25,32,36–39], site-directed spin labeling electron paramagnetic resonance (EPR) [40], and nuclear magnetic resonance (NMR) [41,42] are best accounted for in terms of a piston type motion that involves a modest (1–2 Å) sliding of the transmembrane helices across the membrane within a monomer, which subtly rearranges packing of the cytoplasmic four-helix bundle, thereby transmitting the signal [29].

In both the dimeric signaling and monomeric signaling models (Fig. 3), it is generally accepted that the ligand binding induces a small conformational change resulting in subtle movement in the periplasmic domain as well as transmembrane helices, which, in turn, is transmitted to the cytoplasmic domain. However, conformational differences as small as those observed are subject to other interpretations.

Signaling at the Cytoplasmic Domain

In a mutant of the *E. coli* serine receptor (Tsr), Q mutant, all four methylation site residues of the Tsr cytoplasmic domain are glutamines, thus mimicking the fully methylated state of the receptor. The phosphorylation activity of this mutant receptor is very high [43]. The Q mutant effectively locks the receptor in a signal “on” state. In contrast to the ligand binding domains, crystal structures of the cytoplasmic domains of the Q mutant [27] and the wild-type receptor [44] show no conformational differences. The crystallographic data described in Fig. 4 [44] revealed the presence of significant differences in dynamic flexibilities of the domains, however, suggesting that modulation of or changes in the dynamic properties of the receptor may be the language in which the signal is transmitted from the chemotaxis receptor to CheA, its immediate downstream effector. The structural basis for the reduced dynamic flexibility in the Q mutant is probably the

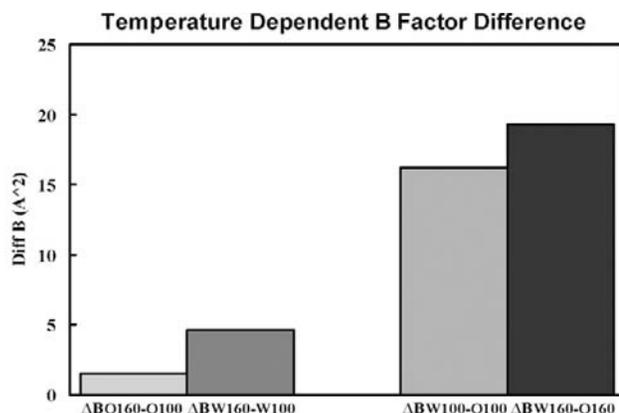

Figure 4 Crystallographic B factors of a molecule reflect the sum of two properties: dynamic flexibility and static disorder of the molecule. The ΔBs are calculated using the average B factors of the entire molecule. Q160, all Q mutant at 160 K; Q100, all Q mutant at 100 K; W160, wild type at 160 K; W100, wild-type at 100 K. The B factors of either the wild type or Q mutant change little between temperatures 60 K apart; however, the wild type displayed a much higher temperature factor when compared with the Q mutant at both temperatures.

extensive inter-helical hydrogen bonding formed by the glutamine residues at the four methylation sites.

Adaptation

The adaptation branch of the chemotaxis pathway enables the cell to adapt to a constant background stimulus so that it can chemotax up a small concentration gradient superimposed on a large background level of attractant. Covalent modifications of the methylation sites of the cytoplasmic domain are responsible for the sensory adaptation. Chemo-receptors possess multiple glutamate residues on the cytoplasmic domain surface that can be reversibly methylated by methyltransferase, CheR, and demethylated by methylesterase, CheB. CheR activity is constitutive, whereas CheB is activated by phosphorylated CheA (Fig. 2). Attractant binding or demethylation of the cytoplasmic domain down-modulates the CheA phosphorylation rate [45,46]. The relative rates of methylation and demethylation define the steady-state level of the receptor methylation [8]. Methylation of the receptor cytoplasmic domain reduces the ligand binding affinity to the periplasmic domain in the receptor–CheW–CheA ternary complex of *E. coli* Tsr [47]. Thus, an elevated level of receptor methylation, which occurs when bacteria encounter persistently high concentrations of attractant, desensitizes the periplasmic domain by lowering ligand binding affinity. In the opposite scenario, reduced receptor methylation increases the sensitivity in a low attractant concentration environment.

The mechanism by which methylation affects the ligand binding affinity and the rate of Che Y phosphorylation is not known. One possibility is that methylation changes the dynamic mobility of the receptor; inter-helical favorable hydrophobic interactions involving the methyl groups may reduce the dynamic flexibility of the receptor, thereby influencing the ligand binding and/or Che A activity.

Clustering of the Chemoreceptor and Sensitivity

A higher order structure of chemoreceptors was demonstrated first in *E. coli* cells by immuno-electron microscopy experiments [48]. These studies showed that chemoreceptor–CheW–CheA complexes are clustered in large arrays localized at the flagellum-bearing pole of the bacterial cells. It was later observed that the leucine-zipper fused cytoplasmic domain of Tar forms a cluster of ≈ 14 receptor signaling domains in the presence of CheA and CheW *in vitro* [49]. *In vivo* clusters of intact receptors and active complexes in the cell membrane may nucleate formation of additional further active complexes, thus amplifying the signal at the receptor level. The positive cooperativity observed for ligand-induced inhibition of CheA activity *in vitro* added to the evidence that receptor cluster have functional importance [47] Bray *et al.* [50] and Zhang and Kim [51] proposed mathematical models for the high sensitivity by proposing

that one ligand-bound receptor can convert the conformation of many neighbors in the cluster. They further showed that the dynamic range can be modeled mathematically if one assumes that the receptors exist as clusters as well as single dimeric receptors and that the degree of receptor clustering depends on the concentration of the ligand. Clustering may promote interaction between receptors, thereby propagating the signal to neighboring receptors. A structural basis for receptor clusters is suggested by the crystal structure of the *E. coli* Tsr cytoplasmic domain [27].

A recent computer modeling of the clustering of chemotaxis receptor [44] based on the crystal structure and packing of the cytoplasmic domain of a serine chemotaxis receptor [27] reveals that each receptor dimer may contacts two other receptor dimers at the cytoplasmic domain and two yet different receptor dimers at the ligand binding domain, thus, making an infinitely extendable two-dimensional sheet of receptors (Fig. 5). In this “trussing” arrangement each receptor

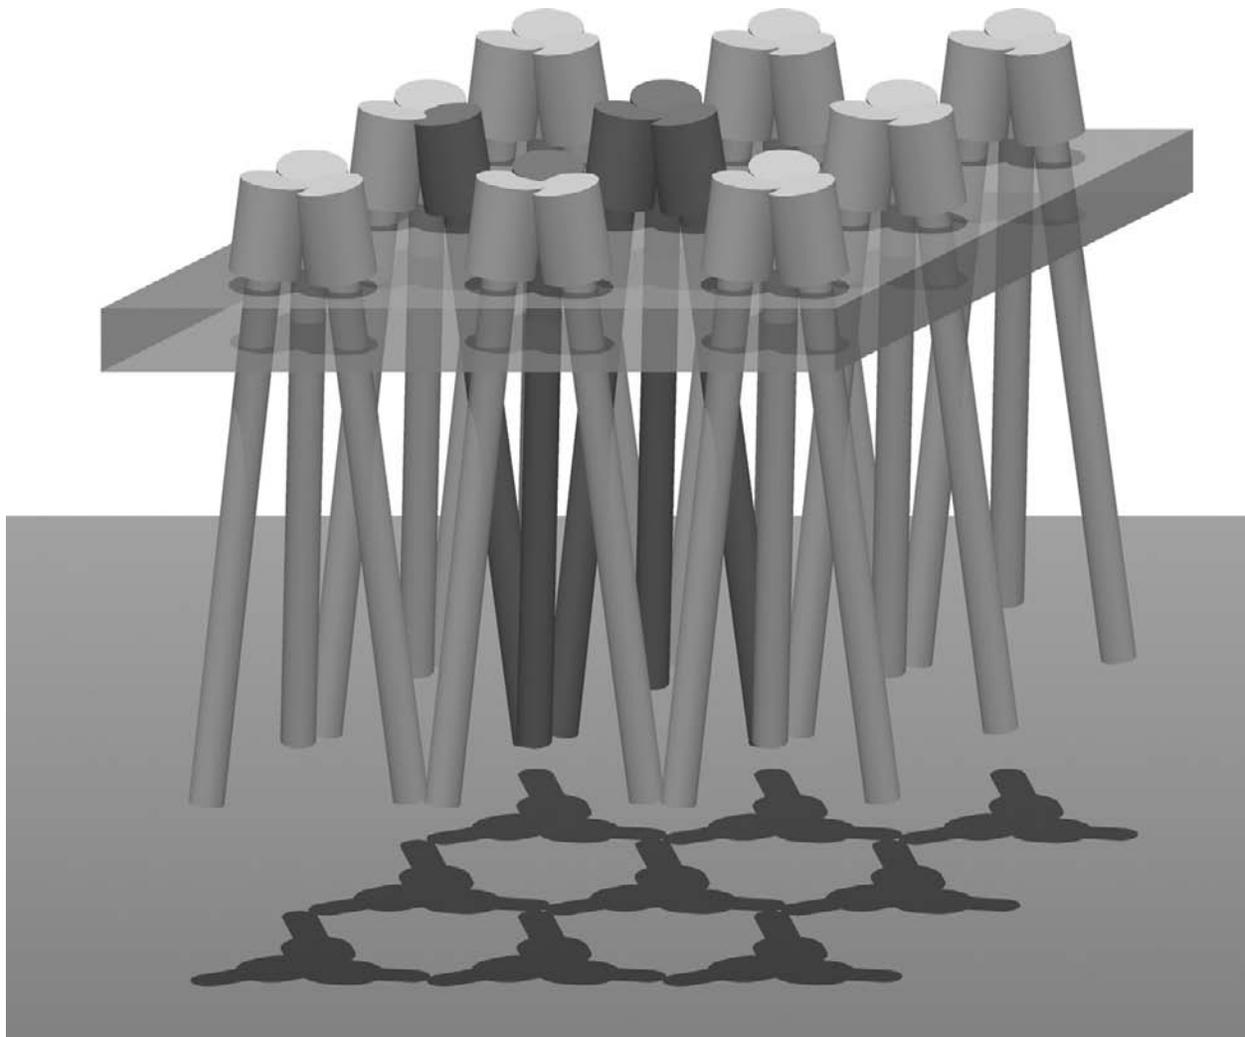

Figure 5 A schematic drawing of the receptor dimer clustering model. Each cylinder represents a dimer of chemotaxis receptors as in Fig. 1 (left). On repellent binding to or departure of bound attractant from one receptor, the dynamic property of the receptor is reduced (shown in blue) and the reduction is “felt” progressively by the first order and second order neighbors (indicated by milder blue colors) propagating through the trussed slab of the receptors. The cluster cast by a vertical light source reveals the contact network in 2-dimension graphically.

dimer is in contact with total of four other receptor dimers. This inter-connection of the receptors is proposed to be the structural basis for the high sensitivity of the bacterial chemotaxis receptors. Furthermore, absence of any significant differences between the average structures, but the presence of significant differences in dynamic flexibilities of signal active and inactive states of the structure suggest that the modulation of dynamic property of the receptor may be the language of the receptor signaling [44].

Future Studies

Our understanding of bacterial chemotaxis at the level of individual molecules, although based on a tremendous body of knowledge, must be combined with studies of chemotaxis at the level of molecular complexes. Furthermore, receptor clustering and high-order interaction among receptor complexes may lead to fundamental explanations of the extraordinary sensitivity and dynamic range of gradient sensing in bacterial chemotaxis.

Overview: Function and Three-Dimensional Structures of Ion Channels

Daniel L. Minor, Jr.

Cardiovascular Research Institute,
University of California, San Francisco, California*

Introduction

Actions speak louder than words. The molecular roots of our actions and the thoughts and feelings that drive us to act are ion channels, proteins that form macromolecular pores in cell membranes. These transmembrane proteins generate and propagate the electrical signals that allow us to sense our surroundings, process information, make decisions, and move.

Ion channel proteins act as gates that span the lipid bilayer that surrounds all cells where they open and close to allow the flow of ions down their electrochemical gradients (Fig. 1). The ion flux through a channel pore can be extremely high, $\approx 10^6$ ions per second [1]. Because of their central role in the function of the excitable tissues such as heart, brain, muscles, and nervous system, investigators have long sought to understand ion channel properties from a molecular perspective. Decades of biophysical measurements and functional studies have been devoted to understanding ion channel function [1]. Yet, the very nature of these molecules—transmembrane proteins that are difficult to obtain in the large quantities and high purity necessary for structural investigation—has impeded attempts to obtain the most essential information for understanding their functions, a three-dimensional description of their molecular architectures at high resolution. In the past 5 years, the once impregnable barrier separating biophysicists and neuroscientists from this essential information has been breached.

The first high-resolution structures of ion channels and ion-channel-associated proteins are providing the substrates for sophisticated tests of the mechanisms of channel gating and permeation. This chapter touches briefly on these pioneering studies and the questions they raise.

Ion channels perform two basic functions. They open and close to control the passage of ions across the cell membrane (see Chapter 36) and they sense and respond to signals that drive them between open and closed states (see Chapters 35 and 37 to 40). The response times of channels to these inputs can be very fast, on the order of tens of microseconds to a few milliseconds [1]. Different classes of ion channels have been designed by nature to respond to the three types of signals one can imagine sensing in a membrane environment: extracellular signals such as neurotransmitters (e.g., acetylcholine and glutamate receptors; see Chapters 37 and 38), transmembrane voltage changes (typified by voltage-sensitive cation channels; see Chapter 35), and intracellular signals such as calcium and cyclic nucleotides (see Chapters 39 and 40). While channels are generally classified based on the primary signal that opens them, many channels serve as integrators and respond to some combination of signals.

The pore-forming domains of most ion channels are multimeric assemblies possessing cyclic symmetry in a general architecture known as *barrel-stave* (Fig. 2). A fixed number of subunits assemble around the axis of the ion conduction pore.

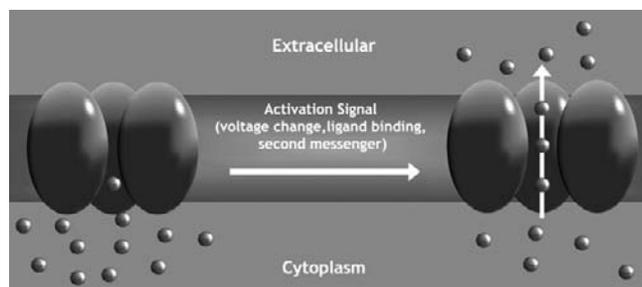

Figure 1 Schematic of ion channel function as viewed from the plane of the membrane. Three subunits of an ion channel are shown in magenta; ions are shown as green spheres. Upon activation by a stimulus, such as a transmembrane voltage change or ligand binding, the channel undergoes a conformational change that opens a pore formed by the protein. Ions flow through the open pore in a direction that is determined by the electrochemical gradient.

The number of subunits is roughly related to the size and selectivity characteristics of the channel. For example, the most selective channels, such as voltage-gated sodium channels and voltage-gated potassium channels, are tetramers in which four identical or highly homologous subunits are arranged around the pore. Pentameric channels such as the nicotinic acetylcholine receptor (nAChR) have larger pores and generally discriminate between positive and negative ions but not among ions within these general classes. Hexameric channels such as gap junctions allow ions and small solutes to pass [2]. The barrel-stave channel arrangement has been a boon to structure–function studies, as the channel symmetry imposes strong constraints on the likely location of amino acids close to the pore. Nature, however, does not always follow this plan when constructing ion channels. Voltage-gated chloride channels have two pores that are formed from a dimer of subunits in which each subunit makes its own ion passageway (Fig. 2c) [3].

Studies of Full-Length Ion Channels

X-ray crystallographic and nuclear magnetic resonance experiments are the most powerful tools for obtaining information about the atomic structure of macromolecules. Unfortunately, it is still extremely difficult to use these methods to study membrane proteins such as ion channels. Ion channels have domains that reside in the hydrophobic environment of the cell membrane as well as domains that reside in the aqueous intra- and extracellular spaces. To keep the transmembrane domains soluble upon removal from the cell membrane, reagents such as detergents or lipids must be used in the purification and handling of full-length channels. The search for the precise detergent or lipid that will work for a given channel complicates purification attempts as well as the search for conditions that produce diffraction-quality protein crystals, the necessary prerequisite for any X-ray crystallographic study. The large size of most ion channel proteins places them outside what is currently possible with the most sophisticated nuclear magnetic resonance (NMR) methods.

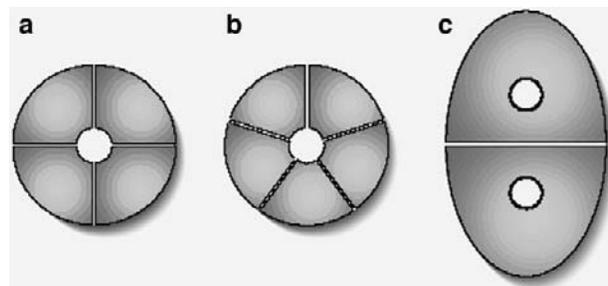

Figure 2 General architecture of ion channels. Parts (a) and (b) show the barrel-stave characteristics of the voltage-gated cation channel family and the nicotinic acetylcholine receptor family. In each of these, the channel subunits are arranged around the pore through which the ions flow. Part (c) shows the general architecture of voltage-gated chloride channels. These channels are dimers in which each subunit makes its own pore. (Adapted from Jentsch, T., *Nature*, 415, 276–277, 2002.)

Furthermore, good overexpression systems for producing eukaryotic membrane proteins in the quantities required for high-resolution studies are not currently available. Solving this technical problem is one of the major requirements for routine high-resolution investigation of membrane protein structure.

Electron microscopy studies have proven particularly useful in obtaining low- to medium-resolution descriptions of eukaryotic ion channels and the conformational changes that accompany ion channel opening. Studies of ion channels found in high abundance in the electric organs of electric rays and electric eels, such as the nicotinic acetylcholine receptor and the voltage-gated sodium channel [4,5], reveal the general cyclic symmetric architecture of both of these channels (Fig. 3). While difficult, these studies require much less protein than other structural methods, and information can be obtained from two-dimensional crystals, tubular membrane crystals, and even single particles.

General Pore Features Revealed by Bacterial Channels

The problems with obtaining material for ion channel structural studies can be overcome by turning to bacterial ion channels. These molecules can be more readily expressed and purified in large quantities than their eukaryotic counterparts. The atomic details of the inner workings of an ion channel were first seen in the X-ray crystallographic structures of the bacterial potassium channel, KcsA (Fig. 4a) [6–9]. The KcsA structure revealed many of the general features of ion channel pores that had been anticipated from careful biophysical studies coupled with structural reasoning (see Chapter 36). For instance, many channels seem to be made on a funnel-shaped plan with a large entryway that tapers to a narrow constriction that can serve as a selectivity filter that allows only particular types of ions to pass.

Potassium channels are remarkable for their ability to discriminate between potassium and sodium ions with very high precision, preferring potassium by a factor of $\approx 10,000:1$ [1].

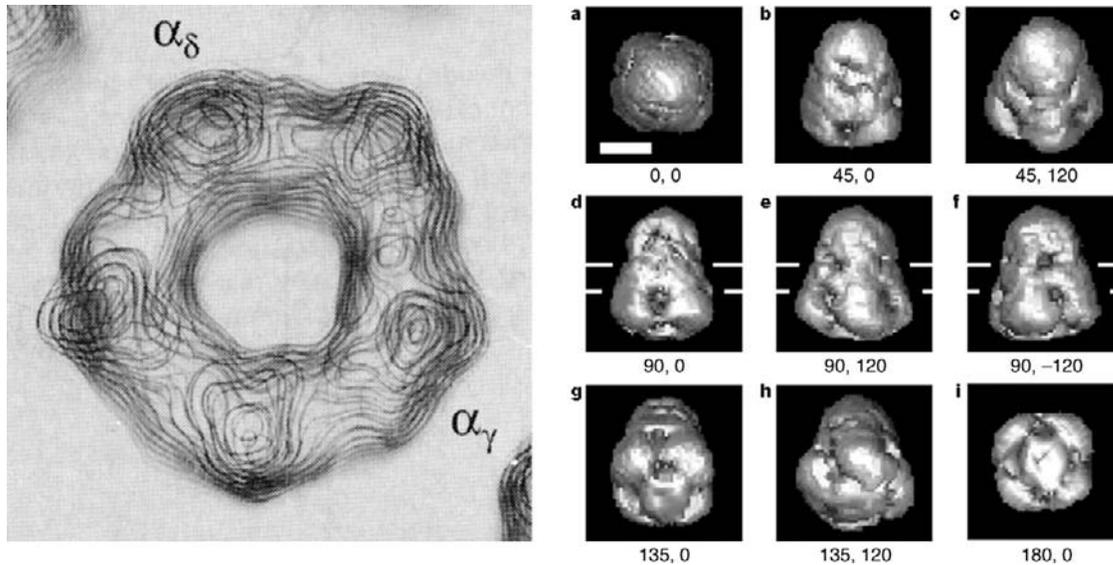

Figure 3 Electron microscopy reveals the general features of the nictotinic acetylcholine receptor seen from the extracellular space at 9-Å resolution, left, and the voltage-gated sodium channel at 25 Å, right. The panels for the sodium channel show successive rotations of a surface representation of the channel and start from the extracellular side (0, 0) through the intracellular side (180, 0). The pairs of numbers indicate the degrees of rotation around the x and y axes. (Adapted from Unwin, N., *Nature*, 373, 37–43, 1995; Sato, C. *et al.*, *Nature*, 409, 1047–1051, 2001.)

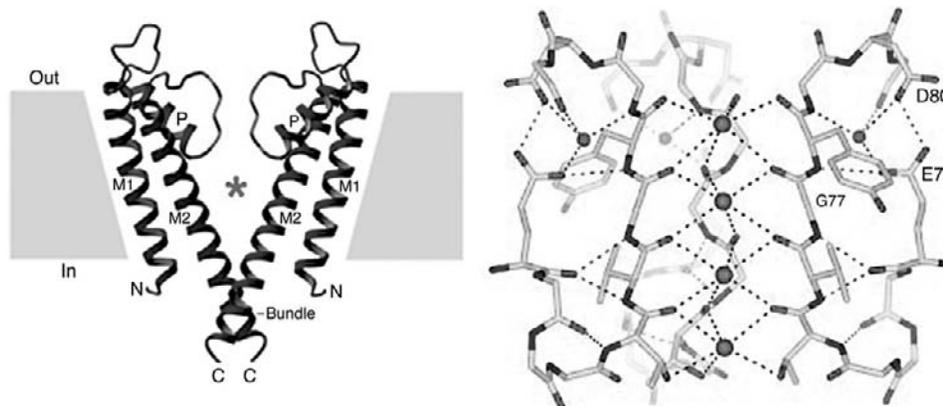

Figure 4 Structural elements of a potassium channel pore. (Left) Two subunits from the KcsA potassium channel are shown. The transmembrane segments are labeled M1 and M2. M2 subunits cross at the region marked “Bundle” and restrict access to the channel pore. The pore helix is indicated by “P” and the selectivity filter is shown in yellow. The red star marks the inner cavity of the channel. (Right) Close-up view of the intimate contacts between the KcsA selectivity filter oxygens (red) and potassium ions (green spheres). (Adapted from Jiang, Y. *et al.*, *Neuron*, 29, 593–601, 2001; Zhou, Y. *et al.*, *Nature*, 414, 43–48, 2001.)

Both ions are monovalent cations. A sodium ion has a radius of 0.95 Å, while potassium has a radius of 1.33 Å. How does the larger potassium ion pass through the potassium channel selectivity filter while the smaller sodium ion does not? Chemistry. All ions have shells of closely associated water molecules in solution [1]. For an ion to enter the filter, it must shed its waters of hydration. The selectivity filter of potassium channels is arranged in a way that displays rings of carbonyl oxygen atoms from the protein backbone at the exact diameter of a potassium ion. Thus, the waters of hydration surrounding a potassium ion are exactly replaced by oxygen atoms from the protein, creating a perfect chemical and

energetic match as the ion enters the selectivity filter (Fig. 4b) [7,9]. Although the smaller sodium ion can pass through the filter, it is much more energetically costly, as fewer of its lost water ligands can be replaced by the channel. Other selectivity filters may work in a similar way in which the protein makes intimate contact with the permeant ion.

Pore Helices: Electrostatic Aids to Permeation

A second feature that is common in the high-resolution ion channel structures (bacterial potassium and bacterial

chloride channels) is the use of the N- or C-terminal ends of short α -helices (known as pore helices) to stabilize the ion as it passes through or near the points of narrow constriction in the channel pore. For example, the pore helices of KcsA have their C-terminal ends aimed at the ion conduction pathway (Fig. 5, left). It is thought that the negative end of the helix dipole (the C-terminal ends of helices bear a small net negative charge, while the N-terminal ends bear a small net positive charge [10]) stabilizes the potassium ion on its journey through the channel [11]. Likewise, the recent structure of a bacterial chloride channel shows that the N-terminal ends (positive end) of two helices that form the narrowest part of the ion conduction pathway form a binding site for the negatively charged chloride ion (Fig. 5, right) [3].

Open Channels

The key thing that ion channels do is open and close. Structural studies are beginning to reveal the general rearrangements that occur when channels are prompted to move between closed and open states. Electron microscopy studies of the nAChR show that ligand binding to the extracellular domain causes a twisting of the subunits that is

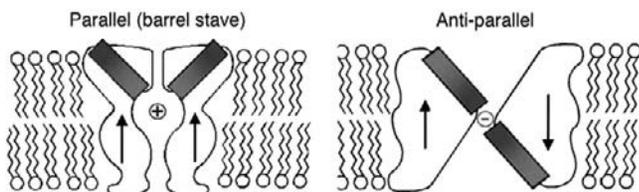

Figure 5 Examples of how pore helices stabilize permeant ions for cation channels (left) and anion channels (right). (Adapted from Dutzler, R. *et al.*, *Nature*, 415, 287–294, 2002.)

propagated some 60 Å away to the narrowest part of the channel pore embedded deep in the membrane. This conformational change widens the narrow constriction, or gate, that prevents ion flow in the closed state [4] (Fig. 6).

Potassium channels also use a distinct portion of the protein as a gate to prevent ion flow in the closed state. X-ray crystallographic comparisons of the homologous pore regions of open [12] and closed [6] bacterial potassium channels suggest that the lower part of the inner helix moves during gating to widen the narrow constriction formed by the bundle crossing of the inner helices [13] (Fig. 6). These conformational changes occur below the selectivity filter, which remains largely unchanged. This mechanism of opening is likely to be conserved among many diverse types of potassium channels.

Eukaryotic Ion Channels at High Resolution: Divide and Conquer

Bacterial channels have provided insight into the guts of ion channel permeation machineries, revealing the intimate details of permeation pathways that are likely to be conserved and recapitulated in their larger eukaryotic cousins. In contrast to prokaryotic membrane proteins (which are difficult to obtain in their own right), eukaryotic membrane proteins are currently extremely difficult to obtain in the quantities required for high-resolution study. Eukaryotic channels often contain a host of extramembranous regulatory domains and subunits that are essential for their activity, signal sensing, and gating. These domains have proven to be a tractable entry point for the study of eukaryotic ion channel structure and function.

A number of groups have successfully “liberated” extramembranous domains from the membrane-spanning part of a variety of ion channels so that they can be expressed, purified, crystallized, and treated like soluble proteins.

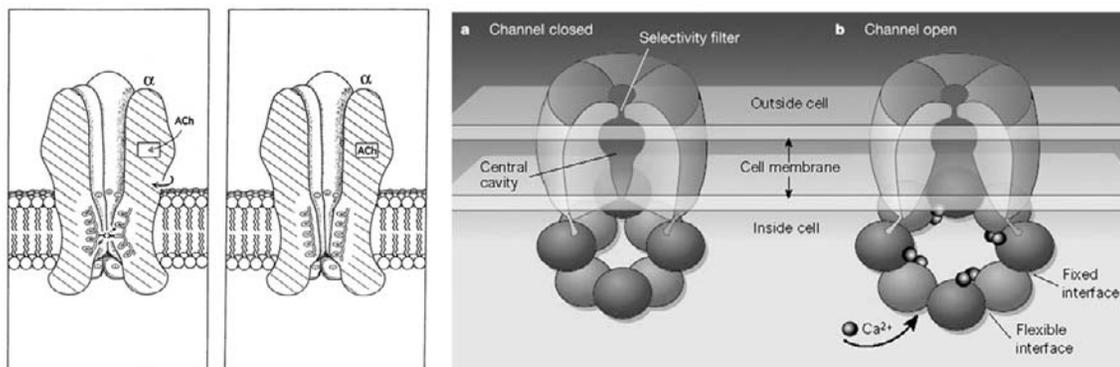

Figure 6 Opening mechanisms of ion channels. (Left) Simplified diagram of the opening mechanism of the nAChR. Acetylcholine (ACh) binds to the extracellular domain of the receptor initiates a rotation that causes the closest approach of the ring of pore-lining helices to widen creating a pathway for the ions. (Right) Schematic model for the opening of a bacterial calcium-gated potassium channel. Calcium binding to the cytoplasmic domains causes a conformational change that is propagated to the inner pore-lining helices. This opens the pathway for the ions to enter the channel. (Adapted from Unwin, N., *J. Struct. Biol.*, 121, 181–190, 1998; Schumacher, M. A. and Adelman, J. P., *Nature*, 417, 501–502, 2002.)

This divide-and-conquer approach has proven particularly powerful for illuminating channel-gating mechanisms when the high-resolution information about these domains is incorporated into structure–function studies of the intact channel. For example, studies of an assembly domain from eukaryotic voltage-gated potassium channels led to the discovery of a new role for this domain in channel gating [14,15]. The structure of a soluble homolog of the extracellular domain of the nAChR found in snail glial cells has provided molecular landmarks for interpreting decades of study by chemical modification, mutagenesis, and electron microscopy of the intact receptor [16]. Similarly, structures of the ligand binding domains of glutamate receptors [17] and calmodulin-activated potassium channels [18] have led to detailed models of channel gating and ligand recognition. This divide-and-conquer approach is likely to remain a fruitful endeavor in the near future while better methods for purifying ion channels from native sources and new means for expressing full-length ion channels are developed.

Ion Channel Accessory Subunits: Soluble and Transmembrane

Many eukaryotic ion channels have soluble subunits that associate with and regulate the properties of the channel *in vivo*. For example, some voltage-gated potassium channels associate with soluble β subunits that affect their ability to rapidly inactivate. Curiously, the structure of the Kv β subunit reveals a structure that is common to oxidoreductase enzymes [19], complete with a firmly bound nicotinamide adenine dinucleotide phosphate (NADP) molecule. This structural observation suggests that Kv β may act as some sort of enzyme that depends on the activity of the channel; however, to date, no functional data support this hypothesis.

Many other channel subunits exist. Some are soluble proteins, such as the calcium channel β subunit, and many are transmembrane proteins that bear intra- and extramembranous domains that affect the function of the pore-forming subunit [1]. Little is known about the structure of any of these molecules.

The Future: Ion Channels as Electrosomes

Beyond the classical pore-forming subunits and auxiliary subunits that comprise ion channels, it is becoming ever more clear that, in real biological settings, ion channels are part of large protein networks. These networks include cytoskeletal components, signaling proteins such as protein kinases and phosphatases, and channel-associated proteins that recruit these signaling molecules to the channel to modify its function. To understand the biological structure of ion channels, it will be necessary to move from thinking about channels as proteins that simply form ion conduction pores to thinking about them as electrical signaling centers (*electrosomes*), large, multiprotein macromolecular complexes

that not only generate electrical signals or changes in the membrane potential but also generate and respond to other chemical signals within a cell.

Perhaps the best example of a channel as an electrosome is the voltage-gated calcium channel [1]. When these channels open, they provide a means to depolarize the cell by allowing calcium entry. Calcium influx through the channel pore interacts with a channel-resident, calcium-sensing protein (calmodulin) that accelerates channel inactivation [20] and also causes the activation of signals that lead to alterations in transcription in the cell nucleus [21]. Together, these actions affect both the immediate electrical properties of the neuron as well as its long-term adaptation to activity. Understanding the activity of channels, the systems that regulate their action (such as G-protein-coupled receptors), and the complex interplay between chemical and electrical signaling pathways in cells will be essential for developing an molecular understanding of complex processes such as the regulation of heartbeat and the molecular basis of learning and memory.

How Do Voltage-Gated Channels Sense the Membrane Potential?

Chris S. Gandhi and Ehud Y. Isacoff

*Department of Molecular and Cell Biology,
University of California at Berkeley,
Berkeley, California*

Introduction

Voltage-gated ion channels transduce changes in the membrane electric field into changes in membrane permeability. These channels consist of four similar or identical subunits, each containing six α -helical transmembrane segments (S1–S6) and a pore-forming loop (P-loop) (Fig. 1A). The subunits may assemble from one continuous polypeptide chain, as is the case for voltage-gated Na⁺ and Ca⁺⁺ channels, or from four separate chains, as is the case for K⁺ channels. Each subunit of a voltage-gated channel contains two functionally distinct domains.

The first of these is a pore domain (Fig. 1C) composed of the S5, S6, and P-loop of each subunit. This domain forms the permeation pathway, which includes the narrow ion selectivity filter, an internal activation gate, and an external slow inactivation gate. The pore domain is homologous to 2-TM channels such as the inward rectifier K⁺ channel and the bacterial KcsA channel (see Chapter 34). The second domain, composed of four transmembrane helices (S1–S4), surrounds the pore domain and regulates opening and closing of the pore gates.

Depolarization drives conformational changes in the voltage-sensing domains that cause the activation gate to open and the slow inactivation gate to close. Channels conduct ions when both gates are open simultaneously. Usually the activation gate responds more quickly, yielding a transient current at depolarized potentials; however, in some channels (e.g., hERG), the inactivation gate responds more quickly, resulting in a transient current upon repolarization [41]. When present, a separate fast inactivation gate (made of the N terminus of K⁺ channels or the linker between

subunits III and IV in Na⁺ channels) closes by blocking the internal mouth of the open channel.

The Voltage-Sensing Gating Particle

Before the advent of molecular biology, through classical electrophysiology experiments, Hodgkin and Huxley [14] established the physical basis for action potential generation and propagation. Working in squid giant axon, they demonstrated that the action potential consists of two voltage-dependent currents carried by an initial inward Na⁺ flux followed by an outward K⁺ flux. Hodgkin and Huxley hypothesized that voltage controlled the Na⁺ and K⁺ conductances by biasing the equilibrium of charged *gating particles* between two stable positions (resting and activated) within the transmembrane electric field. Activation of four independent gating particles in K⁺ channels and three in Na⁺ channels was proposed to turn on the conductances. This led to the prediction that the transmembrane motion of the charged gating particles would generate a small *gating current*. Because all of the gating particles would have to be activated before channels conduct, the movement of the *gating charge* (the charge carried by the gating particle) was predicted to precede the ionic current and be less steep in voltage dependence than the conductance (Fig. 2).

Principles of Voltage-Sensing in Proteins

How could nature have evolved a gating particle/voltage sensor? In principle, any charged particle (q)—for example,

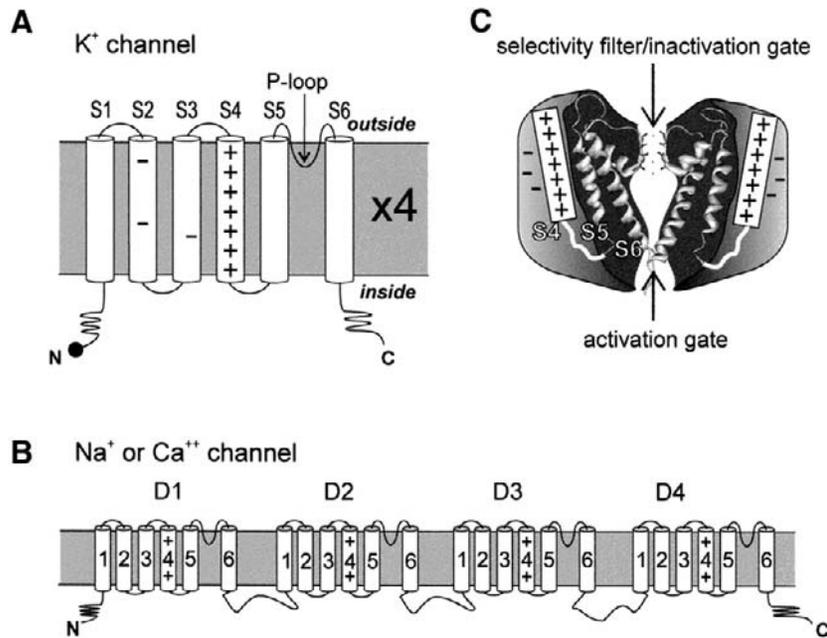

Figure 1 Structure of voltage-gated channels. (A) Membrane topology of one subunit of a voltage-gated K⁺ channel. S1–S4 form the voltage sensing domain. S5, S6, and the P-loop form the pore domain. A series of conserved positive charges in S4 interact with negative counter-charges in S2 and S3. The fast inactivation gate is shown as an N-terminal ball. (B) Membrane topology of voltage-gated Na⁺ and Ca⁺⁺ channels. (C) Side view of two subunits from (A). The pore domain is shown as a gray ribbon. The internal activation gate is located at the S6 bundle crossing. The selectivity filter and slow inactivation gate are located near the external end of the pore. Voltage-sensing domains surround the pore domain and regulate opening and closing of the gates.

the formal charge of a positive (R, K) or negative (E, D) amino acid or the partial charge of a dipole moment of an α -helix—will experience an electromotive force (F) when placed in an electric field (E), with $F=qE$. A typical neuronal resting potential of -70 mV exerts a force of ≈ 3 pN on a single charge in the membrane. For comparison, the typical forces generated by the motor proteins myosin and kinesin are 1.5 and 3 pN, respectively. Depolarization changes the electrical force, allowing the charge to relax to a new position in the electric field. The motion of the charge could be small, on the order of angstroms, or significantly larger. For example, a charged side chain could reorient itself in the electric field due to rotations around its chemical bonds. Alternatively, a rigid body motion of the protein backbone could move several charged side chains on a protein segment together through the electric field.

Simple Models of Voltage-Sensing Protein Structures

It is energetically unfavorable to place a charge in the low dielectric, nonpolar environment of the membrane core. The pore has solved this problem for permeant ions by providing a polar pathway made of backbone oxygens, partial charges, and water (see Chapters 34 and 36). The same energetic constraints apply to the voltage sensor. Charges on the voltage sensor must either be stabilized by counter-charges or be hydrated by water. An early model of the voltage sensor paired

oppositely charged surfaces in two membrane-spanning protein segments [2], providing a favorable pathway for charges to move across the membrane by ratcheting through a series of intermediate positions (Fig. 3A). Alternatively, charges may move from exposure to water on one face of the membrane to exposure on the opposite face through a short, polar pathway analogous to the selectivity filter (Fig. 3B and C). In either case, the pathway of the charge movement, or *gating canal*, must be constricted enough to prevent the leak of ions and contain stabilizing counter-charges.

S4 Is the Primary Voltage Sensor

S4 Sequence and Charge Pairing

A high-resolution structure of the voltage-sensing domain of an ion channel has yet to be obtained; however, some things are already known about the structure of this domain. S1 to S6 form transmembrane helices [8,13,14,19,25,33]. The S4 helix is conserved across voltage-gated cation channels and contains a positively charged arginine (R) or lysine (K) at every third position (Fig. 4). Because S4 spans the membrane, some of these charges sense the electric field. The spacing of positive charges creates a left-handed positively charged spiral (resembling a barbershop pole) along the length of the S4 helix. Three conserved negative charges, two in S2 and one in S3 (Fig. 1A), interact with the charges in S4 [35,36], suggesting that three positive charges of S4 could

reside in the gating canal at one time. Given the gradual pitch of the spiral, three consecutive positive charges would lie on the same face of S4.

S4 Positive Charges Account for the Gating Charge

Wild-type Shaker channels move ~12 to 13 charges per channel (~3 charges per subunit) during activation [28]. If S4 is the voltage sensor, then a mutation that neutralizes a positive

charge on S4 should decrease the total gating charge. The maximum reduction expected is 1 charge per subunit for a position that completely traverses the electric field. Of the seven positive charges in the Shaker S4, single neutralizations of R1, R2, R3, or R4 each decrease the total charge by ~1 to 1.7 charges per subunit, whereas neutralization of K7 has no effect [1,32]. This indicates that only the outer S4 charges move through the gating canal. In addition, neutralization of the deep negative charge in S2 also decreases the gating charge by ~1.5 charges per subunit, suggesting that it may move across the electric field in a direction opposite to that of S4 [32]. The fact that some neutralizations decrease the charge by >1 indicates that a neutralization may affect the remaining charges, possibly by changing the pointing angle of their side chains and/or the shape of the electric field in the gating canal.

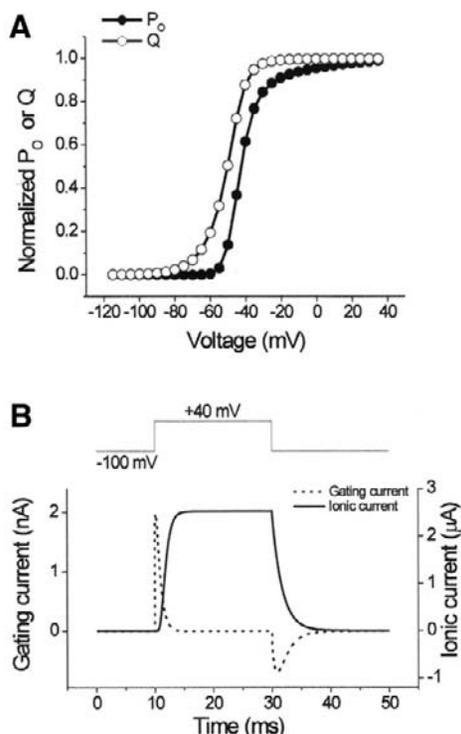

Figure 2 Electrical properties of simulated ion channels. (A) Plot of the movement of the gating charge (Q) and the probability of the channel opening (P_o) at various voltages. Because all voltage sensors must be activated before a channel opens, Q precedes P_o in voltage dependence. (Modeled as in Ledwell and Aldrich [18].) (B) Gating current and ionic current elicited by depolarization. Movement of the voltage sensor generates several nanoamperes of gating current, opens the pore gates, and allows several microamperes of ionic current to flow through the pore.

Residues in S4 Move Fully Across the Membrane

A direct measure of transmembrane motion in S4 has been obtained in Na^+ and K^+ channels by probing the accessibility of engineered single cysteines to internal and external thiol-specific reagents [3,16,37,38,39,40,43]. In the Shaker K^+ channel, the charged and uncharged positions from R1 to R3 are inaccessible to the external solution at negative voltage (resting state) but are accessible to the external solution at positive voltage (activated state). R3 and deeper sites are accessible to the internal solution at negative voltage but inaccessible at positive voltage. The change in accessibility can be accounted for by a rigid body motion of S4 across the membrane (Fig. 4). The motion takes place in multiple steps with at least one intermediate position [3,4]. The model of transmembrane S4 motion is supported by the finding that histidines substituted at positions R2, R3, or R4 can transport protons across the membrane at voltages that allow the voltage sensor to shuttle between resting and activated states [34].

Taking into account all of the accessibility results leads to the following conclusions:

1. S4 moves outward with depolarization in the correct direction to carry the gating charge.

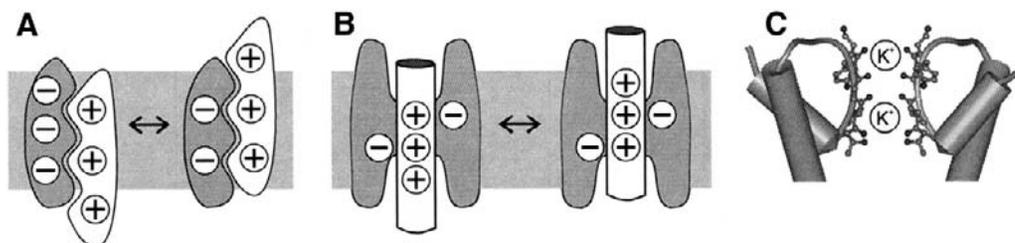

Figure 3 Three ways to move charge through the membrane. (A) Two charged membrane-spanning protein faces slide past each other to move one positive charge across the membrane. (B) A positive membrane-spanning segment slides through adjacent protein and interacts with negative counter charges. Water-filled vestibules formed by the protein shorten the distance required to move one positive charge across the membrane. (C) Movement of K^+ ions through the short KcsA selectivity filter.

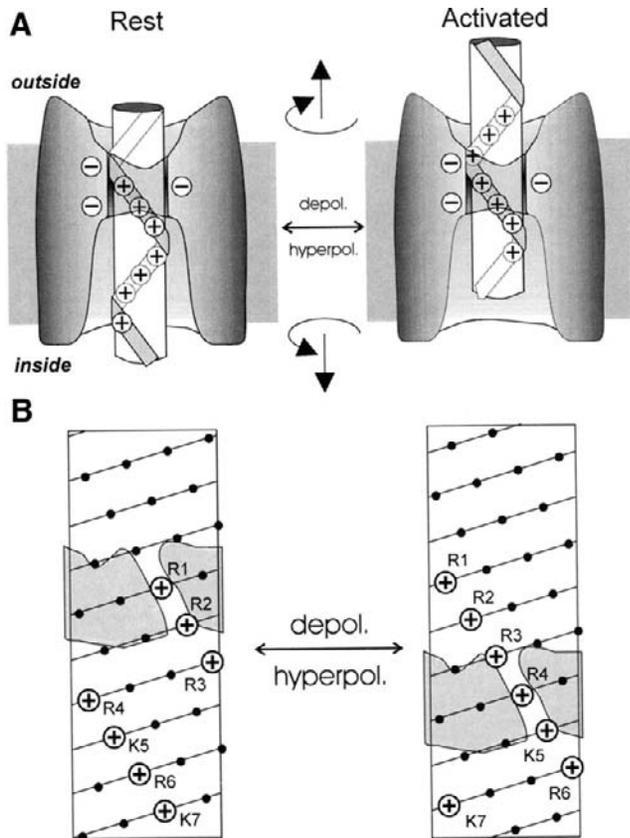

Figure 4 Helical screw motion of S4 activation. (A) Depiction of S4 (the screw) moving through a short gating canal surrounded on either end by two water-filled crevices. Positive charges on S4 interact with negative counter-charges in the adjacent protein (the bolt). The water crevices hydrate S4 charges that do not interact with counter-charges. Depolarization rotates S4 along the stripe of charged positions and in the process moves S4 outwards along its helical axis. (B) Helical net of S4 that illustrates changes in solvent exposure and movement of charge across the gating canal. Positions R1, R2, R3, and R4 move some distance across the gating canal when S4 changes conformation from the resting to activated state.

2. S4 carries the equivalent of 3 charges per subunit across the membrane (R1 to R4 carrying 0.5, 1, 1, and 0.5 charges, respectively), accounting for the total gating charge in wild-type channels.
3. Only a short length of S4 (10 residues, ~ 13.5 Å) lies in the gating canal at any one time, which means that the canal is considerably shorter than the 35 Å thick core of the membrane and that the electric field is focused on S4.

S4 Moves at the Right Time To Generate the Gating Current

The contribution of S4 charges to the gating charge and the measure of transmembrane S4 motion argue that S4 is the primary voltage sensor. To prove this, it is necessary to show that S4 motion occurs during gating charge movement. The kinetics of protein motion in a channel can be measured optically using voltage-clamp fluorometry (VCF). Fluorophores sensitive to their local environment report local structural rearrangements with a change in fluorescence intensity [24]. The fluorescence of a probe attached at or near S4 changes brightness at voltages where channels do not open but where gating charge moves. The fluorescence and gating charge correlate both kinetically and in steady-state voltage dependence (Fig. 5) [6,9,23,24].

S4 moves in the right direction by a sufficient amount and with the correct kinetics for it to generate the gating current. But how does it move? Fluorescence resonance energy transfer (FRET) between donor-acceptor fluorescent probes attached to S4s of different subunits provides a clue. An examination of the pattern of voltage-driven distance changes between S4s suggests that S4 twists in an 180° rotation [7,10]. Thus, the motion of S4 appears to involve both outward and rotary components.

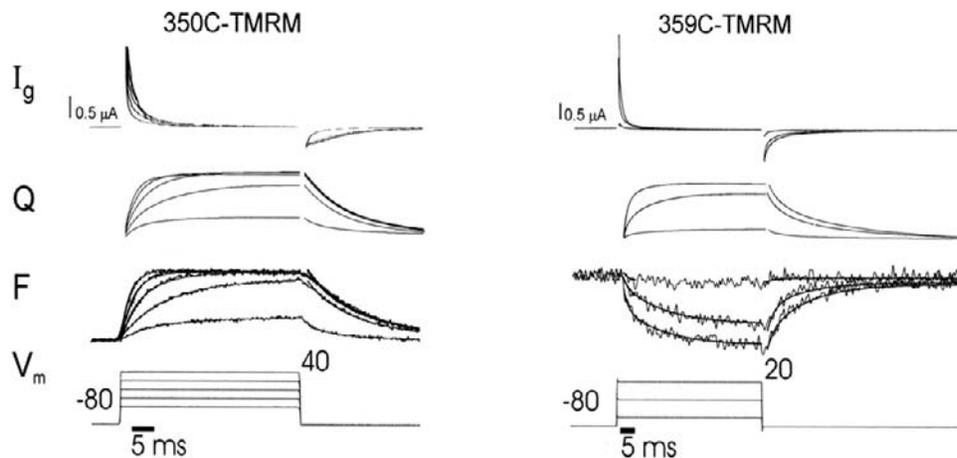

Figure 5 Optical measurements demonstrate that S4 movement generates the gating current. Gating current (I_g), gating charge (Q), and fluorescence (F) were measured simultaneously from a single oocyte expressing non-conducting Shaker channels labeled at either position 350 or 359 with rhodamine maleimide (TMRM). The probe shows voltage-dependent changes in fluorescence intensity for which the kinetics correlate with gating charge movement. The fit to Q is overlaid over the fluorescence trace. For reference, position 359 is located 3 residues before R1 (see Fig. 4).

Physical Models of Activation: Turning a Screw through a Bolt

What kind of physical structure can account for S4 packing and motion? Similar to the short (12 Å) and narrow (~5 Å) ion-selectivity filter that opens to water on either end (see Chapters 34 and 36), the short (13.5 Å) gating canal must also have water-filled crevices at its ends. Unlike the selectivity filter, which is designed for a high rate of flux (~10⁷ per second) and so employs loose coordination of permeant ions by carbonyl oxygens, the gating canal probably employs strong electrostatic interactions with counter-charges in S2 and S3 [26,35,36] and nonpolar interactions with S5 and S6 [20] which together form the walls of the canal. These strong interactions result in relatively slow S4 motion (~10³ per second).

A helical screw motion for S4, originally proposed by Guy and Seetharamulu [11] and Catterall [5], explains how a positive S4 (the screw) would rotate during an outward translation past immobile negative counter-charges (the bolt). As depicted in Figs. 4A and B, a screw motion along the spiral of positive charges translates S4 outward by nine residues during a 180° rotation and accounts for the measured charge movement and exposure changes. The gray cross-section overlapping S4 defines the gating canal or bolt formed by the surrounding protein which includes counter-charges in S2 and S3. The short length of the bolt focuses the electric field on a small portion of S4. On either side of the bolt, water-filled crevices hydrate those S4 charges that do not interact with counter-charges.

The screw clicks through three ratchet steps. Each step moves an S4 charge to the position of the one ahead of it and carries a total charge of ~1. This structural model agrees with a kinetic model based on electrophysiological recordings that proposes that activation involves three sequential steps [29–31].

Although a helical screw motion accounts for the evidence it does not mean that S4 must undergo the full axial translation of nine residues (13.5 Å). The observed rotation of S4 may be accompanied by rearrangements of S1, S2, and S3 that move the negative counter-charges around S4. This would be akin to turning the bolt (S1–S3) around the screw (S4). Also, rearrangements of the other transmembrane segments may move S4 charges simply through S4 rotation [7,10].

Coupling Gating to S4 Voltage-Sensing Motions

Once each S4 has undergone its activation motion, the four subunits undergo cooperative rearrangements to open the internal activation gate and close the slow inactivation gate. How does S4 conformation control these gates? One possibility is that S4 twists open the activation gate by pulling on the internal linker between S4 and S5 [10]. This is intriguing because rotation and tilt of the homologs of S5 and S6 appears to open the activation gate in the bacterial

channel KcsA [21, 27] and MthK [14,15]. A separate coupling mechanism controls closure of the slow inactivation gate [9,17,22] via interaction between the activated S4s and the external face of the pore domain. The strength of coupling between S4 and each of the gates sets the duration and voltage dependence of the conductance. This in turn allows voltage-gated channels to shape the electrical signals of the cell.

It will be particularly revealing to learn how protein motions as different as the transmembrane motion of S4 in voltage-gated channels and the conformational rearrangement produced by binding of internal ligands in a C-terminal region near S6 in cyclic nucleotide or Ca⁺⁺ gated channels can actuate the same gates (see Chapter 40). Perhaps voltage- and ligand-dependent channels open their internal gate by a conserved mechanism that is triggered by two different stimuli.

Ion Permeation: Mechanisms of Ion Selectivity and Block

Bertil Hille

University of Washington School of Medicine,
Seattle, Washington*

Ion channels have been identified in all domains of cellular life—Bacteria, Archaea, and Eukarya—and they are found in every type of cell. They have transport functions—facilitation of net movements of ions and salts—and signaling functions—generation of electrical signals and regulation of cellular free calcium concentration [1]. In each of these roles, ion channels open and close in response to local stimuli and pass a limited subset of ions at high rates. Like enzymes, they are regulated catalysts with high substrate specificity and rapid throughput.

Aqueous Pore

There was much classical biophysical evidence that ion channels have an aqueous pore [1], and the arguments all hinged on measuring fluxes in the channel. The first argument was a technical one. Measurements of forward and backward isotopic K^+ fluxes in K^+ channels showed that K^+ ions move in a coordinated fashion, as if the pore contains a column of several K^+ ions moving in single file in a pore [2]. Similarly, water movement in water channels (aquaporins) has the properties of a continuous column of water molecules moving in correlated fashion [3]. A more intuitive argument for a pore in ion channels is the high throughput rate, which easily reaches values of 10^6 to 10^8 ions per second. This means that all the steps of recognizing and passing each ion across the membrane take place in only 10 to 1000 ns, a time much shorter than any known enzymatic catalysis but perfectly compatible with diffusion in an aqueous pore of atomic dimensions. Another major argument for

a pore was the finding that many small channel blockers act like plugs entering a tunnel that becomes too narrow for them to pass all the way through (Fig. 1). Strikingly, the plug could be knocked out of the pore (thus unblocking the channel) by raising the concentration of permeant ions on the *opposite* side of the membrane. The classic example was the block of K^+ channels by intracellular tetraethylammonium ion (TEA) and analogs, which could be relieved by raising the extracellular K^+ concentration [4]. Armstrong [4] argued that the only way for external ions to push out an internal blocker was if they met each other within a pore. Finally, the ion selectivity of several channels (e.g., voltage-gated Na^+ channels, nicotinic acetylcholine receptors, and γ -aminobutyric acid [GABA] receptor channels) could be explained by assuming a rigid pore size that passes ions smaller than the postulated hole but not those larger than the hole [1,5].

Modern confirmation of these older ideas comes from X-ray crystallography. As had been predicted from the functional studies, the crystal structure of the bacterial KcsA K^+ channel shows beautifully a long pore of atomic dimensions with 2 to 4 K^+ ions residing within the narrow tube ([6]; also see Chapter 34). All ion channels related to K^+ channels should have a similar structure. This would include voltage-gated Na^+ , K^+ , Ca^{2+} , and I_h channels; inward rectifier K^+ channels; and two-P domain K^+ channels, as well as cyclic-nucleotide-gated channels and ionotropic glutamate receptor channels. They all belong to the structural superfamily of ion channels formed by four homologous subunits or by four homologous domains with four P loops (reentrant pore loops) coming together to line the narrowest part of the pore (see Chapter 34).

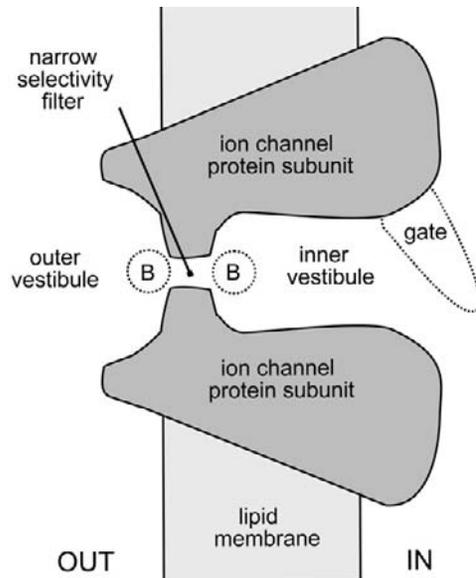

Figure 1 A highly selective ion channel of the voltage-gated family, showing the functional parts discussed in the text. The circles labeled B represent the binding positions of blocking drugs that would act to plug the narrowest part of the pore from the inside or the outside.

Ion Selectivity

Theory

Ion selectivity is necessary for ion channels to play their physiological roles. For electrical signaling it is essential to have two classes of ion channels with different electromotive forces so that alternating opening of one or the other causes the membrane potential to change. The electromotive force generated by a perfectly selective channel is given by the Nernst equation. It depends only on the ratio of the concentrations of the one permeant ion on the two sides and on the absolute temperature. For example, for K^+ ions, the equilibrium potential is

$$E_K = (RT/Fz_K) \ln ([K^+]_o/[K^+]_i) = (59 \text{ mV}) \log_{10} ([K^+]_o/[K^+]_i)$$

where R , T , and F are the usual thermodynamic constants; z_K is the valence of K^+ ; $[K^+]_o$ and $[K^+]_i$ are the outside and inside K^+ concentrations (more properly, thermodynamic activities); and the right-hand form is a practical formula specifically for 25°C . For typical excitable cells, the Nernst potential (equilibrium potential) for K^+ ions (E_K) is near -90 mV , and that for Na^+ ions (E_{Na}) is near $+50 \text{ mV}$. This means that by opening K^+ -selective channels, the cell could achieve a membrane potential of -90 mV (the usual resting condition), and by transiently opening Na^+ -selective channels, it can transiently change the membrane potential to $+50 \text{ mV}$ (a typical strategy during nerve and muscle excitation).

In many ion channels the selectivity is not perfect. If, for example, a channel is permeable to Na^+ and to K^+ , then the electromotive force it generates would lie between E_{Na} and E_K . The exact value depends both on the relative permeabilities to each ion (P_{Na}/P_K) and on the relative concentrations of each ion. In the nicotinic acetylcholine receptor, where P_{Na} and P_K

are approximately equal, the physiological zero-current potential is near 0 mV . Such nonequilibrium, zero-current potentials are often described by an empirical equation called the Goldman–Hodgkin–Katz (GHK) voltage equation [1]. Indeed the GHK equation provides a useful quantitative definition of the relative permeabilities for ions in real channels.

Examples

Most ligand-gated synaptic ion channels are poorly selective. They select primarily for the *charge* of the ion and will pass a large number of either small cations or small anions ([1]; also see Chapter 38). Good examples are the nicotinic acetylcholine and 5-HT_3 receptor channels, which will pass all monovalent *cations* with diameters up to about 6.5 to 7 \AA . Over 65 permeant ions are known for them. Ions such as Na^+ , guanidinium, and isopropyl ammonium have nearly equal permeabilities. Small divalent metals and alkaline earths pass also, although usually less well. Analogously, GABA and glycine receptor synaptic channels will pass monovalent *anions* up to diameters of about 5 \AA . Thus, anions such as Cl^- , nitrate, thiocyanate, and iodide are highly permeant. These ion channels with large pore diameters and poor selectivity form their pores at the axial point of contact of five homologous protein subunits.

On the other hand, the ion channels formed by four homologous protein subunits or internal repeats have higher ion selectivity and smaller effective pore diameters [1]. Most K^+ channels will pass K^+ , NH_4^+ , Tl^+ , and maybe Rb^+ , but they usually do not pass Na^+ , Cs^+ , or methylammonium measurably. The effective pore diameter is around 3 \AA . Voltage-gated Na^+ channels pass 10 cations including Na^+ , Li^+ , H^+ , guanidinium, and even K^+ (with a relative permeability P_{Na}/P_K of about 13). The voltage-gated Ca^{2+} channels select divalent cations over monovalent cations by a factor of 500 to 2000, but they pass Ca^{2+} , Ba^{2+} , and Sr^{2+} with about equal ease. If all divalent cations are removed, Ca^{2+} channels increase their monovalent cation permeability enormously. Among the most selective known channels are some of the epithelial Na^+ channels (ENaC/degenerin) whose K^+ permeability is too low to measure. We are not sure how many homologous protein subunits the ENaC channels contain.

Mechanisms

The mechanisms of ion selectivity are imperfectly understood, but a few principles are clear. The local electrical potential in the general vicinity of the pore and in narrower parts of the pore can strongly bias the selectivity towards cations or anions and tune the preference between monovalents and divalents. All Ca^{2+} -permeable channels have a high density of negative charge in the pore, and neutralizing some of this charge by mutation can make the pore prefer monovalent ions instead of divalents. Similarly, the cation-preferring nicotinic acetylcholine receptor channel can be made permeable to anions by mutations that include neutralizing some negative charges in the pore (see Chapter 38).

Although proteins are not rigid, the concept of a pore size has worked well. The narrowest part of the pore is called the selectivity filter (Fig. 1). Channels usually have a maximum size for permeant ions and are permeable to most ions that are smaller than that size. For channels with a wide pore, simple concepts of friction suffice to describe the greater mobility in the pore of small permeant ions relative to larger permeant ions. In highly selective channels, amino acids of the selectivity filter present polar groups that displace some of the water molecules in contact with the ion. High selectivity cannot be achieved without touching the ion. The relative energies of this electrostatic ion exchange are important determinants of the selectivity sequence in selective channels. The ability to attract ions depends on the relative energy of interaction of water molecules with the ion versus the ligands of the channel wall with the ion. Favorable interaction with the channel can favor permeation up to a point, but an excessive interaction will impede passage by slowing the departure of the ion.

Finally, the mechanics and electrostatics of several ions moving in single file give surprising properties to permeation. The movements of ions become correlated; one ion may interfere with entry of another, and entering ions may help expel other ions electrostatically [2,7].

Block

Many pharmaceutical agents and neurotoxins act by blocking ion channels. For example, local anesthetics and tetrodotoxin block voltage-gated Na⁺ channels. Amiloride blocks epithelial Na⁺ channels. Dihydropyridines block voltage-gated Ca²⁺ channels. TEA, Cs⁺, Ba²⁺, and some scorpion toxins, related to charybdotoxin [8], block voltage-gated K⁺ channels. These agents have in common that they act by physically obstructing the pore near the selectivity filter (Fig. 1) rather than by binding far from the permeation pathway and keeping the channel closed by an allosteric mechanism.

Several biophysical arguments originally led to this conclusion. The first was the finding that many blockers could be driven out of the pore by adding permeant ions to the opposite side of the membrane, as we already described [4]. Another argument was the finding that the block by charged blockers has a voltage dependence. The voltage dependence could be described by two classes of models. In one model, the voltage dependence arose because the charge of the blocker had to move through a portion of the membrane electric field into the pore to reach the blocking position [9]. In the other, the blocker had to displace a column of permeant ions in the pore whose movement through the electric field gave voltage dependence [4,7]. Both models are partially correct, and both require a pore. Finally, measurements of gating currents ([4,10]; also see Chapter 35) showed that voltage-sensitive conformational changes that underlie voltage sensing and normal gating continue to occur when channels are blocked.

Two molecular arguments have greatly strengthened the classical ones. Mutagenesis of amino acid residues of the

pore mouth and walls can have large effects on the potency of blockers [1,11,12] and X-ray crystallography of K⁺ channels has revealed the blocker sitting within the pore as diagramed in Fig. 1 [13].

How and where does the blocker bind? Classical studies of the voltage dependence of various blockers suggested that both voltage-gated and ligand-gated channels have wider vestibules, on the outside and the inside that taper toward the selectivity filter [1]. Subsequent structural and biochemical work has confirmed these ideas (see Chapters 34 and 38). Larger organic blockers such as tetrodotoxin, local anesthetics, dihydropyridines, amiloride, TEA, or charybdotoxin become lodged in the inner or outer vestibule. Typically, several amino acids of the vestibule or of the beginning of the selectivity filter can be identified by mutagenesis as contact sites (i.e., contributing to the receptor for the blocker). They combine hydrophobic, polar, and charge-charge interactions with the blocker. Paradoxically, some blockers are also permeant. These are ions small enough to enter the selectivity filter but having dwell times in that position that are longer than for the typical permeant ion. Thus, they pass through only slowly. While the filter is occupied by the slowly permeant blocker, other permeant ions have to wait for the channel to clear, so the flux is lowered. Ions in this category include Ba²⁺ and Cs⁺ in K⁺ channels [14] and H⁺ in Na⁺ channels [9].

Agonist Binding Domains of Glutamate Receptors: Structure and Function

Mark L. Mayer

*Laboratory of Cellular and Molecular Neurophysiology,
National Institute of Child Health and Human Development,
National Institutes of Health, Bethesda, Maryland*

At the majority of excitatory synapses in the brain, the amino acid L-glutamate acts as the neurotransmitter that is released by calcium-dependent exocytosis from presynaptic nerve terminals. After diffusion across the synaptic cleft, molecules of L-glutamate bind to two families of neurotransmitter receptors in the postsynaptic membrane: the ligand-gated ion channels and G-protein-coupled receptors. The architecture of both families of glutamate-activated signaling proteins differs from that for other ligand-gated ion channels, on the one hand, and the majority of G-protein-coupled receptors, on the other. In both cases, a distinguishing feature of glutamate receptors is the structure that generates the agonist binding site. This domain shares homology with a large family of bacterial periplasmic binding proteins, a number of which have been crystallized. In these bacterial proteins, ligands bind in a cleft between two globular domains connected by beta strands. The binding of ligand stabilizes a closed cleft conformation in which the faces of each domain make contact with each other, while in the absence of ligand the domains assume an open clamshell-like conformation [1]. In the case of glutamate receptors, which are thought to assemble as tetramers for the ion channel family and as dimers for the G-protein-coupled family, each subunit contains a complete copy of an agonist binding domain. Thus, there are four agonist binding sites per glutamate receptor ion channel and two agonist binding sites per G-protein receptor dimer. This understanding of the organization of the architecture of glutamate receptor channels emerged only recently and was brought

into focus by the solution of crystal structures for the ligand binding domains of two ion channels and a G-protein-coupled glutamate receptor [2–6]. However, the picture is still far from complete, and the mechanisms that couple ligand binding to signal transduction have yet to be defined at atomic resolution.

The domain organization of glutamate receptors is shown in Fig. 1. The simplest architecture is found in GluR0, a prokaryotic glutamate receptor ion channel from the photosynthetic bacterium *Synechocystis* PCC 6803 [7]. In this protein, the ligand binding core is formed by a protein with two globular domains that show structural homology to GlnBP, the glutamine binding protein from *Escherichia coli* [5]. The key differences between GluR0 and GlnBP are that in GluR0 the amino acid sequence that generates the ion channel pore interrupts the S1 and S2 amino acid sequence that encodes the ligand binding domain. This is possible without disrupting the common fold found in GluR0 and GlnBP because the ion channel emerges from the external surface of the second globular domain in GluR0, without occluding the ligand binding site, and thus can be removed by protein engineering for crystallographic studies.

Eukaryotic glutamate receptor ion channels from the AMPA, kainate, and N-methyl-D-aspartate (NMDA) subtypes have a more complicated architecture with two differences from GluR0. First, not one but two bacterial periplasmic protein homology domains are present per subunit; second, the ion channel pore contains an additional transmembrane segment followed by a cytoplasmic domain of variable size.

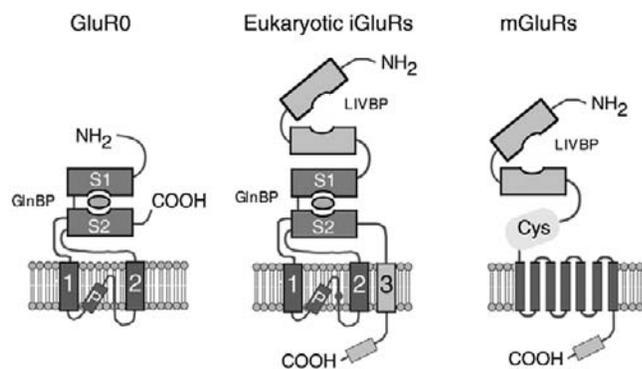

Figure 1 Domain organization of GluR0, a prokaryotic glutamate receptor ion channel, eukaryotic glutamate receptor ion channels (iGluRs), and G-protein-coupled glutamate receptors (mGluRs). The ligand binding domains are shaded to indicate structural homology with two families of bacterial periplasmic binding proteins, glutamine binding protein (GlnBP), and leucine/isoleucine/valine binding protein (LIVBP). The membrane domains of ion channels contain two transmembrane segments (1 and 2) and pore helix (P), combined with a third transmembrane segment for eukaryotic iGluRs; the pore interrupts the GlnBP-homology-domain-creating segments S1 and S2. mGluRs contain a cysteine-rich domain (Cys) that couples the ligand binding core to a seven-segment transmembrane region and intracellular domain.

Starting from the amino terminus, the initial 400 amino acids in eukaryotic glutamate receptor ion channels share weak sequence homology with leucine/isoleucine/valine binding protein (LIVBP). In glutamate receptor ion channels the function of this domain is poorly characterized. The results of functional and biochemical studies show that this region, which is often called the amino terminal domain, plays a major role in subunit assembly [8,9] but does not bind L-glutamate (or in the case of NMDA receptor NR1 subunits glycine) and instead is the site of action of some allosteric modulators [10–12]. Following the amino terminal domain the S1 and S2 agonist binding segments (interrupted by the core of the ion channel pore, similar to the arrangement in GluR0) form the agonist binding domain, as revealed in the structure of the AMPA receptor GluR2 subunit [2,3]. A third transmembrane segment that forms part of the ion channel occurs after segment S2 and precedes the cytoplasmic C-terminal domain. G-protein-coupled glutamate receptors, typified by mGluR1, are also multidomain structures in which each subunit contains a single glutamate binding site that shows structural homology to LIVBP [4,6]. The ligand binding core in G-protein-coupled receptors is followed by a cysteine-rich region, a seven-segment transmembrane region, and a 250-residue intracellular domain. The two subunits are linked together by a disulfide bond between the ligand binding domains.

Despite the fact that L-glutamate is the naturally occurring ligand that activates ion channel and G-protein-coupled glutamate receptors, crystal structures of the ligand binding cores of these proteins reveal distinct mechanisms for the coordination of ligands. In all glutamate receptors, the ligand binds at the interface between the two globular domains that make up an individual subunit. The ligand makes contact with amino acids in domains 1 and 2, but the chemistry

of the binding surface differs substantially in individual proteins. This allows the binding of conformationally restricted ligands such as AMPA with exquisite subtype selectivity. The ligand binding cores of GluR0 and GluR2 share a fold similar to glutamine binding protein but have markedly different substrate binding preferences, while the fold of the G-protein-coupled receptor mGluR1 more closely resembles LIVBP. However, in GluR0 and mGluR1 L-glutamate binds in an extended conformation in which the γ -carboxyl group interacts with domain 1, while in GluR2 the torsion angle of the ligand side chain undergoes a 105° rotation, positioning the γ -carboxyl group for interaction with domain 2. The high-resolution structures obtained for GluR0 and GluR2 reveal that in addition to protein–ligand interactions there are multiple solvent-mediated interactions of the glutamate γ -carboxyl group with the ligand binding core. It is believed that L-glutamate first binds to domain 1 and that subsequent domain closure buries the ligand and permits interactions of the alpha and gamma functional groups with domains 1 and 2, stabilizing the ligand-bound, closed-cleft conformation.

How is ligand binding translated into a signal that causes ion channel gating or G-protein signaling? Crystal structures of all three proteins and equilibrium ultracentrifugation experiments for the ligand binding domains of GluR0 and GluR2 reveal the formation of dimers [3–6,13]. While this was to be expected for mGluR1, due to the presence of an inter-subunit disulfide bond, the presence of dimers for GluR0 and GluR2 was a novel finding. In mGluR1, the cysteine residues responsible for dimerization lie in a disordered segment that probably functions to increase the membrane concentration of the dimeric species. Strikingly, for all three proteins the dimer interface is formed exclusively by domain 1 and suggests mechanisms by which ligand binding mediates signal transduction. For GluR2, comparison of the crystal structures of the glutamate-bound and ligand-free forms does not reveal any rearrangement of the dimer interface produced by the binding of ligand [3]. Instead, the distance between the domain 2 surfaces from which the ion channel emerges *increases* in the ligand-bound, closed-cleft conformation. It is thus plausible that agonist-stabilized domain closure causes the linkers leading to the ion channel transmembrane helices to move farther apart and that this forces the ion channel to open (Fig. 2).

A role for the dimer interface in the process of desensitization, which proceeds on a millisecond time scale for glutamate receptor ion channels, also emerges from these structural studies. Experiments with the AMPA receptor GluR2 subunit revealed that stabilization of the intradimer interface by either mutations at the dimer interface or allosteric modulators that bind to the dimer interface and glue the two subunits together reduces desensitization. On the other hand, perturbations that destabilize the interface enhance desensitization. Desensitization almost certainly occurs via rearrangement of the dimer interface, which disengages the agonist-induced conformational change in the ligand-binding core from the ion channel gate.

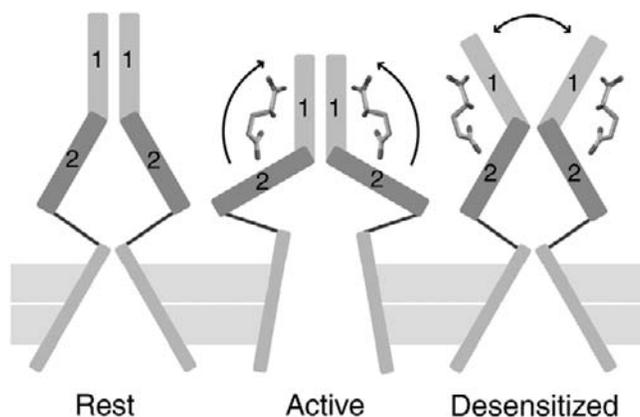

Figure 2 A structural model for iGluR activation and desensitization based on crystallographic and biochemical studies that reveal assembly of the ligand binding cores as dimers via domain 1 surfaces. At rest, the ligand binding domains assume an open conformation and the channel is closed. During activation, the ligand binding cores contract, exerting tension on the ion channel segments and causing the channel to open. During desensitization, the ligand binding cores remain contracted, but movement about the domain 1 dimer interface allows the channel to enter a nonconducting state.

In contrast to the above picture, the binding of agonist for mGluR1 is associated with large changes in the relative orientation of the ligand binding domains which results from a 70° rotation around the dimer interface. This causes the separation between the pair of domain 2 surfaces that leads to the transmembrane segment to decrease in the agonist-bound form, presumably leading to a conformational change that activates G-protein signaling. The different behavior of the dimer interface in response to the binding of agonist in the ion channel and G-protein-coupled glutamate receptors is striking but does not imply that rotations around the dimer interface are absent in the ion channel proteins. Likewise, there may well be additional conformational states available to G-protein-coupled glutamate receptors that do not involve rotations around the dimer interface and which have not yet been crystallized. These structures mark a tremendous advance in our understanding of how glutamate receptors function, but much experimental work remains to be done. There are additional domains and subtypes to crystallize, as well as the full length proteins. There is also the pressing issue of the nature of the conformational states that

correspond to the different functional states identified in functional studies.

Nicotinic Acetylcholine Receptors

Arthur Karlin

*Departments of Biochemistry and Molecular Biophysics,
Physiology and Cellular Biophysics, and Neurology, Center for Molecular Recognition,
Columbia University, New York, New York*

Function

In the 1950s, Katz and his coworkers [1] described the essential functional characteristics of the muscle-type nicotinic acetylcholine receptor in the postsynaptic membrane of the vertebrate neuromuscular junction. This receptor dwells in three types of states: resting, open, and desensitized. In the resting state and the desensitized states, the receptor is nonconducting. In the open state, the receptor conducts Na^+ , K^+ , and Ca^+ , causing depolarization of the postsynaptic membrane. Binding of acetylcholine (ACh) shifts the distribution of states rapidly from resting to open, with the probability of opening being much greater when two AChs are bound than when one is bound. Normally, ACh is removed from the synapse within a few milliseconds by diffusion and by acetylcholinesterase, and the receptor returns directly to the resting state. On longer exposure to ACh, the receptor enters the desensitized state, in which the affinity for ACh is three to four orders of magnitude greater than in the resting state [2], and the receptor returns to the resting state when ACh is removed. Underlying the macroscopic depolarization of the postsynaptic membrane are rapidly fluctuating openings and closings of thousands of receptors [3]. A single open ACh receptor can pass 10^7 cations per second.

Neuronal-type nicotinic ACh receptors are found in peripheral and central neurons. These receptors differ from muscle-type receptors in subunit composition, pharmacology, and channel properties [4,5]. Nicotinic receptors are also found in many invertebrate phyla. At least one invertebrate nicotinic receptor conducts anions rather than cations [6]. Langley [7] observed that muscle contracted on application of the plant alkaloid nicotine and postulated a “receptive substance” for nicotine. Nicotine, known before acetylcholine, is an agonist of the acetylcholine receptor. The archetypical

competitive antagonist of the muscle-type ACh receptor is another plant alkaloid, (+)-tubocurarine, which binds to the muscle-type receptor with a dissociation constant of about 100 nM. Elapid snake venoms contain positively charged polypeptide toxins (α -neurotoxins) that are also competitive antagonists of the receptor but with dissociation constants in the range of 10 to 100 pM. These toxins have been indispensable tools in the exploration of the ACh binding sites and in the assay of muscle-type and some neuronal-type ACh receptors [8].

Structure

Subunit Composition

Muscle-type ACh receptors were first isolated from electric tissue of electric eel (*Electrophorus electricus*) and electric ray (*Torpedo* spp.), which are the richest sources [9]. The receptors in *Torpedo* electric tissue and in fetal muscle are heteropentamers, with the subunit composition $\alpha_2\beta\gamma\delta$ (Fig. 1A) [10]. In adult muscle, the receptor contains an ϵ subunit in place of the γ subunit and has a greater single-channel conductance and a smaller mean single-channel-open time than fetal receptor [11]. The neuronal-type ACh receptors are also pentamers, but of one, two, or three types of subunits [4,5]. There are nine known neuronal α subunits (α_2 to α_{10}) and three known neuronal β subunits (β_2 to β_4); various combinations of α subunits and β subunits, when expressed heterologously, yield functional complexes with distinct functional properties. Some neuronal α subunits (e.g., α_7) form functional homopentamers. Different regions of the peripheral and central nervous system express different combinations of the neuronal subunits.

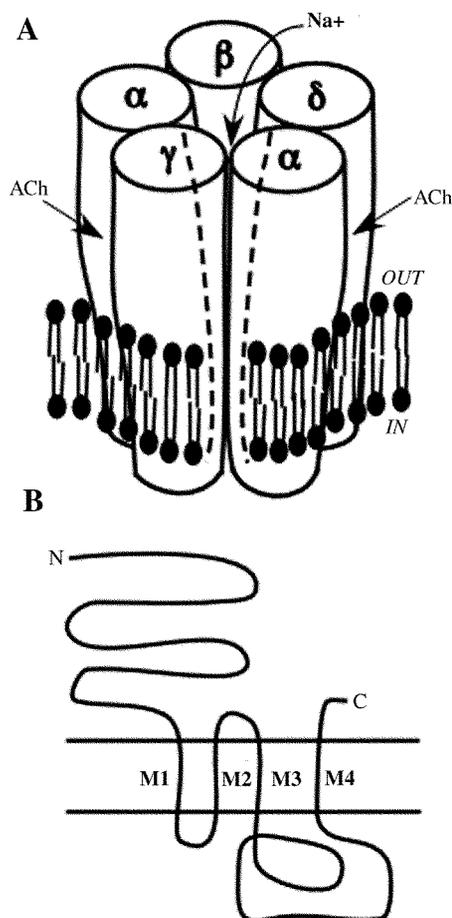

Figure 1 Structure of the nicotinic acetylcholine receptors. (A) Schematic representation of the quaternary structure showing the arrangement of the subunits in the muscle-type receptors, the location of the two ACh binding sites between an α and a γ subunit and an α and a δ subunit and opening to the periphery of the complex, and the axial cation-conducting channel (dashed lines). (B) The threading pattern of the subunits through the membrane.

Primary Structure

The subunits are 450 to 650 residues long. The aligned sequences are sufficiently similar that their common origin is certain; that is, they are all homologous [5,12,13]. One completely conserved characteristic of all of these sequences is a 15-residue loop closed by a disulfide bond between two Cys residues separated by 13 conserved residues. All subunits also contain four hydrophobic segments (M1–M4) sufficiently long to form membrane-spanning α -helices. The subunits of the ionophoric receptors for γ -aminobutyric acid, glycine, 5-hydroxytryptamine, and an invertebrate glutamate receptor are homologous to those of the nicotinic ACh receptors, and these subunits constitute a superfamily of Cys-loop receptors. Conservation of primary structure implies conservation of three-dimensional structure as well.

Secondary and Tertiary Structures

The topology of these subunits with respect to the membrane has been worked out in *Torpedo* ACh receptor

(Fig. 1B) [12]. The N-terminal half of each subunit is extracellular. Three membrane-spanning segments (M1, M2, M3) follow. A long cytoplasmic loop connects M3 to a fourth membrane-spanning segment (M4), and a short C-terminal tail is extracellular. Each subunit is glycosylated at one or more extracellular sites.

The structure of the extracellular domain of the ACh receptor can be inferred from the crystal structure of a water-soluble ACh binding protein secreted by snail glial cells [14]. The ACh binding protein is a homopentamer of a subunit that is homologous to the extracellular, N-terminal half of the ACh receptor subunits. The ACh binding protein subunit starts at its N terminus with two short helices; the remaining sequence forms ten β -strands and connecting loops arranged in a modified immunoglobulin fold. There is less certainty about the structures of the membrane-embedded and cytoplasmic domains of the receptor. Patterns of reactivity, infrared spectroscopy, and prediction algorithms indicate that the membrane-spanning segments are largely, but not completely, α -helical [12,15].

Quaternary Structure

The overall shape of the ACh receptor is known from cryo-electron microscopy of two-dimensionally ordered *Torpedo* receptors in membrane [16] and from the X-ray structure of the ACh binding protein [14]. The receptor is a narrow-waisted cylinder, roughly 120 Å in length, of which 65 Å is extracellular, 30 Å spans the lipid bilayer, and 25 Å is intracellular. The extracellular domain is 80 Å in diameter. The five subunits are arranged like thick barrel staves around an axial channel. The channel lumen is about 30 Å in diameter in the extracellular domain and tapers to less than 10 Å in the membrane domain. It is possible that access to the channel on the cytoplasmic side is through gaps between the cytoplasmic domains of neighboring subunits [16].

ACh Binding Sites

The ACh receptor α subunit was originally identified as contributing to the ACh binding site by its specific reaction with a radioactive affinity label, and the two α subunits correspond to the two ACh binding sites per receptor complex. The labeling was mapped to αCys192 and αCys193 , and these adjacent Cys were shown to be disulfide-bonded to each other [12], a rare arrangement. Four aromatic residues, well separated in the sequence αTyr93 , αTrp149 , αTyr190 , and αTyr198 , were also affinity labeled [17]. These six residues in α are at the interface between the α subunit and a neighboring subunit. They form the principal side of the ACh binding site [14].

In the muscle-type receptor, the complementary side of the first ACh binding site is formed by the γ (or ϵ) subunit, and the complementary side of the second ACh binding site is formed by the δ subunit. Affinity labeling pointed to γTrp53 , γLeu109 , γTyr111 , γTyr117 , and the aligned residues in the δ subunit as contributing to these complementary sides [18].

Mutations of each of the residues from the principal and complementary sides of the site affect agonist binding, gating kinetics, or competitive antagonist binding [17,19]. The location of the ACh binding sites in the interface between subunits is consistent with the idea that binding of ACh promotes relative movement of the subunits that propagates through the bilayer to the gate [12,16].

In the homopentameric ACh binding protein, each of the five binding sites is formed in the interface between opposite sides of adjacent subunits [14]. All of the ACh binding site residues identified in the muscle-type receptor α subunit are on one side of the ACh binding protein subunit, and all of the binding site residues identified in muscle-type γ and δ subunits are on the other side of the ACh binding protein subunit and form the complementary side of the binding site. The ACh binding site is a cage of mostly aromatic residues, the door to which is formed by the adjacent disulfide-bonded cysteines. Based on the ACh binding protein structure, the ACh binding sites in the ACh receptors are about 30 Å above the membrane, opening to the outside of the cylindrical extracellular domain.

Acetylcholine and other specific ligands of the ACh binding site contain at least one quaternary ammonium group or protonated tertiary ammonium group. The preponderance of aromatic residues lining the binding site cavity is consistent with π -cation interaction between aromatic rings and quaternary ammonium groups [20]. In addition, there are conserved negatively charged residues in γ and δ in the vicinity of the binding site that might move toward a bound ammonium group as part of the conformational change leading to channel opening [19].

Channel

The channel has three tasks. It must mitigate the high-energy barrier to the translocation of an ion from one polar aqueous phase to another, through a nonpolar lipid membrane; it must select among ions both by size and by charge; and it must open and close. The energy barrier is partly mitigated by the funnel shape of the channel [16] and by its water content. Only a short section (≈ 6 Å long) near the cytoplasmic end is narrow enough to force water and a cation to move in single file [21]. It is in this section, where the translocating cations contact the walls, that size selection occurs and where some of the residues determining charge selectivity reside [12,17]. The resting-state gate may also be in this section [22].

The channel-lining residues were identified by photolabeling with channel blockers, by the effects of mutations, and by the accessibility to small, charged sulfhydryl reagents of residues mutated to Cys [12,17]. The pseudo symmetry of the ACh structure, the sequence similarity among subunits, and the labeling within the channel indicate that in heteropentameric complexes the five subunits make similar but not identical contributions to the channel lining. Toward the extracellular side of the membrane where the channel is relatively wide, residues from both M1 and M2 form the lining.

Toward the intracellular side of the membrane, where the channel is narrowest, the lining is formed just by M2 and by the residues immediately flanking the cytoplasmic end of M2 in the M1–M2 loop [23]. In the open state, the M2 residues that are exposed in the channel lie within a 100° sector of a helical wheel. By contrast, the M1 residues exposed in the channel do not conform to a regular secondary structure.

It is likely that aligned residues in the sequence are also in register in the channel lining, forming pentameric rings of similar residues exposed at different levels of the channel [17]. The functional roles of some of these rings are clear. Starting from the cytoplasmic end of the channel, in the predicted M1–M2 loop, a ring of four glutamates and one glutamine (five glutamates in homopentameric receptor) strongly determines the magnitude of cation conductance [24] and the intrinsic negative electrostatic potential in the channel [25]. Three steps in the extracellular direction, a ring of four or five threonines and serines strongly determines selectivity among different cations ([26]; also see Chapter 36). These two rings are in the narrowest part of the channel. Rings of hydrophobic residues further in the extracellular direction stabilize the resting state compared to the open state [12].

The structure of the channel is different in the resting, open, and desensitized states. These differences are reflected in electron microscope images of ordered arrays of receptors in membrane [16] and in the binding of channel-blocking aromatic amines, the reactions of channel-lining residues with photolabels, and the reactivity of substituted cysteines with charged sulfhydryl reagents [22]. The reactivity differences and the underlying structural changes are widespread, beyond the immediate vicinity of the gate. One view based on the accessibility of substituted cysteines from the two sides of the membrane is that the resting-state gate is in the same narrow region at the cytoplasmic end of the channel that forms the selectivity filter [22,27]. Another view based on cryo-electron microscopy is that this gate is in the middle of the membrane-spanning portion of the channel [16]. These views could be reconciled if the narrow part of the channel formed by the cytoplasmic end of M2 and the M1–M2 loop led into an antechamber that extended into the plane of the bilayer.

The charge selectivity of a homopentameric ACh receptor [17], as well as of the 5HT₃ receptor [28], is changed from cationic to anionic by a minimum of three changes in the M1–M2 loop and in M2. Two of the changes are in the narrowest region; the glutamate is changed to glutamine, eliminating the negative charge, and a proline is inserted just before it, lengthening this region by one residue. A third change is two-thirds the distance toward the extracellular end of M2, where a valine is changed to a threonine. The new residues match those in the anion-conducting glycine receptor. The reverse mutations in the glycine receptor change its selectivity from anionic to cationic [29]. The mutation of the ring of glutamates indicates an electrostatic contribution to charge selectivity, but the bases for the effects on charge selectivity of the other two mutations are not known.

Cytoplasmic Domain

The cytoplasmic domain of each subunit consists of a short loop between M1 and M2 and a long loop between M3 and M4. As discussed above, the M1–M2 loop is involved in selectivity and gating. The much larger M3–M4 loop is involved in subunit assembly [30] and in targeting [31], clustering [32], and anchoring [33,34] of the assembled receptor in the postsynaptic membrane. Phosphorylation of sites in this loop modifies the rate of desensitization and may regulate interactions of the receptor with cytoplasmic proteins [35,36].

Small Conductance Ca^{2+} -Activated K^+ Channels: Mechanism of Ca^{2+} Gating

John P. Adelman

Vollum Institute, Oregon Health and Science University, Portland, Oregon

Introduction

Small-conductance Ca^{2+} -activated K^+ channels (SK channels) play a fundamentally important role in all excitable cells. They are K^+ selective, voltage independent, and activated by increases in the levels of intracellular Ca^{2+} . SK channels are exquisite Ca^{2+} sensors that couple $[\text{Ca}^{2+}]_i$ to membrane potential. SK channels may be activated by a global rise in Ca^{2+} due to entry through voltage-gated Ca^{2+} channels, such as occur during an action potential in nerve cells. They may respond to the discrete localized Ca^{2+} that enters through agonist-induced opening of Ca^{2+} -permeable ionotropic receptors that are close to SK channels, such as acetylcholine (ACh) receptors in inner-ear hair cells. SK channels may also open due to Ca^{2+} released from intracellular stores as occurs in many gland cells, permitting rhythmic hormone release. Centrally important to the physiological roles of SK channels in a wide variety of cell types are their high Ca^{2+} sensitivity and fast gating kinetics. The SK channel family has been cloned, and the mechanism by which Ca^{2+} ions affect channel gating has been investigated. The results reveal a remarkable molecular marriage between SK channels and the ubiquitous Ca^{2+} sensor, calmodulin. They also suggest a novel chemomechanical gating mechanism in which a dimer-of-dimers with two-fold symmetry translates the gating cue of Ca^{2+} binding to a tetrameric ion-conducting pore.

The first report of a Ca^{2+} -dependent K^+ flux was in 1958 from Gardos [1], who observed Ca^{2+} -stimulated K^+ flux

across red blood cell membranes. Since then, Ca^{2+} -activated K^+ channels have been recorded from almost every cell type in mammalian organisms as well as many other species. Ca^{2+} -activated K^+ channels fall into two broad classes, both of which have been cloned. BK (big K) channels have large unitary conductance values ($\approx 150\text{--}200$ pS in symmetrical 140 mM K^+) that propelled them to prominence as prototypes for single-channel gating and conduction studies [2]. Under physiological conditions, BK channel gating depends upon voltage as well as intracellular Ca^{2+} . However, recent biophysical studies have shown that BK channels are voltage-dependent channels, and voltage dependence is modulated by Ca^{2+} ions; higher concentrations of Ca^{2+} facilitate voltage gating [3–5]. The molecular mechanism of Ca^{2+} -modulated BK channel gating is not well understood. SK (small K) channels have smaller unit conductance values (10–50 pS) and are gated solely by intracellular Ca^{2+} ions. The mechanism by which Ca^{2+} ions affect SK channel gating is discussed in this chapter.

Clones Encoding SK Channels

SK channel sequences were identified by a virtual screen of the EST database using as probe the amino acid sequences from the pores of K^+ channels that endow exquisite K^+ selectivity, the signature sequence [6]. A short sequence that was related but different from known K^+ channel pore sequences was isolated and used as a probe on

brain cDNA libraries, yielding three distinct cDNA clones: hSK1 from human and rSK2, and rSK3 from rat [7]. A fourth homologous sequence was subsequently identified, hIK1 (intermediate K; see later discussion) [8,9]. The coding sequences predict polypeptides that share the transmembrane (TM) topology of voltage-dependent K⁺ channels and cation-selective cyclic nucleotide-gated channels, with the N- and C-terminal domains within the cytoplasm and a core region of six TM domains. The pore loop resides between TMs 5 and 6, and functional channels are tetrameric assemblies. Amino acid sequences of the three different SK clones are remarkably homologous through the transmembrane core and the proximal segment of the intracellular C-terminal domain. As with other K⁺ channel subfamilies, the sequences diverge in their extreme N- and C-terminal cytoplasmic domains. Despite the architectural similarities with voltage-gated K⁺ channels, the sequences differ substantially from other K⁺ channel subfamilies except for the recognizable deep pore sequence surrounding the selectivity filter, clearly defining SK channels as a distinct branch of the K⁺ channel family tree.

Biophysical and Pharmacological Profiles

Heterologous expression of SK cDNAs yields channels with biophysical and pharmacological profiles that recapitulate native SK channel activity. Application of Ca²⁺ to the inside face of inside-out patches activates the channels, and dose-response experiments revealed an EC₅₀ for Ca²⁺ of $\approx 0.5 \mu\text{M}$. Gating is steeply Ca²⁺ dependent, with little or no channel activity at $0.1 \mu\text{M}$ and maximal activity at $1 \mu\text{M}$, resulting in a Hill coefficient of ≈ 4 . This suggests that more than one Ca²⁺ ion is required for SK channel activation and that binding may be cooperative. Rapid application (≈ 1 ms) of solutions containing saturating Ca²⁺ concentrations ($10 \mu\text{M}$) resulted in rapid channel activation with current onset occurring as rapidly as the solution was exchanged (activation time constants of 6–13 ms) [10]. The lack of voltage dependence indicated by macroscopic current responses was verified by showing that when the channels were exposed to internal Ca²⁺, the single-channel-open probability did not differ at various voltages. Single-channel analysis also confirmed the relatively small unit conductance value, ≈ 10 pS in symmetrical K⁺ solutions, consistent with measurements of native SK channels [7].

Native SK channels fall into two pharmacological categories based upon block by different toxins. Most SK channels, such as those in central neurons responsible for the medium afterhyperpolarization [11,12], skeletal [13,14] and smooth muscle [15–18], lymphocytes [19], and gland cells [20,21], are sensitive to the bee venom peptide toxin apamin and the plant alkaloids *d*-tubocurarine and bicuculline salts. The cloned SK channels are all blocked by apamin ($K_i \approx 25$ pM to 25 nM) [7,22–24], *d*-tubocurarine ($K_i \approx 5$ –300 μM) [22,24,25], and bicuculline methylchloride ($K_i \approx 1$ –10 μM) [26]. These results strongly suggest that the cloned

channels represent the apamin sensitive Ca²⁺-activated K⁺ channels recorded from many different cell types.

Mechanism of Ca²⁺-gating

CaM Is the Ca²⁺ Sensor

Ca²⁺ might affect SK channel gating either by binding directly to the channel protein or by binding to a separate Ca²⁺ binding protein and subsequent interactions with the SK channel. The rapid activation kinetics of the cloned SK channels are similar to the opening rates for ionotropic receptors such as GABA_A [27] or NMDA-type glutamate receptors [28], where there is a direct interaction between the ligand and the receptor. This suggests that Ca²⁺ ions directly interact with the SK channel protein to affect gating. Moreover, steady-state Ca²⁺ sensitivities of all of the cloned SK channels are indistinguishable, suggesting that conserved residues on the predicted intracellular aspect of the channel mediate Ca²⁺ gating. The cloned SK channels have a half-maximal open probability when exposed to $\approx 0.5 \mu\text{M}$ Ca²⁺, consistent with an E-F hand Ca²⁺ binding motif [29]. Examination of the amino acid sequences failed to detect either an E-F hand or C2 motif [30,31]; also, no sequences are similar to the Ca²⁺ bowl implicated in Ca²⁺ binding and BK channel gating [32]. However, if the channel protein directly chelates Ca²⁺ ions, then negatively charged side chains, from glutamates (E) or aspartates (D) are likely to mediate Ca²⁺ binding. Site-directed mutagenesis, neutralizing each of the 21 conserved residues on the intracellular side of the channels, failed to alter Ca²⁺ gating, but results from truncation experiments that progressively deleted regions of the C terminus combined with combinatorial site-directed mutations implicated a region in the proximal C-terminal domain. This highly conserved region of ≈ 100 residues could be modeled as a series of α -helices and, contrary to a domain expected to bind Ca²⁺, is highly positively charged (net +14).

The seemingly contradictory fast Ca²⁺ activation kinetics (function) and positively charged domain (structure) were reconciled by showing that the implicated domain serves as a binding site for calmodulin (CaM). Yeast 2-hybrid tests and CaM binding experiments showed that CaM bound to the CaM binding domain (CaMBD), a region of the channel extending ≈ 100 amino acids from the cytoplasmic interface with S6. Binding of CaM to the CaMBD occurred in the presence or absence of Ca²⁺. However, CaM only bound to the C-terminal subdomain of the CaMBD in the presence of Ca²⁺. Coexpression of SK channels and mutant CaMs with reduced Ca²⁺ affinity yielded SK currents with right-shifted, and shallower Ca²⁺ concentration responses ($EC_{50} \approx 1 \mu\text{M}$; Hill coefficient ≈ 2) [10]. These results support a model for Ca²⁺ gating in which CaM is a constitutively associated subunit of the SK channels. Ca²⁺ binding to CaM induces a conformational rearrangement in CaM that is transduced to the channel subunits and results in opening of the SK channel gate.

Calmodulin is an acidic protein composed of 148 amino acids organized into three domains [33]. The N- and C-terminal globular lobes each contain two E-F-hand Ca^{2+} binding domains. A flexible linker region connects the lobes. Ca^{2+} binding is highly cooperative, with binding first occurring at the C-terminal lobe and then the N-terminal lobe. Contributions of the various E-F hands to SK channel gating were investigated by coexpressing the channel subunits, with CaM containing different combinations of mutant E-F hands. Surprisingly, only the N-terminal E-F hands contribute to SK channel gating; loss of either or both of the C-terminal E-F hands to bind Ca^{2+} did not alter Ca^{2+} responses, while loss of either N-terminal E-F hand shifted the response, and loss of both abolished channel function [34].

