Gene knockout studies in mice and *in vitro* studies have convincingly reconfirmed the negative regulatory role of SHIP1 in myeloid cell development, mast cell activation, and antigen-induced B cell activation [15, 16]. SHIP1^{-/-} mice exhibit a myeloproliferative disorder and inability to regulate mature blood cell functions [3]. Different molecular mechanisms can account for the negative regulatory role of SHIP in each cell type, but a few common themes are apparent (Fig. 2). One mechanism, initiated through receptor tyrosine kinases such as Kit or the M-CSF receptor, may regulate the activation of the survival factor Akt/PKB by eliminating the phosphatidylinositol lipid, PIP3, necessary for Akt/PKB activation (Fig. 2A). How SHIP is recruited into this pathway is not clear; however, one possibility is via the Gab-family of proteins. All three Gab proteins contain the consensus YxxL SHIP SH2 binding motif, and both Gab1 and Gab2 interact with SHIP after growth-factor receptor stimulation [17]. A second general mechanism is shown in Fig. 2B. Here the SHIP SH2 domain is recruited to an Ig-binding receptor (Fc γ RIIB in B cells and macrophages, Fc ϵ RI in mast cells). In B cells the Fc γ RIIB-SHIP complex terminates a positive signal from the B cell receptor (BCR) [18–20]. In mast cells aggregation of Fc ϵ RI is sufficient alone for degranulation, a step regulated by SHIP [21]. In contrast to the above mechanisms, the interaction of SHIP with DOK and RasGAP presents a negative regulatory mechanism altogether different [22,23]. RasGAP in this complex is sufficient to convert active RasGTP to the inactive GDP-bound form and attenuate the MAPK pathway (Fig. 2C). No doubt, additional negative regulatory mechanisms will be uncovered in the future, and it is unlikely that all will be mutually exclusive. Future tasks will be directed at understanding the cellular “when, where, and how” of these different mechanisms.

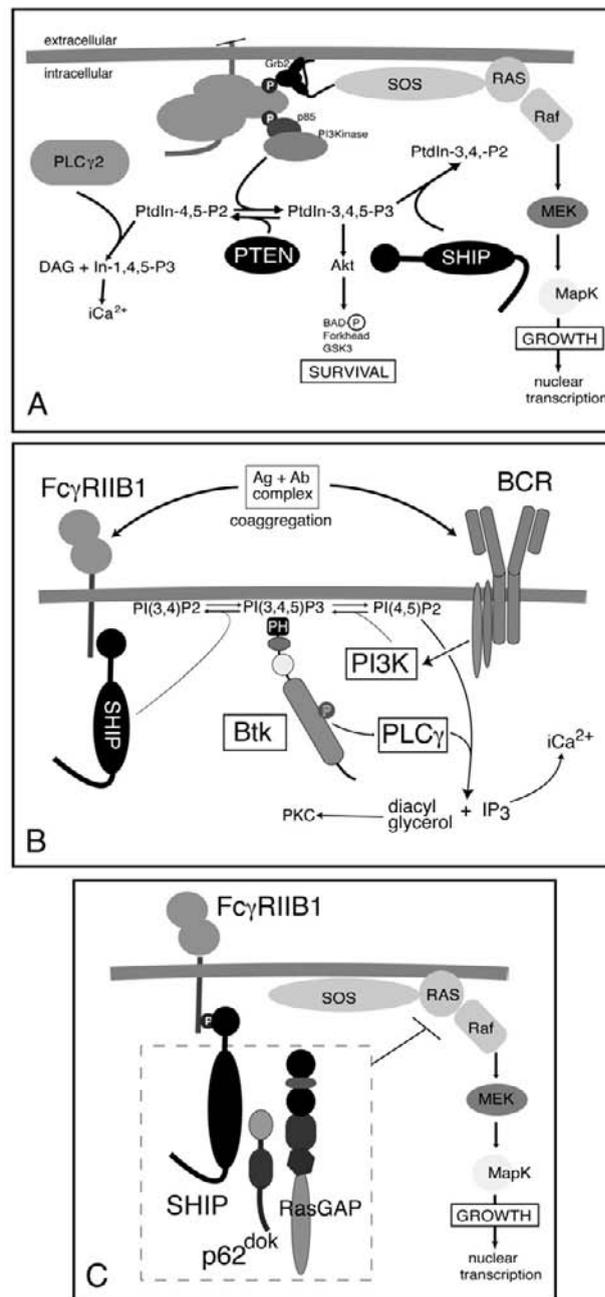

Figure 2 Mechanisms for the negative regulatory function of SHIP in cell signaling. See text for details.

SHIP2 Structure, Expression, and Function

The second member of the SHIP family, the SHIP2 protein, was first isolated by homology to the 51C protein [24]. 51C had been thought, incorrectly, to be a Fanconi anemia protein [25,26]. The 51C protein was also identified simultaneously with SHIP1 as containing an NPXY motif interacting with the PTB domain of Shc [6]. The murine SHIP2 gene is encoded in 29 exons [27]. The full sequence is complete for the mouse genome (AF162781). Translation is predicted to start in the second exon, which would encode part of the SH2 domain, and complete translation would

produce a predicted protein of 142 kDa. Antibodies to the C-tail of the SHIP2 protein recognize a protein with the apparent mass of 160 kDa, a size corresponding roughly to the predicted full-length SH2 domain-containing protein [28].

Spliced isoforms of the SHIP2 protein have not been reported; however, if exons 3–29 alone were transcribed, they might encode an alternative protein product from this gene. The 51C protein might be such a product. The nucleotide sequence for the 51C cDNA (GenBank L36818) comprises exons 3–29 but contains 393 different nucleotides at the 5' end. These nucleotides appear to be the intron immediately upstream of SHIP2 exon 3. If a protein were translated from this 51C mRNA, it would initiate translation at the methionine homologous with the same site in the s-SHIP protein. Therefore, the 51C cDNA could represent an s-SHIP version of the SHIP2 protein; however, it is also possible that this 51C cDNA is merely derived from incompletely-spliced mRNA.

SHIP2 contains, in general, a structure highly related to SHIP1 but the regions between the SH2 domain and the inositol 5-phosphatase domain and the C-tail region exhibit the least identity [24]. The specificity of the 5'-phosphatase enzymatic activity is similar to that in SHIP, but the inositol polyphosphates may be weaker substrates than the phosphatidylinositol analogues [29,30]. The C-tail region contains a single NPXY motif, several potential SH3-domain binding sites, and a C-terminal SAM (Sterile Alpha Motif) domain of yet unknown function in SHIP2 signaling. The amino acid sequence of the SH2 domain of SHIP2 suggests a binding specificity similar to that of SHIP1, and indeed, both are reported to interact with the phosphorylated immunoreceptor tyrosine-based inhibitory motif (ITIM) of Fc γ RIIB [31]. In addition, the SH2 domain of SHIP2 was found to bind tyrosine phosphorylated p130^{Cas} and therefore may have some role in the actin-based cytoskeletal reorganization accompanying cell spreading or migration [32].

Unlike SHIP1, SHIP2 is expressed in a broader range of cells and tissues of the mouse [24,26,27] and is present and constitutively tyrosine-phosphorylated in chronic myelogenous leukemia [30]. Brain and thymus exhibit the most prominent expression in both adult and 15.5 day embryos; liver expression was also highest in the embryo, but all other major embryonic or adult organs express some SHIP2. Testes express both SHIP1 and SHIP2 within the seminiferous tubules. Expression of SHIP2 is strongest at the periphery of the tubules where Sertoli cells and spermatogonia precursors reside. Also strongly positive are the mature spermatozoa occupying the inner portions of the seminiferous tubules. In contrast, SHIP1 expression is strongest in membranes of the developing spermatids located between the periphery and central core of the tubules. Therefore, the largely exclusive expression patterns of SHIP1 and SHIP2 in this tissue follow the developmental stages of spermatozoa production from the immature cells at the periphery of the seminiferous tubules to the mature cells in the central core. Expression of SHIP2 appears strongest in the most immature cells and decreases in spermatids while SHIP1 increases; expression levels again reverse in the mature spermatozoa.

Several growth factor receptors stimulate tyrosine phosphorylation of SHIP2 and activation of the Ras/Map kinase and Akt pathways [24,26,28]. The insulin receptor is extremely proficient at stimulating rapid and prolonged SHIP2 tyrosine phosphorylation and Akt/PKB activity. A negative regulatory role for SHIP2 in insulin-induced glucose uptake and glycogen synthesis has been shown by two independent methods. One study utilized wild-type and an inositol phosphatase-inactive mutant of SHIP2, demonstrating the requirement of the phosphatase activity in suppressing insulin-induced metabolic activities [33]. Another study generated SHIP2 knockout mice (lacking exons 18–29) and concluded that SHIP2 is necessary for the negative regulation of insulin signaling and sensitivity to insulin [34]. The homozygous mice lacking functional SHIP2 exhibited perinatal death, and heterozygous mice expressed symptoms of adult-onset diabetes mellitus. Additional abnormalities were not detected in the SHIP2 knockout mice, suggesting that negative regulation of insulin signaling may be a primary function of SHIP2.

Structural Principles of Lipid Second Messenger Recognition

Roger L. Williams

*Medical Research Council,
Laboratory of Molecular Biology,
Cambridge, United Kingdom*

Introduction

Structural analyses have shown that domains with a variety of different folds can recognize a single type of lipid second messenger and that a single type of fold can evolve different binding sites and alternative modes of interaction for the same lipid second messenger. Specificity in lipid recognition is achieved by both electrostatic and shape complementarity. A common theme suggested by the structures of the lipid-modifying enzymes and the specific recognition modules is that secondary, nonspecific membrane interactions cooperate with specific lipid recognition to increase membrane avidity. Most binding domains have evolved mechanisms such as partial membrane penetration to bind lipids without removing them from the bilayer.

A wide range of lipid second messengers that are generated in response to external signals has been characterized in terms of their molecular biology. This review will focus on underlying structural principles involved in recognizing these messengers both by the enzymes that produce or consume them and by the downstream effector domains. In most cases, the lipid-modifying enzymes are structurally homologous to enzymes that catalyze an analogous reaction using soluble substrates, suggesting that the constraints imposed by the catalytic chemistry are a stronger determinant of fold than specific lipid binding. For example, the lipid kinases are homologous to protein kinases [1,2]. The phosphoinositide phosphatases are homologous to protein phosphatases and endonucleases [3,4]. The phosphoinositide-specific phospholipases C have a catalytic domain with a

TIM-barrel fold similar to many other enzymes and an arrangement of catalytic residues similar to nucleases [5]. A variety of domains present in downstream effector proteins also specifically recognize the lipid second messengers. In contrast to the metabolizing enzymes, these effector domains typically bind lipids with higher affinity and have unique folds.

Phospholipid Second Messenger Recognition by Active Sites of Enzymes

The phosphoinositides are the most diverse family of lipid messengers. All of them share a phosphatidyl *D-myo*-inositol (PtdIns) scaffold that can be phosphorylated at all possible combinations of the 3-, 4-, and 5-hydroxyls to generate lipid messengers with specific roles in intracellular signaling. Several generalizations can be made regarding the recognition of phosphoinositides by proteins. The enzymes that recognize phosphoinositides as substrates tend to envelope the headgroup and make Van der Waals contacts with both faces of the inositol ring (Fig. 1). In contrast, the domains that have evolved simply to bind the phosphoinositides, such as PH domains, tend to form interactions with some or all of the phosphates but to leave one or both faces of the ring exposed (Fig. 2). Presumably, the tendency for the enzymes to more fully bury the headgroup arises from a necessity to exclude water from the active site or to more precisely position the reactive moieties in the active site. Within a family of domains, the affinity of phosphoinositide headgroup binding generally correlates with the number of hydrogen bonds between the

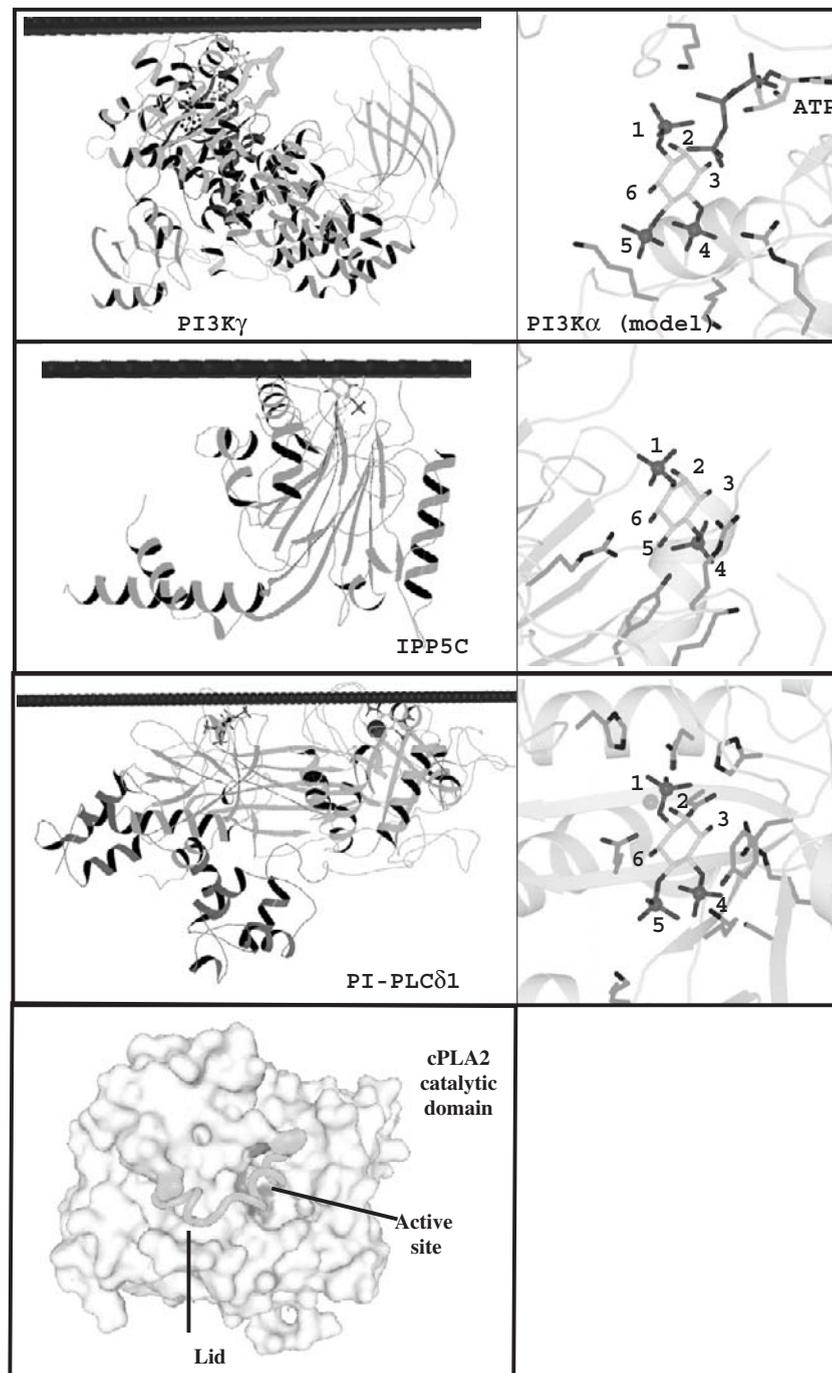

Figure 1 Lipid second messenger recognition by lipid-modifying enzymes. The left panels show the overall folds of the phosphoinositide-modifying enzymes with putative membrane-interacting regions placed in contact with a schematic membrane represented by a layer of spheres. The bound phosphoinositides are shown in stick representation. In the right panels, close-up views of the phosphoinositide/protein interactions are shown. The structures were optimally superimposed on the inositide moieties to present a common view. The molecular surface of cPLA₂'s catalytic domain is shown in the lower panel.

phosphoinositide and the protein. The enzymes generally have a lower affinity for the phosphoinositide headgroup than the highest affinity binding modules—as would be expected from the role of an enzyme to preferentially recognize the transition state rather than the substrate or the product.

Phosphoinositide 3-Kinase (PI3K). PI3Ks catalyze the phosphorylation of phosphoinositides at the 3-OH, giving rise to the second messengers PtdIns(3)P, PtdIns(3,4)P₂, and PtdIns(3,4,5)P₃. The structure of PI3Kγ, representative of both PI 3- and PI 4-kinases, has a catalytic domain with an

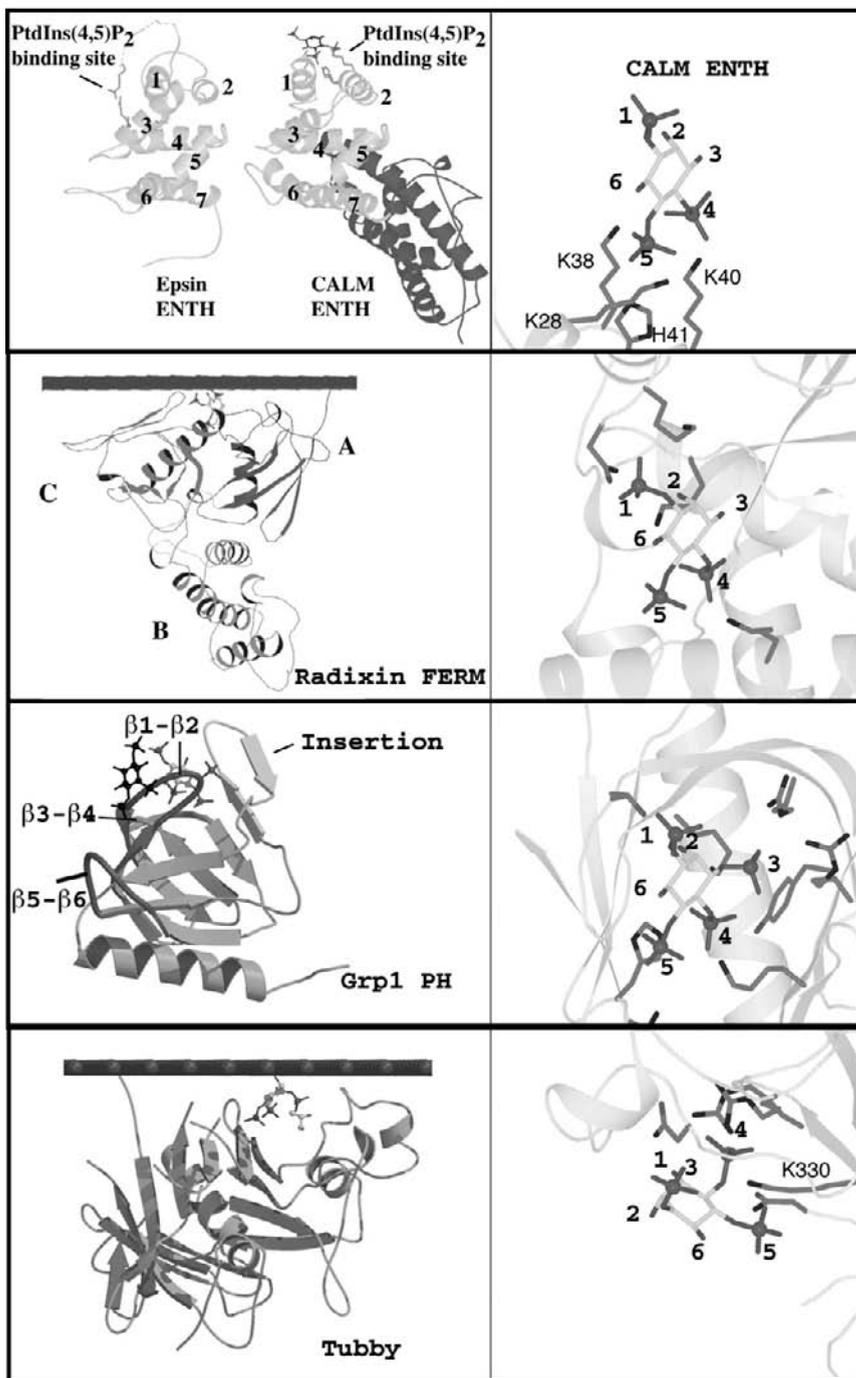

Figure 2 Recognition of polyphosphorylated phosphoinositides by specific binding modules. The representations are as in Fig. 1. In the first pair of panels, the PtdIns(4,5)P₂-binding sites of the epsin and CALM ENTH domains are illustrated. The structurally similar regions of the two domains are colored yellow. Part of the epsin PtdIns(4,5)P₂ site involves N-terminal residues that have been modeled (dotted lines). In the third pair of panels, Ins(1,3,4,5)P₃ bound to the Grp1 PH domain is shown (magenta phosphates). To illustrate the differences in the locations of the phosphoinositide binding pockets in β -spectrin and other PH domains such as Grp1, an Ins(1,4,5)P₃ (black) has been placed on the Grp1 domain in a location analogous to the β -spectrin binding pocket.

N-terminal lobe consisting of a five-stranded β -sheet closely related to protein kinases and a C-terminal lobe that is predominantly helical and more distantly related to protein kinases. The primary determinant of substrate preference for both PI3Ks is a region in the C-terminal lobe analogous to

the activation loop of protein kinases [6,7]. Models of substrate binding proposed for PI3Ks place the phosphoinositide in a shallow pocket (Fig. 1) so that the 4- and 5-phosphates interact with basic residues in the activation loop, and the 1-phosphate contacts a Lys in a loop analogous to the

glycine-rich loop of protein kinases (but without glycines in PI3Ks) [2,7]. As with PLC δ 1, the location of the active site and accessory domains for membrane binding suggest that the enzyme interacts with the membrane in such a manner that substrate lipids do not have to be removed from the lipid bilayer (Fig. 1).

Phosphatidylinositol Phosphate 4- and 5-Kinases (PIPkins). PtdIns(4,5)P₂-mediated signal transduction is essential for cytoskeletal organization and dynamics, membrane trafficking, and apoptosis. Synthesis of PtdIns(4,5)P₂ is catalyzed by PIPkins [8]. The type II β PIPkin has an N-terminal lobe with a seven-stranded antiparallel β -sheet structurally related to protein kinases and a C-terminal lobe consisting of a smaller five-stranded β -sheet [1]. The PIPkins have a requirement for phosphorylated phosphoinositides due to a cluster of four conserved, basic residues in a putative phosphoinositide-binding pocket. The binding pocket is surprisingly shallow and open and suggests that there are few or no contacts with the 2- and 3-OH of the headgroup. The specificity of the enzyme for PtdIns(4)P versus PtdIns(5)P is completely dictated by a loop in the C-terminal lobe analogous to the activation loop of PI3K and protein kinases, and a single point mutation in this loop can swap the specificity [9].

PTEN, a 3-Phosphoinositide Phosphatase. Essential to any signal transduction system is a mechanism to produce second messengers and a mechanism to eliminate them. PTEN has a critical role in cells to antagonize the action of PI 3-kinases by catalyzing the dephosphorylation of the 3-phosphate from PtdIns(3,4,5)P₃. The structure of PTEN has a fold and active site configuration similar to the dual-specificity protein phosphatases [3]. A model for substrate binding places His 93 and Lys 128 as ligands of the 5-phosphate [3]. Although the 4-phosphate is deeply buried in the PTEN active site, there is no basic residue present with which it would associate. This is consistent with the ability of the enzyme to dephosphorylate PtdIns(3)P, PtdIns(3,4)P₂, and PtdIns(3,4,5)P₃. The 3-phosphate is also deeply buried, but, consistent with the presence of the scissile bond on this group, there is a basic residue, Arg 130, interacting with it.

Inositol Polyphosphate 5-Phosphatase (IPP5P). IPP5P plays an essential role in signaling by utilizing both inositol phosphates and phosphatidylinositol polyphosphates as substrates. The 5-phosphatases regulate the levels of both the soluble Ins(1,4,5)P₃ and the membrane-resident PtdIns(4,5)P₂. The structure of the catalytic domain of the synaptojanin IPP5P from *S. pombe* bound to the product of the reaction, Ins(4)P, shows an active site located at the bottom of a funnel-shaped depression containing the histidine essential for catalysis [4]. The catalytic mechanism is closely related to those of nucleases such as DNase I and DNase III. The 4-phosphate of the Ins(4)P interacts with three basic groups in the active site and makes water-mediated interactions with the divalent metal co-factor (Fig. 1). The product of the reaction binds in a catalytically nonproductive manner with the 4-phosphate

remote from the catalytic histidine, thus showing why this family of enzymes is not able to use Ins(1,4)P₂ as a substrate.

Phosphoinositide-specific Phospholipase C (PI-PLC). PtdIns(4,5)P₂ is hydrolyzed by PI-PLC. The catalytic domain of the mammalian PLC δ 1 consists of a (β/α)₈ barrel [5], a common architecture for enzymes in general. Principles of PtdIns(4,5)P₂ headgroup recognition by PI-PLC have been inferred from a complex of PLC δ 1 with the product of the reaction, Ins(1,4,5)P₃. With the exception of the 6-OH of the headgroup, all of the hydroxyls of the bound inositide are stereospecifically recognized by the enzyme. The PtdIns(4,5)P₂ headgroup lodges edge-on in the binding pocket with the 3-OH at the bottom and the 1-OH at the top. This places the 1-OH at the level of the putative membrane-binding surface, suggesting that the enzyme does not remove substrate from the membrane during the catalytic cycle, similarly to most of the phosphoinositide-recognizing enzymes and binding domains (Fig. 1).

Cytosolic Phospholipase A₂. The phospholipase A₂ (PLA₂) family of enzymes hydrolyzes the *sn*-2 bond of phospholipids to generate free fatty acids and lysophospholipids. The cytosolic PLA₂ (cPLA₂) selectively hydrolyzes phospholipids with an *sn*-2 arachidonic acid and therefore has a key role in supplying the precursor for eicosanoid biosynthesis. cPLA₂ has an N-terminal C2 domain that is important for Ca²⁺-dependent membrane translocation and a catalytic domain. The enzyme has a central β -sheet with an active-site nucleophile located in a portion of the structure analogous to the nucleophilic elbow of other phospholipases having an α/β hydrolase fold [10]. Apart from this feature, however, cPLA₂ has a quite divergent fold. Residues in the active site that are buried by a flexible lid accomplish recognition of the substrate. Upon binding to the membrane interface, this lid undergoes a conformational change to expose a wide hydrophobic platform surrounding a funnel-shaped pocket that cradles the substrate (Fig. 1). Even though the structure suggests that the catalytic domain partially penetrates into the hydrophobic portion of the lipid membrane, the cleft leading to the active-site nucleophile is deep enough to require that the substrate be removed from the lipid bilayer [10].

Phosphoinositide-binding Domains

Polyphosphorylated Phosphoinositide-binding Domains

ENTH Domain. Several proteins involved in endocytosis have an N-terminal domain of about 140 residues known as the ENTH domain, which is necessary for binding to PtdIns(4,5)P₂. The ENTH domains of CALM [11], AP180 [12], and epsin [13,14] consist of helices wound into a solenoid reminiscent of other helical domains such as armadillo and TPR. The PtdIns(4,5)P₂ binding sites in the CALM and epsin ENTH domains differ significantly (Fig. 2). The unique

binding site of the CALM ENTH domain is on an exposed surface with the PtdIns(4,5)P₂ headgroup poised at the tips of three lysines (K28, K38, K40) and a histidine (H41) in helices α 1 and α 2 and the loop between them (Fig. 2). The residues involved in the interaction define a KX₉KX(K/R)(H/Y) motif that is present in other AP180 homologues but not in epsin [11]. The binding site in epsin involves basic residues in helices α 3, α 4 and a disordered N-terminal region that changes conformation upon lipid binding (Fig. 2) [14]. As was observed for PH domains, similarity in domain fold does not imply that the same region of the fold is used to interact with phosphoinositides.

The FERM Domain. The FERM domain is found in the ezrin/radixin/moesin (ERM) family of proteins as well as in talin, the erythrocyte band 4.1 protein, several tyrosine kinases and phosphatases, and the tumor suppressor merlin. Members of the ERM family of proteins have three structural domains, and the N-terminal FERM domain binds to PtdIns(4,5)P₂-containing membranes. Phospholipid binding is masked by an intra or intermolecular interaction between the C-terminal domain and the FERM domain. The FERM domain consists of three compact modules, A, B, and C [15–17]. Although the C module has an overall fold similar to PH domains that are known to bind PtdIns(4,5)P₂, the crystal structure of the radixin complex with the Ins(1,4,5)P₃ shows that the phosphoinositide binds between the A and C modules [18]. Two basic residues from the A module interact with the 4- and 5-phosphates and one from the C module interacts with the 1-phosphate (Fig. 2). The binding site is more open than most PtdIns(4,5)P₂ binding sites but less open than the ENTH-type PtdIns(4,5)P₂ binding site. PtdIns(4,5)P₂ binding causes conformational changes in the C module that prevent a self-association with the C-terminal tail of the protein and enable the N-terminal domain to interact with the cytosolic regions of integral membrane proteins. Mutagenesis suggests that the β 5- β 6 and β 6- β 7 loops in the C module may constitute a second PtdIns(4,5)P₂-binding site [19,20]. The phosphoinositide binding pocket defines part of a basic surface that is likely to be juxtaposed to the lipid bilayer, leaving an acidic groove between subdomains B and C free to interact with integral membrane adhesion proteins (Fig. 2) [18].

Tubby C-terminal DNA-binding Domain. A common feature among the tubby family proteins is the presence of a C-terminal DNA-binding domain with a unique fold consisting of a 12-stranded antiparallel β -barrel and a hydrophobic helix running through the barrel [21]. PtdIns(4,5)P₂ binding to the C-terminal domain causes Tubby to be localized to the plasma membrane until the levels of PtdIns(4,5)P₂ fall in response to receptor-mediated activation of PLC- β [21]. Loss of plasma-membrane localization is accompanied by nuclear translocation of the protein. The complex of the C-terminal domain of Tubby with glycerophosphoinositol 4,5-bisphosphate shows the PtdIns(4,5)P₂ headgroup in a shallow pocket that involves residues from three adjacent β -strands [21] and is located at one edge of the putative DNA-binding surface.

The side chain of a single Lys (330) intercalates between the 4- and 5-phosphates in a manner that is unique to Tubby and the CALM-N ENTH domains (Fig. 2). In these domains, Lys side chain approaches the 4- and 5-phosphates approximately parallel to the plane of the inositol ring. In Tubby, the Lys makes an unusually close (2.1 Å) contact with the 5-phosphate. An additional Arg that coordinates the 4-phosphate is also positioned so that 3-phosphorylated lipids could interact with it, which may account for the PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ binding observed *in vitro* [22].

PH Domains. PH domains are among the most common phosphoinositide-binding modules present in mammalian genomes and show a wide range of phosphoinositide affinities and specificities. They consist of two orthogonal β -sheets curving to form a barrel-like structure closed off by a C-terminal α -helix [8,23]. High-affinity binding to phosphoinositides is achieved using residues in the β 1- β 2 (VL1), β 3- β 4 (VL2), and β 6- β 7 (VL3) loops. The PtdIns(4,5)P₂-specific PH domain of PLC- δ 1 [24] differs from other PH domains in that the orientation of the bound inositide is flipped by 180° so that the position occupied by the 5-phosphate in PLC- δ 1 is occupied by the 3-phosphate in the 3-phosphoinositide-specific PH domains that have been characterized (Fig. 2).

Among PH domains recognizing 3-phosphoinositides, three types of specificities are apparent: PtdIns(3,4,5)P₃-specificity such as the PH domain of Grp1 and Btk, dual PtdIns(3,4,5)P₃/PtdIns(3,4)P₂-specificity such as the PH domain of DAPP1 and PKB and PtdIns(3,4)P₂-specificity such as the C-terminal PH domain of TAPP1. The PtdIns(3,4,5)P₃ specificity is achieved by enveloping the 5-phosphate by using insertions in either the β 6- β 7 loop (as in GRP1 [25,26]) or in the β 1- β 2 loop (as in Btk, [27]). DAPP1 makes more interactions with the 4-phosphate while the 5-phosphate is largely exposed. The PtdIns(3,4)P₂ specificity of the TAPP1 PH domain arises from steric clashes of the 5-phosphate with residues in the β 1- β 2 loop [28]. The analogous region of the closely related DAPP1 PH domain has a Gly that makes space to accommodate the 5-phosphate of PtdIns(3,4,5)P₃. Basic and hydrophobic residues in the β 1- β 2 loop of Grp1 and Btk suggest that these PH domains may have additional, nonspecific interactions with lipid bilayers that enhance membrane avidity (Fig. 2) [26].

Other modes of phosphoinositide binding have been shown for PH domains. The PH domain of β -spectrin uses the β 5- β 6 loop and the side of the β 1- β 2 loop opposite that used by PLC- δ 1 to interact with Ins(1,4,5)P₃ [29], showing that the same fold can be adapted to several different binding modes (Fig. 2). The PH domain from β -spectrin is an example of a PH domain with low affinity and little specificity for lipid binding. More recent analyses of the genome suggest that this may be characteristic of the vast majority of PH domains [23].

PtdIns(3)P-binding Domains

PtdIns(3)P is present in mammalian cells at fairly high concentrations relative to such transient lipid second

messengers as PtdIns(3,4,5)P₃. Its distribution in cells is restricted mainly to endosomal membranes. PtdIns(3)P levels can increase rapidly during certain processes such as receptor-mediated phagocytosis [30]. Two structurally unrelated domain types, FYVE and PX, are capable of specifically binding PtdIns(3)P [31].

FYVE Domains. The FYVE domains are found in many proteins involved in membrane transport [32]. The FYVE domains from Vps27 [33], Hrs [34], and EEA1 [35,36] consist of two small β -sheets stabilized by two Zn²⁺ ions and a C-terminal α -helix. The PtdIns(3)P forms hydrogen bonds with the protein by using the 1- and 3-phosphates and the 4-, 5-, and 6-OH groups [36]. The close approach of these hydrogen-bonding partners precludes polyphosphorylated phosphoinositides from binding (Fig. 3). The 3-phosphate forms a hydrogen bond with the last arginine in the (R/K) (R/K)HHCR signature motif characteristic of the FYVE domains. The 1-phosphate interacts with the protein *via* the first Arg of this motif. Like the PH domains, the FYVE domain buries only one face of the bound phosphoinositide. For EEA1, the face with the axial 2-OH is exposed to solution. The presence of the coiled-coil region preceding the EEA1 FYVE domain helps to

unambiguously define the mode of membrane interaction and suggests that a loop flanking the PtdIns(3)P pocket, the “turret” loop, penetrates into the lipid bilayer (Fig. 3). Biophysical measurements indicate that this partial membrane penetration follows rather than precedes specific PtdIns(3)P binding [37].

PX Domains. PX domains are found in a wide range of proteins including many involved in lipid modification, intracellular signaling, and vesicle trafficking [38]. They consist of a three-stranded β -sheet subdomain and an α -helical subdomain that are joined by a conserved RR(Y/F) motif [39,40]. The structure of the PX domain from the p40 cytosolic subunit of the NADPH oxidase in a complex with PtdIns(3)P shows that the first Arg from the RR(Y/F) motif has a structural role in the core of the protein, while the second Arg and the Tyr residue interact with the 3-phosphate and the face of the inositide ring, respectively [40] (Fig. 3). The PX domain buries the face of the inositide adjacent to the axial 2-OH, leaving the opposite face largely exposed. The mode of membrane binding of the PX domain is suggested by the diacylglycerol moiety of the bound PtdIns(3)P and hydrophobic residues adjacent to the phosphoinositide binding pocket (Fig. 3).

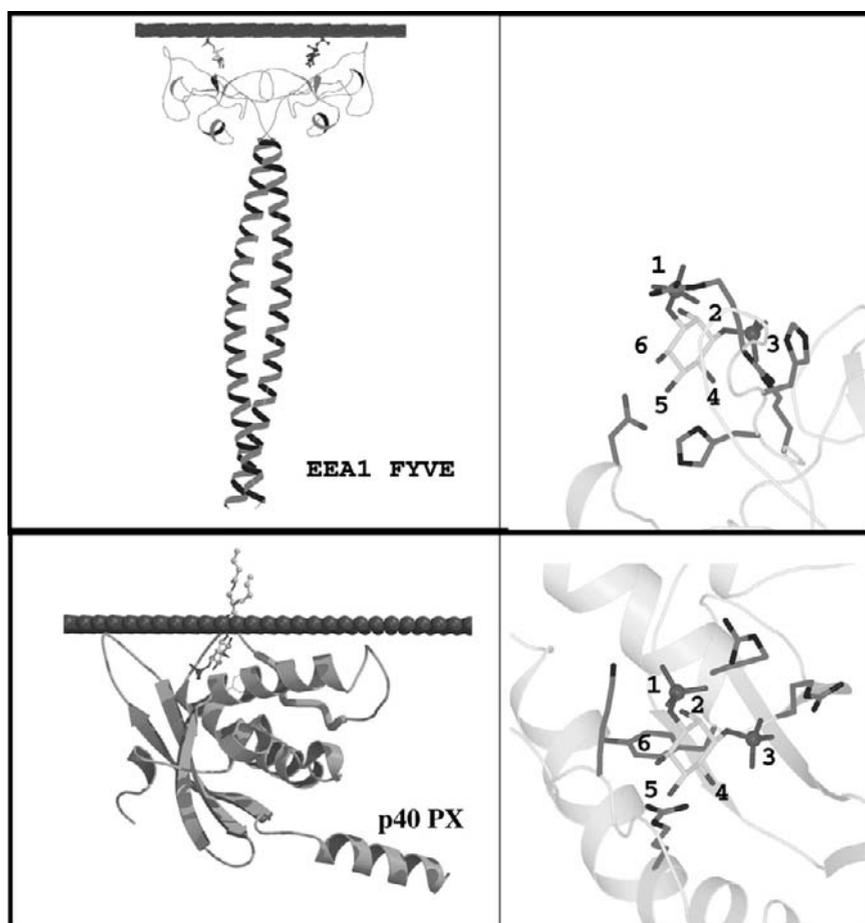

Figure 3 PtdIns(3)P recognition by specific binding modules. The representations are as in Fig. 1

Non-phosphoinositide Lipid Messenger Recognition

C1 Domains. The C1 domain is essential for membrane localization and activation of many proteins involved in signal transduction, including the protein kinase C isozymes [41]. The C1 domains are 50-residue modules containing two small β -sheets and a short C-terminal helix. The domains have been classified into two groups, the “typical” domains that fit a profile derived for phorbol ester or diacylglycerol (DAG) binding and the “atypical” domains that do not [42]. The phorbol ester sits in a groove that is formed by a splaying of adjacent β -strands in a sheet [43,44]. Hydrophilic groups on the phorbol ester intercalate between the strands and make backbone interactions with their exposed main-chain atoms. Once the phorbol ester is bound, the entire end of the domain presents a hydrophobic surface that penetrates into the lipid bilayer. Available binding data are consistent with a model in which the DAG fits into the same groove as the phorbol ester, forming hydrogen bonds with the main-chain atoms of the strands using its 3-OH.

Future Directions

Although much progress has been made in defining the nature of the interactions of lipid second messengers with proteins, many questions remain unanswered. Several lipid second messengers have been characterized for which there is no structural information about specific binding modules, e.g. PtdIns(3,5)P₂ and phosphatidic acid. A dimension of response to lipid-messenger recognition that remains largely unexplored is the effect of membrane binding on membrane structure during processes such as formation of multivesicular bodies. Many proteins use multiple weak interactions to bind to membranes in response to lipid second messengers, but an analysis of the energetics of the individual interactions is often lacking. Although membrane translocation in response to lipid second messengers is common, the nature and extent of allosteric responses mediated by membrane interactions are not clear. With methodologies that have emerged in the wake of genomic studies, we can look forward to answers to many of these questions in the near future.

Note Added in Proof

The details of the PtdIns(4,5) P₂-binding site of the epsin ENTH domain were described in the report of Ford, *et al* [45].

Acknowledgments

I apologize to colleagues whose work I was unable to cite given the wide scope of the review and the severe limitations on space. Marketa Zvelebil is thanked for coordinates of the PI3K α model.

Pleckstrin Homology (PH) Domains

Mark A. Lemmon

*Department of Biochemistry and Biophysics,
University of Pennsylvania Medical Center,
Philadelphia, Pennsylvania*

Identification and Definition of PH Domains

The 100 to 120-amino acid pleckstrin homology (PH) domain was first named in 1993 [1–3] as a region of sequence similarity that occurs twice in pleckstrin [4] and is shared by a large number of other proteins. Levels of sequence identity between PH domains are generally low, lying between around 10 (or less) to 30 percent, and there is no conserved motif that identifies PH domains. Rather, PH domains are defined by a pattern of sequence similarity that suggests a common fold, and may therefore share structural similarity in the absence of functional relatedness. The majority of PH domain-containing proteins require membrane association for some aspect of their function. These proteins participate in cellular signaling, cytoskeletal organization, membrane trafficking, and/or phospholipid modification. Sequences encoding PH domains occur in some 252 genes in the first draft of the human genome sequence [5], making this the eleventh most populous domain family in humans. PH domains occur in 77 genes in *D. melanogaster*, 71 genes in *C. elegans*, and 27 in *S. cerevisiae* [5]. Understanding the functions of these common domains has therefore been a subject of considerable interest.

The Structure of PH Domains

Structures of 15 different PH domains have been determined by NMR and/or X-ray crystallography [6–19]. At the core of each PH domain is the same seven-stranded β -sandwich of two near-orthogonal β -sheets containing four- and three-strands respectively (Fig. 1). A characteristic C-terminal

α -helix (α C) closes off one “splayed” or open corner [20] of the β -sandwich (top in Fig. 1), while three interstrand loops (the most variable in PH domains) close off the opposite splayed corner (abutting the membrane surface in Fig. 1). This core fold has also been seen in several other classes of domain that share no significant sequence similarity with PH domains [21]. These include the phosphotyrosine binding (PTB) domain [22,23], the Enabled/VASP homology 1 (EVH1) domain [24,25], a Ran binding domain [26], and the FERM domain (for band four-point-one, ezrin, radixin, moesin homology domain) [27]. The basic β -sandwich structure has been termed the PH domain “superfold” by Saraste and colleagues [28]. The frequent occurrence of this fold probably reflects its adaptability to multiple functions by creating a stable structural scaffold that can bear loops with quite different recognition properties.

Beyond the conserved β -sandwich fold, one characteristic shared by all PH domains of known structure (except the *C. elegans* Unc89 PH domain [7]) is a marked electrostatic sidedness. Each PH domain is electrostatically polarized, with a positively charged face that coincides with the three most variable loops in the PH domain [9,29]. This positively-charged face abuts the membrane in Fig. 1, and its existence provided part of the motivation for initial tests of PH domain binding to (negatively charged) membrane surfaces.

PH Domains as Phosphoinositide-Binding Modules

The Fesik laboratory was the first to point out that PH domains can bind membranes containing phosphoinositides [30]. Specifically, they showed that the N-terminal PH domain

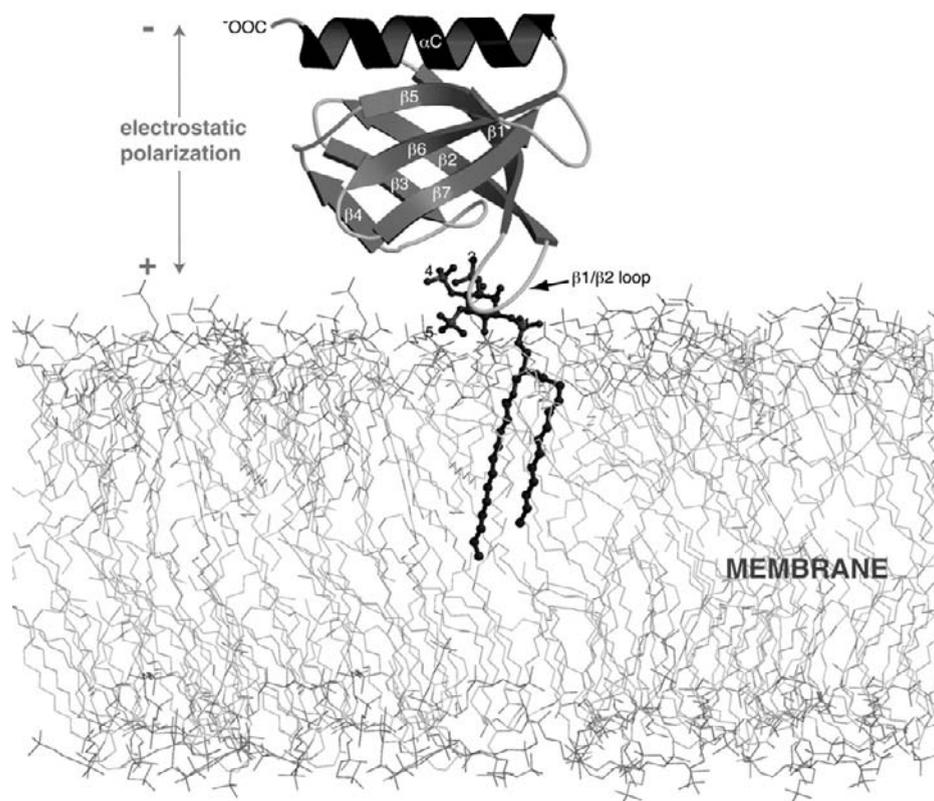

Figure 1 Hypothetical view of how the DAPP1 PH domain binds to PtdIns(3,4,5)P₃ in a membrane. The X-ray crystal structure of the DAPP1 PH domain [11] is shown in a ribbon representation with bound Ins(1,3,4,5)P₄. The β -sandwich structure of the PH domain can be seen, with strands β 1 through β 4 forming a sheet behind the plane of the paper, and strands 5 through 7 forming a β -sheet in front of the plane of the paper. The characteristic C-terminal α -helix (α C) is also labeled (and caps the upper splayed corner of the β -sandwich). The direction of electrostatic polarization of PH domains is depicted schematically on the left. The positive face abuts the membrane in this orientation. A diacylglycerol molecule has been attached to the Ins(1,3,4,5)P₄ molecule to generate a hypothetical view of PtdIns(3,4,5)P₃ bound to the DAPP1 PH domain. The PtdIns(3,4,5)P₃ is embedded in a stick model of a phosphatidylcholine bilayer to guide thinking as to how the PH domain might bind the lipid headgroup in this context. MOLSCRIPT [98] was used to generate this figure.

from pleckstrin binds phosphatidylinositol-(4,5)-bisphosphate (PtdIns(4,5)P₂) with a K_D of approximately 30 μ M. NMR analyses demonstrated that the positively charged face of the domain (shown to abut the membrane in Fig. 1) is the site at which the lipid binds [30]. A large number of subsequent studies have shown that phosphoinositide binding is a characteristic shared *in vitro* by nearly all PH domains, and a view has emerged that phosphoinositide binding is a conserved and likely physiologically relevant function for most PH domains [21,31,32]. For several PH domains, phosphoinositide binding has been convincingly demonstrated to be an important (and perhaps the only) function. In these cases the PH domain specifically recognizes the headgroup of a particular phosphoinositide, and this interaction plays an important role in targeting the PH domain-containing protein to cellular membranes [21,33]. However, PH domains in this category are rare. The majority—perhaps over 90 percent of PH domains—bind phosphoinositides with only low affinity and specificity [21,34–36]. How these PH domains participate in membrane targeting (if indeed they do) is not yet clear.

Highly Specific Recognition of Phosphoinositides (and Inositol Phosphates) by PH Domains

PH DOMAIN BINDING TO PHOSPHATIDYLINOSITOL-4,5-BISPHOSPHATE

The phospholipase C- δ_1 (PLC- δ_1) PH domain was the first shown to recognize a specific phosphoinositide with high affinity [37–39]. The PLC- δ_1 PH domain recognizes both PtdIns(4,5)P₂ (which it binds with a K_D of approximately 2 μ M) and its isolated soluble headgroup, inositol-(1,4,5)-trisphosphate (Ins(1,4,5)P₃), with which it forms a 1:1 complex ($K_D=210$ nM) [39]. An X-ray crystal structure of the Ins(1,4,5)P₃/PLC- δ_1 PH domain complex [10] showed that the three variable loops on the positively-charged face of the PH domain form the PtdIns(4,5)P₂/Ins(1,4,5)P₃ binding site. The detailed structure of this binding site also provided clear explanations for the strong Ins(1,4,5)P₃-specificity of the PLC- δ_1 PH domain (it binds Ins(1,4,5)P₃ at least 15-fold more strongly than any other inositol polyphosphate). When expressed as a green fluorescent

protein (GFP) fusion, or analyzed by indirect immunofluorescence, the PLC- δ_1 PH domain shows clear plasma membrane localization [40–43]. GFP fusion proteins of this PH domain have been used to identify the location of PtdIns(4,5) P_2 in living cells, and to monitor PtdIns(4,5) P_2 dynamics and/or Ins(1,4,5) P_3 accumulation in response to different agonists [41–45].

RECOGNITION OF PHOSPHATIDYLINOSITOL 3-KINASE PRODUCTS

Following the realization that some PH domains recognize specific phosphoinositides, it was found that protein kinase B (PKB, also known as Akt), a serine/threonine kinase with an N-terminal PH domain, is a downstream effector of phosphatidylinositol 3-kinase (PI 3-kinase) [46,47]. Mutations in the PKB PH domain prevent its PI 3-kinase-dependent activation, indicating that the PH domain itself plays a critical role in this step [47]. The PKB PH domain specifically recognizes both PtdIns(3,4,5) P_3 and PtdIns(3,4) P_2 , the major products of agonist-stimulated PI 3-kinase, but does not bind strongly to PtdIns(4,5) P_2 or other phosphoinositides [48–50]. As discussed elsewhere in this volume, PtdIns(3,4,5) P_3 and PtdIns(3,4) P_2 are all but undetectable in quiescent cells but accumulate transiently in the plasma membrane following stimulation of cells with a variety of agonists (to an estimated local concentration of 150 μ M [51]). A PH domain that fails to bind PtdIns(4,5) P_2 (present constitutively in the plasma membrane), but which binds strongly to PtdIns(3,4,5) P_3 and/or PtdIns(3,4) P_2 , will be recruited to the plasma membrane specifically when these PI 3-kinase-generated lipid second messengers are present. The PH domain from PKB has these binding characteristics, and can be shown (as a GFP fusion protein) to be recruited efficiently to the plasma membrane of mammalian cells following growth factor stimulation [52,53]. As discussed elsewhere in this volume, once recruited by its PH domain to PI 3-kinase products at the plasma membrane, PKB is activated at this location by phosphorylation at two sites [54]. One phosphorylation event is performed by a serine/threonine kinase named PDK1 (for phosphoinositide-dependent kinase-1), which also has a PH domain that can recruit it to the plasma membrane in a PI 3-kinase-dependent manner [55,56].

Other PH domains that specifically recognize PI 3-kinase products include that from Bruton's tyrosine kinase (Btk) [34,57–59] and the PH domain from the Arf-guanine nucleotide exchanger Grp1 (general receptor for phosphoinositides-1) [60]. Both of these PH domains bind exclusively (and strongly) to PtdIns(3,4,5) P_3 or its headgroup Ins(1,3,4,5) P_4 [35,59,60]. A point mutation (at arginine-28) in the Btk PH domain, which leads to agammaglobulinemia in humans and mice [61,62], abolishes PtdIns(3,4,5) P_3 /Ins(1,3,4,5) P_4 binding [34,57,58]. The effects of this Btk mutation on B-cell signaling provided the first clue that PH domains may play a role in signal transduction. Like the PKB PH domain, the Btk and Grp1 PH domains are recruited directly to the plasma membrane upon PI 3-kinase activation [53,63–65].

Skolnik and colleagues identified more than 12 different PH domains capable of driving PI 3-kinase-dependent plasma membrane recruitment using a novel yeast-based assay [66]. Where studied, each of these PH domains binds *in vitro* to PtdIns(3,4,5) P_3 (or Ins(1,3,4,5) P_4) with a K_D in the 10–100 nM range, and selects for PtdIns(3,4,5) P_3 over PtdIns(4,5) P_2 by a factor of 20 or more [21]. PH domains in this group share a sequence motif centered around the $\beta 1/\beta 2$ loop that links the first two β -strands of the PH domain sandwich. Several crystal structures of PH domains bound to Ins(1,3,4,5) P_4 have shown how this motif defines a specific binding site for the PtdIns(3,4,5) P_3 [6,11,67] (Fig. 2). The structural details of the binding site are remarkably well conserved across different structures and bear a strong resemblance (in structure and sequence) to the Ins(1,4,5) P_3 binding site of the PLC- δ_1 PH domain. The sequence motif identified by Skolnik and colleagues [66] serves as a strong and reliable predictor of which PH domains specifically recognize PI 3-kinase products.

PTDINS(3,4,5) P_3 VERSUS PTDINS(3,4) P_2

Among the PH domains with the sequence motif shown in Fig. 2, some bind equally well to both PtdIns(3,4,5) P_3 and PtdIns(3,4) P_2 (e.g. the PKB and DAPP1 PH domains) while others bind only PtdIns(3,4,5) P_3 (e.g. the Grp1 and Btk PH domains). PH domains that recognize only PtdIns(3,4,5) P_3 tend either to have extended $\beta 1/\beta 2$ loops or (as in the Grp1 PH domain) insertions elsewhere in the structure that can make specific contacts with the 5-phosphate group. In the complex between the DAPP1 (dual-specific) PH domain and Ins(1,3,4,5) P_4 there are no hydrogen bonds between PH domain side chains and the 5-phosphate group [11], providing one explanation for why this PH domain binds equally well to Ins(1,3,4,5) P_4 /PtdIns(3,4,5) P_3 and Ins(1,3,4) P_3 /PtdIns(3,4,5) P_2 .

There is no currently known PH domain that binds exclusively to PtdIns(3,4) P_2 . Alessi and colleagues identified the C-terminal PH domain from TAPP1 (for tandem PH domain-containing protein-1) as a PH domain that prefers PtdIns(3,4) P_2 over other phosphoinositides according to protein-lipid overlay studies [68]. However, Ferguson *et al.* [11] showed clearly that this PH domain (called AA054961 in that study) binds with high affinity to the headgroups of both PtdIns(3,4) P_2 and PtdIns(3,4,5) P_3 . In several other assays, using isolated headgroups and intact lipids, it has been shown that the C-terminal TAPP1 PH domain does prefer PtdIns(3,4) P_2 , but binds to this phosphoinositide only four-fold more strongly than to PtdIns(3,4,5) P_3 [V. J. Sankaran and M. A. Lemmon, unpublished data]. In spite of this weak selectivity for PtdIns(3,4) P_2 over PtdIns(3,4,5) P_3 , Alessi and colleagues have provided some evidence to suggest that the TAPP1 PH domain is recruited to the plasma membrane *in vivo* when PtdIns(3,4) P_2 production is stimulated but not when PtdIns(3,4,5) P_3 is thought to accumulate without PtdIns(3,4) P_2 production [69]. Whether other proteins exist that are regulated exclusively by PtdIns(3,4) P_2 remains to be seen.

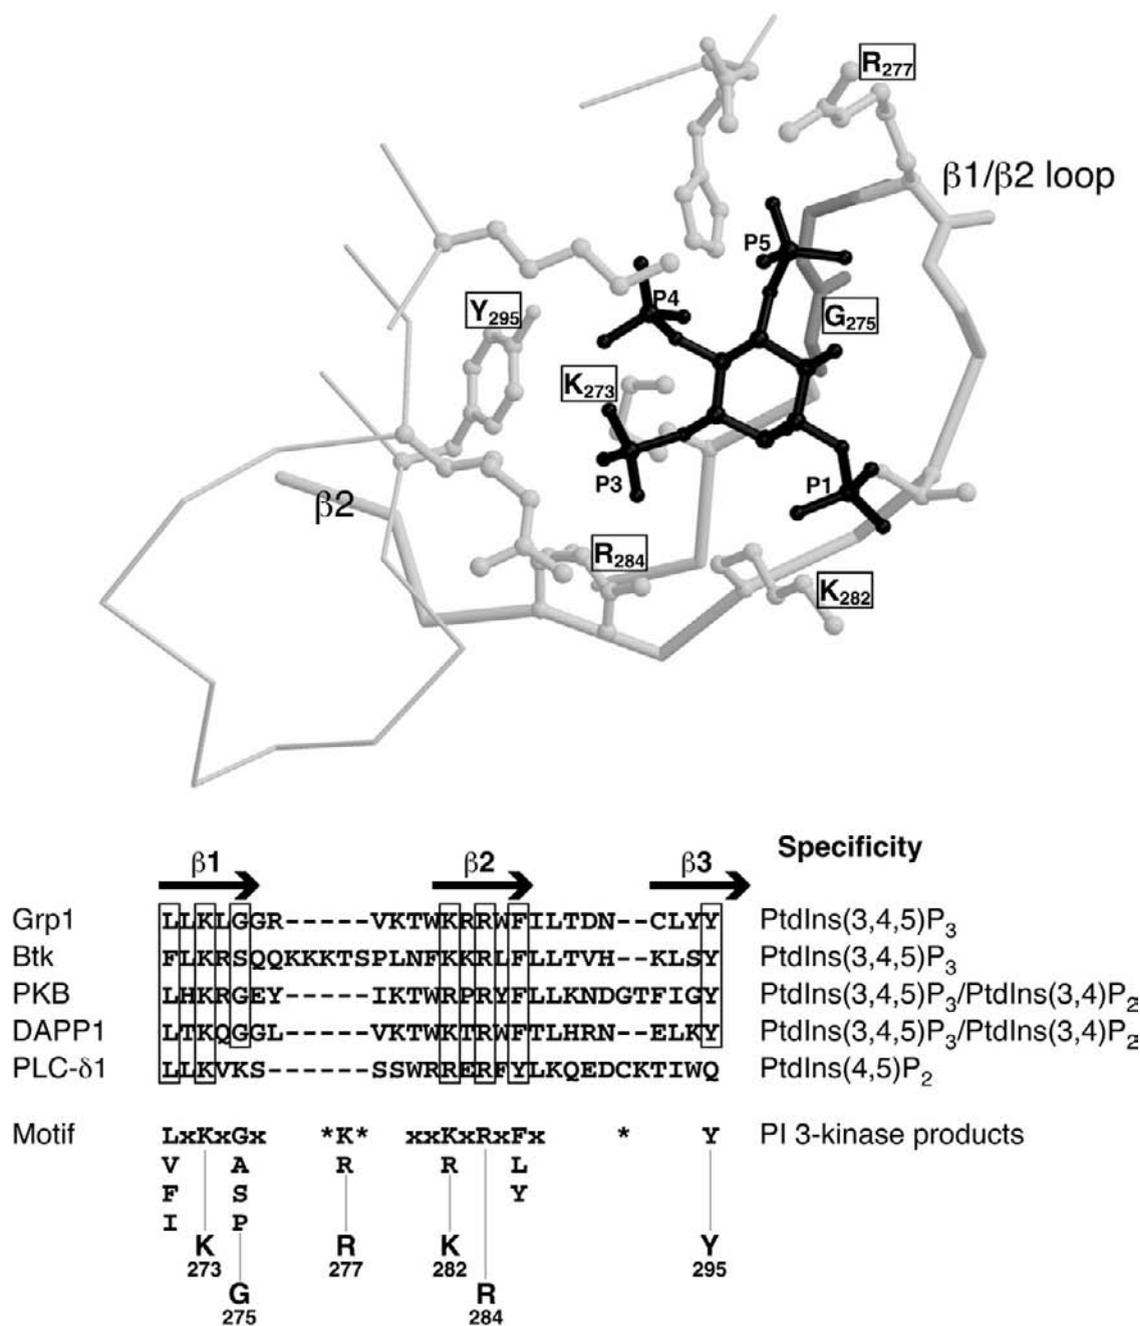

Figure 2 Close-up view of Ins(1,3,4,5)P₄ in the binding site of the Grp1 PH domain, depicting the side chains of residues in the sequence motif that predicts PI 3-kinase product specificity. The $\beta 1/\beta 2$ loop of the Grp1 PH domain is shown to “cradle” the Ins(1,3,4,5)P₄ molecule, with several residues marked forming side-chain hydrogen bonds with the bound lipid headgroup. The motif that predicts specificity for PI 3-kinase product binding is shown in the lower part of the figure, imposed upon the sequences of the N-terminal portions of the Grp1, Btk, PKB, and DAPP1 PH domains. The motif positions corresponding to the residues highlighted in the structural figure are also shown. K273, in strand $\beta 1$ of Grp1, forms a hydrogen bond with both the 3- and 4-phosphates of Ins(1,3,4,5)P₄. G275 must be small in order to allow space for the inositol ring in this binding configuration. K282 forms a hydrogen bond with the Ins(1,3,4,5)P₄ 1-phosphate. R284 forms a critical hydrogen bond with the 3-phosphate. This is equivalent to the arginine at which mutations in Btk cause agammaglobulinemias. Y295, in strand $\beta 3$, is a conserved feature of PH domains that bind PI 3-kinase products, and its side chain forms a hydrogen bond with the 4-phosphate group. These 5 motif characteristics are conserved in all PH domains that recognize PtdIns(3,4,5)P₃ and/or PtdIns(3,4)P₂, and several (but not all) are conserved in PtdIns(4,5)P₂ binding by the PLC- $\delta 1$ PH domain [10]. Equivalents to the additional interaction of R277 with the 5-phosphate of Ins(1,3,4,5)P₄ are seen only in PtdIns(3,4,5)P₃-specific PH domains (Grp1 and Btk), and not those that also bind PtdIns(3,4)P₂ [11]. The extra long $\beta 1/\beta 2$ loop of the Btk PH domain contributes to 5-phosphate interactions, as does the $\beta 6/\beta 7$ loop insertion (not shown) of the Grp1 PH domain.

PH DOMAINS WITH OTHER PHOSPHOINOSITIDE-BINDING SPECIFICITIES

Dowler *et al.* [68] recently identified several PH domains that appear from protein-lipid overlay assays to have novel phosphoinositide specificities. Their strategy was to identify PH domains with sequences that match (or closely resemble) the PI 3-kinase product-binding motif presented in Fig. 2 and to assess phosphoinositide-binding specificity. The C-terminal TAPP1 PH domain was identified as a target for PI 3-kinase products with this approach, as were examples of PH domains that appear in overlay assays to recognize PtdIns-4-P, PtdIns-3-P, or PtdIns(3,5)P₂ specifically. It should be stressed that these phosphoinositide-binding specificities have not yet been confirmed via quantitative approaches *in vitro* or with localization studies *in vivo*, and that several of them appear from surface plasmon resonance (SPR) studies to have rather low affinities [68]. As well as PH domains with apparently novel specificities, Dowler *et al.* found several PH domains (with sequences related to the motif in Fig. 2) that interact with all phosphoinositides tested [68]. These results argue that the PtdIns(3,4,5)P₃-specific binding site depicted in Fig. 2 can be “remodeled” with only a handful of mutations to generate binding sites that instead recognize only the PtdIns(4,5)P₂ headgroup (the PLC- δ_1 PH domain), or perhaps only the PtdIns-4-P, PtdIns-3-P or PtdIns(3,5)P₂ headgroup. Remodeling of a different nature can alternatively generate a binding site that accommodates any phosphoinositide headgroup, so that binding is promiscuous.

Nonspecific Phosphoinositide Binding by PH Domains: The Majority Occupation?

Although this fact may not be immediately clear from a reading of the PH domain literature, by far the majority (>90 percent) of PH domains do *not* have a sequence that significantly resembles the motif shown in Fig. 2. Nonetheless, most PH domains lacking the motif do appear capable of phosphoinositide binding, although binding is weak and non-specific in almost every case [21,35,36]. Where K_D values have been reported for phosphoinositide binding by this class of PH domains, they have ranged from around 30 μ M to 4 mM or weaker [12,13,30,34,36,57,70–73]. In one case, that of the β -spectrin PH domain, a crystal structure of the PH domain with a weakly bound Ins(1,4,5)P₃ was reported [13]. Ins(1,4,5)P₃ binds to the surface of this electrostatically polarized PH domain, in the center of its positively charged face. NMR studies have similarly located the site of weak phosphoinositide binding in other PH domains to the variable loops on the positively-charged face [30,57,73,74], most likely driven by delocalized electrostatic attraction to the negatively charged ligand.

Although the physiological relevance of specific, high-affinity, phosphoinositide binding by PH domains has been well established in several cases, it remains unclear in most cases whether weak and promiscuous binding of phosphoinositides to the majority of PH domains plays any physiological role. It has been shown that the low-affinity, nonspecific

binding of phosphoinositides to the PH domain of dynamin is essential for this protein’s function in receptor-mediated endocytosis [75–77]. Similarly, the low affinity (and usually promiscuous) binding of PH domains from Dbl-family members to phosphoinositides [72] appears to be critical for their Rac/Rho exchange activity *in vivo* and their ability to transform cells [78–81]. Despite intensive study, and three crystal structures of DH/PH fragments from Dbl-family proteins [14,15,17], it remains unclear how low-affinity binding of phosphoinositides to the PH domains of these proteins influences the exchange activity of the adjacent DH (Dbl homology) domain. For many other proteins with PH domains in this class it has been demonstrated that the PH domain is critical for *in vivo* function, but it has not been established whether or not phosphoinositide binding is a physiologically relevant feature of the PH domain. Many more studies are required to address this question for other “promiscuous” PH domains.

Binding of PH Domains to Non-phosphoinositide Ligands

Since the first description of PH domains, many potential protein binding-partners have been reported. The first were $\beta\gamma$ -subunits of heterotrimeric G-proteins, which were suggested to bind all PH domains [82] but now appear only to participate in membrane targeting of a small subset, which includes the PH domains from β -adrenergic receptor kinases (β ARK’s) [83,84]. Other reported protein targets for PH domains include protein kinase C (PKC) isoforms [85,86], the product of the *TCL1* (for T-cell leukemia) oncogene (which binds the PKB PH domain) [87–89], the receptor for activated PKC (RACK1) [90], G₁₂ α [91], a protein called BAP-135 (reported to bind the Btk PH domain) [92], filamentous actin [93], acidic motifs found in proteins such as nucleolin (shown to bind the PH domains of IRS1 and IRS2) [94], and several others (reviewed in [21,95]). Although not all of these PH domain/protein interactions have been demonstrated to have physiological relevance, there is no doubt that some do, and that protein binding by PH domains cannot be ignored. Despite the relative wealth of reported protein targets, however, no common themes emerge from the described PH domain/protein interactions. This should not be surprising given the observed diversity in the modes of protein-target recognition by the structurally related EVH1, PTB, and Ran-binding domains [21].

Possible Roles of Non-phosphoinositide PH Ligands

PH domains for which protein targets have been reported include both examples that bind phosphoinositides weakly and promiscuously (e.g. the β ARK, IRS-1, and dynamin PH domains), *as well as* PH domains that bind strongly and specifically to particular phosphoinositides (e.g. the Btk and PKB PH domains). It can therefore not be argued that the

protein targets described for PH domains are simply alternatives to, or surrogates for, the well-studied (but rare) specific phosphoinositide ligands. Rather, it appears likely that some PH domains bind multiple ligands.

Cooperation of Multiple Ligands in Membrane Recruitment of PH Domains

A requirement for simultaneous PH domain binding to two different ligands was first demonstrated for membrane targeting by the β ARK PH domain [83]. The β ARK PH domain binds very weakly to PtdIns(4,5)P₂ ($K_D > 200 \mu\text{M}$) [12]. It also binds rather weakly to the $\beta\gamma$ -subunits of heterotrimeric G-proteins [82]. Neither of these weak interactions alone is sufficient for high-affinity targeting of β ARK to membranes, but the two interactions can cooperate to recruit β ARK efficiently to relevant membrane surfaces [83].

Golgi Targeting of PH Domains by Multiple Ligands

The PH domain from oxysterol binding protein (OSBP), as well as several other related PH domains, is targeted specifically to the Golgi through interactions that appear to require both phosphoinositides and another unidentified (Golgi-specific) component [96]. These Golgi-targeted PH domains, which include those from FAPP1 and the Goodpasture antigen binding protein (GPBP), are highly promiscuous in their phosphoinositide binding (and are not PtdIns-4-P-specific) [34,96], arguing that phosphoinositide recognition alone cannot possibly determine their Golgi targeting. Phosphoinositide binding by these PH domains is several-fold weaker than PtdIns(4,5)P₂ binding by the PLC- δ_1 PH domain ([96] and D. Keleti, V. J. Sankaran, and M. A. Lemmon, unpublished), further suggesting that it may not be strong enough to drive membrane targeting of the OSBP PH domain independently. Studies in a series of yeast mutants have demonstrated that Golgi targeting of the OSBP and FAPP1 PH domains is dependent on PtdIns-4-P and not on PtdIns(4,5)P₂ production [96,97], but that the activity of Arf1p is also important [96]. It is therefore hypothesized that the presence of two binding partners in the Golgi is responsible for specific targeting of the OSBP, FAPP1, and GPBP PH domains to that organelle. On its own, phosphoinositide binding by these PH domains is not strong enough to drive membrane targeting *in vivo*, and would certainly not provide targeting specificity. The second (so far unidentified) target of these PH domains is thought to be Golgi-specific, but does not bind to the PH domains tightly enough to achieve Golgi targeting on its alone. Rather both phosphoinositide and this unknown component must be present in the same membrane (the Golgi) in order to recruit the OSBP and other PH domains to that compartment with high affinity and specificity. According to this model [96], PtdIns-4-P is implicated in Golgi targeting of the OSBP, FAPP1, and other PH domains not because of headgroup recognition, but because this happens to be the most abundant phosphoinositide in the membranes that contain the second PH domain ligand.

Conclusions

The eleventh most populous domain family in humans is now rather well understood structurally and lends its name to the PH domain superfold that includes proteins involved in binding to variety of phosphoinositide and protein ligands. Ligand binding by a small subgroup of PH domains—those that bind phosphoinositide headgroups with high affinity and specificity—is now understood rather well, although it remains possible that some PH domains from this class have additional, as yet unidentified, binding partners. PH domains that do *not* bind phosphoinositides with high affinity or specificity constitute the majority—perhaps 90 percent. The interactions driven by these PH domains are far less well understood. In many cases it even remains unclear whether phosphoinositide binding observed *in vitro* has any relevance *in vivo*. How weak and nonspecific phosphoinositide binding could contribute to membrane binding is a question that has yet to be fully addressed. It may do so though cooperation of multiple ligands that bind to a single PH domain (as discussed for the β ARK and OSBP PH domains). Alternatively, the PH domain may be one of several domains within a multidomain protein or oligomer that cooperate with one another in driving membrane targeting. In these cases, specificity of membrane targeting may be defined not by the precise nature of the individual interactions (as with PH domains that bind PI 3-kinase products), but rather by the available combinations of interactions. Recruitment to a specific membrane may require that two or more PH domain targets coexist in that membrane.

Massachusetts Institute of Technology,
Cambridge, Massachusetts

History and Overview of PX Domains

The Phox (*phagocyte oxidase*) homology (PX) domain, containing ~100 amino acids, was initially identified by sequence profiling as a conserved region present in the C2 domain-containing class of PI 3-kinases and in the N-terminal region of the p40^{phox} and p47^{phox} subunits of the NADPH oxidase [1]. For nearly five years following their discovery, the function of PX domains remained obscure. A conserved polyproline motif conforming to the consensus sequence PXXP, where X denotes any amino acid, was noted within most PX domain sequences. This observation, coupled with the presence of one or more SH3 domains in numerous PX domain-containing proteins (Fig. 1), led to speculation that one function of PX domains might involve binding to SH3 domains [1].

PX domain-containing proteins are found in all eukaryotes from yeast to human, and can be loosely divided into two groups (c.f. Fig. 1). The first group includes a large family of cytoplasmic and/or para-membrane proteins known as sorting nexins (SNX), including SNX1 through SNX11 and SNX17 in higher eukaryotes [2–5], and Vam7p, Vps5p, Mvp1p, and Grd19p in yeast [6–9]. Most sorting nexins contain no other recognizable domain other than the PX domain (Fig. 1). Collectively, all members of the SNX family are believed to be involved in vesicular trafficking (Table I, top). A second group of PX domain-containing proteins all contain one or more domains of known function in addition to the PX domain (Fig. 1). These co-associating domains include protein-protein interaction domains such as SH3 domains, PDZ domains, and RGS domains; protein-lipid binding domains such as C2 domains and PH domains; and catalytic domains such as the lipid kinase domain of PI 3-kinase or the phospholipase domain of Phospholipase D. These additional

domains play an important role in defining the functions of their constituent proteins, whose intracellular localization is determined, in part, by the PX domain (Table I, bottom).

Lipid-Binding Specificity and the Structure of PX Domain

The observation that many PX domain-containing proteins were membrane associated suggested that their ligands might be specific phospholipids. This was experimentally verified via protein overlay assays on solid-phase immobilized phospholipids and by solution-phase binding assays using phospholipid-containing synthetic liposomes. These experiments demonstrated that the ligands for many PX domains were specific phosphoinositide products of PI 3-kinase [10–13]. Different PX domains show distinct specificity for different phosphoinositides. The PX domains of p47^{phox} and p40^{phox}, for example, bound to phosphatidylinositol-3,4-bisphosphate [PtdIns (3,4)P₂] and PtdIns(3)P, respectively [12,13]. The PX domains of Vam7p and SNX3 bind specifically to PtdIns(3)P [10,11,14] whereas the PX domain of cytokine-independent survival kinase (CISK) interacts with PtdIns(3,5)P₂, PtdIns (3,4,5)P₃, and PtdIns(4,5)P₂ [15]. It appears that the vast majority of PX domains, however, including all of those in the budding yeast *Saccharomyces cerevisiae*, interact primarily with PtdIns(3)P [16].

A sequence alignment of PX domains that shows specificity for PtdIns(3)P binding, including that of p40^{phox}, SNX3, SNX4, MVP1p, Vam7p, and MDM1p, is shown in Fig. 2. Insight into the structural basis of lipid-binding specificity for PX domains is beginning to emerge from a recent NMR structure of the p47^{phox} PX domain without a bound ligand [17], and the X-ray crystal structure of the p40^{phox} PX domain

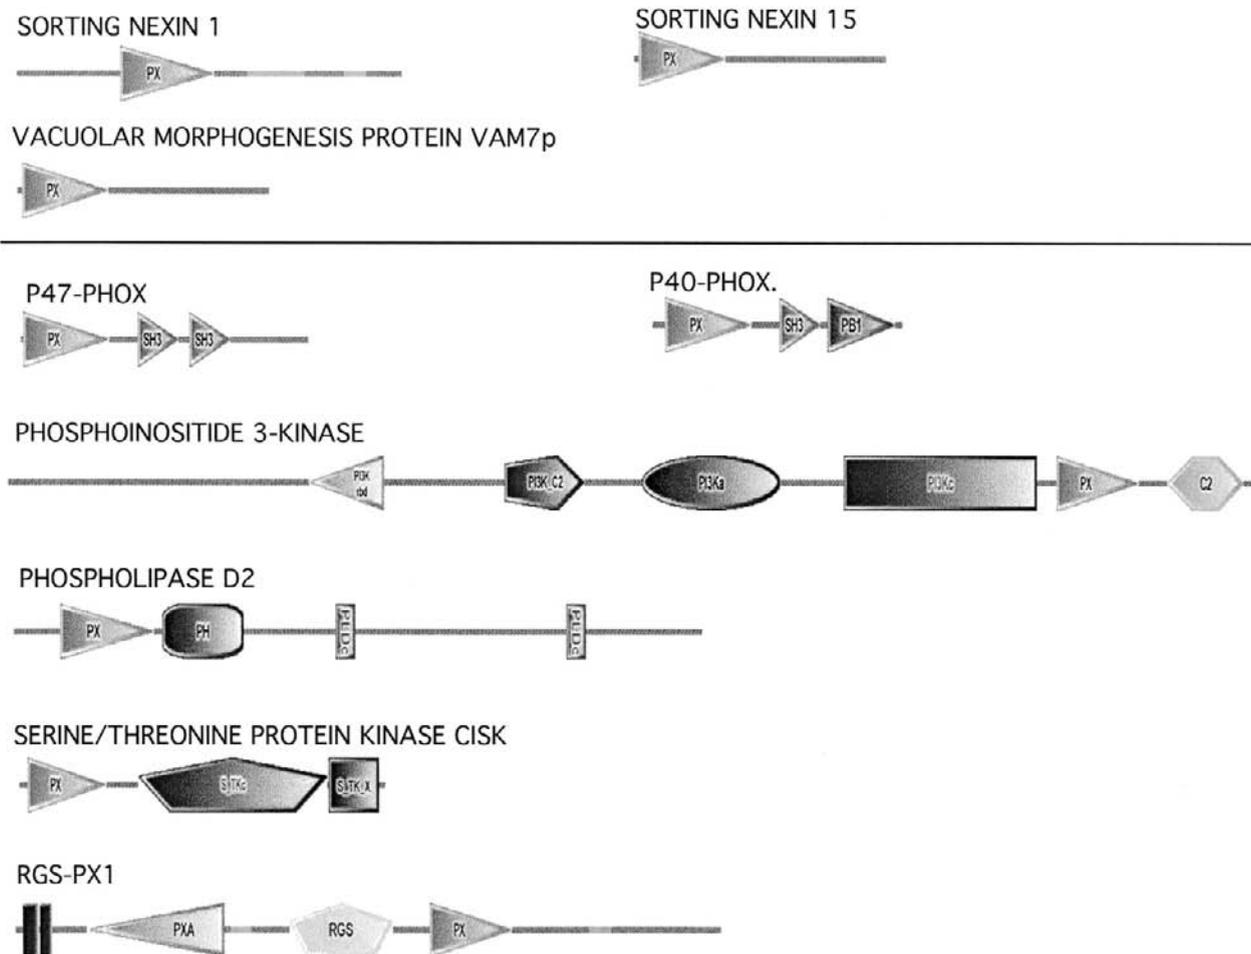

Figure 1 Domain architecture of PX domain-containing proteins. The upper panel shows the structures of sorting nexin proteins and their yeast homologues. The lower panel shows various PX domain-containing signaling molecules that contain additional co-associating domains.

Table I PX Domain-Containing Proteins

Protein	PX domain lipid target	Other domains	Protein function	Reference
SNX1	PtdIns (3)P	—	Binding to EGF receptor Targets EFGR to lysosome	4,7
SNX3	PtdIns (3)P	—	Regulates endosomal function	10
Vps5p/Mvp1p	PtdIns (3)P	—	Sorting carboxypeptidase Y to the vacuole	6
Vam7p	PtdIns (3)P	—	Golgi-to-vacuole transport	11
Grd19p	PtdIns (3)P	—	Retrieval of proteins from prevacuole to late Golgi	9
P40phox	PtdIns (3)P	SH3	Regulation of the NADPH oxidase	12,13
P47phox	PtdIns (3,4)P ₂	SH3	Activation of NADPH oxidase	13
FISH	ND	SH3	Tyrosine kinase signaling	29
RGS-PX1	ND	RGS PXA	Gα-specific GAP Involved in vesicle trafficking	30
PLD1,2	ND	PH PLD Kinase	Cell division, signal transduction, and vesicle trafficking	31
Pi3K C2-γ	PtdIns(4,5)P ₂	C2 Pi3 Kinase	EGF receptor signaling	14
CISK	PtdIns(3)P	Ser/Thr kinase	Cell survival	15
HS1BP3	ND	Leucine zipper	T and B cell development	32

The top section displays SNX proteins and their yeast homologues. The bottom section displays proteins containing other known modular signaling domains. (ND indicates Not Determined.)

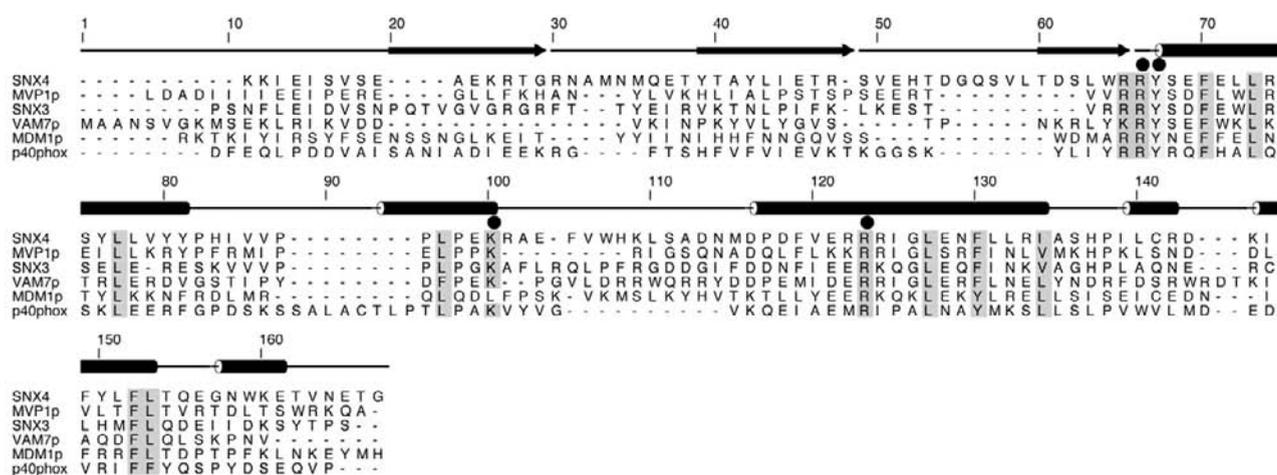

Figure 2 A structure-based sequence alignment of PX domains that bind to PtdIns(3)P. A general numbering scheme is indicated above the alignment, along with a cartoon indicating the positions of β -strands (arrows) and α -helices (cylinders) based on the structure of the p40^{phox} PX domain. Conserved hydrophobic residues within the core of the domain are shaded in green, basic and aromatic residues that are involved in lipid binding are shaded in cyan and yellow, respectively. Sequence numbers for particular amino acid residues within individual PX domains are mentioned in the text.

bound to PtdIns(3)P [18]. The PX domain fold is a small three-stranded β -sheet packed against a helical subdomain containing four α helices and a short stretch of 3_{10} helix (Fig. 3). Both the p40^{phox} and p47^{phox} PX domain structures also contain a conserved PXXP motif that forms a type II polyproline (PP_{II}) helix. Since type II polyproline helices are well known to bind to SH3 domains, this structural observation suggests that some PX domains may, in fact, form intramolecular interactions with their co-associating SH3 domains.

Many PX domains contain a conserved Arg residue immediately preceding a conserved Tyr residue (Tyr-67 in the sequence alignment shown in Fig. 2). The preceding Arg residue (Arg-66 in Fig. 2), which corresponds to R58 in the p40^{phox} PX domain, forms two salt bridges with the 3-phosphate of the lipid in the p40^{phox}PX:PtdIns(3)P crystal structure. The PX domain from the C2-containing PI 3-kinase, which binds to PtdIns(4,5)P₂, lacks an Arg residue at this position, suggesting that residues equivalent to R58 are specific to PX domains that bind to 3-phosphorylated phosphatidylinositols. The 4- and 5-hydroxyl groups of PtdIns(3)P form hydrogen bonds with another highly conserved residue corresponding to R105 in the p40^{phox} structure (Fig. 3) and R123 in the alignment shown in Fig. 2. Phosphorylation on either the 4- or 5-hydroxyl would sterically impinge on the R105 side chain, rationalizing the PtdIns(3)P binding specificity of the p40^{phox} PX domain. However, R105 is also conserved in PX domains that bind phosphatidylinositols other than PtdIns(3)P, including those of CISK and p47^{phox}. Presumably, alterations in the loops surrounding this residue relieve this steric clash and may allow direct interactions of R105 with the lipid phosphates in the 4- and 5- positions, in place of the interaction with the 4- and 5- hydroxyl groups seen in the p40^{phox} structure.

Tyrosine-59 in the p40^{phox}PX:PtdIns(3)P crystal structure (corresponding to Y67 in the alignment in Fig. 2) is another highly conserved amino acid, which forms the floor of the

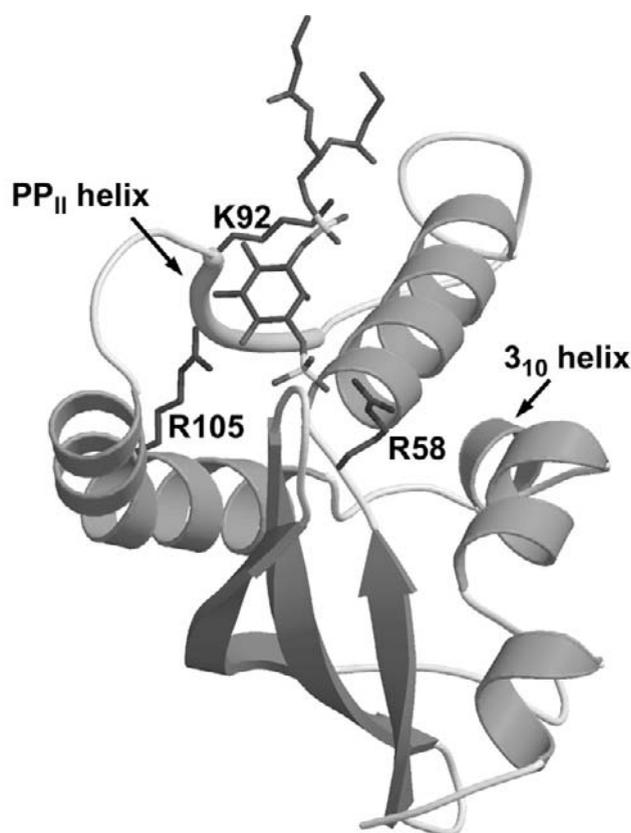

Figure 3 The structure of the p40^{phox}:PtdIns(3)P complex [18]. The lipid is depicted with the acyl chains at the top of the figure, as though it were protruding from a cell membrane. Amino acids that play key roles in PtdIns(3)P-binding are indicated, together with the polyproline-II helix and the 3_{10} helix.

lipid-binding pocket through interactions between its aromatic side chain and the inositol ring. In the p40^{phox} PX:PtdIns(3)P structure, the 1-phosphate forms salt bridges with the side chains of K92 (position 100 in Fig. 2) and R60 (position 68 in Fig. 2) to stabilize the interaction between the domain and

the membrane proximal portion of the inositol lipid. Both of these residues are conserved in some, but not all, PX domains, suggesting that other residues also participate. Additional PX domain structures will clearly be necessary to fully understand the molecular determinants of phosphatidylinositol binding.

Function of PX Domain-containing Proteins

The function of several PX domain-containing proteins is reasonably well understood, although the exact role fulfilled by the PX domain is not yet well defined. The *phox* proteins, after which the PX domain was named, are subunits of the NADPH oxidase, the heme-containing enzyme responsible for superoxide production and killing of microorganisms by phagocytic cells. In resting phagocytes, the inactive NADPH oxidase is separated into a set of cytoplasmic subunits including p47^{phox}, p67^{phox}, and p40^{phox} and a membrane-bound heme-containing flavocytochrome b₅₅₈, which consists of gp91^{phox} and p22^{phox}. Upon phagocyte activation, the cytoplasmic components dock with the membrane-bound subunits to form a catalytically active enzyme that can transfer electrons from NADPH to oxygen to form reactive oxygen species (ROS), such as superoxide [19]. Production of superoxide in response to some stimuli requires the activity of PI 3-kinase, suggesting that specific PI 3-kinase lipid products may be directly involved in regulating oxidase assembly. The different lipid-binding specificities observed for the PX domains of p47^{phox} and p40^{phox} may target oxidase assembly to occur only within specific membrane compartments that contain the appropriate combination of PI 3-kinase-derived lipids [13,20,21].

Several PX domain-containing proteins in the budding yeast *Saccharomyces cerevisiae* participate in vesicular protein trafficking, including the Mvp1p and Vps1p proteins involved in vacuolar protein sorting [22] and the Vps17p and Vps5p proteins which translocate pre-vacuolar endosomes to the Golgi as part of the retromer protein complex [23]. In higher eukaryotes, SNX1, SNX2, SNX4, SNX6, and a splice variant of SNX1 (SNX1A) are known to associate with a variety of growth factor receptors, suggesting that they mediate receptor trafficking to vesicles [7,24].

CISK is a PX domain-containing Ser/Thr kinase, which functions in parallel with Ser/Thr kinase Akt/PKB to mediate IL-3 dependent cell survival in hematopoietic cells. CISK localizes to vesicular compartments, and this localization is dependent on the PX domain [15,25].

Phospholipase D (PLD) catalyzes hydrolysis of phospholipids to produce phosphatidic acid (PA) [26]. Both mammalian isoforms of PLD, PLD1 and PLD2, contain PX domains as well as PH domains that also bind to PI 3-kinase lipid products. The presence of two different lipid binding domains might target the lipase domain to specific phosphoinositide-containing regions of membranes, or might function as some type of lipid-regulated switch to control the activity of the lipase domain. The specificity of the PLD PX domain has not yet been reported.

Class II PI 3-kinases, defined by their *in vitro* usage of phosphatidylinositol and phosphatidylinositol 4-phosphate as substrates, also contain PX domains. The function of Class II PI 3-kinases is not well understood, though recent results suggest that they may participate in clathrin-mediated endocytosis [27,28].

In summary, PX domains join an expanding family of phosphoinositide-binding domains that includes C2 domains, PH domains, FYVE domains, ENTH domains, and tubby domains. The large differences in structure between these domains suggest that their lipid-binding function arose through the convergent evolution of different structures for the same biological function of lipid binding. It will be important for future work to further examine the structural foundation for lipid binding specificity by PX domains, and explore how their lipid-binding ability contributes to the overall function of PX domain-containing molecules.

Introduction

The recruitment of cytoplasmic proteins to specific membrane compartments is important for a diverse spectrum of cellular processes, including intracellular protein trafficking, cytokine and growth factor receptor signaling, actin cytoskeleton organization, and apoptosis [1–4]. Many proteins are localized to membranes through tightly regulated interactions with membrane-associated factors. Derivatives of phosphatidylinositol (PtdIns) that can be reversibly phosphorylated at different positions of the inositol ring are ideally suited for this function. Through the action of a set of well-conserved specific lipid kinases [5], different phosphoinositide (PI) species phosphorylated at the 3', 4', or 5' positions of the inositol headgroup are generated, each of which can recruit or activate a specific subset of cytoplasmic effector proteins. The activity of these target proteins can then be attenuated through the action of PI-specific phosphatases and lipases [6–9]. Several studies have now identified multiple, well-conserved PI-binding motifs, each of which can recognize particular PI isoforms with a high degree of specificity [10]. In this chapter, we discuss the structural basis of a novel zinc finger that binds PtdIns 3-phosphate [PtdIns(3)P], termed the FYVE domain, and the roles played by several proteins harboring this motif in membrane trafficking and cell signaling.

Role for PtdIns(3)P in Membrane Trafficking and Identification of the FYVE Domain

A role for PtdIns(3)P in vesicular transport was first discovered in the study of Golgi to vacuole transport in yeast [11]. *Saccharomyces cerevisiae* expresses one PtdIns 3-kinase isoform, Vps34 [5]. Deletion of the *VPS34* gene resulted in a lack of PtdIns(3)P synthesis and defects in endosomal membrane trafficking from the Golgi and plasma membrane to the lysosome-like vacuole [12]. Likewise, PtdIns(3)P has been shown to play important roles in several membrane trafficking pathways to mammalian lysosomes [13]. The fungal metabolite wortmannin, an inhibitor of PI 3-kinase activity, has been shown to impair homotypic endosome fusion *in vitro* and the transport of enzymes such as cathepsin D to lysosomes *in vivo* [14–16]. Accordingly, the human homolog of the yeast Vps34 PtdIns 3-kinase has been identified and found to be sensitive to wortmannin [5].

Several proteins have been implicated as downstream effectors of PtdIns(3)P in vesicle transport. One of these, mammalian EEA1 (early endosome antigen 1), has been shown to localize to endosomal membranes in a wortmannin-sensitive manner [17,18]. Consequently, deletion of the FYVE domain of EEA1 was shown to diminish its endosomal association, suggesting that this domain may directly bind PtdIns(3)P [19]. The FYVE domain, named after the first four proteins found to contain this motif (*Fab1*, *YOTB*,

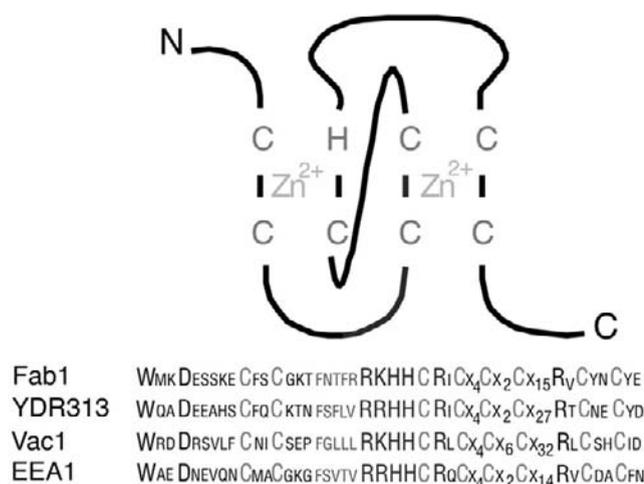

Figure 1 The FYVE domain is a conserved RING finger domain. (Top) Schematic cartoon of the RING finger FYVE domain. The conserved cysteine/histidine residues that coordinate two Zn^{2+} atoms are shown. The highly conserved basic patch surrounding the third cysteine is indicated in blue. (Bottom) Sequence alignment of the FYVE domains of Fab1, Pib1 (YDR313c), Vac1, and EEA1. Identical residues are shown in boldface. The conserved cysteine residues are highlighted in gray. The highly conserved basic patch, R(R/K)HHCR, found in all FYVE domains is shown. The conserved hydrophobic region adjacent to the basic patch is indicated in red.

Vac1 and EEA1), was originally identified as a RING-finger family member that coordinates two Zn^{2+} ions through eight cysteine/histidine residues spaced in a conserved manner [CX₂CX₉₋₃₉CX₁₋₃(C/H)X₂₋₃CX₂CX₄₋₄₈CX₂C] (Fig. 1) [19,20]. An important finding of subsequent studies was the demonstrated ability of FYVE domains to specifically bind PtdIns-3-P *in vitro*, as recombinant EEA1 FYVE sedimented with liposomes containing PtdIns(3)P but not other PI species [21–23]. The identification of modular protein domains that bind PtdIns(3)P with high affinity and specificity, such as the FYVE domain, has been a crucial step in further understanding the roles of this lipid in membrane trafficking events, as described in greater detail below.

Structural Basis for the FYVE Domain

Insight into the molecular mechanisms that mediate the interaction between FYVE domains and PtdIns(3)P is provided by several structural studies on this motif [24,25]. The FYVE domain, as mentioned, is an approximately 80-amino-acid sequence containing eight conserved cysteine/histidine residues that coordinate two Zn^{2+} ions. In addition, several other residues are conserved, most notably a highly basic R(R/K)HHCR patch adjacent to the third cysteine residue, an amino-terminal WxxD motif, and a conserved hydrophobic region upstream of the basic patch (Fig. 1). As first determined from the crystal structure of the yeast Vps27 FYVE domain, the basic patch is localized within $\beta 1$ of two double-stranded antiparallel β -sheets (composed of $\beta 1/\beta 2$ and $\beta 3/\beta 4$), which are stabilized by the two zinc ions and a

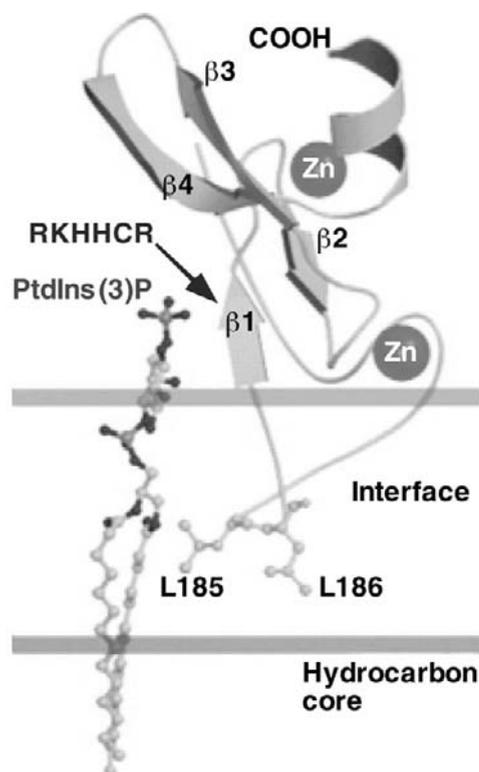

Figure 2 The FYVE domain is a modular PtdIns(3)P-binding motif. The crystal structure of the FYVE domain of yeast Vps27 [26]. The ribbon depicts four β strands followed by a carboxy-terminal α -helix. The two Zn^{2+} atoms are shown. The highly conserved positively charged residues (RKHHCR) in the $\beta 1$ strand predicted to make contacts with the 3'-phosphate group of PtdIns(3)P are indicated. In addition, residues in a hydrophobic loop upstream of the first β -sheet predicted to penetrate into the membrane bilayer are indicated [26]. The membrane layer is divided into an interfacial region (lipid headgroups and the hydrophobic interface) and a hydrocarbon core (lipid acyl chains). (Reprinted from Hurley, Cell, 97, 657–666, 1999. With permission).