Structural Analysis and the Chemomechanical Gating Model

The complex between Ca^{2+} -CaM and the CaMBD was crystallized [35]. The solved structure revealed a symmetrical dimer consisting of two CaMBDs and two CaMs (Fig. 1), with multiple charged and hydrophobic contact points. The initial 17 residues extending from the membrane interface were not resolved. The CaMBDs consist of a relatively short α -helix, followed by a bend and then a long, extended α -helix. The extended helices from the two CaMBDs are in a close antiparallel arrangement and these interactions are the only ones between the channel domains. Two CaMs encase the CaMBDs. Each CaM is in an elongated conformation and touches three helices, two from one CaMBD and one from the other, forming multiple contacts and tying the CaMBDs together. The N-terminal E-F hands are clearly calcified, while the C-terminal E-F hands are Ca^{2+} free, consistent with mutagenesis studies. Closer examination revealed that the Ca^{2+} -dependent reorganization of the N-terminal lobe of CaM is similar to other Ca^{2+} -CaM interactions with substrate proteins, where Ca^{2+} binding to the E-F hand motifs consolidates hydrophobic patches into a larger domain that provides an anchor point for interfacing with the substrate protein [36,37]. These interactions likely underlie the Ca^{2+} -dependent gating process. In contrast, the C-terminal lobe is constrained by multiple interactions with the CaMBD. Several important positions within the E-F hand motifs form strong electrostatic anchoring contacts with the CaMBDs that reorient their side chains so they cannot participate in chelating a Ca^{2+} ion. The strong C-lobe interactions probably form the basis for the constitutive association between the two proteins.

The structure of the Ca^{2+} -free form of the complex has not yet been solved; however, several different biochemical approaches yielded consistent results showing that the CaMBD-CaM complex exists as a monomer in the absence of Ca^{2+} . Taken together, the data support a model in which two monomeric CaMBD-CaM complexes associate to form a dimer upon Ca^{2+} binding to CaM (Fig. 2). The SK channels are tetramers of the pore-forming subunits with a presumed

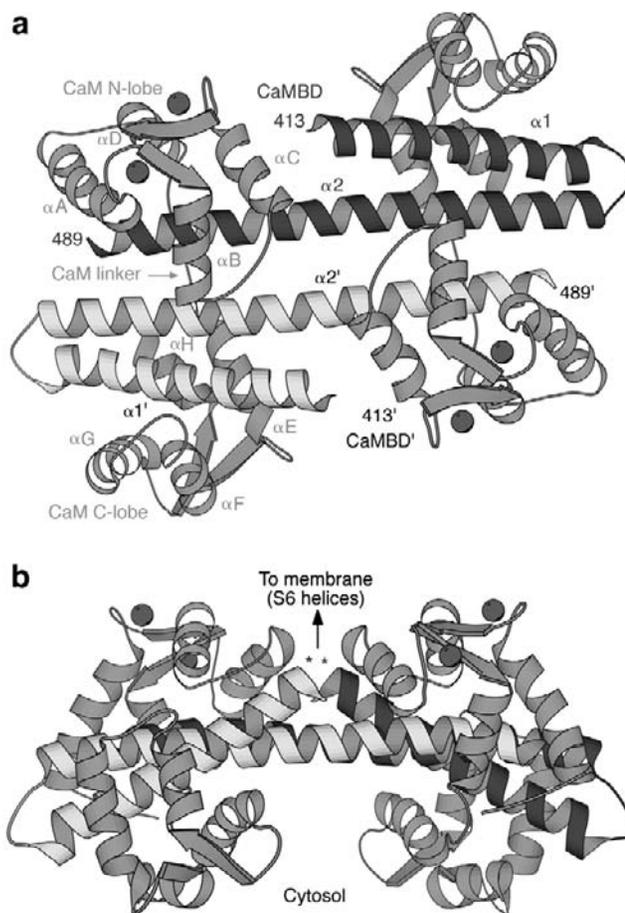

Figure 1 Structure of the CaMBD/ Ca^{2+} /CaM complex. (a) Ribbon diagram of the CaMBD/ Ca^{2+} /CaM dimeric complex. CaMBD subunits are blue and yellow, CaM molecules are green, and the Ca^{2+} ions are red. Secondary structural elements, the CaM linker, and the first and last observed residues in the CaMBD are labeled. (b) View of part (a) rotated by 90° showing the orientation of the complex relative to the membrane. Arrow indicates the positions of the first observed residue of each of the CaMBD monomers that are linked to the S6 helices.

four-fold symmetry around the pore, at least in the absence of Ca^{2+} . Ca^{2+} binding to CaM induces the formation of a dimer-of-dimers within the gating apparatus, and this may exert a force on the attached S6 helices that results in opening of the ion-conducting pore. This implies that Ca^{2+} gating imposes an asymmetry on the pore structure. Interestingly, the initial 17 residues extending from the membrane interface were not resolved in the crystal structure, and this may be due to the ability of this domain to adopt several conformations reflecting the translation of the gating-dimer subunits to the pore.

Ca^{2+} ions are the gating cue for SK channels, and they are sensed by the CaMBD-CaM complex, analogous to the positively charged residues in the S4 voltage sensor of voltage-dependent K^+ channels. In both cases, the gating cue is transduced to the physical gate of the channel, the structure that occludes ion permeation in the closed state and permits permeation in the open state. For voltage-gated K^+ channels, the gate is composed of residues in the distal portion of

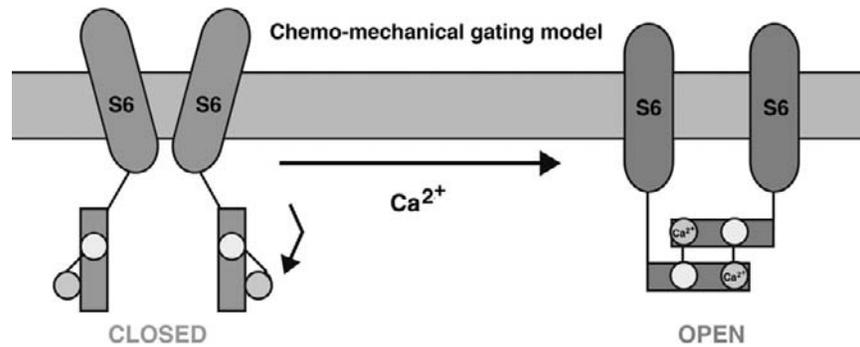

Figure 2 Drawing of the proposed chemomechanical gating model. The cutaway view shows two of the four subunits of the channel (the other two would be in the foreground). For clarity, only the S6 pore helices, the attached CaMBD, and the linker (line) are shown. The CaM C lobe and N lobes are yellow and orange, respectively. In this model, a resulting rotary movement (exaggerated in the figure) would result from formation of the dimeric complex which would drive a rotation between the S6 helices to open the channel gate.

S6 [38–40]. However, for the cyclic nucleotide-gated channels that, like SK channels, are gated by binding of an intracellular ligand, it appears that the selectivity filter of the channel also functions as the gate [41,42]. For SK channels, the location and identity of the gate itself remain to be determined, although studies of SK channels using cysteine-modifying reagents are consistent with a model similar to CNG channels, with the selectivity filter also forming the channel gate.

Pantophobic After All

Prior to the cloning of Ca^{2+} -activated K^+ channels, Kung and colleagues [43] studied behavioral mutants in *Paramecium* that exhibited an exaggerated response to noxious stimuli. Wild-type animals use the Ca^{2+} that enters during a Ca^{2+} -based action potential to activate two Ca^{2+} -dependent conductances—an inward Na^+ and an outward K^+ conductance—that reverse ciliary motion, allowing the animal to move away from the noxious stimulus. Overreacting mutants, called *pantophobiacs*, lack the K^+ conductance, while underreactors, called *pawns*, lack the Na^+ conductance [44]. The mutations reside in the CaM gene [45]. Remarkably, injection of wild-type CaM into the animals restored the current [46]. The individual mutations segregated to the lobes of CaM, with those in the C lobe affecting the K^+ conductance and those in the N lobe affecting the Na^+ conductance [47]. Interestingly, larvae from *Drosophila* mutants lacking CaM show a similar pantophobic phenotype [48].

These studies predicted the mechanisms rediscovered and extended by studies of mammalian channels. Moreover, they predicted that CaM might determine the activities of multiple classes of ion channels through direct and lobe-specific interactions. Indeed, recent results have shown direct interactions and in many cases unexpected functional consequences between CaM and voltage-gated Ca^{2+} channels [49],

Na^+ channels [50; 51], cyclic nucleotide-gated channels [52], trp (transient receptor potential) channels [53], and skeletal [54] and cardiac muscle calcium-release channels [54]. In addition, a growing list of ionotropic receptors is modulated by direct CaM interactions [56]. Moreover, the consequences of CaM–channel interactions extend beyond biophysical regulation of channel function to nuclear signaling and long-term orchestrated changes in the expression profiles of gene networks [57,58].

Regulation of Ion Channels by Direct Binding of Cyclic Nucleotides

Edgar C. Young and Steven A. Siegelbaum

*Department of Pharmacology,
Center for Neurobiology and Behavior,
Howard Hughes Medical Institute,
Columbia University, New York, New York*

Introduction

Certain ion channels are regulated by the direct binding of cAMP or cGMP to a cytoplasmic binding domain. The first such channels to be identified were the cyclic nucleotide-gated (CNG) channels of photoreceptors and olfactory neurons [1,2]. These channels are ligand-gated (i.e., directly opened by cyclic nucleotide) and show only a very weak dependence of gating on voltage. Cyclic nucleotides also modulate the gating of certain channels that open primarily in response to voltage changes, even in the absence of cyclic nucleotides. This review first summarizes the function of cyclic nucleotide-gated channels in visual and olfactory transduction. The molecular bases for these channels and what is known about the structural basis for their function are described next. Finally, the properties of other channels that are regulated by cyclic nucleotides are briefly discussed.

The Cyclic Nucleotide-Gated Channels

The CNG channels of both photoreceptors and olfactory neurons are nonselective cation channels that conduct Na^+ , K^+ , and Ca^{2+} when activated (opened) by cyclic nucleotide binding. Their single-channel conductance is typically greater than 20 pS when divalent cations are absent, indicating a relatively high rate of Na^+ and K^+ flux. Under physiological

ionic conditions, the channels pass an inward current that depolarizes the membrane, but external Mg^{2+} potentially blocks current flow through the channels, reducing their conductance to less than 0.1 pS. The smaller conductance makes sensory transduction less noisy because more channels must open to produce a given change in membrane potential.

Physiological Role of CNG Channels in Visual and Olfactory Signal Transduction

In the dark, photoreceptors have a high resting level of cGMP, so CNG channels in the plasma membrane are activated (open). The influx of cations through CNG channels depolarizes the resting membrane of a photoreceptor to around -40 mV and results in an elevated level of Ca^{2+}_i . One important consequence of elevated Ca^{2+}_i is a decrease in sensitivity of the channel to cGMP in the dark, an effect mediated by binding of calcium/calmodulin ($\text{Ca}^{2+}/\text{CaM}$) to the channel. Activation of the visual signal transduction cascade upon absorption of a photon by rhodopsin results in stimulation of a phosphodiesterase, leading to hydrolysis of cGMP, closure of the CNG channels, and membrane hyperpolarization. Channel closure also leads to a fall in resting Ca^{2+}_i levels, which produces adaptive responses that enable photoreceptors to respond to subsequent increases in light intensity [3].

In olfactory neurons, the binding of odorants to their membrane receptors activates adenylate cyclase or guanylate cyclase, depending on the class of odorant receptor that is stimulated. The rise in cAMP or cGMP opens the olfactory neuron CNG channels, causing membrane depolarization and firing of an action potential [4]. The influx of Ca^{2+} during channel activation is important for olfactory adaptation through a Ca^{2+} /CaM-mediated decrease in cAMP sensitivity of the channel (analogous to that found in photoreceptors) as well as other Ca^{2+} -dependent effects [5]. The major functional difference between the CNG channels of photoreceptors and olfactory neurons is in their selectivity for cyclic nucleotides: both rods and cones are activated by cGMP preferentially to cAMP, whereas olfactory CNG channels are nonselective.

Molecular Basis for CNG Channels in Photoreceptors and Olfactory Neurons

Kaupp and colleagues [6] were the first to clone a CNG channel gene (CNGA1, from bovine rod photoreceptors), and subsequent efforts discovered a family of related genes. To date, six mammalian CNG channel genes have been identified in two phylogenetic groups called CNGA and CNGB (see Fig. 1A.). CNGA1 and B1 were initially cloned from rod photoreceptors, CNGA2 and A4 from olfactory neurons,

and CNGA3 and B3 from cone photoreceptors. Mutations in human CNG channel genes are responsible for certain degenerative retinal diseases and color vision defects.

Each CNG channel gene encodes one subunit, and a functional CNG channel is made of four such subunits. All CNG channel subunits contain six transmembrane segments (S1–S6) and are homologous to voltage-gated K^+ channel subunits (see Fig. 1B). The latter have a positively charged S4 segment that acts as a voltage sensor and a P region between S5 and S6 containing three conserved amino acids (GYG) that form the potassium selectivity filter (see Chapters 34 and 35). Although CNG channel activation depends on ligand binding and is only weakly sensitive to voltage, the CNG channel subunits all contain a positively charged S4 segment. A P region also is found in CNG channels, but it lacks the first two amino acids of the GYG motif and therefore produces no K^+ selectivity.

Each CNG channel subunit contains in its cytoplasmic C-terminus a highly conserved, 120-residue cyclic nucleotide binding domain (CNBD; Fig. 1B), homologous to the binding domains of cAMP- and cGMP-dependent protein kinases (see volume 2, Chapter 198) and to the catabolite-activating protein (CAP) of bacteria. From the X-ray crystal structures of the cAMP binding domains of CAP and protein kinase A (PKA), the CNG channel CNBD is inferred to consist of a short α -helix (A-helix), followed by a β roll of eight

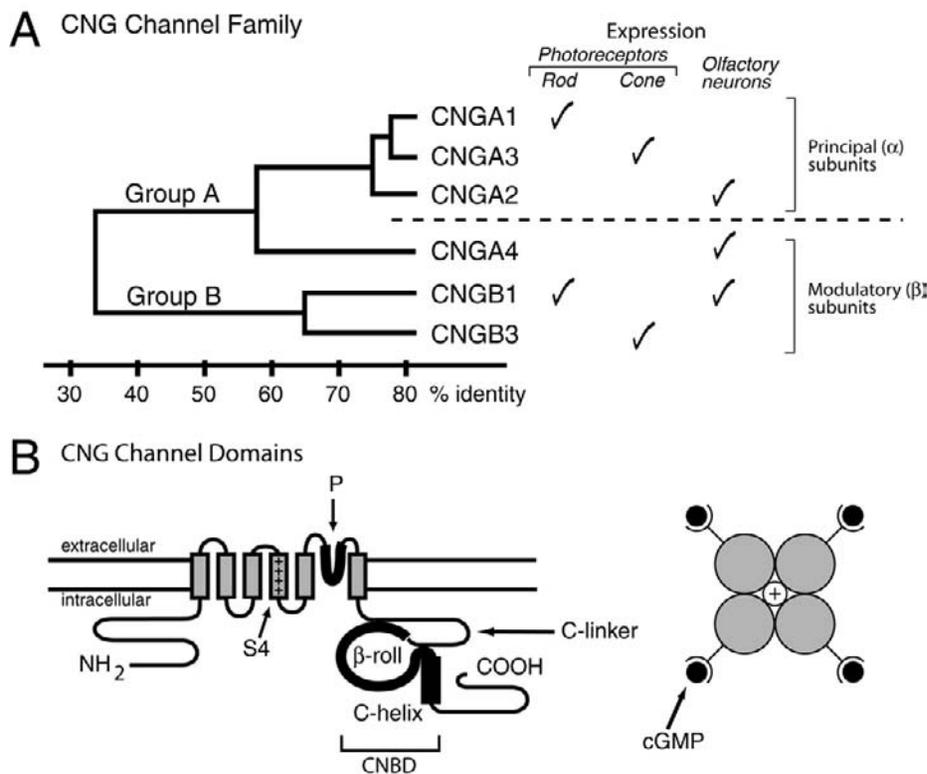

Figure 1 The family of cyclic nucleotide-gated channels. (A) Phylogenetic tree showing relation of six CNG channel genes. (Adapted from Gerstner, A. *et al.*, *J. Neurosci.*, 20, 1324–1332, 2000.) Note the name CNGB2 is not used. (B) Structural features of CNG channels: (left) important domains of a CNG channel subunit; (right) a functional channel composed of four homologous subunits.

antiparallel β -strands, followed by a short B-helix and a long C-helix. A C-linker sequence, connecting the S6 segment to the CNBD, is highly conserved in CNG channels but has no similarity to known sequence motifs.

The CNG channel isoforms exhibit marked diversity in function as well as tissue expression [7]. CNGA1-3 are called principal or α subunits, as they all form functional homomeric channels in heterologous expression systems. The activation properties of these homomeric α channels have been studied by applying cyclic nucleotide to the internal surface of the membrane in cell-free patches. The channels show steep dose-response relations to cyclic nucleotide, with Hill coefficients as high as 2 to 4. Bovine rod CNGA1 channels are highly selective for cGMP relative to cAMP, with 20- to 50-fold higher maximal open probability with cGMP than with cAMP. In contrast cAMP and cGMP activate the rat olfactory CNGA2 channels with equal maximal open probability. The cone CNGA3 channels show an intermediate selectivity for cGMP over cAMP. The structural basis for these differences in selectivity lies, not surprisingly, in the CNBD and is discussed further in the next part.

CNGB1 and B3, as well as CNGA4, are called modulatory or β subunits as they fail to form functional homomers but do coassemble with α subunits to form heteromultimers, whose properties more closely resemble those of native channels than do the homomeric α subunit channels. Thus, the native channels are likely to be heteromultimers of α and β subunits; rods, cones, and olfactory neurons all express different combinations of α and β subunits. Additional diversity arises through differential expression of splice variants of CNGB1 in different tissues. Bovine rods contain predominantly a long 240-kDa form of CNGB1 with a large glutamic acid-rich protein (GARP) domain in its cytoplasmic N terminus. This GARP domain may interact with regulatory proteins in rod signaling cascades. Shorter (100-kDa) CNGB1 splice variants lacking the GARP domain are the predominant forms of CNGB1 in human and rat rods, as well as in olfactory neurons. Different combinations of CNG channel subunits are expressed in other sensory and nonsensory cells; the role of CNG channel-dependent signaling in these tissues remains to be explored.

Structural Basis for Ligand Gating in CNG Channels

CNG channels provide a simple model system for studying allosteric regulation [1,8]. Ligand gating conforms to a cyclic allosteric model in which channels can open spontaneously in the absence of ligand with only low open probability (10^{-3}). Cyclic nucleotides bind more stably to the open state than to the closed state, and this stability difference provides coupling energy, which promotes channel opening. Although binding of ligand to only one or two sites in the tetrameric channel does enhance opening above the spontaneous level, efficient opening requires that all four sites be occupied.

Several domains of the channel important for gating have been identified. In the CNBD, the C-helix is an important

determinant of cyclic nucleotide selectivity. An aspartic acid residue in the C-helix (D604 in bovine CNGA1) favors cGMP binding over cAMP binding by forming a pair of hydrogen bonds with the guanine ring of cGMP and a repulsive interaction with an unshared pair of electrons on N6 of cAMP. Moreover, this interaction occurs selectively when the channel is open, contributing large coupling energy for channel activation with cGMP but not cAMP. In CNG channel subunits that are not selective for cGMP, the aspartic acid residue is replaced by an uncharged amino acid.

The conformational change in the CNBD that enhances ligand binding is coupled by the C-linker to the conformational change in the transmembrane domain that opens the pore. A histidine residue in the C-linker can act in a tetrameric channel to chelate Ni^{2+} , and recent experiments (see Flynn *et al.* [8]) showed remarkably that this Ni^{2+} chelation could either increase or decrease the open probability of the channel, depending on the location of the histidine along the length of the C-linker. The results imply that the C-linker forms an α -helix that rotates longitudinally upon channel activation, probably also causing movement of S6. In voltage-gated K^+ channels, S6 forms a movable gate whose translation controls ion entry into the cytoplasmic end of the pore (see Chapter 35). In CNG channels, however, ion entry into the pore is not blocked by the S6 segment, so the role of C-linker and S6 motion during channel activation may be to cause a conformational change of the P region, which would serve as both the selectivity filter and gate.

Other regions of the CNG channel are important in regulating channel opening. For instance, the N terminus of the olfactory CNGA2 subunit can interact favorably either with the C terminus or with $\text{Ca}^{2+}/\text{CaM}$. Binding of $\text{Ca}^{2+}/\text{CaM}$ to the N terminus suppresses the interaction between the N and C termini and inhibits activation of the channel. A similar mechanism works in rod CNG channels, mediated by $\text{Ca}^{2+}/\text{CaM}$ binding to the CNGB1 subunit.

Other Channels Directly Regulated by Cyclic Nucleotides

The hyperpolarization-activated cation channels (I_h or I_f) are also directly regulated by cyclic nucleotide [9,10]. These channels are voltage gated; they are slowly activated by membrane hyperpolarization (a response opposite to that of most voltage-gated channels) and carry the so-called "pacemaker" current that controls the rhythmic spontaneous firing of action potentials in certain neurons and cardiac muscle cells. Open I_h channels are weakly selective for K^+ over Na^+ (3:1 ratio), and at typically negative resting potentials they pass inward current, which is excitatory (depolarizing the membrane). They contribute to pacemaking because they become activated after the falling phase (repolarization) of an action potential; the resulting excitatory current can depolarize the cell past threshold and cause the firing of

another action potential. DiFrancesco and colleagues [11] first showed that the direct binding of cAMP to these channels enhances the rate of channel opening and thus accelerates the rate of spontaneous firing.

In mammals, the I_h channels are encoded by a family of four closely related genes, termed HCN1–4 (hyperpolarization-activated, cation-nonspecific, cyclic-nucleotide-regulated). The HCN subunits are phylogenetically related to the CNG channels, with a six-segment transmembrane domain and a C-terminal CNBD. The HCN channels contain an S4 voltage sensor with a large number of positive charges, more than are present in many depolarization-activated K^+ channels, and the HCN channel P region conserves intact the GYG motif usually associated with K^+ selectivity (although many other P region residues are not conserved). The structural basis for hyperpolarization gating and lack of high K^+ selectivity in HCN channels is not yet known.

Sequence homology searches have identified more distant phylogenetic relatives of CNG and HCN channels. Many of these are voltage-dependent K^+ channels, such as the ether-à-go-go channel (EAG), the related ERG channel (implicated in the LQT congenital cardiac abnormality), and several K^+ channels from flowering plants. Surprisingly, all these examples have putative CNBDs that lack some amino acids known to be important in CNG and HCN channels and in CAP, such as a conserved arginine that contacts the cyclized phosphate moiety. In many cases, the issue as to whether the channels are indeed regulated by direct binding of cyclic nucleotides is still controversial and calls for further study.

Overview of Cytokine Receptors

Robert M. Stroud

*Department of Biochemistry and Biophysics,
University of California, San Francisco, California*

Cytokine, and cell adhesion receptors are generally single-crossing receptors that are activated by binding a ligand on one side of the membrane that initiates a response on the other side. The ligands associate with binding sites that may lie within one single receptor molecule or may involve bridging interactions between multiple receptors. The relative disposition of transmembrane segments and their associated domains induces a signal transduction cascade on the other side of the membrane. In all cases, this is mediated by changing lateral associations of receptors by horizontal signaling.

Horizontal receptor signaling is primarily found in multicellular organisms. Downstream signaling pathways inside the cell generally control changes in cell metabolism, such as those that lead to changes in transcription, translation, or replication, or changes that result in apoptosis of the cell. The horizontal receptors are activated by binding a protein ligand that can be monomeric or multimeric and induces a reordering of quaternary interactions between receptors in the cell membrane.

Most cytokines can be grouped into four groups (I to IV) based on the preponderance of α -helical β -sheet, mixed α/β , or mosaic substructures. Reordering of receptor associations as a result of binding is a common theme in horizontal signaling, with enormous diversity in the protein folds, binding sites, and stoichiometries of these signaling complexes. Much less accessible, but of increasing significance, is the evidence that cytokine receptors are maintained in an inactive state by their ordered associations prior to binding the cytokines. The first such inactive but preassociated states have now been established; however, because inactive species are more difficult to detect than activated ones, they have only recently been sought. In some cases, these are poised to bind cytokine, as for members of the tumor necrosis factor (TNF) receptor class. In other cases, such as the erythropoietin (EPO) receptor, the receptors are associated

in an “off” state that requires them to dissociate before a productive complex can be made.

In many cases, the intracellular domains of receptors are preassociated with protein kinases, either noncovalently, as is the case with EPO receptors, or by covalent construction on the same gene, as is the case with the epidermal growth factor (EGF) class of receptors. In other cases, the intracellular domains associate with kinases after they bind cytokine, as is the case for human growth hormone (hGH) receptors. Once the receptors are appropriately oriented, the kinases act intermolecularly to phosphorylate each other, regions of the intracellular domains, or other proteins. These in turn act as docking sites for binding and activating other signaling factors. Thus, the membrane surface serves as the nexus for a plethora of pathways within the cell. In their role as the “mailbox” of the cell, they will be the key to intervention by therapeutic drugs as the ability to target protein–protein interfaces reaches maturity.

Cytokine–receptor complexes include those where two identical receptor molecules are dimerized by binding to two different sites on a single cytokine to produce a 2:1 complex, as seen for growth hormone and erythropoietin. Other cytokines form complexes where two cytokine molecules bind two identical receptors, such as in the gp130–interleukin-6 (IL-6), granulocyte colony-stimulating factor (GCSF)–GCSF receptor (GCSFR), and fibroblast growth factor (FGF)–FGF receptor (FGFR) complexes to induce allosteric changes that lead to back-to-back associations of the receptors without any contact between cytokines themselves. Still other cytokines act as monomers to bind two different receptors simultaneously such those found in the IL-4 system and gamma-interferon (γ -IFN). Still higher order trimeric complexes are seen for the TNF receptors class.

Overall, our study of the mechanisms of cytokine signaling via single crossing receptors has been driven by defining the

activated complex structures and their function in recruiting molecular complexes, but this research has also led to determining what constitutes the “off” state of receptors. In the case of erythropoietin receptors, only 50 receptor dimers, oriented by binding erythropoietin on the cell surface, are required to

evoke $\approx 50\%$ signaling. Therefore, our understanding of the reference “off” states is key to understanding the horizontal signaling receptors. The chapters of this section detail some of the most pertinent examples of horizontal signaling mechanisms, which serve to define the pathway to the future.

Growth Hormone and IL-4 Families of Hormones and Receptors: The Structural Basis for Receptor Activation and Regulation

Anthony A. Kossiakoff

Introduction

Within the cytokine superfamily, the growth hormone (GH)/prolactin (PRL) and interleukin-4 (IL-4) families of hormones and receptors are arguably the most extensively studied systems focused on structure–function issues and molecular recognition [2–6]. These studies and those of related cytokine systems have been instrumental in defining modes of hormone action and regulation [7–12]. The structure-based mechanisms by which these systems activate are similar [4,6,7]; however, although these mechanisms are conceptually simple (hormone-induced receptor aggregation), the molecular strategies that are employed are complex and hardly predictable [3,8,9,13].

The GH and IL-4 hormones and receptors share many general structure and functional similarities, but there are also important differences that define the details of how these systems initiate and regulate their biological activities. Most noteworthy is the form of the tertiary complexes that compose their respective active signaling complexes. In the case of GH, activity is triggered through a hormone-induced receptor homodimerization. This gives rise to a

hormone-to-receptor stoichiometry of 1:2. For IL-4, activity is initiated through a heterodimerization process—the binding of two different receptors produces an organization of 1:1:1 for hormone to receptor 1 to receptor 2. These are fundamentally different processes and involve quite different molecular recognition strategies to regulate biological function.

A comprehensive literature describes the structure–function relationships for these two systems; however, with each additional piece of new information and insight it is clear that we are just beginning to scratch the surface in understanding the strategies under which these systems evolved. A common misconception about these systems is that, because the previous studies have produced such a breadth of important results, all the most critical issues have been resolved. The fact is that these studies have really just laid the foundations for a new generation of investigations that will produce a further level of insight about the subtleties under which molecular recognition processes drive biological function. The goal of this review is to provide a background of our current understanding and suggest areas of future investigation.

The Growth Hormone Family of Hormones and Receptors

Growth hormone (GH), placental lactogen (PL), and prolactin (PRL) regulate an extensive variety of important physiological functions. While GH biology generally centers around the regulation and differentiation of muscle, cartilage, and bone cells, it is the PRL hormones and receptors that display a much broader spectrum of activities, ranging from their well-known effects in mammalian reproductive biology to osmoregulation in fishes and nesting behavior in birds [1]. Within the cytokine superfamily, the growth hormone (GH)/prolactin (PRL) endocrine family of hormones and receptors is arguably the most extensively studied system focused on structure–function issues and molecular recognition [2–6]. These studies and those of related cytokine systems have been instrumental in defining modes of hormone action and regulation [7–12]. The structure-based mechanisms by which these systems activate are similar [4,6,7]; however, although these mechanisms are conceptually simple (hormone induced receptor aggregation), the molecular strategies that are employed are complex and hardly predictable [3,8,9,13].

The activities of GH, PL, and PRL and their homologs are triggered by hormone-induced homodimerization of their cognate receptors, which produce subsequent signals through a series of phosphorylation events in the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) signaling pathway [14,15] (Fig. 1). The receptors belong to the hematopoietic receptor superfamily [2,16] and have a three-domain organization. It is the cytoplasmic

domains of the aggregated receptor complex that bind one or several JAK tyrosine kinases, which then transphosphorylate elements on themselves, the receptors, and associated transcription factors belonging to the STAT family [15].

Structural Basis for Receptor Homodimerization

Tertiary structure plays a role in how the hormone regulates receptor activation. The hormones in this family are long chain four α -helix bundle proteins [4,17]. A notable feature of their tertiary structure is that it contains no symmetry that might support equivalent binding environments for the receptors. How the two receptors bind to the asymmetric hormone was first revealed from the crystal structure of human growth hormone bound to the extracellular domain (ECD) of its receptor (hGH-R) [8]. The structure showed that the two ECDs binding to site 2 and site 2, respectively, use essentially the same set of residues to bind to two sites on opposite faces of the hormone [8] (Fig. 1). An identical model is seen in a prolactin hormone–receptor complex [18]. This binding is characterized by extraordinary local and global plasticity at the binding surfaces. The two binding sites have distinctly different topographies and electrostatic character, leading to different affinities for the receptor ECDs (Fig. 2).

The high-affinity site, site 1, is always occupied first by ECD1 [19]. This sequence of events is required because productive binding of ECD2 at site 2 of the hormone requires additional contacts to a patch of the C-terminal domain

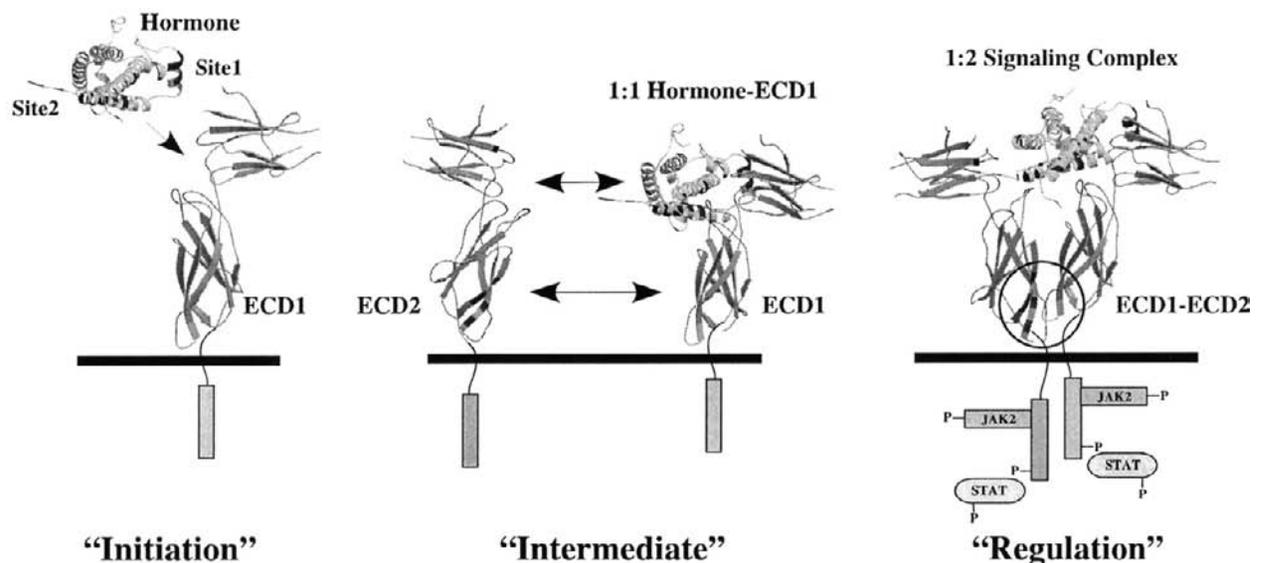

Figure 1 Mechanism of hormone-induced receptor homodimerization. The GH/PRL receptors are three-domain single-pass receptors containing an extracellular domain (ECD), a transmembrane section of about 25 amino acids, and a cytoplasmic domain that forms the binding site for the tyrosine kinase activities. The ECD consists of two fibronectin type III domains (FNIII) connected by a short linker. The hormones are four-helix bundle proteins. The initiation step involves the hormone binding event to the ECD (ECD1). The segments of the molecules that are involved in the contact (site 1) are colored red (hormone) and yellow (ECD1). They form a stable 1:1 intermediate that then recruits a second receptor in the regulation step through two sets of contacts (site 2)—one to the hormone and the other through forming receptor contacts (ECD1–ECD2). This step forms the stable homodimer, which organizes the cytoplasmic components to initiate binding and phosphorylation.

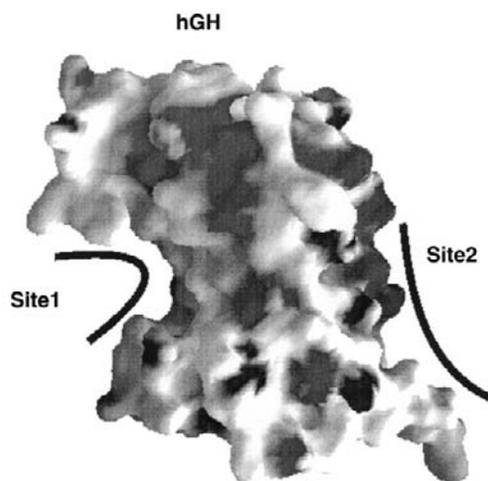

Figure 2 Molecular surface of hGH showing the different topographies of the site 1 and site 2 binding sites. In addition, the two sites possess quite different electrostatic properties (red, negative charge; blue, positive charge) (image rendered between ± 10 kT).

of ECD1. The binding of ECD2 is the programmed regulatory step for triggering biological action, and it involves a set of highly tuned interactions among binding interfaces in two spatially distinct binding sites. The energetic relationships between the ECD1–ECD2 contacts and the hormone–ECD2 site 2 interactions are known to be important. However, quantitative data are few in regard to which residues are the main contributors, whether they contribute in an additive or cooperative fashion, and how the binding energy is distributed in the interfaces.

Hormone Specificity and Cross-Reactivity Determine Physiological Roles

Binding to the two structurally distinct sites on the hormone, while using the same binding determinants, requires the receptor binding surfaces to undergo significant local conformational change [8,18]. The structural requirement is further expanded by specificity factors [9]. The biology of PRL and GH is integrated on many levels [20]; however, over the 400 million years since PRL and GH diverged from a common gene parent, evolution has built in different regulating components distinguishing them [21,22]. In primates, the growth hormone receptor (GH-R) is activated solely by homodimerization through its cognate hormone [8,21], but prolactin biology works through regulated cross-reactivity. Most PRL-R receptors are programmed to bind both prolactin and growth hormone [23].

This pattern of specificity and cross-reactivity involves some rather significant molecular recognition challenges as GH and PRL have little ($\approx 25\%$) sequence conservation even among the residues involved in receptor binding [9,18]. The structure of hGH bound to the prolactin receptor (hPRL-R) showed that in these systems local conformational flexibility of the receptor binding loops, together with rigid-body

movements of the receptor domains, facilitates the creation of specific, but different, interactions with the same binding site. The effects of conformational change on altering specificity were also observed in protein engineering studies that “converted” binding site 1 of two PRL-R-specific hormones, hPRL and hPL, into hGH [24–26]. This could be accomplished by substituting the hGH sequence at only five to six places in their sequence. Surprisingly, several of these positions map outside the site 1 hormone–receptor interface. Presumably, they must act as indirect specificity determinants by inducing conformational changes that subtly reorganize the contact residues into productive binding interactions. The implications of this finding are considerable and may open up totally new ways to look at how specificity and cross-reactivity are developed in cytokine systems.

Hormone-Receptor Binding Sites

Binding site 1 of the hormones in the GH-PRL family is formed by residues that are exposed on helix 4 of the helix bundle, together with residues on the connecting loop between helix 1 and 2 [8]. The total surface area buried on the hormone in the hGH–hGH-R and hGH–hPRL-R complexes is about 1300 \AA^2 . In the ovine placental lactogen (oPL)–rat prolactin receptor (rPRL-R) complex (a fully prolactin complex), about 850 \AA^2 is buried on oPL. Similar surface areas are buried on the respective receptors. The complexes contain approximately the same number of intermolecular H bonds (eight to nine H bonds). The overall packing of the four helices of the hormones is very similar in all the complexes, indicating no global changes of the type seen in the analysis of the structure of an affinity mature hGH mutant [27]. The largest differences in the bound hormones are seen in a small “mini-helix” of two turns (residues 38–47) in the segment connecting helices 1 and 2. In the case of hGH binding to hPRL-R and hPRL-R, the mini-helix differs by about 3 \AA between the respective complexes [9].

For both oPL and hGH, the site 2 binding epitope involves residues in helices 1 and 3 (hGH–hPRL-R is a 1:1 complex and thus does not have a site 2 binding site). In contrast to the concave surface of the hormones at site 1, binding site 2 is a relatively flat surface. Upon binding, about 650 \AA^2 of the oPL surface becomes buried in the interface with rPRL-R.¹ This compares to about 860 \AA^2 that is buried in the equivalent hGH–hGH-R2 interface [8]. A noteworthy difference between prolactin and growth hormone complexes is that the oPL–rPRL-R2 interface contains nine intermolecular H bonds, while that of hGH–hGH-R2 contains only four. Thus, although it is somewhat smaller than its hGH counterpart, the oPL site 2 interaction contains over twice the number of H-bonds.

¹Receptors binding at site 1 are designated by the suffix R1, those binding at site 2 by R2).

The receptor ECDs use essentially the same set of residues to bind to the two distinctly different site 1 and site 2 interfaces on the opposite faces of the hormones [8,18]. The binding surfaces of the receptors are formed by six closely spaced surface loops (L1–L6) that extend from the β -sheet core in a manner somewhat similar to antigen-binding loops in antibodies. Three loops reside in the N-terminal domain (L1–L3), two others in the C-terminal domain (L5–L6). Binding loop L4 serves as the five-residue linker between the domains. The conformation of L4 plays a key role in orientation of the domains with respect to one another. For instance, differences in the conformation of L3 in complexes of hGH binding to hGH-R and hPRL-R result in significant changes in the global positioning of the N- and C-terminal domains of the receptors bound at site 1 [8,9,18]. These differences in the N- and C-terminal domain orientation are an important part of the molecular recognition diversity in these systems.

Receptor–Receptor Interactions

A conserved structural element of the ligand-induced homodimerization of prolactin and growth hormone receptors is a set of extensive contacts between their C-terminal domains. This receptor–receptor interface was described in detail for the hGH:hGH-R 1:hGH-R2 ternary complex [3,8] and modeled for the hGH–hPRL-R ternary complex [3]. Although the topology of the C-terminal domains of the rPRL-R is virtually identical to that of the C-terminal domain of hGH-R, the receptor–receptor interfaces in these two complexes show a marked variation in their orientation and electrostatic character, and different portions of the receptors are involved in the interaction. The surface area buried in the interaction between rPRL-Rs is smaller than that buried between hGH-Rs; the former being $\approx 370 \text{ \AA}^2$ compared to $\approx 470 \text{ \AA}^2$ for the latter.

Eleven residues are involved in the contact interface on each rPRL-R, while 13 and 17 residues from hGH-R1 and hGH-R2, respectively, make up their site 1 and site 2 interfaces in the hGH–hGH-R ternary complex. In the rPRL-R receptor–receptor interface, there are four H-bonding interactions compared to six H bonds or salt-bridging interactions found between hGH-Rs (Table 1). The receptor–receptor interaction of hGH-R1 and hGH-R2 generally involves the same residues on each receptor [3,8]. In the oPRL–rPRL-R complex, about one-third of the interface residues on its rPRL-R1 are also in the interface of rPRL-R2. Although residue 201 in the first receptor H-bonds across the interface in each complex, these interactions are not equivalent interactions because of the differences in orientations of the domains.

Hormone–Receptor Binding Energetics

The energetics of the high-affinity site 1 hGH–hGH-R1 binding that forms the intermediate 1:1 complex has led to a

Table 1 Receptor–Receptor H-Bonding Interactions ($<3.2 \text{ \AA}$) for PRL-R and hGH-R Ternary Complexes

rPRL-R1	rPRL-R2	hGH-R1	hGH-R2

—	D152O δ 2	Y200O ν	—
—	S201O γ	Y200O ν	—

number of important insights into the relationships between binding and specificity determinants and protein–protein interactions, in general [28]. In particular, the seminal work of Wells and colleagues [28–31] demonstrated that the hGH–hGH-R ECD1 protein–protein interactions are characterized by binding “hot-spots” that focus binding energies within a cluster of relatively few residues. Thirty residues of hGH make contact in the site 1 interface with hGH-R1; however, it was shown that about 85% of the binding energy was developed through only eight of the residues, and there were no apparent distinguishing characteristics between the interactions that were energetically important and those of the other side chains that were energetically null [31]. This very efficient use of the binding interface characterized by the concentration of the binding determinants within a relatively small area of the contact surface allows for separate adjacent areas to be used for specificity determinants without compromising the binding.

It has been determined that a similar type of hot-spot also exists for the hGH–hPRL-R1 site 1 interaction and that the interface encompasses the same binding footprint as the hGH–hGH-R1 counterpart [9,31]. The two systems differ, however, in how the energy is distributed within the footprint. For instance, residues such as E174 and R167 make little energetic contribution to binding in the hGH–hGH-R case but play extremely important roles in the hGH–hPRL-R contact surface (≈ 800 -fold difference in binding between the two systems when alanine is substituted at each of these sites). Interestingly, R167 makes a salt bridge to an acidic side chain in both receptors (to E127 in hGH-R and D124 in hPRL-R), yet Ala-scan mutagenesis indicates that only in the case of hGH–hPRL-R does this salt bridge have a positive effect on binding [31]. This is an example of how the energetics of interactions is very context dependent on protein–protein interfaces [3].

The binding properties of ECD2 are intrinsically different than those for ECD1, because they involve the combined effects of two spatially distinct binding surfaces: binding site 2 on the hormone and a contact with the C-terminal domain of the bound ECD1 (Fig. 1). Neither of these surfaces alone supports binding without the interaction of the other. In glaring contrast to the extensive characterization

of the energetics of site 1 binding, there is considerably less biochemical and biophysical information for site 2 in GH/PRL systems. A study by Cunningham *et al.* [32] showed that site 2 did not contain a well-defined hot-spot, as was the case for site 1. However, there is no information about whether the spatially independent hormone–receptor and receptor–receptor interfaces act in additive or cooperative fashion. This deficiency has greatly limited our understanding of the overall energetics driving the homodimerization process. In this regard, recent data show that the receptor–receptor interface contains a hot-spot in the hGH–hGH-R system and probably plays a more important role than the hormone site 2–receptor contact in stabilizing tertiary forms of the complex (Bernat and Kossiakoff, unpublished data).

Biological Implications of Transient Receptor Dimerization

Functional and structural information suggests that the role of receptor homodimerization is more complicated than simply bringing the cytoplasmic elements of the receptors together. For instance, structural studies of erythropoietin (EPO) and its receptor (EPO-R) indicate that a function of the hormone is to establish a fairly exact receptor alignment, as well as to induce dimerization [33–36]. Based on patterns of cross-hormone and cross-species activities and the known structural differences in the active complexes, exact receptor orientation is probably not as crucial for prolactin and growth hormone systems.

Although strict orientation effects may not be crucial, it appears that the dynamics governing the stability of the aggregated signaling complex are an important regulatory element for the prolactins. Consequently, the inefficient site 2 binding is likely an evolved characteristic of homologous prolactin systems distinguishing their homodimerization process from those of GH and EPO. To explain mutagenesis data influencing site 2 binding, Herman *et al.* [37] have suggested a minimal-time mechanism based on the assumption that signal transduction requires a minimal persistence lifetime for the homodimer to facilitate effective transphosphorylation of the associated JAK2 kinases. Once this goal is achieved, the existence of the dimerized receptors is no longer obligatory. It is proposed that this minimal time is generally shorter for PRL-R than for GH-R, perhaps because the JAK2 kinase is preassociated in the case of PRL-R [38] but not GHR [39]. The minimal-time hypothesis is also supported by a study by Pearce *et al.* [40], who engineered tighter and weaker binding interactions between hGH and hGH-R. They found that increasing affinities of the hGH–hGHR associations at both site 1 and site 2 produced no measurable increases in biological activity. However, reducing affinity at site 1 30-fold marked a point that appeared to correspond to a threshold where activity was affected, suggesting that wild-type hGH–hGH-R affinity is higher at site 1 than it needs to be to sustain full biological activity.

A High-Affinity Variant of hGH (hGH_v) Reveals an Altered Mode for Receptor Homodimerization

Using phage display mutagenesis selections, a variant of hGH that binds >100-fold more tightly to hGH-R at site 1 was produced [41,42]. This variant (hGH_v) has 15 mutations localized in its site 1 binding site and is fully biologically active but is totally specific to hGH-R, losing its ability to bind to hPRL-R. (This is a clinically relevant, second-generation hGH used for treating acromegaly). The recent high-resolution X-ray analysis of the ternary complex of hGH_v bound to two copies of hGH-R [43] indicates global similarity to the *wt*–hGH complex but major important structural differences in the binding interfaces [43]. These changes are exemplified in the finding that of the 17 H bonds that are formed between the hormone and receptors at sites 1 and 2, only two correspond to H bonds in the *wt* complex. This demonstrates the inherent plasticity of the protein–protein interfaces in this system where new contacts can be formed and still remain specific to hGHR in a biologically relevant way.

While it was anticipated that site 1 interactions would be altered as a result of the mutations at this site in the hormone, it was surprising that the largest changes in structural conformation were found in the site 2 interface, where no mutations were made [43]. This interface in hGH_v has only limited structural relationship to its *wt* counterpart. The same sets of hormone and receptor residues are used, but their stereochemical relationships are completely different, with several groups differing by more than 10 Å. Interestingly, this new, reconfigured hGH_v–ECD2 interface has a binding association comparable to that found in the *wt* complex. This structure is an excellent example of the structural cooperativity that exists between binding sites in these systems. Another important aspect of this structure is that the distribution of binding energy among the residues energy at sites 1 and 2 is different than their counterparts in the *wt* ternary complex (Walsh and Kossiakoff, unpublished results).

Site1 and Site2 Are Structurally and Functionally Coupled

It is likely that this new binding solution for hGH_v–hGH-R2 is triggered by a structural mechanism linking site 2 to a subset of the mutations in site 1 introduced in the phage display experiments. It is noteworthy that the structurally distinct conformation of hGH_v at site 2 was under no selection pressure and supports binding of the second receptor as tightly as in the *wt* complex. A specific example of the structural coupling is observed from the altered roles of Asp116 in site 2 of the hormone in the two complexes [43]. Asp116 is located near the center of helix 3, thus the side chain extends off a fairly rigid scaffold. Although Asp116 is adjacent to several important receptor side chains, in the *wt* complex it appears to play a bystander role, making no H bond

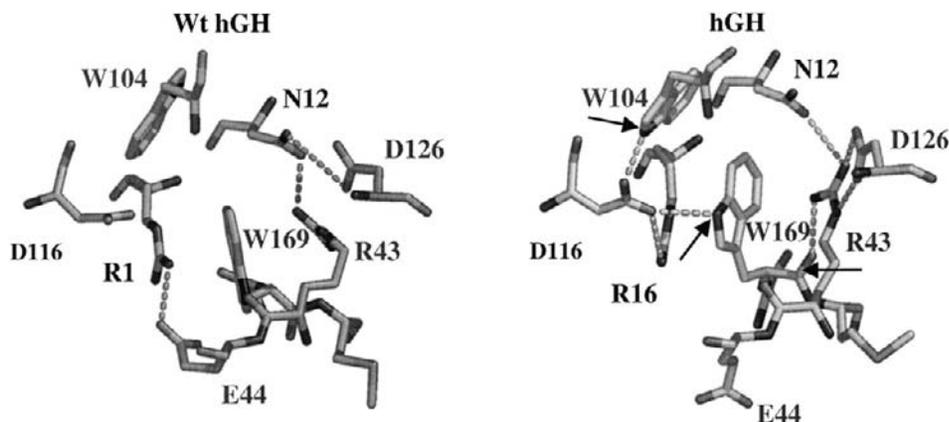

Figure 3 Comparing the structural changes in site 2 of the hGH and hGH_v-hGH-R ternary complexes. Hormone residues are labeled in black and receptor residues in red. Arrows point to the carbonyl oxygen atom of the peptide bond of Trp169 that flips its conformation. The other arrows point to the reorientation of the side chains of Trp169 and Trp104.

to the receptor. It is probable that the small movements of Asp116 that are a consequence of the repacking of the four-helix bundle in hGH_v effectively trigger the new H-bonding scheme where by the carboxylate side chain makes new H bonds to the receptor through the indole nitrogens of the side chains of Trp104 and Trp169, as well as to the side chain of Arg43. As seen in Fig. 3, the Trp side chains undergo a significant reorganization to facilitate the formation of these H bonds. These observations clearly have fundamental importance to our understanding of the inherent efficiencies of these cytokine hormones and receptors as binding entities even outside of evolutionary control.

The concept that the two spatially distinct binding sites on cytokine hormones are structurally and functionally coupled as displayed in the hGH_v complex is novel, and the process whereby new binding surfaces are synthesized by indirect through molecule effects has been termed *functional cooperativity* [43]. In this mechanism, it is not only the mutations in one site that affect the other site. A set of concerted changes also occurs among the hormone and the receptor ECDs. The finding of strong cross-molecular interaction induced during receptor dimerization establishes a new molecular recognition paradigm and opens up fundamental new areas of investigation relating to the mechanisms of biological regulation by protein-protein associations. However, it remains an open question as to how general this is and whether evolution actually uses this strategy to influence the receptor signaling of GH/PRL systems in biologically important ways.

IL-4 Hormone-Induced Receptor Activation

IL-4 is a pleiotropic hormone that mediates several important regulatory responses in the immune system (9A, 10A). The hormone belongs to the short-chain, four- α -helical bundle class of cytokines (4), which is a distinctly different class than the long-chain cytokines represented by GH and PRL.

The IL-4 signaling cascade is triggered by a sequential hormone-induced aggregation of two distinct receptor chains (12A, 13A). The so-called α -chain receptor binds first to IL-4 with high affinity (150 pM), while the γ -chain binds only weakly to the preassociated IL-4/ α -chain complex (8A).

The extracellular parts of these receptors are like those of GH-R/PRL-R consisting of two FNIII domains (11A). Interestingly, neither receptor is specific to IL-4 alone. In contrast to its tight association to IL-4, the α -chain receptor also forms a weak complex with IL-13 (1A). The γ -chain receptor acts as a common receptor element for the IL-2, IL-7, IL-9, and IL-15 signaling complexes (2A). Additionally, the cytoplasmic portions of these receptors differ both in size and function. The cytoplasmic domain of the α -chain receptor is composed of about 600 amino acids and contains the docking sites for JAK1 and STAT6, and the insulin receptor substrate IRS-2, among others (3A, 14A). The γ -chain receptor has a much smaller cytoplasmic domain, which contains a binding site for JAK3. Thus, in contrast to the homodimeric systems GH/PRL, the phosphorylation events that trigger the IL-4 signaling cascade are produced by two different JAK kinases, JAK1 on the α -chain and JAK3 on the γ -chain.

The large difference in binding affinities of the α - and γ -chain receptors to IL-4 results in the active ternary complex being formed in a specific sequential order, similar to GH/PRL (Fig. 1) (see previous discussion). The first step is creating the IL-4- α -chain intermediate, which is followed by the low-affinity binding of the γ -chain. The active ternary complex is short lived because of the weak γ -chain binding. Thus, the transient nature of the ternary complex parallels the dynamics observed in the prolactin system, where formation of the active 1:2 complex was rapidly followed by the dissociation of the second receptor to reform the 1:1 intermediate (22).

Recently, the high-resolution structure of the IL-4: α -chain receptor intermediate complex was reported by Hage *et al.* (4A). Although in many respects this complex is

similar to the 1:1 intermediate complexes formed between hGH and hGH-R/hPRL-R, a notable difference is that the major binding epitope on IL-4 involves helices 1 and 3, rather than 1 and 4, as is the case for the hGH and hPRL receptor binding (5A). This apparent subtle difference actually represents a totally altered site 1 binding stereochemistry between IL-4 and hGH in their respective 1:1 complexes. In fact, the IL-4 orientation is more similar to the low-affinity site 2 of hGH.

A comparison of the structures of the unbound and bound IL-4 molecule indicates that binding not only produces changes in the loops, as expected, but also an adjustment of the four-helix bundle packing (4A). In this respect, it is not known whether a similar packing adjustment happens with hGH binding, as no well-resolved structures of the free wild-type hGH molecule are available. However, the high-affinity hGH variant (hGH_v) [41] shows a similar degree of conformational change on binding [43], albeit the free variant was compared to the bound variant in the context of a 1:2 complex.

IL-4- α -Chain Receptor Interface

The binding interface between IL-4 and the α -chain receptor encompasses slightly over 800 Å² on each molecule. This compares to about 1100 Å² for the hGH site 1 interface (8). The binding epitopes are highly discontinuous and in IL-4 are distributed over three helices, with the principal determinants being on helix 1 and 3. The complementary receptor epitope is composed of residues on five loops connecting the β -sheet structure of the FNIII domains (6A).

A binding model has been developed based on the structural information and the functional mapping of the binding energies of specific residues driving the IL-4- α -chain receptor association (6A). The interface has a high degree of electrostatic complementarity between a cluster of positively charged residues on helix 3 of IL-4 that mate with a set of negatively charged groups on the α -chain receptor. The binding energetics on both sides of the interface are organized in an O-ring arrangement. The energetically important residues, which are predominantly hydrophilic, are centralized, surrounded by a shell of hydrophobic side chains in an O-ring configuration. The hydrophobic groups occlude the bulk solvent from the centralized set of hydrophilic, charged interactions, in essence accentuating the electrostatic effects. It is noteworthy that, while in the GH/PRL systems, the energetically important residues were clustered into a single binding hot-spot; the IL-4, the major binding determinants, are a mixed-pair of charged residues that are spatially separated and surrounded by a number of other side chains of lesser importance. This leads to a two-cluster type of epitope rather than a single hot-spot. The kinetic data suggest that the basic side chains on helix 3 forming one of the clusters on the hormone influence the rates of association, presumably through a mutual attraction to the set of negative side chains in the α -chain receptor interface (5A). Based on

this complementarity it has been proposed that the molecular recognition event that drives the protein-protein association involves a form of electrostatic steering (5A).

Binding of the γ -Chain Receptor

The γ -chain exhibits no measurable binding to either IL-4 or the α -chain receptor alone (8A) and, as is observed for hGH-hGH-R homodimerization, the binding of the second receptor is facilitated by structural properties generated by formation of the 1:1 intermediate. A major difference, however, is that, whereas the second hGH receptor binds to the intermediate 1:1 complex with high affinity (4 nM) (Bernat and Kossiakoff, submitted), the γ -chain binds to the IL-4- α -chain receptor 1:1 complex with an affinity of about 3 μ M, resulting in a highly transient signaling complex similar to that of the homodimeric prolactin-prolactin receptor complex (22).

In contrast to the highly charged IL-4- α -chain interface, the binding epitope on the γ -chain receptor is dominated by hydrophobic side chains: Ile100, Leu102, Tyr103, and Leu208 (7A). The loop containing residues 100 to 103 constitutes a focused binding hot-spot that is spatially separated from Leu208. Thus, as was the case for the IL-4- α -chain receptor contact, there is no single concentrated hot-spot in the interface. There are three residues in IL-4 that have been determined to be crucial for γ -chain receptor binding. The side chains of these groups, Ile11, Asn15 on helix 1, and Tyr124 on helix 4 (Fig. 4), form a single extended patch on the surface of site 2 of IL-4 that presumably is positioned to interact with the residues in the two clusters on the γ -chain receptor. Currently, no functional data exist to provide information about the presence or nature of a contact interface between the α -chain and γ -chain receptors. Presumably, such an interface exists because the γ -chain only binds to the 1:1 intermediate complex.

Comparisons of IL-4 with GH (PRL)

Although the active complexes of IL-4 and GH have a number of similar general structure-function features, there are also a number of important differences in how these hormones initiate and regulate their activities. It is noteworthy that, although both hormones are in the four- α -helix bundle family, the differences in the lengths of the helices and the connecting loops in the short-chain versus the long-chain cytokines result in a significantly different overall topography of the molecules. Both molecules have high- and low-affinity binding receptor sites, but because of these topological differences there is no spatially conserved relationship between them.

A principal difference in the biophysics of formation of the high-affinity 1:1 intermediate complexes of both hormones is the electrostatic nature of the hormone-receptor interfaces. In hGH, this interface is relatively neutral with

about the same number of hydrophilic and hydrophobic atoms involved in the overall contact (8). In fact, the hydrophobic side chains of two receptor tryptophans (Trp104 and Trp169) are the dominant players in the interface (30). In contrast, the IL-4- α -receptor interface is highly charged, and the major contributors to binding are involved in the extensive H-bonding network that characterizes the contact (4A). It is most likely that the electrostatic nature of the interfaces influences the observed differences in the kinetics of the binding process in these two systems. The highly charged IL-4 system results in a very fast on rate that is close to being diffusion controlled (5A). This is coupled to a relatively fast off rate. In the GH system, the on rates for forming the 1:1 complex are almost an order of magnitude slower, but so are the off rates (31). Although the resulting equilibrium binding constants are similar, the large differences in the kinetics of the process suggest that formation of the 1:1 intermediate complexes in the two systems has somewhat different requirements for supporting signaling. However, an important caveat to extrapolating *in vitro* binding kinetics to functional relevance in signaling processes is that changes in binding affinities do not track well with altered binding affinities. Although mutations that eliminate binding of the receptor components in solution-based measurements generally eliminate biological activity, in many cases measurable activities are still elicited in systems involving mutations that significantly alter binding, but do not eliminate it (5A, 8A). This suggests that the dynamics of receptor aggregation play a role in triggering activity, but that it is involved in some nonlinear way with other downstream signaling components.

Concluding Remarks

Although the various structures of hormone-receptor complexes provide information that encompasses both the versatility and specificity components inherent in the recognition system that regulates endocrine biology, a general understanding of this process at the molecular level remains challenging to construct, even combining it with the extensive mutational database available to us. One is struck by the extraordinary adaptability of these molecules to synthesize competent binding epitopes for a wide range of large target surfaces. It appears that the binding sites for cytokine receptors using the FNIII scaffold can adapt to binding cytokines via the hormone's one- to four-helix interface (long-chain cytokines such as GH and PRL) or, in the case of a short-chain cytokine motif such as IL-4, through the one- to three-helix interface. These interactions can have quite different affinities and might involve single or multiple binding hot-spots. The binding epitope can be quite specific, as for the hGH receptor, or very promiscuous, as for the γ -chain receptor.

In the case of hGH, the nature of the adjustments required to form the optimum set of interactions between the hormone of each of its two receptors suggests that recognition and binding of the two protein surfaces is directed by an

induced-fit mechanism. A relatively large set of structural changes in IL-4 is seen during the transition from being free form to its bound state. This, coupled with the fact that the γ -chain receptor is a common binding element to a number of different hormone-induced signaling systems, suggests that a form of an induced-fit binding process must play a role in these systems. Distinct from the process of molecular recognition associated with the antibody-antigen paradigm, where binding is developed mainly through sequence diversity of the antibody complementarity-determining loops, the cytokine receptors can use essentially a constant set of residues to bind surfaces that are diverse both in sequence and in conformation. This is accomplished by employing conformational diversity, both local and global, and is the unifying hallmark of these systems.

Erythropoietin Receptor as a Paradigm for Cytokine Signaling

Deborah J. Stauber, Minmin Yu, and Ian A. Wilson

*Department of Molecular Biology, and The Skaggs Institute for Chemical Biology,
The Scripps Research Institute,
La Jolla, California*

Introduction

The mechanism of how cytokines and growth factors elicit a signaling response via cell surface receptors remains a major question within the field of cell signaling. It was previously thought that dimerization of the extracellular domains was sufficient to elicit activation of a signaling pathway, and, indeed, a variety of studies have shown that a number of different strategies of dimerization can cause signal activation. However, studies on the erythropoietin receptor (EPOR) have suggested that dimerization alone is not sufficient. Rather, subtle differences in ligand binding to receptor extracellular domains, as shown by various structural and biochemical data, can result in structural deviations that can modulate the signal response.

Signaling of erythropoietin (EPO) through the EPOR promotes the proliferation and differentiation of erythroid progenitor cells and is thus crucial to normal red blood cell development [1,2]. The EPOR is a member of the cytokine receptor superfamily [3], which includes receptors for other long-chain cytokines, such as growth hormone (GH), thrombopoietin (TPO), and granulocyte cell signaling factor (GCSF), as well as short-chain cytokines, such as interleukins (ILs) 2, 3, and 4. These receptors are single-transmembrane (TM)-spanning proteins that bind their corresponding ligands in their extracellular (EC) domains. A common motif among these receptors is the cytokine homology domain (CHD), which consists of two seven-stranded β -sandwich motifs connected by a proline linker. Signature characteristics within the CHD include inter-strand disulfide bonds within the N-terminal domain and a WSXWS-conserved motif located in the C-terminal domain.

This WSXWS sequence seems to be essential for productive ligand binding and the resulting activation of the EPOR [4,5], although it is not clear from the structural data how the WSXWS motif carries out any binding or signaling role. The cytokine receptors are coupled to members of the Janus kinase (JAK) family (nonreceptor tyrosine kinases) at a proline-rich sequence in their cytosolic (CT) domain called Box 1. Agonist ligand binding in the EC domain of the receptor leads to a conformational change and reorganization that is permissive for autophosphorylation and activation of the associated JAK, resulting in phosphorylation of the CT domains of the receptors. These phosphorylation events trigger a signaling cascade via the signal transducers and activators of transcription (STATs) that ultimately leads to protein expression and cell proliferation [6]. In the case of EPOR, the associated JAK2 phosphorylates many of the eight CT tyrosines, which serve as docking sites for STAT-5. STAT-5, after being activated by JAK2, travels to the nucleus, where it promotes genes that lead to the proliferation and survival of erythroid progenitor cells.

Erythropoietin, similar to GH [7,8], binds to its receptor in a stoichiometry of 1:2. As EPO itself is not a symmetric molecule, two different binding interfaces exist on the cytokine surface which are each capable of interacting with the EPOR. The EPO interaction sites have been named site 1 and site 2, for which the binding affinities are 1 nM and 1 μ M, respectively [9].

Structural Studies on EPOR

Studies on the binding of different ligand molecules to the EPOR have shown that dimerization of the extracellular

domains itself is not sufficient for a biological response [10]. Furthermore, structural and biochemical data surprisingly revealed that the EPO receptor exists as a preformed dimer on the cell surface, and that a conformational reorganization of the receptor as a result of ligand binding is necessary to elicit the signal transduction cascade [11,12]. The biological appeal of a preformed dimerized receptor can be understood when one considers the low cell-surface density of the EPOR (<1000 receptors, or 1 μM) *in vivo* [9,12–14]. Clustering of the receptors allows EPO to act efficiently at the cell surface by binding to the high-affinity (nanomolar) site 1 immediately followed by interaction with site 2, despite its low micromolar binding affinity. In the absence of this clustering, monomeric receptor–EPO interactions would be prevalent. As a result, the efficiency of the biological response to EPO would be compromised.

The extensive amount of crystal structure data available on a variety of agonist and antagonist EPOR complexes has enabled a comparison and analysis of different activation states of the EPOR. Four EPOR structures, determined by X-ray crystallography (depicted in Fig. 1), allow for the exploration of the dimerization interfaces involved in various signaling states of the EPOR [10,15–17]. These structures allow us to examine how differences in the nature of the bound ligand lead to changes in the receptor structure and assembly on complex formation.

EMP1, an Agonist, Bound to the EPO Receptor

The crystal structure of an EPO mimetic peptide, EMP1, was determined at 2.8 Å resolution in complex with the extracellular EPO-binding protein domain (EBP) of EPOR [15]. EMP1 is a member of a family of peptide mimetics selected by the phage display method that bind specifically and with high affinity (100–200 nM) to the EPOR and have agonist activity [18]. Co-crystals of the EMP1–EBP complex showed that EMP1 binds to two EBP molecules as a peptide dimer, resulting in a 2:2 ligand-to-receptor stoichiometry and generating an almost twofold symmetric assembly of the EMP1–EBP complex [15]. In this arrangement (Fig. 1A), the monomers of the EBP dimer are rotated approximately 180° from each other, and the two domains of each receptor molecule, D1 and D2, are oriented with an elbow angle of approximately 90°. The EPOR dimerization interface in the complex consists almost entirely of interactions with residues from the peptide EMP1 dimer with minimal contact occurring between the receptors themselves.

EMP33, an Antagonist, Bound to EPO Receptor

Studies on the EMP family of mimetics showed the importance of peptide Tyr4 in the peptide-mediated receptor dimerization [19]. A substitution of 3,5-dibromotryosine yielded a biologically inactive peptide, EMP33. Surprisingly, this antagonist was capable of dimerizing the EPO receptor. The crystal structure of EMP33 at 2.7 Å resolution bound to the EBP confirmed that dimerization is indeed not sufficient

for signaling [10]. The structure shows an asymmetrically dimerized receptor (Fig. 1B) in which the D1 domain of each monomer is related by a 165° rotation (in contrast to the two-fold (180°) of the EMP1–EBP dimer). Thus, only 15° of rotation distinguishes an active dimer from that of a complex that is incapable of JAK2 activation.

EPO Bound to its Receptor

Crystal structures of a mutant [10,20] of the natural highly potent cytokine EPO with EBP were determined at 1.9 and 2.8 Å resolutions [16]. This EPO–EBP complex binds in a 1:2 stoichiometry, similar to that of the GH–growth hormone receptor (GHR) complexes [8], using two different binding surfaces of the EPO molecule to mediate interactions with each of the EBP monomers (Fig. 1C). These two surfaces, denoted site 1 and site 2, bind the receptor with high ($K_d=1$ nM) and low ($K_d=1$ μM) binding affinities, respectively [9]. The D1 domain of each monomer is rotated approximately 120° relative to the other. In this complex, the orientations of the D2 domains are approximately in the same plane perpendicular to the membrane, in contrast to the 45° angle of the EMP1–EBP complex. This allows for the C termini of the receptor in the EPO–EBP structure to be in close proximity. Furthermore, this complex confirms the large amount of flexibility associated with receptor assembly, which may explain how a covalently-linked EPO dimer is still capable of binding and activating the EPO receptor, presumably in a 2:2 complex [21,22].

The Unliganded EPO Receptor

An unexpected result surfaced when the crystal structure [17] of the unliganded EPO receptor was determined at 2.4 Å. The asymmetric unit contains an EPOR dimer, such that the dimerization interface is located near the ligand binding site (Fig. 1D). In this unliganded form, the D2 domains are oriented such that their C termini are rotated 135° away from each other [17] and at an angle to the plane of the membrane, placing their expected membrane insertion points approximately 73 Å apart. The equivalent distances of the D2 C termini of the EMP1–EBP and the EPO–EBP dimers are 39 Å and 34 Å, respectively. These values are consistent with the notion that the inter-dimer distance of the unliganded EPO receptor would be too far for the intracellularly associated JAK kinases to interact, thus causing the unbound receptor to be inactive and locked into an off state.

Hot-Spot in EPOR for Ligand Binding

In each of the previous structures examined (Figs. 1A–D), the same binding surface of the EPO receptor is used to interact with the multiple ligands (Fig. 2). Variation of this binding surface is introduced by only small conformational changes in hot-spot hydrophobic residues such as Phe93, Phe205, and Met150 or small adjustments of loops in D1 [23]. This concept of a receptor hot-spot was first introduced by

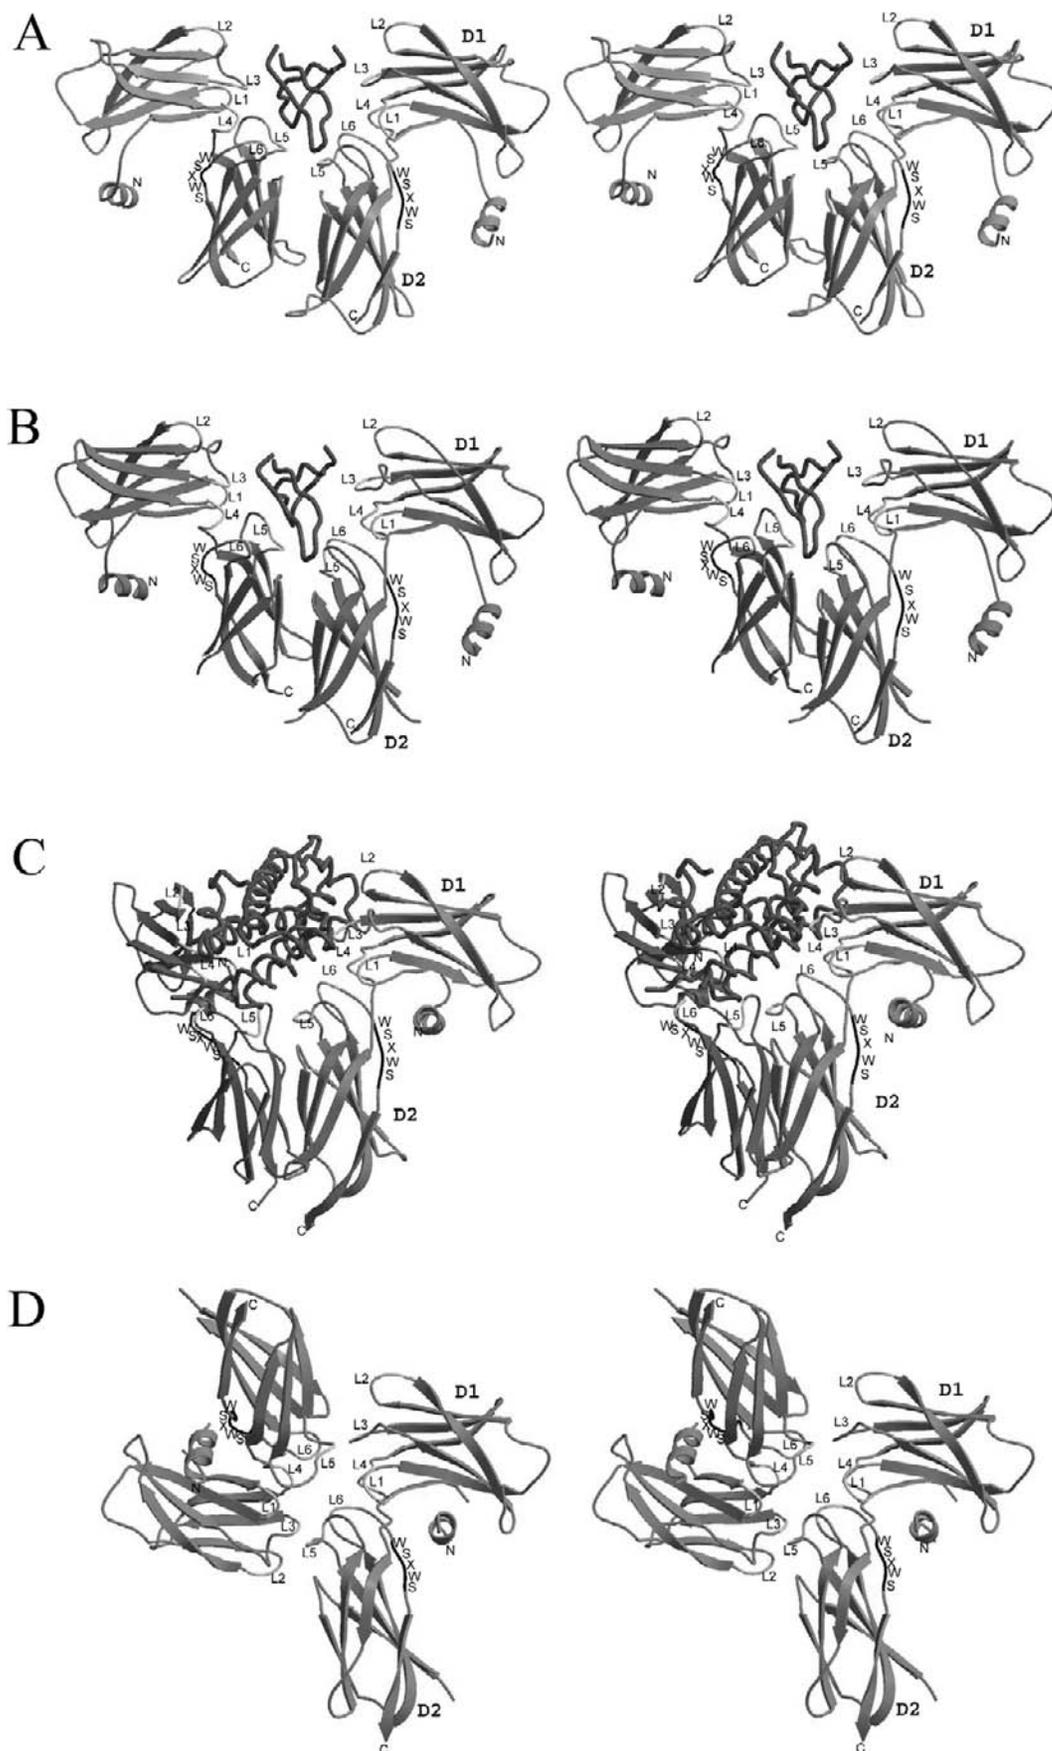

Figure 1 Stereo views of the various crystal structures of the EPOR. In each complex, the receptors are presented as ribbons and the ligands are depicted as tubes. The ligand binding loop tips of the receptor are yellow and labeled L1–L6; the conserved WSXWS signature sequence of the cytokine receptor family is black. The orientation shown for each structure corresponds to superimposing the β -strands of each receptor domain 1 (D1) onto the equivalent D1 domain of the

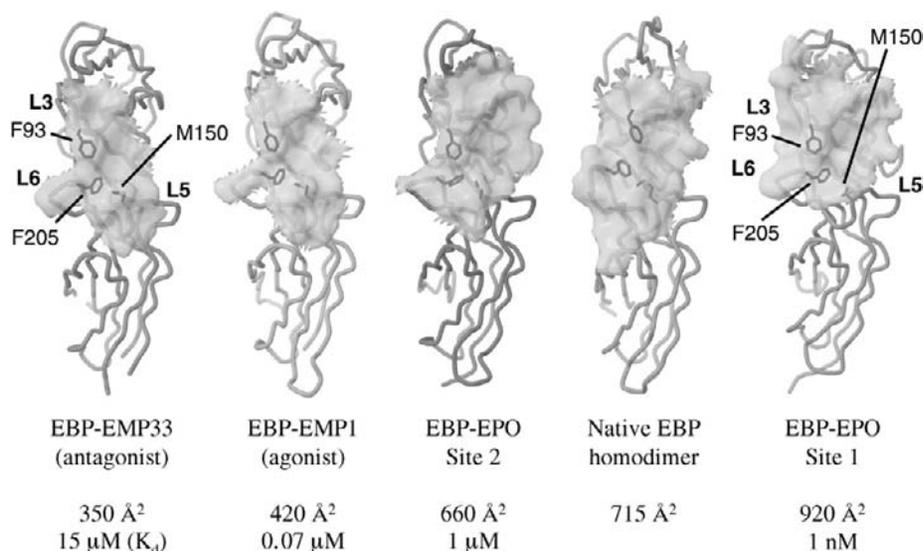

Figure 2 Plasticity of EPOR for ligand binding. EPOR binding surfaces are shown for each ligand receptor interaction, as well as the EBP monomers in the case of the unliganded structure. Molecular surfaces were calculated with GRASP [35], using a probe radius of 1.6 Å. The surface that is within 3.3 Å of the partner ligand and is shown. The representation is shown from the smallest binding interface (left) to the largest (right). This buried interface correlates somewhat, but not exactly, with the approximate K_d. The K_d of the antagonist EMP33 is 15 μM, and the K_d of the agonist EMP1 is 0.07 μM [10,15]. Two views of the EPO-EBP structure are shown; one surface represents the high-affinity EPO site 1 (1 nM), and the other represents the low-affinity EPO site 2 (1 μM) [9]. Surfaces were converted to MOLSCRIPT [34] objects and rendered in Raster3D [33]. (Adapted from Wilson, I. A. and Jolliffe, L. K., *Curr. Opin. Struct. Biol.* **9**, 696–704, 1999.)

Clackson and Wells for the human growth hormone [24]. Differences in K_d approximately correlate with the amount of surface area buried in each of the binding interfaces for the liganded complexes (Fig. 2). Thus, the EPOR is capable of presenting a number of the same interaction surfaces in different contexts for different ligands, each of which correlates with different activation states of the receptor. This example demonstrates that slight differences in the contact surface interaction can lead to a significant shift in receptor orientation, in turn propagating a much larger effect on the signaling response.

Biochemical Studies Supporting Preformed Dimers

Remy *et al.* [11] used an *in vivo* complementation assay to demonstrate that a ligand-induced conformational change of the EPOR dimer is required for activation. In these studies, chimeras that contained the extracellular and transmembrane domains of EPOR were fused to two complementary fragments of murine dihydrofolate reductase (DHFR) through flexible linkers of different lengths. Cells transfected with these chimeras express the receptors at the cell surface. In this experiment, DHFR activity is restored if the two complementary fragments are brought into close proximity. Chimeras containing a short 5-residue linker could not

restore DHFR activity in the absence of EPO. In contrast, chimeras that contained the 30-residue linker allowed complementation both in the presence and absence of EPO. This linker-length correlation agrees well with the crystallographic distances between the C termini of the two EBPs in their free and bound states. Thus, taken with the unliganded EPOR structure, these observations suggest a ligand-induced reorganization of the dimer that results in activation of the signal cascade.

Recent biochemical studies of the transmembrane and juxtamembrane domains of the EPO receptor further support preformed EPOR dimers and the importance of receptor orientation for productive signaling. Constantinescu *et al.* [25] have shown that the transmembrane domains of the EPO receptor interact *in vivo* using antibody-mediated immunofluorescence copatching assays. These oligomerized receptors are not constitutively active, but rather require EPO binding to induce signaling. Furthermore, experiments that swapped the transmembrane domains of the EPO receptor for the strongly dimerizing transmembrane domain of glycoprotein A still showed a dependence on EPO for JAK2 activation.

Further studies demonstrate the importance of the relative orientation of a region in the cytosolic juxtamembrane domains of the EPOR in signaling [26]. Alanine scanning has indicated that three residues, Leu253, Ile257, and

EMP1-EBP complex. (a) Weak agonist EMP1-EBP complex (EBP, cyan; EMP1, red; PDB code 1ebp) [15]. (b) Antagonist EMP33-EBP complex (EBP, salmon red; EMP33, red; PDB code 1eba) [10]. (c) Strong agonist EPO-EBP complex (receptor site 1, green; receptor site 2, purple; EPO, red; PDB code 1cn4) [16]. (d) Self-dimer EBP-EBP native complex (EBP, orange [33]; PDB code 1em) [17]. Molecules were made using MOLSCRIPT [34] and rendered in Raster3D [33]. For color figures, see CD-ROM version of *Handbook of Cell Signaling*. (Adapted from Wilson, I. A. and Jolliffe, L. K., *Curr. Opin. Struct. Biol.* **9**, 696–704, 1999.)

Trp258 (LIW), in this region were necessary for EPO-induced phosphorylation, but not for binding of JAK2. Accordingly, these residues are likely to be involved in a switch mechanism propagated from EPO binding to the EC that positions JAK2 correctly for appropriate activation (Fig. 3a). These three residues are likely to occur on the same face of the protein surface, as the secondary structure analysis predicts an α -helix continuing from the TM through

this region. Experiments in which additional alanine residues were inserted into this juxtamembrane region were performed in order to assess the affect of changing the relative “register” of these regions and, hence the effect transmitted to the intermolecular domains (Figs. 3b–d). Each alanine insertion rotates the register of the predicted α -helix by 109° . A single insertion greatly diminishes signaling by EPO, whereas a three-residue alanine insertion restores signaling

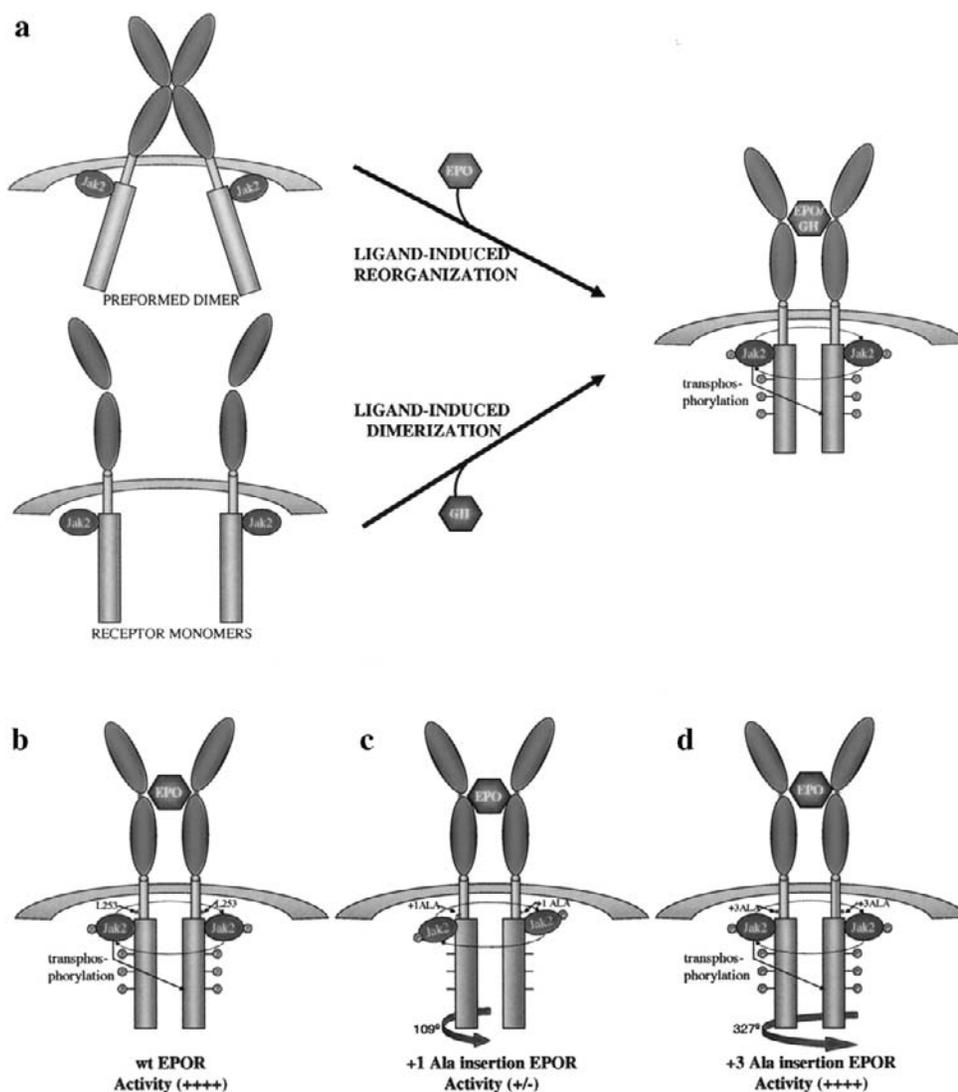

Figure 3 A model of EPO-induced dimerization and activation of the EPO receptor, JAK2 transphosphorylation, and tyrosine phosphorylation of the EPO cytosolic (CT) domain. (a) The schematic depicts contrasting views of ligand-induced signal activation. Top panel depicts a preformed dimer whereby the binding of cytokine (e.g., EPO) induces a structural reorganization, leading to active signaling. Bottom panel (b, c, d) depicts receptor monomers on the cell surface in which the binding of cytokine (e.g., GH) leads to dimerization, resulting in active signaling. EPO receptors are dimerized by EPO. The transmembrane (TM) domain is shown as a yellow cylinder and continues as a rigid helix into the CT domain through residue W258. L253, I257, and W258 comprise a hydrophobic patch expected to be at one face of this α -helix. L253 is shown in this helix. Upon activation (b), JAK2 transphosphorylates its partner JAK2 molecule, which in turn phosphorylates the partner EPOR CT domain tyrosine residues. Phosphorylation sites are marked as red circles. Insertion of one alanine residue prior to L253 (c) rotates the putative transmembrane α -helix by 109° , causing a change in the “register” of the hydrophobic patch. In this case, EPO is capable of inducing JAK2 phosphorylation; however, tyrosine phosphorylation of the EPO CT domains does not occur. Insertion of three alanine residues prior to L253 (d) restores wild-type activity to the EPOR. A three-alanine insertion restores the “register” of the hydrophobic patch, as the helix is rotated by 327° [26].

to the same level as the wild-type protein. Furthermore, it is not the increase in distance ($\approx 5 \text{ \AA}$) from the transmembrane domain (corresponding to one turn of helix) that alters JAK2 activity; instead, variation in the relative orientation of the LIW patch is crucial for proper signal response to EPO. Further insertion of two alanine residues in the TM region confirmed the predicted secondary structure of a continuous rigid helix from the TM through the Trp258, as a two amino-acid insertion restores the register of the LIW hydrophobic patch (Fig. 3b). Sequence alignments reveal that the hydrophobic nature of these three residues is conserved throughout nine other members of the cytokine receptor superfamily. Furthermore, the spacing of these residues relative to each other and their distance from Box 1 are strictly conserved, even though their distance from the membrane varies [26].

Two alternative models can explain the possible mechanisms of activation by cytokines and growth factors (Fig. 3a). For EPOR, the evidence is consistent with the unliganded EPOR existing as a preformed dimer on the cell surface in an “inactive” state and that binding of EPO *in vivo* causes a conformational change that is propagated through the membrane to the cytosolic domain. In addition, the relative orientation of the receptor is critical for signal generation, again consistent with the distinctly different agonist and antagonist structures. This ligand-dependent structural reorganization allows for interaction of JAK2, thereby eliciting a signaling cascade.

Other Cytokine Receptor Superfamily Members

While all cytokines exert their initial signaling response by way of forming active transmembrane receptor complexes on the cell surface, it is unclear whether preformed dimers are the prototype for all members of the cytokine receptor superfamily. The crystal structures of GH–GHR [8] and the ovine placental lactogen (oPL) bound to the extracellular domain of the prolactin receptor (PRLR) [27] reveal a 1:2 stoichiometry similar to that of the EPO–EBP structure. To date, no structures are available for the extracellular domains of these receptors in their unliganded form. Studies of GH mutants infer that GH binds to a monomeric GHR and then forms a stable complex with a second GHR [7] (Fig. 3a); however, the possibility that GH binds to a preformed GHR dimer and alters its conformation is also not inconsistent with these data. The nonsymmetrical nature of the PRLR receptors in the dimerized complex reveals a large amount of flexibility between the N- and C-terminal receptor domains, suggesting a possibility of domain orientation change in response to binding.

The crystal structure of GCSF bound to the cytokine receptor homologous region of the GCSF receptor, denoted gs-CRH, has been determined [28]. This structure shows two 1:1 complexes in the asymmetric unit related by a pseudo two-fold axis of symmetry, resulting in a 2:2 stoichiometry in the crystal structure. The GCSF ligand binds in a different mode than that of the previously described structures. Although the individual components in each of the 1:1 complexes are essentially

identical, differences in the ligand receptor interfaces, as well as the relative orientations between the N- and C-terminal domains, are substantial. Thus, it is possible to extrapolate that the two different interfaces between GCSF and the N-terminal gs-CRH induce a slight difference in the orientation angle with the C-terminal domain, which may propagate an altered signal response. This structure may reveal one stage in the sequential formation of an active complex [28].

The notion of preformed dimers on the cell surface is not solely associated with the cytokine receptor super-family. The epidermal growth factor (EGF) plays important roles throughout development including cell proliferation, differentiation, and survival of multicellular organisms [29]. The EGF receptor (EGFR) is a member of the growth factor receptor tyrosine kinase family. Using chemical cross-linking experiments and sucrose density-gradient centrifugation, experiments have demonstrated that EGFR forms a dimer in the absence of bound ligand [30]. A “flexible rotation” model was proposed for EGFR activation in which the binding of EGF induces rotation of the juxtamembrane domain and, accordingly, the transmembrane domain. Consequently, the dimeric intracellular domains dissociate, allowing for the catalytic kinase domains to become accessible to their substrate tyrosine residues.

Earlier studies on the tumor necrosis factor receptor (TNFR), a member of the nerve growth factor receptor family, also revealed the potential existence of preformed dimers. The unliganded TNFR crystal structure, determined at 2.25 \AA resolution, reveals that two types of dimers, parallel and anti-parallel, exist in the crystal lattice. Both dimer interfaces bury a high amount of surface area and are stabilized by large numbers of van der Waals and ionic interactions and, therefore, are thought to be biologically relevant [31]. These studies propose a model in which the TNFR, in its unliganded form, exists as the anti-parallel dimer with the cytoplasmic domains of each receptor in the pair separated by over 100 \AA . Although the ligand-bound TNFR structure shows a 3:3 stoichiometry [32], in light of the EPOR studies discussed here, the unliganded TNFR dimer may indeed be biologically relevant.

Conclusions

Members of the cytokine receptor superfamily undergo major conformational reorganizations in order to respond to ligand binding and elicit appropriate signal activation. In each member of the family, strict regulation is important for specific response to the signaling molecule, and aberrant signaling can have considerable medical consequences. Studies on EPOR have led to a greater appreciation of the subtleties of receptor activation. The variety of ligands capable of binding to a single interface of the receptor is a consequence of slight variations of loops and side chains on the receptor surface. Furthermore, each of these bound ligands is capable of eliciting a different signal response by propagating slight changes in the orientations of the cytoplasmic domains of

the receptors through the membrane. The knowledge gained from the structural data permits the further design of peptide mimetics and small molecules. These future advances not only may help to further our understanding of the intricacies of the cytokine receptor signaling but also may have direct applications for clinical use.

A New Paradigm of Cytokine Action Revealed by Viral IL-6 Complexed to gp130: Implications for GCSF Interaction with GCSFR

Introduction

The gp130–cytokine system has been the subject of extensive protein structure–function studies aimed at elucidating the basis of ligand recognition and receptor activation. A longstanding question has been the architecture of the higher order signaling assembly. It is clear from functional studies that the paradigm of gp130–cytokine recognition will differ substantially from the classical homodimeric systems typified by human growth hormone and its receptor. Recently, the crystal structure of a viral interleukin-6 (IL-6) complexed with the D1, D2, and D3 domains of the gp130 extracellular domain has reconciled much of the functional and mutagenesis data that exist for a variety of gp130–cytokine systems. The topology of the viral IL-6–gp130 assembly also appears to satisfy the structural requirements of an analogous signaling complex of granulocyte colony-stimulating factor (GCSF) and its receptor. A previous crystal structure of an “inactive” form of this complex can be supplanted by a new model incorporating known functional data implicating the N-terminal immunoglobulin (Ig)-like domain of the GCSF receptor as the key to assembling an interlocking tetramer, as seen in gp130–cytokines.

Receptor/Ligand Interactions

Although many different cytokine systems exist, a relatively restricted set of topological solutions is utilized by the different families to assemble higher order signaling complexes. The most basic building block is the interaction of the cytokine helical faces with the receptor cytokine-binding homology regions (CHRs), as typified by the human growth hormone (hGH) and erythropoietin (EPO) examples, among others [1–5]. This interaction is a universally conserved recognition module that is then utilized in different geometries by various cytokine systems. The majority of cytokines require hetero-oligomerization of cytokine-specific receptors with shared signal-transducing receptor(s) [6], so the structural basis of receptor activation is quite different from the simpler homodimeric systems.

The gp130 System

The gp130–cytokines, also referred to as the IL-6 family, encompass the largest group of cytokines, which utilize shared receptors in hetero-oligomeric signaling complexes [7].

gp130 is a signal-transducing receptor shared by IL-6, Kaposi's sarcoma herpesvirus (KSHV) (viral) IL-6, IL-11, ciliary neurotrophic factor (CNTF), cardiotrophin (CT-1), leukemia inhibitory factor (LIF), oncostatin (OSM), and NNT-1/BSF3. The extracellular domain of gp130 is approximately 597 amino acids, which is divided into five fibronectin type III (FN-III) domains plus a sixth N-terminal domain that appears to be Ig-like. Cytokine engagement by the gp130 extracellular region occurs through three membrane-distal, β -sheet sandwich domains (D1, D2, D3)[8]. The gp130 CHR resides at D2/D3, but gp130 requires an additional N-terminal (D1) Ig-like activation domain (IGD) in order to be functionally responsive to cytokine. The structure, role, and disposition of this IGD in recognition and activation were not known until recently [9]. Exhaustive mutagenesis of gp130–cytokines (particularly IL-6) indicates that the locations for sites 1 and 2 are analogous to those of the hGH and EPO examples, except that site 1 (located on the B and D helices) is recognized by the α -receptor, and site 2 (located on the A and C helices) is recognized by the gp130 CHR to form the heterotrimeric IL-6– $R\alpha$ –gp130 complex (1:1:1) [10].

A transition to a higher order, hexameric (IL-6– $R\alpha$ –gp130; 2:2:2) signaling assembly is a defining feature of gp130–cytokines and is mediated through a functional interaction between the unique third receptor-binding epitope (site 3, located at the tip of the four-helix bundle on the A/B loop and end of D helix) and the gp130 activation domain (D1 or IGD) [11–15].

Viral Interleukin-6

Kaposi's sarcoma herpesvirus (KSHV, or HHV8) is a recently discovered γ herpesvirus that is a likely causative factor for the development of Kaposi's sarcoma, as well as other neoplastic diseases associated with Kaposi's sarcoma [16]. KSHV encodes a functional homolog of interleukin-6 (vIL-6) that has an $\approx 22\%$ sequence homology to human IL-6. A striking feature of vIL-6 is that it has bypassed the human IL-6 (huIL-6) requirement for an α -receptor ($R\alpha$) to activate gp130; vIL-6 directly activates gp130 on cells that do not express an $R\alpha$ [17]. Therefore, vIL-6 is an $R\alpha$ -independent version of IL-6 and would then be predicted to form a tetrameric complex (2:2, 2 vIL-6 to 2 gp130) [9].

GCSF and GCSFR

Granulocyte colony-stimulating factor is a cytokine of the long-chain, class I type that is a growth factor for the differentiation and maturation of neutrophilic granulocytes. Like gp130, GCSF receptor (GCSFR) is composed of six domains subdivided into an N-terminal IgD and five FN-III domains that show an overall sequence homology of 46% [18]. The GCSFR CHR is located at the D2 and D3 domains. A site 2 has been mapped for GCSF interaction with the

GCSFR CHR that is analogous to the gp130–cytokine site 2 that is located on the A and C helices [19,20]. However, like gp130–cytokines, the GCSFR N-terminal IgD is required for activation [18], but the identity of a *bona fide* GCSF site 3 has been elusive [21]. The stoichiometry of the GCSF–GCSFR complex has been experimentally determined to be 2:2. Hence, because GCSF does not have an $R\alpha$ as found for many gp130–cytokines, it has strong analogy to viral IL-6, which also lacks an $R\alpha$ and forms a 2:2 complex.

Structure of the Viral IL-6–gp130 Complex

The structure of the complex assumes a novel “hammock-like” configuration containing a tetrameric arrangement of two vIL-6 molecules and two human gp130 receptors (approximate dimensions $95 \times 56 \times 65 \text{ \AA}$) (Fig. 1A) [9]. The complex is tethered together through the interaction of one face of vIL-6 (site 2) with a gp130 CHR (D2 and D3) and by a second epitope (site 3) at the tip of the vIL-6 four-helix bundle interacting with the IGD (D1) domain of a gp130 different from the other half of the tetramer (Fig. 1). It is clear from this structure that the D1 domain is essential for the formation of the activated, interlocking, higher order assembly. As seen from the top, the overall configuration results in a large hole in the middle of the complex ($\approx 16 \times 45 \text{ \AA}$), a spacing likely critical for the gp130 extracellular domains to orient the intracellular domains correctly for signal propagation (Fig. 1B). The macromolecular architecture of the vIL-6–gp130 tetramer is novel for cytokine–receptor complexes and represents a previously unseen mode of receptor activation mediated by the IGD [9].

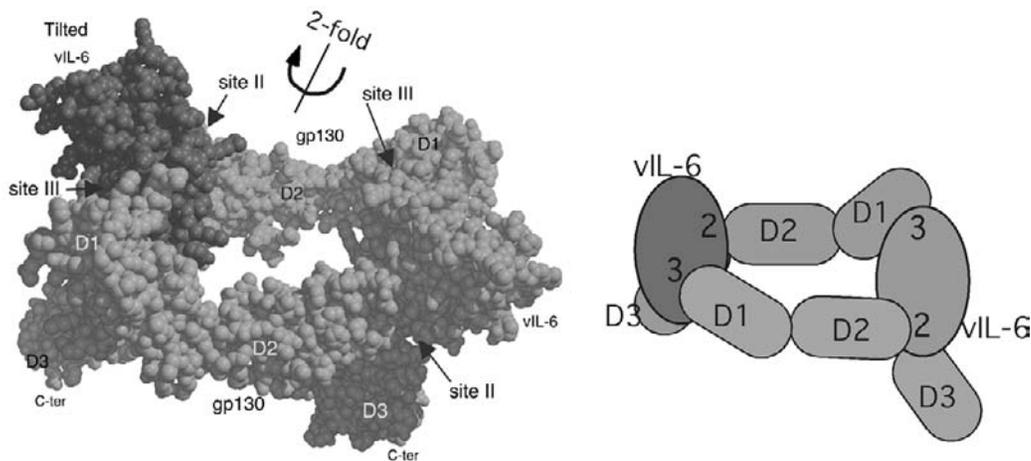

Site 1

The classical site of interaction of α -receptors with gp130–cytokines is known as site 1 and has been mapped to the faces of the B and D helices [10,22]. Because vIL-6 action can be independent of $R\alpha$, it is not required for crystallization of the complex with gp130 [9]. However, by analogy with human IL-6, the location of site 1 is clear. The outward helical face of vIL-6 (B and D helices), where huIL-6 would interact with $R\alpha$ (site 1), is unoccupied (Figs. 1A and B) but openly accessible in the complex.

The Site 2 Interface

The site 2 contact surface between vIL-6 and the gp130 CHR is primarily composed of hydrophobic interactions between the vIL-6 A and C helices and the C/D and E/F loops of the gp130 D2 domain and B/C loop of the D3 domain (Fig. 1A). An exquisite shape complementarity exists between the cytokine and receptor, in which the protruding gp130 “elbow” fits into a slot in a diagonal

A Viral IL-6/gp130 tetramer

B Architecture of vIL-6/gp130 tetramer (top view)

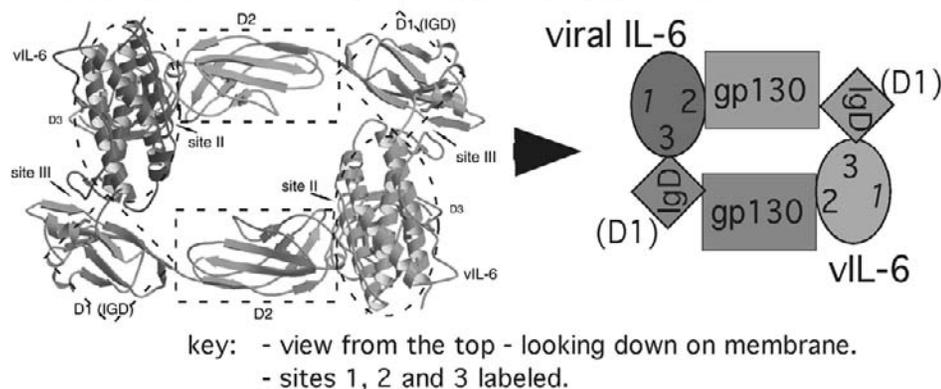

Figure 1 Crystal structure of viral IL-6 in complex with the gp130–D1, D2, D3 [9]. (A) Tilted space-filling view where all domains are in view. Note the large hole in the middle of the tetramer. For clarity, a schematic drawing of this orientation is shown to the right. (B) Ribbon drawing of a top view of this complex, looking down on the membrane. A schematic drawing of the top view, with identical domain coloring as the ribbon figure, is shown to right. In this orientation, the D3 domains are underneath the cytokines and therefore are not visible.

groove on a concave face of vIL-6 created by the crossing angles of the A and C helices. This knob-in-hole packing likely underlies the site 2 recognition mode across all gp130–cytokines.

The Site 3 Interface

The gp130–cytokines possess a third, or site 3, functional epitope that is necessary for receptor activation, but the nature of its interaction with gp130 is unclear [22]. In the structure of the vIL-6–gp130 complex, the site 3 interaction is comprised of an extensive interface between the tips of the vIL-6 four-helix bundle (A/B loop and start of the D-helix) and the edge (GF strands) of the upper three-stranded β -sheet of the gp130 IGD (D1) (Fig. 1B). The complementary shape of the interface is formed by the convex torpedo-like tip of vIL-6 resting in a concave depression formed by the curvature of the upper D1 β -sheet.

Implications of the vIL-6–gp130 Tetramer Structure for the Active GCSF–GCSFR Extracellular Signaling Complex

A crystal structure has been reported for GCSF in complex with the CHR (domains 2 and 3; also called the BN and BC domains, respectively) of the GCSFR (Fig. 2A) [2]. The structure revealed both expected and unexpected results. The complex is a 2:2 tetramer, with each GCSF molecule interacting with each receptor through the canonical site 2 epitope (also called major interface) on the face of the A and C helices (Fig. 2A) [2]. However, the unexpected result was that the two GCSF/GCSFR complexes formed a “side-by-side” dimer mediated by an interaction between the D3 (BC) domain and the N terminus of GCSF (or, minor interface) (Fig. 2A). The minor interface was not expected, as this interaction was not detected in previous structure–function studies. However, because the overall complex in the crystal was 2:2, a case was

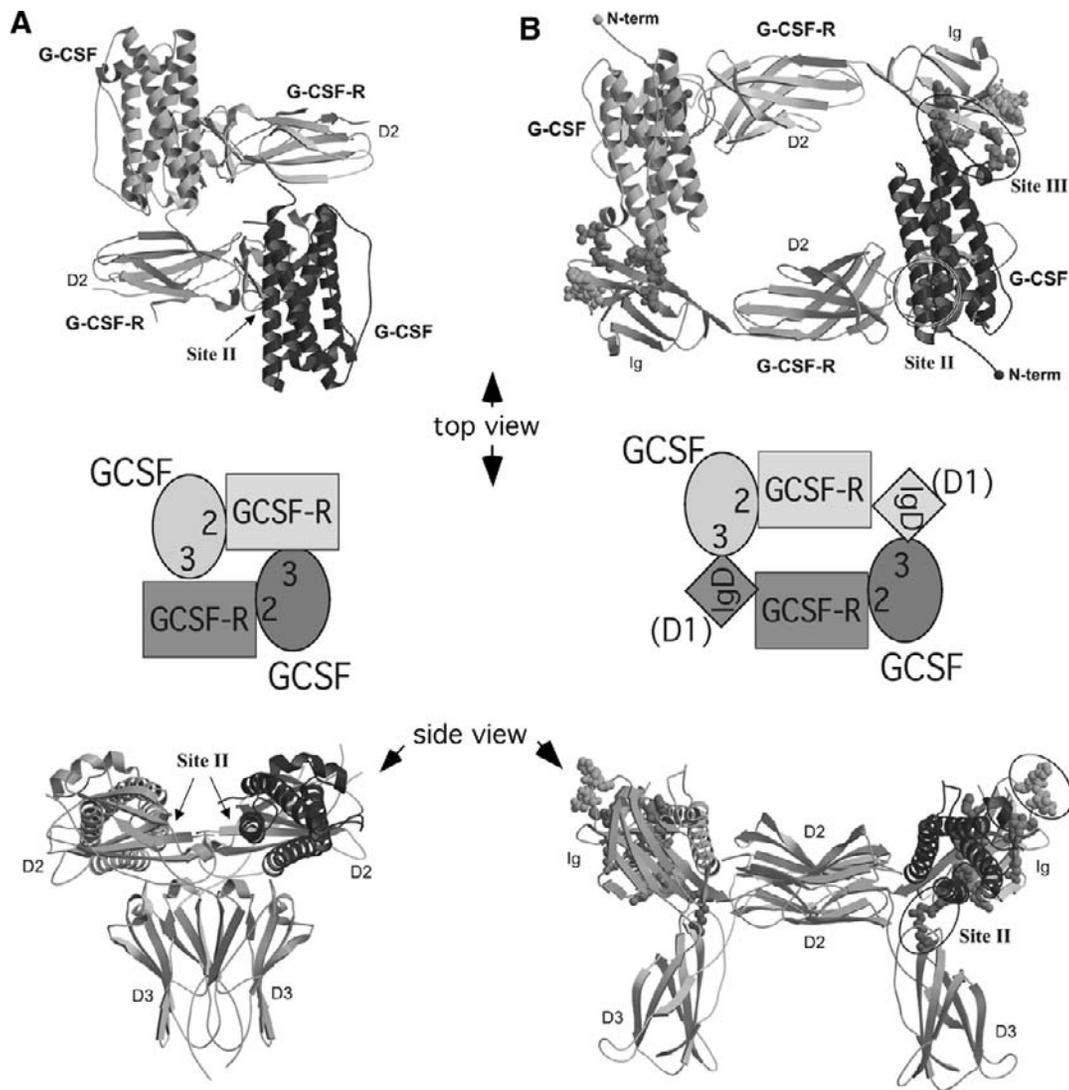

Figure 2 Inactive and active models of GCSF complexed to GCSFR. (A) Top view of the crystal structure of GCSF complexed to the GCSFR D2 and D3 domains as reported by Aritomi *et al.* [2]. Underneath the ribbon drawing is a schematic showing the assembly in the same orientation as the top view. At the bottom is a ribbon diagram of the structure shown from the side. (B) Hypothetical model of the active GCSF-GCSFR complex based on the viral IL-6-gp130 tetramer [9,21]. The D1 domain of GCSFR is included in the model and is shown interacting with site 3 of GCSF from epitope mapping studies (residues in space filling) [21]. A schematic in the middle shows the assembly in the same top-view orientation as in part (A). At the bottom is a ribbon drawing of a side view of the GCSF-GCSFR tetramer model.

made for this assembly representing the active signaling complex even though the GCSFR was missing the N-terminal domain known to be required for signaling[2].

Layton *et al.* [21] undertook an epitope mapping study that placed the elusive GCSF site 3 at the identical location found for gp130-cytokines (Fig. 2B). Further, these authors constructed a molecular model for the active GCSFR signaling complex (D1, D2, D3) based on the structure of the viral IL-6-gp130 tetramer (Fig. 2B). The model satisfies functional data for GCSF and is essentially identical to the vIL-6-gp130 framework, where site 2 on the A/C face and site 3 at the end of the D-helix enables formation of an interlocking tetramer (Fig. 2B). Thus, the utility of spatially distinct functional epitopes on both cytokine and receptor for assembling an interlocking dimer has been repeated in a distinct cytokine system.

The Fibroblast Growth Factor (FGF) Signaling Complex

Fen Wang and Wallace L. McKeehan

Institute of Biosciences and Technology,
Texas A&M University System Health Science Center,
Houston, Texas*

Introduction

The fibroblast growth factor (FGF) signaling system is a ubiquitous cellular sensor of local environmental changes and mediator of cell-to-cell communication with broad roles in development and organ homeostasis in the adult. Through the interaction of heparan sulfate (HS) with both activating FGF polypeptides and transmembrane FGF receptor (FGFR) tyrosine kinases, the system is rigorously modulated by tissue architecture. Diversity and cell and tissue specificity of signaling result from the combinatorial oligomerization of a family of 23 FGF homologs, diverse oligosaccharide motifs within HS chains of proteoglycans, and a plethora of ectodomains resulting from splice variations from four genes coding for four intracellular tyrosine kinases.

FGF Polypeptides

Fibroblast growth factor homologs are single heparin-binding polypeptides sharing a homologous core split by areas of less homology [1,2]. The heparin-binding property reflects the intimate association of the polypeptides with HS chains of proteoglycans in the extracellular matrix. The core sequence is flanked by unique N- and C-terminal sequences. N and C termini of the homologous core are important in receptor and HS interactions, and the unique N terminus outside the core is important in the fine structural arrangements of the oligomeric FGFR signaling complex [3,4]. Most FGFs are translated with a conventional secretory

signal peptide at the N terminus; however, FGF1, FGF2, and several other homologs are not, although they appear in the external environment. This has fueled interest in novel mechanisms of FGF exit from cells as well as intracellular signaling [5]. Of the 23 homologs, the structures of FGF1, FGF2, FGF4, FGF7, and FGF9 have been determined. Crystal structures indicate that the FGFs share a remarkably similar three-dimensional structure characterized by a conserved hydrophobic patch that interacts with FGFR and a unique heparin-binding surface that differs dramatically among FGFs [6]. Functional analysis by site-directed mutagenesis indicates that heparin binding, FGFR binding, and biological activity are intimately associated [2,6,7]. The specificity of an individual FGF is likely determined by a composite of the unique heparin-binding domain and side-chain interactions with the ectodomain of a specific oligomeric HS-FGFR tyrosine kinase complex.

FGFR Tyrosine Kinases

FGFs elicit activity through activation of transmembrane FGF receptor tyrosine kinases in partnership with HS proteoglycans. The FGFR monomer is composed of a single polypeptide chain that has a glycosylated extracellular ligand-binding domain, a transmembrane domain flanked by juxtamembrane sequences, and an intracellular tyrosine kinase followed by a C-terminal domain (Fig. 1). The intracellular juxtamembrane region may be a determinant of conformational activation and interaction of the intracellular domain

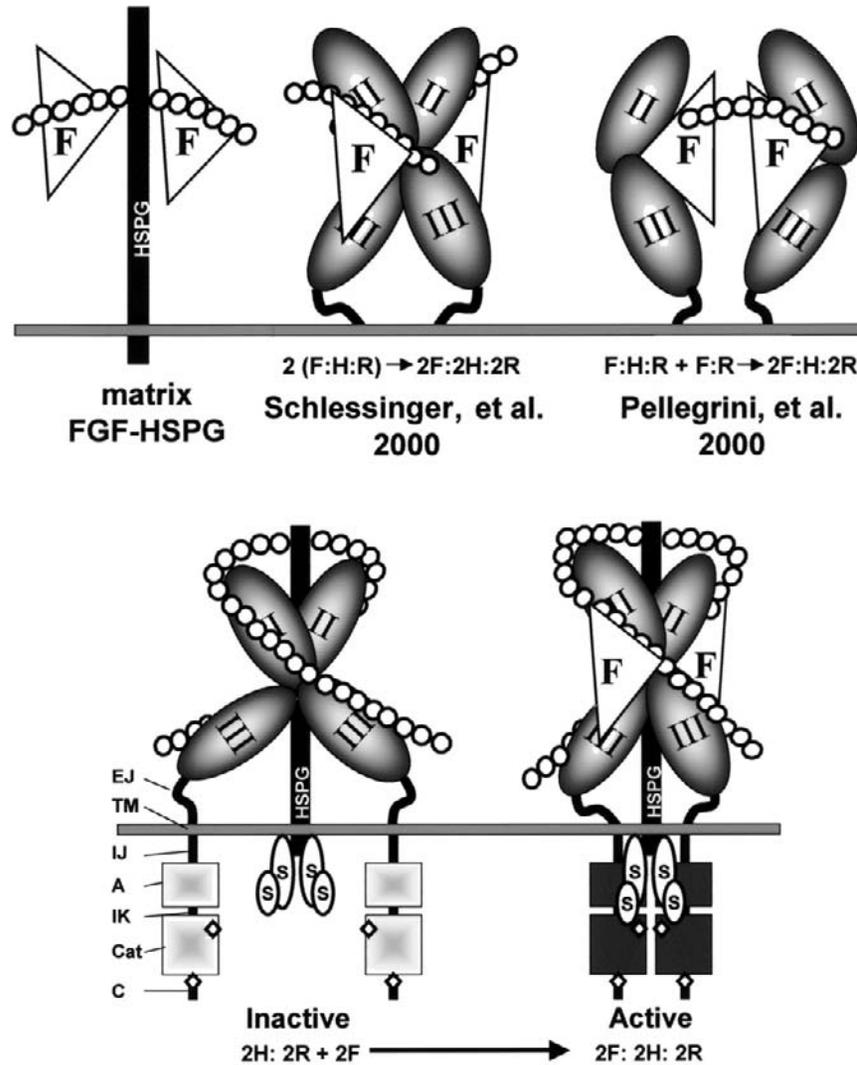

Figure 1 Models of the FGFR signaling complex. Independent binding of FGF to matrix heparan sulfate chains of a membrane-anchored proteoglycan (HSPG) in both orientations confirmed by crystal structures of heparin–FGF complexes is indicated. Also shown are the two divergent models of active dimeric complexes of heparin oligosaccharide (H) (open circles), FGFR (R) comprised of Ig modules II and III, and FGF (F), with the order of assembly proposed by the authors. At the bottom, an alternative conformational model in membrane context is depicted. EJ, extracellular juxtamembrane; TM, transmembrane; A, kinase ATP binding domain; IK, interkinase domain sequence; Cat, kinase catalytic domain; C, C-terminal sequence; S, membrane-anchored FGFR kinase substrates. Functional tyrosine phosphorylation sites are indicated by diamonds.

with membrane-bound substrates [4]. C-terminal to the intracellular juxtamembrane domain is the relatively conserved tyrosine kinase sequence domain comprised of adenosine triphosphate (ATP) binding and catalytic subdomains. Within the kinase domain is a kinase repression/derepression regulatory sequence containing two of the three functional tyrosine autophosphorylation sites [2,8,9]. Extending from the C terminus of the kinase domain is a less-conserved region among the four FGFRs containing a third functional tyrosine autophosphorylation site.

The extracellular domain of the transmembrane FGFR kinase consists of two or three immunoglobulin (Ig)-like modules. Ig module II or III of FGFR independently binds heparin or HS, and, in complex with affinity-selected

heparin or HS, independently binds an FGF [2,10,11]. Heparin–module II complexes bind a wider spectrum of FGFs than Ig module III–heparin complexes [10,11]. However, only one FGF binds to a monomeric ectodomain composed of Ig modules II and III [3,4,10,12]. Ig modules II and III cooperate both within monomers and across dimers with cellular HS to confer specificity for FGF [2,3,12]. The FGFR forms ligand-independent dimers or higher order oligomers on the cell surface that are dependent on the sequence between Ig modules II and III [13]. A highly conserved sequence domain rich in basic amino acids within the N terminus of Ig module II is required for the interaction with heparin and HS [3,14]. Mutations in this domain significantly affect both heparin and FGF binding

and activities of the FGFR complex [14]. N-terminal to Ig module II is an alternatively spliced sequence rich in serines and acidic residues called the *acidic box*. When present, alternatively spliced Ig module I modifies the affinity for both heparin and FGF [15]. The exon coding for the acidic box sequence is always included whenever Ig module I is present. The acidic box sequence between Ig modules I and II may be a structural requirement as well as a functional element that contributes to reduction of affinity for both HS and FGF by Ig module I [3,15].

Heparan Sulfate

Pericellular matrix HS participates in rigorous control of the FGFR signaling system at multiple levels exceeding anticoagulation in complexity and impact on biological processes. The independent interaction of matrix HS with FGFs affects location and trafficking within tissues, access to the FGFR signaling complex, and lifetime and stability by protection against proteases [2,6]. Structure–function analyses and co-crystal structures of FGF1 and FGF2 with heparin oligosaccharides indicate that the heparin-binding domain of FGF is a composite domain contributed by distal sequence residues and formed by secondary and three-dimensional structures [6,16]. Of the 23 FGF homologs, only co-crystal structures of FGF1 and FGF2 with heparin oligosaccharides have been determined. Although a variety of carbohydrate-like electrolytes interact, affinity purification and structural analysis indicate that a hexameric heparin oligosaccharide exhibiting at least 2-O sulfation and both 2-O and 6-O sulfation is required for highest affinity interaction of heparin oligosaccharides to FGF2 and FGF1, respectively [2,6,17]. Crystal structures of FGF4, FGF7, and FGF9 have also been determined, but attempts at co-crystallization with simple 2-O and 6-O sulfated 6- to 12-mer oligosaccharides have failed [6]. Differing heparin-binding domains suggest specific requirements in respect to composition and length of interactive oligosaccharide [6]. As predicted by the unique heparin-binding domain of FGF7 relative to FGF1 and FGF2, a longer heparin oligosaccharide that exhibits anticoagulant activity and the presence of a 3-O sulfate is required to interact with and protect FGF7 against protease [6].

In the absence of FGF, the FGFR ectodomain forms a binary complex with heparin with a K_d of 10 nM that is competent to bind FGF in the absence of additional heparin or cellular HS [2,10,18–20]. The strict dependence of FGF binding on heparin/HS and the high-affinity formation of a functional, specific complex of FGFR with heparin/HS requires the presence of extracellular concentrations of divalent cations [18]. Similar to FGF7, only the fraction of heparin or HS that binds to antithrombin and has anti-Factor Xa activity (anticoagulant heparin/HS) exhibited functional high-affinity binding to FGFR in the absence of FGF [6,20]. An antithrombin-binding species of syndecan-1 from pre-malignant prostate epithelial cells, for which the HS chains form a binary complex with isolated recombinant FGFR1 Ig

module II, is rare and present at an estimated 10,000 molecules per cell [21]. The independent and specific interaction of heparin and HS with the FGFR ectodomain protects it against proteolysis, stabilizes it, and may represent the composite complex into which FGF binds [2,14,18,19]. A partnership between the FGFR isotype and the rare and specific HS that binds FGFR from mixtures determines the specificity of a binary complex for a particular FGF [2,10,19,22].

Oligomeric FGF–FGFR–HS Signaling Complex

It is generally agreed that the activity, or access to substrates, of the FGFR tyrosine kinase is repressed by a flexible structural domain for which tyrosine phosphorylation by a neighboring FGFR kinase within a dimer or higher order oligomer releases the repression [2,9]. Still unclear are the order of assembly; the stoichiometry; the conformation of the inactive and active complexes of FGFR ectodomains, HS chains, and FGF; and how the interactions are transmitted to promote intracellular kinase–substrate interactions. A monomeric unit of the FGFR complex is generally agreed to be a composite ternary complex of one FGF, one FGFR, and one heparin/HS chain in which the sugar chain in a specific orientation concurrently interacts with heparin-binding domains from both FGFR and FGF [2,3,12]. However, prediction of how monomeric units come together to transactivate the intracellular kinases is complicated by models from dimeric crystal structures derived from the same FGF, FGFR ectodomain, and artificial heparin-derived oligosaccharide in which the second unit of the dimer is fundamentally different [3,12] (Fig. 1). One structure suggests a symmetrical complex that arises from back-to-back interaction of two identical ternary complexes of FGF, FGFR, and heparin/HS [3]. This dimer, consisting of FGF, FGFR, and heparin/HS with stoichiometry of 2:2:2, is stabilized by secondary interactions between FGF in one ternary unit and FGFR in the other unit, FGFR–FGFR contacts, and each heparin chain that spans both FGFRs. Another structure [12] suggests that the ternary complex of FGF, FGFR, and heparin/HS recruits a second complex of FGF and FGFR through the single chain of heparin/HS. The heparin/HS chain binds asymmetrically to an FGF bound independent of heparin/HS to a second FGFR. The net result is a heteropentameric complex with overall stoichiometry of two FGFs to two FGFRs to one heparin/HS chain, with minimal direct contacts between the two face-to-face FGFRs. The dimeric complex is stabilized simply by the sugar chain bridge between one ternary unit and FGF bound to the second unit. In both models, sustained derepression of the active sites of the monomeric FGFR kinases by transphosphorylation was proposed to be limited by the concentration and distance of both ecto- and intracellular domains (full-length FGFR), which can be overcome in the two-step dimerization reaction stabilized by both HS and FGF. The basis for the widely divergent crystal structures among the same three subunits is unclear. The differences are likely a consequence of the artificial and simple

sulfated heparin oligosaccharides available for crystallization studies, sensitivity of specific heparin interactions with FGF and FGFR to electrolyte conditions, and difficulty in dissection of specific and nonspecific interactions among heparin, FGFR, and FGF at high concentrations of the heparin polyelectrolyte.

An alternative model of the oligomeric FGFR signaling complex that unifies biochemical, structural and functional data to date has been proposed [2,4,10,18–20]. This model proposes a preexisting, inactive, unliganded complex of two FGFR ectodomains interacting back-to-back upstream of Ig module III while anchored to a proteoglycan core through two HS chains. HS chains interact with a primary heparin-binding domain on Ig module II and extend across the dimer to interact with Ig module III on the adjacent partner (Fig. 1). Specific functional HS binding to FGFR in contrast to nonspecific electrolyte interaction is divalent cation dependent and requires rare oligosaccharide motifs properly spaced within the HS chain. Divalent cations and HS cooperate in the ectodomain to conformationally restrict the kinase–substrate relationship between intracellular domains and maintain dependence of activity of the complex on the binding of FGF or other perturbations of the external matrix HS–FGFR relationship [2,18]. Docking of activating FGF into composite sugar–protein sites formed by Ig modules II and III of the preexisting inactive complex or other perturbations of the FGFR–HS relationship is transmitted to the intracellular kinase domains to overcome conformational restrictions that limit activity and access to substrates. Transmission of conformational change across dimers and to the intracellular juxtamembrane and ATP binding site of the kinase is enhanced by the bivalent contact of FGF with both FGFRs within the dimer [4]. In this model, HS chains of matrix proteoglycans play a central role in negative control of preexisting unliganded kinase complexes, the requirement and specificity for FGF, the cell context specificity of FGF signaling, and integration of signaling with tissue matrix remodeling.

Intracellular Signal Transduction by the FGFR Complex

Despite its ubiquity and broad spectrum of biological activities, there are large gaps in our knowledge of how the FGFR kinases access substrates, activate them, and transmit extracellular changes to intracellular signal pathways. Up to seven phosphorylated tyrosines in the FGFR intracellular domain have been reported, but only three or possibly as few as two sites that are conserved among the four FGFR have been clearly linked to repression/derepression of kinase activity and interaction with a substrate [2,8]. Among the autophosphorylation sites, tyrosine 653 and possibly 654 in concert are important for derepression of the FGFR1 kinase. Autophosphorylated Tyr766 in the COOH terminus interacts directly with phospholipase C γ (PLC γ) through its SH2 domains and is required for PLC γ phosphorylation and

pathways connected to it [8]. However, Tyr766 and the activation of PLC γ appear to be dispensable for FGFR1-elicited cellular responses, including mitogenesis, neuronal differentiation, mesoderm induction, induction of urokinase-type plasminogen activator, and chemotaxis. Although Tyr766 is not essential for the mitogenic activity of the FGFR, it is required for the age-dependent acquisition of the proliferative response to FGFR1 and FGFR1-dependent activation of the MAP kinase signaling pathway in premalignant epithelial cells [23].

The activation of the MAP kinase signaling pathway has been implicated in most FGFR1 responses studied to date. Phosphorylation of one or more membrane-anchored SUC1-associated neurotrophic factor (SNT) (also called FRS2, for FGF receptor substrate 2) proteins by the FGFR1 kinase recruits and activates the GRB2/SOS1 complex that then interacts with *ras* to activate the MAP kinase signaling pathway [24,25]. The quantity and quality of phosphorylation of SNT1 are both FGFR isotype and cell type specific [26]. Similar to FGF and HS specificity and specific structural arrangements within the extracellular domain of FGFR oligomers [2,4,10,13], the differential phosphorylation of SNT1 by FGFR appears only to occur in intact cells and is dependent on cell membrane context [26]. The differential phosphorylation of SNT1, both in quality and quantity, may be involved in determination of the signaling specificity of FGFR isotypes. Cell membrane and cytoskeletal context likely determine FGFR isotype- and cell-type-specific conformational relationships between the FGFR kinases and intracellular membrane-anchored substrates, just as they determine relationships among the FGFR ectodomain, matrix HS, and FGF.

The kinase domains of the four FGFR isotypes exhibit greater than 80% homology [2]. In some systems, the four FGFR isotypes elicit similar and redundant effects on cell responses and activate similar downstream signal transducers [27–30]. In others, individual isotypes exhibit dramatically different effects on cell phenotype, some of which are in opposition. The quantity of or sustained signaling from a single isotype can also affect quality of the response. For example, although FGFR1 and FGFR3 intracellular domains appear redundant in eliciting neurite outgrowth in PC12 neural cells [30], only the FGFR1 kinase elicits neurite outgrowth when the FGFR ectodomain is utilized [31]. The FGFR3 kinase failed to sustain outgrowth and Ras-dependent gene expression, but instead induced neural-specific gene expression pathways that were Ras independent [32]. In bladder [33], prostate [34,35], and salivary tumor epithelial cells [36], the resident FGFR2 kinase promotes homeostasis and suppresses the tumor phenotype. This is in contrast to ectopic FGFR1 that appears in malignant tumors. The appearance of FGFR1 in premalignant epithelial cells initially does not drive malignancy and activate signaling pathways associated with tumor phenotype. However, chronic activity over time causes activation of pathways that promote tumor progression and support the malignant state [23,34]. For more details on the role of the FGF family in specific biological systems and the diverse

signaling pathways perturbed by the FGF signaling system, readers are referred to specialized reviews [1,2,24–25,37,38].

Structure of IFN- γ and Its Receptors

Mark R. Walter

*Department of Microbiology and Center for Macromolecular Crystallography,
University of Alabama at Birmingham, Birmingham, Alabama*

Interferon- γ (IFN- γ) is a pleiotropic cytokine that induces antiviral, antiproliferative, and immunomodulatory effects on numerous target cells [1]. These diverse biological activities are initiated by IFN- γ -mediated aggregation of at least two different cell surface receptors: IFN- γ R1 and IFN- γ R2. X-ray crystallographic studies of IFN- γ and its receptors have been undertaken to delineate the molecular architecture of the receptor complexes and to understand the detailed recognition mechanisms that are ultimately responsible for IFN- γ biological responses. Here, these structures are summarized in the context of current biochemical and bioactivity data.

Natural forms of human IFN- γ are comprised of two 143-amino-acid peptide chains that are posttranslationally modified to contain an N-terminal pyroglutamic acid residue, N-linked glycosylation at two positions, and a heterogeneous C terminus containing the positively charged sequence KTGKRKR (residues 125–131). The crystal structure of human IFN- γ has revealed the tight association of two peptide chains (comprised of six α -helices, labeled A to F, from the N to C terminus) into a remarkable intertwined helix topology to form a symmetric dimer (Fig. 1) [2]. As a result, the two-fold related domains of IFN- γ are formed from the first four helices of one chain (A–D) and the last two helices (E' and F') from the other. Despite almost no sequence identity, the identical intertwined topology is also observed in the crystal structure of IL-10 [3]. The α -helices that form each domain are 9 to 21 residues long and are essentially linear (with the exception of helix F, which displays an $\approx 50^\circ$ bend). The helices are connected by short loops of 3 to 5 residues, except for the 13-residue AB loop that encircles helix F. C-terminal residues 124 to 143 extend away from the core of the molecule and are presumed to be flexible.

IFN- γ R1 and IFN- γ R2 are both type I membrane proteins that contain extracellular and cytoplasmic domains connected by a hydrophobic membrane spanning helix. The extracellular domain of IFN- γ R1 binds IFN- γ with high affinity (≈ 1 nM), while IFN- γ R2 exhibits essentially no affinity for IFN- γ . Coexpression of IFN- γ R1 and IFN- γ R2 on cells results in a fourfold increase in affinity for IFN- γ compared to cells expressing IFN- γ R1 alone, suggesting that the IFN- γ R2 binding site is formed from residues on IFN- γ and IFN- γ R1 as presented in the IFN- γ /IFN- γ R1 complex. IFN- γ -induced formation of the biologically active complex of IFN- γ , IFN- γ R1, and IFN- γ R2 activates the Janus kinases (JAK1 and JAK2) that are associated with the cytoplasmic domains. JAK-dependent phosphorylation of the intracellular domain of IFN- γ R1 results in the recruitment of the nuclear transcription factor STAT1 and subsequent expression of IFN- γ -inducible genes [1].

At this time, structural information is only available for the extracellular domain of IFN- γ R1 (sIFN- γ R1) as it exists in complex with IFN- γ (Fig. 1) [4–6]. Based on this work, sIFN- γ R1 is comprised of two fibronectin type III domains (FnIII). The FnIII modules consist of a sandwich of two antiparallel β -sheets made up of seven β -strands: A, B, E, G, F, C, and C'. The N-terminal domain (D1) and the membrane-proximal or C-terminal domain (D2) are oriented at $\approx 120^\circ$ to one another. The IFN- γ binding site is located at the crevice between D1 and D2. Receptor residues that contact IFN- γ are located on five different segments (labeled L2 to L6) that correspond to CC' and EF loops of D1, the domain linker, and BC and FG loops in D2.

In agreement with solution and cell-surface binding studies, the structure of the IFN- γ /IFN- γ R1 complex revealed the

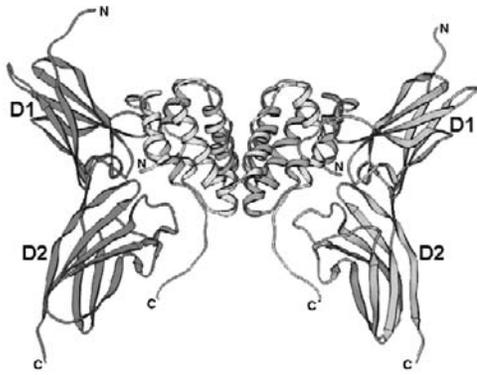

Figure 1 Ribbon diagram of the IFN- γ /IFN- γ R1 receptor complex. The putative position of the cell membrane is at the bottom of the figure. The N and C termini of each molecule are labeled, as well as the D1 and D2 domains of the receptor.

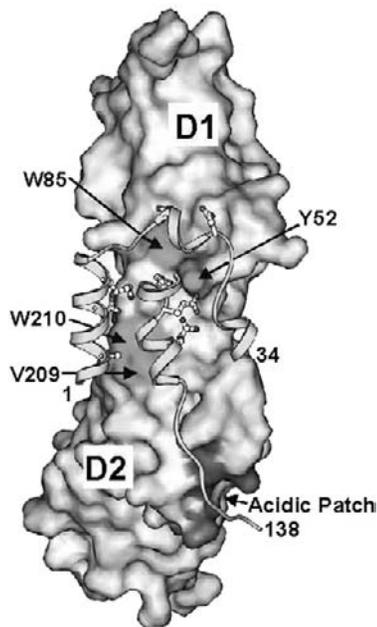

Figure 2 The IFN- γ /IFN- γ R1 interface. IFN- γ R1 is shown as a molecular surface while IFN- γ segments (residues 1–34 and 108–138) that bind IFN- γ R1 are represented by a yellow ribbon. Several IFN- γ R1 residues that participating in important interactions in the interface are labeled by arrows. The sidechains of IFN- γ residues Val-5, Glu-9, Arg-12, Ser-20, Asp-24, His-111, Glu-112, and Gln-115 are shown. The acidic patch located on IFN- γ R1 is labeled, and the predicted interaction with a modeled C terminus of IFN- γ is shown.

symmetric binding of two IFN- γ R1s to one IFN- γ dimer (Fig. 1). The two receptors in the complex do not interact with one another and are separated by about 100 Å at the putative position of the cell membrane. The large distance between the IFN- γ R1s is consistent with the 1:2 complex being an intermediate that is dependent on IFN- γ R2 binding and JAK2 recruitment to initiate the phosphorylation cascade. The two-fold symmetry of the IFN- γ /IFN- γ R1 complex suggests that it contains two binding sites for IFN- γ R2.

The IFN- γ R1 binding site is comprised of IFN- γ residues 1 to 34 from one chain and residues 108 to 123 on the

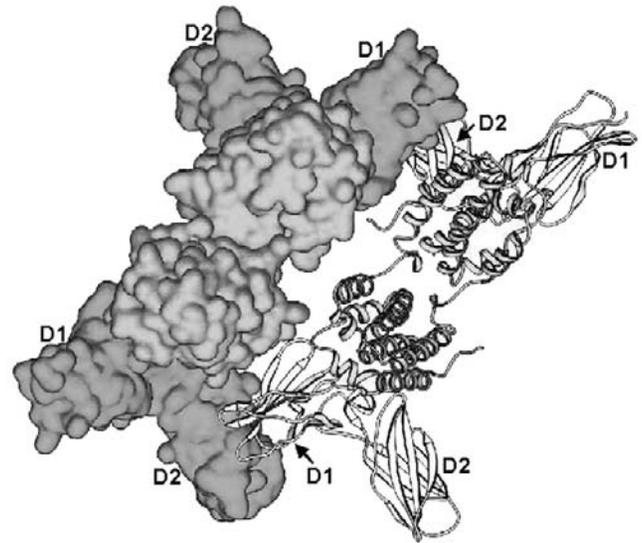

Figure 3 Crystal structure of the 2:4 IL-10/IL-10R1 complex [7]. The view is looking down the two-fold axis of IL-10. The 1:2 IL-10/IL-10R1 complex represented by molecular surfaces is very similar to the IFN- γ /IFN- γ R1 complex shown in Fig. 1. The predicted positions of the IL-10R2s are shown as ribbons. The D1 and D2 domains for each receptor are labeled. This structure provides a possible model for the biologically active IFN- γ /IFN- γ R1/IFN- γ R2 complex.

other (Fig. 2). These residues form a continuous binding site that includes helix A, the AB loop, and helix B from one chain and helix F from the other. More recently, a 2-Å structure of a mutant IFN- γ /IFN- γ R1 complex has revealed additional details of the binding site, including the participation of five ordered waters in the interface and the reassignment of IFN- γ R1 Val-206 to an unfavorable phi-psi value to optimize its interactions with IFN- γ [6]. In all free and bound structures reported to date, the C terminus of IFN- γ that is important for binding and biological activity has not been observed; however, an acidic patch was identified on the receptor that may provide a “Velcro-like” interaction site for the basic C terminus of IFN- γ [4].

Limited sequence identity confirms that IFN- γ R2 is structurally similar to IFN- γ R1; however, the inter-domain angle, receptor binding loops, and binding site cannot be accurately predicted. Currently, the most intriguing model for IFN- γ R2 binding has been proposed from the analysis of the crystal structure of the IL-10/IL-10R1 complex [7]. In solution and the crystals, IL-10 and soluble IL-10R1 form a complex consisting of 2 IL-10 dimers and 4 IL-10R1s (Fig. 3). Structure and sequence comparisons of IL-10 and IFN- γ receptors suggest that high-affinity (IL-10R1 and IFN- γ R1) and low-affinity (IL-10R2 and IFN- γ R2) receptors may share a common binding site on their respective cytokines. The 2:4 IL-10 receptor complex suggests a model for how the low-affinity IFN- γ R2 may simultaneously interact with IFN- γ and IFN- γ R1. This structural model is supported by limited homolog scanning on IFN- γ R1 and radiation inactivation data showing that IFN- γ biological activity requires two IFN- γ dimers [1]. Confirmation of this model will require the structure determination of the IFN- γ /IFN- γ R1/IFN- γ R2 complex.

Structure and Function of Tumor Necrosis Factor at the Cell Surface

Stephen R. Sprang

*Howard Hughes Medical Institute,
University of Texas Southwestern Medical Center,
Dallas, Texas*

Introduction

Among all the members of the tumor necrosis factor (TNF) family, TNF- α and TNF- β are the most pluripotent. TNF- α was first discovered as a factor generated by endotoxin-stimulated macrophages that induces hemorrhagic necrosis of transplanted tumors [1]. TNF- β (lymphotoxin, or LT α) was identified as a lymphocyte-derived cytotoxin [2]. Cachectin, a mediator of fever and cachexia, was shown to be identical to TNF- α (hereafter, TNF refers to both cytokines). Although the systemic toxicity of TNF- α precludes its use in cancer chemotherapy, inhibitors of TNF- α have become important agents in the treatment of certain inflammatory diseases such as rheumatoid arthritis and Crohn's disease [3,4]. The two cell-surface receptors for TNF—TNF-R1 (p55, CD120a) and TNF-R2 (p75, CD120b)—are coexpressed by many types of cells. Stimulation of TNF-R1 induces apoptosis by activation of procaspase 8. The same receptor can induce proinflammatory cell proliferation by activating nuclear factor κ B (NF- κ B) and possibly mitogen-activated protein (MAP) kinases such as p38. TNF-R2 induces proliferation, but not cell death, and appears to be the less potent of the two receptors. The cellular physiology of TNF signaling is discussed in several recent reviews [5–9], and the reader is directed to these for primary references to the TNF literature. (Membrane-proximal events mediated by the TNF receptor (TNF-R) are also described in Chapter 54 of this Handbook.) This chapter focuses on the structural chemistry of TNF–receptor interactions at the cell surface, the state of the receptor before and after engagement with TNF, and the immediate structural consequences of

TNF–TNF-R interactions. Even with this limitation in scope, the author regrets that many significant contributions to the literature could not be acknowledged within this short review.

TNF- α is widely expressed and is the prototypical member of a family that includes at least 19 members. Family members have diverged such that they are only 25 to 30% identical to each other in amino acid sequence [5,8,10]. Like many of its homologs, TNF- α is a type II membrane protein; the human ortholog has a 76-residue N-terminal propeptide composed of a 25-residue intra-cytoplasmic domain followed by a transmembrane sequence. TNF- α is released from the cell surface after cleavage by an extracellular, ADAM family metalloprotease [11]. Secreted and cell-surface TNF- α may play distinct roles in signaling [12]. TNF- β , which is expressed predominantly in lymphocytes, has a normal signal sequence and is secreted.

Structure of Tumor Necrosis Factor

Tumor necrosis factor α , like most of its homologs, is a homotrimer, with the exception of LT β , which is heterotrimer composed of two distinct subunits (LT α_2 and LT β_1) [13]. Trimers of TNF- α are stable and do not dissociate *in vivo*. The three-dimensional structure of TNF- α was the first of its family to be determined [14,15], followed by that of TNF- β [16], CD40L [17], TRAIL [18,19], and most recently sTall [20]. All have a distinctive “Greek key jellyroll” β -sandwich fold, consisting of two five-stranded β -sheets in direct opposition (Fig. 1). The same fold is characteristic of icosahedral virus coat proteins, although the latter have no sequence

Figure 1 Schematic of a trimer of TNF- β in which the polypeptide trace of β -strands are depicted as arrows and loop segments as tubes. Residues that bind to TNF-R1 are red. The membrane-proximal surface of the trimer, as bound to TNF-R1, is located at the bottom of the diagram.

identity to TNF homologs that would establish an evolutionary relationship (although sTall does assemble into an icosahedral cage). On the other hand, TNF family members have distinct sequence similarity and obvious structural homology to trimeric, globular C1q domains [10] of the heteromeric molecules that function in the complement pathway. Hence, the TNF and gC1q domains may share an ancient kinship in the early development of the immune response.

Tumor necrosis factor monomers associate through a conserved girdle of hydrophobic or aromatic amino acid residues that encircle a trimeric axis of symmetry. Beta strands at the edge of the outer β -sheet of each monomer contact an extensive surface of the inner sheet of the adjoining molecule (Fig. 1). TNF- α and other homologs possess a disulfide cross-link between connecting loops that may confer stability to the molecule in the extracellular environment but is unlikely to serve a role in receptor recognition.

TNF Receptors

Nearly 30 TNF-R homologs have been identified [8,10,21]. Most are type I membrane proteins with cytoplasmic C-terminal domains and single transmembrane segments. Extracellular domains are composed of two or more cysteine-rich modules that contain binding sites for TNF family ligands. Both TNF-R1 and TNF-R2 are N-glycosylated, and the former is also O-glycosylated [22,23]. TNF-R1 and TNF-R2 have cytoplasmic domains of 221 and 174 residues, respectively. Those of other family members range from 30 to over 300 residues in length. None are known to exhibit enzymatic (kinase or phosphatase) activity. The cytoplasmic

regions of TNF-R1, Fas, DR-3, and others that mediate apoptotic responses include \approx 80-residue protein modules known as death domains (DDs). Structural studies reveal these to be six- α -helix bundles [24]. Death domains participate in specific homotypic interactions with DDs in other proteins. Death domains belong to a superfamily that includes death effector domains (DEDs) and caspase recruitment domains (CARDs), to which they have obvious structural but little sequence identity [24]. Mutagenic and structural studies indicate that DDs and their cousins can interact with each other through at least three distinct molecular surfaces [25–27], suggesting possible mechanisms by which single domains could interact simultaneously with different partners.

Soluble ligand binding proteins can be generated by proteolytic cleavage of extracellular domains from membrane-bound receptors, as is the case for TNF-R1 and TNF-R2, or by alternative exon splicing of sequences encoding the transmembrane domain, as is the case for the transcript-encoding Fas (see Bodmer *et al.* [10] and references within). Together with virally encoded receptor extracellular domain homologs, these molecules may serve as ligand scavengers and receptor competitors.

Extracellular (Ligand Binding) Domains of TNF Family Receptors

The extracellular domain (ECD) of TNF-R1 is an elongated chain of four interleaved, 40-residue, cysteine-rich domains (CRDs), each of which is stabilized by three disulfide cross-links (Fig. 2a) [28]. High-resolution structural analyses of the TNF-R1 ECD [29,30], together with sequence analysis of homologous domains [31] indicated that CRDs are constructed of binary combinations of three topologically distinct modules of type A, B, and C (Fig. 2a). More recent analyses confirm that this scheme, with modifications, is generally applicable to the TNF-R family [10]. Thus, the four CRDs of the TNF-R1 receptor can be described as A1-B2/A1-B2/A1-B2/A1-C2, while TNF-R2 is A1-B2/A1-B2/A1-B1/A1-B1 (numerals indicate the number of disulfide bridges within the module). Few residues, beside the cysteine pairs that serve as structural scaffolds, are conserved among homologous modules.

Ligand-Receptor Complexes

Tumor necrosis factor α binds tightly to ECD domains of TNF-R1 and TNF-R2 with dissociation constants in the range of 0.1 to 1 nM [22,32]. The structure of the TNF- β -TNF-R1 complex, which contains three receptor ECDs and one TNF- β trimer, immediately suggests a mechanism for the proximal events of signal transduction [28] (Fig. 3). Within the complex, each ECD binds to the crevice formed at the interface between two neighboring, triad-related TNF- β subunits. The receptors do not contact each other, yet all are tethered together by virtue of their mutual interaction with

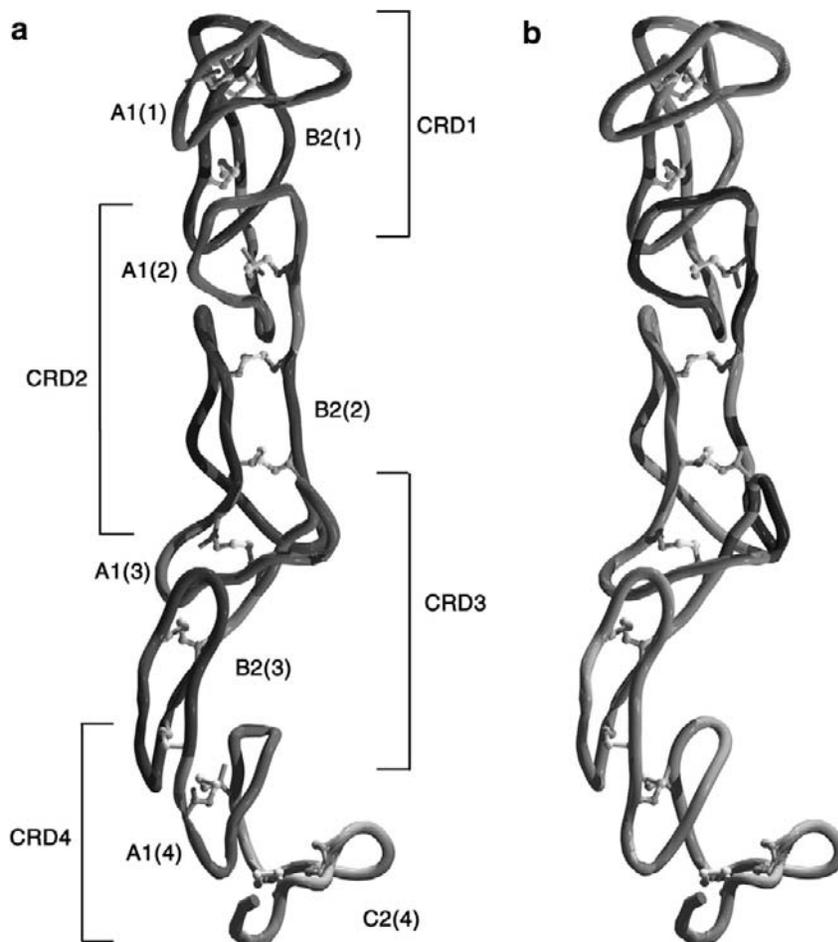

Figure 2 Diagram of the extracellular domain of TNF-R1. In panel (a), brackets show the boundaries of individual CRDs, and modules of type A, B, and C are shown as red, blue, and gray, respectively. In panel (b), residues in CRD2 and CRD3 that bind to TNF-β are blue; residues that mediate parallel dimerization in the crystal structure of unliganded TNF-R1 are red. These residues are located in CRD1 and are located within the PLAD domain. The ECD is oriented with the N-terminus of the molecule at the top of the diagram.

the same trimeric molecule of TNF. The cytoplasmic domains of the three receptors are thus juxtaposed, although the mechanism by which they interact is yet unknown.

The TNF-β–TNF-R1 interaction involves two separate contact regions (Fig. 2b) corresponding to the second and third CRDs of TNF-R1 which bind to protruding polypeptide loops of TNF-β. The recently determined structure of the TRAIL receptor bound to its ligand reveals a similar mechanism of engagement [18,19]. Complexes of other members of the TNF-R family with their ligands are likely to exhibit a similar mode of binding. However, the putative ligand (and receptor) binding regions of homologous receptors and ligands share no apparent sequence identity. This is true even of TNF-R1 and TNF-R2, which recognize the same ligands, and of TNF-α and TNF-β, which bind to the same receptors [10]; hence, the same binding surfaces must perform two different recognition functions. Human growth hormone receptor binds both prolactin and growth hormone, and the structures of its complexes with the two ligands reveals one solution to the dual specificity problem [33].

Consequences of Ligand–Receptor Complex Formation

The death domain of TNF-R1 is capable of self-association and subsequent apoptotic signaling, as demonstrated by over-expression of DD constructs for TNF-R and Fas [34]. It is probable that, upon formation of the TNF–TNF-R complex, interactions among receptor DDs generate interdomain binding sites for adaptor proteins such as the TNF-receptor-associated death domain protein (TRADD) or Fas-associated death domain protein (FADD) that are not present in unliganded receptor molecules. The crystal structure of a death domain complex (involving DDs from the *Drosophila* proteins Pelle and Tube) [35] and that between the CARD domains of Apaf1 and Caspase 9 [36] reveal two non-overlapping interfaces that, it has been postulated [25], could be exploited to form a heterotrimeric DD complex.

Upon its formation, TRADD is recruited to the TNF–TNF-R1 complex via homotypic DD interactions. The C-terminal DD of TRADD binds other DD-containing

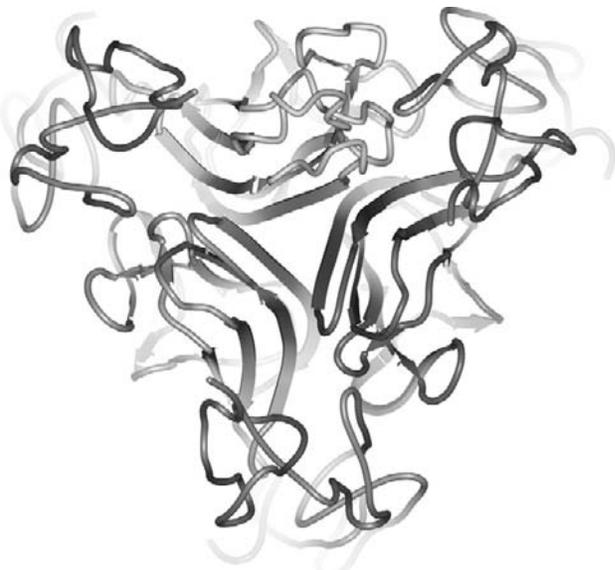

Figure 3 A view of the complex between TNF- β and three molecules of the TNF-R1 ECD [28]. The complex is viewed along the three-fold axis of the TNF- β trimer, looking toward the plasma membrane. Subunits of TNF- β are red, green, and gray, and the polypeptide backbone of the TNF-R1 molecules is gold.

partners, including the adaptor protein FADD and the serine/threonine kinase RIP1 [9,10]. The amino terminal DED of FADD can form a complex with the corresponding DED of procaspase 8, thereby increasing the local concentration of apoptotic proteases at the plasma membrane [37]. TNF-TNF-R1 can also elicit cell proliferation by recruiting TNF-R-associated factors (TRAFs), which mediate the activation of NF- κ B [38]. The C-terminal domain of TRAF-2 trimerizes through a coiled-coil segment and possesses an \approx 150-residue β -sandwich domain that binds to the N-terminal α/β sandwich module of TRADD [39]. TNF-R2 contains no DD and therefore cannot elicit an apoptotic response. It does, however, contain a short \approx 10-residue cytosolic sequence to which TRAF domains bind [40,41]. The affinity of TRAF-2 for TNF-R2 is considerably lower than that for TRADD, suggesting that TNF-R2 is the less potent signaling receptor. TNF and its receptor complex are ultimately cleared from the cell surface through a clathrin-mediated endocytic pathway [42,43].

Receptor Preassociation

The structure of the ECD of TNF-R1 [29] provided the first indication that TNF receptors can associate in the absence of ligand. Two-fold symmetric receptor dimers of two distinct types, both involving substantial intersubunit contact areas, were discovered. So-called anti-parallel dimers involved extensive isologous contacts between receptor CRDs 2 and 3, at an interface that overlaps substantially with the TNF binding site. Although there is no evidence that such interactions occur *in vivo*, such dimers would

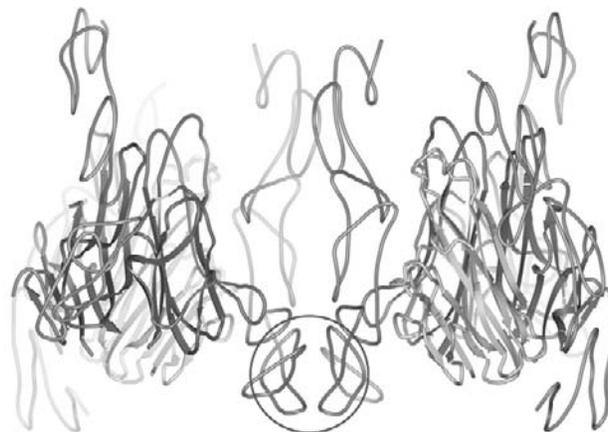

Figure 4 A model showing how TNF- β -TNF-R1 complexes could form aggregates on the cell surface through homodimeric interactions between TNF-bound receptor molecules. The complexes are viewed resting on the surface of the membrane. The receptor dimer (center) that mediates the contact between the two complexes is as observed in crystals of unliganded TNF-R [29]. The dimer interface is formed by residues in CRD1 domains of the interacting ECDs (circled) that correspond roughly to the PLAD [46]. The structure of the TNF- β -TNF-R1 complex is as determined by Banner *et al.* [28].

prevent TNF binding and could also serve an autoinhibitory role in the absence of ligand.

In a different arrangement observed in the same crystals, the ECDs are parallel and packed back-to-back. In this case, the dimerization surface is located in CRD1, which is not involved in TNF binding (Fig. 2b). Indeed, the TNF binding sites are diametrically opposed to the dimerization surface. It was suggested that TNF-TNF-R complexes could be assembled into clusters on the plasma membrane by virtue of homotypic interactions between receptor CRD1 domains (Fig. 4). Recently, two research groups [44–46] demonstrated that, even in the absence of ligand, both the Fas and TNF-R1 exist in a preassociated state in the plasma membrane. Residues responsible for their interaction were found to be located within a contiguous, pre-ligand-binding assembly domain (PLAD). The PLAD domain is located within CRD1 and appears to correspond to the surface defined earlier in the structure of the unliganded receptor [29] (Fig. 2b). Several mutations observed to abrogate preassociation of TNF-R1 correspond to residues at the dimerization interface observed in the crystal structure of unliganded TNF-R1. PLAD domains are receptor specific. Transplantation of the PLAD/CDR1 domain of TNF-R2 onto TNF-R1 allows the latter to associate with other TNF-R2 molecules. Ligand binding and preassociation appear to be cooperative phenomena, in that mutations of certain residues within the PLAD also interfere with TNF binding [46]. Accordingly, the TNF-R1 self-association domain partially overlaps that of the TNF binding domain [28,29]. Whether preassociated receptors form dimers, as observed in crystals, or trimers, as suggested by Chan *et al.* [46] remains to be determined.

Stimulation of certain receptors in the TNF-R family causes large-scale redistribution and clustering of signaling complexes on the cell surface, followed by internalization of

receptor complexes through endocytic pathways. Engagement of Fas by its ligand is facilitated by receptor preassociation and results in the formation of receptor–ligand microaggregates. The structural basis of this process is unknown but may involve associations between ligand-bound receptors that occur cooperatively with ligand binding, as suggested by the model depicted in Fig. 4. Subsequent recruitment of FADD and procaspase-8 to Fas–Fas ligand microaggregates produces the death-inducing signaling complex (DISC) [47], which itself assembles into higher order clusters. This process is amplified by procaspase activation. Actin and actin-binding proteins have been implicated in both the initial recruitment of FADD and the clearance of receptor clusters through endocytic pathways [48].

Conclusion

Signaling through TNF receptors is probably paradigmatic of that which occurs through many of its homologs. The action of TNF is pleotropic in that it can initiate both apoptotic and proliferative pathways. The mechanisms of signal integration that commit the cell to one or the other fate have yet to be fully elucidated. Receptor-proximal events in both cases appear to be mediated through protein-interaction domains in receptors and cytosolic adaptor proteins. Crystallographic analysis of the TNF-R1 receptor and its complex with TNF- β suggests that ligands and their receptors assemble into complexes with two- and three-fold symmetry and that higher order lattice-like structures could be generated though the operation of this symmetry. TRAF proteins are homotrimeric, as are their complexes with TNF-R2 peptides and with TRADD, suggesting that the symmetry of extracellular components is recapitulated in the intracellular signaling complexes formed upon receptor ligation. On the other hand, death domains have not been found to assemble into homotypic complexes with three-fold symmetry. The organization of TNF signaling complexes is likely to be key to the mechanism of signal transduction and propagation. Thus, elucidation of the structures of TNF signaling complexes, however transient, will represent a significant achievement in our understanding of TNF signaling mechanisms.

Introduction

Nerve growth factor (NGF) is the founding member of the neurotrophins, a family of growth factors responsible for the formation and maintenance (survival or apoptosis) of neuronal populations in the peripheral and central nervous system. The neurotrophins are of potential therapeutic interest in a number of neurological disorders such as Alzheimer's and Parkinson's diseases (reviewed in Siegel and Chauhan [1]). In addition to NGF, the neurotrophin family includes brain-derived neurotrophic factor (BDNF), neurotrophin-3 (NT-3), neurotrophin-4/5 (NT-4/5), and neurotrophin-6 (NT-6). These molecules exert their biological activities through binding to two unrelated classes of receptors. One of these, the p75 neurotrophin receptor (p75^{NTR}), also referred to as the low-affinity receptor, binds to all neurotrophins with nanomolar affinity and is responsible for their apoptotic activities. The Trks, or so-called high-affinity receptors, are more specific and mediate the trophic effects of neurotrophins through dimerization-induced tyrosine kinase activity. TrkA binds to NGF (and weakly to NT-3), TrkB to BDNF and NT-4/5 (and weakly to NT-3), and TrkC binds to NT-3. The presence on the same cell of both p75^{NTR} and TrkA results in high-affinity binding sites with picomolar affinities for NGF [2].

Neurotrophins

The neurotrophins share a pairwise sequence identity of about 50% and belong to the family of cystine-knot-containing growth factors [3]. They adopt very similar three-dimensional structures, containing a monomer core of a pair of irregular, anti-parallel, two-stranded β -sheets that carry the cystine-knot motif as well as both termini on one end of the molecule and three hairpin loops on the other [4] (Fig. 1A). Two monomers are assembled in a parallel fashion to yield a non-covalent but tightly packed homodimer with a dumbbell-like shape (Fig. 1B). The conserved residues are clustered in distinct segments that cover about half of the molecule and share a local sequence identity among all neurotrophins of about 70%. Three of these segments map onto three of the β -strands that form the "handle" of the dumbbell as well as a large portion of the dimer interface. To date, crystal structures have been reported for the uncomplexed NGF, NT-3, and NT-4/5 homodimers as well as the BDNF/NT-3 and BDNF/NT-4/5 heterodimers. These structures, in combination with a wealth of mutagenesis studies and truncation experiments, have led to a good understanding of how affinity and specificity between neurotrophins and the Trk receptors are achieved, as demonstrated by the successful creation of multi- and pan-specific neurotrophin variants (reviewed in Wiesmann and de Vos[5]; also see Robinson *et al.* [6]).

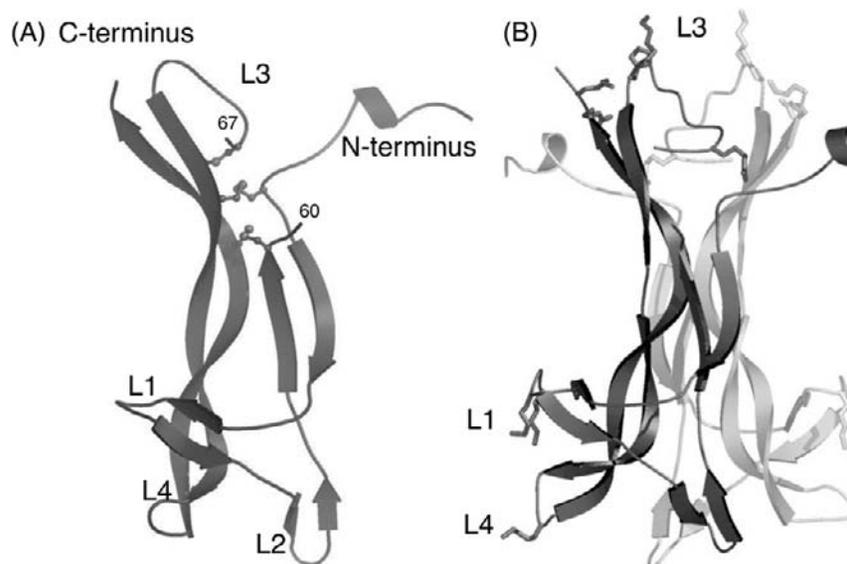

Figure 1 The neurotrophin fold, as exemplified by NGF (taken from the NGF–TrkA–D5 complex [11]); all subsequent figures display NGF in orientations similar to that shown in part (B). One loop, bounded by residues 60 and 67, is poorly ordered or disordered in most neurotrophin structures. (A) Ribbon rendering of the backbone of the NGF monomer. The cystine knot is shown as a ball and stick. (B) Ribbon rendering of the backbone of the NGF dimer.

Trks

The Trks are receptor tyrosine kinases with a molecular weight of about 85 kDa. Their extracellular portions share a sequence identity of about 35% and have five distinct domains [7]. Domain 2 (D2) consists of three leucine-rich repeats and is sandwiched between two cysteine-rich domains (D1 and D3). D4 and D5 have an immunoglobulin (Ig)-like fold, and are followed by a 40-residue-long linker segment connecting the extracellular portion to the transmembrane helix. Domain deletion studies, experiments with truncated and chimeric versions of the Trks, and alanine-scanning mutagenesis experiments have identified D5 as being most critical for high-affinity neurotrophin binding (see references in Wiesmann and de Vos [5]). While some studies indicate that D4 enhances complex formation between the neurotrophins and the Trks, others indicate that D4 is required (at least *in vitro*) for proper folding of the receptor. D4 has also been suggested to be necessary to prevent ligand-independent formation of receptor complexes. The roles of D1, D2, and D3 are even less clear. In contrast to earlier studies indicating that the leucine-rich repeats are involved in neurotrophin binding, the crystal structure of NGF in complex with TrkA–D5 (see below) shows that extensive contacts with NGF are unlikely [5]. Instead, the leucine-rich repeats may be involved in intra- or intermolecular Trk interactions, possibly stabilizing the signaling complex [8]. Finally, D1 through D4 may play a role in complex formation between the Trks and p75^{NTR} in a receptor–receptor assembly that provides high-affinity binding sites for the neurotrophins or, alternatively, in influencing the architecture of a possible ternary complex between NGF, TrkA, and p75^{NTR}.

The crystal structures of D5 of TrkA (TrkA–D5), TrkB (TrkB–D5), and TrkC (TrkC–D5) are all domain-swapped dimers, where strand A of each molecule is replaced by the same strand of a symmetry-related neighbor [9,10]. This domain swapping is believed to be a folding artifact caused by the absence of D4, but the correctly folded structures can be modeled with minor changes. The structures contain two β -sheets in a β -sandwich fold, and belong to the I-set of the Ig superfamily; however, they possess a number of distinct and unusual features that deviate from the canonical I-set fold [9]. For example, the usual buried disulfide bridge, connecting both β -sheets, is absent in D5; instead, D5 possesses a solvent-exposed disulfide bond formed between cysteine residues in two neighboring β -strands. Another noteworthy difference concerns the loop connecting strands A and B which is three residues shorter than in other I-set members. It is likely that the shortness of this loop increases the propensity of these domains to misfold when expressed as single domains.

NGF–TrkA–D5 Complex

The crystal structure of the complex between NGF and TrkA–D5 [11] substantiated the ligand-binding function of D5, revealed the structural basis for specificity and cross-reactivity among the neurotrophins and their Trks, and defined the orientation of the complex with respect to the membrane. The overall shape of the complex resembles a bat, with the wings formed by the two copies of TrkA–D5 arranged symmetrically around the NGF body in the center (Fig. 2). Because the C terminus of D5 is expected to point toward the membrane, NGF is oriented with its two-fold

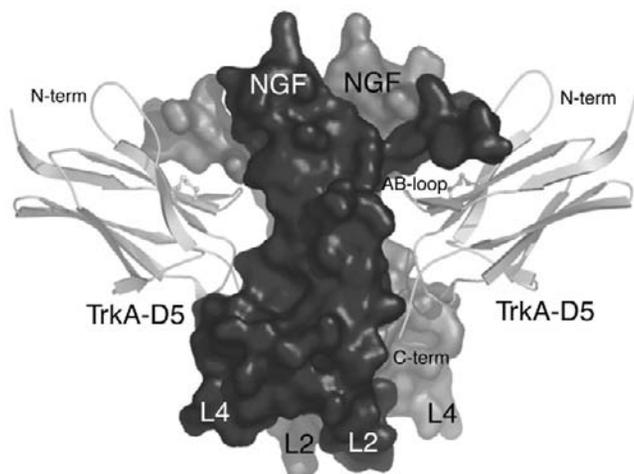

Figure 2 Crystal structure of the NGF–TrkA-D5 complex. NGF is rendered as a solvent-accessible surfaces (dark and light gray) and TrkA-D5 as a gray ribbon with the disulfide bond buried in the interface; NGF is shown as a ball and stick. The first and last ordered D5 residues are labeled “N-term” and “C-term”, respectively. In this figure and in Fig. 3, the cell membrane would be at the bottom.

axis perpendicular to the membrane, with its termini and the cystine-knot motif at the top and the three hairpin loops L1, L2, and L4 facing the membrane (Figs. 1B, 2). In this crystal structure, D5 is correctly folded, and the A/B loop is tightly packed against NGF. While ligand binding does not induce any significant differences in D5, NGF undergoes an important change. The N-terminal residues of NGF, which are known to be critical for receptor binding and are flexible in all crystal structures of neurotrophins in their unbound state, become well-ordered in the NGF–TrkA-D5 complex. The NGF N terminus now forms a helical turn (Fig. 1), which packs tightly into a hydrophobic pocket on the surface of D5; interestingly, the unusual disulfide bridge found in D5 but not in other I-set members forms the bottom of this pocket. A comparison of the D5 structures of TrkA, TrkB, and TrkC reveals that the residues lining the walls of the pocket are not conserved; therefore, the interactions in this patch are likely to confer specificity between the ligands and their receptors [9]. A second binding patch involves residues from the central portion of the NGF dimer. Most of the residues involved in this part of the interface are conserved among both the neurotrophins and the receptors, and similar interactions were predicted for all neurotrophin–Trk complexes [11]. Finally, loops L2 and L4 at the bottom of the NGF dimer (Fig. 1B) share very little sequence conservation and are known from swapping experiments to be important for specificity [12]. Neither of these loops is in contact with D5, but the C terminus of D5 projects toward the groove between them. Therefore, in the native complex with intact TrkA, a portion of the linker segment connecting D5 to the transmembrane helix could interact with these loops, consistent with the observation that deletions or certain point mutations in this segment result in decreases in neurotrophin binding.

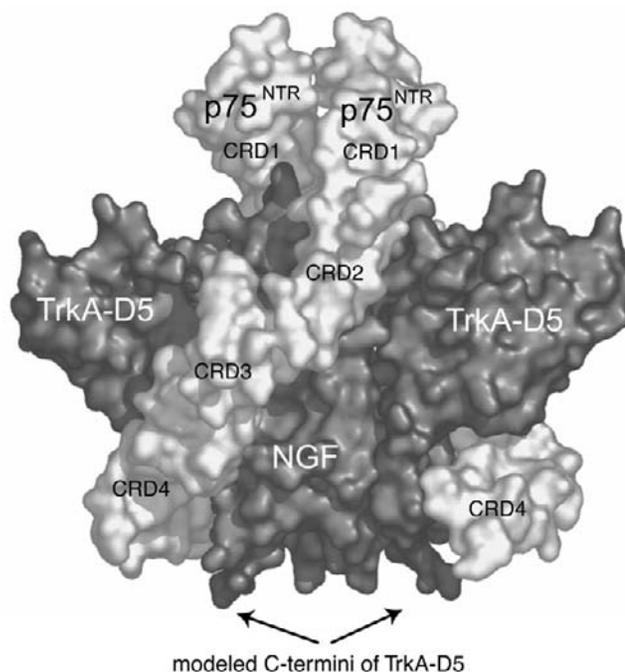

Figure 3 Model of a ternary NGF–TrkA-D5–p75^{NTR} complex. All components are rendered as solvent-accessible surface, with NGF in medium gray, TrkA-D5 in black, and p75^{NTR} in light gray. The C-terminus of TrkA-D5 was modeled to interact with hairpin loops L2 and L4 at the bottom of NGF; in this model, it also interacts with CRD4 of p75^{NTR}.

p75^{NTR}

p75^{NTR} enhances survival signals induced by NGF when in the presence of TrkA, while it activates apoptotic signals in a TrkA-negative background (reviewed in Barker [13]). p75^{NTR} lacks intrinsic catalytic activity and is a member of the tumor necrosis factor receptor (TNF-R) superfamily. Members of this superfamily contain between two and six cysteine-rich domains (CRDs) in their extracellular portion (reviewed in Locksley *et al.* [14]), which usually have six cysteine residues shown from structural studies to form a ladder of three disulfide bridges. These domains are fairly rigid building blocks, and stacking of multiple repeats produces the elongated, rod-like shape of the receptor.

p75^{NTR} has four cysteine-rich repeats. Crystal structures of complexes in this superfamily have shown that CRD2 and CRD3 are most intimately involved in the ligand interaction [15]. Similarly, while all four domains of p75^{NTR} are required for NGF binding, CRD2 appears to be most critical (see references in Wiesmann and de Vos [5]). In contrast to the Trks, the 60-residue-long linker region that connects the CRDs to the transmembrane helix is not required for binding. The binding site for p75^{NTR} on the neurotrophins has been mapped through mutational analyses onto two spatially separated regions. One patch at the top of NGF (see Fig. 1B) involves a number of positively charged residues in loop L3 and the C-terminal region. The second patch, at the bottom of NGF, is defined by positively charged residues from loops L1 and L4. The crystal structure of the NGF–TrkA-D5 complex shows

that neither of these patches is buried by TrkA-D5, allowing for the formation of ternary NGF–TrkA–p75^{NTR} complexes at the cell surface. Based on these observations, a possible model for such a ternary complex is shown in Fig. 3 [5].

Introduction

Vascular endothelial growth factor (VEGF or VEGF-A), also known as vascular permeability factor, is a potent mitogen that is highly specific for endothelial cells. VEGF plays a central role in the development of the vascular system and the processes involved in angiogenesis and is also implicated in diseases that require the formation of new blood vessels such as diabetic retinopathy, age-related macular degeneration, psoriasis, rheumatoid arthritis, and tumorigenesis [1,2]. Additional members of the still expanding VEGF family currently include VEGF-B, VEGF-C, VEGF-D, VEGF-E, and placenta growth factor (PlGF) [3]. These molecules share a sequence identity of approximately 30 to 50%, are generally active as glycosylated homodimers, and bind to one or more of the three VEGF receptors VEGFR-1 (also known as flt1), VEGFR-2 (KDR) and VEGFR-3 (flt4). The biological responses triggered by VEGF are modulated through a number of different isoforms generated through alternative splicing events, the most prominent forms being comprised of 121, 165, 189, and 206 amino acids, respectively. Cleavage of VEGF₁₆₅ with plasmin yields two fragments [4]. The longer fragment includes the N-terminal residues 1 to 110 and remains dimeric in solution. This receptor-binding

domain is about as active as the short splice variant VEGF₁₂₁. The shorter, monomeric fragment is the heparin-binding domain, which is also present in all the longer VEGF isoforms.

Heparin-Binding Domain of VEGF

The enhanced biological activity of the longer VEGF isoforms has recently been attributed to the formation of ternary complexes with VEGFR-2 and neuropilin [5]. The neuropilins are receptors for the class 3 semaphorins and participate in the guidance of growing axons to their targets. Their coreceptor function for VEGF (and PlGF) is mediated through the heparin-binding domain of these isoforms [6], resulting in enhanced affinity of VEGF for VEGFR-2 [7]. Neuropilin-1 also binds directly to flt1, in an interaction that antagonizes binding of VEGF, suggesting a role for flt1 as a negative regulator of angiogenesis [7].

The three-dimensional structure of the 55-residue heparin-binding domain of the longer VEGF isoforms consists of a novel heparin-binding fold that can be divided into two smaller subdomains, each having a short, anti-parallel β -sheet and two disulfide bonds [8] (Fig. 1A). The C-terminal

subdomain contains a short helical segment that packs against the β -sheet. One side of this subdomain together with an adjacent loop stemming from the N-terminal together carries the majority of positively charged residues, and the resulting positively charged surface is believed to be responsible for the heparin-binding functionality [8].

Receptor-Binding Domain of VEGF

Crystallographic analysis of the receptor-binding domain of VEGF [9] confirmed that VEGF is a member of the cystine-knot-containing family of growth-factors [10] and resembles platelet-derived growth factor (PDGF) in overall structure and quaternary arrangement. Each monomer has two pairs of anti-parallel, two-stranded β -sheets in its core with the N terminus and the characteristic cystine-knot motif at one end of the sheet (Fig. 1B). Two monomers are covalently linked by two disulfide bonds and arranged in an anti-parallel manner, with their central β -sheets lying side-by-side and the N-terminal region packing on top of the other monomer. The resulting VEGF homodimer has a flat shape and is about 65 Å long, 40 Å wide, and 10 Å thick in its central portion. One of the more prominent differences between VEGF and PDGF involves the N-terminal segment, which adopts a helical conformation in VEGF but is extended in PDGF. Interestingly, several residues important for receptor binding are located in this region. A recent crystal structure of the receptor-binding domain of PlGF is very similar to that of VEGF, supporting the notion that all members of the VEGF family have very similar overall structures [11].

VEGF Receptors

Given the similarities in overall architecture between VEGF and PDGF, it is not surprising that their receptors,

too, share common features. Both the VEGF receptors and the PDGF receptor family members—PDGFR- α , PDGFR- β , colony-stimulating factor 1 (CSF-1) receptor, stem cell factor (SCF) receptor (or c-kit), and flt3)—have a number of immunoglobulin (Ig)-like repeats in their ectodomain, a single transmembrane helix, and a split tyrosine kinase domain in the cytoplasmic portion. Sequence alignments and functional studies suggest that the five Ig-like repeats of the PDGF receptors correspond to the N-terminal five of the seven Ig-like domains of VEGF receptors [12]. Domain swapping and deletion studies identified the three N-terminal repeats as the growth-factor-binding regions (for references to individual studies, see Robinson and Stringer [3]). The function of the first domain, which is not involved in the interaction with the ligand, may be to regulate binding indirectly, as its deletion from VEGFR-2 enhances the VEGF association rate. The ligand binding determinants are contained in domains 2 and 3, as tandem constructs of these domains of flt1 and of VEGFR-2 bind to VEGF with near wild-type affinity. The isolated second domain of flt1 (but not VEGFR-2) still binds with an affinity of about 1 nM. Its structure shows that this domain is a member of the I-set of the Ig superfamily, but that it contains a number of rare and characteristic features that are conserved in domain 2 of the other receptors of the PDGF and VEGF families, indicating that the structure and function of this domain are conserved [12,13]. The function of the fourth domain has been addressed through ligand-induced cross-linking studies on flt1 and by using dimerization-inhibitory antibodies to SCFR (see references in Robinson and Stringer [3]). For both receptors, a dimerization site was identified within this domain, suggesting that the two copies of domain 4 in the signaling complex may be in direct contact. The function of domains 5 to 7 of the VEGF receptors is less clear, but it has been suggested for VEGFR-2 that they may have a role in inhibiting signaling in the absence of ligand [14].

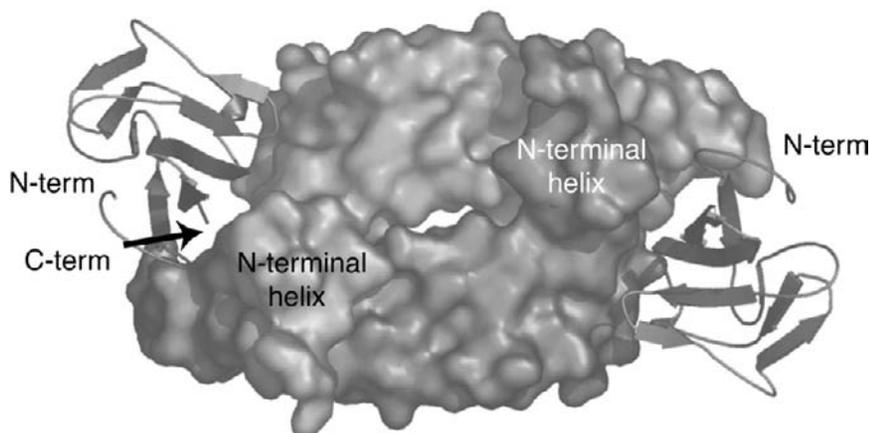

Figure 2 Crystal structure of the VEGF–flt1-D2 complex, viewed toward the membrane. VEGF is rendered as accessible surface, and D2 of flt1 as ribbon [12].

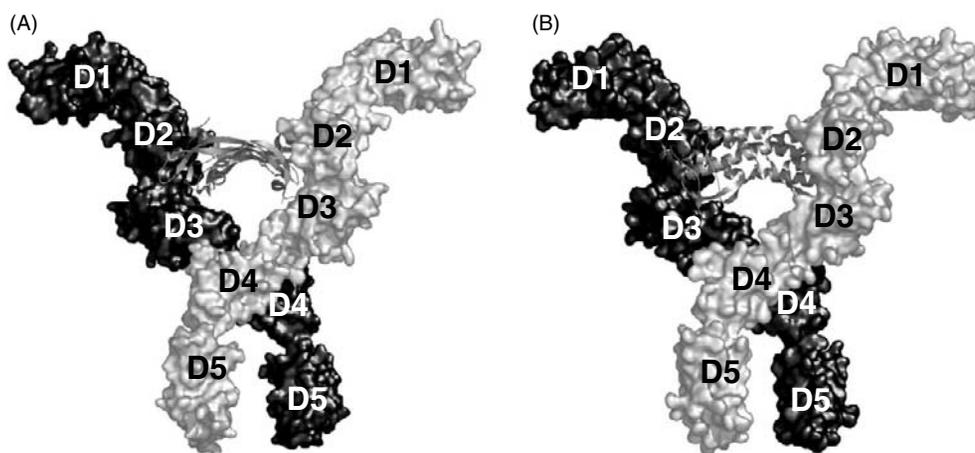

Figure 3 Models of signaling complexes, with receptors rendered as accessible surfaces and ligands as backbone ribbons. The membrane would be at the bottom of the figure. VEGF–flt1-D2 Complex

The crystal structure of the complex between the receptor-binding domain of VEGF and the second Ig-like domain (D2) of flt1 revealed the mode of ligand–receptor interaction, suggested how the third Ig-like domain would contribute to enhance binding between the growth factor and the intact receptor, and defined the overall geometry of the signaling complex. In the structure [12], two copies of flt1-D2 bind symmetrically at the diametrically opposed ends of the VEGF dimer (Fig. 2). Each copy is in contact with both VEGF monomers, forming a flat interface lacking any major knob-into-hole interactions. Approximately 70% of the buried surface is of a hydrophobic nature, with only a single direct polar interaction. From this structure, the identification of residues in contact with receptor made possible the generation of receptor-selective VEGF variants [15] that have proved useful in elucidating the specific biological roles of flt1 and VEGFR-2 [16]. Overall, the binding site on VEGF as seen in the crystal structure is in good agreement

with alanine-scanning experiments mapping residues important for VEGFR-2 binding. However, a number of additional binding determinants that are located at the bottom (membrane-facing) side of VEGF are not in contact with flt1-D2. The C terminus of this domain projects toward a groove at the bottom of the VEGF, suggesting that in the intact receptor the third domain would be positioned in contact with these residues. Based on these data, a model was proposed for the overall geometry of the complex between VEGF and the first four receptor domains (Fig. 3A) [12]. Given the structural homology between VEGF and PDGF, on the one hand, and the similarities in domain structure between their receptors, on the other, all the growth factors in these families are expected to assemble their receptors into signaling complexes of a similar architecture. It is striking, however, that some ligands for members of the PDGF receptor family are structurally unrelated to VEGF and PDGF. Flt3 ligand (Flt3L), SCF, and CSF-1 are helical proteins resembling the class 1 four-helix-bundle cytokines, a family of usually monomeric ligands that interact with members of a distinct

receptor family, namely the hematopoietic receptors [17]. The crystal structures of Flt3L [18], SCF [19,20], and CSF-1 [21] show that these molecules form dimers with overall dimensions that are very similar to those of VEGF and PDGF. Given these similarities and taking into account mutagenesis data mapping the receptor-binding sites, it appears that these three four-helix-bundle ligands interact with their receptor tyrosine kinases in a manner that results in an assembly of signaling complexes of architecture and dimensions similar to those of VEGF (Fig. 3B) [18,19]. Thus, the geometric requirements for productive signaling through the receptors in this family, first deduced for the VEGF–flt1 complex, now appear to be conserved even for a class of ligands with a completely unrelated fold.

Introduction

The transforming growth factor β (TGF β) superfamily is a large group of soluble, dimeric factors that initiate and control proliferation and differentiation of many cell types in animals, thus playing important roles in embryonal development and adult tissue homeostasis. Malfunctioning of this tightly controlled signaling system leads to developmental disorders, and severe defects in organ function and is the cause of several diseases, including various types of cancer [1,2].

Signaling by these factors requires binding of the ligand to two homologous but functionally distinct types of transmembrane serine/threonine receptor kinases, designated type I and type II. Upon ligand-complex formation, the constitutively active type II receptor kinases activate the type I receptor kinases through phosphorylation in a conserved juxtamembrane region (GS-box). Activated type I receptors are then able to phosphorylate targets further downstream of the signaling pathways [1,3,4]. Despite the large number of ligands in the TGF β superfamily, the number of receptors

is comparatively small. Also, in contrast to other highly specific receptor–ligand systems, the members of the TGF β superfamily display some promiscuity, in that several ligands are able to recognize different receptors and most of the receptors can bind different ligands. With a focus on BMP-2 and TGF β , this chapter summarizes current knowledge about the initiating events in signal transduction within the TGF β superfamily based on crystal and solution structures of ligands, receptor ectodomains, and receptor–ligand complexes.

Ligand and Receptor Structures

Currently, more than 30 different ligands within the TGF β superfamily have been described. They can be categorized into the subfamilies of the name-giving TGF β s; growth and differentiation factors (GDFs); activins/inhibins; bone morphogenetic proteins (BMPs), which is the largest of the subgroups; and a few others [5]. A comparison of the three-dimensional structures of TGF β 1 [6], TGF β 2 [7,8],

TGF β 3 [9], BMP-7 [10], GDNF [11], and BMP-2 [12] shows that the ligands share a common fold, which is characterized by an extended nine-stranded β -sheet formation and one α -helix per monomer. Significant differences are only observed in loops and at the N termini. The overall fold of a monomer has been described as a curled hand, in which the extended β -sheets represent the fingers [7] and the α -helix the heel or wrist [13] region of the hand. The monomer fold is stabilized by a network of disulfide bridges forming the so-called cystine knot, a motif that is also found in a number of other growth factors [14,15]. The functionally competent molecule is formed by a covalent connection of two monomers through a disulfide bridge, forming a dimer (usually, but not necessarily, a homodimer) in anti-parallel, face-to-face orientation. This relative orientation of the subunits distinguishes the TGF β superfamily members from those of the vascular endothelial growth factor (VEGF) and nerve growth factor (NGF) families, which have similar monomer structures but dimerize in different ways [16].

The receptor chains are composed of a small extracellular (represented by the subscript "ec") ligand binding domain, typically composed of around 120 amino acid residues, one short transmembrane fragment, and a cytoplasmic part, which differs in size between type I and type II and contains the catalytic kinase domain. Recently, three crystal structures of the ligand binding domains became available, one in the unbound form (ActR-II_{ec} [17]) and two in complex with their ligands (BMPR-IA_{ec} [18] and TGF β R-II_{ec} [19]). Despite the low sequence similarity of less than 20% between type I and type II receptor ectodomains, the overall structure of both groups is very similar (Fig. 1). They fold into single, compact domains with a rigid core formed by a central anti-parallel β -sheet whose architecture

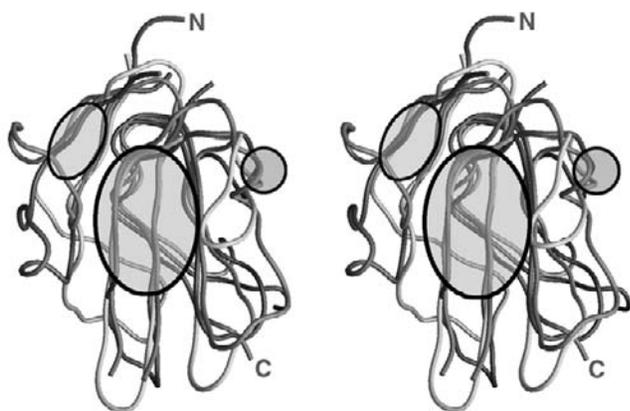

Figure 1 Superposition (stereo) of the receptor chains mActR-II_{ec} (blue), BR-IA_{ec} (red), and TGF β R-II_{ec} (green). The view is looking down onto the central part of the common ligand binding epitopes of BR-IA_{ec} and ActR-II_{ec} (the palm of the receptor hand, shaded magenta). The region shaded in red marks the position of the highly conserved hydrophobic residue of type I receptors (Phe85 in BR-IA) that fits into a conserved hydrophobic pocket of the ligand. The ligand binding area of TGF β R-II_{ec} is shaded in green and is clearly distinct from the ligand binding area in BR-IA_{ec}. The orientation is such that for BR-IA_{ec} the membrane proximal side is at the bottom. The N and C termini are indicated for BR-IA_{ec}.

is maintained by five partially conserved disulfide bridges. Structural variations occur mainly at the edges of the sheet and in loop regions. This fold, which has previously been described for a number of snake venom toxins, can be compared to an open left hand and was named the *three-finger toxin fold* [20]; however, no functional similarities to the receptors have been reported.

Receptor-Ligand Complexes

Although BMPs and TGF β s are very similar in structure, there are significant differences in the molecular mechanism of recognition and signal activation. In TGF β signaling, complex formation is initiated by high-affinity interactions between the ligand and the type II receptor T β R-II. This primary complex subsequently recruits the low-affinity type I receptor (T β R-I), which is not able to bind to the ligands in the absence of T β R-II [21,22]. The sequence of events is likely to be reversed in the case of BMPs, as exemplified by studies with BMP-2: BMP-2 has high affinity for the type I receptors BR-IA and BR-IB (and possibly ActR-I), but lower affinity for BR-II and ActR-II. Affinity for type II receptors is slightly increased in the presence of type I receptor; however, even in the absence of the latter, BMP-2 is able to interact with the type II chains [13,23,24]. In addition, a population of BMP-receptors exists prior to ligand binding in preformed complexes composed of BR-II and BR-IA or BR-IB [25]. Binding of BMP-2 to either preformed receptor complexes or to the high-affinity BR-I receptors results in induction of different signaling pathways [26].

BMP-2-BR-IA_{ec} Complex

Comprehensive mutational studies on BMP-2 mapped two symmetric pairs of spatially separated and functionally independent epitopes on the surface of the dimer for interactions with the two receptor classes [13]. Based on their locations on the BMP-2 hand, the type I receptor binding site is referred to as the *wrist epitope* and the type II receptor site the *knuckle epitope*. This epitope assignment is fully compatible with the crystal structure of the trimeric complex between BMP-2 and a pair of its high-affinity receptor chains BR-IA_{ec} [18]. In the complex, the twofold rotational symmetry of the ligand is retained, with the symmetry axis normal to the plane of the membrane (Fig. 2a). Each of the two receptor molecules, the structures of which can be compared to open left hands, binds with its concave palm side to the wrist of one of the two BMP-2 monomer hands. An extended groove on the receptor surface harbors ligand residues of the pre-helix loop and the α -helix (residues Phe49–Val63 in BMP-2). The binding site on BMP-2 extends to the inner side of the fingers of the adjacent BMP-2 subunit, and thus covers the complete *finger-helix-groove* [12]. Central to the contacts in this second part of the binding epitope is a hydrophobic pocket on the ligand surface, which is found in all currently

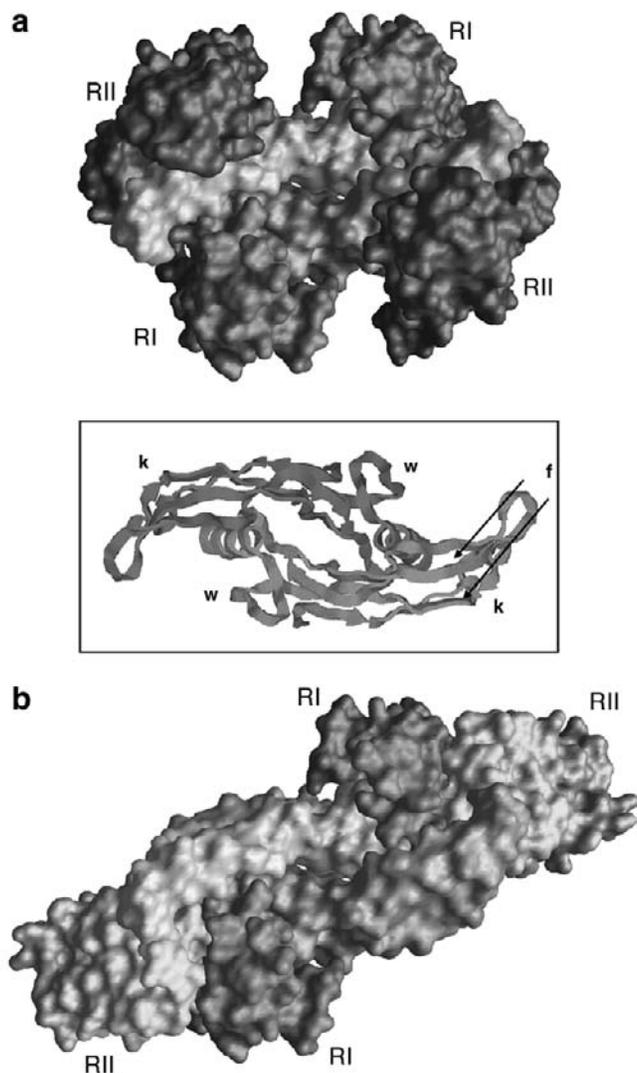

Figure 2 (a) Model of the complete pentameric complex for the BMP-2 subfamily with BMP-2 (L, orange), BR-IA_{ec} (RI, red), and ActR-II_{ec} (RII, blue). The model is based on the crystal structure of the complex between the ligand and the type I receptors. ActR-II_{ec} was fitted onto the knuckle epitope of BMP-2. The view is approximately along the two-fold symmetry axis, (i.e., onto the plane of the membrane). The receptor chains are not in contact with each other. (b) Model of the pentameric complex for the TGF β subfamily according to Hart *et al.* [19], based on the crystal structure of TGF β 3 and TGF β R-II_{ec}, with the ligand (L) and the type I receptor (RI) colored orange and red, respectively, as in part (a), and the type II receptor (RII) in green. Note that in this model, the two receptor chains are in close contact with each other. The orientation is the same as in part (a). The insert shows a ribbon diagram of the ligand depicting the fingers (f, shown in one monomer only), knuckle (k), and the wrist (w) epitopes.

known ligand structures of the superfamily [18]. The counterpart to this pocket is a large hydrophobic residue (Phe85 in BR-IA_{ec}) that is functionally conserved within the class of type I receptors. This residue is located in helix α 1, a secondary structure element not present in the type II receptors ActR-II and TGF β R-II. Based on the high degree of conservation of this knob-into-hole motif, it was deduced that this is a key interaction between the ligand and the type I receptors. Two observations may explain why little cooperation is observed between binding of the two receptor types: (1) the

knuckle epitope on BMP-2, which so far is defined only by functional analyses and which provides the putative type II receptor binding site (experimentally shown for BR-II_{ec} and ActR-II_{ec}), does not overlap with the binding epitope for type I receptors [13]; and (2) the structure of BMP-2 in the complex differs only by a slight opening of the finger-helix-cavity from that of the free ligand [12,18].

Alanine scanning mutagenesis of ActR-II_{ec} [27] identified a cluster of hydrophobic residues that are essential for binding to activin A. This cluster colocalizes with the central part of the palm epitope on BR-IA_{ec} (i.e., the part of the molecule that forms the contacts to the ligand), suggesting a mode of binding of this type II receptor to its ligands that is very similar to that described for the BMP-2–BR-IA_{ec} complex.

Complex Formation with TGF β Is Different than for BMP-2

Our understanding of the receptor–ligand complex, with well-separated type I and type II binding epitopes and assumed to be valid for the entire TGF β superfamily, had to be revised with the publication of the crystal structure of TGF β 3 in complex with TGF β R-II_{ec} [19]. Surprisingly, the receptor does not bind to a region corresponding to the knuckle epitope on BMP-2. Instead, it interacts with a hydrophobic cleft in the fingertips of the ligand and is in close proximity to the expected type I receptor binding site. Although TGF β R-II_{ec} shares the overall fold topology of ActR-II_{ec} and BR-IA_{ec} (Fig. 1), a few structural modifications in loop regions result in a completely different binding mode to the ligand. Most prominent among these modifications is an insertion of seven residues in loop 4 of TGF β R-II which packs against the central β -sheet in a way that the residues corresponding to those crucial to binding the ligand in ActR-II_{ec} as well as in BR-IA_{ec} are no longer accessible. The ligand binding residues in TGF β R-II_{ec} are located in β -strands 1 and 4, whereas the equivalent amino acids in BR-IA_{ec} are on the back side of the receptor and do not contact the ligand. Furthermore, the orientation of the receptor relative to the cell membrane differs significantly; in BR-IA_{ec} the plane of the central β -sheet is almost perpendicular to the membrane, but in TGF β R-II_{ec} it is almost parallel to the plane of the membrane.

Based on these findings a model for the pentameric signaling complex of TGF β s was suggested that combines the evidence from the two known crystal structures of ligand–receptor complexes [19]. In this model, the type I receptor binds to TGF β in a way described by the BMP-2–BR-IA_{ec} complex, as this is accepted to be common within the superfamily, and the type II receptor binds as found in the TGF β 3–TGF β R-II_{ec} complex (Fig. 2b). As a consequence, both receptors are in direct contact with each other, which may account for the cooperativity found for TGF β receptor complex formation.

In conclusion, current structural knowledge shows that, despite high structural similarities among ligands as well as receptors within the TGF β superfamily, substantial differences

exist among subfamilies upon formation of the receptor–ligand complexes. Due to the relatively low stability of the pentameric arrangement of ectodomains and ligands, it will remain challenging to obtain three-dimensional structures of the complete complexes.

Insulin Receptor Complex and Signaling by Insulin

Lindsay G. Sparrow and S. Lance Macaulay

Parkville, Victoria, Australia*

Introduction

Insulin is an important regulatory hormone that mediates energy uptake by the body. It is the major food storage hormone and is secreted in response to rising blood sugar levels following a meal. It regulates energy uptake by inhibiting glucose production by the liver and by increasing sugar uptake into muscle and fat, directing this sugar into the storage forms of glycogen in liver and muscle and fat in adipose cells. Insulin deficiency or resistance to its actions leads to the profound metabolic dysfunctions of Type 1 or Type 2 diabetes, respectively, which are major diseases of the Western world. There is, therefore, intense interest in understanding the mechanisms of action for insulin. Insulin exerts a wide variety of effects on cells, including both metabolic and mitogenic actions that are triggered by binding to its cell surface receptor. This review briefly explores the nature of this receptor, its interaction with insulin, and its signaling to a major metabolic target, glucose transport.

Insulin Receptor Domain Structure

The insulin receptor (IR) is a glycosylated, disulfide-linked homodimer, with each monomer being made up of an α -chain that is entirely extracellular and a β -chain that spans the cell membrane once. The α -chain contains the insulin-binding determinants of the receptor, while the intracellular portion of the β -chain includes a protein-tyrosine kinase domain and domains involved in binding signal transduction proteins. The $\alpha\beta$ monomer of the IR is encoded by a gene with 22 exons; alternative splicing of the IR pre-mRNA

leads to the tissue-specific expression of two isoforms differing by the presence or absence of a 12-residue segment (exon 11) near the C terminus of the α -chain. The receptor is synthesized as a single chain with a 27-residue signal sequence and is glycosylated, oxidized to the disulfide form, and proteolytically processed to the two-chain form during transport to the cell surface. The mature α -chain of the human IR has 731 amino acid residues, while the β -chain has 620. Two receptors with close sequence and structural homology to the IR are the receptor for insulin-like growth factor 1 (IGF-1R) and the orphan receptor, the insulin-receptor-related receptor (IRR) (see references [1] to [3] for reviews).

Analysis of the sequence of the IR has shown that the molecule can be divided into a number of modules or domains [4]. The ectodomain has two large homologous domains of approximately 150 residues, L1 and L2, separated by a 150-residue cysteine-rich domain; in this respect, the IR is similar to the epidermal growth factor receptor (EGFR). C-terminal to these, the IR has three fibronectin type III domains (FnIII-1, -2, and -3) of approximately 100 to 130 residues each. One of these, FnIII-2, has an insertion of 125 residues that contains the α - β cleavage site, resulting in the N-terminal region of FnIII-2 and part of the insert domain (ID) being found at the C terminus of the α -chain, and the remaining portions of these two domains being located at the N terminus of the β -chain. The domain structure of the IR ectodomain is shown schematically in Fig. 1. The discussion in this section focuses largely on the structure of the ectodomain and its interaction with the ligand, insulin. The structure of the kinase domain is discussed in Chapter 53.

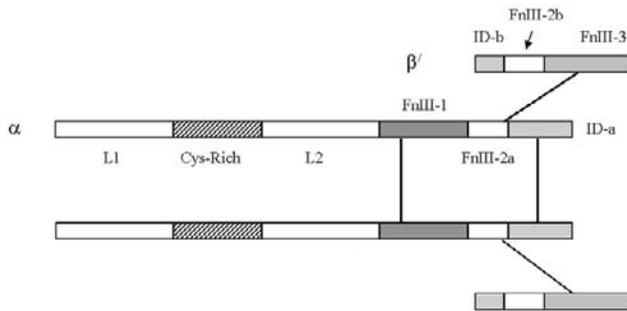

Figure 1 Domain structure of the IR. Heavy lines, chain-linking disulfide bonds; β' refers to that portion of the β -chain that is extracellular.

The IR ectodomain has been shown to have a single disulfide bond linking the α - and β -chains, joining residues 647 and 872 (exon 11 plus form), and at least two disulfides symmetrically linking the α -chains of the dimer, one at residue 524 and the second at one of residues 682, 683, and 685. The human IR has 18 predicted sites for N-linked glycosylation: 14 on the α -chain and 4 on the β -chain. Of the 18 predicted N-linked sites, 16 are occupied by carbohydrate and one is unoccupied; O-linked glycans have been shown to occur on only 4 threonine and 2 serine residues in the 22 residues at the N terminus of the β -chain.

Although no crystal structure of the IR is yet available, a structure for a fragment of the homologous receptor, IGF-1R, has been published [5]. The structure of this fragment (Fig. 2), an expressed recombinant protein encompassing the L1–Cys-rich–L2 domains of the IGF-1R, should give a strong indication of the structure of the corresponding fragment of the IR.