C-terminal α -helix [26]. Molecular modeling suggested that the inositol head group of PtdIns(3)P fits into a pocket created by the backbone of the first β -sheet, and the 3'-phosphate group contacts side groups of the final histidine and arginine residues found in the basic patch (Fig. 2) [26]. In addition, from this model, the 1'-phosphate of PtdIns(3)P is poised to form a salt bridge with the first arginine in the conserved basic patch [26]. In combination, these interactions are specific for PtdIns(3)P as additional or other phosphate groups on the inositol ring would prohibit interaction with the FYVE domain due to spatial constraints, consistent with previous *in vitro* binding studies indicating this motif does not bind to other phosphoinositides.

Although a similar structure was proposed for the FYVE domain of *Drosophila* Hrs, a homologue of Vps27, a different model for PtdIns(3)P binding was suggested [27]. The major difference involved an anti-parallel association of two Hrs FYVE monomers to generate a homodimer with two ligand-binding pockets. Residues from $\beta 1$, including the conserved basic patch, together with a hydrophobic strand from $\beta 4$ of the opposite FYVE monomer, line each pocket.

In addition, this model differed from that of the Vps27 FYVE structure in regard to the orientation of the FYVE domain with respect to the membrane. Thus, even though both models were consistent in regard to the overall structure of the FYVE domain, further studies were required to help resolve the true nature of the interaction between the FYVE domain and PtdIns(3)P containing membranes.

To gain further insight into the interaction of the FYVE domain with PtdIns(3)P, NMR studies of the EEA1 FYVE domain were performed [28,29]. As expected, these studies highlighted the importance of the basic residues found in the first β -sheet as they displayed large chemical shift changes in the presence of PtdIns(3)P. In addition, residues in a hydrophobic loop upstream of the first β -sheet displayed chemical shifts, but only in the presence of micelle-embedded PtdIns(3)P, suggesting that these residues contact the membrane nonspecifically. Similar to the membrane orientation predicted by the Vps27 FYVE structure (see Fig. 2), this hydrophobic loop may extend into the cytoplasmic side of the membrane bilayer, perhaps directly interacting with hydrophobic acyl chains.

However, when fused to GFP or GST, the EEA1 FYVE domain alone failed to efficiently localize to cellular membranes [21–23,30]. Residues from an additional coiled-coil region adjacent to the FYVE domain were required. Most recently, the crystal structure of the EEA1 FYVE domain including these additional residues has revealed the formation of stable homodimers that could bind two molecules of inositol 1,3-bisphosphate, a soluble mimic of PtdIns(3)P [31]. However, unlike the model proposed from studies of the Hrs FYVE domain, each EEA1 FYVE domain independently bound inositol 1,3-bisphosphate. Dimerization of the EEA1 FYVE domains was mediated primarily through interactions between the coiled-coil domains. Taken together, these data suggest that dimerization enhances binding of individual FYVE domains to membrane-restricted PtdIns(3)P. However, while the EEA1 FYVE structures provide an accurate model for PtdIns(3)P binding, additional factors may be involved in targeting and/or stabilization of FYVE domains at cellular membranes. It is interesting that residues adjacent to the EEA1 FYVE domain required for membrane localization are required for EEA1 to bind Rab5, a small GTPase that functions on membranes in the endocytic pathway [18,30]. Together, these data suggest that a combination of protein-PtdIns(3)P and protein-protein interactions is essential for specific and stable localization of FYVE domain-containing proteins to particular cellular membranes.

Conservation of the FYVE Domain and Localization of PtdIns(3)P

To date, analysis of the human genome has uncovered a total of approximately 30 FYVE domain-containing proteins, while the *Caenorhabditis elegans* genome contains 15 and the *S. cerevisiae* genome harbors 5. Thus, while the FYVE domain itself has been well conserved through the

course of evolution, there appears to have been a significant expansion in the roles played by this lipid-binding motif. As described earlier, the major role for PtdIns(3)P, and by extension its FYVE domain-containing effectors, involves endocytic membrane transport. However, recent findings also show that PtdIns(3)P may have roles in growth factor signaling and actin cytoskeleton organization through the recruitment/activation of other FYVE domain-containing proteins. However, before further examining the role of the FYVE domain in cell signaling, localization of PtdIns(3)P itself must first be explored.

Initial studies of PtdIns(3)P localization were carried out via a GFP fusion to the FYVE domain of EEA1 in yeast [21]. Results indicated that the fusion co-localized with prevacuolar endosomes and weakly labeled the vacuolar membrane. An important finding is that this localization was dependent on Vps34 PtdIns 3-kinase activity, demonstrating a requirement for PtdIns(3)P in mediating membrane association *in vivo* [21]. Two FYVE domains in tandem fused to GFP similarly localized to endosomal structures in fibroblasts [32]. However, due to the limitations of light microscopy, a more detailed analysis of PtdIns(3)P localization required more extensive studies of the recombinant FYVE domain dimer. Using an electron microscopic labeling approach, PtdIns(3)P was found to be highly enriched on endosomes as expected from previous work, but the lipid was also observed in the nucleolus and in the internal vesicles of multivesicular bodies (MVBs) [32]. Consistent with the presence of PtdIns(3)P on vesicles inside the lumen of MVBs, the efficient turnover of PtdIns(3)P in yeast was shown to be dependent on hydrolase-mediated degradation in the vacuole [33]. It is likely that most, if not all, PtdIns(3)P effectors are recruited to and/or activated at endosomal/vacuolar membranes, the major sites of PtdIns(3)P accumulation in cells.

FYVE Domains in Membrane Trafficking

Studies of EEA1 have been instrumental in defining the localization of PtdIns(3)P. Closer examination of the protein reveals that it is a large coiled-coil protein (Fig. 3A) that can bind to the GTP-bound form of Rab5, a GTPase required for endosomal membrane fusion [18,34]. Together with PtdIns(3)P, Rab5-GTP recruits EEA1 to endosomal membranes where it functions in membrane fusion. Consistent with this hypothesis, depletion of EEA1 inhibits homotypic endosome fusion *in vitro*, while excess EEA1 stimulates fusion [18,34]. Furthermore, studies suggest that EEA1 may engage in oligomeric complexes during membrane fusion, which may tether Rab5-positive endosomes, thus facilitating pairing of SNARE proteins to drive membrane fusion [34,35].

Similar to EEA1, another FYVE domain-containing protein, Rabenosyn-5 (Table I), is an effector of Rab5-GTP. Its localization to the endosome is dependent on PtdIns(3)P binding and is required for endosome fusion [36]. While EEA1 appears to interact with specific SNARES including syntaxin-13 [35], Rabenosyn-5 directly interacts with the

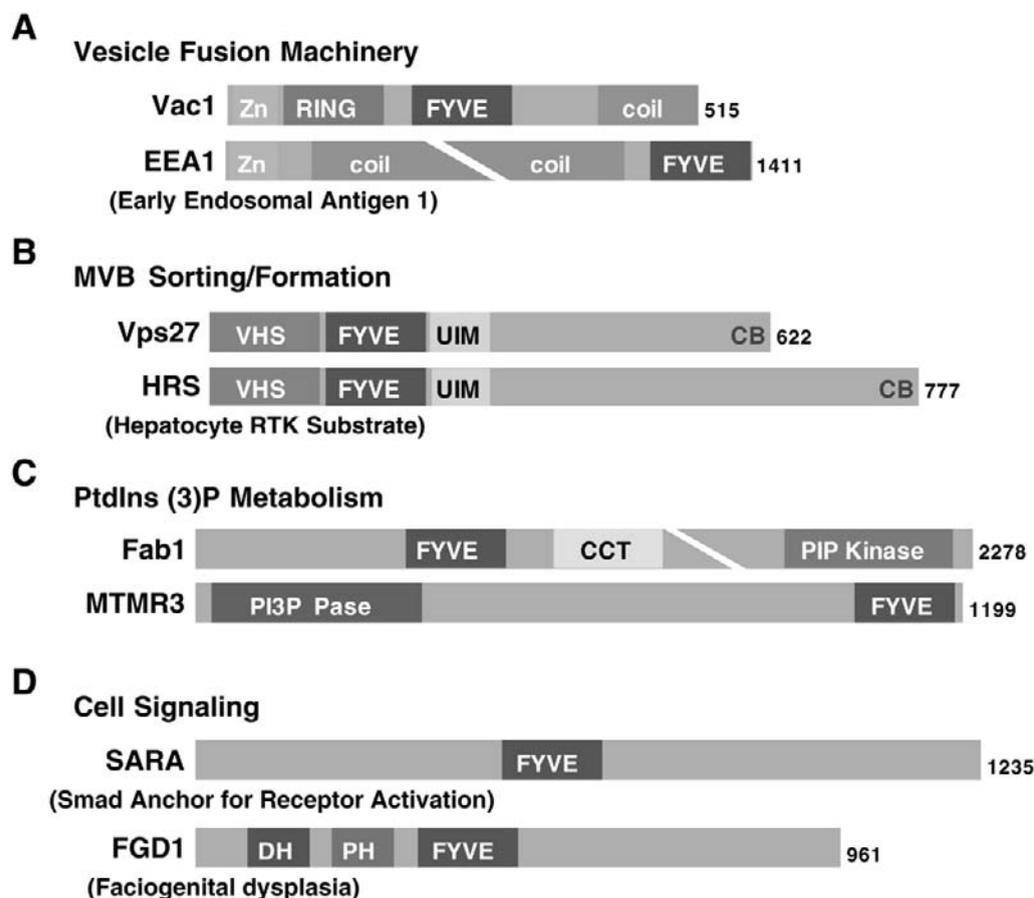

Figure 3 Schematic representation of protein motifs found within FYVE domain proteins. Several FYVE domain proteins have additional domains that bind protein targets. Together, these PtdIns(3)P-protein and protein-protein interactions define the specific function of each FYVE domain protein. Examples of yeast and mammalian FYVE domain proteins that act in various cellular processes are shown. (A) FYVE domain proteins implicated in vesicle targeting and fusion events. (B) FYVE domain proteins involved in endosomal/MVB sorting. (C) FYVE domain proteins containing enzymatic activities implicated in PI synthesis and turnover. (D) FYVE domain proteins involved in cell signaling. Other abbreviations: Zn, Zn²⁺ finger domain; RING, Zn²⁺ finger domain; coil, coiled-coil domain; VHS, conserved domain found in Vps27, Hrs, and STAM; SH3, Src homology 3 domain; UIM, ubiquitin-interacting motif; CB, clathrin box binding motif; CCT, chaperonin-like region; PIP kinase, PtdIns(3)P 5-kinase catalytic domain; PI3P Pase, myotubularin-related PtdIns(3)P phosphatase catalytic domain; DH, Dbl homology domain; PH, pleckstrin homology domain.

Sec1-like protein hVps45, suggesting distinct roles for these Rab5/PtdIns(3)P effectors in endosome fusion [36]. Similarly, the yeast homolog of Rabenosyn-5, Vac1, also contains a FYVE domain (Fig. 3A) and interacts with Vps21 and Vps45, homologs of Rab5 and Sec1 [37–39]. Deletion of *VAC1* results in an accumulation of vesicles destined for the endosome and a defect in protein sorting to the lysosome-like vacuole, suggesting that Vac1 is evolutionarily conserved and required for endocytic docking and/or fusion [38]. Substitutions in the FYVE domain of Vac1 also result in defects in vacuolar protein sorting, indicating a requirement for this domain in Vac1 function. However, these Vac1 mutants can still associate with membranes, suggesting that additional factors are involved in Vac1 localization [38]. Nevertheless, the FYVE domains found in EEA1 and Vac1/Rabenosyn-5 may still be required for concentration of these proteins on PtdIns(3)P-rich endosomes, while Rab binding may further drive specificity of

these interactions. Once on endosomal membranes, EEA1 and Vac1/Rabenosyn-5 appear to intimately participate in the machinery that drives endosome fusion (Fig. 4).

In addition to Rab5, another small GTPase (Rab4) that has been implicated in the recycling of internalized receptors back to the plasma membrane regulates a FYVE domain-containing effector, Rabip4 (Table I). Like EEA1 and Vac1/Rabenosyn-5, Rabip4 localizes to endosomes and can affect endosomal morphology [40]. Moreover, overproduction of Rabip4 leads to the intracellular retention of normally recycled transporters such as Glut1[40]. These data suggest that FYVE domains and thus PtdIns(3)P are not only involved in anterograde trafficking to lysosomes but also endosomal membrane recycling to the plasma membrane.

Another well conserved FYVE domain-containing protein that has been implicated in membrane trafficking is Hrs (Fig. 3B), a hepatocyte growth factor receptor tyrosine

Table I FYVE Domain-Containing Proteins Discussed in the Review

Yeast				
Protein	Cellular function	Domains	Targets	Ref.
Vac1	Golgi to endosome transport	FYVE, RING, COIL	PtdIns(3)P, Vps21, Vps45, Pep12	[37–39]
Vps27	MVB sorting/formation	VHS, FYVE, UIM	PtdIns(3)P, ubiquitin	[42–44]
Fab1	PtdIns(3)P 5-synthesis, MVB sorting	FYVE, PtdIns(3)P 5-kinase	PtdIns(3)P	[44, 51]
Pib1	Ubiquitin ligase	FYVE, E3 ubiquitin ligase	PtdIns(3)P, unknown	[48]
Pib2	unknown	FYVE	PtdIns(3)P?	[21]
Mammalian				
Protein	Cellular function	Domains	Targets	Ref.
EEA1	Endosome fusion	FYVE, COIL	PtdIns(3)P, Rab5, syntaxins	[17–23,35]
Rabenosyn-5	Endosome fusion	FYVE	PtdIns(3)P, Rab5, and hVps45	[36]
Rabip4	Endosomal membrane recycling	FYVE	PtdIns(3)P, Rab4	[40]
Hrs	Endosomal/MVB Sorting	VHS, FYVE, UIM, CB	PtdIns(3), ubiquitin, Clathrin	[45–47]
PIKfyve	Endosome morphology, PtdIns(3,5)P ₂ synthesis	FYVE, PtdIns(3)P 5-kinase	PtdIns(3)	[52]
MTMR4	PtdIns(3)P turnover	FYVE, PtdIns(3)P phosphatase	PtdIns(3)P	[6,55]
endofin	Unknown	FYVE	PtdIns(3)P	[59]
Frabin	Actin cytoskeleton	FYVE, PH, GEF	PI isoforms, Cdc42, Rac	[61,62]
DFCP1	Unknown	FYVE-like	PtdIns(3)P?	[63]

As well as binding to PtdIns(3)P, FYVE domain-containing proteins have other domains that interact with protein targets. Together, these interactions likely play important roles in defining protein function.

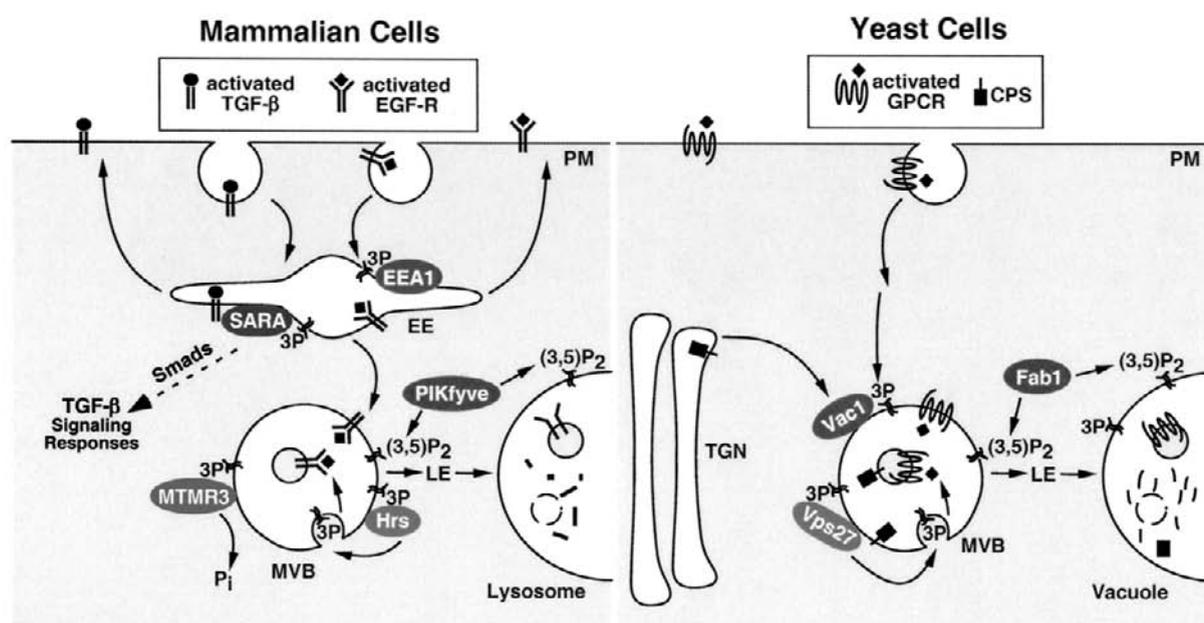

Figure 4 Cellular localization and functions of FYVE domain-containing proteins in mammalian and yeast cells. In mammalian and yeast cells, PtdIns(3)P (designated as 3P) recruits the Rab effectors EEA1 or Vac1 to endosomes where they participate in vesicle fusion in Golgi (TGN) to vacuole transport and endocytic trafficking. The FYVE domain-containing orthologs Hrs and Vps27 are required for MVB sorting pathways that transport PtdIns(3)P and cargo proteins, such as carboxypeptidase S (CPS) and internalized cell surface receptors, to the vacuole lumen where they are degraded. The PtdIns(3)P 5-kinases Fab1/PIKfyve and the PtdIns(3)P-specific phosphatase MTMR3 terminate PtdIns(3)P signaling by converting PtdIns(3)P to PtdIns(3,5)P₂ or PtdIns, respectively. PtdIns(3)P 5-kinase signaling via PtdIns(3,5)P₂ (designated as 3,5)P₂) is also required for MVB sorting. In mammalian cells, the FYVE domain containing-protein SARA recruits Smad proteins, effectors of transforming growth factor beta (TGF-β) signaling, to the endosome.

kinase substrate [41]. Studies of its yeast homolog Vps27 demonstrate a requirement for this PtdIns(3)P effector in protein trafficking, functioning after Vac1 in the endocytic pathway [42]. Specifically, inactivation of Vps27 results in a defect in the generation of intraluminal vesicles within MVBs and the vacuole [43,44]. Similarly, mouse embryos that lack Hrs exhibit defects in endosomal morphogenesis [45]. It is striking that Hrs and EEA1 are localized to different regions on endosomes. Specifically, Hrs colocalizes with clathrin and can bind to clathrin via a carboxy-terminal clathrin interacting motif [46]. Disruption of the PtdIns(3)P-FYVE interaction in Hrs by treatment with the PtdIns 3-kinase inhibitor wortmannin results in loss of both Hrs and clathrin localization to endosomes, again demonstrating the importance of the FYVE domain in endosomal function [47]. Further studies are required to precisely determine what other requirements may be necessary for Hrs/Vps27 to associate with endosomes in addition to PtdIns(3)P.

In addition to Vac1 and Vps27, yeast harbor another FYVE domain-containing protein that localizes to the endosome and vacuole, Pib1 (Table I) [21]. Localization of Pib1 to these structures is dependent on its FYVE domain through an interaction with PtdIns(3)P [48]. In addition to its FYVE domain, Pib1 contains a RING domain that possesses E2-dependent ubiquitin ligase activity *in vitro* [48]. In light of recent studies indicating a role for ubiquitin modification in the sorting of proteins into multivesicular bodies [43,49,50], the finding that Pib1 is an E3 RING-type ubiquitin ligase that localizes to the endosome via a PtdIns(3)P-FYVE interaction is especially interesting. However, deletion of *PIB1* fails to result in a defect in sorting of known ubiquitinated substrates through the MVB pathway [48], suggesting that other E3 ubiquitin ligases may act together with Pib1 in this process. Alternatively, Pib1 may be responsible for ubiquitination of a specific subset of cargo that have not yet been examined.

FYVE Domains Involved in PtdIns(3)P Metabolism

Additional FYVE domain-containing proteins found in both yeast and mammalian cells that appear to be involved in the formation of MVBs are the PtdIns(3)P 5-kinases, Fab1 and PIKfyve (Fig. 3C). Deletion of *FAB1* results in a loss of intraluminal vesicles and drastically enlarged vacuoles [44,51]. This abnormal vacuole morphology may also be in part due to defects in the recycling and/or turnover of membranes deposited at the vacuole. However, this remains to be demonstrated, since effectors of PtdIns(3,5)P₂ generated by Fab1 have yet to be identified. It is interesting that Fab1 has been shown to localize to both prevacuolar and vacuolar membranes, similar to the distribution of PtdIns(3)P, suggesting that its amino-terminal FYVE domain may have a role in localization and/or activity of Fab1 [51]. However, deletion of an amino-terminal fragment of Fab1 including its FYVE domain fails to significantly perturb its function, since this form of Fab1 can rescue a temperature-sensitive

fab1 mutant, suggesting that other determinants for Fab1 localization exist [51]. In contrast, the FYVE domain of mammalian PIKfyve is absolutely critical for its localization to membranes of the late endocytic pathway [52]. These studies highlight a surprising difference between certain yeast members of the FYVE domain family and their mammalian counterparts. Specifically, Vac1, Vps27, and Fab1 contain FYVE domains that are not entirely essential for membrane binding of the intact proteins. Nonetheless, this does not exclude a role for PtdIns(3)P-FYVE interactions for protein localization in yeast, but instead may emphasize the role of additional protein-protein interactions in precise subcellular targeting.

In addition to PtdIns kinases, recent studies have uncovered a set of PI phosphatases that contain a FYVE domain, such as MTMR3 (Fig. 3C) and MTMR4 (Table I). Both are members of the myotubularin family of phosphatases that were originally shown to dephosphorylate serine/threonine and tyrosine residues *in vitro* but have subsequently been shown to act upon PtdIns(3)P as their primary substrate [6,53]. It is interesting that various myotubularin members have been implicated in multiple disorders, including myotubular myopathy [53], which involves defects in muscle differentiation and Charcot-Marie-Tooth disease [54], a condition caused by defects in myelin development. MTMR3 and MTMR4 (also named FYVE-DSP1 and FYVE-DSP2) are localized in membrane fractions [54], but further studies are required to determine whether this localization is dependent on their FYVE domains. What is more important, however, the identification of both PtdIns(3)P 5-kinases and PtdIns(3)P phosphatases that contain FYVE domains raises the possibility that the FYVE domain may serve a regulatory role in the control of these enzyme activities when lipid is bound (Fig. 4). Recruitment of either a PtdIns(3)P 5-kinase or PtdIns(3)P-specific phosphatase could play a role in terminating PtdIns(3)P signaling by converting PtdIns(3)P to PtdIns(3,5)P₂ or PtdIns, respectively. Future work on these members of the FYVE domain family will be informative in shedding light on this question.

FYVE Domains in Signaling

In addition to membrane trafficking and phosphoinositide metabolism, FYVE domains are also found in proteins required for other cellular processes, such as growth factor signaling. The FYVE domain containing-protein SARA (Fig. 3D) recruits Smad proteins, effectors of transforming growth factor beta (TGF-beta) signaling, to the endosome (Fig. 4) [56]. There, bound TGF-beta receptors can phosphorylate Smad2 and Smad3 via their cytoplasmic serine/threonine kinase domain [56]. Phosphorylated Smads can then bind to Smad4, and this resulting complex is able to translocate to the nucleus and activate transcription of target genes [56]. SARA provides an excellent example in which the trafficking of cell-surface receptors is intimately coupled to intracellular signaling [56,57]. In this case, the FYVE

domain of SARA spatially regulates TGF-beta signaling, restricting it to endosomes that contain both PtdIns(3)P and activated TGF-beta receptors. This spatial control permits the cell to prevent inappropriate activation of Smad signaling and allows for a large range of separation between the on and off states of this pathway. Consistent with this, treatment with the PtdIns 3-kinase inhibitor wortmannin results in mislocalization of SARA and leads to defects in Smad phosphorylation and downstream transcriptional activation [58]. Similar to SARA, a largely uncharacterized protein named endofin (Table I) also localizes to endosomes in a PtdIns(3)P-dependent manner [59]. Although 50% identical to SARA, endofin fails to interact with Smad2 and does not play a role in TGF-beta signaling [59]. This suggests that other yet to be defined signaling pathways may be regulated at the level of the endosome in a PtdIns(3)P-dependent manner.

Although less clear, FYVE domains are also found in proteins that regulate the actin cytoskeleton. These include Fgd1, a *faciogenital dysplasia* gene product implicated in the developmental disease Aarskog-Scott syndrome (Fig. 3D), and Frabin (Table I), which act as guanine nucleotide exchange factors (GEFs) for the small GTPases Cdc42 and Rac. Fgd1 specifically activates Cdc42, which in turn regulates actin cytoskeleton organization [60]. Frabin, through the action of Cdc42-dependent and independent pathways, has been implicated in filopodia and lamellipodia formation, respectively [61]. However, these events are not likely to involve endocytic trafficking, since early studies have indicated that this family of FYVE domain-containing proteins does not localize to the endosome [62]. Closer examination of these GEFs shows they also contain PH domains that can bind other PI species [61], and their FYVE domains lack a well-conserved tryptophan residue that is conserved in most other FYVE domains. Further studies are required to determine whether these regulators of actin cytoskeleton organization actually bind PtdIns(3)P through their FYVE domains or bind another ligand that may be structurally related to PtdIns(3)P.

FYVE-like Domains

In addition to the highly conserved FYVE domain, several other FYVE-like domains have recently been uncovered. For example, a protein identified from a human bone marrow cDNA library named DFCP1 contains two FYVE-like domains (Table I), but in both cases, the first conserved arginine in the conserved basic R(R/K)HHCR patch is replaced with a serine or threonine [63]. It remains to be determined how this might effect PtdIns(3)P binding or whether DFCP1 localization is dependent on PtdIns(3)P *in vivo*. Initial studies indicate that DFCP1 localizes to the endoplasmic reticulum, Golgi, and other intracellular vesicles, unlike what has been seen with bona fide PtdIns(3)P effectors, such as EEA1 and Hrs [63]. Future studies aimed at determining the ligand binding specificities of FYVE-like domains should help resolve these apparent discrepancies.

Conclusions

Within the span of a few years, the identification of the FYVE domain as a specific PtdIns(3)P binding motif has had a significant impact on the field of vesicular trafficking and has shed light on additional cellular functions of PtdIns(3)P. Through localization studies of the FYVE domain via both conventional light microscopy and high-resolution electron microscopy, PtdIns(3)P has been found to exist in endosomal membranes, on vesicles contained within endosomes, and in vacuolar/lysosomal membranes. More recently, GFP-FYVE fusions have been used to observe PtdIns(3)P on phagosomes [64]. However, additional PtdIns(3)P interacting proteins are involved in this process, as recent studies indicate that another lipid binding motif, the PX domain, specifically recognizes PtdIns(3)P [65]. Hence, it is likely that new effectors of this lipid will continue to emerge.

The question still remains whether the FYVE domain alone provides sufficient specificity for protein localization. Studies in yeast would favor a significant but not singular role for the FYVE domain in this regard. Instead, PtdIns(3)P-FYVE interactions coupled with protein-protein interactions are likely to ensure specific membrane recruitment of these proteins. This level of specificity would help ensure appropriate membrane-restricted responses and functions. Further studies are required to determine the validity of this concept and whether this is a general principle or may only apply to a certain subset of FYVE domain-containing proteins.

Protein Kinase C: Relaying Signals from Lipid Hydrolysis to Protein Phosphorylation

Alexandra C. Newton

*Department of Pharmacology, University of California at San Diego,
La Jolla, California*

Introduction

Protein kinase C (PKC) has been in the spotlight since the discovery a quarter of a century ago that, through its activation by diacylglycerol, it relays signals from lipid hydrolysis to protein phosphorylation [1]. The subsequent discovery that PKCs are the target of phorbol esters resulted in an avalanche of reports on the effects on cell function of phorbol esters, nonhydrolyzable analogs of the endogenous ligand, diacylglycerol [2–4]. Despite the enduring stage presence of PKC and tremendous advances in understanding the enzymology and regulation of this key protein, an understanding of the function of PKC in biology is still the subject of intense pursuit. Its uncontrolled signaling wreaks havoc in the cell, as epitomized by the potent tumor-promoting properties of phorbol esters. In fact, the pluripotent effects of phorbol esters, compounded with the existence of multiple isozymes of PKC, has made it difficult to uncover the precise cellular function of this key enzyme [5]. Studies with knockout mice have underscored the problem, with knockouts of most isozymes having only subtle phenotypic effects [6]. This chapter summarizes our current understanding of the molecular mechanisms of how protein kinase C transduces information from lipid mediators to protein phosphorylation.

Protein Kinase C Family

The 10 members of the mammalian PKC family are grouped into three classes based on their domain structure, which, in turn, dictates their cofactor dependence (Fig. 1). All members comprise a single polypeptide that has a conserved kinase core carboxyl-terminal to a regulatory moiety. This regulatory moiety contains two key functionalities: an autoinhibitory sequence (pseudosubstrate) and one or two membrane-targeting modules (C1 and C2 domains). The C1 domain binds diacylglycerol and phosphatidylserine specifically and is present as a tandem repeat in conventional and novel PKCs (C1A and C1B); the C2 domain nonspecifically binds Ca^{2+} and anionic phospholipids such as phosphatidylserine. Non-ligand-binding variants of each domain exist: atypical C1 domains do not bind diacylglycerol and novel C2 domains do not bind Ca^{2+} .

Conventional PKC isozymes (α , γ , and the alternatively spliced βI and βII) are stimulated by diacylglycerol and phosphatidylserine (C1 domain) and Ca^{2+} (C2 domain); novel PKC isozymes (δ , ϵ , η/L , θ) are stimulated by diacylglycerol and phosphatidylserine (C1 domain); and atypical PKC isozymes (ζ , ι/λ) are stimulated by phosphatidylserine (atypical C1 domain) [5–7]. (Note that PKC μ and ν were considered to constitute a fourth class of PKCs but are now generally regarded as members of a distinct family

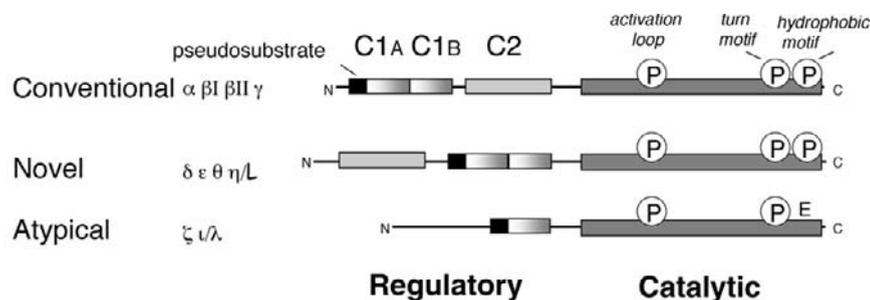

Figure 1 Domain composition of protein kinase C family members showing autoinhibitory pseudosubstrate, membrane-targeting modules (C1A and C1B and C2 domains), and kinase domain of the three subclasses: conventional, novel, and atypical isozymes. Also indicated are the positions of the three processing phosphorylation sites, the activation loop and two carboxyl-terminal sites, the turn motif, and hydrophobic motif. (Adapted from Newton, A. C. and Johnson, J. E., *Biochem. Biophys. Acta*, 1376, 155–172, 1998.)

called protein kinase D.) The role of the novel C2 domain in novel PKCs and that of the atypical C1 domain in atypical PKCs is not clear, but each may regulate the subcellular distribution of these isozymes through protein–protein interactions.

Regulation of Protein Kinase C

The normal function of PKC is under the coordinated regulation of three major mechanisms: phosphorylation/dephosphorylation, membrane targeting modules, and anchor proteins. First, the kinase must be processed by a series of ordered phosphorylations to become catalytically competent. Second, it must have its pseudosubstrate removed from the active site to be catalytically active, a conformational change driven by engaging the membrane-targeting modules with ligand. Third, it must be localized at the correct intracellular location for unimpaired signaling. Perturbation at any of these points of regulation disrupts the physiological function of PKC [7].

Phosphorylation/ Dephosphorylation

The function of PKC isozymes is controlled by phosphorylation mechanisms that are required for the maturation of the enzyme. In addition to the processing phosphorylations, the function of PKC isozymes is additionally fine-tuned by both Tyr and Ser/Thr phosphorylations [8,9]. The conserved maturation phosphorylations are described below.

PHOSPHORYLATION IS REQUIRED FOR THE MATURATION OF PROTEIN KINASE C

The majority of PKC in tissues and cultured cells is phosphorylated at two key phosphorylation switches: a loop near the active site, referred to as the *activation loop*, and a sequence at the carboxyl terminus of the kinase domain [10,11]. The carboxyl-terminal switch contains two sites: the turn motif, which by analogy with protein kinase A is at the apex of a turn on the upper lobe of the kinase domain, and the hydrophobic motif, which is flanked by hydrophobic

residues (note that, in atypical PKCs, a Glu occupies the phospho-acceptor position of the hydrophobic motif). It is the phosphorylated species that transduces signals. While it had been appreciated since the late 1980s that PKC is processed by phosphorylation [12], the mechanism and role of these phosphorylations are only now being unveiled [7,9].

The first step in the maturation of PKC is phosphorylation by the phosphoinositide-dependent kinase, PDK-1, of the activation loop. This enzyme was originally discovered as the upstream kinase for Akt/protein kinase B [13] and was subsequently shown to be the activation loop kinase for a large number of AGC kinases, including all PKC isozymes [14–16]. The name PDK-1 was based on the phosphoinositide-dependence of Akt phosphorylation and is an unfortunate misnomer because the phosphorylation of other substrates (for example, the conventional PKCs) has no dependence on phosphatidylinositol 3-kinase (PI3K) lipid products [17]. Rather, PDK-1 appears to be constitutively active in the cell, with substrate phosphorylation regulated by the conformation of the substrate [18–20].

Completion of PKC maturation requires phosphorylation of the two carboxyl-terminal sites, the turn motif and hydrophobic motif. In the case of conventional PKCs, this reaction occurs by an intramolecular autophosphorylation mechanism [21]. Autophosphorylation also accounts for the hydrophobic motif processing of the novel PKC ϵ [22]; however, it has been suggested that another member of this family, PKC δ , may be the target of a putative hydrophobic motif kinase [23].

Research in the past few years has culminated in the following model for PKC phosphorylation. Newly synthesized enzyme associates with the plasma membrane, where it adopts an open conformation with the pseudosubstrate exposed, thus unmasking the PDK-1 site on the activation loop [17,24]. It is likely held at the membrane by multiple weak interactions with the exposed pseudosubstrate, the C1 domain, and the C2 domain (because the C1 and C2 ligands are absent, these domains are weakly bound via their interactions with anionic phospholipids). PDK-1 docks onto the carboxyl terminus of PKC, where it is positioned to phosphorylate the activation loop [25]. This phosphorylation is

the first and required step in the maturation of PKC; mutation of the phospho-acceptor position at the activation loop to Ala or Val prevents the maturation of PKC and results in accumulation of unphosphorylated, inactive species in the detergent-insoluble fraction of cells [26,27].

Completion of PKC maturation requires release of PDK-1 from its docking site on the carboxyl terminus. Physiological mechanisms for this release have not yet been elucidated, but it is interesting that over-expression of peptides that have a high affinity for PDK-1 promotes the maturation of PKC [25]. One such peptide is PIF, the carboxyl-terminus of PRK-2, which has a hydrophobic phosphorylation motif with a Asp at the phospho-acceptor position [28]. Release of PDK-1 unmasks the carboxyl terminus of PKC, allowing phosphorylation of the turn motif and the hydrophobic motif [7,10].

DEPHOSPHORYLATION: DEACTIVATION SIGNAL

While the phosphorylation of conventional PKCs is constitutive, the dephosphorylation appears to be agonist stimulated [29]. Both phorbol esters and ligands such as tumor necrosis factor α (TNF α) result in PKC inactivation and dephosphorylation [29–31]. In addition, serum selectively promotes the dephosphorylation of the activation loop site in conventional PKCs, thus uncoupling the phosphorylation of the activation loop from that of the carboxyl-terminal sites [17]. The hydrophobic site of PKC ϵ has also been reported to be selectively dephosphorylated by a rapamycin-sensitive phosphatase [32]. It is likely that the uncoupling of the dephosphorylation of these sites has contributed to confusion as to whether the hydrophobic site is regulated by its own upstream kinase rather than autophosphorylation [23].

Membrane Translocation

The translocation from the cytosol to the membrane has served as the hallmark for PKC activation since the early 1980s [33,34]. The molecular details of this translocation have emerged from abundant biophysical, biochemical, and cellular studies showing that diacylglycerol acts like molecular glue to recruit PKC to membranes, an event that, for conventional PKCs, is facilitated by Ca²⁺ [35–37].

Both *in vitro* and *in vivo* data converge on the following model for the translocation of conventional PKC in response to elevated Ca²⁺ and diacylglycerol [35,38]. In the resting state, PKC bounces on and off membranes by a diffusion-limited reaction. However, its affinity for membranes is so low that its lifetime on the membrane is too short to be significant. Elevation of Ca²⁺ results in binding of Ca²⁺ to the C2 domain of this soluble species of PKC. This Ca²⁺-bound species has a dramatically enhanced affinity for the membrane, with which it rapidly associates. The membrane-bound PKC then diffuses in the two-dimensional plane of the membrane, searching for the much less abundant ligand, diacylglycerol. This search for diacylglycerol is considerably more efficient from the membrane than one initiated from the cytosol. Following collision with, and binding to, diacylglycerol, PKC is bound to the membrane with sufficiently

high affinity to allow release of the pseudosubstrate sequence and activation of PKC. Decreases in the level of either second messenger weaken the membrane interaction sufficiently to release PKC back into the cytosol. Note that if PMA is the C1 domain ligand, PKC can be retained on the membrane in the absence of elevated Ca²⁺ because this ligand binds PKC two orders of magnitude more tightly than diacylglycerol [39]. Similarly, if Ca²⁺ levels are elevated sufficiently, PKC can be retained at the membrane in the absence of a C1 ligand.

Novel PKC isozymes translocate to membranes much more slowly than conventional PKCs in response to receptor-mediated generation of diacylglycerol because they do not have the advantage of pre-targeting to the membrane by the soluble ligand, Ca²⁺ [40]. Atypical PKC isozymes do not respond directly to either diacylglycerol or Ca²⁺.

Anchoring Proteins

The control of subcellular localization of kinases by scaffold proteins is emerging as a key requirement in maintaining fidelity and specificity in signaling by protein kinases [41]. PKC is no exception, and a battery of binding partners for members of this kinase family have been identified [42–45]. These proteins position PKC isozymes near their substrates, near regulators of activity such as phosphatases and kinases, or in specific intracellular compartments. Disruption of anchoring can impair signaling by PKC, and *Drosophila* photoreceptors provide a compelling example. Mislocalization of eye-specific PKC by abolishing its binding to the scaffold protein, ina D, disrupts phototransduction [46].

Unlike protein kinase A binding proteins (AKAPs) [47], there is no consensus binding mechanism for interaction of PKC with its anchor proteins. Rather, each binding partner identified to date interacts with PKC by unique determinants and unique mechanisms. Some binding proteins regulate multiple PKC isozymes, while others control the distribution of specific isozymes. There are binding proteins for newly synthesized unphosphorylated PKC, phosphorylated but inactive PKC, phosphorylated and activated PKC, and dephosphorylated, inactivated PKC [43,45]. Anchoring proteins for PKC have diverse functions—some positively regulate signaling while others negatively regulate it. An emerging theme is that many scaffolds bind multiple signaling molecules in a signaling complex; for example, AKAP 79 binds PKA, PKC, and the phosphatase calcineurin [48]. The physical coupling of kinases and phosphatases underscores the acute regulation that each must be under to maintain fidelity in signaling.

Model for Regulation of Protein Kinase C by Phosphorylation and Second Messengers

Figure 2 outlines a model for the regulation of PKC by phosphorylation, second messengers, and anchoring proteins. Newly synthesized PKC associates with the membrane in a conformation that exposes the pseudosubstrate

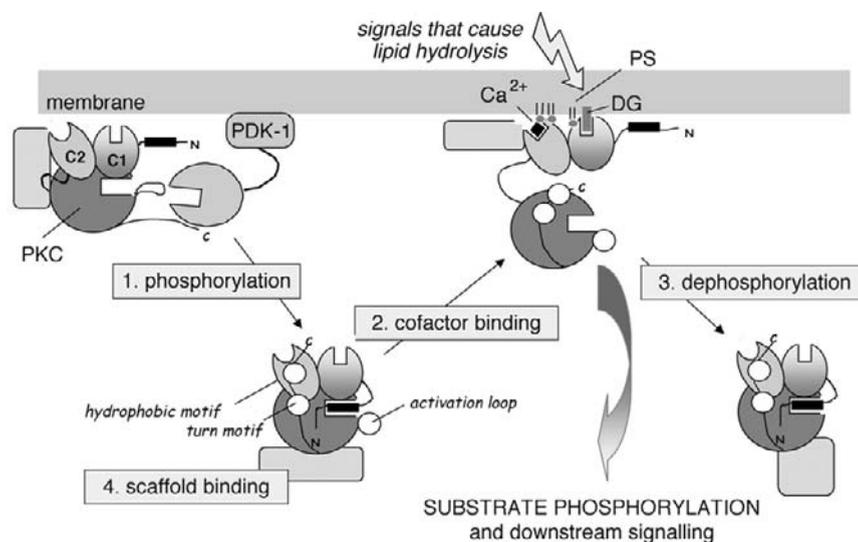

Figure 2 Model showing the major regulatory mechanisms for PKC function: (1) processing by phosphorylation, (2) activation by lipid mediators, (3) deactivation by dephosphorylation, and (4) spatial control by scaffold proteins. See text for details. (Adapted from Newton, A. C., *Chem. Rev.*, **101**, 2353–2364, 2001.)

(black rectangle), allowing access of the upstream kinase, PDK-1, to the activation loop. PDK-1 docks onto the carboxyl terminus of PKC. Following its phosphorylation of the activation loop and release from PKC, the turn motif and hydrophobic motif are autophosphorylated. The mature PKC is released into the cytosol, where it is maintained in an auto-inhibited conformation by the pseudosubstrate (middle panel), which has now gained access to the substrate-binding cavity (open rectangle in the large circle representing the kinase domain of PKC). It is this species that is competent to respond to second messengers. Generation of diacylglycerol and, for conventional PKCs, Ca^{2+} mobilization provide the allosteric switch to activate PKC. This is achieved by engaging the C1 and C2 domains on the membrane (Fig. 2, right panel), thus providing the energy to release the pseudosubstrate from the active site, allowing substrate binding and catalysis. In addition to the regulation by phosphorylation and cofactors, anchoring/scaffold proteins (stippled rectangle) play a key role in PKC function by positioning specific isoforms at particular intracellular locations [43,45]. Following activation, PKC is either released into the cytosol or, following prolonged activation, dephosphorylated and downregulated by proteolysis.

Function of Protein Kinase C

Despite over two decades of research on the effects of phorbol esters on cell function, a unifying mechanism for the role of PKC in the cell has remained elusive. An abundance of substrates have been identified, and the reader is referred to reviews summarizing these and potential signaling pathways involving PKC [5,6,49–52]. However, a unique role for PKC in defining cell function is lacking. This is epitomized

by the finding that there is no severe phenotype associated with knocking-out specific PKC isoforms in mice.

Closer analysis of the phenotypes of knockout animals of various PKC isoforms does suggest a common theme: animals deficient in PKC are deficient in adaptive responses. For example, PKC $\epsilon^{-/-}$ mice have reduced anxiety and reduced tolerance to alcohol [53], PKC $\gamma^{-/-}$ mice have reduced pain perception [54], and PKC $\beta\text{II}^{-/-}$ mice have reduced learning abilities [55]. This theme carries over to the molecular level, where many of the substrates of PKC are receptors that become desensitized following PKC phosphorylation.

Summary

PKC plays a pivotal role in cell signalling by relaying information from lipid mediators to protein substrates. The relay of this information is under exquisite conformational, spatial, and temporal regulation, and extensive studies on the molecular mechanisms of this control have provided much insight into how PKC is regulated. With novel approaches in chemical genetics, analysis of crosses of PKC isoform knockout mice, and proteomics, the PKC signaling field is poised to move to the next level of making headway into the *raison d'être* of this ubiquitous family of kinases.

Introduction

Stimulation of cells with growth factors, survival factors, and hormones leads to recruitment to the plasma membrane of a family of lipid kinases known as class 1 phosphoinositide 3-kinases (PI 3-kinases, [1]). In this location PI 3-kinases phosphorylate the glycerophospholipid phosphatidylinositol 4,5-bisphosphate (PtdIns(4,5)P₂), at the D-3 position of the inositol ring, converting it to PtdIns(3,4,5)P₃, which is then converted to PtdIns(3,4)P₂ through the action of the SH2-containing inositol phosphatases (SHIP1 and SHIP2) or back to PtdIns(4,5)P₂ via the action of the lipid phosphatase PTEN (phosphatase and tensin homolog deleted on chromosome 10).

PtdIns(3,4,5)P₃ and perhaps PtdIns(3,4)P₂ play key roles in regulating many physiological processes, including controlling cell apoptosis and proliferation, most of the known physiological responses to insulin, and cell differentiation and cytoskeletal organization [2]. PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ exert their cellular effects by interacting with proteins that possess a certain type of pleckstrin homology domain (PH domain). A number of types of PH domain containing proteins that interact with PtdIns(3,4,5)P₃ and/or PtdIns(3,4)P₂ have now been identified. These include the serine/threonine protein kinases protein kinase B (PKB; also known as Akt) [3], tyrosine kinases of the Tec family [4,5], numerous adaptor molecules such as the Grb2-associated protein (GAB1 [6]), the dual adaptor of phosphotyrosine and 3-phosphoinositides (DAPP1 [7–10]), and the tandem PH-domain-containing proteins (TAPP1 and TAPP2 [11]), as well as guanosine triphosphate (GTP)/guanosine diphosphate

(GDP) exchange [12–14] and GTPase-activating proteins [15,16] for the ARF/Rho/Rac family of GTP binding proteins (Fig 1). This chapter focuses on research aimed at understanding the mechanism by which PtdIns(3,4,5)P₃ regulates one branch of its downstream signaling pathways, namely enabling PDK1 to phosphorylate and activate a group of serine/threonine protein kinases that belong to the AGC subfamily of protein kinases. These include isoforms of PKB [3,17], p70 ribosomal S6 kinase (S6K) [18,19], serum- and glucocorticoid-induced protein kinase (SGK) [20], p90 ribosomal S6 kinase (RSK) [21], and protein kinase C (PKC) isoforms [22]. Once these diverse AGC kinase members are activated, they phosphorylate and change the activity and function of key regulatory proteins that control processes such as cell proliferation and survival as well as cellular responses to insulin [2,3,23].

Mechanism of Activation of PKB

The three isoforms of PKB (PKB α , PKB β , and PKB γ) possess high sequence identity and are widely expressed in human tissues [17]. Stimulation of cells with agonists that activate PI 3-kinase induce a large activation of PKB isoforms within a few minutes. The activation of PKB is downstream of PI 3-kinase, as inhibitors of PI 3-kinase such as wortmannin or LY294002, or the over-expression of a dominant-negative regulatory subunit of PI 3-kinase inhibit the activation of PKB in cells by virtually all agonists tested [24–26]. Over-expression of a constitutively active mutant of PI 3-kinase induces PKB activation in unstimulated cells [27],

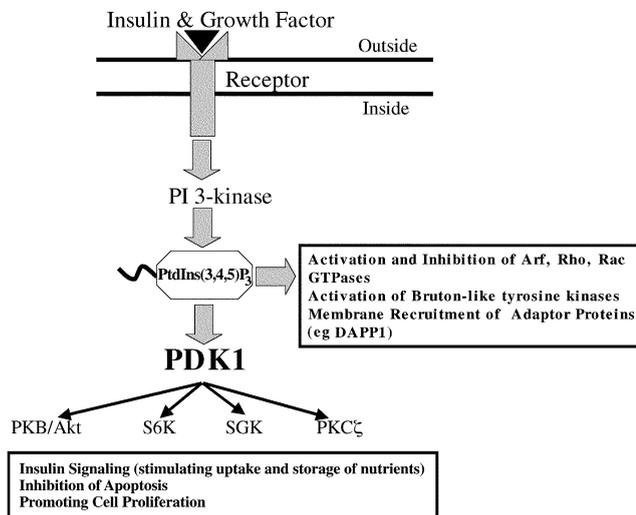

Figure 1 Overview of the PI 3-kinase signaling pathway. Insulin and growth factors induce the activation of PI 3-kinase and generation of PtdIns(3,4,5)P₃. In addition to leading to the activation of PKB/Akt, S6K, SGK, and atypical PKC isoforms such as PKCζ, PtdIns(3,4,5)P₃ also recruits a number of other proteins (outlined in the text) to the plasma membrane to trigger the activation of non-PDK1/AGC-kinase-dependent signaling pathways. Key challenges for future experiments are not only to define the specific cellular roles of the individual AGC kinase but also to understand the function and importance of other branches of signaling pathways activated by PI 3-kinase.

as does deletion of the PTEN phosphatase which also results in increased cellular levels of PtdIns(3,4,5)P₃ [28–32].

All PKB isoforms possess an N-terminal pleckstrin homology (PH domain) that interacts with PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ followed by a kinase catalytic domain and then a C-terminal tail. Stimulation of cells with agonists that activate PI 3-kinase induces the translocation of PKB to the plasma membrane, where PtdIns(3,4,5)P₃ as well as PtdIns(3,4)P₂ are located and, consistent with this, translocation of PKB is prevented by inhibitors of PI 3-kinase or by the deletion of the PH domain of PKB [33–35]. These findings strongly indicate that PKB interacts with PtdIns(3,4,5)P₃ and/or PtdIns(3,4)P₂ *in vivo*. The binding of PKB to PtdIns(3,4,5)P₃ or PtdIns(3,4)P₂ does not activate the enzyme but instead recruits PKB to the plasma membrane where it becomes phosphorylated at two residues at this location, namely Thr308 and Ser473. Inhibitors of PI 3-kinase and dominant-negative PI 3-kinase prevent phosphorylation of PKB at both residues following stimulation of cells with insulin and growth factors [17]. Thr308 is located in the T-loop (also known as *activation loop*) between subdomains VII and VIII of the kinase catalytic domain, situated at the same position as the activating phosphorylation sites found in many other protein kinases. As discussed later, Ser473 is located outside of the catalytic domain in a motif that is present in most AGC kinases and which has been termed the *hydrophobic motif*. The phosphorylation of PKBα at both Thr308 or Ser473 is likely to be required to activate PKBα maximally, as mutation of Thr308 to Ala abolishes PKBα activation, whereas mutation of Ser473 to Ala reduces the

activation of PKBα by approximately 85%. The mutation of both Thr308 and Ser473 to Asp (to mimic the effect of phosphorylation by introducing a negative charge) increases PKBα activity substantially in unstimulated cells, and this mutant cannot be further activated by insulin [3]. Attachment of a membrane-targeting domain to PKBα results in it becoming highly active in unstimulated cells and induces a maximal phosphorylation of Thr308 and Ser473 [33,36]. These observations indicate that recruitment of PKB to the membrane of unstimulated cells is sufficient to induce the phosphorylation of PKBα at Thr308 and Ser473. Furthermore, there must be sufficient basal levels of PtdIns(3,4,5)P₃/PtdIns(3,4)P₂, T308 kinase, and Ser473 kinase located at the membrane to stimulate phosphorylation and activation of membrane-targeted PKB. PKBβ and PKBγ are activated by phosphorylation of the equivalent residues in their T-loops and hydrophobic motifs [37,38].

PKB Is Activated by PDK1

A protein kinase was purified [39,40] and subsequently cloned [41,42] that phosphorylated PKBα at Thr308 only in the presence of lipid vesicles containing PtdIns(3,4,5)P₃ or PtdIns(3,4)P₂. Because of these properties it was named 3-phosphoinositide-dependent protein kinase 1 (PDK1) and is composed of an N-terminal catalytic domain and a C-terminal PH domain which, like that of PKB, interacts with PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ [42,43]. The activation of PKB by PDK1 is stereospecific for the physiological D-enantiomers of these lipids, and neither PtdIns(4,5)P₂ nor any inositol phospholipid other than PtdIns(3,4)P₂ can replace PtdIns(3,4,5)P₃ in the PDK1-catalyzed activation of PKB [39,42].

Although co-localization of PKB and PDK1 at the plasma membrane through their mutual interaction with 3-phosphoinositides is likely to be important for PDK1 to phosphorylate PKB, the binding of PKB to PtdIns(3,4,5)P₃ or PtdIns(3,4)P₂ is also postulated to induce a conformational change in PKB, exposing Thr308 for phosphorylation by PDK1. This conclusion is supported by the observation that in the absence of 3-phosphoinositides, PDK1 is unable to phosphorylate wild-type PKB under conditions where it is able to efficiently phosphorylate a mutant form of PKB that lacks its PH domain, termed ΔPH-PKB [40,41]. Consistent with this, a PKB mutant in which a conserved Arg residue in the PH domain is mutated to abolish the ability of PKB to bind PtdIns(3,4,5)P₃ cannot be phosphorylated by PDK1 in the presence of lipid vesicles containing PtdIns(3,4,5)P₃ [40]. Moreover, artificially promoting the interaction of PDK1 with wild-type PKB and ΔPH-PKB by the attachment of a high-affinity PDK1 interaction motif to these enzymes is sufficient to induce maximal phosphorylation of Thr308 in ΔPH-PKB but not in wild-type PKB in unstimulated cells [44].

More recently, the three-dimensional structure of the isolated PH domain of PKB complexed with the head group of

PtdIns(3,4,5)P₃ has been solved [45]. Interestingly, the structure of the PH domain of PKB complexed to the inositol head group of PtdIns(3,4,5)P₃ revealed that the 3- and the 4-phosphate groups form numerous interactions with specific basic amino acids in the PKB PH domain, but in contrast the 5-phosphate group does not make any significant interaction with the protein backbone and is solvent exposed, thus providing the first structural explanation of why PKB interacts with both PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ with similar affinity [45].

The interaction of PDK1 with PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ is thought to be the primary determinant in enabling PDK1 and PKB to colocalize at membranes and permitting PDK1 to phosphorylate PKB efficiently. These conclusions are supported by the finding that the rate of activation of PKB α by PDK1 *in vitro*, in the presence of lipid vesicles containing PtdIns(3,4,5)P₃, is lowered considerably if the PH domain of PDK1 is deleted. Furthermore, the mutant of PKB that lacks its PH domain is also a very poor substrate for PDK1, compared to wild-type PKB, as it is unable to interact with lipid vesicles containing PtdIns(3,4,5)P₃.

Activation of Other Kinases by PDK1

The finding that the T-loop residues of PKB are very similar to those found on other AGC kinases suggested that PDK1 might phosphorylate and activate these members [46,47]. An alignment of the T-loop sequences of insulin and growth-factor-stimulated AGC kinases is shown in Fig. 2. It was found that the AGC kinases activated downstream of PI 3-kinase (namely, S6K1 [48,49], SGK isoforms [50–52], and atypical PKC isoforms [53,54]) were phosphorylated specifically at their T-loop residue by PDK1 *in vitro* or following the over-expression of PDK1 in cells. Moreover, AGC kinases that were not activated in a PI 3-kinase-dependent manner in cells—such as the p90 ribosomal S6K (p90RSK)

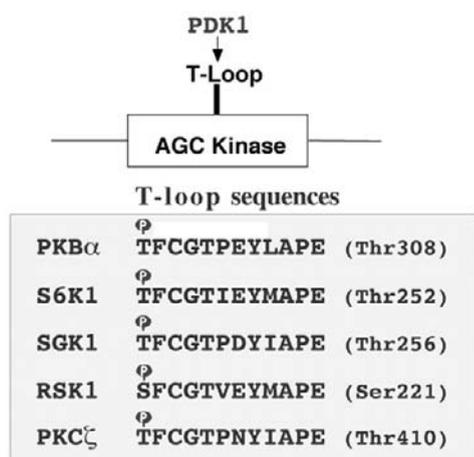

Figure 2 Alignment of the amino acid sequences surrounding the T-loop of insulin and growth-factor-stimulated AGC kinases.

isoforms [55,56], conventional and related PKC isoforms [57–60], PKA [61], and the non-AGC Ste20 family member PAK1 [62]—were also proposed to be physiological substrates for PDK1, as they could all be phosphorylated by PDK1 at their T-loop residue *in vitro* or following over-expression of PDK1 in cells.

Genetic evidence for the central role that PDK1 plays in mediating the activation of these AGC kinases was obtained from the finding that in PDK1^{-/-} ES cells, isoforms of PKB, S6K, and RSK could not be activated by agonists that switch on these enzymes in wild-type cells [63]. In ES cells lacking PDK1, the intracellular levels of endogenously expressed PKC α , PKC β I, PKC γ , PKC δ , PKC ϵ , and PRK1 are also vastly reduced compared to wild-type ES cells [64], consistent with the notion that PDK1 phosphorylation of these enzymes plays an essential role in post-translational stabilization of these kinases [65,66]. The levels of PKC ζ were only moderately reduced in the PDK1^{-/-} ES cells and PKC ζ in these cells is not phosphorylated at its T-loop residue [64], providing genetic evidence that PKC ζ is a physiological substrate for PDK1. In contrast, PKA was active and phosphorylated at its T-loop in PDK1^{-/-} ES cells, to the same extent as in wild-type ES cells [63], thus arguing that PDK1 is not rate limiting for the phosphorylation of PKA in ES cells. It is possible that PKA phosphorylates itself at its T-loop residue *in vivo*, as it has been shown to possess the intrinsic ability to phosphorylate its own T-loop when expressed in bacteria. Thus far, we have no genetic data in PDK1-deficient cells as to whether or not PAK1 is active, but it should be noted that PAK1 can also phosphorylate itself at its T-loop in the presence of Cdc42-GTP or Rac-GTP, stimulating its own activation in the absence of PDK1 [67].

Phenotype of PDK1 PKB- and S6K-Deficient Mice and Model Organisms

PDK1^{-/-} mouse embryos die at day E9.5, displaying multiple abnormalities that include a lack of somites, forebrain, and neural-crest-derived tissues, although the development of the hind- and midbrain proceeds relatively normally [68]. Other eukaryotic organisms also possess homologs of PDK1 that activate homologs of PKB and S6K in these species [69]. As in mice, knocking out PDK1 homologs in yeast [70–72], *Caenorhabditis elegans* [73], and *Drosophila* [74,75] results in nonviable organisms, confirming that PDK1 plays a key role in regulating normal development and survival of these organisms. Elegant genetic analysis of the PI 3-kinase/PDK1/AGC kinase pathway in *Drosophila* has demonstrated that this pathway plays a key role in regulating both cell size and number [76,77]. For example, the over-expression of dPI 3-kinase [78,79] or inactivation of the PtdIns(3,4,5)P₃ 3-phosphatase dPTEN [80–82] results in an increase in both the cell number as well as the cell size of *Drosophila*. Moreover, loss-of-function mutants of Chico, the fly homolog of insulin receptor substrate adaptor protein [83], dPI 3-kinase, or over-expression

of dPTEN results in a decrease in cell size and number. More recently, a partial loss-of-function mutation in dPDK1 was shown to cause a 15% reduction in fly body weight and a 7% reduction in cell number [74]. Loss of function mutants of dS6K1 [84] or dPKB reduce *Drosophila* cell size without affecting cell number [82,85]. PKB and S6K have also been knocked out in mice, but these studies are complicated by the presence of two isoforms of S6K (S6K1 and S6K2) and three isoforms of PKB (PKB α , PKB β , and PKB γ) encoded for by distinct genes, in contrast to *Drosophila*, which have one isoform of these enzymes. Mice lacking S6K1 were viable, but adult mice were 15% smaller and possessed 10 to 20% reduced organ masses [86]. It was subsequently shown that S6K1 knockout mice possessed a reduced pancreatic islet β -cell size but the size of other cells types investigated was apparently unaffected [87]. Mice lacking PKB α were also reported to be 20% smaller than wild-type animals, but it was not determined whether the lack of PKB α resulted in a reduction of cell size or cell number [88,89]. In contrast, deletion of PKB β caused insulin resistance without affecting mouse size [90].

PDK1 hypomorphic mutant mice that express only $\approx 10\%$ of the normal level of PDK1 in all tissues have been generated [68]. These mice are viable and fertile, and despite the reduced levels of PDK1, injection of these mice with insulin induces the normal activation of PKB, S6K, and RSK in insulin-responsive tissues. Nevertheless, these mice have a marked phenotype, being 40 to 50% smaller than control animals. The volumes of the kidney, pancreas, spleen, and adrenal gland of the PDK1 hypomorphic mice are reduced proportionately. Furthermore, the volume of adrenal gland zona fasciculata cells is 45% lower than control cells, whereas the total cell number and the volume of the nucleus remains unchanged. Cultured embryonic fibroblasts from the PDK1 hypomorphic mice are also 35% smaller than control cells but proliferate at the same rate. Embryonic endoderm cells completely lacking PDK1 from E7.5 embryos were 60% smaller than wild-type cells [68]. These results establish that, as in *Drosophila*, PDK1 plays a key role regulating cell size in mammals. However, the finding that AGC kinases tested are still activated normally in the PDK1 hypomorphic mice may suggest that PDK1 regulates cell size by a pathway that is independent of PKB, S6K, and RSK, although this hypothesis requires further investigation. In this regard, Tian *et al.* [91] have recently reported that PDK1 can interact via its noncatalytic N terminus with the PI 3-kinase-regulated Ral GTP exchange factor, leading to its activation. The Ral GTPase has not been implicated in regulating cell size, but it will be important to investigate whether activation of Ral GTPases is defective in PDK1 hypomorphic or knockout cell lines or mice tissues.

Hydrophobic Motif of AGC Kinases

All insulin and growth-factor-activated AGC kinases, in order to become maximally activated, require phosphorylation

of a residue located in a region of homology to the hydrophobic motif of PKB α that encompasses Ser473. This is located ≈ 160 amino acids C-terminal to the T-loop residue lying outside the catalytic regions of these enzymes. This hydrophobic motif is characterized by a conserved motif: Phe-Xaa-Xaa-Phe-Ser/Thr-Tyr/Phe (where Xaa is any amino acid and the Ser/Thr residue is equivalent to Ser473 of PKB). Atypical PKC isoforms (PKC ζ , PKC λ , PKC τ) and the related PKC isoforms (PRK1 and PRK2), instead of possessing a Ser/Thr residue in their hydrophobic motifs, have an acidic residue. PKA, in contrast, possesses only the Phe-Xaa-Xaa-Phe moiety of the hydrophobic motif, as the PKA amino acid sequence terminates at this position [92]. PDK1 is the only AGC kinase member that does not appear to possess an obvious hydrophobic motif [92], and the implications of this are discussed below. A major outstanding challenge is to characterize the mechanism by which PKB and other AGC kinases are phosphorylated at their hydrophobic motifs. In spite of considerable effort to discover the kinases responsible for the phosphorylation of AGC kinase members, no convincing evidence has thus far been obtained. The extensive literature and considerable controversy in this area have been extensively reviewed [93]. The only exception is for RSK and conventional PKC isoforms. For RSK, the phosphorylation of the C-terminal non-AGC kinase domain of this enzyme by ERK1/ERK2 triggers this domain to phosphorylate the N-terminal AGC kinase domain at its hydrophobic motif [21]. In the case of conventional PKC isoforms, there is good evidence that these enzymes can autophosphorylate themselves at their hydrophobic motifs following phosphorylation of their T-loops by PDK1 [22].

Mechanism of Regulation of PDK1 Activity

An important question is to determine the mechanism by which the ability of PDK1 activity to phosphorylate its AGC kinase substrates is regulated by extracellular agonists. When isolated from unstimulated or cells stimulated with insulin or growth factors, PDK1 possesses the same activity toward PKB or S6K1 [41,49,94]. Furthermore, although PDK1 is phosphorylated at 5 serine residues in 293 cells, insulin or insulin-like growth factor 1 (IGF1) did not induce any change in the phosphorylation state of PDK1 [95]. Only one of these phosphorylation sites (namely, Ser241) was essential for PDK1 activity. Ser241 is located in the T-loop of PDK1, and, because PDK1 expressed in bacteria is stoichiometrically phosphorylated at Ser241, it is likely that PDK1 can phosphorylate itself at this residue [95]. Although PDK1 becomes phosphorylated on tyrosine residues following stimulation of cells with peroxovanadate (a tyrosine phosphatase inhibitor) or over-expression with a Src-family tyrosine kinase [96–98], no tyrosine phosphorylation of PDK1 has been detected following stimulation of cells with insulin [95,96].

Taken together, these observations suggest that PDK1 might not be activated directly by insulin/growth factors.

Instead, one possibility that might explain how PDK1 could phosphorylate a number of AGC kinases in a regulated manner is that PDK1, instead of being activated by an agonist, is constitutively active in cells and that it is the substrates that are converted into forms that can interact with PDK1 and thus become phosphorylated at their T-loops. In the case of PKB as discussed above, it is the interaction of PKB with PtdIns(3,4,5)P₃ that converts it into a substrate for PDK1. In the case of other AGC kinases that are activated downstream of PI 3-kinase, such as S6K, SGK, and PKC isoforms, which do not possess a PH domain and thus do not interact with PtdIns(3,4,5)P₃ and whose phosphorylation by PDK1 *in vitro* is not enhanced by PtdIns(3,4,5)P₃, it is not obvious how PtdIns(3,4,5)P₃ can regulate the phosphorylation of these enzymes *in vivo*. Recent studies indicate that a conserved motif located C-terminal to the catalytic domains of isoforms of most AGC kinases (the hydrophobic motif of S6K1, or SGK1 [44]) and atypical (PKC ζ) and related PKC (PRK2) isoforms [57] can interact with a hydrophobic pocket in the kinase domain of PDK1 (the PIF pocket) [92]. Evidence indicates that this results in a docking interaction, which is required for the efficient T-loop phosphorylation of AGC kinases that do not interact with PtdIns(3,4,5)P₃/PtdIns(3,4)P₂. These experiments indicate that the interaction of S6K and SGK with PDK1 is significantly enhanced if these enzymes are phosphorylated at their hydrophobic motifs in a manner equivalent to that of the Ser473 phosphorylation site of PKB [44]. It is therefore possible that PtdIns(3,4,5)P₃ does not activate PDK1 but instead induces phosphorylation of S6K and SGK isoforms at their hydrophobic motifs, thereby converting these enzymes into forms that can interact with PDK1 and hence become activated. Consistent with this notion, the expression of mutant forms of S6K1 and SGK1 in which the hydrophobic motif phosphorylation site is altered to Glu to mimic phosphorylation is constitutively phosphorylated at their T-loop residues in unstimulated cells [50,99,100]. It is currently not clear how PtdIns(3,4,5)₃ could stimulate the phosphorylation of the hydrophobic motif, but it is possible that it could either activate the hydrophobic motif kinases or inhibit the hydrophobic motif phosphatases.

Frodin *et al.* [101] demonstrated that phosphorylation of the hydrophobic motif of p90RSK (which is induced following phosphorylation of p90RSK by ERK1/ERK2 [21]) strongly promotes its interaction with PDK1, therefore enhancing the ability of PDK1 to phosphorylate p90RSK at its T-loop motif. Thus, the phosphorylation of p90RSK by ERK1/ERK2 converts RSK into a form that can interact with and be activated by PDK1. Thus, the mechanism by which PDK1 recognizes isoforms of RSK is analogous to that by which it recognizes SGK/S6K, the only difference being the mechanism regulating phosphorylation of the hydrophobic motifs of these enzymes. The model of how isoforms of PKB, S6K, SGK, and RSK are activated by PDK1 is summarized in Fig. 3.

Related PKC isoforms (PRK1 and PRK2) and atypical PKC isoforms (PKC ζ and PKC τ) possess a hydrophobic

motif in which the residue equivalent to Ser473 is Asp or Glu, and these enzymes can in principle interact with PDK1 as soon as they are expressed in a cell [57]. However, it is possible that the interaction of related PKC isoforms and atypical PKC isoforms with PDK1 could be regulated through the interaction of these enzymes with other molecules. For example, the interaction of PRK2 with Rho-GTP [60] or PKC ζ with hPar3 and hPar6 [102] might induce a conformational change in these enzymes that controls their interaction with PDK1.

PDK1 would be expected to activate PKB at the plasma membrane and its other non-3-phosphoinositide binding substrates in the cytosol. Consistent with this finding, PDK1 has been found to be localized in mainly the cytosol and plasma membrane of both stimulated and unstimulated cells [43,94]. It is controversial as to whether or not PDK1 translocates to the plasma membrane of cells in response to agonists that activate PI 3-kinase. Three reports [43,94,96] indicate that a small proportion of PDK1 is associated with the membrane of unstimulated cells, and they do not report any further translocation of PDK1 to membranes in response to agonists that activate PI 3-kinase and PKB. However, other groups have reported that PDK1 translocates to cellular membranes in response to agonists that activate PI 3-kinase [103,104]. Indeed, as mentioned earlier, there is evidence that at least some PDK1 is likely to be located at cell membranes of unstimulated cells as the expression of a membrane-targeted PKB construct in such cells is active and fully phosphorylated at Thr308 [33,36].

Structure of the PDK1 Catalytic Domain

Further insight into the mechanism by which PDK1 interacts with its AGC kinase substrates has been obtained recently from the high-resolution crystal structure of the human PDK1 catalytic domain. The structure defines the location of the PIF pocket on the small lobe of the catalytic domain—a marked hydrophobic pocket in the small lobe of the kinase domain [105] that corresponds to the region of the catalytic domain predicted from previous modeling and mutational analysis to form the PIF pocket [92]. Interestingly, mutation of several of the hydrophobic amino acids that make up the surface of this pocket abolish or significantly inhibit the ability of PDK1 to interact and activate S6K1 and SGK1 [44], indicating that this hydrophobic pocket does indeed represent the PIF pocket. As phosphorylation of the hydrophobic motif of S6K1 and SGK1 promotes the binding of S6K1 and SGK1 with PDK1, this suggests that a phosphate-interacting site is located near the PIF pocket. Interestingly, close to the PIF pocket in the PDK1 crystal structure, an ordered sulfate ion was interacting with four surrounding side chains (Lys76, Arg131, Thr148, and Gln150). Mutation of Lys76, Arg131, or Q150 to Ala reduces or abolishes the ability of PDK1 to interact with a phospho-peptide that encompasses the phosphorylated residues of the hydrophobic motif of S6K1, thereby

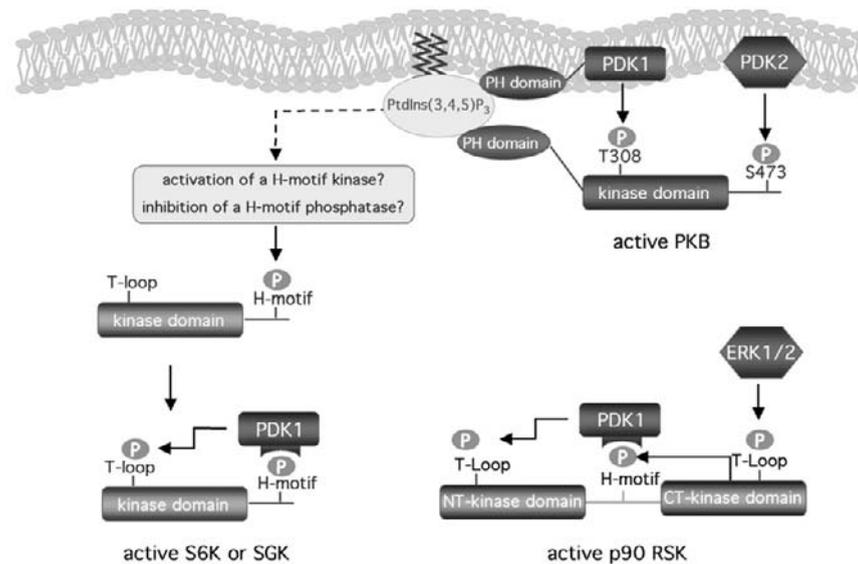

Figure 3 The mechanism by which phosphorylation of PKB, S6K, SGK, and RSK by PDK1 is regulated. It should be noted that in this model of how PKB, S6K, SGK, and RSK are phosphorylated at their T-loop, PDK1 activity is not directly activated by insulin or growth factors, consistent with the experimental observation that PDK1 is constitutively active in cells. Instead, it is the substrates of PDK1 that are converted into forms that can be phosphorylated. In the case of PKB, it is the interaction of PKB with $\text{PtdIns}(3,4,5)\text{P}_3$ at the plasma membrane that colocalizes PDK1 and PKB and also induces a conformational change in PKB that converts it into a substrate for PDK1. In the case of S6K and SGK, which do not possess PH domains and cannot interact with $\text{PtdIns}(3,4,5)\text{P}_3$, this is achieved by the phosphorylation of these enzymes at their hydrophobic motif (H-motif) by an unknown mechanism, which thereby generates a docking site for PDK1. RSK isoforms possess two catalytic domains: an N-terminal AGC-kinase-like kinase domain and a C-terminal non-AGC kinase domain. The activation of RSK isoforms is initiated by the phosphorylation of these enzymes by the ERK1/ERK2 classical MAP kinases, which phosphorylate the T-loop of the C-terminal kinase domain. This activates the C-terminal kinase domain, which then phosphorylates the hydrophobic motif of the N-terminal AGC kinase. This creates a binding site for PDK1 to interact with RSK isoforms, leading to the phosphorylation of the T-loop of the N-terminal kinase domain and activating it. Phosphorylation of all RSK substrates characterized thus far is mediated by the N-terminal kinase domain; however, it is possible that the C-terminal domain of this enzyme will phosphorylate distinct substrates that have not as yet been identified.

suggesting that this region of PDK1 does indeed represent a phosphate docking site [105]. The only other AGC kinase for which the structure is known (namely, PKA) also possesses a hydrophobic pocket at a region of the kinase catalytic domain equivalent to that of PKA which is occupied by the four C-terminal residues of PKA(FXXF) and resembles the first part of the hydrophobic motif phosphorylation site of S6K and SGK (FXXFS/TY) in which the Ser/Thr is the phosphorylated residue [92]. Occupancy of this pocket of PKA by the FXXF residues is likely to be essential to maintaining PKA in an active and stable conformation, as mutation of either Phe residue drastically reduces PKA activity toward a peptide substrate, as well as reducing PKA stability [106,107]. In contrast to the PIF-pocket in the PDK1 structure, PKA does not possess a phosphate docking site located next to the hydrophobic FXXF binding pocket. Sequence alignments of the catalytic domains of AGC kinases, including PDK1, indicate that all AGC kinases possess a PIF pocket, and kinases such as isoforms of RSK, PKB, S6K, and SGK possess a phosphate docking site next to this pocket. The role of these pockets of the AGC kinases

is probably to interact with their own hydrophobic motifs, and this interaction may account for the ability of these kinases to be activated following the phosphorylation of their hydrophobic motif. However, unlike other AGC kinases, PDK1 does not possess a hydrophobic motif C-terminal to its catalytic domain and therefore utilizes its empty PIF/phosphate binding pocket to latch onto its substrates that are phosphorylated at their hydrophobic motifs, thereby enabling PDK1 to phosphorylate these enzymes at their T-loop residue and activate them.

Concluding Remarks

Elucidation of the mechanism by which PKB was activated by PDK1 in cells provided the first example of how the second messenger $\text{PtdIns}(3,4,5)\text{P}_3$ could activate downstream signaling processes. However, there remain many major unsolved questions for future research to address. A major challenge will be to clarify the mechanism by which $\text{PtdIns}(3,4,5)\text{P}_3$ induces the phosphorylation of the

hydrophobic motif of PKB and other AGC kinases members, which is a key trigger for the activation of these enzymes. The results discussed in this chapter also provide a framework within which drugs could be developed to inhibit the PDK1/AGC kinase pathway to treat forms of cancers in which this pathway may be constitutively activated. Indeed, it is now estimated that PTEN is mutated in up to 30% of all human tumors, resulting in elevated PtdIns(3,4,5)P₃ levels and hence PKB and S6K activity which are likely to contribute to the proliferation and survival of these tumors [108]. It could be envisaged that a PDK1 inhibitor would be effective at reducing the PKB and S6K activities that contribute to growth and survival of these tumors.

Babraham, Cambridge, United Kingdom*

Introduction

Most, if not all, membranes in eukaryotic cells carry low mole percent phosphoinositides. These lipids act as regulatable scaffolds, dictating the localization and functions of many proteins on the membrane surface. A clear example of this principle is at the inner leaflet of the plasma membrane, where PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ are rapidly generated following cell-surface receptor activation of type I phosphoinositide 3OH-kinases (PI3K; Chapter 25 by D. Fruman) and act to recruit several PH domain containing proteins. These translocations are driven by the high specificity and affinity of specific PH domains for PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ (Chapter 29 by M. Lemmon). Many of the proteins that harbor PH domains are enzymes that regulate the activity of monomeric (small) GTPases: the guanine nucleotide exchange factors (GEFs), which promote GTP-loading of the GTPase, and GTPase activating proteins (GAPs), which enhance the endogenous GTPase activity of the GTPase. Small GTPases are considered to be active or “on” in their GTP-bound form and inactive or “off” in their GDP-bound form. Thus, historically, GEFs are generally considered to be activators and GAPs to be inactivators. More recent work suggests this is too simplistic. It appears that monomeric GTPases often need to cycle between on/off states to function effectively and that the GAPs can themselves be the target or effector of the monomeric GTPase or act as scaffolds to bring the monomeric GTPase together with targets and hence dictate the context of its activation. We summarize here recent evidence on the modulation of GEFs and GAPs by phosphoinositides with a focus on events regulated by PI3K.

Rho Family Small GTPases

Rho family GTPases are best known for their ability to modulate the actin cytoskeleton (where Rho regulates the formation of stress fibers, Rac regulates membrane ruffles, and Cdc42 regulates filopodia) but they are also involved in the control of such diverse processes as NADPH oxidase, transcriptional activation, G1 cell cycle progression, cell transformation, and secretion [1].

Direct Interactions of Rho family GTPases with Phosphoinositides

Both Rac and Cdc42 interact directly with PtdIns(3,4,5)P₃ and PtdIns(3,4)P₂ with an apparent affinity of 4.5 μM [2]. Lipid binding has been mapped to two sites containing abundant hydrophobic and positively charged sites on the GTPase, and leads to the enhanced dissociation of Rac-associated guanine nucleotides but not association of GTP and hence activation.

Modulation of Rac GEFs by Phosphoinositides

PI3K is thought to be involved in the activation of Rac by stimulating the following Dbl family GEFs: SOS, Vav1, Tiam-1, P-Rex, and possibly PIX. Like all Rho family GEFs [3] they contain the characteristic Dbl homology (DH)-PH domain module (see Fig. 1).

Apart from its well-characterized function as a Ras GEF, SOS functions also as a Rac GEF. The SOS PH domain translocates to the plasma membrane and preferentially to

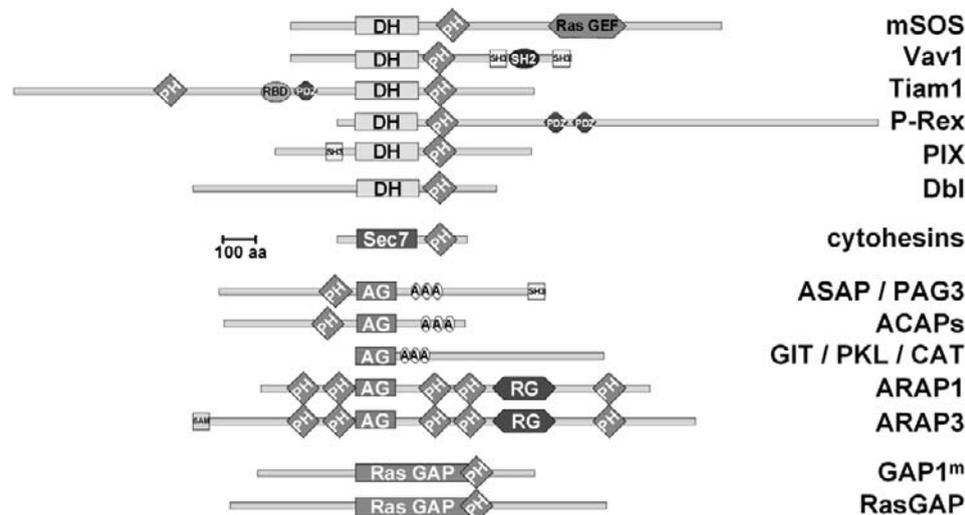

Figure 1 Alignment of all GEF and GAP proteins discussed along their relevant catalytic domains. Domains are drawn as determined via the SMART program. Abbreviations: A, ankyrin repeat; RBD, Ras binding domain; RG, Rho GAP; AG, Arf GAP domains.

leading edges after serum stimulation [4], and this is PI3K dependent. This phenomenon depends on the presence of key residues within the SOS PH domain mediating the interaction with PtdIns(3,4,5)P₃. The SOS DH domain alone functions as a Rac GEF both *in vitro* and *in vivo* [5], but a DH-PH construct is active only in the presence of an activating signal for PI3K. Current evidence suggests PtdIns(3,4,5)P₃-binding to the PH domain relieves an autoinhibitory constraint on the DH domain leading to an increase in catalytic activity toward Rac [6,7].

Vav proteins (Vavs 1–3) are essential for cytoskeletal, proliferative, and developmental pathways in lymphoid cells. Vav-1 is the only family member known to be regulated by PI3K; its regulation has been studied in-depth *in vitro*. Based on structural studies of Vav1 [8], the current model is that GEF activity of Vav1 is autoinhibited by the binding of its N-terminus to the DH domain. Phosphorylation of Y174 by Src-type tyrosine kinases [9] causes the release of the N-terminal inhibitory peptide and this transition is facilitated by PtdIns(3,4,5)P₃, but not PtdIns(4,5)P₂, binding to the PH domain [6,10]. The evidence is less clear-cut *in vivo*, but Gringhuis *et al.* [11] demonstrated convincingly, that in CD5 receptor signaling in T lymphocytes, Vav lies upstream of Rac and downstream of PI3K.

Tiam-1 is a broadly expressed, PI3K-regulated Rac GEF involved in cell adhesion and migration. It contains two PH domains. The N-terminal one binds with high affinity to PtdIns(3,4,5)P₃, is crucial for activation of Rac (ruffling), and plays a role in, but does not dictate, membrane localization [12,13]. Both *in vivo* and *in vitro* evidence suggests that Tiam-1 is regulated by threonine phosphorylation by CaMKII [14] and by binding of PtdIns(3,4,5)P₃ to the Tiam1 N-terminal PH domain [15], both of which moderately activate Tiam-1 catalytic activity, in a cooperative fashion [15]. Neither interactions with nor activation by PtdIns(3,4,5)P₃

of a Tiam1 DH–PH domain construct could be reproduced in a recent study [16].

P-Rex (PtdIns(3,4,5)P₃-dependent Rac exchanger) was purified from porcine neutrophils as a PtdIns(3,4,5)P₃-activated Rac GEF that would be responsible for regulating Rac downstream of activation of heterotrimeric G proteins [17]. Analysis of recombinant P-Rex1 shows that it interacts with lipid vesicles in a PtdIns(3,4,5)P₃-dependent fashion. P-Rex1 RacGEF activity is directly and substantially activated by G protein βγ subunits and PtdIns(3,4,5)P₃ in a synergistic fashion both *in vivo* and *in vitro*.

PIX was identified as a Pak-binding protein with GEF activity toward Rac and Cdc42 involved in the recruitment of PAK to focal adhesions. PIX binds directly to GIT, a potential PtdIns(3,4,5)P₃-stimulated Arf GAP ([18]; see s “PtdIns(3,4,5)P₃-regulated Arf GEFs: The Cytohesin Family,” below). PIX interacts with the p85 regulatory subunit of type IB PI3K, and PIX GEF activity is very weakly stimulated by PtdIns(3,4,5)P₃ [19], but the mechanism is unclear.

Phosphoinositide Binding to Cdc42 GEFs

The PH domain of Dbl is reported to bind to PtdIns(4,5)P₂ and PtdIns(3,4,5)P₃. Both phosphoinositides inhibit Dbl GEF activity. Dbl is partially localized to the plasma membrane in a PH domain dependent fashion [20]. It is interesting that Dbl PH domain point mutants that do not bind phosphoinositides and confer increased Cdc42 GEF activity do not promote focus formation. Another study reports binding of PtdIns(4,5)P₂ to DH–PH constructs of Dbs (Dbl’s big sister) and intersectin, but neither GEF activity was found to be affected by its inclusion into assays *in vitro* [16].

Arf Family GTPases

Arf family G proteins [21] differ from other small G proteins in that they do not have any detectable intrinsic GTPase activity; therefore they have an absolute requirement for both GEFs and GAPs to cycle rapidly between GTP- and GDP-bound states. The closely related Arf family members are grouped into class I (Arfs 1–3), class II (Arfs 4 and 5) and Class III (Arf 6). Class I Arfs are primarily involved in trafficking in the ER-Golgi and endosomal systems. Little is known about class II Arfs. Arf 6 functions in endosomal and plasma membranes to regulate secretion and coordinate cytoskeletal changes (ruffling) in collaboration with Rac, which it transports to the plasma membrane [22]. Phosphoinositides have regulatory inputs into Arfs 6 and 1 by acting on both their GEFs and GAPs.

PtdIns(3,4,5)P₃-regulated Arf GEFs: The Cytohesin Family

Out of the growing number of Arf GEFs [23] only the cytohesin family (comprising the highly homologous Cytohesin 1 and 4, ARNO and Grp1) are regulated by phosphoinositides. Cytohesins share with other Arf GEFs the catalytic Sec7 domain and contain further a characteristic C-terminal PH domain (Fig. 1), which selectively binds specific phosphoinositides. The cytohesins exhibit characteristically dramatic translocations from the cytosol to the plasma membrane that are both dependent on PI3K activity and a functional PH domain. This translocation probably represents their main mode of activation. The field is littered with controversy regarding cytohesin family lipid-binding specificities, an issue that may be explained by the presence of allelic variants of all cytohesins bar cytohesin 4 [24]. The variants are distinguished by the insertion of a single glycine residue into the lipid-binding specificity-determining region of the PH domain. Binding and selectivity of diglycine PH domains to PtdIns(3,4,5)P₃ over PtdIns(4,5)P₂ or PtdIns(3,4)P₂ is exquisite; tri-glycine PH domains are less selective and bind less tightly. Hence, isolated diglycine PH domain constructs can translocate to membranes containing PtdIns(3,4,5)P₃, whereas triglycine PH domains translocate only in the context of the full-length GEFs [25], when a polybasic stretch C-terminally adjacent of the PH domain enhances membrane association [26]. ARNO is phosphorylated by PKC on serine 392, which lies in the polybasic stretch adjacent to the PH domain. The negative charge conferred by the phosphate reduces catalytic activity and binding to membranes, suggesting that PKC may act to switch off ARNO GEF activity [27]. It is interesting that 80% of GRP-1 is expressed in the diglycine version whereas Arno and cytohesin-1 are predominantly in the triglycine form [24], possibly conferring differential sensitivity to PI3K activation.

A second issue of controversy concerns Grp1 and ARNO substrate specificities. Their abilities to use Arf6 as a substrate *in vitro* appear to depend on the precise assay conditions used, whereas Arfs 1 and 5 act as more robust substrates [28,29].

In vivo, all cytohesins have been shown very convincingly to translocate from a cytoplasmic location to the plasma membrane in a PI3K-dependent fashion ([30] and references therein). This coincides with Arf6 distribution, which cycles between endosomal compartments and plasma membrane, but not Arf1, which is confined to intracellular membranes. Indeed, Arf6 and ARNO have been shown to co-localize in ruffles in a PtdIns(3,4,5)P₃-, GEF activity-, and PH domain-dependent fashion [30].

PtdIns(4,5)P₂ and PtdIns(3,4,5)P₃-regulated Arf GAPs

Arf GAPs are characterized by a Zn-finger containing Arf GAP domain and adjacent ankyrin repeats. Our knowledge of Arf GAPs has expanded dramatically over the last few years [23]. Many Arf GAPs are regulated by phosphoinositides. The Pap/ASAP/ACAP family is activated by binding to PtdIns(4,5)P₂ whereas the GIT/CAT/PKL and ARAP families bind to and are activated by PtdIns(3,4,5)P₃ (Fig. 1). Both Pap (PAG3)/ASAP/ACAPs and GIT/CAT/PKLs function in cytoskeletal remodeling and associate with paxillin (reviewed in [31]).

The Pap, ASAP, and ACAPs ([31] and references therein; [32,33]) are all robustly activated in their Arf GAP activities by PtdIns(4,5)P₂ (in the context of phosphatidic acid), which they bind to using their PH domains. ASAP and Pap/PAG3 function as Arf 1 and 5 GAPs *in vitro*, but there is some *in vivo* evidence for Pap/PAG3 acting on Arf 6 also. ACAPs function as PtdIns(4,5)P₂-stimulated Arf 6 GAPs *in vitro* and *in vivo*. There is an intriguing link between PDGF and ASAP/ACAP Arf GAPs, which are reported to localize to PDGF-induced dorsal ruffles ([34]; although this has not been demonstrated by video imaging) and inhibit their formation when overexpressed [35,36]. The role of the PH domain has been investigated further in the context of ASAP [34]. It doesn't bind preferentially to PtdIns(3,4,5)P₃ and supports but is not vital for the observed translocation; it is crucial for catalytic Arf GAP activity, leading to a model of ASAP regulation, where Arf GAP and PH domains interact until lipid binding by the PH domain allows freeing of the Arf GAP catalytic site.

GIT family proteins have been identified in various screens as binding partners for paxillin [see 31], the Rho GEF PIX [18,35], and G-protein coupled receptor kinases (GRK; [36]). Several family members exist in addition to multiple spliced variants, which appear to be expressed tissue-specifically [36]. GIT1 and 2 were analyzed in terms of their GAP activities and both were found to use Arfs 1, 5, and 6 as substrates. Their catalytic activity was enhanced moderately by high concentrations (200 μM) of PtdIns(3,4,5)P₃ but not PtdIns5P, PtdIns(4,5)P₂, or diacylglycerol [37]. We do not know how PtdIns(3,4,5)P₃ interacts with GIT proteins, since they lack domains known to mediate interactions with lipids.

The second class of PtdIns(3,4,5)P₃ regulated Arf GAPs are ARAPs. Their unusual domain structure comprising 5 PH domains, as well as Arf- and Rho GAP domains, predicts that these proteins are ideally suited to mediate cross-talk

between small G-protein families. ARAP1 and 2 were identified by homology-based cloning [38] and ARAP3 on the basis of its binding to PtdIns(3,4,5)P₃ [39]. ARAP1 is a PtdIns(3,4,5)P₃-dependent Arf GAP specific for Arf 1 and Arf 5 *in vitro*. *In vivo*, ARAP1 localizes to Golgi structures and regulates cell spreading and the formation of filopodia via the regulation of Arf 1/5 and Cdc42. In contrast, ARAP3 is a promiscuous Rho GAP *in vitro* and is a very specific, PtdIns(3,4,5)P₃-dependent Arf 6-GAP *in vitro* and *in vivo*. *In vivo*, ARAP3 causes dynamic remodeling of the actin cytoskeleton and a striking loss of adhesion in a PI3K dependent manner.

Modulation of Ras Family GTPases by PI3K

The best understood pathway regulated by Ras family G proteins is the Raf-Erk-MAPK cascade. In addition, Ras has a well-established role in the activation of class I PI3K [40], but there are now numerous, cell-type specific examples in which PI3K has a regulatory role upstream of Ras. One hypothesis is that low amounts of PtdIns(3,4,5)P₃ (generated in most attached cells via integrin-engagement) may fulfill a permissive role in the activation of Ras, possibly allowing the recruitment of Shc-Grb2-SOS RasGEF complexes to the plasma membrane in the absence of significant recruitment via the phosphorylated tails of activated growth-factor receptors [41]. Alternatively, PI3K might modulate some RasGAPs (p120RasGAP, GAP1^m) as they clearly possess PH domains capable of binding PtdIns(3,4,5)P₃. Insulin-stimulation of Swiss 3T3 adipocytes causes a PI3K-dependent inhibition of RasGAP, leading to activation of Ras [42]. Similarly, in U937 cells, PI3K inhibitors act to inhibit Ras, which is mediated via an increase in GTP hydrolysis on Ras, indicating negative control of a RasGAP by PI3K [43]. GAP1^m has been shown to be recruited to the plasma membrane in a PH-domain and PI3K-dependent fashion [44]. Curiously, neither PtdIns(3,4,5)P₃ nor its soluble headgroup Ins(1,3,4,5)P₄ could significantly influence GAP1^m RasGAP activity *in vivo* or *in vitro* [44,45], thus raising the question as to whether it may influence an effector function of the RasGAP rather than the GAP activity.

Conclusion

Monomeric GTPases are molecular switches that drive many complex processes involving cellular membranes. They are characteristically lipid modified in their active states and hence retained at the lipid bilayer. Their activities are controlled by the actions of "GTP-loading" GEFs and "GTP-hydrolyzing" GAPs whose activities appear to be regulated by the presence of phosphoinositides in the lipid surface in which they reside. In some cases, it is clear that the phosphoinositides act predominantly to localize and hence concentrate the GEF/GAP with the GTPase (usually via direct binding to an appropriate PH domain); perhaps the clearest example is in PtdIns(3,4,5)P₃-dependent recruitment of

cytohesin family Arf GEFs from the cytosol to the plasma membrane. In other examples of GEF/GAP regulations by phosphoinositides, bulk translocation is probably irrelevant or only part of the regulatory mechanism; in these cases phosphoinositide binding allows some form of allosteric change leading to an increase in catalytic activity. In the best-studied examples, phosphoinositide binding to a PH domain relieves an autoinhibitory constraint on a neighboring catalytic domain, and given the almost universal positioning of PH domains adjacent to GEF and GAP catalytic modules (see Fig. 1), this may prove to be a general principle. Both of these types of mechanisms can be seen as "acutely regulatory" (where the levels of the appropriate phosphoinositides are changed rapidly, e.g. PtdIns(3,4,5)P₃ synthesis via receptor regulated PI3Ks) or more "permissive" (where the levels of the phosphoinositides are more constant, e.g. arguably in examples of PtdIns(4,5)P₂ regulation). Clearly more focused work needs to be done before we have a satisfactory explanation of how phosphoinositides regulate the activity of individual GEFs and GAPs, but it is already clear just how universal this form of regulation appears to be and hence how important phosphoinositides are for coordinating the regulation of this class of molecules.

Historical Perspective

Cytoskeletal proteins were the first proteins shown to be regulated by phosphoinositides (PPIs), beginning with the report by Lassing and Lindberg that PIP₂ dissociated profilin-actin complexes *in vitro* and promoted actin polymerization [1]. This finding suggested that increases in cellular PIP₂ would drive the polymerization of cytoskeletal actin. At that time products of the PI3-kinase pathway had not yet been implicated in cell signaling, and it was thought that PI(4,5)P₂ was the primary lipid responsible for direct effects on profilin, a hypothesis that is largely supported by many subsequent studies of actin-binding proteins. Since that time dozens of actin-binding proteins have been found to be either activated or inhibited by PPIs *in vitro*, usually by PIP₂, and studies in the last few years confirm that at least some of these reactions occur in a similar way in cytoplasm. The fundamental predictions that increased PPI synthesis leads to actin assembly and depletion of PPIs triggers actin depolymerization have been borne out in studies in which PPI levels are altered in cells either by manipulation of expression of lipid kinases [2–5] or phosphatases [3,6–10] or by introduction of constructs such as PH domains [8,11] or PIP₂-binding peptides [12–15] that sequester the lipids and may mimic the effects of endogenous proteins whose cellular role appears to involve sequestration of membrane phosphoinositides [16–18].

In the last several years the number of PPI-binding proteins has increased greatly, and actin-binding proteins are now a minority of the total ligands proposed for these lipids.

Many of the newly reported proteins were identified by their possession of PH, FYVE, PX, or other PPI-binding motifs and the lipid-binding potential measured after this identification. Often these protein modules bind specifically to PPIs generated by PI3-kinases rather than to PI(4)P or PI(4,5)P₂. In contrast, most PPI-binding cytoskeletal proteins were first identified biochemically to interact with PIP₂ and the specific binding sites sought only afterward. It is noteworthy that the structures of PPI binding sites in cytoskeletal proteins are less well characterized than the motifs listed above, and it is perhaps not a coincidence that the PPI-binding domains common to proteins involved in vesicle traffic or spatial localization of signaling are conspicuously missing from most actin-binding proteins.