Binding Determinants of the IR

Insulin is thought to have two distinct receptor binding surfaces, with one site encompassing at least the residues G1, E4, Q5, and N21 of the insulin A-chain and the other site being made up of residues V12, Y16, F24, F25, and Y26 of the B-chain; other residues apart from those listed above are almost certainly involved in this interaction [6]. Binding of insulin to the native, dimeric IR is characterized by curvilinear Scatchard plots and the phenomenon of negative cooperativity, both interpreted as showing the presence of two states of the receptor, one of high-affinity insulin binding and the other of low affinity. Half receptors, i.e., $\alpha\beta$ -monomers, formed by mild reduction of the dimeric $(\alpha\beta)_2$ receptor, do not show these phenomena and bind insulin with only low affinity [7], as does the expressed recombinant IR ectodomain. High-affinity binding is restored when the IR is truncated below the transmembrane domain or when a dimerization moiety such as the IgG- γ domain or a leucine-zipper segment is fused to the C terminus of the expressed ectodomain [2]. Clearly, not only is the dimeric state of the IR essential for high-affinity binding, but also the relative disposition of the two monomers in the

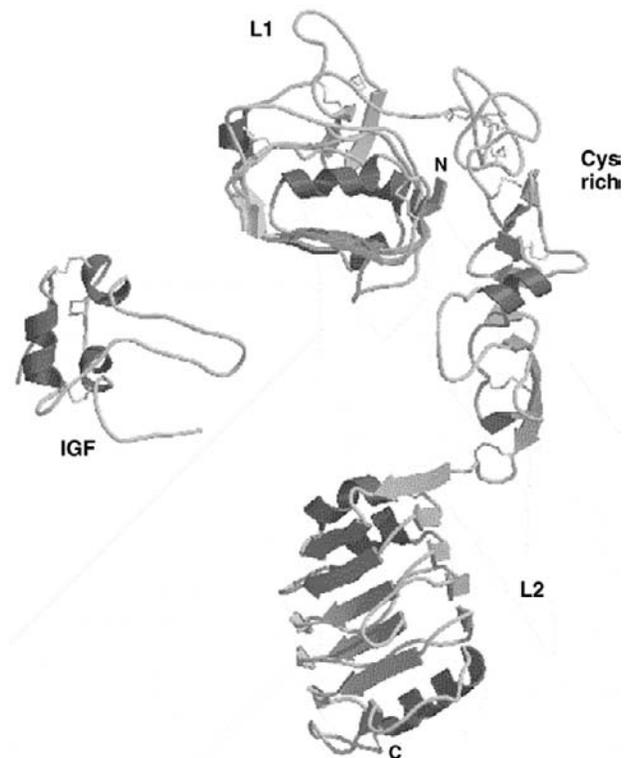

Figure 2 Structure of the fragment, L1–Cys-rich–L2, of the IGF-1R. Helices are depicted as broad ribbons and β -strands as broad arrows. Also shown, to scale, is the ligand IGF-1.

dimer is critical; it seems that the C termini of the two α -chains must be in close proximity for effective high-affinity binding to insulin.

The isolated α -chain of the IR binds insulin, although with an affinity lower than that of the wild-type receptor, and thus appears to have all the insulin-binding determinants of the receptor. By alanine-scanning mutagenesis, studies of chimeric receptors, and direct cross-linking of insulin to the IR, binding determinants on the receptor have been located in the L1 domain, in the Cys-rich region, and near the N terminus of the L2 domain. Additionally, important determinants are also found close to the C terminus of the α -chain [2]. For both the IR and the IGF-1R, the L1–Cys-rich–L2 fragment does not bind the cognate ligand, despite the presence of many of the binding determinants and despite the fact that the horseshoe-like structure reveals a cavity of sufficient dimensions to partly encircle the ligand. Thus, the X-ray structure of this fragment does not yield details of the complete ligand-binding site. However, ligand binding can be restored by adding to the C terminus of this fragment a 16-residue peptide that includes the binding determinants identified at the C terminus of the α -chain. The peptide can be attached directly to the L1–Cys-rich–L2 fragment or by using linkers of varying length. This suggests that the mode of attachment is perhaps not critical, a view supported by the observation that the addition of the free peptide to the fragment also restores ligand binding [8]. The 16-residue peptide itself probably does not directly bind insulin, as

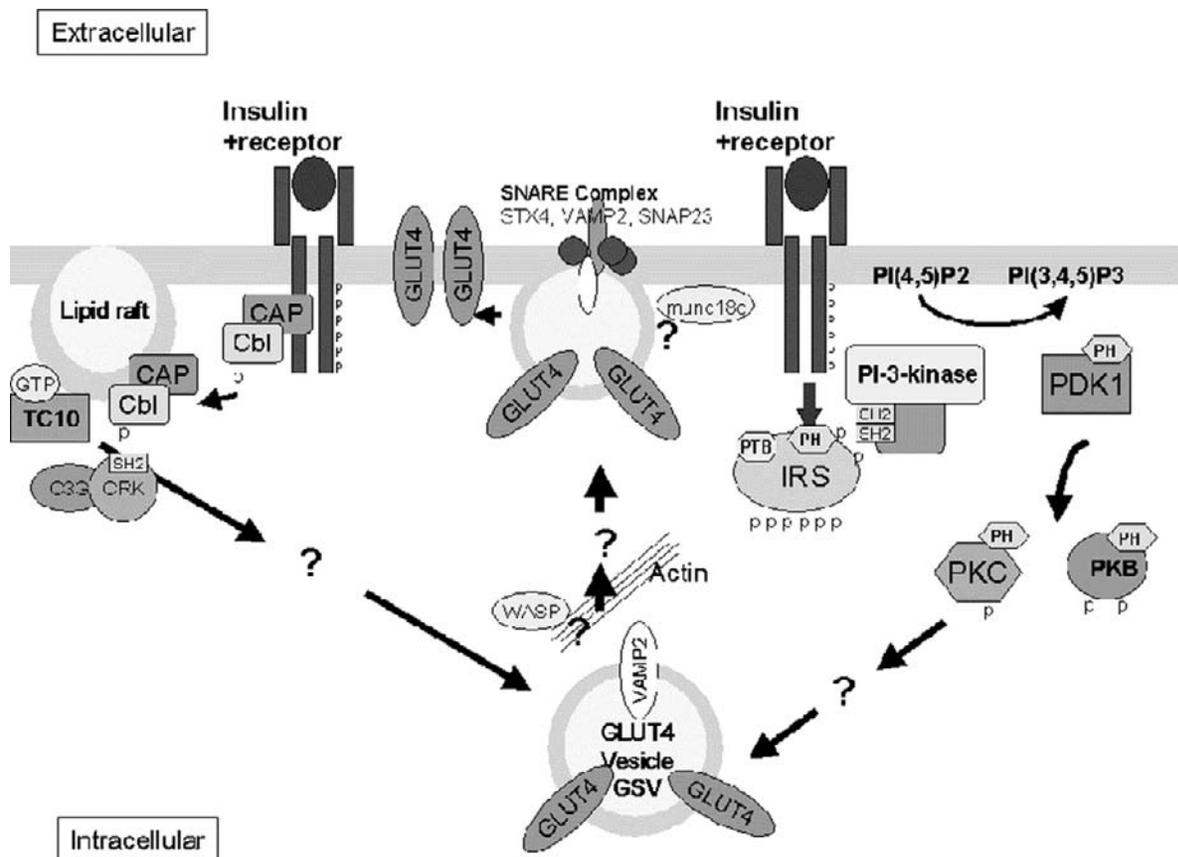

Figure 3 Putative signaling pathways involved in insulin-stimulated GLUT4 trafficking.

C-terminal fragments of the IR comprising two or three FnIII domains and including this 16-residue segment of the α -chain do not bind insulin [9].

Although each α -chain of the IR has all the determinants necessary for binding of insulin, high-affinity binding requires two α -chains held in appropriate juxtaposition by at least two disulfide bonds between these chains and by a single disulfide bond linking each α -chain to a β -chain that is itself anchored to the cell membrane. This suggests that two $\alpha\beta$ monomers are involved in binding a single insulin molecule, thus providing a cross-link between the chains in addition to the disulfide bonds. A significant observation is that the IR undergoes an obvious conformation change (Stokes radius from 9.1 to 7.5 nm) on binding insulin [7]. The nature of this change is unclear, but it may in some way bring together the two kinase domains of the homodimer so that the activation loop of one is accessible to the active site of the other. Such a movement may be equivalent to that observed for other receptor molecules, such as the EGFR, that undergo dimerization following ligand binding, resulting in activation of the receptor tyrosine kinase. Full details of the binding of insulin to its receptor and the subsequent conformation change will probably not be known until crystal structures of the receptor with and without bound ligand are available. Activation of the IR kinase is accompanied by autophosphorylation at up to six tyrosines which both further activates the kinase and creates binding sites for

signaling proteins, which in turn become phosphorylated and bind their downstream targets.

Insulin Signaling to Glucose Transport

A major, if not *the* major, endpoint of insulin signaling is the stimulation of glucose uptake (transport) in muscle and fat, the focus of the remainder of this chapter. Currently, at least two distinct pathways (Fig. 3) have been implicated in this process. Both pathways may be required for translocation of the insulin-regulated glucose transporter, GLUT4, a 12-transmembrane-spanning protein, from a vesicular storage compartment (GSV) within the cell, to the plasma membrane. Its insertion makes it competent to transport glucose into the cell (for reviews, see references [10] to [12]). The most extensively characterized of these pathways begins with the IRS family of proteins (see Chapter 71). Tyrosine phosphorylation of these proteins by the insulin receptor provides recognition sites for Src homology domain 2 (SH2)-containing proteins. Of significance for several pathways in insulin action, including those leading to glucose transport and glycogen synthesis, is the binding and activation of the type 1A phosphatidylinositol 3 (PI3) kinase (for reviews, see references [10], [12], and [13]). This enzyme phosphorylates inositol phospholipids in the plasma membrane, increasing PI3,4,5-trisphosphate (PI345P3)

levels and enabling the recruitment and activation of a serine/threonine kinase, phosphoinositide-dependent protein kinase (PDK1), via association of its pleckstrin homology (PH) domain with this phospholipid. PDK1 can then phosphorylate and activate two families of proteins implicated in stimulating glucose transport, the atypical protein kinases C ζ / λ , and protein kinase B (PKB) isoforms (for reviews, see references [12] and [13]). Unfortunately, downstream targets of these kinases relevant for stimulation of glucose transport have remained elusive despite intensive investigation.

Another putative pathway implicated in insulin stimulation of glucose transport is PI3-kinase independent and involves tyrosine phosphorylation of the protooncogene Cbl by the insulin receptor tyrosine kinase, possibly via association with the Cbl-associated protein (CAP) to the receptor within caveolin-rich lipid rafts (for reviews, see references [10] and [11]; Fig. 3). This enables the recruitment of the adaptor protein CrkII and its associated guanine exchange factor, C3G, resulting in activation of the Rho family GTPase, TC10. How this pathway intersects the PI3-kinase-dependent pathway to stimulate GLUT4 translocation is unclear. At least one of the pathways must act on the vesicular compartments storing GLUT4 to move them to the cell surface.

Recent data suggest involvement of cytoskeleton proteins such as vimentin, α -tubulin, dynein, and/or cortical actin in moving GLUT4 to the cell surface [14–16]. Indeed, one recent study provided a possible link between the TC10 pathway and mobilization of cortical F-actin, demonstrating in adipocytes that insulin causes cortical localization of the regulatory Wiscott–Aldrich syndrome protein (WASP) and actin-related protein 3 (Arp3), as well as actin polymerization [15]. Thus, it seems likely that the cytoskeleton is involved in trafficking GLUT4, although the detail remains to be determined.

Following translocation of GLUT4 vesicles to regions below the cell surface, the final stages of trafficking and fusion of the GLUT4 vesicles have been shown to involve soluble N-ethylmaleimide-sensitive factor attachment protein receptor (SNARE) proteins (for reviews, see references [11] and [16]). These were first described as proteins mediating the fusion of neurotransmitter vesicles at synaptic terminals, and much of the molecular detail of SNARE protein interactions has been elucidated for this system [18]. In the case of plasma membrane trafficking of GLUT4, the functional vesicle-associated membrane protein (VAMP; also known as synaptobrevin) isoform is VAMP2. This protein binds two plasma membrane SNARE proteins, syntaxin 4 (STX4) and SNAP23, to form a so-called SNARE complex involving interaction between coiled-coil regions of the three proteins. Although the formation of this complex is possibly sufficient to enable fusion of the GLUT4 vesicle with the plasma membrane, thus placing GLUT4 proteins on the cell surface to transport glucose into the cell, effective fusion also requires N-ethylmaleimide-sensitive factor (NSF) and soluble NSF attachment protein (α -SNAP)-driven hydrolysis of adenosine triphosphate (ATP). The precise role of NSF and α -SNAP in fusion, however, is unclear.

Additional accessory proteins have been demonstrated to regulate this fusion process, although the roles of these accessory factors are likewise unclear (for reviews, see references [11] and [16]). Munc18c is a STX4-binding protein that may have a role as a molecular chaperone for STX4 and in fusion. Other proteins implicated in regulation of fusion events include synip (STX4-interacting protein), synaptotagmin, VAP-33, and Rab4. How these proteins interact with the fusion proteins to regulate this important process remains to be established. Further regulation is provided by the endosomal trafficking of the transporters via clathrin-coated pits for recycling via constitutive or insulin-regulated compartments (for reviews, see references [12] and [17]). Although there is general agreement that the majority of GLUT4 is segregated into a unique insulin-sensitive endosomal compartment (GSV) in the basal state, the nature of this compartment and its regulation remain unclear despite the identification of targeting motifs within the C- and N-terminal regions of GLUT4. These areas offer fruitful avenues for investigation over the coming years.

Acknowledgment

The authors regret that due to space restrictions there was not space to cite the significant contributions of many investigators to the field; we have instead cited representative reviews that cover the respective areas in greater detail. The authors thank Dr. Tom Garrett for permission to use Fig. 2.

New York, New York*

Introduction

The hormone insulin activates signaling pathways that regulate cellular metabolism and growth [1]. The actions of this essential hormone are mediated by the insulin receptor [2,3], a member of a large family of transmembrane receptors known as receptor tyrosine kinases (RTKs), which contain intrinsic tyrosine kinase activity in the cytoplasmic domain. These receptors catalyze the transfer of the γ -phosphate of adenosine triphosphate (ATP) to tyrosine residues in protein substrates. The RTK family also includes, among others, the receptors for insulin-like growth factor 1 (IGF-1), epidermal growth factor (EGF), fibroblast growth factor (FGF), platelet-derived growth factor (PDGF), and vascular endothelial growth factor (VEGF). There is also a large family of non-receptor tyrosine kinases that includes Src, Abl, Jaks, Syk/Zap70, and Fak. Receptor and nonreceptor tyrosine kinases are critical components of signaling pathways that control cellular proliferation, differentiation, migration, and metabolism [4].

In contrast to most other members of the RTK family, which are monomeric and activated by ligand-induced oligomerization, the insulin receptor is an $\alpha_2\beta_2$ heterotetramer (Fig. 1), with disulfide linkages between the two extracellular α -chains and between the α -chains and the transmembrane β -chains. Insulin binding to the α -chains induces a structural rearrangement within the receptor, resulting in autophosphorylation of specific tyrosines in the β -chain: at least one in the juxtamembrane region (Tyr972), three in the tyrosine kinase domain (Tyr1158/1162/1163), and two in the C-terminal tail (Tyr1328/1334) (Fig. 1).

The phosphorylated tyrosines either stimulate catalytic activity (pTyr1158/1162/1163) [5] or serve as recruitment sites for downstream signaling proteins (pTyr972) [6]. Both phosphotyrosine functions—stimulation of catalytic activity and recruitment—are critical to the activation process. Following insulin stimulation, two distinct downstream pathways are activated to facilitate fusion of Glut4-containing vesicles with the plasma membrane for glucose uptake [7].

Structural/Mechanistic Studies

Overview

Structural studies of the insulin receptor have been limited largely to the cytoplasmic portion of the β -subunit. Within the cytoplasmic portion are 36 residues in the juxtamembrane region (membrane-proximal), 295 residues in the tyrosine kinase domain, and 72 residues in the C-terminal tail (Fig. 1). Crystal structures of the insulin receptor kinase domain (IRK) have been determined in different states of phosphorylation [8,9] and for several mutants [10] (S. R. Hubbard, unpublished data). IRK shares a similar overall architecture with protein serine/threonine kinases [11], with an N-terminal lobe composed of a five-stranded anti-parallel β -sheet and one α -helix, and a larger C-terminal lobe that is mainly α -helical (Fig. 2). ATP binds in the cleft between the two lobes, and the tyrosine-containing segment of a protein substrate interacts with residues in the C-terminal lobe. Several residues are highly conserved in all functional tyrosine kinases, including several glycines in the nucleotide binding loop; a lysine in β -strand 3 (β_3); a glutamic acid

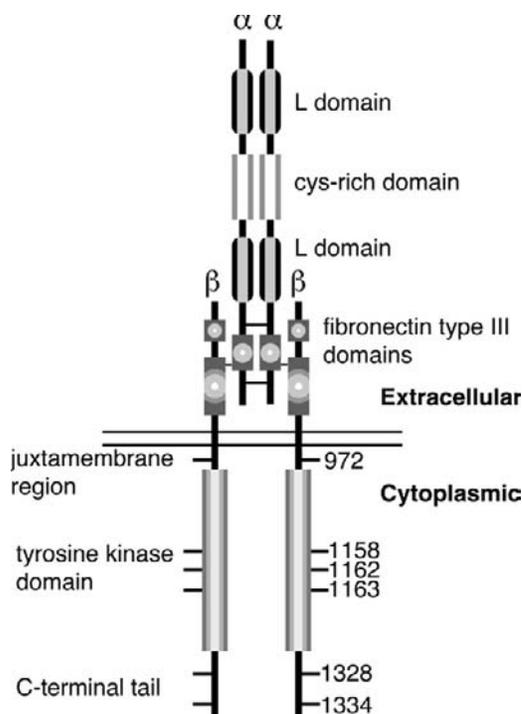

Figure 1 Overall architecture of the insulin receptor. The α -chains are extracellular and the β -chains pass through the plasma membrane. The major sites of tyrosine autophosphorylation are numbered according to Ebina *et al.* [2]. There are two fibronectin type III domains in the extracellular portion of the receptor. The N-terminal portion of the first domain is on the α -chain, and the C-terminal portion of this domain resides in the beginning of the β -chain, which is followed by a second, intact domain. Solid lines between the α -chains and between the α - and β -chains represent disulfide linkages.

in α -helix C (α C); an aspartic acid, arginine, and asparagine in the catalytic loop; and, in the activation loop, a DFG motif in the beginning and a proline at the end (Figs. 2 and 4).

Although no crystal structure has been reported for the extracellular region of the insulin receptor, a crystal structure of the first three domains of the highly related IGF-1 receptor has been published [12]. This structure shows the probable site of interaction between the ligand (IGF-1 or insulin) and the L domains and cysteine-rich domain of the receptor. Recently, a low-resolution image reconstruction of the full-length insulin receptor with bound insulin has been determined using electron microscopy, providing a putative model for the spatial organization of the various domains in the intact receptor [13].

Receptor Activation Mechanism

The binding of insulin to its receptor induces a conformational change in the receptor, measured (among other techniques) as a reduction in the Stokes radius of the insulin-occupied versus -unoccupied receptor [14]. The physical mechanism by which binding of insulin to the extracellular portion of the receptor is transduced to the cytoplasmic portion is not well understood. From the image reconstruction

Figure 2 Ribbon diagram of the tyrosine kinase domain of the insulin receptor [9]. The α -helices are lettered, and the β -strands are numbered. The ATP analog (AMP-PNP) and the side chain of the substrate tyrosine are shown in ball-and-stick representation. The N terminus is denoted by N; the C terminus is not visible but follows shortly after α J.

of the insulin-occupied receptor, a model for this mechanism has been proposed in which insulin binding produces a movement of the transmembrane helices toward one another, facilitating autophosphorylation between the kinase domains [15].

Once the insulin-triggered conformational change has been transmitted to the cytoplasmic domains, most biochemical data are consistent with tyrosine autophosphorylation proceeding via a *trans* mechanism, in which the tyrosine kinase domain of one β -chain phosphorylates tyrosines on the other β -chain within the same heterotetramer [16]. Simple modeling studies based on IRK crystal structures [8,9] indicate that the activation loop is too short to be autophosphorylated in *cis*, and solution studies support a *trans* mechanism for the activation loop [17]. Autophosphorylation of Tyr972 in the juxtamembrane region is also likely to occur in *trans*, for steric reasons, whereas autophosphorylation of the C-terminal tyrosine sites could potentially occur in *cis* after *trans*-autophosphorylation of the activation loop.

Activation Loop Autoinhibition

A key mechanism by which the insulin receptor and other tyrosine and serine/threonine kinases regulate catalytic activity is through positioning of the activation loop [18]. The activation loop of the insulin receptor begins with a protein kinase-conserved 1150 DFG motif and ends with tyrosine-kinase-conserved Pro1172. Between these conserved residues are three sites of tyrosine autophosphorylation: Tyr1158, Tyr1162, and Tyr1163. The activation loop in the crystal structure of the unphosphorylated, low-activity form of

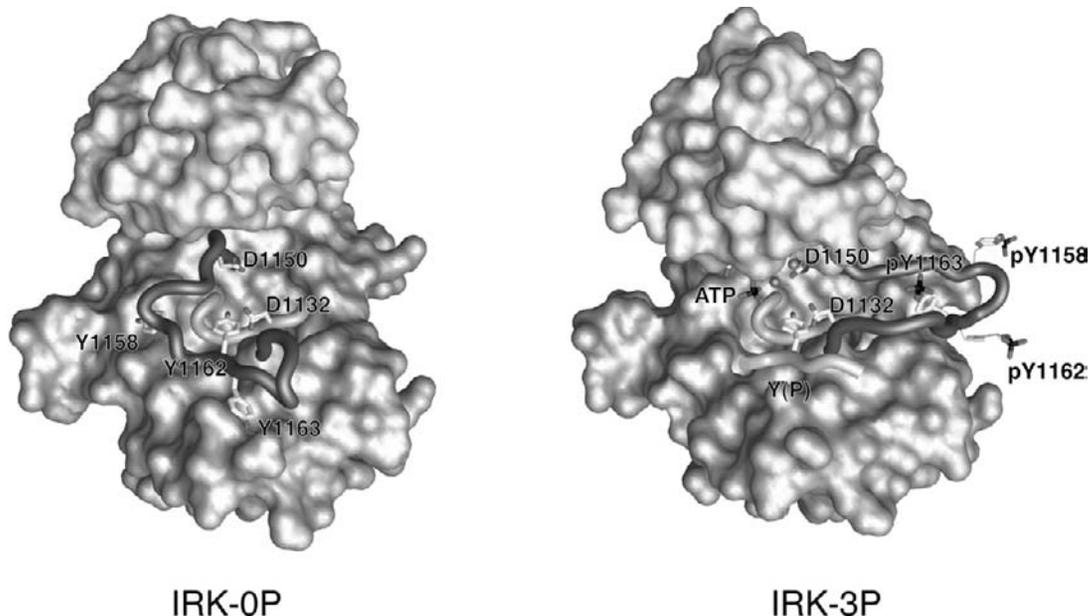

Figure 3 Comparison of the activation loop conformations in unphosphorylated IRK (IRK-0P) [8] and tris-phosphorylated IRK (IRK-3P) [9]. The activation loop contains Asp1150, Tyr1158, Tyr1162, and Tyr1163. The catalytic loop contains Asp1132. The remainder of the protein in each case is represented by a molecular surface. For IRK-3P (right), the substrate peptide (containing Y(p)) and the ATP analog are shown, the latter of which is partially masked by the N-Terminal lobe of IRK-3P.

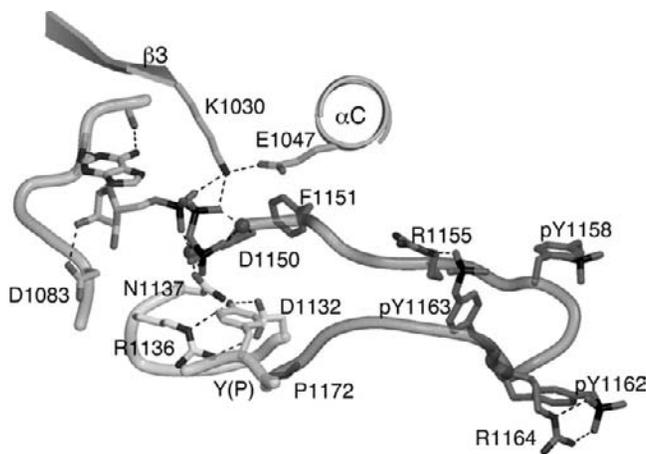

Figure 4 Properly configured active site in IRK for phosphoryl transfer derived from the ternary IRK-3P structure [9] with the following modifications: the Lys1030 side-chain rotamer and the ATP γ -phosphate dihedral angle have been changed to coincide with those in the structure of ternary protein kinase A (PKA) [28]. Two active site Mg^{2+} ions are shown as spheres. Hydrogen bonds are represented as black dashed lines.

IRK (IRK-0P) traverses the cleft between the two kinase lobes, with Tyr1162 bound in the active site, hydrogen-bonded to conserved residues Asp1132 and Arg1136 of the catalytic loop (Figs. 3 and 4) [8]. This conformation of the activation loop obstructs the substrate and nucleotide binding sites via Tyr1162 (acting as a pseudosubstrate) and residues of the DFG motif, respectively. Solution studies of IRK indicate that in the presence of millimolar quantities

of ATP (comparable to cellular levels), the activation loop is actually in equilibrium between inhibiting, gate-closed conformations, as represented by the IRK-0P crystal structure, and gate-open conformations in which the activation loop is displaced from the active site cleft [19].

The crystal structure of the tris-phosphorylated, activated form of IRK (IRK-3P), co-crystallized with a Mg-ATP analog and substrate peptide, reveals how autophosphorylation of the three activation loop tyrosines stabilizes a particular gate-open conformation that is optimal for catalysis (Figs. 3 and 4) [9,20]. More specifically, the autophosphorylation-induced rearrangement of the activation loop accomplishes four main mechanistic objectives: (1) release of steric constraints to Mg-ATP and substrate binding, (2) proper positioning of Asp1150 (DFG motif) for coordination of an active site Mg^{2+} ion, (3) proper positioning of Phe1151 (DFG motif) to facilitate lobe rotation for productive ATP binding, and (4) proper positioning of the end of the activation loop, which acts as a platform for substrate binding. The positions of residues in the catalytic loop remain virtually unchanged in the basal (unphosphorylated) and activated (tris-phosphorylated) states of IRK.

The activation loop conformation in the IRK-3P structure is stabilized by direct interactions between the phosphate groups of pTyr1162 and pTyr1163 and basic residues in the activation loop (Arg1164 and Arg1155, respectively) and by short, anti-parallel β -strand interactions between segments of the activation loop and the C-terminal lobe. These interactions are also observed in the structure of the related IGF-1 receptor kinase [21]. Interestingly, the phosphate group of pTyr1158 makes no contacts with other kinase residues and

has been reported to bind a subset of Src homology 2(SH2) domain-containing proteins including SH2-B γ [22] and APS [23].

It has not been possible to crystallize IRK-OP with bound Mg-ATP analog and substrate peptide, presumably due to the high K_m values for ATP and substrate peptide in the unphosphorylated state (≈ 1 and 2 mM, respectively) [24]. An approximate view of the initial, basal-state autophosphorylation event was provided by the crystal structure of an IRK activation loop mutant, Asp1161 \rightarrow Ala, with bound Mg-ATP analog [10]. This structure, in combination with biochemical studies [24,25], demonstrates that a single residue change can result in loss of pseudosubstrate autoinhibition by the activation loop. In the Asp1161 \rightarrow Ala mutant, K_m for ATP is decreased and k_{cat} is increased to levels comparable to the tris-phosphorylated form [24], although K_m for substrate peptide remains high.

The structure of this mutant with bound Mg-ATP analog shows that the activation loop is disengaged from the active site and mostly disordered. In the beginning of the activation loop, the residues of the DFG motif, particularly Phe1151, are not properly positioned for catalysis. Positioning of the Phe1151 side chain in a hydrophobic pocket below αC is critical for free rotation of the N-terminal lobe with respect to the C-terminal lobe, required for productive ATP binding, and for the independent (with respect to the N-terminal β -sheet) rotation of αC , which positions Glu1047 (αC) for salt-bridge formation with Lys1030 ($\beta 3$) (Fig. 4) [10]. This structure indicates that despite release of activation loop autoinhibition (in this case through mutation), autophosphorylation of the activation loop tyrosines is still necessary to stabilize the loop in a configuration optimized for catalysis.

Prospects

An understanding of the signal transduction mechanisms intrinsic to the insulin receptor is not only of academic interest. The prevalence of non-insulin-dependent diabetes mellitus (NIDDM) in the populations of developed countries is increasing at an alarming rate. One therapeutic strategy for NIDDM is to activate (in the absence of insulin) or potentiate (in the presence of insulin) the insulin receptor. Indeed, small-molecule activators/potentiators of the insulin receptor which act cytoplasmically have been discovered through screening procedures [26,27]. Knowledge of the structural transitions that occur in the insulin receptor kinase during the activation process should aid in the design of more potent and specific small-molecule activators of the insulin receptor.

What Does the Structure of Apo2L/TRAIL Bound to DR5 Tell Us About Death Receptors?

Sarah G. Hymowitz and Abraham M. de Vos

Department of Protein Engineering, Genentech, Inc., South San Francisco, California

Introduction

The cell-surface receptors of the tumor necrosis factor receptor (TNF-R) superfamily mediate many cellular functions, including cell death, proliferation, and inflammatory responses. Within this superfamily, the death receptors, including TNF-R1, FAS, DR3, DR4, DR5, and DR6, activate the apoptotic machinery [1]. Ligand binding and clustering of the extracellular domains (ECDs) of these receptors are thought to trigger the oligomerization of their cytoplasmic death domains and assembly of the death-inducing signaling complex (DISC), leading to activation of apoptotic pathways. While the downstream effects of signals from the death receptors are very different from those of other TNFR family members, the extracellular clustering process is thought to be conserved throughout the superfamily.

The ECDs of the members of the TNFR superfamily are composed of cysteine-rich pseudo-repeat domains termed CRDs, which typically contain six cysteine residues. The crystal structures of TNF-R1 both unliganded and bound to lymphotoxin (LT) reveal that the structure of these CRDs consists of a ladder of disulfide bridges connected by intervening loops [2,3]. The ligands all have the prototypical fold first seen in the structure of TNF [4]. This fold is comprised of a trimer of jelly-roll domain protomers, with each protomer consisting of two flat β -sheets composed of strands A'AHCF and B'BGDE (Fig. 1). The B'BGDE sheet is more solvent accessible than the A'AHCF sheet. In the complex of LT with TNF-R1, the thin and elongated receptors bind at the interfaces between ligand monomers (Fig. 2) [3].

Novel Features in the Structure of Apo2L/TRAIL

Two independent crystal structures of unbound Apo2L/TRAIL show that it resembles the TNF trimer in its basic architecture [5,6]. Apo2L/TRAIL has two unusual features with respect to other TNF family members. First, it has a distinct, long loop between strands A and A' (residues 130 to 150) that traverses its surface but is poorly ordered or even disordered between residues 131 and 143 (Fig. 1). Second, a novel zinc-binding site buried in the trimer interface is formed by the single cysteine residue from each monomer [6,7]. This binding site appears to be unique to Apo2L/TRAIL among TNF family members. Its importance for the structural integrity and biological activity of the protein was revealed when the site was removed using chelating agents or mutation of the cysteine residue [6,8,9]. The resulting protein showed changes in its circular dichroism and tryptophan fluorescence spectra, indicating a more open trimer, and had reduced thermal stability, receptor-binding affinity, and bioactivity. Therefore, the role of the zinc site is to stabilize the trimer and, in particular, the conformation of the adjacent loops that interact with receptor.

Apo2L/TRAIL:DR5 structures

Overview

The crystal structure of Apo2L/TRAIL bound to the ECD of one of its signaling receptors, DR5, has recently been

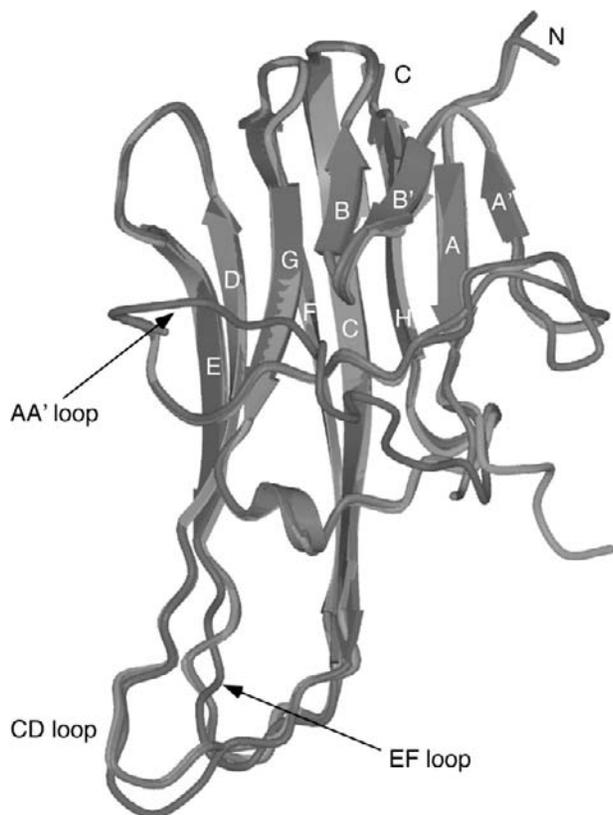

Figure 1 Superposition of monomers from independent crystal structure determinations of Apo2L/TRAIL taken from complex structures with DR5, showing the variations in loop conformation. Monomer A (Hymowitz *et al.* [7]) is rendered in light gray; monomer B (Mongkolsapaya *et al.* [10]), in medium gray; and monomer D (Cha *et al.* [11]), in dark gray.

determined by three different groups [7,10,11]. These three independent structures are in good overall agreement, especially around the receptor binding site. As in the LT–TNF-R1 complex, the three symmetrical binding sites on the ligand are nestled between the monomer–monomer interfaces; each site forms two distinct patches, one centered around Tyr 216 and the other around Gln 205 (Fig. 2). Both of these residues have been shown to be critically important for Apo2L/TRAIL activity [6]. Two loops from DR5, the 50s loop in CRD2 and the 90s loop in CRD3, make almost all the contacts with the ligand. The conformation of the 90s loop is very different between DR5 and TNF-R1, and its sequence in other TNF-Rs is highly variable. This loop was proposed to be important for defining the specificity and cross-reactivity among TNF-R family members [11]. In contrast, the 50s loop has a backbone conformation very similar to the corresponding loop in TNF-R1 (the C α atoms of DR5 residues 50 to 62 superimpose to within 0.4 Å on the C α atoms of TNF-R1 residues 60 to 72). Moreover, the sequence of this loop is well conserved among TNF-R family members, suggesting that its conformation and binding characteristics may be conserved as well (Fig. 3). Most of the differences in the independent structures of Apo2L/TRAIL–DR5 occur at loops on the ligand and away from the receptor binding site and involve poorly ordered parts of the molecule. In exception to this, the most

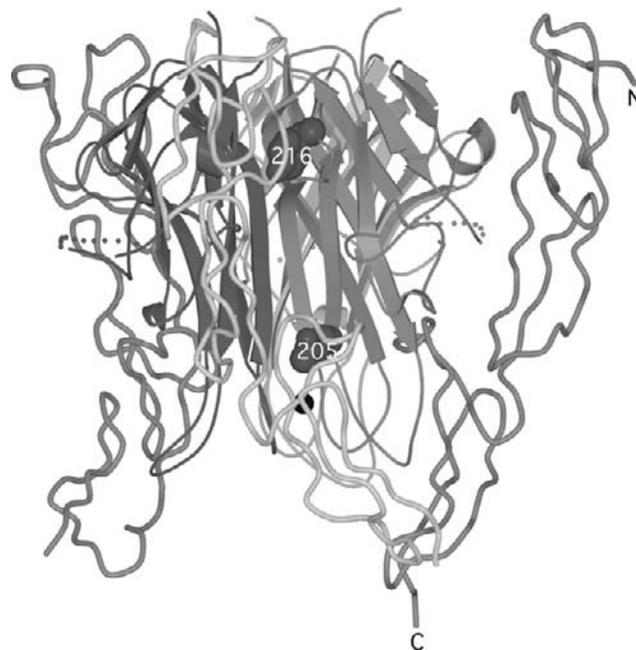

Figure 2 Crystal structure of Apo2L/TRAIL (light gray) bound to the ECD of DR5 (dark gray and black) (Hymowitz *et al.* [7]). Residues 132 to 143 of Apo2L/TRAIL are disordered and shown as small balls. The internal zinc ion is shown as a small dark sphere at the tip of the Apo2L/TRAIL trimer. The side chains of Apo2L/TRAIL residues Tyr 216 and Gln 205 are shown in close-packed rendering for one protomer (in gray).

dramatic and functionally relevant difference occurs in the EF loop of Apo2L/TRAIL in the structure by Mongkolsapaya *et al.* [10], for which the lack of zinc resulted in a different, less ordered conformation than that seen in the other two structures. As indicated above, zinc is required for maintaining the structural integrity and activity of Apo2L/TRAIL, and the conformation observed in the structures by Hymowitz *et al.* [6,7] and Cha *et al.* [11] likely represents the native conformation.

Variation in the Orientation of CRD3 of DR5

Overall, the conformation of the receptors, and particularly of the loops that contact Apo2L/TRAIL, is well conserved among the three independent structures. One exception is revealed by a comparison of all independent copies of DR5 (Fig. 3). This comparison shows that the orientation of CRD3 with respect to the other domains is variable even among receptors within the same complex, resulting in a displacement of structurally equivalent residues by up to 5 Å. Similar variation is seen when individual DR5 structures are compared to TNF-R1 as well as in comparisons between different structures of TNF-R1 alone or bound to LT (Fig. 3). Therefore, this variability is likely to be an intrinsic property of the structure of TNF-Rs with multiple CRDs rather than a source for specificity among family members as was suggested on the basis of a single unique copy of DR5 in the structure of Mongkolsapaya *et al.* [10]. A structure of Apo2L/TRAIL bound to the extracellular

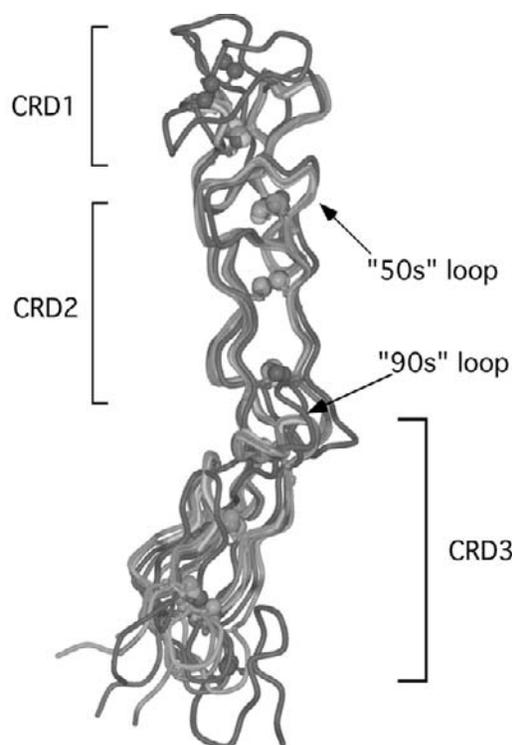

Figure 3 Superposition of the $C\alpha$ traces of ten independent DR5 structures. The three chains from Hymowitz *et al.* [7] are shown in light gray; one chain from Mongkolsapaya *et al.* [10], in medium gray; six chains from Cha *et al.* [11], in dark gray; and TNF-R1 from Banner *et al.* [3], in black. The DR5 chains were superimposed using the $C\alpha$ atoms of residues 22 to 101 (the ordered portion of CRD1, all of CRD2, and the first loop of CRD3). TNF-R1 was superimposed on DR5 using the $C\alpha$ atoms of the structurally equivalent residues in CRD2.

domain (ECD) of DR4 or to one of its decoy receptors would reveal if variation in CRD3 orientation is a common feature of other Apo2L/TRAIL receptors.

The AA' Loop of Apo2L/TRAIL

Much interest has centered on a possible role for the unusually long AA' loop of Apo2L/TRAIL (residues 130 to 150). In the structures by Hymowitz *et al.* [7] and Mongkolsapaya *et al.* [10], this loop turns away from the receptor at residue 131 and becomes poorly ordered. In contrast, in the structure by Cha *et al.* [11] residues 130 to 135, while still poorly ordered, are in a different conformation, allowing for additional contacts to DR5. However, in this model there appears to be insufficient space between DR5 and Apo2L/TRAIL for the disordered part of the chain (residues 136 to 145) to fold back across the protein, suggesting that the conformation of the last few marginally ordered residues in this model may not be biologically relevant.

In all three structures, the rest of the AA' loop uses residues 130 and 145 to 149 to make minor contacts with the receptor; however, none of these contacts involves burying significant accessible surface area. These observations are consistent with the lack of effect on binding (to DR4, DR5, or DcR2) or on the activity of single alanine substitutions

at residues 130, 134, 136, 138, 140–143, and 149 within this loop. The reduction or elimination of receptor binding activity observed upon deletion ($\Delta 137$ –152 [5]), shortening ($\Delta 132$ –135 [11]), or multiple mutation [10] of this loop may therefore be an indirect effect on the conformation of other binding determinants. In light of the point mutation results and the high degree of conformational heterogeneity seen in this loop among the three crystal structures, we conclude that these peripheral interactions are likely to vary in other death receptor complexes and that, even when present, they are unlikely to contribute as much binding energy as contacts made by residues analogous to Apo2L/TRAIL Tyr 216 and Gln 205.

Ligand-Independent Receptor Assembly

In addition to the role of CRDs 2 and 3 in ligand binding, CRD1 of receptors DR4, FAS, CD40, TNF-R1, and TNF-R2 mediates pre-ligand-binding receptor association into inactive receptor oligomers, which are thought to be altered upon ligand binding to allow intracellular DISC assembly [12–14]. In all DR5 structures, CRD1 is only partially ordered (Fig. 3). Its sequence and structure are very different from the corresponding domain in TNF-R1; furthermore, the sequences of DR4 and DR5 vary most in this CRD, and CRD1 contains no obvious motifs conserved with other TNF-R family members. For these reasons, it is unclear if ligand-independent pre-association is a universal feature of the death receptor family.

Intracellular Consequences of Ligand Binding

Ligand binding causes the cytoplasmic domain of the death receptors to interact with downstream adaptor proteins and other members of the apoptotic cascade. Some signaling components are shared; in particular, Fas, DR4, and DR5 recruit FADD and caspase 8 after binding ligand [15–17]. The geometry of the signaling complex appears to be conserved for all ligand–TNF-R complexes. Ligand binding by DR5 and TNF-R1 results in a defined geometry in which the membrane proximal residue of the three symmetrical receptor monomers forms a triangle with sides of approximately 50 Å. This geometry is likely to be biologically relevant, as a cytoplasmic triangle of these same dimensions was observed in the structure of the trimeric adaptor protein TNF-R-associated factor 2 (TRAF2) bound to peptides from intracellular portions of TNF-R2 or CD40 [18,19]. These shared features suggest that the components and geometry of the signaling complex for other death receptors are likely to be similar to those of DR5.

Conclusion

The three independent structures of death receptor 5 interacting with Apo2L/TRAIL agree well with each other

and with the general features of TNF-R1 bound to LT, indicating that the diverse receptors of the TNF-R superfamily interact with their trimeric ligands in a conserved manner. These receptors bind their ligands through modular, flexible CRDs with conserved cysteine locations presenting intervening loops of varying size and sequence. Despite the great diversity of sequence among both the receptors and the ligands, this basic mode of interaction appears to be conserved. In both the DR5 and the TNF-R1 complexes, CRD2 and the first loop of CRD3 provide almost all receptor contacts. Therefore, a structural motif barely larger than a single CRD would appear to be the minimal ligand-binding unit. Interestingly, a recently discovered, distantly related TNF-R-like molecule, B-cell maturation activity, contains only a single CRD [20]. Further insights into this important family of signaling molecules await determination of either multi-component interactions or the structures of more distantly related death receptor–ligand pairs.

TNF Receptor Associated Factors

Jee Y. Chung, Young Chul Park, Hong Ye, and Hao Wu

Department of Biochemistry, Weill Medical College of Cornell University, New York, New York

Unlike receptors with intrinsic kinase activity in their intracellular domains or in direct association with intracellular enzymes, members of the tumor necrosis factor (TNF) receptor superfamily and the interleukin-1 (IL-1) receptor/Toll-like receptor (IL-1R/TLR) superfamily use adapter proteins to couple to enzymatic activation and signal amplification. The TNF-receptor-associated factors (TRAFs), which currently consist of six members (TRAF1–6) in mammals [1–8], have emerged to be the major adapter proteins for these receptors. Through versatile protein–protein interactions, TRAFs link receptor activation to downstream kinase activation and eventually the stimulation of nuclear factor κ B (NF- κ B) and AP-1 transcriptional activity. Collectively, a wide range of cellular effects including cell survival, proliferation, and differentiation may be elicited by TRAF signaling.

The TRAFs participate in receptor signal transduction by either direct association with receptors or indirect interaction through additional adapter proteins, in at least three distinct pathways (Fig. 1). Members of the TNF receptor superfamily that do not contain intracellular death domains, such as TNF-R2 and CD40, recruit TRAFs directly via short sequences in their intracellular tails [1,2,5,7]. The Epstein–Barr virus transforming protein LMP1 has also been shown to directly recruit TRAFs for viral survival and cell transformation [3]. Receptors that contain an intracellular death domain, such as TNF-R1, first recruit an adapter protein TRADD via a death domain–death domain interaction [9]. TRADD then serves as a central platform of the TNF-R1 signaling complex, which assembles TRAF2 [10] and RIP [11,12] for survival signaling and Fas-associated death domain (FADD) and caspase-8 for inducing apoptosis [10,13]. Members of the IL-1R/TLR superfamily contain a protein interaction module known as the TIR domain, which

recruits sequentially MyD88 [14], a TIR-domain- and death-domain-containing protein, and IRAK [15], an adapter Ser/Thr kinase with a death domain. Oligomerization of IRAK appears to result in its association with intracellular TRAF6 to elicit signaling [8].

Members of the TRAF family are characterized by the presence of a novel TRAF domain at the C terminus which in turn consists of a coiled-coil domain followed by a conserved TRAF-C domain 1 (Fig. 2). The TRAF domain plays an important role in TRAF function by mediating self-association, receptor interaction, and interactions with other signaling proteins such as TRADD and IRAK [8,10,16]. The N-terminal portion of most of the TRAF proteins contains a RING finger and several (five to seven) zinc finger motifs, which is important for downstream signaling events [16,17]. The presence of TRAFs is conserved genetically in other multicellular organisms such as *Drosophila* [18], *Caenorhabditis elegans* [19], and *Dictyostelium discoideum* [4].

Crystal structures and biochemical characterizations have revealed a conserved trimeric association of TRAFs that is mediated by both the coiled-coil domain and the TRAF-C domain (Fig. 3A) [20–22]. This trimeric stoichiometry of TRAFs provides a structural basis for the signal transduction across the cellular membrane after receptor trimerization by trimeric extracellular ligands in the tumor necrosis factor (TNF) superfamily [23]. Interestingly, recent studies suggest that specific ligand-induced receptor trimerization may be primed by nonsignaling receptor preassociation prior to ligand binding [24]. Thermodynamic characterization reveals the low-affinity nature of monomeric TRAF2–receptor interactions, thereby confirming the importance of oligomerization-based affinity enhancement or avidity in receptor-mediated TRAF recruitment [25].

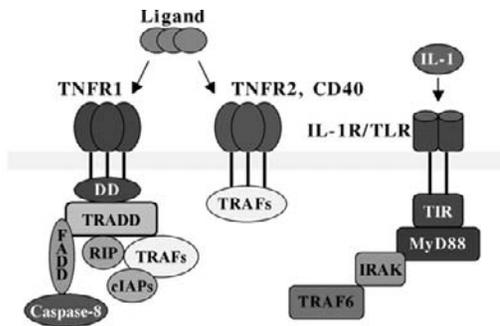

Figure 1 Membrane-proximal events in TRAF signaling, showing direct and indirect TRAF recruitment to post-receptor signaling complexes.

Figure 2 Domain organization of TRAFs.

Receptor sequences bind symmetrically to the surface groove on the TRAF-C domain of TRAF2 in an extended conformation (Fig. 3A) [20,22]. It makes main-chain hydrogen bonding interactions with the edge of the β -sandwich structure of the TRAF-C domain. Specific side-chain interactions observed in multiple TRAF2–receptor complexes have led to the establishment of short TRAF2-binding motifs [26]. Residues on the TRAF2 surface used for receptor interaction is generally conserved in TRAFs 1, 3, and 5, suggesting that these TRAFs interact with similar receptor sequences. However, a somewhat different binding mode has been observed for the interaction of TRAF3 with the same sequence from CD40, which forms a hairpin on the TRAF3 surface [27].

The mode of TRAF2 recruitment by TRADD has been revealed by the crystal structure of the TRAF2–TRADD complex (Fig. 3B) [28]. The more extensive TRAF2–TRADD interface overlaps spatially and therefore potentially competes with TRAF2–receptor–peptide interactions. Biochemical characterization of the interaction has shown that TRAF2 has a significantly higher affinity for TRADD than for the peptide motifs in direct receptor interactions, which leads to more efficient initiation of TRAF2 signaling by TRADD. In addition, TRADD interacts with only TRAF1 and TRAF2, but not other members of the TRAF family. It appears that TRAF1 and TRAF2 work in conjunction with associated caspase inhibitors, cIAP-1 and cIAP-2, to fully suppress TNF-induced apoptosis in the TNF-R1 signaling complex [28,29]. This leads to a dominance of survival signaling for TNF-R1 under most circumstances.

The TRAFs appear to undergo specific intracellular trafficking upon receptor stimulation, from either a diffuse or punctate cytoplasmic distribution to a cell-surface relocalization [3,30]. Accumulating evidence suggests that the recruitment of TRAFs to membrane microdomains or rafts is a crucial step for the initiation of TRAF signaling events [31–33]. The formation of TRAF-containing rafts may stabilize the receptor–signaling complex and bring TRAFs to the

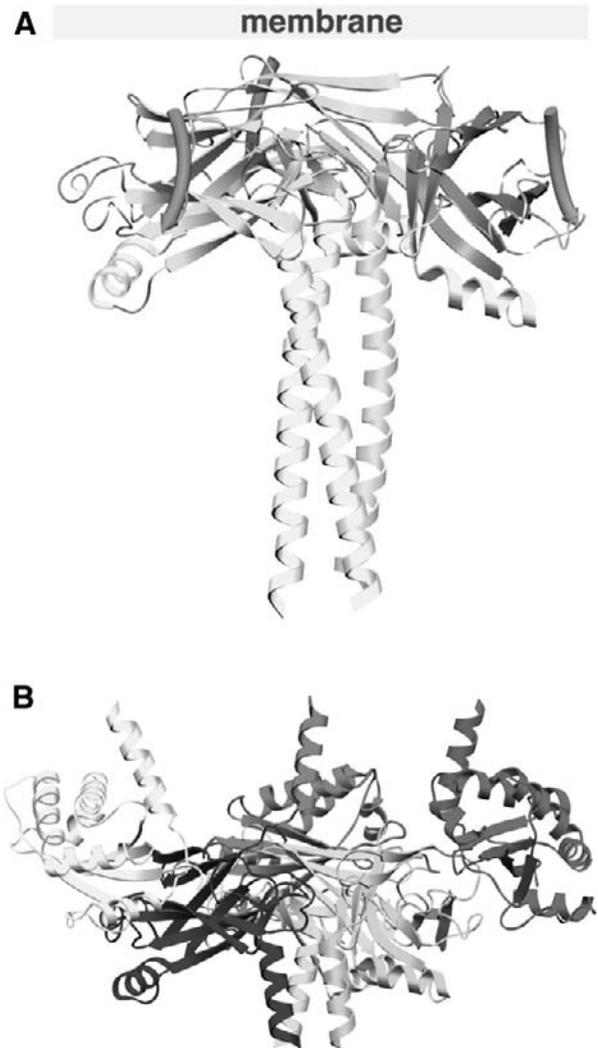

Figure 3 TRAF structures. (A) Mushroom-shaped trimeric structure of the TRAF domain of TRAF2 in complex with TNF-R2 [20], shown with the three-fold axis vertical. The coiled-coil region (stalk) is in yellow. The β -strands of the three TRAF-C domains are shown, respectively, in blue, green, and purple. Bound peptides from TNF-R2 are shown as orange arrows indicating the direction of the peptide chains. (B) Ribbon diagram of the complex between TRADD and TRAF2 [28], shown with the three-fold axis vertical. TRAF2: blue, green, and purple; TRADD: magenta, red, and yellow.

proximity of kinases and other signaling proteins. Because many different receptors recruit the same TRAFs, the availability of intracellular TRAFs can be a limiting factor in TRAF-mediated signal transduction. It has been shown that receptor activation can lead to depletion of the cytoplasmic pool of TRAF2 via relocalization to insoluble fractions [34] and/or TRAF degradation [35,36]. This suggests a competitive nature of TRAF signaling by different receptors and adds to the potential complexity of TRAF-mediated signal regulation.

Introduction

The tumor necrosis factor receptor family (TNFR-F) of molecules is a large, diverse group of molecules that participate in the regulation of cellular activation, development, and programmed cell death [1]. This brief overview summarizes and integrates currently available information on how this interesting family of receptors assembles signaling complexes at the cell membrane and how this may regulate cellular signaling pathways.

Receptor Aggregation

A common property of TNFR-F molecules is their trimeric ligands, which can be found in both membrane-bound and soluble forms [1]. Many other cell surface receptors can be fully activated by dimerization, so it has been asked whether trimerization of TNFR-F receptors is integral to their proper signaling. Numerous studies of TNFR-F molecules have used agonistic receptor-specific antibodies to successfully mimic ligand-initiated signaling. Additionally, fusions of the cytoplasmic domains of CD120a (TNF-R1), CD120b (TNF-R2), and CD40 to extracellular domains that can be dimerized but not trimerized results in chimeric molecules that clearly retain many signaling functions *in vitro* [2–4]. It has also been shown that TNF receptors and CD95, when overexpressed in transformed epithelial cells, can self-aggregate and signal in the absence of ligand binding [5,6]. However, as a greater

variety of signaling events have been examined, it has become clear that dimerization of TNFR-F receptors does not reproduce all the effects of trimerization, nor is it likely that endogenous levels of receptors are normally sufficient for self-aggregation. Sensitivity of T cells to apoptosis mediated by CD95/Fas is substantially altered depending upon whether agonistic anti-CD95 Ab or various forms of CD95L are used to ligate CD95 [7]. Similarly, CD40-mediated interleukin-6 (IL-6) production by B cells cannot be effectively induced by anti-CD40 or even soluble CD154 (CD40L) but requires membrane-bound trimeric ligand [8].

Raft Recruitment

While aggregation of TNFR-F members in the plasma membrane is required to initiate signaling (Fig. 1), additional organization of the receptors and their associated signaling molecules may also be necessary. Recent work indicates that the signaling complexes of several members of the TNFR-F are assembled in specialized regions of the plasma membrane known as membrane microdomains, or *rafts*. These regions of the plasma membrane, enriched in sphingolipids and cholesterol, are known to be sites of organization for various transmembrane signaling complexes [9]. Members of the TNFR-F associated with rafts include CD40 [10,11], CD95 [12], and TNFR1 [13]. The oncogenic Epstein–Barr virus protein LMP-1, which mimics CD40 signaling in many respects, also localizes to rafts [14,15].

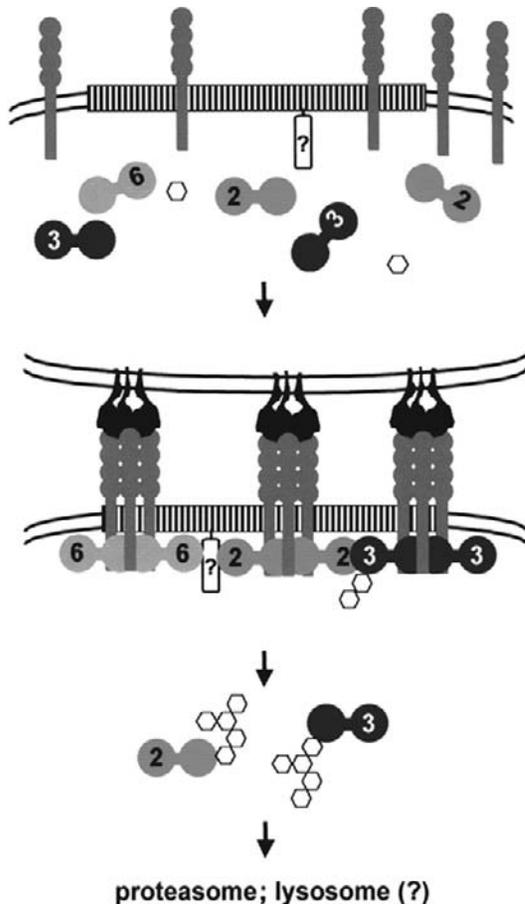

Figure 1 Working model of assembly of TNFR-F molecule signaling complexes in the plasma membrane. Aggregation of receptors (gray) by their trimeric ligands can lead to their movement into cholesterol rich lipid rafts (striped bars), to which they can recruit the TRAF molecules. TRAFs can interact with one another, and with incompletely characterized raft-resident proteins (box with question mark). It is likely that there is diversity of complexes of the same receptor, due to binding of different TRAFs to individual trimers; also, distinct members of the TRAF family may show different temporal association with particular receptors. Following receptor binding, some of the TRAF molecules can induce their own ubiquitin-dependent degradation (hexagons), in addition to facilitating the degradation of neighboring TRAFs. This may be an important mechanism for regulation of the signal cascade.

Assembly of TNFR-F signaling complexes in microdomains may serve several purposes. First, concentrating receptors in rafts may promote interactions between intracellular molecules that do not otherwise interact in unstimulated cells. For example, CD40 is known to bind several members of the TNF-receptor-associated factor (TRAF) family, including TRAF2, TRAF3, and TRAF6. Based on the crystal structures of TRAF2 or TRAF3 complexed with CD40 peptides [16–18] and the tendency of TRAF2 and 3 to form homotrimers [19], it is unlikely that a single CD40 trimer will contain both TRAFs 2 and 3. However, the aggregation of CD40 trimers in microdomains may allow TRAF2 molecules associated with one CD40 trimer to interact with TRAF3 (or other signaling molecules) bound by a neighboring CD40 trimer. Assembly of TNFR-F signaling complexes in microdomains may also foster interactions of the TRAFs

(acting as adaptor molecules) with as yet uncharacterized signaling molecules residing in microdomains [10]. Finally, membrane rafts may be integral to the timely termination of signaling. The CD40 signaling complex is internalized following its aggregation at the plasma membrane [10,20], and while it is not yet known if this internalization is raft mediated, membrane microdomains do appear to participate in a number of endocytic processes [9].

Ubiquitination

Potentially related to the downregulation of TNFR-F signaling is the activation-induced degradation of receptor-associated molecules. The activation of cells through CD30 or CD40 results in the degradation of TRAF2 and, in the case of CD40, TRAF3 as well [10,21,22]. Similarly, degradation of TRAF6 has also been observed following stimulation of cells through the TNFR-F member RANK [23]. Degradation appears to be preceded by ubiquitination of the TRAFs through a mechanism that involves their Zn-RING domains [24]. Interestingly, the oncogenic Epstein–Barr virus protein LMP-1, whose signaling also involves TRAF proteins, is deficient in mediating the activation-induced degradation of TRAFs 2 and 3 [22]. It has been suggested that the failure to engage this potentially important regulatory mechanism contributes to the oncogenic activity of LMP-1. While perhaps important for the negative regulation of signaling, ubiquitination events may also contribute to the activation of certain signaling pathways by TNFR-F members. The Zn-RING domain of TRAF6 appears to have the ability to activate inhibitory factor κ B (I- κ B) kinase and nuclear factor κ B (NF- κ B) through a novel ubiquitin-dependent mechanism [25].

Receptor Interactions

The majority of studies seeking to understand assembly of signaling complexes focus upon individual receptors. However, receptors deliver their signals *in vivo* to cells that receive a variety of other stimuli preceding, simultaneous with, or subsequent to the ligation of any one particular receptor, and it is often demonstrated that signals from one receptor can enhance or inhibit signals from another. The most frequently studied points of interaction between distinct receptors, including those of the TNFR-F, include production of pro- or anti-apoptotic proteins, including members of the Bcl family and various transcription factors. However, key points of receptor cross-talk may occur much earlier following receptor ligation and involve molecules participating in the assembly of receptor signaling complexes at the plasma membrane. This may be particularly important for effective inhibition of cell death mediated by pro-apoptotic members of the TNFR-F, such as CD95. Irreversible DNA damage mediated by such receptors can occur too quickly for an intervention mechanism that relies exclusively upon *de novo* transcription and translation, and

it has been shown that CD95L-triggered apoptosis in lymphocytes and hepatocytes cannot be blocked by Bcl family proteins [26], suggesting that signals influencing CD95 effects may do so at early points in the signal cascade. The finding that proteins found in the signaling complexes for CD95 (Fas-associated death domain, or FADD), CD120a (TNF-receptor-associated death domain, or TRADD), or both (receptor interacting protein, or RIP) can associate with each other via their death domain motifs [27] supports this possibility. A number of subsequent studies have demonstrated that CD95-mediated apoptosis can be altered by modifying early stages of the signaling pathway. Induction of activation of protein kinase C [28,29] or phosphatidylinositol 3'-kinase [30] by signals through B- or T-cell antigen receptors can block CD95-mediated apoptosis and inhibit the aggregation and lateral diffusion of CD95 in the plasma membrane. As mentioned earlier, it has recently been reported that CD95 is constitutively located in membrane rafts [12,31], and both the BCR and TCR show ligation-induced raft localization [32], which could facilitate receptor interactions. Interestingly, the first protein to associate with ligated CD95 in its signaling complex, FADD, is not localized to rafts until CD95 binds its ligand [12], and it has been shown that BCR signals can prevent the CD95-FADD association [33]. Additional B-cell activation signals through major histocompatibility complex (MHC) class II and CD40 molecules also inhibit CD95-induced apoptosis independently of *de novo* RNA or protein synthesis [34,35]; both of these receptors are also recruited to rafts following ligation [10,36,37]. However, neither of these signals inhibits CD95-FADD binding, but instead they act at the subsequent step of the pathway to decrease the cleavage and activation of caspase-8 [34,35]. TCR-enhanced membrane recruitment of the protein FLIP is a powerful mechanism for inhibition of CD95-activated caspase-8 [38]; FLIP is structurally similar to caspase-8 but lacks residues necessary for catalytic activity and may thus act as a decoy to block signaling in the receptor complex [39]. It is thus clear that a variety of events that occur during formation of receptor signaling complexes by TNFR-F molecules can be regulated by signaling cascades initiated by other TNFR-F receptors, as well as members of additional receptor families.

Conclusions

Although this chapter has focused upon mechanisms by which members of the TNFR family of receptors assemble membrane signaling complexes, knowledge gained through study of these receptors will undoubtedly apply to signaling complexes formed by a variety of receptors. The degree and intensity of receptor clustering, initiated either by ligand binding or self-aggregation, affects the nature of the signal delivered by a wide variety of receptors. Similarly, it is now appreciated that membrane microdomains contribute to the regulation of signaling through a number of receptor families, serving to influence interactions between receptors and cytoplasmic signaling proteins and between receptors themselves,

as well as regulating receptor movement and internalization. The way in which receptor complexes are organized in membrane microdomains can also provide a major mechanism by which degradation of components of the complex is regulated, by affecting trafficking of the complex, and/or associations leading to regulatory posttranslational modifications. Thus, these features of TNFR-F complex assembly and signal regulation illustrate principles common to signal transduction by many different types of receptors.

Introduction

CD40 is a 48-kDa type I membrane glycoprotein belonging to the tumor necrosis factor receptor (TNFR) superfamily. It is expressed on a wide variety of cells including B cells, dendritic cells (DCs), macrophages, endothelial cells and a number of human carcinomas [1]. The ligand for CD40 is CD154, a 39-kDa type II membrane glycoprotein belonging to the TNF superfamily which exists as a self-associating homotrimer mainly on activated CD4+ T cells. However, CD154 is also present on a small population of activated CD8+ T cells, natural killer (NK) cells, monocytes, basophils, mast cells, eosinophils, and activated platelets [1,2].

The CD40–CD154 interaction plays a critical role in both humoral and cell-mediated immune responses [2,3]. The importance of CD40 signaling during humoral immunity is highlighted in patients with hyper IgM syndrome, an immunodeficiency characterized by mutations in CD154 that render it nonfunctional, and in mice deficient in either CD40 or CD154. Under these circumstances, B cells still develop but, due to the absence of CD40 signaling, they fail to undergo antibody class switching in response to T-dependent antigens. Patients with this syndrome produce only IgM antibodies [2].

In cell-mediated inflammatory responses, CD40 is critical in controlling the maturation of antigen-presenting cells (APCs), such as DCs, macrophages, and B cells. CD40 signaling appears particularly important in triggering the release of proinflammatory cytokines, such as interleukin-12 (IL-12), and the upregulation of a number of adhesion and costimulatory ligands, such as CD80, CD86, CD134 ligand, and CD137

ligand on APC [3]. In this way, helper T cells, by upregulating CD154 and other costimulatory ligands, can initiate the maturation of DCs, which in turn allows them to drive CD8+ cytotoxic T cell (CTL) responses [3]. Hence, through intermediary DCs, helper T cells can use accessory molecules such as CD154 to control CTL responses without necessarily making direct cell-to-cell contact with the responding CD8 cells [4–6].

Finally, it has recently been found that certain neoplastic cells, such as high-grade non-Hodgkin's lymphoma, express both CD40 and CD154 on their plasma membranes in signaling structures called *signalosomes* that form within the cholesterol- and sphingolipid-rich plasma membrane microdomains known as *membrane rafts*. This configuration seems to allow the malignant cells to continuously trigger CD40 without a need for CD154-expressing accessory cells [7]. Because of its profound effects on all aspects of the immune system, strategies to inhibit or stimulate signaling via CD40 are currently being pursued as a means to alleviate a range of autoimmune and malignant diseases [8,9]. Work in a number of laboratories has demonstrated that extraneous stimulation via CD40, with monoclonal antibody (mAb) or soluble CD154, is particularly effective in boosting CD8 responses against weak tumor antigens, resulting in eradication of existing tumors and long-term immunity [8].

Signaling Pathways Triggered by CD40 Engagement

The CD40 cytoplasmic tail lacks intrinsic enzymatic activity, and, as such, signaling via CD40 is mediated through

its interaction with a family of genetically conserved adaptor proteins known as TNF-receptor-associated factors (TRAFs). These are the major signal transducers for the TNFR and IL-1 receptor/Toll-like receptor superfamilies (see below) [10]. Although TRAFs themselves have no intrinsic enzymatic activity, they are thought to be capable of activating Ser and Thr kinases, which in turn activate the downstream inhibitory factor κ B (I- κ B) kinase and mitogen-activated protein kinase cascades (JNK, p38, ERK2 MAPKs) [11].

Engagement of CD40 also results in the activation of protein tyrosine kinases, including the Src-family kinase Lyn and the Syk kinase [12–15]. Interestingly, the binding of CD154 to CD40 can result in recruitment of CD40 to membrane rafts and thus may facilitate the association with raft-located Src-family kinases, such as Lyn [15]. To date, however, no direct interaction has been demonstrated between CD40 or TRAF proteins and Lyn. Inhibition of Lyn and other Src-family kinases following engagement of CD40 on DCs, using the selective inhibitor PPI, resulted in diminished activity of the ERK2 MAPK but had only minor inhibitory effects on the activity of p38 MAPK [15]. These data suggest that CD40-mediated activation of ERK2 is dependent on the activation of upstream Src-family kinases, most probably Lyn. The role of ERK2 and p38 MAPK in CD40-triggered regulation of proliferation and gene expression has recently been established. In DCs, CD40-mediated ERK2 activation regulates IL-1 α , IL-1 β , and IL-1Ra and to a lesser extent IL-12 p40 mRNA levels, whereas CD40-triggered p38 MAPK activation appears to be a potent regulator of IL-12 p40 mRNA [15]. CD40-mediated activation of p38 MAPK has also been shown to play an important role in B-cell activation, for which it is required for CD40-induced B-cell proliferation, NF- κ B activation, and the expression of CD54 [16,17].

CD40 Signaling Is Mediated by TRAF-Dependent and TRAF-Independent Pathways

The TRAF family consists of six members (TRAFs 1 to 6), of which TRAFs 1, 2, 3, and 6 can bind directly to the cytoplasmic tail of CD40 through their C-terminal TRAF domain [18–20]. TRAF1 and TRAF5 also interact with CD40 indirectly as a result of forming hetero-oligomers, with TRAF2 and TRAF3, respectively. With the exception of TRAF1, the N-terminal portion of TRAF proteins contains a RING finger and several zinc finger motifs that are involved in mediating downstream signaling events. Indeed, deletion of the RING domain results in the generation of dominant-negative TRAF mutants.

TRAF2 and TRAF3 bind to an overlapping region of the CD40 cytoplasmic tail, whereas TRAF6 binds to a remote proximal region of the CD40 tail [18,20]. Engagement of CD40 by CD154 results in the recruitment of trimeric TRAF proteins to the receptor complex [21,22]. The crystal structure of the complex between the receptor-binding fragment of TRAF2 and its corresponding recognition site within the

CD40 cytoplasmic tail showed that one trimeric TRAF protein is capable of binding to three cytoplasmic tail regions [23]. This implies that the binding of trimeric CD154 to CD40 organizes the cytoplasmic tails of the receptor in an orientation that allows the docking of a single TRAF2 trimer; however, recent studies have shown that receptor trimerization may not be sufficient to trigger all CD40 signaling pathways effectively and that higher order oligomers are required for optimal signaling [19,24]. We have recently described a method for producing a soluble dodecameric form of CD154 by fusing the extracellular domain of CD154 to a truncated form of the tetrameric lung surfactant protein-D. This highly defined multimeric form of CD154, which is more active than soluble trimeric CD154, could have potential for *in vivo* use [24]. It is possible that highly oligomeric forms of CD40 are more effective at sustaining the interaction with TRAF proteins, particularly those that bind to the trimeric cytoplasmic tail of CD40 with low affinity, such as TRAF6 [19]. Alternatively, it is conceivable that highly multimerized forms of CD40 are recruited into kinase-rich membrane rafts more effectively than trimeric CD40. Interestingly, CD95 (Fas), another member of the TNFR superfamily, is recruited into rafts only after engagement by soluble trimeric CD95 ligand that is additionally cross-linked with antibodies to induce further aggregation [25].

CD40 signaling has recently been shown to trigger the translocation of acid sphingomyelinase (ASM) to the plasma membrane, where it initiates the release of extracellularly orientated ceramide, which in turn mediates the clustering of CD40 into membrane rafts [26]. Interestingly, ASM-deficient cells or cultures where surface ceramide had been neutralized were resistant to antibody-triggered CD40 clustering and CD40-mediated cell signaling [26] in a manner similar to that reported for CD95 [27]. Moreover, CD40 clustering into membrane rafts is also triggered by the more physiologically relevant, membrane-bound CD154 [28]. Importantly, Grassme *et al.* also inferred that clustering of CD154 occurs during the CD40–CD154 interaction through an ASM/ceramide-dependent process and that this clustering is in fact critical for efficient aggregation and signaling through CD40. However, it should be noted that ASM may not be required for CD40 signaling in all circumstances; at high concentrations of anti-CD40 antibody, CD40 clustering into rafts occurs in the absence of ASM [26].

Following engagement of CD40 by soluble or membrane-bound CD154, TRAF2 and TRAF3, but surprisingly not TRAF6, are translocated to membrane rafts [22]. Subsequently, stimulation of CD40 signaling leads to proteasomal degradation of TRAF2 and TRAF3, and this probably serves as an elegant mechanism to control signaling through CD40 [29]. It is interesting to note that this degradation of TRAF proteins is not promoted by the Epstein–Barr virus transforming protein LMP-1, which mimics many structural and signaling aspects of CD40 (including recruitment of TRAFs to membrane rafts) independent of CD154 ligation [29]. Recently it has been shown that CD40-mediated TRAF2 degradation requires the ring domain of TRAF2 and is

preceded by TRAF2 ubiquitination. This was confirmed by blocking 26 S proteasomal degradation, which maintained TRAF levels and resulted in sustained CD40-mediated JNK activity, similar to the enhanced activity seen from LMP-1 [29]. It has also been shown that signaling by TNF-R2 leads to TRAF2 degradation, again mediated by ubiquitination. In this case, cIAP1 (cellular inhibitor of apoptosis 1) associates with TRAF2 in the TNF-R2 signaling complex [30]. Therefore, it is possible that cIAP1 could play a similar role in CD40-triggered degradation of TRAF2.

While the mechanisms by which CD40 mediates signaling have been intensely studied and important mediators have been identified, it is clear that a number of factors remain to be revealed. For example, recent data suggest that CD40 mediates signaling independently of TRAF proteins. The importance of these TRAF-independent signaling pathways was studied using CD40 mutants that lack either the TRAF2/3 site or the TRAF6 site, or both [31,32]. In B cells, a CD40 mutant lacking the TRAF2/3 site was defective in the phosphorylation of I- κ B α , JNK, and p38 MAPK, although I- κ B α phosphorylation was not completely abolished. In contrast, a mutant without the TRAF6 site was capable of phosphorylating I- κ B α , JNK, and p38 MAPK to an extent similar to wild-type CD40. Furthermore, even in the absence of both TRAF2/3 and TRAF6 sites, some I- κ B α phosphorylation was apparent, confirming that at least some CD40-induced signaling is independent of TRAF binding to the CD40 cytoplasmic tail [32]. These results are in contrast to previous studies conducted using epithelial 293 cells, where both TRAF2/3 and TRAF6 sites were required for optimal NF- κ B and JNK activation, and the TRAF6 site was primarily required for p38 MAPK activation [19]. These differences demonstrate the disparate requirements for activation of these signaling pathways in these two cell types.

Recently, the generation of transgenic mice expressing mutated CD40 protein lacking the ability to bind to TRAFs has provided for the first time a critical evaluation of the role of TRAF adapters in CD40 signaling *in vivo* [32]. Although CD40-induced B cell growth, upregulation of cell surface molecules, and early antibody production are independent of the interaction with TRAF proteins, later events such as germinal center formation are dependent on the binding of either TRAF2/3 or TRAF6. Furthermore, affinity maturation of antibodies and the generation of long-lived bone marrow plasma cells specifically require recruitment of TRAF6 to the CD40 receptor complex. Thus, TRAF proteins appear to regulate only the terminal phases of CD40-mediated B-cell differentiation [32]. CD40 still raises many questions, particularly with regard to how it mediates signaling within membrane rafts and the importance of non-TRAF signaling pathways. Furthermore, CD40 is expressed on many different cell types and exerts a variety of effects ranging from the induction of proliferation and differentiation in B cells [33] to the initiation of apoptosis in a number of carcinomas [34]. The immediate challenge is to completely define the signaling pathways that mediate the many functions of CD40 in order to exploit its full potential in future therapeutics.

Role of Lipid Domains in EGF Receptor Signaling

Linda J. Pike

*Department of Biochemistry and Molecular Biophysics,
Washington University School of Medicine, St. Louis, Missouri*

Introduction

Epidermal growth factor (EGF) is a 53-amino-acid polypeptide that promotes growth and differentiation of a wide variety of cells. Its existence was first recognized over 40 years ago when it was identified as a factor in mouse submaxillary glands that induces precocious eyelid opening when injected into newborn mice [1].

Epidermal growth factor elicits its cellular effects through binding to the cell-surface EGF receptor. The EGF receptor is a transmembrane tyrosine kinase composed of an \approx 620-amino-acid extracellular domain, a 24- to 26-amino-acid transmembrane domain, and an \approx 450-amino-acid cytoplasmic portion that contains the kinase domain [2]. The EGF receptor is a member of the ErbB receptor family, which has four members: EGF receptor (ErbB1), HER2/neu (ErbB2), ErbB3, and ErbB4. The receptors are structurally similar; however, in ErbB3 the kinase domain is inactive. The ErbB receptors bind a family of ligands, with each receptor having a slightly different ligand selectivity. ErbB2 is the exception in that there is no known ligand for this receptor (for review, see Olayioye *et al.* [3]).

Upon ligand binding, the EGF receptor dimerizes and undergoes interchain autophosphorylation, primarily in the C-terminal tail of the receptor. This promotes complex formation with proteins containing Src homology domain 2 (SH2) and the phosphotyrosine binding (PTB) domain and initiates intracellular signaling cascades. The EGF receptor can also form heterodimers with ErbB2, yielding a complex with slightly different signaling and regulatory properties than EGF receptor homodimers. Both the EGF receptor and ErbB2 are frequently found over-expressed in tumors,

particularly in breast cancer. A recently introduced therapy for breast cancer is based on the targeted downregulation of ErbB2 through the use of an antibody directed against this receptor (Herceptin). In addition, small-molecule tyrosine kinase inhibitors specific for the EGF receptor are also in clinical trials [4].

A variety of studies have demonstrated that the EGF receptor is enriched in low-density, cholesterol-enriched regions of the membrane known as *lipid rafts* [5–8] and that this localization is important in receptor function. This review describes what is known regarding the mechanism through which the EGF receptor is targeted to lipid rafts and discusses the role of localization to lipid rafts in EGF-receptor-mediated signaling.

Localization of the EGF Receptor to Lipid Rafts

Data from early studies suggested that the EGF receptor resided in a low-density membrane fraction that also contained the marker protein caveolin-1 [5–8]. As a result, the EGF receptor was initially thought to reside in the caveolin-1-coated membrane invaginations known as *caveolae*. However, recent studies suggest that the EGF receptor is present in flattened, low-density lipid rafts that lack caveolin-1, rather than in caveolae proper [9,10]. The initial confusion was due to the fact that caveolae are isolated along with EGF-containing lipid rafts in most subcellular fractionation protocols. Although no specific data are available, it appears from these studies that, in most cells, the majority of EGF receptors are present in the low-density lipid raft fraction.

The EGF receptor localizes to lipid rafts under basal conditions; however, upon stimulation with EGF, the receptor rapidly exits lipid rafts and is eventually internalized by coated pits [11]. Thus, the association of the EGF receptor with caveolae/lipid rafts is readily reversible. Experiments have demonstrated that movement of the EGF receptor out of rafts requires an active kinase domain as well as at least one available autophosphorylation site; therefore, EGF receptor localization to rafts appears to be a highly regulated phenomenon [11].

Several structural features of proteins have been identified that serve to target the proteins to lipid rafts. These include palmitoylation, myristoylation, and prenylation of the protein as well as the addition of a GPI-anchor [12–14]; however, none of these mechanisms appears to function in the case of the EGF receptor, which has never been shown to acquire any such posttranslational lipid modifications. Mutational analysis of the EGF receptor demonstrated that a receptor in which the entire cytoplasmic domain has been deleted still localizes to lipid rafts, indicating that the intracellular domain is not required for localization of the receptor to these low-density domains [11]. Similarly, a receptor lacking the first 270 amino acids of the extracellular domain continues to localize to rafts, indicating that this portion of the receptor is not required for localization [11]. Recent work has demonstrated that a 60-amino-acid segment in the most membrane-proximal region of the extracellular domain of the EGF receptor is responsible for targeting the receptor to lipid rafts [15]. This suggests that the EGF receptor may localize to lipid rafts as a result of the interaction of its extracellular domain with a resident raft protein or lipid. It also suggests that the ability of ligand to promote release of the EGF receptor from lipid rafts may be due to an EGF-induced conformational change in the extracellular domain that reduces its affinity for its raft-localized binding partner.

Rafts and EGF-Receptor-Mediated Signaling

Because lipid rafts harbor a variety of proteins that are involved in signal transduction, it has been hypothesized that these low-density domains serve to organize cell signaling, enhancing the specificity or efficiency of the processes. While some experiments have demonstrated that the integrity of caveolae/lipid rafts is necessary for signal transduction via some pathways, other data seem to indicate that EGF-receptor-mediated signaling can take place both inside and outside lipid rafts.

Both EGF- and bradykinin-stimulated phosphatidylinositol turnover appear to occur exclusively in lipid rafts [16]. Disruption of lipid rafts by depletion of cholesterol completely ablated the ability of both hormones to stimulate phosphatidylinositol turnover, implying that intact rafts are absolutely required for this response [7]. By contrast, while EGF receptor autophosphorylation in intact cells appears to occur largely in low-density, noncaveolar membranes [8], depletion of cholesterol is associated with an increase in

both receptor binding and autophosphorylation [9,17]. These findings suggest that both EGF receptor binding and kinase activity are suppressed when the receptor is present in lipid rafts. Similarly, EGF stimulation of the initial steps in activation of mitogen-activated protein (MAP) kinase (namely, the recruitment of ras and raf to plasma membranes) appears to take place within the lipid raft compartment [6]; however, lipid rafts are not essential for the EGF-induced activation of MAP kinase. Depletion of cholesterol from cells leads to hyperactivation of MAP kinase by EGF [17,18]. As cholesterol depletion results in disruption of lipid rafts, these data suggest that activation of MAP kinase can occur in the absence of intact rafts. This is consistent with recent studies that indicate that GTP binding causes H-ras to move out of lipid rafts and that activation of Raf by H-ras is less efficient when it occurs in rafts as compared to bulk plasma membrane [19]. Thus, the events leading to the activation of the kinases upstream of MAP kinase can apparently occur outside of lipid rafts.

Because of the differential effects of raft disruption on EGF-receptor-mediated signaling pathways as well as the EGF-dependent movement of the receptor out of lipid rafts, it is possible that some pathways are stimulated only through EGF receptors residing in lipid rafts, while other pathways are stimulated only when the EGF receptors exit caveolae/lipid rafts. Additional studies with nonlocalizing EGF receptors will be necessary to test this hypothesis.

The EGF Receptor and Caveolin

Caveolin is a 21-kDa membrane protein that was first identified as a substrate for pp60^{src} (20) and appears to be responsible for stabilizing the invaginated structure of caveolae [21,22]. Cells lacking caveolin-1 do not exhibit plasma membrane caveolae, yet these cells still have low-density, cholesterol-enriched lipid rafts that contain high levels of signaling proteins. The relationship between caveolae proper and lipid rafts is not clear, but they appear to be distinct entities based on the ability to separate caveolin-containing low-density membranes from other similar membranes that contain raft markers such as GPI-linked proteins [23]. The EGF receptor appears to be present in lipid rafts rather than caveolae [9,10].

Despite the fact that the two proteins appear to reside in different compartments, numerous studies have reported evidence for a physical or functional relationship between caveolin-1 and the EGF receptor. Upregulation of caveolin-1 expression was shown to inhibit EGF-stimulated MAP kinase activation in human diploid fibroblasts [24]. This has been attributed to the ability of caveolin to interact directly with the EGF receptor and inhibit its activity. Using GST-caveolin-1 and synthetic peptides corresponding to the scaffolding domain of caveolin-1 (residues 81 to 101), Couet *et al.* [25] reported a physical association of the EGF receptor with caveolin-1 as well as an inhibition of EGF receptor kinase activity by caveolin-1 *in vitro*. Similar findings were

reported regarding the effect of caveolin-1 expression on the activity of the EGF receptor homolog, ErbB2 [26]. However, EGF-mediated MAP kinase activation appeared to be normal in caveolin-1 knockout mice [27], suggesting that in the *in vivo* situation, caveolin-1 does not suppress EGF receptor signaling. The discrepancy may be due to the use of recombinant proteins and synthetic peptides in the *in vitro* studies that apparently do not accurately reflect the relationship of caveolin-1 and the EGF receptor *in vivo*.

Studies from other investigators have provided data consistent with the results from the caveolin-1 knockout mice. Immunodepletion of low-density membrane fractions with an antibody to caveolin results in the physical separation of EGF receptors from caveolin-containing membranes [8]. In addition, Waugh *et al.* [8] reported that coimmunoprecipitation of the EGF receptor and caveolin was “irreproducible,” consistent with the absence of a stable association between the two proteins. Thus, direct interaction between the EGF receptor and caveolin-1 *in vivo* seems unlikely.

Epidermal growth factor does affect caveolin-1 phosphorylation and trafficking. Over-expression of the wild-type EGF receptor or a C-terminally truncated form of the EGF receptor results in an EGF-dependent tyrosine phosphorylation of caveolin-1 that appears to be mediated by pp60^{src} [28]. Furthermore, EGF induces the redistribution of caveolin-1 from the plasma membrane to an early endocytic compartment [29]. The recent observation that EGF also stimulates the phosphorylation and endocytosis of phospholipid scramblase 1, a resident lipid raft protein [30], is consistent with the notion that EGF may regulate the trafficking of a variety of proteins present in low-density membrane domains. An interesting question is whether the EGF receptor itself can be internalized via lipid rafts.

Summary

The EGF receptor localizes to low-density, cholesterol-enriched plasma membrane domains known as lipid rafts via an interaction that is mediated by its extracellular domain. Raft integrity appears to be important for the appropriate function and regulation of EGF-receptor-mediated signaling. Other receptor tyrosine kinases, including ErbB2, the PDGF receptor, the NGF receptor, and the insulin receptor, have been found to reside in or be recruited to lipid rafts [11,31–35]. Disruption of rafts by depletion of cholesterol has been shown to modulate signaling mediated by many of these growth factors [36,37]. Thus, lipid rafts appear to play a general role in the signaling function of receptor tyrosine kinases.

Structure and Function of B-Cell Antigen Receptor Complexes

Michael Reth and Michael Huber

*Department of Molecular Immunology, Biology III,
University of Freiburg, and Max-Planck-Institute for Immunobiology,
Freiburg, Germany*

Introduction

Upon activation, B lymphocytes produce antibodies or immunoglobulins (Igs), thus they are an essential part of the humoral immune system. The activation of a B lymphocyte and its differentiation into the antibody-producing plasma cell is controlled by the B-cell antigen receptor (BCR) (*antigen* being the term immunologists use to describe a substance that elicits an immune response). In most cases, B-cell antigens are substances foreign to the body and include a heterogeneous group of molecules, such as proteins, polymeric sugars, polyglycans, DNA, or other polymeric molecules. The ability of the BCR to become activated upon binding to such a structurally diverse library of antigens indicates that the activation mechanism of the BCR must be different from that of other receptors that have only one or a limited set of ligands [1]. The latter receptors are often brought into a precise signaling-active conformation by the bound ligand, whereas signaling of the BCR is largely independent of the precise structure of the antigen.

The Structure of the B Cell Antigen Receptor

The BCR is composed of two protein modules, the membrane-bound immunoglobulin (mIg) molecule and the Ig- α /Ig- β heterodimer, which mediate antigen binding and signaling, respectively (Fig. 1A) [2,3]. The proper assembly between the mIg molecule and the Ig- α /Ig- β heterodimer in the membrane of the endoplasmic reticulum is a prerequisite for the transport of the BCR to the cell surface. All five

major classes of mIg (mIgM, mIgD, mIgG, mIgA, and mIgE) are associated with the Ig- α /Ig- β heterodimer, presumably in a 1:1 stoichiometry. In the case of the IgM- and IgD-BCR, evidence suggests an oligomeric organization of the BCR [4]. These data support the model that conformational changes within oligomeric antigen receptors lead to initiation and amplification of the BCR signal (see below).

The mIg molecule is a tetramer consisting of two identical heavy (H) chains and two identical light (L) chains. The H chain and L chain each contain an N-terminal, variable (V) Ig domain, and an antigen-binding site is formed by the combination of one V_H and one V_L domain. Thus, a given mIg molecule has two identical antigen-binding sites. During B-cell development, the sequence coding for a V domain is assembled from a library of variable gene segments. The highly variable assembly process generates a huge set of different V domains and, thus, antigen-binding sites. However, expression of these genes is clonally and allelically regulated so that each B cell expresses only one set of H and L chains [5]. The mIgM molecule does not contain a cytosolic part that can interact with intracellular proteins; thus, the signaling function of the BCR relies mostly on the Ig- α /Ig- β heterodimer. Ig- α and Ig- β share many structural features. Both proteins carry a glycosylated extracellular Ig domain, a linker region with the heterodimer-forming cysteine, one transmembrane part, and a cytoplasmic tail sequence of either 61 (Ig- α) or 48 (Ig- β) amino acids. These cytoplasmic sequences are the most conserved parts of these transmembrane proteins, indicating that they have an important cellular function. The cytoplasmic tails of Ig- α and Ig- β contain the consensus sequence immunoreceptor tyrosine-based

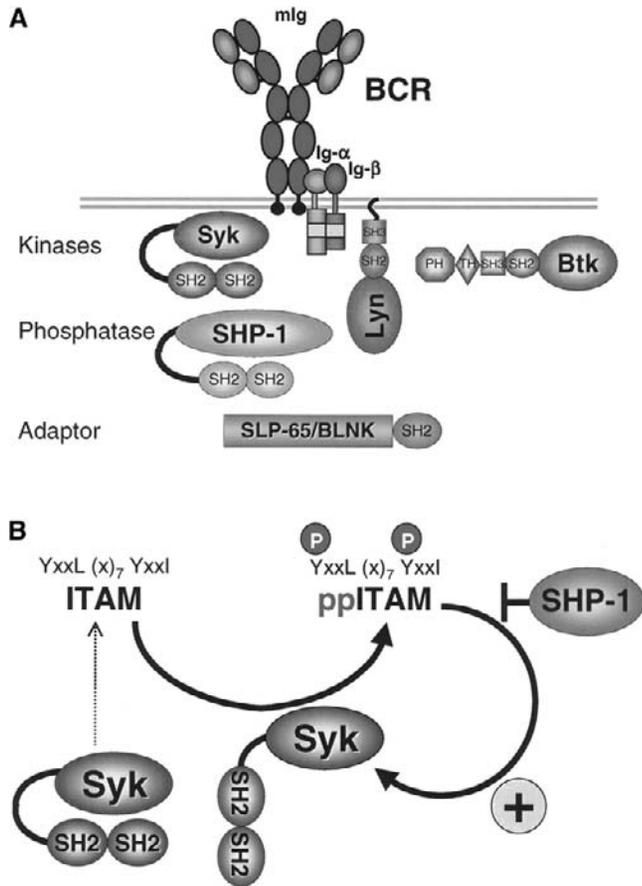

Figure 1 The BCR, its early signaling elements, and an ITAM-mediated positive feedback mechanism. (A) The BCR is comprised of the membrane-bound immunoglobulin molecule (mIg) and the Ig- α /Ig- β heterodimer, which are responsive for antigen binding and signaling, respectively. The early signaling elements of the BCR signal transduction machinery are the tyrosine kinases Syk, Lyn, and Btk, as well as the tyrosine phosphatase SHP-1 and the adaptor protein SLP-65. (B) Syk in its closed conformation is able to slowly phosphorylate the ITAM tyrosines. Once dual-phosphorylated, the ITAM can be bound by Syk via the two Syk SH2 domains, resulting in stabilization of Syk in its open, active conformation. Active Syk can now amplify the initial signal by phosphorylating further ITAMs within the oligomeric BCR complex, thus establishing a positive feedback. SHP-1 can stop the positive feedback of Syk and the ITAM by dephosphorylating the ITAM phosphotyrosines.

activation motif (ITAM), which is also found in other receptors of the multi-subunit immune recognition receptor (MIRR) family and has the following consensus sequence: D/ExxYxxL(x)₇YxxI/I. The two tyrosines in the ITAM sequence are phosphorylated during activation of the BCR and become a binding-target for interactions with signal-transducing elements.

Initiation of BCR Signaling Is Controlled by Redox Regulation

How signals are initiated upon antigen binding to the BCR is not completely understood and is still a matter of controversy. It has been found that the three protein tyrosine

kinases (PTKs) Syk, Lyn, and Btk, as well as the adaptor protein SLP-65/BLNK and PLC- γ 2, are required for an optimal calcium response following engagement of the BCR (Fig. 1A) [6]. In the absence of Syk and Btk, no calcium response is observed, but in the absence of the Src-family kinase Lyn the amplitude of the calcium response is only reduced [7]. A synergy between Src- and Zap-70/Syk family kinases in the tyrosine phosphorylation response was also observed in cotransfection studies with COS cells [8]. These data support the model of sequential interaction between the two PTKs and the antigen receptor. According to this model, it is thought that Lyn is preassociated with the receptor and that, upon cross-linking of the BCR by antigens, Lyn becomes active and phosphorylates the two ITAM tyrosines. This modification then leads to the binding of the two N-terminal Src homology 2 (SH2) domains of Syk to the double-phosphorylated ITAM, cross-wise Syk phosphorylation and activation, phosphorylation of several Syk substrate proteins, and progression of the signal.

Recent data, however, contradict this BCR cross-linking and sequential Lyn/Syk ITAM interaction model. For example, exposure of B cells to reactive oxygen species (ROS), such as H₂O₂ or pernanadate (VaO₄³⁻/H₂O₂), results in substrate tyrosine phosphorylation and calcium flux in the absence of any engagement of the BCR by antigen [9]. These data suggest that BCR cross-linking is not a mandatory step for signaling; rather, it seems that signal initiation is under the direct control of protein tyrosine phosphatases (PTPs) such as SHP-1, which is efficiently inhibited in contact with H₂O₂ or pernanadate [10–12].

In Lyn-deficient DT40 B cells, Syk becomes activated via the BCR (albeit less efficiently than in Lyn-containing cells), suggesting that Lyn is not located upstream of Syk in the BCR signaling cascade [7]. In a new experimental system allowing the inducible coexpression of the BCR and its signaling elements in *Drosophila* S2 cells, it was found that only Syk but not Lyn can phosphorylate both ITAM tyrosines [13]. Furthermore, in the presence of at least one ITAM sequence, that of either Ig- α or Ig- β , the kinase activity of Syk is strongly increased. These data suggest that initiation of signaling at the BCR involves a positive feedback between Syk and the ITAM sequences resulting in rapid amplification of the BCR signal (Fig. 1B).

A key to understanding this signal amplification process is the regulation of the kinase activity of Syk. A detailed mutational analysis showed that Syk is an allosteric enzyme, whose activity is regulated by its tandem SH2 domains. Apparently, in the absence of an ITAM sequence, Syk resides primarily in a closed conformation in which the two SH2 domains block the kinase domain. Therefore, Syk in solution has only low kinase activity. However, once Syk encounters an ITAM sequence, it phosphorylates the two ITAM tyrosines and binds to this sequence via its tandem SH2 domains. This binding fixes Syk in an open, active conformation, which results in a strongly increased kinase activity. At the same time, the increased activity of Syk is focused at the inner leaflet of the plasma membrane and can rapidly phosphorylate

neighboring ITAM sequences, resulting in more Syk activation and rapid amplification of the signal (Fig. 1B). This amplification process occurs even more efficiently inside an oligomeric BCR complex where ITAM-containing sequences are located close to each other. This Syk activation model is supported by the phenotype of a Syk mutant carrying a C-terminal SH2 domain deficient in ITAM binding. This mutant is nearly as deficient in tyrosine phosphorylation as a kinase-dead mutant of Syk.

Another important protein controlling initiation of the BCR signal is SHP-1 [14]. This PTP was previously thought to play a role only in the termination phase of signaling by dephosphorylating PTK substrates. However, we found that the Syk/ITAM signal amplification process can occur only at the BCR under conditions where PTPs are absent or inhibited. In the S2 cell system, the Syk-mediated signal amplification at the BCR is completely prevented by coexpression of SHP-1 [13]. In this system, the inhibitory function of SHP-1 seems not to be due to a dephosphorylation of Syk but rather to the dephosphorylation of the dual-phosphorylated ITAM, which removes the sequence required for the allosteric activation of Syk. Thus, signal initiation at the BCR not only involves activation of a kinase but also inactivation of a phosphatase. Newer studies on other receptor systems also have found that signal transduction from these receptors requires both kinase activation as well as phosphatase inhibition [12].

Given that kinases are often activated by conformational changes, how then are phosphatases inhibited? All phosphatases carry an invariant, reactive cysteine (Cys-SH) in their catalytic center that takes part in the removal of phosphate groups from phosphorylated substrate proteins. In the presence of H_2O_2 , this cysteine is reversibly oxidized (Cys-SOH), thus the phosphatase activity is transiently inhibited [10]. Via the inhibition of phosphatases, H_2O_2 can function as a second messenger in signal transduction [15]. H_2O_2 is indeed produced in stimulated B and T cells via activation of the membrane-bound NADPH-oxidase complex producing singlet oxygen molecules (1O_2) which react with water to yield H_2O_2 . Interestingly, recently it was found that the BCR and TCR, apart from their binding and signaling function, are enzymes that efficiently catalyze this reaction and thus contribute to H_2O_2 production [16,17].

In summary, the following scenario of BCR activation seems feasible. Upon antigen binding, the BCR is rapidly translocated to a membrane region where Lyn and the NADPH-oxidase reside. A transient activation of Lyn and Syk by the BCR give a synergistic signal that activates the NADPH-oxidase which results in increased H_2O_2 production and subsequent PTP inhibition in the vicinity of the BCR. This inhibition of the PTP by Lyn and Syk establishes a double-negative feedback at the BCR that may explain the observed synergy between the two kinases in signal transduction [18]. In the absence of PTP activity, the Syk/ITAM signal is rapidly amplified, resulting in full BCR activation. Thus, at least two feedback loops are involved in BCR signal initiation: a positive feedback between Syk and the ITAM

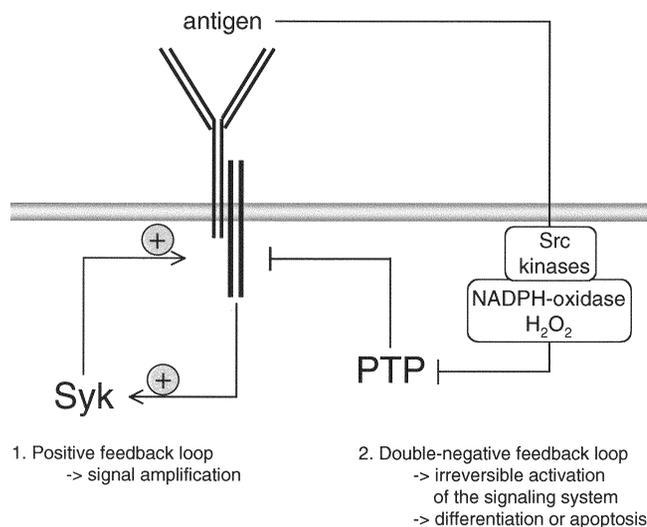

Figure 2 The BCR and its early signaling elements establish a positive feedback as well as a double-negative feedback loop. The positive feedback involving Syk and the ITAMs and the double-negative feedback involving the ITAMs, SHP-1, and the H_2O_2 -producing enzymes are described in the text. In principle, double-negative feedback systems have the potential to convert graded inputs into irreversible responses such as differentiation or apoptosis.

sequences and a double-negative feedback between the ITAM, SHP-1, and the H_2O_2 -producing enzymes (Fig. 2).

Lipid-Mediated Localization of Signaling Proteins

Maurine E. Linder

*Department of Cell Biology and Physiology,
Washington University School of Medicine, St. Louis, Missouri*

Introduction

Extracellular signals elicit responses by binding to receptors at the cell surface and activating signal transducers localized at the inner leaflet of the plasma membrane. Signals propagate to intracellular effectors, resulting in changes in enzyme activity, ion channel gating, or protein-protein interactions. The components of a signaling pathway must be oriented spatially and temporally to execute the appropriate response to an extracellular cue. Many effectors are constitutively present at the membrane, but others must be recruited from the cytoplasm in response to signals. Lipids participate in the localization or recruitment of signaling proteins to cellular membranes through several mechanisms. First, lipids covalently modify proteins, thereby increasing their hydrophobicity and affinity for membranes. Second, lipids anchor proteins to membranes by serving as ligands for protein domains. Third, lipids form domains rich in sphingolipids and cholesterol that may organize signal transduction complexes at the plasma membrane.

Covalent Attachment of Lipids

Some signal transducers do not harbor transmembrane-spanning segments that confer membrane association. Instead, heterotrimeric G proteins, Src family kinases, and monomeric GTPases associate with cellular membranes through covalent lipid modifications [1]. Src family kinases and G-protein α subunits are fatty acylated, whereas G-protein γ subunits and most monomeric GTPases are prenylated. Inhibiting protein lipidation leads to mislocalization of the signal transducer, either to the cytoplasm or intracellular membranes, and

an inability to convey the signal from receptor to effector. Thus, covalent lipid modifications are essential for function and are discussed in greater detail in this chapter.

Lipid-Binding Domains

A large number of proteins involved in signal transduction and membrane trafficking contain protein modules that bind to specific lipids embedded in cell membranes [2,3]. The phosphatidylinositol phospholipids (PIs) represent the largest class of lipid ligands. The inositol headgroup can be phosphorylated at the D3, D4, and D5 positions, singly or in combination, thereby generating at least seven unique PI species. Regulation of the production and degradation of these versatile lipids spatially and temporally provides a mechanism for reversible recruitment of proteins to specific cellular membranes. PI-binding protein modules include PH (pleckstrin homology), FYVE (Fab1p/YOTP/Vac1p/EEA1), and PX (Phox homology) domains. Phosphoinositides and their effectors are covered in Volume II, Section E.

Lipid Rafts

Our view of the lateral organization of plasma membrane constituents has evolved from the conventional picture of membrane proteins diffusing freely in a sea of lipid to one where there is selective confinement of lipids and proteins in discrete regions of the membrane [4]. These domains, lipid rafts, are rich in sphingolipids and cholesterol and have been implicated in a variety of cellular processes, including signaling. It has been proposed that the spatial concentration of specific sets of proteins increases the efficiency and

specificity of signal transduction by facilitating interactions between proteins and by preventing inappropriate crosstalk between pathways. This chapter focuses on how covalent lipid modifications target proteins to rafts.

Protein Lipidation

N-Myristoylation

Protein N-myristoylation is the addition of myristic acid to a protein through an amide linkage to an N-terminal glycine residue. Modification of the protein occurs cotranslationally upon removal of the initiator methionine by methionylpeptidase [5], or posttranslationally following proteolytic cleavage that exposes an N-terminal glycine [6]. N-myristoylation is a stable modification. Examples of signaling proteins that are N-myristoylated can be found in Table 1.

Prenylation

Prenylated proteins are recognized by their characteristic C-terminal motifs (Table 1) [7]. Ras, other monomeric GTPases, and G-protein γ subunits undergo posttranslational processing at a CaaX motif (C, cys; aa, small aliphatic amino acid; X, uncharged amino acid). When the protein terminates in serine, methionine, or glutamine, the protein is modified

with a C15 farnesyl isoprenoid. When the protein terminates in leucine, the protein is modified with a C20 geranylgeranyl isoprenoid. The prenyl group is added through a thioether linkage. This is just the first of a series of posttranslational processing steps. Following prenylation in the cytoplasm, the protein associates with the endoplasmic reticulum where the $-aaX$ peptide is proteolytically cleaved, followed by methylation of the carboxyl group on the prenylated cysteine. Although prenylation is a stable modification, methylation of the prenylated cysteine residue is reversible and may be regulated. Members of the Rab family of GTPases are modified with two geranylgeranyl groups at C-terminal motifs $-CC$ or $-CXC$. Methylation of the prenylated cysteine occurs only on proteins ending with $-CXC$.

S-Palmitoylation

In addition to modification with amide-linked myristate, proteins are also fatty acylated at cysteine residues through reversible thioester linkages [8]. This is commonly referred to as palmitoylation, although other long-chain fatty acids besides palmitate are incorporated into proteins through this mechanism. Palmitoylation is a posttranslational event that occurs both on intracellular membranes and at the plasma membrane. Palmitate modifies cysteine residues in a variety of sequence motifs (see Table 1). In signal transducers, palmitoylated

Table I Lipid Modifications of Selected Signaling Proteins^a

cysteines are frequently located near N-myristoylated glycine residues or immediately upstream of prenylated C-terminal cysteines. However, some G-protein α subunits are modified exclusively with palmitate. Integral membrane proteins can also be palmitoylated. Many G-protein-coupled receptors are modified at cysteine residues in the C-terminal cytoplasmic domain. Insertion of the fatty acid into the membrane creates a fourth cytoplasmic loop in these serpentine receptors. Palmitate turnover is regulated in response to agonist stimulation on heterotrimeric G proteins and receptors. This topic is discussed in Volume II, Section D.

Other Lipid Modifications

Fatty acylation and prenylation are modifications of intracellular proteins. On the extracellular face of the plasma membrane, proteins are anchored by glycosylphosphatidylinositols (GPI) through insertion of the acyl chains of the phosphatidylinositol moiety into the bilayer [9]. The GPI anchor is added *en bloc* by transamidation to the C-terminal carboxyl group of a protein that has been cleaved previously near the C-terminus. This process occurs in the lumen of the endoplasmic reticulum. GPI-modified proteins then travel through the secretory pathway to the cell surface.

Hedgehog proteins, which are important for growth and patterning in animal development, undergo unusual lipid modifications [10]. Hedgehog is secreted from cells following a complex series of posttranslational processing steps. Following synthesis and translocation into the lumen of the ER, the signal sequence of Hedgehog is cleaved, leaving an N-terminal cysteine residue. Hedgehog then undergoes an autocatalytic cleavage reaction yielding an N-terminal signaling domain and a C-terminal fragment. The signaling domain is modified at its C terminus with cholesterol and with palmitate at its N terminus through a stable amide bond. Lipidation of Hedgehog influences the range and potency of the signals generated. How the lipids exert these effects remains to be determined.

Membrane Interactions

Covalent lipid modifications promote membrane association by direct insertion of the fatty acid or isoprenoid into the lipid bilayer [5]. However, N-myristoylated and prenylated proteins are found in the cytoplasm as well as on cellular membranes, whereas S-palmitoylated proteins appear to be exclusively associated with membranes. Measurements of the apparent affinities of lipid-modified peptides for liposomes demonstrate that a farnesyl or myristoyl group is not sufficient to confer stable membrane association. Thus, proteins modified singly by myristate or a farnesyl isoprenoid are predicted to be exquisitely sensitive to other properties of the protein that promote or interfere with membrane association.

Two well-characterized properties that act cooperatively with N-myristoylation or farnesylation to promote membrane binding are electrostatic interactions or additional lipid modifications [5]. Examples of both mechanisms are found

in the Src family kinases. All members of this family are N-myristoylated. Positively charged residues near the N terminus of Src cooperate with the myristoyl moiety to provide a stable membrane anchor by binding to the negatively charged phospholipid head groups of the lipid bilayer. Lck and Fyn are palmitoylated at cysteine residues adjacent to or nearby the myristoylated N terminus. The additional hydrophobicity provided by the thioester-linked fatty acids promotes long-lived interactions with membranes [11]. Similar mechanisms operate in prenylated proteins. Electrostatic interactions promote membrane interactions of the G-protein $\beta\gamma$ complex [12] and K-Ras proteins [13]. H- and N-Ras are modified with palmitate subsequent to prenylation and C-terminal processing [13]. In addition, membrane affinity of prenylated proteins is increased approximately 10-fold by carboxyl methylation [11].

How do lipidation motifs target proteins to specific membranes? A short peptide sequence that directs tandem N-myristoylation and palmitoylation is sufficient for plasma membrane localization, suggesting that the lipid modifications themselves can provide specificity [14]. The kinetic membrane-trapping model proposes that an N-myristoylated protein will undergo transient associations with membranes until it encounters a membrane with an appropriate “membrane-targeting receptor” [12]. This interaction leads to the addition of the second lipid modification, palmitate, and the dually lipidated protein is now “trapped” on the membrane. A protein acyltransferase (PAT) at the plasma membrane would fulfill such a role, and PAT activity for N-myristoylated substrates is enriched in the plasma membrane [8]. However, it is clear that protein interactions and lipidation work in concert to localize signaling proteins appropriately. For example, interaction of G-protein α subunits with $G\beta\gamma$ is important for $G\alpha$ palmitoylation and localization at the plasma membrane [15,16]. Furthermore, not all signaling proteins are palmitoylated at the plasma membrane. Palmitoylation of myristoylated $G\alpha$ and Fyn appears to be coincident with their arrival at the plasma membrane [17], but other palmitoylated signal transducers such as Lck [18] and H-Ras [19,20] are palmitoylated early in the secretory pathway and then traffic to the plasma membrane. This is consistent with the membrane-trapping model in that palmitoylated H-Ras or Lck move to their final destination as membrane-bound cargo.

Protein Lipidation and Lipid Rafts

Raft lipids have been proposed to exist in a separate phase from the rest of the bilayer, in a state similar to the liquid-ordered (l_o) phase described in model membranes [21]. Lipid raft formation in the exoplasmic leaflet of the plasma membrane is driven by the tight packing of the long saturated acyl chains of sphingolipids with cholesterol. The structure of raft lipids in the cytoplasmic leaflet is less clear, but these domains are also believed to exist in a state where acyl chains of lipids are tightly packed, highly ordered, and extended. Proteins with a high affinity for an ordered

lipid environment are selectively recruited to rafts. These are proteins with GPI anchors (which contain predominantly saturated fatty acids) or proteins such as Src family kinases that are modified with dual fatty acylation motifs. Interestingly, the signaling domain of the Hedgehog protein is also associated with lipid rafts [10]. How the cholesterol and palmitate modifications of Hedgehog contribute to its raft association is unknown. Other lipid modifications exclude proteins from rafts. Proteins modified with unsaturated fatty acids or prenyl groups do not associate with lipid rafts in cells or in model membranes [22–24]. Unsaturated acyl chains or bulky prenyl groups prefer regions of the bilayer that are disordered. Thus, lipid modifications are sufficient for directing proteins to specific subdomains of the plasma membrane.

Summary

In the study of signal transduction, much of the effort in the past has focused on identifying the protein players and how they interact with one another. However, the last decade has led to a greater appreciation of the role that lipids play as second messengers, in protein localization, and in the organization of cellular membranes. These areas will continue to be active areas of investigation as we try to extend our understanding of how cells respond to extracellular signals.

Introduction

A remarkably large number of extracellular stimuli, including peptides, polypeptide, and glycoprotein hormones, monoamine neurotransmitters, autacoids, photons, odorants, and even ions, such as Ca^{2+} , signal to their target cells through binding and activation of heptahelical membrane receptors that belong to the superfamily of G-protein-coupled receptors (GPCRs). On the inner membrane surface of cells, heterotrimeric G proteins (composed of α , β , and γ subunits) transduce receptor-activated signals into intracellular responses that underlie physiological responses of cells and tissues [1].

In the inactive heterotrimeric state ($\text{G}\alpha\beta\gamma$), GDP is bound to the $\text{G}\alpha$ subunit. Upon activation by a GPCR, guanosine diphosphate (GDP) is released and, in intact cells, guanosine triphosphate (GTP) binds immediately to the empty guanine-nucleotide-binding pocket. An activated GPCR goes through multiple rounds of G-protein activation, leading to signal amplification (Fig. 1). The $\text{G}\alpha$ subunit in the GTP-bound form dissociates from $\text{G}\beta\gamma$ and the receptor. Both free $\text{G}\alpha$ -GTP and $\text{G}\beta\gamma$ are able to activate downstream effectors. The timing of the activity of the effector is controlled both by the turnoff of GPCRs and by GTP hydrolysis by the intrinsic GTPase activity of $\text{G}\alpha$, which terminates the actions of both the G protein and its effectors. The turn-off reaction of $\text{G}\alpha$ can be accelerated either by the effector itself or by a family of proteins termed regulators of G protein signaling (RGSs), which act as GTPase-activating proteins (GAPs) to reduce the lifetime of the $\text{G}\alpha$ -GTP form. $\text{G}\alpha$ -GDP reassociates

with $\text{G}\beta\gamma$, reconstituting the inactive heterotrimer that is ready for a new activation cycle (Fig. 1). This chapter reviews and summarizes current knowledge on heterotrimeric G-protein structural and functional organization and signaling.

G-Protein Molecular Organization

The crystal structures of inactive (GDP-bound) [2], active (GTP-bound) [3–5], and transition-state ($\text{GDP}\text{-AlF}_4^-$) [4, 6] $\text{G}\alpha_t$, $\text{G}\alpha_i$, and $\text{G}\alpha_s$, as well as structures for inactive heterotrimeric complexes [7,8], have provided the framework for understanding the biochemical basis of G proteins as molecular switches. In addition, comparison of $\text{G}\alpha$ structures delineates the molecular basis for heterotrimeric G-protein specificity. A discussion of the specific intramolecular contacts within heterotrimeric G proteins can be found in a detailed review [9] and in another chapter of this handbook.

We currently know of 20 $\text{G}\alpha$, 5 $\text{G}\beta$, and 12 $\text{G}\gamma$ subunits. On the basis of $\text{G}\alpha$ subunit similarities, G proteins are grouped into four families: $\text{G}_{i/o}$, G_s , $\text{G}_{q/11}$, and $\text{G}_{12/13}$ (Table 1). Classically, members of the $\text{G}\alpha_s$ group stimulate isoforms of adenylate cyclase (AC); however, $\text{G}\alpha_s$ proteins also modulate the activity of other effector molecules (Table 1). The $\text{G}\alpha_{i/o}$ group can be subdivided into $\text{G}\alpha_{i/o/z}$ and $\text{G}\alpha_{u/g}$ subunits. The former subunits inhibit some isoforms of AC but also interact with and activate other proteins (Table 1). The latter subunits stimulate the retinal cGMP-phosphodiesterase ($\text{G}\alpha_t$) and presumably a related gustatory effector ($\text{G}\alpha_g$). The $\text{G}\alpha_{q/11}$ subunits activate the β -isoforms of phospholipase C (PLC)

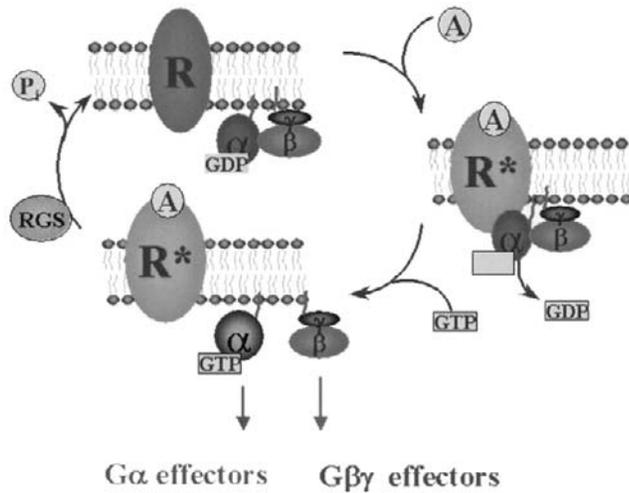

Figure 1 Schematic of the GTP-binding-protein regulatory cycle. Receptor (R) interacts with a specific agonist to induce a conformational change leading to activation (R*). R* is able to interact with the heterotrimer, G α -GDP $\beta\gamma$ and catalyze the release of GDP from the G α subunit. Upon the binding of GTP, G $\beta\gamma$ and R* are released from G α -GTP. G α -GTP and free G $\beta\gamma$ regulate the appropriate effectors. The intrinsic hydrolysis of GTP to GDP, with the assistance of GTPase-activating proteins (RGS proteins) returns the system to the resting, basal state.

Table I Classification of G α Subtypes and Their Effectors

Family	Subtype	Effector
G $_s$	G $\alpha_{s(S)}$	\uparrow Adenylyl cyclase
	G $\alpha_{s(L)}$	\uparrow GTPase of tubulin ^a
	G α_{olf}	\uparrow src ^a
G $_i$	G α_{i1}	\uparrow Adenylyl cyclase
	G α_{i2}	\downarrow Adenylyl cyclase
	G α_{i3}	Rap1 GAP
	G α_{i3}	GRIN 1 and 2
	G α_{oA}	\uparrow GTPase of tubulin ^a
	G α_{oB}	\uparrow src ^a
	G α_z	Ca ²⁺ and K ⁺ channels ^a
	G α_{t1}	\uparrow cGMP-PDE
	G α_{t2}	
	G α_g	?
G $_q$	G α_q	
	G α_{11}	\uparrow PLC β s
	G α_{14}	\uparrow Bruton's tyrosine kinase (G α_q)
	G α_{15}	
	G α_{16}	
	G α_{16}	
G $_{12}$	G α_{12}	\uparrow NH-1 ^a
	G α_{13}	\uparrow PLD ^a
	G α_{13}	\uparrow p115RhoGEF \uparrow iNOS ^a

^aSee references [89] to [95].

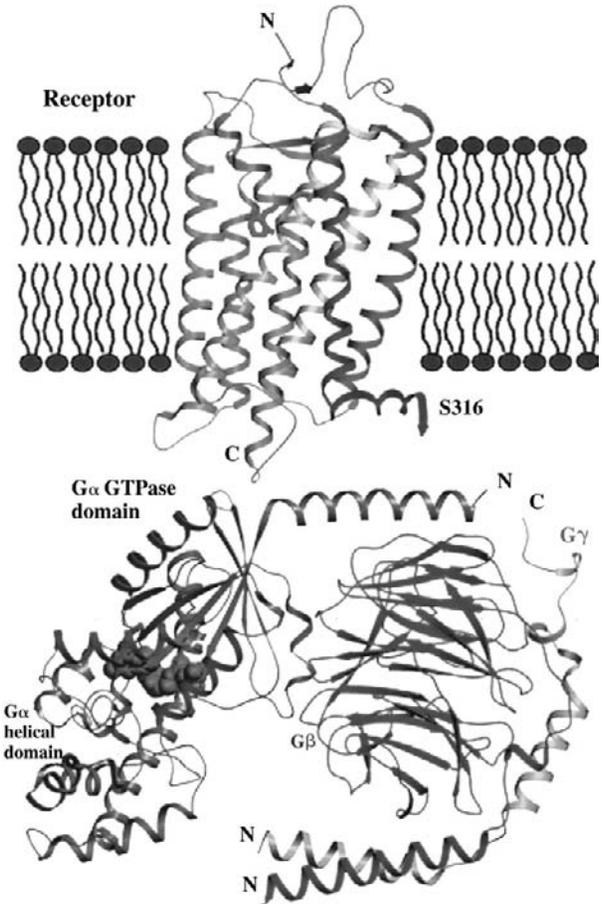

Figure 2 Hypothetical model showing the orientation of rhodopsin, the photoreceptor G protein G $_t$, and the membrane. The refined rhodopsin structure is from reference [98], and G $_t$ is from reference [7]. The individual ribbon drawings are based on the crystal structures and are shown to scale. The C-terminal residues after S316 are not shown, as there is no evidence that these residues interact with G $_t$, and they appear to occlude the G $_t$ binding site. The orientation of G $_t$ with respect to rhodopsin and the membrane is modeled on the basis of the charge and hydrophobicity of the surface, the known rhodopsin-binding sites on G $_t$, and the sites of lipidation of G α and G γ [7].

and nonreceptor protein kinases of the *Btk*-family (Bruton's tyrosine kinase). The G $\alpha_{12/13}$ subunits regulate the activity of low-molecular-weight G proteins of the Rho family, the Na⁺/H⁺-exchanger, phospholipase D (PLD) and the inducible isoform of NO synthase (iNOS).

All G α subunits are formed by two domains: a GTPase domain that is involved in binding and hydrolysis of GTP and a helical domain that buries the guanine nucleotide within the core of the protein (Fig. 2). The helical domain is the most divergent domain among G α families and may have a role in directing specificity of interaction with partner proteins. In the GTPase domain, three nonconsecutive flexible regions undergo structural change between the GDP- and GTP-bound conformations [2,3]. These regions, designated Switch I, II and III, become more rigid and well ordered in the GTP-bound conformation. The structures of the extreme amino (N)- and carboxyl (C)-terminal domains are not solved in the isolated G α crystals, as the N- and C-termini were either removed from the protein or disordered [2-4].

However, in two separate crystal structures of heterotrimeric complexes, the N-terminal helix is ordered by its interaction with G β [7,8].

Crystallographic studies of G $\beta\gamma$ heterodimer alone [10] and in the heterotrimeric complex [7,8] revealed that the G β subunit has a β -propeller structure containing 7 WD-40 repeats (Fig. 2). The G γ subunit interacts with the G β subunit through an N-terminal coiled-coil and makes extensive contacts along the base of the G β subunit. G β , but not G γ , contacts G α in two regions, the N-terminal helix and a hydrophobic pocket present in G α -GDP that includes the switch II region [7,8].

Structural Features of G Protein Activation

The rate-limiting step in G protein activation is the release of GDP from the nucleotide-binding pocket. GDP is spontaneously released from the heterotrimeric G protein at a rate that varies depending on the type of G α subunit. However, in the basal state, the rate of GDP release is much lower than the rate of GTP hydrolysis, and G $\beta\gamma$ binding controls this state. GDP release is greatly facilitated by receptor activation of the G protein [11]. Mutations in the TCAT sequence of G α in the β 6– α 5 loop of the GTPase domain enhance receptor-independent spontaneous GDP release [12–14]. In addition to the TCAT motif, residues within the helical domain as well as the N- and C-terminal domains of G α subunits are mediators of spontaneous GDP release. For example, in G α_t , mutations of three residues located on the inward facing surface of the α 5 helix dramatically increase the basal nucleotide exchange rate and enhance the receptor-catalyzed nucleotide exchange rate [15]. Mutations in the switch IV helical domain of G α_s decrease the rate of GDP release, GTP γ S binding, and GTP hydrolysis [16]; disruption of the contacts between the helical and GTPase domains also influences basal dissociation rates [17,18]. The C-terminal domain of a G α_t /G α_i chimera moves into a more hydrophobic environment upon AIF $_4^-$ activation as determined by the fluorescence increase of a covalently bound probe at Cys 347 [19]. Substitution of 31 N-terminal residues of a G α_{ti} chimera (low intrinsic exchange rate) with the corresponding 42 residues of G α_s (high intrinsic exchange rate) significantly enhanced the nucleotide exchange rate [20]. Thus, structural interactions between the N- and C-termini of G α_t appear to be important to the maintenance of a slow GDP release rate for G α_t .

Receptor-mediated GDP release depends on the ability of the GPCR to interact with the G protein and trigger conformational changes in the G α subunit that cause release of GDP. Comparing the crystal structures with biochemical data, we can deduce that the receptor contacts G α at a site that is more than 20 Å away from the guanine nucleotide binding site [1,20]; thus, GPCRs work at a distance to release GDP. Interaction of intracellular loops of an activated GPCR with the G α C-terminus leads to conformational changes that are propagated to the GDP binding site

of G α [1]. However, the requirement of G $\beta\gamma$ for receptor–G-protein coupling and G-protein activation suggests that the heterodimer may actively participate in the GDP release by opening an exit route for the guanine nucleotide [21]. The heterotrimer structure also suggests that the activated receptor could use G $\beta\gamma$ as a lever to release GDP [22]. Thus, the G $\beta\gamma$ dimer may not simply be a passive binding partner stabilizing inactive conformation of G α , but it may actively participate in receptor-mediated G-protein activation.

Structural Determinants of Receptor–G-Protein Specificity

The last five C-terminal residues of G α play an important role in receptor–G-protein interaction [21,23,24]. Much experimental evidence supports such a role: (1) ADP-ribosylation of a Cys residue at position –4 by *Pertussis toxin* uncouples G $_{i/o}$ proteins from receptors [25]; (2) mutations in this region alter receptor–G-protein specificity [26–28]; (3) antibodies targeting G α C-terminal domains block receptor–G-protein signaling [29]; (4) sequence-specific C-terminal synthetic peptides can stabilize the active agonist-bound form of the receptor by mimicking the G protein [30–32] and serve as competitive inhibitors of receptor–G protein interactions [31–33].

The C-terminus is not the only region that controls the specificity of receptor–G-protein interactions. Several G α subunits possess identical or nearly identical residues within the extreme C-terminus but exhibit differential coupling to receptors. Two residues within the α 4 helix of G α_{i1} are critical for specific coupling between G $_{i1}$ and 5-HT $_{1B}$ receptors [34,35]. Key residues for coupling specificity have also been identified within the N-terminus [27,30,36], the α 2 helix and α 2– β 4 loop regions [37,38], and the α 4 helix and α 4– β 6 loop domain [34,38,39]. Segments of the β and γ subunits also seem to participate in forming the heterotrimer interaction surface for receptors [36,40–43]. Receptor–G-protein specificity is clearly not mediated by only one structural feature, but appears to result from a network of specific contacts between the receptor and heterotrimeric G protein that differ for each G protein and receptor, resulting in a large number of possible combinations on top of a basic general framework.

G α Interactions with Effector Molecules

The specific effectors activated by G α -GTP are dependent on the G α subtype and are summarized in Table 1. Some properties of G α -mediated effector activation deserve mention: (1) Each G α family activates a distinct profile of effectors. Co-crystallization of G α_s with the catalytic domains of adenylyl cyclase (AC) has allowed the identification of specific contact sites within the subunit at the α 2 helix and α 3– β 5 loop [44]. In addition to the G α -GTP bound form the inactive form, G α -GDP, can also stimulate AC but with

a lower potency [45]. These data suggest that reassociation of $G\alpha$ with $G\beta\gamma$ is required for complete termination of $G\alpha_s$ signaling. (2) Within a $G\alpha$ family, each $G\alpha$ subunit shows a differential profile of effector activation. For example, $G\alpha_{i2}$ was shown to be required to inhibit forskolin-mediated AC activity, while $G\alpha_{i3}$ inhibits $G\alpha_s$ -activated AC [46]. (3) Some $G\alpha$ subunits interact with only one effector, such as $G\alpha_t$ with cGMP-phosphodiesterase, while others couple to several different effectors. For example, $G\alpha_{i2}$ and $G\alpha_{o1}$ can inhibit AC, modulate Ca^{2+} and K^+ channels and other activities [47]. (4) Effectors for some $G\alpha$ subunits have not yet been definitively identified, while a number of proteins have been recognized to directly interact with $G\alpha$ subunits. For example, Hart *et al.* [48] recently identified p115RhoGEF as a direct effector for $G\alpha_{i3}$. The RGS protein, p115RhoGEF, serves as the GAP for both $G\alpha_{i2}$ and $G\alpha_{i3}$ but only activated $G\alpha_{i3}$ stimulates p115RhoGEF to trigger GDP/GTP exchange on the low-molecular-weight G protein Rho.

Other proteins have been identified via their interactions with certain types of $G\alpha$ subunits and are considered as possible effector molecules. For example, direct interactions between $G\alpha_o$ and Rap1 GTPase-activating protein (Rap1 GAP), Gz GAP, and RGS17 have been identified using a yeast/two-hybrid screen [49]. These interactions seem to be specific for the G_i protein family. So far, receptor-mediated activation of these proteins has not been demonstrated. Activated $G\alpha_i$, $G\alpha_o$ and $G\alpha_z$ subunits bind to two proteins identified in neuronal tissue, named GRIN1 and GRIN2 for G-protein-regulated inducer of neurite outgrowth [50]. The calcium-binding protein calnuc is considered a potential effector for $G\alpha_{i3}$ and $G\alpha_s$ [51, 52]. Bruton's tyrosine kinase (*Btk*) is a novel effector for G_q proteins, as $G\alpha$ activates *Btk* both *in vivo* and *in vitro* [53]. This activation is required for receptor-mediated stimulation of p38 mitogen-activated protein kinase (MAPK).

G $\beta\gamma$ Interactions with Effector Molecules

The $G\beta\gamma$ subunit was originally thought to passively facilitate intracellular information transfer by binding to $G\alpha$, thus facilitating the return of the heterotrimer to the plasma membrane. Overwhelming evidence now indicates that the $G\beta\gamma$ heterodimer plays a more active role. As mentioned before, $G\beta\gamma$ actively participates in the process of receptor-mediated G-protein activation by directly interacting with the receptor and facilitating GDP release from the $G\alpha$ binding pocket. Moreover, $G\beta\gamma$ is able to interact with and activate several effectors, including PLC β_2 and β_3 [54,55], ACs [56], β -adrenergic receptor kinase [57], phosphoinositide 3-kinase (PI $_3$ kinase) [58,59], components of the MAPK cascade [60], and K^+ and Ca^{2+} channels (Table 2) [61–64]. Currently, 5 different $G\beta$ and 12 different $G\gamma$ subunits have been identified [65–69], so many combinations are possible. Do different dimers have different or similar effector specificity? What is the physiological significance of the formation of different $G\beta\gamma$ dimers?

Table II Effectors Regulated by $\beta\gamma$ Dimers

Effector	Regulation
PLC β s	Stimulation
AC I	Inhibition
AC II, IV, and VII	Stimulation
K^+ channel (GIRK 1, 2, 4)	Stimulation
Ca^{2+} channels	Inhibition
G protein receptor kinase	Recruitment to membrane
PI $_3$ K	Stimulation
Bruton's tyrosine kinase	Stimulation
Tsk tyrosine kinase	Stimulation
Protein kinase D	Stimulation
Calmodulin	Inhibition of CaM kinase
Tubulin	Increased GTPase activity
Dynamin I	Increased GTPase activity
Shc phosphorylation ^a	Indirect activation of MAPK (?)
Raf-1 protein kinase	Sequestration of $\beta\gamma$
Ras exchange factor ^a	Indirect activation of MAPK (?)
KSR-1	Sequestration of $\beta\gamma$

^aSee references [96] and [97].

Previously, it was thought that $G\beta\gamma$ dimers were for the most part interchangeable, but current research indicates that the dimer composition determines the quality and efficiency of effector activation and may mediate receptor–G-protein coupling specificity similar to $G\alpha$ subunits. For example, when nine unique dimers of $G\beta_1$ or $G\beta_2$ with $G\gamma_{(1, 2, 3, 5 \text{ or } 7)}$ were tested for the ability to activate various PLC β isoforms, all dimers could activate PLC β isoforms, except the retinal-specific $G\beta_1\gamma_1$ [70,71]. Likewise, $G\beta_1\gamma_1$ is less effective at stimulating ACII and inhibiting ACI than other $G\beta\gamma$ combinations [70,71]. The $G\beta_5\gamma_2$ dimer is a much weaker inhibitor of ACI, ACV, and ACVI than $G\beta_1\gamma_2$. In addition, $G\beta_1\gamma_2$ stimulates ACII activity, while $G\beta_5\gamma_2$ inhibits the activity of this enzyme [72]. However, both dimers activate PLC β_2 with similar potency and efficacy [73]. The various $G\beta$ subtypes also inhibit the N-type voltage-dependent Ca^{2+} channels with different potency, such as $G\beta_1 = G\beta_2 > G\beta_5 \gg G\beta_3 = G\beta_4$ [74]. These data demonstrate that the primary sequence of the $G\beta$ subunit is a major determinant for effector coupling and efficiency.

Other proteins have recently been found to interact with $G\beta\gamma$ subunits. In many cases, the $G\beta\gamma$ and $G\alpha$ subunits interact with a number of common effectors, such as PLC β , Bruton's tyrosine kinase, and certain AC isoforms. These effector interactions can be independent, synergistic, or antagonistic. In addition, $G\beta\gamma$ dimers interact with a number of novel effectors that are not regulated by $G\alpha$ subunits. Putative $G\beta\gamma$ effectors recently identified include protein kinase D (PKD) [75], PI $_3$ kinase [58,59], tubulin [76], KSR-1 [77], dynamin I [78], calmodulin (CaM) [79], Raf-1 protein kinase [80], and Tsk protein kinases [81] (Table 2).

Recently, our laboratory has found that the receptor for activated C kinase 1 (RACK1) and the dynein intermediate chain interact with the $G\beta_1\gamma_1$ dimer [82]. $G\beta\gamma$ can inhibit neurotransmitter release independently of second messenger formation and ion channel modulation, perhaps by direct interaction with the exocytotic fusion machinery, as both syntaxin 1B and SNAP25B are $G\beta\gamma$ binding partners [83].

Unlike $G\alpha$, the conformation of $G\beta\gamma$ dimers does not change significantly between the inactive heterotrimeric complex and the free, active state. The only known exception is that phosphatidylinositol 3-kinase binding to $G\beta\gamma$ induces a conformational change mainly in blades 1 and 7, thus preventing $G\beta\gamma$ association with additional effectors [84]. Several site-directed mutagenesis studies [85–87] have indicated that each effector contacts a unique but overlapping set of residues on $G\beta$ and some of these sites also represent $G\alpha$ interacting sites. Indeed, these studies are consistent with the idea that interaction with $G\alpha$ precludes $G\beta\gamma$ binding to effector molecules.

Conclusions

Structural and functional aspects of heterotrimeric G proteins, their binding partners, and the signaling networks they participate in are the subjects of intense investigation. Dramatic progress has been made in recent years. The next frontier is to understand how signaling pathways interact with each other to form signaling networks [88]. Cells are bombarded by a multiplicity of ligands, and the cellular response is somehow integrated based on all its responses. The experimental approaches to this problem are beginning to be available but are in their infancy. Certainly, many new approaches to these issues of complexity in cellular signaling must be pioneered and will surely lead to new insights.

JAK–STAT Signaling

Rashna Bhandari and John Kuriyan

Departments of Molecular and Cell Biology and Chemistry, Howard Hughes Medical Institute, University of California, Berkeley, Berkeley, California; and Physical Biosciences Division, Lawrence Berkeley National Laboratory, Berkeley, California

Introduction

Initially brushed aside as “just another kinase,” JAKs are now known to be central to signal transduction pathways involved in hematopoiesis and immune function. The JAK tyrosine kinases are associated with cytokine receptors and, along with the STAT transcription factors, are central components of pathways that result in the activation of gene expression upon cytokine stimulation [1]. These pathways involve a series of tyrosine phosphorylation steps resulting in the dimerization of cytoplasmic STATs and their translocation to the nucleus, where they activate gene expression. Both JAKs and STATs are large, multidomain proteins, and we are only beginning to understand the organization of these components at the biochemical and structural level. This article summarizes our current understanding of the initiation, organization, and downregulation of the JAK–STAT signaling pathway.

Cytokine Signaling Proteins

Cytokines are a loosely defined set of secreted factors that control a variety of important biological responses related to hematopoiesis and immune function. There are over 40 members of this family of small (≈ 15 – 30 kDa) glycoproteins, and many of them display functional redundancy [2]. Cytokines bind receptors that are characterized by sequence and structural similarities in their extracellular regions and the lack of catalytic domains in their intracellular portions [3]. The intracellular regions of these receptors are associated with the Janus tyrosine kinases (JAKs), which are activated upon cytokine binding to the receptor. The JAKs then phosphorylate and activate a family of intracellular proteins known as STATs (signal transducers and activators

of transcription), which translocate to the nucleus and activate gene expression. This signaling pathway, referred to as the JAK–STAT pathway, is notable for the direct and rapid transmission of the signal from the cell surface to the nucleus. The essential steps in the JAK–STAT pathway are outlined in Fig. 1.

Cytokine receptors signal as oligomers, ranging from dimers to tetramers [4]. These receptors have been broadly classified into two subgroups (type I and type II cytokine receptors), based on patterns of conserved amino acid residues within their extracellular domains [5,6]. Type I cytokine receptors include receptors for interleukins, colony-stimulating factors, and hormones; type II receptors include the receptors for interferons and interleukin-10 [7]. Cytokine receptors have also been classified into subgroups based on the use of shared subunits [8]. There are three subfamilies of cytokine receptors that share common signal transducing receptor subunits within the family: (1) interleukin-6 (IL-6) subfamily of receptors, which have a common gp130 subunit; (2) granulocyte–macrophage colony-stimulating factor (GM-CSF) subfamily, which have a common β subunit (β_c); and (3) the interleukin-2 (IL-2) subfamily of receptors that share a γ subunit (γ_c). In each case, the multi-subunit receptor consists of one or more ligand-specific subunits and a common subunit that is essential for signal transduction. Thus, different cytokines can bind to distinct receptors that share a signal transducer.

The four mammalian JAKs are JAK1, JAK2, JAK3, and Tyk2. The JAKs have two tandem kinase-like domains, one of which is a functional catalytic tyrosine kinase domain and is located at the C-terminal end of the protein. Immediately upstream of this functional kinase domain is a non-functional pseudokinase domain [3] that possesses many of the sequence motifs of tyrosine kinases but lacks several residues that are essential for kinase activity.

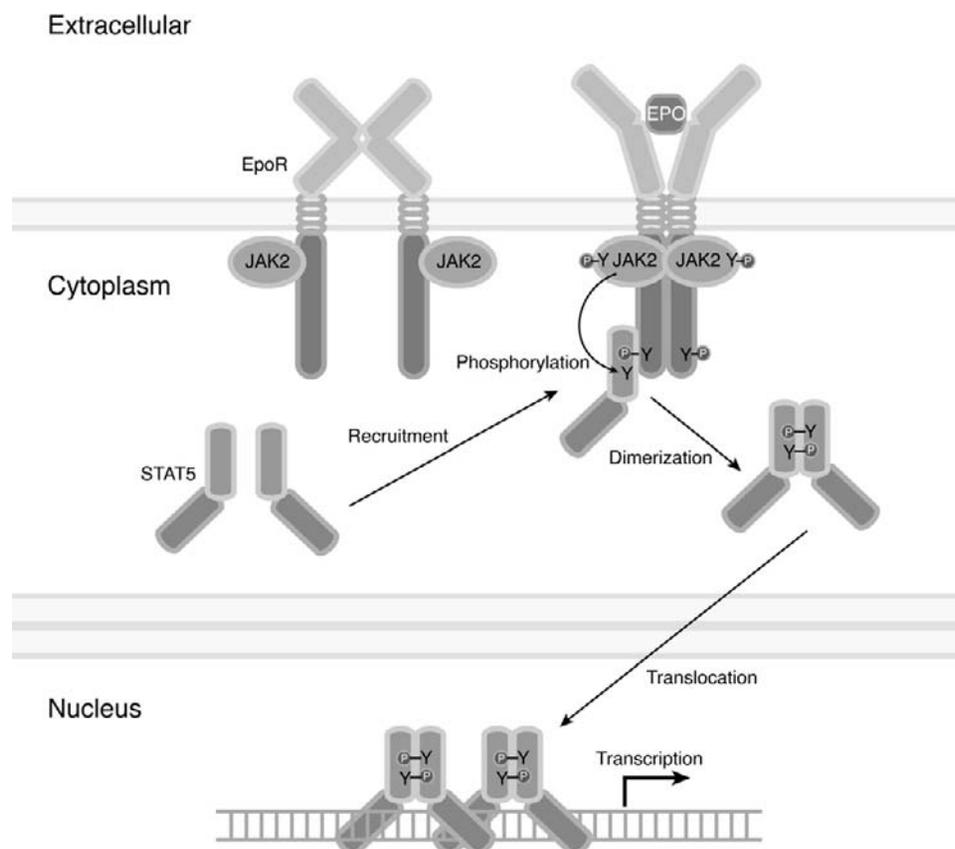

Figure 1 An overview of the JAK–STAT signalling pathway. The binding of erythropoietin (Epo) to its homodimeric cell surface receptor (EpoR) leads to a conformational change resulting in the apposition and transphosphorylation of receptor-associated JAK2 molecules. JAK2 phosphorylates EpoR on tyrosine residues, creating docking sites for the SH2 domains of STATs. The receptor-bound STAT5 molecules are phosphorylated by JAK2, leading to their dimerization via reciprocal SH2–phosphotyrosine interactions. Dimeric STAT5 molecules translocate to the nucleus, where they bind DNA and activate gene transcription.

The cytokine receptors and the JAK kinases are associated constitutively, and this requires an ≈ 60 -amino-acid membrane proximal domain in the signaling receptor. This domain contains two sequence motifs, referred to as box 1 and box 2, that are conserved in most cytokine receptors [9]. It is believed that ligand binding to the extracellular portion of the receptor causes the two JAK molecules associated with the intracellular region of the receptors to come into apposition, such that they are now able to phosphorylate each other. This phosphorylation occurs at tyrosines in the activation loop of the functional kinase domain, in the (E/D)YY motif that is conserved in all JAKs [10]. This transphosphorylation process is essential for the activation of the tyrosine kinase.

Some examples of the various receptor types and associated JAKs are shown in Fig 2. The simplest signaling complex is that of the homodimeric hormone receptors, such as the erythropoietin receptor (EpoR) and JAK2. Structural studies on the unliganded and ligand-bound extracellular domains of the EpoR have revealed some surprises and changed the way we view ligand-mediated tyrosine kinase activation. Contrary to the idea that receptor activation is brought about by ligand-induced oligomerization, the unliganded EpoR

extracellular domain crystallizes as a dimer [11]. This dimer, however, is in an open scissor-like conformation, in which the transmembrane domains are separated by ≈ 70 Å, suggesting that the receptor-associated JAKs would be too far from each other to allow transphosphorylation. Structures of liganded receptors have shown how a single ligand molecule binds two Epo receptors, with two distinct surfaces of the ligand making contact with equivalent binding regions on the two receptors. This causes a conformational switch in the molecule, resulting in the transmembrane regions coming closer together so that they are now separated by only ≈ 30 Å [12–14]. This would bring the two JAK molecules sufficiently close to each other so as to promote transphosphorylation. It is not yet certain if this mechanism is applicable to all cytokine receptors, as there are no structures of unliganded cytokine receptors other than for EpoR.

JAK Structure and Localization

The JAK kinases are relatively large proteins, with molecular weights of approximately 120 to 140 kDa. Seven regions

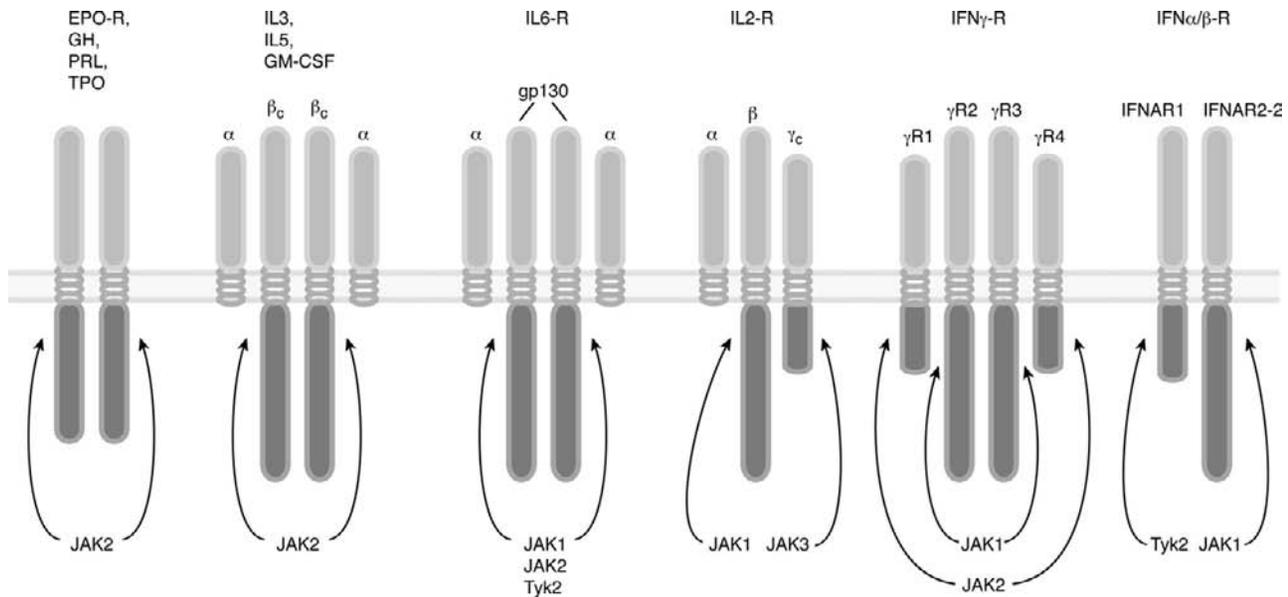

Figure 2 Cytokine receptor families and associated JAKs. From left to right, (1) the homodimeric hormone receptors, which signal via JAK2; (2) the IL-3 family of receptors, each having a unique ligand binding α chain and sharing a common beta (β_c) subunit associated with JAK2; (3) the IL-6 subfamily of receptors, which have a common gp130 subunit that can interact with different members of the JAK family; (4) the IL-2 receptor family, which shares a common gamma (γ_c) subunit and is the only cytokine receptor subunit that interacts with JAK3. The receptor-specific α or β subunit binds JAK1. The type II cytokine receptors, the interferon γ (5) and interferon α/β (6) receptors, signal via JAK1, JAK2, and Tyk2. (Adapted from Pellegrini, S. and Dusanter-Fourt, I., *Eur. J. Biochem.*, 248, 615–633, 1997.)

Figure 3 Structure of JAKs. The JAK family of kinases contains seven conserved sequence regions, JAK homology (JH) domains 1 to 7. The JH1 domain is a tyrosine kinase domain, and the JH2 domain is a pseudokinase domain without catalytic activity but is essential for normal JAK function. The region encompassing the C-terminal portion of JH4 and the JH3 domain has sequence similarity with SH2 domains. The N-terminal region of JAKs contains a FERM domain, which is critical for their association with the receptor and for kinase function.

with conserved sequence have been identified within the JAKs, and these are designated JAK homology (JH) domains 1 to 7 (Fig. 3) [4]. JH1 refers to the functional kinase domain, and JH2 is the pseudokinase domain. Sequence analysis showed that the region spanning JH7 to the N-terminal half of JH4 contains a domain known as the FERM domain (band four-point-one, ezrin, radixin, moesin homology domain) (Fig. 3) [15]. In other proteins, this domain of ≈ 300 amino acids is involved in binding to the cytoplasmic regions of several transmembrane proteins, thereby localizing the FERM domain containing protein to the plasma membrane [16]. The FERM domain of JAKs is now known to be responsible for anchoring JAKs to the cytoplasmic region of cytokine receptors [17,18]. Crystal structures of the FERM domains of radixin [19] and moesin [20] reveal three subdomains that form a compact, clover-shaped structure. Although there is only a low level of sequence identity between this segment of the JAKs and other FERM domains, there are several conserved blocks of sequence within this region [15], suggesting that the overall structures may be similar. The region spanning the C-terminal part of JH4 to JH3 has sequence similarity to

Src homology 2 (SH2) domains, the modular phosphotyrosine binding domains [21,22]. As with the FERM domain, the level of sequence similarity of the JAK SH2-like domain with other SH2 domains is very low, and to date the function of this domain in JAK kinases is not known.

Certain mutant forms of JAK3 isolated from patients with severe combined immune deficiency (SCID) revealed point mutations in the FERM domain [18]. Interestingly, these mutations not only disrupted kinase-receptor association, but also abrogated adenosine triphosphate (ATP) binding to the kinase domain, thereby destroying kinase activity. The mutation Gly 341 to Glu that maps to the FERM domain of the *Drosophila* Hop protein (a JAK homolog) has been shown to hyperactivate the kinase [23]. Furthermore, mutations in the pseudokinase domain of JAKs have been shown to alter the activity of the kinase, with different mutations resulting in either a loss of kinase activity [24] or a hyperactive kinase [25]. These results suggest a complex interplay between the various domains of JAKs, an understanding of which will require a crystal structure of the entire JAK molecule.

STAT Structure and Function

The final signaling components in the JAK–STAT pathway are the STAT molecules. STATs are so named because they serve as both signal transducers in the cytoplasm and activators of transcription in the nucleus. Seven mammalian STAT proteins have been discovered so far [26]. Like the JAKs, STATs are also large, multidomain proteins, and the availability of three-dimensional structural information on STATs has provided us with a deeper understanding of the molecular mechanism of STAT activation [27,28]. STATs possess a DNA binding domain and a transcription activation domain. In addition, each STAT molecule also contains an SH2 domain that acts as a phosphorylation-dependent switch controlling the activation of STATs. Phosphorylation of the cytokine receptors by activated JAK kinases creates docking sites for the STAT SH2 domains, thereby recruiting STATs to the receptor–JAK complex (Fig. 1). The JAKs then phosphorylate a tyrosine residue located C-terminal to the STAT SH2 domain [29], following which the SH2 domains and phosphotyrosines in each of the two STATs interact in a reciprocal manner to form a dimer [30]. This dimer is then translocated to the nucleus, where it binds DNA and directs specific transcription initiation.

Crystal structures of tyrosine-phosphorylated STATs bound to DNA revealed that STAT dimers form C-shaped clamps around DNA that are stabilized by interactions between the SH2 domain of one monomer and the tyrosine-phosphorylated, C-terminal segment of the other (Fig. 4) [27,28]. STATs have been shown to form dimer–dimer complexes on promoters containing two neighboring STAT binding sites [31–33]. This interaction between STAT dimers is cooperative and is mediated by the amino-terminal 130 residues that form a separable functional domain (N-domain) [31,32]. STATs interact with a number of transcription factors and other proteins that form part of the transcription machinery via various domains, including the C-terminal transcription activation domain [26], the structure of which is not yet known. These interactions result in the formation of a cluster of proteins that form a transcription enhancer complex, termed an *enhanceosome* [34]. This complex is responsible for the final step in the JAK–STAT pathway—that is, the activation of gene expression.

Inhibition of Cytokine Signaling

The JAK–STAT pathway is turned off some time after signaling is activated. There are three classes of proteins that

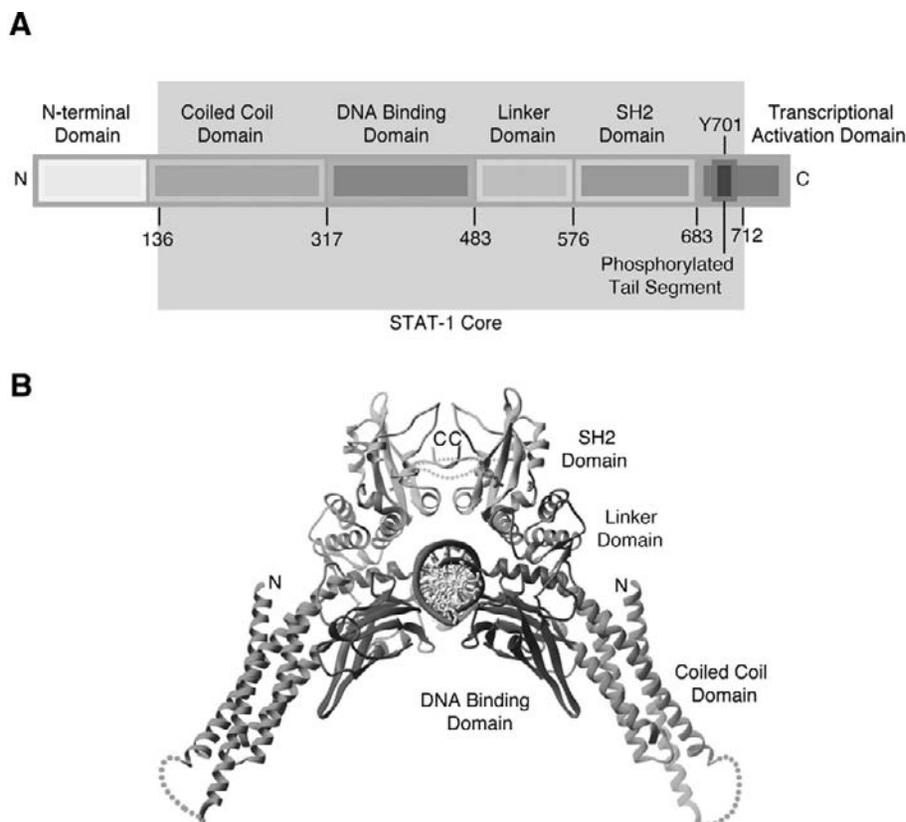

Figure 4 Structure of STATs: (A) schematic diagram showing the domains of STAT1; (B) crystal structure of the core domain of STAT1 bound to DNA. Dimeric STATs form a C-shaped clamp around DNA that is stabilized by reciprocal interactions between the SH2 domain of one monomer and a phosphorylated tyrosine of the other. The phosphotyrosine-binding site of the SH2 domain in each monomer is coupled structurally to the DNA-binding domain, suggesting a potential role for the SH2–phosphotyrosine interaction in the stabilization of DNA interacting elements. (Part B from Chen, X. *et al.*, *Cell*, **93**, 827–839, 1998. With permission.)

deactivate cytokine signaling at a number of levels [35]. Because the entire cascade is dependent on tyrosine phosphorylation as an activation signal, dephosphorylation by tyrosine phosphatases is obviously an important regulatory step. Specifically, the SH2 domain containing protein tyrosine phosphatase, SHP-1, binds tyrosine-phosphorylated cytokine receptors, such as EpoR, via its SH2 domain and dephosphorylates JAK2 [36]. SHP-1 has also been shown to associate directly with and dephosphorylate JAK2, and this association is independent of the SH2 domain [37]. Tyrosine phosphatases are also implicated in the dephosphorylation and consequent inactivation of phosphorylated STAT molecules, although a specific phosphatase–STAT association has yet to be demonstrated [38].

Another class of proteins involved in switching off the JAK–STAT signal is the suppressor of cytokine signaling (SOCS) family of proteins [39]. SOCS proteins contain a central SH2 domain flanked by an N-terminal domain of variable length and sequence and a C-terminal region containing a conserved motif called the *SOCS box* [38]. SOCS proteins inactivate JAK–STAT signaling by different mechanisms; SOCS-1 (also known as STAT-induced STAT inhibitor [SSI-1] or JAK2 binding protein [JAB]) binds JAKs in their activation loop in a phosphorylation-dependent manner and blocks ATP binding to the kinase, thereby inhibiting any further kinase activity [40–42]. Another member of the SOCS family, CIS (cytokine-inducible, SH2-containing protein), directly binds phosphorylated tyrosine residues on the cytokine receptor, blocking STAT recruitment and phosphorylation [43]. Interestingly, as the name SSI-1 suggests, transcription of the SOCS genes is induced by cytokines, at least partially via STAT transcription factors, thereby forming a negative feedback loop. Recent studies have shown that the SOCS box interacts with components of the proteasome machinery, suggesting that binding of SOCS to the receptor–JAKs complex might target them for ubiquitination and degradation [44].

The third class of JAK–STAT negative regulators is the protein inhibitors of STAT (PIAS) family of proteins [35,45]. Unlike SOCS, PIAS proteins are expressed constitutively but associate with STATs only upon stimulation of the cell by cytokines. PIAS proteins bind activated STAT dimers and inhibit their DNA binding activity. It is thought that these proteins might buffer the concentration of active STAT dimers in the cell.

Summary

In conclusion, the JAK–STAT pathway is a rapid membrane-to-nuclear, signaling pathway that is chiefly responsible for proliferation and differentiation of cells of the immune system. Perturbation of this pathway is seen to be an underlying cause of a variety of diseases [46]. Given that the JAK–STAT pathway was only discovered about a decade ago, the pace at which we have progressed in our understanding of this signaling mechanism has been rapid. There is

hope that it will not be long before a biochemical and structural picture of the JAKs and the STATs is fleshed out in detail.

Organization of Photoreceptor Signaling Complexes

Susan Tsunoda

Department of Biology, Boston University, Boston, Massachusetts

Phototransduction is the conversion of light into a change in the electrical potential across the cell membrane. This process involves the sequential activation of a series of signaling proteins, leading to the eventual opening or closing of ion channels in the photoreceptor cell membrane. Traditionally, it has been thought that G-protein-coupled signaling pathways, like phototransduction, transmit signals from one signaling protein to the next by diffusing freely about a cell, until randomly contacting the appropriate downstream component in the pathway. Recently, however, the phototransduction cascade in *Drosophila* has become a prime example of how signaling proteins do not roam freely about but are physically bound in macromolecular complexes, or signaling complexes [1,2]. An eye-specific scaffold protein binds to multiple signaling components, bringing them into close proximity and localizing them to a subcellular compartment specialized for phototransduction. With increasing evidence of similar strategies used in other cell types and systems, the diffusion-based model of intracellular signaling is being replaced by a model in which the formation of macromolecular complexes is essential for normal signaling [3–5].

Phototransduction is a prototypical G-protein-coupled signaling pathway. Vertebrates and invertebrates share a similar overall strategy but differ in their underlying molecular machinery [6,7]. In *Drosophila*, light stimulation of the seven-transmembrane domain receptor rhodopsin leads to the activation of a G protein, $G_{\alpha q}$, which in turn activates a phospholipase C β (PLC β). Activated PLC β catalyzes the hydrolysis of phosphatidylinositol-4,5-bisphosphate (PIP $_2$) into inositol trisphosphate (IP $_3$) and diacylglycerol (DAG). These events lead to the opening of at least two types of cation channels encoded by the *transient receptor potential* (*trp*) [8–10], *trp-like* (*trpl*) [10,11], and *trp γ* [12] genes.

Deactivation of the light response includes calcium-dependent activation of an eye-specific protein kinase C (eye-PKC) [13,14] and calmodulin [15].

INAD Organizes Signaling Complexes

Phototransduction in *Drosophila* is one of the fastest G-protein-coupled signaling pathways known, taking less than 20 ms from light activation to maximum response. This high speed of signaling is primarily due to the incorporation of signaling components into multi-protein complexes. Signaling complexes bring components into close proximity, promoting rapid interaction as well as ensuring the proper subcellular localization of components. The central organizer of these signaling complexes is the inactivation/no-afterpotential D protein (INAD), which functions as a scaffold for complexes. The original *inaD* mutant, *inaD*²¹⁵, was first isolated in a large genetic screen for mutants with a defect in light responsiveness [16]. The *inaD* gene was later identified as the affected gene [17]. The predicted protein sequence of INAD was found to contain five protein–protein interaction domains called postsynaptic-density-95/Discs-large/ZO1 (PDZ) domains [18]. In general, PDZ domains, like other protein–protein interaction domains, such as Src homology 2 (SH2), SH3, and phosphotyrosine binding (PTB) domains, constitute the glue that holds such macromolecular complexes together [2,5,3,19].

PDZ domains are conserved sequences of 80 to 100 amino acids that have been shown to most commonly bind C-terminal protein motifs (–S/T–X–V/I–COOH, or ϕ -X- ϕ -COOH, where ϕ represents a hydrophobic residue, or –X–X–C–COOH) of proteins [5,20]. Some PDZ domains,

however, have been shown to bind internal sites of the protein [21,22] as well as other PDZ domains [23,24]. About 200 PDZ-domain-containing proteins have been identified in yeast, *C. elegans*, *Drosophila*, and humans [25]. Many scaffolding proteins have been reported to contain multiple PDZ domains [5,26–28]. PDZ domains are found more frequently in multiples within a single protein than any other protein–protein binding domain [5]. These findings suggest that multiple PDZ domains are a common feature of scaffold proteins.

As its sequence would suggest, the eye-specific INAD protein, which consists almost entirely of PDZ domains (PDZ1 to PDZ5 from N to C terminus), has been found to interact with multiple members of the phototransduction cascade. Studies in both *Drosophila* and *Calliphora erythrocephala*, using co-immunoprecipitation experiments, GST-fusion “pull-down” assays, ligand overlay assays, and the yeast-two-hybrid technique, have revealed three major proteins that interact with INAD: the effector PLC β , the light-activated ion channel TRP, and the eye-PKC required for normal deactivation [1,2]. Each PDZ domain appears to be specific for a particular protein partner. PDZ3 binds to the TRP channel [18,21,29–32]. PDZ1 and PDZ5 bind to the extreme C terminus (–F–C–A–COOH) and an internal

sequence, respectively, of PLC β [22,33]. PDZ2 and PDZ4 have been reported to bind eye-PKC [18,34]. The interaction of PDZ4 with eye-PKC depends on the C-terminal–T–I–I–COOH of eye-PKC [34].

To understand the functional significance of INAD in photoreceptors, a null mutant of *inaD* (*inaD*¹) was isolated and examined [18]. In *inaD*¹ null mutants, three key observations were made: (1) PLC β , TRP, and eye-PKC are all mislocalized in young flies; (2) light-responsiveness in these young flies is severely impaired; and (3) with age, flies display a further degradation of PLC β , TRP, and eye-PKC. In wild-type flies, phototransduction components, including INAD-signaling complexes, are exclusively localized to the rhabdomere (see Fig. 1); the rhabdomere is a specialized subcellular compartment of photoreceptors that contains $\approx 60,000$ tightly packed microvilli, a structure analogous to the membranous discs of the vertebrate rod photoreceptor. In the *inaD*¹ null mutant, PLC β , TRP, and eye-PKC are all mislocalized from the time of eclosion (adult fly emergence from its pupal stage): PLC β and eye-PKC are found in the cytoplasm of the cell body, and TRP localizes to the plasma membrane of the cell body outside of the rhabdomere [18]. While these core components of the INAD-signaling complex are mislocalized, other phototransduction components,

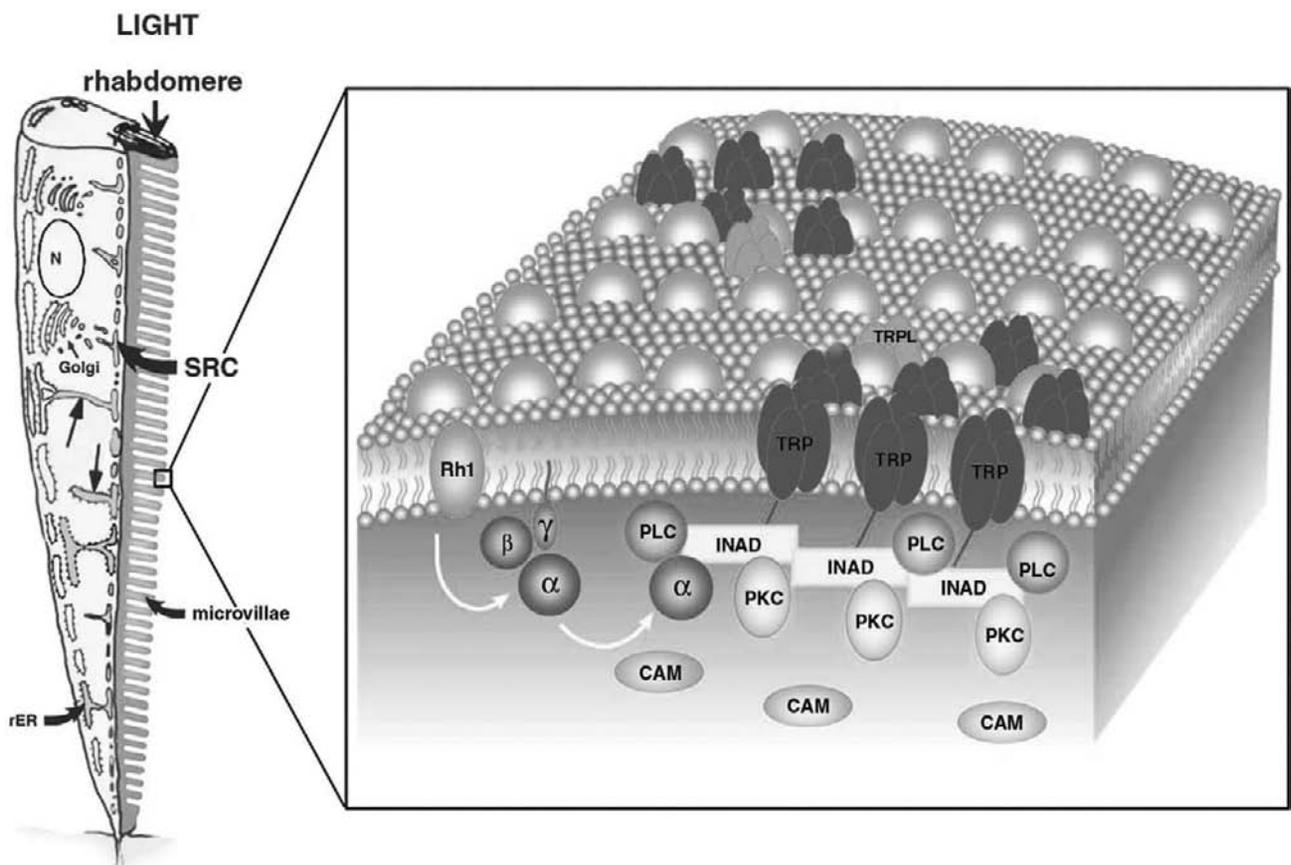

Figure 1 Illustration shows a *Drosophila* photoreceptor with the rhabdomere of the cell indicated. An expanded view of a microvillus membrane from the rhabdomere is shown. INAD-signaling complexes are clustered in the membrane, while rhodopsin molecules (Rh1, gray balls) are distributed randomly at a high density throughout the membrane. (From Tsunoda, S. and Zuker, C. S., *Cell Calcium*, 26(5), 166, 1999. With permission.)

such as rhodopsin, G_{oq} , and TRPL, remain normally localized in the rhabdomeres of *inaD*¹ null photoreceptors. These results show that INAD is essential for localizing its target proteins to the rhabdomere.

Light responsiveness of photoreceptors was examined in newly eclosed flies by electroretinogram (ERG) recordings and whole-cell voltage-clamp recordings; *inaD*¹ null flies were found to be nearly blind, displaying very small responses with slowed activation and deactivation kinetics [18,35]. Although newly eclosed *inaD*¹ null flies have somewhat reduced levels of PLC β , TRP, and eye-PKC, their mislocalization most likely produces the defective signaling observed. The placement of signaling complexes at the appropriate subcellular location has proven to be critical for signaling in other systems as well. The role INAD plays in assembling signaling complexes, targeting and/or anchoring components to the rhabdomere is just beginning to be explored (see below).

As *inaD*¹ null flies age, levels of PLC β , TRP, and eye-PKC all become progressively reduced, while rhodopsin, G_{oq} , and TRPL protein levels are unaffected [18,36]. In addition, point mutations in single PDZ domains of INAD affect steady-state protein levels as well as the localization of the corresponding target protein, but not those of any other target proteins [18,30,36]. Thus, each target protein depends on its interaction with the scaffold protein INAD for both its subcellular localization as well as its stability.

In addition to PLC β , TRP, and eye-PKC, there may be other protein partners that transiently or constitutively interact with INAD. INAD has been reported to bind to rhodopsin, TRPL, calmodulin, and the eye-specific unconventional myosin III, neither-inactivation-nor-afterpotential C (NINA C) [30,37,38]. These interactions are not observed under all conditions and are present in co-immunoprecipitates in much lower levels than INAD, TRP, PLC β , and eye-PKC [39]. In addition, the localization and stability of rhodopsin, TRPL, calmodulin, and NINA C are unaffected in *inaD*¹ null mutants [30,38]. Thus, it may be that these interactions are transient in nature. Future studies may reveal their significance.

INAD-Signaling Complexes in Phototransduction

Two of the most significant features of *Drosophila* phototransduction are a high sensitivity to light and a high speed of signaling. A single photon is thought to randomly activate one rhodopsin molecule. Thus, a high sensitivity to light is equivalent to a high probability of capturing any single photon. This is accomplished by having a high concentration of rhodopsin molecules in the photoreceptive membrane. The structure of the rhabdomere, like the discs of the outer segment of vertebrate rod photoreceptors, has evolved to maximize membrane surface area, allowing for the insertion of an enormous number ($\approx 10^8$) of rhodopsin molecules (Fig. 1). In the simplest and most likely scenario, rhodopsin would not be bound to INAD-signaling complexes but

would be randomly distributed at a high density throughout the rhabdomeric membrane [1,2,39]. The role of the G protein would be to report the activation of rhodopsin molecules in a local area to the downstream INAD-signaling complexes (Fig. 1). Similarly, the G protein would also not be expected to be a part of the INAD-signaling complexes.

The organization of downstream components into signaling complexes ensures a high speed of signaling. Interaction between proteins in complexes eliminates the reliance on diffusion and coincidental collisions between components. Fast activation and deactivation gives rise to high temporal resolution, essential for a flying organism such as *Drosophila*. In fact, the temporal resolution of the visual system in flies is about five times higher than in humans. It is still unclear, however, whether the high speed of signaling in *Drosophila* photoreceptors is primarily dependent on components being tethered to signaling complexes or on components being concentrated in the rhabdomeres of photoreceptors. Signaling complexes may also prevent cross-talk between different signaling pathways, promoting specificity of signaling. For example, Ca^{2+} ions that enter the cell through TRP channels may reach higher concentrations within a restricted microdomain created by signaling complexes, enabling the specific activation of eye-PKC and calmodulin within the same complex.

Multiple INAD-signaling complexes are proposed to be bound together, making up larger transduction units, or *transducisomes* [18]. Transducisomes may promote coordinated gating of the channels that are opened in response to the activation of one rhodopsin molecule by one photon [35]. Several potential mechanisms may underlie the interaction of multiple INAD-signaling complexes. One possibility is that one INAD scaffold may interact with another INAD scaffold, perhaps via PDZ–PDZ interactions [23,24]. Another possibility is that TRP channel subunits, which form tetramers, may bring as many as four different INAD-signaling complexes together. Because INAD interacts with PLC β at two different sites, PLC β could also link two different INAD-signaling complexes together.

Assembly, Targeting, and Anchoring of Signaling Complexes

Because the localization of INAD-signaling complexes to the rhabdomeres of photoreceptors is critical for normal signaling, studies have begun to focus on the underlying mechanism of this subcellular localization. How and where are signaling complexes assembled? One possibility is that signaling components are targeted independently to the rhabdomere, where they are then incorporated into complexes. Another possibility is that signaling components are preassembled into complexes in the soma before being targeted together to the rhabdomere. Recent evidence suggests this latter scenario, with preassembly dependent on the scaffold INAD [32]. Preassembly of signaling complexes may serve as a regulatory mechanism for ensuring that signaling

complexes in the rhabdomere contain the correct stoichiometry of signaling components. To date, almost nothing is known about how INAD-signaling complexes are assembled, how assembly is regulated, and how signaling complexes are targeted to the rhabdomere.

Because INAD is a soluble protein that organizes signaling complexes associated with the membrane, an anchoring mechanism that retains INAD-signaling complexes in the rhabdomere must also exist. Recent studies [31,32,36] suggest that the TRP channel is one component required for anchoring INAD in the rhabdomere. INAD and TRP appear to be targeted independently to rhabdomeres but somehow require one another to remain in the rhabdomeres. Although TRP may serve as an indirect anchor to the cytoskeleton, there is likely to be another anchoring protein of INAD-signaling complexes. Little is known about what other factors and proteins function in targeting, transporting, assembling, and anchoring signaling components/complexes in the rhabdomere.

Signaling Complexes in Vertebrate Photoreceptors

The assembly of phototransduction components into signaling complexes is not limited to *Drosophila*. Vertebrate rod photoreceptor cells have been reported to share a similar organization. In vertebrate photoreceptors, rhodopsin activates the G protein transducin. Transducin activates a cGMP phosphodiesterase (PDE) that hydrolyzes cGMP to GMP. The transient reduction in cGMP levels causes the closure of cGMP-gated channels. The β -subunit of these cGMP-gated channels consists of six-transmembrane-spanning domains, which make up the characteristic structural component of the channel, and a large cytosolic N-terminal region. This large N-terminal region contains a glutamic-acid-rich region, giving this region the name GARP. Two additional splice variants give rise to soluble forms of this GARP region alone; these proteins are called GARP1 and GARP2. GARP proteins are especially intriguing because they contain four homologous repeats (R1 to R4) that have been reported to bind to different components of the vertebrate phototransduction pathway [41]. Affinity chromatography columns carrying GARP repeats R1 to R4 were found to bind to PDE, guanylate cyclase (GC), and a retina-specific ATP-binding cassette transporter (ABCR). Thus, GARP containing cGMP-gated channel subunits or soluble GARP1 or 2 may serve as a scaffold to bring PDE, GC, ABCR, and cGMP-gated channels together into macromolecular complexes. Similar to INAD-signaling complexes, vertebrate signaling complexes do not display significant interaction with rhodopsin or the G protein.

Vertebrate rod signaling complexes are also proposed to be localized to a particular subcellular region; GARPs are localized to the space between the plasma membrane and the edge or rim of the intracellular membranous discs in the outer segment [41]. It has been suggested that GARPs bridge the space between the plasma membrane and membranous

discs, forming complexes consisting of cGMP-gated channels in the plasma membrane and GC and ABCR in the disc margins. The interaction of GARP with tubulin and actin may serve to tie signaling complexes to the cytoskeleton, anchoring them at the proper subcellular site.

A growing number of studies are proving that the organization of signaling proteins into macromolecular complexes is a universal cellular strategy not restricted to photoreceptors. Many PDZ-mediated complexes are found at neuronal synapses [27,42–45] and in epithelial cells [46]. Two major functions of these signaling complexes are (1) to bring components into close proximity for fast and specific interaction, and (2) to localize components to specific subcellular sites critical to their function. Understanding how signaling complexes are assembled and localized is likely to reveal much about intracellular signaling as well as how specialized subcellular structures are established and maintained.

Protein Localization in Negative Signaling

University of California at Berkeley, Berkeley, California*

Introduction

Cellular activation is regulated by the integration of both positive and negative signals. While positive signaling can be simplistically thought of as the initiation of a biochemical pathway leading to activation of a cellular process, negative signaling can have multiple meanings. From the standpoint of a cellular process such as proliferation or protein secretion, the initiation of any pathway that functions to downregulate these events can be defined as negative signaling. For instance, transforming growth factor β (TGF β) receptor can transduce a negative signal by upregulating cyclin-dependent kinase inhibitory proteins (CKIs) leading to cell cycle arrest [1]. Negative signaling can also refer to the activation of specific pathways that inhibit cellular stimulation, such as the inhibitory function of the glycine and γ -aminobutyric acid (GABA) receptors in neurons. Upon binding to their respective ligand, these receptors undergo a conformational change that allows the entry of chloride ions into the cell, thereby generating a hyperpolarizing inhibitory signal [2]. The signals generated in the above examples have inhibitory consequences for cellular activation; however, the intricacies of these processes can be thought of as being similar to those of positive signaling. In both cases, specific signaling pathways are activated but with differing downstream effects.

This article will focus on a distinct form of negative signaling in which extrinsic cell signals serve to directly antagonize positive signals. Direct antagonism is accomplished either by recruitment of specific proteins that serve to counteract signals generated by a stimulatory receptor or

by direct competition with the stimulatory receptor for ligand binding. In general, this form of negative signaling increases the ability of a cell to regulate a given activation pathway by providing a mechanism to attenuate or terminate the response. However, a potential danger in this scenario is that the negative signal could constitutively suppress the activation pathway, thereby rendering it useless. Here, we will discuss how differential protein localization of activating and inhibitory receptors regulates a critical balance between positive and negative signals. The T-cell stimulatory protein CD28 and the T-cell inhibitory protein cytotoxic T-lymphocyte antigen 4 (CTLA-4) will be used as models.

The Role of CD28 and CTLA-4 in T-Cell Activation

T-cell activation is governed by interactions between the T-cell antigen receptor (TCR) and major histocompatibility complex (MHC) molecules expressed on the surface of antigen-presenting cells (APCs). When a T cell bearing a specific TCR recognizes an MHC bearing an antigenic peptide, multiple phosphorylation-mediated signaling pathways are initiated, eventually leading to cell proliferation and upregulation of specific gene products involved in T-cell function. While signaling through the TCR is required for T-cell activation, it is not sufficient and a second distinct signal is needed. CD28, expressed on the surface of the T cell, is the most potent generator of this costimulatory signal. Interactions between CD28 and B7 family member proteins expressed by APCs result in enhancement of T-cell proliferation, cytokine production, and resistance to apoptosis [3].

CTLA-4 is homologous to CD28 and also binds to B7, although with a much higher avidity [4,5]. Both of these proteins are members of the immunoglobulin superfamily and are expressed as disulfide-linked homodimers. Importantly, while CD28 delivers an activating costimulatory signal, CTLA-4 functions to inhibit the T-cell response [6]. Perhaps the most convincing demonstration of the significance of CD28 and CTLA-4 mediated regulation of T-cell activation came from the generation of mice lacking functional gene products. CD28-deficient mice have severely compromised immune responses against a variety of pathogens [7,8], while CTLA-4-deficient mice die of a severe lymphoproliferative disorder at around three weeks of age [9–11].

The activating and inhibitory signals respectively generated by CD28 and CTLA-4 represent an interesting paradigm to study positive and negative regulation of cellular activation. The net costimulatory signal perceived by the T cell is a function of the integration of CTLA-4 and CD28 signals. The trafficking of these molecules during T-cell–APC interactions is a critical factor in regulating the balance between CD28-mediated activation and CTLA-4-mediated inhibition.

Expression and Localization of CTLA-4 and CD28: Consequences for Receptor Function

Although CD28 and CTLA-4 are homologous proteins, they have different expression and trafficking patterns within the cell. CD28 is constitutively expressed by T cells and localizes to the cell surface. In contrast, CTLA-4 is upregulated only after T-cell stimulation [12] and primarily localizes to an intracellular compartment due to a tyrosine-based internalization motif (Yxx ϕ) within its intracellular tail [13]. This motif results in the binding of the medium chain of the clathrin-coated pit adaptor complex, AP2, to the intracellular tail of CTLA-4, leading to its endocytosis from the cell surface [14–17]. CTLA-4 may also bind to the adaptor protein AP1, suggesting that intracellular trafficking of CTLA-4 emanating from the Golgi apparatus may also be a highly regulated process [18].

Intracellular sequestration has two important consequences for the ability of CTLA-4 to inhibit the T-cell response. First, sequestration provides a mechanism for decreasing the amount of CTLA-4 that can interact with ligand at the cell surface and thereby deliver an inhibitory signal. Second, it provides access to lysosomal compartments which allows for greater regulation of CTLA-4 expression by increasing the protein turnover rate.

CTLA-4 Expression

CTLA-4 expression is controlled by multiple factors. In addition to transcriptional and translational regulation [19,20],

several studies have demonstrated that protein levels are limited through posttranslational mechanisms. While CTLA-4 is found in several different intracellular compartments, a significant portion localizes to lysosomes [18,21,22], presumably accounting for its rapid turnover rate in activated T cells [22,23]. A short protein half-life ensures that CTLA-4 gene activity is tightly linked to expression levels within the cell. Thus, when gene expression is reduced or terminated, protein levels will rapidly reflect this change. A protein with a slower rate of turnover, such as CD28, could persist in the cell even after gene expression had been terminated [23]. Thus, the rapid rate of CTLA-4 degradation provides a high level of control over when and where CTLA-4 is capable of inhibiting the T cell response.

CTLA-4 Protein Trafficking

Because inhibitory signals generated by CTLA-4 are mediated through interactions with B7 molecules on the APC surface, a pathway must exist to specifically localize CTLA-4 to the T-cell plasma membrane. Intracellular CTLA-4 is known to rapidly polarize to a site facing antigenic stimulation upon T-cell encounters with APCs [24]. This pattern of trafficking may serve at least two purposes. First, it may ensure that CTLA-4 interacts only with B7 molecules expressed by APCs that are also displaying antigenic peptide. This would limit the origin of CTLA-4-mediated inhibitory signals to the specific APC with which the T cell is engaged. Second, it provides a regulatory point for controlling CTLA-4 expression levels on the T-cell surface. Factors controlling both exocytosis of CTLA-4 from intracellular vesicles and its subsequent stabilization at the cell surface play an important role in regulating CTLA-4-mediated inhibitory signals (Fig. 1).

During T-cell activation, CTLA-4 surface expression is regulated by at least two events that occur downstream of TCR signaling. First, an increase in intracellular calcium levels can enhance the rate of fusion between CTLA-4-containing vesicles and the plasma membrane, thereby leading to increased surface expression [24]. Second, tyrosine phosphorylation of the intracellular localization motif within the cytoplasmic tail of CTLA-4 prevents interactions with the AP2 complex, suggesting that TCR-mediated kinase activity can stabilize CTLA-4 on the cell surface [14,16]. These trafficking properties may explain the observation that CTLA-4 expression on the cell surface at the T-cell–APC interface is regulated by the strength of the TCR signal. TCR signals of higher quality (affinity of TCR for antigenic peptide–MHC) are more efficient at translocating CTLA-4 from intracellular sources to the T-cell plasma membrane [23]. This may represent a negative feedback mechanism in which a T cell receiving a strong stimulatory signal will specifically recruit CTLA-4 to the cell surface, where it can function to inhibit the response.

By coupling the recruitment of an inhibitory molecule to the stimulatory signal, the cell is able to achieve a higher degree of regulation over cellular activation. Under conditions of

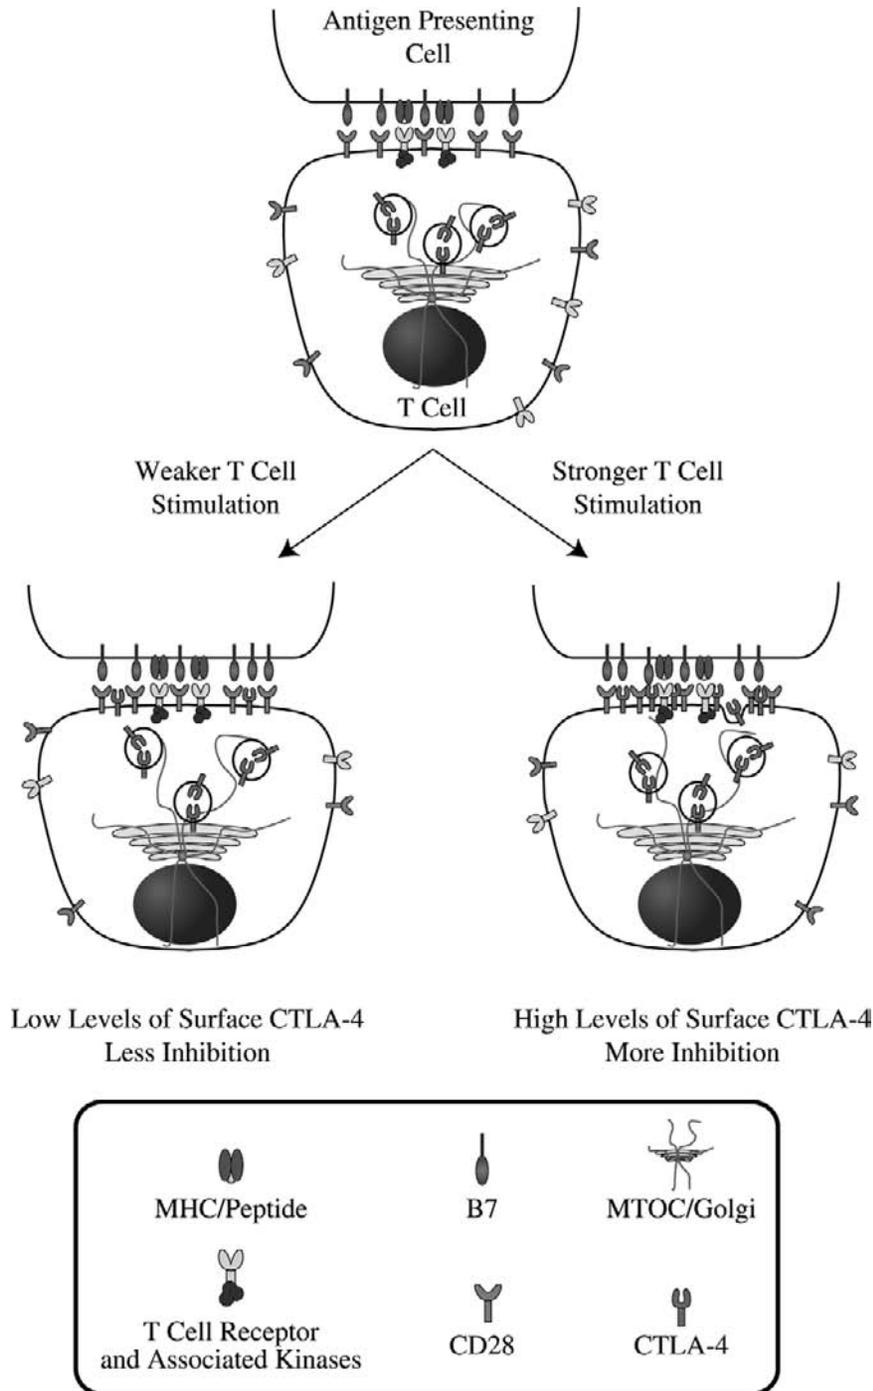

Figure 1 Protein trafficking of the T cell inhibitory protein CTLA-4 during antigen specific T cell-APC interactions. T cell antigen receptor signaling induces the rapid polarization of CTLA-4 toward the site of T cell-APC contact. This is likely caused by a reorientation of the microtubule cytoskeleton and its associated intracellular membrane compartments. Polarization of CTLA-4-containing vesicles enables CTLA-4 to be specifically targeted to the immunological synapse. Importantly, accumulation of CTLA-4 on the T cell surface at the site of contact with the APC is regulated by the strength of the TCR signal, with stronger signals being more efficient at localizing CTLA-4 to the cell surface. This trafficking property is not observed with CD28, a homologue of CTLA-4 which generates stimulatory signals. Because of these unique protein trafficking patterns, CTLA-4 may exert a greater inhibitory effect on T cells that receive stronger levels of stimulation and could thus function as a negative feedback control mechanism for TCR signaling.

weak stimulation, the cell can still respond, as these conditions will not efficiently recruit the inhibitory molecule to a functionally relevant site, yet a mechanism still exists to attenuate or terminate strong stimulatory signals so as not to overload the cellular response.

Mechanisms of CTLA-4-Mediated Negative Signaling

While the precise mechanism of CTLA-4-mediated inhibition remains unclear, several possibilities have been suggested. These include passive models in which binding

of CTLA-4 to B7 molecules can by itself inhibit T-cell activation and active models in which CTLA-4 functions by recruitment of accessory proteins that are capable of limiting the T-cell response. In both of these models, the key component regulating the ability of CTLA-4 to inhibit stimulatory signals is its localization within the cell. The passive models for CTLA-4-mediated inhibition include two distinct but related ideas. First, the finding that CTLA-4 binds to B7 with a much higher avidity than CD28 suggests that CTLA-4 may limit stimulatory signals by out-competing CD28 for ligand binding. This would effectively raise the levels of B7 on an APC required to fully activate a T cell. A second model for CTLA-4 function was recently proposed based on the solution of the B7.2:CTLA-4 crystal structure [25,26]. A single dimeric CTLA-4 molecule was shown to interact with two distinct B7 molecules. This binding mode, which is distinct from other immunoglobulin superfamily member receptor–ligand interactions in which the two chains of a dimeric receptor combine to form a monovalent ligand binding site, may explain the unusually high avidity of the B7:CTLA-4 interaction. Combining these data with evidence that B7 receptors may exist as non-covalent dimers on the surface of APCs [27] has led to a novel model for CTLA-4 function. CTLA-4 may form a lattice structure at the T-cell–APC interface consisting of repeated core units containing a single CTLA-4 dimer binding two distinct B7 dimers. This lattice structure may be sterically unfavorable for the formation of activating complexes at the T-cell–APC interface.

These models suggest that negative signaling by CTLA-4 does not require the specific interaction of accessory proteins with its cytoplasmic tail. This observation is supported by the demonstration that CTLA-4 can function to inhibit T-cell activation even after deletion of its intracellular tail, presumably by competing with CD28 for limited levels of B7 [28]. However, these and other studies have demonstrated that CTLA-4-mediated negative signaling can inhibit T-cell responses even when ligand is not limiting [29,30]. Thus, in addition to functioning through competition, CTLA-4 may also recruit proteins capable of downregulating the T-cell response. In support of this idea, CTLA-4 has been shown to bind the tyrosine phosphatase, SHP2, as well as the serine/threonine phosphatase, PP2A [31,32]. Recruitment of these phosphatases may explain the ability of CTLA-4 to reduce the tyrosine phosphorylation of the TCR complex itself, as well as several downstream effector molecules [28,29,30].

Conclusions

The ability of surface membrane receptors to relay extrinsic signals to the cell is often dependent upon their localization to functionally relevant sites on the cell surface. In activation pathways that are regulated by the convergence of positive and negative signals, differential localization of stimulatory and inhibitory receptors can be critical

for regulating a balance between activation and inhibition. The localization patterns of CD28 and CTLA-4 exemplify this concept. Here, the stimulatory receptor is constitutively localized to a site where it is capable of binding ligand, but the inhibitory receptor is recruited from intracellular compartments only after activation. Intracellular retention of inhibitory receptors essentially gives stimulatory receptors a temporal advantage. Without this advantage, the threshold for stimulation may be too high. In general, depending on the potency of the signal, sequestration of inhibitory receptors away from the cell surface may be a requirement for initiation and/or maintenance of activation pathways. Upon activation, inhibitory receptors can then be recruited to the cell surface in a regulated manner where they can function to inhibit a cellular response.

Transmembrane Receptor Oligomerization

University of California, Irvine, California

Introduction

Signal transduction in eukaryotes is initiated from receptors that are activated by the binding of exogenous ligands. The majority of these receptors is localized in the plasma membrane and can be generally separated into several categories based on structure and signaling properties (see Table 1). Although there are many similarities among these families, the most common is the quaternary structure of the activated species. In most (if not all) cases, signaling requires that one or more types of monomers (protomers) assemble themselves in a complex, and the formation of this receptor complex is prerequisite for function. The active complexes can range from simple homodimers to heterotetramers; in some cases, higher order complexes may be required. However, what controls the oligomerization process and the role that ligand plays are, in most cases, poorly defined. While ligand is certainly required to complete the activation, it is less clear whether it is required to induce the formation of the receptor complexes themselves. Evidence supporting both induced and constitutive oligomerized states has been reported for many receptor types, and indeed both mechanisms may be utilized.

The formation of oligomers to generate active (or activatable) species is a common biological mechanism found throughout living systems. It is a primary example of protein–protein interactions, which are a major component of the developing field of proteomics, and it affords several basic physiological advantages [1], including regulatory, kinetic, and specificity opportunities of various types. For example, a simple receptor dimer can easily be viewed as

binding its ligand with significantly higher affinity than a monomer due to increased surface binding area. A dimer would also have twice the signaling capacity and provide a simple on/off switch (assuming the monomer is inactive) by dissociating. In addition, the formation of heteromeric complexes offers another means to broaden the range of specificity in terms of both ligand binding and the signals produced. Furthermore, a heterodimer of a potentially active protomer with one that cannot be activated could produce a nonfunctioning complex (even though it can still bind ligands), thereby acting as a negative regulator of receptor signaling. This natural control mechanism has been extensively exploited in the research laboratory in recent years and is referred to as the “*dominant-negative*” strategy. The sections that follow provide a brief description of how oligomerization is utilized by the major cell transmembrane receptor classes.

Tyrosine Kinase-Containing Receptors

It has long been known that cell-surface receptors possessing intrinsic tyrosine kinase activity (RTKs) minimally require a dimeric state for their full activity. It has generally been accepted that RTK dimerization occurs as a result of ligand binding, (i.e., the receptors occur as monomers at the cell surface in the unstimulated state), and the ligand-bound monomer then recruits another monomer into the complex, allowing for the interaction of the kinase domains and their subsequent transphosphorylation. The initial phosphorylation events usually occur on the activation loop and help

Table I

Principal receptor classes	Reported oligomeric states	Examples
Tyrosine-kinase-containing receptors (RTK)	Homodimer	EGFR, TrkA, FGFR, CSF1R
	Heterodimer	EGFR/ErbB2, PDGFR α/β
Cytokine receptors, type I	Homodimer	EPOR, GHR
	Heterotrimer	IL-2R $\alpha/\beta/\gamma$, IL-4R $\alpha/\beta/\gamma$
	Heterotetramer	IL-6R/gp130, IL-11/gp130
Cytokine receptors, type II	Heterotetramer	IFN γ R1/2, IL-3R
Guanylyl-cyclase-containing receptors	Homodimer	ANPR
Serine/threonine-kinase-containing receptors	Heterotetramer	T β R1/2, BMPR1/2
TNF receptors	Homotrimer	TNFR1, Fas, CD40
	Homodimer	TNFR1
Heptahelical receptors (G-protein-coupled receptors)	Homodimer	δ -OpioidR, GluR
	Heterodimer	GABA _B R1/2, β_2 AR/ α_2 AR

stabilize the “open” (active) conformation, thereby allowing access of adenosine triphosphate (ATP) and substrate to their respective binding sites within the kinase domain (see Section IIA, Protein Phosphorylation, for more detail). The activated kinases can then carry out further tyrosine phosphorylation events. Both chemical and physical evidence has been obtained to support this model, most of which depends on a lack of evidence for detecting receptor dimers except in cells exposed to stimulation. However, the growing body of evidence that at least some RTKs can exist as preformed dimers in the absence of ligand includes both direct [2–4] and indirect [5] measurements. There are indeed substantial reasons why this would be advantageous to cells. The presence of ligand-independent dimers could provide a precise regulation of the activation of RTKs. Preformed dimers would reduce the time necessary for widely dispersed monomers to associate, thereby reducing the time required to form the active dimeric structure. Additionally, a preformed dimer could present a higher affinity ligand binding site by allowing the interaction of the ligand with both receptors simultaneously. Finally, suppression (inhibition) of the kinase domains in such ligand-independent complexes would provide a means to suppress spurious signaling in the unstimulated state.

A natural example of a ligand-independent dimer is the insulin receptor (IR), which exists as a covalently bound heterotetramer consisting of two α and two β chains joined by disulfide bonds (see chapters 51 and 52). The α and β chains are actually derived from a single precursor, hence the unprocessed insulin receptor resembles the other RTKs except for the covalent links that ensure that the unliganded state will be dimeric. It is also clear that dimerization alone is insufficient for the activation of IR. Somehow, ligand binding to the receptor ectodomain modulates a conformational change of the endodomain even though the plasma membrane is transversed by a single membrane-spanning segment of approximately 20 to 25 residues in each protomer.

Although the mechanisms by which this occurs remain largely unknown, it may be surmised that the two protomers (in this case, the protomer is an α/β chain unit) rotate relative to each other. A similar mechanism would be equally effective in the RTKs that are not covalently linked.

The active complexes of dimerized RTKs are stabilized by multiple contacts, such as interactions between monomers and ligand and between monomers. Interaction between monomers stabilized in a dimeric state has been shown to occur within the ectodomains, transmembrane domains, and endodomains of various receptors. For example, the crystal structure of a ligand-bound domain of TrkA shows direct contacts between the two domains as well as direct contacts to the ligand, nerve growth factor (NGF) (see chapter 48). In addition, regions within the ectodomains of fibroblast growth factor receptor (FGFR) and platelet-derived growth factor receptor (PDGFR) have been identified that mediate receptor–receptor interactions in the absence of ligand [6,7]. Furthermore, the transmembrane domains of ErbB family members self-associate in cell membranes [8], suggesting that the association may occur in the context of the full-length receptor provided that the ecto- and endodomains do not sterically hinder their association. Residues within the cytoplasmic domains of RTKs also are important for stabilization of dimers [9,10].

Cytokine Receptors

The cytokine receptors are comprised of numerous kinds of transmembrane receptors that are characterized by conserved patterns of amino acid residues in their ectodomains and the lack of enzymatic activity within their endodomains [11,12]. In lieu of intrinsic kinase activity, they associate with nonreceptor tyrosine kinases such as the Janus kinases (Jaks) or Src family kinases. Nevertheless, the active signaling complex induced by ligand is oligomeric and seems to

involve the juxtaposition of these nonreceptor tyrosine kinases. The quaternary structure of the cytokine receptor superfamily is both complex and varied, ranging from simple homodimers to heterotrimers, and can be separated into two subclasses, type I and type II, with the majority belonging to class I [11,12]. The class II receptors primarily consist of receptors for interferons (IFNs) and interleukin-10 (IL-10).

Type I Cytokine Receptors

The most-studied class I cytokine receptors are the growth hormone receptor (GHR) and erythropoietin receptor (EPOR) that function as homodimers (reviewed by Frank [13]). Recently, the unliganded and ligand-bound crystal structures of the receptor for erythropoietin have been described and provide substantial insight into the mechanisms of activation of this receptor [14,15]. EPOR appears to exist at the cell surface as an inactive dimer [14,15], and this state is mediated by the transmembrane domain [16]. The inactive dimer exists in a conformation in which the transmembrane domains (and presumably the endodomains) are separated by approximately 73 Å, thereby preventing the interaction of the associated Jaks [14,15]. Upon ligand binding, the separation of the transmembrane domains is reduced to 30 Å, which would likely be sufficient to allow the Jaks to transphosphorylate each other and thus become activated. The ligand-bound structure of GHR, also deduced from X-ray diffraction studies, suggests a similar mechanism of activation in that the endodomains appear to be brought into proximity, allowing activation of the associated Jaks [17]. It is not clear, however, whether the receptors exist in a predimerized state on the cell surface (either loosely or tightly associated) or whether ligand induces the dimerization. Neither is it known whether GHR requires a conformational change upon ligand binding for its activation, although if GHR is predimerized this would almost certainly be required for its activation. Interestingly, there is evidence to suggest that some GHRs, upon ligand stimulation, form covalent dimers through disulfide bridges [13].

Some type I cytokine receptors require three different subunits for their activity. The receptor for interleukin-2 (IL-2R) is one such case, as it has three subunits, α , β and γ (also known as the common γ chain [γ_c], as it is used by multiple receptors, including IL-4R). The β and γ receptors together are sufficient for signaling but do not possess sufficient affinity for ligand to be activated by normal levels of IL-2. IL-2R α is not a member of the cytokine receptor superfamily, as it does not possess the conserved motifs within its ectodomain; however, when present in the complex with the β and γ subunits, it increases the affinity for ligand binding [18] and may induce higher order oligomerization [19]. The ectodomains of the receptor subunits have been shown to interact at the cell surface in the absence of ligand as α/β or β/γ pairs or $\alpha/\beta/\gamma$ heterotrimers [20], although the presence of preassociated, full-length IL-2R subunits remains controversial. In any case, the downstream signaling initiated by IL-2R subunits conforms to

the common theme among many cell surface receptors: the juxtaposition of two catalytically active factors allows for their transactivation. With respect to IL-2R, the juxtaposed effectors appear to be Jak1 and Jak3 [21]. It has been shown, however, that the mere juxtaposition of the Jaks is insufficient for signaling and that the correct orientation of these entities is also required [22,23]. This observation supports the idea that the conformation of receptor endodomains is as important as their proximity within the active receptor complex in the activation process.

Analogous to the use of γ_c by IL-2R and IL-4R, the IL-6 and IL-11 receptors each require the common gp130 subunit for activity (reviewed in Taga and Kishimoto [24]). IL-6 cannot bind to gp130 alone, and IL-6R alone has a low affinity for IL-6. However, when IL-6R and gp130 are co-expressed, both high- and low-affinity binding sites for IL-6 are generated. IL-6 binds IL-6R on the cell surface or the soluble form of IL-6R (sIL-6R), which then recruits gp130 into the complex. The activity of gp130 requires its association to form homodimers as part of the IL-6/IL-6R/gp130 complex. The stoichiometry of the active receptor complex has been determined to be 2:2:2 [25,26], suggesting a two-fold symmetry. IL-6R has a short cytoplasmic tail that is dispensable for its function, and gp130 provides all of the required cytoplasmic signaling motifs. Because gp130 has been shown to be constitutively associated with Jak1, Jak2, and Tyk2, the presumed mechanism of activation again involves a juxtaposition of these kinases that allows their transactivation and the phosphorylation of tyrosine residues in the C-terminal region of the endodomain of gp130.