This review will focus on recent advances that demonstrate how PPIs are involved in stimulation of actin polymerization *in vivo*, or activation of proteins involved in the formation of cytoskeleton and membrane links, and how binding of cytoskeletal proteins to membrane PPIs may relate to the lateral or transverse movement of lipids to affect raft formation or lipid asymmetry.

Stimulating Cellular Actin Polymerization

There is increasing evidence for a localized increase in PIP₂ at sites of actin polymerization and remodeling using the fluorescent chimera GFP-PH-PLC δ 1 as a PIP₂ reporter [19] (see section entitled Relation of Actin Assembly to

Phosphoinositide-containing Lipid Rafts). Localized PIP2 increase may depend on small GTPases in the Rho family (Rac and Rho) and the ADP ribosylation factor family (Arf6, Arf1). These GTPases have profound effects on the actin cytoskeleton, and can either alter the activity of type I phosphatidylinositol 4 phosphate 5 kinases (PIP5K), the enzymes that convert PI4P to PIP2, or recruit them to sites of actin polymerization [5]. For example, Rac and Rho bind PIP5Ks and recruit them to the plasma membrane [20] while Arf6 acts downstream of Rac to activate PIP5Ks [21].

The Mechanisms of Actin Polymerization

Since actin polymerization *in vivo* occurs primarily through the rapid growing end (+) of actin nuclei, the mechanisms by which (+) ends are generated are of intense interest. Three mechanisms have been proposed (reviewed in [22,23]): first, *de novo* actin nucleation by the Arp2/3 complex as a result of activation by the Wiskott-Aldrich syndrome family proteins (WASP, N-WASP etc.) or other proteins; second, severing of preexisting filaments by cofilin/actin depolymerizing protein (cofilin/ADF) or gelsolin family proteins; third, uncapping of the (+) end by capping proteins such as CapZ. Once the (+) ends are liberated, actin monomer delivery is accelerated by profilin and funneling of actin monomers to the favored sites by (+) end capping at other sites. The supply of actin monomer is sustained by severing and facilitated depolymerization from the (-) end by cofilin/ADF.

PIP2 alters *in vitro* the activity of critical proteins in each of these steps. It activates N-WASP, synergistically with Cdc42 [24] or with SH3 adapters such as Nck independently of Cdc42 [25], to promote *de novo* nucleation from the Arp2/3 complexes by an unmasking mechanism depicted in Fig. 1C. In contrast, PIP2 inactivates cofilin/ADF, CapZ, profilin and gelsolin-related severing and capping proteins (reviewed in [18]). The mechanism for PIP2 inhibition of these proteins is not completely understood but may involve the changes depicted in Figs. 1A and B (see section entitled Different Mechanisms of PPI-Actin Binding Protein Regulation).

Several recent studies implicate PIP2 in control of the cytoskeleton *in vivo*. Genetic disruption of *Mss4m*, which encodes the single PIP5K in yeast, or *skittles* (one of two PIP5K) in *Drosophila* produce cytoskeletal defects. Since mammalian cells have multiple PIP5Ks, and knockout animals are not yet available, other approaches have been used to examine the role of PIP5K *in vivo*. These include micro-injection of an anti-PIP2 antibody [26], introduction of a cell-permeant gelsolin PIP2-binding peptide [13,15], addition of PIP2 or a PIP2-binding peptide to semi-intact cells [5], overexpression of actin regulatory proteins with defective PIP2 binding [27], and manipulation of the expression levels of PIP5Ks [9] and the phosphoinositide phosphatases that dephosphorylate PIP2 [10].

PIP5K overexpression induces dramatic actin phenotypes, establishing a causal relation between PIP2 and actin cytoskeletal dynamics. The responses vary depending on the cell

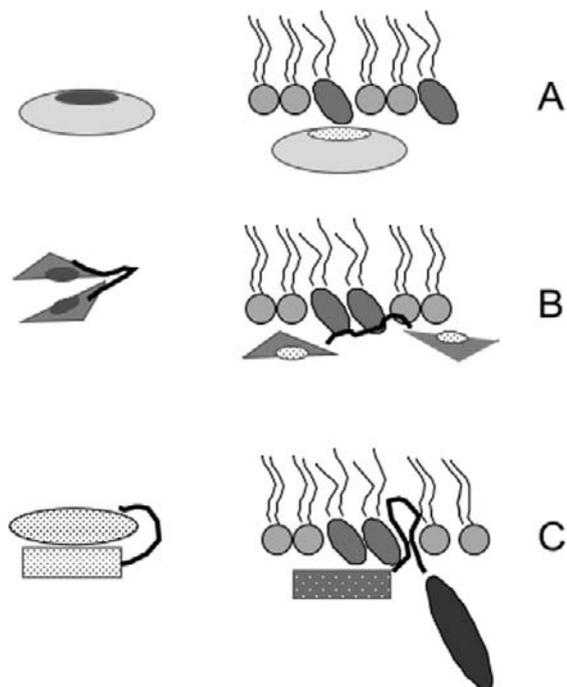

Figure 1 Three models for regulation of protein function by membrane-bound phosphoinositides. Actin-binding sites are shown in blue. Solid patches denote active sites and dotted patches inhibited sites. PIP2 is shown as large-headed lipids within one leaflet of a bilayer composed of neutral lipid. (A) The actin site is occluded by the lipid without other structural change. (B) PIP2 binding reorients two protein domains such that structures required for actin binding can no longer function cooperatively. (C) Protein binds and inserts in membrane to simultaneously stabilize membrane association and expose sites for actin and membrane proteins.

types used and most likely the extent of overexpression. They include N-WASP-dependent actin comet tail formation [9], Rho and Rho-kinase dependent actin stress fiber formation [28], and the arrest of Arf6-regulated plasma membrane-endosome recycling [29]. The multiple phenotypes are not surprising, given that PIP5Ks may be regulated by several small GTPases that induce distinct actin structures in a sometimes sequential and at other times mutually exclusive manner. Furthermore, the site of PIP2 generation as well as the subset of actin regulatory proteins at those sites will dictate the dominant response. The actin-modulating proteins that contribute to these phenotypes have been identified in the first two cases, thus providing mechanistic insight into how PIP2 regulates the actin cytoskeleton *in vivo*.

PIP5K Overexpression Induces Actin Comet Formation

Actin comets formed around pathogens, such as *Listeria*, *Shigella*, and vaccinia, have contributed significantly to our understanding of the mechanism of cellular actin polymerization because they either introduce their own membrane protein or hijack the host's N-WASP to initiate actin assembly by the same mechanism used at the cell membrane. Since N-WASP also stimulates actin comet formation around

intracellular vesicles and lipid vesicles in cell extracts [30] and in *Xenopus* eggs [31], the possibility that PIP2 promotes vesicle trafficking by generating actin comets is particularly attractive. Indeed, tiny comets that form spontaneously have been sighted, and much more robust comets are found in cells that overexpress PIP5K [9]. Overexpressed PIP5K is enriched at the head of the comets, establishing that the *in situ* generation of PIP2 at the vesicle may recruit and activate N-WASP to promote *de novo* actin nucleation by Arp2/3. Dynamin, another PIP2-activated protein that is involved in vesicle trafficking, is also recruited to the head of the PIP5K-induced comets, and overexpression of dominant negative dynamin mutants inhibits comet formation [4,32].

Actin comets are formed from endocytic and Golgi-derived exocytic vesicles, particularly those with cholesterol and sphingolipid-enriched membrane microdomains (rafts), and raft disruption reduces the number of comets dramatically [9]. Rafts have previously been shown to contain an agonist-sensitive pool of phosphoinositides that responds to PLC signaling, and they are the primary sites of PIP2 synthesis [17]. The preferential formation of actin comets in raft domains establishes that rafts are platforms for the integration of PIP2 signaling and actin polymerization, reinforcing the concept that specialized regions of the membrane are closely related to specific cytoskeletal structures discussed in the section on mechanisms of PPI-actin binding protein regulation.

PIP5K Overexpression Induces Actin Stress Fiber Formation

PIP5K overexpression in CV1 cells induces robust actin stress fiber formation and inhibition of membrane ruffling in response to growth factors due to an inability to generate (+) end actin nuclei [28]. These two effects are consistent with activation of Rho and inhibition of Rac-dependent cytoskeletal pathways, respectively, and are remarkably similar to that observed in fibroblasts isolated from gelsolin knockout animals [34]. Gelsolin binding to actin is inhibited in PIP5K-overexpressing cells, suggesting that inhibition of severing by gelsolin and perhaps by cofilin/ADF may account for the formation of long actin filaments and the inability to generate (+) end nuclei to mount an actin polymerization response. Furthermore, profilin and CapZ are also inhibited, while ezrin/radixin/moesin, the membrane-linker proteins (see below), are activated. Together, these changes can amplify the consequences of severing inhibition. In conclusion, these studies show that several PIP2-sensitive actin modulating proteins behave *in vivo* as predicted from their well-characterized behavior *in vitro*.

Relation Among PIP5K, Arf6, and Actin Remodeling

Arf6 overexpression induces actin comets [35] and stimulates membrane ruffling [29]. However, although one study finds comet formation is not inhibited by an antibody to PIP2 [35], other studies show that Arf6 activates PIP5K

in vitro and *in vivo* [21,29]. Overexpression of a constitutively active Arf6 or PIP5K induces PIP2 generation and actin polymerization around recycling endosomes, eventually trapping them into an aggregate that cannot recycle back to the plasma membrane [29]. The phenotype suggests that cycling of Arf6 between the GTP- and GDP-bound forms is important for actin regulation, and this is likely to be achieved through activation and inactivation of PIP5K. Sustained high-level PIP2 production due to constitutive Arf6 overexpression or PIP5K overexpression promotes polymerization and inhibits depolymerization to generate abnormal actin structures around the vesicles. The abnormally large actin comets found in other cellular contexts [9] are another manifestation of sustained actin polymerization. The requirement for transient changes in PIP2 levels highlights the importance of dissipating PIP2 in a spatially and temporally defined manner. Although PIP2 is hydrolyzed by PLC during agonist signaling, PIP2 is likely to be cleared primarily by phosphoinositide phosphatases.

Effects of Manipulating the Level of Phosphoinositide Phosphatases

Phosphatases that dephosphorylate phosphoinositides or inositol polyphosphates at the 5' position are classified into four groups, according to their substrate specificity [10]. The type II phosphatases that hydrolyze PIP2 have been used to study the effect on the actin cytoskeleton. Overexpression of synaptojanin or other type II phosphatases decreases actin stress fibers [6,36] or induces actin arborization [37]. However, it is not known whether the effects are due specifically to a decrease in PIP2 or water-soluble inositol phosphates.

The most definitive evidence is obtained by disruption of the synaptojanin 1 gene [38], which results in an accumulation of clathrin-coated vesicles and polymerized actin in the endocytic zones of nerve terminals. These changes are correlated with an increase in PIP2 concentration. Synaptojanin and PIP5K are both concentrated at synapses, and they antagonize each other in the recruitment of clathrin coats to lipid membranes *in vitro* [3]. These results strongly suggest that the PIP2 level at the synapse is critically dependent on the balance of phosphoinositide kinase and phosphatases, and that PIP2 has a pivotal role in the regulation of actin and endocytic vesicle formation at the synapse [39].

Actin-Membrane Linkers Localized or Activated by PIP2

In contrast to actin monomer-binding or severing proteins that are generally inactivated by PPIs, proteins that crosslink actin filaments to each other or link them to the cell membrane are usually activated to bind actin or directed to link actin to transmembrane receptors by the lipids [40]. Evidence from mutational analyses suggests how this activating switch occurs, and interfering with PPI binding disrupts this linking process in cells.

Alpha Actinin

Recent studies of alpha actinin provide a good example of how activation of actin or other ligand binding may occur. In this case, an actin- and titin-binding motif of the antiparallel alpha actinin dimer is occluded in the inactive state because it binds a complementary domain within the same homodimer [41]. When PIP₂ binds to alpha actinin, self-association is disrupted, exposing the actin- and titin-binding motifs so that they can bind their targets (see Fig. 1C). Similar activation switches have been proposed for band 4.1/ezrin/radixin/moesin (FERM) protein family members and for the focal adhesion proteins talin and vinculin.

Ezrin/Radixin/Moesin

ERM proteins are among the best currently characterized PPI-activated proteins. Both actin and membrane protein binding sites are inactive in the dormant state of the protein because of self-association between the two domains responsible for these separate activities, and the structural basis for this self-inactivation is now clear from protein structures determined by crystallography for radixin [42] and moesin [43,44]. This self-inactivation is a common feature of several actin-membrane linkers, including talin and vinculin, and in retrospect explains why the *in vitro* actin binding of these proteins was so difficult to characterize compared to proteins such as cofilin or filamin, where the actin-binding sites appear to be constitutively exposed. Biochemical and cell localization studies show that ERM proteins colocalize with transmembrane proteins in activated cells and that *in vitro* this association is stimulated by PPIs. The PIP₂-dependent linkage of ezrin to ICAMs [45,46] involves reordering of the FERM domain, which contains an acidic loop distinct from the IP₃-binding site that may also participate in binding to the basic juxta-membrane regions present in adhesion receptors such as CD44 [42]. The importance of the PIP₂-binding regions for cellular localization and function of ERM proteins has been increasingly well demonstrated in recent studies. Mutation of four basic residues found in the PIP₂-binding site prevented localization of ezrin to actin-rich membrane structures [47].

Talin

Like ezrin, talin is also activated by PIP₂ to increase membrane association. In this case one consequence of PIP₂ binding is an increased affinity of the intact protein for the cytoplasmic domain of beta 1 integrins [48]. The relevance of this interaction in a cellular context is reinforced by evidence that PIP₂ cosediments after immunoprecipitation with anti-talin antibodies, and the amount of PIP₂ shows a strong transient increase after suspended cells are plated on fibronectin, reaching a maximum 15 minutes after engagement of integrins that is five times higher than the initial state or the levels 1 hour after plating. The finding that only PIP₂, but not PIP or PI, shows this transient change rules out the possibility that the lipid in the immunoprecipitates results from nonspecific contaminating membranes but also raises

the question of the state of the lipid in these lipid-protein complexes.

Relation of Actin Assembly to Phosphoinositide-containing Lipid Rafts

The finding that the specialized regions of the plasma membranes such as caveoli or lipid rafts are potentially enriched in PPI [49] and that several cytoskeletal proteins do not bind PIP₂ unless it is present in bilayers at approximately 10 mol percent [50] suggests that clustering of inositol lipids in specialized regions of lipid monolayers is an important aspect of their ability to modify specific cellular processes. Experiments with liposomes show that in the presence of multivalent cations PIP₂ organizes into domains [51] and domains in PIP₂-containing monolayers bind and are reorganized by peptides based on the PIP₂-binding site of gelsolin [52]. Evidence that areas of local PIP₂ concentration form in cells and are associated with actin assembly has emerged from several recent studies. In fibroblasts, the PH domains of PLC δ 1 fused with GFP localized to actin-rich membrane ruffles and the selective concentration of the PLC δ 1-PH-GFP in highly dynamic regions of the plasma membrane, which are rich in F-actin, supports the hypothesis that local synthesis and lateral segregation of PI(4,5)P₂ spatially restrict actin polymerization [53]. In macrophages, the PLC δ 1-PH-GFP protein localizes transiently to the phagosomal cups along with PLC γ 2, PI(4)P 5-kinase and actin [54,55]. The dissociation of a PLC δ 1-PH-CFP fusion protein was accompanied by recruitment of a C1-PKC δ -C1-YFP fusion protein, which suggests that PLC γ 2 mediates the conversion of PI(4,5)P₂ to diacylglycerol upon sealing of the phagosomal cup.

An immunocytochemical study with PI(4,5)P₂ antibodies in PC12 cells, COS-7 cells, and hippocampal neurons has visualized clusters of PIP₂ that co-localize with plasmalemma-associated PKC substrates that affect actin cytoskeleton: GAP43, myristoylated alanine-rich C kinase substrate (MARCKS), and CAP23 (GMC proteins) [17]. These clusters are interpreted to be raft domains, which were dispersed by membrane cholesterol extraction by using cyclodextrin. Cells that overexpress MARCKS exhibited larger macroscopic PIP₂ clusters, whereas expression of MARCKS lacking basic effector domain exhibited reduced PIP₂ clusters. These results suggest that GMC proteins regulate the availability of PIP₂ for interaction with actin-binding proteins. A focal pattern of labeling suggesting colocalization of actin with PIP₂ at the membrane has also been recently observed in NIH3T3 fibroblast plasma membranes treated with a fluorescent gelsolin-derived, cell permeant phosphoinositide-binding peptide [13].

Different Mechanisms of PPI-Actin Binding Protein Regulation

There are at least three distinct mechanisms and several variations by which membranes containing PPIs can alter

actin-binding protein function. The simplest mechanism shown in Fig. 1A is that an actin-binding site coincides with a PIP2-binding site and therefore targeting of the protein to PPI-rich membranes dissociates actin competitively without necessarily changing the protein structure. However, even for small monomer-sequestering proteins such as cofilin/ADF/actophorin, careful mapping of the actin- and PIP2-binding sites shows that they are not precisely coincident, and that specific residues can be altered to perturb one but not the other activity [27,56]. The recent finding that PIP2 promotes oligomerization of cofilin and subsequent actin filament bundling [57] further complicates the model of simple competition. Profilin likewise appears to have an extensive surface that interacts with PIP2, and binding to the lipid promotes increased alpha-helix in the protein [58].

A different model for inhibition of actin-binding function shown in Fig. 1B is that the binding to PIP2 causes a rearrangement of actin-binding domains or a local unfolding of polypeptide within these domains to derange the surface required to bind actin. This model appears to account for effects on gelsolin and related proteins [50]. This type of allosteric regulation may occur either with or without the protein inserting into the hydrophobic domain of the membrane.

The third mode of binding (Fig. 1C) involves docking of the protein to the membrane in a manner that disrupts interactions between domains within monomers or homo-oligomers that mask binding sites for actin or membrane anchors. This model, which may apply to ERM proteins, talin, alpha actinin, N-WASP, and vinculin, would result in activation rather than inhibition of the protein function. In the model drawn, both sites are activated after PIP2 binding, but it is also plausible that one of the sites remains occupied by the lipid and is then available only after PIP2 hydrolysis or reorganization of the membrane. Such a mechanism would explain how PIP2 binding can work to activate vinculin *in vivo* whereas purified PIP2 may inhibit vinculin-actin binding *in vitro* [59] and would allow for sequential activation of two sites as PIP2 is turned over at the cell membrane.

Effects on Lipid Membrane Structure

Binding of protein to membranes containing PPIs can have a number of effects on the membrane depending on the charge of the protein docking site, the degree of penetration into the hydrophobic domain, and the number of lipids to which the protein binds. In contrast to the extensive documentation of changes in protein function or structure, changes in lipid structure are less often studied but are likely to be equally important in a cellular context. Although it is often assumed that protein docking to PPIs in a membrane mainly localizes the protein to the surface, there are many specific changes that can occur, such as the recently documented extended conformation [60], especially for a lipid such as PIP2, which is relatively unstable in a bilayer. One interesting possibility is that some forms of binding to PIP2 can destabilize bilayer packing to the extent that loss of membrane

asymmetry occurs. Recent observations indicate that PIP2 is a positive regulator of Ca²⁺-induced lipid scrambling due to PIP2-enriched domain formation [61]. The possibility to reorganize membranes by specific interaction with PIP2 has been documented by electron spin resonance measurements that show disordering of lipid bilayer vesicles by myristoylated ARF6 only when the vesicles contain PIP2 [62]. Phospholipid scrambling was also observed in platelets and lipid vesicles containing PIP2 treated with a gelsolin-derived peptide [12]. These observations suggest that the binding of cytoskeletal proteins to membrane phosphoinositides has a vast potential for regulation and reorganization of cells that is now beginning to be appreciated.

Introduction

Chemotaxis, or directional movement of eukaryotic cells toward a small molecular attractant, is highly conserved evolutionarily and is regulated by a variety of ligands (including chemoattractants, chemokines, and growth factors) that activate G-protein-coupled and receptor tyrosine kinase effector pathways. Concentration differences of only a few percent over the length of a cell are sufficient to be recognized and converted into directional motility. Chemotaxis of *Dictyostelium* cells toward the extracellular chemoattractant cyclic AMP (cAMP) provides a model for the mechanisms underlying chemotaxis in a number of mammalian cell types, including neutrophils and macrophages. The ability to employ genetic, biochemical, and single-cell assays makes *Dictyostelium* an exceptional system for finding new genes involved in chemotaxis and understanding the interplay of known and novel gene products in the signal transduction processes underlying chemotactic responses. Furthermore, the simplicity of *Dictyostelium* chemotaxis combined with a

vast body of experimental knowledge makes this organism an ideal system for testing predictions made by theoretical models of the chemotactic response.

Here, we discuss the signaling events that control the ability of a cell to sense the direction of a chemoattractant gradient. The phosphatidylinositol-3 kinase (PI3K) pathway plays a pivotal role in the conversion of such a shallow external gradient into the extreme cytoskeletal polarization necessary for directed cell movement of neutrophils, macrophages, and *Dictyostelium* cells.

Directional Movement

When cells are placed in a chemoattractant gradient, there is a rapid polymerization of actin on the side of the cell closest to the chemoattractant source resulting in the formation of a new leading edge [1–6]. Polymerization of F-actin leads to protrusion of the plasma membrane [7]. Assembly of conventional, nonmuscle myosin II and F-actin at the

posterior of the cell enables actin-myosin contractility, which lifts off the posterior (also called a uropod) and promotes a rapid contraction of the posterior of the cell [3,6].

Localization of Cytoskeletal and Signaling Components

Even in the absence of an external gradient, many chemotaxis-competent cells exhibit a polarized distribution of cytoskeletal components, with the majority of F-actin found at the leading edge and myosin II and the remaining F-actin found at the cell's posterior. Only when cells are placed in a gradient is there a dynamic activation of localized F-actin polymerization and myosin assembly resulting in directional cell movement. When the chemoattractant gradient changes direction, the cells respond by dismantling the old actin/myosin cytoskeleton and forming a new leading edge and uropod, thereby realigning their axis with the external gradient [1,3,4,6]. In *Dictyostelium*, neutrophils, and macrophages, members of the Rac/Cdc42 and RhoA family of small GTPases regulate WASP proteins (e.g. WASP, Scar/WAVE), members of the PAK family of serine/threonine protein kinases, and myosin kinases are required for chemoattractant-mediated actin polymerization, myosin assembly, and directional movement (Fig. 2). For a more detailed discussion of this topic see Nobes *et al.*, 1999 [8]. In contrast to cytoskeletal elements, upstream signal transduction components exhibit a uniform distribution in the absence of an external signal. In response to stimulation, some of these components undergo a dramatic redistribution and polarization, reflecting an underlying signal processing that can recognize and amplify a shallow external gradient enabling the chemotactic response. Recent experimental progress has identified some of these proteins and has shed light on some of the mechanistic aspects regulating their change in subcellular localization.

Analysis of the subcellular localization of known cell surface sensors such as G-protein-coupled chemoattractant receptors has demonstrated that these receptors in *Dictyostelium* and neutrophils are uniformly localized along the plasma membrane [1,4–6], even in the presence of an external signal. Although the concentration of G $\beta\gamma$ subunits is highest at the anterior of the cell, the gradient is extremely shallow, comparable to the gradient of the external signal, and cannot account for the steep intracellular gradient of other signaling components [9].

The Signaling Pathways Controlling Directional Movement

Activation of PI3K at the leading edge appears to play a predominant role in controlling directional movement in many amoeboid cell types such as neutrophils, macrophages, and *Dictyostelium* cells [1,4–6]. Class I members of the PI3K family phosphorylate PI(4,5)P₂ and PI(4)P at the

3' position in the inositol ring to produce the membrane lipids PI(3,4,5)P₃ and PI(3,4)P₂ (Fig. 1). PI(3,4)P₂ is also derived through the dephosphorylation of PI(3,4,5)P₃ by the 5' inositol lipid phosphatase SHIP [10].

Studies in which PI3K function is abrogated through gene knockouts, use of PI3K-specific inhibitors, or PI3K isoform-specific antibodies demonstrate that PI3K is required for proper chemotaxis in neutrophils, macrophages, and *Dictyostelium* cells (see [1] for references). *Dictyostelium pi3k1/2* null cells, in which two of the three genes encoding the Class I PI3Ks PI3K1 and PI3K2 have been disrupted by homologous recombination, exhibit strong chemotaxis defects [11–15]. *Dictyostelium* wild-type cells chemotaxing toward cAMP are highly polarized, preferentially form a single pseudopod at the leading edge, and produce few if any lateral pseudopodia. In contrast, *pi3k1/2* null cells or wild-type cells treated with the PI3K inhibitor LY294002 exhibit a significant loss of polarity, move more slowly than wild-type cells, and produce multiple pseudopodia simultaneously along the periphery of the cell, although the cells still move predominantly toward the chemoattractant source [14]. These results indicate that PI3K is an important component of chemotaxis regulating directionality and polarity; however, these findings also imply that there are pathways parallel to those regulated by PI3K1 and PI3K2 contributing to directional movement. The nature of this pathway is currently unknown.

These observations make the PI3K pathway a likely candidate to be involved in polarization amplification. This notion is further supported by the subcellular localization of PI3K pathway components. Initial evidence for the localized activation of PI3K has derived from the demonstration, first in *Dictyostelium* and then in neutrophils and fibroblasts, of the preferential localization of a subfamily of PH-domain-containing proteins that preferentially bind the PI3K products PI(3,4,5)P₃ and PI(3,4)P₂ [14,16–19]. GFP fusions of these proteins function as reporters for local accumulation of PI(3,4,5)P₃/PI(3,4)P₂ corresponding to localized activation of Class I PI3Ks. These proteins are cytosolic in unstimulated cells and rapidly and transiently move to the plasma membrane in response to cells being globally stimulated by a chemoattractant (cells being rapidly bathed in chemoattractant) so that all of the receptors around the cell are uniformly activated. When cells are placed in a chemoattractant gradient, these proteins preferentially localize to the leading edge, suggesting that PI3K is preferentially localized in this region of the cell (Fig. 3). The localization of these PH-domain-containing proteins, which in *Dictyostelium* peaks at ~6–8 seconds after global stimulation with a chemoattractant, is one of the most rapid responses that has been described [14,16,17]. In *Dictyostelium*, three PH-domain-containing proteins exhibit identical patterns of spatial localization in chemotaxing cells and in response to global stimulation by a chemoattractant. These include CRAC, a PH-domain-containing protein required for chemoattractant-mediated activation of adenylyl cyclase; the serine/threonine protein kinase Akt/PKB, which is a PI3K effector important in

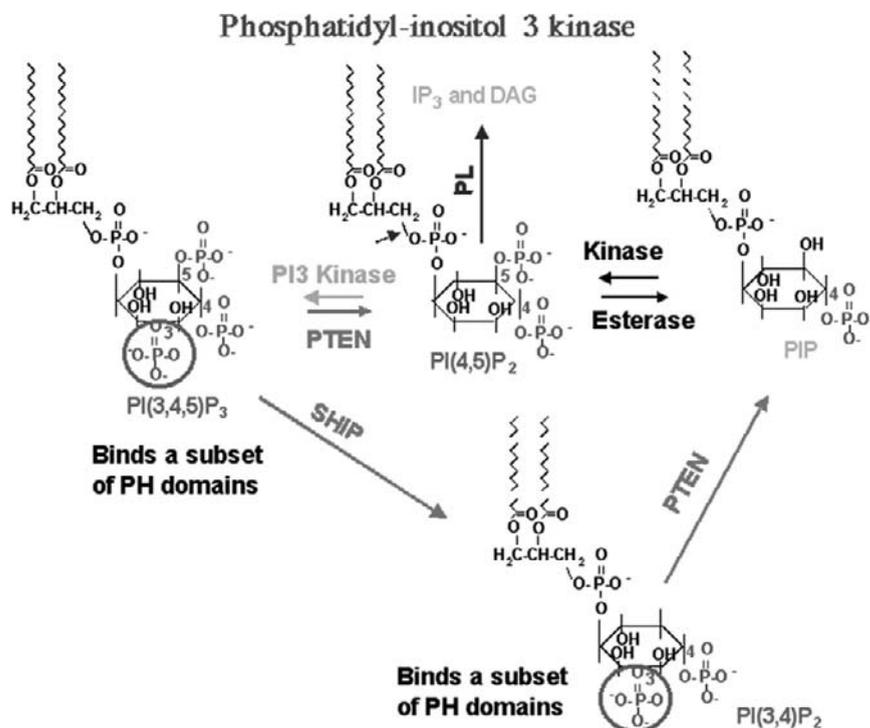

Figure 1 The phosphatidylinositol kinase/PTEN biochemical pathway. The figure illustrates the biochemical pathway for the production and degradation of PI(3,4,5)P₃ and PI(3,4)P₂, PI3K products that preferentially bind a subclass of PH-domain-containing proteins involved in chemotaxis. PI3K phosphorylates on the 3' position of inositol, PI(4,5)P₂, also a substrate of phospholipase C (PLC), or PI(4)P. PI(3,4,5)P₂ can be degraded by the 5' inositol phosphatase SHIP to produce PI(3,4)P₂. The tumor suppressor PTEN dephosphorylates PI(3,4,5)P₃ and PI(3,4)P₂ on the 3' position of the inositol ring, thereby removing the binding sites for the PH domains on the plasma membrane.

regulating cell growth and cell survival; and PhdA, which is involved in the spatial-temporal control of F-actin polymerization at the leading edge. In neutrophils, the PH domain of Akt/PKB exhibits changes in its spatial distribution in response to chemoattractant stimulation similar to those of its counterpart in *Dictyostelium* cells [18].

Genetic and biochemical studies have demonstrated that these localizations occur in response to activation of PI3K. First, the localization is inhibited by the PI3K-specific inhibitor LY294002. Second, in *Dictyostelium* cells carrying disruptions of the genes encoding two of the Class I PI3Ks (PI3K1 and PI3K2), chemoattractant-mediated membrane localization is not observed. Finally, point mutations in the PH domain that abrogate the ability of the PH domain to bind PI3K lipid products prevent the PH domains from localizing to the leading edge in response to global chemoattractant stimulation (see [1] for references). These findings indicate that PH domain localization and thus PI3K activation respond to one of the primary downstream responses to chemoattractant stimulation. These findings have been reproduced in mammalian leukocytes [18].

The activation of this response at the leading edge is reflected by a very steep intracellular gradient of the PH domain localization at the plasma membrane from the front to the back of the cell. Since this occurs in a very shallow

chemoattractant gradient (as low as a 2–5% difference between the front and back of the cell), there must be a mechanism by which an external, shallow gradient gives rise to a very steep intracellular gradient of the second messengers PI(3,4,5)P₃ and PI(3,4)P₂. Recent studies have demonstrated that PI3K in *Dictyostelium* preferentially localizes to the leading edge (Fig. 3). GFP fusions of PI3K1 or PI3K2 localize to the leading edge when cells are placed in a chemoattractant gradient and are transiently localized to the plasma membrane in response to global stimulation [20]. This provides for the localized activation of PI3K at the leading edge and thus the localized production of PI(3,4,5)P₃/PI(3,4)P₂. What localizes PI3K to the leading edge is presently unknown. However, as already mentioned, PI3K's localization is not due to a corresponding localization of either the chemoattractant receptor or the coupled heterotrimeric G protein.

PI3K Effectors and their Roles in Controlling Chemotaxis

pi3k1/2 null cells exhibit strong chemoattractant defects. *Dictyostelium pi3k1/2* null cells chemotaxing toward cAMP exhibit a significant loss of polarity and move more slowly than wild-type cells. Whereas wild-type cells preferentially

form a single pseudopod at the leading edge and produce few if any lateral pseudopodia, *pi3k1/2* null cells produce multiple pseudopodia simultaneously along the periphery of the cell, although the cells still move predominantly toward the chemoattractant source. Results from neutrophils and macrophages in which the function of PI3K γ and PI3K δ , respectively, are abrogated are consistent with the observations in *Dictyostelium* (see [1] for references).

Biochemical analysis of *Dictyostelium pi3k1/2* null cells has provided insight into the downstream effector pathways. *pi3k1/2* null cells exhibit a reduced chemoattractant-mediated F-actin assembly and a more severe defect in the spatial-temporal regulation of F-actin assembly. When cells are chemotaxing toward a micropipette emitting a chemoattractant and the location of the micropipette is changed, resulting in a change in direction, the kinetics of the directional change in *pi3k1/2* null cells are delayed compared to those of wild-type cells. *Dictyostelium* cells carrying a disruption of the gene encoding PhdA, a PH domain-containing protein with PI3K-dependent localization to the leading edge, exhibit actin phenotypes similar to those observed for *pi3k1/2* null cells, suggesting that this function of PI3K is mediated, at least in part, through PhdA [14].

Akt/PKB is activated in response to chemoattractants in both *Dictyostelium* and neutrophils and probably in other cell types as well, and this activation is lost in *Dictyostelium* and mammalian *pi3k* null cells (see [1] for references), indicating these pathways are probably conserved between *Dictyostelium* and mammalian cells. Ligand-regulated Akt/PKB activity is required for proper chemotaxis in *Dictyostelium* and has been linked to the migration of mammalian endothelial cells [17,21].

In *Dictyostelium*, a gene knockout of Akt/PKB exhibits a subset of the *pi3k* null defects, including a reduction in cell movement, directionality, and chemoattractant-mediated myosin II assembly, providing a link between the activation of PI3K at the front of the cell and the regulation of myosin assembly at the cell's posterior [17,22] (Fig. 2). Myosin assembly and disassembly in *Dictyostelium* is regulated by phosphorylation of myosin heavy chain kinase (MHCK). Phosphorylation of myosin II by MHCK leads to myosin II disassembly, whereas phosphatase treatment leads to assembly [23]. Genetic and biochemical evidence demonstrates that PAKa, a p21-activated serine/threonine kinase related to mammalian PAK1 and yeast Cla4 and Ste20, is essential for myosin II assembly during cytokinesis and chemotaxis; *paka* null cells exhibit phenotypes similar to those of cells lacking myosin II. Moreover, PAKa colocalizes with myosin at the posterior of chemotaxing cells and at the contractile ring during cytokinesis. Studies have demonstrated that PAKa is a direct substrate, both *in vivo* and *in vitro*, of Akt/PKB. Phosphorylation of PAKa by Akt/PKB leads to its activation [22]. PAKa then is thought to function by inhibiting MHCK, leading to myosin II assembly. It is interesting that one of the MHCKs, MHCK-A, preferentially localizes to the leading edge in chemotaxing cells, where it is presumably activated, causing disassembly of myosin and more efficient pseudopod extension [24].

The Tumor Suppressor PTEN Regulates the Chemoattractant PI3K Pathways

PTEN, the tumor suppressor that acts as a negative regulator of the PI3K cell growth and cell survival pathway by dephosphorylating PI(3,4,5)P₃ and PI(3,4)P₂ on the 3' position [25], also functions as a negative regulator of chemotaxis. *Dictyostelium* cells overexpressing PTEN exhibit a reduced activation of Akt/PKB and chemotaxis defects consistent with a reduced level of PI3K pathway activity [20]. Hypomorphs, cells expressing a lower level of PTEN, exhibit higher levels of Akt/PKB activation. The strongest link between PTEN and chemotaxis derives from the analysis of *Dictyostelium* PTEN null cells [26]. These cells exhibit prolonged localization of PH-domain-containing proteins in response to chemoattractant stimulation. Moreover, when chemotaxing cells are examined, PH domain protein localization extends around the side of the cell, including some localization to the cell's posterior. These phenotypes are very similar to those obtained by expressing myr-tagged PI3K. These results demonstrate that PTEN restricts the domain of PI(3,4,5)P₃/PI(3,4)P₂ localization and regulates the function of the PI3K pathway. Further linkage of the PI3K pathway to chemotaxis was demonstrated by the finding that PTEN null cells exhibit an elevated and prolonged level of chemoattractant-mediated F-actin assembly, indicating a linkage between PI3K and F-actin assembly. This observation suggests that PI3K activation at the leading edge may be one of the mechanisms that drives the expected activation of Rho exchange factors and F-actin polymerization at these sites. The results are consistent with the phenotypes of *pi3k* null cells and those of PhdA, a PI3K effector.

The subcellular localization of PTEN is also consistent with a role as a negative regulator of the PI3K pathway during chemotaxis: PTEN is uniformly localized around the plasma membrane of unstimulated cells and rapidly delocalizes from the plasma membrane in response to chemoattractant stimulation [20] (Fig. 3). In polarized, chemotaxing cells, PTEN is preferentially excluded from the leading edge, while it remains along the sides of the cell. This finding suggests that PTEN localization, like that of PI3K, is dynamic and is complementary to that of PI3K. Presumably, PTEN exclusion from the leading edge allows an amplification of the PI3K activity at this site of the cell, whereas its localization on the plasma membrane on the sides of the cell helps restrict PI3K activity and sharpen the boundary of PIP₃/PIP₂ localization.

Conclusions

Results in *Dictyostelium* provide a model of the mechanism controlling directional movement (Fig. 2). The localization of PI3K to the leading edge results in the production of the second messengers PI(3,4,5)P₃ and PI(3,4)P₂, causing a localization of PH-domain-containing proteins and regulation of downstream effector pathways. The delocalization of

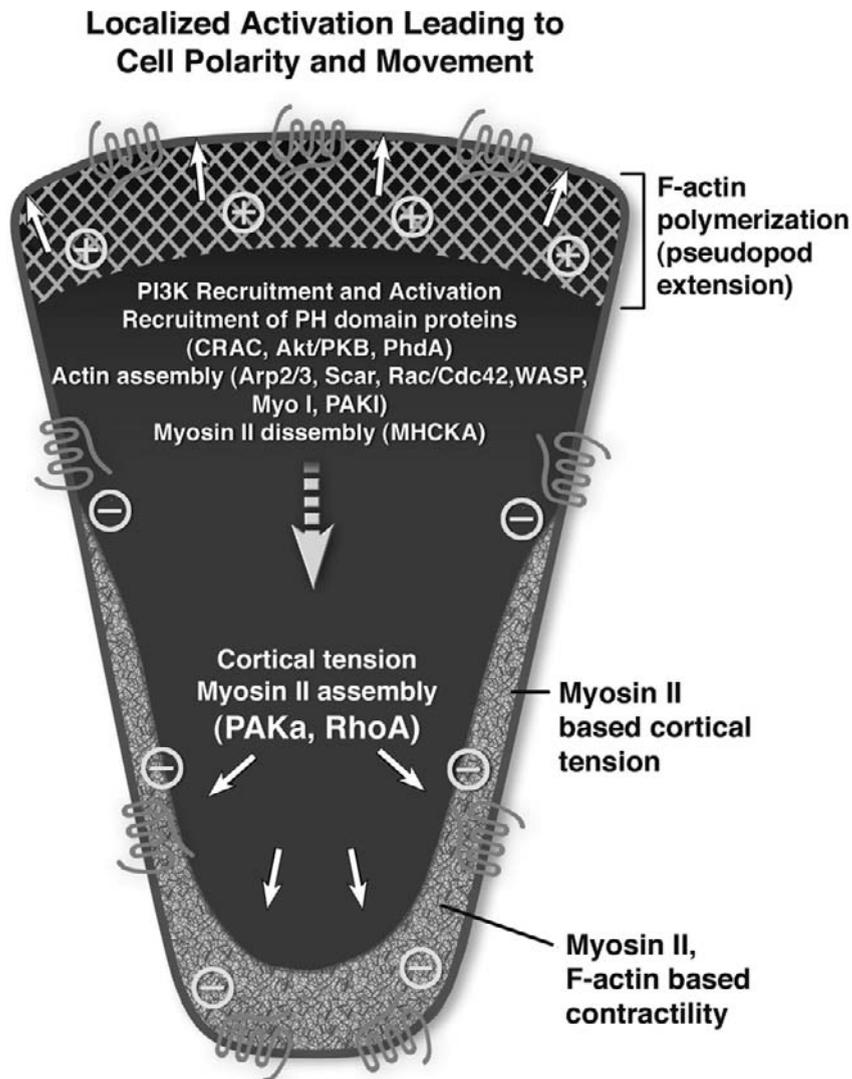

Figure 2 Spatial regulation of signaling components and the actin/myosin cytoskeleton. The image shows a polarized, chemotaxing amoeboid cell. Preferential activation in a series of signaling pathways at the leading edge results in F-actin polymerization and extension of the pseudopod. The pathways activated include phosphatidylinositol-3 kinase (PI3K), leading to the recruitment and activation of PH-domain-containing proteins. Other components that are localized to the leading edge include those regulating actin assembly (the Arp2/3 complex, the Wiskott-Aldrich Syndrome protein WASP and its relative Scar/WAVE, and the small GTPases Rac and Cdc42), and myosin I, which may regulate the translocation of the WASP/Arp2/3 complex along the F-actin filaments. Mammalian PAK1 is also vital in regulating pseudopod extension. Myosin assembly and contractility at the posterior of the cell is required for uropod contraction. In *Dictyostelium*, these processes are mediated by myosin heavy chain kinase A (MHCKA), which localized to the front of the cell, and PAKa found at the posterior of the cell. In mammalian cells, it is regulated by the small GTPase RhoA and downstream pathways. See text for additional details.

PTEN from the leading edge while PTEN remains along the sides of the cell helps localize and restrict the PI3K pathway. Downstream effector pathways include F-actin polymerization at the leading edge and myosin assembly at the cell's posterior. Other studies have implicated this pathway in controlling cell polarization, which is necessary for effective chemotaxis. Parts of this pathway have also been described in neutrophils and macrophages, including the essential

role of PI3K in directional sensing and the localization of PH-domain-containing proteins at the leading edge. Because of the increased recognition of the importance of chemotaxis in a variety of cellular processes, including cell polarization, metastasis, and embryonic cell movement, understanding these mechanisms is paramount to providing mechanistic insights into basic biological processes and many aspects of human disease.

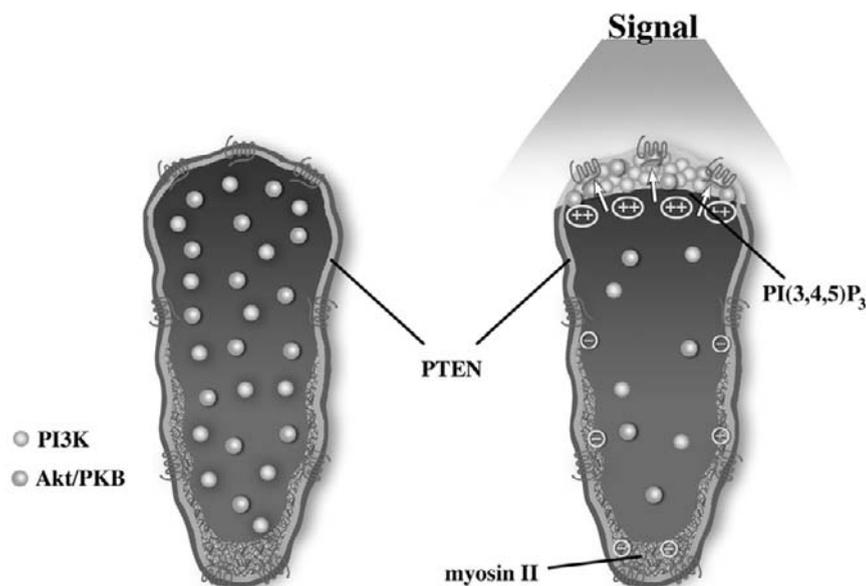

Figure 3 Differential localization of PI3K and PTEN in a chemotaxing cell. The figure on the right shows that in a resting cell, PI3K and PH-domain-containing proteins Akt/PKB, CRAC, and PhdA are uniformly distributed in the cytosol, whereas the tumor suppressor PTEN is localized uniformly at the edge of the cell. When cells are placed in a chemoattractant gradient, as illustrated in the panel on the right, PI3K preferentially localizes to the leading edge, causing the production of PI(3,4,5)P₃ and the localization of the PH-domain-containing proteins. PTEN is preferentially lost from the leading edge. This loss is thought to help sharpen the gradient by preferentially limiting the site of PI(3,4,5)P₃ membrane localization.

Phosphatidylinositol Transfer Proteins

Shamshad Cockcroft

*Department of Physiology,
University College London,
London, United Kingdom*

Introduction

The phosphatidylinositol transfer protein (PITP) family is defined by its ability to bind one molecule of either phosphatidylinositol (PtdIns) or phosphatidylcholine (PtdCho) and facilitate lipid transfer between separate membrane compartments [1]. PITPs have now emerged as critical regulators of phosphoinositide metabolism in specific cellular compartments where they participate in signal transduction and membrane traffic [2]. PITP was originally purified as a soluble 35 kDa protein, which is now known to contain a single structural domain [3]. The PITP domain has now been found in the larger RdgB proteins, originally identified in *Drosophila* as retinal degeneration (Class B) mutants. Today, the mammalian PITP family includes five proteins divided into three subgroups, all containing a PITP domain: the classical PITPs, α and β (35 kDa), two larger related proteins M-rdgB α 1 and M-rdgB α 2 (160 kDa), and the soluble M-rdgB β protein (38 kDa) [4]. In addition to mammals, proteins with a PITP domain are found in *Caenorhabditis elegans* (worms), *Drosophila melanogaster* (flies) and *Dictyostelium discoideum* (soil amoebae), but not yeast or plants. The larger rdgB proteins are not found in *Dictyostelium*, however. The yeast Sec14p and its related family members form a separate group of PtdIns transfer proteins that, although they share lipid binding properties and transfer function with mammalian PITPs, have no sequence or structural similarity [3,5].

The Classical PITPs: α and β

PITP α and PITP β are expressed ubiquitously in all tissues, are abundant proteins, and share 77% identity and 94% similarity in amino acid sequence. In addition to PtdIns and PtdCho transfer, PITP β can also transfer sphingomyelin [6]. Transfer occurs down a concentration gradient without input of energy *in vitro*. Thus PITPs solubilize specific lipids from membranes and can facilitate their movement through the aqueous phase (Fig. 1). Although PITPs are defined by their ability to bind either one molecule of PtdIns or PtdCho, the affinity of PITP α for PtdIns is 16-fold greater compared to PtdCho. This reflects the lower levels of PtdIns compared to PtdCho in cells, and typically 30 to 40% of the PITP α and β proteins are PC-bound compared to 60 to 70% that are loaded with PtdIns.

PITP α and PITP β are localized in different compartments. PITP α is present in the cytosol and the nucleus whereas PITP β is localized at the Golgi and in the cytosol. In mammalian cells, the function of PITP was first identified in biochemical studies involving reconstitution of phospholipase C-signaling and exocytosis in cytosol-depleted cells [7,8]. Phospholipase C hydrolyses phosphatidylinositol(4,5)bisphosphate (PIP₂) to generate the second messengers, diacylglycerol and inositol(1,4,5)trisphosphate. Activation of G-protein-coupled receptors or receptor tyrosine kinases is responsible for increasing phospholipase C activity, and PITP α was identified as an essential component in ensuring PIP₂ supply for the enzyme [9,10]. Exocytosis could be similarly recovered in

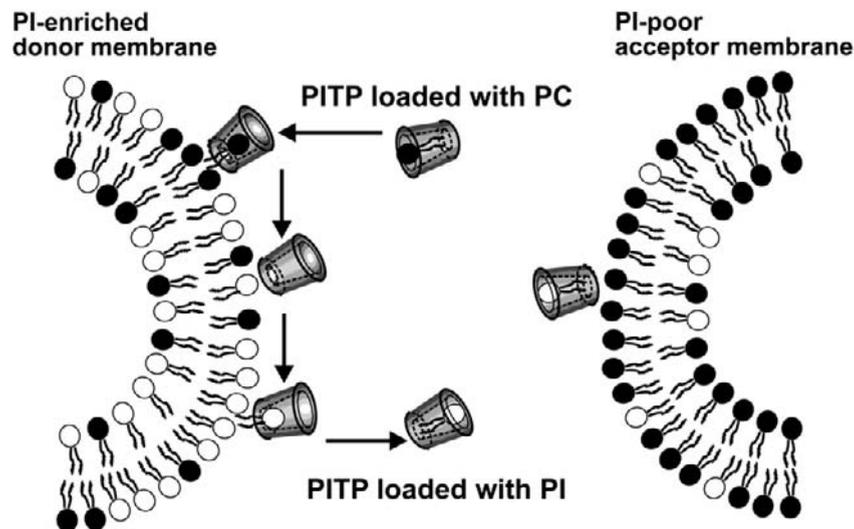

Figure 1 PITPs bind and transfer PtdIns and PtdCho between membrane compartments. Phosphatidylinositol transfer proteins (PITPs) were first purified based on their ability to transfer PtdIns between two membrane compartments *in vitro*.

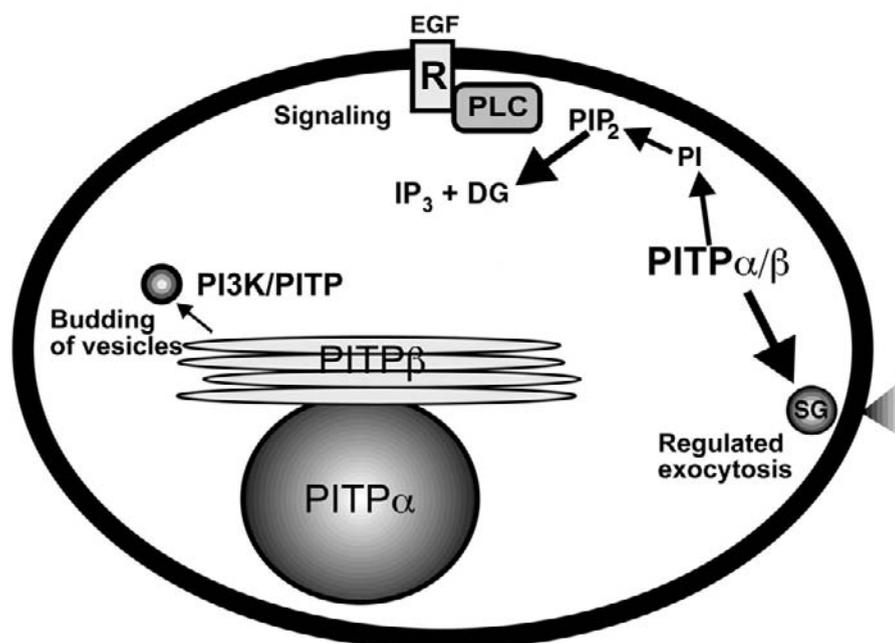

Figure 2 Functions and location of PITP α and PITP β . PITP α is primarily localized in the cytosol and the nucleus. PITP α is required for supplying the substrate, PtdIns for PIP $_2$ synthesis utilized by phospholipase C and for maintaining a pool of PIP $_2$ for exocytosis. PITP β is primarily localized at the Golgi and cytosol and is involved in the budding of vesicles by making available a pool of phosphoinositides at the Golgi. The function of PITP α in the nucleus is probably in making substrate available for phosphorylation.

permeabilized cells where PITP α and a PIP 5-kinase worked in synergy to make PIP $_2$ [11,12]. Finally, biogenesis of vesicles from Golgi was also dependent on cytosolic proteins, and PITP was thus purified [13,16]. In all these studies, both PITP α and PITP β were equally capable of restoring function. Several of these functions are summarized in Fig. 2.

Studies aimed at elucidating the mechanism of action of PITP in each of these seemingly disparate functions have yielded a singular theme. The activity of PITP stems from its

ability to transfer PtdIns from its site of synthesis (ER) to sites of cellular activity and to stimulate the local synthesis of phosphorylated forms of PtdIns, including PtdIns(4)P, PtdIns(4,5)P $_2$, PtdIns(3)P, and PtdIns(3,4,5)P $_3$ [14,15]. It is speculated that PITP could present PtdIns to the lipid kinases within a signaling complex. This concept is supported by observations that PITP α does associate with the EGF receptor phospholipase C γ and PtdIns 4-kinase following stimulation with EGF [9].

A reduction in the expression levels of PITP α , as seen in the *vibrator* mutation in mice leads, to neurodegeneration [17] in the presence of normal concentrations of PITP β , suggesting that although these proteins share transfer activity and can substitute for each other in reconstitution assays [8,13,18], they do have distinct functions *in vivo*. PITP β is an essential protein, since mice carrying mutations in PITP β die early in embryogenesis, and PITP β may be essential for stem cell viability [19]. PITP β was originally cloned from a rat brain cDNA library by its ability to rescue *Sec14* mutants in yeast, *S. cerevisiae*. Mutations in *Sec14* lead to a defect in the formation of secretory vesicles destined for the plasma membrane. Despite the absence of sequence or structural homology, PITP β was able to rescue the temperature-sensitive *Sec14* mutants. In mammalian cells, PITP β also localizes to the Golgi, and considerable data have accumulated that suggest that PITP β may be involved in vesicle budding in this compartment by maintaining a pool of phosphorylated PtdIns [16].

The amino acid sequence of the PITP domain is highly conserved in all isoforms, and no characteristic short sequence motifs have been identified. From the crystal structure of PITP α bound to PtdCho, the PITP domain comprises an amino-terminal lipid-binding region that contains an eight-stranded, concave, mostly anti-parallel β -sheet and two helices, the carboxy-terminal helical region, and the intervening regulatory loop region [3]. Upon stimulation with receptor-directed agonists or PMA, PITP α is phosphorylated at Ser164, which resides in the regulatory loop region. This is an important regulatory control as mutation of the serine residue to glutamate (which mimics phosphorylation) inhibits transfer function as well as the ability to provide substrate for phospholipase C signaling.

The mechanism of how PITP can abstract a lipid from a bilayer and facilitate exchange can be conjectured from the extensive biochemical and structural analysis of PITP α . For PITP α to perform its task, a change in affinity for membranes has to occur for it to associate with membranes to exchange its bound lipid, but this change in affinity has to be reversed so that the protein can move rapidly away from the membrane. Deletions of the C-terminus induce a more relaxed conformation and enhances its affinity for membranes without affecting its lipid binding properties. Thus movement of the carboxy-terminal helical region very likely governs change in membrane affinity and also exposes the lipid tails toward the membrane. The lipid is now able to move out of its cavity, and lipid exchange can then occur. Following exchange the protein has to return to its compact structure to be released from the membrane.

One of the major roles of PITP α is to provide PtdIns for PLC signaling. PLC signaling is thought to occur in inositol-lipid enriched membranes rafts, since destruction of rafts inhibits PLC activation [20,21]. It may be speculated that the localized depletion of the inositol lipids in membrane rafts could result in changes of membrane bilayer curvature. Since the activity of PITP α is sensitive to membrane curvature, this would mean that the transfer activity is regulated by changes

in the local membrane environment. This conclusion is supported by the observation that upon stimulation with EGF, PITP α is part of a signaling complex, which includes the EGF receptor, Type II PI-4-kinase, and phospholipase C γ [9]. Thus in cells, PITP α does not randomly transfer lipids but does so at specific sites of active consumption of phosphoinositides.

RdgB Family of PITP Proteins

As already mentioned, the RdgB acronym is derived from a retinal degeneration mutant phenotype (type **B**) in *Drosophila* where this family of PITP proteins were first identified. The *D-rdgB* mutation causes abnormal photoreceptor responses and light-enhanced retinal degeneration, and genetic evidence indicates that the D-rdgB product acts within the light-triggered phosphoinositide cascade responsible for phototransduction. The *D-rdgB* gene encodes a 160 kDa protein that has an N-terminal PITP domain, an acidic Ca²⁺-binding domain, and an extended hydrophobic region; in mammals, there are of two homologues, M-RdgB α 1 and M-RdgB α 2. In addition, a smaller protein of 38 kDa (RdgB β) was identified by homology to rdgB α and this isoform is also found in both flies and mammals [4]. Transgenic expression of murine rdgB α 1 or 2 rescues *rdgB* null *Drosophila*. However, deletion of RdgB α 2 in mice has no obvious phenotype and phototransduction and photoreceptor survival is unaffected, whereas deletion of RdgB α 1 is embryonically lethal [22].

M-RdgB1 specifically associates with phosphatidylinositol 4-kinase (α -isoform) and can increase the kinase activity [23]. These data are consistent with our proposal that PITP proteins mediate spatially restricted synthesis of phosphorylated inositol lipids. In conclusion, proteins with a PITP domain all appear to function in many aspects of biology by virtue of its ability to regulate phosphoinositides synthesis. Phosphoinositides play important roles not only for providing substrate for signaling pathways but also as ligands for proteins containing specific domains, including PH domains, PX domains, ENTH domains.

Inositol Polyphosphate Regulation of Nuclear Function

John D. York

*Departments of Pharmacology and Cancer Biology and of
Biochemistry, Howard Hughes Medical Institute,
Duke University Medical Center,
Durham, North Carolina*

Introduction

As several chapters in this Handbook attest, inositol signaling pathways have emerged as a multifaceted ensemble of cellular switches that regulate a number of processes well beyond calcium release, including membrane trafficking, channel activity, and nuclear function. Over 30 inositol messengers are found in eukaryotic cells that may be generally grouped into two classes: (1) inositol lipids or phosphoinositides (PIPs) and (2) water-soluble inositol polyphosphates (IPs). Insights into the roles of these messengers have come through the characterization of numerous gene products that control the metabolism of PIPs and IPs, over eighty in humans and twenty-six in budding yeast. This review will discuss in brief a small subset of the overall inositol signaling pathway, namely higher IPs, generally defined as having four or more phosphates. Two important concepts have emerged: (1) the higher IPs discussed here are derived from phospholipase C-dependent activation, thus IP_3 is both a messenger and a precursor to others, and (2) the higher IPs have been linked to the regulation of several nuclear processes. Emphasis will be placed on the gene products that synthesize IP_4 , IP_5 , IP_6 and diphosphoryl IPs and the processes they have been found to regulate. Several of these kinases appear to localize within the nucleus, and their activities are necessary for proper gene expression, mRNA export, and DNA metabolism. The breadth of nuclear processes regulated and the evolutionary conservation of the genes involved in their synthesis have sparked

renewed interest in higher IPs as important intracellular messengers.

Inositol Signaling and the Molecular Revolution

The molecular revolution has left an indelible mark on inositol signaling pathways, fueling an expansion of our thinking [1–8]. As the roles of inositol 1,4,5-trisphosphate (IP_3) and 1,2-diaclyglycerol were forged as intracellular messengers, many researchers questioned whether other inositol lipids and inositol polyphosphates, some 30 in all, had important roles in cell signaling. The cloning and characterization of kinases, phosphatases, lipases, and effectors has made it clear that the functions of inositol phosphate derivatives are numerous. Over the past decades, dozens of gene products have been characterized as players that act in concert to generate a combinatorial ensemble of distinct chemical messengers with instructions for the cell. Nature may have utilized *myo*-inositol as a signaling scaffold because of its elegant chemistry—a six-carbon asymmetric cyclitol that is readily modified by combinatorial phosphorylation—and because it may be formed through two metabolic steps from glucose 6-phosphate. Ancestral relationships have been identified at the sequence and structural level among proteins involved in inositol signaling and those involved in nucleotide, protein, and carbohydrate metabolism, thereby providing clues as to how signaling machinery evolved. Examples of genetic economy are found among several promiscuous IP kinases and

phosphatases harboring multiple specificities. Remarkably, a dual-functional gene product has been identified, conserved from yeast to man, which has two distinct autonomously folded inositol lipid phosphatase domains that together are capable of dephosphorylating all known PIPs. Three inositol lipid phosphatases—OCRL-1, MTM, and PTEN/MMAC—have been identified in which a loss of function results in human disease. Together these findings have generated much new excitement within the signaling community, and as we look to the future there is every expectation that we are in for many more surprises.

Links of Inositol Signaling to Nuclear Function

A recurring theme in intracellular signaling is the spatial restriction of pathways to selective compartments. In the past 15 years, discrete nuclear specific pathways of inositol metabolism have been identified that may provide a provocative mechanism by which extracellular stimuli may ultimately elicit nuclear responses. Initially it was demonstrated that phosphoinositides are present in nuclear membranes and that activities required for their synthesis and breakdown are within nuclear fractions [9–11]. The functional importance of such pathways were then suggested through studies of insulin-like growth factor I (IGF-I), which stimulates nuclear but not cytoplasmic phosphoinositide metabolism [12,13]. Studies by Crabtree and coworkers [14] have found that PIP_2 regulates chromatin-remodeling complexes. Many other studies have been recently reviewed by Divecha and coworkers [13], and hint that inositols influence nuclear processes such as DNA synthesis, cell cycle, nuclear calcium, chromatin structure, gene expression, and messenger RNA export.

Genetic and biochemical studies of a phospholipase C-dependent pathway in the budding yeast have provided compelling functional evidence for regulation of three distinct nuclear processes by higher IPs. The budding yeast genome contains a single phosphoinositide-specific phospholipase C gene (*PLC1*) whose activation induces a kinase pathway that sequentially converts $I(1,4,5)P_3$ to higher IPs, including $I(1,4,5,6)P_4$, $I(1,3,4,5,6)P_5$, IP_6 , and PP-IPs (see Fig. 1) [15]. Examination of IP metabolism in a variety of yeast strains reveal that activation of *Plc1* results in the production of IP_3 , which is then sequentially phosphorylated by two kinases, *Ipk2* and *Ipk1*, to IP_6 [15–17]. A third kinase, *Kcs1*, has been identified as a diphosphoryl inositol synthase, which generates PP-IP branches from IP_5 and IP_6 substrates [18,19].

Individual mutations in *plc1*, *ipk2*, or *ipk1* result in defects in the production of IP_6 as well as defects in efficient mRNA export [15]. In contrast, mutation in *kcs1* and hence PP-IP production does not appear to alter mRNA export [19]. Furthermore, induction of the pathway through overexpression of *Plc1* results in suppression of defects in a *gle1-1* mRNA export mutant [15]. These data suggest that phospholipase C and kinase-dependent higher IP production, possibly IP_6 or some yet identified product of the *Ipk1* 2-kinase, regulates mRNA export. The cloning of *Ipk1* orthologs from plants and

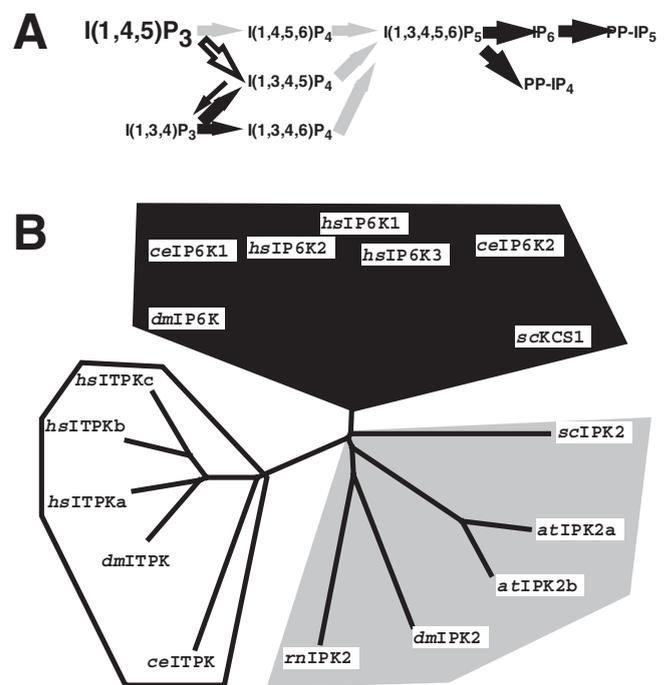

Figure 1 Higher inositol polyphosphate synthesis pathways. (A) An abridged description of IP_3 metabolism—most phosphatase activities and several higher IP intermediates have been omitted for clarity. Species are abbreviated: *hs*, *Homo sapiens*; *rn*, *Rattus norvegicus*; *dm*, *Drosophila melanogaster*; *at*, *Arabidopsis thaliana*; *sc*, *Saccharomyces cerevisiae*; *ce*, *Caenorhabditis elegans*. Color legend: red—Ipk2 family members having 6-/3-/5-kinase activities; green— $I(1,4,5)P_3$ 3-kinase (ITPK); blue—diphosphoryl inositol synthetase, which generate PP-IPs (IP_6K); black— IP_3 2-kinase; magenta— $I(1,3,4)P_3$ 5-/6-kinase; and cyan— IP_3 5-phosphatase.

mammals, and a recent report that reduction of higher IPs in mammalian cells also affects mRNA export suggests this pathway is conserved throughout eukaryotes (J. Stevenson-Paulik, R. A. Frye, and J. D. York, unpublished; [20,21]).

Second, a role for IP_4 and/or IP_5 in the regulation of gene expression has come from studies of a yeast IP_3/IP_4 kinase, *Ipk2*, which found it is identical to Arg82 [16,17]. Messenguy and co-workers [22,23] have studied Arg82 as a regulator of gene expression through the ArgR-Mcm1 transcription complex. *Ipk2* is a dual-specificity 6-/3-kinase that sequentially converts IP_3 to IP_5 , is localized within the nucleus, and is required to assemble protein complexes on DNA-promoter elements. Both *Plc1* activity and *Ipk2*-mediated IP_4/IP_5 production are required for ArgR-Mcm1 transcriptional activation. Our results indicate that *Ipk2* influences transcriptional responses through a two-step mechanism. First, *Ipk2* protein but not IP synthesis is needed to enable formation of ArgR-Mcm1 complexes on DNA promoter elements. Second, production of IP_4 and possibly IP_5 through both phospholipase C and *Ipk2* kinase activity is required to properly execute transcriptional control. While Messenguy and colleagues [24] have recently suggested that higher IPs are not required for ArgR-Mcm1 transcription, we find in using both genome-array

analysis and transcriptional reporter assays that both Plc1 and Ipk2 kinase activities are required for appropriate gene expression [A. R. Odom and J. D. York, unpublished]. Because Ipk1 is not required for complex formation or transcription control [16], we conclude that these two IP kinases generate distinct nuclear messengers.

It is also important to mention earlier studies of Henry and Coworkers that found that changes in cellular levels of *myo*-inositol regulate the transcription of *INO1*, whose gene product converts glucose 6-phosphate to D-inositol 3-phosphate (reviewed in [25]). This enables cells to initiate *de novo* synthesis of inositol under conditions in which it is unavailable in the growth medium. This transcriptional regulation is accomplished through defined *cis*-acting DNA elements and *trans*-acting factors. An important future area of study will be to determine how the cell detects changes in inositol.

A third role for phospholipase C pathway in nuclear function has come from studies of the Kcs1, a diphosphoryl synthase that generates PP-IPs from IP₃ and IP₆ substrates (referred to as an IP₆ kinase by Snyder and coworkers). *KCS1* was originally identified on a genetic screen as one of two genes that when mutated overcome a hyper-recombination phenotype found in certain mutant alleles of protein kinase C [26]. Snyder and coworkers [27] have demonstrated that Kcs1 has IP₆ kinase activity and find that a point mutation in the kinase domain results in rescue of hyper-recombination, indicating that PP-IPs play a role in DNA metabolism. Of note, Shears and co-workers [19,28] have suggested a role for PP-IPs in binding components involved in membrane trafficking and have recently reported that *kcs1* mutant yeast strains have aberrant vacuole morphology. Thus, it is possible that PP-IPs have distinct compartment specific functions.

An additional role for higher IPs in DNA metabolism is suggested by the work of West and coworkers [29]. This group finds that IP₆ is a regulator of non-homologous end-joining (NHEJ), a DNA repair pathway mediated through the DNA-dependent protein kinase (DNA-PK). Through an elegant biochemical purification of a cellular regulator of NHEJ, IP₆ was identified [29]. Subsequently it has been shown that binding of IP₆ occurs via the *KU* heterodimer, the noncatalytic subunit of DNA-PK [30,31]. While both *KU* heterodimer and NHEJ pathways are found in yeast, the yeast *KU* heterodimer does not bind IP₆, and unpublished studies of Llorente and Symington (referred to in [31]) have indicated that loss of IP₆ production does not impair NHEJ in yeast. It will be important to show that changes in IP₆ levels, or one of its metabolites such as PP-IP₅, within the cell regulate NHEJ *in vivo*.

The Inositol Polyphosphate Kinase (IPK) Family

The sequence motif "PxxxDxKxG" is conserved among a growing family of inositol polyphosphate kinases, which in general we have called IPKs, depicted by the dendrogram in Fig. 1B. This motif was originally described as common to IP₃ 3-kinases (reviewed in [32]), and subsequently it was shown by several research groups to be a hallmark of IPK

family members discussed in the preceding section, which include IP₃ 3-kinases, IP₃/IP₄ dual-specificity 6-/3-kinases, and diphosphoryl IP synthase. This motif is not found in IP kinases that phosphorylate the axial second position of the inositol ring [15], nor in I(1,3,4)P₃ 5/6 kinases [33], suggesting these kinases evolved from different ancestors. Thus there appear to be three branches on the tree, each of which encodes kinases that regulate distinct processes within the cell.

The Ipk2 and diphosphoryl inositol synthase (IP6K) branches are conserved from yeast to man, but the IP₃ 3-kinase (ITPK) branch is not. Two groups have found that certain Ipk2 proteins exhibit diphosphoryl synthase activity [34,35]. These data indicate that the Ipk2 branch may be the oldest and raises a question related to the origins of soluble inositol polyphosphate signaling and higher IP function. What is remarkable, all eukaryotes have pathways in which the activation of phospholipase C results in cleavage of PI(4,5)P₂ to produce inositol 1,4,5-trisphosphate (IP₃) and diacylglycerol. However, the commonly viewed cellular function of these two messengers in releasing intracellular calcium and stimulation of protein kinase C has not yet been described in lower eukaryotes. Budding yeast do not appear to have IP₃-mediated calcium release pathways (and no evidence of the IP₃ receptor in their genome), nor does diacylglycerol appear to activate yeast Pkc1. I will leave you with a final question: does this indicate that the primordial role of phospholipase C induced production of IP₃ is to serve as fuel for production of higher IPs and regulation of nuclear processes?

Acknowledgments

I wish to thank members of the lab, past and present, and numerous colleagues for helpful discussions. I would also like to apologize to the authors of numerous studies whose work had to be omitted from discussion due to extreme space limitations.

Ins(1,3,4,5,6)P₅: A Signal Transduction Hub

Stephen B. Shears

*Laboratory of Signal Transduction,
National Institute of Environmental Health Sciences,
Research Triangle Park, North Carolina*

Introduction

All nucleated cells contain approximately 15 to 50 μM Ins(1,3,4,5,6)P₅ [1]. In this review, I will illustrate how Ins(1,3,4,5,6)P₅ serves a number of signaling roles, both by itself, and also as a precursor pool for other physiologically active inositol polyphosphates (Fig. 1).

For example, Ins(1,3,4,5,6)P₅ dephosphorylation by a receptor-regulated 1-phosphatase [2] generates Ins(3,4,5,6)P₄, which inhibits CaMKII-dependent activation of a family of Cl⁻ channels in the plasma membrane [3–5]. This carefully controlled regulation of ion channel conductance, through a dynamic balance between competing stimulatory and inhibitory signals, permits a high degree of signal amplification. Enhancement of the signaling process is aided by the precipitous dose-response curve that describes the highly cooperative manner with which Ins(3,4,5,6)P₄ inhibits Cl⁻ channels [3,4,6]. Specificity is another of the hallmarks of an efficient cellular signal; this is certainly the case here. Cl⁻ channels are unaffected by Ins(1,3,4)P₃, Ins(3,4,5)P₃, Ins(3,4,6)P₃, Ins(4,5,6)P₃, Ins(3,5,6)P₃, Ins(1,3,4,6)P₄, Ins(1,3,4,5)P₄, Ins(1,4,5,6)P₄, and Ins(1,3,4,5,6)P₅ [2–4,7]. The efficacy of Ins(3,4,5,6)P₄ (IC₅₀ = 3–7 μM) reflects a physiologically relevant concentration range (1–10 μM ; [8]).

Ca²⁺ also directly activates some Cl⁻ channels, independently of CaMKII; this effect of Ca²⁺ is also blocked by Ins(3,4,5,6)P₄ in certain situations [7] although not in others [5]. Both CaMKII- and Ca²⁺-regulated Cl⁻ channels regulate salt and fluid secretion [8,9], cell volume homeostasis [10], and electrical excitability in neurones and smooth muscle [11]. Recently [12] we showed that at least one member of a

molecularly distinct Cl⁻ channel family, CIC, is also inhibited by Ins(3,4,5,6)P₄. These channels are located in secretory vesicles, endosomes, and lysosomes, where they act as a charge shunt that facilitates functionally indispensable vesicle acidification by ATP-driven H⁺ pumps [13]. Inhibition of insulin granule acidification by Ins(3,4,5,6)P₄ attenuates Ca²⁺-dependent insulin secretion [12]. We anticipate that further cellular functions for Ins(3,4,5,6)P₄ will emerge from its effect upon vesicle acidification. Thus, receptor-activated Ins(1,3,4,5,6)P₅ dephosphorylation regulates a versatile range of physiological activities that depend upon Cl⁻ channel activity.

The Ins(1,3,4,5,6)P₅ 1-phosphatase is of particular interest because it is reversible *in vivo* [2]; in fact, this enzyme was originally identified as an Ins(3,4,5,6)P₄ 1-kinase [14]. Furthermore, the 1-phosphate group that is removed from Ins(1,3,4,5,6)P₅ can be directly transferred to the 6-OH of Ins(1,3,4)P₃ [2]. By accepting this phosphate group, Ins(1,3,4)P₃ enhances the Ins(1,3,4,5,6)P₅ 1-phosphatase activity [2]. This is how PLC-initiated increases in levels of Ins(1,3,4)P₃ elevate Ins(3,4,5,6)P₄ levels [15]. Thus, the 1-kinase and 1-phosphatase activities of a single enzyme switches Ins(3,4,5,6)P₄ signaling on and off. These opposing reactions offer an alternative to general doctrine that intracellular signals are regulated by integrating multiple, distinct phosphatases and kinases [16].

A different role for Ins(1,3,4,5,6)P₅ concerns its interaction with PTEN, a tumor suppressor [17]. PTEN has classically been recognized as a PtdIns(3,4,5)P₃ 3-phosphatase that downregulates the lipid's enhancement of cell proliferation and Akt-dependent cell survival [17]. My laboratory

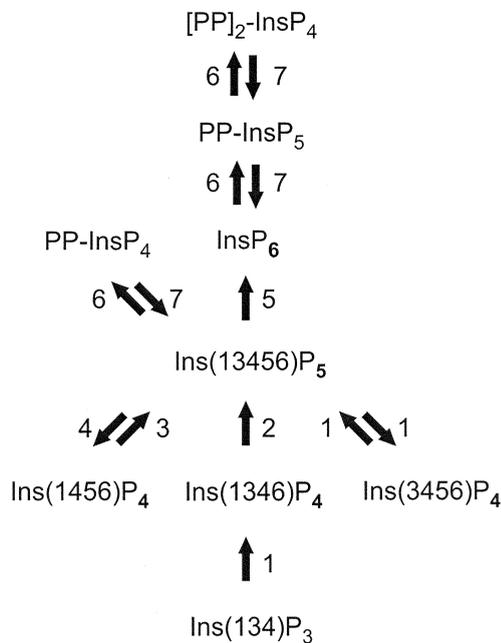

Figure 1 Enzymes that synthesize and metabolize Ins(1,3,4,5,6)P₅. (1) The multifunctional Ins(1,3,4)P₃ 6-kinase/Ins(3,4,5,6)P₄ 1-kinase/Ins(1,3,4,5,6)P₅ 1-phosphatase [2]. (2) Ins(1,3,4,6)P₄ 5-kinase [1]. (3) Ins(1,4,5,6)P₄ 3-kinase [1,21,23]. (4) PTEN [18] and MIPP [26]. (5) Ins(1,3,4,5,6)P₅ 2-kinase [27]. (6) Diphosphoinositol polyphosphate synthase (a.k.a. “InsP₆ kinase”) [30,31]. (7) Diphosphoinositol polyphosphate phosphatase [33].

recently discovered that PTEN is also a high-affinity Ins(1,3,4,5,6)P₅ 3-phosphatase [18]. Competition from soluble Ins(1,3,4,5,6)P₅ will temper the ability of PTEN to bind and dephosphorylate PtdIns(3,4,5)P₃ and further restrict PTEN’s already weak protein phosphatase activity [19]. Ins(1,3,4,5,6)P₅ may therefore be viewed as “clamping” PTEN activity, the significance being that overall regulation of a signaling system is much tighter, and permits greater amplification, if it has to be de-inhibited (i.e. when PTEN escapes Ins(1,3,4,5,6)P₅) as well as activated (i.e. when PTEN locates PtdIns(3,4,5)P₃). Ins(1,3,4,5,6)P₅ that is dephosphorylated by PTEN will be replenished by Ins(1,4,5,6)P₄ 3-kinase activity; we discovered this kinase over 10 years ago, and we also demonstrated the dynamic nature of Ins(1,3,4,5,6)P₅ 3-phosphatase/Ins(1,4,5,6)P₄ 3-kinase metabolic cycling *in vivo* [1,20]. Perhaps this cycling is simply the metabolic “price” for regulation of PTEN. Alternately, this cycle may itself have specific functions, for example in the nucleus, since that is where most mammalian Ins(1,4,5,6)P₄ 3-kinase is located [21], together with some PTEN [22]. Furthermore, in yeast there is evidence that Ins(1,4,5,6)P₄ synthesis regulates transcription [23]. Salmonella’s SopB and SopE virulence factors activate rapid Ins(1,3,4,5,6)P₅ hydrolysis to Ins(1,4,5,6)P₄ as an obligatory part of the process by which the bacteria activate host cell Rac/Rho GTPases, which promotes cellular invasion [24,25]. There is a mammalian enzyme (MIPP; multiple inositol polyphosphate phosphatase) that further dephosphorylates Ins(1,4,5,6)P₄ to Ins(1,4,5)P₃ [26]. Thus, Ins(1,3,4,5,6)P₅

potentially provides a PLC-independent source of Ins(1,4,5)P₃, although to date, only *Dictyostelium* MIPP is proven to generate Ins(1,4,5)P₃ in this manner [26].

Ins(1,3,4,5,6)P₅ is also phosphorylated by a 2-kinase [27], yielding InsP₆, to which a number of diverse functions have been attributed, but unfortunately, *in vitro* experiments with InsP₆ provide many opportunities for nonphysiological artifacts, so the significance of many of these studies has been criticized [28]. This is why genetic manipulations of InsP₆ levels inside cells are more likely to uncover useful information. Finally, there are enzymes that convert Ins(1,3,4,5,6)P₅ to a diphosphorylated derivative (PP-InsP₄) [29]. This kinase family generally receives more attention for phosphorylating InsP₆ [30], but Ins(1,3,4,5,6)P₅ is also a substrate [31]. Indeed, metabolic cycling between Ins(1,3,4,5,6)P₅ and PP-InsP₄ is at least as extensive in intact cells as is the cycling between InsP₆ and its diphosphorylated derivatives (PP-InsP₅ and [PP]₂-InsP₄ [29]). All of the diphosphorylated inositol phosphates are considered “high-energy” phosphate donors that apparently regulate vesicle trafficking and possibly other energy-demanding processes [31,32].

Phospholipase D

Paul C. Sternweis

*Department of Pharmacology, University of Texas,
Southwestern Medical Center at Dallas,
Dallas, Texas*

Introduction

Phospholipase D (PLD) activity is found throughout the biological world, and enzymes have been characterized from a broad spectrum of organisms. Phosphatidic acid is a key molecule in the metabolic pathways for phospholipid synthesis and degradation. One pathway for the production of this lipid is hydrolysis of glycerophospholipids by PLD enzymes, which produce phosphatidic acid (PA) and the associated base or headgroup.

Numerous hormones, growth factors, neurotransmitters, and other cellular stimuli regulate the generation of PA by PLD in mammalian cells. This has led to an emerging role for the mammalian enzymes and PA in signal transduction. Phosphatidic acid is hypothesized to act as a second messenger through direct interaction with a variety of targets, which are discussed elsewhere [1,2]. In addition, PA is a precursor for formation of diacylglycerol (DAG) and lysophosphatidic acid (LPA). DAG can act as a second messenger to regulate the activity of protein kinase C (PKC) isozymes; LPA can function as an autocoid or paracrine through interaction with receptors in the edg family.

This brief overview summarizes the properties and functions of PLD enzymes with a focus on the mammalian proteins. More detailed information can be found in several reviews that provide excellent depth [1] and earlier perspectives [2–4], as well as description of the enzymes in plants [5,6] and yeast [7].

Structural Domains and Requirements for Activity

Two mammalian PLD isozymes have been identified and characterized at the molecular and biochemical levels.

A schematic representation of the domain structure of these and several PLD enzymes from other organisms is presented in Fig. 1A. The phospholipase D enzymes belong to a larger family of proteins that includes several endonucleases, cardiolipin synthases, and phosphatidylserine synthases. These enzymes are characterized by the presence of HKD motifs (consensus sequence, HxKxxxxD). Structures have been determined for two members of this superfamily, the PLD from *Streptomyces* sp. Strain PMF [8] (MMDB, 15995; PDB, 1FO1) and the dimer of the endonuclease, Nuc, from *Salmonella typhimurium* [9] (MMDM, 11347; PDB, 1BYR). The structures clearly show that two HKD motifs come together to form a single functional catalytic site with the two histidines as likely nucleophiles for catalysis. Whereas most of the enzymes in this superfamily contain both HKD motifs in a single polypeptide, Nuc contains only a single motif and dimerizes to form its active site (Fig. 1B). Mutations of conserved residues in the HKD motifs have indicated their requirement for catalytic activity in the mammalian enzymes. The C-terminus is a second region required for activity by the mammalian enzymes. Evidence from Liu and colleagues [10] indicates that C-terminal residues and especially the C-terminal α -carboxyl group were required for activity. The actual role of these residues in the catalytic reaction is unknown.

Figure 1A identifies other potential regulatory features that distinguish PLD enzymes. The classical plant PLDs, represented by the enzyme from maize, contain an N-terminal C2 domain, which provides for binding of Ca^{2+} and phospholipids [6]. In contrast, the mammalian enzymes contain putative PX and PH domains that may be important for interaction with regulatory molecules. The presence of the latter domains extends to PLDs from many organisms, including *D. melanogaster*, *C. elegans*, and yeast. Recently, two PLD

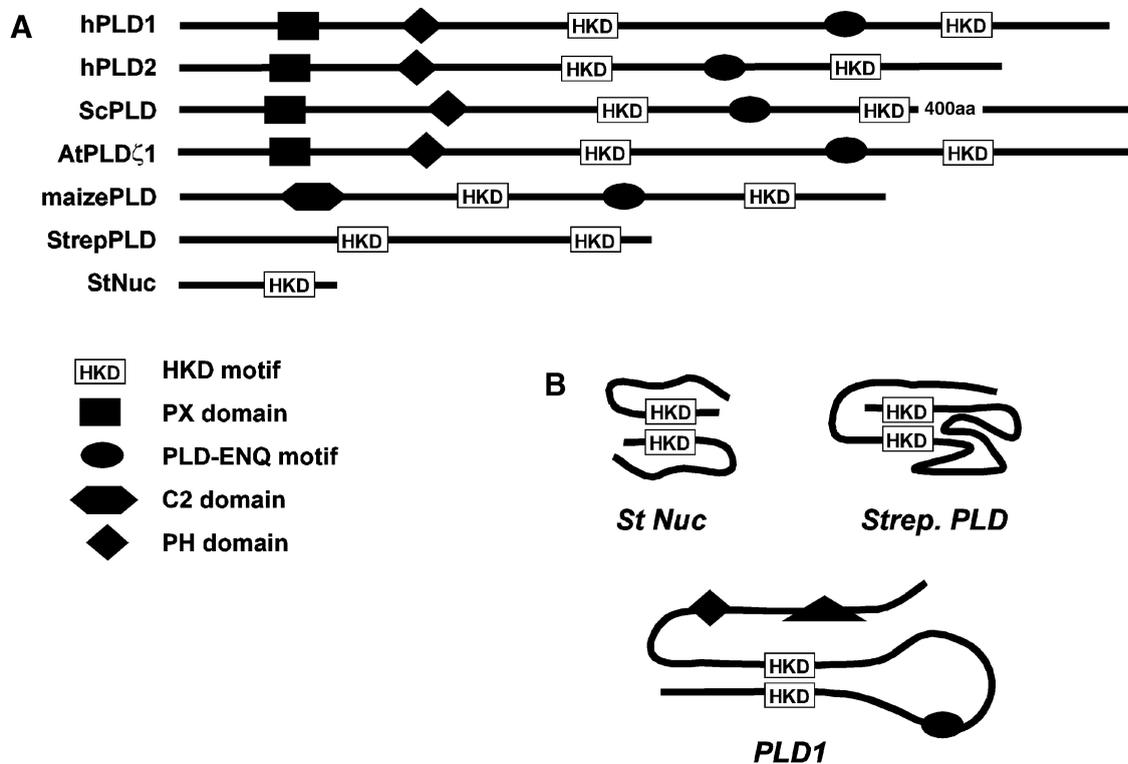

Figure 1 A. Schematic representation of several members of the PLD superfamily: hPLD1, human PLD1 (GI:4505873); hPLD2, human PLD2 (GI:20070141); ScPLD, SPO14 gene from *Saccharomyces cerevisiae* (GI:1174406); AtPLD ζ 1, isozyyme from *Arabidopsis thaliana* (GI:20139230); maizePLD, PLD α 1 from *Zea mays* (GI:2499708); StrepPLD, enzyme from *Streptomyces septatus* (GI:15823702); StNuc, nuclease from *Salmonella typhimurium* (GI:6435643). B. Dual HKD motifs cooperate to form a single active site. In the case of Nuc, which only contains one HKD motif, the protein dimerizes to form an active catalytic site.

enzymes that closely resemble the mammalian structural paradigm were identified in *Arabidopsis thaliana* (see AtPLD ζ 1, Fig. 1). This departure from the classical plant PLDs suggests a much broader scope for regulation of PLD activity in plants [11].

Catalysis: Mechanism and Measurement

It has been appreciated for some time that the enzymatic cleavage carried out by PLD is a two-step process (Fig. 2, see [12] for details). The preferred substrate for the mammalian enzymes is phosphatidylcholine (PC) [13]. The initial reaction involves the formation of a phosphatidylated enzyme with the concomitant release of choline. This attachment is presumably to one of the histidines of the HKD motifs. Under physiological conditions, water is used to release phosphatidic acid and regenerate the active enzyme. A common substrate for assessment of PLD activity *in vitro* is [3 H-choline]-PC; the reaction is easily followed by measurement of released choline. Optimal assay procedures, which use phospholipid vesicles containing the labeled PC, have been described in detail [14].

Primary alcohols are much better acceptors for the phosphatidic acid than water. In solutions containing 1% ethanol,

the primary product of PLD is phosphatidylethanol rather than PA. This property, referred to as transphosphatidylation, is unique to PLD enzymes and is exploited to measure PLD activity *in vivo*. The pool of PC in cultured cells can be preferentially labeled with [3 H]-myristate or labeled lysophosphatidylcholine. The exposure of cells to ethanol or lower concentrations of n-butanol results in the formation of the labeled phosphatidyl alcohol, which can be uniquely distinguished after separation by thin layer chromatography or other resolving techniques. An extensive discussion of this and other methods to measure PLD activity is available [13].

Modification of Mammalian PLDs

Two types of modification have been observed in the mammalian enzymes. Two cysteines (Cys240 and Cys241) in the PH domain of PLD1 can be acylated [15]. Elimination of this acylation in PLD1 [15] and PLD2 [16] results in altered cellular location and modest reduction in membrane association. However, a definitive role of this modification in physiological regulation remains to be elucidated.

The PLD isozyymes can be phosphorylated by PKC α , *in vitro*, and on Ser/Thr and Tyr, *in vivo*. While these modifications are putative mechanisms for modulation of PLD

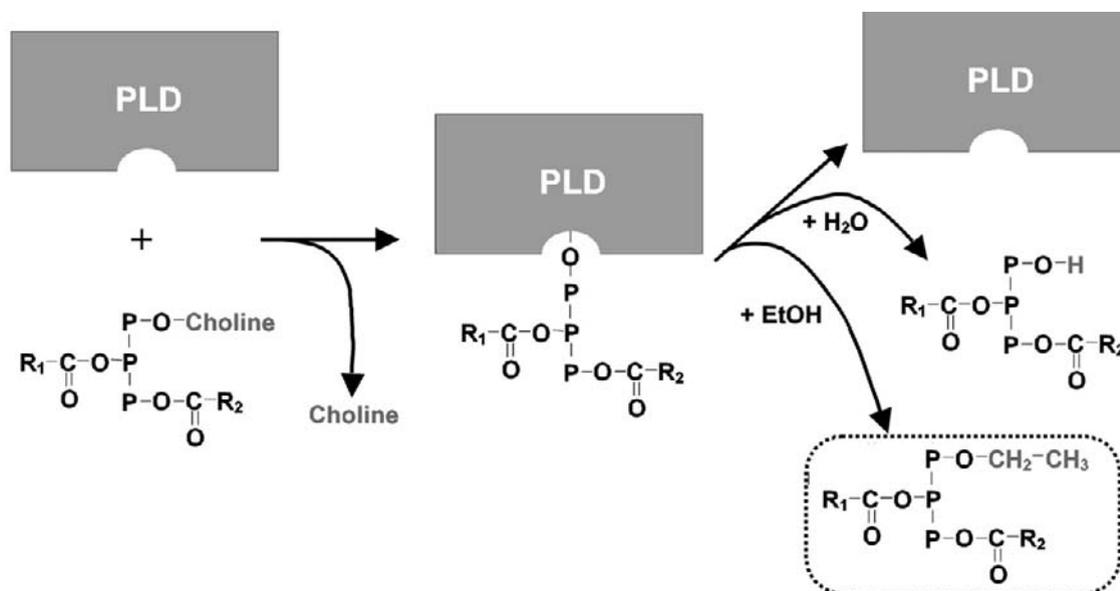

Figure 2 Catalytic mechanism for PLD. Hydrolysis of PC involves two steps. The first cleavage releases choline while forming an intermediate phosphatidylated enzyme. Subsequent hydrolysis with water yields the normal product, phosphatidic acid. In the presence of low concentrations of primary alcohols, the reaction can be shunted to form the phosphatidyl alcohol.

activity by G-protein-coupled receptors and growth factors, the evidence for stimulation of PLD activity by direct phosphorylation is not clear [1].

Regulatory Inputs for Mammalian PLD

Phospholipase D activity in mammalian cells can be stimulated by numerous hormones that act through G-protein-coupled receptors, growth factor receptors, and other stimuli (see [1,2] for surveys). Potential mechanisms for regulation include at least four direct activators that have been identified and characterized, *in vitro*; these are two families of monomeric GTPases (Arf and Rho), protein kinase C (PKC), and phosphatidylinositol 4,5-bisphosphate (PIP₂) (Fig. 3). The lipid PIP₂ was originally identified as a key component of substrate vesicles used to assay the mammalian enzyme [17,18]. Subsequently, this lipid was shown to be an efficacious activator of both PLD1 and PLD2, SPO14 from yeast, and most recently two isoforms of PLD from *Arabidopsis* [11]. While many reviews and papers have stated that this lipid is a cofactor or essential for phospholipase activity, the mammalian PLD1 is clearly active and regulated by Arf in the absence of PIP₂ [14]. Thus, this lipid should be considered a bonafide regulator of the enzyme. Phosphatidylinositol 3,4,5-trisphosphate has also been shown to activate PLD, but the low abundance of this lipid in cells suggest this is unlikely to be a physiological mechanism.

Members of the Arf family of monomeric GTPases were the first identified protein regulators of PLD activity [17,19]. Although they are potent activators of PLD1, Arfs provide only slight modulation of wild type PLD2 [20]; this becomes

more efficacious if the N-terminus of PLD2 is truncated [21]. The physiological relevance of this is not known. A second family of monomeric GTPases, the Rho proteins, can also directly activate PLD1 but not PLD2. All subgroups of the Rho family (Rho, Rac, and Cdc42) have proven effective in this function. For both Arf and Rho proteins, regulation of PLD activity occurs through the activated form of the GTPase and thus downstream of the regulation of these proteins.

A more traditional pathway for regulation of PLD is via the classical forms of PKC. It had been noted for some time that direct stimulators of PKC (e.g. phorbol myristate acetate, PMA) increased the activity of PLD in cells. The unusual feature of this regulation, when assessed *in vitro*, is that direct stimulation of PLD by activated PKC α does not require phosphorylation, but rather may occur through the regulatory domain [22]. There is evidence, however, that phosphorylation mechanisms may be required *in vivo* [1].

An intriguing property of these activators is their synergistic action when combined *in vitro* [22,23]. Such action is especially noted among the protein activators, as well as in conjunction with PIP₂. This finding suggests that the most efficacious stimulation of PLD activity *in vivo* may require the action of multiple regulatory pathways.

Regulatory Pathways

Evidence has been presented to implicate these stimulatory molecules in the regulation of PLD activity in cells. Extensive discussions are found elsewhere [1,2]. One clear mechanism for G-protein-coupled receptors is through the stimulation of phospholipase C β and activation of protein kinase C (Fig. 3). Similarly, growth factors can stimulate PKC via PLC γ .

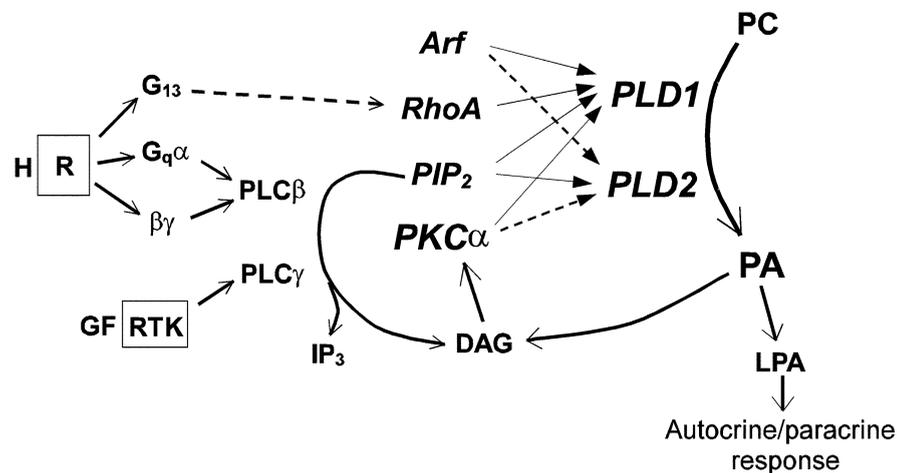

Figure 3 Potential pathways for regulation of mammalian PLD isozymes. See text for discussion of interactions and pathways.

Use of inhibitors of PKC and other strategies to reduce PKC activity in cells is generally effective for attenuation of PLD activity due to direct stimulation of PKC with PMA. In contrast, hormone responses are often retained. The use of PKC to stimulate PLD is intriguing because it potentially leads to an autocatalytic cycle in which the product of PLD activity could lead to further activation of PKC via conversion of PA to DAG. The ineffectiveness of PKC inhibitors in many systems (including some hormones that stimulate PLC activity) indicates that this regulation is more complex and that other mechanisms for hormonal stimulation are operative.

Evidence for the role of Rho proteins in regulation of PLD activity derives largely from the use of C3 toxin from *C. botulinum* and expression of dominant negative forms of the GTPases (summarized in [1]). The interpretation of these data is complicated by the potential regulation of PIP₂ synthesis by Rho proteins and the potential for nonspecific effects of disruption of cytoskeletal architecture through attenuation of these GTPases. The Rho proteins offer an attractive mechanism for regulation of PLD by receptors coupled to the G₁₂ and G₁₃ proteins. At this time, evidence for this regulation by endogenous receptors and G proteins is lacking.

Physiological regulation of PLD by PIP₂ is still an open question. Various studies, especially in permeabilized cells, that correlate PLD activity with manipulations to vary PIP₂ are suggestive [1,2]. However, the multiple actions of PIP₂ in cells suggests that global change in the concentration of PIP₂ is an unlikely regulatory mechanism. Recent studies that show increased activity of PLD2 when coexpressed with Type1α PIPkinase and the potential association between this kinase and the PLDs [24] support hypotheses that regulation could occur through localized and coordinated changes in the lipid.

The emerging picture predicts that several pathways regulate PLD activity *in vivo*. The primary pathways used in any one system will probably depend on the cell type, the

stimulus used, and the local and temporal environment, such as the state of other pathways being utilized in the cells.

Physiological Function of PA

The number of stimuli that regulate PLD activity strongly indicate the importance of PA in signal transduction. The known activators of PLD have given rise to hypotheses that include roles in basic hormone signaling (PKC), vesicle trafficking (Arf), cytoskeletal rearrangements (Rho), and exocytosis (Arf and Rho) [1,2]. Yet the various roles proposed are largely unproven.