Type II Cytokine Receptors

The type II cytokine receptors consist primarily of receptors for interferons and interleukin-10 (IL-10) [11]. The receptors for interferon- γ (IFN γ R) and IL-10 (IL-10R) have a similar structure in that they are each comprised of two type 1 receptors and two type 2 receptors forming a heterotetramer (reviewed by Kotenko and Pestka [27]). As with many of the cytokine receptors, IFN γ R subunits are constitutively associated with Jaks: IFN γ R1 with Jak1 and IFN γ R2 with Jak2. IFN γ R1 dimers can bind IFN γ , but this complex is not functional even though the complex contains the associated Jak1. In contrast to the ligand-bound EPOR, which transposes the transmembrane domains within 30 Å in the active conformation, the 27-Å spacing between IFN γ R1 molecules acts to prevent downstream signaling [28], exemplifying the importance of the orientation and/or conformation of the cytoplasmic domains. Indeed, it has recently been shown using FRET analysis [S. Pestka, personal communication] that the IFN γ R1 and 2 heterotetramer (with the associated Jaks) is, contrary to commonly held opinion, preformed and that binding of IFN γ actually causes the intracellular domains (with their associated Jaks) to move apart. This new model suggests that there are likely inhibitory interactions that keep the Jaks inactive and that displacement is necessary to alleviate this or allow room for

substrates (e.g. STATs) to bind. The similarity of this model with that observed for FGFR3 is striking [5].

Guanylyl Cyclase-Containing Receptors

The receptors of this type are organized much like the RTKs in that they have an ectodomain, a single transmembrane-spanning domain, and an endodomain composed of a two interacting subdomains: a kinase-homologous regulatory domain that binds ATP and a guanylate cyclase domain that produces cGMP [29]. This group contains seven members, the best studied of which is GC-A, the atrial natriuretic peptide (ANP) receptor [30]. The three-dimensional structure of the ectodomain dimer has been solved by X-ray methods which revealed a bilobal periplasmic binding protein, similar to that found in several other proteins, including several DNA binding proteins [31]. Interestingly, these receptors clearly form unliganded dimers, and activation by ANP occurs through binding to and stimulation of these preformed structures; however, it is currently unclear how this activation is transmitted through the structure. Considering the overall similarity with the RTKs, it is likely that the preformed dimers are in a conformation that results in inhibition of the cyclases, and that binding causes a rotational motion that alleviates this, perhaps by the release of steric hinderances.

Serine/Threonine Kinase-Containing Receptors

The serine/threonine kinase receptors are typified by the receptors for transforming growth factor β (TGF- β), a dimeric ligand that exerts its effects through receptors composed of two different subunits designated type I and type II. Each possesses serine/threonine kinase activity. Both classes of receptor protomers are required for mediating the signaling response to ligand binding. The type II TGF- β receptor (T β R-II) exists as a constitutively active dimer and is responsible for the initial interaction with TGF- β , as the type I receptor (T β R-I) cannot bind TGF- β in the absence of T β R-II. Although the exact stoichiometry has not been elucidated, the minimal active signaling complex consists of TGF- β bound to two molecules of T β R-II and two of T β R-I. Two theories exist regarding the association and activation of this complex. The first involves the initial interaction of TGF- β with T β R-II. This complex then actively recruits T β R-I, leading to the phosphorylation and activation of this receptor. The second theory involves an inactive, preexisting (albeit weakly associated) heterotetramer of T β R-I and T β R-II that undergoes a conformational change upon ligand binding that alters the juxtaposition of T β R-I with T β R-II in such a way as to allow the phosphorylation and activation of T β R-I. In either case, ligand is required to induce or stabilize an active conformation that allows the phosphorylation of T β R-I by T β R-II.

The structure of T β R-II complexed with TGF- β , deduced from X-ray studies, has recently been described [32].

The structure supports the formation of a TGF- β /T β R-II/T β R-I heteropentameric complex in which T β R-I directly contacts both the ligand and T β R-II. These findings do not preclude either theory of receptor association, but they do provide evidence for direct interaction of T β R-I and -II that would be required for association of the receptors in the absence of ligand. It has been shown that T β R-I and -II can associate in the absence of ligand *in vitro* and when co-expressed in mammalian cells [33], two observations giving support for preexisting heterotetramers in the absence of ligand.

Tumor Necrosis Factor Receptors

The specific oligomeric nature of active tumor necrosis factor receptor (TNFR) family members has not been definitively proven. The ligands for these receptors are usually trimeric, suggesting that the functional oligomeric complex of the receptors may also be trimeric; however, the receptors may actually function as dimers. At least three different hypotheses have been proposed for the activation of TNFRs. The first, and most widely accepted, involves receptor trimerization. The earliest crystallographic studies of TNFR and TNFR1 bound to TNF- β demonstrate that one receptor molecule binds to each of the three monomer-monomer interfaces of the trimeric TNF ligand [34,35]. Interestingly, no direct contacts between any of the receptor monomers other than nonspecific crystal contacts were detected; however, the receptor endodomains presumably would be sufficiently close to allow interaction. TNF-receptor-associated factors (TRAFs), primary effectors of TNF-Rs, have been crystallized as trimers in association with domains of the TNFR family member CD40, and the structure of trimerized TRAFs supports a model of interaction with trimerized CD40. Furthermore, TRAF activity is greater when induced by trimeric forms of CD40 as compared to monomers or dimers [36]. Biochemical studies of TNFR also suggest that the receptors exist as trimers even in the absence of ligand [37]. There are numerous other studies supporting the notion that the active form of TNFR is trimeric.

Nonetheless, evidence also suggests that active TNFR is assembled as dimers [38]. First, biochemical studies of the ectodomain of TNFR2 determined that two or three TNFR2 molecules bind to each trimer of TNF- α or TNF- β ligand, suggesting that a receptor dimer may interact with the trimeric ligand [39]. CD27, a TNFR family member, functions as a disulfide-linked dimer, analogous to the insulin receptor. Chimeric receptors consisting of EPOR or PDGFR ectodomains inframe with the TNFR transmembrane, and cytoplasmic domains function as dimers, either constitutively (the EPOR chimera [40]), or ligand dependently (PDGFR [41]), indicating that two subunits are sufficient for signaling. Furthermore, secreted forms of TNFR have been purified as dimeric proteins. Most substantially, structural studies of crystallized ectodomains of TNFR1 in the absence of ligand indicated that TNFR could exist in at least

two different dimeric conformations [42]. These structural studies led to models of dimeric receptor activation.

Two different models exist for the activation of dimeric receptor complexes [43], and both models arise from crystallographic studies of unliganded ectodomains [42]. The first involves a conformational change via an axial rotation that would juxtapose the cytoplasmic domains [44]. The second is the so-called *expanding-network hypothesis* and involves the formation of higher order oligomeric complexes of dimeric receptors and trimeric ligand [42]. Even though the specific organization of receptor–ligand complexes has not been definitively determined, it is clear that the oligomerization of TNFR family members is required to allow signaling from these receptors.

Heptahelical Receptors (G-Protein-Coupled Receptors)

The heptahelical or G-protein-coupled receptors are one of the largest families in the human genome (and likely other mammalian genomes, as well), and with more than 1000 distinct entities they are the most used family of transmembrane signaling receptors. Not surprisingly, as a group, they form one of most popular targets for drug discovery. Their mechanism is well understood in general terms; that is, they interact with trimeric G-protein complexes, of which there are many, which in turn couple them to a wide variety of signaling effector systems, including adenylyl cyclase, the producer of cAMP, which was the first second messenger to be identified.

It has been generally believed that this class of receptors is monomeric and remains so during the binding of ligand and the activation of the trimeric G-protein complex; however, recent evidence suggests that this is not the case [45–47]. Indeed, these receptors appear to exist as homodimers, heterodimers, or even larger oligomers. The identification of these higher order structures has, of course, been aided by improved technology that has allowed detection of the oligomers both in solution and in viable cells [45,46]. The formation of heterodimers is a particularly interesting phenomenon as it allows a greatly increased range of ligand binding and subsequent responses. Apparently, even distantly related receptors have been observed to form complexes and, given the size of this family, the number of possibilities afforded by these interactions is enormous.

Concluding Remarks

In this brief overview, we have summarized much of the salient observations that support the view that oligomerization is a prevalent and perhaps universal requirement for transmembrane receptor function. There is clearly growing evidence, in part attributable to better technology, that many of these oligomeric structures form independent of ligand and that activation by ligand binding is not due to association

of the receptor protomers but rather allows them to seek a different juxtaposition relative to each other, almost certainly at least in part by rotational motions. Such a model eliminates the diffusion control that ligand-induced dimerization (oligomerization) requires and provides additional opportunities for the regulation of signal flux by allowing inhibitory interactions in the unliganded complexes. The reader is directed to the many chapters in this Handbook describing individual systems for more specific details.

Introduction

Tony Hunter

Signals received by receptors at the cell surface are transduced across the cell membrane and then propagated in the cytoplasm through a variety of mechanisms. We chose to subdivide Part II of the Handbook into sections according to the different mechanistic principles that are used to initiate and transmit receptor-activated signals in the cytoplasm, namely Protein Phosphorylation, Protein Dephosphorylation, Calcium Mobilization, Lipid-Derived Second Messengers, Protein Proximity Interactions, Cyclic Nucleotides, and G proteins. In addition, we included a section on Developmental Signaling, because of the increasing information about signaling pathways used in developmental processes. Space limitations precluded comprehensive coverage of the hundreds of cytoplasmic signaling molecules individually. Indeed, this type of information is much more effectively achieved through web-based molecule pages, and a number of databases of this sort are being developed. For this reason, we decided to use a thematic approach, focusing on systems, pathways and protein families. We realize that there are many important topics that are not covered, and we hope that these can be added during the development of future print and electronic editions of the Handbook. Much of the recent progress in our understanding of signaling has come from the development of new techniques and reagents, and, while not wanting this to be a methods book, we have included descriptions of particularly important recent technical developments that have already begun to have a major impact on research in most of the sections.

Protein phosphorylation and dephosphorylation is the main regulatory mechanism through which protein activity is regulated in eukaryotic cells, and the major classes of protein kinase and phosphatases are reviewed in these two sections. Some emphasis is given to the emerging concept that phosphorylation is frequently used to promote inducible protein-protein interactions through phosphoamino acid specific binding domains. Cognizant of the enormous impact of bioinformatics on the field of signal transduction,

we have included articles on the genomic catalogues of protein kinases and phosphatases. Protein phosphatases were for a long time the poor cousins of the protein kinases. However, over the past decade protein phosphatases have come into their own, and the burgeoning numbers of protein phosphatases and the complexity of their regulation and substrate targeting justifies a complete section on protein dephosphorylation.

Cytoplasmic signaling is a highly organized in space and time, and the next frontier in intracellular signaling will be the elucidation of the spatial and temporal aspects of signaling at the single cell level. Calcium-mediated signal transduction is one of the best systems in which to study the spatiotemporal events of receptor induced signaling making use of fluorogenic calcium-binding dyes. The dynamic and oscillatory nature of calcium fluxes in the cytoplasm are surely a reflection of the dynamic nature of other signaling events in the cytoplasm. Articles describing the basis for the dynamic behavior intracellular calcium and the targets that propagate the calcium signal are collated in the section on calcium mobilization.

Lipid-derived second messengers have become increasingly important in signal transduction, particularly with the realization that a number of modular protein domains recognize differently phosphorylated forms of phosphatidylinositol, thus allowing these lipids to act as second messengers and recruit target proteins to distinct cellular membrane compartments. The early discovery of ligand stimulated synthesis of phosphoinositides and the finding that diacylglycerol derived through hydrolysis of PIP₂ is a second messenger that activates protein kinase C were the harbinger of an increasing number of phospholipid-derived second messengers, which are either membrane anchored or soluble. In particular, the discovery of 3' phosphoinositides has opened up a whole new area of signaling in which proteins are inducibly brought to the membrane through recognition by protein domains that specifically bind

phospholipid head groups. These concepts are emphasized in this section.

Cyclic nucleotide mediated signaling is the oldest and best understood signaling system; cAMP continues to be the model for second messenger signaling, and the cAMP-dependent protein kinase remains the paradigm for the protein kinase superfamily. Nonetheless, new targets for cyclic nucleotides have been identified within the past few years, and this advance is described in this section, which also includes articles on biosensors that can be used to study cAMP-dependent signaling in real time in single living cells.

Signaling through heterotrimeric G proteins is also a venerable system, and it has become increasingly important with the proliferation of G protein subunit types, and the genomics revelation that G protein coupled receptors are by far the largest class of cell surface receptor. These switch-like proteins and their regulators and effectors have functions in a wide diversity of cellular processes that are reviewed in this section. The large family of small monomeric G proteins have become increasingly prominent. The small G proteins play key roles in propagating receptor signals to and from the cytoskeleton and in orchestrating cytoplasmic vesicular trafficking systems, nuclear import and export and cell cycle progression, and many of these are covered in this section.

A number of signaling pathways have been uncovered through genetic analysis of developmental processes in model eukaryotic organisms, and these pathways have revealed a number of new, highly conserved principles of signaling. Good examples are the Notch, Hedgehog and Wnt signaling pathways, whose main purpose is to regulate gene expression that is critical for development. All three pathways use regulated proteolysis; for instance, activation of the Notch pathway results in intramembrane cleavage of the Notch receptor releasing its cytoplasmic domain, which migrates into the nucleus and acts as a direct transcriptional regulator. This type of processing is now emerging for other types of receptor signaling system. The major signaling pathways used in development are reviewed in this section,

with an emphasis on the developmental systems where they participate.

The concept that signal propagation in the cytoplasm involves freely diffusible second messengers and proteins has to some extent been supplanted with the idea that signal transmission may be more akin to a solid state system in which proteins are organized into transient and constitutive multiprotein complexes. Signaling through protein–protein interaction is an emergent theme, and both inducible and stable protein–protein interactions form the basis for many signal pathways. Indeed, signaling pathways that use induced protein–protein interaction as a primary signal initiation mechanism, such as the TNF receptor family, furnished a few principle of signaling that now impinges on many systems. This concept will be increasingly important to our understanding of signal propagation and specificity in the cytoplasm. Anchoring and scaffolding proteins that organize adjacent components of signaling pathways are a paradigm that is highlighted by articles in this section. Methods for studying protein–protein interactions *in vivo* and *in vitro*, and for analyzing protein complexes are also included.

If one looks forward to where cytoplasmic signaling will be in ten years time, we can foresee that a complete cellular parts list will be available, and that proteomic analysis will have told us the composition of multicomponent protein complexes and revealed all the possible protein–protein interactions that can occur. Cytoplasmic signaling is a highly organized and localized process and its often stochastic nature means that single cell analysis is vital for further progress. The development of high sensitivity biosensors to study the localization of active forms of signaling enzymes, such as protein kinases, to determine where and when protein–protein interactions occur and second messengers are generated is going to be needed in order to study spatiotemporal aspects of all types of signaling pathway in single living cells. Finally, one hopes it will be possible to use all this information to accurately model signaling networks and understand cooperative and inhibitory interactions between cytoplasmic signaling pathways.

Introduction

Ever since the discovery nearly 50 years ago that reversible phosphorylation regulates the activity of glycogen phosphorylase, there has been intense interest in the role of protein phosphorylation in regulating protein function. With the advent of DNA cloning and sequencing in the mid-1970s it rapidly became apparent that a large family of eukaryotic protein kinases exists, and the burgeoning numbers of protein kinases led to the speculation that a vertebrate genome might encode as many as 1001 protein kinases [1]. The importance of protein phosphorylation as a regulatory mechanism has continued to grow, and it is estimated that more than 30% of intracellular proteins can be phosphorylated at one or more sites. Phosphorylation not only regulates enzymatic activity through inducing conformational changes or through direct steric effects, but also modulates the function of structural proteins through conformational and charge effects. In addition, a major revelation has been the finding that protein-linked phosphates can act as binding sites for other proteins [2].

The first eukaryotic protein kinases to be identified in the 1950's (i.e., the casein kinases and phosphorylase kinase) were found to phosphorylate serine and/or threonine in their substrate proteins. For many years thereafter all the newly characterized protein kinases proved to be serine/threonine-specific, and it was not until the early 1980's that

tyrosine-specific protein kinases were discovered. Subsequent molecular analysis showed that the catalytic domains of the serine/threonine- and tyrosine-specific protein kinases are in fact related in sequence, and belong to what is referred to as the eukaryotic protein kinase (ePK) superfamily. Members of the ePK superfamily all have a similar hinged bilobate catalytic domain structure. A few other types of protein kinase are known; these atypical protein kinases (aPKs) are either very distantly related to the ePK superfamily or have no sequence relationship at all. Nevertheless, the three-dimensional structures of the catalytic domains of several of the aPKs prove to be similar to that of the canonical ePK catalytic domain, even in cases when there is little or no detectable sequence similarity. In addition to Ser, Thr and Tyr, several other amino acids in proteins can be phosphorylated, including Lys, Arg, and His, but the provenance of the cognate protein kinases remains unclear. The prokaryotic two component protein kinases, commonly known as "histidine kinases" form yet another distinct family. In contrast to the ePKs, which transfer phosphate from ATP to protein in a concerted reaction, the histidine kinases use a phosphoenzyme intermediate, in which the phosphate from a phosphohistidine is donated to an acceptor protein, usually on an aspartate. This type of protein kinase is rare in eukaryotes, and, with exception of plants where a few exist, multicellular eukaryotes appear to have none of these protein

kinases, apart from the unusual mitochondrial PDHK family members.

The ePK superfamily catalytic domain is characterized by a series of short sequence motifs, which define 11 sub-domains, and serve as key elements in the catalytic core of the kinase domain [3,4]. These motifs in combination with the overall catalytic domain sequence can be used to identify genes that encode protein kinases through pairwise sequence alignments and hidden Markov model searches. Such analysis of complete genomic sequences and corresponding cDNA sequence information permits prediction of the number of ePKs encoded by a eukaryotic organism. Similar approaches can be used to identify members of the aPK families. Using this strategy, we have surveyed a series of sequenced eukaryotic genomes to define the protein kinase complement (kinome) of each organism [5–8]. In many cases, the assembled genomic sequences still have small gaps, and therefore a few protein kinase genes may be missing. Additional families of aPKs may also remain to be found by biochemical approaches. In this regard, protein kinase activities that phosphorylate Lys, Arg, and His have been reported, but these have not been characterized molecularly, and it seems unlikely that there are large numbers of these enzymes.

A summary of the protein kinases in the budding yeast *Saccharomyces cerevisiae*, the nematode *Caenorhabditis elegans*, the insect *Drosophila melanogaster*, and the vertebrate *Homo sapiens* is provided in Table 1. A complete listing of the individual protein kinases, dendrograms,

sequence alignments, etc., can be found at <http://kinase.com/>. The protein kinase classification we adopted in 1988 forms the basis for the major subdivisions of protein kinases, including the AGC, CMGC, CAM kinase and tyrosine kinase (TK) groups [3]. However, our more detailed and sophisticated genome-wide kinome analysis has led us to parse a number of protein kinases originally included in the large “Other” group into three additional groups, namely tyrosine kinase-like (TKL), STE and CK1. Within groups the protein kinases are divided into families (e.g., the MAP kinase family), which form major branches on the kinome tree; families can often be subdivided into several related subfamilies, which form twigs at the end of the branches (e.g., ERK, JNK and p38 MAP kinase subfamilies of the MAP kinase family). The sizes of protein kinase families/subfamilies are quite variable, with some families having more than 10 members, and others being represented by only a single protein kinase. Although most of the protein kinases fall into major groups, there are still a number of protein kinases that are outliers, either singly or as small families.

The Yeasts: *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*

The first eukaryotic genome sequence to be completed was that of the budding yeast *S. cerevisiae*. Out of ~6200 genes, our most recent estimate is that 130 encode protein kinases

Table I Protein Kinases in Budding Yeast, Nematodes, Flies and Humans

Group	Protein kinase families	Protein kinase subfamilies	Budding yeast kinases	Nematode kinases	Fly kinases	Human kinases	
AGC	14	19	17	30	30	63	
CAMK	17	33	21	46	32	74	
CK1	3	3	4	85	10	12	
CMGC	8	24	21	49	33	61	
Other	37	38	38	67	45	83	
Ste	3	13	14	25	18	47	
Tyrosine Kinase-like	7	13	0	15	17	43	
Tyrosine Kinase	30	30	0	90	32	90	
RGC	1	1	0	27	6	5	
Total ePK families	120	174	Total ePKs	115	434	223	478
Atypical - PDHK	1	1	2	1	1	5	
Atypical - Alpha	1	2	0	4	1	6	
Atypical - RIO	1	3	2	3	3	3	
Atypical - A6	1	1	1	2	1	2	
Atypical - Other	7	7	2	1	1	9	
Atypical - ABC1	1	1	3	3	3	5	
Atypical - BRD	1	1	0	1	1	4	
Atypical - PIKK	1	6	5	5	5	6	
Total families	134	196	Total PKs	130	454	240	518
			Total genes	~ 6200	~ 19100	~ 13600	~ 31000

(2.1% of all genes) [5,7]. Of these, 115 are conventional ePKs, and the rest are aPKs. None of the yeast protein kinases belongs to the metazoan tyrosine kinase group, even though there are yeast protein kinases, like Swe1p, that can phosphorylate tyrosine in their targets. The recently completed genome sequence of the fission yeast *S. pombe* predicts a similar number of protein kinase genes, but *S. pombe* also lacks genes encoding *bona fide* tyrosine kinases. The tyrosine kinases appear to have arisen concomitantly with multicellular organisms, and may have played a critical role in metazoan evolution as a result of their ability to facilitate intercellular communication. Interestingly, most of the protein kinase families present in budding yeast are also found in fission yeast, despite their great evolutionary distance, and, as will be discussed below, there are 7 families of protein kinases that are unique to the fungi.

Nematodes: *Caenorhabditis elegans*

The nematode *C. elegans* is a complex multicellular organism, which undergoes a deterministic developmental program. Out of the ~19,100 genes in the *C. elegans* genome, 454 (2.4% of all genes) encode protein kinases, of which 434 are ePKs [6,7]. A striking aspect of the nematode kinome is the emergence of the tyrosine kinase (TK) group. *C. elegans* encodes 90 tyrosine kinases (20% of all protein kinases), which are of receptor and nonreceptor types. Both types of tyrosine kinase arose early in metazoan evolution, being present in sponges and coelenterates. Compared to *Drosophila*, the relatively large number of tyrosine kinase genes is in part accounted for by the expansion of two families, the Fer nonreceptor tyrosine kinase (42 genes) and the Kin16 receptor tyrosine kinases (16 genes). Many of the major tyrosine kinase families are already evident in the nematode. Most of the major serine kinase families present in higher eukaryotes are already in place in *C. elegans*, with some families being greatly expanded (e.g., there are 85 CK1 genes in *C. elegans* compared with 12 in humans and 10 in *Drosophila*). Some of these expansions appear to be very recent, and are not seen in draft sequence from the related *C. briggsae*. Moreover, the lack of ESTs indicates that some members may be pseudogenes, although detailed sequence analysis is needed to establish this.

Insects: *Drosophila melanogaster*

The dipteran insect *D. melanogaster* has ~13,600 genes, which is significantly fewer than *C. elegans*, even though by most criteria the fly is a more complex organism. *Drosophila* has 240 protein kinase genes (1.8% of all genes), of which 223 are ePKs, with 32 tyrosine kinase genes (14% of all protein kinases) [7,9]. In fact, the percentage of protein kinase genes in *Drosophila* is very similar to that of *C. elegans*, if one trims away the highly expanded protein kinase families in *C. elegans*. Some new protein kinase families emerge

in *Drosophila*, which have functions in immunity (e.g., JAK), morphogenesis (e.g., LIMK) and the nervous system (e.g., MuSK).

Vertebrates: *Homo sapiens*

The *Homo sapiens* genome, with ~31,000 genes, has a predicted total of 518 protein kinase genes (1.7% of all genes) [8]. Of these 478 are in the canonical ePK family (Table 1), and the others are divided between 9 small aPK families, which include the PIKK (PI3 kinase-like kinase), the PDHK (pyruvate dehydrogenase kinase) and alpha kinase (E2F kinase) families. There are 90 tyrosine kinase genes (16% of all protein kinases); several of the tyrosine kinase families present in *Drosophila* and *C. elegans* have undergone significant expansion in mammals (e.g. Eph receptor tyrosine kinases, where there are 14 members in humans, and only 1 in *Drosophila* and 1 in *C. elegans*). The total number of protein kinases is about half that predicted 15 years ago [1], but it is still a strikingly large number, comprising about 1.7% of all human genes. Moreover, the total number of protein kinase gene products is surely much greater than 518, due to the expression of alternatively spliced forms, which are known for many well-studied protein kinases. A few new protein kinase families arose during the evolution of vertebrates, including the Tie and Axl families of receptor tyrosine kinases, which play roles in angiogenesis and immune system homeostasis respectively. New serine kinase families are also present, such as Trio, which is involved in secondary myogenesis and neural organization. Our analysis of the mouse kinome is not as complete, but >95% of the human protein kinases have orthologues in the mouse, and it seems likely that the mouse kinome will be very similar indeed to the human kinome [8].

Our extensive analysis of the human kinome has revealed a number of other features [8]. Out of the 478 conventional ePK catalytic domains, 50 (~10%) are missing one or more of the 3 conserved catalytic residues (Lys72/Asp166/Asp184 in PKA C subunit) suggesting that most of them lack catalytic activity. These “kinase domains” may serve as docking platforms or scaffolds (e.g., ErbB3 and ILK), structural elements (receptor guanylyl cyclase kinase homology domains) and/or regulatory domains, which might bind and sense ATP levels. Many of these catalytically-dead protein kinases have been conserved throughout evolution (e.g., ILK and Derailed/RYPK), implying that they serve a critical function in the absence of catalytic activity [9].

There are 106 predicted pseudogenes in the human genome that contain recognizable elements of the protein kinase catalytic domain (~20% of the total number of protein kinases), as defined by a lack of ESTs, reading frames with stop codons, and in many cases (75) a lack of introns, indicating that these genes underwent retrotransposition (“processed pseudogenes”). For reasons that are unclear, some protein kinase families have a very high ratio of pseudogenes to functional genes (e.g., MARK 28:4). Since the

prediction of pseudogenes is not an exact science, some of these 106 genes may ultimately prove to have functional products, although possibly not active protein kinases.

The kinome analysis also has implications for human disease. Mutational activation/inactivation and overexpression of protein kinase genes is a frequent cause of hereditary and sporadic human disease. For instance, as many as half of the 90 tyrosine kinases have been implicated in cancer, through mutational activation or overexpression. For this reason, one might certainly expect mutation of some of the new protein kinase genes revealed by genomic analysis to be causal in human disease. Our analysis indicates that 80 protein kinase genes map to chromosomal disease loci, and these are candidate genes for the causative mutation. In addition, 164 protein kinase genes map to amplicons found in tumors.

Protein kinase catalytic domain function is often dependent on additional domains in the protein, which serve to regulate activity, localize, and recruit regulatory proteins/second messengers and substrates. The nature of these domains can provide insight into the functions of new protein kinases. About half the protein kinases are predicted to have additional domains, many of which are implicated in signaling processes. Of the tyrosine kinases, 25 have P.Tyr-binding SH2 domains that play a cardinal role in establishing tyrosine phosphorylation based signaling networks. In contrast, perhaps surprisingly, only one serine kinase contains a P.Ser/Thr-binding domain (an FHA domain in CHK2). In addition, 46 protein kinases have domains that interact with other proteins (e.g., SH3); 42 protein kinases have lipid interaction domains (e.g., PH) (present in both tyrosine and serine kinases); 38 protein kinases have domains linked to small GTPase signaling (present in both tyrosine and serine kinases); and 28 protein kinases have domains linked to calcium signaling (all are serine kinases). Generally, most members of a protein kinase family have the same constellation of ancillary domains, but there are some exceptions. A complete listing of additional domains found in human protein kinases is given at <http://kinase.com/>.

Comparative Kinomics

A great deal can be learned about the evolution of the protein kinase superfamily through the comparison of the kinomes of different eukaryotes [7,8] (Figures 1 and 2). Fifty one protein kinase families are common to all eukaryotes; these serve cell essential functions; examples are Cdk, CAMK, PKA, MAP kinase, etc. Interestingly, most of the atypical protein kinase families exist in all four kinomes yeasts, but clearly were not selected for diversification during evolution. Seven families are unique to the budding and fission yeasts. These have functions commensurate with a fungal life style, such as cell wall biosynthesis and stress responses.

Among the metazoan kinomes analyzed to date there are 93 families in common, which presumably were present in the last common ancestor of nematodes, flies and vertebrates.

Two major new groups of protein kinase are revealed in metazoa; tyrosine kinase (TK) (Figure 2) and TK-like. Many of these latter protein kinases are engaged in intercellular signaling, an activity vital for the development and viability of multicellular organisms. Tyrosine kinases rely on P.Tyr-binding domains for recruiting signaling proteins to transmit the signal, and the evolution of tyrosine phosphorylation based signaling may have depended on the development of SH2 domains. P.Tyr-specific tyrosine phosphatases are also a requisite, but members of the PTP family are already present in the yeasts, where their function is to dephosphorylate Cdc28/Cdc2 and the MAP kinases. Choanoflagellates, which are protists that can exist in multicellular colonies, possess at least one receptor tyrosine kinase, suggesting that tyrosine kinases may have evolved prior to the emergence of true metazoans, and indeed this may have been an essential step [11].

There are 8 protein kinase families present in humans and nematodes but not flies (e.g., Met/HGF receptor). These could have been present in the common ancestor, but lost as the insect lineage evolved. Fifteen protein kinase families are unique to *C. elegans*, and these may have evolved to serve specialized functions in the nematode. As discussed earlier, there are 18 families common to *Drosophila* and humans not found in *C. elegans*, which could have been lost in the evolution of nematodes from the common ancestor, or they could have evolved later. Finally, there are 13 protein kinase families unique to the human kinome, which presumably evolved hand in hand with the vertebrate lineage. As indicated, these serve functions in differentiation of novel cell types and tissue structures, particularly the vascular, immune and nervous systems. In terms of vertebrate kinome evolution, our ongoing analysis of the pufferfish (*Fugu rubripes*) genome sequence, and of the zebrafish (*Danio rerio*) when it becomes available, will surely be revealing. The various shared and unique protein kinase families in the yeasts, worms, flies, and humans can be explored online at <http://kinase.com/>.

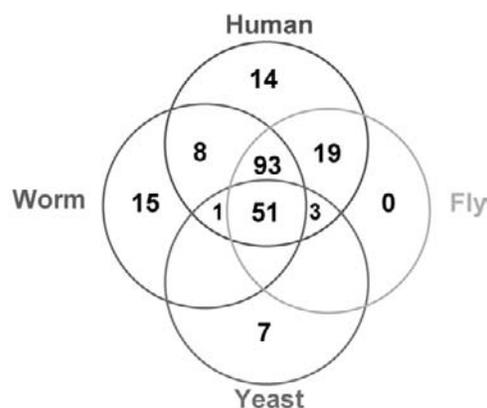

Figure 1 Occurrence of protein kinase families and subfamilies in the budding yeast, nematode, fly and human genomes illustrated by a Venn diagram. Comparison of 'orthology groups' across large evolutionary distances shows 51 distinct families/subfamilies conserved between all 4 kinomes, and 93 more in all three metazoan kinomes.

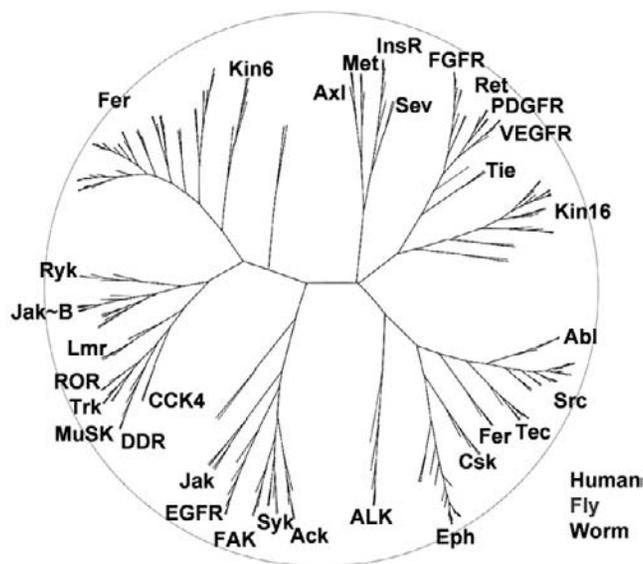

Figure 2 Trikinome dendrogram depicting the distribution of tyrosine kinases in nematode, fly and human. Most tyrosine kinases fall into distinct families (labeled), some of which are expanded greatly in worm (Fer, Kin6, Kin16), others in human (Eph, Src). As for other kinase groups, there are no significant expansions in fly. Of 30 tyrosine kinase families, 14 are present in all three genomes. Vertebrate-specific families include Tie, Axl and Lmr; coelomate-specific families (fly+human) are Jak, Syk, Tek, CCK4, MuSK, Ret, Sev and PDGFR/VEGFR, while Met and Trk are present in worm and human but not fly.

Interestingly, the flowering plant *Arabidopsis thaliana*, with ~25,500 genes, is predicted to have 1085 protein kinase genes [12], which is a significantly higher percentage of total genes (4%) than in vertebrates. None of the plant protein kinases belong to the tyrosine kinase family, and the greater number of protein kinases is in part accounted for by large families, several of which are unique to plants, such as a leucine-rich repeat (LRR) receptor serine kinases, which act as receptors for fungal pathogens and other environmental agents, and the calcium-dependent protein kinases (CDPK) (<http://plantsp.sdsc.edu/>). In addition, a partial genomic duplication in *Arabidopsis* may also contribute to the large number of protein kinase genes [13]. However, the total number of protein kinase genes in rice appears to be similar. The ability to respond rapidly and appropriately to ones external environment is obviously particularly important in sessile organisms like plants, and this selection pressure could account for the development and expansion of these new families of protein kinase.

Coda

The elucidation of the kinomes of both unicellular and multicellular eukaryotes provides us with rich insights into the evolutionary history of protein kinases, and also defines

the precise number of protein kinases that can participate in phosphorylation reactions in a given eukaryotic cell type. On the other side of the coin, we have to remember that phosphorylation cannot regulate protein function unless there are protein phosphatases to remove the regulatory phosphate moieties. Genomics has also had a major impact on the world of protein phosphatases, and the number of protein phosphatases in the three major superfamilies (the ‘phosphatome’) has also burgeoned. In combination, the protein kinase and phosphatase genes account for nearly 2.5% of all genes in most eukaryotic species. The protein kinase catalogue also has profound implications for the understanding of the basis for human disease and for the development of small molecule drugs that target individual disease-causing protein kinases. Indeed, the first protein kinase inhibitors have recently been approved for the treatment of specific cancers. The existence of a thousand and one protein kinases may have seemed farfetched in 1987, but the human genome sequence has taught us that the enzymes that regulate protein phosphorylation are indeed myriad and exceedingly complex.

Modular Protein Interaction Domains in Cellular Communication

Tony Pawson and Piers Nash

*Samuel Lunenfeld Research Institute,
Mt. Sinai Hospital, Toronto, Ontario, Canada*

Introduction

Cellular regulation is largely accomplished by proteins acting in a coordinated fashion to transmit signals from outside and within the cell to produce a coherent output that guides the behavior of the cell. Intracellular signaling proteins are generally made up of modular domains that either have a catalytic function (such as kinase activity) or mediate the interactions of proteins with one another or with phospholipids, nucleic acids, or small molecules. These latter interaction domains typically fold in such a way that their N and C termini are juxtaposed in space, while their ligand binding site is located on the opposing surface; therefore, they are ideally configured for incorporation into a preexisting polypeptide while retaining their binding properties. Interaction domains play a critical role in the selective activation of signaling pathways through their ability to recruit target proteins to activated receptors and to regulate the ensuing assembly of signaling complexes. Such interaction domains can control not only the specificity of signal transduction but also the kinetics with which cells react to external and intrinsic stimuli, and they can thereby generate complex cellular behaviors. This chapter outlines these general themes; more detail is provided in a number of recent reviews [1–6].

Phosphotyrosine-Dependent Protein–Protein Interactions

The biological activities of protein kinases are, by definition, exerted through their ability to modify substrate proteins by phosphorylation, most commonly in eukaryotic cells on the hydroxyamino acids serine, threonine, and tyrosine. To understand how protein kinases regulate intracellular functions, it is critical to appreciate the mechanisms through which phosphorylation alters the biochemical properties of target proteins. One important consequence of phosphorylation is the creation of binding sites for modular interaction domains that recognize specific phosphorylated motifs. Such phospho-dependent protein–protein interactions induce the formation of heteromeric complexes that localize signaling proteins to their sites of action within the cell, juxtapose polypeptides that act within the same pathways, and induce conformational changes that regulate enzymatic activity. In addition, by binding a phosphorylated site within the same polypeptide chain, an interaction domain can mediate an intramolecular interaction, resulting in allosteric regulation.

The principal mechanism by which protein-tyrosine kinases engage downstream targets is through the ability of Src homology 2 (SH2) domains of cytoplasmic proteins to recognize specific phosphotyrosine-containing motifs on

activated receptors. SH2 domains (containing ≈ 100 amino acids) have a conserved phosphotyrosine-binding pocket with an invariant arginine that anchors the phosphorylated tyrosine residue through a buried ionic bond (7–11). Recognition of the phosphotyrosine residue provides about half of the binding energy in the interaction of an SH2 domain with a phosphorylated motif; for this reason, SH2 domains generally bind phosphorylated sites with about 1000-fold higher affinity than their nonphosphorylated counterparts [12,13]. Because the dissociation constants of SH2 domains associated with optimal phosphorylated sites is commonly in the 0.5- to 1- μM range, this means that phosphorylation effectively serves as a switch for the recruitment of SH2-containing proteins to activated receptors [14]. SH2 domains also recognize at least three residues C-terminal to the phosphotyrosine in a fashion that differs from one SH2 domain to another, and this discrimination provides an element of specificity in tyrosine kinase signaling [15–17]. For example, the SH2 domain of the Grb2 adaptor protein binds preferentially to pTyr–X–Asn motifs, whereas the SH2 domains of phosphatidylinositol 3'-kinase (PI3K) recognize pTyr–X–X–Met sequences. Activated receptor tyrosine kinases become autophosphorylated on sites that bind SH2-containing proteins (see Chapter 68), and the sequence contexts of these phosphorylation sites influence which SH2 proteins bind the receptor and which cytoplasmic signaling pathways are stimulated in the cell [18].

Both the affinity and specificity of SH2 domain interactions can be increased by the presence of two tandem SH2 domains in a single protein that recognize a bisphosphorylated ligand, as in the case of the ZAP-70 cytoplasmic tyrosine kinase binding to the signaling subunits of the T-cell antigen receptor [19]. SH2 domains are also often linked to other interaction modules, such as SH3 domains that typically bind Pro–X–X–Pro motifs [20,21], as in the case of the c-Src cytoplasmic tyrosine kinase. In the inactive state, when c-Src is phosphorylated on a C-terminal tyrosine residue, its SH2 and SH3 domains both make intramolecular interactions that repress kinase activity. However, upon dephosphorylation of the tail, both the SH2 and SH3 domains are liberated to bind other proteins, such as substrates for phosphorylation, through the recognition of both phosphotyrosine and proline-based motifs [22–25] (see Chapter 75).

Although most receptor tyrosine kinase targets have SH2 domains, these proteins otherwise have a diverse set of biochemical and biological functions. These include the regulation of small Ras-like GTPases, control of phosphoinositide metabolism, tyrosine phosphorylation and dephosphorylation, transcriptional regulation (STAT proteins), organization of the cytoskeleton, and protein ubiquitination (SOCS box proteins and RING domain proteins such as c-Cbl) (Fig. 1A). SH2-containing proteins, therefore, couple tyrosine kinases to a broad range of regulatory biochemical pathways within the cell. In addition, SH2 domains are often found in adaptor proteins that are composed exclusively of SH2 domains and other interaction modules, such

as SH3 domains; these adaptors act as a bridge to physically link phosphotyrosine signaling to multiple targets [26].

In addition to SH2 domains, a quite distinct interaction module, the phosphotyrosine binding (PTB) domain, can bind proteins in a phosphotyrosine-dependent fashion [27]. The PTB domains of proteins such as Shc, IRS-1, and FRS2 recognize Asn–Pro–X–pTyr motifs in activated receptor tyrosine kinases, including the epidermal growth factor receptor, the insulin receptor, or the Trk nerve growth factor receptor [28–30]. Upon binding activated receptors, PTB proteins themselves become phosphorylated on multiple SH2 binding sites and recruit distinct sets of SH2-containing proteins. In this sense, they function as docking proteins to amplify and expand the range of receptor signaling.

It is evident from these observations that tyrosine kinase signaling requires a complex series of modular, phospho-dependent protein–protein interactions. Interestingly, SH2 domains are a recent evolutionary adaptation that arose only with the advent of multicellular organisms. Both tyrosine kinases and SH2 domains are absent from yeast but make a concomitant appearance in multicellular animals. The emergence of tyrosine kinases together with SH2 domains to mediate the effect of tyrosine phosphorylation represents an evolutionary step that likely facilitated intercellular signaling required for the formation of metazoan animals. The human genome encodes some 114 distinct SH2 domains, in 104 proteins; 49 PTB domains are found in 46 human proteins, although only a subset of these have phosphotyrosine-binding activity. Knowing the complete set of tyrosine kinases (see Chapter 65) and proteins with phosphotyrosine recognition domains, it should be feasible to establish the complete wiring circuitry of phosphotyrosine signaling.

Interaction Domains: A Common Theme in Signaling

Interaction domains are essential in signaling from many different types of cell-surface receptors, as well as in cellular events such as the cell cycle, protein and vesicle trafficking, targeted protein degradation, DNA repair, and control of the cytoskeleton. Thus, the SH2 domain serves as a prototype for a growing family of protein-interaction modules (Table 1), some of which specifically recognize posttranslationally modified motifs, in a fashion akin to the selective binding of SH2 and PTB domains to phosphotyrosine-containing sequences [1,31]. A number of domains can bind phosphothreonine/phosphoserine-containing motifs (i.e., 14-3-3, FHA, MH2, WD40, WW) and thereby mediate the effects of protein-serine/threonine kinases [32]. For example, in a series of interactions analogous to receptor tyrosine kinase signaling, the activated type I TGF β receptor serine/threonine kinase becomes autophosphorylated within its juxtamembrane region, thereby creating binding sites for the MH2 domain of a regulatory (R-) SMAD protein, which recognizes pSer–X–pSer motifs [33,34]. Subsequent phosphorylation of the R-SMAD itself leads to binding to the MH2 domain of SMAD4 and translocation of the R-SMAD/SMAD-4 complex

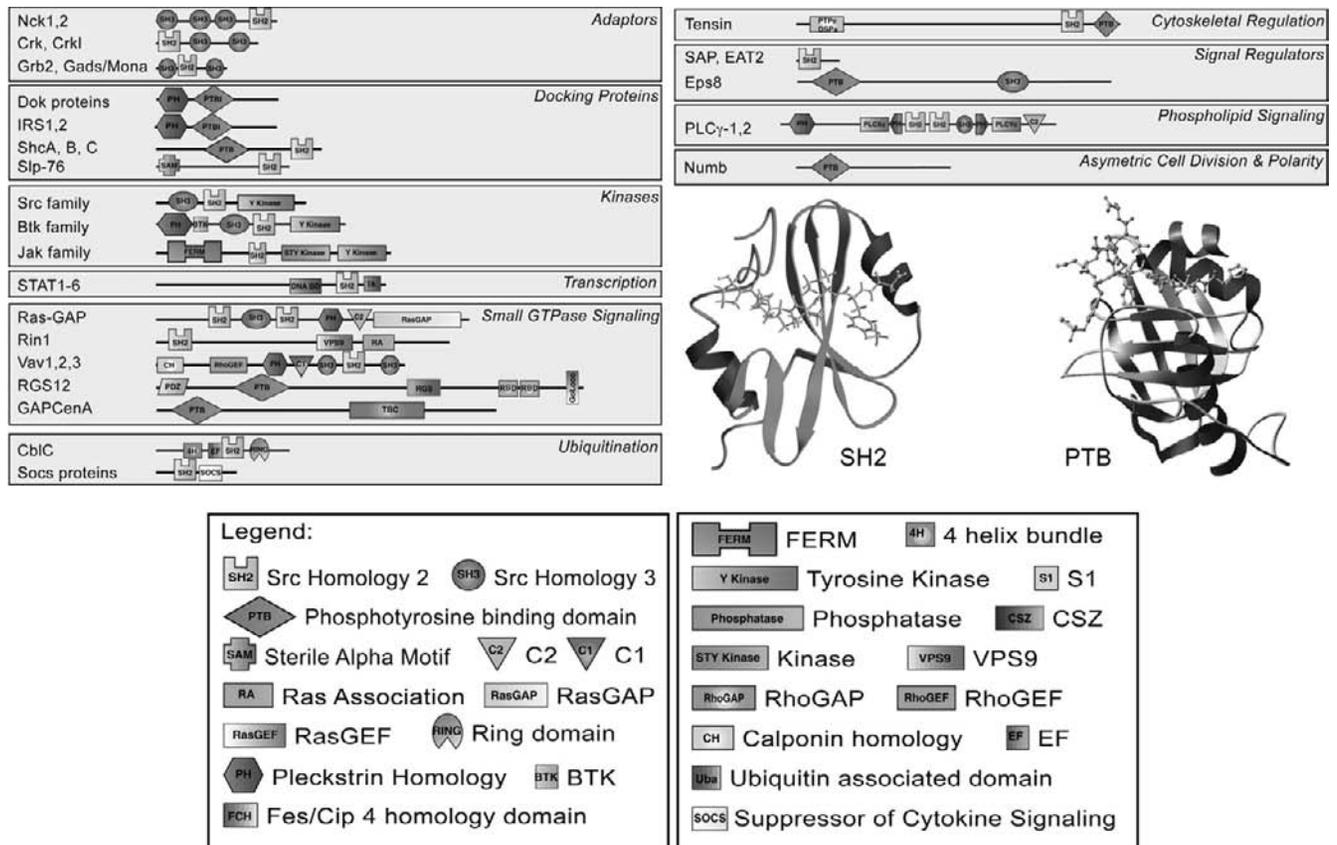

Figure 1 The modular nature of proteins containing SH2 or PTB/PID domains; a comparison of the modular protein domains and positional organization of a representative sample of the approximately 162 proteins that contain phosphotyrosine interaction modules and thus represent the key link between activated tyrosine kinases and cellular signaling cascades. The selected proteins demonstrate the variety of cellular functions and pathways in which the proteins containing these interaction modules are implicated. (Additional information on individual domains can be found at <http://www.mshri.on.ca/pawson/research1.html> and <http://smart.embl-heidelberg.de/>.) Ribbon diagrams show the SH2-C domain of phospholipase-C γ bound to a specific phosphotyrosine-containing peptide (DNDpYPLPDPK) and the PTB domain of Shc bound to an HIIENPQpYFS peptide.

to the nucleus, where it acts to regulate gene expression (see Chapter 81) [35]. In contrast, bromo- and chromo-domains bind lysine-based motifs (notably in histones) in a fashion dependent on acetylation or methylation, respectively, of the lysine residue and thereby play an important role in chromatin organization and transcriptional control. Ubiquitin interaction motifs (UIM), a common feature of endocytic proteins, bind mono- or polyubiquitinated sites and appear to regulate protein trafficking to endosomes [36]. Other protein-interaction domains recognize unmodified peptide motifs, such as proline-rich sequences (SH3, WW, and EVH1 domains) [37] or the extreme C-terminal residues of target proteins (PDZ domains) [38].

A separate class of interaction domains (i.e., PH, FYVE, PX, ENTH, FERM, Tubby) recognizes specific phospholipids, particularly phosphoinositides, and therefore directs proteins to regions in the plasma membrane enriched for the appropriate phospholipid [39,40]. These phospholipid-binding domains mediate the effects of lipid kinases and phosphatases and function in synchrony with protein-interaction domains. For example, autophosphorylated receptor tyrosine kinases bind the p85 SH2-containing subunit of PI3K, thereby stimulating PI3K to produce PI-3,4,5-P₃.

This phospholipid engages the PH domains of intracellular targets such as the serine/threonine protein kinases PKB/Akt and phosphoinositide-dependent protein kinase (PDK1), which consequently are recruited to the membrane, resulting in PKB activation. PKB, in turn, phosphorylates targets that include the pro-apoptotic protein BAD and the transcription factor FKHRL at Ser residues, which subsequently bind 14-3-3 proteins [32]. 14-3-3 binding represses the ability of the phosphorylated proteins to induce apoptosis by sequestering them in the cytoplasm away from their sites of action. Thus, a signaling pathway can be constructed from a series of protein and lipid kinases and a succession of phospho-dependent protein–protein and protein–phospholipid interactions.

Adaptors, Pathways, and Networks

As noted above, SH3 domains can be linked to SH2 domains to create adaptor proteins that connect a tyrosine kinase upstream signal to pathways that are engaged by the SH3 domains. The Grb2 family of adaptor proteins, for example, links tyrosine kinase signals to Ras and mitogen-activated protein (MAP) kinase pathways. Grb2 contains an

Table I Functions of Selected Protein Interaction Modules

Interaction module or domain	Example	Binding functions
<i>Phospho-recognition</i>		
SH2	Grb2 & Gads adaptors, Src family kinases, phospholipase C- γ	Phosphotyrosine
PTB	Shc, IRS-1, FRS2	Phosphotyrosine
FHA	Rad53	Phosphothreonine/ phosphoserine
14-3-3	14-3-3 proteins	"
WD40	Cdc4, β -TRCP (F-box proteins)	"
WW	Pin1	"
<i>Proline recognition</i>		
SH3	Src, Crk	Pro-X-X-Pro
WW	YAP, Nedd4	Pro-Pro-X-Tyr
EVH1	Mena, homer	Pro-rich
Gyf	CD2	PPPPGHR motif
<i>Phospholipid recognition</i>		
PH	PKB, mSos, phospholipase C- γ	PI(3,4)P ₂ , PI(4,5)P ₂ , PI(3,4,5)P ₃
FYVE	SARA, Hrs, EEA1	PI(3)P
PX	p40phox, p47phox	PI(3)P
FERM	ERM, Radixin	PI(4,5)P ₂
Tubby	TULP1, tubby	PI(4,5)P ₂
<i>Methylated or acetylated residue recognition</i>		
Bromo	P/CAF	Acetylated lysine
Chromo	HP1	Methylated lysine
<i>Other motif recognition</i>		
SH3	Gads & Grb2 C-terminal SH3	Arg-X-X-Lys
PDZ	PSD-95	C-terminal motifs
PDZ	Neural nitric oxide synthase (nNos)	PDZ
SAM	—	SAM

SH2 domain flanked on either side by an SH3 domain. The SH2 domain of Grb2 binds preferentially to pTyr-X-Asn motifs on activated receptors or cytoplasmic docking or scaffolding proteins, while the N-terminal SH3 domain associates with a Pro-X-X-Pro motif on Sos, a Ras GDP-GTP exchange factor (GEF) (Fig. 1B) [41,42]. Genetic data from invertebrates and mammals has shown that this pathway is critical for RTKs to activate the Ras-MAP kinase pathway *in vivo*, leading to cell growth and differentiation [43–45]. The C-terminal SH3 domain of Grb2, however, has a different function, binding to the Gab1/2 docking proteins through an Arg-X-X-Lys motif [46–48]. Thus, Grb2 recruits Gab1/2 to activated RTKs such as the epidermal

growth factor (EGF) receptor. The ensuing phosphorylation of Gab1 creates binding sites for additional SH2 proteins, particularly the p85 subunit of PI3K, resulting in the localized production of PI-3,4,5-P₃ and activation of survival pathways through the PH-containing serine/threonine kinases PKB and PDK1. Grb2 therefore coordinates the activation of two distinct signaling pathways (and in fact is implicated in several more). This suggests that intracellular signaling likely operates as a network, rather than as a simple linear scheme. A signaling network can therefore be established from the reiterated use of rather simple interaction modules.

Evolution of a Phospho-Dependent Docking Protein

As animals have become more complex, modular signaling proteins appear to have evolved through the acquisition of additional modules or binding sites. For example, Shc is a docking protein with a C-terminal SH2 domain and an N-terminal PTB domain flanking a central region containing a proline-rich section and an adaptin binding motif. The distinct binding properties of SH2 and PTB domains allow Shc to interact with multiple phosphotyrosine-containing motifs on cell-surface receptors. The prototypic Shc from *Caenorhabditis elegans* contains this basic organization but is simpler than its *Drosophila* or human counterparts [49]. *Drosophila melanogaster* Shc has an additional tyrosine-based motif in its central region, not present in the *C. elegans* protein, that can be phosphorylated and potentially act as an SH2-binding sequence [50]. In mammals, the situation has become significantly more complex. Mice and humans contain three distinct Shc genes (ShcA, ShcB, and ShcC), the latter two of which are largely restricted to the nervous system (Fig. 2A). Furthermore, mammalian Shc proteins have acquired yet an additional tyrosine phosphorylation site and thus have two motifs that upon phosphorylation bind Grb2 and potentially other SH2-containing proteins [51]. Finally, mammalian ShcA is expressed as three isoforms through alternative splicing; the largest form of these isoforms (ShcA^{p66}) contains an additional proline-rich N-terminal extension implicated as a factor in cellular response to oxidative stress and in longevity [52]. These data suggest that Shc proteins have multiple functions in signaling that have evolved through the acquisition of new phosphorylation sites and interaction motifs. The tyrosine phosphorylation sites of mammalian Shc allow this protein family to function as docking subunits of activated RTKs to enhance the range of receptor signaling (Fig. 1B). Shc most probably has additional functions as yet to be uncovered.

Multisite Phosphorylation, Ubiquitination, and Switch-Like Responses

An important issue in the design of cell signaling networks is how protein-protein interactions can be used to integrate signals and create all-or-none responses. A typical

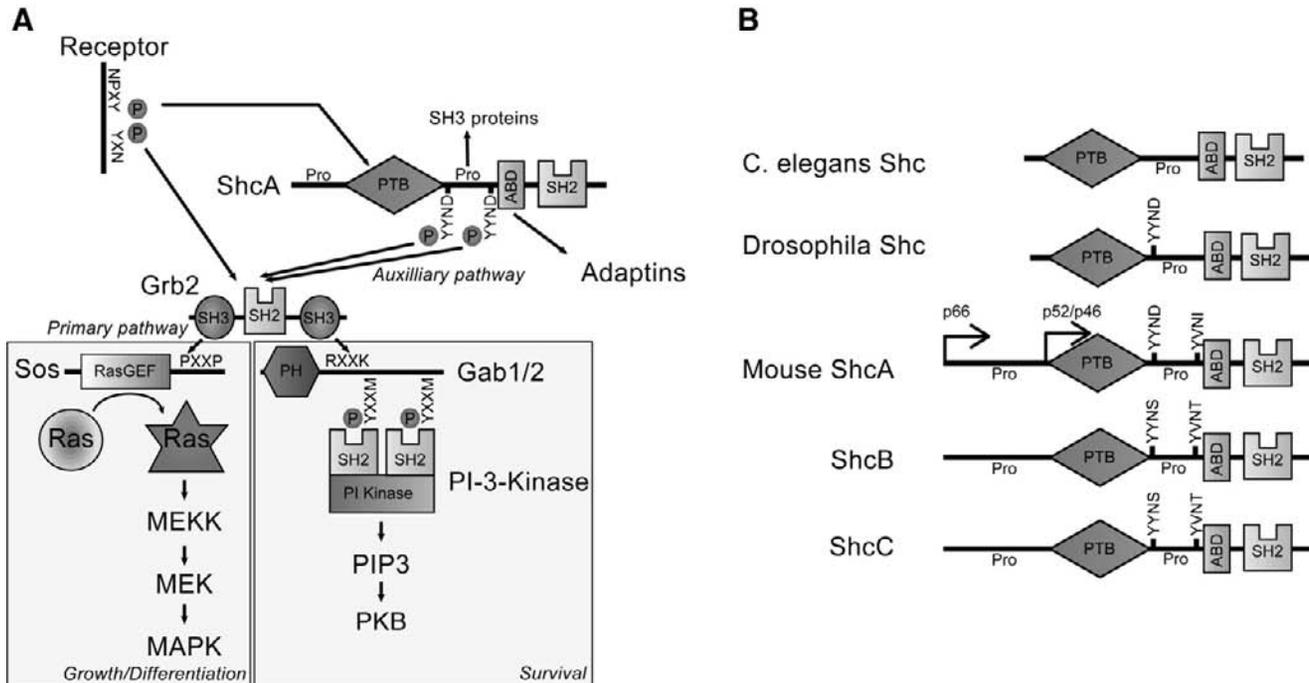

Figure 2 (A) The Grb2 SH3–SH2–SH3 adaptor couples a pTyr–X–Asn docking site to multiple downstream targets through a series of protein–protein and protein–phospholipid interactions. One core pathway to cell growth is assembled through the N-terminal SH3 domain of Grb2 interacting with Pro–X–X–Pro motifs on the Ras–GTPase-activating protein Sos leading to MAP kinase activation. A second core pathway to cell survival is linked through the C-terminal SH3 domain of Grb2 binding to an Arg–X–X–Lys motif within the scaffolding protein Gab1. Ancillary control over this pathway is generated by the ShcA docking protein. ShcA acts, in part, to extend or amplify the functional potential of a receptor to recruit binding partners that convey signals. (B) The Shc docking protein serves as a prototypic example of evolved complexity in signal transduction within a conserved modular architecture. Shc evolution extends the binding capacity of the protein from a primordial form containing an SH2 and PTB domain flanking a central region containing an adaptin-binding and proline-rich section. Shc has gained in complexity, concomitantly with evolution from simple to complex multicellular organisms, by gaining increasing numbers of tyrosine residues that act as binding sites for SH2 domains of other proteins such as Grb2. In mammals, Shc has expanded to a three-gene family with additional forms created by alternate splicing of the ShcA mRNA. ShcB and ShcC are predominantly localized in the brain of mammals, perhaps reflecting the requirement for additional complexity in the signal transduction cascades in this tissue.

enzymatic event, such as a kinase phosphorylating its substrate, or a simple binding event, such as an SH2 domain binding to a phosphorylated tyrosine site, conforms to Michaelis–Menton kinetics and therefore produces graded responses. In other words, the response to a given stimulus is initially linear and then tapers off in a hyperbolic manner (see Box 1). This contrasts with digital switches in which a certain amount of stimulus converts the system from zero to a complete response. Some signaling pathways have steps at which noise is filtered out, signals are integrated, and all-or none decisions are made [53]. This is particularly important in key decisions such as progression through the cell cycle, when the cell must exercise precise control to avoid catastrophic events such as initiating DNA replication prematurely. One mechanism by which a signaling cascade can create a switch-like response (referred to as an *ultrasensitive biological switch*), is through the requirement for multiple, independent phosphorylation events in order to sanction a requisite protein–protein interaction. Under these conditions, the response varies as a higher order of the kinase concentration, such that three independent phosphorylation events create a stimulus–response that responds to the third order of kinase concentration (modeled with a Hill coefficient of three). This has been observed biologically in a number of situations. In the maturation

response of *Xenopus* oocytes, two independent phosphorylation events within the MAP kinase pathway set up conditions for an all-or-none activation of the ERK MAP kinase [54]. In a related example, degradation of the yeast cyclin-dependent kinase (CDK) inhibitor Sic1, a key event required for the G1 to S transition (or START in the cell cycle), requires six of nine serine/threonine phosphorylation sites on Sic1 to be phosphorylated by the CDK activity present in the G1 phase of the cell cycle in order for Sic1 to be targeted for ubiquitination and degradation. Phosphorylated Sic1 is bound by the WD40 repeat domain of an F-box protein, Cdc4, that serves as the substrate binding subunit of an E3 protein-ubiquitin ligase complex. Thus, Sic1 acts to monitor G1 CDK activity, setting a threshold for kinase activity that must be met in order for START to occur [55]. In this case, multisite phosphorylation, coupled with a simple binary interaction, creates an ultrasensitive response that ensures the orderly and timely transition into the S phase of the cell cycle [56,57]. In both *Xenopus* maturation factor response and yeast cell-cycle progression, additional factors may conspire to create extremely sharp switch-like responses.

A corollary to these observations is that phosphorylation of proteins on serine/threonine residues induces protein ubiquitination and destruction. The phosphorylated target is

Box 1: Modeling Ultrasensitivity with Stimulus–Response Curves

The shape of a given systems stimulus–response curve is a key aspect of the steady-state behavior of a signaling system. Typical Michaelis–Menten enzymes exhibit hyperbolic stimulus response curves (Fig. 3, $n^H=1$). At very low stimulus levels, the response grows linearly with the stimulus. As the extent of the stimulus increases, the response to each quanta of stimulus becomes progressively smaller. In other words, a Michaelian (also referred to as graded or hyperbolic) system obeys the law of diminishing returns. A system that obeys Michaelian sensitivity requires an 81-fold increase in input stimulus to drive it from 10% to 90% maximal activation. By contrast, some systems can achieve sigmoidal stimulus–response curves, and this can be well approximated by the Hill equation:

$$y = x^{n^H} / (EC_{50} + x^{n^H})$$

where n^H is the Hill coefficient. In such a system, the first increments of stimulus produce little response, but once the system does begin to respond, it reaches its maximal response rapidly. The higher the Hill coefficient, the more switch-like the response becomes. This is represented graphically in Fig. 3 for Hill coefficients (n^H) of 1, 6, and 40.

Biologically, this has several significant outcomes. By incorporating an ultrasensitive biological switch into a signal transduction pathway, a cell can filter out noise in a system as small amounts of stimuli will fail to yield any consequential response. Such a switch could also be used to allow precise control over key decisions in which an exact degree of stimuli rapidly creates a complete response. It also sets a threshold for the signal, allowing the system to effectively collect inputs and precisely monitor when these exceed the threshold level set to convert the system to a complete response. In this last case, the signals are integrated at the level of the switch.

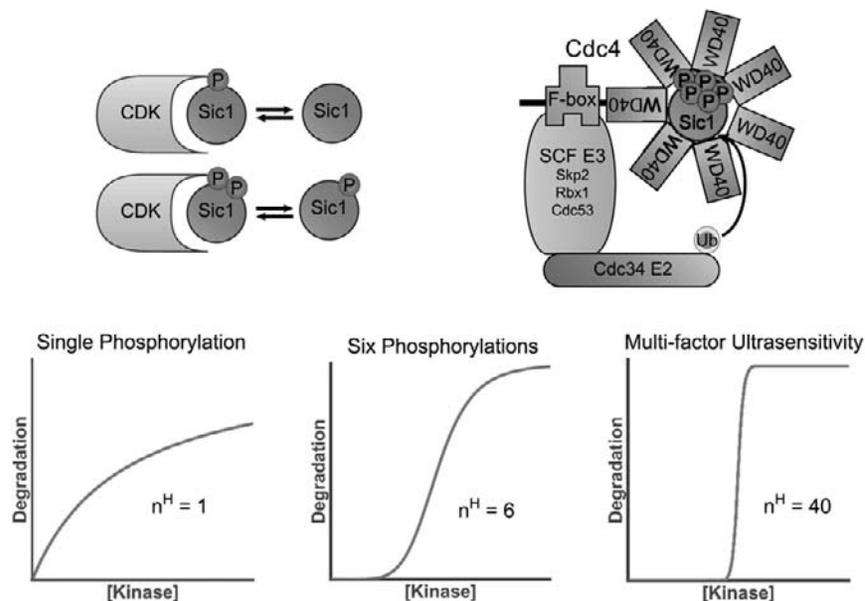

Figure 3 Multiple, independent phosphorylation events of Sic1 by a cyclin-dependent kinase (CDK) create the basis for an ultrasensitive biological switch for the onset of DNA replication in yeast. Phosphorylation of the CDK inhibitor Sic1 by the Cln1/2-Cdc28 kinase on at least six independent sites is required for the productive interaction of Sic1 with the WD40 repeat region of the Cdc4 F-box protein. Binding of Sic1 to Cdc4 allows the ubiquitination of Sic1 by the SCF E3 ubiquitin protein ligase complex and subsequent degradation of Sic1. The requirement for multisite phosphorylation results in a sigmoidal stimulus-response curve with a Hill coefficient (n^H) of six, forming the basis for an ultrasensitive biological switch. Additional factors in the biological milieu of the cell likely conspire to significantly improve the degree of ultrasensitivity, as indicated by the curve shown with a Hill coefficient of 40. By contrast, a single phosphorylation event, or simple protein–protein interaction is inherently Michaelian in nature with $n^H=1$.

recognized by the phospho-dependent interaction domain of an E3 protein-ubiquitin ligase and is thereby recruited into a ubiquitination complex [58].

Summary

Protein phosphorylation frequently induces specific protein-protein interactions mediated by specific phosphotyrosine- or phosphoserine/threonine-binding domains. These phospho-dependent interaction domains are important for the specificity of signal transduction downstream of cell-surface receptors and serve as the prototype for a large family of binding modules that control many aspects of cellular organization.

Introduction

Eukaryotic protein kinases that phosphorylate serine/threonine or tyrosine residues constitute a large family of enzymes that are critical components of cell signaling and regulatory pathways [1]. The nature of the amino acid that is phosphorylated defines the two major classes of protein kinases in eukaryotic cells: serine/threonine (Ser/Thr) kinases and tyrosine (Tyr) kinases [2]. Despite the differences in their substrate specificities, Ser/Thr and tyrosine kinases are very closely related in terms of the structure of their catalytic domains. Ser/Thr kinases are found in all eukaryotes and function in a broad range of signaling pathways, including those that control transcription or the regulation of metabolic pathways. Tyrosine kinases are a later evolutionary offshoot of the family and are predominantly found in multicellular animals, where they play important roles in intercellular signaling.

The human genome is estimated to encode several hundred distinct protein kinases [3,4] that function as molecular switches, in which the signaling state of the switch is related to the level of enzymatic activity of the kinase domain. The activity of protein kinases can be regulated by other signaling molecules using a number of different mechanisms [5]. The most common regulatory mechanisms include protein localization, ligand-coupled allosteric activation or inhibition, and reversible conformational changes at the catalytic site of the kinases that are controlled by phosphorylation or dephosphorylation. The improper activation of protein

kinases can be highly disruptive to the cell, and as a consequence protein kinases are emerging as an extremely important set of targets for drug development [6,7].

Structures of Protein Kinases

The first crystal structure of a protein kinase to be determined was that of the catalytic domain of cyclic-AMP-dependent kinase, also known as protein kinase A (PKA) [8,9]. PKA is a ubiquitously expressed Ser/Thr kinase involved in several different signaling pathways. The overall fold of the catalytic domain, first seen for PKA, is highly conserved among all Ser/Thr and tyrosine protein kinases. Additional sequences and domains that are located both C-terminal and N-terminal to this structurally conserved catalytic domain account for most of the functional diversity among different protein kinases.

The structure of the catalytic domain of PKA, co-crystallized with adenosine triphosphate (ATP)-Mg and an inhibitor peptide molecule, is shown in Fig. 1 [8,9]. The protein kinase domain is composed of two lobes with an overall length of roughly 275 residues. The N-terminal lobe, alternatively referred to as the N lobe or the small lobe, contains an anti-parallel β -sheet and one important α -helix (helix C), while the C-terminal lobe (or large lobe) is primarily α -helical in composition.

This structure is an example of a protein kinase that is in a catalytically competent conformation and serves as a

model for the structure of active protein kinases. The two substrates of the phosphorylation reaction, ATP and the polypeptide phosphate acceptor, both bind in a cleft formed between the N lobe and the C lobe. The highly charged chemical groups of the ATP and two associated Mg^{2+} ions are coordinated by a collection of highly conserved Lys, Asn, Asp, and Phe residues (Fig. 2). A recent crystal structure of PKA with a transition state analog supports an in-line mechanism of phosphate transfer from ATP to a target Ser-containing substrate [10]. This mechanism is believed to be conserved among protein kinases, consistent with the highly conserved kinase fold.

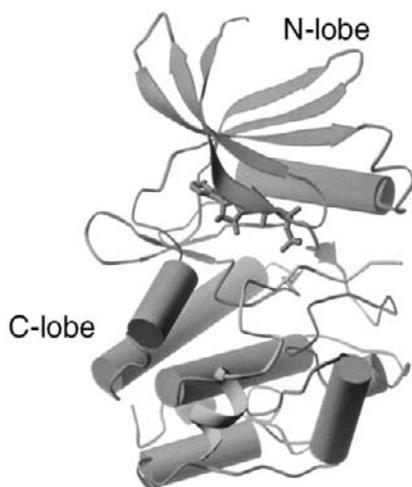

Figure 1 Structure of the Ser/Thr kinase PKA complexed with ATP- Mg^{2+} and a specific inhibitor peptide (PDB code 1ATP) [8,9]. ATP is gray, the peptide inhibitor PKI is yellow, α -helix C is pink, and the activation loop is red.

The structure of the catalytic domain of Lck [11] provides an example of the catalytically active conformation of a tyrosine kinase enzyme. Despite the absence of both nucleotide and substrate, the conformations of key catalytic residues are primed for catalysis, in line with the conformations of homologous residues seen in the structure of PKA. The active form of the kinase domain of Lck is phosphorylated on Tyr 394, which lies in the activation loop of the kinase domain, a segment of roughly 15 to 20 residues located between the N and C lobes of the kinase domain. Phosphorylation on one or more residues in the activation loop is a signature of the activated state of many protein kinases. In active Lck, phosphorylated Tyr 394 forms a salt bridge with Arg 387, thereby stabilizing the conformation of the activation loop and locking the enzyme in a catalytically active state.

Structures of Inactive Protein Kinases

The modulation of catalytic activity in protein kinases is achieved by a diverse range of mechanisms. The structures of the active states of kinases that are constrained to be similar by the chemical requirements for catalysis of phosphate transfer. In contrast, the structures of inactive states of protein kinases show considerable diversity [5]. In this review, we present examples of the inactivation mechanisms of two different tyrosine kinases for which structure determinations have been carried out in both the active and inactive states of the enzymes. The first is the insulin receptor kinase (Irk), and the second is the Src family of tyrosine kinases.

The structures of the kinase domains and the extracellular ligand binding domains of several receptor protein

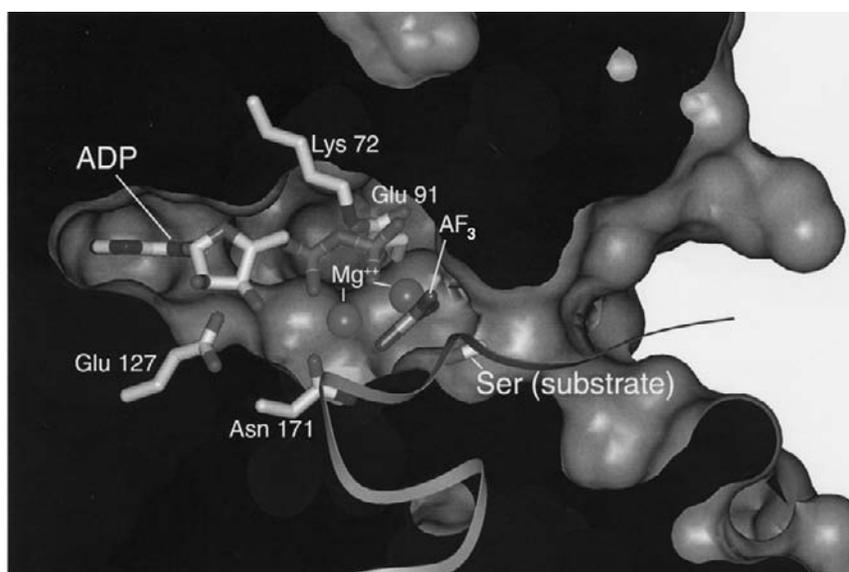

Figure 2 Active site of a crystal structure of PKA trapped in a transition state intermediate conformation bound to ADP- AlF_3 and substrate peptide (PDB code 1L3R) [10]. Charged sidechains that make key interactions with the ATP and Mg^{2+} ions are shown: Lys 72, Glu 91, Glu 127, Asn 171, and Asp 184. The serine acceptor on the peptide substrate is also indicated.

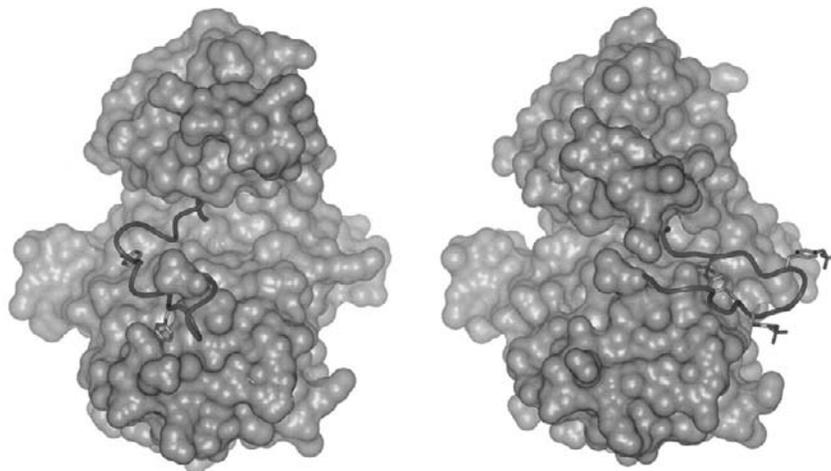

Figure 3 Structures of the catalytically inactive (left) and active (right) forms of the kinase domain of Irk (PDB codes 1IRK and 1IR3, respectively) [15,16]. The active state is stabilized by the phosphorylation of three tyrosine residues in the activation loop.

kinases have been solved in recent years (for reviews, see references [12] and [13]). Receptor tyrosine kinases contain a variety of extracellular ligand binding domains in the N-terminal extracellular region, followed by a short membrane-spanning region, and finally a catalytic tyrosine kinase domain in the C-terminal cytoplasmic portion of the proteins. Ligand-induced alterations in the oligomeric state of the receptor or in the conformation of oligomeric forms of the receptor can stimulate phosphorylation of the kinase domains, facilitating the propagation of a downstream cytoplasmic signal [14].

Structures of catalytically active and inactive states of the catalytic domain of insulin receptor kinase are shown in Fig. 3 [15,16]. Activation of this receptor involves the phosphorylation of three tyrosine residues located in the activation loop. The effect of this chemical modification is to induce a major conformational change in the structure of the loop. In the inactive state, the activation loop is found in a relatively compact buried conformation that sterically blocks access to the protein active site and further attenuates catalytic activity by causing conformational changes within the catalytic center. The addition of three negatively charged phosphate groups to the tyrosine residues in the loop destabilizes the buried conformation of the activation loop and favors a more solvent exposed conformation that opens up the enzyme active site for the entry of a peptide substrate.

The Src family kinases comprise a closely related family of nine distinct nonreceptor tyrosine kinases that function downstream of membrane-associated proteins in intercellular signaling pathways. Src kinases possess two peptide binding domains, the SH2 and SH3 domains, that are located upstream of the catalytic domain. In addition to having a single Tyr phosphorylation site (Tyr 416 in chicken c-Src numbering) in the activation segment that serves to activate the kinase when phosphorylated, Src family kinases also possess an important regulatory segment that is located immediately after the kinase domain (Fig. 4) [17].

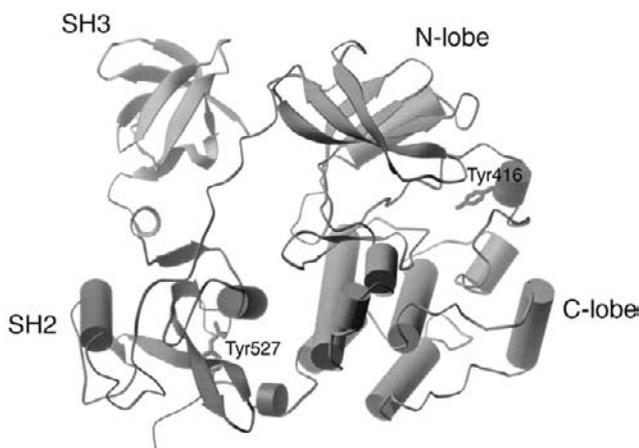

Figure 4 Crystal structure of inactive Hck (PDB code 1QCF) [18]. The two peptide binding domains (SH3 and SH2) bind intramolecularly to form an assembled inactive conformation. Tyr 416 in the activation loop (red) is dephosphorylated. Tyr 527 in the C-terminal tail of the protein (red) is phosphorylated and bound to the SH2 domain (green).

The crystal structures of inactive Src kinases have been determined [18,19]. The crystal structure of the catalytically inactive state of the Src family member Hck is shown in Fig. 4 [18] (the structure of inactive c-Src is very similar [19]). The downregulated state of Src-family kinases is characterized by phosphorylation on Tyr 527 in the C-terminal tail, with Tyr 416 in the activation loop unphosphorylated. A distinguishing structural feature of these kinases is that upon inactivation these proteins adopt a closed and assembled state in which the SH2 domain binds intramolecularly to phosphorylated Tyr 527. The assembled state also finds the SH3 domain, located immediately upstream of the SH2 domain, bound intramolecularly to a type II polyproline helix that is part of the connector between the SH2 domain and the kinase domain. Displacement of either of these two intramolecular interactions via external ligands will stimulate activation

of the kinase, demonstrating that these intermolecular docking domains function as protein localization handles as well as playing a role in the allosteric inactivation of the kinase.

Members of the Src family of Tyr kinases share roughly 75% sequence identity with each other in the SH3, SH2, and catalytic domains. The structure of the activated state of the Src family member Lck can thus be contrasted with the structures of the inactive state of Hck and c-Src to highlight specific conformational changes that occur in this family of kinases upon inactivation. The two most dramatic changes include the closing down of the activation segment to sterically block the peptide–substrate binding cleft, and the nearly 45° rotation of α -helix C to bring a catalytically important Glu residue (Glu 310 in chicken c-Src) out of alignment such that it can no longer interact with a conserved lysine residue that coordinates ATP. While the former mechanism is similar to the inactivation mechanism found in both Irk and PKA, the specific misalignment of α -helix C is tightly coupled to the unique assembled closed state that the three domains Src family kinases adopt upon inactivation and is an example of diversity found in the inactivation mechanism of distinct protein kinases.

Summary

In conclusion, the structures of Ser/Thr and tyrosine kinases are strikingly similar when these enzymes are released from inhibitory interactions. In contrast, the mechanisms by which kinases are inhibited are numerous, and these distinct regulatory mechanisms result in quite different conformations for the inactive states of kinases. The unexpected diversity in the structures of inactive kinases provides routes to the acquisition of specificity by small-molecule inhibitors of kinase function [20].

Protein Tyrosine Kinase Receptor Signaling Overview

Carl-Henrik Heldin

Ludwig Institute for Cancer Research, Uppsala, Sweden

Introduction

Protein tyrosine kinase (PTK) receptors constitute an important class of transmembrane receptors that transduce signals regulating cell growth, differentiation, survival, and migration. PTK receptors are also conserved in lower species, and much of our knowledge about their functional properties comes from studies of *Drosophila* and *Caenorhabditis elegans*. Several PTK receptor genes that have been inactivated in mice have revealed the important functional roles of individual PTK receptors in different organs at various stages of the development. Overactivity of PTK receptors has been implicated in a number of diseases, particularly cancer, and several of the PTK receptors were first identified as transforming oncogene products. This chapter reviews the general principles for PTK receptor structure, activation mechanism, and regulation.

PTK Subfamilies

In the human genome, 58 genes encode PTK receptors [2,36]. Each receptor consists of an extracellular ligand-binding part, a single transmembrane domain, and an intracellular part with an intrinsic kinase domain. Based on their overall structures, the PTK receptors can be placed into 20 subfamilies (Fig. 1). Individual subfamilies are characterized by specific structural motifs in their extracellular parts (e.g., Ig-like domains and fibronectin type III domains). Moreover, the sequences of the kinase domains are normally more similar within the subfamilies than between the subfamilies. The major families are briefly introduced below (for reviews, see Fantl *et al.* [8] and Schlessinger [29]).

The epidermal growth factor (EGF) receptor was the first PTK receptor to be identified. The four members of the family are important for the morphogenesis of epithelial tissues. Members of this family are often amplified or activated through mutations in human malignancies.

The three members of the insulin receptor family are disulfide-bonded dimers that undergo cleavage during processing to generate α - and β -subunits. In addition to the well-known metabolic effects mediated by the insulin receptor, this family mediates important survival signals.

The platelet-derived growth factor (PDGF) family members are characterized by 5 Ig-like domains in the extracellular domain and by the presence of an intervening sequence that splits the kinase into two parts. PDGF receptors are of particular importance for the development of the connective tissue compartments of various organs, as well as for the development of smooth muscle cells of blood vessels. The related receptors for stem cell factor and colony-stimulating factor 1 (CSF-1) are implicated, for example, in the development of hematopoietic cells, germ and neuronal cells, and macrophages.

The vascular endothelial cell growth factor (VEGF) receptor family members have seven Ig-like domains extracellularly and are primarily expressed on endothelial cells; thus, they are implicated in vasculogenesis, angiogenesis, and lymphangiogenesis.

The fibroblast growth factor (FGF) receptor family members are characterized by three Ig-like domains extracellularly, although splice variants with only two Ig-like domains have been described. Like the VEGF receptors, FGF receptors are expressed on endothelial cells and are implicated in angiogenesis; however, these receptors are also expressed in other cell types and have important roles in the embryonal development of several organs and tissues.

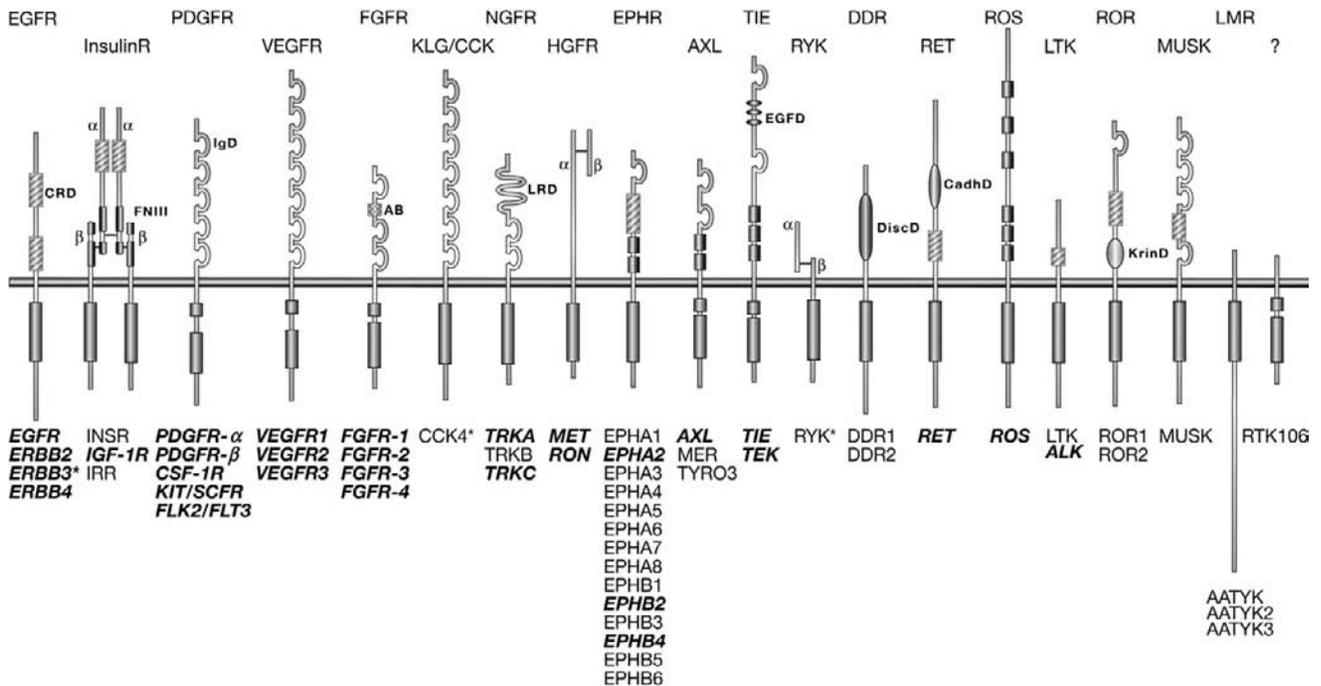

Figure 1 Organization of human PTK receptors in 20 subfamilies of structurally related receptors. The designations of the members in each family are given below each schematic figure. Receptors implicated in malignancies are written in italics and bold. An asterisk after the name indicates that the PTK receptor has an inactive kinase domain. (From Blume-Jensen, P. and Hunter, T., *Nature*, 411, 355–365, 2001. With permission.)

Members of the neurotrophin receptor family (TrkA, B, and C) bind members of the NGF family of neurotrophins and have important functions during the development and maintenance of the central nervous system.

The two members of the hepatocyte growth factor (HGF) receptor family (Met and Ros) undergo cleavage of their extracellular domains after their syntheses. They have important roles in regulation of cell motility and in organ morphogenesis during embryonal development.

The Eph receptor family, the largest of the PTK receptor subfamilies, has 14 members. Eph receptors are expressed in the nervous system and also in endothelial cells; thus, they are implicated in neuronal guidance and angiogenesis. Interestingly, one class of their ligands, ephrin-Bs, are also transmembrane molecules expressed on the surface of cells; binding of ephrin-Bs to Eph receptors leads not only to activation of the Eph PTK receptor but also to initiation of signaling events at the intracellular part of the ephrin molecules [31].

The remaining PTK subfamilies generally consist of single members and are generally less well characterized. Interestingly, one of these families, the DDR family, has collagens as ligands [33,38], thus exemplifying the observation that PTK receptors mediate signals not only from soluble or membrane-associated growth factors but also from the surrounding extracellular matrix.

Of note is that three examples of PTK receptor family members have mutations in their kinase domains, rendering them devoid of kinase activity (Fig. 1); however, they may still have important roles in signaling (see later discussion).

In general, each subfamily binds a family of structurally related ligands. The specificity is not always absolute within the subfamilies; several receptors bind more than one ligand and several ligands bind more than one receptor. In contrast, high-affinity interactions of individual ligands with more than one subfamily of PTK receptors, or of individual PTK receptors with more than one class of ligands, have not been observed.

Mechanism of Activation

Ligand-Induced Receptor Dimerization

Protein tyrosine kinase receptors are activated by ligand-induced dimerization in all cases that have been investigated [29]. This brings the receptor kinase domains close to each other, which results in autophosphorylation in *trans* within the intracellular parts of the receptors. The autophosphorylation occurs on tyrosine residues located within or outside the kinase domain of the receptor.

There are, however, many different modes whereby ligand binding induces receptor dimerization [13]. Some ligands are disulfide-bonded dimers, such as PDGFs and VEGFs; the binding of these ligands leads to formation of a symmetric complex consisting of two receptors and one dimeric ligand [39]. In contrast, ephrins are monomeric molecules; after binding of two ephrin molecules to Eph receptors, a dimeric receptor complex is formed in which each ephrin molecule contacts two receptors and each receptor contacts two ligands [15]. Ligand binding to the EGF receptor causes

a conformational change allowing direct receptor-receptor interaction which stabilizes dimerization [9a,24a]. There are also examples of accessory molecules helping to stabilize a dimeric complex; FGFs are monomeric molecules that interact with receptors at a 1:1 stoichiometry, and receptor dimerization is induced by binding of heparin or heparan sulfate to the complex of FGF and receptor [30]. Finally, members of the insulin receptor family are already disulfide-bonded dimers before ligand binding; binding of ligand presumably induces a conformational change that allows receptor autophosphorylation and activation.

Although receptor dimerization is likely to be necessary for activation of PTK receptors, it is not always sufficient. Evidence suggests that the orientation of the two intracellular domains in the receptors relative to each other is important [19]. Moreover, there are indications that the initial dimerization of EGF receptors may be followed by further oligomerization, which may be necessary to obtain a fully active receptor [4].

Homo- and Heterodimerization

In the classical case of ligand-induced dimerization of PTK receptors, two identical receptors form a homodimer; however, two related receptors from the same subfamily may also form a heterodimer. Examples from the PDGF [14] and EGF [41] receptor subfamilies show that heterodimeric receptors may have quantitatively or qualitatively different signaling capacities.

There are also examples of heteromeric complexes between individual PTK receptors and unrelated receptors. Examples include interactions between PTK receptors from one subfamily with PTK receptors from another subfamily (e.g., PDGF and EGF receptor have been shown to interact [27]). In addition, PTK receptors have been shown to bind to integrins, an interaction that has been shown to enhance integrin signaling [10]. In some cases, interactions with non-kinase receptors enhance the affinity for ligand binding (e.g., a long splice form of VEGF binds to its PTK receptors with higher affinity if the receptor neuropilin is also part of the complex [34]).

Activation of the Receptor Kinase

Ligand-induced PTK receptor dimerization leads to autophosphorylation of the receptors in *trans* within the complex. The autophosphorylation serves two important roles: (1) it causes activation of the kinase domain and (2) it creates docking sites for downstream SH2-domain-containing signaling molecules. Autophosphorylation may lead to activation of the kinase via several different mechanisms, of which more than one may apply for individual PTK receptors [2]. Tyrosine residues exist within the activation loops of kinases; after phosphorylation, these residues cause the loop to swing out and open up the active site of the kinase [17]. Because most PTK receptors are phosphorylated in this region, this is likely to be a common mechanism for activation of the

kinase domain. However, members of the EGF receptor family are not autophosphorylated in the activation loop. In these receptors, it is possible that the activation loops do not efficiently inhibit the kinase of the receptors. Instead, it has been proposed that the long C-terminal tails of these receptors block the active site of the kinase, an inhibition that may be relieved by autophosphorylation and a conformational change of the C-terminal tail, as has been shown for the PTK receptor Tek [32]. Finally, the recent elucidation of the three-dimensional structure of the Eph receptor revealed that in the inactive receptor the juxtamembrane domain forms a helical structure that distorts the small lobe of the kinase domain and prevents access to the active site of the receptor; after autophosphorylation in the juxtamembrane domain, this loop moves away and opens up the active site of the receptor [40].

Docking of SH2 Domain Signaling Proteins

The SH2 domain is a protein module that folds to form a pocket into which a phosphorylated tyrosine residue fits [25]. Genes encoding 87 SH2-domain-containing proteins with a total of 95 SH2 domains are present in the human genome [36]. They interact with phosphorylated tyrosine residues in a specific manner that is directed mainly by the three to six amino acid residues downstream of the phosphorylated tyrosine residue.

As an example, Fig. 2 illustrates the interaction between the autophosphorylated PDGF β -receptor and different SH2-domain-containing molecules. One class of SH2 domain proteins has intrinsic enzymatic activity (e.g., the tyrosine kinase Src, phospholipase C γ , the tyrosine phosphatase SHP-2, and the GTPase-activating protein (GAP) for Ras). The respective enzymatic activities are induced by binding of the SH2 domain to the receptor or by tyrosine phosphorylation induced by the receptor kinase; alternatively, the enzyme is constitutively active and, by binding to the receptor, may simply be brought to the inner leaflet of the cell membrane, where the next component in the signaling chain is located.

Other SH2 domain proteins are devoid of intrinsic enzymatic activity and serve as adaptors that connect the activated receptors with downstream signaling molecules. Adaptors often have additional domains that mediate interactions with other molecules, such as the SH3, PTB, and PH domains [25]. Examples of such adaptors include Nck, Crk, and Shc, as well as Grb2, which forms a complex with Sos, a nucleotide exchange molecule for Ras, and the regulatory subunit p85, which forms a complex with the catalytic subunit p110 of phosphatidylinositol 3'-kinase (PI3-kinase).

The interaction between the activated and autophosphorylated receptor and individual SH2-domain-containing molecules initiates signaling pathways that lead to growth stimulation, survival, migration, and actin reorganization. The signaling capacity of a receptor is thus dependent on which SH2 domain proteins it can dock. Differential autophosphorylation may also be the mechanism by which

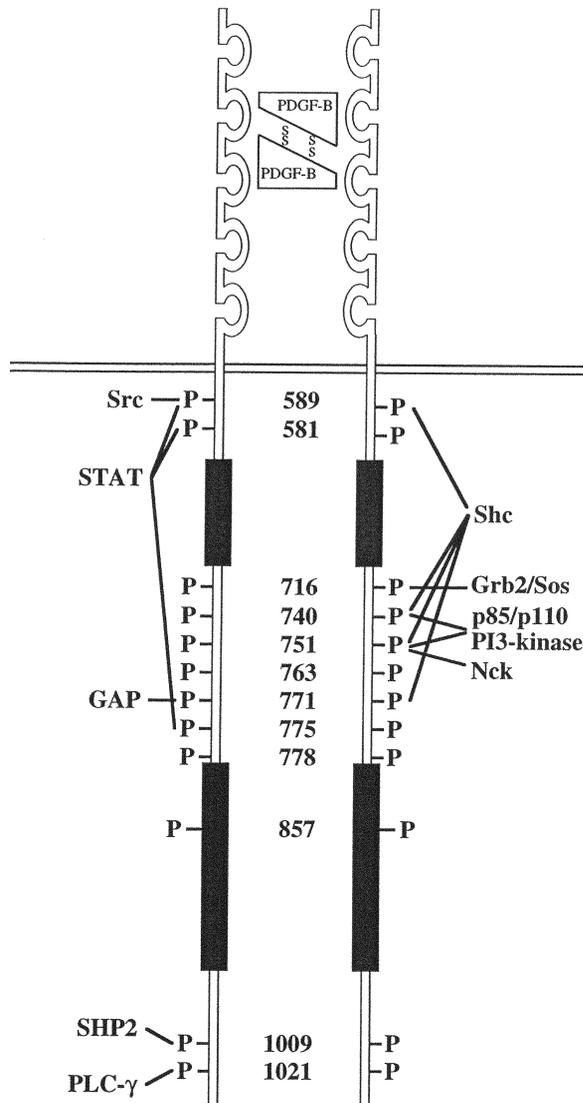

Figure 2 Schematic illustration of a complex between PDGF-BB and two PDGF β receptors. Known autophosphorylated tyrosine residues (P) and their numbers in the receptor sequence are indicated, as well as their interactions with SH2-domain-containing signaling molecules. Signaling molecules with intrinsic enzymatic or transcription factor activity are to the left, and adaptors to the right. Note that it is not known how many SH2 domain proteins can bind simultaneously to a dimeric receptor complex.

heterodimeric receptor complexes acquire unique signaling properties [14]. It should be noted that one member of the EGF receptor family, ErbB3, is devoid of kinase activity, yet in heterodimeric configuration with other members of the family it has a potent signaling capacity due to its ability to provide docking sites for SH2 domain proteins [41].

Inhibition of Phosphatases

The phosphorylation events performed by PTK receptors are counteracted by dephosphorylation by specific tyrosine phosphatases. Recent studies have shown that in order for efficient signaling via PTK receptors, tyrosine phosphatases must be inactivated [35,37]. This may be done by transient, specific oxidation of a cysteine residue in the active site of

phosphatases, induced after PTK receptor activation in a PI3-kinase-dependent manner [1].

Regulated Intramembrane Proteolysis

Although activation of cytoplasmic signaling pathways by docking of SH2 domain signaling proteins is a major mode of signaling via PTK receptors, an alternative mechanism was recently revealed. The EGF receptor family member ErbB4 was shown to undergo regulated proteolysis in two steps. First, the extracellular domain is cleaved off by a metalloprotease, then another protease, γ -secretase, cleaves within the transmembrane domain and liberates the intracellular domain of ErbB4 for translocation to the nucleus, where it potentially can regulate transcription directly [24]. A similar situation may prevail for the EGF receptor [23]. Although regulated intramembrane proteolysis is a well-established signaling mechanism for another receptor type (i.e., Notch), its general importance in PTK receptor signaling remains to be elucidated.

Control of PTK Receptor Activity

Receptor Internalization and Degradation

After ligand-induced receptor activation, PTK receptors are often accumulated in coated pits and thereafter internalized in endosomes [5], where they are deactivated by several different mechanisms. Upon acidification of the milieu inside the endosomes, the ligand may dissociate from the receptor, which then monomerizes, becoming dephosphorylated by tyrosine phosphatases and then being recycled back into the membrane. Alternatively, the ligand-receptor complex is degraded after fusion of the endosomes with lysosomes. Moreover, PTK receptors have been shown to become ubiquitinated after activation. The ubiquitination may be mediated by interaction of the activated receptor with the ubiquitin ligase Cbl and may trigger degradation also in proteasomes [20,22].

Control of PTK Receptor Signaling

There are several examples of mechanisms that control PTK receptor signaling. When pathways that stimulate certain cellular responses are initiated, signals that inhibit the same responses are often induced. Examples include Ras activation by the PDGF receptor; at the same time as Ras is activated (i.e., converted to its GTP-bound form by the actions of the Grb2/Sos complex), it is also inactivated (i.e., converted to the GDP-bound form by RasGAP). The net effect on Ras activation by the PDGF receptor is thus dependent on the stoichiometry in phosphorylation of the tyrosine residues that can bind Grb2/Sos and RasGAP; evidence suggests that this balance can differ, for example, between homo- and heterodimeric receptor complexes [6].

Other examples of such mechanisms are the tyrosine phosphatases SHP-1 and -2, each of which has two SH2 domains through which they can bind to several PTK receptors. The binding to tyrosine-phosphorylated residues activates the

enzymatic activities of SHP-1 and -2, which may then counteract signaling by dephosphorylating the receptor or its substrates. It is an interesting possibility that SHP-1 and -2, or other tyrosine phosphatases, may dephosphorylate individual tyrosine residues with different efficiency and thereby modulate signaling not only quantitatively but also qualitatively [42].

To complicate the issue even further, evidence indicates that SHP-2 and possibly RasGAP, in addition to their negative modulatory role in signaling, also influence signaling by serving as adaptor molecules providing a bridge between the PTK receptor and downstream signaling molecules.

Another mechanism for feedback control of signaling is via activation of protein kinase C (PKC). The classical members of the PKC family are activated by Ca^{2+} and diacylglycerol, which are produced downstream of phospholipase $\text{C}\gamma$. For instance, the receptors for EGF, insulin, HGF, and stem cell factor are phosphorylated by PKC in such a way that inhibits the tyrosine kinase activities of the receptors [3].

Cross-Talk Between Signaling Pathways

In addition to examples of negative modulation of one signaling pathway on another, as discussed for RasGAP and SHP-1 and -2, components in certain signaling pathways have been found to activate components in other signaling pathways. Examples include Ras and PI3-kinase, which can form a physical complex and activate each other mutually [16,26].

The cross-talk between signaling pathways downstream of PTK receptors may be the reason why the effects of activating one receptor or another in the same cell are rather similar, as illustrated, for example, by the use of microarray analysis of 3T3 cells after activation of PDGF or FGF receptors [7]. Even though there are several indications that the signaling capabilities of PTK receptors overlap extensively, it is likely that qualitative and quantitative differences in signaling capacity occur between PTK receptors, particularly in the situation (common *in vivo*) when the availability of ligand is limiting and only a small fraction of the receptors on the cell surface is activated.