Evidence for prolonged production of DAG via PLD activity is clear, and downstream regulation is probable. This pathway offers a mechanism for regulation by DAG that is independent of Ca²⁺ and selective for a spectrum of PKC isozymes different from those activated by the action of phospholipase C. The potential role of PA in facilitation of membrane rearrangements required for vesicle budding and fusion is attractive. Thus, production of PA, and subsequent products, DAG or LPA, could profoundly affect curvature and stability of the membranes involved. However, the evidence for these events is controversial. Finally, numerous proteins have been shown to interact with or be affected directly by PA *in vitro* [1,2]. These represent potential targets for regulation by the lipid, but definitive demonstration of these putative pathways has been elusive.

Localization of PLD

Phospholipase D activity is found primarily in particulate fractions of mammalian cells and tissues. Subcellular distribution of PLD isozymes within the cell is still in question and has been inferred largely from studies with exogenous expression of tagged proteins [1,2]. In several studies, overexpression of PLD1 resulted in localization to perinuclear regions,

frequently with a punctate appearance. In contrast, overexpressed PLD2 was found in the plasma membrane and potential endosomal vesicles near the surface of cells. One report, which examined endogenous PLD1, found the enzyme enriched in the Golgi apparatus, but diffuse staining also indicated a more diverse distribution [25].

Future Directions

Which PLD isozyme is responsible for activity observed in response to hormones? PLD1 was initially favored because of its responsiveness *in vitro* to regulatory molecules in the known hormone pathways (PKC and Rho in particular). Yet the presumed main site for regulation of PLD activity by hormones is the plasma membrane, and by this criterion, localization studies suggest PLD2 as the potential target. Studies with overexpressed enzymes demonstrate that PLD2 is responsive to activation by PKC in the cellular environment and can enhance stimulations observed with some hormonal stimuli. In contrast, overexpressed PLD1 can be unresponsive to agonists that stimulate putative activators of the enzyme. The discordance between regulation observed *in vitro* and *in vivo* indicates there is still much to be learned about the molecular mechanisms of PLD regulation.

In addition to understanding the responsiveness of individual isozymes, basic questions about the putative roles of PA and its metabolites abound. Fundamental to this are clear determinations of the specific regulation of putative effector proteins and the potential role for these lipids as mediators of membrane restructuring. As for the enzyme itself, little is known about its three-dimensional structure or the molecular mechanisms by which multiple activators can synergistically stimulate its activity. A clear understanding of these mechanisms *in vitro* should facilitate investigation of hormonal pathways *in vivo*.

Diacylglycerol Kinases

M. K. Topham and S. M. Prescott

*The Huntsman Cancer Institute and
Department of Internal Medicine,
University of Utah, Salt Lake City, Utah*

Introduction

Many signaling cascades are initiated by phospholipase C (PLC) isozymes. One product of this reaction is diacylglycerol (DAG), a prolific second messenger that activates proteins involved in a variety of signaling cascades. The protein kinase Cs (PKCs) are the best-characterized DAG-activated proteins, but diacylglycerol also activates other proteins [1], including RasGRP and two guanine nucleotide exchange factors (GEFs), CalDAG GEFs I and III. The chimaerins, which are GTPase-activating proteins (GAPs) for Rac, and the *Unc-13* gene product from *Caenorhabditis elegans* also bind to DAG. Because it can associate with a diverse set of proteins, DAG potentially activates numerous signaling cascades. Thus, its accumulation needs to be strictly regulated. Diacylglycerol kinases (DGKs), which phosphorylate DAG, are widely considered to be responsible for terminating diacylglycerol signaling [2,3]. But the product of the DGK reaction, phosphatidic acid (PA), also can be a signal: it can activate phosphatidylinositol 4-phosphate 5-kinases and PKC ζ , participates in recruiting Raf1 to the plasma membrane, and is involved in vesicle trafficking. Because they manipulate both DAG and PA signaling, the DGKs can regulate numerous signaling events.

The DGK Family

DGKs have been identified in most organisms that have been studied, and it appears that they have gained specialization in more complex species. For example, bacteria express only one DGK, which is an integral membrane protein capable of phosphorylating DAG and other lipids such as ceramide. This DGK does not appear to have structural elements that

allow regulation of its activity, indicating that the limiting factor is access to its substrates. With the exception of yeast, in which no DGKs have been identified, higher organisms appear to have several DGKs that can be grouped by common structural elements into five subfamilies. The mammalian DGKs are the best characterized, and nine of them have been identified [2,3]. All of these DGKs have two common structural features: a catalytic domain and at least two C1 domains, which are thought to bind diacylglycerol (Fig. 1). Other structural domains, which form the basis of the five subtypes, appear to have regulatory roles. For example, type I DGKs, α , β , and γ , have calcium-binding EF hand motifs that make these enzymes more active in the presence of calcium. Type II DGKs, δ and η , have pleckstrin homology (PH) domains near their amino termini. DGK δ also has a sterile alpha motif (SAM) at its carboxy terminus that may allow protein-protein interactions. The only type III DGK, ϵ , does not have identifiable structural motifs outside its C1 and catalytic domains. It is interesting that this is the only DGK that displays specificity toward acyl chains of DAG—it dramatically prefers DAGs with an arachidonoyl group at the *sn*-2 position. Type IV DGKs, ζ and ι , have a motif enriched in basic amino acids that acts as a nuclear localization signal and is a substrate for conventional PKCs. This motif is homologous to the phosphorylation site domain of the myristoylated alanine rich C kinase substrate (MARCKS) protein. Type IV DGKs also have four ankyrin repeats at their carboxy termini that may be sites of protein-protein interactions. The only type V DGK, θ , is distinguished by three C1 domains, a PH domain, and a Ras-association (RA) domain. To date, no binding partners for the PH and RA domains have been identified. Based on their structural diversity, the mammalian DGKs likely have specific roles dictated by their unique structural motifs.

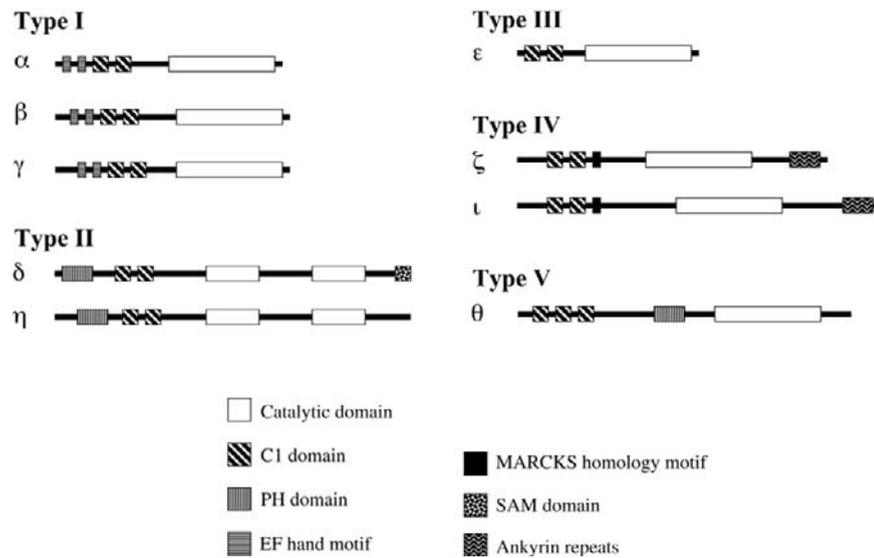

Figure 1 The nine members of the mammalian diacylglycerol kinase family are grouped by sequence homology into five subtypes. Shown are protein motifs common to several DGKs.

Regulation of DGKs

Activation of DGKs is complex, requiring translocation to a membrane compartment as well as binding to appropriate cofactors. Additional regulation of their activity occurs by posttranslational modifications. This complexity allows tissue- or cell-specific regulation depending on the availability of cofactors and the type of stimulus that the cell receives. Tissue-specific alternative splicing of DGKs β and ζ —and probably other isoforms—adds additional opportunities for regulation.

DGK α demonstrates the complex regulation of DGKs. In T lymphocytes, it translocates to at least two membrane compartments depending upon the agonist used to activate the cells. For example, stimulation of T cells with IL-2 causes DGK α to translocate from the cytosol to a perinuclear region [4]. But activation of the antigen receptor causes DGK α to translocate to the plasma membrane [5]. At the membrane, the activity of DGK α can be modified by the availability of several co-factors. Calcium is known to bind to the EF hand structures and stimulates DAG kinase activity *in vitro*, and lipids modify its activity: phosphatidylserine and sphingosine activate DGK α *in vitro* and probably *in vivo*. Finally, DGK α can be phosphorylated by several protein kinases, including PKC isoforms and Src. Although the consequences of these phosphorylations are not clear, evidence suggests that phosphorylation by Src enhances DAG kinase activity [6]. Thus, several events can modify the activity of DGK α , and combinations of them likely allow titration of its activity depending upon the cellular context.

Like DGK α , other DGK isoforms appear to be regulated by access to DAG through membrane translocation and by the availability of lipid or protein co-factors. Members of each DGK subfamily are likely to be regulated similarly, although there probably are subtle differences between

subfamily members due to tissue-specific expression patterns, unique binding partners, alternative splicing, and subcellular localization. Type II DGKs, for example, have a PH domain, and this motif in DGK δ binds to phosphatidylinositols. Sakane *et al.* using an *in vitro* system, could not detect activation of DGK δ by phosphatidylinositols [2], suggesting that binding to these lipids instead provides a localization cue. The activity of types III and IV DGKs can be modified by lipids: DGK ϵ is inhibited by phosphatidylinositols and by phosphatidylserine, while type IV DGKs are activated by phosphatidylserine. Type IV DGKs are also strongly regulated by subcellular translocation. They are imported into the nucleus, which requires their MARCKS homology domain, a nuclear localization signal that is regulated by PKC phosphorylation [7]. There is also evidence that the syntrophin family of scaffolding proteins regulates nuclear import of DGK ζ by associating with its carboxy-terminal PDZ binding domain to sequester DGK ζ in the cytoplasm [8]. And we have observed that DGK ζ has a strong nuclear export signal (M. K. Topham, unpublished). Thus, nuclear accumulation of type IV DGKs is exquisitely regulated, suggesting an important nuclear function for these isozymes. Finally, DGK θ , a type V DGK, can be regulated through its association with active RhoA [3]. Binding to RhoA completely inhibits its DAG kinase activity and is the only example of regulation of a DGK through a protein-protein interaction.

Paradigms of DGK Function

Although there is substantial information regarding their regulation, little is known of the biologic functions of the individual DGKs. But recently, a few paradigms have emerged.

Spatial Regulation of DAG Signaling

Evidence suggests that DGKs selectively associate with and regulate DAG-activated proteins. Van der Bend *et al.* [2] initially tested this concept by either initiating spatially restricted DAG synthesis through receptor activation or by causing nonspecific, global DAG generation with exogenous PLC. They observed DAG kinase activity—measured by generation of PA—following receptor activation, but not after treating the cells with exogenous PLC. Their data demonstrate that DGKs are active only in spatially restricted compartments following physiologic generation of DAG. Recently, more specific examples of spatially restricted DAG kinase function have emerged. We found that DGK ζ associated with RasGRP, a guanine nucleotide-exchange factor for Ras [9]. Their association was enhanced in the presence of phorbol esters, which are slowly metabolized DAG analogues. Since RasGRP requires DAG to function, we hypothesized that DGK ζ associated with it to spatially metabolize DAG and consequently to regulate the function of RasGRP. Indeed, we found that kinase-dead DGK ζ did not affect the function of RasGRP. Demonstrating the specificity of this regulation, we found that five other DAG kinases did not significantly inhibit RasGRP activity. Thus, our data demonstrate that in some cases DAG kinase activity is spatially restricted and serves to specifically regulate DAG-activated proteins.

Nurrish *et al.* presented another example of compartmentalized DGK function [3]. They isolated a *Caenorhabditis elegans* strain resistant to serotonin-induced inhibition of locomotion. The mutated gene responsible for the effect, *dgk-1*, is homologous to DGK θ . Their data suggested a model in which serotonin signaling activated DGK-1 to reduce local accumulation of DAG. This resulted in inhibition of UNC-13, a protein activated by DAG that may mediate acetylcholine release. Thus, their results represent another example of compartmentalized DGK function that modulates the activity of a DAG-activated protein.

Regulation of Signaling Through Fatty Acid Specificity

Inositol phospholipids, including PIP₂, a precursor of DAG, are enriched in arachidonate at the *sn*-2 position. Some DAG targets, including PKCs, are specifically activated by diacylglycerol-containing unsaturated fatty acids, such as arachidonate. So to maintain the integrity of some DAG-activated signaling cascades, it is important that phosphatidylinositols maintain a proper fatty acid composition. Because DGK ϵ selectively phosphorylates arachidonoyl-DAG, the first step in resynthesis of phosphatidylinositols, DGK ϵ may be responsible for their enrichment with arachidonate. Inositol lipid signaling is an important component of neuronal transmission. In a collaborative effort we examined seizure susceptibility in mice with targeted deletion of DGK ϵ [10] and found that the null mice were resistant to seizures induced by electroconvulsive shock.

Examination of brain lipids revealed that compared to wild-type mice, DGK ϵ -deficient mice had reduced levels of arachidonate in both PIP₂ and DAG. This lipid profile demonstrated a critical role for DGK ϵ in maintaining a proper balance of arachidonate-enriched inositol phospholipids. Thus, through its selectivity for arachidonoyl-DAG, DGK ϵ regulates lipid signaling events and, consequently, seizure susceptibility.

Nuclear DGKs

There is a nuclear phosphatidylinositol cycle regulated separately from its plasma membrane/cytosolic counterpart [7]. DAG is present in nuclear preparations and appears to fluctuate with the cell cycle, but the specific pattern of its accumulation is not clear because of the many different methods used to isolate nuclei. DAG kinases have also been observed in nuclei and appear to have a prominent role there. Some DGKs, like DGKs α , ζ , and ι , translocate to the nucleus, while others, like DGK θ , are constitutively located there [3]. These DGKs are confined to specific compartments within the nucleus. For example, both DGK θ and DGK ζ appear in a speckled pattern within the nucleus, while DGK α associates with the nuclear envelope [3]. This compartmentalization suggests that DGK isotypes have specific roles in the nucleus. Movement of proteins in the nucleus largely occurs by random diffusion, so overexpression of one DGK isotype may interfere with the function of another DGK. This fact, combined with the lack of specific DGK inhibitors, has made it difficult to study the nuclear function of the different DGK isotypes. But they are likely to affect nuclear signaling either by terminating DAG signals or by generating PA. For example, in T lymphocytes, the PA produced by nuclear DGK α appears to be necessary for IL-2-mediated progression to S phase of the cell cycle [4]. Conversely, nuclear DGK ζ inhibits exit from G1 phase of the cell cycle by metabolizing DAG [7]. These data indicate both the complexity and importance of lipid signaling and DGK function in the nucleus.

Visual Signal Transduction

A clear role for DGK function has been demonstrated in *Drosophila*. A mutant strain, *rdgA*, undergoes rapid retinal degeneration after birth. The defect is due to a deficiency in retinal DGK activity because of a point mutation that inactivates dDGK2, a DAG kinase very similar to mammalian type IV DGKs. Although there are differences in photoreceptor signaling between *Drosophila* and vertebrates, these observations indicate that DGKs may be functionally important in the vertebrate retina. Three mammalian DGK isoforms, γ , ϵ , and ι , have been definitively localized to the retina, but their functions there have not yet been identified [2]. However, there is evidence of light-dependent activation of PIP₂ hydrolysis and generation of PA in vertebrate retina, indicating a role there for DGK activity.

Conclusions

Diacylglycerol kinases are expressed in all multicellular organisms that have been studied. Their structural diversity and complexity indicate that they are functionally important in a variety of cellular signaling events. Since they can affect both DAG and PA signals, DGK activity plays a central role in many lipid signaling pathways.

Sphingosine-1-Phosphate Receptors

Michael Maceyka and Sarah Spiegel

*Department of Biochemistry, Medical College of Virginia Campus,
Virginia Commonwealth University, Richmond, Virginia*

Introduction

The endothelial differentiation gene (EDG) family of G-protein coupled receptors (GPCRs) comprises high-affinity receptors for the lysophospholipids, lysophosphosphatidic acid (LPA), and sphingosine-1-phosphate (S1P) [1,2]. The homologous EDG receptors are clearly divided into two classes: three that bind LPA (EDG-2/LPA₁, EDG-4/LPA₂, EDG-7/LPA₃) and five that bind S1P (EDG-1/S1P₁, EDG-3/S1P₃, EDG-5/S1P₂, EDG-6/S1P₄, EDG-8/S1P₅). Molecular modeling and targeted mutagenesis have shown that S1PRs and LPARs use very similar motifs for binding of ligands, with one amino acid primarily determining the difference in specificity [3]. As several excellent reviews have recently appeared on LPARs and our studies have concentrated on dissecting molecular signaling pathways regulated by S1P [4,5], we have focused in this chapter on lipid signaling to and through S1PRs.

S1P is formed by sphingosine kinase (SphK), of which there are two known mammalian isoforms (for review, see [6]). SphKs are evolutionarily conserved and catalyze the ATP-dependent phosphorylation of the primary hydroxyl of sphingosine, the common backbone of mammalian sphingolipids. S1P is an interesting molecule that is an intercellular messenger and an intracellular second messenger [7]. This greatly complicates interpretation of results when adding exogenous S1P to cells: Is the response observed due to cell surface receptors, effects on intracellular targets, or both? A preponderance of studies have indicated that many of the biological effects of S1P are mediated by specific S1PRs and the lack of confirmed intracellular targets appears to bolster these claims. However, others have suggested that certain results are better explained by receptor-independent intracellular effects of S1P. First, the well-known S1PRs typically have

K_d s in the 2–30 nM range [2,8], whereas effects of S1P on growth and suppression of apoptosis usually require micromolar concentrations [9]. In addition, dihydrosphingosine-1-phosphate (dhS1P), which has the same structure as S1P but only lacks the 4,5-*trans* double bond, binds to and activates all of the S1PRs. However, dhS1P does not mimic the effects of S1P on growth and survival [10], thus suggesting that these effects are likely to be mediated by intracellular actions of S1P.

The S1PRs

S1P was identified as the natural high affinity ligand of S1P₁ [2], which was shown to be highly specific, only binding S1P and dhS1P [11,12]. S1P₁ is coupled to G_{αi} and G_{αo} [13] but not G_{αs}, G_{αq}, or G_{α12/13} [14]. Thus, pertussis toxin, which inhibits G_{αi/o} proteins, is a useful tool for dissecting signaling through S1P₁. *sIp1* deleted mice died *in utero* between E12.5 and E14.5 due to massive hemorrhaging [15]. Although vasculogenesis and angiogenesis are normal in the *sIp1*^{-/-} mice, vascular smooth muscle cells failed to completely surround and seal the vasculature, thereby leading to hemorrhage. On a cellular level, the defect was linked to an inability of S1P₁ null fibroblasts to migrate toward S1P, likely due to dysfunctional Rac activation, and indicated the important role of S1P/S1P₁ signaling in motility.

S1P₂ is unique in being the only one of the S1PRs with a significantly poorer affinity for dhS1P than S1P [16]. S1P₂ has a wide tissue distribution [17] and a K_d for S1P of 20–30 nM [11]. In addition to G_{αi/o}, S1P₂ couples to G_{αq} and G_{α12/13} [14]. S1P₂ has been linked to increases in cAMP levels and thus may couple weakly to G_{αs} in some cell types depending on the pattern of expression of both GPCRs and

G proteins [18]. S1P₂ regulates diverse signaling pathways, including calcium mobilization, stimulation of NF- κ B, and inhibition of Rac-dependent cell migration in certain cell types [19,20]

S1P₂ has also been knocked out in mice [21] and in contrast to *s1p1*^{-/-} mice, these mice have no obvious anatomical or physiological phenotypes. It is interesting that mammalian S1P₂ is highly homologous to the zebrafish gene *miles apart* [22]. Two inactivating mutations in *miles apart* prevent the normal migration of heart primordia, thus resulting in abnormal cardiac development. The heart precursor cells from the *miles apart* mutants migrated normally when transplanted into wild-type embryos, but wild-type cells failed to migrate in mutant embryos, a result that suggests that the zebrafish S1P₂ homologue is required for generating a migration-permissive environment.

S1P₃ was shown to be activated by S1P [23] with a K_d of 20–30 nM [11,12] and to couple to G_{ai/o}, G_{aq}, and G_{α12/13}, but not G_{os} [14]. S1P₃-null mice have been generated and also have no obvious phenotype [24]. S1P₃ has been linked to many signaling pathways, including calcium mobilization, stimulation of NF- κ B, and NO production [25,26].

The two remaining S1PRs have a more narrow tissue distribution. S1P₄ is expressed almost exclusively in lymphoid and hematopoietic cells, as well as in the lung [27]. S1P₄ has a K_d for S1P of 12–63 nM, as determined by different groups [28,29], and couples to G_{ai/o}. The final S1PR, S1P₅, previously named EDG-8 and *nrg-1*, is expressed predominantly in the central nervous system and to a lesser extent in lymphoid tissue [8,30]. S1P₅ couples to G_{ai/o} and G_{α12/13}, but not to G_{os} or G_{αq} [31] and has a K_d for S1P of 2–6 nM [8,31].

S1P Signaling via S1PRs

Intriguing questions concerning lysolipid messengers are what regulates the levels of these amphipathic molecules and how do they get to their target cells? Platelets are known to store S1P and release it upon stimulation (reviewed in [32]). HUVECs and C6 glioma cells release S1P to the extracellular milieu [33,34]. Moreover, even when S1P release from cells is below detectable limits, co-culturing cells expressing S1P₁ with cells producing S1P due to overexpression of SphK induced activation of S1P₁ on adjacent as well as distant cells, thus indicating either that vanishingly small amounts of S1P are released or that it can be transferred from one cell to another by cell–cell interactions, or both [35]. Thus, S1P can act in an autocrine and/or paracrine manner. In support of this concept, the chemoattractant PDGF recruits SphK to the plasma membrane, where S1PRs are located, and especially to structures known as lamellipodia [36]. Given the importance of lamellipodia and S1PRs in chemotaxis, this finding suggests that S1P is produced and released from the cell in a spatially restricted manner, providing cells with a sense of direction. In addition, a recent report claims that type 1 SphK is secreted from cells in a catalytically active form and may catalyze the formation of S1P at or near the

plasma membrane [33]. Further studies are necessary to confirm a role for extracellular SphK.

Transactivation of S1PRs

An intriguing aspect of the *s1p1*^{-/-} phenotype is that it appears to be nearly identical to that of the PDGF-BB and PDGFR- β knockouts [15], as these embryos also die because of a vascular smooth muscle cell migration defect. Because PDGF stimulates SphK and increases S1P [10], it therefore appeared possible that S1P₁ and PDGF signaling pathways are linked. Indeed, embryonic fibroblasts from *s1p1*^{-/-} mice, in contrast to wild-type cells, failed to migrate toward both S1P and PDGF [35]. Moreover, enforced expression of S1P₁ in HEK 293 cells, which express low basal levels of S1P₁, increased their ability to migrate toward PDGF, and antisense ablation of S1P₁ significantly inhibited migration toward PDGF [36]. A specific inhibitor of SphK also blocked PDGF-induced motility. Taken together, these results suggest a transactivation pathway linking PDGF through SphK to the autocrine and/or paracrine release of S1P that then stimulates S1P₁ to regulate motility. Furthermore, it was independently shown that S1P₁ potentiated the response to PDGF in HEK 293 cells overexpressing PDGFR [37]. However, in this case, these effects appeared to be independent of SphK, and it was suggested that PDGFR and S1P₁ were tethered in a complex that was activated independently of S1P.

Downstream Signaling from S1PRs

Because the S1PRs are coupled to heterotrimeric G proteins, the types of signals transduced are many and varied, depending on the specific isoforms of G α and G $\beta\gamma$ that are present. Thus, signals linked to a S1PR in one cell type may not be linked in the same manner in a second cell type. For example, transfection with S1P₁ increases S1P-induced calcium mobilization in CHO cells [38] but not in COS-7 cells [39]. Determining which specific S1PR is involved in a particular response is difficult because most cells express multiple S1PRs. To date, S1PR specific agonists or antagonists have not been developed. Thus, to elucidate the role of a particular S1PR, either transfection of receptor negative or knockout cells or antisense approaches have been used. Given the diversity of GPCR signaling, it is not surprising that results from these experiments demonstrate that S1PRs control the major lipid-mediated signaling pathways, as discussed below.

Phospholipase C. Many of the responses linked to S1PR signaling involve increases in intracellular calcium. Generation of the second messenger inositol trisphosphate (IP₃) by activation of phospholipase C (PLC) is the major pathway leading to intracellular calcium increases. CHO cells transfected with S1P₁, S1P₂, S1P₃, or S1P₄, but not vector controls, had increased IP₃ production and calcium release in an

S1P-dependent manner [28]. In contrast, in Jurkat T cells, S1P₂ and S1P₃, but not S1P₁, elicited IP₃-mediated calcium responses [25]. On a more physiological level, in HUVECs, which express S1P₁, and to a lesser extent S1P₃, S1P stimulated nitric oxide (NO) production by calcium-dependent epithelial nitric oxide synthase (eNOS) [40]. NO production was blocked by the PLC inhibitor U73122, the calcium chelator BAPTA-AM, and antisense oligonucleotides to S1P₁ or S1P₃, thus demonstrating a role for both S1PRs in activation of PLC. Furthermore, fibroblasts from S1P₃-null mice, but not littermate controls, failed to activate PLC upon S1P addition [24].

Phospholipase D. Another important lipid second messenger is phosphatidic acid (PA), which is generated by activation of phospholipase D (PLD). Overexpression of S1P₁ in HEK 293 or NIH 3T3 cells did not result in activation of PLD [9]. However, in C2C12 skeletal muscle cells, S1P stimulated PLD via either S1P₁, S1P₂, or S1P₃ in a pertussis toxin-sensitive manner [41]. Transfection of either S1P₁ or S1P₂ in C6 glioma cells conferred S1P-dependent PLD stimulation and PA formation [42]. S1P₃ also induced production of PA, specifically through activation of PLD2 in CHO cells [43].

Phosphatidylinositol-3-kinase. Activation of phosphatidylinositol-3-kinase (PI3K) promotes cell survival, cytoskeletal remodeling, and vesicular trafficking [44]. PI3K also promotes activation of the protein kinase Akt in two ways: translocation of Akt to the membrane by binding phosphatidylinositol-3,4-bisphosphate and activation of phosphoinositide-dependent kinases, which phosphorylate and activate Akt (reviewed in [45]). Though the S1PR(s) involved were not identified, S1P induced chemotaxis and angiogenesis of endothelial cells both *in vivo* and *in vitro* in a PI3K- and Akt-dependent manner [46,47]. S1P₁ transiently transfected in COS-7 cells led to activation of Akt, which was inhibited by the PI3K inhibitor wortmannin [48]. Further work from this group implicated G_{βγ} stimulation of the PI3K_β isoforms in S1P-dependent signaling to PI3K [49]. On a more physiological level, ventricular cardiomyocyte hypertrophy induced by S1P was inhibited by both wortmannin and by S1P₁ antibody [50]. S1P₁, S1P₂, and S1P₃ transfected into CHO cells each activated PI3K in response to S1P [43,51]. It is interesting that in this system, S1P₁ and S1P₃ promoted S1P-induced chemotaxis, while S1P₂ inhibited it.

Sphingosine Kinase. S1P has been demonstrated to release calcium from non-IP₃ releasable microsomal stores, though the intracellular receptor(s) are unknown [52–54]. Meyer zu Heringdorf and colleagues demonstrated that HEK 293 cells endogenously expressing S1P₁, S1P₂, and S1P₃ mobilized calcium in response to S1P [55]. However, in these cells, PLC was not activated and there was no measurable production of IP₃. What is especially interesting, they found that S1P stimulated SphK and S1P production, and the increase in S1P levels, as well as calcium release, was

reduced by inhibitors of SphK. S1P production was also completely blocked by pertussis toxin, indicating the involvement of G_i-linked GPCRs in the process. Thus, the remarkable observation was made that extracellular S1P regulates intracellular S1P formation [55].

Introduction

Among LPLs, the biological effects and signaling mechanisms of lysophosphatidic acid (LPA), sphingosine-1-phosphate (S1P), and their receptors (LPA₁₋₃ and S1P₁₋₅) have been studied most extensively [1–4]. The signaling mechanisms of their corresponding choline derivatives, lysophosphatidylcholine (LPC) and sphingosylphosphorylcholine (SPC), however, have been examined to a much lower extent, although their extracellular existence and evidence of their signaling properties have long been recognized.

Addition of a positively charged choline group to the negatively charged phosphate group provides LPC and SPC with zwitterionic and detergent-like properties. In fact, LPC is cell lytic at concentrations >30 μM when bovine serum albumin (BSA) is absent [5]. Moreover, the specific receptors for LPC and SPC were not previously identified. Thus, controversy has arisen as to whether LPC, and possibly SPC, act as specific signaling molecules or molecules modulating cellular functions nonspecifically, and whether their actions are receptor-mediated. This situation has been changed recently with the identification of three G-protein-coupled receptors (GPCRs)—OGR1, GPR4, and G2A—as receptors for LPC and SPC [6–8]. These discoveries provide an intriguing and novel opportunity to study the pathophysiological and functional roles of SPC, LPC, and their receptors.

Physiological and Pathological Functions of LPC and SPC

The potential physiological and pathological functions of LPC and SPC have been recently reviewed [9,10]. While LPA,

S1P, LPC, and SPC may share similar, overlapping, or opposing effects in some cellular systems, each of these lipids may also have its own unique functions. For example, all four of these LPLs have been shown to play some role in wound healing and some inflammatory processes [11–15]. LPA and its receptors are involved in nervous system development, and S1P has been implicated in cardiovascular development [12,16,17]. LPC and SPC are implicated more specifically in diseases involving immunological and inflammatory processes, such as atherosclerosis and systemic lupus erythematosus [18–21].

The metabolic pathways involved in synthesis and release of LPC and SPC are closely related to those of LPA and potentially S1P. A lysophospholipase-D (lysoPLD) activity, which directly converts LPC to LPA, has been reported previously [22,23]. We have recently observed that when sterile, cell-free ovarian cancer ascites samples, but not non-malignant ascites, were incubated at 37°C, LPA levels were increased over time (Fig. 1A). The LPA production was completely abolished when EDTA or EGTA was added to the ascites, indicating that the LPA production in ovarian cancer ascites was probably due to a soluble enzymatic activity that requires bivalent metal ions and calcium. It is interesting that during the same time course, LPC levels were decreased (Fig. 1B), suggesting that a lysoPLD-like activity may be responsible for LPA production in ovarian cancer ascites. Furthermore, SPC is a substrate for bacterial PLD (unpublished observations), and thus SPC may be converted to S1P in mammalian cells *in vivo*, although such an endogenous activity has not been identified. These data support the notion that the physiological roles of LPLs may be closely related and intertwined and therefore may play a more complex role *in vivo* than what is observed *in vivo* when a single LPL is tested.

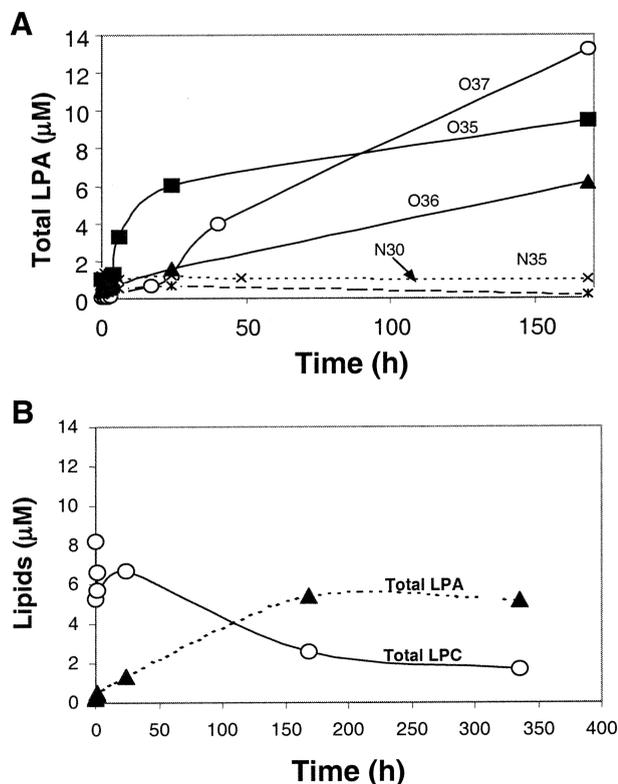

Figure 1 LPA production and LPC degradation in ascites samples. The ascites samples were incubated at 37°C for different durations as indicated, and then quantitatively analyzed for LPA and LPC content by ESI-MS [34,35]. (A) LPA production in ascites from patients with ovarian cancer (O35, O36, and O37) and nonmalignant diseases (N30 and N35). (B) LPC reduction and LPA production in ascites from a patient with ovarian cancer.

Identification of Receptors for SPC and LPC

The identification of receptors for SPC and LPC first began with the cloning of OGR1 from the HEY ovarian cancer cell line by using a PCR-based cloning strategy with primers based on the sequences of receptors for platelet-activating factor (PAF) and thrombin [24]. OGR1 shares approximately 30% sequence homology with the PAF receptor, a finding that indicated that the ligand for OGR1 may be also a lipid molecule and may also contain a choline group. Functional analyses were performed, which provided evidence for OGR1 as the first high-affinity receptor identified for SPC [6]. Similar studies were performed to determine whether SPC and/or LPC are ligands for GPR4 and G2A [7,8]. OGR1, GPR4, and G2A have no or very low affinity to LPA, S1P, PAF, lyso-PAF, lysophosphatidylinositol (LPI), PAF, sphingomyelin, ceramide, psychosine, glucosyl- β 1,1'-sphingosine (Glu-Sph), galactosyl- β 1,1'-ceramide (Gal-Cer), and lactosyl- β 1,1'-ceramide (Lac-Cer) [6–8]. TDAG8, a fourth related receptor that is 36% homologous to OGR1, has been recently identified as a receptor for a glycosphingolipid, psychosine (galactosyl- β 1,1'-sphingosine) [25]. Due to the relative high homologies of these receptors, the potentials exist for TDAG8 to also be a LPC/SPC receptor and/or for OGR1, GPR4, and G2A to be receptors for psychosine.

Although LPA/S1P and SPC/LPC subfamily receptors are GPCRs for structurally related lysolipids, the two receptor subfamilies share little sequence homology and may prefer different G-protein coupling in certain signaling pathways. Evidence supports that three major G protein families (G_i , G_q , and $G_{12/13}$) are coupled to these receptors. Compared to the majority of GPCRs, which employ G_q as a mediator for calcium mobilization, SPC- and LPC-induced calcium release from intercellular stores are mediated through G_i in MCF10A cells, although other cell lines remained to be tested. Furthermore, while ERK activation via GPCRs is mainly mediated through G_i , SPC-induced PI3K and ERK activation via OGR1 appear to be mediated by a PTX-insensitive G protein ([6] and unpublished observations). Nonetheless, these differences are not restricted to LPC/SPC receptors. G_i -mediated calcium release and G_q -mediated PI3K and ERK activation have been reported previously [26–29].

The K_d values for LPC/SPC ligand binding are about one to two orders of magnitude higher than those for LPA/S1P receptors. Likewise, the serum and plasma concentrations of LPC are usually one to two orders of magnitude higher than those of LPA. Thus, the K_d values of their receptors may reflect a physiological adaptation to their concentrations. At the normal physiological concentrations of LPC (5–180 μ M), if all of the LPC were in an active form, then its receptors would be saturated, downregulated, and/or desensitized. However, *in vivo*, the functionally available concentration of LPC may be affected by such conditions as percentage of LPC bound to albumin or lipoprotein and compartmentalization (i.e., tissue, cellular, and subcellular distribution) of LPC [30–32]. The concentrations of both S1P and SPC in physiological fluids are in the nM to sub- μ M range. The lower affinity of SPC for its receptors may suggest (1) a physiological adaptation for a lower response to SPC; (2) the presence of a different, higher-affinity receptor(s) for SPC, which cannot be ruled out; and (3) these receptors (LPC/SPC subfamily receptors) may have different endogenous ligand(s). These issues remain to be further investigated.

Perspectives

Until now, very limited information has been accumulated regarding the pathophysiological functions of SPC, LPC, and their receptors. G2A-null mice develop a late-onset autoimmune disease [33]. Some of the effects of G2A may be compensated by other LPC receptors. Generation of OGR1- and GPR4-null mice is in progress and will provide important information about the physiological functions of these receptors. Comparative studies between LPA/S1P and LPC/SPC may generate interesting data to advance our understanding of these lipids, since: (1) LPA and S1P are prototypes of bioactive extracellular lipid signaling molecules; (2) LPC and SPC share similar, yet distinct signaling pathways as those induced by LPA and S1P; (3) the metabolic pathways LPA/S1P and LPC/SPC; are linked between and (4) all of these LPLs are present in serum and plasma. LPA, SPC, and

LPC levels are elevated under pathological conditions. It can be foreseen that the identification of their receptors will facilitate our understanding of the roles these LPLs play in physiological and pathological processes.

The Role of Ceramide in Cell Regulation

Yusuf A. Hannun and L. Ashley Cowart

*Department of Biochemistry and Molecular Biology,
Medical University of South Carolina,
Charleston, South Carolina*

During the past several years there has been a dramatic increase in information on the role of ceramide in many cellular events. Many excellent and thorough reviews have been written on ceramide; therefore, the purpose of this chapter is to offer the reader a starting point in the body of literature focused on the role of ceramide in cell regulation.

Ceramide-Mediated Cell Regulation

Ceramide is involved in several cellular processes, including apoptosis, cell senescence, differentiation, and cell stress. Many cytokines and stress agents, such as tumor necrosis factor (TNF) heat, and chemotherapy agents induce the production of ceramide, and several studies suggest critical roles for ceramide in regulating specific cell responses to these agents (Fig. 1). For example, augmentation of ceramide levels can lead to apoptosis in many cancer cells, whereas inhibition of ceramide formation can attenuate apoptosis in many, but not all, cell types and in response to several agonists. In other cell types, such as endothelial cells and fibroblasts, ceramide is more closely related to cell cycle arrest, differentiation, and senescence rather than apoptosis [1].

Biochemical Pathways of Ceramide Generation

De Novo Biosynthesis

The sphingolipid class of cell membrane lipids includes the sphingoid bases, ceramides (sphingoid bases with N-linked acyl groups), and complex sphingolipids based on ceramide

and containing polar head groups. The committed step in sphingolipid biosynthesis is the condensation of palmitate with serine, which is catalyzed by serine palmitoyltransferase (SPT), a pyridoxal 5'-phosphate-dependent enzyme composed of two subunits and requiring (at least in yeast) another small subunit for maximal activity [2]. SPT generates 3-ketosphinganine, which is then reduced to dihydrosphingosine (DHS). The N-linked addition of a fatty acid to DHS, catalyzed by dihydroceramide synthase, yields dihydroceramide, which is subsequently desaturated to form ceramide in mammalian cells, or hydroxylated to form phytoceramide in yeast. From ceramide a variety of complex sphingolipids are derived. For example, complex glycosphingolipids including cerebrosides are formed by the addition of sugar groups to the ceramide backbone, and gangliosides are formed by the further addition of sialic acid. Sphingomyelin (SM) is generated by the transfer of a phosphocholine headgroup from phosphatidylcholine to ceramide. Each of these sphingolipid classes has distinct structural and/or functional roles [3].

Importantly, Fas, TNF, B-cell receptor stimulation, angiotensin II, palmitate loading, several chemotherapeutic agents (such as etoposide, CPT-11, and daunorubicin), phorbol esters, and UV radiation have been shown to activate the *de novo* pathway, leading to ceramide accumulation. Inhibition of this pathway with either myriocin, an SPT inhibitor, or with Fumonisin B₁, an inhibitor of dihydroceramide synthase, blocks formation of ceramide and attenuates the apoptotic response to these agents, thus implicating this pathway in the regulation of apoptosis [2]. Also, overexpression of glucosyl ceramide synthase (GCS), which clears

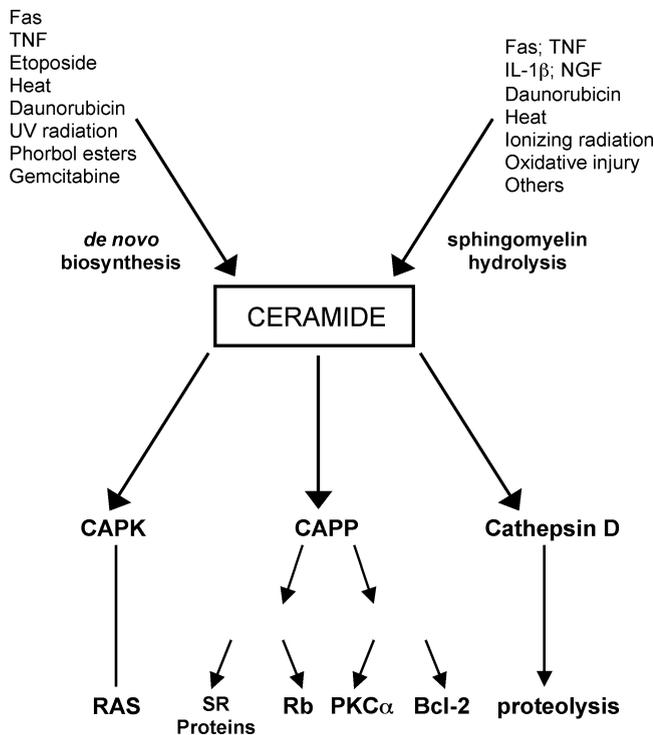

Figure 1 Several mechanisms of ceramide mediation of cell responses to extracellular signals.

ceramide (possibly with preference to *de novo* generated ceramide), attenuates apoptotic responses.

The Sphingomyelin Cycle

Ceramide can also be formed from hydrolysis of complex sphingolipids by stepwise removal of headgroups. Thus, sphingomyelinases (SMases) catalyze hydrolysis of SM, generating ceramide and phosphorylcholine. SM-derived ceramide can then act as a lipid mediator, undergo cleavage into sphingoid bases, or be reincorporated into SM, the latter completing the SM cycle. There are several different sphingomyelinase isoforms, displaying different pH optima, subcellular localization, and cofactor requirements [4].

SMase-derived ceramide has been shown to be an important component of the cell response to factors such as TNF, FAS, IL-1 β , Ara-C, heat, and ionizing radiation. Cellular activities of ceramide derived from SM hydrolysis depend on the subcellular colocalization of the SMase as well as the SM pool, and studies suggest that the topology of ceramide production by SMase is a key factor in determining ceramide's ultimate cellular effects [4]. For example, recent results suggest that SM hydrolysis in the mitochondrion is sufficient to promote apoptosis [5], whereas ceramide at the membrane inhibits protein kinase C (PKC) translocation [6] and augments Fas action [7].

Moreover, as subsequent resynthesis of sphingomyelin from SMase-generated ceramide consumes phosphatidylcholine, yielding diacylglycerol (DAG), the dual action of SMase and SM synthase plays a role in the regulation of both ceramide and DAG, another important lipid mediator,

primarily through activation of PKC, whose effects are often antagonistic to those of ceramide [4].

Ceramide Targets

Several important biochemical signaling pathways are regulated by ceramide, including pathways of stress and apoptosis. There are several key enzymes regulated by ceramide *in vitro*; thus serving as direct targets of ceramide, mediating at least some of its effects on these pathways.

CAPK

A ceramide-activated kinase activity which phosphorylates Raf has been shown to be the same as the kinase suppressor of Ras (KSR). KSR is activated by cytokine-induced ceramide production, coupling agents such as TNF α to apoptosis through regulation of MAP kinase pathways [8]. Other protein kinases for which there is evidence for direct ceramide-activation include PKC ζ [9] and Raf [10].

CAPP

The discovery that ceramide specifically increased phosphatase activity in crude cell extracts resulted in the purification of the activity and subsequent identification of protein phosphatase 2A (PP2A) and protein phosphatase 1 (PP1) as ceramide-activated protein phosphatases (CAPP) [11]. Indeed, ceramide causes dephosphorylation of several key phosphoproteins with important roles in cell regulation. For example, inhibitors of ceramide biosynthesis blocked the TNF-induced, PP2A-dependent, dephosphorylation of PKC α , thus providing strong evidence for the involvement of *de novo* synthesized ceramide in PKC α regulation. Ceramide generation has also been shown to couple TNF α to the dephosphorylation of c-jun via PP2A. Furthermore, ceramide activation of PP2A caused dephosphorylation of bcl-2 and blocked its anti-apoptotic effects. Akt, a kinase involved in insulin signaling, mitogenesis, and apoptosis, has been shown to be dephosphorylated and inhibited in response to ceramide. Also, ceramide induces the PP1-mediated dephosphorylation of the retinoblastoma gene product (Rb), a key regulator of the cell cycle. Additionally, data indicate that the FAS-mediated dephosphorylation of SR proteins, which play important roles in mRNA splicing, is mediated by ceramide activation of PP1.

Cathepsin D

Cathepsin D is a lysosomal protease that has recently been shown to be activated by ceramide *in vitro*. Association of ceramide with the pre-pro cathepsin D causes autocatalytic cleavage to produce the 32-kDa active protease [12], which is thought to mediate several apoptotic events. This is particularly interesting as it presents a novel mechanism of ceramide-mediated responses independent of protein

phosphorylation, and it highlights the compartment-specific functions of ceramide.

Mechanisms of Ceramide-Protein Interaction

Mechanisms of ceramide activation of these proteins are far from fully understood, however, some proteins that interact with ceramide have cysteine-rich domains which have been hypothesized to accommodate protein-ceramide interaction [13], but this has not been demonstrated. On the other hand, many ceramide-interacting proteins, including PP1 and PP2A, lack such domains. Therefore more research is needed to define ceramide-binding motifs.

Physical Properties of Ceramide

Because sphingolipid-enriched lipid microdomains such as rafts and caveolae exhibit distinct biophysical properties, it is possible that some of the described effects of ceramide are mediated via organization of such structures and/or assembly of signaling complexes [14]. Furthermore, ceramide is located in the membrane fractions of cells, and, based on its biochemical and biophysical properties, ceramide should not diffuse freely throughout the cell [15].

Conclusions

The field of ceramide signaling has rapidly expanded as studies reveal diverse roles for ceramide in cell biology and mechanisms of its regulation and action. Priorities for further study include determining the downstream actions of ceramide on protein targets that mediate specific cellular responses as well as determining the upstream events leading to ceramide production. Other key areas in need of further investigation include the subcellular localization of the substrates, enzymes, and protein targets of these sphingolipid signaling cascades.

Introduction

Phospholipase A₂ (PLA₂) has attracted considerable interest in view of its role in lipid signaling and its involvement in a variety of inflammatory conditions. PLA₂ cleaves the sn-2 ester bond of cellular phospholipids, producing a free fatty acid and a lysophospholipid, both of which are implicated in lipid signaling. The free fatty acid produced is frequently arachidonic acid (AA, 5,8,11,14-eicosatetraenoic acid), the biosynthetic precursor of the eicosanoid family of potent inflammatory mediators that includes the prostaglandins, thromboxane, leukotrienes, and lipoxins. The other product of PLA₂ action on phospholipids is a lysophospholipid, which, depending on its molecular composition, may be converted into platelet-activating factor, another potent inflammatory mediator.

Phospholipase A₂ (PLA₂) consists of a superfamily of enzymes that catalyze the hydrolysis of the sn-2 ester bond in phospholipids, generating a free fatty acid and a lysophospholipid. This reaction is of the utmost importance in the context of cellular signaling, since it constitutes the main pathway by which arachidonic acid (AA) is liberated from phospholipids. Free AA is the precursor of a large family of compounds known as the eicosanoids, which includes the cyclooxygenase-derived prostaglandins and the lipoxygenase-derived leukotrienes [1]. If the other product of PLA₂ action on phospholipids is a choline-containing lysophospholipid possessing an alkyl linkage in the sn-1 position, then an acetyltransferase can act upon it to produce platelet-activating factor (PAF, 1-O-alkyl-2-acetyl-sn-3-phosphocholine).

The importance of the eicosanoids and platelet-activating factor as key mediators of inflammation as well as other pathophysiological conditions is now universally accepted [1]. Aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) are well established as cyclooxygenase inhibitors, and are widely used in clinical practice. Similarly, the pharmaceutical industry has been actively pursuing lipoxygenase inhibitors and receptor antagonists for both leukotrienes and PAF. Note that since prostaglandins, leukotrienes, and PAF all derive from the action of a PLA₂, direct inhibition of such an enzyme would have the potential of blocking all three of the pathways at once, which could be of therapeutic advantage in certain settings. This is why the pharmaceutical industry has been actively pursuing the design of drugs with potential anti-PLA₂ effects, and some compounds are now in advanced clinical trials. Furthermore, cPLA₂ knock-outs show distinct advantages in certain diseases [2,3].

The above approach is hampered, however, by the fact that cells in general contain multiple PLA₂ enzymes. For example, in humans, no less than 15 different proteins have been identified to possess PLA₂ activity [4]. Thus a first step in a rational PLA₂ drug design strategy is to define the different PLA₂ classes present in cells, as well as their putative roles in eicosanoid and PAF synthesis.

PLA₂ Groups

PLA₂s have been systematically classified according to their nucleotide sequence [4]. The latest update to this classification,

published in October 2000, included eleven groups, most of them with several subgroups [4], but new PLA₂ enzymes have been described since, leading to a twelfth group [5–7]. Only PLA₂s whose nucleotide sequence has been determined should be included in the classification. However, this obvious criterion is the cause of some confusion, since many reports have appeared that erroneously link certain enzyme activities and functions to particular PLA₂ groups without it having been verified that such an association actually exists.

A parallel classification of the PLA₂s on the basis of biochemical properties is also frequently used, and it has value in describing PLA₂ activities for which sequence data are unavailable. This classification contemplates three main PLA₂ classes based on whether the enzyme is secreted (sPLA₂), cytosolic Ca²⁺-dependent (cPLA₂), or cytosolic Ca²⁺-independent (iPLA₂). One must be aware of the fact that this classification is not devoid of problems either, e.g. the Group IVC PLA₂ is generally referred to as cPLA₂-γ, despite its being a Ca²⁺-independent enzyme. In addition, the PAF acetylhydrolase PLA₂s (Groups VII and VIII) also distribute among these categories.

Generally, the sPLA₂s (Groups I, II, III, V, IX, X, XI, XII) require millimolar levels of Ca²⁺ for activity, have low molecular masses, and lack specificity for arachidonate-containing phospholipids. The cPLA₂s (Group IV, comprising three subgroups) have higher molecular masses, require Ca²⁺ for translocation to membranes but not for activity, and are selective for arachidonate-containing phospholipids. Finally, the iPLA₂s (Group VI, and also Group IVC; see above) have high molecular masses but are not selective for arachidonate-containing phospholipids [4].

Cellular Function

A key determinant of the role of PLA₂s in a given cellular function is the mechanism of PLA₂ regulation/activation during such a process. A myriad of agents that exert effects on cells via receptor-dependent or independent pathways elicit a series of signals that ultimately lead to increased PLA₂ activity. Elucidation of these signals has been the subject of much effort for the last ten years [8]. The situation is further complicated by the evidence that most cells contain several PLA₂ forms and that all of them may eventually participate in the signaling process. Figure 1 shows the PLA₂ signal transduction mechanism developed over the years in our laboratory for the P388D₁ macrophage-like cells.

The scheme shown in Fig. 1 has been generally confirmed by many other laboratories and thus can be regarded as the currently accepted paradigm of PLA₂ signaling in immunoinflammatory cells. The cells may respond to two different kinds of signals that generate either a delayed response (bacterial lipopolysaccharide, LPS) or an immediate one (PAF). LPS acts primarily by inducing the cells to synthesize new proteins involved in the process. However, PAF acts on preexisting proteins. In either case, the foremost event is the translocation and activation of the cPLA₂ in an intracellular compartment. The mechanism of activation of this enzyme has been the subject of many studies, and generally involves the concerted action of the mitogen-activated protein kinase (MAPK) cascade and transient elevations of the intracellular Ca²⁺ concentration [9]. There are a few exceptions however, in which cPLA₂ activation has been described as being activated in a Ca²⁺-independent manner [10] and/or

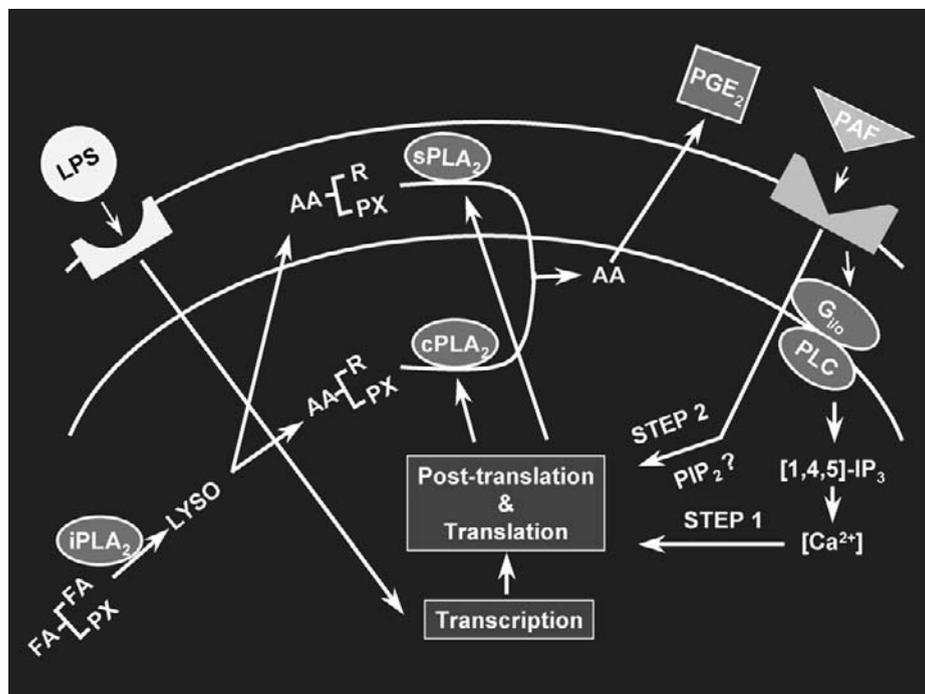

Figure 1 Signal transduction mechanism in P388D₁ macrophages. Adapted from [13].

phosphorylated by kinases not of the mitogen-activated protein kinase family [11].

Activation of the cPLA₂ is followed by activation of a sPLA₂, which, depending on cellular type, may belong to Groups IIA, V, or perhaps other groups. Depending on the stimulation conditions, the cPLA₂ modulation of sPLA₂ cellular activity may occur at a gene regulatory level (delayed responses) [12] or at the level of regulation of enzyme activity itself (immediate responses) [13]. In the latter case, a variety of cellular mechanisms may account for this activation, from cPLA₂-induced rearrangement of membrane phospholipids that enables further sPLA₂ attack to more sophisticated biochemical mechanisms such as inactivation of endogenous sPLA₂ inhibitors or Ca²⁺ fluxes. While it is clear that the cPLA₂ acts on perinuclear membranes, the precise site of action of the sPLA₂ has been the subject of numerous recent studies. The enzyme appears to be released to the extracellular medium, from which it re-associates with the outer cellular surface, where it hydrolyzes phospholipids. However, recent studies have suggested that the enzyme is re-internalized deep into the cell, probably via the caveolin system to the vicinity of nuclear membranes [14]. Whether the enzyme is still active in the cellular interior or this represents a signal termination mechanism is unclear at present [15]. This is currently an area of active study.

Free arachidonate generated by both cPLA₂ and sPLA₂ should be readily converted to prostaglandins and other eicosanoids by the cyclooxygenases and/or lipoxygenases. These eicosanoids are subsequently secreted to the extracellular medium, where they can act in both autocrine and paracrine manners.

Summary

The model depicted in Fig. 1 contemplates a scenario where the concerted action of two distinct PLA₂s leads to a full AA release response. The cPLA₂ appears to initiate the response and plays primarily a regulatory role, whereas the sPLA₂ acts in a second “wave” to amplify the response by providing the bulk of the AA liberated. Needless to say, in those cells that do not express a sPLA₂, the cPLA₂ would be the only one responsible for the release.

Cells usually also contain measurable levels of iPLA₂. This enzyme is frequently suggested to play a role in AA mobilization and eicosanoid production [16]. However, such an involvement remains controversial because practically all the evidence favoring this view has been inferred from studies utilizing bromoenol lactone, a compound that manifests high selectivity for the iPLA₂ *in vitro* but fails to do so *in vivo*. For example, a recent report has shown that the cPLA₂ counts among the cellular targets of bromoenol lactone in cells [17]. The iPLA₂ may also be involved indirectly in AA mobilization by modulating fatty acid reacylation reactions. The lysophospholipids produced by the iPLA₂ may be

used to re-incorporate part of the fatty acids (including AA) that have previously been released by its Ca²⁺-dependent counterparts. Thus, by regulating AA reacylation reactions, the iPLA₂ may participate in the formation of the cellular AA pools. Thus, all three types of PLA₂ (sPLA₂, cPLA₂, iPLA₂) appear to serve important but distinct functions in cells.

Introduction

Arachidonic acid (AA), a 20-carbon unsaturated fatty acid containing four double bonds ($\Delta 5,8,11,14$; C20:4), circulates in plasma in both free and esterified forms and is a natural constituent of the phospholipid domain of cell membranes. AA is mobilized for release by phospholipases (PLs) A₂, particularly type IV cytosolic (c) PLA₂, [1] following its calcium-dependent translocation to the nuclear membrane and the endoplasmic reticulum (Fig. 1). Three major groups of enzymes, prostaglandin G/H synthase (PGHS), lipoxygenase, or cytochrome p450, then catalyze the formation of the prostaglandins (PGs) and thromboxane A₂ (TxA₂), the leukotrienes, or the epoxyeicosatrienoic acids, respectively. Collectively, these products are known as eicosanoids. A parallel family of free radical catalyzed isomers, the isoeicosanoids, are formed by direct peroxidation of AA *in situ* in cell membranes [2]. This chapter will focus on the PGs and TxA₂, collectively termed the prostanoids.

The Cyclooxygenase Pathway

Prostanoids are formed by the action of PGHS, or cyclooxygenase (COX), on AA to form bisenoic products containing two double bonds, denoted by a subscript 2, (e.g. PGE₂ [3]). COX-1 or COX-2 dimers [4], homotypically inserted into the ER membrane, contain both cyclooxygenase and hydroperoxidase activities [3]. AA is sequentially transformed into the unstable cyclic endoperoxides, PGG₂ and PGH₂, for delivery to downstream isomerases and synthases to generate TxA₂ and D, E, F, and I series PGs (Fig. 1). It is presently not understood either how AA is delivered specifically to COX or how PGH₂ is presented to downstream enzymes. Two COX genes have been identified: COX-1 is expressed constitutively in most cells while COX-2 is upregulated by cytokines, shear stress, and tumor promoters [3].

These observations suggest housekeeping functions, such as gastric epithelial cytoprotection and hemostasis, for COX-1-derived prostanoids, although it appears that both enzymes contribute to the generation of autoregulatory prostanoids. Conversely, the inducible COX-2 is considered the dominant source of prostanoid formation in inflammation and cancer, although both isozymes can contribute to prostanoid formation in syndromes of human inflammation, including atherosclerosis [5] and rheumatoid arthritis [6].

COX-1 and COX-2 are closely related in their amino acid sequence [7] and crystal structure [8]. Although both isozymes demonstrate similar subcellular distribution [9], preference for downstream enzymes is sometimes evident in heterologous expression systems and apparently *in vivo*. COX-1 preferentially couples with TxS, PGFS [10], and the cytosolic (c) PGES isozymes [11]. COX-2 prefers PGIS [10] and the microsomal (m) PGES isozymes, which are induced by cytokines and tumor promoters [12]. Two forms of PGDS [13,14] and PGFS [15,16] have been identified, underscoring the diversity of the isomerases and synthases.

COX Deletion Deletion of COX-2 results in multiple defects of implantation and reproduction, leading to breeding difficulties [17]. Offspring have variably revealed cardiac fibrosis, renal defects and impaired inflammatory responses; however, the extent to which these phenotypes are modulated by genetic background is presently unclear. Impaired inflammatory responses [18] and delayed parturition [19] secondary to COX-1 deletion have been reported. Deletion of the COX-2 but not the COX-1 gene increases the frequency of patent ductus arteriosus (PDA) in newborn pups [20]. Coincidental deletion of COX-1 increases the frequency of the COX-2 knockout PDA phenotype [20]. It is the absence of PGE₂ that underlies this phenotype; deletion of 15 PGE₂ dehydrogenase, the major inactivating enzyme of PGE₂, produces sustained high levels of PGE₂ throughout the perinatal period and results in ductal closure [21]. Both COX-1 and

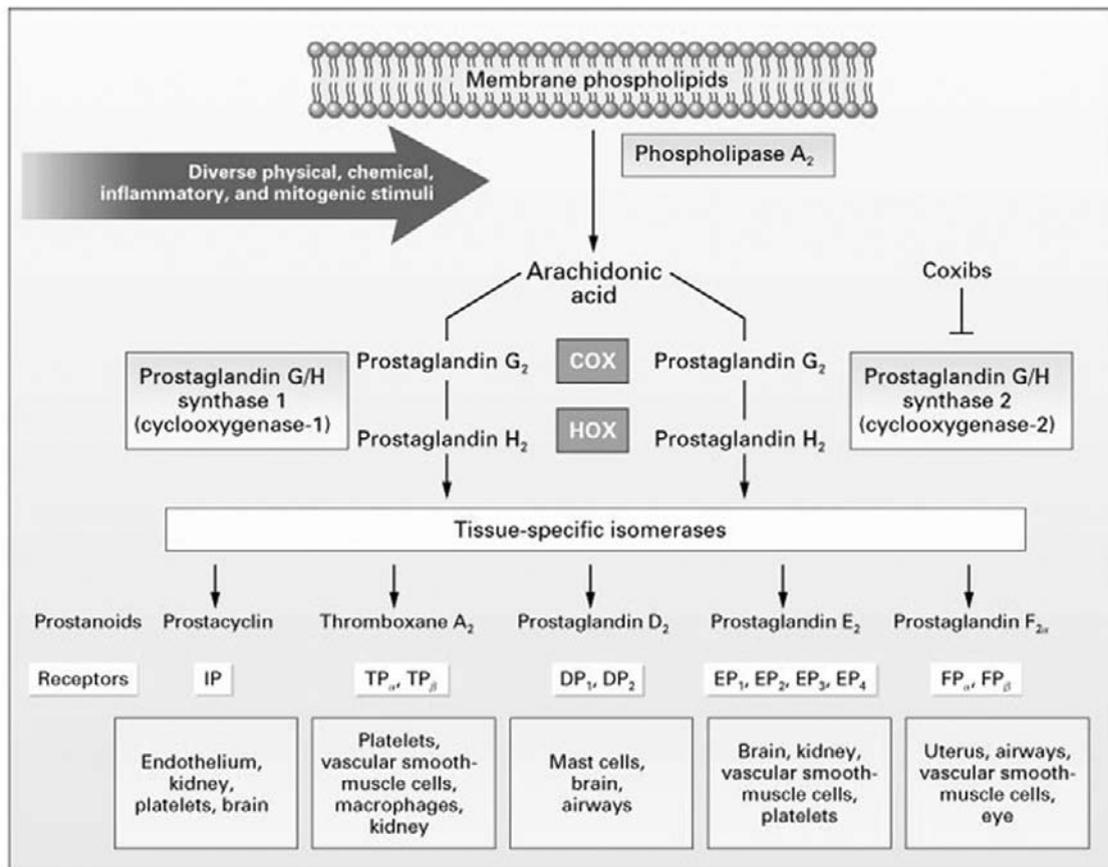

Figure 1 Production and actions of prostanoids: Arachidonic acid, a 20-carbon fatty acid containing four double bonds, is liberated from the *sn2* position in membrane phospholipids by PLA₂. COX converts arachidonic acid to the unstable intermediate prostaglandin H₂, which is converted by tissue-specific isomerases to multiple prostanoids. These bioactive lipids activate specific cell-membrane receptors of the superfamily of GPCRs.

COX-2 are subject to developmental regulation, and interference with their developmental expression may condition adult phenotypes [22]. COX-1 and COX-2 are expressed in a spatially and temporally segregated manner during thymic development, where they influence T-cell maturation [23].

Prostanoid Receptors

Due to their short half lives (seconds to minutes), prostanoids act as autacoids, rather than circulating hormones, by activating membrane receptors at, or close to, the site of their formation. Specific G-protein-coupled receptors (GPCRs) have been cloned for all the prostanoids [24]. A single gene product has been identified for prostacyclin (the IP), PGF_{2α} (the FP), and TxA₂ (the TP), while four distinct PGE₂ receptors (the EP₁₋₄) and two PGD₂ (DP₁ and DP₂) have been cloned. The prostanoid receptors appear to derive from an ancestral EP receptor and share high homology [24]. Phylogenetic comparison of this family reveals three sub-clusters: first the EP₂, EP₄, IP, and DP₁, the relaxant receptors, which increase cAMP generation; second EP₁, FP, and TP, the contractile receptors, which increase intracellular calcium levels; and third the EP₃, which elevates intracellular

calcium and decreases cAMP [24,25]. The DP₂, a member fMLP receptor superfamily [26,27], is the exception to this characterization. Differential mRNA splicing gives rise to additional isoforms of the TP (α and β) [28], FP (A and B) [29], and EP₃ (A–D) [30]. The prostanoid receptors have been reviewed thoroughly elsewhere [24,31].

Thromboxane A₂ (TxA₂)

TxA₂, the major product of platelet COX-1, is a potent vasoconstrictor [32], mitogen [33] and platelet activator [34]. Despite the diversity of platelet agonists, inhibition of platelet TxA₂ formation apparently accounts for cardioprotection from aspirin [35], reflecting the importance of TxA₂ as an amplification signal for more potent agonists, such as thrombin and ADP [34]. TxA₂, also a major product of macrophage COX-2, contributes to atherogenesis in mouse models [36]. Analogous to its role in vascular proliferation (see below), TxA₂ may also mediate cellular hypertrophy [37].

Two forms of the platelet TP have been segregated pharmacologically, one mediating shape change, the other aggregation [38]. However, the cloned human TP splice variants (splice variants of the mouse TP are not apparent),

do not account for this distinction, and TP α is apparently the sole isoform expressed in platelets [39,40]. Recognized differences between the splice variants are limited to G-protein activation in heterologous expression systems [41,42] and agonist-induced desensitization and sequestration [43,44]. Given the identification of distinct low homology GPCRs mediating ADP-induced platelet shape change and aggregation [45], it seems likely that at least one more distinct TP remains to be identified. In this regard, evidence suggests that iPF_{2 α} -III, an isoprostane, acts *in vivo* at the TP [46] but does not bind to either isoform *in vitro* [47], further suggesting the existence of another TP. Distinct receptor sites can be generated through GPCR heterodimerization [48]. It is interesting that TP α and TP β appear to dimerize, and their coexpression augments iPF_{2 α} -III signaling compared to either receptor alone [49]. The extent to which associations between TP α with TP β , and/or other prostanoid receptors, might contribute to the family of prostanoid receptors remains to be examined. The cloned TPs couple via G_q, G₁₁, G_{12/13}, and G_h (which is also tissue transglutaminase II) to activate PLC-dependent inositol phosphate generation and elevate intracellular calcium [24,31]. Activation of the TP isoforms may also activate or inhibit adenylyl cyclase, via G_s (TP α) or G_i(TP β), respectively, and signal via G_q and related proteins to MAP kinase signaling pathways.

TP mRNAs are expressed widely in lung, liver, kidney, heart, uterus, and vascular cells with TP α usually the predominant isoform [50]. Despite reports of abundant TP expression in thymus, the role of TxA₂ in lymphocyte development and function is presently unclear. A naturally occurring mutation in the first intracellular loop of the TP is associated with a mild bleeding disorder and platelet resistance to TP agonists [40], while a polymorphism in the TP has been linked to bronchodilator resistance in asthma [51].

TP Deletion, Overexpression Deletion of the TP reveals a mild haemostatic defect and resistance to AA-induced platelet activation [52], reflecting the role of TxA₂ in vascular biology. TP null mice have reduced proliferative responses to vascular injury, while the opposite is true of mice engineered to overexpress TP β in the vasculature [53]. TP β overexpressors also develop a syndrome reminiscent of intrauterine growth retardation, probably secondary to placental ischemia [54].

Prostacyclin (PGI₂)

A major product of COX-2 in healthy individuals [55], PGI₂ is a potent vasodilator, inhibitor of platelet aggregation by all recognized agonists [56], and an inhibitor of cell proliferation *in vitro* [57]. PGI₂ biosynthesis is increased in syndromes of platelet activation [58,59], perhaps as a homeostatic response to accelerated platelet-vascular interactions. Chronic PGI₂ treatment can reduce pulmonary vascular resistance in patients with primary pulmonary hypertension [60]. Delivery of the gene for PGIS *in vivo* diminishes vascular smooth muscle cell proliferation and migration in response

to injury [61]. PGIS polymorphs have been associated with essential hypertension [62] and myocardial infarction [63], while PGI₂ attenuates angiotensin II-induced renal vasoconstriction and systemic hypertension [64]. PGI₂ also attenuates the response to thrombotic stimuli in dogs [65] and specifically limits the effects on TxA₂ on platelets and the vessel wall in mice [53].

The sole identified IP couples to activation of adenylyl cyclase via G_s, although it can also activate phospholipase C via G_q. IP mRNA is abundantly expressed in kidney, where PGI₂ may regulate renal blood flow, renin release, and glomerular filtration rate and in lung, where PGI₂ can modulate vascular tone [24,31]. The IP is also expressed in the spinal column, where PGI₂ plays a role in pain perception, and in the liver, where its role is unknown. Expression within the cardiovascular system is most abundant in the aorta, consistent with the major biological role of PGI₂ in platelet and macrovascular homeostasis. IP expression in the heart, together with reports that COX-2-dependent PGI₂ formation limits oxidant-induced injury in cardiomyocytes [66], suggests a possible protective role for PGI₂ in cardiac tissue. A major difference between humans and rodents is the marked expression of IP in the thymus [67], although the functional relevance of this observation is not clear.

It is likely that at least one other IP remains to be identified. Pharmacologically distinct IP sites in the brain and kidney are not attributable to the cloned IP [68,69]. In addition, PGI₂ may activate the peroxisome proliferator activated receptors (PPARs). However, while both PGI₂ and iloprost activated PPAR α and PPAR δ *in vitro*, another PGI₂ analog, cicaprost, did not [70], and it is as yet unclear whether PGI₂ activation of PPARs occurs *in vivo*. The loss of PGI₂-mediated PPAR δ activation was thought to underlie the implantation defect in COX-2-deficient mice, although no implantation defect was evident in PPAR δ -deficient mice [71]. Two IP polymorphs, with some alterations in ligand binding and signaling in overexpression systems, have been identified [72].

IP Deletion Although results in IP-deficient mice have implicated PGI₂ in the mediation of pain and inflammation [73], these consequences seem conditioned by genetic background. Platelets of IP-null mice are resistant to disaggregation by IP agonists [73] and the thrombotic and proliferative response to vascular injury is enhanced [53], as is hypoxia-induced pulmonary hypertension and remodeling [74]. Despite its expression in murine thymus, disordered T-cell function secondary to IP deletion has not been reported, and the IP appears to play a minor role, if any, in murine T cell maturation [23]. Deletion of the IP undermines the atheroprotective effect of female gender in LDL receptor deficient mice [75], a possible consequence of estrogen-mediated upregulation of PGIS [76] and/or its protection from free radical attack. Interestingly, unlike their normotensive IP knock out counterparts, mice deficient in PGIS are hypertensive [77]. However, while this supports the possibility of a second IP, formation of both PGE₂ and TxA₂ are increased in the PGIS knockouts, perhaps due to redirection of PGH₂.

Prostaglandin D₂ (PGD₂)

PGD₂, the major COX product formed by mast cells, is released during allergic responses, including asthma and systemic mastocytosis [78,79]. Infusion of PGD₂ in humans results in flushing, nasal stuffiness, and hypotension [80]. In mice, overexpression of lipocain-like PGDS increases response to bronchial challenge with ovalbumin [81]. The hematopoietic PGDS is expressed abnormally in patients with coronary disease [82] and a polymorphic variant has been linked to human asthma [83]. PGD₂, an abundant COX product in brain, is considered an important regulator of sleep-wake cycles [84]. Deletion of PGDS abolishes allodynia (touch-evoked pain) in mice [85], demonstrating a role for PGD₂ in pain perception.

The DP₁ is coupled positively to adenylyl cyclase through G_s [24,31], which directs PDG₂-induced inhibition of platelet aggregation, bronchodilation, and vasodilation. Among the prostanoid receptors the DP₁ is the least abundant, with minor expression reported in mouse ileum, lung, stomach, and uterus and expression in the CNS limited specifically to the leptomeninges. Recently, a chemoattractant receptor-homologous molecule (CRTH2), expressed on T-helper (H) type-2 cells [27], was classified as the DP₂. This receptor is distinct from other prostanoid receptors, couples to increased intracellular Ca²⁺, and directs PGD₂-induced chemotaxis and migration of TH2 cells. Both DP₁ and DP₂ integrate coordinately the effects of PGD₂ on eosinophils, modulating chemokinesis, degranulation, and apoptosis [86]. DP₂ and PGDS are coordinately expressed at the fetal/maternal interface in human deciduas, where they may participate in lymphocyte recruitment [87].

PGD₂ may be metabolized to PGJ₂ and its metabolite, 15-deoxy Δ (12,14) PGJ₂ [88], a possible natural ligand for PPAR γ , regulating adipogenesis, inflammation, tumorigenesis, and immunity [89]. However, while PGJ₂ and its metabolite can activate the nuclear receptor *in vitro* [90], it is presently unclear whether sufficient concentrations are formed *in vivo*.

DP Deletion Deletion of the DP₁ sharply reduces ovalbumin-induced lymphocytes and eosinophils infiltration and airway hyperreactivity, reflecting PGD₂'s apparent role in asthma [91]. Work with these mice demonstrates the action of PDG₂ on arachnoid trabecular cells in the basal forebrain to increase extracellular adenosine, which in turn facilitates induction of sleep [92]. DP₂ null mice have not yet been generated.

Prostaglandin E₂ (PGE₂)

PGE₂ regulates diverse biological processes, including cell growth, inflammation, reproduction, sodium homeostasis and blood pressure [93]. Its biological effects are complex and often opposing; vasodilation in the arterial and venous systems [94] but constriction of smooth muscle in

the trachea, gastric fundus, and ileum [95]. Like COX-2, the inducible mPGES isoforms [96] may contribute to the increase in PGE₂ associated with inflammatory and pyretic responses. The COX-1-cPGES axis is considered the predominant source of homeostatic PGE₂ [11], although mPGES and COX-1 seen coupled in the mouse kidney [97]. However, COX-2-derived prostanoids may differentially regulate salt excretion and glomerular circulation in volume overload or depletion [98]. PGE₂, along with PGI₂, apparently derived from COX-2, maintains renal blood flow and salt excretion [99], effects that may be counterbalanced by COX-1-derived TxA₂ [64].

Both the EP₂ and the EP₄ activate adenylyl cyclase via G_s [24,31]. Differences in agonist-induced desensitization may be one reason for the presence of such similar receptors for PGE₂. The EP₁, via an unclassified G-protein, and the EP_{3D}, via G_q, are coupled to PLC activation [24,31]. A splice variant of the EP₁ in the rat may antagonize coupling of other EPs [100]. The EP_{3B}/EP_{3C} couple to G_s-mediated activation, and the EP_{3D}/EP_{3A} to G_i-mediated inhibition, of adenylyl cyclase.

The mRNAs for all four EPs are widely expressed; however, the limited distribution of EP₁ and EP₂, compared with EP₃ and EP₄, together with induction of EP₂ in response to inflammatory stimuli [101], suggests specialized functions for the different EPs [24,31]. The biological actions of PGE₂ may be conditioned by this differential receptor expression and/or PGE₂ levels. EP₄ directs platelet inhibition at low PGE₂ concentrations, while increased PGE₂ levels in, for example, inflammation, lead to EP₃-mediated platelet aggregation [102]. Indeed, high concentrations of PGE₂ condition platelet responses through EP₃- and IP-mediated regulation of intracellular cAMP [102]. Despite higher renal EP₄ expression [31], evidence supports EP₂-mediated renal vasodilation and salt handling [103], while an EP₁-directed increase salt excretion may contribute to PGE₂-dependent natriuresis [31]. PGE₂ may also directly stimulate renin and angiotensin II generation in the kidney [104], or directly constrict the renal vasculature [105] leading to hypertension. In the gastrointestinal tract, cytoprotective effects are mediated by EP₁ in stomach [106] but by EP₃ and EP₄ in the intestine [107]. EP₁ and EP₃ receptors appear responsible for myometrial contractility caused by PGE analogs, such as misoprost, used to induce labor [108], while selective EP₂-mediated inhibition of myometrial contractility [109] may be useful against preterm labor. EP₂- [110] and EP₃-mediated [111] interactions with growth factors may underlie the proliferative and angiogenic actions of PGE₂ in cancer. In the immune system, activation of the EP₂ inhibits T-cell proliferation, while both EP₂ and EP₄ receptors regulate antigen-presenting function *in vivo* [112]. Circulating levels of interleukin-1 β induce coordinate COX-2-mPGES expression at the blood brain barrier, permitting activation of the central EPs [113]. Localized infusions of PGE₂ into the third ventricle induce wakefulness via the EP₁ and EP₂ receptors, while EP₄ activation in subarachnoid space induces sleep [114]. Pyrexial responses may be mediated through the EP₃ [115], while the EP₁ and the EP₃ increase neuronal excitability and pain perception [115,116].

EP Deletion Knockout mouse models have been generated for all the EPs. EP₁-deficient mice have reduced nociceptive perception, while male, but not female, knockouts have reduced systolic blood pressure accompanied by elevated renin-angiotensin activity [116]. EP₂-deficient mice are normotensive at baseline but demonstrate increased salt- and pressor hormone-induced hypertension, although this is modified by genetic background [103]. The EP₂ knockouts also demonstrate a preimplantation defect, which may underlie some of the breeding difficulties seen in the COX-2 knockouts (see above). EP₃-deficient mice are resistant to pyrogen-induced fever [115]. However, despite its abundant expression in the kidney, there is no renal phenotype in EP₃ knockouts [117]. Deletion of the EP₄ results in PDA and neonatal death [118].

Prostaglandin F_{2α} (PGF_{2α})

PGF_{2α} actions include luteolysis [119] and smooth muscle contraction across a variety of tissues [120,121]. PGFS catalyzes the reduction of PGH₂ to PGF_{2α}, PGD₂ to 9α,11β-PGF_{2α} [122], and retinal to retinol [123]. It exists in at least two isoforms, identified initially in liver [16] and lung [122], and is also expressed in lymphocytes [122] and spinal chord [124]. PGF_{2α} induces cardiac myocyte hypertrophy and induction of myofibrillar genes, independent of muscle contraction [125], suggesting a role for this eicosanoid during development, in compensatory hypertrophy, and/or in recovery of the heart from injury.

Thus far, one GPCR for PGF_{2α}, the FP, which couples via G_q activation of PLC, has been cloned [24,31]. Stimulation of FP also activates Rho kinase, leading to the formation of actin stress fibers, phosphorylation of p125 focal adhesion kinase, and cell rounding [126]. Similar to the EP₃ and TP, carboxy terminal splice variants, FP_A and FP_B [29], have been identified. These are indistinguishable in their ligand-binding properties and signaling but may differ in their constitutive activity [29] and rates of desensitization [127]. FP_A and FP_B also differ in coupling to the Tcf/β catenin-signaling pathway, which may underlie the prolonged cytoskeletal effects mediated through FP_B [128]. The FP is expressed in kidney, heart, lung, and stomach; however, it is most abundant in the corpus luteum, where its expression varies during the estrus cycle, consistent with the role for PGF_{2α} in luteolysis. The FP is also expressed in the ciliary body of the eye, where FP agonists have clinical utility in the treatment of raised intraocular pressure in patients with glaucoma [129]. Although activation of the FP results in vaso- and broncho-constriction [121], cell proliferation [130], and cardiomyocyte hypertrophy [131], the role of this prostanoid in cardiopulmonary disease is poorly characterized. Similarly, activation of the FP blocks preadipocyte differentiation *in vitro* [132], but the role of the FP, if any, in obesity is poorly understood.

FP Deletion Mice deficient in the FP do not deliver at term, resulting from a failure to induce the oxytocin receptor

and lack of the normal decline in elevated progesterone levels [133]. Ovariectomy restores responsiveness to oxytocin and permits successful parturition. COX-1-derived PGF_{2α} in these mice appears important for luteolysis, consistent with delayed parturition in COX-1-deficient mice [19]. Subsequent upregulation of COX-2 generates prostanoids, including PGF_{2α} and TxA₂, important in the final stages of parturition [134]. Mice lacking both COX-1 and oxytocin underwent normal parturition, demonstrating the critical interplay between PGF_{2α} and oxytocin in onset of labor [19].

Concluding Remarks

The cyclooxygenase pathway of arachidonic acid metabolism generates a family of evanescent mediators with wide and varied physiological and pathophysiological actions. Understanding the biological role of the prostanoids requires examination of the biosynthetic pathways that lead to their temporal and tissue-specific generation together with the array of signaling pathways activated by their multiple receptors.

Introduction

The leukotrienes (LT) constitute a group of bioactive lipids derived from the metabolism of polyunsaturated fatty acids, e.g., arachidonic acid [1]. In two consecutive reactions, arachidonic acid is transformed into an unstable epoxide compound, LTA₄. This intermediate is either hydrolyzed into the dihydroxy acid LTB₄ or conjugated with glutathione to form LTC₄. The latter compound together with its metabolites LTD₄ and LTE₄ are referred to as the cysteinyl-containing leukotrienes (cys-LTs).

Leukotrienes possess a wide range of biological activities elicited via specific, G-protein-coupled, cell surface receptors [2]. LTB₄ is a very potent chemoattractant for neutrophils and recruits inflammatory cells to the site of injury. This compound also induces chemokinesis and increases leukocyte adhesion to the endothelial cells of the vessel wall. The cys-LTs are potent constrictors of smooth muscles, particularly in the airways, leading to bronchoconstriction. In the microcirculation, the cys-LTs constrict arterioles and increase the permeability of the postcapillary venules, which results in extravasation of plasma. Due to their potent biological activities, leukotrienes are considered to be chemical mediators in a number of inflammatory and allergic disorders, e.g. rheumatoid arthritis, inflammatory bowel disease, and bronchial asthma [3].

Five-Lipoxygenase

Five-lipoxygenase (5-LO) catalyzes the first two steps in leukotriene biosynthesis [4] (Fig. 1). Free arachidonic acid is oxygenated into the hydroperoxide 5-HPETE, which is

subsequently dehydrated to yield the unstable epoxide intermediate LTA₄. The enzyme, which predominantly is found in bone marrow derived cells, is stimulated by Ca²⁺ and ATP. Furthermore, it contains one atom of non-heme iron that is involved in catalysis [5]. Mutagenetic analysis has demonstrated that His-372, His-550, and the C-terminal isoleucine Ile-673 are iron ligands [6]. The gene encoding human 5-LO, as well as the promoter, has been characterized, and some important features are listed in Table I, together with data for the other key enzymes in the leukotriene cascade.

The only crystal structure of a mammalian lipoxygenase that has been determined is rabbit 15-LO [7]. This enzyme contains an N-terminal β-barrel domain, a structure also found in the C-terminal domain of lipases. The role of this domain for lipoxygenases is presently unclear but for 5-LO it has been shown to bind Ca²⁺, which stimulates enzyme activity and presumably facilitates its association of 5-LO with membranes during catalysis (see following section) [8]. 5-LO is also a substrate for p38 kinase-dependent MAPKAP kinases *in vitro*, suggesting that phosphorylation may be one additional factor, which determines 5-LO translocation and enzyme activity [9].

Five-Lipoxygenase Activating Protein (FLAP) and Cellular Leukotriene Biosynthesis

Cellular 5-LO activity is dependent on a small membrane protein, five lipoxygenase activating protein (FLAP), which presumably presents or transfers arachidonic acid to 5-LO [10].

Early studies showed that upon cell stimulation leading to an increase in Ca²⁺, 5-LO is activated and translocates to a membrane compartment [11]. Of particular interest was the discovery that FLAP is localized to the nuclear envelope of

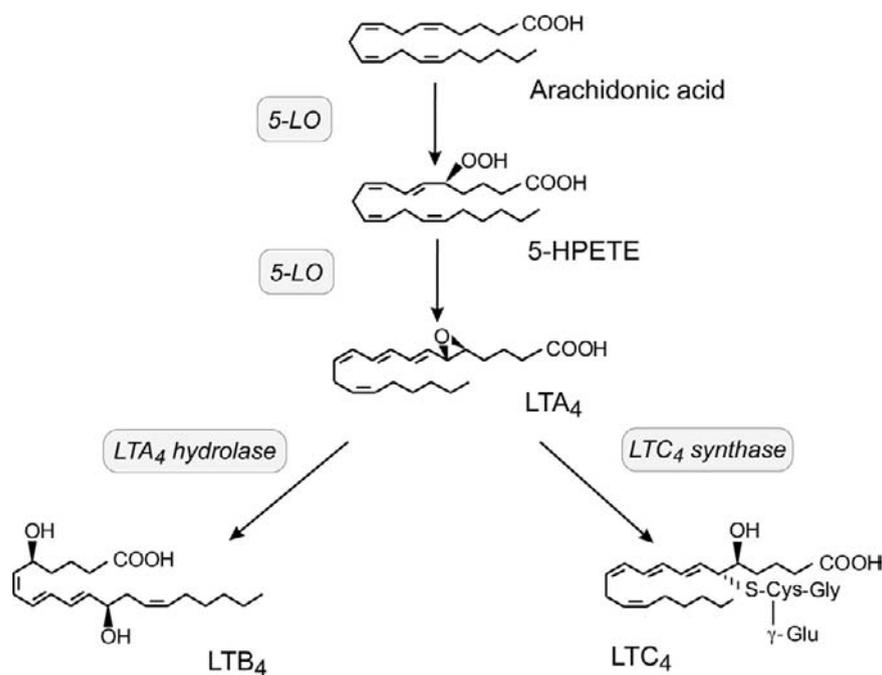

Figure 1 Enzymes and intermediates in the leukotriene cascade.

Table I Properties of Enzymes and Receptors in Leukotriene Biosynthesis and Action^a

Protein	Protein size (no. of amino acids) ^b	Prosthetic group ^c	Gene size (kb)	Exon no.	Putative <i>cis</i> -elements of promoter regions	Chromosomal location	Gene deficient mice
5-Lipoxygenase	673	Fe	>82	14	Sp1, AP-2, NF-κB	10	+
FLAP	160	—	>31	5	TATA, AP-2, GRE	13	+

^dThe ORF of BLT₂ is included in the promoter of the BLT₁ gene.

neutrophils and that 5-LO, upon cell activation, translocates to the same compartment [12] (Fig. 2). Further analysis revealed that 5-LO can also be present in the nucleus of *resting* cells associated with the nuclear euchromatin, a site from which it translocates to the nuclear envelope. In addition, 5-LO has been shown to associate with growth factor receptor-binding protein 2 (Grb2), an “adaptor” protein for tyrosine kinase-mediated cell signaling, through Src homology 3 (SH3) domain interactions [13]. It is interesting that inhibitors of tyrosine kinase activity, a determinant of SH3 interactions, also inhibited the catalytic activity of 5-LO and its translocation during cellular activation. In addition, an internal bipartite nuclear localization sequence, spanning Arg-638–Lys-655,

has been shown to be necessary for the redistribution of 5-LO to the nuclear compartment [14,15]. Moreover, recent data indicate that also the N-terminal β-barrel domain in 5-LO plays a role in this process [16].

Not only 5-LO and FLAP are associated with the cell nucleus and nuclear membrane. Thus, LTC₄ synthase (see section entitled Leukotriene C₄ Synthase) resides in this compartment, and recent data suggest that the enzyme is located on the *outer* nuclear membrane and peripheral endoplasmic reticulum [17]. It is interesting that the soluble LTA₄ hydrolase (see section entitled Leukotriene A₄ Hydrolase) was also reported to reside in the nucleus of rat basophilic leukemia cells and rat alveolar macrophages [18].

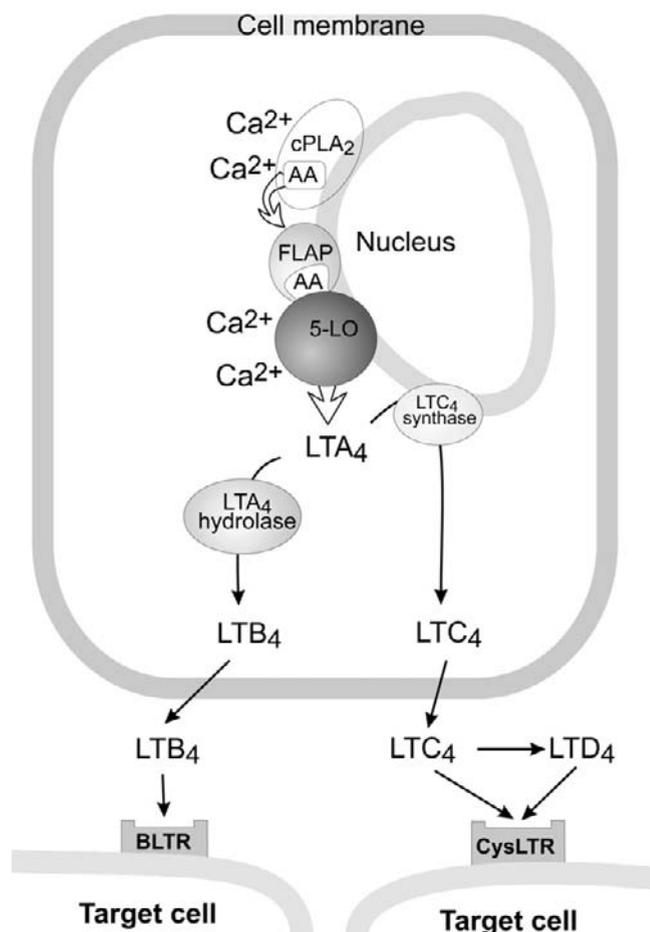

Figure 2 Leukotriene biosynthesis at the nuclear membrane of an activated leukocyte.

Together, these findings imply that leukotriene biosynthesis is carried out by a complex of enzymes assembled at the nuclear membrane (cf. Fig. 2). This conclusion in turn suggests that these enzymes and/or their products may have additional intracellular and intranuclear functions, perhaps related to signal transduction or gene regulation. In line with this notion, it has been reported that LTB₄ is a natural ligand to the nuclear orphan receptor PPAR α , suggesting that LTB₄ may have intranuclear functions [19]. It was also reported that 5-LO can interact with several cellular proteins, including coactosin-like protein (CLP) and transforming growth factor type β -receptor-I-associated protein (TRAP-1) [20]. In addition, 5-LO interacts with a human homologue of the protein "Dicer," a member of the RNase III family of nucleases, which is implicated in the RNA interference mechanism of gene regulation [20,21].

Leukotriene A₄ Hydrolase

Leukotriene A₄ hydrolase catalyzes the final step in the biosynthesis of the proinflammatory compound LTB₄ (Fig. 1). In contrast to 5-LO, LTA₄ hydrolase is widely distributed

and has been detected in almost all mammalian cells, organs, and tissues examined. The enzyme has been purified from several mammalian sources, and cDNAs encoding the human, mouse, rat, and guinea-pig enzymes have been cloned and sequenced [22].

Sequence comparison with certain zinc metalloenzymes revealed the presence of a zinc-binding motif (HEXXH-X₁₈-E) in LTA₄ hydrolase [23]. Accordingly, LTA₄ hydrolase was found to contain a catalytic zinc. The three proposed zinc-binding ligands, His-295, His-299, and Glu-318, were verified by mutagenetic analysis. Furthermore, the enzyme was found to exhibit a chloride-activated peptidase activity. Based on its zinc signature, sequence homology, and aminopeptidase activity, LTA₄ hydrolase has been classified as a member of the M1 family of the MA clan of metalloproteases [24].

Identification of Catalytically Important Amino Acid Residues and Crystal Structure of LTA₄ Hydrolase

In addition to the zinc-binding ligands, several amino acid residues of catalytic importance have been identified by site-directed mutagenesis. Thus, mutagenetic replacements of Glu-296 in LTA₄ hydrolase abrogated only the peptidase activity, a finding that suggests a direct catalytic role for Glu-296 in the peptidase reaction, possibly as a general base [25]. Furthermore, sequence comparisons and mutational analysis have demonstrated that Tyr-383 plays an important role in the peptidase reaction of LTA₄ hydrolase, presumably as a proton donor [26].

Typically, LTA₄ hydrolase undergoes "suicide" inactivation with a concomitant covalent modification of the enzyme by its substrate LTA₄ [27]. Mutational analysis has demonstrated that Tyr-378 is a major structural determinant for suicide inactivation [28]. Mutated proteins, carrying a Gln or Phe residue in position 378, were neither inactivated nor covalently modified by LTA₄.

Recently, the X-ray crystal structure of LTA₄ hydrolase in complex with the competitive inhibitor bestatin was determined [29]. The protein molecule is folded into an N-terminal, a catalytic, and a C-terminal domain, packed in a flat triangular arrangement. Although the three domains pack closely and make contact with each other, a deep cleft is created between them. At the bottom of the interdomain cleft, the zinc site is located. As predicted from previous work, the metal is bound to the three amino acid ligands, His-295, His-299, and Glu-318. In the vicinity of the prosthetic zinc, the catalytic residues Glu-296 and Tyr-383 are located at positions that are commensurate with their proposed roles as general base and proton donor in the aminopeptidase reaction.

Close to the catalytic zinc, a glutamic acid residue (Glu-271), belonging to a conserved GXMEN motif in the M1 family of zinc peptidases, was identified [29]. By mutational analysis and crystallography it was shown that Glu-271 is necessary for *both* catalytic activities of LTA₄ hydrolase [30]. Presumably, the carboxylate of the glutamic acid residue participates in the opening of the epoxide moiety of LTA₄

and formation of a carbocation intermediate. In the peptidase reaction, the role of Glu-271 may be to serve as an N-terminal recognition site and to stabilize the transition state during turnover of peptide substrates.

The crystal structure, in combination with site-directed mutagenesis studies, also suggested that Asp-375 is a critical determinant for the introduction of the 12R-hydroxyl group of LTB₄ [31].

Leukotriene C₄ Synthase

Leukotriene C₄ synthase catalyzes the committed step in the biosynthesis of cys-LTs through conjugation of LTA₄ with glutathione. The enzyme is a membrane-bound homodimer with a subunit molecular mass of 18 kDa [32]. LTC₄ synthase has been cloned and sequenced [33,34]. Two consensus sequences for protein kinase C phosphorylation were found, and subsequent studies have shown that phosphorylation reduces the LTC₄ synthase activity [35]. Sequence comparisons of LTC₄ synthase and FLAP demonstrated a surprising 31% identity between the two proteins. In addition, recent work has identified two microsomal GSH transferases (MGST2 and MGST3) that possess LTC₄ synthase activity and exhibit a high degree of similarity to both LTC₄ synthase and FLAP [36,37].

Leukotriene Receptors

For LTB₄, two types of surface receptors are known (BLT₁ and BLT₂). The BLT₁-receptor has been cloned and characterized as a 43 kDa, G-protein-coupled receptor with seven transmembrane-spanning domains (7TM) [38]. The BLT₁ receptor is only expressed in inflammatory cells [39] and shows a high degree of specificity for LTB₄ with a K_d of 0.15–1 nM [38,40].

A second G-protein-coupled 7TM receptor for LTB₄, BLT₂, has recently been identified [40–42]. This receptor is homologous to the BLT₁ receptor but has a higher K_d value for LTB₄ (23 nM) [43]. In contrast to the BLT₁ receptor, BLT₂ is ubiquitously expressed in various tissues.

The cys-LTs are recognized by at least two receptor types (CysLT₁ and CysLT₂), both of which have been cloned and characterized as G-protein-coupled 7TM receptors [44–48]. The CysLT₁ receptor mRNA is found in, for example, spleen, peripheral blood leukocytes, lung tissue, smooth muscle cells, and tissue macrophages [45,47]. The preferred ligands for the CysLT₁ receptor are LTD₄ followed by LTC₄ and LTE₄ in decreasing order of potency.