In addition, cross-talk in signaling occurs via PTK receptors and other receptor types. Cytokine receptors, for example, which do not have any intrinsic kinase domain but interact with cytoplasmic tyrosine kinases of the JAK family, exert much of their signaling via activation of members of the STAT family [18]. However, STATs are also activated by certain PTK receptors [29]. Moreover, classical signaling pathways downstream of PTK receptors, such as Ras, PI3-kinase, and phospholipase $\text{C}\gamma$, are also activated after ligation of cytokine receptors [28] or integrins [10].

Protein serine/threonine kinase receptors, which mediate growth inhibitory signals, activate SMAD molecules, which after translocation into the nucleus act as transcription factors. The MAP kinase Erk, which is activated by PTK receptors via Ras, has been shown to phosphorylate and inhibit SMADs [21], providing one example of how PTK-receptor-induced signals can modulate in an inhibitory manner signaling by other receptors.

Another example of cooperation between different receptor types is the finding that the mitogenic activity of certain seven-transmembrane-spanning G-protein-coupled receptors occur by transactivation of the EGF receptor [11].

PTK Receptors and Disease

Given the importance of PTK receptors in the control of cell proliferation and migration, it is not surprising that overactivity of PTK receptors occurs in cancer and other diseases that involve excess cell proliferation, such as inflammatory and fibrotic conditions and psoriasis. About half of the PTK receptors are implicated in various human malignancies (Fig. 1) [2]. Often, the receptors are constitutively activated by amplification or mutational events. Several mutations of PTK receptors cause constitutive dimerization (1) by mutations affecting disulfide bonding in the extracellular parts of the receptors, thus causing the formation of covalent dimers, mutations of other residues in the transmembrane, or juxtamembrane domains that promote dimerization; or (2) by formation of fusion proteins between the kinase domains of the receptors and proteins that normally occur as dimers or oligomers. The end result is a constitutively active kinase that drives cell growth.

Another mechanism of activation of PTK receptors seen in disease is overproduction of the corresponding ligand. If a cell produces a growth factor for which it has the corresponding receptor, autocrine stimulation of growth may result. Alternatively, the growth factor may stimulate cells in the environment in a paracrine manner, which is relevant in tumor progression. Tumor-derived factors (e.g., VEGFs and FGFs) act on angiogenic PTK receptors and cause vascularization of the tumors, which is a prerequisite for tumor growth [9]. Likewise, other growth factors produced by tumor cells (e.g., PDGFs) may stimulate the formation of tumor stroma, which is important for the balanced growth of tumors [43].

Given the importance of PTK receptors for serious diseases, clinically useful PTK receptor antagonists are warranted. Several types of antagonists are currently used clinically or are in clinical trials for cancer, including a monoclonal-antibody-recognizing ErbB2 and low-molecular-weight selective inhibitors of various tyrosine kinases [12]. It is likely that PTK receptor antagonists will be important tools in the treatment of cancer and possibly other diseases characterized by an excessive cell growth.

Signaling by the Platelet-Derived Growth Factor Receptor Family

M. V. Kovalenko and Andrius Kazlauskas

Schepens Eye Research Institute, Harvard Medical School, Boston, Massachusetts

Introduction

The platelet-derived growth factor (PDGF) family causes cellular responses by engaging its cell-surface receptors. These receptors are tyrosine kinases, which initiate many signaling cascades that result in cell proliferation, motility, and survival. This chapter reviews current understanding of the signaling enzymes that serve as the intracellular effectors of the PDGF receptors. In addition, it discusses the impact of integrins, phosphotyrosine phosphatases (PTPs), and cell cycle on PDGF-induced signaling pathways and subsequent cellular responses.

Platelet-Derived Growth Factors, Their Receptors, and Assembly of the PDGF Receptor Signaling Complex

Platelet-Derived Growth Factor Isoforms

At present, four genes encoding different platelet-derived growth factor chains are known: A, B, C, and D. Biologically active PDGFs exist as disulfide-bonded homodimers designated AA, BB, CC, and DD. A and B chains form a heterodimeric PDGF AB (Fig. 1). The history of the discovery of PDGFs dates back to as early as 1974, when mitogenic activity of whole blood serum was linked to the presence of platelets [1]. PDGF AB was the first to be purified and biochemically characterized a few years later, followed by PDGF BB and AA [2–5]. Cloning of PDGF A and B cDNAs and determination of the structure of corresponding genes were completed in the 1980s [6–8].

The newest members of the PDGF family, PDGF C and PDGF D, were found only recently by searching the database

of human expressed sequences [9–12]. PDGFs C and D have a two-domain structure with an N-terminal CUB domain and C-terminal PDGF/vascular endothelial growth factor (VEGF) (core) domain, separated by a hinge region (Fig. 1). No heterodimers involving C or D chains have been detected. The unique feature of these two new PDGFs is the requirement for proteolytic cleavage of the CUB domain upon secretion in order to achieve biological activity. Thus, latency may be the reason why these growth factors were not originally detected by functional assays.

Core domains of PDGF C and PDGF D have more structural similarity to each other than to PDGF A and B, sharing about 43% of identical amino acids [11,12]. PDGFs A and B are even more closely related, with 60% identity [13]; only 25 to 35% amino acid identity is found when A and B are compared to C and D [9,11].

Another ligand related to the PDGF/VEGF family, Pvf1, was recently discovered in *Drosophila* [14]. It is 29% identical to human PDGF A and regulates migration of border cells to oocytes during oogenesis. There is evidence that at least two more proteins with PDGF motifs may exist in *Drosophila*.

Platelet-Derived Growth Factor Receptors

PDGFs exert their biological functions by binding to two isoforms of PDGF receptors, α and β , with different degrees of affinity. Both receptors are composed of extracellular, transmembrane, and intracellular parts. The extracellular part consists of five immunoglobulin-like domains that are involved in ligand binding (domains I–III) [15,16] and receptor dimerization (domain IV) [17]. The intracellular kinase domain of the PDGF receptors is split in two by an approximately 100-amino-acid insert (Fig. 1) [18].

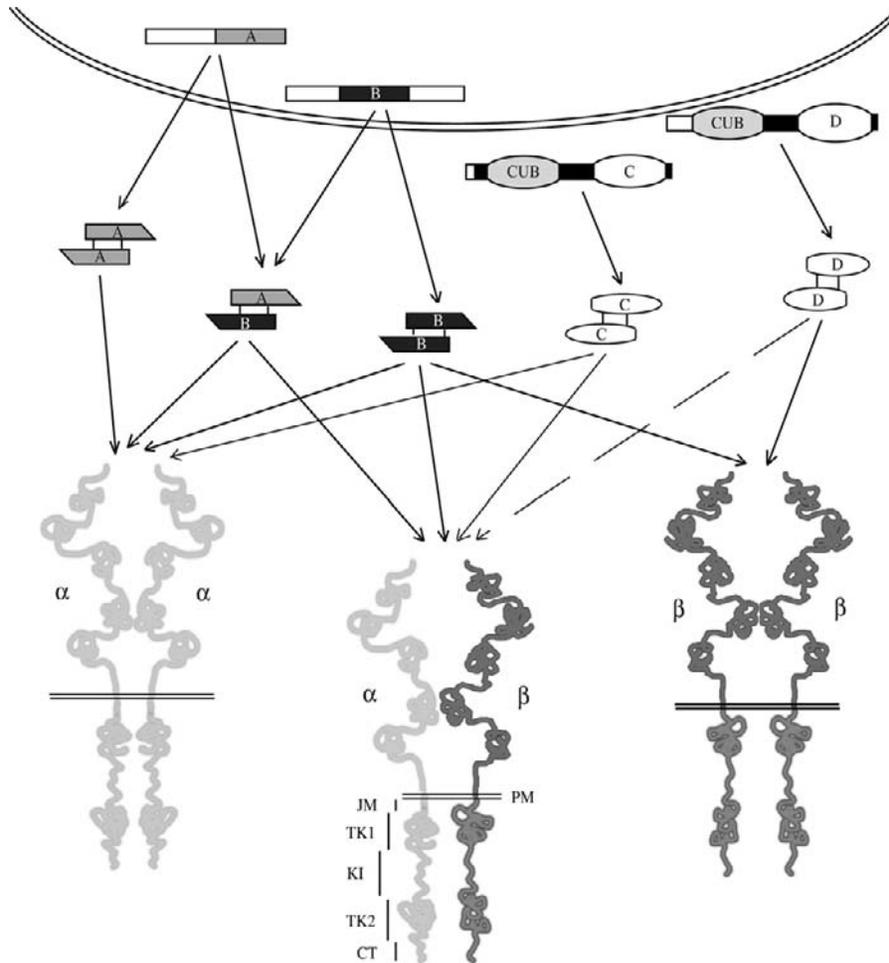

Figure 1 Platelet-derived growth factors and their receptors. PDGFs A and B are synthesized as precursors that are proteolytically processed before secretion. PDGFs C and D are secreted in latent form and activated by proteolytic cleavage of the CUB domain. All PDGF isoforms dimerize prior to the proteolytic cleavage (not shown in the figure). Specificity of binding of mature active PDGFs to their receptors is shown; dashed arrow indicates that controversy exists with regard to the ability of PDGF DD to cause the formation of a heterodimeric receptor (reference [11] versus [12]). Domain structure of the PDGF receptor α subunit (identical to that of the β subunit) is presented. The extracellular part of the receptor consists of five Ig-like domains. PM, plasma membrane; JM, juxtamembrane domain; TK1 and TK2, proximal and distal parts of tyrosine kinase domain, respectively; KI, kinase insert; CT, carboxyl-terminal tail.

PDGF A chain binds specifically to α -receptor, and PDGF B can bind both α and β receptors [19,20]. PDGF C was originally described as a ligand for PDGF α , but not β receptor [9]; however, later it was shown to bind PDGF β receptor in cells expressing both α and β isoforms [10]. PDGF D has been reported to be a β receptor ligand [12], but its ability to bind α receptor in α/β -expressing cells remains controversial [11,12]. Interactions of PDGFs with α and β receptors are summarized in Fig. 1. A bivalent dimer, PDGF molecule binds to two receptor subunits, causing them to dimerize. Upon dimerization, PDGF receptors become rapidly phosphorylated on multiple tyrosine residues. One of them (regulatory tyrosine) is located in the second part of the kinase domain and is important for receptor kinase activity (Tyr857 in β receptor [21] and, by homology, Tyr849 in α receptor). Most of the other phosphorylation sites lie in noncatalytic parts of the receptor (Fig. 2). The exact sequence of events

during receptor activation and formation of signaling complex is unknown. By analogy to other receptor tyrosine kinases (RTKs), it seems likely that ligand binding and subsequent dimerization of the receptor induce a conformational change that facilitates transphosphorylation of regulatory tyrosine residues within the dimer. Importantly, the regulatory tyrosine lies within the activation loop, the region that is conserved among receptor tyrosine kinases [22]. In the insulin receptor, the position of the activation loop is regulated by phosphorylation of homologous residues Tyr 1059, 1061, and 1062 [23]. In the nonphosphorylated state, the activation loop blocks the catalytic site, whereas upon ligand-induced phosphorylation it moves away, providing access to the substrate. It is possible that the events that follow transphosphorylation of the PDGF receptors are similar to those described for the insulin receptor, although there is no direct evidence for this in the absence of crystal structure of the PDGF receptors.

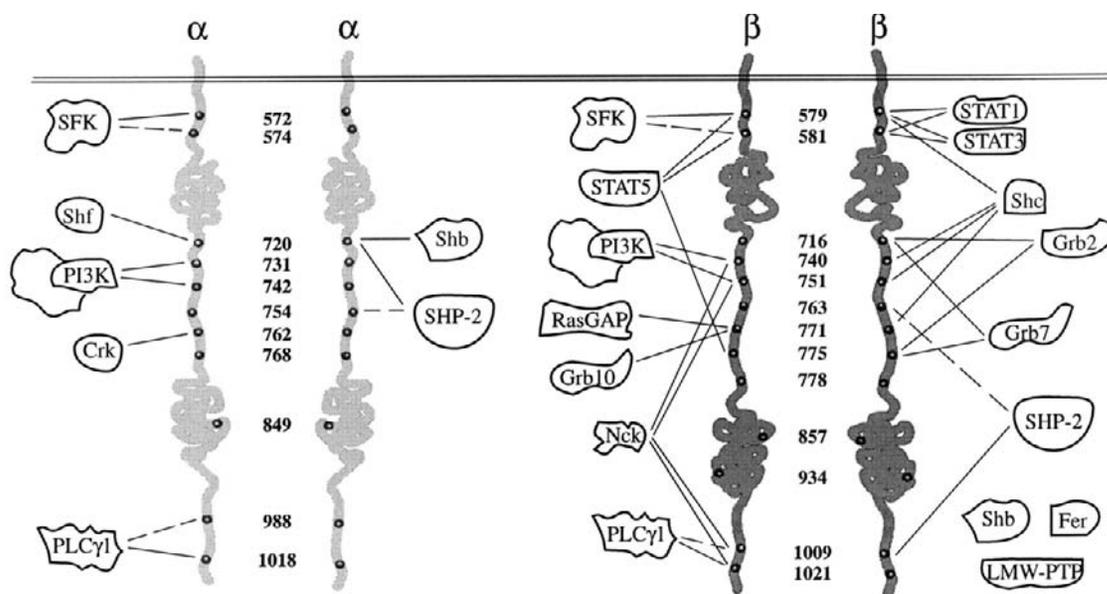

Figure 2 Intracellular domains of $\alpha\alpha$ and $\beta\beta$ homodimers of the PDGF receptor. Phosphorylated tyrosine residues are shown (dark circles). Numbers indicate their positions in the human PDGF receptor sequence. Association of signaling proteins with phosphorylation sites of the activated PDGF receptors is shown by solid lines (major binding sites) or dashed lines (additional sites). Proteins binding with high affinity (e.g., PI3-kinase, PLC γ 1, RasGAP) occupy one or two phosphotyrosine residues on the receptor, whereas low-affinity binding (e.g., Nck, Shc, or Shb binding to β receptor) involves multiple sites. Shb was found to bind to most of the phosphorylated tyrosines on the PDGF β receptor [61]. Fer and LMW-PTP bind to as-yet-unidentified sites on the PDGF β receptor.

As discovered recently, the juxtamembrane domain of the EphB2 receptor is involved in autoinhibition of the receptor kinase. The inhibition is relieved by ligand-induced phosphorylation of juxtamembrane tyrosine residues [24]. It is tempting to speculate that a similar regulatory mechanism exists for the PDGF β receptor, as mutation of the corresponding juxtamembrane tyrosines 579 and 581 of the PDGF β receptor inhibits PDGF-dependent activation [25]. Interestingly, this form of regulation may not be operative in the PDGF α receptor, even though these tyrosines and surrounding amino acids are conserved. Mutation of these tyrosine residues has little effect on the activation of the PDGF α receptor [41].

An additional PTP-linked mechanism that is likely to contribute to receptor activation has been proposed recently. When PTP activity in cells was blocked, phosphorylation of most tyrosine residues on the monomeric PDGF β receptor was increased to the level comparable to that of ligand-stimulated receptor, showing that PTP action might contribute to keeping non-activated receptor in unphosphorylated state. In a cell-free system, ligand-bound dimerized β receptor was found to be less susceptible to dephosphorylation by PTPs than monomeric receptor, indicating that receptor dimerization might protect it from dephosphorylation by PTPs. However, phosphorylation of the regulatory tyrosine (Tyr857) was strictly dependent upon ligand binding, i.e. it could not be induced by blocking PTP activity [26]. As known from earlier studies, catalytic activation (significant change of enzymatic parameters) of purified β receptor kinase is caused by PDGF binding and dimerization [27].

Therefore, the initial elevation of the receptor kinase activity, which involves phosphorylation of Tyr857, appears to require PDGF-induced dimerization and changes in the receptor's tertiary structure. "Phosphatase protection" caused by receptor dimerization may contribute to maintenance of its activated (phosphorylated) state.

Proteins Associated with the PDGF Receptors and PDGF-Driven Signaling Pathways

A total of 13 tyrosine residues in the β receptor and 11 in the α receptor are phosphorylated upon PDGF stimulation [19,30]. As discussed earlier, some of these phosphorylation events may be involved in stabilizing a catalytically active conformation of the receptor.

Phosphorylation of most of the tyrosines within PDGF receptors results in the creation of docking sites for a variety of proteins, many of which in turn are phosphorylated upon association with the receptors (Fig. 2) [19,20]. These proteins include enzymes (e.g., PI3-kinase, phospholipase C γ 1 [PLC γ 1], SHP-2, RasGAP, or Src family kinases [SFKs]), adaptor proteins (e.g., Grb2, Grb7, Shc, Shb, Nck, or Crk) linking the receptor to signaling proteins further downstream, or transcription factors (members of STAT family). Some enzymes may have adaptor function; for example, SHP-2 is able to recruit Grb2 via its phosphorylated C terminus [28]. Association is mediated in most cases by SH2 domains of these proteins [29] and is remarkably specific, each phosphorylation site having its own binding partners. This specificity is based on the ability of SH2 domains to

differentially recognize amino acid sequences following the phosphorylated tyrosine. Recruitment of other signaling molecules to the complex is facilitated by SH3, phosphotyrosine binding (PTB), or PH domains present in many of the receptor binding proteins.

It is yet uncertain whether the PDGF receptor is solely responsible for phosphorylating both itself and its substrates. Because other tyrosine kinases are present in the PDGF receptor signaling complex (e.g., SFK), their involvement in phosphorylation is possible and has indeed been confirmed. Using a specific inhibitor for Src family kinases, Blake *et al.* [43] showed that some proteins, including c-Cbl and protein kinase C δ (PKC δ), were SFK substrates, whereas others (PLC γ) were not. However, this approach leaves out other possible players (JAKs, FAKs, or yet

unidentified kinases) and can be complemented by other methods. One possible strategy involves introducing a single amino acid substitution into the adenosine triphosphate (ATP) binding site of the kinase of interest so that it acquires the unique ability to bind a bulkier synthetic ATP analog. In cells depleted of regular ATP and loaded with the analog, the mutant kinase will be the only one capable of phosphorylating its substrates [44].

Assembly of the PDGF receptor complex initiates a number of signaling pathways leading to cellular responses (Fig. 3). Some of the pathways are redundant and converge on the same cellular effect. For instance, chemotaxis can be driven by PI3-kinase via Rac and different PKC isoforms [30], as well as by Grb2/Sos1/Ras [33] via p38 [34] and possibly Rac. There is evidence of cross-talk between these

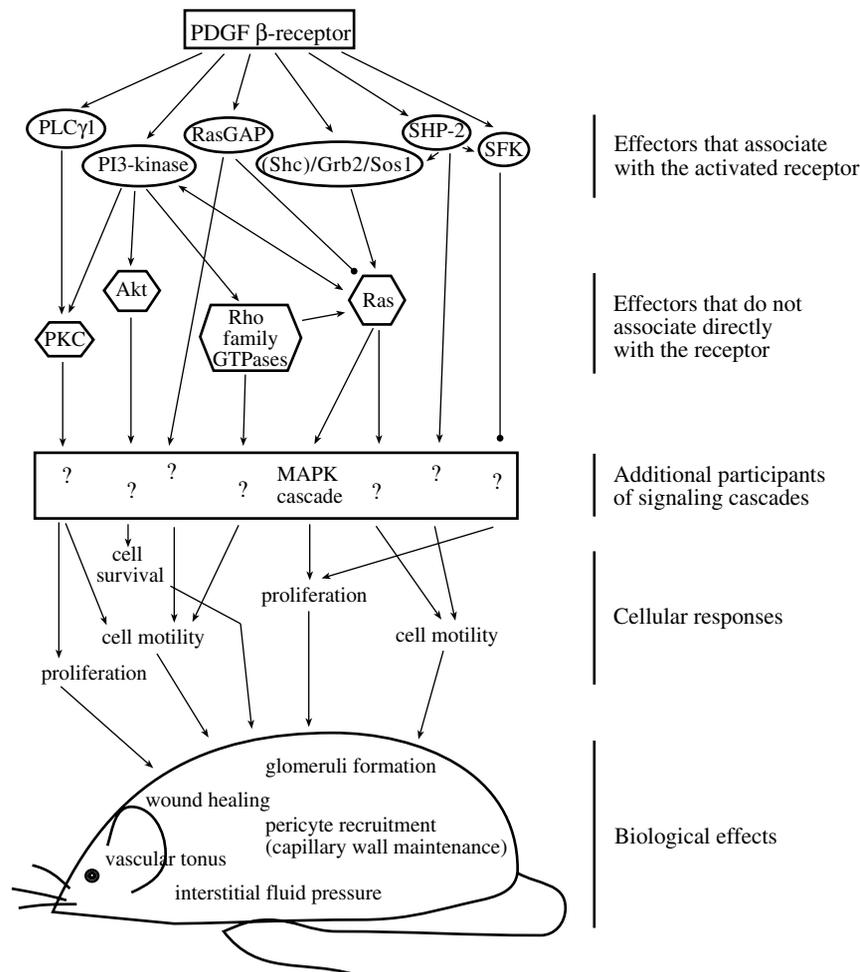

Figure 3 Major events initiated by the PDGF β receptor and culminating in biological responses. Upon ligand binding, activated PDGF β receptor recruits enzymes and adaptor proteins that start a number of distinct signaling pathways, some of which are shown on the figure. Note that not all of them are initiated by the same receptor dimer or in the same cell. Arrows represent either physical or functional interactions along the pathways. Inhibitory effect of RasGAP is shown with \bullet . At present, only proteins that directly associate with the PDGF receptor and their immediate downstream effectors are best characterized. The least defined part of the signaling cascade is the one that bridges the receptor-proximal events with proteins that carry out cellular responses. PDGF is necessary but not sufficient to achieve biological effects. In a living organism, other growth factors and hormones, as well as cell-cell and cell-matrix interactions within tissues and organs are indispensable.

pathways, as Ras and PI3-kinase are able to interact and activate each other [35,36]. PLC γ -dependent activation of sphingosine kinase [37,38] and PKC and can also be important for motility response. RasGAP, a negative regulator of Ras, has been shown to inhibit chemotaxis [39]. However, RasGAP has also been shown to have a positive impact on motility that is most likely independent of Ras [40]. Another chemotaxis pathway is initiated at SFK binding sites in the juxtamembrane domain of the PDGF α receptor, as determined by mutating these tyrosines to phenylalanine residues [41]. However, it is not yet clear whether it is Src family kinases or other signal transduction molecules binding to the same sites that are responsible for cell migration, as in triple SFK knockout cells PDGF-AA-dependent cell migration was intact [42]. Other positive mediators of PDGF-induced cell motility include SHP-2, which can work as adaptor molecule for Grb2/Sos1, and LMW-PTP, which acts presumably by inactivating p190RhoGAP and, consequently, activating Rho and causing cytoskeletal rearrangements [30].

In addition to chemotaxis, other PDGF-induced cellular responses include proliferation, differentiation (in certain cell types), and protection from apoptosis, as well as rapid Ca²⁺ fluxes and cytoskeletal rearrangements [19,20]. It is necessary to note that $\alpha\alpha$ and $\beta\beta$ homodimers of the PDGF receptor cause different, although partially overlapping, cellular responses [20], due to the differences in their ability to bind signaling proteins (Fig. 2). Heterodimeric α/β receptor is believed to have unique signaling properties due to altered phosphorylation pattern of both the α and β subunits [31,32].

Some Aspects of Regulation of the PDGF Receptor-Initiated Signaling

Until recently, it has not been entirely clear whether each receptor molecule carried a complete set or a selected subset of phosphorylated tyrosines and corresponding downstream signaling proteins. By now, a considerable amount of data indicates that signaling output of the PDGF receptor complex is a result of interaction of various factors. Both intracellular and extracellular conditions may contribute to selective activation of some pathways and suppression of others. The sections that follow provide a brief discussion of some important aspects of this regulation, such as the influence of extracellular matrix (ECM) interactions, the input of PTPs, and how the cell-cycle stage determines which PDGF-driven pathways will have an effect on cells continuously treated with PDGF.

PDGF Receptor Signaling and Cell-Cycle Progression

To drive quiescent cells out of G₀ and through one round of the cell cycle, continuous treatment with PDGF for at least 8 to 10 hours is required [45]. It has been shown that prolonged exposure to PDGF induces two distinct peaks of

PI3-kinase activity, one within minutes and another after a few hours' delay [46]. Only the second peak was found to be critical for cell-cycle progression, whereas the early increase of activity was required only for an immediate response to PDGF such as chemotaxis. Ras activation, induced by growth factors, remained elevated throughout G₀/late G₁. However, injection of neutralizing antibodies at different time points showed that the requirement for active Ras was not continuous but was restricted to at least two distinct phases of this transition [47]. These findings indicate that Ras and perhaps PI3-kinase use different effectors depending on the cell-cycle stage.

It still remains an open question as to how this complex interplay of early and late events induced by PDGF is linked to the cell-cycle machinery. According to recent findings, continuous treatment can be substituted by two separate pulses of the growth factor [48], the first getting cells out of G₀ and into early G₁, and the second pushing them through late G₁ and into the S phase. Early elevation of *c-myc* and sustained activation of the Erk pathway can replace the first pulse of PDGF but are not sufficient to drive the cell through late G₁. To complete cell-cycle progression, a properly timed second peak of PI3-kinase activity (second pulse of PDGF or just the addition of PI3-kinase lipid products) is required. It is hypothesized that early *c-myc* and Erk activation triggers expression of new proteins for which interaction with the late PI3-kinase products is critical for S phase entry. This two-step mechanism would prevent mitogenesis in response to a single accidental spike of PDGF. Consequently, mitogenesis is possible when the growth factor is present continuously or released in pulses frequent enough to ensure proper timing of early and late events in G₁ (which would reflect either normal physiological requirement or a serious disorder).

PTPs and Effect of Intracellular Reactive Oxygen Species (ROS)

As is the case for other cellular proteins, the phosphorylation level of the PDGF receptor and its substrates is a balance of kinase and phosphatase activities. LMW-PTP binds to activated PDGF receptor within the first five minutes after PDGF stimulation. It has been shown that this PTP selectively interferes with two pathways initiated by the receptor: Src-dependent induction of *c-myc* and STAT1/3-mediated *c-fos* expression. LMW-PTP association with the receptor prevents binding and activation of Src [49]. Because STAT1 and 3 use the same binding sites on the PDGF receptor as Src does, it is possible that LMW-PTP counteracts STAT1/3 signaling the same way (i.e., by competition for receptor binding).

Another PTP directly associated with the PDGF receptor upon its stimulation is SHP-2, which can have both negative and positive effects on signaling. SHP-2 is able to dephosphorylate selectively tyrosines 771 and 751 on the β receptor, potentially turning off RasGAP and PI3-kinase pathways [50]. On the other hand, a recent report indicates that SHP-2 is involved in growth-factor-dependent activation of

PI3-kinase [51]. Also, SHP-2 was reported to serve as an adaptor for Grb2 binding [28], thus initiating Ras-mediated signaling. SHP-2 has been implicated as a positive regulator in the stimulatory effect of integrins on PDGF receptor signaling.

The activity of PTPs is widely believed to be regulated by intracellular redox status. Elevation of ROS content would lead to reversible oxidation of catalytic cysteine residues of PTPs and consequently to their inhibition, whereas a reducing environment results in PTP activation. An increase of intracellular ROS is an early PDGF-dependent event mediated by PI3-kinase [52] and Rac, and it was shown to be important for mitogenic signaling [53]. It is likely that this event helps to prevent the negative input of (receptor-associated) PTPs on early stages of signaling. In contact-inhibited cells that do not respond mitogenically to PDGF, ligand-induced PDGF receptor phosphorylation is diminished [54] due to elevated PTP activity [55,56], which in turn has been linked to dramatically decreased ROS content in these cells [57]. LMW-PTP, in particular, can be regulated by ROS [58] and may contribute to reduced PDGF receptor activation in these cells. These data suggest that changes in the cellular redox environment determine whether PTPs will counteract PDGF receptor signaling.

Input of Integrins

The PDGF receptor is capable of initiating both positive signals (e.g., through SFK, PI3-kinase, or PLC γ 1) and negative signals (RasGAP) with relation to the mitogenic response. Because proper attachment to matrix is critical for cell proliferation, ECM-dependent engagement of integrins may be expected to affect signaling output of the PDGF receptor in such a way that positive signals prevail. Indeed, plating cells on vitronectin, an α v β 3 ligand, leads to increased PDGF-dependent mitogenicity and chemotaxis. Along with this, a small, highly phosphorylated fraction of PDGF β receptors becomes associated with α v β 3 integrin after PDGF stimulation [59]. Another set of data shows that activation of integrins leads to increased association of SHP-2 with the receptor, and, as a consequence, to dephosphorylation of the RasGAP binding site and decreased RasGAP binding [60]. This is followed by prolonged activation of Ras and Erk. Thus, integrins can alter the recruitment of signaling enzymes to the PDGF receptor in favor of increased mitogenic signaling. It is also noteworthy that, due to its substrate specificity, SHP-2 (a member of the PTP family generally consisting of RTK antagonists) acts under these conditions as a positive component of the PDGF receptor signaling by inactivating a negative regulatory pathway at the receptor level.

EGF Receptor Family

Mina D. Marmor and Yosef Yarden

*Department of Biological Regulation,
The Weizmann Institute of Science, Rehovot, Israel*

Introduction

Receptor tyrosine kinases (RTKs), transmembrane molecules with intrinsic tyrosine kinase activity, couple binding of growth factor ligands to the intracellular signaling pathways that regulate diverse processes such as cell division, differentiation, and survival. The receptor for the epidermal growth factor (EGFR) represents a prototypical RTK and was the first cell-surface signaling protein characterized by molecular and genetic methods [1]. The EGFR or ErbB family of RTKs is now known to be comprised of four closely related members: EGFR (also known as ErbB1 or HER1), ErbB2 (HER2), ErbB3 (HER3), and ErbB4 (HER4), which are widely expressed on cells of epithelial, mesenchymal, and neuronal origin. Analyses of the function of ErbBs have revealed their critical developmental role in inductive cell fate determination in mammals (see Table 1).

The EGFR pathway is evolutionarily conserved in invertebrates, with a single ErbB homolog, LET-23, binding to a single ligand, LIN-3, to induce development of the vulva and other organs in *Caenorhabditis elegans*. In *Drosophila melanogaster*, the interactions of a single ErbB homolog, DER, with its four ligands regulate several stages of development including oogenesis, embryogenesis, and wing and eye development. In higher organisms, a complex network composed of the four ErbB receptors and ten ligands has evolved. This layered information processing module allows for the combinatorial interactions of ligands, receptors, effectors, and transcription factors and provides a high degree of signal diversification with multiple levels of output control [2].

Domain Structure of ErbBs

ErbB receptors contain an extracellular ligand binding domain with two cysteine-rich regions and a single

hydrophobic transmembrane domain. The intracellular portion consists of a tyrosine kinase domain and a carboxy-terminal tail containing tyrosine autophosphorylation sites. ErbB2 does not appear to bind growth factor ligands directly, while ErbB3 is devoid of intrinsic kinase activity. All ErbB family ligands include an EGF-like domain consisting of three disulfide-bonded intramolecular loops and are generated upon the regulated proteolytic cleavage of glycosylated transmembrane precursors. Binding of these ligands, the specificity of which is depicted in Fig. 1, involves two non-consecutive portions of both the ectodomain of the receptor and the ligand molecule, suggesting bivalent interactions. An essential feature of transmembrane signaling is the ability of all ligands to promote homo- and heterodimers of ErbBs. Although the resulting three-dimensional structures have not been solved, modeling based on other RTKs predicts 2:2 ligand/receptor complexes stabilized by a long loop of each receptor forming the interface of the dimer. Dimerization of ErbBs is essential for receptor auto- or transphosphorylation on tyrosine residues, leading to the initiation of signaling by serving as docking points for signaling effectors containing SH2 and phosphotyrosine binding (PTB) domains.

Subcellular Localization of ErbB Proteins

The localization of LET-23 at the basolateral face of precursor epithelial cells is important for vulval development in *C. elegans*. In mammalian skeletal muscle, the clustering of ErbB2, ErbB3, and ErbB4 at the postsynaptic membrane of neuromuscular junctions is required for efficient binding to neuron-derived neuregulins and subsequent induction of acetylcholine receptor synthesis. In polarized epithelial cells, most EGFR and ErbB2 molecules are localized to the basolateral face where signaling can be initiated by

Table I Phenotypes of Mice Deficient in ErbB Proteins

EGFR ^{-/-}	Strain-dependent phenotypes (embryonic or perinatal lethality): death <i>in utero</i> due to defects in placental spongioblasts; after birth: progressive neurodegeneration and abnormalities in multiple organs, including brain, skin, lung, eyes, GI tract, and hair follicles.
ErbB2 ^{-/-} (lethal E10.5)	Insufficient heart development, with trabeculae malformation in ventricles. Introduction of transgenic ErbB2 into myocardial cells results in perinatal lethality and nervous system defects, including lack of Schwann cells, defects in motor and sensory neurons and neuromuscular junctions.
ErbB3 ^{-/-} (lethal E13.5)	Defects in valve formation in heart development and nervous system defects, including neural crest defects, lack Schwann cells, degeneration of peripheral nervous system.
ErbB4 ^{-/-} (lethal E10.5)	Insufficient heart development and trabeculae malformation in ventricles and central nervous system defects, including hindbrain innervation.

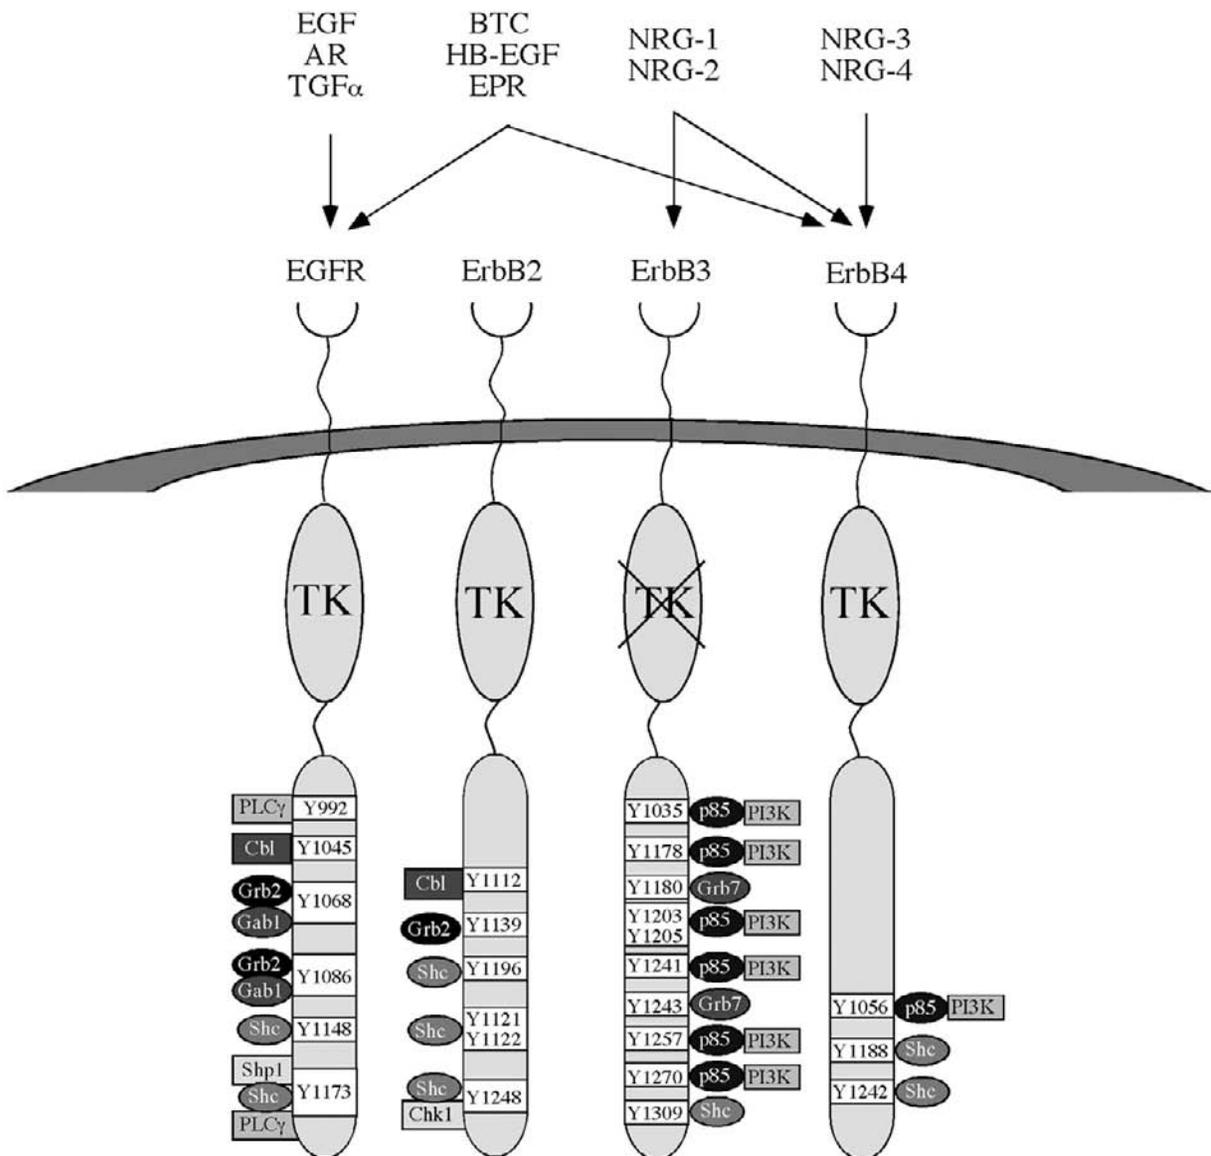

Figure 1 ErbB ligands, receptor tyrosine kinases, and signal transduction pathways. Ten growth factor ligands bind ErbB RTK: EGF, amphiregulin (AR), and transforming growth factor- α (TGF- α) bind EGFR; betacellulin, heparin-binding EGF-like growth factor (HB-EGF), and epiregulin bind both EGFR and ErbB4; the neuregulins (also called Neu differentiation factors; NDFs) NRG-1 and NRG-2 bind ErbB3 and ErbB4; and NRG-3 and NRG-4 bind ErbB4. Ligand binding induces receptor homo- or heterodimerization and activation of tyrosine kinase activity. Phosphorylation of tyrosine residues within ErbBs enables the recruitment of SH2 and PTB domain-containing proteins. The binding sites for such molecules are indicated and include adaptor proteins such as Grb2, Shc, Grb7, and Gab1 and enzymes such as PLC γ , Chk kinase, SHP-1 phosphatase, p85 subunit of PI3K, and Cbl, a ubiquitin ligase.

stroma-derived ligands. Three PDZ-containing proteins (Lin-2, Lin-7, and Lin-10) are implicated in the regulation of LET-23 localization. In addition, the PDZ-containing proteins PSD-95 and Erbin, as well as their binding partner PICK1, are important for ErbB2 targeting to and retention and clustering at specific cell surface sites in mammalian cells.

In resting cells, a large proportion of EGFR, as well as ErbB2 and ErbB4, is localized in caveolae, which are membrane microdomains enriched in caveolin proteins, glycosphingolipids, and cholesterol. Caveolae are thought to regulate signaling through the preassembly of signaling molecules and have also been implicated in non-clathrin-mediated internalization. Caveolin-1 interacts with ErbBs and inhibits their catalytic activity. In response to ligand, both EGFR and ErbB4 migrate out of caveolae, which may remove the inhibitory effect of caveolin. Interestingly, the localization of ErbB2 in caveolae is unchanged upon stimulation [3]. In addition, some signaling pathways induced through ErbBs, notably the Ras-MAPK pathway, were observed to occur in caveolae. The significance of the caveolar retention of ErbB2 as well as the function of caveolae in regulating signaling and endocytosis of ErbB RTK remain to be fully elucidated.

ErbB-Induced Signaling Pathways

Signaling pathways induced through ErbBs are dictated by their pattern of autophosphorylation, as the specificity of SH2 and PTB domain binding is conferred by amino acids surrounding the tyrosine phosphorylation site. Thus, individual ErbBs couple to distinct subsets of signaling proteins, as depicted in Fig. 1. All ErbB ligands and receptors couple to activation of the Ras-MAPK pathway through recruitment of Grb-2 and/or Shc and the Grb-2-bound exchange factor Sos. Activation of phosphatidylinositol 3-kinase (PI3K) is differentially induced: ErbB3 contains six putative binding sites for the SH2 domain of the PI3K p85 regulatory subunit, while ErbB4 contains one binding site, and EGFR and ErbB2 couple to PI3K indirectly through adaptor proteins such as Gab1 and c-Cbl [4]. Thus, ErbBs induce the proliferative and survival signals resulting from the activation of PI3K and its downstream effectors, such as Akt and p70^{S6} kinase, with differing potencies and kinetics. Other signaling effectors are recruited only to some ErbB family members, such as the recruitment of PLC γ to EGFR and ErbB2. Subsequent PLC γ activation results in the hydrolysis of phosphatidylinositol-4,5-bisphosphate and the generation of the second messengers diacylglycerol and inositol trisphosphate, leading to activation of protein kinase C (PKC) and increases in intracellular calcium concentrations.

Signaling through EGFR has been more extensively characterized than other ErbB family members and is known to involve multiple additional pathways. c-Src is activated upon stimulation with EGF and phosphorylates two of the tyrosine residues within EGFR implicated in mitogenesis. Furthermore, c-Src phosphorylates and activates STAT

family transcription factors, cytoskeletal proteins, and proteins involved in endocytosis. The FAK and Pyk2 kinases are implicated in EGF-induced cell migration and link EGFR to integrin signaling pathways. The JNK pathway is also activated by ErbBs, likely through the adaptor protein Crk, Dbl family exchange factors, and the small GTPases Rac1 and Cdc42. Further, EGFR and ErbB4 have recently been detected in the nucleus of cells, where EGFR may function as a transcription factor [5,6].

EGFR can also integrate signals through other cellular stimuli, notably by G-protein-coupled receptor (GPCR) agonists which may require EGFR-induced signaling for MAPK activation [7]. Transactivation of EGFR may involve its phosphorylation by non-receptor tyrosine kinases such as FAK, Pyk2, or Src. Phosphorylation may lead to the catalytic activation of EGFR or may enable the receptor to function as a scaffold for the recruitment of signaling molecules as outlined above. In addition, activation of PKC by GPCRs may in turn result in the activation of membrane metalloproteinases, resulting in the generation of the cognate ligands of EGFR and its subsequent direct activation [8].

Negative Regulatory Pathways

The principal route of signal attenuation is the downregulation of surface receptor levels through ligand-induced receptor endocytosis. Receptor dimers are internalized through clathrin-coated regions of plasma membrane that invaginate to form endocytic vesicles. These vesicles mature into early and late endosomes, while their internal pH increases and they accumulate hydrolytic enzymes leading to receptor degradation. EGFR is one of the most extensively studied receptors with respect to endocytosis. Ligand-induced phosphorylation and coupling of EGFR to proteins involved in the endocytic machinery, such as Eps15, are critical for accelerated endocytosis. Further, phosphorylated EGFR recruits c-Cbl, a ubiquitin ligase that directs the receptor to lysosomal degradation through polyubiquitination [9,10]. In contrast to the rapid internalization and degradation of EGFR, sorting in the early endosome or multivesicular body leads to the recycling of other ErbBs back to the cell surface, thus potentiating signaling. Moreover, as c-Cbl does not bind ErbB3, this receptor demonstrates impaired ligand-induced polyubiquitination and downregulation relative to EGFR.

Other negative regulatory pathways serve to limit signaling through ErbB proteins [11]. Ras-GAP is recruited to and activated by EGFR and inhibits the MAPK pathway by accelerating the GTPase activity of Ras. Studies in *D. melanogaster* demonstrate that Argos is a soluble EGF-like molecule that inhibits ligand binding to DER, while Kekk1 is a transmembrane protein that interacts with DER and interferes with ligand activation. Further, the cytosolic protein Sprouty binds c-Cbl and inhibits activation of the Ras-MAPK pathway. In *C. elegans*, the Ark-1 kinase was shown to inhibit LET-23/EGFR signaling in a SEM5/Grb-2-dependent manner. Mammalian homologs of Kekk1 (Lig-1), Sprouty (Spry1-4),

and Ark-1 (ACK-1) have been identified but their functions remain to be fully characterized.

Specificity of Signaling Through the ErbB Network

The specificity of signaling through ErbB receptors is regulated at multiple levels. The distinct organ and developmental stage-specific expression profiles of ErbB ligands regulate biological responses throughout development and adulthood. The ligand influences ErbB homo- or heterodimer formation, as well as the identity of the phosphorylation sites within individual ErbBs [12]. Ligand affinity influences signal strength and duration, although low-affinity ligands may not induce normal receptor downregulation and degradation thereby functioning more potently, as was shown for low-affinity virally encoded ligands [13]. Further, the pH stability of the ligand-receptor interaction influences receptor trafficking; the pH-resistant interaction of EGFR with EGF targets the receptor to the lysosome, whereas TGF α and NRG-1 dissociate from their receptors in early endosomes, thus favoring receptor recycling and signal potentiation.

Dimerization of ErbBs adds an additional level of signal diversification. Homodimeric receptor combinations are less potent and mitogenic than heterodimers. The critical role of heterodimers is most clearly demonstrated in mice with targeted deletions in individual ErbBs. The defective heart formation phenotype of both ErbB2 and ErbB4 knockouts demonstrate that ErbB4 homodimers cannot functionally substitute for ErbB4–ErbB2 heterodimers. Although ErbB2 does not bind directly to ligands, it is the preferred heterodimer partner for other ErbBs. ErbB2-containing heterodimers are the most potent complexes due to an increased affinity of ligand binding, decreased ligand dissociation, decreased rate of endocytosis, and increased receptor recycling [2].

ErbB Proteins and Pathological Conditions

Due to their widespread expression and signaling potency, ErbB molecules are involved in a variety of physiological processes (e.g., myelination, implantation, wound healing, mammary development, angiogenesis) and pathological states (airway inflammation, asthma, ulcers, and other gastrointestinal tract diseases). However, the best studied is the oncogenic aspect of the ErbB network in human malignancies. ErbBs were first implicated in cancer upon the characterization of an aberrant form of EGFR encoded by the avian erythroblastosis tumor virus. EGFR and ErbB2 have since been implicated in various forms of human cancers. Abnormal activation of these receptors occurs through overexpression, gene amplification, constitutive activation of mutant receptors, or autocrine growth factor loops. ErbB2 has been used as a prognostic marker as its overexpression is associated with shorter overall and relapse-free survival of patients with breast or ovarian cancer [13]. Further, ErbB molecules serve as therapeutic targets in cancer treatment.

Herceptin/Trastuzumab[®] and Cetuximab[®] are EGFR- and ErbB2-specific monoclonal antibodies in use in the treatment of breast cancer patients, and ErbB-specific tyrosine kinase inhibitors are in clinical trials. Also under examination are derivatives of the antibiotic geldanamycin, which block the growth of ErbB2-overexpressing cells by inducing ErbB2 degradation subsequent to binding the ErbB2 chaperone Hsp90. ErbB receptors are similarly implicated in other hyperproliferative disorders such as coronary atherosclerosis and psoriasis. Conversely, signaling through ErbBs may promote wound healing. Thus, a more complete understanding of the ErbB network may allow for the development of therapeutic strategies that may be of clinical benefit in a variety of pathological conditions.

IRS-Protein Scaffolds and Insulin/IGF Action

Morris F. White

*Howard Hughes Medical Institute, Joslin Diabetes Center,
Harvard Medical School, Boston, Massachusetts*

IRS-Proteins: The Beginnings

After the discovery of the insulin receptor tyrosine kinase, many groups searched for insulin receptor substrates (IRS-proteins) that might regulate downstream signaling [1,2]. The first evidence for an IRS-protein came from phosphotyrosine antibody immunoprecipitates that revealed a 185-kDa phosphoprotein (pp185) in insulin-stimulated hepatoma cells [3]. This phosphoprotein seemed to be biologically important because it was phosphorylated immediately after insulin stimulation, and catalytically active insulin receptor mutants that failed to phosphorylate it were biologically inactive [4]. Purification and molecular cloning of pp185 revealed one of the first signaling scaffolds, and the first insulin receptor substrate (IRS1) [5]. IRS1 contains many tyrosine phosphorylation sites that are phosphorylated during insulin and IGF1 stimulation and bind to the Src homology-2 domains in various signaling proteins [6,7]. The interaction between IRS1 and p85 activates the class IA phosphatidylinositol 3-kinase (PI 3-kinase), revealing the first insulin signaling cascade that could be reconstituted successfully in cells and test tubes [8].

IRS-Proteins and Insulin Signaling

Insulin and IGF1 receptors, like the receptors for other growth factors and cytokines, are composed of an extracellular ligand-binding domain that controls the conformation and activity of the intracellular tyrosine kinase [9,10]. Unlike most receptor tyrosine kinases that are activated upon ligand-induced dimerization, insulin and IGF1 receptors exist as

inactive covalent dimers composed of two extracellular α -subunits and two transmembrane β -subunits. Insulin and IGF1 bind between the two α -subunits, thus inducing a conformation change that promotes tyrosine autophosphorylation on the cytoplasmic side of the adjacent β -subunits [11,12]. Autophosphorylation occurs in three distinct regions of the β -subunits, including the regulatory loop, the juxtamembrane region, and the C-terminus. Phosphorylation of three tyrosine residues in the regulatory loop activates the tyrosine kinase by opening the catalytic domain to facilitate entry of adenosine triphosphate (ATP) and peptide substrates; autophosphorylation of the NPEY motif in the juxtamembrane region creates a binding site for IRS-proteins and other substrates that have similar phosphotyrosine binding (PTB) domains. The role of phosphorylation in the C terminus is poorly understood.

The mammalian insulin receptor is biologically inactive without its substrates, suggesting that most signals are generated through complexes that are assembled around tyrosyl-phosphorylated scaffolds, including IRS1 and its homologs; Shc, APS, and SH2B [13]; and Gab1/2, Dock1/2, and cbl [14–20]. Although the role of each of these substrates merits attention, work with transgenic mice reveals that many insulin responses, especially those that are associated with somatic growth and carbohydrate metabolism are mediated largely through IRS1 and IRS2 [21]. IRS-proteins are composed of multiple interaction domains and phosphorylation motifs [22]. At least three IRS-proteins occur in mice and people, including IRS1 and IRS2, which are widely expressed, and IRS4, which is limited to the thymus, brain, kidney, and β -cells [23]. Rodents also express IRS3, which is largely restricted to adipose tissue and displays activity similar to

IRS1; however, an IRS3 ortholog might not occur in people [24]. Disruption of the genes for IRS3 or IRS4 in mice is uninformative [25,26]. By contrast, mice lacking IRS1 are small and those without IRS2 are infertile and develop diabetes [5,27]. The *Drosophila* genome contains a single IRS-protein called Chico that promotes growth and regulates metabolism in flies (Fig. 1) [28], while a functional IRS-protein is not expressed in *Caenorhabditis elegans*. However, the insulin and IGF receptor orthologs in flies and worms contain a significant C-terminal extension that is absent from mammalian orthologs and contains potential tyrosine phosphorylation sites that can recruit PI 3-kinase without IRS-proteins [29].

IRS-Protein Structure and Function

Alignment of the amino acid sequences of the IRS-proteins reveals important similarities and subtle differences (Fig. 1). IRS1–4 and Chico contain an NH₂-terminal pleckstrin homology (PH) domain adjacent to a PTB domain. The structures of the PH and PTB domains are remarkably similar [30], and both facilitate recruitment of IRS-proteins to the activated insulin and IGF1 receptors; deletion of the PH and PTB domain almost completely prevents phosphorylation of the C-terminus. The PTB domain binds to the phosphorylated NPEY motif in the β -subunit of the insulin or IGF1 receptor [31–33]. At ordinary expression levels, deletion of the PTB domain reduces that ability of insulin to promote tyrosine phosphorylation of IRS1 or IRS2; however, overexpression of the insulin receptor restores phosphorylation and signaling, suggesting that the PTB domain enhances coupling but is not essential for signaling [31].

The PH domain also promotes interaction between IRS-proteins and physiological levels of insulin receptors. Like the PTB domain, the PH domain is not required in cells overexpressing the insulin receptor [31]. However, the mechanism of coupling employed by the PH domain is not understood. Some, but certainly not all, PH domains bind to membrane phospholipids which provides membrane targeting [34]; however, the PH domain in IRS-proteins has a relatively low affinity for phospholipids. The PH domains can be exchanged between IRS-proteins without noticeable loss of bioactivity, but chimeric IRS-proteins composed of heterologous PH domains fail to be phosphorylated by the insulin receptor [35]. Because IRS-protein PH domains do not bind to the insulin receptor, other proteins of membrane lipids might be involved. Yeast two-hybrid screens reveal a few potential binding partners, including nucleolin or a novel protein called PHIP [35,36].

The tyrosine phosphorylation sites in the COOH-terminal end of each IRS-protein recruit and regulate various downstream signaling proteins (Fig. 1). IRS1 and IRS2 have the longest tails, which contain 20 potential tyrosine phosphorylation sites; however, only a few sites have been formally identified, and little information is available on the phosphorylation sites in IRS3 and IRS4 (Fig. 1). Many of the

tyrosine residues cluster into common motifs that recruit or activate enzymes (PI 3-kinase, SHP2, fyn) or adapter molecules (Grb-2, nck, crk, Sh2b) (Fig. 1). Grb2 and possibly SHP2 couple Grb2/SOS to IRS-proteins, which promotes the ras \rightarrow raf cascade [37]. All IRS-proteins contain multiple p85 binding motifs that recruit PI 3-kinase, which is the best-studied insulin-signaling pathway.

In addition to the tyrosine phosphorylation sites, sequence alignment of IRS-proteins reveals several conserved motifs that might be binding sites for other cellular proteins. One of the best characterized is the binding site for the c-Jun N-terminal kinase (JNK), which resembles the sites in the JNK-interacting proteins (JIP1 and JIP2) [38,39]. This site occurs in IRS1, IRS2, and Chico but has only been validated in mouse and human IRS1 [40]. During stimulation by proinflammatory cytokines or by insulin, JNK binds to IRS1 and promotes phosphorylation of Ser³¹² in human IRS1 (Ser³⁰⁷ in rat/mouse IRS1) [41]. Phosphorylation of this serine residue inhibits binding of the PTB domain to the phosphorylated NPEY motif in the activated insulin receptor [40]. JNK also phosphorylates IRS2, but the homologous site is absent and the inhibitory mechanism is poorly described.

IRS1 and IRS2 contain several putative 14-3-3 binding sites (Fig. 1). 14-3-3 proteins are highly conserved acidic scaffold proteins that bind to specific amino acid sequence motifs. In some cases, serine phosphorylation of the target motif directs the binding of a 14-3-3 isoform, which might inhibit signaling by sequestering the complex to an inappropriate subcellular compartments [42]. IRS1 and IRS2 contain several serine phosphorylation motifs that bind to 14-3-3 ϵ or 14-3-3 ζ might inhibit signaling [43,44]. Some of these sites are in the PTB domain, which might inhibit coupling to the activated insulin receptor. Recent evidence suggests that 14-3-3 binding might displace serine-phosphorylated IRS-1 from particular structures, thus reducing PI 3-kinase activity [45]; however, a role for 14-3-3 binding in IRS-protein regulation remains to be validated in animal models. Whether 14-3-3 binding regulates IRS2 function is unknown.

Work with transgenic mice reveals that IRS1 and IRS2 have distinct signaling potential even though the structures of the two proteins and their functions in cell-based assays are rather similar; however, certain differences do exist that might establish specificity. For example, IRS2 contains a unique region of undefined structure that binds to the phosphorylated regulatory loop of the insulin receptor kinase, called the kinase-regulatory-loop-binding (KRLB) domain. The discovery of this interaction was unexpected, as it maps to the portion of the COOH-terminal region between amino acid residues 591 and 786 that contains tyrosine phosphorylation sites (Fig. 1). Two tyrosine residues in the KRLB domain at positions 628 and 632 are crucial for this interaction. Phosphorylation of tyrosine residues in the KRLB domain by the insulin receptor inhibits the binding to the receptor, suggesting that a novel mechanism regulates the interaction of the insulin receptor and IRS-2 and may be able to distinguish the signal of IRS2 from IRS1 [46].

PI 3-Kinase Cascade

IRS-proteins couple insulin and IGF receptors to various signal pathways, including the PI 3-kinase → protein kinase B (PKB)/AKT cascade and the Grb2/SOS → p21^{ras} cascade (Fig. 2). Activation of class 1A PI 3-kinase is required for many insulin responses, including the stimulation of glucose uptake, glycogen synthesis, and gene transcription [47]. PI 3-kinase is composed of a catalytic and a regulatory subunit. Catalytic subunits encoded by *Pik3ca* (p110 α), *Pik3cb* (p110 β), and *Pik3cd* (p110 δ) associate noncovalently with a regulatory subunit encoded by *Pik3r2* (p85 β), *Pik3r3* (p55^{PIK}), or the alternatively spliced *Pik3r1* (p85 α , p55 α , and p50 α) [48]. *Pik3r1* and *Pik3r2* are ubiquitously expressed; p85 α is usually more abundant than p85 β , whereas *Pik3r3* displays a restricted pattern of expression [49]. Each regulatory subunit contains a p110-binding region flanked by an SH2 domain, and p85 α and p85 β have an

NH₂-terminal SH3-domain that is replaced by short unique sequences in p55 α , p50 α , and p55^{PIK}. The importance of these structural differences is unknown.

During insulin stimulation, phosphorylated YMXM motifs in IRS-proteins occupy both SH2 domains in the regulatory subunits which directly activates the PI 3-kinase [8]. Products of the PI 3-kinase, including phosphatidylinositol 3,4-bisphosphate and phosphatidylinositol 3,4,5-trisphosphate, recruit and activate the PDK(1/2) → PKB (1/2/3) cascade (Fig. 2). During colocalization at the plasma membrane, PDKs phosphorylate and activate PKB isoforms, which control various biological processes, including glucose transport, protein synthesis, glycogen synthesis, cell proliferation, and cell survival in various cells and tissues (Fig. 2) [14,50,51].

The role of IRS-proteins in PI 3-kinase signaling is complex, as IRS1 and IRS2 play distinct regulatory roles in liver and muscle. Basal PI 3-kinase activity in muscle and liver is

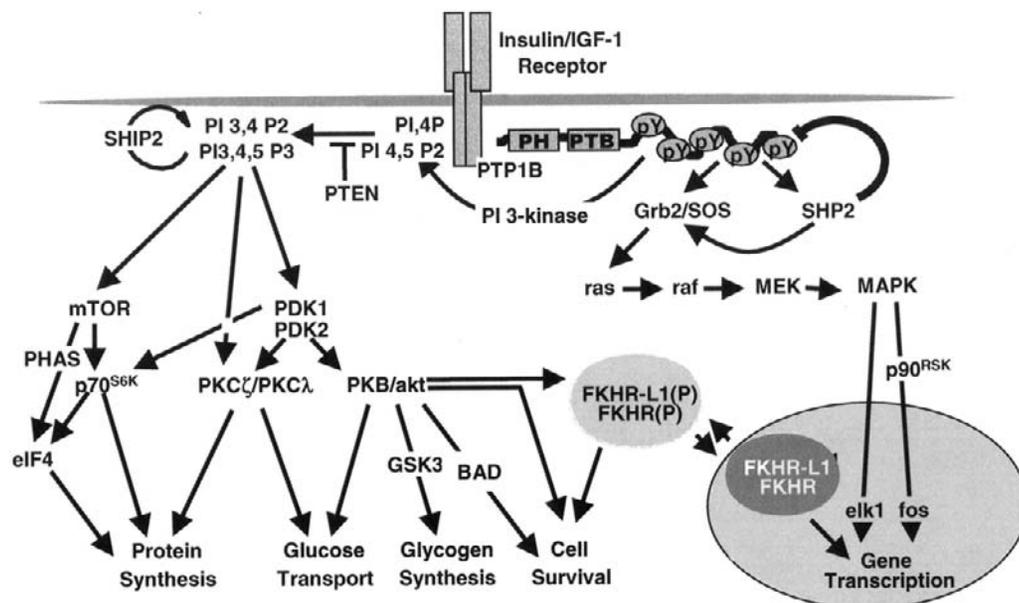

Figure 2 IRS-proteins coordinate downstream signaling pathways; the activation of intracellular signaling pathways by insulin is shown. The diversity of insulin action in various tissues is partly explained by the different signaling pathways activated by the hormone. The two main limbs that propagate the signal generated through the insulin receptor are the insulin receptor substrate/phosphatidylinositol 3-kinase (IRS/PI3K) pathway, and the Ras/mitogen-activated protein kinase (MAPK) pathway. Activation of the receptors for insulin and IGF1 results in tyrosine phosphorylation of the IRS-proteins. The IRS-proteins bind PI 3-kinase, Grb2/SOS, and SHP2. The GRB2/SOS complex mediates the activation of p21^{ras}, thereby activating the ras → raf → MEK → MAP kinase cascade. SHP2 feeds back to inhibit IRS-protein phosphorylation by direct dephosphorylation of the IRS-protein but might also transmit an independent signal to activate MAP kinase. The activated MAP kinase phosphorylates p90^{RSK}, which itself phosphorylates *c-fos*, thus increasing its transcriptional activity. MAP kinase also phosphorylates ELK1, also increasing its transcriptional activity. The activation of PI 3-kinase by IRS-protein recruitment results in the generation of PI3,4P₂ and PI3,4,5P₃ (antagonized by the action of PTEN or SHIP2). In aggregate, PI3,4P₂ and PI3,4,5P₃ activate a variety of downstream signaling kinases, including mTOR, which regulates protein synthesis via PHAS/p70^{S6k}/EIF4. These lipids also activate alternate PKC isoforms and PDK isoforms. The PDKs activate protein kinase B (PKB), which appears to mediate glucose transport in concert with the atypical PKC isoforms. PKB also regulates GSK3, which may regulate glycogen synthesis, and a variety of regulators of cell survival. PKB-mediated BAD phosphorylation inhibits apoptosis, and phosphorylation of the forkhead proteins results in their sequestration in the cytoplasm, in effect inhibiting their transcriptional activity. Abbreviations: AKT, product of the *akt* protooncogene; GAP, guanosine-triphosphatase-associated protein; GLUT4, glucose transporter 4; GRB-2, factor receptor binding protein 2; GSK3, glycogen synthase kinase 3; MAPKK, MAPK kinase; PDK, PI-dependent protein kinase; PKC, protein kinase C; SOS, son-of-sevenless.

elevated upon disruption of IRS2, which reduces the relative increase during insulin stimulation (Fig. 3). By contrast, without IRS1, basal PI 3-kinase activity is reduced significantly while insulin-stimulated activity is preserved, so the relative activation by insulin is increased. Apparently, IRS1 has a greater impact on basal PI 3-kinase activity and IRS2 has it greatest impact on insulin-stimulated activity. Thus, IRS2 might be the principle regulator of the metabolic insulin actions in liver and muscle [52].

The PI 3-kinase regulatory subunits also influence the signal specificity and signal strength. Complete disruption of the *Pik3r1* gene that eliminates p85 α , p55 α , and p50 α causes death of newborn mice [53]. By contrast, complete disruption of *Pik3r2* is not lethal [48]. Interestingly, mice lacking p85 β display improvised insulin sensitivity. These results suggest that the strength of the IRS \rightarrow PI 3-kinase signal might be determined, at least in part, by the stoichiometry between the regulatory and catalytic subunits. Because the number of regulatory subunits generally exceeds that of the catalytic subunits, a competition apparently exists for IRS-protein binding sites between catalytically competent heterodimers and catalytically deficient regulatory monomers [48,54]. This hypothesis is supported by the finding that the selective reduction of p85 α increases insulin sensitivity [48]. Although the stoichiometry between IRS-proteins and PI 3-kinase regulatory subunits is important for signal strength, other mechanisms might also contribute to feedback inhibition through direct inhibition of IRS-protein function.

IRS-Protein Signaling in Growth, Nutrition, and Longevity

The disruption of IRS-proteins in mice and flies reveals their role of coordinating multiple biological processes, including growth, nutrition, and fertility. The framework relating IRS-proteins to these biological processes might be easier to establish in *Drosophila*, because fewer signaling protein are involved. Deletion of Chico, the *Drosophila* IRS-protein, causes female sterility as well as reduced somatic growth and increased lipid storage [55]. Moreover, specific mutations of the binding sites for the *Drosophila* PI 3-kinase adapter p60 completely abrogates Chico function in growth control; however, mutating the consensus binding site in Chico for Grb2/Drk, which regulates the *ras* cascade, does not interfere with growth [28]. The important role of the PI 3-kinase cascade is further supported by the finding that growth is restored in Chico mutants by reducing the level of the PTEN ortholog, confirming that the PI 3-kinase cascade is a critical pathway for growth regulation [28].

In mice, the PI 3-kinase \rightarrow PKB cascade also regulates growth, but the control appears to be parsed between IRS1 and IRS2. Mice lacking IRS1 are about 50% smaller, where IRS2 $^{-/-}$ mice are nearly normal size; however, mice lacking alleles of each gene reveal a role for IRS2 in growth (Fig. 4). Growth curves based on daily weights from birth to 30 days

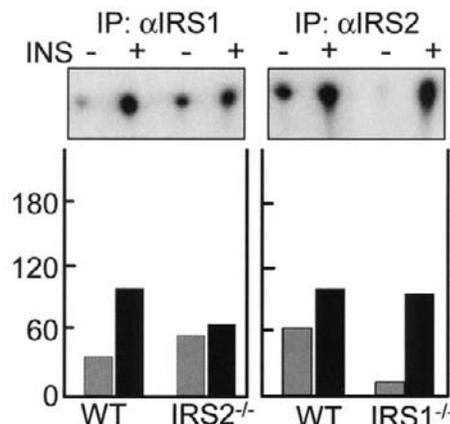

Figure 3 Phosphorylation of IRS1 or IRS2 and activation of PI 3-kinase in mouse liver. Wild-type mice, or mice retaining expression of IRS2 (IRS1 $^{-/-}$ mice) or IRS1 (IRS2 $^{-/-}$ mice) were stimulated with insulin as previously described [56]. Both IRS1 and IRS2 are tyrosine phosphorylated during insulin stimulation; however, the activation of the PI 3-kinase is distinctly different. In IRS2 $^{-/-}$ liver, IRS1 barely mediates insulin-stimulated activation of the PI3K because the basal activity is relatively high. By contrast, in *Irs1* $^{-/-}$ livers, *Irs2* strongly promotes insulin-stimulated activation of the PI 3-kinase because the basal activity is relatively low. This difference has been detected in 6-week-old mice when the circulating insulin levels are approximately equivalent.

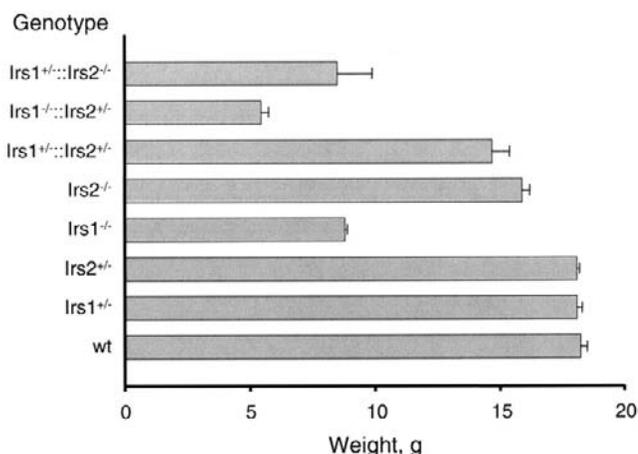

Figure 4 Growth characteristics of progeny of IRS1 $^{+/-}$ \times IRS2 $^{+/-}$ intercross; mean weights \pm SEM of mice of the various genotypes on a C57Bl/6 \times 129SV background at 30 days of age. Data are from 170 litters with a total of at least 4 animals per genotype [98].

of age reveal that *Irs1* $^{+/-}$ mice, *Irs2* $^{+/-}$, and IRS2 $^{-/-}$ mice are normal compared to controls [56]. Compound heterozygous mice (IRS1 $^{+/-}$ \times IRS2 $^{+/-}$) weigh 25% less than wild-type animals, whereas IRS1 $^{+/-}$ \times IRS2 $^{+/-}$ mice were of similar size to IRS1 $^{-/-}$ animals (Fig. 4). By contrast, IRS1 $^{-/-}$ \times IRS2 $^{+/-}$ are nearly 75% smaller than normal throughout their life. IRS1 $^{-/-}$ \times IRS2 $^{+/-}$ mice are among the smallest viable mice that have been generated from a variety of knockout strategies aimed at components of growth factor signaling pathways and demonstrate that a single copy of IRS-2 is sufficient to allow viability of very small mice, but only for a year. It is important to emphasize that owing to multiple system failure

in $Irs1^{-/-} \times Irs2^{+/-}$ mice, longevity is markedly reduced. The popular conclusion based on work with invertebrates that partial inhibition of insulin and IGF signaling extends life span must be applied to mammalian system with caution [57]; however, application of this hypothesis to specific tissues might be another story.

Interleukin-4 and IRS2 Signaling

IRS2 was originally identified as a tyrosyl-phosphorylated protein called 4PS in interleukin-4 (IL-4)-stimulated cells [58]. 4PS was also stimulated by insulin and insulin-like growth factor 1 (IGF1), and IL-4- or insulin-insensitive 32D cells lacking 4PS were rescued by expression of IRS1 [59]. Although 4PS was found to comigrate with IRS1 during sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE), IRS1 antibodies failed to immunoprecipitate it, suggesting that 4PS was a distinct protein [60]. The cloning of 4PS revealed a novel protein with important similarity to IRS1 (Fig. 1), so its name was changed to IRS2 even before its central importance to insulin action and secretion was realized [61].

The story of IRS2 reveals an unexpected and possibly important molecular link between immune system function and nutrient homeostasis. IL-4, a multifunctional cytokine made by T helper type 2 (Th2) cells, basophils, mast cells, and NK1.1 T cells, influences the viability, proliferative capacity, and differentiation of B and T cells, as well as other cell types [62]. Cellular responses to IL-4 are mediated through the IL-4 receptor alpha chain (IL-4R α) functioning as a heterodimer with the common gamma chain (γ c) [63]. During IL-4 stimulation, the PTB domain of IRS2 binds to the phosphorylated NPAY motif in the activated IL-4R α chain, promoting IRS2 tyrosine phosphorylation and signaling [64]. Other proteins in addition to IRS2 are also phosphorylated in response to IL-4R stimulation, such as JAK1 and JAK3, which phosphorylate IRS2 and other cellular proteins including FRIP, SHIP, SHP2, and the transcription factor STAT6 [65]. STAT6 plays an important role during IL-4 signaling by directly regulating gene expression that controls differentiation and cell growth [66]; however, IRS2 also plays an important role in the mitogenic response of T lymphocytes to IL-4 and in the development of Th2 cells *in vitro* [65].

In addition to IL4, other cytokines promote IRS1 or IRS2 tyrosine phosphorylation, including IL-7, IL-9, and IL-13; growth hormone; prolactin and leukemia inhibitory factor (LIF); and interferon [14]. In particular, comparisons between IL-4 and IL-9 reveal unique signaling [67]. IL-4 and IL-9 receptors share the common IL-2R γ chain, so the signaling mechanism that establishes cytokine specificity and redundancy are not well understood. However, unlike IL-9, IL-4 receptors utilize IRS-protein in unique ways. IL9-R α does not contain an NPXY motif to engage the PTB domain of IRS1 or IRS2, so it couples through the pleckstrin homology. Unlike IL-4 signaling, IL-9 does not promote SHP2 binding

and does not require PKB activation for cell proliferation [67]. Thus, IRS-protein scaffolds provide a common interface between various membrane receptor, but mediate distinct signals depending on the cell context and the type of receptor involved.

Heterologous Regulation of IRS-Protein Signals

Infection, traumatic stress, obesity, inactivity, and aging are common physiologic causes of insulin resistance that contribute to various metabolic disorders, including diabetes. Experiments with transgenic mice and clinical investigation reveal that insulin resistance associated with diabetes is usually accompanied by downregulation of IRS-protein expression and function [68]. A common mechanism explaining the occurrence of acute or chronic insulin resistance in people is difficult to identify. Mutations in the insulin receptor are an obvious source of life-long insulin resistance, but these are rare and not necessarily accompanied by β -cell failure [69–72]. Recent experiments with transgenic mice teach us that dysregulation at many steps in the signaling cascade (especially regulatory interactions) might lead to insulin resistance. Elevated activity of protein or lipid phosphatases, including PTP1B, SHIP2, or PTEN, might be a clinically relevant cause of insulin resistance. Inhibition of these phosphatases by gene knockout or by chemical inhibitors increases glucose tolerance, suggesting that specific phosphatase inhibitors might be useful treatments for diabetes [73–75]; however, modulation of the activity of shared signaling proteins might result in undesirable phenotypes, including activation of signals that promote cancer.

Various cytokines or metabolites promote serine phosphorylation of the IRS-proteins which inhibits signal transduction and causes insulin resistance. Adipose-derived cytokines, especially tumor necrosis factor alpha (TNF α), inhibit signaling by serine phosphorylation of IRS1/IRS2 [76–78]. The signaling cascades regulated by TNF α are complex and involve many branch points, including the activation of various serine kinases and transcription factors that promote apoptosis or proliferation [79]. Inhibition of I κ B kinase (IKK β) with high doses of salicylates reverses hyperglycemia, hyperinsulinemia, and dyslipidemia in obese rodents by sensitizing the insulin signaling pathway [80,81]. Although no physical interaction occurs between IRS-proteins and IKK β , salicylates increase insulin-stimulated tyrosine phosphorylation of the IRS-proteins in the liver, suggesting that IKK β might indirectly inhibit insulin receptor function or its coupling to the substrates [82].

A more direct mechanism to inhibit IRS-protein function might involve activation of the c-Jun N-terminal kinase (JNK) [83–85]. JNK is a prototype stress-induced kinase that is stimulated by many agonists during acute or chronic inflammation. JNK phosphorylates numerous cellular proteins, including IRS1 and IRS2, Shc and Gab1 [86]. A role for JNK during insulin action is compelling, as both IRS1 and IRS2 contain JNK-binding motifs, originally identified

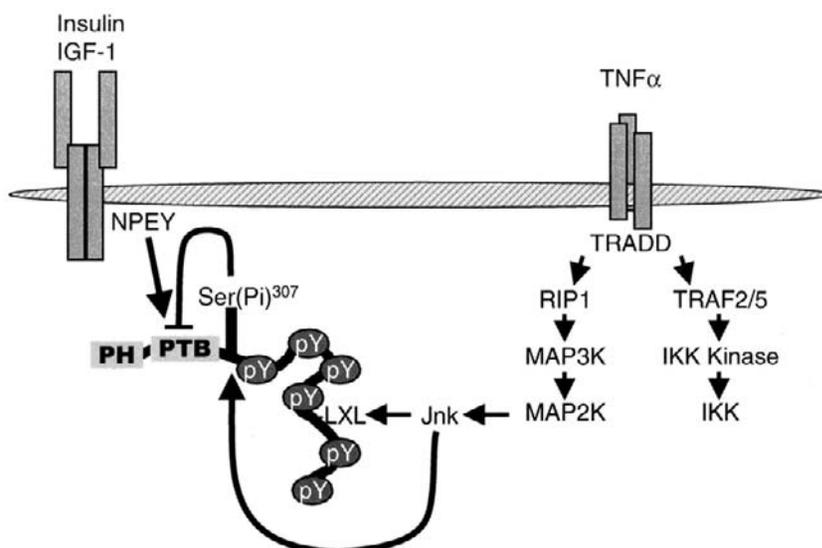

Figure 5 TNF α -induced inhibition of Irs-protein signaling. TNF α binding to TNFR1 results in recruitment of TRAF2/5, RIP1, and FADD through the adapter protein TRADD. TRAF2/5 and RIP1 appear to lead to activation of the protein kinases JNK and IKK. Activated JNK associates with IRS-1 and the JNK-binding LXL motif and promotes phosphorylation of Ser³⁰⁷. Phosphorylation of Ser³⁰⁷ inhibits PTB domain function and inhibits insulin/IGF-stimulated tyrosine phosphorylation and signal transduction. Abbreviations: FADD, Fas-associated death domain protein; IKK, I κ B kinase; JNK, c-Jun N-terminal kinase; RIP1, receptor-interacting protein 1; TNF α , tumor necrosis factor α ; TNFR1, TNF receptor type 1; TRAF2, TNF-receptor-associated factor 2.

in the JNK-interacting proteins JIP1 and JIP2. This motif mediates the specific association of JNK with IRS1, which promotes serine phosphorylation on the COOH-terminal side of the PTB domain, which inhibits recruitment to the insulin receptor (Fig. 5). Insulin also promotes the binding of active JNK to IRS-proteins, suggesting that it might mediate negative feedback control (Fig. 5).

Degradation of IRS-proteins is also regulated and might contribute to inhibition of insulin signaling. Prolonged insulin stimulation substantially reduces IRS1 and IRS2 protein levels in multiple cell lines, which is blocked by specific inhibitors of the 26S proteasome [87]. These results suggest that proteasome-mediated degradation of IRS2, rather than inhibition of transcription and/or translation of IRS2, determines protein levels and activity of IRS2-mediated signaling pathways [74]. Consistent with this idea, insulin stimulates the ubiquitination of IRS2 [88]. Reduction of IRS2 by ubiquitin/proteasome-mediated proteolysis in mouse embryo fibroblasts lacking IRS1 dramatically inhibits the activation of AKT and ERK1/2 in response to insulin/IGF1; strikingly, proteasome inhibitors completely reverse this inhibition. The activity of the ubiquitin/proteasome system is elevated in diabetes, which might promote degradation of the IRS-proteins and exacerbate insulin resistance [89,90].

IRS2 and Pancreatic β -Cells

Peripheral insulin resistance is a well-known component of Type 2 diabetes, but it clearly is not enough, as clinical

experience and work with many transgenic mice reveal [91]. However, a compelling molecular link to diabetes emerges from the finding in mice that inhibition of the IRS2 branch of the insulin/IGF signaling system impairs the capacity of the pancreatic β -cells to compensate for insulin resistance [21,56]. Not only do IRS2^{-/-} mice develop peripheral insulin resistance, but they also eventually fail to sustain compensatory insulin secretion [56]. The convergence of peripheral and islet defects around the IRS2 branch of the insulin/IGF signaling pathway reveals a common pathway to diabetes.

In mice, IRS1 and IRS2 contribute to peripheral insulin response, and there is no reason to suspect different roles for these proteins in people [27,56,92]. IRS1 exerts its greatest effect on metabolism by regulating insulin signals in muscle and adipose tissue, whereas it plays a lesser role in mediating the effects of insulin on liver metabolism [56,93–97]. But, IRS1^{-/-} mice never become diabetic because they develop lifelong compensatory hyperinsulinemia. The amount of functional β -cell mass increases throughout the life of IRS1^{-/-} mice, and the β -cells continue to detect changes in the serum glucose levels [93,98]. By contrast, IRS2^{-/-} mice display dysregulated lipolysis, peripheral glucose uptake, and hepatic gluconeogenesis and ultimately develop diabetes due to β -cell failure [99]. Although IRS2^{-/-} mice are nearly normal at birth and up to weaning, IRS2^{-/-} mice develop hyperinsulinemia as young adults; males die at 12 weeks of age and females by 30 weeks of age [100]. As the disease progresses, pancreatic islet size invariably decreases and β -cell function fails [98].

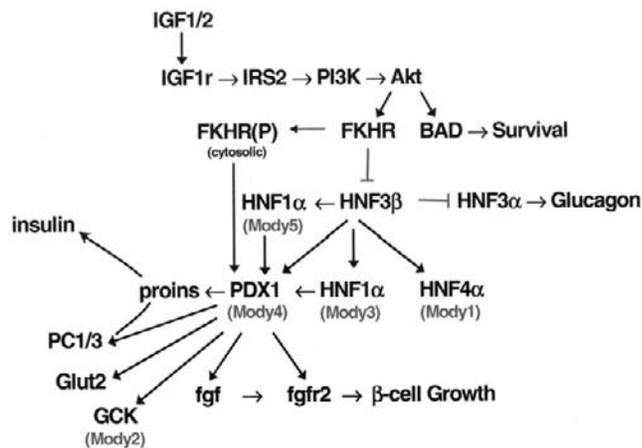

Figure 6 A potential pathway linking IRS2 signaling to the expression and function of the homeodomain transcription factor PDX1. The diagram shows the relation between the MODY genes, especially PDX1, and the IRS2 branch of the insulin signaling pathway [101]. Drugs that promote IRS2 signaling are expected to promote PDX1 function in β -cells which will support glucose tolerance and cure diabetes.

The progressive loss of β -cell function and the onset of diabetes in $Irs2^{-/-}$ mice might be associated with decreased expression in pancreatic islets of the homeodomain transcription factor PDX1 (also called IDX1 and IPF1) [101]. PDX1 is critical for the development of the pancreas in mice and people, and pancreas agenesis occurs upon the complete disruption of PDX1 [102,103]. Moreover, PDX1 is required in adult humans and mice to promote normal glucose sensing and insulin secretion [104,105]. Genetic defects in the PDX1 gene occur in about 5% of people with Type 2 diabetes. Inactivating mutations are associated with autosomal early-onset diabetes (MODY), whereas missense mutations predispose humans to late-onset Type 2 diabetes [106,107]. The functional association between IRS2 signaling and Pdx1 expression observed in mice creates a molecular link between Type 2 diabetes and the less frequent and less severe autosomal forms of diabetes (MODY) [101]. Dysregulation of PDX1 by genetic or functional mechanisms might be one of the common links between early-onset (MODY) and ordinary Type 2 diabetes (Fig. 6). This hypothesis is supported by the finding that transgenic expression of PDX1 postpones β -cell failure and reduces by years the progression of diabetes in $Irs2^{-/-}$ mice [108]. If insulin resistance in people includes an IRS2 component, then reduced PDX1 function might eventually impair β -cell function as noted in people with MODY, and drugs that promote the IRS2→Pdx1 pathway might provide new strategies to promote β -cell growth and function in both Type 1 and Type 2 diabetes.

Summary

The IRS-protein family, particularly IRS-2, plays a fundamental role in insulin and IL-4, IL-7, and IL-9 signaling. Failure of IRS2 might be central to the development of Type 2

diabetes and its associated complications by dysregulating multiple biological processes, including peripheral insulin sensitivity, insulin secretion, and the immune response. Moreover, understanding the function of IRS-proteins during inflammatory responses might reveal rational approaches to modify the effect of stress on cell function and metabolism. Understanding the differences between IRS1 and IRS2 for growth control might reveal strategies to slow general tissue aging or tumor growth while promoting peripheral insulin action and the survival and regeneration of pancreatic β -cells.

Eph Receptors

Rüdiger Klein

*Department of Molecular Neurobiology,
Max-Planck Institute of Neurobiology,
Martinsried, Germany*

Introduction

Eph receptors represent the largest known family of receptor tyrosine kinases (RTKs) and are activated by interaction with cell-surface ligands, termed *ephrins*, presented by neighboring cells. The physiological roles of Ephs and ephrins range from early embryonic developmental processes such as cell migration and the establishment of compartment boundaries to processes in the adult brain, such as the regulation of neuronal plasticity. At the cellular level, ephrins guide migrating cells and navigating axonal growth cones by repulsion; that is, they induce, via Eph receptor signaling, the local collapse of cellular processes, thereby redirecting cellular growth. In other processes, ephrins may regulate cellular adhesion and de-adhesion and thereby influence cellular behavior. A peculiarity of this ligand–receptor system is that signals are transduced not only by the Eph receptor (referred to as *forward signaling*), but also by the ephrin ligand (referred to as *reverse signaling*). Components of the signaling pathways downstream of Ephs and ephrins have been characterized and correlated with biological functions [1]. This chapter summarizes current knowledge on Eph and ephrin signaling and makes reference to recent reviews summarizing the relevant biology.

Ephs and Ephrins

Eph receptors are type I transmembrane proteins with amino termini located outside of the cell; they have a single transmembrane-spanning region. The Eph ectodomain contains two fibronectin type III (FnIII) repeats, a cysteine-rich region with homology to EGF-like repeats, and an amino-terminal globular domain that constitutes the primary ligand

binding region. Based on sequence similarity and ligand affinity, Eph receptors are subdivided into an A subclass, which contains eight members (EphA1–EphA8) and a B subclass, which contains six members (EphB1–EphB6) [18]. The ephrins also fall into two subclasses (A and B) based on their mode of membrane attachment. The ephrinA ligands (ephrinA1–A5) are tethered to the cell surface via a glycosylphosphatidylinositol (GPI) anchor, whereas ephrinB ligands (ephrinB1–B3) contain a transmembrane domain and a cytoplasmic tail. EphA receptors typically bind most or all ephrinA ligands, and EphB receptors bind to most or all ephrinB ligands, with the exception of the EphA4 receptor, which binds both groups of ephrin ligands. Membrane attachment and clustering appear to be required for ephrins to activate receptors, because only membrane-bound or artificially clustered ligands, but not soluble ligands, can trigger receptor signaling. Because Eph receptors and ephrins are both membrane-bound molecules, it is believed that they mediate direct cell–cell communication rather than long-range interactions. For practical reasons, however, signaling is typically studied using soluble fusion proteins consisting of the Fc portion of human immunoglobulin G (IgG) fused to the ectodomain of either ephrin or Eph (i.e., ephrin-Fc and Eph-Fc, respectively).

Eph Receptor Signaling Via Cytoplasmic Protein Tyrosine Kinases

Upon ligand binding, Eph receptors are thought to dimerize, perhaps oligomerize, and autophosphorylate specific tyrosine residues of the cytoplasmic part of the partner receptor. Somewhat unusual among RTKs, Eph kinase activity is autoinhibited by the unphosphorylated juxtamembrane

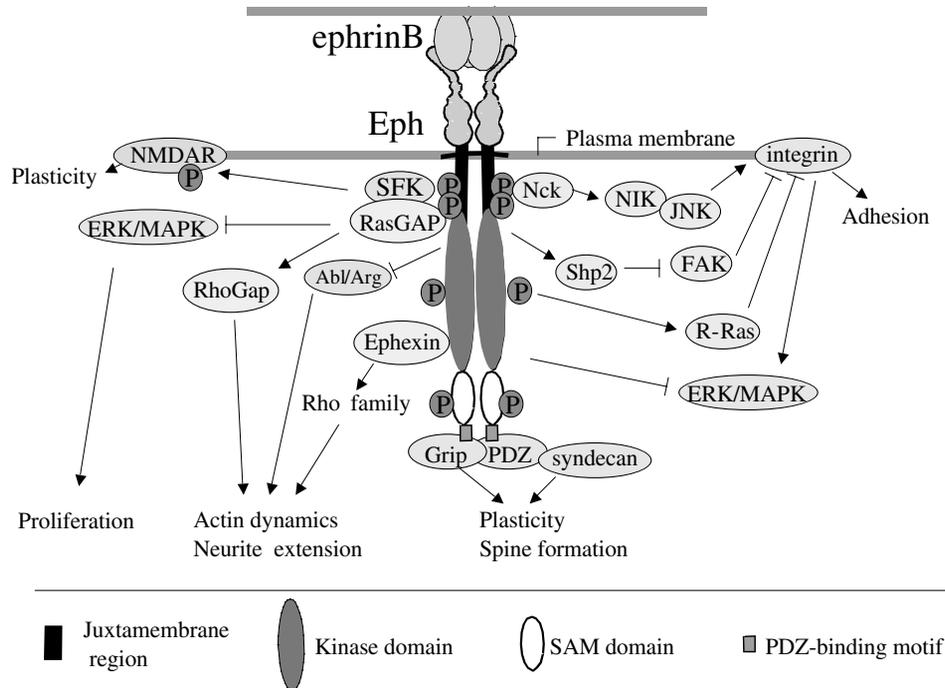

Figure 1 Eph receptor structure and cytoplasmic interactions. The intracellular part of Eph receptors consists of a juxtamembrane region, tyrosine kinase domain, SAM domain (of unknown function), and a PDZ binding site. Upon engagement with ephrins attached to the cell surface, Eph receptors dimerize, perhaps form oligomeric complexes, and autophosphorylate at several tyrosine residues (orange circles). Signaling effectors containing SH2 domains (SFKs, Abl/Arg, RasGAP, Nck) are recruited to these phosphotyrosines. Other effectors bind to the kinase domain (ephexin) or to the PDZ target site (Grip). Again, other effectors may interact with Ephs in an indirect manner (additional interactors are described in references [1], [3], and [18]). Cellular functions mediated by Eph forward signaling include regulation of actin dynamics and suppression of neurite extension, block of proliferation and integrin mediated adhesion, promotion of spine formation, and neuronal long-term plasticity (see text for details).

region, and autophosphorylation of juxtamembrane tyrosine residues not only creates docking sites for phosphotyrosine binding proteins but also releases autoinhibition [2]. Among the first proteins to be identified as Eph effectors were Src family kinases (SFKs), which bind to juxtamembrane phosphotyrosine residues via their SH2 domains (Fig. 1) [3]. Although SFKs mediate mitogenic effects in many cellular contexts, as downstream effectors of Ephs they are more likely to regulate cytoskeletal changes. Activated forms of Src kinases have been implicated in the phosphorylation of various cellular proteins, such as paxillin, Fak, and tensin, which are associated with integrin-harboring focal adhesions and with proteins such as p120 and β -catenin found in cadherin-containing adherens junctions [1].

Recently, the EphB2 receptor was shown to interact and to form clusters with the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors at excitatory synapses in primary neurons [4]. Stimulation with soluble ephrinB-Fc triggered EphB forward signaling through SFKs and caused tyrosine phosphorylation of NMDA receptors. The latter process required SFK activation, as shown by the usage of SFK inhibitors [5]. Functionally, EphB2 protein, but not EphB2 kinase activity, was required for protein-synthesis-dependent, long-lasting changes in neuronal plasticity in the

hippocampus [6] [7]. Plasticity defects in ephB2 null mutant mice correlated with defects in performance for learning paradigms requiring an intact hippocampus. Whether or not the interaction of EphB2 with NMDA receptors and the activation of SFKs account entirely for the observed defects remains to be investigated.

The Abelson cytoplasmic tyrosine kinase (Abl) and the Abl-related gene product (Arg) also bind EphB2 and EphA4 receptors via phosphotyrosine-dependent and -independent interactions [8]. Unlike SFKs, Abl and Arg kinase activities are decreased by activated Ephs. Abl kinase is thought to promote neurite growth, whereas Eph forward signaling leads to localized growth-cone collapse and to repulsive guidance of growing axons. Inhibition of Abl kinase may be one of the mechanisms by which Ephs prevent local axonal growth.

Eph Receptor Signaling Via Rho Family GTPases

The small GTP-binding proteins of the Rho GTPase family, including RhoA, Rac, and Cdc42, are important regulators of the actin cytoskeleton and neuronal morphogenesis [9]. Rho GTPases are molecular switches that cycle between

an active GTP-bound state and an inactive GDP-bound state. GTP-bound forms are converted into GDP-bound forms by the action of GTPase-activating proteins (GAPs), whereas guanine nucleotide exchange factors (GEFs) perform the opposite conversion. The Rho-specific GAP, p190RhoGAP, is indirectly recruited to activated EphB2 by binding to p120RasGAP, which binds juxtamembrane phosphotyrosine residues of EphB2 via its SH2 domain [10]. The consequences of p190RhoGAP recruitment to EphB2 are not entirely clear; however, p190RhoGAP appears to be an important link between SFKs and the regulation of neurite outgrowth and axon guidance. Src-mediated phosphorylation of p190RhoGAP is required for binding to p120RasGAP, and mice lacking p190RhoGAP display defects in axon tract formation and fasciculation, reminiscent of the defects seen in mice lacking EphB2 receptors [11].

EphA receptor signaling was also connected to Rho family GTPases, although different *in vitro* assays were employed and direct comparisons are difficult to draw up. Conversely, EphA receptors bind Ephexin (Eph-interacting exchange protein), a novel Rho family GEF required for ephrinA-induced growth-cone collapse of retinal ganglion cells [12,13]. Ephexin appears to have differential effects on Rho GTPases, such that RhoA is activated but Cdc4 and Rac are inhibited, at least *in vitro*. Ephexin-mediated activation of RhoA shifts actin cytoskeleton dynamics to increased contraction and reduced extension, providing an explanation how Ephexin may mediate growth-cone collapse.

Effects on Cell Proliferation

In contrast to other RTKs, Eph receptor forward signaling does not provide a mitogenic stimulus, despite the recruitment of SFKs and the adaptor Grb2 [1]. One possible mechanism may be the recruitment of SLAP, a non-catalytic Src-like adaptor protein that may compete with SFK binding to Ephs and thereby suppress mitogenesis [14,15]. More recently, EphA and EphB forward signaling was shown to suppress MAPK signaling [16,17]. MAPK activation by platelet-derived growth factor (PDGF) and vascular endothelial growth factor (VEGF) of different cell lines was reduced by application of ephrinA1 [17]. Moreover, ephrinB1-induced activation of EphB2 in neuronal cells downregulated the levels of GTP-bound Ras, which caused collapse of growth cones and retraction of neurites. Expression of a dominant active form of Ras reversed EphB2-mediated neurite retraction [16].

Eph Receptor Signaling through PDZ-Domain-Containing Proteins

The PDZ binding motif in the carboxy terminus of most Eph receptors has been shown to bind PDZ-domain-containing proteins, including syntenin, Pick1, Grip, and AF6 [18]. For most of these reported interactions, the functional significance

of binding is unknown. A recent study has demonstrated that, *in vitro*, the EphB2 carboxy terminus binds the AMPA-type glutamate receptor GluR2 in membranes prepared from rat brain. This interaction is likely to be indirect through the multi-PDZ-domain protein Grip1, which binds EphB2 and GluR2 using different PDZ domains. Interfering with EphB2–PDZ interactions by infusion of EphB2 C-terminal peptide or EphB2 anti-C-terminal antibodies has led to a decrease in tetanus-induced long-term potentiation (LTP) at the mossy fiber–CA3 synapse. Contractor *et al.* [19] speculated that the ephrinB–EphB signaling system may regulate synaptic plasticity by providing a retrograde signal that links postsynaptic induction of LTP to presynaptic changes in neurotransmitter release.

Postsynaptic Eph signaling may also regulate dendritic spine morphogenesis, potentially involving interactions with PDZ domain proteins [20]. The transmembrane cell-surface proteoglycan syndecan-2 induces the formation of morphologically mature dendritic spines in immature hippocampal neurons, in part via regions in its cytoplasmic domain that contain potential tyrosine phosphorylation sites. Activated EphB2 receptors phosphorylate syndecan-2 on tyrosine residues and induce clustering of syndecan-2. Phosphorylated syndecan-2 acquires the ability to recruit cytoplasmic proteins, including PDZ-domain proteins CASK, syntenin, and synbindin, which may also interact with EphB2. It is this complex that is thought to promote the morphological maturation of spines [20].

Eph Receptors and Cell Adhesion

Eph receptors seem to regulate cell adhesion primarily by modulating integrin signaling (Fig. 1). Integrins are receptor molecules embedded in the plasma membrane and consist of two polypeptides: α and β chains. Their ectodomains bind extracellular matrix proteins such as laminin, collagen, and fibronectin. Focal adhesion kinase (FAK) is a cytoplasmic tyrosine kinase that links integrin receptors to intracellular signaling pathways. Activation of endogenous EphA2 in tumor cell lines suppresses integrin-mediated cell adhesion by recruiting the protein tyrosine phosphatase SHP2 and by dephosphorylation of FAK [21]. Similarly, activation of EphB2 inhibits cell adhesion through phosphorylation of R-Ras, which suppresses the ability of R-Ras to support integrin activity [22]. These studies are in contrast to the findings in P19 teratocarcinoma cell lines, in which EphB1 signals pro-adhesion to fibrinogen via recruitment of Nck and activation of Nck-interacting Ste20 kinase (NIK) and c-Jun N-terminal kinase (JNK) [23].

Ephrin Reverse Signaling

The concept of ephrin reverse signaling is well established for ephrinB ligands, whose cytoplasmic regions make them look like receptor molecules. GPI-anchored ephrinA

ligands may also signal by interaction with other raft-associated proteins, including Src family kinases [24], or by interaction with an unknown protein that spans the membrane. Evidence for ephrinA reverse signaling was derived from genetic studies in *Caenorhabditis elegans*, whose genome contains four potential GPI-anchored ephrins and one Eph receptor (VAB-1). Different alleles of VAB-1 have been shown to have different effects on cellular organization and have suggested the kinase-independent functions of VAB-1, consistent with reverse signaling by *C. elegans* ephrins [25,26].

EphrinB Reverse Signaling Via Phosphotyrosine

Phosphorylation of conserved tyrosine residues in the cytoplasmic domain of ephrinB ligands is thought to be a critical event in triggering reverse signaling. EphrinB phosphorylation is induced either by stimulation with the soluble ectodomain of Eph receptors or by contact with neighboring cells expressing Eph receptors. Alternatively, ephrinB phosphorylation can be induced by treatment of cells with fibroblast growth factor (FGF) or platelet-derived growth factor (PDGF) via the co-expressed FGF or PDGF receptors. Src family kinases are regulators of ephrinB phosphorylation induced by the EphB ectodomain. SFKs are rapidly recruited into ephrinB-positive membrane patches, and their kinase activity is activated by treatment of cells with the soluble EphB ectodomain (Fig. 2). Most importantly, SFK activity is required for EphB-induced sprouting of endothelial cells that express ephrinB ligands.

Phosphotyrosine-dependent signaling is at least in part mediated by recruitment of the SH2-SH3 adaptor protein

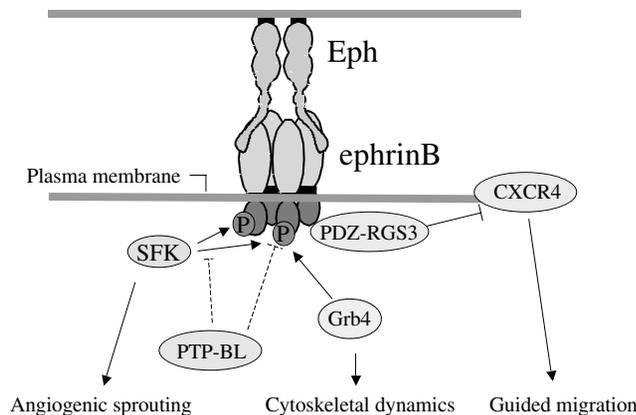

Figure 2 Structure of ephrinB ligand and associated signaling molecules. Upon binding of their cognate Eph receptor on neighboring cells, ephrinB ligands are clustered and Src family kinases (SFKs) are rapidly recruited to ephrinB clusters. SFKs phosphorylate the ephrinB cytoplasmic tail, which leads to angiogenic sprouting through an unknown mechanism. Phospho-ephrinB recruits the Grb4 adaptor, which mediates changes in cytoskeletal organization. The tyrosine-specific phosphatase PTP-BL negatively regulates Src kinase activity and dephosphorylates ephrinB with delayed kinetics (dashed line). PDZ-RGS3, through binding to ephrinB, suppresses CXCR4-induced cell migration (see text for details).