The CysLT₂ receptor contains 345 amino acids with approximately 40% sequence identity to the CysLT₁ receptor [44,46,48]. This receptor binds LTC₄ and LTD₄ equally well, whereas LTE₄ shows low affinity to the receptor. Studies on the tissue distribution of the CysLT₂ receptor show high levels of mRNA in heart, brain, peripheral blood leukocytes, spleen, placenta, and lymph nodes, whereas only small amounts are found in the lung. The functional role(s) of the CysLT₂ receptor is presently unclear, but its wide tissue

distribution suggests many possibilities, including regulation of brain and/or cardiac functions.

Gene Targeting of Enzymes and Receptors in the Leukotriene Cascade

The roles of the key enzymes and two of the receptors (BLT₁ and CysLT₁) in the leukotriene cascade have been studied by gene targeting. 5-LO-deficient mice are more resistant to lethal effects of PAF-induced shock and also show a marked reduction in the ear inflammatory response to exogenous arachidonic acid [49]. Furthermore, 5-LO null mice are more susceptible to infections with *Klebsiella pneumoniae* [50], exhibit a reduced airway reactivity in response to methacholine, and have lower levels of serum immunoglobulins [51].

FLAP deficient mice, like the 5-LO (–/–) mice, showed a blunted response to topical arachidonic acid, had increased resistance to PAF induced shock, and responded with less edema in zymosan-induced peritonitis [52]. Furthermore, the severity of collagen-induced arthritis was substantially reduced in FLAP (–/–) mice, thereby indicating a role for leukotrienes in this model of inflammation [53].

LTA₄ hydrolase (–/–) mice are resistant to the lethal effects of systemic shock induced by PAF, thus identifying LTB₄ as a key mediator of this reaction [54]. In zymosan A-induced peritonitis, LTB₄ modulates only the cellular component of the response, whereas the LTC₄ synthase (–/–) mice displayed a reduced plasma protein extravasation in this type of inflammation [55]. Furthermore, the LTC₄ synthase (–/–) mice were less prone to develop passive cutaneous anaphylaxis. Recently, the role of LTC₄ in plasma protein extravasation following zymosan A-induced peritonitis and IgE-mediated passive cutaneous anaphylaxis was confirmed in mice lacking the CysLT₁ receptor gene [56].

Finally, the role of the BLT₁ receptor has also been studied by targeted gene disruption [57,58]. The receptor was necessary to elicit the physiological effects of LTB₄ (e.g. chemotaxis, calcium mobilization, and adhesion to endothelium) and important for the recruitment of leukocytes in an *in vivo* model of peritonitis. As also observed in mice lacking 5-LO, FLAP, or LTA₄ hydrolase, BLT₁ (–/–) mice were protected from the lethal effects of PAF-induced anaphylaxis.

ASA	acetylsalicylic acid
ATL	aspirin-triggered lipoxin, 15 <i>R</i> -LXA ₄
COX-2	cyclooxygenase 2
EPA	eicosapentaenoic acid
HEPE	hydroxyeicosapentaenoic acid
HETE	hydroxyeicosatetraenoic acid
LT	leukotriene
LX	lipoxin
LXA₄	5 <i>S</i> , 6 <i>R</i> , 15 <i>S</i> -trihydroxy-7,9,13- <i>trans</i> -11- <i>cis</i> -eicosatetraenoic acid
15-epi-LXA₄	5 <i>S</i> , 6 <i>R</i> , 15 <i>R</i> -trihydroxy-7,9,13- <i>trans</i> -11- <i>cis</i> -eicosatetraenoic acid
NSAID	non-steroidal anti-inflammatory drug
PUFA	polyunsaturated fatty acid
PMN	polymorphonuclear leukocytes

Lipoxins are a separate class of mediators produced from arachidonic acid in that they contain a conjugated tetraene and trihydroxy structure, a feature that departs from the other structural classes of eicosanoids (see [2] and chapters therein) and that gives them distinct biological roles. The lipoxins are generated by two main routes (Fig. 1): the first involves initial lipoxygenation by 15-LO that inserts molecular oxygen in predominantly the *S* configuration at carbon 15 followed by 5-LO based transformation. This route is particularly relevant when polymorphonuclear leukocytes (PMN) interact with mucosal surfaces. A second route, which occurs predominantly as a major intravascular origin within blood vessels when, for example, platelet intracellular glutathione is depleted, involves the conversion of 5-LO-derived LTA₄ that is released from leukocytes and subsequently converted to lipoxins. On their own, human platelets do not generate lipoxins but become an important source of LX as they interact with leukocytes (reviewed in [3]).

Lipoxin Signals in the Resolution of Inflammation

Biosynthesis

Cell-cell interactions and transcellular biosynthesis of mediators are now well recognized as important means of generating new signals [1]. In humans, lipoxin (LX) biosynthesis is an example of LO-LO interactions via transcellular circuits.

Relation of Lipoxins to Diseases and Bioactions

In humans during disease processes, lipoxins are generated by airway, kidney, joints [see reviews [3,4] and references therein] and liver [5]. Their production within exudates is both temporally and spatially separated from the formation

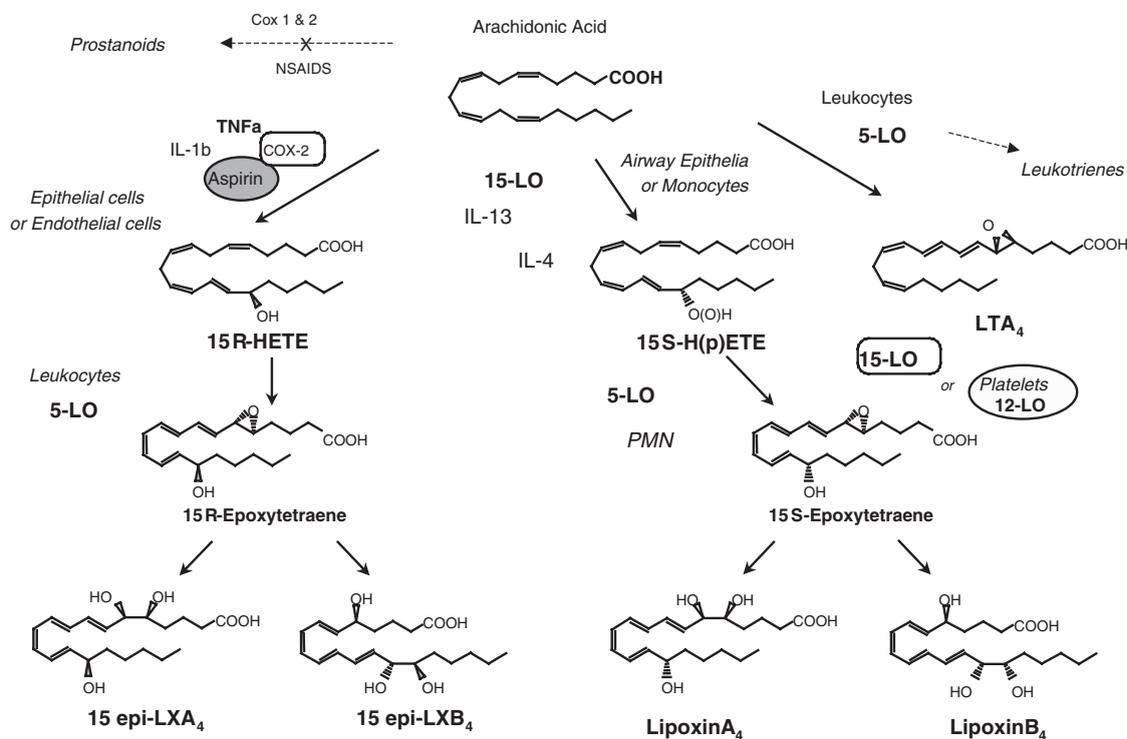

Figure 1 Biosynthesis of lipoxins and aspirin-triggered 15-epi-lipoxins. *Right*: 15-lipoxygenase initiated pathway and 5-lipoxygenase-12-lipoxygenase pathway. *Left*: ASA triggered pathway; irreversible acetylation of COX-2 by aspirin changes the enzyme's product from prostaglandin intermediate to precursors of ATL. The acetylated COX-2 remains catalytically active (see text).

of leukotrienes or prostaglandins [6], and the main actions of lipoxins stand apart from other known eicosanoids and lipid mediators (Table I). Acting in the nanomolar range, native lipoxins selectively regulate the motility of PMN, eosinophils, and monocytes in a stereospecific fashion, a result that raised our awareness to the possibility that lipoxins and related compounds could serve as endogenous "stop signals" of select leukocytes to help resolve local inflammation [3,4]. Much as lipoxins serve as endogenous suppressors of leukocyte-mediated tissue injury, their epimeric form generated with aspirin treatment (Fig. 1), namely aspirin-triggered lipoxins (ATL) 15-epi-LX (stereoisomers at carbon 15 position of native LX) and related compounds, may be the effectors of well-established anti-inflammatory therapies.

Lipoxins are rapidly generated within seconds to minutes, act locally, and are swiftly inactivated via enzymatic routes. Based on knowledge of LX routes of inactivation and the identity of a receptor for LXA₄ [7], metabolically stable LX and ATL analogs that resist rapid metabolic inactivation and are potent regulators of leukocyte traffic (*in vitro* and *in vivo*) were designed and synthesized by total organic synthesis [8]. Some of these more potent LX-mimetics are also topically active inhibitors of acute inflammation (Table I) and are potent inhibitors of TNF_α signals as well as IL-8 formation [9]. ATL and its active analogs compete with LXA₄ at its own receptor on leukocytes and act as agonists that stimulate and induce intracellular "stop signaling" that can have both rapid and gene transcriptional associated events [10]. These recent findings support the notion that ATL and

Table I Main Anti-Inflammatory and Resolving Actions of Lipoxins and Novel Aspirin-Triggered Lipoxins^a

Compound/mediator	Response/action
LX and/or ATL ^b	<ul style="list-style-type: none"> Regulate leukocyte traffic in acute inflammation & injury ("stop" PMN and eosinophils, "go" monocytes non-phlogistic activation) [3, 4] Redirect chemokine-cytokine axis (gene expression, i.e. IL-8, IL-1) [10] Reduce edema [11] Stimulate clearance and phagocytosis of apoptotic PMN [12] Turn down pain signals: downregulate PMN in neuropathic pain [25]
18R-EPA series (i.e. 18R,5,12-tri-HEPE) and 15-epi-LXA ₅ series	<ul style="list-style-type: none"> Inhibit PMN transmigration and block cytokine-stimulated inflammation <i>in vivo</i> [19]

^bSee abbreviations list in text.

native lipoxin prevent tissue damage by serving as endogenous anti-inflammatory molecules that also stimulate macrophage clearance of spent PMN and resolution of edema [11,12].

Aspirin-Triggered Lipoxins and Other Polyunsaturated Fatty Acid-Derived Mediators

Despite nearly 100 years of wide use, the therapeutic impact of acetylsalicylic acid (ASA) is still evolving, and new beneficial effects are still being uncovered [13,14]. The irreversible acetylation of both cyclooxygenase 1 and 2 (COX-1 and COX-2) with subsequent inhibition of prostaglandin biosynthesis is well appreciated and explains some, but not all, of ASA's pharmacological actions [15], and until recently the mechanism for ASA's impact *in vivo* on PMN recruitment in inflammation remained largely unknown. In 1995, Clària and Serhan found that ASA treatment triggers formation of novel series of lipid mediators termed the aspirin-triggered lipoxins (ATL). Their formation relies on cell-cell interactions (15-epi-LX; Fig. 1). Co-activation of neutrophils with either endothelial cells treated with ASA or certain epithelial cells generates a novel class of 15*R*-containing lipoxins (ATL) that in turn downregulate PMN-endothelial cell interactions as well as epithelial function [8,9,16].

In most clinical arenas ASA is held to act strictly as an inhibitor of prostaglandins. However, the ASA-acetylated form of COX-2 is still active and converts arachidonate to 15-HETE, which carries its C15 alcohol in the *R* configuration [16]. The COX-2 substrate channel [17] is larger in this isoenzyme (cf. crystal structures for COX-2 [18]) and gives rise to an unusual L-shaped binding of arachidonic acid that gets oxygenated in the 15*R* position. 15-epi-LXA₄ is more potent and longer acting than its 15*S*-containing form because it is not as rapidly inactivated [8]. It appears that ASA triggers formation of endogenous eicosanoids and related substances that could mediate some of the many beneficial actions of ASA by pirating the native pathway of lipoxin production and signaling. It is important to note that the biosynthesis of 15-epi-lipoxins does not arise from a simple pathway shunt, but rather represents the effect of ASA on the oxygenating function of COX-2 at foci of inflammation.

The biological importance of this difference in the enzyme structure (COX-1 versus COX-2) is not clear, but the presence of an additional binding pocket in COX-2 for NSAID was exploited to make COX-2-inhibitors [18]. Acetylation of COX-1 by ASA does not permit substantial amounts of arachidonate conversion to 15*R*-HETE. Once formed, 15*R*-HETE is rapidly esterified in inflammatory cells, altering signal transduction as well as priming the supply of LX precursors [3]. The endothelial cell production of 15-HETE is highly effective *in situ* [19] and *in vivo* at sites of inflammation. Given the vast size of the vasculature and its role in host defense and inflammation, the vascular endothelium is likely to contain focal regions or "hot spots" under stress that express COX-2 and can generate substantial amounts of COX-2-derived products with ASA treatment.

Novel Anti-Inflammatory Signals and Pathways

Over the past 25 years, numerous studies reported that dietary supplementation with omega-3 polyunsaturated fatty

acids (ω -3 PUFA) has beneficial effects in disease. Recent reviews discuss potential antithrombotic, immunoregulatory, and anti-inflammatory responses relevant in arteriosclerosis, arthritis, and asthma as well as anti-tumor and anti-metastatic effects [20]. The possible preventative or therapeutic actions of ω -3 PUFA supplementation in infant nutrition, for cardiovascular diseases, and for mental health led an international workshop to call for recommended dietary intakes [20], and data from one large trial (GISSI—Prevenzione, which included over 11,300 subjects) that evaluated the benefits of aspirin with or without ω -3 PUFA supplementation for patients surviving myocardial infarction found a significant decrease in death in the group taking the supplement [21].

Fish oils or n-3 PUFA per se are proposed to act by one or several possible mechanisms [20]. None of the proposed explanations are widely accepted, largely because of the supra-pharmacologic amounts, usually milligram to microgram range of ω -3 PUFA, that are required *in vitro* to achieve the supposed beneficial effects. Because compelling molecular evidence has been lacking and in view of beneficial profiles attributed to dietary ω -3 PUFA and those of aspirin in a variety of diseases, we sought evidence for possible new lipid-derived signals that could explain the epidemiological findings from humans.

A Protective Role for Vascular COX-2 in Micro-inflammation

Inflammatory exudates formed in murine dorsal pouches treated with ω -3 and ASA generate several novel compounds [19], including 18*R*-hydroxy-eicosapentaenoic acid (18*R*-HEPE) and several trihydroxy-containing compounds derived from the ω -3 fish oil eicosapentaenoic acid (EPA) (C20:5) used as an n-3 PUFA prototype. Human cells also generate these new 18*R* and 15*R* series of compounds from EPA, which carry intriguing bioactivities. When human endothelial cells expressing COX-2 are pulsed with EPA and treated with ASA, they generate 18*R*-HEPE or a mixture of 18*R*-HEPE and 15*R*-HEPE. A role for COX-2 in this biosynthetic pathway was confirmed with recombinant human COX-2, in which acetylation by ASA dramatically increased the production of both 18*R*-HEPE and 15*R*-HEPE, findings that could be of clinical significance [19].

When engaged in phagocytosis, activated human polymorphonuclear leukocytes (PMN) process the intermediates derived from acetylated recombinant COX-2 to produce two series of trihydroxy-containing compounds; one series carries an 18*R*-position hydroxyl group, and the other series in the 15*R* position that are related to 15-epi-LX₅. Trout macrophages and human leukocytes can indeed convert endogenous EPA to 15*S*-containing LX also denoted as 5-series LX₅ [22]. Briefly, we found that human PMN take up and convert 18*R*-HEPE via 5-lipoxygenation to insert molecular oxygen and, in subsequent steps, form 5-hydro(peroxy)-18*R*-DiH(p)EPE and a more labile intermediate 5(6)epoxide that gives rise to 5,12,18*R*-triHEPE. In a similar biosynthetic pathway, 15*R*-HEPE released by endothelial cells is converted by

activated PMN via 5-lipoxygenation to a 5-series LXA₅ analog that also retains their C15 *R* or *epi* configuration, namely 15-*epi*-LXA₅ [19]. The stereochemistry of compounds in this pathway is different from those of the LO-LO driven pathways that give predominantly C15 *S* containing LX₅ structures (so-called 5-series of five double bonds) as with endogenous sources of EPA in trout macrophages (cf. [22] and references therein). The chirality of the precursor with ASA-COX-2 (predominantly *R*) is retained when converted by human PMN to give 15-*epi*-LXA₅ [19].

The new 18*R*-series members might serve as dampers for inflammatory responses, since 18*R*-HEPE gave some inhibitory activity and its product 5,12,18*R*-triHEPE potently inhibits PMN transmigration and infiltration [19]. These results raise the question of whether arachidonate is the sole substrate for COX-2 in physiologic settings in human tissues or whether EPA or other PUFA are important as well [19]. Despite the many reports of possible beneficial impacts of ω-3 PUFAs and EPA in humans [20,21], oxygenation by COX-2 to generate bioactive compounds, as referenced herein, has not been addressed. In fish leukocytes and platelets, EPA (C20:5) and arachidonic acid are both mobilized and converted to both 5-series and 4-series eicosanoids (including PG, LT, and LX) with roughly equal abundance [22]. Given the gram amounts of ω-3 PUFA taken as dietary supplements by humans, as in [20,21], and the large area of the vasculature that can express COX-2 (vascular “hot spots” during local inflammation), the conversion of EPA by vascular endothelial cells and neighboring cells could represent a significant *in vivo* source.

Concluding Remarks

Inappropriate control of inflammation and its resolution is now recognized to contribute to many diseases. Aspirin as well as other NSAIDs that affect these signaling systems (Fig. 1) are in wide use, yet these agents are not without *unwanted* side effects, particularly in kidney and stomach. The discovery of the second isoform of COX (reviewed in [23]) sparked a large-scale search for safer aspirin-like drugs, namely COX-2 inhibitors, that would bypass the unwanted side effects. Results reviewed here indicate that lipoxins, their aspirin-triggered epimers (ATL), and broader arrays of aspirin-triggered lipid mediators derived from omega-3 PUFA reveal previously unappreciated *endogenous* anti-inflammation and pro-resolution signaling mechanisms (Table I) that could offer new treatment approaches. The finding that lipoxin counters inflammatory events led to more general concepts, namely that aspirin-triggered lipid mediators could serve as local mediators of anti-inflammation or endogenous agonists that favor resolution of inflammation. Additional support for this notion that lipoxins are protective and that ATLs share this property [3,19] comes from finding that LXA₄ stimulates macrophages to clear apoptotic PMN [12], and that LXA₄ receptors regulate gene expression, cytokines, and metalloproteases (see [24] and references within). These signaling

pathways add a new dimension to the well-established use of low-dose ASA as a specific COX-1 inhibitor in platelets, which also triggers COX-2 generated protective products, thus underscoring the importance of transcellular biosynthetic signaling pathways.

AR,	androgen receptor
FPP,	farnesyl diphosphate
GGPP,	geranylgeranyl diphosphate
PE,	phosphatidylethanolamine

Introduction

Numerous intermediates are formed either during the biosynthesis or catabolism of cholesterol that function as important components in many cell signaling events (Fig. 1). In this review we will briefly discuss some of the recent studies that have revealed the importance of these newly identified signaling molecules.

Cholesterol Precursors

HMG-CoA reductase is the rate-limiting enzyme of cholesterol biosynthesis. The expression level of this membrane-bound enzyme is controlled by many factors that in turn regulate cholesterol synthesis and cellular cholesterol

homeostasis (reviewed in [1]). However, the most important mechanisms involve those that control the stability of the protein and transcription of the gene. Studies utilizing both mammalian cells and yeast have shown that increased degradation of HMG-CoA reductase occurs when cellular levels of either the 15-carbon isoprenoid farnesyl diphosphate (FPP), farnesol (dephosphorylated FPP), or an unidentified derivative of FPP are increased [2–4]. The isoprenoid-dependent increase in degradation of both mammalian [2] and yeast [5] HMG-CoA reductase also requires an oxysterol.

Some of the many biologically active oxysterols that are synthesized from cholesterol are illustrated in Fig. 1 (reviewed in [6] and discussed below). However, 24(*S*), 25-epoxycholesterol is synthesized in many tissues from squalene, and not from cholesterol (Fig. 1) [7]. Recent studies have shown that this epoxysterol is one of the most potent activators of the nuclear receptor LXR (discussed below) [8]. Nonetheless, the physiological importance of the endogenous pathway that generates this epoxysterol is currently unknown.

FPP lies at a critical branch point in the cholesterol biosynthetic pathway, since it is a precursor of several important compounds (Fig. 1) (reviewed in [1]). One such compound is the 20-carbon isoprenoid geranylgeranyl diphosphate (GGPP) (Fig. 1). Both FPP and GGPP are important isoprenoid donors that are subsequently covalently linked, via a thioether bond, to a cysteine, located at or near the carboxy terminus of many proteins. This prenylation reaction is necessary for both the intracellular location and function of many proteins, including many members of the ras, rab, or rho family of small G proteins, kinases, and G-protein-coupled receptors [1].

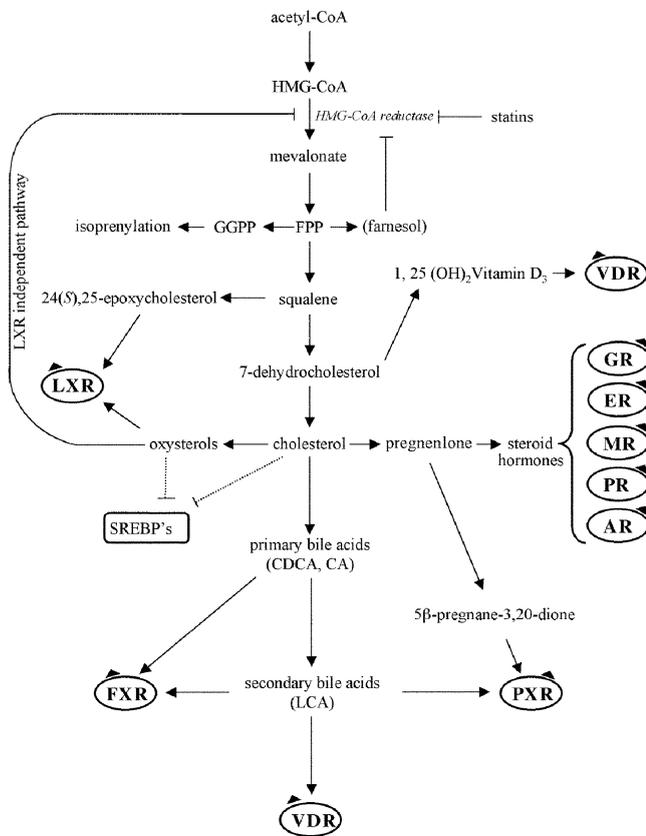

Figure 1 Signaling molecules generated during the synthesis and catabolism of cholesterol. Only some of the intermediates in the synthesis and catabolism of cholesterol are shown. The regulatory enzyme HMG-CoA reductase is indicated in italics. The catabolism of cholesterol to primary bile acids, chenodeoxycholic acid (CDCA), and cholic acid (CA) occurs only in the liver. The subsequent synthesis of the secondary bile acid lithocholic acid (LCA) from CDCA occurs as a result of a 7α -dehydroxylation pathway present in certain intestinal bacteria. These bile acids activate FXR, PXR, or VDR, as indicated. The synthesis of steroid hormones that activate the steroid receptors (GR, ER, MR, PR, and AR) primarily occurs in steroidogenic tissues. The conversion of 7-dehydrocholesterol to 1,25(OH)₂ Vitamin D₃, the ligand for the vitamin D receptor (VDR), is discussed in the text. Oxysterols derived from cholesterol or squalene can either activate the nuclear receptor LXR or inhibit the cleavage and maturation of SREBPs by a process that is independent of LXR. Ligands/hormones that function to activate members of the nuclear receptor family are indicated (▲).

7-Dehydrocholesterol, one of the late intermediates in the cholesterol biosynthetic pathway, is found in high concentrations in the skin. Exposure of the skin to UV radiation results in cleavage of the B ring of 7-dehydrocholesterol to produce cholecalciferol. The latter is subsequently converted in the liver and kidney to 1,25(OH)₂ vitamin D₃, the biologically active form of vitamin D. Until very recently, 1,25(OH)₂ vitamin D₃ was considered to be the major endogenous ligand that activates the vitamin D receptor (VDR). This activated nuclear receptor is essential for the normal absorption of dietary calcium and for the control of calcium homeostasis. However, the secondary bile acid lithocholic acid has recently been shown to function as a potent agonist of VDR [9]. Secondary bile acids are synthesized by bacteria in the

intestinal lumen from the primary bile acids that are secreted from the liver. These results imply that secondary bile acids, via activation of VDR in enterocytes, may have a heretofore unrecognized role in maintaining calcium absorption and metabolism.

Cholesterol

In May 1953, Gould *et al.* reported that hepatic cholesterol synthesis decreased when dogs were fed a cholesterol-rich diet [10]. Forty-nine years later we know much about the mechanisms involved in this feedback inhibition. One mechanism involves the accelerated degradation of pre-formed HMG-CoA reductase protein by a process that requires oxysterols and a derivative of FPP (see preceding section, Cholesterol Precursors).

A second mechanism involves transcriptional repression. Studies initiated in the 1970s demonstrated that the enzymatic activity of many enzymes involved in cholesterol synthesis, including HMG-CoA reductase [11], HMG-CoA synthase, and FPP synthase, was repressed when cells were exposed to oxysterols but not pure cholesterol. It is now clear that cellular accumulation of cholesterol and/or oxysterols results in decreased transcription of these and many other genes that encode enzymes involved in cholesterol biosynthesis. In addition, transcription of the low-density lipoprotein receptor is also repressed by these sterols (reviewed in [12–14]). Goldstein and Brown and colleagues have identified a novel mechanism that controls the transcription of these genes. Transcription is dependent on the nuclear localization of a transcription factor termed sterol regulatory element binding protein (SREBP) (reviewed in [12–15]). In brief, there are two mammalian SREBP genes that, as a result of the use of alternative promoters and splicing, encode three proteins: SREBP1a, SREBP1c, and SREBP2. Each of these proteins is synthesized as a larger precursor that is embedded in the endoplasmic reticulum via a central hairpin loop containing two transmembrane domains [12]. When levels of cellular sterols are reduced, SREBP is escorted from the endoplasmic reticulum to the Golgi by the membrane-bound chaperone SCAP (SREBP-cleavage activating protein) [16–19]. Once in the Golgi, the SREBPs are sequentially cleaved by the site 1 and then the site 2 proteases (S1P and S2P, respectively) to release the mature amino terminal fragment of SREBP [19–21]. This protein fragment translocates to the nucleus, binds to SREBP response elements (SREs) in the promoters of target genes, and activates transcription [12]. These target genes encode enzymes that control the synthesis of cholesterol, fatty acids, triacylglycerides, phospholipids, and NADPH [13,14]. Space limitations prevent further discussion of this area, but the reader is referred to several reviews [1,12,15,32].

The cleavage and maturation of SREBPs is prevented by specific oxysterols but is relatively unaffected by pure cholesterol [22]. However, since exogenously added oxysterols have been shown to enhance the translocation of

cholesterol from the plasma membrane to the endoplasmic reticulum [23], it is still unclear whether cholesterol or oxysterols are the active lipid that interferes with the movement of SREBPs and SCAP out of the endoplasmic reticulum.

A recent publication has shed light onto the possible mechanism by which cholesterol/oxysterols inhibit this translocation in mammalian cells; Dobrosotskaya *et al.* reported that the *Drosophila* SREBP protein undergoes a similar translocation and cleavage prior to the entry of the mature protein into the nucleus [24]. However, in contrast to the sterol-regulated translocation and cleavage of SREBPs in mammalian cells, the translocation of the *Drosophila* SREBP was prevented by phosphatidylethanolamine (PE) [24]. This effect specifically required PE containing the saturated fatty acid palmitate [25]. A surprising finding is that cholesterol had no effect on the processing of the *Drosophila* SREBP [24]. Based on these studies, the authors suggest a mechanism by which cholesterol and PE regulate the translocation of SREBP in mammals and flies, respectively; they propose that excess cellular cholesterol or PE may alter or distort the lipid phase of the endoplasmic reticulum membrane [24]. Such a change in the lipid phase may be sensed by SCAP (possibly via its "sterol sensing domains") and result in altered conformation of the SCAP protein, such that it can no longer bind and chaperone SREBP to the Golgi [24,26]. Since three other membrane-bound proteins (HMG-CoA reductase, Neimann-Pick C and Patched) are also reported to contain homologous sterol sensing domains [27], these data suggest that the function of all four proteins may be dependent upon their ability to "sense" the fluidity of the membranes in which they reside.

In addition to cholesterol/oxysterols, long-chain unsaturated fatty acids also repress the maturation of mammalian SREBPs [28–31]. In contrast, unsaturated fatty acids do not regulate the maturation of the *Drosophila* SREBP [25]. Taken together, these data suggest that a phospholipid containing one or more unsaturated fatty acids may function to regulate the maturation of mammalian SREBP, whereas in flies, this process is regulated by PE containing the saturated fatty acid palmitate.

Cholesterol Derivatives: Ligands for Nuclear Receptors

As shown in Fig. 1, cholesterol can be metabolized to many steroid hormones, including estrogen, testosterone, dihydrotestosterone, progesterone, aldosterone, and glucocorticoids. Each of these steroids activates specific members of the steroid receptor family (Fig. 1) (reviewed in [33,34]). Cholesterol can also be metabolized to a number of other biologically active compounds that function as potent agonists for other members of the nuclear receptor superfamily (Fig. 1). These agonists, which include oxysterols, primary bile acids (chenodeoxycholic acid and cholic acid), secondary bile acids (lithocholic acid), and 5 β -pregnane,3,20-dione, activate LXR, FXR, PXR, and/or VDR, as illustrated in

Fig. 1 [35,36]. Each of these latter nuclear receptors form functional heterodimers with RXR and bind to specific DNA sequences termed hormone response elements (reviewed in [34,37]). In general, agonists must bind to these DNA-bound nuclear receptor factors in order to activate transcription (reviewed in [38]).

The recent identification of novel nuclear receptors, which include FXR, LXR, CAR, and PXR, their natural ligands (see Fig. 1), their activated target genes [35,39–41], and the generation of nuclear receptor null mice, has led to a wealth of information about the physiological importance of each receptor. The results indicate that these nuclear receptors may represent useful targets for pharmacological intervention. For example, activation of LXR results in decreased cholesterol absorption [42]; activation of FXR results in decreased plasma triglyceride levels [43–45]; and activation of PXR results in the catabolism of a myriad of drugs, xenobiotics, and natural compounds (reviewed in [41]). The recent observations that St. John's Wort (taken as an antidepressant) contains a potent agonist of PXR [46] and that guggulipid (taken as a hypocholesterolemic agent) contains guggulsterone, an antagonist of FXR [47], are particularly intriguing. Based on these reports, it seems likely that many other natural compounds will be discovered that function as agonists or antagonists for these nuclear receptors.

When mevinolin, a natural fungal metabolite, was discovered in 1976 and shown to inhibit HMG-CoA reductase [48] (Fig. 1), few investigators would have guessed that this would lead to a class of drugs called statins that are used extensively worldwide to lower plasma cholesterol levels. Perhaps new agonists-antagonists of the recently discovered nuclear receptors that are activated by derivatives of cholesterol will prove to be equally useful in the clinical arena in the next few years.

Acknowledgments

We apologize to all those investigators whose work we should have referenced but were unable to do so because of severe space limitations. This work was funded by grants from the National Institutes of Health (HL30568 and HL68445 to P.A.E.), the Laubisch fund (to P.A.E.), and a National Institutes of Health Postdoctoral Fellowship (M.A.K.).

Oregon Health and Sciences University,
Portland, Oregon*

Introduction

Location, location, and location are the three most important aspects of real estate. The same may be true for intracellular signaling as the subcellular localization of protein kinases and phosphatases are key determinants that control the response time and specificity of many signal transduction pathways. This is equally true for growth factor, phosphotyrosine, and second messenger regulated signaling events where the localization of enzymes in close proximity to substrates ensures an efficient relay of information and directs the signal toward a subset of target proteins. This “protein proximity” section of the handbook highlights a range of cellular mechanisms that contribute to the compartmentalization of signaling enzymes and the assembly of multiprotein networks. Three general areas are covered:

1. Techniques for the analysis of protein-protein interactions,
2. Subcellular structures and multiprotein complexes that contribute to cell signaling and
3. Kinase and phosphatase targeting proteins.

Techniques for the Analysis of Protein-Protein Interactions

The first four chapters describe some of the methods that are used to define protein signaling networks. Advances in mass spectrometry techniques have revolutionized the analysis of multiprotein complexes. The opening chapter by Shao-En Ong and Mathias Mann (chapter 172) introduces this approach and provides a practical step by step explanation of how signaling complexes are dissected. Paul Graves and Tim Haystead (chapter 173) expand on this theme by discussing some innovative approaches that use affinity

chromatography and fluorescent tagging to isolate and characterize native signaling complexes. Peter Verver and Philippe Bastiaens (chapter 174) introduce Fluorescence Resonance Energy Transfer (FRET) and optical techniques that provide sensitive means to quantify and detect protein interactions in living cells. Finally, Gary Bader and colleagues (chapter 175) describe a combined phage display and yeast two-hybrid approach that has been successfully used to map protein-protein interactions within the yeast proteome.

Subcellular Structures and Multiprotein Complexes

The next six chapters define some of the specialized subcellular structures where signaling networks are organized and describe certain cellular events that are controlled by multiprotein transduction units. Benjamin Geiger and colleagues (chapter 176) describe the molecular architecture of focal adhesions, where cells attach to the extracellular matrix and transfer signals to the actin cytoskeleton. Karl Saxe (chapter 177) presents evidence for SCAR/Wave and WASP proteins in the coordination of signals from Rho family GTPases to the actin remodeling machinery. Mary Kennedy (chapter 178) defines NMDA receptor signaling complexes at the postsynaptic densities of neurons. Hana Bilak and colleagues (chapter 179) describe the Toll family of receptors, which detect pathogen-associated materials and activate the innate immune response. Andrey Shaw (chapter 180) introduces a protein/membrane compartment called the immune synapse that provides a molecular basis for T cell signaling. Mark Hochstrasser (chapter 181) outlines the ubiquitin-proteasome system, an important group of cellular proteins and enzymes that target degradation, and removal of selected proteins. Finally Guy Salvesen (chapter 182) describes the role of caspase cascades in the interleukin mediated apoptosis.

Kinase and Phosphatase Targeting Proteins

The final seven chapters of this section introduce some of the anchoring, adapter and scaffolding proteins that organize broad specificity protein kinases and phosphoprotein phosphatases. Elaine Elion (chapter 183) provides a historical perspective by describing the identification and analyses of scaffolding proteins that maintain Mitogen Activated Protein (MAP) kinase cascades in yeast. A complementary chapter by Roger Davis (chapter 184) defines MAP kinase and Jun kinase scaffolds in mammalian cells. Mark Dell'Acqua introduces the A-kinase Anchoring Proteins (AKAPs) that localize the cAMP-dependent protein kinase at specific sites inside cells in chapter 185. This theme is

expanded in chapter 186 by Lorene Langeberg and myself as we explore the cellular roles of AKAP signaling complexes containing PKA, PKC and signal termination enzymes such as phosphatases and phosphodiesterases. Peter Parker and colleagues (chapter 187) cover the topic of PKC binding partners and document the various classes of interacting proteins that compartmentalize this enzyme family. Roger Colbran (chapter 188) reviews the extensive literature on protein phosphatase localization with special emphasis of the role of targeting subunits that direct their enzymes to synaptic sites. Finally, in chapter 189, Marc Mumby and colleagues catalog the numerous families of targeting subunits that compartmentalize and modulate the activity of protein phosphatase 2A.

Introduction

The complex web of signaling pathways and their mechanisms of action rely heavily on protein-protein interactions. These interactions often involve large signaling complexes containing many different protein kinases, protein phosphatases, their substrates, and scaffold proteins. For instance, the scaffold proteins, kinase suppressor of Ras (KSR) and Mek partner 1 (MP-1), bind members of signaling cascades in close proximity and help maintain the stoichiometric binding of these molecular scaffolds to kinases, which can determine the amplitude of the transduced signal[1].

The classical approach to the study of protein-protein interactions has been to employ antibodies and glutathione S-transferase (GST) fusions for the coprecipitation of proteins. These studies often make use of Western blotting as readout and as such are limited to use in verification rather than discovery, since antibodies or epitope tags specific to each potential interaction partner are required.

As studies of protein-protein interactions developed, new genetic approaches like the yeast two hybrid (Y2H) method [2] appeared that allowed the screening of large libraries of proteins for interacting partners. This approach is now commonly used to test for protein-protein interactions in functional characterization of proteins and has also been used in several large-scale Y2H studies (see Chapter 53, this volume).

With the advent of sensitive mass spectrometric technologies that allow the rapid identification of proteins in complex mixtures, protein interaction mapping on the scale of whole organisms has now become technologically feasible. In this chapter, we discuss the general principles that govern the study of multiprotein complexes by coprecipitations and subsequent analysis by mass spectrometry (MS), highlighting the role of MS as an especially useful and powerful tool in the field of cellular signaling.

General Considerations of the Coprecipitation Experiment

The coprecipitation experiment consists of three fundamental steps—presentation of the bait, providing the “hook” or affinity tag, and employing a particular mass spectrometric technology for binding partner identification (Table I). The examples described below (and in references cited therein)

Table I The Three Tiers of the Coprecipitation and Mass Spectrometric Approach to the Study of Protein-Protein Interactions

Introduction of bait		
<i>In vitro</i>	<i>In vivo</i> with transient/ inducible overexpression	<i>In vivo</i> with endogenous promoter
Separate expression of bait (e.g. with GST vector in bacterial expression, incubation of lysate with GST-protein for pulldown)	Bait is epitope tagged expressed directly in system studied under the control of a inducible promoter (e.g. <i>GALI</i>)	Bait is epitope tagged, homologous recombination of tagged gene to achieve genomic replacement.
Choice of affinity separation/elution		
Single tag	Single tag with enzymatic cleavage	Multiple tags
Many options available: Can be large tags (GST), small moieties (biotin) or specific reactivities (6xHis). Monoclonal antibody specific epitopes (Flag, Myc, Hemagglutinin)	Affinity selection is similar to single tag, release from column is performed with an enzyme specific to the tag to increase specificity. (for example, Protein A or 3xMyc and TEV cleavage [29])	Several variants now exist incorporating different affinity tags and often an internal enzymatic cleavage site. Increased specificity, though more steps perhaps resulting in sample loss.
Mass spectrometric methods		
Gel with MALDI	Gel with tandem MS	Gel free with LC-MS/MS
Matrix assisted desorption ionization time-of-flight MS (MALDI-TOF MS) and peptide mass fingerprinting. Analysis of bands containing only one protein. Less specific than tandem MS.	Prefractionation of sample with SDS-PAGE Nano electrospray and tandem MS and MS/MS. Analysis of simple mixtures. Sequence information allows unambiguous protein identifications.	Liquid chromatography and MS/MS allows analysis of complex mixtures. Separation of peptides in time as well as automated data acquisition will make this tool highly suited for large-scale approaches.

Depending on the experimenter's needs and the system studied, some combinations may prove more useful. Refer to text for further discussion.

illustrate the use of coprecipitation and mass spectrometry in a variety of ways and are not intended to be an exhaustive review. The pros and cons of each choice (bait format, type of tag, type of MS used) should be evaluated for each study. Important variables that govern these choices include the amount and type of starting material available (cell lysates versus tissue); the type of complexes to be purified, the strength of their interactions; the inherent tradeoff between specificity of purification and the loss of weaker interacting proteins; and the degree of prefractionation and the scale of the experiment (single bait versus proteome-wide).

GST-Tagged Proteins

Glutathione S-transferase (GST) fusions with bait proteins are well established as a means for coprecipitating interacting proteins. The major advantage of GST-fusions is that large amounts of the bait can often be easily made in bacterial expression systems. These fusion proteins can be used for coprecipitation studies in an *in vitro* format; that is, large

volumes of cell lysate are incubated with the GST-fusion and subsequently purified over glutathione-agarose. Fig. 1 shows an example in which GST-fusions with an interaction domain like SH2 yielded promising results in coprecipitation experiments. Other examples of coprecipitation experiments with GST-fusions and mass spectrometry include the identification of novel binding partners for Shc [3] and the Cdk5 activator protein p35^{neck5a} [4].

Although the use of GST fusions is widespread and it is a tremendously useful technique, there are some disadvantages in its application to large-scale proteomics studies. First, the large size of GST (220 aa) may sterically inhibit complex formation. Second, the production of GST fusion proteins in bacterial expression systems may also mean that the protein may not be folded in its native state. Third, bacterially expressed recombinant proteins are sometimes unstable and/or less soluble and do not carry mammalian posttranslational modifications. Fourth, bait presentation is not done within the cell and so the physiological relevance of the protein interactions is less certain than with *in vivo* methods.

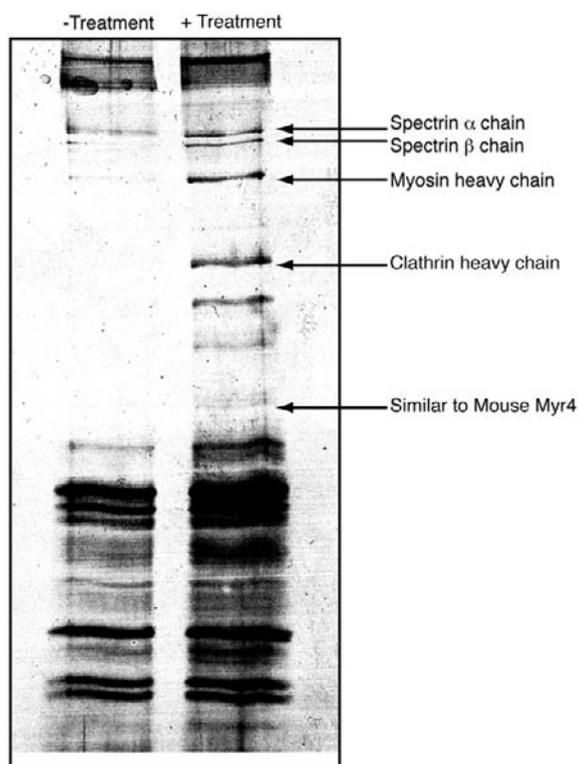

Figure 1 GST-SH2 coprecipitation experiment in mammalian cell lysates. Proteins in the right lane (marked with an arrow) are pulled down by the GST-fusion with SH2 following treatment, suggestive that these bands are specific. Gel bands were excised and then analyzed by Nano ES tandem MS.

For the above reasons, this approach is most useful as a validation method for protein interactions suggested by other evidence. For large-scale fishing strategies where coprecipitation is used as a discovery tool, we suggest considering other tags (refer to Table I for a summary of features in some of the more commonly used tags).

Antibodies

In discovery-oriented approaches—that is, where the interacting partners were not already suspected—the coupling of coimmunoprecipitation and mass spectrometry has proven to be an elegant and effective approach for finding novel substrates and novel proteins in growth factor and cytokine receptor signaling [5]. In addition to directing an antibody against a single “bait” protein, the antibody can also be directed against a common feature of a group of proteins, such as a phospho-residue. Pandey *et al.* were able to identify novel substrates of both the epidermal growth factor receptor (EGFR) and the platelet derived growth factor receptor (PDGFR) signaling pathway with the use of antiphosphotyrosine antibodies to immunoprecipitate phosphoproteins from cell lysates [6–8]. In these pull-down experiments, gel bands resolved by one-dimensional SDS-PAGE from immunoprecipitates of experimental samples treated with cytokine or

growth factor were compared with untreated controls. Gel bands specific to treated cells were excised, digested, and analyzed by tandem mass spectrometry. In the example of the analysis of immunoprecipitated proteins from EGFR signaling, nine proteins were identified. Of these two were previously undescribed substrates in EGFR signaling and seven others were previously known.

The use of antibodies against endogenous bait protein is attractive because the bait is in its *in vivo* state, which makes this experiment the closest to the *in vivo* situation. However, it should be noted that it can be quite time consuming to develop antibodies against a large set of proteins and that the subset of antibodies capable of immunoprecipitating proteins is small. The specificity and ability to pull down proteins is also exceedingly variable (for example, the antiphosphoserine and antiphosphothreonine antibodies are not as effective as currently available antiphosphotyrosine antibodies). Large-scale collections of validated antibodies against all human proteins would solve these problems.

Epitope Tags

Epitope tags were historically derived by mapping the interaction site of monoclonal antibody (linear epitope of less than ten amino acids), and then fusing this epitope to bait proteins of interest. A commonly used epitope tag is the FLAG peptide [9,10]. Its salient features are its small size (8 aa), its hydrophilicity, and the availability of good monoclonal antibodies for highly specific purification. The size and hydrophilic nature of the tag were specifically designed to minimize the tag’s effect on the formation of native protein complexes. Plasmid vectors for adding N- and C-terminal versions of the FLAG tag to the bait of interest exist, and each have specific conjugated monoclonal antibodies raised against them. Although these antibodies are highly specific, they do not have a large binding capacity. In MS-coupled approaches, this high specificity is a desirable tradeoff versus the lower cost of the GST-based approach, and the high sensitivity of MS may mean that large preparations are unnecessary. As shown in Table II, other epitope tags, such as Myc and HA, have also been used, but they may not be appropriate for use for their own reasons: Myc tagged proteins are difficult to elute from the monoclonal antibody (9E10) and should be used in conjunction with enzymatic cleavage (see below); anti-HA (12CA5) antibodies are not as specific as anti-Myc or anti-Flag antibodies.

In an effort to increase specificity of the affinity purification without the use of monoclonal antibodies, the combination of multiple epitopes in a single tag has recently been popularized (for example, TAP for tandem affinity purification [11]) and has been used successfully in several recent studies [12,13]. In the TAP example, the tag consists of a calmodulin-binding peptide and an IgG-binding region (ProtA) with a tobacco etch virus (TEV) cleavage site separating the two epitopes. Briefly, the tagged protein and its associated proteins are first purified on IgG beads, washed, and then eluted by

Table II A Summary Table of Common Tags Used in coprecipitation Studies

Types of Tags ^a	GST	Biotinylated	6xHis	Epitope	Affinity tag with enzymatic cleavage
Size of tag	Large, 26 kDa protein (220 aa residues)	Biotin plus linker region is small	Small	Less than 10 amino acids; (FLAG, Myc; HA)	Large, bulky (e.g. TAP is 184 aa residues)
Features	Many commercial vectors available in different expression systems	Biotin as a reactive hook for fishing with avidin conjugated beads Requires a chemical modification that attaches biotinylated tag to reactive moieties on peptide chain	Polyanionic	FLAG has an enterokinase cleavage site, hydrophilic tag; Myc binds tightly and should be combined with enzymatic release; HA is less specific	ProtA and TEV (29); TAP tag as a modification-Multiple affinity tags Protein A, Calmodulin binding peptide, Internal cleavage site (11, 30)
Purification	Fairly specific, glutathione conjugated agarose for affinity purification	Avidin binding is extremely strong, fairly specific depending on the type of avidin	Commonly Immobilized Metal Affinity Chromatography (IMAC) like Ni-NTA resin, not very specific.	Monoclonal antibodies-very specific	Enzymatic cleavage is one of the first steps to elute bound material. In TAP tagging, first bound to one affinity matrix (IgG beads), cleave purification tag internally to release, bind to second affinity matrix (calmodulin beads) elute with EGTA
Ease of elution	Competitive elution with glutathione; enzyme cleavage (e.g. thrombin)	Requires harsh elution conditions, typically organic solvent/acid.	Mild elution conditions with 100mM imidazole or with L-histidine	Gentle-competitive elution with the peptide constituting the epitope	Enzymatic cleavage is generally specific. Dual elution steps-both fairly mild but might be biased against specific classes of proteins (EGTA)
Potential Pitfall	Large size of tag may interfere with native protein or protein complexes	Chemical modification is not specific-requires purification of complex to homogeneity which is generally impractical; harsh treatment of sample.	Affinity matrix is not very specific to His-tagged proteins. Might also pull down other proteins.		More complicated purification procedure; Complex needs to be stable under enzymatic release

^aSee also [31,32], for a good discussion of available tags.

incubating with the TEV protease. The enzyme will cleave the tag, resulting in the elution of the protein complex. The eluate is affinity purified in the next step over calmodulin beads and subsequently eluted with EGTA. The TAP tag and other purification methods based on two orthogonal principles significantly reduce background. Often, a single tag, for example Protein A or $n \times$ Myc, achieves similar specificity when combined with enzymatic release of the complex and is simpler to perform. Limitations of the TAP method include the large size of the tag (184 aa residues), the requirement for stability of the complex during enzymatic cleavage, and the fact that some mammalian proteins contain the recognition site for the TEV protease.

Mass Spectrometric Approaches

Since the mid-1990s, mass spectrometry (MS) has been the definitive method used for protein identification. Technological developments have brought significant advances in the sensitivity and throughput of MS approaches [14,15]. Quantitative approaches using stable isotopes together with MS greatly enhance the utility of such experiments [15].

A well-established and still commonly used approach is the identification of proteins following separation by gel electrophoresis. Proteins are visualized by staining with either silver or Coomassie-based stains. Gel bands from one-dimensional SDS-PAGE gels or spots from two-dimensional

IEF-SDS-PAGE gels are excised, reduced, and alkylated, then digested with a proteolytic enzyme (typically trypsin) in order to yield peptides that are more easily characterized by mass spectrometric methods [16].

The MS method used for the identification of proteins may vary depending on the degree of prefractionation of the sample. For instance, it may be acceptable to use matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) instruments and peptide mass fingerprinting (PMF) for protein identification of well-resolved proteins on two-dimensional gels. Analyses of large proteins (and correspondingly large numbers of peptides) or mixtures of proteins may require the use of tandem mass spectrometry in order to yield unambiguous identifications from femtomole (nanogram) amounts of protein.

Two recent studies in yeast involving the use of epitope tags for the study of multiprotein complexes by mass spectrometry have demonstrated the feasibility of large-scale approaches [17–19]. Notably, up to 25% of the yeast genome was identified in immunoprecipitations of tagged proteins in both studies. An important finding was that datasets from both of these interaction mapping studies did not show considerable overlap with known protein interaction data obtained from Y2H experiments [20]. Datasets from Y2H experiments have also shown that these derived interaction maps show variability even when the same approach is used [21,22]. This may be an indication that such studies, though large in scale, still only sample a small area of the interaction space in the overall scope of protein interactions.

It is important to bear in mind the principal differences between the Y2H approach and the pull-down experiment. Y2H experiments are more suited to the discovery of binary or tertiary (with yeast-three hybrid) of moderate to strong binding strengths. The pull-down experiment is more likely to yield protein complexes that interact strongly within a complex but may consist of a large number of interacting proteins that individually might have a much weaker binding affinity for other proteins within the complex. Another attractive feature of the coprecipitation approach is that the complex is pre-assembled *in vivo* and subsequently affinity purified. It is likely that the maintenance of the physiological conditions where these interactions form would have a positive impact on the biological relevance of the interaction data obtained. In contrast, the Y2H experiment is based on the inherent assumption that the cDNAs will express in yeast and that the interactions persist (or form) in possibly nonphysiological contexts.

Outlook

The combination of affinity purification of proteins and subsequent detection by mass spectrometry has become a very powerful tool over the last few years. Although different tags are continually being developed, the goal remains the same: the specific enrichment of certain proteins either in a modification-dependent fashion or as a member of a larger

protein complex. The choice of the tag depends on the experimental context.

Recently, the move toward high-throughput analyses of complex protein mixtures has led to the increased use of liquid chromatographic separation as an orthogonal method of separation before mass spectrometric analyses [23,24]. In this approach, complex mixtures of proteins (e.g. a cell lysate) are digested in-solution and loaded onto a reverse phase C₁₈ column, desalted, and eluted with a gradient of organic solvent directly into the mass spectrometer for analysis. Present approaches require that one determine the validity of a coprecipitating protein by visualizing the differences with a “control” sample (Fig. 1). It would therefore be necessary to incorporate quantitative information directly in protein complexes studied. This is also necessary because mass spectrometry is becoming ever more sensitive and can detect trace amounts of proteins in a pull-down. Labeling of protein complexes before mass spectrometric analyses with chemical reagents such as ICAT [25] or other derivatizing agents [26,27] may serve this function. In addition, recent methods for the labeling of cells *in vivo* [28,33] may be more suitable as proteins are quantitatively coded at the amino acid level even before any purification steps are performed. By using quantitatively labeled proteins from two different states in coprecipitation experiments, specific protein interactions can be easily distinguished from non-specific ‘background’ with a high degree of confidence and sensitivity [34,35]. Furthermore, this quantitative data can facilitate the determination of stoichiometries of protein binding within complexes.

Acknowledgment

We thank Leonard Foster for critical reading of the manuscript, Blagoy Blagoev for the figure, and other members of the Protein Interaction Laboratory for useful discussions and support. Work done in PIL is supported by a generous grant from the Danish Research Foundation.

Introduction

In this chapter, we discuss how affinity chromatography can be used to purify protein complexes or isolate specific proteomes for further analysis. This approach can facilitate the investigation of protein-protein interactions, enable the identification of novel binding proteins, or allow changes in protein expression or modification to be monitored under different conditions.

Isolation of Specific Proteomes

Proteomics, the study of all proteins expressed in a cell, can provide insight into complex cellular processes. However, studying the entire proteome of a typical eukaryotic cell can be difficult because (1) the number of proteins may exceed the capacity of the systems used to analyze them, and (2) abundantly expressed proteins can dominate the analysis, obscuring less abundant yet potentially interesting proteins. Therefore, we have used affinity chromatography to select for specific types of proteins to simplify and direct the analysis.

Gamma-Phosphate Linked ATP-Sepharose

Several years ago we developed gamma-phosphate linked ATP-sepharose for the affinity purification of protein kinases from complex mixtures [1]. The design of this resin was based upon the orientation of ATP when bound in the active site of a protein kinase. The crystal structure of cyclic-AMP-dependent

protein kinase revealed that the adenine portion of ATP is buried within the binding pocket of the enzyme while the gamma-phosphate group of ATP is exposed to the solvent [2]. Therefore, we linked ATP to sepharose via its gamma-phosphate group to enable binding of protein kinases. An important property is that if ATP is linked through adenosine at N6, the resin becomes nonfunctional [P. R. Graves *et al.*, in preparation].

In addition to protein kinases, ATP-sepharose is capable of binding a large number of other purine-utilizing enzymes including the NAD⁺/NADP⁺ utilizing dehydrogenases, DNA ligases, nonprotein kinases, mononucleotide ATPases, and nonconventional purine utilizing enzymes. Indeed, the number of proteins that utilize purines (the purine binding proteome) is quite large and has been estimated to represent about 4% of the human genome [3]. Characterization of proteins that specifically bound ATP-sepharose from a whole mouse lysate revealed that a significant portion of the purine-binding proteome was captured (P. R. Graves *et al.*, in preparation).

The following experiment illustrates how ATP-sepharose (or another type of affinity matrix specific for certain types of proteins) can be used (Fig. 1). Two sets of cells are prepared, one as a control, and one that undergoes some form of treatment (stimulation with growth factors, drug treatments, and so forth). The cells are lysed, and the extracts passed over a column of ATP-sepharose to capture the purine-binding proteome from each sample. After washing to remove non-specific proteins, proteins are eluted with ATP and resolved by one- or two-dimensional gel electrophoresis. Proteins that are altered in their expression levels or have undergone

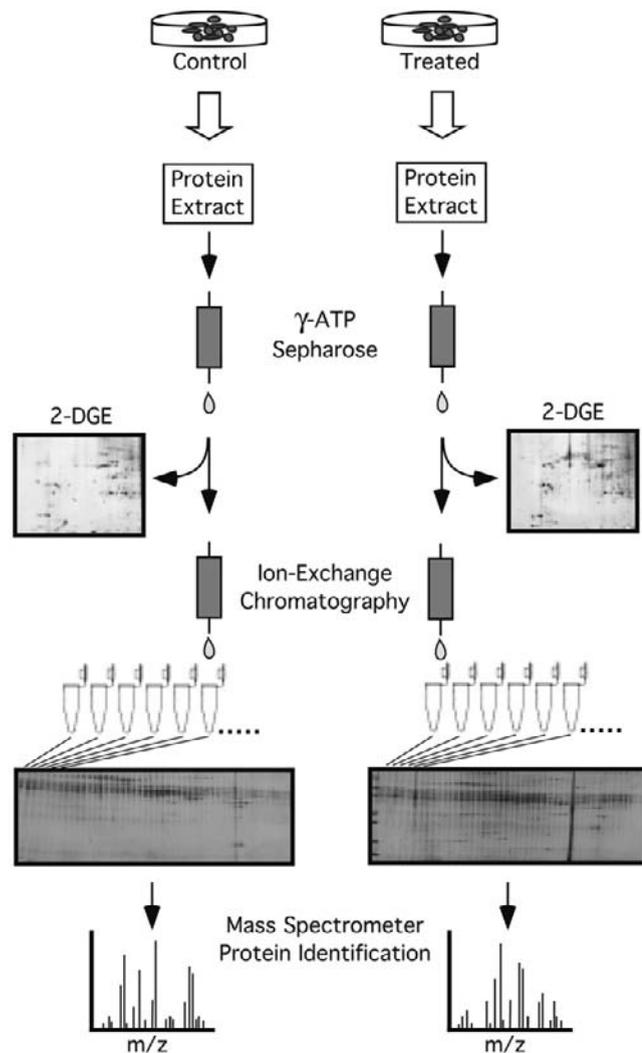

Figure 1

changes in modification (such as phosphorylation) are excised from the gel and identified by mass spectrometry (Fig. 1). Alternatively, proteins isolated by ATP-sepharose can be further purified by more specific techniques before analysis.

Phosphoprotein Enrichment

Protein phosphorylation is a reversible and widespread mechanism for regulating protein function. One goal of proteomics is to allow study of the phosphoproteome, or all the phosphorylated proteins expressed in the cell, under different conditions. However, many phosphorylated proteins are in low abundance and cannot be detected in a whole cell extract. Therefore, a number of techniques have emerged to enrich for phosphorylated proteins. Two methods were recently reported that capture phosphorylated proteins by converting the phosphoamino acids in proteins to groups that allow attachment of affinity ligands for their subsequent purification [4–6]. However, because of the chemistry and the purification strategy involved in these methods, it is still

unclear whether low-abundance phosphoproteins can be recovered [4,5]. We developed a method to label phosphoserine in proteins or peptides with a fluorophore [7] based upon the work of Meyer and colleagues [8]. The labeling of phosphorylated amino acids with fluorescent moieties could serve as an alternative to labeling with the radioisotope ^{32}P and be used to study phosphorylation in animals, intact tissues, and humans [7].

Affinity Chromatography for the Isolation of Protein Complexes

Microcystin-Sepharose Chromatography for the Study of Protein-Protein Interactions

Microcystin is a cyclic heptapeptide known to inhibit type 1 and 2 protein phosphatases by binding to their catalytic subunits [9]. Microcystin-sepharose was developed by Sugimura and colleagues [10] and has been used for the purification of PP-1 and PP-2A [11,12]. We have used this resin for the identification of novel protein phosphatase interacting proteins [11,12]. Skeletal muscle lysates were applied to microcystin-sepharose and bound proteins analyzed by one-dimensional gel electrophoresis and protein sequencing. Using this approach, 36 protein phosphatase 1-binding proteins were detected and sequenced [12]. In addition to the recovery of many known protein phosphatase binding proteins, a novel PP-1 regulatory subunit was defined [12].

Gamma-Phosphate Linked ATP-Sepharose

Because ATP-sepharose is capable of binding protein kinases, it can also be used to characterize protein kinase complexes. For example, the subunit structure of AMP-activated protein kinase was established by purifying native AMP-kinase with ATP-sepharose [13]. ATP-sepharose was also used for the purification of Cdc28p kinase complexes from budding yeast [14]. Since ATP-sepharose binds protein kinases in the catalytic domain, it offers another method for the isolation of protein kinase interacting proteins.

Specificity of Protein-Protein or Protein-Ligand Interactions

When starting with a cell extract, the recovery of proteins with an affinity matrix will depend on the solubility of the protein target in the lysis buffer, the binding constant between the protein and the ligand, the abundance of the protein, and the stability of the protein in the cellular extract. Regardless of which affinity approach is used, proteins will be isolated that are not specific for the protein or ligand used because of interaction with the affinity ligand support. Therefore, in each case the appropriate controls need to be performed. If two samples are being compared, ideally, an identical affinity

column should be used for both samples. If a “bait” protein is being used to isolate interacting proteins, then it is a good idea to use a scrambled or irrelevant protein of the same mass as a control. In some cases, specific mutations can be introduced into the bait protein to prevent protein interactions. Double epitope tagging (also known as tandem affinity purification, or TAP) has also been used to increase the stringency of protein complex isolation [15].

One of the most important steps in affinity chromatography is the elution step. Elutions should be performed with an excess of the ligand used for the affinity matrix. In this way, the risk of nonspecific protein elutions is likely to be eliminated. As an example, to increase specificity, we linked microcystin to biotin for the capture of phosphatase interacting proteins [11]. This provides two advantages. First, since mild conditions can be used to elute the bound proteins, holoenzyme complexes remain intact. Second, since the elution is performed with biotin, only proteins that bind to microcystin are eluted, eliminating proteins that bind to the column matrix. Some additional factors to be considered are (1) Can the binding of the recovered proteins to an affinity column be rationalized? For example, if a protein is recovered with ATP-sepharose, is it a purine-utilizing enzyme or does it have a binding site for a molecule resembling ATP? (2) Does pretreatment of the extract with free ligand prevent binding of proteins to the column? (3) Does the protein binding survive stringent washing conditions? (4) Can the result be confirmed by other methods such as far western or co-immunoprecipitation experiments? Because of the complexity of the proteome of a eukaryotic cell and the fact that many proteins of low abundance cannot be detected in a cell lysate, affinity chromatography will continue to be an important method for the isolation of specific types of proteins.

Introduction

Detection of fluorescence resonance energy transfer (FRET) by optical techniques provides a sensitive means of detecting and quantifying molecular interactions and protein modifications in cells. Several strategies are available to develop sensors for use in FRET assays based on fluorescent labeling or green fluorescent protein (GFP) fusions. By using these sensors, techniques such as ratio imaging, sensitized emission measurements, photobleaching methods, or fluorescence lifetime imaging can be employed to spatially and temporally resolve the occurrence of FRET in cells. In this contribution, the strengths and weaknesses of the different sensors and measurement methods are discussed and compared and their use illustrated by reviewing the recent literature. We conclude that the spatially and temporally resolved measurement of FRET in cells has opened new opportunities to image biochemistry in intact cells and expect that these techniques will play an increasingly important role in cell biology.

Optical microscopy provides a sensitive, specific, and noninvasive approach to localize fluorescently labeled macromolecules in cells with high spatial and temporal resolution. Moreover, the spectroscopic properties of fluorescence probes can be used to obtain information on their molecular environment. With the advent of genetically encoded variants of green fluorescent proteins, the observation of biochemistry in cells has become feasible *in vivo* [1–3]. Fluorescence resonance energy transfer is one photophysical phenomenon

that has been put to good use to detect and quantify molecular interactions and protein modifications [4]. FRET cannot be measured directly, but the resulting changes in the fluorescence properties of the fluorophores can be detected by several optical techniques with spatial and temporal resolution inside cells. FRET is a photophysical effect whereby energy is transferred from an excited donor fluorophore to an acceptor fluorophore. This does not involve the emission and subsequent absorption of a photon but occurs by a direct electromagnetic interaction. The efficiency of transfer depends on the spectral properties of donor and acceptor, and on their relative orientation and distance. An important factor is that the energy transfer efficiency has an inverse sixth order dependence on the distance between the two fluorophores, and typically FRET only occurs when the distance is less than 10 nm, which is generally only achieved when donor and acceptor are attached to the same macromolecule or to interacting molecules. For this reason FRET can be applied to specifically image such events as molecular interactions or conformational changes. FRET can be observed by its consequences, which are reflected by a change in the fluorescence kinetics of both the donor and the acceptor. Due to the transfer of energy the rate at which the donor returns to its ground state increases, and hence its fluorescence lifetime decreases. As a consequence the quantum yield of the donor, and therefore its steady-state fluorescence intensity, also decreases. The steady-state fluorescence of the acceptor, however, is increased by the sensitized emission that is emitted when the acceptor returns to its ground state.

Fluorescent Probes for FRET

The design of the fluorescent probes for FRET measurements must match the problem at hand. Single component molecule sensors, consisting of two fluorophores flanking a protein domain or subunit, change FRET efficiency upon a change of conformation or cleavage. These types of sensors are commonly constructed by fusing cyan and yellow variants of GFP to the reporter domains. They can be used to detect physiologically relevant ions [5–7] and small organic compounds [8–10], or report on protein activity or conformational or covalent state [11–14]. They can be targeted to specific cellular compartments by incorporating suitable localization signals. Another class of sensors is based upon the interaction between different compounds tagged with a donor or acceptor fluorophore [15–20]. One application is the detection of covalent modification of a protein, in which case the protein is tagged by a donor, and an acceptor-tagged reagent interacting with the conjugated group is present in large excess. The state of donor-tagged proteins can then be probed by FRET. An example is the use of generic phosphoamino-acid-specific antibodies to probe the phosphorylation state of a protein, whereby the protein is tagged with a donor fluorophore (e.g. by fusing a GFP molecule) and the antibody with the acceptor fluorophore (e.g. Cy3). Another application, not necessarily employing an excess of one species, is using cyan and yellow GFP variants to measure interactions between different proteins, or homo- or hetero-dimerization *in vivo*. The use of GFP variants is attractive for live cell applications, but FRET measurements can also be done via labeled antibodies. This may seem potentially problematic due to the antibody size, but depending on the donor/acceptor configuration and the type of FRET measurement this may in fact be an advantage. Consider an assay to probe the state of a protein based on the observation of the donor fluorophore (e.g. a GFP) only and an antibody labeled with multiple acceptor fluorophores (e.g. Cy3; see [20]). In this case, the increased density of acceptor fluorophores implies a higher probability that upon antibody binding, the donor is in close proximity of an acceptor. However, using an antibody labeled with multiple donor fluorophores would lead to an increased probability of detecting a donor that is too far away from an acceptor for efficient FRET and therefore a lower average signal. In general, the choice of sensor, fluorophore (GFP or fluorescent dye), and where donor and acceptor are located is also determined by the measurement method that is used. The different techniques are described in the next section, where the types of sensors that are appropriate for the respective techniques will also be discussed.

FRET Detection Techniques

Ratio Imaging

Upon the occurrence of FRET the steady-state fluorescence of the donor is quenched, since part of the excited state energy

is transferred to the acceptor rather than emitted as photons. Simultaneously, emitting this energy as photons increases the steady-state fluorescence of the acceptor. Therefore, a change in FRET is reflected in an increase in the ratio of sensitized emission over donor emission. This type of measurement is straightforward, as it requires only measurements at two filter settings, and is therefore well suited to live cell imaging.

In an ideal situation, the sensitized emission and donor emission would be directly measured by choosing appropriate combinations of excitation and emission filters, exciting the donor specifically, and detecting the intensities through filters specific for donor and acceptor emissions. Indeed, the donor emission can be imaged specifically; however, in practice the measured acceptor channel contains significant contributions of leak-through of the donor emission and of direct excitation of the acceptor. This implies that the signal in the acceptor channel is strongly dependent on the relative concentrations of donor and acceptor, and that interpretation of the ratio as a diagnostic for FRET is problematic. However, if the relative concentrations of donor and acceptor are fixed, then a change in the donor/acceptor fluorescence ratio can be attributed to a change in FRET. Therefore this approach should mainly be used with sensors that consist of donor and acceptor fluorophores attached to a single molecule. A change in FRET due to a conformational change can then be reliably detected. Another situation is presented by a sensor where donor and acceptor disassociate, for instance by proteolytic activity. In such a case the relative concentrations are known before cleavage and, if no significant differential relocation of the cleaved products is expected, the ratio may still be a good measure of FRET. Also, if one is only interested in the total signal integrated over a cell, the relative total concentrations can be considered to remain the same, although this assumption may be incorrect in a confocal microscope, where molecules may relocate to a position outside the focal plane.

In general, quantification of ratio measurements in terms of the concentrations of the species that exhibit FRET is not straightforward, due to the unknown contributions of leak-through and direct excitation. However, it is possible to externally calibrate the ratio values to physiologically relevant quantities by using reference samples where a known concentration of the species of interest can be related to the measured ratio.

Ratio measurements of FRET have been utilized in a wide spectrum of applications. They have been used as an indicator for adenosine 3',5'-cyclic monophosphate (cAMP) [8,10], guanosine 3',5'-cyclic monophosphate (cGMP) [9], and Ca^{2+} [5,6]. More recently sensors for protein kinase [11,12,14], and GTPase [13] activity have been described.

Sensitized Emission Measurements

Whereas ratio measurements are difficult to quantify, it is possible to make use of reference measurements to further quantify results. Generally three measurements are made: (1) using a filter set where the donor is excited and the donor

emission is measured (donor filter-set); (2) using a filter set where the acceptor is excited and the acceptor emission is measured (acceptor filter-set); (3) using a filter set where the donor is excited and the acceptor emission is measured (FRET filter-set). The images from the donor and acceptor filter sets are multiplied with correction factors and subtracted from the image taken with the FRET filter-set to obtain the sensitized emission, corrected for contributions of donor leak-through and direct excitation. The correction factors are determined via reference samples that contain only donor or only acceptor molecules. The resulting estimation of the intensity of the sensitized emission is then normalized for donor and/or acceptor concentration by using an expression for apparent energy transfer, for which several approaches have been taken [21–23]. Ideally, quantification should provide the relative fraction of molecules that are exhibiting FRET. Up to a scalar factor, it is indeed possible to determine the fraction of acceptor molecules that are exhibiting FRET, since the acceptor concentration can be directly related to the acceptor fluorescence. Determining the fraction of donor molecules that exhibit FRET is much more difficult, since the donor fluorescence is not proportional to the donor concentration, owing to the quenching of the donor fluorescence by FRET. The donor concentration can, however, be measured using acceptor photobleaching, as described below.

In contrast to ratio measurements, this approach is suited to applications where donor and acceptor are not on the same molecule, due to the correction for leak-through and direct excitation. They are also suitable to live cell imaging since only three measurements need to be made. Mostly these approaches are used when donor- and acceptor-tagged molecules have concentrations that are in the same order of magnitude [17]. This FRET method may become less effective in cases where the acceptor is in large excess, since the corrections for direct excitation become large and the result is more susceptible to noise. Similarly, a large excess of donor leads to large corrections for donor leak-through, with associated problems to estimate the sensitized emission. Thus this approach is likely to be less suitable for sensors where a protein state is determined by a large excess of a probe, although sensors to probe the state of a protein have been reported [18]. Even if donor and acceptor concentrations are similar, the corrections can be large, depending on the spectral properties of the donor/acceptor pair that is employed. The different variants of GFP are examples in which the corrections may be substantial, and in such cases this method works best with a high energy transfer efficiency between donor and acceptor, implying a large relative contribution of sensitized emission.[18]. We note that the correction factors are generally determined from averages of images of reference samples, and are therefore scalar factors. It is not known how much these factors change as a function of the environment or whether scalar correction factors are sufficient.

Sensitized emission measurements have been used to study the interactions between different molecules. Examples are the studies by Sorkin and colleagues, who looked at the

interaction of the EGF receptor with Grb2 in living cells [17], and by Mahajan *et al.*, who investigated interaction of Bcl-2 with Bax [24]. The sensitized emission method was also used to localize the activity of the GTPase Rac [18].

Methods Based on Photobleaching

Photobleaching of either the donor or acceptor molecules can be utilized to detect the effects of FRET on the kinetics of the fluorescence of either. Photobleaching is the process whereby a fluorophore is converted to a nonfluorescent species, for instance in the presence of oxygen. This essentially happens only when the donor is in the excited state and therefore the rate at which photobleaching occurs is proportional to the average time it spends in the excited state, which in turn is inversely proportional to the rate at which the molecule returns to its ground state. Hence, an increase in the latter due to FRET can be detected by a decrease in the photobleaching rate. Thus, one approach to measure and quantify FRET is to measure the kinetics of photobleaching of the donor [25,26]. Generally, the kinetics are described by a sum of exponentials, and it is possible to quantify the fraction of donor molecules exhibiting FRET. Although this is a potentially precise approach, it is not in much use nowadays for several reasons. First, the requirement to photobleach the donor over extended time periods leads to long acquisition times. Therefore the method is mostly useful on fixed samples, although presumably live cells could be used if one is only interested in the integrated response of a complete cell. Second, the mechanisms of photobleaching are not understood very well, although the assumption of a multi-exponential model is reasonable in first approximation.

Rather than examining the photobleaching kinetics of the donor, one can utilize photobleaching of the acceptor [16,27]. Acceptor molecules can be excited specifically, since their absorption spectrum generally does not overlap with that of the donor. One makes use of the simple property that destroying all acceptor fluorophores abolishes FRET. Thus, after photobleaching the acceptor, the donor intensity should increase, since it is not quenched anymore by FRET. Therefore, comparing the intensity of the donor before and after acceptor photobleaching should indicate whether FRET was occurring. Dividing the difference of the donor intensity before and after photobleaching by the intensity after photobleaching yields an apparent energy transfer measure that is directly proportional to the fraction of donor molecules exhibiting FRET. Obviously this approach is attractive since it is experimentally easy, and also interpretation does not require extensive analysis. Acceptor photobleaching does suffer from the same drawback as donor photobleaching in that it is a time-consuming approach less suitable for imaging of FRET in live cells. A point of possible concern that has not been addressed much so far is that photobleaching of the acceptor may create a different species of molecule that fluoresces in the donor channel, leading to an overestimation of the unquenched donor signal. Alternatively, a dark species could be created that absorbs light and

still acts as an acceptor, leading to an underestimation of the unquenched donor fluorescence.

Acceptor photobleaching has been used as an independent technique to measure FRET. For instance, it was used to study the localization of the A- and B-subunits of cholera toxin [16], and recently to image the three-dimensional distribution of receptor tyrosine kinases interacting with protein tyrosine phosphatase 1B [28]. It is also increasingly being used in combination with other techniques as a standard control for the occurrence of FRET [10,14,29,30].

Fluorescence Lifetime Imaging Microscopy

The kinetics of fluorescence can be measured by fluorescence lifetime imaging microscopy (FLIM). This makes it possible to detect whether the rate at which an excited donor molecule returns to the ground state increases by FRET, since the fluorescence lifetime of a fluorophore is inversely proportional to the sum of rates of all possible pathways by which an excited molecule returns to the ground state [31].

FLIM has been applied in a qualitative fashion where an average lifetime is measured that decreases upon FRET [31]. In such a case, photobleaching the acceptor may serve as an internal control since after destruction of the acceptor fluorophore the lifetime of the donor should attain its normal value [30]. In this case, the acceptor photobleaching can also be applied in live cell imaging by photobleaching after FLIM measurements are made. Since the fluorescence lifetime of the donor is independent of concentration and light path-length, the average donor lifetime can then serve as the control value. FLIM has also been applied quantitatively by resolving the multi-exponential decay kinetics of the donor to determine the fractions of donor molecules exhibiting FRET [20].

So far, FLIM has been applied mostly to donor-only imaging. It is therefore well suited to applications in which the acceptor is present in excess, e.g. to probe the state of a donor-tagged molecule [19,20]. However, it is also suited to cases in which the donor and acceptor are available in comparable concentrations [28]. FLIM has also been applied by imaging both donor and acceptor simultaneously. In this case, the kinetics of the acceptor come into play, and it becomes possible to use fluorophores that are difficult to separate spectrally, such as GFP and YFP [32]. In principle, it is then possible to quantitatively determine both the fractions of donor and acceptor that are participating in FRET, but this has not been demonstrated yet. FLIM requires the acquisition of multiple images but is rapid enough to enable live cell imaging. One drawback of the method in comparison with other FRET methods is that it is more technically involved and equipment cost is higher.

FLIM has been used in a wide variety of applications, among others to probe the phosphorylation state of proteins such as PKC α [19] and the EGF-receptor [20,30] and to study the proteolysis of PCK β 1 [15], the oligomerization of EGF-receptors [33], and the interactions between PKC α and ezrin [29]. In a rather different type of application, Murata *et al.* [34]

studied the organization of DNA in cell nuclei by visualizing FRET between the AT-specific donor Hoechst 33258 and the GC-specific acceptor 7-aminoactinomycin D.

Conclusions and Prospects

Exploitation of the physical phenomenon of FRET in biomolecular systems has opened new ways to image biochemistry in live cells. Several optical techniques to measure FRET have been developed in recent years and the number of applications of these techniques to relevant biological systems has been increasing steadily. All of these techniques have their strengths and weaknesses, and it is to be expected that the technological developments will continue for some time. In addition, the development of novel sensors that are based on FRET measurements promises to open more fields of applications, not in the least due to the large variety of GFPs that is becoming available [35,36]. FRET is complementary to biochemical approaches for investigating the complex signaling systems that are encountered at the cellular level in the fundamental biological sciences. We therefore expect that FRET measurements will play an increasingly important role in cell biology in the future.

Introduction

Many of the protein-protein interactions of macromolecular signaling complexes are mediated by domains that function as recognition modules to bind specific peptide sequences found in their partner proteins [1]. For example, SH3, WW, and EVH1 domains bind to proline-rich peptides [2–4], EH domains bind to peptides containing the NPF motif [5,6], and SH2 and FHA domains bind to peptides phosphorylated on Tyr and Thr, respectively [7,8]. For particular modules within the same family, specificity is determined by critical residues in the binding partner flanking the core peptide motif [9,10]. A major challenge is to construct protein-protein interaction networks in which every module within

the predicted proteome of a sequenced organism is linked to its cognate partner.

To address this problem, we developed a four-step strategy for the derivation of protein-protein interaction networks mediated by peptide recognition modules [11–13]. First, the consensus sequences for preferred ligands for each peptide recognition module are defined by isolating 10 to 20 different peptide ligands from screens of phage display libraries. Second, the consensus sequences resulting from the phage display experiments are used to computationally derive a protein-protein interaction network that links each peptide recognition module to proteins containing a preferred peptide ligand. Third, a protein-protein interaction network is experimentally derived via large-scale two-hybrid analysis.

Fourth, the intersection of the predicted and experimental networks is determined.

As a test of this strategy, we constructed a protein interaction network for the SH3 domains of the yeast *Saccharomyces cerevisiae*. The SH3 domain is one of the more commonly used protein recognition modules. In fact, over 1500 different SH3 domains have been identified in the protein databases of eukaryotic organisms [14]. The yeast proteome contains a total 28 SH3 domains, found in 24 different proteins [15], the majority of which had been implicated in signal transduction (Bem1, Boi1, Boi2, Cdc25, Sdc25, and Sho1) or reorganization of the actin cytoskeleton (Abp1, Bud14, Cyk3, Hof1, Myo3, Myo5, Rvs167, Sla1) [16,17]. A set of eight SH3 proteins remained to be characterized (Bbc1, Bzz1, Nbp2, Yfr024c, Ygr136w, Yhl002w, Ypr154w, and Ysc84).

We were able to express 24 different SH3 domains in a soluble form as glutathione S-transferase (GST)-SH3 fusion proteins in *Escherichia coli*. Because some of the SH3 domains did not select a ligand from the nonapeptide library, we were able to obtain a consensus sequence for only a subset of 20 different SH3 domains. Most SH3 domains bind to a core PxxP ligand motif (P=proline, x=any amino acid), with particular residues that occur on either side of the core determining binding specificity. Two general classes of SH3 ligands have been defined; class I peptides conform to the

general consensus RxxPxxP (R=arginine) and class II peptides conform to PxxPxR [2]. Most of the yeast SH3 domains selected peptides that aligned to yield a class I or class II consensus ligand, with one to six domain-specific residues constrained outside the PxxP motif (Table I).

The consensus sequences were used to search the yeast proteome for proteins that contained potential SH3 ligands. Because hundreds of the predicted yeast proteins contain an SH3 class I and class II consensus ligand, we used a position specific scoring matrix (PSSM) to rank the peptides present in yeast proteins based upon their similarity to the peptides selected from the phage display libraries. The peptides within the top 20% of the PSSM scores captured most of the literature-validated SH3 domain interactions, and therefore this set was considered as potential ligands. The predicted protein-protein interactions were imported into the Biomolecular Interaction Network Database (BIND) [18] and formatted for visualization in the Pajek package [19], a program originally designed for visualization of social networks. The resulting phage display protein-protein interaction network contained 394 interactions among 206 proteins (Fig. 1A). Proteins are represented as nodes on the graph and the interactions represented as edges connecting the nodes.

Proteins found within highly connected subgraphs can be extracted from more complex networks by using graph

The consensus peptides were derived from an alignment of the selected phage-display peptides (x, any amino acid; lowercase letters, residues conserved in 50 to 80% of the selected peptides; uppercase letters, residues conserved in more than 80% of the selected peptides). Abbreviations for the amino acid residues are as follows: A, Ala; H, His; K, Lys; L, Leu; N, Asn; P, Pro; R, Arg; S, Ser; T, Thr; V, Val; W, Trp; Y, Tyr; #, hydrophobic residues; @, aromatic residues. The consensus sequences corresponding to Class I peptides, first column, Class II peptides, second column; unaligned, third column.

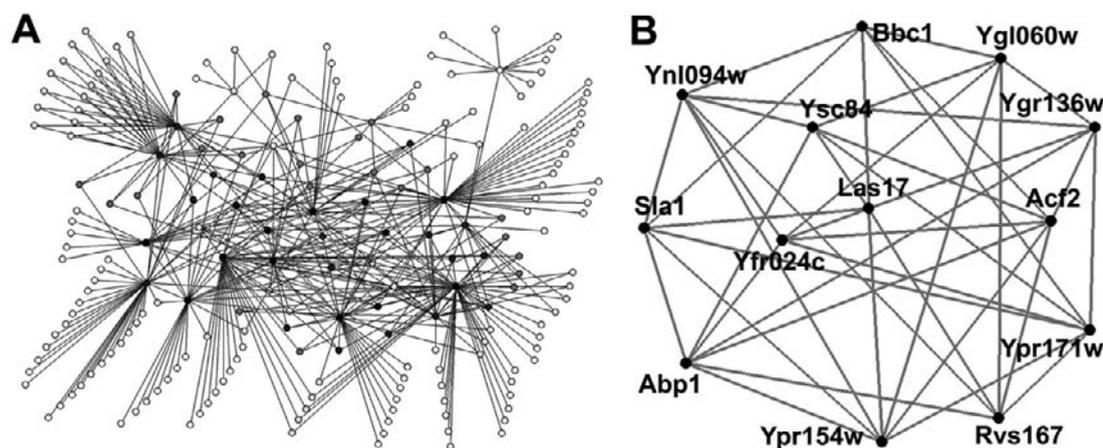

Figure 1 (A) Yeast SH3 domain protein-protein interaction network predicted via phage display selected peptides; 394 interactions and 206 proteins are shown; a network with each gene name labeled is included in the supplementary material [7]. The proteins are colored according to their k-core value (six-core=black, five-core=cyan, four-core=blue, three-core=red, two-core=green, one-core=yellow), identifying subsets of interconnected proteins in which each protein has at least k interactions. By definition, lower core numbers encompass all higher core numbers (e.g. a four-core includes all the nodes in the four-core, five-core, and six-core). The interactions of the six-core subgraph are highlighted in red. (B) The six-core subgraph derived from the phage display protein-protein interaction network, expanded to allow identification of individual proteins. The six-core subset contains eight SH3 domain proteins (Abp1, Bbc1, Rvs167, Sla1, Yfr024c, Ysc84, Ypr154w, and Ypr171w) and five proteins predicted to bind at least six different SH3 domains (Las17, Acf2, Ypr171w, Ygl060w, and Ynl094w).

theoretical algorithms. The phage display network contained a highly connected six-core subgraph, in which each protein has at least six interactions with the other proteins in the subgraph (Fig. 1B). Because the phage display network represents an integration of all potential interactions and does not take into account temporal expression or protein localization information, the six-core is subject to various biological interpretations. It may represent a single complex, provided all the proteins are co-expressed *in vivo* and all of the interactions occur simultaneously; however, it may represent multiple dimers or other oligomers, each of which forms independently under some cellular state. In any case, the presence of a highly connected core suggests a functional association between the interacting proteins. We examined 1,000 random model networks, in which a similar number of random proteins were linked to each SH3 domain. The model networks were not as highly connected as the phage display network and at most contained a four-core subgraph, indicating that the six-core within the phage display network was unlikely to occur by chance. Indeed, the six-core contains a number of functionally related proteins. At the center of the six-core is Las17, the yeast homolog of human Wiscott-Aldrich syndrome protein, which binds and activates the Arp2/3 actin nucleation complex and assembles the filamentous actin of yeast cortical actin patches [20–23]. The six-core also contains Acf2, a protein required for Las17-dependent reconstitution of actin assembly *in vitro* [24] and a set of proteins that were either implicated previously in the endocytotic role of cortical actin patches (Abp1, Sla1, Rvs167) [25–27] or found to localize to cortical patches (Bbc1, Ysc84, Ynl094w, and Ypr171w) [11,28]. Thus, the construction of a protein-protein interaction network from *in vitro* peptide binding information and the graphical analysis of its connectivity revealed known components of the yeast cortical actin patch complex.

To construct a two-hybrid protein-protein interaction network for comparison to the phage display network, we screened 18 SH3 domain baits against conventional two-hybrid libraries and an ordered genome-wide array of yeast Gal4 activation domain–open reading frame fusions [29]. The results from these screens were assembled into a network containing 233 interactions and 145 proteins (Fig. 2A). Only a subset of the interactions within the phage-display network and the two-hybrid network are expected to overlap. In particular, the phage display and two-hybrid methodologies will lead to different sets of false positives, which should exclude them from the overlap network. A total of 59 interactions in the phage display network also occurred in the two-hybrid network (Fig. 2B). All of the overlap interactions are mediated directly by SH3 domains; the precise ligand of the binding partner was predicted by the phage display analysis. Three lines of evidence suggest that the interactions within the overlap network are meaningful. First, the phage display network was highly enriched for overlap interactions when compared to the random model networks, which contained an average of 0.84 overlap interactions (SD=1.01). Second, the overlap network was enriched for interactions validated previously in the literature, over three-fold compared to the two-hybrid network and over five-fold compared to the phage display network. Third, a focused analysis of the proline-rich peptides within Las17 revealed that the phage display ligand analysis consistently predicted the ligand fragment that showed the strongest binding.

Future experiments of this type may be able to achieve better results by optimizing specific steps. For example, some false positives in the phage display approach undoubtedly arise because the predicted ligand peptide is, in fact, buried in the core of the protein. This aspect of the analysis could be improved by assessing surface accessibility with a program

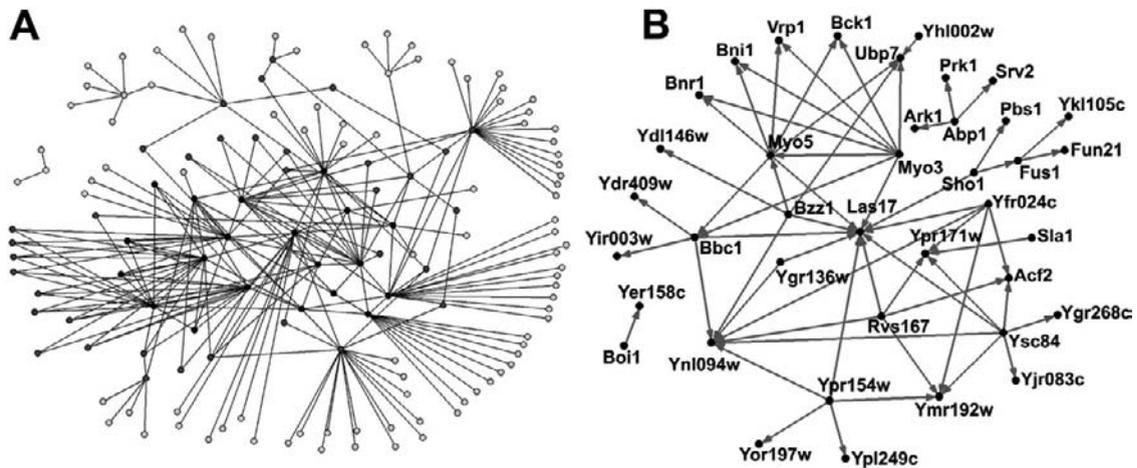

Figure 2 (A) Two-hybrid SH3 domain protein-protein interaction network. Two-hybrid results, based largely on screens with SH3 domains as baits, generated a network containing 233 interactions and 145 proteins. Proteins are colored according to their k-core (see Fig. 1A). The largest core of the two-hybrid network is a single four-core (blue nodes). Interactions common to the phage display network are highlighted in red. (B) Overlap of the protein-protein interaction networks derived from phage display and two-hybrid analysis. Expanded view of the common elements of the phage display and two-hybrid protein-protein interaction networks, 59 interactions, and 39 proteins. All of these interactions are predicted to be mediated directly by SH3 domains. The arrows point from an SH3 domain protein to the target protein. Additional evidence to support the relevance of several of these interactions is provided as supplementary material.

such as PHDacc [30], or homology models [31] of the protein could be scanned. Another means to improve proteome scanning would use a specificity and sensitivity analysis to assess what PSSM score threshold would retain the largest number of physiologically relevant interactions (true positives) and discard as many potential false positive interactions as possible. In this case, false positives can be defined operationally as those not identified within the literature or the yeast two-hybrid network. Thus, the optimization could be based on maximizing overlap with the yeast two-hybrid network or a set of confirmed interactions from a literature-based benchmark.

The overlap step could be improved in a number of ways. While the reasons for the false-positives and false-negatives of yeast two-hybrid screens seem satisfyingly orthogonal to those of the phage display predicted network, other protein interaction experimental methods, such as co-immunoprecipitation coupled with mass spectrometry [32,33], should also be evaluated. The current network representation, with a single node corresponding to a protein and a single edge corresponding to an interaction, could be much improved by making it probabilistic. The attachment of a probability value as a weight on the edges could enter into the overlap calculation to result in a more realistic model. For instance, a weight value on an edge could be high if the interaction has been characterized by several different methods, or found by multiple laboratories. These highly probable edges could be made to appear in the weighted combination of networks; in this fashion, “textbook” interactions would be included even if they were not found by both the phage display and two-hybrid derived networks. A review by Gerstein *et al.* (2002) addresses some of these points in more detail [12]. A better visualization tool that could draw networks with probabilistic

information and allow one to examine parameter changes (for example, in the PSSM score threshold) in real-time would complement these method improvements and facilitate evaluation of the results.

Many of these future improvements depend on the availability of a literature-based benchmark, a manually curated collection of high-quality, expert-validated interactions. Sources of more stringently validated interactions are MIPS [17], YPD [34] and PreBIND [33]. Collecting these together in a nonredundant set creates a benchmark of over 3,300 protein-protein interactions for yeast. Because some experimental methods are more likely to yield physiologically relevant information (for example, interactions detected with full length proteins expressed at native levels), the literature benchmark could also include a reliability score for each record.

A set of over 15,000 unique protein interactions collected for yeast from the literature and from all available large-scale studies contained 519 interactions involving 364 proteins in which one interaction partner has an SH3 domain [18]. Because many of these proteins are highly conserved, it will be of interest to determine the extent to which the connectivity of the network is conserved. The prospects for applying this interaction network mapping approach to other organisms are reasonable; for example, *Caenorhabditis elegans* has only 99 SH3 domains in 77 proteins, according to the SMART database, whereas the mouse has on the order of 327 SH3 domains in 172 proteins. A map of peptide-binding module-mediated interaction networks across organisms will provide a powerful dataset to study the specificity of domain-mediated interactions, the evolution of complexity, and the biology that these interactions dictate. Finally, the systematic analysis of binding properties and

protein-protein interaction networks for peptide recognition modules will enable the development of sets of dominant interfering small molecules for systematic functional interrogation of the network [35].

Introduction

Focal adhesions (FA) and related structures are specialized subcellular sites through which cells in culture or in tissues attach to the extracellular matrix (ECM). The molecular structure and dynamics of these plaque-like adhesion sites [1–4], as well as their roles in adhesion, motility, and signaling, have been established in numerous studies over the past decades [5–8]. Although various types of cell-ECM adhesions are formed, affecting anchorage, motility, or ECM assembly, FA are still the best-studied type of adhesion.

The overall structural organization of FA consists of three major domains: transmembrane receptors, the attached cytoskeleton, and interconnecting plaque molecules. These three domains are structurally and functionally interlinked, and mutations that perturb their interactions disrupt the adhesive process. For example, mutations of integrin receptors that truncate the cytoplasmic domains through which they interact with cytoplasmic partners produce functional inactivation. Similarly, disruption of the actin cytoskeleton by use of drugs that inhibit actin polymerization or block actomyosin contractility leads to the loss of FA.

At the molecular level, both the transmembrane and cytoskeletal domains (but not the plaque domain) are relatively simple, with limited numbers of molecular components. The primary molecular constituents of the membrane domain are members of the integrin receptor family that bind specifically to the ECM molecule to which the cell is adhering. For example, when a fibroblast adheres to fibronectin, clusters of both the fibronectin receptor $\alpha_5\beta_1$

and the multipurpose receptor $\alpha_v\beta_3$ accumulate initially in FA, whereas only $\alpha_v\beta_3$ accumulates on a vitronectin substrate [4,9–11].

The cytoskeletal domain of FA consists mainly of actin filaments, with a few associated proteins, such as α -actinin and filamin. In contrast, the submembrane plaque between integrins and cytoskeleton is considerably more complex, consisting of a large number of linker and signaling molecules (more than 50 reported components). Some major actin-associated proteins are also potent linkers of actin to the membrane at FA. For example, α -actinin and filamin may bind to an integrin and also serve as an actin-integrin linker. Because the molecular components of FA have been extensively described and discussed in a number of recent reviews [8,12], they will not be addressed here in detail. Instead, we describe some key properties of the various constituents of the plaque and their interactions.

FA plaque constituents include both structural molecules, which can physically cross-link different FA molecules to each other and stabilize the adhesion complex, and signaling molecules, such as a variety of kinases, adapter proteins, and other signal transduction proteins. Some FA proteins contain specific motifs involved in protein-protein interactions. The best-characterized involve the SH2 domains, which interact with tyrosine-phosphorylated motifs, and the SH3 domains, which bind proline-rich motifs. Other types of interactions can be mediated by LIM, PDZ, and PH domains. Many of these proteins can bind to more than one partner, and thus they can potentially serve as “nodes” in the formation of multi-molecular adhesion complexes.

Although the binding affinity between many of these components might be weak, they form aggregates or molecular complexes that cumulatively generate high-avidity interactions. Their low intrinsic affinity may facilitate dynamic rearrangements of molecular complexes, for example during cell migration. Information on the modes of interaction of the different FA molecules with each other *in vivo* is quite limited. Consequently, “wiring diagrams” [12,13] or “network hierarchy schemes” (Fig. 1) can provide a general idea about potential interactions. Yet future research is needed to determine which interactions actually occur *in vivo* and in various physiological states (see below). It is also noteworthy that the actual complexity of FA in specific cell types is not clear, and that it may be less than expected by simply combining all information on the many plaque components in various cell types described in the scientific literature.

Connectivity-Based Ordering of FA Components

Although network schemes currently involve all potential interactions, rather than only interactions that actually occur in adhesion sites, they can shed novel light on molecular connectivity within FA. For example, Fig. 1A shows that actin and integrins can interact with many partners. High connectivity is also seen for several plaque proteins, such as FAK, vinculin, paxillin, α -actinin, and talin, which have at least nine potential interactions each. Less connected are a variety of signaling molecules, which have relatively few links. It is interesting that there are a number of molecules that have only one known link to another FA molecule, suggesting that even though they may be associated with the protein network, their interaction is not as an integral component.

This network type of analysis is presently preliminary, since the published data used for the construction of the network are incomplete and of variable quality. Nevertheless, integration of the currently available data on the players and their interactions into a network presentation allows one to gain some new information. For example, some insight can be gained about the effects of gene knockout (or mRNA inactivation), overexpression, or inhibition of specific certain signaling processes on the network. In Fig. 1B, a vinculin-null version of the network is shown. Such analysis predicts that in vinculin-null cells, vinexin and ponsin will be excluded from FA whereas other vinculin-binding molecules (e.g. talin, α -actinin, and paxillin) may remain via interactions with other components. Similarly, based on a FAK-null network, PLC- γ is predicted to be lost from FA (Fig. 1C). Obviously, such predictions can be challenged experimentally.

In order to illustrate a situation in which one molecular interaction dominates others, we have tested restricting the interactions mediated by the cytoplasmic domain of the integrin to only one molecule: talin (Fig. 1D). As a consequence, some molecules might lose their specific anchorage in FA (DRAL and uPAR) and many others are downshifted in their connectivity. Other scenarios presented here are the changes in molecular connectivity in networks in which

phosphotyrosine-SH2-based interactions are excluded, either with or without the presence of FAK (Fig. 1E and 1F, respectively). Again, in these networks some proteins lose their connection to any FA component whereas others are lowered in their connectivity.

Despite its rather speculative and preliminary nature, this approach provides a novel tool for molecular modeling of FA interactions. It makes a number of specific predictions that can be directly tested experimentally. Note that even the deletion of the most highly connected proteins, namely FAK or vinculin, resulted in a surprisingly minor loss of other components (at most two). Furthermore, none of these network modifications caused a split into two unconnected sub-networks. These findings emphasize the robust nature of the connections between most components of FA.

Molecular Switches in FA

An obvious limitation of a network scheme, such as that shown in Fig. 1, is that all of the intermolecular links are presented as though they can all take place simultaneously. In fact, the structure and function of FA, and hence the interactions between its components, need to be regulated physiologically in many processes, including cell spreading, migration, and response to different growth factors and cytokines. By using different modes of regulation (defined here as “switches”), cells can employ a number of potentially important regulatory mechanisms, some of which are illustrated in Fig. 2.

Transcriptional Switches The level of a specific component can be regulated at the level of gene transcription, which in turn affects FA composition. For example, mRNA levels of vinculin can be modulated by matrix adhesiveness.

Protein Stability Switches The dynamic turnover of FA can be initiated by proteolytic cleavage of specific plaque components such as talin and FAK by proteases like calpain.

Tyrosine Phosphorylation Switches Dynamic changes in phosphorylation of plaque components such as FAK are thought to be involved in FA assembly and turnover.

Other Posttranslational Switches Changes in serine/threonine phosphorylation can also regulate integrin and plaque protein (e.g. paxillin) functions [14,15].

Conformational Switches The molecular conformation of proteins or their clustering can be regulated by phosphorylation or binding of other molecules. For example, vinculin can be transformed from a folded state to an open state with exposed intermolecular interaction sites after binding the signaling lipid PIP₂. Tensin conformation may also be regulated by tyrosine phosphorylation, and integrin clustering might trigger its binding to cytoplasmic partners and activate FAK autophosphorylation.

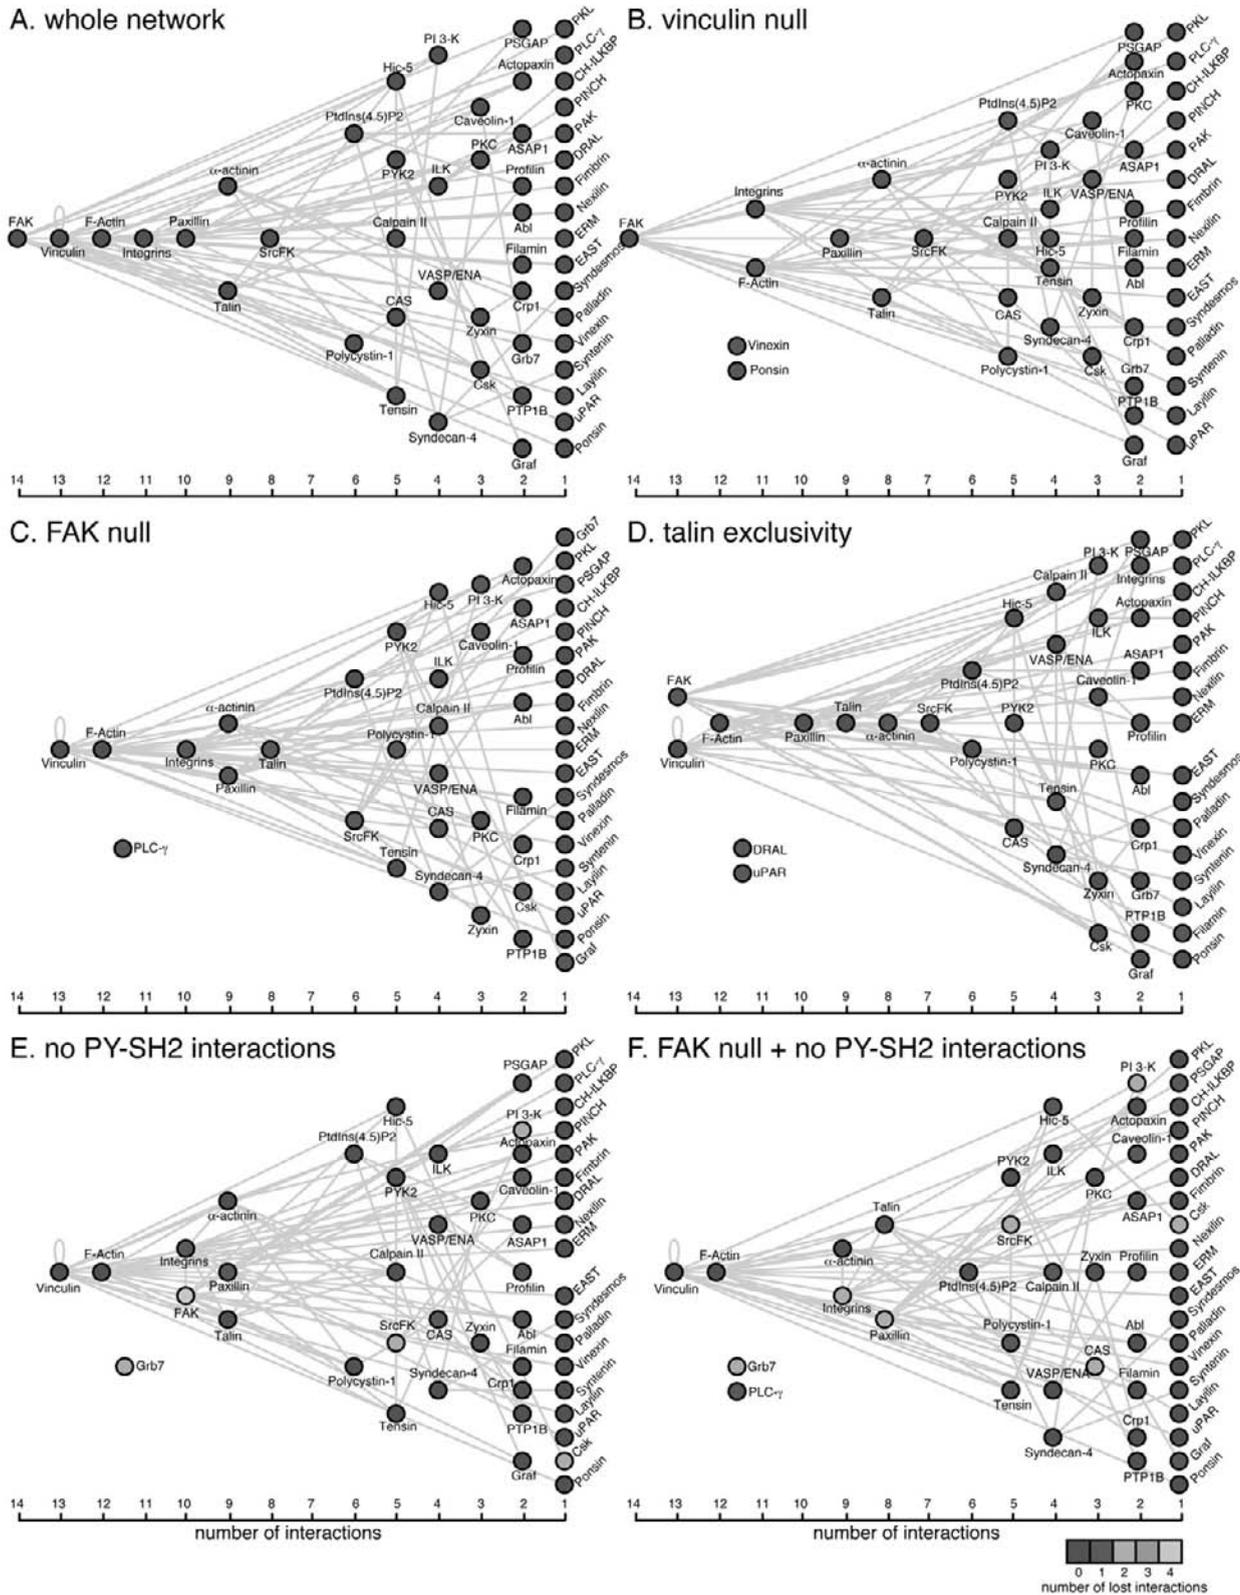

Figure 1 Connectivity-based ordering of FA components. In each of the network diagrams, the proteins were ordered from the most connected to the least connected, as indicated by the scale on the horizontal axis. Proteins listed in the lower left corner of each diagram have no known connections with the network. The connectivity data were taken from previous reviews [12,13] and analyzed via the Pajek program (<http://vlado.fmf.uni-lj.si/pub/networks/pajek>). (A) The whole network. (B) The network from which vinculin was removed. (C) The network from which FAK was removed. (D) The network in which talin dominates over all of the other cytoplasmic interactions with integrin. Thus, integrin is connected exclusively to talin and to membrane caveolin. (E) The whole network after removing all connections that are mediated by phosphotyrosine-SH2 motifs. (F) The same as (E) with the exclusion of FAK. The color of each vertex (circle) indicates the number of connections lost in comparison to the whole network; For each component, the number of lost connections can be realized by comparison with the whole network, or by the color of its node (a color representation of this figure is available on the CD-ROM version of *Handbook of Cell Signaling*).

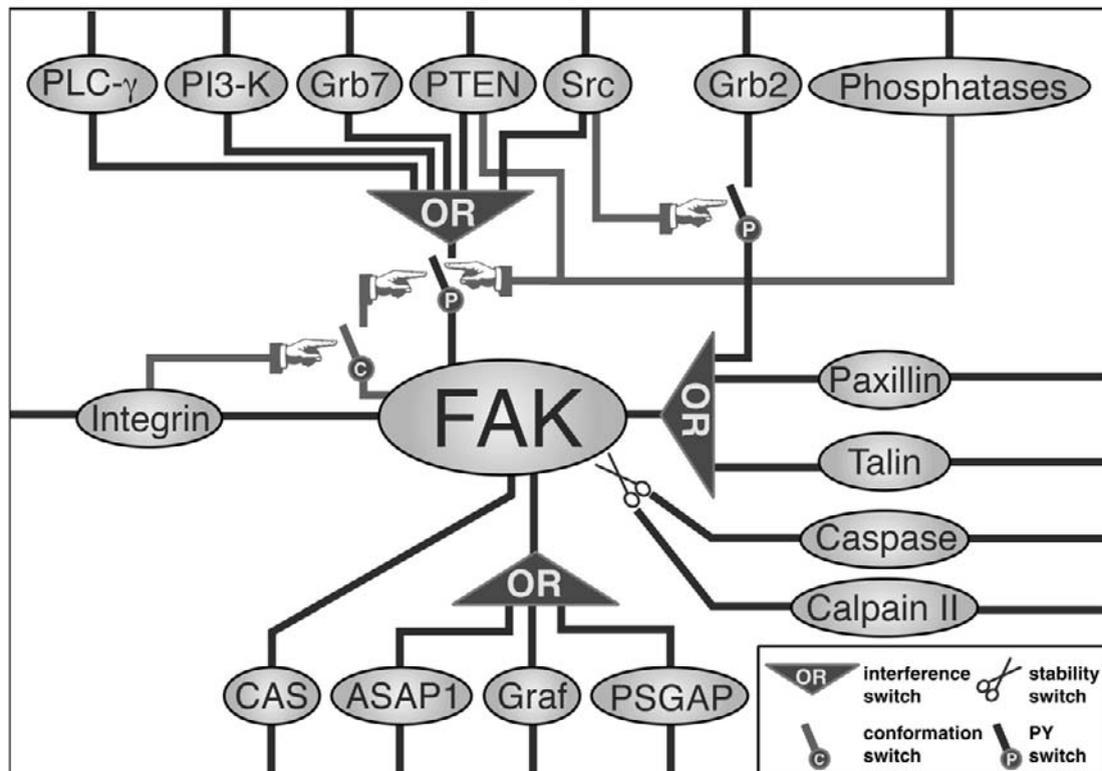

Figure 2 Molecular switches that might regulate protein-protein interactions in FA. The example shown here involves FAK (for general reviews about FAK see [20,21]), which can interact with multiple FA molecules (Fig. 1A). It is proposed that several types of “switches” can significantly constrain the possible combination of interactions with individual FAK. Molecular interference prevents more than one protein from interacting simultaneously with the same site or a nearby site. Thus, an exclusive “OR gate” can restrict the interactions of FAK with Src, Grb7, PTEN, PLC- γ , and PI3-K (all bind FAK Tyr397). Similarly, ASAP1, Graf, and PSGAP interact via their SH3 domain with the proline-rich motif located between amino acids 778–881 of FAK, and thus may interfere with each other. However, CAS interacts with a distinct proline-rich motif, located between amino acids 715–718 of FAK, and thus may be unaffected by other FAK interactions. An additional interference is predicted among paxillin, talin (both interact with the FAT domain of FAK), and Grb2 (which interact with Tyr925 at the FAT domain of FAK). Tyrosine phosphorylation of FAK at residues Tyr397 and Tyr925 is an additional “switch” activating binding sites for several SH2-containing proteins such as Src or Grb7 (Tyr397) and Grb2 (Tyr925) (“P-switch”). The phosphorylation at Tyr397 is performed by FAK itself (autophosphorylation) and can be induced by the clustering of integrin receptors, which aggregates FAK molecules together (“conformational (C) switch”). Phosphatases such as PTEN and Shp2 have been reported to dephosphorylate FAK, presumably targeting Tyr397, which could turn off all FAK interactions mediated by that phosphorylated residue. The phosphorylation of Tyr925 is mediated by Src and may play a role in the recruitment of Grb2, which, in turn, can interfere with FA localization. Finally, caspases and calpain II, in response to various signals, can mediate the proteolytic cleavage of FAK (“stability switch”).

Tension Switches Although the mechanisms are still poorly understood at the molecular level, external tension on cells and intracellular actomyosin contractility can dramatically regulate the initiation and sizes of FA [16–18]. Shear stress can also trigger FAK tyrosine phosphorylation [19].

Molecular-interference Switches The binding of one component to a site may block the binding of other molecules to the same or neighboring sites in a dominant-negative fashion. A related switch involves the dominant-negative inhibition of FAK binding of its target molecules by a truncated form of the molecule, termed FRNK, the levels of which are regulated by alternative splicing.

In conclusion, it appears that in constructing meaningful interaction networks, such as those shown in Fig. 1, the various switches described above should be taken into account. We provide here one example how a set of switches can affect

the molecular interactions of one of the busiest components of FA, namely FAK (Fig. 2). We show, for example, that many of FAK’s partners compete with each other for binding to the same or adjacent sites, and that conformational, phosphorylation, and stability switches can all affect the actual connectivity of this molecule and its signaling activity. Obviously, it would be highly desirable to incorporate such switches into molecular interaction maps.

Future Challenges

Focal adhesions have been studied intensively for the past decade, and there is now a large body of literature on their composition and functions. Even so, our current understanding of the mechanisms involved in FA organization and function is still highly preliminary and speculative. Moreover, even

though FA are thought to serve as signaling centers initiating signaling cascades (ranging from activation of MAP kinases to phosphoinositol lipid signaling), the evidence that signaling comes directly from interacting components located within FA is still minimal. Rigorous studies will be needed to establish which integrin-triggered signals come directly from FA or other cell-matrix adhesions.

A further challenge comes from the fact that many FA components and adapters have multiple potential binding sites. Therefore, it seems likely that FA contain complex mixtures of interacting components with variable binding to different components. That is, a given protein may be bound to multiple combinations of five to ten different proteins, and each of these complexes may behave differently. In addition, local heterogeneity of protein complexes within FA will also need to be evaluated. The approaches for probing these different sources of complexity will have to include experimental molecular perturbation of each component alone and then in various combinations. Obvious methods will include regulated overexpression, anti-sense and RNAi methods, enzymatic activity modulation, and dominant-negative inhibition approaches. However, because of the complexity of FA, computer-based network analysis seems essential. A combination of “wet” biochemical and molecular biology approaches with computerized analyses and generation of specific predictions for experimental testing should provide a powerful approach to understanding the role of these adhesive structures in regulating cell signaling and function.

School of Medicine, Atlanta, Georgia*

Introduction

The regulation of actin dynamics is central to a variety of biological events, including cell motility, chemotaxis, nerve growth cone extension, and establishment of cell polarity. A number of signaling mechanisms control these events and play a role in determining the position and extent of new actin assembly. Our understanding of the details is still incomplete, but many of these signals involve receptor stimulation and activation of members of the rho family of small GTPases [1]. One mechanism by which signaling pathways regulate actin polymerization is by controlling the formation of new actin filaments. Activation of the Arp2/3 complex appears to be critical in the nucleation step of this process. In turn, activation of members of the Wiskott-Aldrich protein (WASp) family leads to activation of the Arp2/3 complex (reviewed in [2]). WASp family members appear to play the role of signal integrator, responding to inputs from a variety of extracellular and intracellular signals and converting those signals into effects on actin dynamics.

The WASp protein family has two major branches, WASp and Scar/WAVE. WASp and Scar/WAVE proteins share a distinct modular architecture (Fig. 1). Conserved among all members of the family is a central proline-rich region, followed by a monomeric actin-binding domain (alternatively referred to as a Wiskott-Aldrich homology 2 domain, WH2, or verprolin homology domain, V; Fig. 1). Also common to all members of the family is a C-terminal acidic region shown to be essential for binding the Arp2/3 complex. The precise number and position of the acidic amino acids at the C-terminus are believed to influence the activity of the protein [3]. Between the WH2 and Acidic domains is a region that connects the two (C) that is important for WASp family proteins to activate Arp2/3. What distinguishes WASp (and the closely related N-WASp) from the Scar/WAVE subfamily is the N-terminal region. WASp and N-WASp have, at their most

N-terminus, a region termed a WH1 domain, with structural similarities to the EVH1 domain of Ena/VASP proteins [4]. WASp and N-WASp also have in their N-terminus a basic region followed immediately by a small GTPase-binding domain (GBD or CRIB motif). The former, basic, region interacts with acidic phospholipids, particularly phosphatidylinositol 4,5-bisphosphate (PIP₂). The latter CRIB domain binds Cdc42 (and weakly rac1), and both regions are thought to be important in regulating the activation of WASp (see below). Scar proteins have neither a WH1 domain nor a conserved GBD, and though a distinct basic region is present, the role of PIP₂ in Scar function remains unclear. The difference in N-terminal domain structure has led to speculation that WASp and Scar proteins are regulated by different mechanisms. Recent evidence supports this idea (see below). For a more complete discussion of the role(s) and regulation of WASp/Scar/WAVE proteins see the extensive reviews of Higgs and Pollard [2] and Takenawa and Miki [5].

WASp

WASp was originally described as the protein defective in patients with Wiskott-Aldrich syndrome (WAS), an X-linked hematopoietic disease characterized by abnormalities in platelets and lymphocytes [6]. Hematopoietic cells from WAS patients have defects in actin-associated structures such as podosomes and microvilli and motility defects in cells such as macrophages. Independently, a related, more ubiquitously expressed protein, N-WASp, was identified as a binding partner for Ash/Grb2 [7]. It was recognized that both proteins contained a Cdc42-binding site, suggesting that they might provide a connection between the rho family of small GTPases and actin polymerization. More distantly related proteins, Las17p/bee1p and Wsp1p, were subsequently identified in *Saccharomyces* and *Schizosaccharomyces*, respectively,

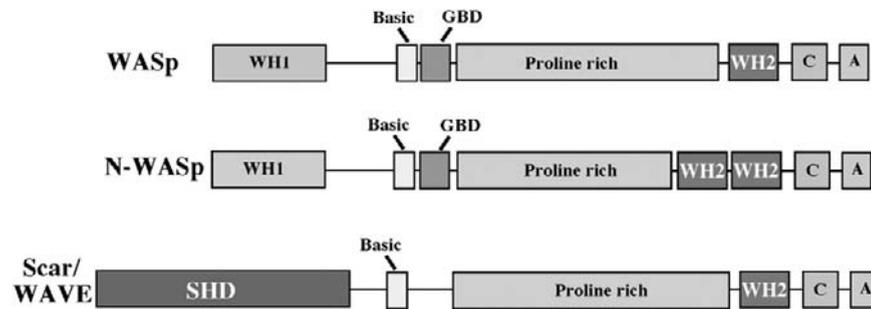

Figure 1 Diagram of domain structure of WASp family proteins. Abbreviations: WH1, Wiskott-Aldrich homology region 1; GBD, GTPase binding domain (also called CRIB motif); WH2, Wiskott-Aldrich homology region 2 (also called verprolin (V) domain); C, connecting domain (also called cofilin-like domain); A, acidic region.

and shown to be essential for actin patch formation and endocytosis [8,9].

The connection between WASp and the Arp2/3 complex came when it was determined that the C-terminal acidic domain of WASp (and hScar1) bound, in a yeast two hybrid screen, to the p21-Arc subunit [10]. Subsequently it was shown that C-terminal fragments of WASp, N-WASp, and Scar could all facilitate the ability of the Arp2/3 complex to nucleate new actin filament formation *in vitro* (reviewed in [2]). Further studies showed that full length WASp (and N-WASp) were significantly less effective at activating Arp2/3 than a C-terminal fragment. Addition of activated Cdc42 enhanced the ability of full-length N-WASp to activate Arp2/3. These data and other studies in cell culture led to a basic model whereby WASp/N-WASp is normally autoinhibited in the cell due to interaction of the C region of the protein with the GBD domain. Activation of WASp/N-WASp involves binding of Cdc42 and/or PIP₂ and unmasking of the carboxyl-terminal region, allowing it to bind actin and Arp2/3 (with an ancillary role for profilin binding to the proline rich region). There are subtle, but important, differences in the way WASp and N-WASp react in the presence of GTP-Cdc42 and PIP₂ suggesting that the model is incomplete. This notion is discussed in more detail in Higgs and Pollard [2]. In addition to Cdc42, a number of other proteins bind to various regions of WASp and/or N-WASp and are believed to be critical in regulating WASp/N-WASp function (Table I). The WH1 region provides a binding site for WASp-interacting protein (WIP) and two related proteins, CR16 and WICH (also called WIRE) [11–14]. These proteins bind not only WASp and N-WASp but also actin and isoforms of the adaptor Nck. The cellular role of these proteins is still unclear, but ectopic expression studies suggest they may couple WASp and N-WASp to SH3-containing proteins such as Nck and regulate subcellular localization, as well as affecting actin polymerization. The protein WISH (WASp-interacting SH3 protein) also binds to the proline-rich region of N-WASp and stimulates actin polymerization in an N-WASp, Arp2/3-dependent, but Cdc42 independent manner [15]. Cdc42 and PIP₂-independent signaling also has been reported in *Drosophila* where rescue of a WASp null mutation can be accomplished by expressing a

form of WASp missing both the PIP₂- and Cdc42-binding domains [16]. SH3-containing tyrosine kinases also bind WASp and/or N-WASp (Table I). The importance of these interactions is incompletely understood. It appears, however, that there are many layers to WASp/N-WASp regulation. How this relates to specific function(s) is still unknown.

Some aspects of WASp function are relatively clear. WASp and N-WASp affect Arp2/3 activation and thus actin polymerization, and they can be found localized to filopodia, consistent with their being regulated by Cdc42. In humans the lack of WASp results in defects in filamentous actin formation that leads, among other things, to abnormal T-cell activation, abnormal formation of microvilli and podosomes, and cell motility defects in macrophage. Not so clear is why constitutively activating WASp should result in a severe neutropenia and monocytopenia [17]. Also, GTP-Cdc42 is still able to induce filopodia in fibroblasts derived from N-WASp null mice [18]. Likewise, the loss of WASp in *Drosophila* results in errors in cell fate determination, largely as a result of defects in asymmetric cell division. Defects in other fundamental aspects of actin function are not disturbed [19]. Clearly there is much more about WASp/N-WASp function and regulation that needs to be understood.

Scar/WAVE

Scar family proteins were originally identified in a genetic suppressor screen of a G-protein-coupled receptor mutation in *Dictyostelium* (Suppressor of cAMP receptor defect; [20]). Though the original report described the existence of Scar-like proteins in a variety of other organisms, the first study of a vertebrate ortholog was by Machesky and Insall [10] followed shortly by Miki *et al.* [21]. The latter group identified the protein, based on a database search, as WAVE (WASp family, Verprolin homology protein). All three early reports provided evidence that, like WASp, Scar proteins affect actin polymerization. In *Dictyostelium*, *C. elegans*, and *Drosophila* single isoforms of Scar exist. In the vertebrates reported to date there are (at least) three isoforms, Scar1, Scar2, and Scar3 (WAVE1, WAVE2, and WAVE3, respectively). The distribution

Binding protein and domain on WASp family member are indicated. Domains are as shown in Fig. 1. Effects are meant as a broad description of the consequence based on either *in vitro* or *in vivo* interaction.

of each is somewhat different, though none seems as restricted as WASp. Although all three isoforms share the same basic domain structure there is evidence that their cellular roles and regulation may be somewhat different (see below). Mutations in Scar genes in *Dictyostelium* and *Drosophila* have established the importance of Scar in regulating actin assembly. In *Dictyostelium*, basic cell motility is abnormal in Scar mutants, and actin assembly in response to chemoattractant stimulation is severely impaired (Steiner *et al.* submitted). In *Drosophila*, Scar mutants are impaired in several aspects of development and oogenesis owing to defects in filamentous actin assembly. Scar, rather than WASp, appears to be the mediator of most Arp2/3-dependent events in this organism [22].

The presence of Scar proteins at the leading edge of cells suggests that they might be regulated by rac-like small GTPases, and Miki *et al.* showed that transvection of a

nonfunctional Scar into cells blocked the activity of an activated rac1 but not an activated Cdc42 [21]. There is no obvious rac-binding region in Scar, and there is no evidence that Scar proteins directly bind rac proteins. Evidence does exist for at least two indirect mechanisms by which rac proteins regulate Scar activity. Using a yeast two-hybrid screen Miki *et al.* found that the rac-binding protein IRSp53 binds directly to the proline-rich region of hScar/WAVE proteins [23]. They further found that the interaction of IRSp53 and Scar2 was necessary for the formation of membrane ruffles induced by ectopic expression of activated rac1 in COS7 cells. It is interesting that interaction with IRSp53 seems to be largely (though perhaps not exclusively) restricted to the Scar2/WAVE2 isoform, and IRSp53 can associate with Scar2 in the absence of rac. In another recent study, Eden *et al.* reported the existence of a Scar1-containing complex that includes the rac1-binding proteins NCKAP1 and PIR121, as well as

Scar and the 8 KDa protein HSPC300 [24]. When a purified form of this complex is added to Arp2/3 complex and actin monomers *in vitro*, little actin polymerization occurs unless GTP γ S-rac1 is added to the reaction. In the same assay purified Scar alone activates Arp2/3 complex to the maximal extent. The data suggest that in the cell Scar1 is retained in an inactive complex until GTP-bound rac1 binds either, or both, NCKAP1 and PIR121. The complex then separates into two components, one containing NCKAP1 and PIR121 and the other containing Scar and HSPC300. In this form Scar is able to activate Arp2/3 complex and facilitate formation of new actin polymers [24]. It should be noted that Nck can substitute for rac1 in this experiment. Whether this same inhibitory mechanism is common to all the isoforms of Scar is unknown, but it appears to be a possibility [24]. The relationship between the complexes containing IRSp53 and the one containing NCKAP1/PIR121/HSPC300 is not yet clear. It may be that different isoforms of Scar are retained in different complexes or that Scar proteins can each be sequestered in multiple ways. Further work is necessary to clarify this issue. What is true is that activation of WASp/N-WASp and Scar by small GTPases is performed by different mechanisms. Scar proteins are indirectly regulated by rac-like GTPases and can involve disassembly of a multiprotein complex that inhibits Scar function. WASp is autoinhibited and it is the direct binding of Cdc42 (and or other proteins) that can relieve the inhibition. The difference in regulation may provide a basis for the difference in localization seen for Scar and WASp proteins.

Another mechanism by which Scar function may be regulated involves a novel rac-GAP, WRP [25]. This GTPase-activating protein was identified as a binding partner of Scar through immunoprecipitation of rat brain extracts. The interaction is direct and involves the SH3 domain of WRP and the proline-rich region of WAVE-1. The direct interaction between a racGAP and Scar/WAVE proteins may provide at least part of the mechanism for terminating Scar-mediated signaling. It is interesting that in the same report, a number of other signaling/cytoskeleton proteins were reported to immunoprecipitate with WAVE-1. These included the Abl kinase interacting proteins, abi-1 and abi-2, α -tubulin, and SNAP-25 interacting protein. The *in vivo* significance of these interactions awaits further study.

Another level at which Scar/WAVE proteins may be regulated involves cAMP-dependent protein kinase (PKA). Scar1 binds directly to the regulatory subunit (RII) of PKA, and the binding site overlaps the region of monomeric actin binding [26] (Table I). Actin and PKA compete for this binding site, and the interaction is unique to Scar1 and does not occur with Scar2 or Scar3. Scar1 may, therefore, act as an A-kinase anchoring protein (AKAP) and be involved in regulating PKA activity at the sites of new actin assembly. The same study found that the tyrosine kinase abl also bound Scar. To date, there is no report of tyrosine phosphorylation of Scar (though phosphorylation downstream of MEK has been found; [27]), so the significance of abl binding remains to be determined.

Whereas WASp and N-WASp are enriched throughout extending lamellipods, in the general cell periphery and in the tips of filopodia, Scar proteins are localized in a very narrow region at the edge of a cell and at the tips of pseudopodia and lamellipodia ([28,29], Steiner *et al.*, submitted). The use of Scar-GFP in *Dictyostelium* has shown that Scar does not localize to the rim of the whole pseudopod but only to sub-regions that presumably reflect points of active actin filament assembly. The localization is thus transient and dynamic. Much has been learned about WASp and Scar/WAVE proteins during the last several years, but much remains to be determined. Even though they share a basic structure at the C-terminal end, how similar is the mechanism of activation of Arp2/3 complex? How do the mechanisms affect the branched structure of actin filaments associated with Arp2/3 activation? Are there proteins besides PKA that can compete for binding by the core components to that region of these molecules? What is the mechanistic significance of being able to bind multiple SH3-containing proteins? Does binding of each have a subtly different effect on WASp/Scar activation? Is binding of individual partners competitive or is it used to integrate responses via WASp/Scar proteins? How does all of this relate to the different localizations of Scar/WASp proteins and their potentially different roles in the formation of lamellipodia and filopodia. Although the field has progressed very rapidly, there is still a long way to go.

Synaptic NMDA-Receptor Signaling Complex

Mary B. Kennedy

*Division of Biology, California Institute of Technology,
Pasadena, California*

Introduction

Glutamate is the neurotransmitter released from presynaptic terminals at most excitatory synapses in the central nervous system. It binds to two major classes of postsynaptic ligand-gated ion channels called AMPA (α -amino-3-hydroxy-5-methylisoxazole 4-propionic acid)-type glutamate receptors and NMDA (*N*-methyl-D-aspartate)-type glutamate receptors (further abbreviated NMDA receptor). Each of these receptors can trigger influx of ions across the membrane to produce an excitatory postsynaptic potential, but the NMDA receptor is also linked to a complex signaling pathway that produces biochemical changes in the postsynaptic neuron. The linkage is both physical [1], through direct interactions with cytosolic signaling molecules and scaffolds, and metabolic, through influx of Ca^{2+} ion through its ion channel [2,3].

The NMDA receptor is specialized to initiate and control changes in synaptic strength, based on the firing patterns of the synapse. When its channel opens, a large portion of the current across the membrane is carried by influx of Ca^{2+} ions [4,5]. The Ca^{2+} interacts with a variety of signaling molecules present just below the postsynaptic membrane. Opening of its channel is delicately controlled by the combination of glutamate-binding and concurrent depolarization of the postsynaptic membrane. At resting membrane potentials, the pore of the channel is blocked by Mg^{2+} ions. The block is relieved in a graded way by depolarization of the membrane. Thus, the NMDA receptor can “titrate” the amount of Ca^{2+} influx through its channel depending on how much the membrane is depolarized when glutamate is bound to it [6–8]. The required membrane depolarization can come from “back-propagating” action potentials that spread into the dendrites

when the neuron fires an action potential, or from activation of several nearby synapses at the same time [9]. Ca^{2+} influx is highest when the synapse is activated a few milliseconds after the neuron has already fired an action potential that is spreading back into the dendrites [10]. Because of this “coincidence detection” property [11], the NMDA receptor can trigger synaptic changes when the presynaptic neuron and postsynaptic neuron are activated concurrently, fulfilling the prediction of Donald Hebb for a synaptic learning mechanism [12].

Here, I will discuss the structure and function of the signaling complex assembled in the cytosol around the NMDA receptor.

Structure of the NMDA Receptor Signaling Complex

Like other ligand-gated channels, the NMDA receptor is assembled from four (or five) distinct subunits that fall into structural and functional classes. However, it differs significantly from other ligand-gated channels because one major class of subunits, the NR2A-D subunits, have long (~300 residues) carboxyl terminal tails that extend into the cytosol and associate with a variety of proteins. The signaling complex that assembles around this tail does not appear to be a rigid structure with a fixed stoichiometry. Instead, it is believed to be assembled stochastically by associations with a set of scaffold proteins and, in some instances, by direct association of the tails of the NMDA receptor with signaling molecules. The meshwork of proteins that results is often referred to as the postsynaptic density, a structure that can be observed at synapses in the electron microscope [13].

Scaffold Proteins

At least three classes of scaffold molecules participate in organizing the interactions of signaling molecules associated with NMDA receptors in the postsynaptic density. A fifth class, the GRIPs/ABPs, associate primarily with AMPA receptors.

PSD-95

PSD-95 is the only known scaffold protein that associates directly with the NMDA receptor in the postsynaptic density. It was discovered as a prominent component of the "postsynaptic density fraction" recovered after detergent extraction of synaptosomes [14]. PSD-95 comprises three amino terminal "PDZ-domains" named after three proteins in which they were first recognized (PSD-95, Discs-large, and ZO-1), an SH3 domain, and a carboxyl terminal guanylate kinase domain. The first two PDZ domains interact directly with a terminal T/SXV motif at the carboxyl terminus of the NR2 class of NMDA receptor subunits [15,16]. The SH3 domain and guanylate kinase domains are fused into a structure that also appears to mediate a variety of protein interactions [17,18].

Immunocytochemical studies show that PSD-95 is highly concentrated in postsynaptic densities at glutamatergic synapses where it strongly co-localizes with the NMDA receptor [16,19]. Nearly all synapses that contain NMDA receptors appear to also contain PSD-95, indicating that it is an ubiquitous scaffold and associates with a variety of NMDA-receptor complexes. Several cytosolic signaling molecules have been shown to bind to PSD-95, including neuronal nitric oxide (NO) synthase; the protein kinase scaffold AKAP (next section); synGAP, a synaptic Ras GTPase activating protein; and GKAP, a protein that appears to link PSD-95 to an additional scaffold protein, shank (see below). At least one family of transmembrane proteins, the neuroligins, also binds to PSD-95.

Nitric Oxide Synthase. The neuronal form of NO synthase (nNOS) contains a PDZ domain near its amino terminus. Bredt and co-workers have shown that this PDZ domain associates directly with the second PDZ domain of PSD-95 by an atypical PDZ/PDZ interaction [20,21]. Thus, PSD-95 can link nNOS to the NMDA receptor. Neuronal NOS is activated by Ca^{2+} /calmodulin, and in cerebellar synapses nNOS is preferentially activated by Ca^{2+} flowing through NMDA receptors [22]. It seems likely that association of nNOS with PSD-95 plays an important role in controlling the specificity of its activation in cerebellar and other synapses.

SynGAP. SynGAP was discovered both as a prominent component of the PSD fraction [23] and in a two-hybrid screen for proteins that interact with SAP-102, a homologue of PSD-95 [24]. Its GTPase-activating (GAP) domain is highly homologous to that of the canonical p120 RasGAP, and the protein has RasGAP activity. Thus, it is assumed that its principal function is to inactivate Ras that has been activated by GTP exchange factors (GEFs) or by the action

of protein tyrosine kinases such as Trks or Ephrin receptors. Although it is not a transmembrane protein, SynGAP nevertheless interacts strongly with the membrane via a combined PH/C2 domain near its amino terminus. It interacts with PSD-95 through a T/SXV motif at its carboxyl terminus. Immunocytochemical studies have shown that SynGAP is almost as highly concentrated at synaptic sites as PSD-95 itself [23,25], but it is also located on small vesicles throughout the cytosol and dendrite. Its precise functions are still mysterious. However, there are some clues. SynGAP is a prominent target for phosphorylation by Ca^{2+} /calmodulin-dependent protein kinase II (CaMKII) in the postsynaptic density (see below) [23]. Furthermore, deletion of synGAP is lethal to mice a few days after birth, producing abnormalities in development of certain brain areas and altering the number and size of synaptic sites in cultured hippocampal neurons (H.-J. Chen, L. Vazquez, Knuesel, and M. B. Kennedy, unpublished).

C. Neuroligins. Neuroligins are a large family of alternatively spliced transmembrane molecules that are located primarily in postsynaptic membranes, where they are believed to interact with the presynaptic neuroligin proteins to mediate heterophilic adhesion [26–28]. Neuroligins were found to bind in a two-hybrid screen to PSD-95 through a terminal T/SXV motif [29]. Recent evidence suggests an important role for neuroligins in synaptic differentiation [30,31]. However, it is not yet known how their interaction with PSD-95 contributes to their function.

GKAP. GKAP (Guanylate kinase associated protein), a 70 kD protein with no identified functional domains, was isolated from a two-hybrid screen for proteins that bind to PSD-95 [32]. GKAP interacts specifically with the guanylate kinase homology domain of the PSD-95 family of proteins. GKAP was soon found to interact directly with an additional scaffold molecule termed Shank (or ProSAP; see below) [33,34]. Thus, one function of GKAP appears to be the formation of a link between the two scaffold proteins PSD-95 (and its family members) and Shank.

AKAPs (A-KINASE INTERACTING PROTEINS)

The AKAPs are a family of scaffold proteins that bind to the regulatory subunit of the cAMP-dependent protein kinase (PKA) and direct the kinase holoenzyme to particular subcellular compartments [35]. Many of the AKAPs also bind other enzymes in the cAMP pathway, forming discretely localized signaling complexes. AKAP79/150 provides a scaffold for PKA, protein kinase C, and calcineurin, a calcium-dependent protein phosphatase, positioning them adjacent to one another. AKAP79/150 binds to the SH3 and GK domains of both PSD-95 and SAP-97 (a relative of PSD-95 that associates specifically with the AMPA-receptor rather than with the NMDA receptor) [36]. It is localized together with glutamate receptors in most, but not all, excitatory synapses in hippocampal neurons in culture, and evidence suggests that it helps orchestrate phosphorylation of the AMPA receptor

by PKA [36]. Calcineurin, a Ca^{2+} -dependent phosphatase that is localized to the PSD by its association with AKAP79/150, is a likely target of Ca^{2+} flowing through the NMDA receptor and may play a crucial role in control of LTP and LTD (see below).

SHANKS

The shank family was discovered in a two-hybrid screen for proteins that interact with GKAP (mentioned above) [33,34,37]. They are a particularly interesting family because they interact with other scaffold proteins and appear to be “scaffolds of scaffolds” linking the NMDA receptor complex, metabotropic glutamate receptor complexes [38], and perhaps also the AMPA receptor complex [37]. The shank proteins vary in size from ~240 kD to ~120 kD. The largest shank contains multiple ankyrin repeats, an SH3 domain, a PDZ domain, a long proline-rich region that occupies more than half the protein, and a sterile alpha motif (SAM) domain. Many of these domains are known to bind to specific proteins; the SH3 domain binds GRIP (AMPA receptor scaffold), the PDZ domain binds GKAP (linking to PSD-95 scaffold), and the proline rich domain binds homer (metabotropic glutamate receptor scaffold). A different region of the proline rich domain binds cortactin, an actin-associated protein. Thus, shank may provide a link between the postsynaptic density complexes and the actin cytoskeleton of the spine [33]. Overexpression of shank in hippocampal neurons in culture results in early formation of enlarged spines and enhanced recruitment of homer, the IP3 receptor, PSD-95, GKAP, and the NMDA receptor into these spines [39]. Thus, shank plays an important role in shaping the size and structure of spines.

Ca^{2+} /Calmodulin-Dependent Protein Kinase II (CaMKII) Binds Directly to the NMDA Receptor

CaMKII is highly enriched in the PSD [40,41] and is an important target for Ca^{2+} flowing through activated NMDA receptors [42–44]. Mice with a deletion mutation in the α -subunit of CaMKII are epileptic, exhibit deranged long-term potentiation at their hippocampal synapses, and perform poorly in learning tests [45,46].

CaMKII is anchored in the PSD through direct binding to at least two PSD components, the NMDA receptor itself and a transmembrane PSD protein termed densin. Binding of the CaMKII holoenzyme to the tail of the NR2A or NR2B subunits is strengthened by autophosphorylation of CaMKII that occurs upon activation of the kinase [47–49]. Binding to the tail of NR2B *in vitro* stabilizes the kinase in its activated state, suggesting that it may also do so *in vivo* [50].

Association of CaMKII with the PSD is highly dynamic in hippocampal neurons. Application of glutamate to neuronal cultures causes massive movement of CaMKII holoenzymes from dendritic shafts into the PSD over a period of a few minutes [51]. The process can be reversed by removal of Ca^{2+} from the medium. Thus, both activation of CaMKII and its localization at the postsynaptic site are delicately regulated by synaptic activity. Activation of CaMKII in the PSD can

lead to phosphorylation and upregulation of AMPA-type glutamate receptors [43], or addition of new AMPA receptors to the synapse through a second process that does not require direct phosphorylation of the AMPA receptor [52].

Orchestration of Responses to Ca^{2+} Entering Through the NMDA Receptor

Two features of activity-dependent plasticity at excitatory synapses in the central nervous system are central to learning mechanisms in the brain and have been the focus of many recent studies. One is the tight dependence of synaptic plasticity on “spike-timing” of pre- and postsynaptic neurons [53]. The second is “metaplasticity” or the adjustment of the sensitivity and sign (LTP or LTD) of synaptic plasticity controlled by patterns of prior activity [54]. These mechanisms depend on the amplitude, time course, and location of origin of Ca^{2+} influx. Thus, the spatial arrangement of calcium-dependent signaling enzymes such as CaMKII, calcineurin, and nitric oxide synthase are likely to be critical determinants of both. Our understanding of the arrangement of signaling molecules at the postsynaptic site will set the stage for a precise quantitative understanding of these mechanisms of learning.

Introduction

In recent years, Toll receptors have emerged as an important family of molecules activating the innate immune response. Mammalian Toll receptors detect pathogen-associated molecular patterns (PAMPs) such as lipopolysaccharides (LPS) from Gram-negative bacteria or peptidoglycan (PGN) from Gram-positive bacteria, and activate signaling cascades that induce the transcription factors NF- κ B and AP1.

Structure Function of Toll Receptors

Discovery of Toll and Toll-like Receptors

The *Toll* gene was first identified in the early 1980s by Nusslein-Volhard and Anderson during a mutagenesis screen to identify the genes controlling the establishment of the dorso-ventral (DV) axis of the *Drosophila* embryo, and was found to encode a new kind of type I transmembrane receptor [1]. The eleven remaining genes identified in this screen encode factors acting upstream and downstream of Toll in the signaling pathway. Activation of Toll on the ventral side of the embryo results in a ventral to dorsal gradient of nuclear translocation of the transcription factor Dorsal, thus establishing embryonic polarity. It was also through studies in *Drosophila* that Toll was assigned an immune function in the control of the inducible expression of antimicrobial peptides. The transcriptional activation of the genes encoding these peptides requires transcriptional activators of the Rel family, to which NF- κ B belongs. At the time, Dorsal was the only identified member of this family in *Drosophila*. This prompted analysis of the known mutant strains of the Toll pathway for immunodeficiency phenotypes, which led to the

demonstration by Hoffmann and collaborators that the Toll pathway controls the response to fungal and Gram-positive bacterial infections [2,3]. These results were rapidly followed by the first description by Medzhitov and coworkers of a mammalian Toll homologue (now known as TLR4) capable of activating NF- κ B and the synthesis of cytokines and co-stimulatory molecules [4]. Shortly after, Beutler and colleagues showed that mice from the LPS-hyporesponsive strains C57BL/10ScCr and C3H/HeJ carry mutations in their *tlr4* gene, indicating that Toll-like receptors (TLRs) play an important role in the control of infection in mammals [5]. Since these initial discoveries, a family of 10 TLRs has been described in mammals, the properties of which are described below.

Structure of Toll Family Receptors

The cytoplasmic domain of Toll bears striking similarities to that of the Interleukin-1 type I receptor (IL-1R), and is referred to as the TIR (Toll/IL-1R) homology domain. TIR domains are also present in intracellular signaling molecules such as MyD88 or TIRAP/MAL (see below). Plants also express TIR domain-containing factors [6]. The structures of the TIR domains of human TLR1 and TLR2 have been solved and shown to be composed of a central five-stranded parallel β -sheet surrounded by five α -helices [7], (Fig. 1).

The extracellular domain of Toll family receptors does not contain Ig domains, like the IL-1R, but comprises several leucine-rich repeats flanked by characteristic cysteine-rich motifs. This feature is shared by a number of membrane receptors such as the pattern recognition receptor CD14, the adhesion molecule GpIb α , or the members of the Trk family of neurotrophins receptors. Leucine-rich repeats are generally recognized as a protein-protein interaction domain [8].

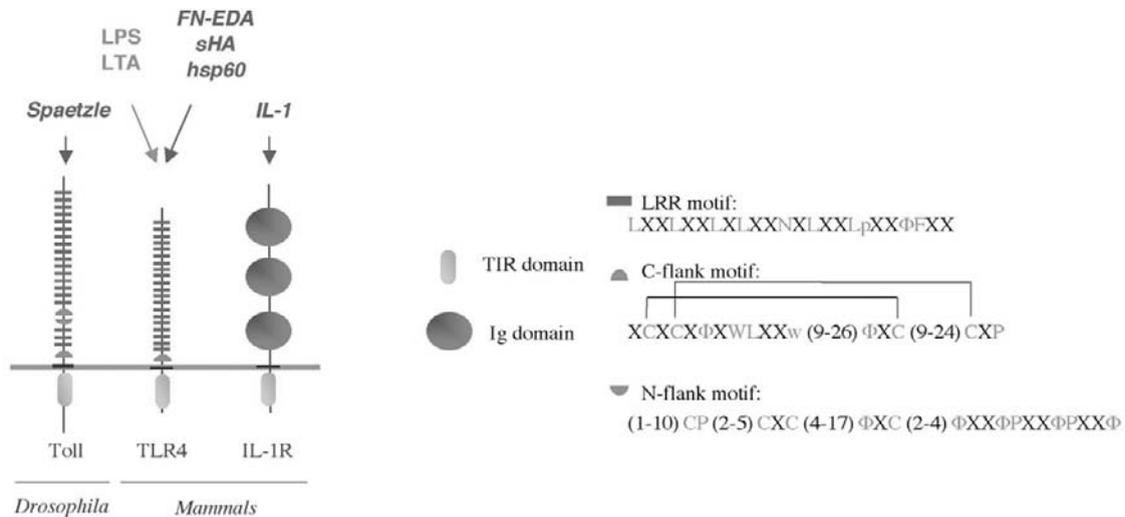

Figure 1 TIR domain receptors in *Drosophila* and mammals. (A) Domain architecture of members of the three groups of TIR domain membrane receptors. TIR domains are represented in yellow, LRR motifs as green rectangles, and flanking cysteine-rich regions as orange half-circles. Microbe-derived ligands are in blue, and endogenous ligands in mauve. FN-EDA, fibronectine extra domain A; sHA, soluble Hyaluronic Acid. (B) Amino-acid sequence of the motifs found in the ectodomains of Toll family receptors. Φ, hydrophobic residue; X, any amino-acid [8].

Despite their similarity of structure and function, members of the family of Toll receptors can be subdivided in two different classes, based on phylogenetic analysis of their TIR domain [9]. All mammalian TLRs cluster to one of these subfamilies, together with a single *Drosophila* receptor, Toll-9. The eight other *Drosophila* Toll family members cluster to the second subfamily, together with the *Caenorhabditis elegans* *Tol-1* gene product. Close examination of the ectodomain of these molecules also reveals differences, the most evident being the presence of a single C-flank cysteine rich motif in TLRs and *Drosophila* Toll-9, as opposed to other Tolls, which most often contain additional C-flank motifs and always share at least one N-flank cysteine rich motif. Thus it appears that most *Drosophila* Tolls have evolved independently from mammalian TLRs, possibly to fulfill different functions. In agreement with this hypothesis, TLRs do not appear to be required for murine development, in contrast to Toll in *Drosophila* [10].

Activation of Toll and Toll-like Receptors

In *Drosophila* embryos, a cascade of proteases is activated on the ventral side of the embryo and promotes proteolytic maturation of the cysteine-knot growth factor Spaetzle, which is structurally related to neurotrophins. The cleaved Spaetzle is thought to bind to the Toll receptor, prompting its dimerization and activation [1]. In adult flies, activation of Toll in response to infections also requires a processed form of Spaetzle, although genetic experiments indicate that the proteases of the embryonic cascade upstream of Spaetzle are largely dispensable for the immune response [2]. Recognition of Gram-positive bacteria is mediated by a member of the PGN recognition protein (PGRP) family, PGRP-SA, which is thought to activate a protease(s) leading to Spaetzle activation [11].

No Spaetzle homologues have been described so far in mammals. Rather, TLRs appear to be directly activated by PAMPs. Analysis of macrophages derived from TLR knock-out (KO) mice has revealed that (1) TLR4 is required for the response to LPS and lipoteichoic acid (LTA) derived from Gram-positive bacteria; (2) TLR2 is necessary for activation by several ligands, including PGN, bacterial lipopeptide (BLP), and the mycobacterial lipopeptide MALP2; (3) TLR3-deficient cells do not respond to dsRNA from viruses; (4) TLR5 recognizes flagellin, the principal constituent of bacterial flagella; (5) TLR6 deficient cells do not respond to MALP2; (6) TLR9 is required for cell activation by bacterial DNA containing unmethylated CpG motifs (reviewed in [10,12–14]).

Despite the genetic evidence, biochemical data for a direct interaction between most TLRs and their ligands are still lacking. There is good pharmacological evidence for a direct interaction between LPS and TLR4, or CpG and TLR9. In addition, biochemical experiments using radiolabeled LPS demonstrated that it can be specifically cross-linked to TLR4, thereby indicating that the two molecules directly interact [15].

Some TLRs associate with coreceptors to interact with PAMPs. For example, in the case of LPS, CD14 plays an essential role in the receptor complex. This protein is also required for maximal cell activation by PGN, a TLR2 agonist. In addition, plasma membrane expression of TLR4 requires the coexpression of MD2, a secreted accessory molecule that also seems to interact with LPS (Fig. 2a). In some cases, recognition of PAMPs involves heterodimerization of TLRs. For instance, activation of cells by MALP2 requires both TLR2 and TLR6. TLR6 coimmunoprecipitates with TLR2 in cell lines, and heterodimerization of the TIR domains of TLR2 and TLR6 elicits a cellular response. TLR2 is believed

to associate with another TLR to recognize BLP. It so appears that cooperation between TLRs is a means of broadening the recognition repertoire of these receptors [10,12,13].

One critical question about regulation of the innate immune response is the distinction by immune cells between harmless commensal microorganisms and infectious microbes, which often share common PAMPs. Cellular distribution of TLRs may contribute to this discrimination. For example, TLR5 is asymmetrically distributed in gut epithelial cells: it is absent from the apical side of the cells, which are exposed to the commensal bacterial flora of the gut lumen, and present on the basolateral side of the cells, to which noninvading bacteria do not have access [16]. In addition, it is becoming clear that some TLRs can be activated by host-derived molecules. These include hsp60, oligosaccharides from hyaluronic acid, and a fibronectin fragment [10,12,13]. A common feature of these molecules is that they are produced during stress responses in general and inflammation in particular. One intriguing possibility is that these endogenous products generated in response to infection synergize with PAMPs to

activate TLRs and stimulate an efficient innate immune response.

Signaling by Toll Family Receptors

Activation of Toll family receptors results in the transcriptional induction of a number of genes involved in host defense such as antimicrobial molecules or cytokines. A common feature of these genes is the presence of binding sites for the transcription factor NF- κ B and AP-1 in their promoters. As described below, a pathway leading from TIR domain receptors to the nucleus has been deciphered. The various ligands that activate TLRs induce overlapping but distinct sets of genes during infection, thus revealing the existence of receptor-specific alternative signaling pathways (Fig. 2b).

The Classical Toll/IL-1R Signaling Pathway

TIR domain receptors are associated with an intracytoplasmic plurimolecular platform in which the MyD88 factor

plays a central role. MyD88 is composed of an amino-terminal death domain (DD) and a carboxy-terminal TIR domain. It interacts in a ligand-dependent manner with the receptors through homophilic TIR-TIR domain interactions. The DD of MyD88 interacts with the DD of the serine-threonine kinase IRAK (IL-1R associated kinase) [10,12,13]. Another adaptor protein, Tollip, is also recruited transiently to the receptor complex upon activation [17]. Tollip does not contain a TIR domain, and its function may be to bring IRAK to the receptor complex. Interaction of IRAK with MyD88 triggers autophosphorylation of the kinase. This progressive phosphorylation affects interaction with the receptor complex and allows IRAK to interact with TRAF6.

TRAF6 belongs to a family of signal transducers originally identified for their role downstream of receptors of the TNF α family. TRAF6 associates with a dimeric ubiquitin-conjugating enzyme complex composed of Ubc13 and Uev1A. This complex mediates activation of the TAK-1 kinase through a nonclassical ubiquitination mechanism, which does not involve the proteasome. TAK1 then phosphorylates the I κ B kinase (IKK) and MKK6 kinases, which in turn activate NF- κ B and AP-1 [18].

Significant differences exist in the Toll pathway in flies. The receptor platform contains an additional DD component named Tube, which interacts with the IRAK homologue Pelle. Three TRAF factors are encoded by the *Drosophila* genome, but their role in the Toll pathway is not clear. Curiously, the *Drosophila* homologues of TAK1, Uev1a, Ubc13, IKK β and γ are not required downstream of Toll during the antifungal response in adults or during embryonic development [19].

Subunit-Specific Alternative Pathways

Analysis of MyD88 KO mice confirmed the importance of this central factor in the signaling pathway downstream of the cytokines IL-1 and IL-18 and several PAMPs including LPS. However, the response to LPS differs between TLR4 and MyD88-deficient cells. Notably, activation of NF- κ B and AP1 is only delayed in MyD88^{-/-} cells whereas it is abolished in TLR4^{-/-} cells. Furthermore, maturation of dendritic cells (DC) in response to LPS stimulation, though abolished in TLR4^{-/-} cells, is still functional in MyD88^{-/-} cells [20]. These data clearly point to the existence of a MyD88-independent pathway of cell activation, which also seems to operate downstream of TLR3. Nevertheless, this alternative signaling pathway is not activated by all TLRs. For example, in response to the TLR9 and TLR2 agonists CpG and MALP2, respectively, induction of NF- κ B and DC maturation is completely abolished in both TLR(9 or 2) and MyD88 KO cells [10,12].

A new cytosolic factor has recently been identified and is likely to play a role in the MyD88-independent pathway of LPS signal transduction. This factor (MAL for MyD88 adaptor like protein, or TIRAP for TIR associated protein) contains a TIR domain but no DD [21,22]. TIRAP/MAL associates with TLR4 through its own TIR domain but not with TLR9. In addition, a dominant-negative version of the

molecule has been shown to block activation of NF- κ B by TLR4 but not by TLR9, IL-1R, or IL-18R. Treatment of DCs with a synthetic TIRAP-blocking peptide inhibits their LPS-induced maturation in both wild-type and MyD88^{-/-} backgrounds [22]. These data strongly suggest that TIRAP/MAL controls the MyD88-independent pathway activated by TLR4. By contrast to MyD88, this factor does not interact with IRAK but with the related kinase IRAK2 through which it activates TRAF6. TIRAP/MAL can also associate with the dsRNA binding kinase PKR.

Another subunit-specific pathway seems to operate downstream of TLR2. This pathway is initiated by a ligand-dependent tyrosine phosphorylation of TLR2, which leads to recruitment of the p85 regulatory subunit of phosphatidylinositol 3 kinase (PI3K) and the small GTPase Rac-1, and to activation of the protein kinase Akt (protein kinase B) [23]. Although the effectors downstream of Akt remain to be identified, it is clear that this pathway regulates phosphorylation of NF- κ B, rather than targeting its inhibitor I κ B. Because this phosphorylation is required for the transactivation properties of NF- κ B, it is possible that other TLRs will activate this pathway. However, the PI3-kinase binding motif, which contains the phosphorylated tyrosine residue is only conserved in TLR1, 2, and 6, thus suggesting specificity of this Rac-1 dependent pathway.

The RIP2 serine-threonine kinase was also recently shown to function downstream of some TLRs. Induction of cytokines in RIP2^{-/-} macrophages is reduced upon stimulation with LPS, LTA, PGN, and dsRNA but not CpG. This result indicates that RIP2 is involved in TLR2, TLR3, TLR4 but not TLR9 signaling [24,25].

It is therefore becoming obvious that different combinations of transducing factors can dock to the receptor platform, depending on its molecular composition. This finding probably explains why some TLRs, such as TLR4, TLR3, and TLR9, can signal as homodimers, whereas others, such as TLR2 or TLR6, cannot. These distinct transduction factors initiate discrete signaling events, the combination of which may explain the panel of different responses elicited by the various TLR agonists. The understanding of these regulatory events holds promise for improved vaccination strategies and better control of infectious diseases.

Note Added in Proof

Recent work, including characterization of TIRAP/MAL deficient mice indicate that the MyD88-independent pathway does not involve this molecule, but may rely on a third TIR domain adaptor, TRIF/TICAM-1 (reviewed in Imler and Hoffmann (2003). *Nature Immunol.* **4**,105–106).

Introduction

Although considerable progress has been achieved over the last decade in the field of T-cell activation, many interesting questions remain. We now understand the basic biochemical pathways that underlie the basis of T-cell receptor (TCR) signaling, but we don't know how these signals are used to regulate T-cell function. For example, how does the T cell recognize antigens with such high sensitivity and specificity? How are these signals modulated to mediate such diverse processes as T-cell development, T-cell survival, and T-cell effector functions? Understanding these processes will require new approaches that incorporate principles of biochemistry, cell biology, immunology, and systems biology. Recent work using state of the art methods of digital imaging have revealed a process of membrane protein rearrangement known as immunological synapse formation. Immunological synapse formation is intimately associated with the T-cell activation process. Here, I review recent progress in this field (also recently reviewed in [1–4]). Because the study of immunological synapse addresses issues pertaining mainly to the field of cellular immunology, and to put a discussion of immune synapses into a broader context, a brief summary of T cell biology is given first.

Brief Introduction to T Cell Biology

One of the central challenges today is to understand how the TCR can specifically and sensitively sense foreign antigens. The TCR binds to short peptide fragments that are

themselves bound to membrane proteins known as major histocompatibility antigens (MHC). These short peptide fragments are generated by antigen-presenting cells via the proteolytic degradation of all proteins (intracellular and extracellular) in the cellular milieu. Thus, at any given time, a large variety of peptides compete for binding to a limited number of MHC molecules expressed on the surface of cells. The ability of the T cell to discern a rare antigenic peptide from an ocean of other, nonrelevant peptides attests to the incredible accuracy of TCR sensitivity. Recent studies verify this sensitivity by demonstrating that for CD8+ T cells, even a single peptide-MHC molecule is sufficient to activate a T cell [5]. The specificity of TCR recognition is also impressive. Conservative changes in the peptide sequence can change a peptide from being a strong agonist to one that is ignored by the T cell [6].

The trafficking of naïve T cells and professional antigen-presenting cells (APC) is designed so that both cells can interact with each other in secondary lymphoid organs like the lymph node or spleen. Although professional APCs include macrophages and B cells, the most important professional APC is the dendritic cell. Professional APCs function to not only carry foreign proteins from the periphery to the secondary lymphoid organs, but each also have specialized roles in the activation of T cells. The expression of membrane proteins like B7 on professional APCs functions to control the activation of naïve T cells via interaction with co-stimulator molecules such as CD28 expressed on the surface of naïve T cells.

Activated naïve T cells proliferate and differentiate into effector T cells. In the CD4+ T cell lineage, the most important effector cells are known as Th1 and Th2 cells and can be

distinguished by the cytokines that they secrete. Th1 cells secrete IL-2 and γ -interferon and mediate delayed-type hypersensitivity (DTH) responses by activating macrophages. Th2 cells secrete IL-4 and function to stimulate humoral immune responses by controlling B-cell activation and immunoglobulin switching. Similar pathways operate in the differentiation of cells in the CD8 lineage with the development of Tc1 and Tc2 cells. The primary function of CD8 cells is to kill infected target cells. Finally, T cells differentiate into memory T cells, long-lived cells that enhance secondary responses to pathogens.

Initiation of TCR Signaling

How T-cell receptors are initiated by binding to antigenic ligands is still a controversial area [7]. Although receptor clustering is the trigger that initiates signaling in most signaling systems, the small numbers of antigenic ligands present on the surface of the APC *in vivo* and the ability of very small numbers of peptide/MHC molecules to activate a T cell makes receptor clustering an unlikely mechanism. A recent study suggests that ligand binding results in a conformational change that promotes the assembly of signaling molecules with the TCR [8], but such changes have not been seen by structural studies [9]. Another model proposes that the association of accessory molecules with the TCR may be the trigger for T cell activation [10]. Higher-affinity binding would be discerned from low-affinity binding because longer-lived complexes would allow accessory molecules to be recruited to the TCR. The ability of T cells, however, to become activated in the absence of accessory and co-stimulatory molecules suggests that this mechanism is not required for signal initiation [11]. Finally, it has been proposed that T-cell receptors may form microclusters [12,13]. This is supported by structural studies demonstrating that MHC molecules, as well as accessory molecules such as CD4 and CD28, can form dimers [14], but these studies are controversial [15]. One problem with this model is that given the low abundance of antigenic peptides on the surface of the APC, the chances that both halves of an MHC dimer would contain the same peptide are extremely unlikely. But it has also been shown that non-agonist peptides may also play a role in triggering T-cell activation [16]. Thus, it is possible that TCR dimerization could be achieved by combinations of antigenic and non-antigenic ligands.

Definition of the Immunological Synapse

Kupfer and coworkers were the first to demonstrate a specific reorganization of proteins in the contact area between the T cell and the APC [17]. Using digital reconstruction of confocal microscopic images, they noted that T-cell membrane proteins segregated into a bull's-eye pattern during T-cell activation. The center of the bull's-eye, dubbed the C-SMAC, is notable for the clustering of T-cell receptor,

PKC- θ , and CD28. The outer ring consists of a zone containing the adhesion molecule, lymphocyte function-associated antigen (LFA-1). In a third zone, proteins excluded from the C-SMAC and P-SMAC, such as CD43 and CD45, are found. Recent work suggests that at least for CD43, there is an active process that targets it outside of the immunological synapse [18–20]. This pattern of a peripheral ring of LFA-1 surrounding a central zone of T-cell receptors is referred to as a classical or mature synapse.

Excitement about this concept and its rapid adoption by those studying T-cell activation is based on the possibility that the morphology of synapses may give important clues about how interactions with APCs lead to distinct T-cell responses (Fig. 1). Since interactions with other cells are fundamental to the T-cell activation process, one possibility is that different synapse morphologies may lead to different outcomes. Thus, recent publications have analyzed synapses during T-cell development [21,22], the activation of Th1 or Th2 cells [23], the synapses of CD8 [24,25] and NK cells [26–30], and those formed using different types of APCs [12,31].

Initial experiments were performed using CD4+ T cell clones and B-cell tumor lines as APCs [17]. These experiments showed that formation of a classical synapse occurs quickly, usually within minutes. Many other groups obtained similar results with T-cell hybridomas and T-cell tumor lines. Using fluorochrome-labeled MHC and adhesion molecules embedded in a planar lipid bilayer, Grakoui *et al.* were able to study the kinetics of synapse formation. Their studies suggested a distinct pattern that preceded mature synapse formation [32]. At early time points, TCRs were first recruited to the periphery of the contact, surrounding a central zone of LFA-1/ICAM complexes. This pattern, the opposite of that seen in the classical synapse has been referred to as an immature synapse. Over the next twenty minutes, this pattern inverts with movement of TCRs into the center of the synapse now surrounded by LFA-1 at the periphery of the contact.

Because mature synapses form very rapidly using T cell clones and cell lines, and the immature pattern is almost never seen, there was some question about the validity of the immature synapse pattern. However, the two-step formation of the immunological synapse was recently confirmed using naïve T cell/APC conjugates [31]. In this system, naïve T cells were incubated with primary APCs (T and B cell depleted splenocytes). Synapses formed very slowly, with the immature pattern achieved between 5–15 minutes after cell contact followed by the pattern of the mature synapse between 15–30 minutes. Because naïve T cells form synapses on lipid bilayers with kinetics similar to T cell blasts [33], the APC is likely to control the rate and pattern of synapse formation. In fact Richie *et al.* showed this directly when they tested the morphologies of synapses formed using blasted T cells or thymocytes with a variety of different APCs [21]. This suggests that synapse formation is strongly influenced by the APC.

Live-cell imaging studies further suggest that interactions with dendritic cells may be distinct from the interactions with other antigen presenting cells [34]. When T cells were

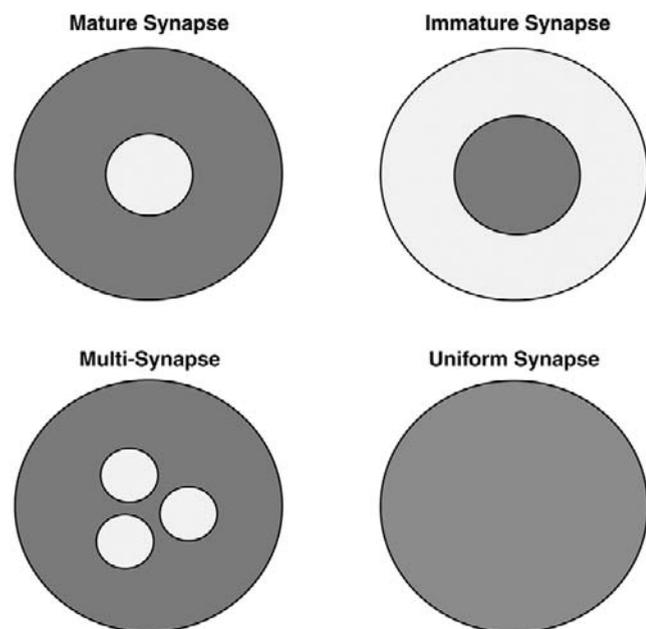

Figure 1 Basic synapse morphologies. Depicted are four basic synapse morphologies. The classical synapse has a central zone known as a C-SMAC surrounded by a peripheral ring of LFA-1 called a P-SMAC. The immature synapse is seen in some systems before the classical synapse. It is also seen in thymocytes undergoing negative selection. The multisynapse consists of multiple clusters of TCRs that are dynamic and stable for long periods. The uniform synapse represents contact areas where there is no visible segregation of membrane protein components. The significance of such synapses is not clear.

incubated with dendritic cells in a collagen matrix, T cell interactions with dendritic cells were transient (minutes) suggesting that a sustained interaction with an antigen-presenting cell might not be required for an activation response. T cells can also form synapses with dendritic cells in the absence of antigenic peptide [35]. But two recent studies imaging T cell/dendritic cell interactions in lymph nodes gave conflicting results. Stoll *et al.* injected fluorescently labeled dendritic cells and T cells into a mouse and imaged movement of T cells in a lymph node using standard one-photon confocal microscopy [36]. They found that T cells formed long-lived stable contacts for about 20 hours after which the T cells become highly motile and started to proliferate. In contrast, Miller *et al.* using two-photon fluorescent microscopy, found instead that the vast majority of antigen-specific T cells were highly motile in the lymph node [37]. T cells were described to be “swarming”. Whether differences in the technique of microscopy or immunization procedure account for this difference is unclear. Clearly, this is an area that will require further investigation.

Another active area of interest has been the morphology of synapses formed with APCs displaying altered peptide ligands (APLs). APLs are modified antigenic peptides, in which single amino acids have been changed. These changes can result in a variety of different effects ranging from changing the peptide to a null, or completely non-antigenic peptide, to converting the peptide into an antagonist to having

no effect at all. Early interest in the synapse focused on the morphology of synapses formed with APLs. Grakoui *et al.* found that weak agonist peptides still formed mature immunological synapses but accumulated lower levels of MHC-peptide complexes [32]. This suggests that MHC-peptide accumulation is related to the strength of the antigen. Antagonist peptides were able to accumulate MHC-peptide complexes in the junction between the T cell and the APC, however, a C-SMAC did not form and the T cells were unable to stop moving. Consequently, synapses were short lived. In a more recent study, Zal *et al.* used energy transfer techniques to analyze the interaction of the co-receptor, CD4, with the TCR after stimulation with agonist or antagonist peptides [38]. They found that CD4 and the TCR interact in the immunological synapse when stimulated with agonist. Antagonist peptides, interestingly, still recruited CD4 and TCR to the complex, but an interaction between the two never occurred. This is likely related to the shorter half-lives of antagonist peptide/MHC complexes with the TCR preventing association of CD4 with the TCR.

Immunological Synapses and T-Cell Development

During development, T cells must be “educated” to distinguish between self versus foreign antigens. It is thought that T cells learn first to recognize self-MHC in a process known as positive selection. Only T cells that are able to bind to self-MHC molecules are allowed to survive as well as expand. To rid this immature T-cell population of potentially self-reactive, autoimmune cells, cells that react strongly to self-MHC are deleted in a process known as negative selection. This results, at the end of development, in T cells that are weakly reactive against self and that are strongly reactive against foreign antigens. This property is important, for the low self-reactivity is required for the long-term survival of the T-cell population. The foreign reactivity results in the activation, proliferation, and differentiation of T cells into effector T cells. Are the processes of positive and negative selection distinct at the level of the immunological synapse?

Davis and coworkers developed an *in vitro* system to study thymocyte-positive and negative selection and were able to image contacts between thymocytes and thymic epithelial cells during negative selection [21]. They found that thymocytes undergoing negative selection form a variety of synaptic patterns that is most notable by the absence of a C-SMAC. For the most part, the synapses of negative selection are long-lived and are reminiscent of the immature synapse with peripheral localization of the TCR. This pattern was unique to synapses with thymic epithelial cell, as synapses using thymocytes with other types of antigen presenting cells had different morphologies. This suggests that the antigen-presenting cell plays a key role in synapse formation. Hailman *et al.*, using a planar bilayer system, also noted a distinct synapse pattern for negative selection [39]. They found that the synapses of thymocytes undergoing negative selection were dynamic, long-lived, and notable for sustained TCR signaling.

The morphology was different from the Richie *et al.* study [21] with synapses showing multiple clusters of TCRs. But common to both studies is the lack of a single, central C-SMAC and the long-lived nature of the synapses. Neither study was able to study positive selection because of inefficient conjugate formation. However, Buosso *et al.* recently imaged cells undergoing positive selection by using two-photon microscopy and a three dimensional organ culture system [22]. They found cell-cell interactions were both stable and highly dynamic. Clearly much more work is necessary to understand whether there is a relationship among cell contacts, synapse morphology and T-cell development.

Synapses and Different Kinds of T Cells

Understanding T cell activation is further complicated by the fact that different types of T cells have different activation requirements. Naïve T cells have relatively high thresholds for T-cell activation, require secondary signals mediated by receptors classified as co-stimulators, and can only be activated by professional antigen-presenting cells in secondary lymphoid organs such as lymph node and spleen. Memory T cells, in contrast, have much lower thresholds for T-cell activation, do not require co-stimulation, and can be activated outside of secondary lymphoid organs. The activation requirements for CD4 T cells versus CD8 T cells also appear to be distinct. Although CD4 T cells appear to require sustained periods of TCR engagement, CD8 T cells can apparently make the decision to fire or not within minutes. Whereas CD4 activation requires 100–1000 peptide-MHC complexes [40], CD8 activation requires only a single peptide-MHC complex [5,41]. Important subgroups of CD4 T cells, the so-called TH1 and TH2 T cells, also appear to have distinct signaling requirements.

Although several groups have imaged synapses of both naïve and previously activated T-cell blasts, there is relatively little analysis about any possible differences. This issue is complicated by the fact that a careful analysis will also require use of a variety of types of antigen-presenting cells. This requirement is critical because *in vivo*, different types of T cells are stimulated by different types of APCs. Both naïve and blasted T cells can form immature and classical synapses, but the kinetics may be slower in naïve T cells [31]. The specific differences between the two will need to be examined closely in the future.

One area that has seen progress in recent years is the nature of CD8+ T-cell synapses. This is an interesting topic because CD8 T-cell activation occurs very quickly and can be stimulated by a single peptide-MHC complex. In addition, multiple targets can be killed within a 10 to 20 minute period. Kupfer and coworkers demonstrated that naïve CD8 T cells form classical synapses even at extremely low levels of peptide-MHC complex [24]. These synapses have a normal P-SMAC but surprisingly have no detectable enrichment of TCRs in the C-SMAC at very low levels of antigen. The C-SMAC, however, can be identified by the recruitment and

concentration of PKC-theta in a zone that is central to the P-SMAC. At higher concentrations of antigen, however, visible recruitment of the TCR is seen. This suggests that recruitment and enrichment of the TCR in the C-SMAC is not required for T-cell activation, at least in CD8 cells. A beautiful high-resolution study by Griffiths and coworkers confirmed these findings and also demonstrated that the contact contains a small cleft into which secretory granules empty their contents [25]. This suggests that one important function of the synapse is to help form a target zone for the secretion of cytolytic granules. Electron microscopic studies demonstrated that there is fusion between the plasma membranes of the T cell and the target cell in the synapse. Combined with the tight adhesion of the P-SMAC, the synapse might be important in preventing the spillage of cytolytic proteins into the extracellular space.

Natural Killer Cell Synapses

Three groups have also imaged synapses formed by natural killer (NK) cells and their targets [26,27,39,30,42]. This is an interesting area because NK cells like CD8+ cells must quickly make a decision to kill or not kill a target cell. Unlike CD8+ cells, this decision is not solely dependent on antigen but is negatively regulated by recognition of normal membrane proteins. Thus, the NK cells must integrate information from both stimulatory and inhibitory receptors before they can make a decision to fire or not. First, Leibson and coworkers imaged the recruitment of lipid rafts to synapses in the presence or absence of inhibitory signaling [42]. They found that rafts were recruited when a target cell was killed but that inhibitory signaling blocked raft recruitment. The Strominger and Dupont groups have analyzed these cytolytic and noncytolytic synapses in greater detail. They found that in cytolytic synapses, NK cells formed a P-SMAC as defined as an outer ring of LFA-1 and talin and a C-SMAC as defined by the central accumulation of PKC-theta and other signaling molecules [26,27]. In noncytolytic synapses, while a contact surface is generated, no clearly defined P-SMAC and C-SMAC can be seen, nor is there recruitment of lipid rafts [29]. This is an active process because addition of an inhibitory ligand to the system results in the loss of receptor segregation in the contact area as well as lipid raft recruitment. Thus, in this system, classical synapse formation appears to be linked to not only to antigen recognition but also to the absence of inhibitory receptor signaling.

The Function of the Immunological Synapse

Early studies proposed that the synapse functioned to initiate T-cell receptor signal transduction [32]. This was based on the fact that T-cell receptors were clustered and concentrated in the C-SMAC. In addition, it was noted that lipid rafts, a rich source of signaling molecules, also clustered in the synapse [43]. Thus it seemed logical that the C-SMAC

might function as a way to crosslink and aggregate T-cell receptors. Although early studies suggested that calcium signaling might precede formation of immunological synapse, in many systems, especially those using T-cell clones and T-cell hybridomas, the formation of the immunological synapse occurred quickly, within minutes of contact formation. Thus it was difficult to say definitively whether synapse formation preceded or followed the initiation of signal transduction.

Support for the idea that the C-SMAC serves as an active area of signal transduction was the finding that lipid rafts are enriched in immunological synapses [43]. Since lipid rafts are a rich source of signaling components [44], it was logical to assume that formation of the C-SMAC accompanied by lipid raft recruitment would form a strong trigger and an amplifier of TCR signal transduction. Burack *et al.* were the first to show that lipid rafts are enriched in the C-SMAC and depleted in the P-SMAC [45]. However, the level of raft enrichment is low, about two- to three-fold over basal levels and likely to be due to displacement from the P-SMAC rather than active recruitment from other areas of the plasma membrane.

As discussed above, Lee *et al.*, using naïve T cells and primary antigen-presenting cells, were able to demonstrate that synapse formation occurs in two distinct phases [31]. Up to 15 minutes after conjugate formation, the synapses have an immature morphology; TCRs are found mainly at the periphery of the contact, surrounding a central zone of LFA-1/ICAM-1. Between 15 and 30 minutes, the zones invert, with T-cell receptors moving to the center of the contact and LFA-1/ICAM-1 complexes moving to the periphery. The slow development of the mature synapse in this system allowed a careful analysis of the kinetics of TCR signal transduction via phospho-specific antibodies. The activation of LCK and ZAP-70 occurred in the immature synapse and had largely abated by the time the mature synapse had formed. Not only does this suggest that immunological synapse formation is not involved in initiating T-cell receptor signaling, it also suggests that large-scale aggregation of T-cell receptors is not required to initiate T cell receptor signaling. This in turn suggests that TCR signaling is initiated before mature synapse formation.

Work from Krummel *et al.* examining the recruitment of Lck and CD4 to the synapse is consistent with these findings [46]. They found that CD4 and CD3 zeta, components of the TCR, were both recruited rapidly to the contact area. Their recruitment was coincident with the initiation of calcium signaling. Although CD3 zeta was recruited to the C-SMAC, CD4 surprisingly moved out of the contact area. This result is consistent with the idea that the initiation of TCR signaling does not require the C-SMAC, nor does a significant portion of signaling occur there, and suggests that the C-SMAC is involved in some other biological activity occurring between T cell/APC conjugates.

Perhaps the immunological synapse functions to sustain T-cell receptor signaling. Several groups have now showed that sustained contact for over two hours is required before

a naïve T cell is committed to proliferate [3,47]. The synapse might function, therefore, to help sustain signaling. What signals are required for two hours remains unclear, however. Studies using phospho-specific antibodies suggest that TCR signaling has largely abated by 30 minutes after contact formation [31]. This scenario does not rule out that low-level TCR signaling continues at levels below the level of detection. It is also possible that the immunological synapse may function to facilitate engagement of receptors in addition to the TCR. Important candidates include co-stimulatory molecules as well as cytokine receptors [48].

The engagement of co-stimulatory molecules such as CD28 is required for the activation of naïve T cells, whose sustained signaling may be required in the synapse. The ligand for CD28, B7, is expressed on professional antigen-presenting cells, and CD28/B7 complexes are recruited to the C-SMAC [33]. Although the exact signals transduced by CD28 are still controversial, activation almost certainly will involve more than one signaling pathway. CD28 functions by directly potentiating TCR signaling, enhancing cell survival, and increasing the metabolism of the T cells. One important signaling pathway mediated by CD28 is the PI-3 kinase pathway, and prolonged signaling by the PI-3 kinase/AKT pathways may be required for T-cell commitment [49]. It is also interesting to note that other co-stimulatory molecules, such as CTLA-4 and ICOS, are upregulated hours after the initiation of TCR signaling [50,51]. This finding emphasizes the important role for prolonged co-stimulatory signaling after initiation of TCR signaling. In addition, long-term stability of synapses may play roles in regulating the differentiation of naïve T cells into effector T cells. Cytokine released by the APCs may be more effective if the cells are attached to each other [48]. Thus, it seems logical to consider that the persistence of the immunological synapse would enhance engagement and signal transduction by these accessory molecules.

Immunological Synapses and TCR Downregulation

Because a few peptide MHC molecules are able to downregulate thousands of T-cell receptors, it has been proposed that T-cell activation occurs via the serial triggering of T-cell receptor molecules [52,53]. The immunological synapse might therefore serve to allow multiple receptors to be engaged by the same few MHC peptide molecules clustered into the synapse. Although a provocative model, the serial triggering model is still controversial. First, it has been shown that T-cell receptors can internalize their MHC peptide ligands in the APC plasma membrane [54]. If this occurs *in vivo*, it is difficult to explain how antigen can be maintained in the immunological synapse for many hours. Long-term stability of the peptide-MHC complex in the synapse is also complicated by the half-life of peptide/MHC complexes; sustained signaling could not be maintained for 20 hours if the stability of the peptide-MHC complex is much shorter than this. Finally, it has been shown that

T cells expressing engineered receptors that have very high affinities and that should therefore limit serial engagement are still able to efficiently activate T cells [55]. Thus, whether serial engagement plays an important role in T-cell activation is not currently known.

Still, the formation of a classical immunological synapse might function to direct the internalization and degradation of engaged TCR complexes. In resting T cells, the TCR is recycled continuously from the surface to an early endosomal compartment and back [56]. During activation, TCRs are internalized and instead of being recycled to the plasma membrane are directed for degradation in lysosomes [57,58]. Since the C-SMAC has been shown to be the spot where secretory granules are inserted into the membrane [25], it is likely that it is also the spot where membranes are retrieved. To maintain membrane homeostasis, much of the inserted membrane will need to be retrieved. Thus, it seems possible that the C-SMAC denotes an area of the T-cell plasma membrane where membrane dynamics are particularly active.

Conclusion

More than a contact surface, the immunological synapse is a specific arrangement of proteins in the contact area. Many different patterns of the immunological synapse have been discovered, and it is suggested that these patterns are related to the biological outcome of T-cell activation. Although exactly what determines the morphology of the immunological synapse remains unknown, it almost certainly is due to differences in the antigen-presenting cell as well as differences in the particular T cell studied. It will be important as this field grows to analyze this phenomenon in greater detail. Although the immunological synapse was first proposed to function to initiate T-cell signaling, it is clear now that TCR signaling can occur in the absence of organized synapse formation. Rather, the formation of the immunological synapse appears to be a consequence of activation rather than a requirement for activation. The jury is still out on whether the synapse functions to sustain TCR signaling, but it seems very likely that the synapse is required for several hours to commit the naïve T cell to enter cell cycle. Although much remains to be learned, all can agree that the immunological synapse does represent the polarization of the T cell, a process that is required to allow T-cell effector functions to be accomplished—be that cytolysis or cytokine release. It seems likely, given the rapid progress in this field, that much more will be known about immunological synapses in the very near future.

The Ubiquitin-Proteasome System

Mark Hochstrasser

Introduction

The ubiquitin-proteasome system provides the major route of degradation for most short-lived intracellular proteins in eukaryotes. Ubiquitin is an extraordinarily well-conserved 76-residue polypeptide that is found either free or covalently joined through its C-terminus to a variety of cytoplasmic, nuclear, and membrane proteins. Although the best defined function of ubiquitin is to direct substrate proteins to their destruction by the 26S proteasome, this is not its only role. In recent years, protein ubiquitination has also been shown to regulate endocytosis and intracellular trafficking of membrane proteins, modify proteins in signal transduction pathways, and alter activity of the ribosome. Moreover, we have become aware of a broader set of structurally related proteins—the *ubiquitin-like* proteins or Ubls—that are also covalently ligated to and removed from other macromolecules by specific enzymatic pathways. These enzymes are generally similar in both mechanism and sequence to those that act on ubiquitin. The purpose of this short review is to give a general description of the ubiquitin-proteasome system, while highlighting some of the key regulatory pathways that depend on it.

Overview of the Ubiquitin-Proteasome System

Ubiquitin is joined reversibly to proteins by an amide (isopeptide) linkage between the C-terminus of ubiquitin and lysine ϵ -amino groups of the acceptor proteins. A simplified view of the ubiquitin pathway, which is highly conserved among diverse eukaryotes, is depicted in Fig. 1 [1,2]. The C-terminus of ubiquitin must be activated before it can form

isopeptide bonds with other proteins. Initially, ubiquitin is adenylated by the ubiquitin activating enzyme, E1. The activated carbonyl in the ubiquitin~AMP intermediate is then attacked by a sulfhydryl group of the E1 enzyme, yielding an E1-ubiquitin thioester. Ubiquitin is subsequently passed to one of a large number of distinct ubiquitin-conjugating enzymes or E2s to form an E2-ubiquitin thioester. The E2s almost always catalyze substrate ubiquitination in conjunction with a specificity factor known as ubiquitin-protein ligase or E3. For proteolytic substrates, assembly of a multi-ubiquitin chain(s) on the protein is generally necessary for degradation. Ubiquitinated proteins are in a dynamic state, subject to either further rounds of ubiquitin addition, ubiquitin removal by deubiquitinating enzymes (DUBs), or degradation by the 26S proteasome (Fig. 1). The proteasome specifically recognizes multiubiquitin-protein conjugates; it then unfolds the substrate moiety and degrades it into small peptides, while releasing intact ubiquitin for further rounds of protein tagging.

A series of ubiquitin-related proteins (Ubls) that can be ligated to target molecules has also been uncovered, primarily as a result of genomic-scale DNA sequencing efforts. At present, over a dozen proven or putative Ubls are known [3,4]. Some, such as Rub1/NEDD8 and Smt3/SUMO, are known to make important contributions to cell signaling.

Components of the Ubiquitin Ligation and Deubiquitination Pathways

Ubiquitin-Activating Enzyme (E1) The E1 proteins are well-conserved proteins that are about 100 kD in size and

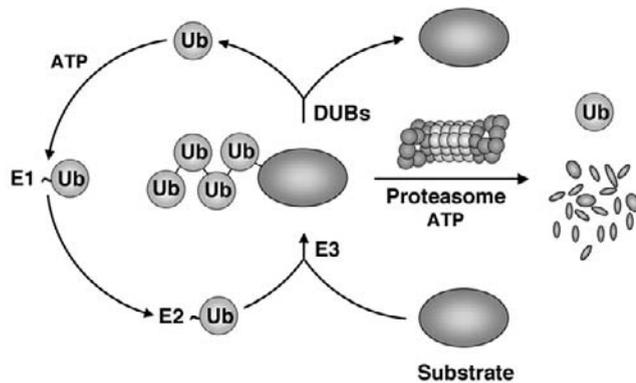

Figure 1 Outline of the ubiquitin-proteasome system. See text for details.

have a recognizable nucleotide-binding motif for ATP binding and a conserved cysteine residue that serves as the site of ubiquitin thioester formation. Most organisms have a single E1-encoding gene, which is essential for survival. No three-dimensional structure for a ubiquitin-activating enzyme has been solved, but a set of structures for an evolutionarily related bacterial protein required for molybdenum cofactor synthesis has been reported recently [5]; the structures suggest a mechanism for ubiquitin adenylation as well.

Ubiquitin-Conjugating Enzyme (E2) There is considerable diversity among the E2 isozymes but they share a core domain of ~120–150 residues with roughly 35 percent sequence identity. A cysteine in this domain accepts ubiquitin from the E1-ubiquitin thioester in a transthioesterification reaction. Multiple E2 crystal structures have been reported. Different E2s are specifically required with the ubiquitination of particular substrates. This requirement appears to reflect both specific E2 association with a subset of E3 ligases and direct E2 contacts with the substrate [1].

Ubiquitin-Protein Ligase (E3) The E3s generally make the greatest contribution to substrate recognition and are usually essential for efficient ubiquitin transfer. They can be either single polypeptides or multisubunit complexes. Two mechanically and structurally distinct classes of E3s have been reported to date. One class appears to function primarily as an adaptor between E2 and substrate, and the most recent structural data are consistent with this view [6]. All E3s of this mechanistic class share a common structural feature, namely, a RING domain. The RING motif utilizes a characteristic arrangement of Cys and His residues to coordinate two zinc ions, and this structural domain can bind directly to E2s. (In a structurally related motif, called the U-box, the same RING-like fold is predicted, but without the coordination of zinc ions; several E3s with U-boxes have been reported [7].) A distinct domain or subunit of the E3 associates with substrate, and the E2-E3-substrate ternary complex is thought to optimize the position or orientation of the E2-linked ubiquitin for attack by a substrate lysine.

In the second class of E3s, an additional ubiquitin transthioesterification occurs, in this case between the E2 and E3, and the ubiquitin is then finally transferred from the E3 thiol to the substrate lysine. All E3s of this type bear a conserved ~350-residue stretch called the HECT domain, the key feature of which is the conserved cysteine that forms the thioester with ubiquitin. A crystal structure of a HECT E3 ligase-E2 complex is available, but the relevant cysteines in the E2 and E3 are over 40 Å apart, so very little can be inferred about how ubiquitin is transferred between the two thiols [8]. Although there are many fewer HECT E3s than RING E3s, it was a mutation in a HECT E3, the E6-AP gene mutated in Angelman's Syndrome, that provided the first direct link between the ubiquitin system and a heritable human disease [9].

Deubiquitinating Enzymes (DUBs) In terms of individual physiological functions, most DUBs remain enigmatic. Nevertheless, both the broad requirements for such enzymes and some of their basic molecular features are fairly well understood [10,11]. DUBs are required first of all to process the precursor forms of ubiquitin insofar as all ubiquitin genes encode either head-to-tail fusions of multiple ubiquitin moieties or ubiquitin sequences fused to ribosomal peptides. Because ubiquitin ligation involves intermediates of ubiquitin susceptible to nucleophilic attack, adventitious conjugation to abundant intracellular nucleophiles such as lysine or glutathione is believed to be common, and this must be reversed by DUBs to maintain adequate free ubiquitin pools. DUBs also can negatively regulate ubiquitin-dependent processes by removing the protein modification; for example, they can prevent or limit ubiquitin-dependent proteolysis by the proteasome. Finally, an important positive regulatory function of DUBs is the recycling of ubiquitin from proteins following their commitment to proteolysis by either the proteasome or lysosome/vacuole [10,11].

There are two known classes of DUBs: the ubiquitin C-terminal hydrolases (UCHs) and the ubiquitin-specific processing proteases (UBPs). Both are specialized cysteine proteases. The UCHs, which are usually <40 kD in size, are the less common class, and generally can only cleave ubiquitin from small adducts or disordered protein segments. This substrate constraint reflects the presence of a loop in the UCH enzymes that lies over the active site; segments of the ubiquitin-substrate conjugate may need to be threaded through this loop for efficient cleavage [12]. Less is known about the structure and enzymatic mechanism of the UBPs, which are generally larger than the UCHs. The UBPs are extremely heterogeneous in sequence and are primarily classified together by virtue of two short conserved sequence elements, the Cys box and the His box, which appear to constitute part of the active site of these enzymes. *Saccharomyces cerevisiae*, for example, has 16 such enzymes, and the only regions that can be unequivocally aligned in all of them are the Cys and His boxes. Surprisingly, none of the individual yeast enzymes is required for viability [13].

The 20S and 26S Proteasomes

The 26S proteasome is both the largest and most complex of ubiquitin system components (reviewed in [14]). The most rigorous measurements put its mass at ~2.5 MDa, which is on the same order as ribosome subunits. The complex comprises some 32–35 distinct polypeptides, with additional proteins that either interact with only a subset of proteasomes or associate only transiently with proteasomes. In the absence of ATP, the 26S proteasome readily dissociates into a 19S regulatory particle and a 20S core particle. The 20S proteasome core is a cylindrical structure made of a set of 28 subunits arranged in four coaxially stacked rings. A protected interior chamber houses the protease active sites; access to this hydrolytic chamber is restricted by a set of narrow channels that extend from the two ends of the particle, which at their narrowest are ~13 Å across. Therefore, for a protein to be translocated into the catalytic core, it must be completely unfolded or nearly so. Proteolysis proceeds processively until short peptides are generated and released from the inner chambers.

Unfolding and translocation into the 20S core are controlled by the 19S regulatory particles that are positioned over each axial pore. The 19S complex includes six distinct AAA-type ATPase subunits; these are believed to form a ring that interacts directly with the outer heptameric ring of the 20S proteasome. Functions of the 19S complex include recognition of polyubiquitinated proteins (and less frequently, of nonubiquitinated substrates), protein unfolding, translocation of protein into the 20S proteasome, and recycling of ubiquitin from protein substrates bound to the proteasome. Under some conditions, the 19S regulatory complex can be further dissociated into lid and base subcomplexes. The base, which interacts directly with the 20S proteasome, includes all the ATPase subunits and the two largest non-ATPase subunits.

Degradation Signals or Degrons

A fundamental question about protein degradation is exactly what structural features render a particular protein into a target for ubiquitin-dependent proteolysis [15]. Despite its importance, this remains one of the least well understood aspects of ubiquitin-dependent degradation. Short peptide stretches can sometimes target a protein to an E2/E3 ubiquitin ligase complex, and in some cases their ability to function as targeting signals or degrons is controlled by their phosphorylation. In other examples, it is clear that a higher order structure, which may be made up of discontinuous sequence elements, is required for E2/E3 recognition [15,16]. Virtually any protein that is misfolded or misassembled can become a substrate for the ubiquitin-proteasome system. This implies that there are common features that help a cell distinguish a correctly folded protein from one that is not. The most straightforward idea, for which there is experimental evidence, is that surface-exposed hydrophobic structures, which are normally buried in subunit interfaces or in

the hydrophobic core of a protein, can function as folding-dependent degradation signals.

Examples of Regulation by Protein Ubiquitination

Protein ubiquitination is now recognized to be almost as pervasive as protein phosphorylation, and it would be impossible to enumerate here all the known instances in which ubiquitination is an important component of a cellular regulatory mechanism. Instead, a few illustrative examples will be briefly described. Perhaps the most widely appreciated function of ubiquitin-dependent proteolysis is in cell cycle control. Multiple, irreversible transitions in the cell cycle, including G1-to-S, metaphase-to-anaphase, and mitotic exit, require the timed degradation of specific positive or negative cell-cycle regulators. For instance, separation of sister chromatids to initiate anaphase depends on the ubiquitin-dependent destruction of an inhibitor called securin [17]. Securin binds to and keeps inactive a caspase-related protease, called separase or separin. Degradation of securin frees separase to cleave a subunit of the cohesin complexes, which prior to subunit cleavage maintain connections between sister chromatids even while they are under tension from the mitotic spindle.

Another well-studied example of ubiquitin-dependent regulation is in the NFκB signaling pathway. The NFκB transcription factor initiates transcription of multiple genes in response to an array of different environmental signals [18]. Most of these signals work by inactivating an inhibitor of NFκB called IκB, which sequesters NFκB in the cytoplasm by enhancing its export from the nucleus. Signaling leads to the site-specific phosphorylation of IκB, which triggers its multiubiquitination by an ubiquitin-protein ligase and rapid degradation by the proteasome. An interesting finding is that protein multiubiquitination appears to serve an additional, nonproteolytic signaling function upstream of the kinase that phosphorylates IκB, but the mechanism of this regulation remains to be fully elaborated [18].

A final example of how ubiquitin is deployed as a regulator of signaling is the remarkable finding that the ubiquitination of certain transcription factors is both a requirement for their activator function and a prelude to their silencing by proteasomal degradation [19]. A single ubiquitin moiety is sufficient for activation, but a multiubiquitin chain is necessary for subsequent degradation. This latter finding is consistent with the fact that proteasomes only bind efficiently to ubiquitin chains with at least four ubiquitin moieties [20]. Monoubiquitination, however, is also a known signal in other processes, particularly in the endocytosis and trafficking of cell surface receptors [21].

Caspases: Cell Signaling by Proteolysis

Guy S. Salvesen

Burnham Institute,
San Diego, California*

Protease Signaling

Proteolytic enzymes, including the cell's degrading machine the proteasome, calpains, and integral membrane proteases such as γ -secretase and rhomboid, participate in several intracellular signaling processes (Table I). But given that the human genome contains in excess of 500 genes that encode proteases, it seems odd that only the caspases constitute a formal multistep pathway able to transmit intracellular signals by proteolysis. In contrast, extracellular multistep signaling pathways frequently use the principle of proteolysis extensively for coagulation, fibrinolysis, complement activation in mammals, and gastrulation in flies. What is it about the caspases that makes them so suitable to transmit intracellular signals?