Grb4, a relative of Nck (which is implicated in Eph forward signaling). The Grb4 SH2 domain, but not the Nck SH2 domain, binds to phosphorylated ephrinB after engagement with EphB receptors. Grb4 binds, through its SH3 domains, to several polyproline-containing proteins (Abi-1, CAP, axin, and others), all of which are modifiers of the actin cytoskeleton. Consequently, recruitment of Grb4 to ephrinB causes loss of polymerized F-actin structures and disassembly of focal adhesions [27].

EphrinB Reverse Signaling Via PDZ Domain Interactions

Similar to Eph receptors, ephrinB ligands carry a C-terminal PDZ binding site, which was shown to interact with a number of PDZ-domain-containing proteins, some of which also interact with Eph receptors, at least *in vitro*; these include syntenin, Pick1, Grip1, Grip2, Fap1, PDZ-RGS3, PTP-BL, and PHIP [18]. For most of these ephrin interactors, it is not known whether they regulate ephrinB localization, clustering, or function. Most notably, PDZ-RGS3 provides a link between cell migration and ephrinB reverse signalling. Coinjection of ephrinB1 and PDZ-RGS3 into *Xenopus* embryos led to de-adhesion of the cells in a PDZ-domain-dependent manner [28]. Furthermore, migration of cerebellar granule cells by stromal-cell-line-derived factor 1 (SDF-1), a ligand of the G-protein-coupled receptor CXCR4, was inhibited by adding clustered EphB2-Fc receptor bodies. EphrinB reverse signaling may activate PDZ-RGS3, which may regulate the critical GEF activity (GTP exchange factor) required for efficient signaling of CXCR4 [28]. The mechanism by which ephrins stimulate the activity of PDZ-RGS3 is not known, but the interaction between ephrinB and PDZ-RGS3 seems to be constitutive.

The protein tyrosine phosphatase PTP-BL appears to be a negative regulator of ephrinB signaling based on its ability to inactivate SFK activity [29,30] and to dephosphorylate ephrinB [30] (Fig. 2). The action of positive regulators of ephrin phosphorylation, such as SFKs, and of negative regulators, such as PTP-BL, appear to be regulated in time, at least *in vitro*. SFKs are recruited with rapid (5 min) kinetics to ephrin-containing clusters, whereas PTP-BL is recruited slowly (30 min). This may be part of a switch mechanism whereby ephrin reverse signaling shifts from phosphotyrosine-dependent to PDZ-dependent signaling [30].

Summary

Eph receptors and their ephrin ligands play important roles in many developmental and plasticity processes, which are rapidly being elucidated, primarily by mouse genetics. Rapid progress is also being made in the biochemical characterization of cytoplasmic interactors of Ephs and ephrins, mainly in immortalized cell lines. Their functional characterization in cell-based assays, however, turns out to be more

difficult; likewise, the cellular mechanisms underlying ephrin-/Eph-mediated biology is in most cases unclear. Axon guidance is probably mediated by repulsive interactions; however, the cellular mechanism underlying vascular remodeling, and neuronal plasticity is currently unknown.

Cytokine Receptor Superfamily Signaling

A number of cytokines can be functionally grouped by their similarity in structure as well as by the similarity of the receptors that they utilize. One group of 26 cytokines (Table 1) is characterized by a common predicted 4- α -helical bundle structure [1]. This group of cytokines is further characterized by their common utilization of receptors that are members of the cytokine receptor superfamily [2]. The defining structural elements of the receptors include a cytokine binding module that typically contains two fibronectin type III domains with four positionally conserved cysteine residues in the extracellular domain. In the membrane-proximal region of the extracellular domain, most receptors also contain a WSXWS motif of unknown function. The cytoplasmic domains of the cytokine receptors have only very limited similarity, located in the membrane-proximal region and consisting of what has been termed the box 1 and box 2 motifs. Based on structural considerations, the receptors are often further divided into class I and class II receptors, as indicated in Table 1. A single gene (*dom*) in *Drosophila* has functional and structural similarity to the mammalian cytokine receptor superfamily, with the greatest similarity being with the IL-6 subfamily of receptors [3]. This would suggest that the cytokine receptor superfamily has recently evolved to provide expanded opportunities for physiological regulation of cell functions in vertebrates.

As shown in Table 1, a functional cytokine receptor can consist of one or more chains. The nature of the contributions of the individual chains can be quite different depending upon the complex. Frequently a receptor chain contributes only to

affinity of cytokine binding. For example, the α -chain of the interleukin-2 (IL-2) receptor, which is the only receptor component listed in Table 1 that is not structurally of the cytokine receptor superfamily, increases the affinity of the cytokine binding complex approximately 10-fold. Conversely, the α -chain of the IL-6 receptor binds the cytokine either as a component of the cell-surface complex or as a soluble extracellular protein. The complex of IL-6 and the IL-6 receptor α -chain in turn has high-affinity binding for the β component of the complex gp130. Similarly, the receptors for IL-3, granulocyte-macrophage colony-stimulating factor (GM-CSF), and IL-5 have a low-affinity, ligand-specific binding chain (α) that associates with a signal transducing chain that is shared (β_c) or, in the case of IL-3 in mice, with a highly related but specific signaling chain (β_{IL3}). Finally, a number of receptors have two chains that are required for signal transduction. For example, in the IL-2 subfamily of receptors both the unique β -chain and the γ_c are required for signal transduction. Similarly, within the type II receptors, the cytoplasmic domains of both chains are required for signal transduction.

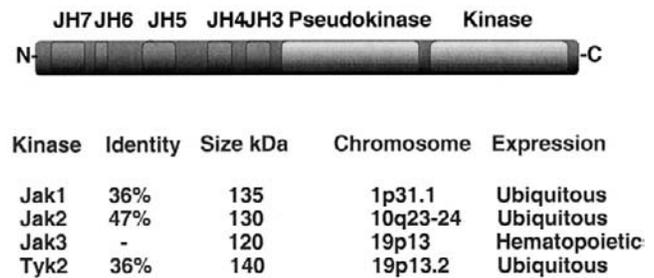

In all the receptor complexes, one or more of the receptor chains associates with one or more of the Janus family of protein tyrosine kinases (Jak), as indicated in Table 1 [4–6]. The Jak family of kinases consists of four members (Fig. 1). The family members have a large amino-terminal domain that contains blocks of homology among family members. It is through this region that the Jaks have been shown to interact with receptor chains. The carboxyl domain contains a pseudokinase domain followed by a functional protein tyrosine kinase catalytic domain. The role of the pseudokinase

Table I

Cytokine receptor	Chains	Associated Janus kinases
Type I receptors		
<i>Single-chain/Jak2</i>		
Erythropoietin (EPO)	1	α (Jak2)
Thrombopoietin (TPO)	1	α (Jak2)
Growth hormone (GH)	1	α (Jak2)
Prolactin (PRL)	1	α (Jak2)
<i>Common β chain</i>		
Interleukin-3	2	α , β_c (Jak2), or β_{IL3} (Jak2)
Granulocyte-macrophage CSF	2	α , β_c (Jak2)
Interleukin-5	2	α , β_c (Jak2)
<i>Common γ or γ-like:</i>		
Interleukin-2	3	α_{IL2} (none), β_{IL2} (Jak1), γ_c (Jak3)
Interleukin-4	2	α_{IL4} (Jak1), γ_c (Jak3)
Interleukin-7	2	α_{IL7} (Jak1), γ_c (Jak3)
Interleukin-9	2	α_{IL9} (Jak1), γ_c (Jak3)
Interleukin-13	2	α_{IL4} (Jak1), α_{IL13} (Tyk2)
Interleukin-15	2	α_{IL15} (Jak1), γ_c (Jak3); α_{IL15} (Jak1), ξ (Jak2)
Interleukin-21	2	α_{IL21} (Jak1), γ_c (Jak3)
Thymic stromal lymphopoietin	2	α_{IL7} (Jak1), γ -like (Jak2)
<i>IL-6 family:</i>		
Granulocyte-CSF	1	α (Jak1, Jak2, Tyk2)
Interleukin-6	2	α , β_{gp130} (Jak1)
Leukemia inhibitor factor	2	α_{LIFR} (Jak1), β_{gp130} (Jak1)
Ciliary neurotrophic factor	3	α_{CNTF} , β_{gp120} (Jak1), β_{LIFR} (Jak1)
Cardiotrophin 1	2	α_{CT1} , β_{gp130} (Jak1), β_{LIFR} (Jak1)
Oncostatin M	2	α_{OSMR} , β_{gp130} (Jak1)
Interleukin-11	2	α_{IL11} , β_{gp130} (Jak1)
Interleukin-12	1	α (Tyk2 or Jak2)
Type II receptors		
Interferon- α,β	2	α (Jak1), β (Tyk2)
Interferon- γ	2	α (Jak1), β (Jak2)
Interleukin-10	2	α (Jak1), β (Jak2)

domain is not known, although some studies have shown that it negatively influences kinase activity and may confer specificity. Unfortunately, no molecular structures have been reported for a Jak. The association of Jaks with receptor chains has been shown to be variable and to exist prior to ligand binding or following ligand binding. Whether the variability is due to technical differences in detecting the association prior to ligand binding or an inherent difference in the nonligated complex is not known.

Irrespective of the number of receptor chains and their individual contributions, the primary function of the complex is to induce the aggregation of the signal transducing component of the complex to activate the associated Jaks.

**Figure 1** Structure and properties of the Janus family of protein tyrosine kinases.

Through the use of cross-linking approaches, ligand induces the aggregation of a number of receptor complexes, resulting in the formation of very large complexes. Recent studies have identified small molecules that can also induce receptor aggregation and thereby mimic ligand binding [7,8]. In one case, it was shown that drug binding occurred at sites distinct from the ligand binding region. Regardless, like ligand binding, drug binding results in the activation of receptor-associated Jaks.

The activation of Jaks involves the transphosphorylation of a specific tyrosine in the activation loop that dramatically increases kinase activity. In addition, there are multiple additional sites of auto- or transphosphorylation, but the potential significance of these additional phosphorylation sites has not been examined in detail. From the structure of the known receptor complexes, it can be deduced that Jak2 is capable of activation in complexes in which Jak2 is the only family member present. However, in the other complexes, it has not been determined whether more than one Jak is required for transphosphorylation between different Jaks. For example, it is known from the phenotypes of Jak-deficient mice that both Jak1 and Jak3 are required for the function of the IL-2 subfamily of cytokines receptors. In addition, evidence has been presented that the Jaks may be required in the receptor complex to form a high-affinity receptor complex [9].

The essential role that the Jaks play in cytokine receptor signaling has been established through the derivation of mice deficient in one or more of the Jaks [4]. For example, a deficiency in Jak3 results in a phenotype of severe combined immunodeficiency (SCID) due to the lack of function of the IL-2 subfamily of cytokine receptors. Genetic deficiencies of Jak3 also occur in children, for whom the deficiency is similar to that associated with a SCID phenotype. Jak2 deficiency is linked with an embryonic lethality caused by the lack of production of sufficient red cells, and Jak1 deficiency is associated with a perinatal lethality and with loss of function of the IL-6 and IL-2 subfamilies of receptors. Finally, Tyk2 deficiency specifically affects the interferon (IFN)- α/β receptor and IL-12. Importantly, in addition to confirming the role of these kinases in cytokine receptor superfamily signaling, analysis of Jak-deficient mice failed to identify an essential role for the kinases in other receptor complexes, in spite of the observation that Jaks have frequently been shown to be inducibly tyrosine phosphorylated

in other receptor systems. In *Drosophila*, a single Jak (hop-scotch, *hop*) is critical for signal transduction through the single *Drosophila* cytokine receptor gene (*Dome*, *dome*) [3]. The identical nature of the phenotypes of mutations of *hop* and *dome* suggest that, as in mammals, the receptor/Jak complex is a dedicated signaling complex.

The cytokine receptor superfamily members activate a variety of signal transduction pathways. One of the most consistently activated pathways is that of induced tyrosine phosphorylation of the transcription factors of the signal transducers and activators of transcription (STATs) family. The details of this family of transcription factors are covered elsewhere in this Handbook; however, in general terms, the STATs mediate the specific physiological functions associated with individual cytokines [10]. For example, the function of IFNs to elicit an antiviral response is dependent on STAT1 and, conversely, the primary function of STAT1 is to mediate these responses. Equally striking, STAT4 and STAT6 mediate the unique physiological responses induced by IL-12 or IL-4, respectively. This specificity is dramatically illustrated by the observation that Epo, Tpo, GH, and PRL all induce the activation of STAT5; the physiological functions of GH and PRL are totally dependent upon this activation, but the functions of Epo and Tpo are not.

In addition to specific physiological functions, however, many cytokines have as their primary function the ability to promote the proliferation and survival of cells. The elements that are involved in this response are largely unknown. For example, the primary function of Epo is to expand early erythroid lineage cells to provide sufficient numbers to sustain embryonic development. This capability is not unique to Epo, as the prolactin receptor can mediate the same expansion [11]. Conversely, the cytoplasmic domain of the Epo receptor can fully support the expansion and differentiation of granulocytes when it replaces the cytoplasmic domain of the G-CSF receptor *in vivo* [12]. The ability of the cytoplasmic domain of the Epo receptor to function requires only a small portion of the cytoplasmic domain and specifically does not require receptor tyrosines or the ability to activate a STAT-dependent pathway [13]. The conclusion from these types of studies is that, in these cases, the primary function of the receptor complex may be to activate the Jaks, which then function in much the same manner as the receptor

tyrosine kinases by recruiting critical signaling mediators to the kinase.

Negative Regulation of the JAK/STAT Signaling Pathway

Joanne L. Eyles and Douglas J. Hilton

Victoria, Australia*

Introduction

Cytokines are a group of secreted proteins that mediate important cellular processes such as growth, differentiation, and immune defense [1]. They exert their effects by binding to specific receptors expressed on the surface of target cells [2] and trigger intracellular signaling cascades that ultimately result in changes in gene transcription. Despite the diversity of their biological actions, cytokines use a common signal transduction pathway: the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) pathway (Fig. 1A). Cytokine receptors typically lack intrinsic tyrosine kinase activity. Instead, they constitutively associate with cytoplasmic JAKs. Cytokine binding induces oligomerization of receptor chains to bring JAKs into close proximity, allowing them to cross-phosphorylate each other and the receptor itself. Downstream signaling molecules such as the STAT proteins are then recruited to the receptor complex. STAT proteins bind via their SH2 domains to specific phospho-tyrosine motifs on the receptor and become phosphorylated by the JAKs. Once phosphorylated, STAT proteins homo- or heterodimerize and enter the nucleus where they activate the transcription of a specific set of genes [3]. The combination of JAKs and STATs utilized by a given cytokine accounts for both the specific and redundant actions of cytokines.

The JAK/STAT pathway activated by cytokines is also tempered to control both the duration and intensity of signaling. There are various levels at which negative regulation can occur, including downregulation of the receptor–ligand complex, dephosphorylation or degradation of signaling

intermediates, and production and/or activation of specific suppressor proteins. This review focuses on three classes of proteins: the phosphatases, the protein inhibitors of activated STATs (PIAS), and the suppressors of cytokine signaling (Figs. 1B–D).

The Phosphatases

Cytokine signaling involves a cascade of tyrosine phosphorylation events. Tyrosine phosphorylation of many proteins is rapid but transient. It is therefore not surprising that dephosphorylation of activated signaling molecules by specific phosphatases is an important mechanism for the termination of cytokine signaling [4].

SHP-1

The Src homology domain 2 (SH2)-containing tyrosine phosphatase SHP-1 has been identified as a critical negative regulator of cytokine signaling [5]. SHP-1 is a cytosolic phosphatase that is expressed predominantly in hemopoietic cells, and the importance of SHP-1 is evident in mice harboring a spontaneous mutation in the SHP-1 gene known as *motheaten* mice. *Motheaten* mice, which do not express SHP-1, suffer from a range of hemopoietic abnormalities, including hyperproliferation and abnormal activation of macrophages and granulocytes [6,7].

The multiple hemopoietic defects in *motheaten* mice are likely to be attributed to the ability of SHP-1 to suppress the signaling by various cytokines, including erythropoietin

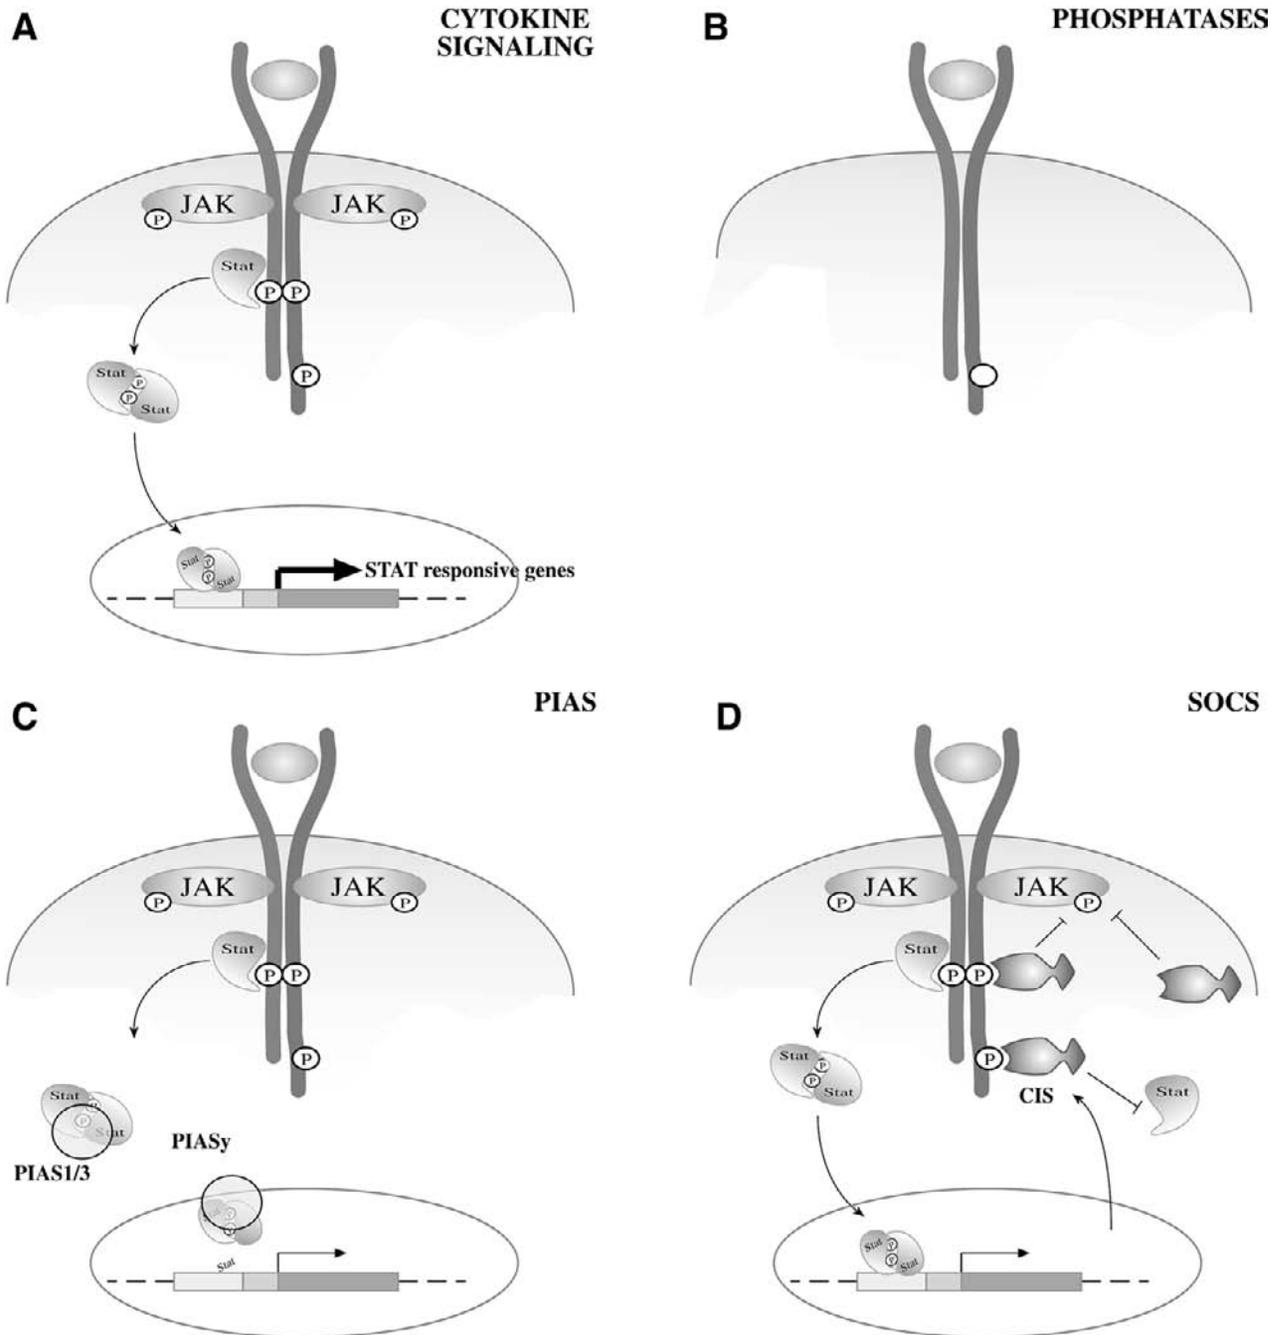

Figure 1 Schematic illustration of mediators and inhibitors of cytokine signaling. (A) Cytokines initiate signaling through binding to multimeric cell surface receptors. Receptor aggregation leads to juxtaposition of JAKs, which cross phosphorylate each other and phosphorylate tyrosines within the receptor cytoplasmic domain. These phospho-tyrosines provide docking sites for cytoplasmic proteins, such as STATs, which are themselves phosphorylated by JAKs. STATs then dimerize, migrate to the nucleus, and regulate the transcription of genes required for mediating the biological response to the cytokine. Phosphatases (B), PIAS proteins (C), and SOCS proteins (D) each attenuate signaling by acting at different levels within the cascade.

(EPO) [8], interleukin-3 (IL-3) [9], IL-4 and IL-13 [10], interferons [11–13], colony-stimulating factor 1 (CSF-1) [14], and Steel factor [15,16].

Among these cytokines, the evidence for regulation of EPO signaling by SHP-1 is most compelling. *In vitro* studies have shown that, upon EPO stimulation, SHP-1 can bind to the activated EPO receptor complex and dephosphorylate the receptor-associated kinase JAK-2. Additionally, cells

expressing a mutant EPO receptor that is unable to recruit SHP-1 show prolonged tyrosine phosphorylation of JAK-2 and an enhanced mitogenic response [17,18]. The importance of recruitment of SHP-1 to the phosphorylated receptor cytoplasmic domain in regulation of signaling is highlighted by families in which polycythemia is caused by a mutation that results in truncation of the EPO receptor and an inability to bind SHP-1 [19,20].

CD45

CD45 is a transmembrane phosphatase that was initially identified as being an important regulator of antigen receptor signaling in B and T cells [21–25], with its primary targets being the Src family kinases [26,27]. Recent evidence suggests, however, that CD45 is also a JAK phosphatase and can negatively regulate cytokine signaling [28,29]. CD45 appears to inhibit IL-3-induced proliferation, erythropoietin-induced hematopoiesis, and antiviral responses, both *in vitro* and *in vivo*. *In vitro* studies have shown CD45 can bind and directly dephosphorylate JAKs. Furthermore, IL-3 stimulation of a CD45-deficient, bone-marrow-derived mast cell line induced hyperphosphorylation of JAK-2 and an increased phosphorylation of STAT-3 and STAT-5 [29].

STAT Phosphatases

Phosphorylation of a single tyrosine residue within the C-terminal region of STATs is critical for their activation and function. *In vitro* studies using phosphatase inhibitors have demonstrated the important role of phosphatases in the regulation of STAT phosphorylation [30,31]. Specific regions of STAT proteins have been identified as being critical for their inactivation. The generation of mutant STAT proteins that are constitutively tyrosine phosphorylated revealed that STAT-1 inactivation is dependent on an N-terminal region [13] and contrasts with inactivation of STAT-3 and STAT-5, which rely on a C-terminal region. Phosphatase binding sites are likely to localize to these regions, and consistent with this the N-terminal region of STAT-1 has been shown to bind a phosphatase [13]. The identity of the enzymes responsible for STAT dephosphorylation has been the subject of much study. Recent evidence suggests that PTP-1B [32] and TC-PTP [33] are both STAT phosphatases. The relative importance of each in the physiological dephosphorylation of the various STAT proteins remains to be determined.

PIAS (Protein Inhibitors of Activated STATs)

PIAS Family

The PIAS family is composed of five members: PIAS1, PIAS3, PIAS α , PIAS β , and PIASy [34]. PIAS proteins are greater than 50% homologous and contain several highly conserved regions, including a putative zinc binding motif and a highly acidic region. PIAS1 and PIAS3 have been shown to negatively regulate cytokine-activated STAT-1 and STAT-3, respectively [34,35]. The specificity of their action has been demonstrated by *in vitro* studies; PIAS1 co-immunoprecipitated with STAT-1 but not STAT-2 or STAT-3, blocked STAT-1 DNA binding in EMSA analysis, and inhibited STAT-1-mediated gene expression in luciferase reporter assays [35]. Similarly, PIAS3 interacts with STAT-3 but not

STAT-1 and inhibits STAT-3- but not STAT-1-mediated gene expression [34]. More recently, PIASy has also been shown to inhibit STAT-1 activity [36].

The PIAS–STAT Interaction

A modified yeast two-hybrid system demonstrated that PIAS1 interacts specifically with STAT-1 dimer and cannot interact with STAT-1 monomer [37]. *In vitro* mutational studies have given important insights to the molecular basis of the PIAS1–STAT-1 interaction. In contrast to full length PIAS1, which fails to bind to STAT-1 monomer, the removal of the first 50 amino acid residues of PIAS1 is sufficient to allow the PIAS1–STAT-1 interaction to occur. Therefore, the N-terminal region of PIAS1 serves as a modulatory domain by preventing PIAS1 from interacting with the STAT-1 monomer. In the same study, the C-terminal region of PIAS1 (amino acids 392–541) was defined as being the STAT-1-binding domain [37].

A series of STAT-1 deletion mutants was also generated and used to define the precise region of STAT-1 capable of binding PIAS1. The N-terminal region of STAT-1 (amino acids 1–191) was shown to be the PIAS1-binding domain; however, the PIAS1 fragment used in the assay lacked the N-terminal modulatory region and was therefore capable of interacting with STAT-1 monomer. Consequently, whether this region also represents the physiological PIAS-binding domain in dimeric STAT-1 remains to be confirmed [37].

The *in vivo* PIAS1–STAT-1 interaction requires IFN stimulation. Although it is possible that PIAS1 may be modified by interferon (IFN) stimulation it has been shown that PIAS1 interacts specifically with STAT-1 dimer and cannot interact with phosphorylated or unphosphorylated STAT-1 monomer. This suggests that the critical IFN-stimulated event is the dimerization of STAT-1, which then allows PIAS binding.

The JAK/STAT pathway also operates in *Drosophila* [38,39]. A *Drosophila* PIAS homolog, dPIAS, was found to negatively regulate the STAT homolog, stat92E [40]. Similar to the PIAS1–STAT-1 interaction, the central domain of dPIAS was found to directly interact with stat92E. This observation is important, as it demonstrates the *in vivo* role PIAS family members play in the regulation of cytokine signaling. The generation of mice lacking the various PIAS family members may allow their contribution to the regulation of mammalian cytokine signaling to be assessed.

PIAS: Mechanisms of Action

Different PIAS proteins appear to inhibit STAT activity through distinct mechanisms. PIAS1 and PIAS3 prevent dimeric STAT-1 and STAT-3 binding of DNA [34,35]. In contrast, PIASy inhibits STAT-1-mediated gene activation without blocking the DNA binding ability of STAT-1. A conserved N-terminal LXXLL coregulator motif located in N-terminal region of PIASy is required for the transrepression

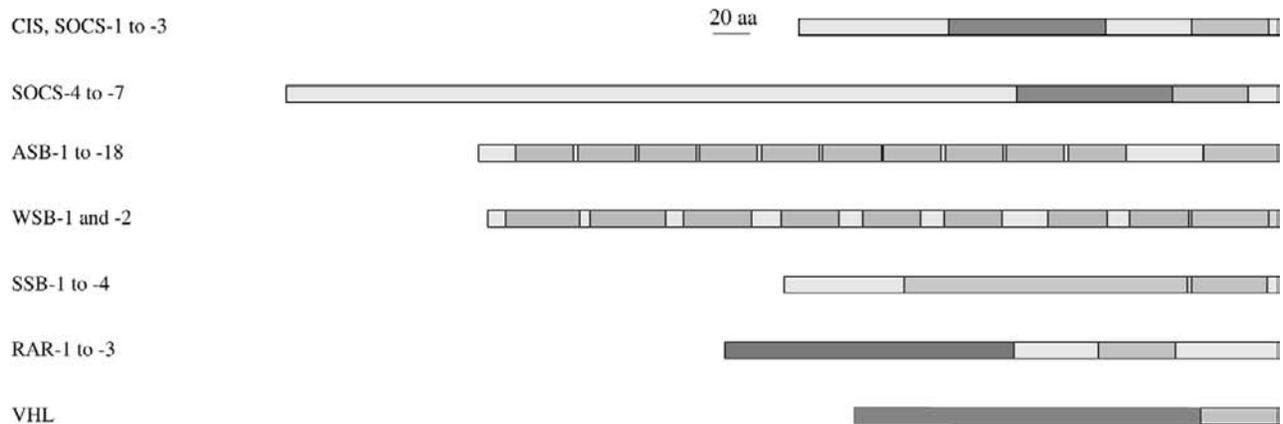

Figure 2 Schematic illustration of SOCS box containing proteins. The various families of SOCS-box-containing proteins are shown. The SOCS box is shown in orange; the SH2 domain of the canonical SOCS proteins (CIS and SOCS-1 through 7), in mauve; the ankyrin repeats of the ASB proteins, in green; the WD40 repeats of WSB1 and 2, in turquoise; the SPRY domain of the SSBs, in grey/blue; and the a domain of the VHL protein, in cerise. Non-conserved regions are shown in grey.

activity of PIASy [36]. It has therefore been proposed that PIASy may act as an adaptor protein to link STAT-1 to a transcriptional corepressor.

PIAS proteins have been shown to exert effects independent of cytokine signaling. PIAS1 shares characteristics of a nuclear scaffold attachment protein; it localizes to nuclei in a speckled pattern and can bind AT-rich, double-stranded DNA. DNA binding depends on a conserved N-terminal sequence (amino acids 11–45) referred to as the scaffold attachment factor (SAF) box [41], SAF-A/B, Acinus, or PIAS (SAP) domain [42]. Additionally, both PIAS1 and PIASx α have been shown to be capable of interacting with steroid receptors, which are ligand-inducible transcription factors [43]. The extent to which the PIAS family acts specifically to modulate cytokine signaling or more widely as regulators of transcription may be clarified by further analysis of *Drosophila* or mice harboring PIAS mutations.

SOCS (Suppressors of Cytokine Signaling) Family

Overview

As with many breakthroughs, three groups simultaneously discovered suppressor of cytokine signaling 1 (SOCS-1), also known as JAK binding protein (JAB) and STAT-inducible STAT inhibitor 1 (SSI-1), using three very different strategies: (1) SOCS-1 was cloned based on its ability to inhibit interleukin-6 (IL-6)-induced macrophage differentiation of the monocytic cell line, M1 [44]; (2) JAB was isolated in a yeast two-hybrid screen for JAK-2 binding proteins [45]; (3) SSI-1 was isolated by an antibody screen for proteins with homology to the SH2 domain of STAT-3 [46].

Database searches using the predicted SOCS-1 amino acid sequence showed it to be related to the previously characterized cytokine-inducible SH2-domain-containing protein

(CIS) and identified an additional six SOCS family members (SOCS-2 through SOCS-7) [44–48], each of which contained an SH2 domain and a conserved 40-amino-acid motif, the SOCS box [44]. Further database mining using the highly conserved C-terminal SOCS box revealed that this motif is shared by an additional group of proteins [47–49]. Instead of an SH2 domain, these proteins have a different protein–protein interaction domain (Fig. 2), such as WD40 repeats (WSB proteins), SPRY domains (SSB), ankyrin repeats (ASB), or GTPase (RAR).

SOCS Proteins Are Part of a Negative Feedback Loop

Various *in vitro* studies showed that a range of cytokines can induce SOCS gene and protein expression, and when over-expressed SOCS proteins can inhibit cytokine signaling (Table 1) [50,51]. Taken together, these data suggest that SOCS proteins may act as part of a negative feedback loop to regulate cytokine signaling (Fig. 1D, Table 1). Because many cytokines act via the JAK/STAT pathway, SOCS proteins may also act to mediate cytokine cross-talk. An intriguing feature of certain cytokines is their ability to regulate the response of a cell to subsequent exposure to another cytokine. Although the mechanisms of cross-talk between cytokines are not well understood, recent *in vitro* studies have suggested the involvement of SOCS proteins such that, although SOCS expression can be induced by a specific cytokine, SOCS proteins may have the capacity to regulate multiple cytokine signaling cascades occurring within the same cell. For example, SOCS-1 expression may mediate IFN α -induced inhibition of thrombopoietin (TPO) signaling [52] and IFN γ -induced inhibition of IL-4 signaling [53]. The evidence for the role of SOCS proteins in mediating cytokine cross-talk remains largely circumstantial and needs to be confirmed *in vivo* using models of specific SOCS protein deficiency.

Table I Specificity of SOCS Protein Production and Action

	Cytokines inducing expression	Cytokine signaling sensitive to inhibition
CIS	IL-2 ⁽¹⁰⁰⁾ , IL-3 ⁽⁶³⁾ , IL-6 ⁽⁴⁴⁾ , IL-9 ⁽¹⁰¹⁾ , IL-10 ⁽¹⁰²⁾ , GM-CSF ⁽⁶³⁾ , GH ⁽¹⁰³⁾ , PRL ⁽¹⁰⁰⁾ , TSLP ⁽¹⁰⁴⁾ , EGF ⁽¹⁰⁵⁾ , CNTF ⁽¹⁰⁶⁾ , leptin ^(107, 108) , EPO ⁽⁶³⁾ , TPO ⁽¹⁰⁹⁾	IL-2 ⁽¹⁰⁰⁾ , IL-3 ⁽⁶³⁾ , GH ⁽¹¹⁰⁾ , IGF-I ⁽¹¹¹⁾ , leptin ⁽¹¹²⁾ , EPO ⁽⁶³⁾

Abbreviations: IL, interleukin; GM-CSF, granulocyte–macrophage colony-stimulating factor; GH, growth hormone; PRL, prolactin; TSLP, thymic stromal lymphopoietin; EGF, epidermal growth factor; CNTF, ciliary neurotrophic factor; EPO, erythropoietin; LIF, thrombopoietin; IGF-I, insulin-like growth factor I; G-CSF, granulocyte colony-stimulating factor; TSH, thyrotropin; SCF, stem cell factor; LIF, leukemia inhibitory factor; CT-1, cardiotrophin-1; IFN, interferon; M-CSF, macrophage colony-stimulating factor; OSM, oncostatin M; TNF α , tumor necrosis factor α ; PDGF, platelet-derived growth factor; bFGF, basic fibroblast growth factor.

Mechanisms of Action

There is good evidence that SOCS proteins are produced as a result of JAK/STAT signaling and that once produced they can inhibit JAK/STAT signaling. Biochemical analyses over the past few years suggest, as with PIAS proteins, that the different SOCS family members may act in distinct ways: (1) SOCS-1 binds via its SH2 domain to phosphorylated tyrosine residues contained within the activation loop of JAKs and inactivates JAK activity via an N-terminal motif known as the kinase inhibitory region (KIR), which may act as a pseudosubstrate [54–56]; (2) SOCS-3 interacts with phosphorylated tyrosines in the cytoplasmic domain of the various cytokine receptor components and may inhibit JAK activity via its KIR [55–61]; and (3) CIS, like SOCS-3, binds to phosphorylated tyrosine residues within the cytoplasmic domain of receptors and inhibits their signaling by competing with STATs for binding sites [62,63].

Another important component of the ability of SOCS proteins to inhibit cytokine signaling may involve the conserved C-terminal SOCS box. Interaction studies have shown that the SOCS box can interact with a complex of elongins B and C [64,65]. The SOCS box has structural and functional parallels with the F box [49,66,67]. The F box and the SOCS box both couple specific protein–protein interaction domains with generic components of the ubiquitination machinery. The F box complex (SCF) is composed of Skp2, Cullin-1, and an F-box-containing protein, as well as the RING finger protein Rbx/Roc-1 [68]. The SOCS box complex (ECS) is composed of Elongin B/C, Cullin-2 or -5 and a SOCS-box-containing protein, as well as Rbx/Roc-1 [49]. The SCF and ECS complexes are E3 ubiquitin ligases that, with E1 and E2 ubiquitin ligase subunits, mediate poly-ubiquitination of proteins bound to the SOCS-box- or

F-box-containing protein. The von Hippel-Lindau (VHL) tumor suppressor protein also contains a SOCS box and has been shown to poly-ubiquitinate the transcription factor hypoxia-inducible factor 1 (HIF-1), leading to its degradation [69–74]. In the case of SOCS-1, there is also good evidence that JAKs are bound by the SH2 domain, are poly-ubiquitinated in a SOCS-1-dependent manner, and are degraded by the proteasome [75–77]. Moreover analysis of mice in which only the DNA encoding the SOCS box has been deleted supports the notion that this motif plays an important physiological role in attenuating signaling. If targeting proteins for proteasomal degradation proves a general mechanism by which SOCS-box-containing proteins act, then it is important to determine which proteins interact with the SH2 domains in other SOCS proteins and the ankyrin repeats, SPRY domains, and WD40 repeats in ASB, SSB, and WSB proteins.

In vitro over-expression studies have also demonstrated that deletion of the SOCS box results in a shorter half-life for SOCS-1 and the VHL protein, leading to the suggestion that a major role for the interaction of the SOCS box with elongins B and C is to stabilize the SOCS protein [65,78]. The reduced half-life of SOCS proteins lacking a SOCS box might be incidental to the primary role of the SOCS box in linking specific substrate recognition with generic components of the ubiquitin ligase complex. Indeed, this increased lability might reflect the degradation of individual proteins that normally form part of a multi-subunit complex, a phenomenon that occurs frequently in the endoplasmic reticulum [79]. It has also been suggested that phosphorylation of SOCS-1 by Pim kinases prolongs the half-life of the SOCS-1 protein [80]. This may provide a mechanism by which the inhibitory effect of SOCS-1 on JAK/STAT activation can be extended.

The regulatory actions of the SOCS proteins may not be restricted to JAK/STAT signaling. In over-expression systems,

SOCS-1 has been shown to interact with KIT and FLT3 receptors, FGF receptor, TEC, VAV, GRB2, and PYK2 [45,81–83]. Similarly, SOCS-2 has been shown to interact with IGF-1 receptor [84], and SOCS-3 has been found to associate with IGF-1 receptor, LCK, the FGF receptor, and PYK2 [85]. The physiological relevance of these *in vitro* observations requires confirmation using primary cells and study of animals lacking one or more of the SOCS genes.

The *In Vivo* Role of SOCS: SOCS Knockout Mice

The apparent promiscuity of SOCS induction and action *in vitro* may be the result of the expression of these proteins in a temporally inappropriate manner and at excessive levels. For this reason, SOCS knockout mice were generated to determine the biologically relevant functions of the SOCS proteins. SOCS-1 knockout mice survive embryogenesis and are born at the expected Mendelian frequency but die neonatally of a severe inflammatory disease that is characterized by monocyte infiltration of several lymphoid organs, abnormal T-cell activation, and fatty degeneration of the liver [86,87]. The SOCS-1 knockout disease is reminiscent of that induced by the administration of IFN γ to neonatal mice [88–90]. Subsequently, IFN γ levels were discovered to be elevated in the serum of SOCS-1 knockout mice [91], and these animals are hyper-responsive to IFN γ [92].

Consistent with the central role that SOCS-1 plays in regulating IFN γ action, administration of neutralizing anti-IFN γ antibodies was shown to delay the disease observed in SOCS-1 deficient mice [93]. Likewise, SOCS-1/IFN γ double-knockout mice survive until adulthood and appear healthy [93–95]. However, SOCS-1/IFN γ double-knockout mice are not completely normal. Inflammatory infiltrates are detectable in several organs, abnormal numbers of activated T cells are present, and the mice die prematurely in their second year of life from a variety of chronic inflammatory diseases [95]. These results suggest that other cytokines may be deregulated in the absence of SOCS-1.

SOCS-2-deficient mice and high growth (hg/hg) mice, which harbor a naturally occurring deletion of the SOCS-2 locus, both exhibit enhanced growth as young adults. This phenotype is typical of an increased response to growth hormone and/or insulin-like growth factor 1 (IGF-1) [96,97]. SOCS-3-deficient mice die embryonically of placental insufficiency [98] and have also been reported to exhibit excessive erythropoiesis, which has been postulated to be caused by an enhanced response to erythropoietin [99].

Concluding Comments

At least three families of proteins act to attenuate cytokine signal transduction: phosphatases, PIAS, and SOCS. These proteins act in fundamentally different ways. Phosphatases and PIAS are present constitutively and are capable of inhibiting signaling in an acute manner. These proteins might be expected to act as buffers to determine the

magnitude of an initial response. In contrast, SOCS proteins are, in general, produced as a consequence of signal transduction, some hours after cells are exposed to cytokines. SOCS proteins therefore appear to regulate the duration and perhaps steady-state level of signaling, rather than the magnitude of the initial response.

Despite some progress in understanding how these individual components function, little is currently known of how they act in concert to regulate the intensity and duration of signal transduction in response to acute or chronic cytokine stimulation. Even more tenuous is our grasp of how a cell can integrate signals from several cytokines, each of which stimulates a signaling pathway that contains shared elements (JAKs and STATs) and which is tempered by common negative regulatory proteins (phosphatases, PIAS, and SOCS protein). The reconstruction and reconstitution of such complex situations are key challenges of research in the next decade.

Introduction

The evolution of a tumor cell requires multiple genetic and epigenetic alterations. Some of these changes result in activation of protooncogenes, while others result in inactivation or loss of tumor suppressor genes [1]. The progressive evolution to malignancy is probably facilitated by the genetic instability that appears to be an intrinsic characteristic of cancer cells [2,3]. The end result is that tumor cells acquire a set of characteristic properties that confer upon them a selective growth advantage [4]. These properties include the ability to proliferate in the presence of inhibitory signals that restrict the growth of normal cells and the ability to proliferate in the absence of signals upon which normal cells are dependent, such as growth factors and attachment to the extracellular matrix. Also critical for tumor growth is the ability to evade processes that normally limit cell proliferation, such as terminal differentiation, programmed cell death (apoptosis), and telomere erosion and replicative senescence. Finally, the growth of solid tumors is limited by the supply of nutrients and room to expand, and in order to continue proliferation solid tumors must elicit a vascular supply (tumor angiogenesis) and then acquire the ability to invade surrounding tissues and migrate to distant sites (metastasis). Tumor progression is thus a Darwinian process in which mutations accumulate and progressively confer upon the evolving cancer cell an ever greater proliferative advantage [4].

All of these changes involve perversions of normal regulatory mechanisms. In normal embryos or adult tissues, complex regulatory mechanisms control cellular proliferation, differentiation, movement, function, and survival. As described elsewhere in this volume, many of these regulatory

mechanisms involve protein kinases that function either as receptors transmitting signals across the plasma membrane, or as relays transmitting signals from the plasma membrane to effector proteins in the cytoplasm or within the nucleus. Protein kinases are themselves complex molecular machines that are normally restrained and regulated by autoinhibitory mechanisms or by interactions with *trans*-acting inhibitors [5]. Inactivation of these autoinhibitory constraints, whether by mutational or nonmutational events, results in constitutive activation of kinase activity. Given the central role that protein kinases play in cellular regulation, and the fact that they can be constitutively activated by loss of autoinhibitory regulation, it is (at least in hindsight) no surprise that activation of protein kinases plays a central role in cancer [6]. In this chapter, we review the autoinhibitory mechanisms involved in the regulation of protein kinases and then describe the mechanisms that result in their activation in tumor cells. Finally we discuss the exciting prospect that protein kinase inhibitors will be useful therapeutic agents for the treatment of cancer, an issue that will be discussed in greater detail in the following chapter.

Physiological Regulation of Protein Kinases

As described elsewhere in this volume (see Chapter 67), the catalytic domain of eukaryotic tyrosine and serine/threonine kinases is a conserved structure in which the nucleotide-binding and catalytic sites lie within a cleft between two lobes [7,8] (see Fig. 1). All protein kinases can adopt at least two conformations, an active or “on” state and an inactive or “off” state. Tolstoy wrote in *Anna Karenina* that,

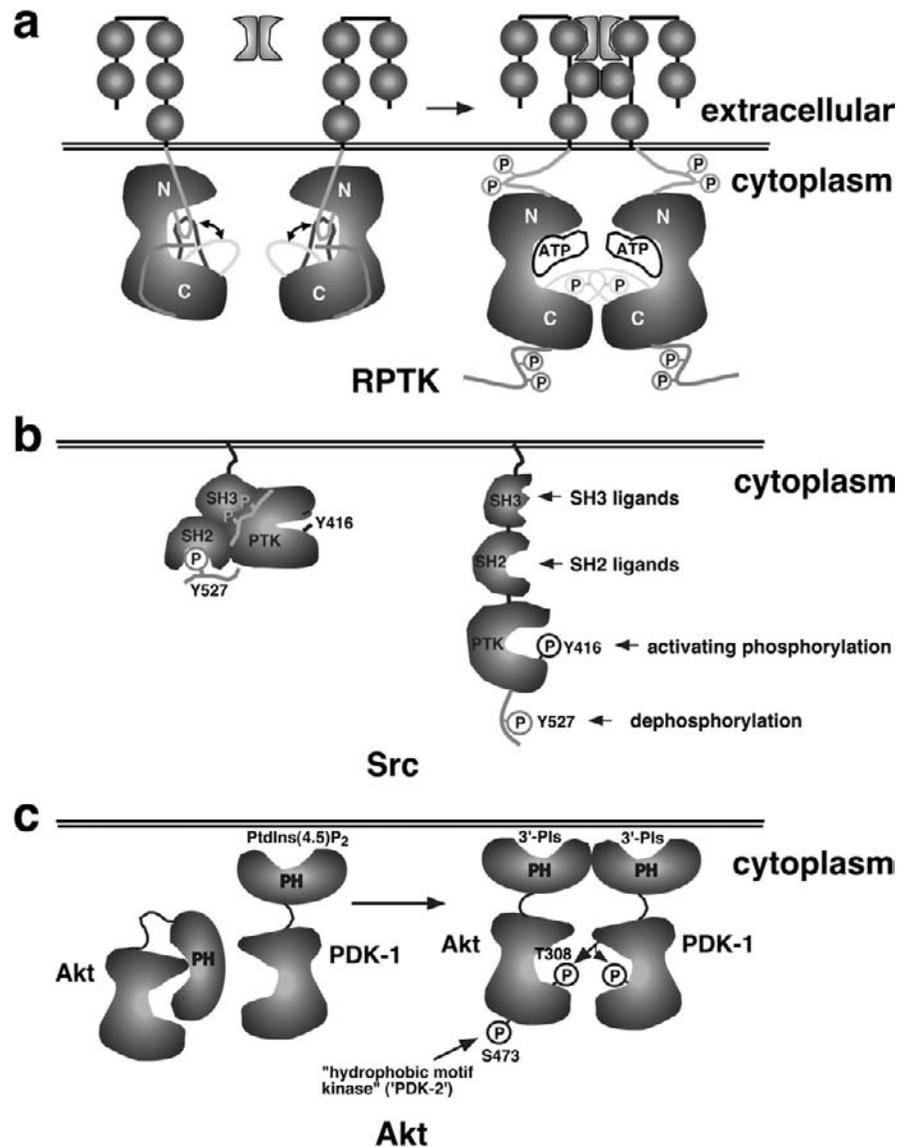

Figure 1 Regulation of protein kinases. (a) Regulation of receptor tyrosine kinases. *Left*, the inactive monomeric state; the activation loop is in equilibrium between conformations that either exclude or allow substrate access. The juxtamembrane and C-terminal regions may also inhibit activity through interactions with the N-lobe or the active site. *Right*, the active dimeric state; ligand-induced dimerization results in tyrosine autophosphorylation and relief from auto-inhibition by the activation loop and juxtamembrane and C-terminal regions. (b) Regulation of c-Src activity. *Left*, the inactive “closed” conformation; phosphotyrosine 527 (chicken c-Src) interacts with the SH2 domain, positioning the SH3 domain to interact with a polyproline type II helix induced in the linker between the SH2 and catalytic domains. The linker region and the SH3 domain in turn interact with the surface of the N-lobe and stabilize the α C helix in an inactive conformation. *Right*, the active “open” conformation; activation results from binding of ligands to the SH2 and/or SH3 domain, dephosphorylation of phosphotyrosine 527, and phosphorylation of Tyr 416 in the activation loop. (c) Regulation of Akt by phosphatidylinositol(PI)-3-kinase. *Left*, the inactive conformation; the N-terminal PH domain of Akt does not interact with membrane lipids and blocks activation by PDK1. *Right*, the PH domain of Akt binds to 3'-phosphoinositides generated by PI 3-kinase. This allows PDK1 to phosphorylate the activation loop of Akt at Thr 308. (From Blume-Jensen, P. and Hunter, T., *Nature*, 411, 355–365, 2001. With permission.)

“Happy families are all alike; every unhappy family is unhappy in its own way.” Similarly, the conformations of active protein kinases, which must all catalyze the same reaction, are very similar, but nature has evolved many different ways to inactivate kinase activity [5].

X-ray crystallographic studies on the active and inactive forms of protein kinases have revealed conserved regulatory and catalytic elements. The N-terminal lobe (the “N-lobe” or “small lobe”) is primarily a β -sheet structure. However the N-lobe contains an α -helical segment, the α C helix,

which contains a conserved glutamate residue that plays a critical role in regulation. In the active conformation this glutamate residue ion-pairs with and positions a conserved lysine in the N-lobe, that in turn functions to position the α and β phosphates of the bound ATP. The C-terminal lobe (the “C-lobe” or “large-lobe”), which is primarily α -helical, contains the residues that bind substrate and segments critical for catalysis. The catalytic loop at the base of the active site cleft contains an aspartate residue, which (in its non-protonated form) acts as a catalytic base. At the front of the active site cleft the C-lobe bears a loop termed the *activation loop*. These regulatory elements form an interacting network, so that perturbations of any one element are propagated throughout the structure.

Movements of the activation loop and the α C helix are central elements in the regulation of protein kinases [5]. In the inactive conformation, the activation loop collapses into the active site cleft and inhibits catalytic activity, generally by occluding the access of substrate and/or nucleotide. In the active state, the loop adopts an open extended conformation that permits substrate binding. Activation generally requires phosphorylation of a residue or residues within the activation loop. The phosphorylated residues in the activation loop interact with residues in the C-lobe that position the catalytic aspartate. The phosphorylated residues in the activation loop also interact with the α C helix in the N-lobe, positioning it so that the glutamate residue can ion-pair with the lysine that anchors the α and β phosphates of adenosine triphosphate (ATP). Phosphorylation of the activation loop may be brought about by an intermolecular autophosphorylation. This is the case with the receptor-tyrosine kinases, which are activated by ligand-induced dimerization or oligomerization and/or by a ligand-induced conformational change [9,10] (Fig. 1a); the collapsed conformation of the unphosphorylated activation loop is in equilibrium with the open extended conformation, allowing intermolecular autophosphorylation to occur [11]. Alternatively, phosphorylation of the activation loop may be brought about by an upstream activating kinase, as in the case of members of the MAP kinase family that are activated by activation loop phosphorylation by MAP kinase kinases [12]. Autoinhibition by the activation loop and its relief by phosphorylation represent a conserved mechanism for the regulation of kinase activity.

Superimposed on the regulatory machinery intrinsic to the catalytic domain are a variety of autoinhibitory mechanisms that rely on regions of the molecule outside the catalytic domain itself. In the case of certain receptor tyrosine kinases, such as PDGF-R, c-Kit, CSF1-R, Eph-R, and the insulin receptor, juxtamembrane segments of the receptor can act as negative regulators of catalytic activity by binding to the N-terminal lobe and thus affecting the positioning of the α C helix (Fig. 1a) [13]. This autoinhibition is relieved by phosphorylation of tyrosine residues within the juxtamembrane segment, which results in both dissociation of the juxtamembrane segment from the catalytic domain and the formation of docking sites for SH2-containing

signaling molecules. In some receptor tyrosine kinases, the C-terminal segment of the molecule can similarly act as an intrasteric regulator by folding back upon and occluding the active site; again, autophosphorylation of this segment causes dissociation of the inhibitory segment and generation of a phosphotyrosine SH2 docking site (Fig. 1a) [14].

The non-receptor tyrosine kinases provide further examples of autoinhibitory mechanisms that depend on regulatory segments outside the catalytic domains. The mechanism of this inhibition has been characterized in greatest detail for Src and related Src family kinases. These kinases contain SH3 and SH2 domains N-terminal to the catalytic domain and a short regulatory sequence at the C-terminus containing a critical phosphotyrosine residue (Fig. 1b). In the inactive or “closed” state, the SH2 and SH3 domains are located at the back of the kinase domain, positioned there by an interaction between the SH2 domain and the C-terminal phosphotyrosine residue [15,16]. The SH3 domain is thus positioned to interact with the linker between the SH2 domain and the N-lobe of the catalytic domain. The linker region and the SH3 domain in turn interact with the surface of the N-lobe and stabilize the α C helix in an inactive conformation. The interaction between the α C helix and the activation loop stabilizes the activation loop in the “off” conformation that occludes substrate access [17,18]. Activation of Src can thus be achieved by disturbing this network of inhibitory interactions (Fig. 1b). Activation can occur either by dephosphorylation of the C-terminal phosphotyrosine [19] or by interaction of Src with SH2 ligands, such as autophosphorylated receptors [20], or with SH3 ligands, such as PxxP motifs in substrate proteins [21]. Full activation is dependent on phosphorylation of a tyrosine residue in the activation loop.

Intramolecular autoinhibitory mechanisms of this type are not restricted to receptor and non-receptor tyrosine kinases. Many serine/threonine kinases are regulated by active site occlusion by pseudosubstrate sequences [22]. The Raf group of serine/threonine kinases contains two conserved regions (CR1 and CR2) in a regulatory segment N-terminal to the kinase domain; deletion of these regions activates kinase activity [23].

Finally, it should be noted that protein kinases are also regulated by intermolecular interactions with activators or inhibitors. For example, cyclin-dependent kinases are activated by binding of a cyclin molecule. Cyclin binding reorients the α C helix, causes the activation loop to adopt a position accessible to phosphorylation by an activating kinase, and reorients the ATP binding site to allow a productive binding geometry [24,25]. Cyclin-dependent kinases are also regulated by CDK inhibitors such as p21^{WAF-1/CIP-1}, p27^{KIP-1}, p16^{INK4a}, and p15^{INK4b}. The INK4 inhibitors bind to both the N- and C-lobe of the cyclin-dependent kinases Cdk4 and Cdk6, distorting the ATP-binding site, reorienting the α C helix, and holding the activation loop in a position that blocks ATP and substrate binding [26,27].

In summary, protein kinases are regulated by a variety of intramolecular autoinhibitory mechanisms. Inhibition by the

nonphosphorylated activation loop within the catalytic domain represents a conserved autoinhibitory mechanism. In addition, kinase activity may be inhibited by segments of the kinase outside the catalytic domain, such as the juxtamembrane region of certain receptor tyrosine kinases, the SH2 and SH3 domains of Src family kinases, and the CR1 and CR2 regions of Raf. Physiological regulators act by modulating these autoinhibitory mechanisms. As we shall now discuss, loss of these autoinhibitory mechanisms is responsible for the activation of oncogenic protein kinases.

Activation of Protein Kinases by Retroviruses

Retroviral oncogenesis, while very rare in humans, is common in avian and mammalian models. The most common mechanism is insertional mutagenesis, in which the provirus integrates into, or adjacent to, a protooncogene [28]. The insertion is believed to result from random integration and is followed by selective growth of cells in which the protooncogene has been activated. Activation of the protooncogene can involve transcriptional promotion or enhancement by the retroviral long terminal repeat and/or structural changes in the product of the protooncogene due to the proviral insertion. The classical example of insertional activation of a protein kinase is the activation of the *c-erbB* gene, encoding the EGF receptor, in line 15₁ chickens infected by an avian leukosis virus [29–32]. In these birds, an erythroleukemia is induced as a result of insertion of the provirus into the first intron of the *c-erbB* gene and splicing of the *gag*-leader into the second exon, resulting in the formation of *gag-erbB* or *gag-env-erbB* fusions that contain the transmembrane and kinase domains of the EGF receptor but lack the ligand binding domain. The resulting insertionally activated EGF receptor can induce erythroleukemia when expressed in a retroviral vector [33]. Activation of transforming capacity appears to involve constitutive dimerization resulting from loss of the ligand binding domain.

A much rarer type of retroviral oncogenesis involves incorporation of part or all of the protooncogene into the retroviral genome, a process referred to as *retroviral transduction*. This appears to occur as a result of multistep recombination between an insertionally activated oncogene and the adjacent provirus. The resulting retrovirus is rapidly transforming and can induce tumors with a very short latency upon injection into a susceptible host. In the case of the line 15₁ chickens mentioned above, the process of retroviral transduction is unusually frequent [29,30]. In approximately 50% of line 15₁ chickens infected with an avian leukosis virus, rapidly transforming erythroleukemia viruses are generated. The high frequency of this event probably results from the fact that the activating proviruses are complete and have not sustained the deletions generally observed in other instances of insertional mutagenesis. The new erythroleukemia viruses encode *gag-erbB* fusions in which the ligand binding domain of the EGF receptor has been deleted and induce a rapid erythroleukemia. In some

cases, the erythroleukemia viruses encode an EGF receptor that has also sustained a deletion within the C-terminal segment and/or point mutations within the catalytic domain, and these viruses can induce not only erythroleukemia but also sarcomas [34]. This indicates that additional mutations can induce further activation of transforming capacity.

There are many examples of retrovirally transduced protein kinases, including receptor tyrosine kinases, such as v-Fms and v-Ros, non-receptor tyrosine kinases such as v-Src and v-Abl, and serine/threonine kinases such as v-Raf and v-Mos. The mechanism of activation has been described in greatest detail for the v-Src protein encoded by Rous sarcoma virus. In this protein, the C-terminal 19 amino acids of c-Src have been substituted by 12 amino acids encoded by a sequence downstream from the c-Src gene, deleting the C-terminal phosphotyrosine that anchors the c-Src SH2 domain [35]. In addition, the v-Src gene has sustained activating mutations within the SH3 domain, decreasing the ability of the SH3 domain to interact with the SH2-catalytic domain linker, plus an activating mutation within the catalytic domain. Similarly v-Abl and v-Raf have been activated by deletion or substitution of autoinhibitory segments, the N-terminal “cap” and the SH3 domain in the case of v-Abl [36,37], and the CR1 and CR2 domains in the case of v-Raf [23]. In a few instances where retroviral structural proteins are fused to the activated kinases these retroviral sequences may supply functions necessary for transformation. For example, the myristoylation site in Gag is required for membrane attachment of v-Abl and v-Fgr and for transformation of 3T3 fibroblasts by these kinases [38,39], while additional Gag sequences within v-Abl stabilize the protein in lymphoid cells [40].

Activation of Protein Kinases in Human Cancer

Activation by Chromosomal Translocations

Chromosomal translocations can activate protooncogenes, either by linking the protooncogene to a more powerful or inappropriately regulated promoter or by generating a gene fusion linking the protooncogene product to a heterologous protein. In the latter case, activation can occur either by deletion of an autoinhibitory domain or because the fusion partner provides an activating function, such as dimerization or localization to a novel intracellular compartment. Fusions of receptor or non-receptor tyrosine kinases to heterologous proteins are observed in a variety of cancers and leukemias. Examples include the Tel-PDGFR β fusion in chronic myelomonocytic leukemia [41], the ZNF198-FGFR1 fusion in certain forms of acute myelogenous leukemia [42], and a variety of fusions involving TrkA, Met, or Ret in papillary thyroid carcinomas [43] (for a complete listing, see Table 1 in Blume-Jensen and Hunter [6]).

The classic example of protein kinase activation by translocation is the generation of Bcr-Abl, which is responsible for the induction of chronic myelogenous leukemia (CML).

In this disease, a reciprocal translocation occurs that results in the fusion of the *abl* protooncogene on chromosome 9 to the breakpoint cluster region (*bcr*) gene on chromosome 22. The resulting fusion protein, Bcr–Abl, is activated by several mechanisms. First, the Bcr coiled-coil domain supplies an oligomerization function [44]. Second, the Bcr sequence retains the Bcr–Abl protein in the cytoplasm, promoting the activation of oncogenic signaling pathways [37] and inhibiting the proapoptotic activity that Abl exerts in the nucleus [45]. Third, the fusion deletes the N-terminal 80 residues of c-Abl, which function as an autoinhibitory “cap” [36]. Finally, the Bcr-sequences contain a tyrosine residue that is subject to phosphorylation by the Abl kinase, generating a phosphotyrosine residue that binds the adaptor Grb2, leading to the activation of Ras [46]. The Bcr–Abl fusion protein is of particular interest because it is a target of the drug Gleevec™ (STI571) (see later discussion).

Activation by Gene Amplification and Overexpression

Because protein kinases can be activated by intermolecular autophosphorylation, an increase in kinase expression can lead to increased activity. Although overexpression can occur without any apparent genetic change, a frequent underlying mechanism is gene amplification. Amplification is often associated with complex chromosomal rearrangements and is manifested by the presence of chromosomal abnormalities, either double-minute chromosomes or homogeneously staining regions. The mechanisms by which these amplified and rearranged segments are generated are not entirely clear and may involve unequal sister chromatid exchange, extrachromosomal amplification and reintegration, localized over-replication, and breakage–fusion–bridge cycles [47]. The process appears to be initiated by DNA double-strand breaks that have escaped repair by the cellular enzymatic repair machinery. In cells that retain p53 function, these events would lead to apoptosis, but in tumor cells deficient in p53 these lesions are not eliminated. In one mouse model system it has been shown that the recombinogenic unrepaired chromosome ends associate into dicentric intermediates, which in turn lead to cycles of breakage–fusion–bridge events, generating amplified and rearranged segments [48].

Amplification of members of the EGFR family, in particular EGFR/ErbB1 and HER2/ErbB2/Neu, is common in mammary carcinomas and other types of cancer, while amplification of both EGFR and PDGFR α occurs in some gliomas and glioblastomas [6,49,50]. Amplification of the *bcr-abl* locus can also occur in response to treatment with Gleevec and is associated with resistance to the drug. Because amplification frequently also results in rearrangements, the products of the amplified genes may also be altered. For example in gliomas there is a common variant form of the amplified EGFR, termed vIII, in which DNA rearrangements and alternative splicing have resulted in the deletion of exons 2 to 7, encoding residues 6 to 276 in the extracellular domain; this yields an EGFR that is ligand

independent and constitutively activated and which displays enhanced tumorigenicity [51].

Activation of Protein Kinases by Mutation

The mutations found in tumor cells may arise somatically or can be transmitted as germline mutations that predispose to cancer. It has been argued that the genetic instability characteristic of tumor cells may involve not only an enhanced rate of generation of chromosome abnormalities (translocations, amplifications) but also a mutator phenotype [52]. A subset of tumors are initiated by defects in DNA repair that lead to an increased mutation rate [2]. In addition, many carcinogens appear to act as mutagens; these include both exogenous carcinogens in the diet and endogenous carcinogens such as reactive oxygen species [53].

In the case of receptor tyrosine kinases, mutations can occur within the extracellular domain, the transmembrane domain, the intracellular juxtamembrane region, the catalytic domain, or the C-terminal tail. Deletions or mutations within the extracellular domain can lead to ligand-independent activation, as in the case of the EGFR in gliomas as mentioned above. Another example is provided by the Ret tyrosine kinase, a component of the receptor for neurotrophins of the glial-derived neurotrophic factor (GDNF) family: germline Ret mutations in the extracellular domain are the cause of multiple endocrine neoplasia type 2A (MEN2A) [54,55]. These mutations substitute conserved cysteines in the extracellular domain of Ret that are believed to form intramolecular disulfide bonds in the wild-type receptor. These mutations result in an unpaired cysteine, which then forms an activating intermolecular bridge. In rat neuro- and glioblastomas, activating point mutations arise in the transmembrane segment of Neu/ErbB2 (the rodent ortholog of HER2) [56], but similar mutations have not been identified in human cancers. Activating mutations can also occur in the inhibitory juxtamembrane region. Thus, point mutations in the juxtamembrane region of Kit, the stem cell factor receptor, are implicated in gastrointestinal stromal tumors [57,58], while internal duplications in this region of Flt3 occur in acute myelogenous leukemias [59,60]. Mutations within the catalytic domain close to the activation loop can prevent autoinhibition by the activation loop and thus lead to constitutive activity. These types of mutations occur in Ret in multiple endocrine neoplasia type 2B (MEN2B) [55], in Kit in mast cell/myeloid leukemias [61,62] and seminomas [63], and in Met in papillary renal carcinomas [64,65]. The predominant Ret mutation in MEN2B, Met918Thr, is of particular interest because in addition to activating catalytic activity it also alters peptide substrate specificity. Wild-type Ret has the substrate specificity characteristic of receptor tyrosine kinases (which generally have Met at this position), while the mutant Ret has the substrate specificity characteristic of non-receptor tyrosine kinases (which generally have Thr at this position) [54,55,66,67]. Finally, truncations of the C-terminal autoinhibitory segments also occur, as in the case of FGFR2 (K-SAM) in gastric carcinomas [68,69].

Activation of non-receptor tyrosine kinases similarly occurs by mutation in autoinhibitory domains. c-Src is truncated in a fraction of metastatic colon cancers by a point mutation that generates a Stop codon close to the C-terminus, thus deleting the regulatory phosphotyrosine [70]. Mutational activation of Ser/Thr kinases also occurs. For example, the B-Raf protein, a MAP kinase kinase, is mutant in 66% of human melanomas and at a lower frequency in a wide range of human cancers. The most common mutation is a Val to Glu substitution at residue 599 in the activation loop, immediately adjacent to the serine residue that is phosphorylated when B-Raf is activated; the V559E mutation probably activates by mimicking this regulatory phosphorylation [71].

Activation by Mutation of Upstream Regulators

Activation of protein kinases may occur not only as a result of direct mutational effects on the kinases or alterations in their level of expression, but also because of mutations in upstream regulators. This is too large a topic to review here, so two examples must suffice.

Activation of the small GTPase Ras occurs in some 30% of human cancers and results from mutational inactivation of its autoinhibitory GTPase activity. Mutational activation of Ras leads to activation of the Raf/MEK/MAPK cascade. Ras activation also leads to activation of phosphatidylinositol (PI) 3-kinases, which are lipid kinases that generate 3'-phosphoinositides and thereby activate 3'-phosphoinositide-regulated kinases such as PDK1 and Akt (Fig. 1c) [72]. Both Akt and the catalytic subunit of class IA PI 3-kinase are transforming when incorporated into retroviral genomes [73,74]. An increase in 3'-phosphoinositide levels and activation of Akt can also result from mutational inactivation of the tumor suppressor PTEN, a 3'-phosphoinositide phosphatase; PTEN mutations are observed in breast cancers, glioblastomas, and germ cell tumors [75]. Another event leading to activation of Akt is mutation and/or amplification of either the regulatory or the catalytic subunit of PI 3-kinase [76,77].

The cyclin-dependent kinase Cdk4 is an important regulator of the cell cycle, controlling the transition through the G1 restriction point by phosphorylating and inactivating the tumor suppressor Rb. Its activity is dependent on binding to cyclin D1, a protooncogene product overexpressed in many different types of cancer; for example, in a substantial fraction of mantle cell lymphomas expression of cyclin D1 is activated by a translocation involving the cyclin D1 locus (*CCND1*) [78]. Cdk4 is also inhibited by the cyclin-dependent kinase inhibitor INK4a. The locus encoding INK4a (which also encodes p14ARF) is frequently mutated in human cancers. Thus, INK4a is a tumor suppressor that acts by inhibiting the activity of a protein kinase [79,80]. Interestingly, mutations in the *CDK4* gene itself are also observed, particularly in hereditary and sporadic melanomas, although they are much less common than loss of INK4a; these mutants encode a Cdk4 protein that is resistant to inhibition by INK4a [81–83].

Oncogenic Protein Kinases as Targets for Therapy

Because of their prominent role in tumor progression, protein kinases are promising targets for therapy. Many kinase inhibitors are at various stages of development, but two types are of particular interest. One strategy for inhibiting receptor tyrosine kinase function is the use of anti-receptor antibodies that recognize the ectodomain of the receptor, block ligand binding, and induce receptor endocytosis. Herceptin™ (trastuzumab), a humanized version of a mouse monoclonal antibody against HER2, inhibits the growth of breast cancer cells that overexpress HER2 [84] and has been approved for the treatment of breast cancer patients with HER2-positive tumors. This antibody may act by promoting the c-Cbl-dependent polyubiquitination and degradation of the receptor [85]. A chimeric humanized version of a mouse monoclonal antibody against the EGF receptor (Erbix™, formerly known as IMC-C225 or Cetuximab) has also been reported to give positive results in clinical trials, but these findings have been questioned, and this antibody has not yet received FDA approval.

The other class of drugs under development are small molecule inhibitors that inhibit kinase function. A few inhibitors have been developed that block SH2 domain-phosphotyrosyl ligand binding, thus inhibiting substrate recognition by non-receptor tyrosine kinases. However, most inhibitors developed are those that target the ATP binding site in the catalytic domain. In the case of tyrosine kinases, these inhibitors include a variety of flavone and isoflavone natural products such as quercetin and genistein, quinazolines and pyridopyrimidines, phenylamino-pyrimidines, benzylidene malonitriles (tyrphostins), and indoles and oxindoles (reviewed in Al-Obeidi and Lam [86]). Two anti-EGFR inhibitors, OSI-774 (Tarceva™) and ZD1839 (Iressa™), have given positive results in clinical trials.

Of these inhibitors the most spectacularly successful has been the phenylamino-pyrimidine derivative Gleevec™ (or Glivec in the U.K.), otherwise known as STI-571, CGP57148, or Imatinib [87]. This compound was derived from a lead phenylamino-pyrimidine compound by a series of chemical optimization steps that increased activity against tyrosine kinases and increased solubility and bioavailability. The compound efficiently inhibits ($IC_{50} \approx 0.1$ to $0.5 \mu M$) the activity of Bcr-Abl, c-Kit, PDGFR, and the Abl-related kinase Arg but does not inhibit ($IC_{50} > 10 \mu M$) other tyrosine kinases such as Src, EGFR, insulin and IGF-1 receptors, and Fms. Gleevec inhibits Bcr-Abl by binding with high affinity to, and thus stabilizing the inactive form of the kinase [88]. Its specificity results from the fact that the structure of the inactive form of Abl differs from that of Src and most other tyrosine kinases, in particular in the conformation of the nonphosphorylated activation loop when collapsed into the active site cleft. Gleevec is effective in the treatment of chronic myelogenous leukemia when administered in the chronic phase, increasing progression-free survival. When administered in CML blast crisis, most patients develop resistance, primarily due to amplification of

the *bcr-abl* gene and mutations in the Bcr–Abl kinase domain that render the catalytic activity less sensitive to the inhibitor [89]. Gleevec is also effective in the treatment of c-Kit-positive gastrointestinal stromal tumors, in which as noted earlier, oncogenic mutations in *c-kit* occur in the extracellular domain, the juxtamembrane domain, or the catalytic domain. Gleevec may also prove to be effective in treatment of chronic myeloproliferative disorders with Tel-PDGFR β fusions, and in targeting PDGF-dependent cells in the tumor stromal microenvironment.

The success of Gleevec as an anticancer drug is particularly encouraging because it suggests that the diversity of inactivation mechanisms in oncogenic protein kinases can be exploited for the development of specific inhibitors. Herceptin and Gleevec provide the first two examples of rationally developed anticancer drugs. It is to be hoped that the next few years will see the development of further successful anticancer drugs that target activated protein kinases.

Signal Transduction Therapy

The realization that the cancer cell differs from the normal cell in its aberrant signal transduction has given impetus to cancer researchers targeting them for therapy. The altered signal transduction network in cancer cells allows them to utilize their normal environment to their advantage without obeying the network of signals that regulate the normal cell [1]. Cancer cells sprout due to mutations in their growth signaling pathways. These mutations induce stress, which the mutated cells are able to evade due to further mutations that enhance survival signals to overcome the cellular stress. These two sets of mutations enhance the proliferation of tumor cells, which resist apoptotic messages. During its evolution, the cancer cell becomes highly dependent on this abnormal signaling network. Because of the many mutations that accumulate in the cancer cell, it loses a significant portion of its signaling genes and thrives on the few advantageous genes that remain. Unlike normal cells, cancer cells are devoid of the complex signaling networks characteristic of normal cells and are therefore much less robust than normal cells. It depends on fewer, but enhanced, signaling pathways and is deficient in many of the regulatory pathways characteristic of normal cells. Thus, the few enhanced pathways on which the cancer cell thrives are actually its Achilles' heel. Depriving the cancer cell of one or more of these enhanced signaling elements may sensitize it to stress and even induce its demise [2]. Interception of these pathways could inflict a decisive blow to the cancer cell with little harm to its neighboring normal cells, which would retain their robustness. Indeed, this type of reasoning led to the development of tyrosine phosphorylation inhibitors (tyrphostins), as it was recognized early on that protein tyrosine kinases comprise a major fraction of the signaling elements whose activities are enhanced in the

cancer cell and on whose activities the survival of the cancer cell highly depends [3–9]. The type of therapy aimed at modifying the signaling pathways of the cancer cell is known as *signal transduction therapy* [1]. Signal transduction therapy primarily targets the aberrant signaling elements within the cancer cell but also consists of anti-angiogenic therapy, which targets the newly dividing endothelial cells lining the fresh blood vessels surrounding the tumor and generated in response to vascular endothelial growth factor (VEGF) secreted by the tumor [10].

Protein Tyrosine Kinase Inhibitors

Although protein kinases have been known since the discovery of protein phosphorylation in the 1950s, no one turned to them as drug targets until protein kinase C (PKC) and tyrosine phosphorylation were discovered over 20 years later. Identifying tyrosine kinase activity as being the hallmark of the oncogenic activity of pp60^{c-Src} (and dozens of other oncoproteins) prompted researchers to investigate these proteins as novel targets for drugs. Tyrosine phosphorylation inhibitors (tyrphostins) were subsequently developed as a strategy to combat cancer and other proliferative diseases in the late 1980s [3,11,12]. Also discovered were a number of serine/threonine kinases such as cyclin-dependent kinases (Cdks), Erks, Raf, and PKB/Akt, which play a key role in cell proliferation, cell division, and anti-apoptotic signaling. In contrast to most Ser/Thr kinases known to be involved in housekeeping cellular duties, the more recently discovered protein kinases are directly involved with cellular signaling. In the human genome, we currently identify 409 Ser/Thr kinases, 59 receptor protein tyrosine kinases (RPTKs) and 32 non-RPTKs. Most of the Ser/Thr kinases

Table I Protein Kinase Inhibitors in Clinical Development

Company	Agent	Indication	Target	Status
Genetech/Roche	Herceptin(mAb)	Breast cancer	Her-2	Marketed
Novartis	STI571/Gleevec	Chronic myeloid leukemia (CML)	Bcr-Abl	Marketed
Novartis	STI571/Gleevec	Gastrointestinal stromal tumor (GIST)	C-Kit	Marketed
AstraZeneca	ZD 1839/Iressa	Solid tumors	EGFR, Her-2	Marketed
Pharmacia/Sugen	SU 6668	Solid tumors	VEGFR, PDGFR, FGFR	Phase 3
OSI Pharmaceuticals	Tarceva (OSI 774)	Solid tumors	EGFR	Phase 2
Cephalon/Lundbeck	CEP-1347	Parkinson's disease	Mixed lineage kinase	Phase 1
Cephalon/Lundbeck	CEP-701	Prostate cancer	NGFR	Phase 2
Ludwig Institute for Cancer Research	AG 1478/CDDP	Glioblastoma multiforme	EGFR	Phase 1
Bayer/Onyx	BAY 43-9006	Colon cancer	Raf	Phase 1
Falvopiridol	—	—	Cdk4/1	Phase 1
Eli Lilly	LY 333531	Diabetic retinopathy	Protein kinase C	Phase 3

are housekeeping metabolic enzymes for which only a small fraction is involved in cellular signaling, in contrast to PTKs, which are primarily involved in signaling. The activities of PTKs are associated with enhanced proliferation and strong survival signals, the two most prominent traits of cancer cells.

The development of PTK inhibitors originally known as tyrosine phosphorylation inhibitors (tyrphostins) led to the approach of signal transduction therapy aimed at eradicating cancer cells. Research in this area has demonstrated that one can generate small molecules with a high degree of selectivity against different PTKs, even closely related ones such as endothelial growth factor receptor (EGFR) and Her-2/neu. Table 1 lists PTKs and Ser/Thr kinase inhibitors currently in clinical development. It is interesting to note that, in a number of cases, the PTK inhibitor, even as a single agent, induces apoptosis in the treated cancer cell but has no such effect on normal cells and is well tolerated by the treated animal.

The first striking example is the case of the Jak-2 inhibitor AG 490 (Fig. 1) [13]. This tyrphostin was found to induce apoptosis of recurrent pre-B acute lymphoblastic leukemic (pre-B ALL), eliminating completely the pre-B ALL cells from severe combined immunodeficiency (SCID) mice engrafted with the disease; treatment of the animals began 5 to 9 weeks after disease engraftment. Furthermore, AG 490 was not inhibitory to normal B or T cells when stimulated by various means. This pioneering study validates the hypothesis discussed here [14] and is considered to be an important milestone in signal transduction therapy. The diseased Pre-B ALL cells depend for their survival and growth on the persistently active Jak-2, but normal B cells (and normal T cells) are completely oblivious to the inhibition of Jak-2. Indeed, the inhibition of Jak-2 is sufficient to induce apoptosis in the pre-B ALL cells, whereas its inhibition in normal cells seems to have no effect whatsoever [13]. Similar results have also been obtained with interleukin-6 (IL-6)-dependent multiple myeloma cells, which are also driven by

Jak-2. Very recently, a novel class of Jak2/3 kinase inhibitors has been developed but the *in vivo* activity of these inhibitors has not been reported [15].

Chemistry of Tyrosine Kinase Inhibitors

Initially, a large number of natural compounds were found to be rather potent inhibitors of PTKs. Although many showed initial promise, they all were found to be highly promiscuous and toxic in that they hit many cellular targets. The first PTK inhibitors to be synthesized were benzene malonitrile tyrphostins [11,12]. These compounds (Fig. 1) are competitive with the substrate and noncompetitive with ATP. Structure-activity relationship studies generated compounds that are 1000-fold more active against the EGFR kinase as compared to insulin receptor kinase, with no measurable activity against protein kinase A (PKA) and other serine/threonine kinases. As the number of identified tyrphostins grew, a more complex pattern of kinetics of inhibition of the EGFR kinase began to emerge. Tyrphostins competitive against either substrate or ATP were common, but so were compounds competitive with both [17]. Some compounds were found to be partially competitive (mixed competitive); their interactions with the EGFR [17] or PDGFR [18] reduce the binding affinity of ATP and substrate as well as causing a reduction in the catalytic activity of the enzyme [16]. This type of behavior suggests that the inhibitor binds to sites different than the active site and therefore qualifies as an allosteric inhibitor. As tyrphostins became cyclized (Fig. 2), incorporating nitrile nitrogen into the second ring caused most of the compounds to become ATP competitive [19-22].

Since 1994, the main thrust in the development of PTK inhibitors, especially by pharmaceutical companies, has been toward the generation of ATP mimics (ATP-competitive kinase inhibitors) [23]. Most of the inhibitors generated are based on a scaffold structured around two or more

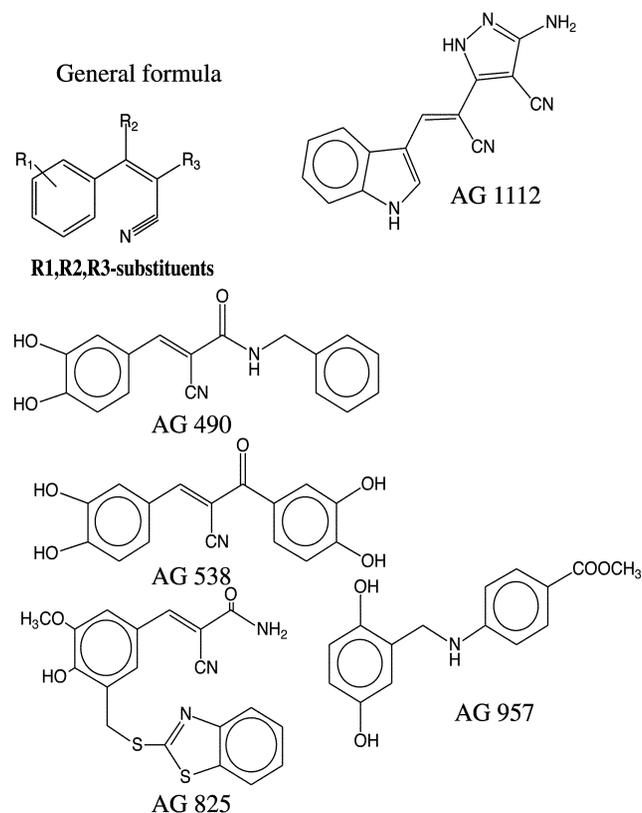

Figure 1 Early Tyrphostins. AG 1112 and AG 957 were prepared as inhibitors of Bcr-Abl; AG 490 is an inhibitor of Jak-2, AG 825 is a Her-2/neu inhibitor, and AG 538 is a potent inhibitor of IGF1-R.

aromatic rings. These compounds were designed to be ATP mimics, but their kinetic behavior toward the substrate was not always investigated. Because the degree of conservation in the ATP binding site is not absolute, one can obtain a high degree of selectivity among closely related ATP binding domains. In 1993, the Jerusalem group [24] was able to demonstrate that ATP-competitive tyrphostins such as AG 825 (Fig. 1) can discriminate between the kinase domains of Her-2/neu and EGFR by almost two orders of magnitude in affinity, in spite of the almost 80% identity in the kinase domains of the two related PTKs. In 1994, the quinazoline ZD 1839 (Iressa; Fig. 3) was shown to be a potent EGFR kinase inhibitor with excellent bioavailability [25]. Quinazolines were originally identified by Zeneca and were shown to selectively inhibit EGFR at low nanomolar concentrations [25], whereas Her-2/neu is inhibited only at micromolar concentrations. Quinaxaloines such as AG 1296 [19,26] or AGL 2043 [27] (Fig. 2) were found to block PDGFR kinase with inhibitory effects on related receptors such as c-Kit and Flt-3 and with 10- to 50-fold less efficacy against the more distantly related receptor VEGFR (unpublished data). The crystal structure of the inactive form of Hck with the Pfizer inhibitor PP1 [28] and of the active form of Lck with PP2 [29] explained why this ATP mimic binds better to the Src family kinase binding domain than does EGFR and much better than to a number of other tyrosine kinases and PKA. It was found that when threonine 338 is

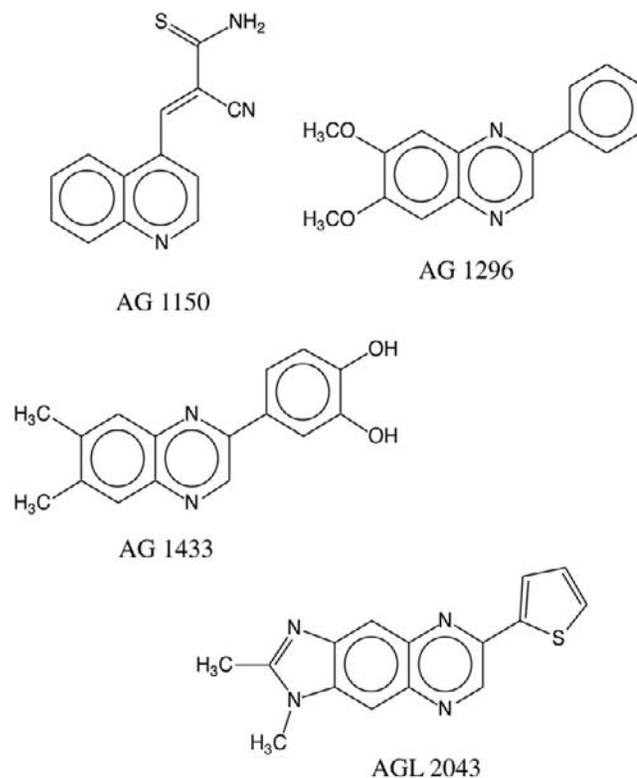

Figure 2 Cyclized tyrphostins. Incorporating the nitrilo(cyano) nitrogen within a second ring generated two-ring tyrphostins as opposed to the one-ring system (see Fig. 1). When a second nitrogen is introduced into the second ring, selective ATP mimics emerge. Interestingly, similar compounds have been identified as PTK inhibitors by random screening rather than by semi-rational design. AG 1150 is rather inactive, whereas AG 1296 and AGL 2043 are potent and selective PDGFR kinase inhibitors.

substituted for methionine or alanine 402 is substituted for another amino acid, the affinity to PP1 drops markedly [28].

EGFR Family Kinase Inhibitors

The role of EGFR in many cancers was appreciated early on and was one of the first targets for therapy. Indeed, the quinazoline Iressa (ZD 1839) (Fig. 3) [21,25] is in advanced clinical trials for treatment of cancers for which EGFR plays an important role, such as lung cancer and head and neck cancer. Similarly, the quinazoline AG 1478 (Fig. 3) [22] is in clinical development for the treatment of glioblastoma multiforme in which the EGFR and its persistently active $\Delta(2-7)$ EGFR are overexpressed [30,31]. This tyrphostin will be used in combination with CDDP, with which it synergizes to induce apoptosis in glioma multiforme cells *in vitro* and *in vivo* [31]. OSI 774 (Fig. 3) is also an effective quinazoline in clinical development [32]. Over the years, we have come to realize that heterodimer combinations of the four members of the Her family play a role in the oncogenic phenotype of many cancers; therefore, attempts are being made to generate inhibitors that inhibit both Her-1 and Her-2. The Glaxo-Wellcome Her-1/Her-2 inhibitor GW 2016 (Fig. 4), blocks both receptor tyrosine kinases at 12 nM [33], and it is to be expected that more compounds aimed at the Her family will emerge in the near future.

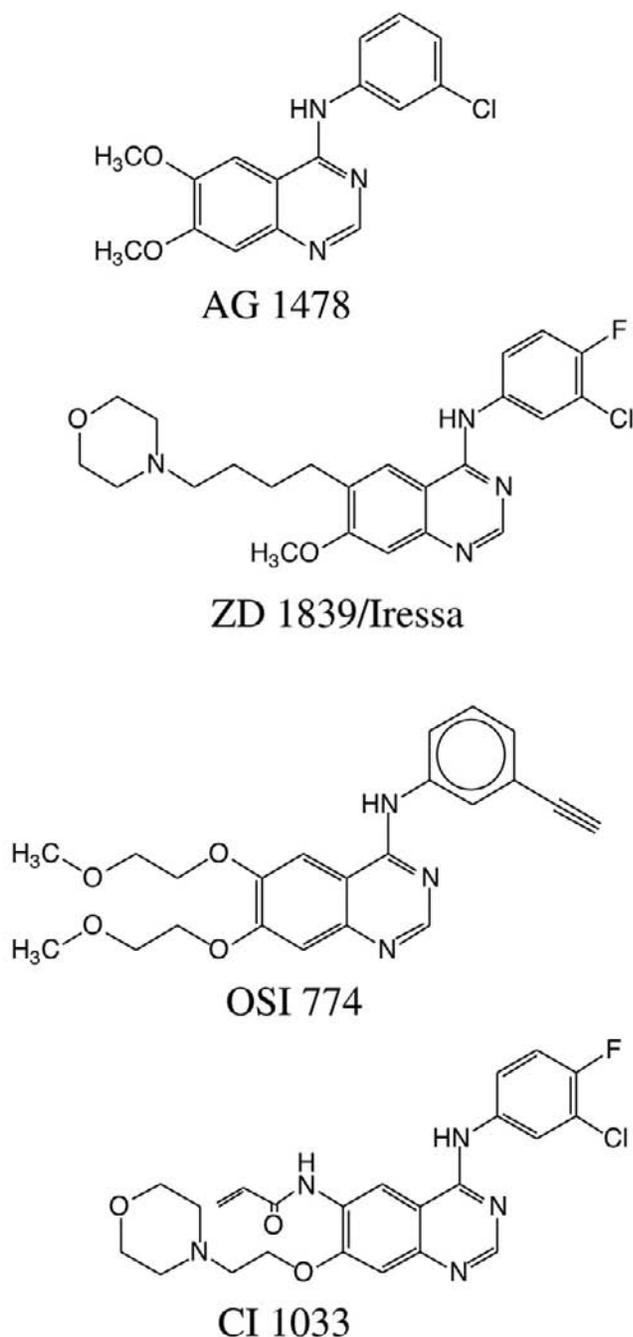

Figure 3 Quinazoline EGFR kinase inhibitors. AG 1478, ZD 1839, and OSI 774 are reversible EGFR kinase inhibitors, whereas CI 1033 is an irreversible inhibitor.

Covalent EGFR Kinase Affinity Labels

The covalent attachment of a selective inhibitor to the EGFR kinase domain (or to any target PTK domain) completely abolishes the catalytic activity of the receptor and is therefore believed to possess better clinical potential. The Parke-Davis compound CI-1033 (Fig. 3) [34] is highly effective *in vivo* as an EGFR kinase inhibitor; the effect of CI-1033 is long lasting and seems to possess higher efficacy than its reversible analogs. The covalent label attaches to cysteine 773, close to the ATP binding domain, and most

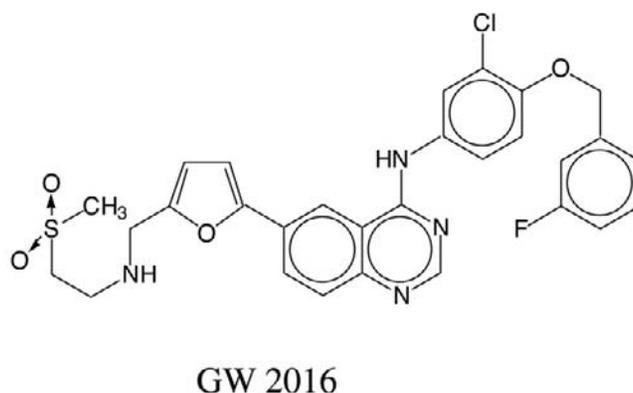

Figure 4 Her-1/2 kinase inhibitor.

probably targets the receptor for degradation followed by cell death. Other covalent labels of the EGFR kinase site were also reported to possess strong antitumor activity *in vivo* at relatively low doses.

From Tyrphostins to Gleevec

In 1993, it was demonstrated that selective Bcr-Abl kinase inhibitors such as tyrphostin AG 1112 (Fig. 1) induce the terminal differentiation of K562 cells [35]. Similarly, another Bcr-Abl-selective kinase inhibitor, AG 957 [36,37], induces the purging of Ph⁺ cells and synergizes with anti-Fas receptor antibody to induce their demise [38]. Druker *et al.* [39] followed up on these studies by utilizing CGP 57148, renamed STI 571/Gleevec/Glivec and produced by Novartis (Fig. 5) [40,41]. This highly potent inhibitor inhibits PDGFR kinase as well as its homologous PTK c-Kit but is also a powerful inhibitor of Bcr-Abl kinase. Gleevec was found to induce complete remission in chronic myeloid leukemia (CML) patients which has lasted for nearly 3 years for most patients. It is interesting to note that these patients, who take about 400 to 800 mg daily, suffer only minor side effects and tolerate the drug well. This is a rather surprising, as STI 571 blocks c-Abl, PDGFR, and c-Kit, which play important roles in the function of normal cells. The most likely explanation is that normal cells that utilize c-Abl, PDGFR, or c-Kit can get by even when over 90% of these targets are blocked by utilizing the alternative pathways that all normal cells possess.

Chronic CML cells are highly dependent on Bcr-Abl for their survival and therefore die when the target is blocked, thus validating the principle of enhanced sensitivity of the cancer cell to an inhibitor that targets the element whose signaling is enhanced and on which the cancer cell depends for its survival. The findings on Bcr-Abl are reinforced by the remarkable activity of Gleevec on a subpopulation of gastrointestinal stromal tumor (GIST) patients [42]. The common denominator of the patients who respond to the drug with complete remission or almost complete remission is that their tumors express Kit receptors carrying mutations in exon 11, which converts the receptor to a persistently active kinase. As is true for chronic CML, it seems that the survival of the tumor cells is highly dependent on the signaling of mutated

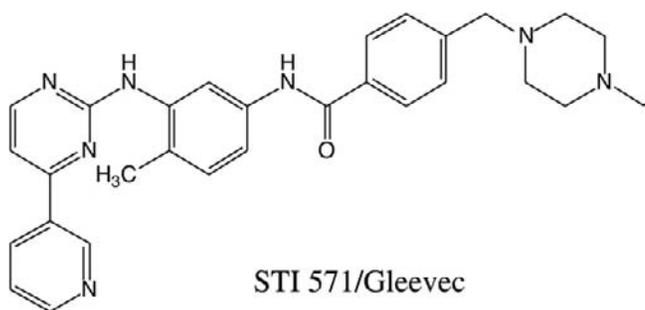

Figure 5 STI 571/Gleevec.

Kit receptor kinase, whereas normal cells can sustain and compensate for c-Kit blockade. Again, as for chronic CML patients, STI 571 has little side effects, probably because normal cells utilize alternative pathways when c-Kit is blocked or can get by even when a high fraction of the normal c-Kit molecules are blocked by utilizing alternative pathways.

ATP Mimics and Substrate Mimics

We have suggested that the optimal PTK inhibitors would be compounds that compete for the substrate binding site within the kinase binding domain. Such agents would be less toxic than ATP mimics because they bind to those domains at the kinase site that are less conserved than the substrate binding domains. Indeed, tyrphostins such as AG 490 (which blocks Jak-2 [13]) and AG 556 (which possesses antiinflammatory properties) have been shown to be highly nontoxic *in vivo* [43–46]. The main problem with these compounds is that they possess hydroxyl groups, which are metabolized relatively quickly, although this characteristic has not eliminated DOPA as an anti-Parkinsonian drug. Recently, we have developed substrate mimics in which the hydroxyls are replaced with *bioisosteres*. Half of the hydroxyl groups in AG 538 [47] were replaced with a type of bioisostere without losing much of the potency against IGF-1R and still retaining the substrate-competitive nature of the compound [48]. The double bond, which is present in many tyrphostins, may be a substrate for the Michael addition, which shortens the half-life of these compounds. Although this is rarely a problem, as most tyrphostins are stable in tissue culture medium for many hours [13,24], higher chemical stability can be achieved by eliminating this double bond. Work in progress indeed suggests that one can probably design substrate-competitive inhibitors devoid of double bonds.

A strong argument for developing substrate-competitive protein kinase inhibitors is that they are likely to offer higher selectivity, as the portion of the kinase site outside the ATP binding domain is less conserved among protein kinases. This in principle should enable one to discover highly selective kinase inhibitors, which even at high doses will exhibit minimal toxicity *in vivo*. All of the kinase inhibitors currently in development (Table 1) are used at high doses, between 20 and 100 mg/kg. These high doses reflect the relatively low

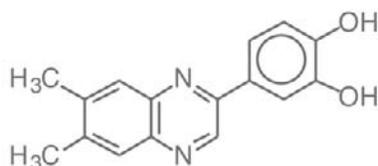

efficacy of these compounds *in vivo*, despite the fact that their IC_{50} values for their molecular targets, such as the EGFR, VEGFR-2/Flk-1 etc., are in nanomolar concentrations.

When one examines the efficacy of the ATP-competitive inhibitors in cellular assays, it is observed that these nanomolar compounds act on cells at micromolar concentrations. For example, quinazolines that bind to the EGFR with K_i of a few nanomolars [7,20] inhibit EGFR autophosphorylation in intact cells at micromolar concentrations [22,49]. Similarly, PP1 and PP2 that inhibit Src family kinases with IC_{50} values of 20 to 170 nM in cell-free assays [50] block Src activity in cells in the range of 5 to 40 μ M [49,51]. It seems, therefore, that the high doses required *in vivo* probably at least partly reflect the competitive relationship between the intracellular millimolar concentrations of ATP and the administered drug. It is noteworthy that drugs such as β -adrenergic blockers are administered at doses that are lower by about 100-fold. In this case, a drug possessing an affinity at nanomolar concentrations must compete with the up to 200-nM concentration of the endogenous ligand adrenaline or noradrenaline. Thus, β -blockers can be administered to patients at doses of 1.0 mg/kg or less with great efficacy. The same is true for other receptor-directed drugs for which the endogenous ligand is present at low concentrations within body fluids.

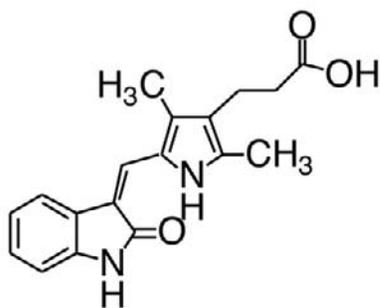

Adenosine triphosphate competitors suffer from another potential problem—the selectivity of newly developed compounds is only tested against a limited number of PTKs and Ser/Thr kinases. The number of PTKs is around 150 and the number of Ser/ kinases ranges from 500 to 600. It has already been observed that the so-called selective Src family kinase inhibitor PP1 is equipotent as a PDGFR kinase inhibitor [52]. Similarly, the Novartis Bcr-Abl kinase inhibitor, STI 571/Gleevec, used to treat CML, is as potent against PDGFR kinase and c-Kit [42]. An inhibitor that competes for both ATP and substrate simultaneously may actually be highly useful. Such tyrphostins have been generated [17], but their toxicity and efficacy *in vivo* have not been evaluated. It has been generally assumed that one should aim to treat patients for short periods in order to diminish side effects, a goal that is particularly applicable to cytotoxic drugs because of their severe side effects. Perhaps not surprisingly, Gleevec has been given to patients for many months with very minor side effects. In fact, the absence of toxicity may allow the prolonged use of protein kinase inhibitors and other signal transduction inhibitors, maximizing their therapeutic effect.

Angiogenesis

Angiogenesis is mediated by the activity of various receptors, primarily VEGFR but also PDGFR and FGFR. Following development of AG 1433 (Fig. 6) [10], Sugen developed SU 6668 (Fig. 6) as a PTK inhibitor for VEGFR, PDGFR, and FGFR simultaneously. This very interesting and promising agent (Table 1) is currently in clinical studies [53].

AG 1433

SU 6668

Figure 6 AG 1433 and SU 6668. AG 1433 was found to be a potent PDGFR and EGFR kinase inhibitor. This compound was found to inhibit angiogenesis [10] but was not suitable for development. SU 6668 [53] with a new scaffold was developed and is currently in clinical development (see Table 1).

PTK Inhibitors Synergize with Pro-Apoptotic Agents