The consensus view of caspases places them in two main camps. First are the cytokine activators related to caspase 1, probably including mouse caspase 11 and its close homologs caspases 4 and 5 in humans. Their main role is to respond to bacterial infection by rapidly converting active cytokines (IL-1 β , IL-18) from intracellular stores. Confirmation of the important roles of the caspases in the inflammatory cytokine response comes from gene ablation experiments in mice. Animals ablated in caspase 1 or 11 are deficient in cytokine processing [1,2] but without any overt apoptotic phenotype. The second camp constitutes the apoptotic caspases that transduce and execute death signals. The phenotypes of these knockouts are very gross, evidently anti-apoptotic, and vary from early embryonic lethality (caspase 8) to perinatal lethality (caspases 3 and 9) [3–5] to relatively mild with

defects in the process of normal oocyte ablation [6]. Techniques in biochemistry and cell biology have allowed us to place the apoptotic caspases in two converging pathways, such that some are activated by others (Fig. 1). This core pathway probably represents a minimal apoptotic program, and certainly their simplicity is complicated by cell-specific additions that help fine-tune individual cell fates. Nevertheless, the basic order and at least some of the essential functions and, especially important, endogenous regulators of the caspases are now known.

Apoptosis and Limited Proteolysis

Apoptosis is a mechanism to regulate cell number and is vital throughout the life of all metazoan animals. Though several different types of biochemical events have been recognized as important in apoptosis, perhaps the most fundamental is the participation of the caspases [7–9].

The name caspase is a contraction of cysteine-dependent aspartate specific protease [10], thus their enzymatic properties are governed by a dominant specificity for protein substrates containing Asp, and by the use of a Cys side chain for catalyzing peptide bond cleavage. The use of a Cys side chain as a nucleophile during peptide bond hydrolysis is common to several protease families. However, the primary specificity for Asp turns out to be very rare among proteases throughout biotic kingdoms. Of all known mammalian proteases only the caspase activator granzyme B, a serine protease, has the same primary specificity [11,12]. Caspases cleave a number of

cellular proteins [13], and the process is one of limited proteolysis whereby a small number of cuts, usually only one, are made. Sometimes cleavage results in activation of the protein, sometimes in inactivation [14], but never in degradation, since their substrate specificity distinguishes the caspases as among the most restricted of endopeptidases.

Table I Proteases Involved in Intracellular Signaling

Protease	Signaling function
Caspases	Apoptosis Pro-inflammatory cytokine activation
Proteasome	Cell cycle progression NFκB activation
Rhomboid	EGF signaling
γ-Secretase	Toll receptor signaling
SREB Site2 Protease	Upregulation of sterol synthesis genes
Separase	Anaphase
Calpains	Various signaling events

While not an exhaustive survey, the table highlights the principle of proteolysis as a mechanism of signal transmission.

This is an important distinction from the proteasome, which permits signaling by wholesale destruction of regulatory proteins such as IκB in NFκB signaling and PDS1 in anaphase promotion [see Chapter 291 in Volume 3].

The most primitive organism with a bona fide caspase appears to be *Caenorhabditis elegans*. Indeed, the first apoptotic caspase, Ced3, was identified in this organism, a finding that galvanized the apoptotic research field [15]. As the complexity of primitive cell death pathways developed, so apparently did the number of caspases. *Drosophila* have at least seven caspases [16] and humans have at least 11. Mapping the inherent substrate specificity of caspases has allowed some broad consensus to be recognized [17]. These consensus also allow apoptotic caspases to be distinguished from pro-inflammatory caspases, since the latter have a rather distinct specificity that presumably allows them to carry out their job without threatening cell viability. What is interesting, there seems to have been a parallel evolution of apoptotic caspases along with their substrates. Consensus caspase targets in humans such as nuclear lamins and poly (ADP)ribose polymerase have easily recognizable caspase cleavage sites in *Drosophila* but apparently not in organisms such as yeast and plants, which lack an apoptotic pathway.

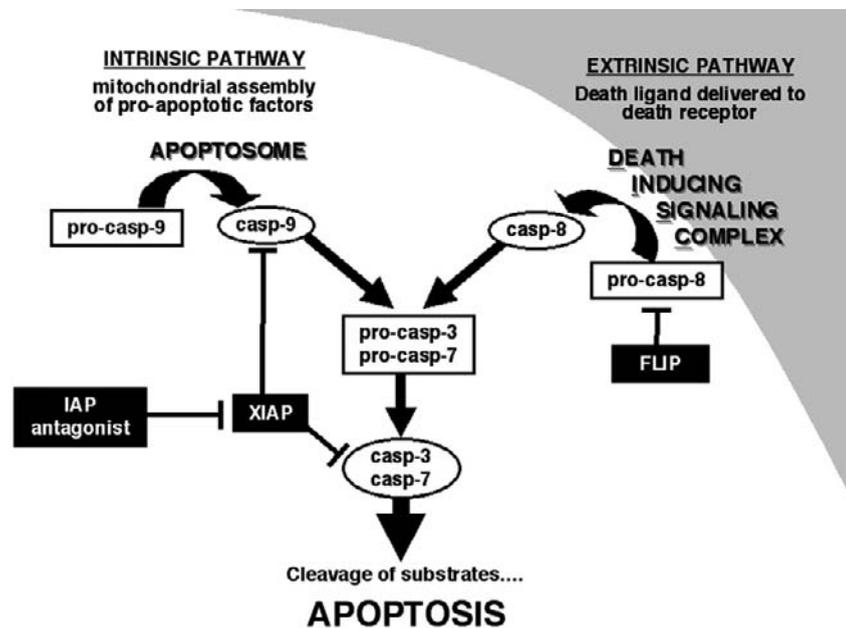

Figure 1 The framework of apoptosis. Death may be signaled by direct ligand-enforced clustering of receptors at the cell surface, which leads to the activation of initiator caspases 8 [46]. This caspase then directly activates the executioner caspases 3 and 7 (and possibly 6), which are predominantly responsible for the limited proteolysis that characterizes apoptotic dismantling of the cell. Alternatively, irreparable damage to the genome caused by mutagens, pharmaceuticals that inhibit DNA repair, or ionizing radiation—transmitted by a mechanism thought to involve the release of cytochrome c from mitochondria—engages the same executioner caspases [47]. The latter events progress through the initiator caspase 9 and its cofactor Apaf-1 [21]. Activation of the extrinsic pathway is regulated by FLIP, which serves to modulate the recruitment of caspase 8 to its adapters [48]. The common execution phase is regulated through direct caspase inhibition by IAPs, some of which can also regulate the active form of caspase 9. In turn, the IAPs are under the influence of antagonist proteins that compete with caspases for IAPs [38]. Though other modulators may regulate the apoptotic pathway in a cell-specific manner, this framework is considered common to most mammalian cells.

Caspase Activation

Induced Proximity

The seminal discovery that death receptor signaling requires, in its most basic form, simply a transmembrane receptor, an adapter molecule, and a caspase [18,19] revealed a solution to the perplexing problem of how the first proteolytic signal was generated during apoptosis, since it implicated a caspase directly in the triggering event. Prior to this work receptors were thought to signal by either altering the phosphorylation status of key signaling molecules or by functioning as ion channels. Death receptors such as Fas signal by direct recruitment and activation of a protease (caspase 8). Concomitantly with this work, groundbreaking studies showed that the intrinsic pathway was activated by a cofactor known as apoptosis protease activating factor (Apaf-1) [20]. Subsequently, Apaf-1 was found to recruit and activate caspase 9, forming the “apoptosome” [21].

In common with most proteolytic enzymes, caspases reside as latent forms that are usually activated by limited proteolysis. It is relatively easy to imagine that the caspases operating at the bottom of the pathway are activated by ones above. Until recently the question of how the first caspase in a pathway became activated, how the first death signal was generated, was a perplexing issue. Now several groups have focused on this issue and a consensus has been arrived at to describe the intriguing operation of the initiation of the proteolytic pathways that execute apoptosis (reviewed in [22,23]). This mechanism is known as the “induced proximity hypothesis” and although it originally referred to death induced by caspase 8 (the extrinsic pathway), it has now been extended to death induced by caspase 9 (the intrinsic pathway); see Fig. 1. Notably, this mechanism does not apply to the executioner caspases.

How exactly does a recruited zymogen become active? To understand this, as a basis for formulating an adequate hypothesis, one must understand the unusual properties of caspase zymogens that set them apart from most other proteases. Unlike most other proteases, simple expression of caspase zymogens in *E. coli* usually results in their activation by limited proteolysis within a “linker segment” that separates the large (~20 kD) and small (~10 kD) subunits of the catalytic domain [24,25]. This activation results from processing that is a consequence of intrinsic proteolytic activity residing in the caspase zymogens. It is not due to *E. coli* proteases, since catalytically disabled C285A (caspase 1 numbering convention) mutants fail to undergo processing.

Initiator Caspases

At the cytosolic concentration in human cells (<50 nM), pro-caspase 9 is a monomer [26] and requires oligomerization within the apoptosome to become active [27,28]. Significantly, unlike the executioner caspases 3 and 7, pro-caspase 9 does not need to be cleaved in the linker region to become active [29,30]. Not only is cleavage unnecessary, but

also it is insufficient to produce an active enzyme. Instead, caspase 9 is activated by small-scale rearrangements of surface loops that define the substrate cleft and catalytic residues [26]. In the simplest model, this is achieved by dimerization of caspase 9 monomers within the apoptosome [31], with the dimer interface providing surfaces compatible with catalytic organization of the active site. More recently, it has been demonstrated that a similar dimerization mechanism activates the caspase 8 Zymogen to trigger the extrinsic pathway [51,52].

Executioner Caspases

Once an initiator caspase has become active, the ensuing activation of the executioners is more straightforwardly explained. At cytosolic concentration in human cells, the caspase-3 and 7 zymogens are already dimers, but cleavage within their respective linker segments is required for activation [32,33]. The same re-ordering of catalytic and substrate binding residues occurs in caspase 7 as seen in caspase 9, so the fundamental mechanism of zymogen activation is equivalent. Only the driving forces are distinct, since the linker segment of pro-caspase 7 blocks ordering of the active site, and upon cleavage the new N- and C-terminal sequences so generated aid in active site stabilization. The property that allows the distinct driving forces to converge on the same activation mechanism seems to be the unusual plasticity of the residues constituting the caspase active site, which, rather unusually for proteases, are predominantly placed on flexible loops and not on an ordered secondary structure.

Regulation by Inhibitors

The first level of regulating proteolytic pathways is by zymogen activation, but an equally important level is achieved by the use of specific inhibitors that can govern the activity of the active components. The endogenous inhibitors of caspases, those present in mammalian cells, are members of the inhibitor of apoptosis (IAP) family. In addition to these endogenous regulators are the virally encoded cowpox virus CrmA and baculovirus p35 proteins that are produced early in infection to suppress caspase-mediated host responses. Each of the inhibitors has a characteristic specificity profile against human caspases, as determined *in vitro*, and these profiles, with few caveats [34], agree with the biologic function of the inhibitors (reviewed in [35]). Though IAPs and CrmA would be expected to regulate mammalian caspases *in vivo*, p35 would never be present normally in mammals because it is expressed naturally by baculoviruses.

The best-characterized endogenous caspase inhibitor is the X-linked IAP (XIAP), a member of the IAP family. The IAPs are broadly distributed and, as their name indicates, the founding members are capable of selectively blocking apoptosis, having initially been identified in baculoviruses (reviewed in [36]). Eight distinct IAPs have been identified

in humans. XIAP (which is the human family paradigm) has been found by multiple research groups to be a potent but restricted inhibitor targeting caspases-3, 7, and 9 (reviewed in [37]). Similarly, evidence implicates human cIAPs 1 and 2, ML-IAP, *Drosophila* DIAP-1, as well as ILP-2, as caspase inhibitors (reviewed in [38]). IAPs certainly have functions in addition to caspase inhibition because they have been found in organisms such as yeast, which neither contain caspases nor undergo apoptosis [39].

IAPs contain one, two, or three baculovirus IAP repeat (BIR) domains, which represent the defining characteristic of the family. Currently there is no known function for BIR1; however, domains closely related to the second BIR domain (BIR2) of XIAP specifically target caspases 3 and 7 ($K_i \approx 0.1$ – 1 nM), and regions closely related to the third BIR domain (BIR3) specifically target caspase 9 ($K_i \approx 10$ nM). This led to the general assumption that the BIR domain itself was important for caspase inhibition. The recent structures of BIR2 in complex with caspases 3 and 7 have surprisingly revealed the BIR domain to have almost no direct role in the inhibitory mechanism. All the important inhibitory contacts are made by the flexible region preceding the BIR domain [40–42]. It is interesting that the mechanism of inhibition of caspase 9 by the BIR3 domain requires cleavage in the inter-subunit linker to generate the new sequence NH_2 -ATPF [30]. In part this explains the cleavage of caspase 9 during apoptosis, which as described above is not required for its activation. Paradoxically, it seems required for its inactivation by XIAP.

Neither CrmA-like nor p35-like inhibitors, which operate by mechanism-based inactivation [35], have been chosen for endogenous caspase regulation; rather, IAPs have been adapted to regulate the executioner caspases. Although the reason for this is not certain, it seems likely that the IAP solution provides a degree of specificity that mechanism-based inhibitors cannot achieve. Thus, XIAP inhibition of caspases 3 and 7 requires a nonstandard interaction with the extended 381 loop that is specific to these two caspases (reviewed in [35]). Possibly the 381 loop has evolved to achieve substrate specificity in the executioner caspases [43]. But an equally likely possibility is that the 381 loop has been generated to enable the IAP scaffold to provide a unique control level over the execution phase of apoptosis. Adding to this level of sophistication, IAPs, but not CrmA or p35-like proteins, are subject to negative regulation by IAP antagonists that go by the names of Hid, Grim, Reaper, and Sickie in *Drosophila* and Smac/Diablo, and HtrA2/Omi in mammals (reviewed in [38]).

IAP Antagonists

Biochemical studies led to the identification of a potentially important IAP-interacting protein known as second mitochondrial activator of caspases (Smac) in humans [44] and Diablo in mice [45]. Smac is a nuclear-encoded mitochondrial protein whose 55 amino terminal residues are removed by a proteolytic process during translocation.

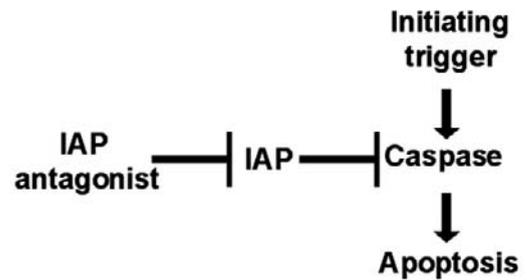

Figure 2 The basis of IAP antagonists as pro-apoptotic proteins. Genetic screens in *Drosophila* initially revealed a genomic region encoding three proteins—head involution defective (Hid), Grim, and Reaper—that together seemed responsible for almost all developmental apoptosis in the fly [49]. These proteins, along with the more recently discovered Sickie, constitute the currently known IAP antagonists in flies. In flies there is evidence for a continuous low-level production of caspases, which are neutralized by *Drosophila* IAP-1 [50]. In this scenario simple upregulation of one or more fly IAP antagonists could send the system into apoptosis, and to this extent the system is transcriptionally regulated. Input from the left of the diagram may be the most important event. In contrast to flies, the currently known mammalian IAP antagonists are mitochondrial proteins and require translocation before they can influence the inhibitory activity of IAPs. This implies a more complex role for IAP antagonists in mammals, since both positive initiator caspase signaling and mitochondrial fluxes would presumably be required, and the system could only be transcriptionally regulated in an indirect manner. In mammals, input from the top of the diagram could be more important.

Smac can be released, apparently along with cytochrome *c*, in response to apoptotic stimuli. Upon its release from mitochondria, mature Smac binds XIAP and probably several other IAPs, in a manner that displaces caspases from XIAP. Thus, Smac is a negative regulator of IAPs and therefore an apoptosis-enhancing molecule. Residues 56–59 of Smac and DIABLO are homologous to the exposed amino terminal motif utilized by caspase 9 to bind BIR3 of XIAP (see preceding section), and Smac has been found to bind to the same pocket in XIAP, thereby attenuating the affinity and displacing caspase 9 from the complex. The remarkable similarity in binding mode of caspase 9 and Smac to XIAP is not limited to these two proteins. In *Drosophila* the death-inducing proteins Hid, Grim, Reaper, and Sickie all contain homologous IAP binding motifs at their N-terminus (sometimes called the RHG or IBM motif). In distinction to the known mammalian IAP antagonists, the *Drosophila* ones do not have transit peptides and are therefore presumably fully functional following synthesis and removal of their initiator methionine. The mitochondrial versus nonmitochondrial disposition of IAP antagonists between mammals and flies suggests a rather different IAP regulation process (Fig. 2), which may have profound consequences for the interpretation of IAP function.

MAP Kinase in Yeast

Elaine A. Elion

Molecular Pharmacology,
Harvard Medical School,
Boston, Massachusetts*

Introduction

Yeast cells use multiple mitogen-activated protein (MAP) kinases to respond to a wide variety of external stimuli that regulate proliferation, differentiation, survival, and response to stress. As in mammalian cells, yeast MAPKs are activated within MAPK cascades that form the cores of larger signal transduction cascades. Activation of MAPKs leads to the phosphorylation of a variety of effector proteins, including many nuclear transcription factors. This chapter presents a brief overview of the different MAPK kinases in yeast, discusses how physical interactions with regulatory proteins such as scaffolds, activating kinases, and substrates regulate pathway specificity, and elucidates how their function is dynamically controlled at the level of localization and the strength and duration of activation.

Yeast Cells Use Multiple MAPKs to Respond to a Wide Variety of Stimuli

All eukaryotic cells have multiple MAPK cascades that are activated by one or more environmental stimulus and that mediate a variety of cellular responses [1,2]. Much of our knowledge about how MAPK cascades function has come from analysis in yeast. The proliferation, differentiation, morphogenesis, and response to stress of budding yeast *S. cerevisiae* is governed by five different MAPKs (Fig. 1), which function in six MAPK cascades that respond to different nutritional and hormonal inputs (Fig. 2). Three of the MAPKs are expressed in dividing haploid and diploid cells (Kss1, Mpk1/Slt2, Hog1), the fourth MAPK (Fus3) is expressed

in dividing haploid cells (Fus3), and the fifth MAPK (Smk1) is expressed in cells undergoing meiosis and sporulation. MAPKs Fus3 and Kss1 function in the mating pathway, which is activated by peptide pheromones and causes cell cycle arrest in G1 phase along with polarized growth and additional differentiative events that prepare cells for cell attachment and fusion (reviewed in [3]). The Kss1 MAPK also functions in the filamentous growth pathways that respond to altered nutritional conditions and induce pseudohyphal diploid cells with higher surface-to-volume ratio and altered budding pattern and invasive haploid cells that can digest the substratum (reviewed in [4]). The Mpk1 MAPK functions in the PKC-regulated MAPK cascade, which is essential for mitotic growth, particularly the G1 to S phase transition, and plays a key role in maintaining cell integrity through cell wall synthesis and the actin cytoskeleton. The PKC-regulated pathway is activated under conditions that perturb the cell wall or plasma membrane (e.g. heat shock) (reviewed in [5,6]). The Kss1 MAPK cascade plays a lesser role in regulating cell integrity in parallel with the PKC-regulated MAPK cascade and is also thought to be activated under conditions of cell wall stress [7]. The Hog1 MAPK functions in the high osmolarity glycerol (HOG) pathway, which responds to hypertonic stress by increasing intracellular pools of glycerol (reviewed in [8]). This pathway is the closest functional equivalent of mammalian p38/JNK pathways. Finally, the Smk1 MAPK functions in a less-defined MAPK cascade that regulates sporulation and meiosis [9]. As in other eukaryotes, the yeast MAPKs phosphorylate many different proteins, including transcription factors in the nucleus (Fig. 2).

The yeast MAPKs are activated by a wide variety of means, including (1) a serpentine receptor and heterotrimeric G protein in the mating pathway, (2) a Ras-linked mechanism for the

filamentous growth pathways, (3) a plasma membrane sensor and two component system in the HOG pathway, and (4) integrin-like sensors that physically link to Rho guanine exchange factors in the PKC-regulated pathway (Fig. 2). Additional signal transduction enzymes that regulate pathway activity include G-protein regulators, adapter proteins, and phosphatases. G-protein regulators include the RGS protein Sst2 that positively regulates Gpa1, the G α subunit of the mating pathway G protein [10], Cdc25 (GEF) and Ira1, Ira2 (GAPs) that regulate Ras2 [4], and Rom1, 2 (GEFs) that regulate Rho1 [6]. Adapter proteins include the

Ste5 scaffold in the mating pathway [11], Pbs2 MAPKK in the HOG pathway (reviewed in [12]), and the Ste11 MAPKKK regulator Ste50 [3] (Fig. 3).

Functionally Defining *S. cerevisiae* MAPK Cascades

The *S. cerevisiae* MAPKs and their activating kinases were identified through genetic screens for mutations or high copy plasmids that affect growth and differentiation. The mating MAPK cascade was the first to be identified and is the best characterized. Full assessment of MAPK function should involve analysis of null alleles as well as catalytically inactive mutants. Useful mutations include a lysine→arginine change in the binding site for ATP, which does not block phosphorylation by MKK or protein substrate binding, and threonine→alanine or tyrosine→phenylalanine changes in the T-X-Y sequence, which block phosphorylation by MKK and can affect protein substrate binding. A combined use of these different types of alleles has shown, for example, that certain MAPKs are functionally redundant (e.g. Fus3 and Kss1 for mating, [3]; Fig. 2) and that inactive kinases serve regulatory functions (e.g. Kss1, [13], Fig. 3B).

The core elements of a *S. cerevisiae* MAPK cascade module are three sequentially activated protein kinases [i.e. MAPKK kinase (MKKK) →MAPK kinase (MKK) →MAPK, Fig. 2]. *S. cerevisiae* MAPK modules show remarkably high conservation with MAPK modules in humans [14]. Fus3 and

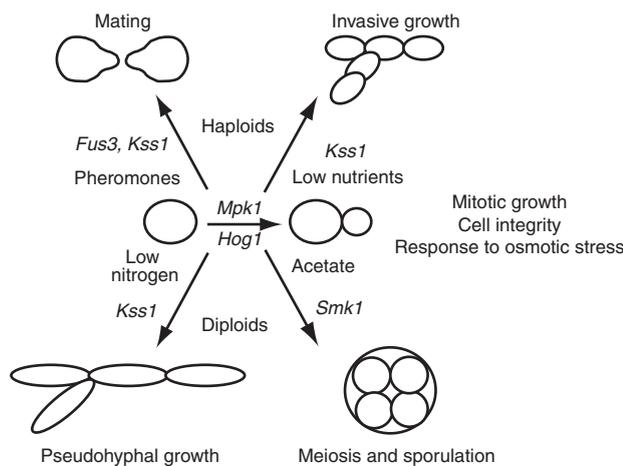

Figure 1 *S. cerevisiae* life cycle is regulated by 5 MAPKs.

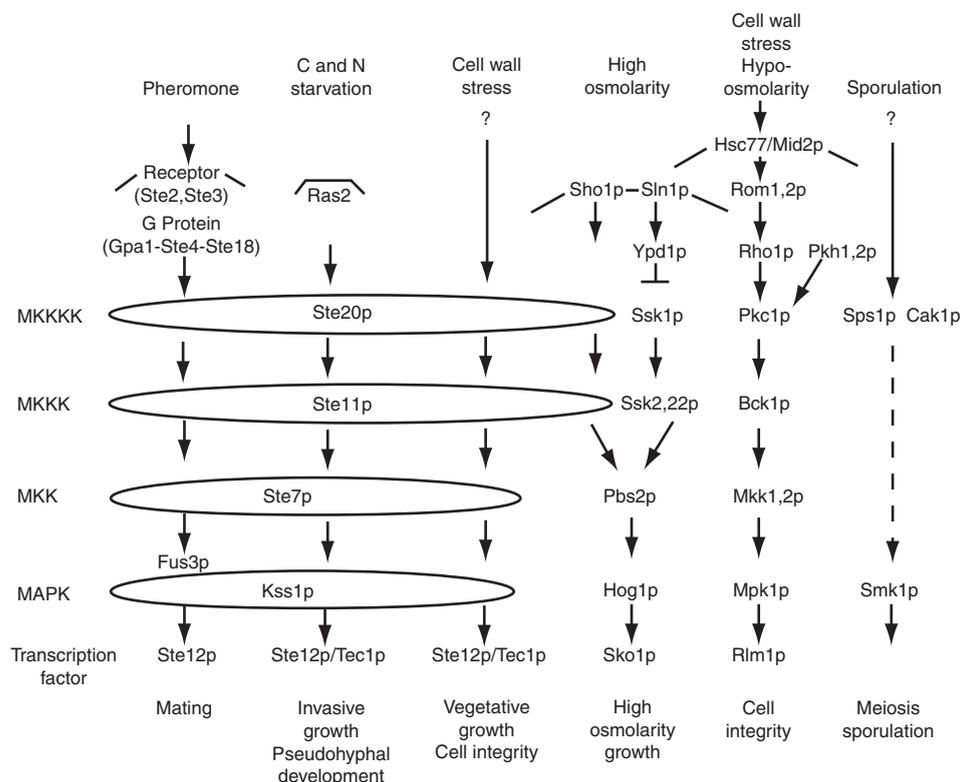

Figure 2 *S. cerevisiae* MAPK cascades.

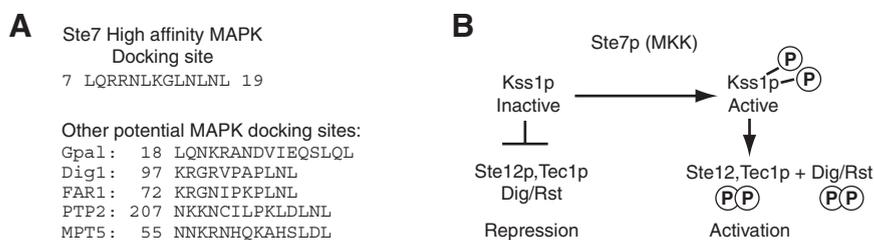

Figure 3 MAPK interactions with activating kinases and targets.

Kss1 are most similar to ERK1, 2, and Hog1 is most similar to p38 MAPK, whereas Mpk1 and Smk1 are distinct [14]. The activation mechanism for the *S. cerevisiae* MAPKs is highly conserved and involves phosphorylation of conserved threonine and tyrosine residues in the signature T-X-Y sequence within the activation (or T) loop at the catalytic cleft by the appropriate dual specificity MKK. Similar to ERK1, Fus3 autophosphorylates on tyrosine 182; however, dual phosphorylation is required for full activation. The yeast MAPKs are tightly regulated and are highly active only in the presence of a stimulus. However, the basal activities of Mpk1, Kss1, and Fus3 perform specific functions in the absence of stimulus [7–8,13]. Biochemical and genetic data support a series of direct phosphorylation events within each MAPK module, leading to serial activation of the MKK and MAPK tiers. A third upstream activating kinase (a putative MKKKK) is thought to activate the uppermost kinase (the MKKK) in a number of MAPK cascades. This third upstream activating kinase includes two subtypes, Ste20 p21-activated kinases (PAK) and protein kinase C (Fig. 2). Ste20 has been shown to directly phosphorylate MKKKK Ste11; its activation involves derepression of a negative regulatory domain and association with a conserved protein called Ste50 through mutual SAM domains [3]. MKK Ste7 may be activated by dual phosphorylation of serine-threonine residues within a conserved domain near the activation loop [15].

Major Regulatory Mechanisms that Control Specificity in *S. cerevisiae* MAPK Cascades

A major biological question is how specificity is achieved to assure that the appropriate response takes place for a given stimulus. The individual *S. cerevisiae* MAPK cascades exhibit exquisite specificity based on the phenotypes of cells with mutations in the individual MAPKs. This specificity is remarkable because four of the pathways use subsets of the same kinases (Fig. 2). Pathway specificity occurs through multiple layers of control, which include preferred kinase-kinase and kinase-substrate interactions, the use of scaffold or adapter-like proteins to route signals through specific MAPK modules, cross-regulation between MAPK modules, controlled localization of MAPKs, and control of the strength of the activation. Common themes of signal transduction through yeast MAPK cascades are that they form molecular

assemblies within cells and spatial organization at specific locations plays a critical role in mediating efficient activation and specificity [16,17]. The pathways are also highly dynamic at the level of movement of signal transduction proteins [18–20].

Kinase Interactions within a MAPK Cascade

MAPKs prefer to bind to specific activating kinases within a module, providing one level of pathway specificity. For example, the yeast MKK Ste7 preferentially binds to and activates MAPKs Fus3 and Kss1 of the mating and invasive growth and pseudohyphal development pathways, but does not bind to or activate MAPKs Mpk1 or Hog1. Consistent with this, *ste7Δ* null mutants only have defects in mating and invasive growth and pseudohyphal development. A docking site of charged residues has been defined for the interaction of Ste7 with Fus3 and Kss1 [21]; this docking site defines a consensus sequence that is generally applicable for other MAPK binding partners (Fig. 3A; [22]).

Functional analysis in yeast demonstrates that MAPK cascade specificity is enhanced through the use of different MKKs and MAPKs that recognize specific substrates. The mating, invasive growth and pseudohyphal development, and high osmolarity growth pathways use some of the same MAPK module components (i.e. MKKKK Ste20, MKKK Ste11, MKK Ste7, MAPK Kss1), yet elicit very different responses by using a specific MKK (Pbs2) and MAPK (Hog1) for high osmolarity growth and a specific MAPK (Fus3) for mating (Fig. 2). For example, during mating, MAPK Fus3 specifically regulates G1 arrest and mating through phosphorylation of the Far1 protein [23], which is a poor substrate for MAPK Kss1 [24].

Yeast MAPKs form stable complexes with their targets, either as active or inactive kinases, suggesting that such complexes may play a regulatory role [23,25]. The functional importance of catalytically inactive MAPK/substrate complexes was first demonstrated for MAPK Kss1, which exerts both negative and positive control over pseudohyphal development and invasive growth (Fig. 3B; [26,27]). Kss1 forms a stable complex with the Ste12 transcription factor in its unphosphorylated inactive form and acts as a transcriptional repressor. When phosphorylated, Kss1 becomes a positive regulator, presumably through dissociation from Ste12 together with phosphorylation of Ste12, Tec1, and the

Dig1,2 repressors (Fig. 3B). The fact that the same MAPK provides both negative and positive functions for signaling means that a *kss1* null mutation does not block signaling whereas catalytically inactive Kss1 derivatives do. These findings argue that it is important to analyze catalytically inactive kinase mutations in addition to null mutations in assigning function.

Scaffold Proteins

A variety of biochemical and genetic evidence suggests that simple activation of the kinases within a MAPK module is not sufficient for function *in vivo*. Scaffold proteins have been found to play key roles in maintaining MAPK function and fidelity by linking individual components to each other, to upstream activators, downstream targets, and specific cellular locales [16,17]. Many of our ideas about scaffolds are based upon work on the prototype MAPK scaffold Ste5 of the mating pathway (Fig. 4, reviewed in [11]). The criteria for assigning a scaffold function to Ste5 included (1) definition of separable binding sites for each of the three tiers of protein kinases (i.e. Ste11, Ste7, and Fus3/Kss1) and (2) biochemical evidence for a Ste5-multikinase complex that enhances Ste11/Ste7 interactions and increases the specific activity of MAPK Fus3. In addition to tethering kinases, Ste5 plays a direct role in the activation of MKKKK Ste11 by MKKKK Ste20, which is normally associated with the Rho-type G protein Cdc42 at the cell cortex (Fig. 4). Ste11 must be properly targeted to Ste20 for activation to take place. This function is tied to proper recruitment of Ste5 through its conserved RING-H2 domain to G $\beta\gamma$ dimers at the plasma membrane, which also bind to Ste20 upon release from G α after pheromone induction of the receptor. Formation of an active signaling complex requires oligomerization of Ste5; glycerol sedimentation is consistent with Ste5 functioning as a dimer.

The MKK Pbs2, of the yeast high osmolarity growth (HOG) pathway, also appears to serve a scaffold function based on pair-wise interactions between Pbs2 and the other two kinases in the MAPK module and separate binding sites for these kinase (reviewed in [12]). Pbs2 has a large regulatory domain in addition to its catalytic domain. A variety of evidence suggests that Pbs2 tethers the Hog1 MAPK and Ste11 MKKK to a transmembrane sensor called Sho1 that senses changes in osmolarity. This interaction is thought to occur through a proline-rich domain in Pbs2. Much like Ste5, Pbs2 is thought to recruit Ste11 to Ste20 while it is linked through its CRIB domain to Cdc42, which is asymmetrically enriched at the plasma membrane, with the end result of phosphorylation and activation of Ste11 by Ste20. Thus, the common theme of Ste5 and Pbs2 is that they link the cytosolic kinases to a plasma membrane-linked G protein or sensor and an activating GTPase-linked PAK. This arrangement allows a proximal sense of the status of the environment and provides a spatial arrangement that promotes phosphorylation of the uppermost kinase of each MAPK module.

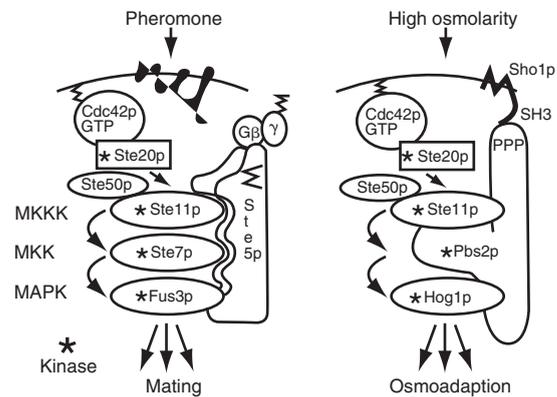

Figure 4 Ste5 and Pbs2 scaffold proteins regulate MAPK cascades of overlapping components.

It is interesting that a common regulatory scheme is used for the two pathways that share signaling components and respond to stimulus in a polarized manner—perhaps the scaffolds allow for a highly localized activation mechanism that facilitates a polarized response, such as by targeting the MAPK to substrates, and also prevent cross-activation.

MAPK cascade scaffolds are now being described in mammalian cells [17]. None bear homology to each other, suggesting that they have evolved independently for the individual requirements of individual subsets of kinases and upstream activating events. It is interesting, however, that the JIP and KSR scaffolds dimerize and are localized to the cell periphery through interactions with membrane-linked receptors or GTPases, thus suggesting that aspects of their function are similar to Ste5's. It has been proposed that a three-tier MAPK cascade has ultrasensitive switch-like responses [28]. The existence of MAPK cascade scaffolds raises the important question of how they affect signal propagation [11,17]. For example, co-localization of three tiers of kinases by a scaffold may prevent amplification by physical sequestration or provide a means to ensure feedback control and prevent cross-activation of other pathways that utilize the same kinases, localize the MAPK to targets, or protect it from phosphatases. Alternatively, a MAPK cascade scaffold could promote kinase-kinase phosphorylation and dissociation after activation and could enhance amplification.

Dynamic Localization of MAPK Cascades

Specificity is also regulated by proper localization of the MAPKs. MAPKs are stably associated with a variety of subcellular structures, including tubulin and centromeres (reviewed in [29,30]). MAPKs can shuttle between the nucleus and cytoplasm and be retained in the cytoplasm by a cognate MAPKK or undergo nuclear translocation as a result of activation and dimerization [30]. In *S. cerevisiae*, the MAPK Hog1 translocates to the nucleus in response to osmotic stress [18], then forms a stable complex with the transcription apparatus at specific promoters and activates

transcription through derepression of Sln1 ([32], Fig. 5). MAPKs Fus3 and Kss1 are predominantly nuclear; however, Fus3 shuttles continuously between the nucleus and cytoplasm and is translocated to the projection tip of pheromone treated cells along with MKK Ste7, possibly through Ste5 [19,20]. This localization event may serve to promote polarized growth and attenuation by co-localizing Fus3 with targets such as Far1 or other components of the morphogenesis apparatus in addition to upstream signaling components such as Ste5, Sst2, and Gα (Gpa1) (Fig. 6). Once activated, Fus3 dissociates rapidly from Ste5 and translocates to the nucleus, where it phosphorylates transcription factors. The Ste5 scaffold also shuttles through the nucleus, and this localization event positively regulates its recruitment and activation of MAPK Fus3 [19]. The Far1 and Cdc24 signaling proteins involved in morphogenesis are anchored together in the nucleus and exported to the cell cortex as a result of pheromone activation (Fig. 6, [3]). Thus, a majority of components in the mating MAPK cascade are dynamic. These findings may be generally applicable to other pathways.

Signal Strength

DOWNREGULATION

The duration and strength of activation of a given MAPK cascade may also affect the ultimate outcome of a response. For example, transient activation of the Ras/Raf/ERK pathway by epidermal growth factor in PC12 cells causes cell proliferation, whereas sustained activation of the same pathway by nerve growth factor (NGF) causes terminal differentiation as shown by neurite outgrowth [33]. Multiple factors can regulate the duration of activation of a MAPK cascade. The *S. cerevisiae* MAPKs are inactivated by several phosphatases that may form stable associations with their target MAPKs [30,34]. These include a dual-specificity phosphatase Msg5 that inactivates Fus3, protein tyrosine phosphatases Ptp2 and Ptp3 that inactivate Hog1, Fus3, and Mpk1 with different specificities, and a serine-threonine phosphatase Ptc1 that inactivates Hog1 MAPK (reviewed in [35]). Yeast MAPK phosphatases can be induced by their cognate MAPK either by direct phosphorylation or increased expression [34].

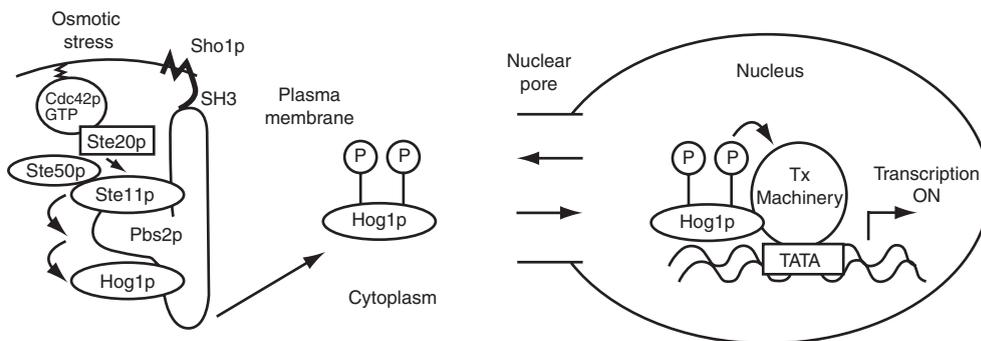

Figure 5 Hog1 forms a stable part of the transcriptional activation machinery.

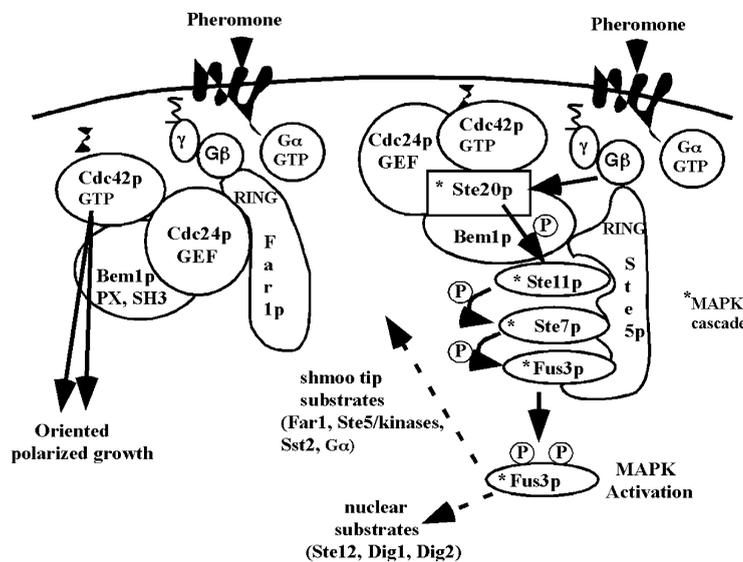

Figure 6 MAPK Fus3 at cell cortex may promote polarized growth fusion.

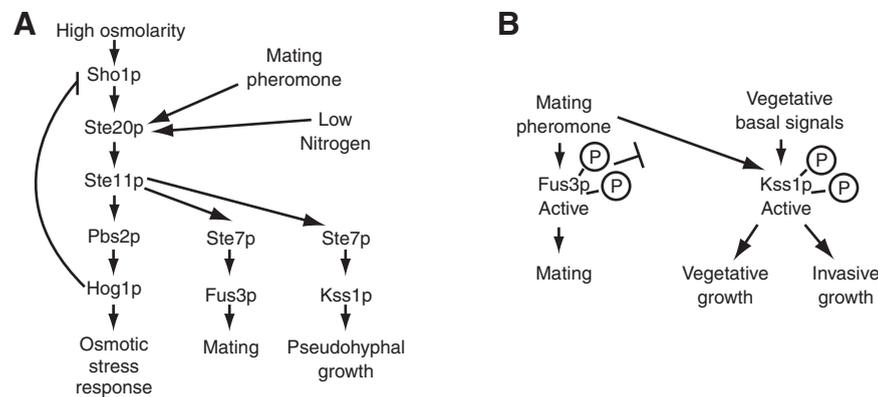

Figure 7 Yeast MAPKs crossregulate one another to maintain specificity.

Because there is considerable sharing of signal transduction components between the MAPK cascades, inputs into one MAPK cascade have the potential to affect multiple pathways. An interesting feature of the yeast MAPKs is their propensity to act as attenuation factors and prevent cross-talk with MAPKs within the same or other pathways. In haploid cells, the mating MAPK Fus3 inhibits the invasive growth and vegetative growth pathways and prevents their activation by mating pheromone (Fig. 4B, [7,13]). Activated Fus3 attenuates the activity of MAPK Kss1 [36], thereby reducing the strength and duration of its activation by pheromone, presumably preventing hyperactivation of the invasive growth pathway. The osmoregulatory pathway MAPK Hog1 inhibits the Fus3 and Kss1 MAPKs both in the absence and presence of hyperosmotic stress (Fig. 7, [37,38]). This cross-regulation requires Hog1 kinase activity and may involve attenuation of the transmembrane sensor Sho1 to prevent persistent activation of the MKKK Ste11. A variety of evidence suggests that MAPKs attenuate the activity of their own pathway through direct phosphorylation of upstream signaling components. For example, MAPK Fus3 phosphorylates Ste5, Ste7, and Ste11 *in vitro* and could directly regulate signal amplification. Fus3 also associates Gpa1-GTP ($G\alpha$) *in vivo*, and this interaction appears to attenuate pathway activity [22].

CELL ARCHITECTURE

The strength and nature of the MAPK cascade activation process is dependent upon proper cellular architecture. Regulators of the actin cytoskeleton, such as the Rho family member Cdc42 and an SH3-domain morphogenesis protein Bem1, have been demonstrated to modulate the activity of the *S. cerevisiae* mating and invasive growth and pseudohyphal development MAPK cascades [39]. A MAPK cascade can also be secondarily activated as a consequence of changes in cellular architecture that arise from activation of a primary MAPK cascade. For example, activation of the mating MAPK by pheromone induces polarized growth, which in turn activates the PKC1-regulated MAPK cascade [40].

Introduction

MAP kinases are critical mediators of signal transduction in mammalian cells [17,43,54,58,95]. The MAP kinases are encoded by a group of genes that are related in sequence. These enzymes are also functionally related. For example, MAP kinases phosphorylate substrate proteins on conserved Ser-Pro and Thr-Pro motifs [22]. However, the substrate specificity of MAP kinases is different for individual MAP kinase isoforms. This substrate specificity is mediated, in part, by the selective docking of MAP kinases to substrate proteins [29]. A second functional similarity between MAP kinases is the mechanism of activation. MAP kinases are activated within conserved protein kinase signaling modules composed of a MAP kinase, a MAP kinase kinase, and a MAP kinase kinase kinase. Phosphorylation and activation of MAP kinases by MAP kinase kinases occurs on two residues within a tripeptide motif (Thr-Xaa-Tyr) located within the T loop that controls the conformation of the MAP kinase active site [18].

There are three major groups of mammalian MAP kinases, the extracellular signal regulated protein kinases (ERK), the p38 MAP kinases, and the c-Jun NH₂-terminal kinases (JNK) (Table I). These groups of MAP kinases can be distinguished by the sequence of the dual phosphorylation motif that mediates MAP kinase activation: Thr-Glu-Tyr (ERK), Thr-Gly-Tyr (p38), and Thr-Pro-Tyr (JNK). In addition, there are several protein kinases that are related to the MAP kinases with similar dual phosphorylation motifs: Thr-Glu-Tyr (MAK and MOK), Thr-Asp-Tyr (ICK, KKIAMRE, KKIALLRE), and Thr-His-Glu (NLK). Here I review the properties of these MAP kinases and MAP kinase-related protein kinases.

The ERK Group of MAP Kinases

ERK1 and ERK2

The ERK1 and ERK2 protein kinases are activated by phosphorylation of the Thr-Glu-Tyr motif located in the T loop by the MAP kinase kinases MEK1 and MEK2 (Table II). Structural analysis of nonphosphorylated and inactive ERK2 [114] and phosphorylated and activated ERK2 [13] by X-ray crystallography reveals that the mechanism of activation involves conformational changes that remodel the T loop and the active site. The activated form of ERK2 has been identified as a homodimer [50] and it is likely that this dimeric form of ERK2 is critical for nuclear accumulation [19].

The ERK1 and ERK2 protein kinases are major targets of the Ras signaling pathway. Substrates of these MAP kinases include a wide array of proteins, including the epidermal growth factor receptor [22], cytoplasmic phospholipase A2 [59], and Ets family transcription factors [64]. The ERK1 and ERK2 protein kinases are implicated in proliferation [119], tumorigenesis [63], and differentiation [21]. It appears that the time course of ERK1 and ERK2 activation may be critical for specifying the biological outcome of signal transduction: transient activation correlates with growth and sustained activation correlates with growth arrest and differentiation [21].

Recent studies indicate that the targeted disruption of the *Erk1* gene in mice causes defects in thymocyte development [83] and causes increased synaptic plasticity associated with improved striatal-mediated learning and memory [67]. It is likely that these limited phenotypes reflect the partial complementation of ERK1-deficiency by ERK2. Further studies of ERK2-deficiency and compound mutations in ERK1 and ERK2 will be important to establish the function of these protein kinases *in vivo* (Table III).

Table I Nomenclature of Human MAP Kinases

Name	Alternative name	Gene name	Chromosomal location	LocusID/accession number
ERK1	p44 MAPK	<i>MAPK3</i>	16p11.2	5595
ERK2	p42 MAPK	<i>MAPK1</i>	22q11.21	5594
ERK3-related	p63 MAPK	<i>MAPK4</i>	18q12-q21	5596
ERK3	p97 MAPK	<i>MAPK6</i>	15q21	5597
ERK5	Big MAP kinase, BMK	<i>MAPK7</i>	17p11.2	5598
ERK7		<i>ERK7</i>		XM 139448
ERK8		<i>ERK8</i>	Chromosome 8	225689
p38 α	CSBP, RK, SAPK2A	<i>MAPK14</i>	6p21.3-p21.2	1432
p38 β	p38-2, p38 β 2, SAPK2B	<i>MAPK11</i>	22q13.33	5600
p38 γ	SAPK3, ERK6	<i>MAPK12</i>	22q13.33	6300
p38 δ	SAPK4	<i>MAPK13</i>	6p21.1	5603
JNK1	SAPK γ , SAPK1C	<i>MAPK8</i>	10q21.1	5599
JNK2	SAPK α , SAPK1A	<i>MAPK9</i>	5q35	5601
JNK3	SAPK β , SAPK1B	<i>MAPK10</i>	4q22.1-q23	5602

Human MAP kinases corresponding to the ERK group (ERK1, ERK2, ERK3, ERK3-related, ERK5, ERK7, and ERK8), the p38 MAP kinase group (p38 α , p38 β , p38 γ , p38 δ), and the JNK group (JNK1, JNK2, and JNK3) are presented with their alternative names, the gene name, the chromosomal localization, and the LocusID or Accession Number.

Table II Nomenclature of Human MAP Kinase Kinases

Name	Alternative name	Gene name	Chromosomal location	LocusID
MEK1	MAPKK1, MKK1	<i>MAP2K1</i>	15q22.1-q22.33	5604
MEK2	MAPKK2, MKK2	<i>MAP2K2</i>	7q32	5605
MKK3	MEK3, SKK2	<i>MAP2K3</i>	17q11.2	5606
MKK4	MEK4, SEK1, JNKK1, SKK1	<i>MAP2K4</i>	17p11.2	6416
MEK5	MKK5	<i>MAP2K5</i>	15q22.1	5607
MKK6	MEK6, SKK3	<i>MAP2K6</i>	17q25.1	5608
MKK7	MEK7, SEK2, JNKK2, SKK4	<i>MAP2K7</i>	19p13.3-p13.2	5609

Human MAP kinase kinases are presented with their alternative names, the gene name, the chromosomal localization, and the LocusID.

ERK3

The ERK3 subgroup of MAP kinases is encoded by two genes [10,36]. These protein kinases are not true members of the ERK group because they contain the sequence Ser-Glu-Gly instead of the dual phosphorylation motif Thr-Glu-Tyr. A MAP kinase kinase activity for ERK3 has been described, but the regulation of the ERK3 protein kinases is not understood [17]. The physiological function of the ERK3 protein kinases is also unclear [17].

ERK5

The ERK5 protein kinase is activated by the MAP kinase kinase MEK5 by dual phosphorylation on the conserved T-loop motif Thr-Glu-Tyr [28,137]. Substrates of ERK5 include members of the MEF2 family of transcription factors [47]. The signaling pathways that lead to the activation of

the ERK5/MEK5 module are poorly understood. However, ERK5 is critical for survival signal transduction by retrograde NGF receptors localized in endosomes [115] and for proliferation caused by epidermal growth factor [48]. Recent studies indicate that ERK5 is essential for viability during murine embryonic development because ERK5-deficiency causes defects in cardiovascular development [87].

ERK7 and ERK8

The ERK7 and ERK8 protein kinases form a subgroup of ERK-related protein kinases that contain the dual phosphorylation motif Thr-Glu-Tyr [2,3]. ERK7 and ERK8 are not activated by MEK1 and MEK2. Recent studies indicate that ERK7 is constitutively activated by autophosphorylation [1]. However, ERK8 appears to have a low basal activity that is increased in cells with activated Src or following

Table III Targeted Disruption of Genes in Mice

	Phenotype	Reference
ERK1	Viable. Defects in thymocyte maturation. Increased synaptic plasticity and improved striatal-mediated learning and memory.	[83,67]
ERK5	Lethal. Embryos die during mid-gestation. Defects in cardiovascular development.	[87]
p38 α	Lethal. Defects in formation of the placenta and expression of erythropoietin.	[4,5,104]
JNK1	Viable. Defects in CD4 effector T cell differentiation and function. Defects in CD8 T cell activation.	[25,24,92,20]
JNK2	Viable. Defects in CD4 effector T cell differentiation and function. Increased CD8 T cell activation.	[90,24,92,20]

The effect of disruption of the murine genes that encode MAP kinases and MAP kinase kinases is summarized.

serum stimulation [3]. Interestingly, ERK7 appears to be associated with an intracellular chloride channel [85]. The physiological function of ERK7 and ERK8 is unclear and further studies of these MAP kinases are warranted.

The p38 Group of MAP Kinases

The regulation of the p38 group of MAP kinases differs from the ERK group of MAP kinases [95,54]. The ERK1 and ERK2 protein kinases are activated by many growth factors by a Ras-dependent mechanism. In contrast, the p38 MAP kinases are activated by inflammatory cytokines and by the exposure of cells to environmental stress. It is thought that members of the Rho family of small GTPases, rather than the Ras family of GTPases, are critical mediators of p38 MAP kinase activation. The p38 group of MAP kinases is activated by three different MAP kinase kinases [43]. Two of these MAP kinase kinases specifically activate the p38 MAP kinases (MKK3 and MKK6). In contrast, the third MAP kinase kinase (MKK4) activates both the JNK and p38 MAP kinases.

p38 α and p38 β MAP Kinases

The p38 α and p38 β MAP kinases are structurally related protein kinases that contain the dual phosphorylation motif Thr-Gly-Tyr [54,95]. The structure of p38 α MAP kinase has been determined by x-ray crystallography [14,122]. This structure is similar to ERK2. However, there are significant differences that distinguish p38 α MAP kinase from ERK2. Included among these differences is the structure of the active site of p38 α MAP kinase. This difference has allowed the

discovery of active site-directed inhibitors that are extremely selective for p38 α and p38 β MAP kinases [27]. These drugs are useful for functional dissection of the p38 α and p38 β MAP kinase signaling pathway. In addition, it is likely that such drugs may be useful for therapeutic intervention. In particular, a major role for p38 α and p38 β MAP kinases in inflammatory responses has been identified. The p38 α and p38 β MAP kinases appear to be critical for the expression of several inflammatory cytokines, including interleukin-1, interleukin-6, and tumor necrosis factor [56]. These p38 MAP kinases regulate several steps in cytokine expression including transcription, mRNA stability, and translation. The transcriptional effects of the p38 α and p38 β MAP kinases are mediated by phosphorylation of several transcription factors, including ATF2 and members of the MEF2 and Ets families [39,86,121]. The mechanisms that account for the effects of p38 α and p38 β MAP kinases on mRNA stability and translation have not been defined. However, recent studies have implicated proteins that bind to the 3' ARE element of regulated mRNAs and MAPKAP2, a protein kinase that is phosphorylated and activated by p38 α and p38 β MAP kinases [52,62,77,123].

Mice with targeted disruption of the p38 α MAP kinase gene have been described [4,5,104]. These mice die during mid-gestation because of defects in the formation of the placenta. p38 α MAP kinase-deficient cells derived from these embryos exhibit severe defects in the expression of inflammatory cytokines [5].

p38 γ and p38 δ MAP Kinases

The p38 γ and p38 δ MAP kinases are related enzymes that represent a separate subgroup of p38 MAP kinases [54,95].

Like other members of the p38 family, the p38 γ and p385 MAP kinases contain a Thr-Gly-Tyr dual phosphorylation motif. However, the p38 γ and p385 MAP kinases are not inhibited by drugs that selectively inhibit the p38 α and p38 β MAP kinases [27]. The regulation of the p38 γ and p385 MAP kinases is similar to the p38 α and p38 β MAP kinases, and all four p38 MAP kinases are activated by inflammatory cytokines and exposure to environmental stress. Interestingly, p38 γ MAP kinase interacts with the PDZ domain of *od-syntrophin*, although the functional significance of this interaction is unclear [40]. The physiological role of p38 α MAP kinase is unclear. However, recent studies have demonstrated an important role for p38 δ MAP kinase in the regulation of translation by eEF2 kinase [51].

The JNK Group of MAP Kinases

The JNK group of MAP kinases is activated by many of the same stimuli that cause activation of the p38 MAP kinases, including the exposure of cells to inflammatory cytokines and environmental stress [23]. This similarity in regulation indicates that the JNK and p38 MAP kinases may be functionally related. Indeed, both the JNK and p38 MAP kinases are collectively named stress-activated protein kinases (SAPK). However, the mechanism of JNK activation differs from the p38 MAP kinases. First, the dual phosphorylation motif located in the T loop of JNK is Thr-Pro-Tyr. Second, the signaling module that activates JNK includes the MAP kinase kinases MKK4 and MKK7 [23]. The protein kinase MKK7 is a specific activator of the JNK pathway, while MKK4 can activate both p38 MAP kinase and JNK [23]. Biochemical studies demonstrate that MKK4 and MKK7 can cooperate to activate JNK by selectively phosphorylating JNK on Tyr and Thr, respectively, and gene disruption experiments in mice demonstrate functional cooperation of MKK4 and MKK7 *in vivo* [30,55,111].

The JNK protein kinases are encoded by three genes. Two of the genes (*JNK1* and *JNK2*) are expressed ubiquitously and one gene (*JNK3*) is expressed in a limited number of tissues, including the brain, heart, and testis [23]. Alternative splicing creates ten different JNK protein kinases: four JNK1 isoforms, four JNK2 isoforms, and two JNK3 isoforms [38]. Analysis of JNK3 by x-ray crystallography indicates that this MAP kinase is structurally related to both ERK2 and p38 α MAP kinase [127].

The physiological role of JNK appears to be complex. It is established that JNK is required for the normal regulation of AP-1 transcription activity [23]. This is mediated, in part, by the phosphorylation of the transcription factors ATF2, c-Jun, JunB, and JunD on two sites within the NH₂-terminal activation domain [23]. JNK can also regulate other transcription factors by phosphorylation. Nevertheless, although it is known that JNK causes increased AP-1-dependent gene expression, the physiological consequence of JNK activation appears to be both cell-type and context dependent. JNK can cause apoptosis by a mechanism that involves the

mitochondrial pathway [57,112]. JNK can also signal cell survival [41,84]. The mechanism that accounts for these markedly divergent cellular responses to JNK activation is unclear. However, it is likely that the cellular response to JNK activation reflects the activation state of other signal transduction pathways within the cell. A reasonable hypothesis is that the program of gene expression that is induced by JNK-stimulated AP-1 activity depends on the cooperation of AP-1 with other transcription factors bound to the promoters of relevant genes. Further studies will be required to test this hypothesis.

Gene disruption studies in mice demonstrate that JNK1, JNK2, and JNK3 are not essential for viability [20,25,90,92,129,130]. However, these mice exhibit defects in apoptosis and immune responses. Compound mutations in JNK1 and JNK2 cause early embryonic lethality associated with neural tube defects and markedly increased apoptosis in the developing forebrain [53,91]. Studies of *Jnk1*^{-/-} *Jnk2*^{-/-} CD4 T cells isolated from *Rag1*^{-/-} chimeric mice indicate that JNK is required for effector CD4 T-cell function, but is not required for CD4 T-cell activation [24]. Primary embryo fibroblasts isolated from *Jnk1*^{-/-} *Jnk2*^{-/-} embryos exhibit severe growth defects with premature senescence associated with increased expression of ARF and p53. These JNK-deficient fibroblasts also exhibit marked resistance to stress-induced apoptosis [112]. This resistance to apoptosis was also observed in *Mkk4*^{-/-} *Mkk7*^{-/-} fibroblasts that contain JNK, but lack a mechanism to allow JNK activation [111]. Together, these data indicate that JNK contributes to multiple physiological processes, including differentiation, survival, and apoptosis.

MAP Kinase-Related Protein Kinases

There are three major groups of mammalian MAP kinases (ERK, p38, and JNK). Several additional human protein kinases have been identified that exhibit similarities with these MAP kinases (Table IV). Thus, two protein kinases (MAK and MOK) contain the same dual phosphorylation motif that is found in the ERK group of MAP kinases (Thr-Glu-Tyr). It is established that MOK is regulated by phosphorylation on this motif, but the mechanism that causes this phosphorylation is unclear [73]. Similar studies of MAK have not been reported [66]. The physiological role of MAK is unclear because MAK-deficient mice lack an obvious phenotype [100]. Three protein kinases have been identified (ICK, p42 KKIALRE, p56 KKIAMRE) that contain a related dual phosphorylation motif (Thr-Asp-Tyr). The role of the dual phosphorylation motif in these kinases is unclear. Mutational analysis indicates that the dual phosphorylation motif is required for the regulation of ICK [110], but it is not essential for the regulation of p42 KKIALRE and p56 KKIAMRE [103]. The protein kinase (NLK) contains the divergent motif Thr-His-Glu. Phosphorylation of this motif in response to the MAP kinase kinase kinase TAK1 is required for NLK activation [99]. Further studies are warranted to discover whether these protein kinases (and other related protein kinases) represent additional members of the MAP kinase family.

Table IV Human MAP Kinase-related Protein Kinases

Name	TXY motif	Gene name	Chromosomal location	LocusID
ICK	TDY	<i>ICK</i>	6p12.3-p11.2	22858
p42 KKIALRE	TOY	<i>CDKL1</i>	14q21.3	8814
p56 KKIAMRE	TDY	<i>CDKL2</i>	4q21.1	8999
MAK	TEY	<i>MAK</i>	6q22	4117
MOK	TEY	<i>RAGE</i>	14q32	5891
NLK	THE	<i>NLK</i>	17q11.2	51701

Human protein kinases that are related to MAP kinases are presented with the sequence of the TXY dual phosphorylation motif, the gene name, the chromosomal location, and the LocusID.

MAP Kinase Docking Interactions

Although MAP kinases can phosphorylate Ser-Pro and Thr-Pro sites on substrate proteins, the substrate specificities of individual MAP kinases are distinct. One mechanism that can dictate the substrate specificity of a MAP kinase is the requirement for a docking site on the substrate [29]. The docking site is physically separate from the site of phosphorylation and is required for efficient substrate phosphorylation by MAP kinases. Mutational removal of the docking site prevents substrate phosphorylation by MAP kinases. Examples of docking sites include the δ domain on c-Jun that interacts with JNK [23], the D domain on the Elk-1 transcription factor that binds ERK and JNK [132,133], the D domain on MEF transcription factors that binds p38 α MAP kinase [131], and the FXF motif on the SAP-1 transcription factor that binds ERK and p38 δ MAP kinase [31,45]. The δ and D domains are similar and consist of a Leu-Xaa-Leu motif separated from several basic residues [29]. In contrast, the FXF domain contains the motif Phe-Xaa-Phe-(Pro) [29].

Interestingly, these docking domains are conserved in many proteins that interact with MAP kinases. Thus, the NH₂-terminal region of MAP kinase kinases contains a D domain [7]. Disruption of this MAP kinase docking site on MAP kinase kinases is caused by the anthrax lethal factor protease and prevents MAP kinase activation [26]. Docking sites are also observed in MAP kinase phosphatases and scaffold proteins [29]. It therefore appears that many proteins that interact with MAP kinases contain conserved motifs that mediate this interaction [29]. Mutational analysis indicates that these motifs bind MAP kinases at a common site [106–108]. A recent study has provided structural insight into the mechanism of protein docking to MAP kinases. This study used x-ray crystallographic analysis to determine the structures of the complexes of p38 α MAP kinase with the D domains of MKK3 and MEF2 [14]. This analysis demonstrated that the Leu-Xaa-Leu motif is directly involved in the protein-protein contact and that the basic residues in the D domain may interact with acidic residues in the common docking site [116]. The site of interaction on the surface of p38 α MAP kinase is not located close to the T loop or

the active site. Thus, the active site and the T loop of MAP kinases are available for interaction with docked proteins, including MAP kinase kinases, MAP kinase phosphatases, and substrates.

Scaffold Proteins

The protein kinases that form MAP kinase signaling modules can interact via a series of sequential binary interactions to create a protein kinase cascade. One example is represented by MKK4, which can dock to both an upstream kinase (MEKK1) and to a downstream MAP kinase (JNK) [126]. Alternatively, the protein kinases may simultaneously interact with a common component of the cascade. Thus, MEKK2 can synergistically interact with both MKK4 and JNK [16] and MEKK1 can bind c-Raf-1, MEK1, and ERK2 [46]. MEKK1 can also bind JNK in a phosphorylation-dependent manner [32]. These interactions may lead to the assembly of a functional signalling module [118].

Functional MAP kinase signaling modules can also be created by the interaction of the protein kinases with scaffold molecules that serve to assemble the protein kinases [118]. These putative scaffold proteins include KSR, MP1, the JIP proteins, β -arrestin-2, and SKRP1/MKPX (Table V). In addition, several other molecules have been proposed to function as MAP kinase scaffolds, including Filamin [65], Crk II [34], and IKAP [42].

KSR

Kinase suppressor of Ras (KSR) shares structural similarity with the MAP kinase kinase kinase c-Raf-1 [74,89]. One major difference between KSR and c-Raf-1 is that while KSR does have a protein kinase-like domain, KSR does not function as a protein kinase [70]. KSR binds to c-Raf-1, MEK1/2, and ERK1/2 and appears to function as a scaffold for the activation of the ERK1/2 signaling module that is activated by growth factors [74,89]. Following the activation of growth factor receptors, KSR is recruited to the cell surface by a phosphorylation-dependent mechanism that involves the

Table V Nomenclature of Human MAP Kinase Scaffold Proteins

Name	Alternative name	Gene name	Chromosomal location	LocusID
KSR-1	KSR	<i>KSR</i>	17q11.1	8844
KSR-2			Chromosome 12	125806
MP-1		<i>MAP2K1IP1</i>	4q22.3	8649
JIP-1	IB1	<i>MAPK8IP1</i>	11p12-p11.2	9479
JIP-2	IB2	<i>MAPK8IP2</i>	22q13.33	23542
JIP-3	JSAP1, SYD2	<i>MAPK8IP3</i>	16p13.3	23162
β -Arrestin-2		<i>ARRB2</i>	17p13	409
SKRP1	JKAP	<i>SKRP1</i>	2q32.1	142679
MKPX	VHX, JSP-1	<i>MKPX</i>	6p24.3	56940

Human MAP kinase scaffold proteins are presented with their alternative names, the gene name, the chromosomal localization, and the LocusID.

C-TAK1 protein kinase [75]. Gene disruption studies in mice have examined the requirement of KSR for growth-factor-stimulated ERK1/2 activation. KSR-deficient cells derived from these mice were found to exhibit partial defects in ERK activation [78]. This partial defect may reflect a specialized role for KSR under certain conditions. Alternatively, it is possible that the functions of KSR are redundant with the product of another gene that encodes a KSR-like protein (Table V). Further studies are required to define the role of these KSR proteins. Nevertheless, it is very likely that the mammalian KSR proteins do function as an essential scaffold for ERK1/2 activation because RNAi experiments have demonstrated an important role for KSR in the activation of ERK in *Drosophila* [88].

MP1

The MP1 scaffold protein binds to MEK1 and ERK1 [94]. Transfection assays demonstrate that MP1 potentiates the activation of ERK1 caused by MEK1 [94]. Recent studies demonstrate that MP1 also binds to the late endosomal protein p14 [124]. MP1 therefore localizes a MEK1/ERK1 signaling module on the cytoplasmic surface of late endosomes. It is possible that MP1 contributes to ERK activation following ligand-induced endocytosis of growth factor receptors. This role of MP1 on late endosomes serves to distinguish MP1 from the KSR scaffold proteins that appear to function at the cell surface. The possible functional interaction between the MP1 and KSR scaffold proteins warrants further study. In addition, gene disruption studies are required to establish the physiological function of MP1 in ERK activation *in vivo*.

JIP

Three genes encode the JIP group of scaffold proteins [23]. The JIP1 and JIP2 proteins are structurally similar and contain an SH3 domain and a PTB domain in the COOH-terminal region [9,76,117,134]. The PTB domain can interact

with p190 RhoGEF and with members of the low density lipoprotein receptor family, including ApoER2 [37,69,101]. In addition, JIP2 has been reported to bind the Rac exchange factor Tiam1, Ras-GRF, and members of the fibroblast growth factor homologous protein family [12,96,97]. The JIP3 protein is structurally distinct and consists of an extended coiled-coil domain [44,49]. All of these JIP proteins share several common properties. Each JIP isoform binds to JNK, MKK7, and members of the mixed-lineage group of MAP kinase kinase kinases. An interaction of JIP3 with MEKK1 and MKK4 has also been described [44]. Transfection studies demonstrate that the JIP proteins potentiate the activation of JNK [44,49,117,134]. Some studies have demonstrated that JIP2 can also activate p38 MAP kinases under some circumstances [96,97].

The JIP1, JIP2, and JIP3 proteins bind to kinesin light chain and are transported by the microtubule motor protein kinesin [11,113,120]. This interaction with motor proteins accounts for the accumulation of the JIP proteins in the growth cones of developing neurons. In mature neurons, the JIP1 and JIP2 proteins accumulate at synapses and JIP3 is mostly localized to perinuclear vesicular structures. The JIP proteins may act as adapter molecules for the transport of cargo by the kinesin motor protein. In addition, the JIP proteins may act to locally regulate JNK activation in response to specific stimuli.

Two groups have reported the phenotype of mice with targeted disruption of the *Jip1* gene. One group reported that the JIP1-deficiency causes very early embryonic lethality prior to implantation [109]. In contrast, a second group reported that JIP1-deficient mice are viable [120]. It is possible that the difference in viability reflects an effect of the mouse strain background. The viable JIP1-deficient mice were found to exhibit defects in stress-induced JNK activation in hippocampal neurons following exposure to stress. Studies of JIP2- and JIP3-deficient mice will be required to identify the redundant and nonredundant functions of these JIP scaffold proteins.

β-Arrestin

Ligand-induced activation of seven transmembrane-spanning receptors causes receptor phosphorylation, recruitment of arrestin molecules, and subsequent downregulation of heterotrimeric G protein signaling [71]. The arrestin molecules can also serve as a platform for the recruitment of additional molecules to the receptor [71]. Evidence has been presented that indicates that the ubiquitously expressed isoform β-arrestin-1 may serve as a scaffold for components of the ERK pathway [61]. More detailed studies have been performed on β-arrestin-2. This scaffold protein contains a D domain that selectively binds to JNK3 [68,72]. Interestingly, both β-arrestin-2 and JNK3 are selectively expressed in the brain and the heart. The β-arrestin-2 scaffold also binds the MAP kinase kinase kinase ASK1 [68]. The signaling module assembled by β-arrestin-2 also contains MKK4, which interacts with both JNK3 and ASK1, but does not directly contact β-arrestin-2 [68]. Biochemical assays demonstrate that β-arrestin-2 is essential for the activation of JNK3 caused by the angiotensin II receptor [68]. Interestingly, the activated receptor bound to the β-arrestin-2 scaffold complex is localized to endosomal structures. The β-arrestin-2 scaffold provides a mechanism for the activation of JNK by seven transmembrane-spanning receptors. In addition, the signaling module assembled by β-arrestin-2 provides a mechanism for the selective activation of the JNK3 isoform of JNK. Studies of β-arrestin-2-deficient mice have been reported [8]. Further studies of these mice to investigate defects in the activation of JNK3 are warranted.

SKRP1/MKPX

SKRP1 and MKPX are two related small phosphatases that belong to the MAP kinase phosphatase (MKP) family. Like other MKPs, these phosphatases can inactivate MAP kinases [6,135]. However, it appears that the normal function of these phosphatases is to activate JNK [15,98,136]. Interestingly, the phosphatase catalytic activity is required for these MKPs to activate JNK, but the physiologically relevant substrates have not been identified. It appears that these phosphatases interact with MKK7 [15,136] and may also interact with ASK1 [136]. Gene disruption studies in mice demonstrated that SKRP1 is not an essential gene, but SKRP1 is required for JNK activation caused by tumor necrosis factor-α and transforming growth factor-β, but not for JNK activation caused by ultraviolet radiation [15]. Together, these data suggest that these MKPs may act as scaffold proteins for the JNK signaling pathway.

Subcellular Targeting of PKA Through AKAPs: Conserved Anchoring and Unique Targeting Domains

Mark L. Dell'Acqua

*Department of Pharmacology,
University of Colorado Health Sciences Center,
Denver, Colorado*

Introduction

Regulation of the opposing actions of adenylyl cyclases (AC) and phosphodiesterases (PDE) that control levels of the diffusible intracellular second messenger cAMP is central to many signaling responses. The major effector of cAMP in eukaryotic cells is the cAMP-dependent protein kinase (PKA). PKA is a heterotetrameric enzyme consisting of two regulatory subunits (R) that dimerize and each bind and inhibit a single catalytic subunit (C) to form an R₂C₂ holoenzyme (Fig. 1A) [1]. Activation of the inactive PKA holoenzyme by cAMP occurs when two molecules of cAMP bind to each R subunit, resulting in a conformational change that releases the active C-subunits from the inhibitory R₂ dimer (Fig. 1A). The released active C-subunits phosphorylate serine and threonine residues commonly found in sequence contexts of RRXS/T or KRXXS/T to regulate target protein function. The catalytic subunit (C) of PKA can phosphorylate target proteins rapidly near the site of release and in time diffuse to more distant location such as the nucleus, where additional targets are phosphorylated [2]. It is remarkable that this ubiquitous signaling pathway is used in different cell types to transduce signals to myriad different yet very specific

target proteins in a variety of cellular compartments. Thus, elucidating how this PKA signaling versatility is achieved without compromising specificity is fundamental to understanding cAMP signal transduction pathways.

Over the last decade we have learned that both diversity and specificity in cAMP signaling is in large part achieved by targeting the PKA holoenzyme to discrete subcellular locations such that, upon release of the C subunit, phosphorylation of co-localized target substrates is greatly enhanced (Fig. 1B) [2]. This subcellular targeting of PKA is mediated by a class of anchoring-scaffolding proteins called AKAPs (A-kinase anchoring proteins) [3–5]. AKAPs anchor PKA by binding the R-subunit dimer through a structurally conserved anchoring domain and then target the holoenzyme to specific locations within the cell through unique targeting domains (Fig. 1B). AKAPs frequently contain additional protein-protein interaction motifs that serve as tethering sites for the target substrates, as well as additional signaling proteins such as other kinases, phosphatases, scaffold, and adapter proteins. Thus, many AKAPs function as signal-integrating scaffolds that coordinate both subcellular localization and complex assembly of multiprotein signal transduction machines. This chapter will focus on the structurally conserved R-subunit

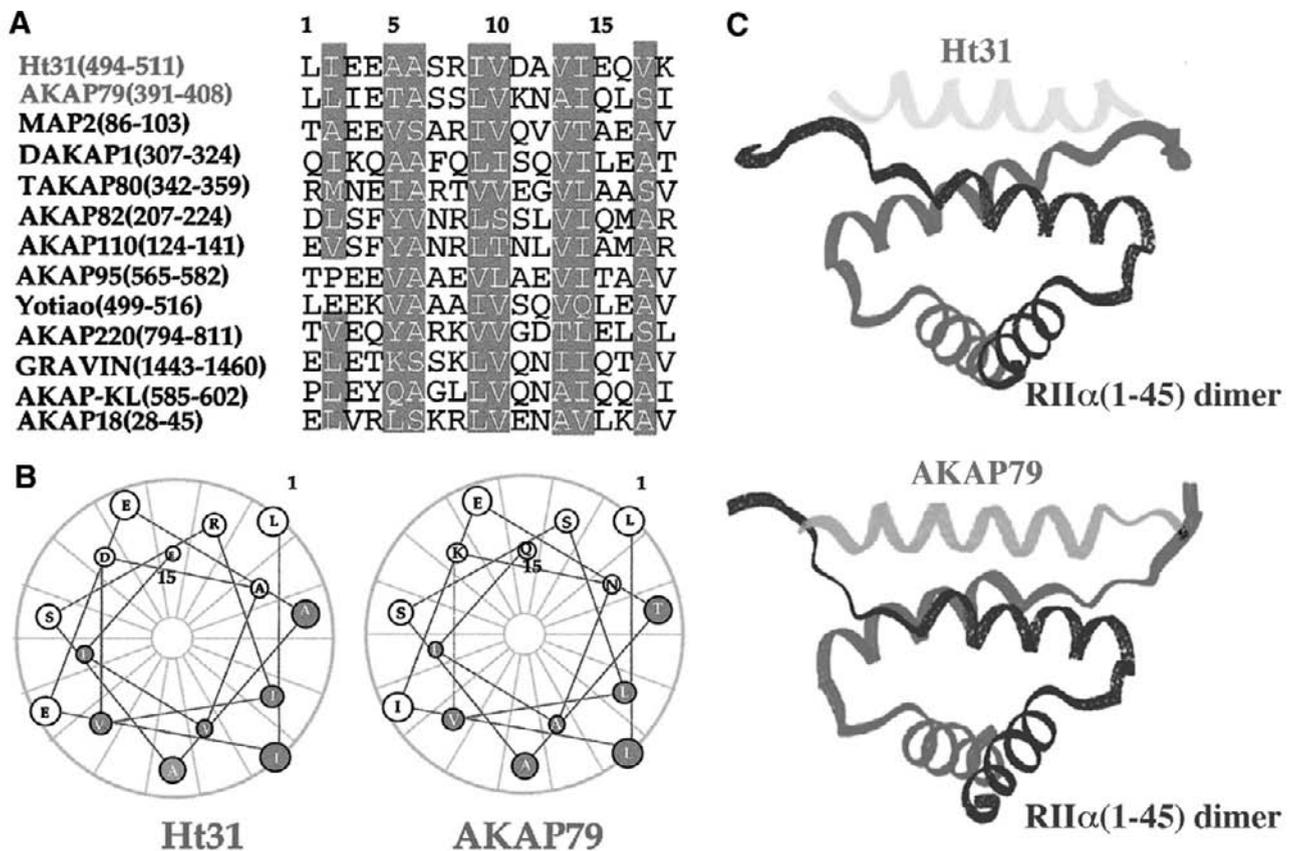

Figure 2 Structurally conserved AKAP-PKA anchoring domains. (A) Divergent primary structures for PKA-anchoring in AKAP family members. Hydrophobic residues are blocked. (B) Conserved amphipathic alpha-helical secondary structures for AKAP PKA-anchoring domains. Hydrophobic residues are shaded on helical wheel diagrams. (C) Conserved mechanisms of PKA anchoring revealed by NMR solution structures of AKAP-RII complexes. The structures show AKAP anchoring domain peptides from Ht31(493-515) and AKAP79 (392-413) in green bound to an RII α (1-45) N-terminal domain dimer. This figure was adapted from Newlon *et al.* (2002) *EMBO J.* **20**, 1651–1662 (18) with permission from P. A. Jennings and Oxford University Press.

binding of isolated AKAP-anchoring domain peptides has allowed them to be used as competitive inhibitors of PKA-anchoring in cells to probe numerous cellular functions of AKAP-PKA complexes in cAMP signaling (discussed more below).

Unique Subcellular Targeting Domains

The variety and specificity that is made possible by AKAP-PKA anchoring is in large part a function of unique targeting domains in different AKAP molecules (Fig. 1B). AKAP molecules have been identified at many distinct subcellular locations (Fig. 3A,B), including the plasma membrane, intracellular vesicles [23,24], actin and microtubule cytoskeletons, mitochondria, endoplasmic reticulum (ER), Golgi, and centrosomes [25,26]. For example, MAP2 is targeted to dendritic microtubules in neurons by direct binding to tubulin [27–29]. Scar/Wave1, an AKAP that also anchors the abl-Tyrosine kinase, binds to actin both in focal adhesions (Fig. 3B) and membrane ruffles in fibroblasts, where it regulates the actin polymerization activity of the Arp2/3 complex (see next chapter) [30]. The skeletal and cardiac

muscle-enriched mAKAP protein, which also anchors PDE4D3 (see next chapter) [11], is targeted by a series of spectrin repeats to perinuclear ER/SR membranes, including most prominently the nuclear membrane (Fig. 3B) [31,32]. D-AKAP1/sAKAP84 can be targeted either to the ER (in the liver) or mitochondria (in most other cells) by two different N-terminal targeting sequences produced by alternate mRNA splicing [33–35]. One AKAP, AKAP95, has even been shown to associated with the nuclear matrix and chromatin, even though PKA holoenzyme/R-subunits are excluded from the nucleus during interphase (Fig. 3A) [36,37]. However, interactions of AKAP95 with PKA and chromatin could have important functions in regulating chromosome condensation during mitosis when the nuclear envelope is absent [38,39].

In certain cell types precise localization to discrete plasma membrane domains is seen, such as localization to apical or basolateral membrane domains in polarized epithelial cells and synaptic membrane specializations in neurons. AKAP75/79/150, an AKAP scaffold protein that also binds protein kinase C and calcineurin-protein phosphatase 2B(CaN-PP2B) (see next chapter), is targeted to the plasma membrane/cortical cytoskeleton (Fig. 3A) by three N-terminal

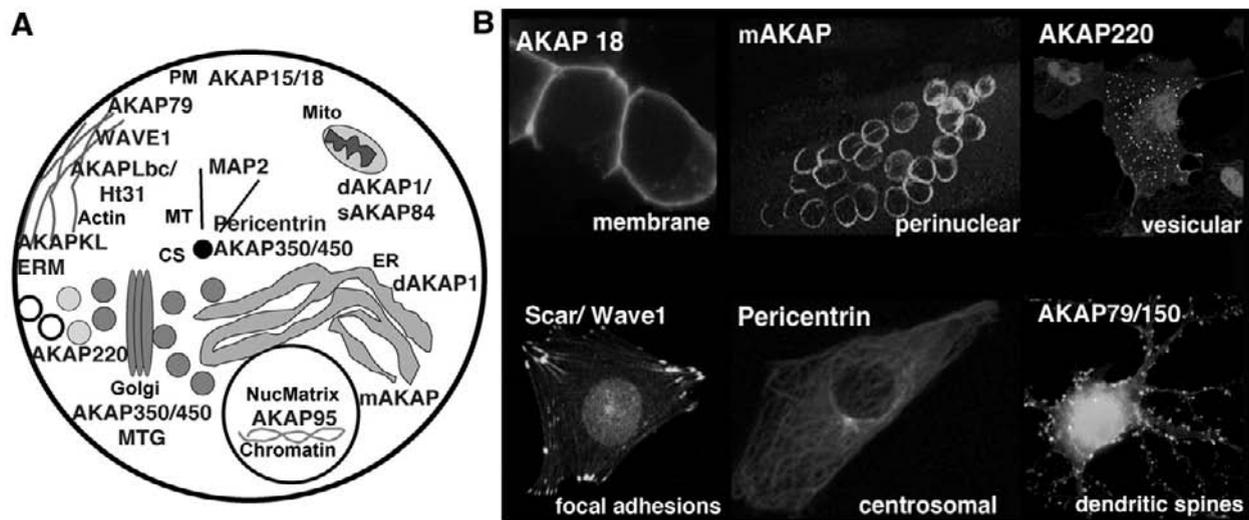

Figure 3 Unique AKAP targeting domains and subcellular localizations. (A) Subcellular compartmentalization of different AKAP family members. polybasic domains that bind to acidic phospholipids, including phosphatidylinositol-4,5-bisphosphate, as well as F-actin [40–42]. This same N-terminal basic domain mediates targeting to excitatory postsynaptic membrane specializations located on actin-rich dendritic spines in neurons (Fig. 3B) [42]. The low-molecular-weight AKAP15/18 α is targeted to the plasma membrane in HEK-293 cells by N-terminal lipid modifications of myristoylation of Gly-1 and dual palmitoylation of Cys-4, Cys-5 (Fig. 3B) [43]. In MDCK epithelial cells this AKAP15/18 α isoform selectively targets to the basolateral membrane. However, an alternate splice variant, AKAP15/18 β , which contains an additional exon coding for a 24 amino acid insert, localizes to the apical membrane [44]. It is interesting that two additional AKAP families, the AKAP-KL and ERM proteins (Ezrin/Radixin/Moesin), are also specifically targeted to apical membranes, where they bind to cortical actin (Fig. 3A) [45,46].

Probing Cellular Functions of AKAP-PKA Anchoring

The importance of compartmentalized pools of PKA has been implicated in numerous cellular responses, including transcription [47,48], secretion [43,49,50], and cell cycle-regulation [39,51,52]. However, functional roles for AKAP-PKA targeting have been studied in the greatest detail for cAMP regulation of membrane ion channels [53,54]. These studies of ion channel regulation have either used anchoring inhibitor peptides such as Ht31(493-515) to displace PKA from endogenous AKAPs or heterologous co-expression of an AKAP with the ion channel of interest. Some of the best examples of both of these approaches come from studies of PKA-regulation of neuronal ionotropic glutamate receptors

and skeletal and cardiac muscle L-type calcium channels. In each case, use of anchoring inhibitor peptides to disrupt PKA-R-subunit anchoring was first shown to block cAMP regulation of endogenous plasma membrane channel activity similar to inhibition of PKA-C subunit catalytic activity [55–58]. Thus, these studies suggested that endogenous AKAPs were important for targeting PKA to the plasma membrane in close proximity to the regulated channels. Subsequent studies confirmed these results by showing that co-expression of these channels with an appropriate membrane-targeted AKAP partner, such as AKAP15/18 α or AKAP79, could reconstitute cAMP-PKA regulation of channel activity in heterologous HEK-293 cell expression systems [57,59,60]. In contrast, heterologous expression of the channels by themselves was characterized by a complete lack of PKA regulation or abnormal PKA regulation relative to that seen for endogenous channels. Very recently it has been appreciated that AKAPs and their anchored pools of PKA can be even more directly targeted to membrane ion channel substrates through protein-protein interactions (see next chapter; Fig. 1B). In heterologous systems, AKAP79 and AKAP15/18 α were shown to be able to substitute for each other in some aspects of PKA channel regulation [43,57,60]; however, more recent biochemical and electrophysiological studies clearly indicate that these AKAPs serve more specific functions *in vivo* as well as in heterologous systems. In particular, AKAP15/18 α is very likely to serve specifically in PKA regulation of skeletal and cardiac L-type channels through forming a complex with channel proteins [61]. In contrast, AKAP79 seems to be adapted for PKA and CaN-PP2B regulation of postsynaptic AMPA-subtype ionotropic glutamate receptors linked through additional protein-protein interactions with PSD-95 family MAGUK scaffold proteins (see next chapter) [60,62].

Conclusions and Future Directions

In summary, subcellular targeting of PKA by AKAPs appears to be a very efficient mechanism for adapting the versatile cAMP signal transduction pathway for highly selective local regulatory phosphorylation events. The key factors in maintaining both the diversity and specificity of this system are the unique subcellular targeting domains present in different AKAP family members. Thus, it is these targeting interactions that might serve in the future as targets for the development of novel therapeutics. The attractiveness of this approach is already supported by studies described in the next chapter that show that selective disruption of interactions between AKAPs and ion channel substrates has the same functional effect as disrupting PKA anchoring to the AKAPs with the nonselective anchoring inhibitor peptides [61]. Furthermore, recent studies of AKAP79/150 targeting to excitatory synapses suggest that regulation of AKAP-targeting domains by cell signaling pathways may serve as important endogenous mechanisms that control PKA signaling [42]. Thus, further dissection of the mechanisms of AKAP targeting, as well as the substrate binding and scaffolding interactions discussed in the following chapter, will continue to be active and important areas of AKAP research in the next few years.

Understanding the molecular organization of intracellular signaling pathways is a topic of considerable research interest. Multiprotein signaling complexes create focal points of enzyme activity to disseminate the intracellular action of many hormones and neurotransmitters. The spatio-temporal activation of protein kinases and/or phosphatases is important in controlling where and when phosphorylation events occur. Anchoring proteins and targeting subunits provide a molecular framework that orients protein kinases and phosphatases toward selected substrates. Prototypic examples of these “signal-directing molecules” are A-kinase anchoring proteins (AKAPs) that sustain multicomponent signaling complexes of the cAMP dependent protein kinase (PKA) and G proteins and other enzymes. These protein-protein interactions not only focus PKA toward certain substrates but also spatially segregate parallel signaling pathways.

Introduction

The efficient transmission of cellular signals often involves the positioning of signaling proteins in proximity to their upstream activators and downstream targets. In fact, the clustering of receptors, G proteins, and enzymes with their substrates is believed to contribute significantly to the specificity

of signaling. This sophisticated degree of organization may also help prevent the indiscriminate activation of related signaling complexes that are close by. This is of particular importance for second messenger dependent signaling pathways that lead to the activation of broad specificity enzymes such as the cAMP dependent protein kinase (PKA), protein kinase C (PKC), and a variety of calmodulin dependent kinases (CaM kinases). Compartmentalization of these enzymes is often achieved through their association with scaffolding proteins that simultaneously coordinate the location of several enzymes [1–4].

A-kinase anchoring proteins (AKAPs) are a growing family of scaffolding proteins that package PKA and other signaling enzymes into multiprotein complexes [5,6]. As discussed in the previous chapter, each AKAP contains both a conserved amphipathic helix that binds to the R subunit dimer with high affinity and a targeting domain that directs the PKA-AKAP complex to specific subcellular compartments [7,8]. Another important role for AKAPs is to place PKA in the proximity of enzymes such as phosphatases and phosphodiesterases that terminate cAMP signaling events [9–11]. The focus of this chapter is to highlight advances in our understanding of AKAP signaling complexes and their role in facilitating this bi-directional control of various signaling events.

G-Protein Signaling Through AKAP Signaling Complexes

A shared property of several AKAPs is to position enzymes in microenvironments where they can respond to upstream signals. Clearly, there are potential advantages of anchoring PKA in close proximity to primary transduction elements such as G-protein coupled receptors and the cAMP synthesis machinery. In fact, two anchoring proteins, gravin/AKAP250 and AKAP79/150, maintain kinase complexes that bind to the β 2-adrenergic (β 2-AR) receptor [12,13]. The AKAP79 complex binds to regions within the third cytoplasmic loop and C-terminal tail of the β 2-AR in an agonist-independent manner, whereas gravin/AKAP250 recruits PKA and PKC to the receptor in an agonist-dependent manner [13–15] (Fig. 1). These receptor based AKAP complexes also contribute to β 2-AR phosphorylation, desensitization, and indirect activation of MAP kinase pathways that emanate from the receptor [16]. Furthermore, dephosphorylation of β 2-AR and the receptor kinase GRK2 are likely to be important signal termination events in this process and could be mediated by an anchored pool of PP-2B that associates with AKAP79. Another anchoring protein MAP2 seems to nucleate a membrane associated signaling complex that includes β 2-AR, adenylyl cyclase, PKA, PP-2B, and a substrate for the kinase of the class C L-type Ca^{2+} channel [17,18]. The identification of such a signaling complex emphasizes the notion that receptors, effectors, kinases, and their substrates are spatially coordinated. However, it also confirms the view put forward by a number of investigators that in some cases

cAMP may not have to diffuse very far from its site of synthesis to activate the PKA holoenzyme.

Other classes of G proteins have been implicated in the channeling of signals through AKAP complexes, although not necessarily via cAMP dependant mechanisms [4]. Scar/WAVE-1 is a member of the Wiskott-Aldrich syndrome family of scaffolding proteins that binds PKA, the Abl tyrosine kinase, and the Arp2/3 complex, a group of seven proteins that control actin remodeling [19–21] (Fig. 1). The dynamic assembly of this complex at sites of lamellapodial extension occurs in response to growth factor signals that activate the low-molecular-weight GTPase Rac [19]. Consequently, Scar/WAVE may direct PKA and Abl toward cytoskeletal substrates and synchronize cell movement by ensuring efficient transmission of Rac-mediated signals to the actin remodeling machinery. Analogous AKAP signaling networks participate in the formation of actin stress fibers. AKAP-Lbc, a splice variant of the Lbc oncogene, encodes a chimeric molecule that anchors PKA and functions as a Rho-selective guanine nucleotide exchange factor [22]. Application of lysophosphatidic acid or selective expression of $\text{G}\alpha_{12}$ enhances cellular AKAP-Lbc activation and leads to the formation of actin stress fibers in fibroblasts [22]. This provides an example where the spatial organization of heterotrimeric and small molecular weight G proteins may involve interactions with the same AKAP. Finally, certain unconventional modes of signaling to PKA may also be governed by G-protein recruitment to AKAP-signaling complexes. For example, the testis specific anchoring protein, AKAP110, has been reported to interact with the heterotrimeric

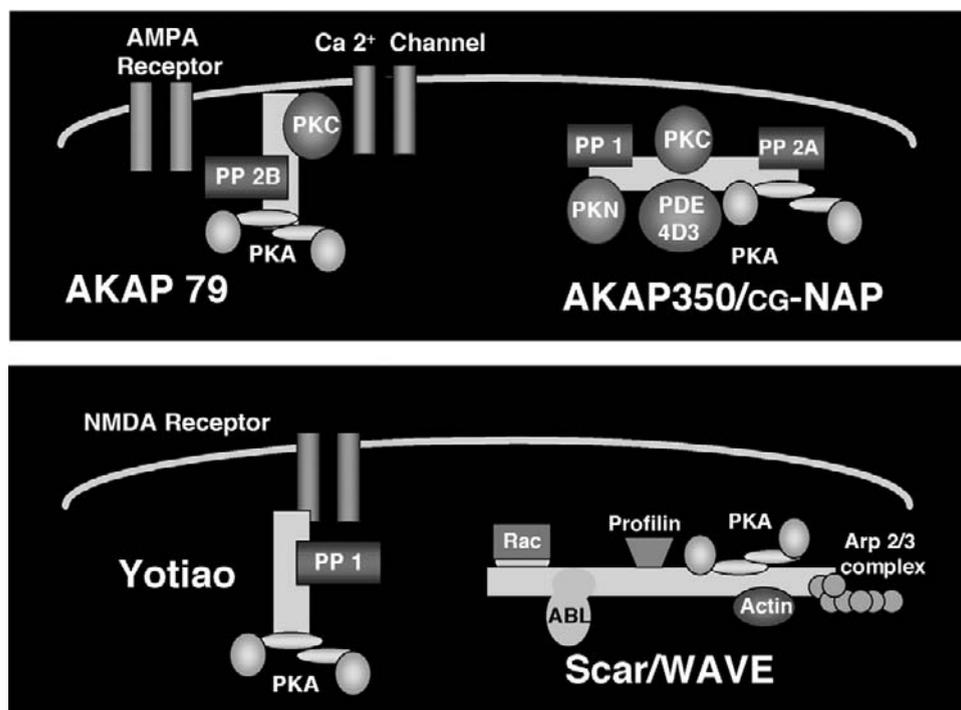

Figure 1 AKAP signaling complexes. A schematic representation of certain AKAP signaling complexes discussed in this chapter. Each interacting protein is labeled.

G-protein subunit $G\alpha_{13}$ that activates AKAP110-associated PKA via a cAMP-independent mechanism [23]. Each of these examples underscores the notion that AKAP-signaling complexes can respond to G-protein signaling events in a variety of pathways.

Kinase/Phosphatase Signaling Complexes

Several AKAP signaling complexes include both signal transduction and signal termination enzymes. This generates a locus to regulate the forward and backward steps of a given signaling process. One example of this, mentioned in other chapters, is the clustering of second messenger regulated kinases and phosphatases at the excitatory synapses of neurons by the AKAP79/150 family of anchoring proteins [24].

The human form AKAP79 and its bovine and murine counterparts AKAP75 and AKAP150, respectively, are enriched in the synaptosomal and postsynaptic density fractions of neuronal lysates and are present in dendritic spines [25,26]. In 1995 the A subunit of the calcium/calmodulin dependent phosphatase PP2B was identified in a two-hybrid screen with AKAP79 as bait [27]. Subsequent biochemical and cellular analyses defined the phosphatase-binding site and demonstrated that both enzymes simultaneously associate with AKAP79/150 in neurons [28]. A year later it was demonstrated that PKC is also a component of the AKAP79 signaling complex [29]. At that time it was postulated that the simultaneous anchoring of these three signaling enzymes generated a locus for the integration of distinct second messenger signals at the postsynaptic membranes [30]. Functional studies have largely confirmed this notion by showing that the AKAP79/150-signaling complex controls the phosphorylation status and facilitates the regulation of a variety of ion channels, including L-type calcium channels, KCNQ potassium channels, aquaporin water channels, and AMPA type glutamate receptor ion channels [30–33] (Fig. 1).

The most detailed studies have dissected the phosphorylation events that occur on the cytoplasmic tail of AMPA type glutamate receptors. This channel is present at the terminals of excitatory synapses and is gated by the release of glutamate across the synaptic cleft [34,35]. A series of reports have shown that the AKAP79 signaling complex is recruited into a larger transduction unit with the GluR1 subunit of the AMPA type glutamate receptor (reviewed by Dodge and Scott [24]). Simultaneous association with the membrane-associated guanylate kinase bridging protein SAP97 brings the channel and the signaling complex together [36]. Functional studies indicate that AKAP79-bound PKA enhances GluR1 phosphorylation on serine 845 in the cytoplasmic tail of the channel subunit, an important site for the regulation of channel function during the induction of long-term synaptic depression (LTD) [37–39]. These findings extend an earlier report showing that perfusion of anchoring inhibitor peptides into cultured hippocampal neurons antagonizes PKA anchoring and causes rundown of synaptic AMPA-type glutamate receptor activity [40]. Since this phenomenon occurs with a time-course

that is similar to the inhibition of the kinase, it was initially assumed that disruption of PKA anchoring displaced the kinase from the proximity of the AMPA receptor. However, more recent studies indicate that the phosphatase PP2B may play a prominent role in the downregulation of channel activity. Electrophysiological recordings suggest the proximity of the AKAP79-bound phosphatase to sites of calcium entry ensures that the enzyme is rapidly activated upon synaptic elevation of intracellular calcium and is responsible for the dephosphorylation of serine 845. It is interesting that serine 845 is phosphorylated by PKA upon elevation of synaptic cAMP levels [41,42]. Thus AKAP79/150 maintains a kinases and a phosphatase in close proximity to the channel in a manner that allows second messenger dependant changes in the phosphorylation status and activity of GluR1 (Fig. 1).

Other synaptic AKAPs also maintain kinase/phosphatase complexes. For example, yotiao interacts with the NR1a subunit of synaptic NMDA glutamate receptor ion channels and anchors PKA and protein phosphatase 1 (PP-1) [10,43–46]. The modulation of NMDA receptors containing NR1a requires interactions with the scaffolding protein as peptide-mediated displacement of either PKA or PP-1 causes changes in the modulation of channel activity [10]. Thus yotiao maintains a signaling complex that is directly attached to the substrate, the NMDA receptor (Fig. 1). Although this example certainly highlights the role of AKAPs to ensure the rapid preferential phosphorylation of substrates, the compartmentalization of enzymes in the yotiao complex may also contribute to the segregation of signals at excitatory synapses, where the GluR1/AKAP79 complex is also in the immediate vicinity.

Two AKAP additional signaling complexes are found at the centrosome. AKAP350/CG-NAP, a large centrosomal AKAP of unknown function, has been reported to bind three kinases (PKA, PKC, and PKN) and two phosphatases (PP-1 and PP2A; Fig. 1) [20,47–49]. Likewise, pericentrin, an integral component of the centrosomal machinery, anchors PKA and other enzymes, presumably for a role in the coordination of centrosomal phosphorylation events. An interesting finding is that both AKAP350, CG-NAP and pericentrin contain a c-terminal PACT domain that is responsible for targeting each anchoring protein to the centrosome. Expression of this 100 amino acid region alone is sufficient to promote centrosomal targeting of GFP [50]. This raises the intriguing possibility that the PACT domains of these anchoring proteins might interact with the same structure in the centrosome in a mutually exclusive manner. This could represent one mechanism to generate greater diversity, as distinct signaling complexes could be tethered to the same cellular locus. Thus, the possibilities for coordinated phosphorylation and dephosphorylation events mediated by association with AKAPs are increased.

cAMP Signaling Units

Another way to exert tight control of PKA phosphorylation events is to compartmentalize the kinase with enzymes that

control the intracellular concentrations of its activator, cAMP. In fact, two recent reports have demonstrated that phosphodiesterases, the enzymes that catalyze cAMP degradation, are components of AKAP/PKA signaling complexes [51,52]. These findings add to the complexity of cAMP signaling as they point toward a role for anchored pools of phosphodiesterase in the tight control of local second messenger concentrations. This in turn controls where and when PKA becomes active. For example, a muscle-selective anchoring protein mAKAP directly binds PKA and a splice variant of the cAMP-specific, type 4 phosphodiesterase PDE4D3 and targets them to the perinuclear membranes of cardiomyocytes [51]. Yet in Sertoli cells the PDE4D3 interacts with AKAP350/CG-NAP, one of the large centrosomal AKAPs discussed above (Fig. 1) [52].

Two important regulatory factors that are built into these cAMP-signaling modules favor the signal termination process. First, the tethered PDE is constitutively active and will rapidly restore basal cAMP levels when the flow of second messenger is turned off from its site of synthesis at the plasma membrane. Second, elegant experiments have demonstrated that PKA phosphorylation of PDE4D3 on serine 54 increases the V_{max} of the enzyme two- to three-fold over basal conditions [53–57]. Phosphorylation of PDE4D3 increases cAMP degradation to favor reformation of the PKA holoenzyme. PKA anchoring is a unique and critical element in this PKA-PDE4D3 feedback loop, as displacement of the kinase with the anchoring inhibitor peptide Ht31 prevents cAMP-dependent stimulation of the mAKAP associated PDE4D activity [51]. This finding emphasizes the importance of PDE localization to maintain the balance of intracellular cAMP levels. This notion is also supported by recent imaging studies using intermolecular FRET that have shown that micro-gradients of cAMP emanate from sites of synthesis at the plasma membrane. Hormonal stimulation of cardiomyocytes induced changes in the rate and magnitude of local cAMP gradients with the concomitant effect on the activation of anchored PKA pools [58]. Thus multiple regulatory processes are involved in controlling where and when cellular PKA activation occurs.

Although PDE4D3 is a substrate for the kinase, it is clear that there are other PKA substrates associated with the mAKAP scaffold. For example, the regulation of ryanodine receptor (RyR) phosphorylation is important for maintaining contractility in response to β -adrenergic signaling and increases in intracellular Ca^{2+} concentration in the heart. Hyperphosphorylation of sarcoplasmic reticulum RyR leads to increased Ca^{2+} sensitivity of the channel and decreased sensitivity to β -adrenergic stimulation [59–61]. These changes are manifest in human heart tissue undergoing heart failure where changes in RyR phosphorylation are also detected [59]. Atypical regulation of RyR function may be due to several factors that regulate cAMP/PKA signaling in heart, including loss of phosphatase activity from the RyR complex [59] and defects in regulation of cAMP levels by PDE activity associated with the complex [51]. It is interesting that two groups have detected PP1 and PP2A

phosphatase subunits in the mAKAP signaling complex. Given the myriad binding partners for mAKAP, it is plausible to suggest that the composition of this signaling network may be altered in response to different intracellular stimuli and in disease states.

Conclusions and Perspectives

AKAPs provide the platforms for the assembly of multiprotein signaling complexes in a variety of cellular compartments. Two factors contribute to the diversity of these signaling units. First, individual AKAP complexes may control distinct signaling events within the same subcellular compartment. This may be best exemplified by WAVE-1 and AKAP-Lbc that nucleate the formation intracellular signaling cascades to catalyze distinct forms of cytoskeletal reorganization. In both cases receptor occupancy at the plasma membrane triggers the assembly of signaling complexes that transmit distinct signals to the actin cytoskeleton [19,22]. Likewise, AKAP350 and pericentrin may synchronize different phosphorylation events at the centrosome, and three anchoring proteins, D-AKAP-1/sAKAP82, D-AKAP-2, and Rab32, are involved in mitochondrial signaling processes [62–64]. Second, the recruitment and release of individual enzymes from the signaling complex provides a dynamic component to the composition of a given protein network. For example, Ca^{2+} /calmodulin antagonizes PKC anchoring by competing for binding to AKAP79. The calcium influx from ion channels within the synaptic membrane releases PKC from its anchor, changing the activity status of this kinase. Presumably the soluble enzyme is more available to propagate calcium/phospholipid signaling events, as it has a less restricted access to its substrates. An additional level of complexity may be present, as biochemical and proteomic experiments have detected each PKC isoform in AKAP79/150 complexes isolated from rat brain [65,66]. This implies that at these synapses a variety of AKAP79/150 signaling complexes exist that contain conventional, novel, or atypical PKC isozymes. Again this adds to the diversity of AKAP signaling, as each PKC class responds to different combinations of phospholipid activator. These examples not only highlight the sophisticated degree of spatial organization achieved by anchoring proteins but also emphasize the degree of specificity that can be generated through the combinatorial assembly of unique AKAP signaling complexes.

Introduction

Protein kinase C (PKC) was initially identified in screens for broad specificity kinases that could, like protein kinase A (PKA), respond to second messengers and so integrate agonist-induced responses (see [1]). There is no doubt that the PKC family, comprising the classical (α, β, γ), novel ($\delta, \epsilon, \eta, \theta$), and atypical ($\zeta, \iota/\lambda$) isoforms, fulfil both elements of this definition, that is, they are responsive to second messengers and they are of broad specificity (at least *in vitro*). This latter property has triggered the question of how specificity is imposed on this rather promiscuous group of proteins. In part such considerations have led to the identification of binding partners and substrates that provide specificity to the system. However, this is not all that is achieved by such PKC-binding partners; interactions are seen to operate at a number of levels that can be related to the “life cycle” of the kinase. These can be summarized as follows (see Fig. 1):

PKC priming
PKC activation
PKC substrate engagement
PKC inactivation

Although a number of reviews on this subject have described classes of binding proteins or specific examples (see [2] and references therein), here we discuss examples of PKC-binding proteins with reference to the above properties conferred on PKC proteins.

Priming

Although considered to be under acute allosteric control by diacylglycerol (DAG) and possibly other bioactive lipids [3], PKC proteins all appear to require multisite phosphorylation for their optimum function (see [4]). In some respects this can be viewed as a priming device for subsequent DAG-dependent (or other) activation.

The dephosphorylated form of PKC α is intrinsically insoluble [5], and it is likely that the unphosphorylated primary translation product is associated with an as yet unidentified chaperone. This is suggested by the observation that the newly synthesized protein is soluble, unlike its phosphorylated and then dephosphorylated counterpart [5]. There is to date no evidence that PKC α is a client protein for known chaperones such as Hsp90, and the identity of its “chaperone” remains to be determined. However, for PKC ϵ , which undergoes a similar array of phosphorylation events, the anchoring protein CG-NAP (centrosome and Golgi localized PKN-associated protein) binds the hypophosphorylated form of the protein. It has been proposed that CG-NAP acts as a scaffold to promote phosphorylation of PKC ϵ [6], taking the chaperone role for this member of the family.

The subsequent steps in this priming process are the phosphorylations themselves. There is general agreement that a key step in this process involves the action of the upstream kinase PDK1 ([7,8] and see Newton, this volume). This PtdIns3,4,5P₃-activated kinase can bind directly to all

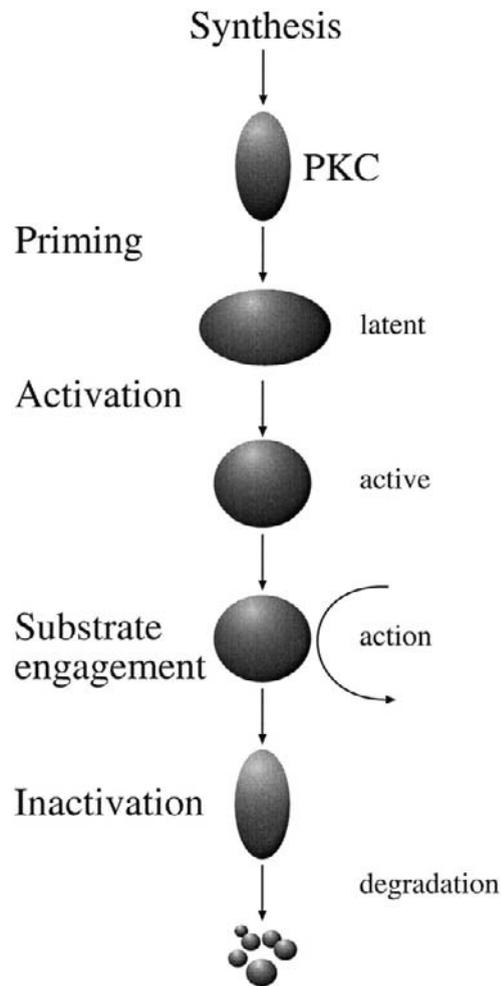

Figure 1 The life and death of PKC. Various states along the pathway of PKC synthesis, modification, activation, and proteolysis are indicated. The generic events associated with the different phases of existence are denoted on the left and referred to in the text in respect of PKC-binding proteins. These events take place in distinct compartments in part defined by binding partners (see text).

members of the PKC superfamily (α , β , γ , δ , ϵ , ζ , η , θ , ι / λ) [7]. PDK1-PKC interaction appears to be mediated through the PKC kinase domain [7], and based upon the PRK2-PDK1 interaction studies it would appear to involve the conserved phosphorylated C-terminal hydrophobic motif FXXF{S(P),T(P),E}F/Y [9]. Thus PDK1 can engage these PKC substrates at a site distal to its target site of phosphorylation, which resides in the activation loop of the kinases at the conserved TFCGTP motif. It is unclear whether these PKC-PDK1 interactions confer specificity, efficiency, or some other property to the system. In principle this may reflect an ordering of events at least for those PKCs requiring hydrophobic motif phosphorylation.

14-3-3 proteins act as dimers and engage phosphorylated proteins with a preference for RXXSXP or RXXXSXP motifs [10]. It is known that PKCs can bind 14-3-3 proteins *in vitro* and also *in vivo*, although the role of the interaction is not clear. However, the precedents set by the c-Raf1 protein kinase and its functional interaction with 14-3-3 (as established

genetically [11]) indicate that this is likely to be important also in PKC function. Perhaps as for c-Raf1 [12], 14-3-3 facilitates stabilization of phosphorylated conformers of PKCs, thereby contributing to the priming process.

Though not a priming device, tyrosine phosphorylation of PKC, in particular PKC δ , has critical effects on cellular responses (see for example [13]). The distinct functions and reported properties for different phosphorylated forms of PKC δ (reviewed [14]) indicate that some of these tyrosine phosphorylations may be protein autonomous; however, there remains the probability that some involve direct recognition, with the likely recruitment of partners via SH2 domain (<http://www.ncbi.nlm.nih.gov/Structure/cdd/cddsrv.cgi?uid=smart00252>) interactions.

Activation

An intrinsic property of the classical and novel PKC allosteric activator DAG is that it is membrane-limited. It is the ability of PKCs to “sample” the membrane environment that provides the opportunity for activation. This feature of PKC activation lends itself to the compartmental targeting of PKC to provide for selectivity of activation.

Targeting of PKC prior to activation is clearly exemplified in the *Drosophila* compound eye, where the scaffolding protein InaD is responsible for assembling the eye-specific phospholipase C NorpA, the eye-specific PKC InaC, and the ion channel protein TRPL (recently reviewed [15]). This assembly contributes to the efficiency with which photo-reception is relayed and by which it is terminated. In this instance the interaction of the scaffolding protein InaD with the downstream effectors occurs via PDZ domains (<http://www.ncbi.nlm.nih.gov/Structure/cdd/cddsrv.cgi?uid=smart00228>), with the different proteins binding to distinct PDZ domains. A similar PDZ-dependent interaction is seen for PKC α and the binding partner PICK1 [16]; PKC α has a canonical PDZ binding motif (...SAV) at its C-terminus. The physiological role of this partnership is not understood.

AKAPs (A-kinase associated proteins) represent a distinct class of scaffolds that were first identified as protein kinase A (PKA) binding proteins [17]. Elegant studies by Scott and colleagues have provided evidence for the ability of AKAPs to direct PKA to sites of activation and action (see Chapters 62, 63, this volume). Two of these proteins, AKAP79 and Gravin (AKAP250), independently bind PKC as well as PKA and other proteins [18,19]. In particular, Gravin, which has been isolated in a number of different guises, scaffolds a broad spectrum of signal transducers and cell-cycle regulators (reviewed [20]). One other AKAP (AKAP78) has been identified as ezrin [21], which has been shown recently also to bind PKC α [22] (see further below). Although the specific roles for this group of PKC-binding proteins remain largely unknown, the precedents set by the studies on PKA provide a clear paradigm, and it is anticipated that these scaffolds serve to place PKCs at sites where their action is required. The ability of this class of scaffolds to assemble multiple

transducers also provides for integration (as for InaD) and duplication of signal outputs (for example, a common target for distinct upstream pathways, such as PKA and PKC).

For the atypical PKCs (ι/λ , ζ), activation is not DAG-dependent but can be effected by the assembly of a cdc42/PAR6/PAR3/aPKC complex (recently reviewed [23]). The importance of such an assembly was demonstrated in *C. elegans*, where it was shown that PKC3 (the only aPKC in *C. elegans*) ablation produced a polarity phenotype related to that documented for PAR3 and PAR6 mutants [24]. Subsequent studies have shown that the mammalian homologues of these proteins are involved in establishing the polarity of epithelial cells, where they assemble at and control the formation of tight junctions (see [23]). The sites of interaction for these proteins have been mapped (see Fig. 2). For aPKC the binding site for PAR6 resides in the aminoterminal domain whereas that for PAR3 is in the carboxyterminal, catalytic domain. It also remains possible that subcomplexes form, for example between the brain-specific PKM ζ protein (catalytic domain protein from the PKC ζ gene involved in memory; see [25]) and PAR3; however, this possibility requires further investigation.

Transmembrane proteins (including receptors) also interact with PKCs, targeting them to the resident compartment. These include β_1 -integrin [26], syndecan 4 [27], and tetraspanins [28]. In the case of β_1 -integrin, the interaction with PKC α occurs between the cytoplasmic C-terminal integrin tail and the central variable region (V3) of PKC α [29]. This interaction has been reported to be involved in β_1 -integrin migratory responses by controlling the traffic of β_1 -integrin [26]. There is a complex two-way relationship between β_1 -integrin and PKC α , a part of which represents an integrin-scaffolding role in the local assembly with, and PKC phosphorylation of the protein ezrin (see below).

A broad class of transmembrane proteins long-associated with PKC function are ion channels (see [30]). Although it has become apparent that in fact DAG can directly control the TrpL proteins [31], DAG also acts via PKC in other contexts. For example, PKC forms a complex with the GABA(A) receptor β_1 and β_3 subunits [32]. This association, like that conferred by InaD, predisposes the receptor to localized and efficient control by PKC—in this instance through phosphorylation of sites within a conserved motif shared by β_1 , β_2 , and β_3 subunits [33,34].

The interaction of PKC α with syndecan is distinctive in being promoted by PtdIns4,5, P $_2$ [35], and the association is negatively regulated by phosphorylation of syndecan on S183, possibly by PKC δ [36]. In the syndecan 4/PtdIns4,5P $_2$ complex, PKC α is in an active conformation resembling the interaction with RACKs (see below). Syndecan 4 is implicated in responses to FGF2, and the association and activation of PKC α via syndecan 4 is thought to contribute to FGF2-induced endothelial cell migration and proliferation [37].

There is a well-documented class of PKC-binding proteins that interact selectively with the activated conformer. These are typified by the RACKs (receptors for activated c-kinases) first documented by Mochly-Rosen and colleagues [38]. The two characterized RACKs are RACK1 [39] and β -COP (RACK2) [40]. Although the specific roles for these RACKs in the context of PKC action remain incompletely understood, their interactions with PKCs have proved informative. In particular, two features are notable here. First, interaction of PKC with RACK1 has been shown to lock the protein in an active conformation, providing a mechanism for DAG-triggered but DAG-independent sustained activation. Second, the site of interaction of RACKs with PKCs appears to be through the PKC C2/C2-like domain [41]. The latter property has been exploited to demonstrate that short

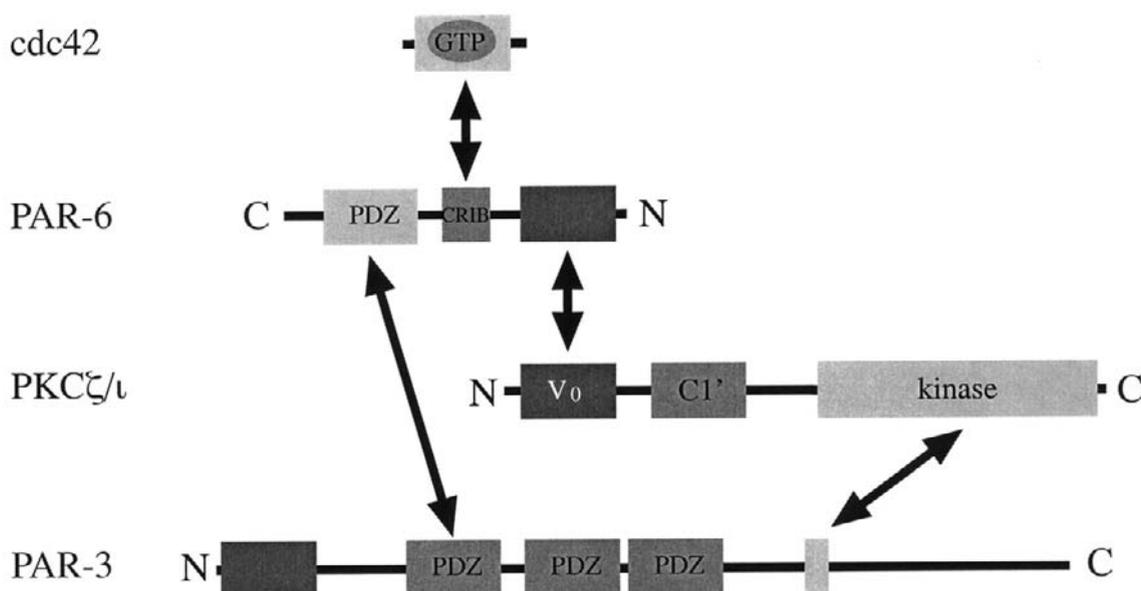

Figure 2 PAR-aPKC associations. The various interactions that compose the aPKC-PAR complex are illustrated (adapted from [23]). The defined domains are as indicated. The PKC ζ C1 domain is a C1'-related domain that does not bind DAG/phorbol esters. The association of the small GTP-binding protein cdc42 with PAR6 requires its GTP-bound state.

oligopeptides corresponding to the sites of interaction can block PKC translocation and PKC effects (see [41]). Thus, interactions through these regions of PKC (whether with RACKs or other proteins) appear to be important in PKC action. Corroboration of this has come from studies showing the inhibition of preconditioning in cardiac myocytes with a PKC ϵ inhibitory peptide [42] and the subsequent demonstration in knockout mice that PKC ϵ is essential for one component of preconditioning *in vivo* [43].

Annexin VI is another example of a PKC-binding protein that interacts with PKC (PKC α and β) but is not itself a substrate for the kinase [44]. This interaction is of interest because both proteins bind phospholipids in a Ca²⁺-dependent fashion and their interaction is dependent upon lipid binding. Nevertheless, there is evidence for direct protein-protein contact in this association [44].

Substrates and Pathways

The distinctions between scaffolds and substrates are somewhat blurred where the scaffolds themselves are substrates. However, conceptually there is a clear distinction between those proteins that bind PKC in its inactive conformation predisposing it to localized responses and those that are recruited postactivation. This latter category is exemplified by the STICK proteins (substrates that interact with c-kinase) [45]. These proteins have been identified by far-western analysis and include the PKC substrates clone72/SSECKS and γ -adducin (see [2]).

The STICK adducin is associated with actin and forms specific heterotetramers of the types α - β or α - γ (reviewed [46]). The PKC-dependent phosphorylation of γ -adducin (at serine 660) is associated with its release from this cytoskeletal location [47]. SSECKS binds a number of other signaling proteins (see above). It is interesting that like the PKC substrates MARCKS and GAP-43, the phosphorylation of SSECKS by PKC occurs at a calmodulin-binding site, interfering with calmodulin interaction [48]. SSECKS also undergoes an interaction with cyclin D, which is attenuated by PKC phosphorylation of SSECKS [48]. Phosphorylated SSECKS is associated with membrane protrusions and ruffles, thus implying an involvement in the reorganization of cortical actin. How this relates to the nonbinding/release of calmodulin and cyclin D is as yet unclear. The cortical actin association and its control by phosphorylation is also observed for another PKC α -interacting protein, ezrin [22]. In this latter case, there is evidence for the phosphorylation of ezrin by PKC α playing an essential role in β 1-integrin dependent directional movement of cells [Ng, 2001 #6991]. As noted above, this also involves integrins (see Fig. 3).

In the context of substrates and pathways, phospholipase D (PLD) is a very interesting example of a PKC-binding protein. PKC α will activate PLD1 *in vitro*, and, as first evidenced in membrane reconstitutions [49], the complex formed between PKC α and PLD1 is sufficient for activation in the presence of other factors; phosphorylation is not required.

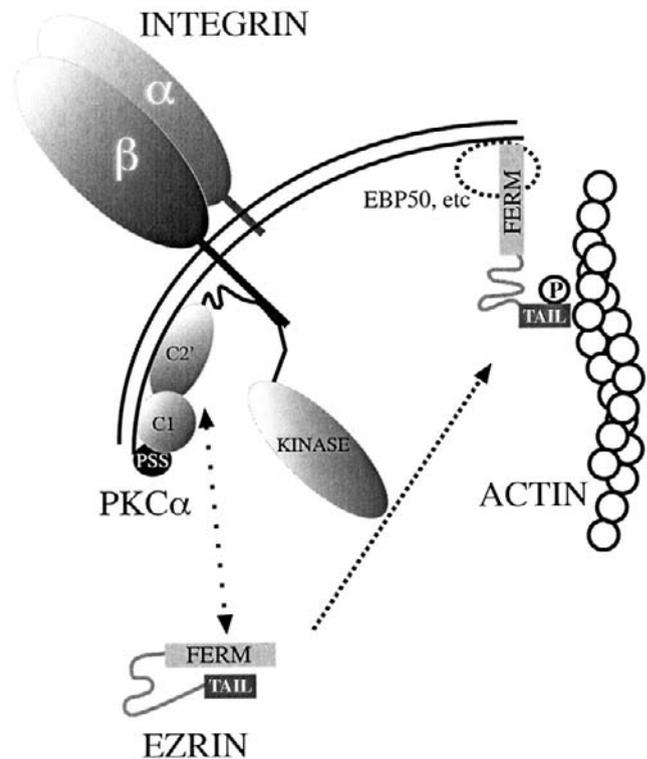

Figure 3 Integrin-PKC α -ezrin associations. PKC α and integrin β 1 form a complex through the V3 domain of PKC α and the C-terminal tail of integrin β 1 [29]. Ezrin can be recruited into this complex, and this leads to ezrin phosphorylation on T567. This phosphorylation alters the conformation by reducing the FERM-tail domain interaction and so permitting distinct contacts to be made through the FERM domain (for example with EBP50) and through the tail domain with actin (see [74]). The domains of PKC α and ezrin are indicated. PSS refers to the PKC pseudosubstrate site, which, along with the C1 and C2 domains, can interact with membranes.

This interaction occurs through the regulatory domain of PKC α and requires the open/active conformer [50]; how the activity of PKC relates to the downstream pathways in this context remains to be determined.

Mammalian genetic analysis of PKC functions has provided a number of insights. Of note here, the mouse knockout of the PKC β gene leads to a B-cell phenotype reminiscent of Btk loss-of-function [51]. This implies that there is a functional relationship between these two kinases, and indeed they have been shown to interact [52]. This interaction occurs through the PH domain of Btk [52]. Other PH domain-PKC interactions have been documented, including that for PKC η -PH^{PKC μ /PKD} [53]; PKC μ /PKD, like Btk, is also a downstream target for PKC [54].

PKC Inactivation

A characteristic property of classical and novel forms of PKC is that their chronic activation frequently leads to their inactivation and/or degradation. This feature is often observed on phorbol ester (or functionally related pharmacological agonist) stimulation of cells. For PKC α this

process of activation-induced degradation has been documented to proceed via caveolae/raft-dependent traffic, dephosphorylation, and then degradation [55]. PKC α can interact with caveolin 1 through its scaffold domain [56]. This interaction may well contribute to its traffic through the caveolae compartment, although the serum deprivation protein, sdr, has also been proposed as a caveolae targeting device for PKC α [57]. It is possible that a related role is played by p62/ZIP, a PKC ζ -interacting protein [58,59] that has been reported to recruit PKC ζ and traffic through endosomal fractions in response to EGF [59] and NGF [60].

Dephosphorylation of PKC appears to be effected through protein phosphatase 2A (PP2A) (for example [61]) and there is evidence that PP2A can associate with certain PKC isoforms [62], as has been described for other AGC kinase family proteins [63]. As noted above, dephosphorylated PKC is often found to be associated with the neutral detergent-insoluble fraction. Although this may reflect an intrinsic property, it is of note that the p32 protein recovered from the detergent-insoluble fraction of hepatocytes has been shown to interact with certain conformers of PKC isoforms and hence may contribute to this behavior [64].

The process of degradation of PKC is a ubiquitin-dependent one [65,66], implying that E3 component(s) recognize and interact with PKCs to facilitate ubiquitination. To date the only such component identified that binds PKC isoforms is the VHL tumor suppressor gene product [67]. Whether this is the only interacting E3 protein remains to be determined.

Perspectives

There is an increasing need to be able to monitor at a sub-cellular level the interactions of PKCs and their binding partners. It will be important to be able to follow such events in real time and in the context of catalytic activity, for example by using antisera that monitor phosphorylation events [68,69]. The elucidation of the spatio-temporal behavior of complexes promises to be very informative in defining how individual ones contribute to responses. Beyond this, application of accumulating molecular knowledge to the development of improved health care is increasingly tractable. Indeed, our understanding of PKC targets has already started to have an impact on clinical trials [70].

In a broader context, it is of interest that comprehensive interaction maps have been compiled for yeast (for example [71]) and other organisms (see web sites in [71]). To date these generic activities have had limited novel input into our appreciation of PKC and its partners in higher eukaryotes; in yeast the defined partner for PKC1, a Rho family member, in fact reflects a property of the PKC-related kinases (PRKs/PKNs) [72]. However such mapping approaches promise much for the future.

It will be evident to those in the field that this review has really only touched on what is a substantial collection of PKC-interacting proteins. Indeed, the diversity of these PKC-associated proteins means that we must acknowledge

that the majority have not been discussed in this commentary, and we hope colleagues will accept our apologies if their favorite PKC partner is missing.

Vanderbilt University School of Medicine, Nashville, Tennessee*

AKAP	A-kinase (PKA) anchoring protein
AMPA	a-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid
AMPA	AMPA-type glutamate receptor
CaM	calmodulin
CaMKII	Ca ²⁺ /CaM-dependent protein kinase II
CREB	cyclic AMP-response element binding protein
DARPP-32	dopamine and cyclic AMP-regulated phosphoprotein of 32 kDa
I1	inhibitor 1
LTD	long-term depression
LTP	long-term potentiation
NMDA	<i>N</i> -methyl-D-aspartate
NMDAR	NMDA-type glutamate receptor
PKA	protein kinase A, A-kinase, or cyclic AMP-dependent protein kinase
PP1	protein phosphatase 1
PP2B	protein phosphatase 2B or calcineurin
PSD	postsynaptic density

Introduction

Fast excitatory glutamatergic synaptic transmission is a primary contributor to many normal behaviors such as learning and memory and is often disrupted in complex neural disorders. The primary mediators of excitatory transmission are dendritic ionotropic AMPA-type and NMDA-type glutamate receptors, which are phosphorylated by many protein kinases. The modulatory actions of these kinases are antagonized by dendritic protein phosphatases, although there are incomplete, often contradictory, data implicating specific

enzymes in modulating synaptic function, because only a relatively limited number of these enzymes often display promiscuous *in vitro* activity (see chapter 91, Volume 1 by Cohen). This review focuses on the nature and roles of dendritic protein phosphatase (PP1) and calcineurin (PP2B), the two phosphatases that have been best implicated in post-synaptic signaling.

The Importance of Dendritic Localization

The glutamate receptors involved in excitatory transmission are localized to the synapse by association with other proteins in a cytoskeletal structure called the postsynaptic density (PSD), which is often located at the tip of dendritic spines (see Chapter 55 by Kennedy). “Extra-synaptic” glutamate receptors are found in the membrane of dendritic shafts and the cell body. Synaptic and extra-synaptic receptors may be differentially regulated depending on the localization of enzymes involved in their regulation. Although specific receptors may be *in vitro* substrates for kinases and phosphatases or be modulated in whole-cell electrophysiological studies, this may not reflect synaptic regulation. Thus, understanding mechanisms that localize the relevant kinases and phosphatases to PSDs is a critical part of this puzzle.

Protein Phosphatase 1

Three mammalian genes encode four distinct but highly homologous PP1 catalytic subunits (PP1 α , PP1 β , PP1 γ_1 , and PP1 γ_2), which interact with about 50 divergent proteins. Most PP1-binding proteins contain a binding motif

defined by a consensus sequence, R/K-I/V-X-F. The interacting proteins modulate the activity or subcellular location of PP1_C (see chapters 103 and 105 by DePaoli-Roach and Shenolikar in Volume 1, and [1]).

All four PP1 isoforms are expressed in mammalian brain, but with variable cellular distribution [2–5]: PP1 β and PP1 γ_1 also exhibit differential subcellular distribution. For example, PP1 β is enriched in microtubule fractions whereas PP1 γ_1 is selectively abundant in F-actin enriched extracts [3]. In addition, PP1 γ_1 , but not PP1 β , is highly enriched in PSDs [6,7], which also contain F-actin. Consistent with these observations, immunohistochemistry shows that PP1 γ_1 is enriched in synaptic layers and dendritic spines of neurons in brain slices [2,3], whereas PP1 β is enriched in cell body layers [3]. Moreover, PP1 γ_1 is localized to synapses in cultured cortical neurons, whereas PP1 β colocalizes with microtubules in the cell body [3]. PP1 α exhibits similar distribution to PP1 γ_1 [2,6,7], but the subcellular localization of PP1 γ_2 is unknown. Thus, PP1 isoforms are differentially targeted, suggesting that they have at least partially distinct neuronal functions. Furthermore, targeting appears to be dynamically regulated by synaptic NMDAR activation, which recruits additional unidentified PP1 isoforms to synapses [8]. Understanding the isoform selectivity and modulation of PP1 localization, and thus PP1 functions, demands a thorough understanding of the mechanisms involved. Several dendritic PP1-binding proteins (see Fig. 1) may play critical roles, as discussed below.

Inhibitor Proteins

PP1 interacts with I1 and DARPP-32, primarily soluble proteins that both inhibit PP1 activity when phosphorylated

by PKA at homologous Thr residues (Thr35 in I1 and Thr34 in DARPP-32). Inhibition is mediated by interactions involving an R/K-I/V-X-F consensus motif (approximately residues 6–12) and residues surrounding Thr34/Thr35 [9,10]. Phospho-Thr34/35 in I1/DARPP-32 are effective substrates for calcineurin, the Ca²⁺/CaM-dependent phosphatase [11]. Thus, cAMP and Ca²⁺ signaling modulate PP1 activity by antagonistic regulation of Thr34/35 phosphorylation [12]. In addition, regulation of PP1 by both DARPP-32 and I1 is modulated by phosphorylation at distinct sites by other kinases (reviewed in [13] and chapter 105 in Volume 1 by Shenolikar). Although there is no evidence indicating that I1 or DARPP32 distinguish between PP1 isoforms, their differential but overlapping expression suggests that they have different roles. For example, each protein appears to regulate dendritic PP1, but DARPP-32 is more abundant in the striatum, whereas I1 is prevalent in hippocampus [14].

Targeting Proteins

Four major PP1-binding proteins (216,175,134, and 75 kDa) were initially detected in isolated PSDs [15]. The 175 and 134 kDa proteins selectively bound PP1 γ_1 over PP1 β , and were identified as *neurabin* and *spinophilin* [16], proteins previously identified as F-actin- and PP1 α -binding proteins [17,18], respectively. Spinophilin also was isolated as an F-actin binding protein and termed neurabin II [19]. Both spinophilin and neurabin are selectively associated with PP1 α and PP1 γ_1 in brain extracts, but not PP1 β [16,20], and may contribute to the differential localization of PP1 β and PP1 γ_1 in neurons (see above). An R/K-I/V-X-F motif is critical for binding and inhibition of PP1 by both proteins *in vitro*, but additional residues are also important

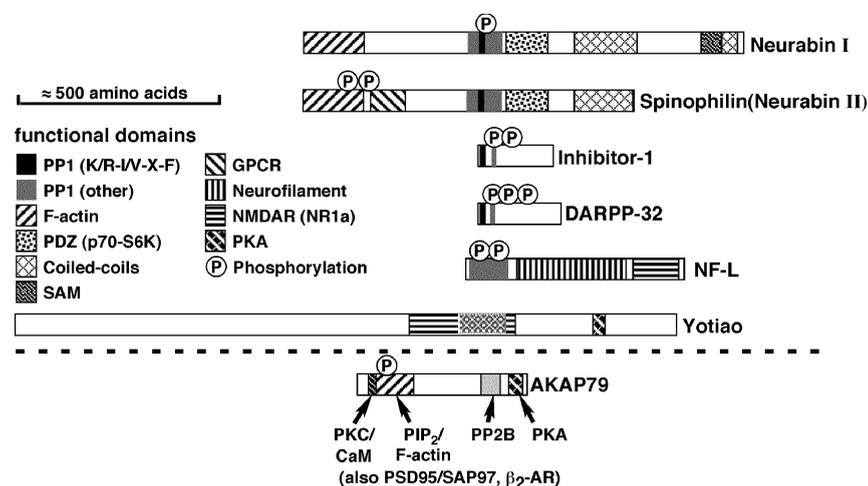

Figure 1 Dendritic PP1- and calcineurin-associated proteins. Amino acid sequences of the selected proteins are represented by open bars drawn to approximate scale. Many interact with PP1 via K/R-I/V-X-F motifs (black boxes) or other domains (gray boxes) (above dashed line), whereas AKAP79 interacts with calcineurin (PP2B). Most of these proteins also interact with protein kinases, cytoskeletal proteins, or other signaling proteins, probably serving as signaling scaffolds, and are phosphorylated, as indicated by additional shaded boxes (see legend). GPCR, G-protein coupled receptor; PDZ, PSD95/Dlg/ZO-1 domain; SAM, sterile alpha motif.

for inhibition [21,22]. However, it should be noted that PP1 activity is detected in neurabin complexes immunoprecipitated from brain extracts [21]. Although the activity of these complexes was not compared to that of free PP1, it seems that endogenous PP1 complexes with spinophilin or neurabin may possess phosphatase activity.

Subsequently, neurabin and spinophilin were shown to interact with many additional proteins that play critical roles in signal transduction, subcellular trafficking, and cytoskeletal dynamics (Fig. 1). Despite functional homology (e.g., interaction with PP1, F-actin, p70 S6 kinase), spinophilin and neurabin are likely to serve different cellular functions. For example, only spinophilin binds D2 dopamine and $\alpha 2$ adrenergic receptors [23,24], although it is not clear whether these interactions occur in neurons. In addition, reduction of neurabin expression in cultured neurons blocks neurite outgrowth [17], whereas neurons cultured from mice lacking spinophilin prematurely develop processes and the neurons from mature animals have an overabundance of spines [25].

The 216 and 75 kDa binding proteins in PSDs [15] may be yotiao and the neurofilament-L protein (NF-L), respectively. Yotiao, a protein first identified by binding NR1a subunits of NMDARs, was shown to be a PP1-targeting protein in addition to an AKAP [26]. It is interesting that small PP1-binding fragments of yotiao lack a recognizable K/R-I/V-X-F motif, although peptides containing the consensus motif compete for binding. Unusually for a PP1-binding protein, yotiao did not significantly inhibit PP1. High constitutive phosphatase activity in the NR1a-yotiao-PP1 complex may maintain the NMDAR in a dephosphorylated state under basal conditions [26]. PP1 also binds to the head domain of NF-L, resulting in inhibition of PP1, although this domain also lacks a K/R-I/V-X-F consensus motif. NF-L was identified in isolated PSDs [7] and also binds to the NMDAR NR1a subunit [27]. Thus, both yotiao and NF-L may contribute to PP1 targeting to NMDARs, but their isoform selectivity and specific contributions to subcellular localization remain unknown.

Calcineurin (Protein Phosphatase 2B)

Calcineurin was originally identified as an abundant Ca^{2+} /CaM-binding protein in brain extracts and was later shown to possess Ca^{2+} /CaM-dependent phosphatase activity identical to PP2B. The holoenzyme is a heterodimer of a Ca^{2+} /CaM-binding catalytic A subunit with a Ca^{2+} -binding regulatory B subunit (see chapter 106 in Volume 1 by Klee & Yang). Calcineurin is largely soluble in brain extracts, but it is also present in isolated PSDs [6] and colocalizes with F-actin in dendritic spines [28]. Calcineurin activity is inhibited by AKAP79, a PSD- and actin-associated dendritic spine protein that also interacts with many other synaptic proteins ([29–31] and see Fig. 1). Ca^{2+} influx via NMDA receptors stimulates calcineurin-dependent remodeling of actin in dendritic spines [28] and also the re-distribution of AKAP79, calcineurin, and PKA [29].

Dendritic Phosphatase Substrates

NMDARs and AMPARs

Phosphorylation may regulate the conductance, open probability, or trafficking of AMPARs and NMDARs. Initially, relatively nonselective inhibitors implicated PP1, PP2A, and PP2B in the regulation of AMPARs [32,33] and NMDARs [34]. Later studies in mice with a DARPP-32 knockout or overexpressing a constitutively active I1 mutant specifically implicated PP1. PKA-mediated regulation of extrasynaptic AMPAR and NMDAR is disrupted in striatal neurons from DARPP-32 knockout mice [35–37]. Although PP1 activities in extracts from wild-type and DARPP-32 knockout mice were not directly compared, these data suggest that PP1 inhibition by PKA-phosphorylated DARPP-32 is essential for phosphorylation of other PKA substrates. In contrast, expression of constitutively active I1 reduced hippocampal PP1 activity by 68 percent and enhanced phosphorylation of hippocampal AMPARs, as well as that of CaMKII and CREB [38]. In combination these data implicate I1/DARPP-32 modulation of PP1 activity in normal AMPAR and NMDAR regulation.

PP1 targeting has also been implicated in modulation of glutamate receptors. Intracellular perfusion of peptides containing the R/K-I/V-X-F PP1-binding motif disrupts dopamine D1 receptor regulation of extrasynaptic AMPARs in striatal neurons [39] but does not affect the basal activities of synaptic AMPARs and NMDARs in hippocampal neurons [8]. However, interpretation of these data is complicated because similar peptides disrupt PP1 interactions with spinophilin, neurabin, yotiao, NF-L, DARPP-32, and I1 *in vitro*. Subsequently, it was shown that striatal AMPARs and hippocampal NMDARs were abnormally regulated in spinophilin knockout mice [25]. These studies suggest that in wild-type animals spinophilin targets PP1 to appropriate subcellular locations to permit efficient regulation (dephosphorylation) of extrasynaptic AMPARs and NMDARs. However, the role of spinophilin in regulation of synaptic receptors is not as clearly defined.

Yotiao and NF-L also may play a role in PP1 modulation of NMDARs. PP1-binding to yotiao and NF-L is disrupted by R/K-I/V-X-F peptides; thus, disruption of these complexes may account for some of the effects of similar peptides in cells (see above). However, disruption of PP1 complexes with yotiao and NF-L would not be expected in spinophilin knockout animals. Thus, although ternary complexes containing NMDAR subunits, PP1, and either spinophilin, yotiao, or NF-L have not been reported, it seems that the mechanism of PP1 targeting to NMDARs may depend on the cell type, developmental stage, or other factors.

Calcineurin is also strongly implicated in NMDAR regulation [40–42] and mediates Ca^{2+} -dependent rundown of AMPARs in hippocampal neurons [43]. Association of calcineurin with AMPARs via AKAP79 and SAP97 promotes Ca^{2+} -stimulated rundown of AMPAR currents in HEK293 cells, an effect requiring an intact PKA site (Ser845) in the AMPAR [43]. However, despite evidence for PSD targeting

of calcineurin by AKAP79, direct actions of calcineurin on synaptic AMPARs or NMDARs have not been clearly established. Calcineurin-dependent regulation of PP1 via I1 or DARPP-32 may contribute to some of the observed effects.

Ca²⁺/CaM-Dependent Protein Kinase II (CaMKII)

Autophosphorylation at Thr286 generates a Ca²⁺/calmodulin-independent form of CaMKII [44–46] and is critical for stable association of CaMKII with PSDs *in vitro* and in brain slices [47], as well as in cultured neurons [48]. Some forms of synaptic plasticity, learning, and memory require an intact Thr286 autophosphorylation site in CaMKII [49]. Thus, protein phosphatases have a potentially important role in regulating CaMKII.

Initially, PP1 was identified as the major CaMKII phosphatase in PSDs, with a minor role for PP2A and no significant direct role for calcineurin or PP2C [50,51]. Subsequently, PSD-associated CaMKII was shown to be primarily dephosphorylated by PP1, but PP2A was the major activity toward soluble CaMKII [6,47]. Thus, CaMKII translocation to PSDs may modulate its availability to cellular phosphatases. Although mechanism(s) accounting for this effect are unclear, it could play a role in determining the half-life of autophosphorylated CaMKII in cells. Addition of okadaic acid to cells enhances CaMKII autophosphorylation [52], consistent with a dominant role for PP1 and PP2A in intact cells. Moreover, inhibition of hippocampal PP1 by induced overexpression of constitutively active I1 results in enhanced autophosphorylation of CaMKII at Thr286 [38]. Thus, calcineurin may play a role in CaMKII regulation by modulating PP1 (see above) and PP2C-related phosphatases may be involved in some cells [53].

Role of Phosphatases in Synaptic Plasticity

Synaptic plasticity describes the long-lasting adaptations of synaptic function that are thought to underlie certain forms of memory. The best-studied forms of long-term potentiation (LTP) and long-term depression (LTD) in hippocampal CA1 neurons require dendritic Ca²⁺ influx via the NMDARs, and modulate the phosphorylation, activity, and subcellular trafficking of AMPARs. LTP requires Thr286 autophosphorylation of CaMKII and the activation of several other kinases (reviewed in [54–56]). The actions of protein phosphatases oppose the kinases, thus depressing or depotentiating synaptic transmission (see Fig. 2).

Initially, calcineurin and PP1 were implicated in LTD induction [57,58], in part because LTD required Ca²⁺ influx and the Ca²⁺/CaM-dependent calcineurin regulates PP1 via I1 or DARPP-32 or both. One relevant substrate appears to be GluR1 subunits of AMPARs. LTD of naïve cells correlates with dephosphorylation of Ser845 (a PKA site), whereas depotentiation (LTP reversal) induces dephosphorylation of Ser831 (a CaMKII site) [59]. In contrast, LTP of naïve cells enhances Ser831 phosphorylation, and potentiation of

“previously depressed” synapses enhances Ser845 phosphorylation [59]. However, these changes occur in the total AMPAR pool, not just in synaptic receptors, and the identity of the relevant phosphatases remains unclear.

Genetic manipulation of calcineurin activities in mice provided important insight into mechanisms of synaptic plasticity. A surprising finding was that mice expressing either constitutively active calcineurin or a calcineurin inhibitory peptide exhibited no detectable defect in LTD induction [60,61]. Rather, both transgenic models implicate calcineurin as exerting a negative effect on LTP [60,61], consistent with some prior pharmacological data [57,62]. It is interesting that mice lacking the calcineurin α gene, but retaining the minor calcineurin β gene, exhibit normal LTD and LTP but are defective in depotentiation [63]. Given the known changes in AMPAR phosphorylation during LTP, LTD, and depotentiation (see above), these data implicate calcineurin in the dephosphorylation of Ser831 but not Ser845 in synaptic AMPARs. However, this could be due to direct dephosphorylation of Ser831 by calcineurin or, indirectly, to PP1-mediated dephosphorylation/inactivation of CaMKII. Although this model is inconsistent with data implicating calcineurin in Ser845 dephosphorylation ([43]; see above), the synaptic AMPARs relevant to synaptic plasticity may be regulated differently.

Synaptic plasticity may involve modulation of PP1 activity by DARPP-32 or I1 or targeting of PP1 to AMPARs by spinophilin or other PP1-binding proteins. R/K-I/V-X-F motif peptides disrupt PP1 interactions with I1, DARPP-32, spinophilin, neurabin, and yotiao *in vitro* and block induction of some forms of LTD [8]. More specifically, spinophilin knockout mice are deficient in the induction of LTD but not LTP [25]. Moreover, PP1 plays a role in selective dephosphorylation of AMPARs at Ser845 but not Ser831 in striatal neurons [35]. Thus, AMPAR dephosphorylation at Ser845 associated with LTD may be due to activation of PP1 associated with spinophilin. Dephosphorylation of I1 by calcineurin may liberate PP1 to interact with spinophilin [8] and dephosphorylate Ser845, whereas dephosphorylation of Ser831 associated with depotentiation may be due to a direct action of calcineurin (Fig. 2).

In addition to a role for PP1 activation in LTD induction, inhibition of hippocampal PP1 appears important for LTP induction. LTP induces PKA-mediated phosphorylation of I1 and inhibition of PP1, thereby “gating” Thr286 autophosphorylation of CaMKII and promoting phosphorylation of AMPARs (Ser831) and other substrates [64,65]. Consistent with this model, Thr286 phosphorylation of CaMKII and Ser831 phosphorylation of AMPARs were enhanced in transgenic mice induced to overexpress a constitutively active mutant I1, correlating with enhanced learning and memory [38]. Thus, at least some forms of LTP require PKA-dependent inhibition of PP1 activity via the phosphorylation of Thr35 in I1. This contrasts with data obtained from I1 and spinophilin knockout mice in which LTP at the hippocampal CA3-CA1 synapses is normal [25,66]. However, these observations may reflect adaptations to chronic protein deficiency

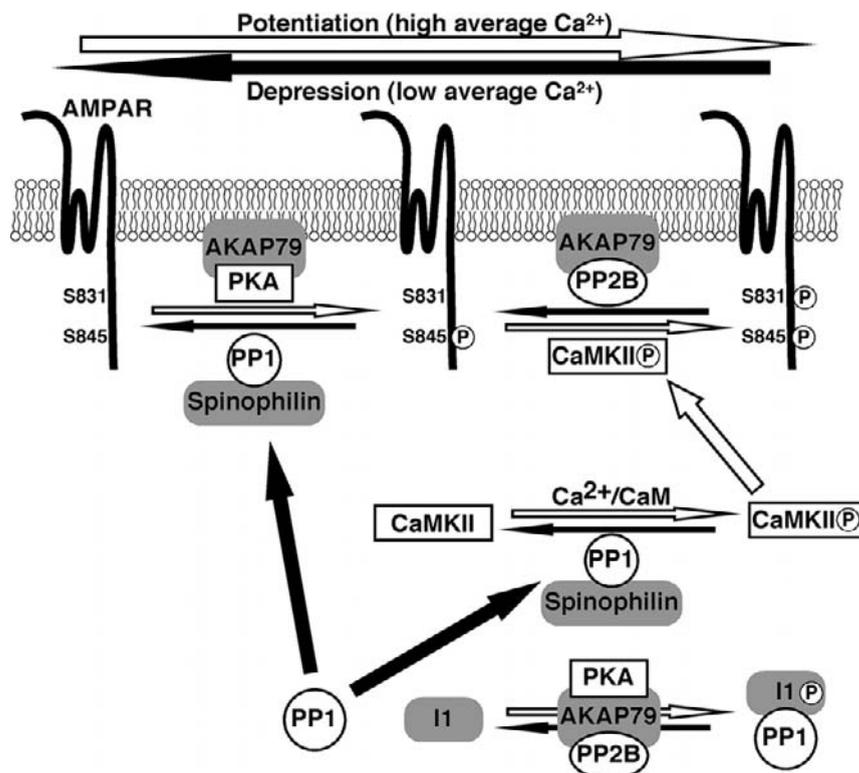

Figure 2 Working model implicating dendritic protein phosphatase complexes in hippocampal CA1 synaptic plasticity. Phosphorylation-dephosphorylation of AMPARs (black line) in synaptic membranes and other locations is associated with synaptic plasticity. *Unfilled arrows* indicate reactions and promoted by intense synaptic stimulation (e.g., high-frequency stimulation) that potentiate synaptic transmission. Activation of NMDARs results in high-average Ca^{2+} concentrations that favor activation of protein kinases (open rectangles), such as CaMKII and PKA (via $\text{Ca}^{2+}/\text{CaM}$ -dependent adenylyl cyclases). PKA substrates include AMPARs (Ser845) and inhibitor 1 (I1). Phosphorylated I1 directly inhibits PP1 activity and may compete PP1 away from spinophilin. PP1 inhibition promotes the accumulation of Ser845 phosphorylated AMPARs and autophosphorylated (activated) CaMKII, which phosphorylates AMPARs at Ser831. In contrast, *solid arrows* indicate reactions promoted by low-intensity synaptic stimulation (e.g., prolonged low-frequency stimulation). NMDAR activation again provides the primary signal, but lower average Ca^{2+} concentrations favor phosphatase (open circles) activation, since calcineurin (PP2B) has a higher affinity for $\text{Ca}^{2+}/\text{CaM}$ than CaMKII or adenylyl cyclases. Dephosphorylation of I1 by calcineurin liberates free PP1 that may associate with spinophilin and dephosphorylate (inactivate) CaMKII. Calcineurin and PP1 may dephosphorylate Ser831 and Ser845 in AMPARs, respectively. Assembly of phosphatases and kinase in complexes with anchoring targeting or regulatory proteins (gray) plays a critical role in dictating signaling specificity and fidelity.

in these knockout animals. Thus, the precise role of specific PP1 complexes in CaMKII regulation and LTP induction remains unclear.

Summary

There is compelling evidence that multiprotein complexes containing PP1 and calcineurin are critical for synaptic regulation, but specific roles of their molecular components still need to be determined. Roles for other serine/threonine and tyrosine phosphatases are also likely to be better described. Apparently contradictory data in the cited literature may be due to cell-specific issues related to differences in cellular functions, prior synaptic activity or developmental stage analyzed, and variations in experimental conditions. The challenge

is to carefully control all the variables and use emerging animal models and specific molecular tools to more precisely understand the roles of these phosphatase complexes in synaptic regulation.

Acknowledgments

I appreciate the critical review of an initial draft by Eric D. Norman, Brian E. Wadzinski, Danny G. Winder, and members of my laboratory. I apologize to colleagues whose significant related contributions may not have been cited due to space constraints. Work in my laboratory was funded by the NIMH, NINDS, and AHA.

Introduction

Serine/threonine phosphatases are integral components of many signal transduction pathways. There are eight classes of serine/threonine phosphatases in vertebrates. Protein serine/threonine phosphatases 1, 2A, 2B/calcineurin, 4, 5, 6, and 7 are members of the PPP gene family that contain a conserved serine/threonine phosphatase domain. Protein phosphatase 2A (PP2A) is a ubiquitously expressed member of the PPP gene family that accounts for a substantial portion of the total serine/threonine phosphatase activity in many cell types. PP2A is an essential enzyme that functions in fundamental cellular processes, including metabolism and the cell cycle. Like the other signaling molecules discussed in this chapter, proximity interactions play a primary role in regulating PP2A.

Once thought of as a single, broad-specificity phosphatase, PP2A is actually many different enzymes composed of complexes between catalytic subunits, scaffold subunits, regulatory subunits, and interacting proteins [1–3]. The catalytic and scaffold subunits bind tightly to form a core dimer that is the common component of most, but not all, forms of PP2A. The core dimer interacts with an array of regulatory subunits to generate multiple heterotrimeric holoenzymes. Additional interactions between PP2A and a variety of interacting proteins generate additional diversity. The regulatory subunits and interacting proteins target PP2A to specific substrates and intracellular locations. The existence of many different forms of PP2A accounts for the ability of the enzyme to regulate a wide variety of biological processes.

Interaction of the core dimer with regulatory subunits is critical for PP2A function. The regulatory subunits bind to the core dimer through interactions with both the scaffold and the

catalytic subunits. The scaffold subunit is composed entirely of 15 copies of a conserved motif termed the HEAT repeat [4]. HEAT repeats 1–10 mediate interactions with regulatory subunits whereas repeats 11–15 mediate interaction with the C subunit [5]. The regulatory subunits must form contacts with both the scaffold and the catalytic subunits to generate stable heterotrimers [5,6]. The regulatory subunits bind to the core dimer in a mutually exclusive manner. Although some sites of interaction are conserved, there are unique amino acids within the scaffold subunit that are involved in the interaction with individual regulatory subunits [7] (Fig. 1).

PP2A Regulatory Subunits Mediate Proximity Interactions

Regulatory subunits play a primary role in specifying the proximity interactions of PP2A. Three families of PP2A regulatory subunits have been identified in vertebrates by biochemical and genetic methods. A list of PP2A subunits is presented in Table I. In order to avoid confusion, we have used a nomenclature for the PP2A subunits derived from their official human gene symbols. In contrast to the scaffold and catalytic subunits, which are ubiquitously expressed, the PP2A regulatory subunits are expressed in a cell- and tissue-specific manner. PP2A regulatory subunits are also differentially expressed during development and have distinct subcellular localizations. Neither the structural basis for interaction of regulatory subunits with the PP2A core dimer nor the biochemical effects of these interactions have been clearly elucidated. The PP2A regulatory subunit families have little overall amino acid sequence similarity. Several regulatory

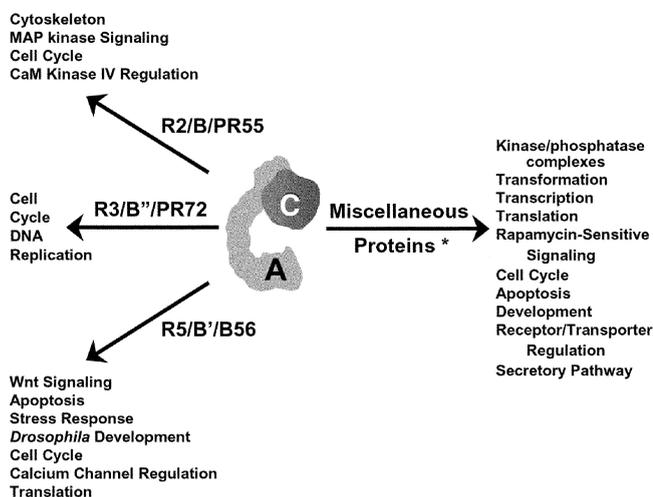

Figure 1 PP2A is a family of enzymes with multiple cellular functions. The PP2A holoenzyme consists of a common core dimer (AC) that complexes with a wide variety of regulatory molecules to generate a diversity of enzyme forms. These regulatory molecules include three regulatory subunit families (R2, R3, and R5) and a variety of miscellaneous proteins that interact with the core dimer or the free catalytic subunit. The regulatory molecules target PP2A to distinct substrates and intracellular locations, allowing the enzyme to participate in numerous cellular functions. The types of functions targeted by the individual regulatory subunits and miscellaneous proteins are listed.

subunits contain WD domains, which have been proposed as a conserved motif responsible for the interaction with the core dimer [3,8–10]. Recently a loosely conserved A-subunit binding domain has been identified in each of the regulatory subunit families [11]. The regulatory subunits have effects on the kinetics of dephosphorylation that are consistent with a role in controlling the binding of substrates to PP2A [12–15]. This model is consistent with the notion that regulatory subunit-mediated proximity interactions play a role in targeting PP2A to phosphoprotein substrates. In contrast to simple enzyme-substrate interactions, the interaction of PP2A with many substrates involves a stable interaction involving regions of the enzyme removed from the active site. These stable interactions serve to maintain a high effective concentration of PP2A in the vicinity of the substrate.

Consistent with roles in defining PP2A specificity, different families of PP2A regulatory subunits have non-overlapping functions. The stress-induced growth arrest caused by mutations in the R5 subunit gene (RTS1) in yeast can be rescued by introduction of wild-type versions of either the yeast R5 gene or the human R5 γ gene [16]. In contrast, wild-type R5 cannot rescue the cold-sensitive phenotype resulting from mutations in the yeast R2 subunit gene (CDC55). Knockdown of individual PP2A regulatory subunits in *Drosophila* S2 cells by RNA interference causes distinct defects. Loss of the R2 subunit

Table I Nomenclature of Mammalian PP2A Subunits

Name	Gene symbol	Aliases	Chromosomal location	LocusID/accession number ^a
<i>Catalytic subunits</i>				
α isoform	PPP2CA	C α , PP2A _{Cα}	5q23–31	5515
β isoform	PPP2CB	C β , PP2A _{Cβ}	8p21–12	5516
<i>Scaffold subunits</i>				
α isoform	PPP2R1A	A α , PR65 α	19	5518
β isoform	PPP2R1B	A β , PR65 β	11q23	5519
<i>R2 subunits</i>				
α isoform	PPP2R2A	B α , PR55 α	8	5520
β isoform	PPP2R2B	B β , PR55 β	5q31–5q33	5521
γ isoform	PPP2R2C	B γ	4p16	5522
δ isoform		B δ		AF180350

causes an increase in insulin-dependent MAP kinase signaling, whereas loss of both R5 isoforms induces apoptosis [17]. These data suggest that PP2A holoenzymes containing the R2 subunit play a negative regulatory role in MAP kinase signaling whereas holoenzymes containing the R5 subunit function in cell survival.

The R2 Family

The R2 family comprises a set of proteins present in a form of PP2A originally designated PP2A₁ [18]. This family currently contains four known isoforms (Table I) that are 79–87 percent identical. R2 α mRNA is ubiquitously expressed and is the most abundant PP2A regulatory subunit in many cells and tissues. The R2 β and R2 γ isoforms are only expressed at high levels in brain and testis. Although R2 α and R2 β are both expressed in the brain, they are present at different levels in different types of neurons [19]. R2 α is distributed mainly in neuronal cell bodies and is localized in both the cytosol and nucleus. In contrast, the β isoform is excluded from the nucleus and is localized in axons and dendrites in addition to the cell body. Expression of R2 subunit mRNA is also differentially regulated during development. The differential expression and localization of R2 subunits support the idea that different members of this family play distinct roles in regulating PP2A functions.

Information about the functions of PP2A regulatory subunits has been derived from genetic analysis in yeast, *Drosophila*, and *C. elegans*. The pleiotropic phenotypes of mutant alleles of the R2 subunit in yeast and its numerous genetic interactions indicate that the R2 (*cdc55p*) protein plays multiple roles during mitosis, including the bud morphogenetic checkpoint and the mitotic spindle-assembly checkpoint [20–22]. The genetic results suggest that R2/*cdc55p* is involved in promoting activation of the yeast cell cycle regulatory kinase CDC2 (cyclin B/*Cdc28* in *S. cerevisiae*) via dephosphorylation of the inhibitory tyrosine 19 phosphorylation site. Since PP2A does not directly dephosphorylate tyrosine, a likely target of R2 action is the *cdc25* dual-specificity phosphatase, which is responsible for dephosphorylating tyrosine 19 in *S. cerevisiae* *cdc28p*.

Reduced levels of the R2 subunit in *Drosophila* result in varied phenotypes depending on the severity of the alleles. The *aar1* allele (for abnormal anaphase resolution) contains a P-element insertion in the R2 gene [23]. Mutant *aar1* flies die as larvae or early adults with overcondensed chromosomes and abnormal anaphase figures in larval brain cells. These defects can be rescued by reintroduction of the wild-type R2 gene. The *aar1* phenotype is reminiscent of the mitotic spindle-assembly checkpoint defects seen in the yeast R2 mutants. Another P-element mutant allele of *Drosophila* R2 (*twins^P*) causes death at an early pupal stage and shows pattern duplication of wing imaginal discs [24]. Flies harboring a weaker allele, *twins⁵⁵*, survive but have duplicated bristles in sensory neurons [25]. The effects of the *twins* mutation are consistent with a role for the R2 subunit in *Drosophila* embryonic cell fate determination.

Both the *aar1* and *twins^P* mutant larvae have a specific reduction in phosphatase activity toward substrates of cyclin-dependent kinases, suggesting the R2 subunit directs PP2A toward these substrates.

The R2 subunit targets PP2A to pathways that regulate MAP kinase activity. Overexpression of the small-t antigen of SV40 virus disrupts endogenous PP2A complexes containing the R2 subunit. This leads to enhanced activation of MAP kinase in response to growth factors in some but not all cell types [26,27]. The small-t antigen effects may involve protein kinase C and the PI-3 kinase pathway [28]. Depletion of the R2 subunit in *Drosophila* S2 cells via RNA interference also leads to a prolonged activation of MAP kinase in response to insulin [17]. These studies indicate that the R2 subunit plays a negative role in regulating MAP kinase activity, presumably by targeting PP2A to a component that is activated by phosphorylation. The *C. elegans* R2 subunit (*sur-6*) was isolated as a suppressor of the multivulval phenotype caused by an activated ras mutation [29]. *Sur-6* mutations do not cause defects in vulval development by themselves but enhance the effects of weak mutant alleles of the *C. elegans* Raf protein kinase. These genetic interactions indicate that *sur-6* mutations reduce signaling through the Ras pathway and may act with the kinase suppressor of raf (KSR) protein in a common pathway to positively regulate signaling through the Ras-Raf-MAP kinase pathway. The PP2A core dimer can associate with the Raf-1 protein kinase (Table II). This interaction appears to mediate the dephosphorylation of inhibitory phosphorylation sites and enhance activation of Raf-1 during mitogenic stimulation [30]. This interaction does not appear to be mediated by the R2 subunit, since neither R2 α nor R2 β were detected in Raf-1 complexes. These studies suggest that PP2A is targeted to components of signaling pathways that regulate MAP kinase in both positive and negative ways. At least some of this targeting is mediated by R2 subunits. Multiple roles in MAP kinase signaling are consistent with genetic studies showing that mutations in the PP2A catalytic subunit have both positive and negative effects on MAP kinase activation in *Drosophila* [31]. The multiple actions in MAP kinase signaling are likely to be due to different forms of PP2A acting at distinct sites in this regulatory network.

Another R2-mediated proximity interaction regulates the microtubule cytoskeleton. A population of PP2A is associated with microtubules in neuronal and non-neuronal cells [32]. The association of PP2A with microtubules in brain is specific for R2 α - and R2 β -containing isoforms, and can be enhanced by a heat-labile anchoring factor [15]. PP2A holoenzymes containing R2 α or R2 β also interact with the neuronal microtubule-associated protein tau (Table II) and act as potent tau phosphatases [33]. The microtubule-binding and organizing activity of tau is regulated by phosphorylation. Hypophosphorylated forms of tau bind to microtubules, leading to increased microtubule stability. In contrast, hyperphosphorylated tau dissociates from microtubules, leading to a decrease in microtubule stability. Tau-dependent stabilization of microtubules is important for formation and maintenance

Table II PP2A Interacting Proteins

Protein	Comments	Refs
<i>Signaling proteins/transcription factors</i>		
Adenomatous polyposis coli (APC)	APC binds to R5 subunits in yeast two-hybrid assays. This interaction may target PP2A to the Wnt signaling pathway, but physical complexes between PP2A and APC have not been demonstrated. Overexpression of R5 subunits decrease β -catenin levels and suppress Wnt signaling.	[49]
Axin	Axin forms complexes with the C and R5 subunits. The interaction targets PP2A to a complex of axin, APC, GSK3, and β -catenin and plays a role in regulating Wnt signaling.	[50, 51]
Cas (p130 Crk-associated substrate)	Cas is a Src substrate that has increased association with PP2A when Src is activated. PP2A dephosphorylates serine residues on Cas <i>in vitro</i> .	[60]
E-cadherin/ β -catenin	The C $_{\alpha}$ but not the C $_{\beta}$ subunit is required for stabilization of E-cadherin/ β -catenin complexes at the Plasma membrane.	[61]
Heat shock transcription factor 2 (HSF2)	HSF2 interacts with the A-subunit in two-hybrid and co-immunoprecipitation assays. HSF2 may displace the catalytic subunit from PP2A holoenzymes.	[62, 63]
HOX11	HOX 11 is homeobox transcription factor that controls development of the spleen. HOX11 binds to the PP2A catalytic subunit and inhibits phosphatase activity. HOX 11 also interacts with protein phosphatase 1.	[64]
HRX	HRX binds to PP2A through the SET/I $_{2}^{PP2A}$ inhibitor protein. HRX is commonly mutated in acute leukemias.	[65]
Sex combs reduced (SCR)	SCR is a <i>Drosophila</i> homeobox transcription factor that interacts with the <i>Drosophila</i> R5 subunit in two-hybrid assays. SCR is homologous to human HOX5 and HOX6. PP2A may control phosphorylation and DNA binding activity of SCR.	[57]
RelA	RelA interacts with the scaffold subunit <i>in vitro</i> . The association may be transient since cross-linking is required to isolate a PP2A/RelA complex. RelA is dephosphorylated by PP2A <i>in vitro</i> .	[66]
Shc	PP2A associates with the PTB domain of Shc in the basal state and dissociates in response to insulin- and EGF-induced tyrosine phosphorylation. Expression of SV40 small-t antigen also causes dissociation of this complex.	[67]
Sp1	The Sp1 transcription factor interacts with the catalytic subunit in dividing T lymphocytes.	[68, 69]
Stat5	Stat5 associates with PP2A in an IL-3-dependent manner in the cytoplasm but not the nucleus.	[70]
<i>Cell cycle related proteins</i>		
Anaphase-promoting complex/cyclosome (APC/C)	APC/C binds to the adenovirus E4orf4-PP2A complex. E4orf4 may target PP2A to APC/C, leading to its inactivation. This interaction may play a role in E4orf4-mediated cell cycle arrest and apoptosis.	[71]
Cdc6	Cdc6 binds to the R3 γ /PR48 subunit and interacts with the AC-R3 γ heterotrimer. The interaction may regulate Cdc6 phosphorylation and DNA replication. Overexpression of R3 γ causes G1 arrest.	[43]
Cdc25c dual-specificity phosphatase	Cdc25c co-immunoprecipitates with PP2A following cross-linking of cell lysates. The interaction requires the R2 subunit and results in dephosphorylation of cdc25c. The interaction is enhanced by the HIV-1 Vpr protein, suggesting that dephosphorylation and inactivation of cdc25c is involved in Vpr-mediated G2 arrest.	[72]
Cyclin G2	The association of cyclin G2 with PP2A catalytic and R5 subunits correlates with its ability to inhibit cell cycle progression.	[54]
DNA polymerase α -primase	PP2A is recovered with the hypophosphorylated form of DNA polymerase α -primase in G1. PP2A dephosphorylates DNA polymerase α -primase and restores its origin-dependent initiation activity <i>in vivo</i> .	[73]
p107	p107 (a retinoblastoma-related protein) binds the R3 β /PR59 subunit-containing holoenzyme. Overexpression of R3 β /PR59 causes p107 dephosphorylation and G1 arrest.	[41]
<i>Membrane receptors/transporters</i>		
Beta $_{2}$ -adrenergic receptor	The association of PP2A with this G-protein coupled receptor is dependent upon agonist stimulation, receptor internalization, and acidification of endosomes. PP2A dephosphorylation is important for receptor resensitization and recycling to plasma membrane.	[74]
Biogenic amine transporters	Dopamine, norepinephrine, and serotonin transporters associate with PP2A. Transporter phosphorylation results in disruption of the PP2A association. The interaction may be involved in the regulation of the surface expression of transporters.	[75]
Class C L-type calcium channel (Ca $_{v}$ 1.2)	PP2A binds to the pore-forming α_{1C} subunit of this channel and reverses PKA-catalyzed serine phosphorylation. The interaction is selective for R5 γ -containing PP2A complexes.	[58]
CXCR2 chemokine receptor	The chemokine receptor CXCR2 is a G-protein coupled receptor involved in chemotaxis. CXCR2 interacts with the AC core dimer. The interaction is dependent on internalization of the receptor following agonist stimulation.	[76]
NMDA receptor	PP2A forms a stable complex with NR3A subunit of the NMDA receptor. The association increases phosphatase activity and dephosphorylation of the NR1 subunit. Stimulation of the receptor leads to dissociation of PP2A and a reduction in phosphatase activity.	[77]

Table II *continued*

Protein	Comments	Refs
<i>Protein kinases</i>		
CaM kinase IV (CaMKIV)	CaMKIV binds to the AC-R2 form and is dephosphorylated by PP2A.	[78]
Casein kinase II (CK2)	CK2 binds to the AC core dimer. CK2 can phosphorylate and stimulate PP2A activity <i>in vitro</i> .	[79]
JAK2	There is a transient association of JAK2 and PP2A upon interleukin-11 stimulation of adipocytes.	[80]
p21-Activated kinase (PAK1)	PAK1 interacts with and is a substrate of PP2A.	[81]
p70 S6 kinase	p70 S6 kinase is a PP2A substrate.	[81]
PKC α	The PP2A catalytic subunit co-immunoprecipitates with PKC α . PKC α is dephosphorylated by PP2A. This association may be involved in the regulation of mast cell IL-6 production.	[82]
PKC δ	PKC δ is a substrate for PP2A.	[83]
PKR (Double-stranded RNA-dependent protein kinase)	PKR binds to and phosphorylates the R5 α regulatory subunit. Phosphorylation of R5 α enhances PP2A activity and may alter the activity of the translation initiation factor eIF4.	[84]
RAF-1	RAF-1 interacts with the AC core dimer. PP2A dephosphorylates inhibitory sites on RAF-1.	[30]
Src	PP2A binds to the SH2, SH3, and catalytic domains of Src. This interaction decreases Src tyrosine kinase activity.	[85]
<i>Apoptotic proteins</i>		
Cyclin G1	Cyclin G1 binds to R5 subunits and the association is dependent on the induction of p53. Cyclin G1 plays a role in enhancing apoptosis.	[53, 55]
Bcl-2	Bcl-2 interacts with the PP2A isoform containing the R5 α subunit. PP2A dephosphorylates Bcl-2 and regulates the function of Bcl-2 in apoptosis.	[86–88]
<i>Cytoskeletal proteins</i>		
CG-NAP (AKAP 350/450/CG-NAP)	This 450-kDa centrosome and Golgi localized PKN-associated protein coimmunoprecipitates with PP2A in R3 α -130 expressing cells. CG-NAP is involved in regulation of centrosome dynamics during the cell cycle.	[40]
Mid-1	Mid-1 binds to the PP2A interacting protein alpha 4 at a site independent from the C-subunit binding site. This interaction may regulate mid-1 binding to microtubules and formation of the midline during embryonic development.	[89]
Myosin	PP2A associates with myosin following mast cell activation. This interaction may play a role in regulating cytoskeletal remodeling and mast cell secretion.	[90]
Neurofilament proteins (NFs)	The AC-R2 complex associates with NF proteins. PP2A dephosphorylates sites in all three NF proteins (NF-L, NF-M, and NF-H). Dephosphorylation by PP2A promotes assembly of NF-L into filaments.	[91, 92]
Paxillin	Paxillin interacts with C-subunit and R5 γ regulatory subunit. R5 γ 1 co-localizes with paxillin at focal adhesions and may target PP2A to paxillin.	[59]
Tau	Tau specifically interacts with R2-containing trimers. AC-R2 trimers dephosphorylate tau, promote microtubule binding, and stabilize microtubules.	[33, 93]
Vimentin	The AC-R2 complex associates with and dephosphorylates vimentin in an interaction mediated by the R2 subunit. Depletion of R2 by antisense RNA causes hyperphosphorylation of vimentin and reorganization of intermediate filaments.	[94]
<i>Secretory pathway proteins</i>		
Carboxypeptidase D (CPD)	PP2A binds to and dephosphorylates the cytoplasmic tail of this secretory pathway protein. PP2A may play a role in the intracellular trafficking of CPD between the cell surface and the trans-Golgi network.	[95]
Mannose-6-phosphate receptor (cation-independent)	PP2A binds to the cytoplasmic tail of this secretory pathway protein.	[95]
Peptidylglycine-a-amidating mono-oxygenase (PAM)	PP2A binds to the cytoplasmic tail of this secretory pathway protein.	[95]
TGN38	PP2A binds to the cytoplasmic tail of this secretory pathway protein.	[95]
<i>Translation</i>		
Eukaryotic termination factor-1 (eRF1)	eRF1 binds to the AC core dimer through C subunit. This interaction may target PP2A to ribosomes.	[96]
α 4/Tap42 (IGBP1)	Alpha 4 interacts directly with the C subunit and decreases phosphatase activity toward eIF4E-BP1 that has been phosphorylated by the mTOR kinase.	[97–100]

continues

Table II *continued*

Protein	Comments	Refs
<i>Viral proteins</i>		
Adenovirus E4orf4 protein	E4orf4 binds to the AC-R2 and AC-R5 complexes. Formation of a complex with AC-R2 is required for E4orf4-mediated apoptosis.	[56, 101, 102]
HIV Vpr protein	Vpr binds to AC-R2 complex and mediates Vpr-induced G2 arrest. This interaction regulates the Cdc25 dual-specificity phosphatase and Wee1 kinase.	[68, 72, 103]
Polyomavirus middle tumor antigen	Middle-T antigen binds to the AC core dimer and targets PP2A to the signaling complex assembled by middle-T antigen. The role of this interaction in middle-T mediated transformation is not clear.	[104–106]
Polyomavirus small tumor antigen	Similar to SV40 small-t antigen. Binds to the AC core dimer.	[104–106]
SV40 small tumor antigen	Binds to AC core dimer, displacing the R2 subunits and inhibiting PP2A activity toward some substrates. This interaction enhances MAP kinase signaling and viral transformation.	[104, 105]
<i>Other cellular proteins</i>		
I ₁ ^{PP2A} (PHAP1, mapmodulin)	I ₁ ^{PP2A} can inhibit PP2A activity <i>in vitro</i> , but its physiological function is unknown.	[107]
I ₂ ^{PP2A} (SET)	I ₂ ^{PP2A} can inhibit PP2A <i>in vitro</i> , but its function is unknown.	[108]
Phosphotyrosyl phosphatase activator (PTPA)	PTPA displays a weak interaction with PP2A and can enhance the low activity of the AC core dimer toward phosphotyrosine.	[3]
Protein phosphatase 5 (PP5)	PP5 interacts with the scaffold subunit of PP2A and may replace the catalytic subunit. The interaction appears to involve the R3 α subunit, which co-immunoprecipitates with PP5.	[39]
Protein phosphatase methyltransferase (PME-1)	Associates with catalytically inactive C-subunit point mutants. Demethylates the catalytic subunit <i>in vitro</i> .	[109]
SG2NA	SG2NA binds to the AC core dimer. The protein is localized in nucleus. SG2NA contains WD repeats, such as R2 subunits and striatin, and binds calmodulin. The function of SG2NA is currently unknown.	[10]
Striatin	Striatin binds to the AC core dimer. The protein contains WD repeats, such as R2 subunits and SG2NA, and binds to calmodulin. The function of Striatin is currently unknown.	[10]

of axons in the central nervous system [34]. Disruption of the PP2A-tau interaction by expression of SV40 small-t antigen (which disrupts interaction of R2 subunits with the core dimer) causes hyperphosphorylation of tau and its dissociation from microtubules [33]. These observations suggest that proximity interactions among R2-containing forms of PP2A, microtubules, and tau play important roles in maintaining tau in a hypophosphorylated state. The targeted dephosphorylation of tau is important for axonal integrity, since inhibition of PP2A leads to tau hyperphosphorylation, loss of organized microtubules, and axonal degeneration in cultured neuronal cells [35]. The R2-mediated interactions of PP2A with microtubules and tau may have implications in neurodegenerative diseases, including Alzheimer's disease, where tau becomes hyperphosphorylated.

Expansion of a novel CAG trinucleotide repeat within the human R2 β gene (PPPR2B) is associated with a form of autosomal dominant spinocerebellar ataxia termed SCA12 [36]. SCA12 is caused by neurodegeneration with atrophy of the cortex and cerebellum. The CAG expansion lies near the transcription start site of the R2 β gene and could alter expression of this brain-specific isoform. The presence of the CAG expansion in affected individuals and its absence in non-affected family members suggest that altered expression of R2 β may cause this disease. Although the mechanism of R2 β loss in SCA12 is unknown, these data suggest that R2 β may play a role in maintenance of neuronal viability.

The R3 Family

The second family of regulatory subunits identified by molecular cloning was the R3 family (Table I). The R3 subunit was first identified as a 74 kDa protein present in a PP2A holoenzyme termed PCS_M [37]. Current evidence indicates that this family plays a role in targeting PP2A to proteins involved in cell cycle regulation, including Cdc6, p107, and CG-NAP (Table II). The gene encoding the R3 subunit (designated R3 α in Table I) produces two alternatively spliced transcripts encoding proteins of 72 and 130 kDa [38]. R3 α -72 and R3 α -130 contain the same C-terminal protein sequence, but PR130 contains a 665-amino-acid N-terminal extension. Both the 72 and 130 kDa variants are selectively but not exclusively expressed in skeletal muscle and heart. *In vitro*, the R3 α subunit suppresses the activity of the AC dimer toward exogenous substrates and increases sensitivity of the enzyme to polycations [37]. The functions of R3 α -72 or R3 α -130 subunits have not been identified. Protein phosphatase 5 (another member of the PPP gene family) can interact with PP2A. Immunoprecipitated PP5 is associated with R3 α -72 but not other regulatory subunits [39]. Although the significance of this interaction is not known, the data suggest that PP5 can be present in a PP2A oligomer containing the scaffold and R3 α -72 subunits and that PP5 might act as the catalytic subunit in this heterocomplex. R3 α -130 interacts with the giant scaffolding protein CG-NAP (centrosome and

Golgi localized PKN-associated protein). CG-NAP anchors a signaling complex containing protein kinase-A, protein kinase-N, protein kinase-C ϵ , PP2A (R3 α -130), and protein phosphatase 1 to the centrosome and Golgi apparatus in a cell-cycle-dependent manner [40]. The CG-NAP signaling complex may mediate some of the complex phosphorylation-based regulation of the centrosome that occurs during the cell cycle. One potential substrate for PP2A in this complex is protein kinase-N.

The R3 family contains additional isoforms that function in cell cycle regulation through unique proximity interactions. The R3 β (PR59) protein was discovered in a yeast two-hybrid screen via the retinoblastoma-related protein p107 as bait [41]. R3 β forms complexes with the PP2A core dimer when expressed in cells. Although R3 β shares 56 percent identity with R3 α -72, the interaction with p107 is specific. Furthermore, although R3 β binds to p107, it fails to interact with the retinoblastoma protein. Forced overexpression of R3 β results in dephosphorylation of p107 and cell cycle arrest in the G1 phase. R3 β -mediated cell cycle arrest may be the result of hypophosphorylation of p107 (due to increased PP2A targeting) and its association with the E2F transcription factor. Binding of p107 to E2F would repress expression of genes required for entry into S phase. R3 β may be targeted to dephosphorylate p107 in response to UV irradiation [42].

The R3 γ regulatory subunit (PR48) was discovered in a yeast two-hybrid screen with the Cdc6 protein as bait [43]. Cdc6 is required for formation of pre-replication complexes during DNA replication. Phosphorylation of Cdc6 by S-phase cyclin-dependent kinases is the rate-limiting step for initiation of DNA replication. In mammalian cells, phosphorylation of Cdc6 at the beginning of S phase causes its dissociation from chromatin and triggers replication. In addition, Cdc6 phosphorylation induces its nuclear export and ubiquitin-dependent degradation. R3 γ shares 50 and 68 percent sequence identity with R3 α and R3 β , respectively. R3 γ localizes to the nucleus in mammalian cells and, like PR59, forced overexpression of PR48 results in cell cycle arrest at G1.

The R5 Family

The R5 regulatory subunits are a complex family of proteins that are components of a PP2A holoenzyme originally termed PP2A₀ [18,44]. There are at least five isoforms (Table I) that have distinct patterns of expression [45–47]. The α and γ isoforms are expressed predominantly in muscle, the β and δ isoforms in brain, and the ϵ isoform in brain and testis. In cardiac muscle, nearly all of the PP2A holoenzyme is composed of the R5 α subunit [44]. *In vitro*, the R5 subunits suppress phosphatase activity toward multiple substrates [14]. This implies that the R5 subunits target PP2A by disfavoring interactions with some substrates while favoring interactions with others. The R5 family has been subdivided into cytosolic and nuclear types based on localization of transiently expressed proteins [46,48]. The R5 α , R5 β , and

R5 ϵ isoforms are cytoplasmic whereas R5 γ and R5 δ are present in both the cytoplasm and nucleus. Ectopically expressed R5 subunits are also phosphorylated in intact cells. Thus, the regulation of PP2A or interaction with other proteins may be modulated by covalent modification of R5 family members.

The R5 subunits mediate interactions between PP2A and components of the Wnt signaling pathway involved in cell growth and transformation. Members of the R5 family were identified in a yeast two-hybrid screen by using the adenomatous polyposis coli (APC) protein as bait [49]. APC forms a signaling complex with axin and glycogen synthase kinase 3 β that mediates the phosphorylation and proteasome-dependent degradation of β -catenin. A basal level of β -catenin degradation normally prevents transcription of β -catenin target genes involved in cell growth and transformation. Stimulation of the Wnt pathway causes inhibition of β -catenin phosphorylation and degradation, leading to increased transcription of β -catenin target genes. Ectopic expression of R5 subunits in mammalian cells causes a reduction in β -catenin levels and a decrease in expression of β -catenin target genes. Further supporting a role for PP2A in the Wnt/ β -catenin pathway, the catalytic subunit of PP2A interacts with axin in two-hybrid assays and can be co-immunoprecipitated with axin [50]. Subsequent studies have shown that the scaffold subunit, the catalytic subunit, and R5 subunits can be immunoprecipitated with axin from *Xenopus* embryos [51,52]. Ectopic expression of the PP2A scaffold subunit, the catalytic subunit, or R5 subunits all have ventralizing activity in *Xenopus* embryos, consistent with a negative role in Wnt/ β -catenin signaling. The R5 subunits appear to interact directly with axin at a site that is distinct from the sites that interact with APC, GSK-3 β , and β -catenin [51]. The data are all consistent with an important role for R5 subunits in targeting PP2A to the axin/GSK-3/APC complex and regulating the Wnt signaling pathway.

The R5 subunits are also linked to cell survival and apoptosis. Cyclin G1, cyclin G2, and cyclin I are members of a unique family of cyclin-related proteins that are expressed in brain and muscle. R5 subunits interact with both cyclin G1 [53] and cyclin G2 [54]. Cyclin G1 and R5 subunits can be co-immunoprecipitated from neurons whereas cyclin G2-R5-catalytic subunit complexes can be isolated from cultured cells [54]. Although the function of the cyclin G1 is not known, the p53 tumor suppressor protein regulates its transcription. Ectopic expression of cyclin G1 enhances apoptosis in response to multiple stimuli in cultured cells [55]. Similarly, forced overexpression of cyclin G2 causes formation of aberrant nuclei and cell cycle arrest [54]. These observations raise the possibility that the cyclin G1-PP2A interaction could be involved in cell cycle arrest and apoptosis. The interaction of R5 subunits with the adenovirus E4orf4 protein is essential for E4orf4-mediated apoptosis [56]. Finally, the use of RNA interference in *Drosophila* cells has shown that loss of both of the *Drosophila* R5 subunits results in apoptosis [17].

R5 subunits interact with a variety of other proteins, thus indicating roles for this family in other signaling pathways (Table II). A *Drosophila* homolog of R5 interacts with a homeodomain-containing transcription factor called Sex Combs Reduced. This interaction positively modulates transcriptional activity [57]. The R5 γ subunit is associated with L-type calcium channels, where it appears to target PP2A to regulatory sites phosphorylated by protein kinase A [58]. R5 α interacts with the double-stranded RNA-dependent protein kinase PKR. PKR phosphorylates R5 α , leading to an increase in PP2A phosphatase activity. PKR-enhanced PP2A activity may lead to decreased phosphorylation of eIF4E and altered protein synthesis. R5-containing PP2A may also be targeted to focal adhesions through interaction with paxillin [59].

PP2A-Interacting Proteins

Proximity interactions are the most important mechanism for regulating the activity of PP2A. Association with interacting proteins mediates many proximity interactions of PP2A, and allows targeting of this phosphatase to a wide variety of signaling pathways. PP2A interacting proteins include phosphoproteins that are PP2A substrates, scaffold proteins, and components of the cytoskeleton. As discussed above, many of these interactions occur with PP2A holoenzymes and are mediated by specific regulatory subunits. However, interacting proteins have been identified that interact directly with the PP2A core dimer and the catalytic subunit. PP2A-interacting proteins include virally encoded proteins and a host of cellular proteins that participate in interesting aspects of signal transduction. A compilation of the currently identified PP2A-interacting proteins is presented in Table II. Although many of the proteins listed in the table are substrates for PP2A, others act to target PP2A to specific signaling complexes, and some alter signaling by disrupting endogenous PP2A complexes. These proteins have been grouped into categories based on functional similarities. Brief descriptions of individual proteins and their interaction with PP2A are presented in the table.

University of Michigan Medical School, Ann Arbor, Michigan*

Introduction

The second messenger cyclic AMP is a key component in intracellular signaling pathways in both prokaryotes and eukaryotes [2]. The enzyme responsible for its synthesis, adenylyl cyclase, is found in these organisms as either membrane-bound or soluble forms. Ten genes have been identified in mammals that encode either membrane-bound (AC1 to AC9) or soluble forms (sAC) of AC, and may be regulated by various factors [3–5]. Soluble and membrane-bound forms of AC encoded by genes from various genera have also been identified, although their modes of regulation are not fully appreciated [6,7].

In eukaryotes the primary role cAMP plays is to activate protein kinase A (PKA), however, cAMP also directly activates exchange factors of small molecular weight G proteins (Rap1A) [8,9], activates cyclic nucleotide-gated channels, and regulates the activity of some cGMP-specific phosphodiesterases [10]. Through protein phosphorylation activated PKA can regulate a plethora of enzymes, secondary kinases, transcription factors, receptors, and channels [11]. The actions of PKA may support mechanisms of feed-forward (activation) or feedback (desensitization and downregulation). In bacteria, cAMP binds directly to transcription factors and is responsible for repression of expression of genes involved in metabolism, also serving as a feedback mechanism [12].

In higher eukaryotes such as mammals, receptor-activated G proteins, Ca²⁺-activated calmodulin (CaM), protein kinases, and bicarbonate ions appear to be the native modulators of AC activity [3,4,13,14]. AC function may also be affected by cellular stress [15,16], as well as by exogenous small molecules such as adenosine analogs and the diterpene, forskolin. The responses to these regulators are exquisitely AC-subtype specific. Although several AC isoforms may be expressed together in the same cell, each isoform

may be selectively regulated by specific factors. Even though this complicates studies evaluating the physiological role of ACs, overexpression studies, gene knockouts, and gene mutations have been developed to elucidate these roles. Furthermore, aberrant AC is implicated in several human diseases, making this a very important molecule to study.

In recent years the biochemical characterization of ACs has been the subject of intense research. Through structural and functional approaches, researchers have gained a firm understanding of how ACs are regulated and even elucidated the mechanism of catalysis [17–19]. Moreover, improvements in biochemical approaches have allowed scientists to study the function of AC at cellular and even atomic detail. The following few pages will place emphasis on the mammalian forms of AC but highlight some differences in the ACs from other genera. We will summarize our current understanding of the mechanism of regulation of ACs, summarize the catalytic mechanism, and discuss the physiological roles this regulation plays in the function of AC.

Structure-Function

Ten AC isoforms, nine membrane-bound and one soluble, have been identified and cloned in mammals [3,4,6,13]. The membrane-bound forms share the same topology in that they are composed of 12 transmembrane (TM) segments and 2 large cytoplasmic domains (C1 and C2). These proteins exist in the membrane as tandem repeats of 6-TM regions followed by a large cytoplasmic loop (Fig. 1A and Fig. 2A). The sequence similarity between the different ACs is about 60% with the most conserved residues residing in the cytoplasmic domains. These two loops also share considerable sequence similarity with guanylyl cyclases (GC), to the degree that as few as two point mutations may be introduced into AC to convert it to a functional GC.

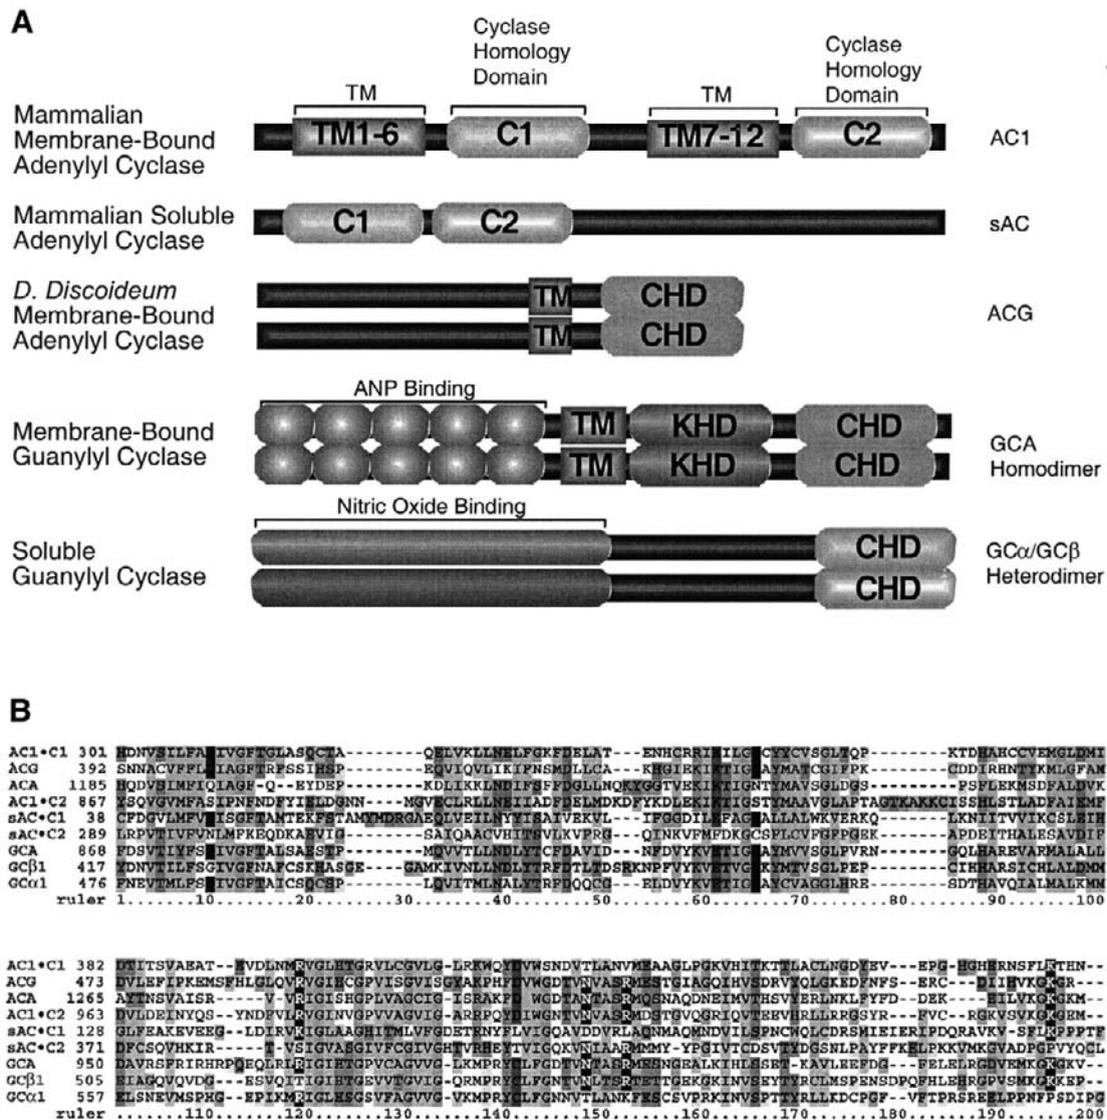

Figure 1 (A) This is the alignment of the domain structure of adenylyl and guanylyl cyclases. The putative domain structures of the cyclase homology domain (CHD), green and light blue; transmembrane domain (TM), yellow; ligand binding domain for atrial natriuretic peptide (ANP), pink; heme binding domain where nitric oxide binds, silver; and the kinase homology domain (KHD), purple. Note that the functional enzymes are organized as homo- or heterodimers of the catalytic domains. Membrane-bound and soluble ACs have both domains contained within one polypeptide, whereas the other cyclases require two proteins to have activity. (B) This is the alignment of the amino acid sequences of the adenylyl and guanylyl cyclases. Amino acid sequences bovine AC1 (GI: 162612), rat sAC (GI: 11067412), *Dictyostelium discoideum* ACG (GI: 167661) and ACA (GI: 457431), rat GC-A (GI: 204265), rat soluble GC α 1 (GI: 1655846), and rat soluble GC β 1 (GI: 6980995). The mammalian ACs (AC1 and sAC) are divided into the C1 and C2 domains. Only the C2 domain from the *D. discoideum* ACA was included. The selected cyclase sequences were chosen as representative of eukaryotic nucleotide cyclase and were not singled out based on regulatory or mechanistic attributes. Residues are color coded to outline residue conservation. Residues that are important to enzyme function are also color coded as follows: lysine (K), glutamate (E), aspartate, (D) and cysteine (C) residues which contribute toward substrate specificity are boxed in red; conserved aspartate (D) residues which coordinate the two magnesium ions are boxed in royal blue; residues (arginine, R; asparagine, N; and lysine, K) which contribute toward stabilizing the transition state and that coordinate polyphosphate binding are boxed in black.

Several other unique forms of AC have been found in invertebrates as well as pathogenic bacteria. In the slime mold *Dictyostelium discoideum*, two diverse ACs containing a single TM region (ACA and ACR) have been identified, in addition to the canonical 12-TM form [20,21]. The bacteria *Bordetella pertussis*, *Bacillus anthracis*, and *Pseudomonas aeruginosa* each excrete exotoxins, which possess AC

activity [22–24]. These soluble ACs are taken up by host cells where they are then activated and begin producing very high levels of cAMP, thereby disrupting intracellular signaling pathways.

The X-ray crystal structure of the cytoplasmic C1 and C2 domains has recently been solved and has provided much information about the relevant active sites as well as the

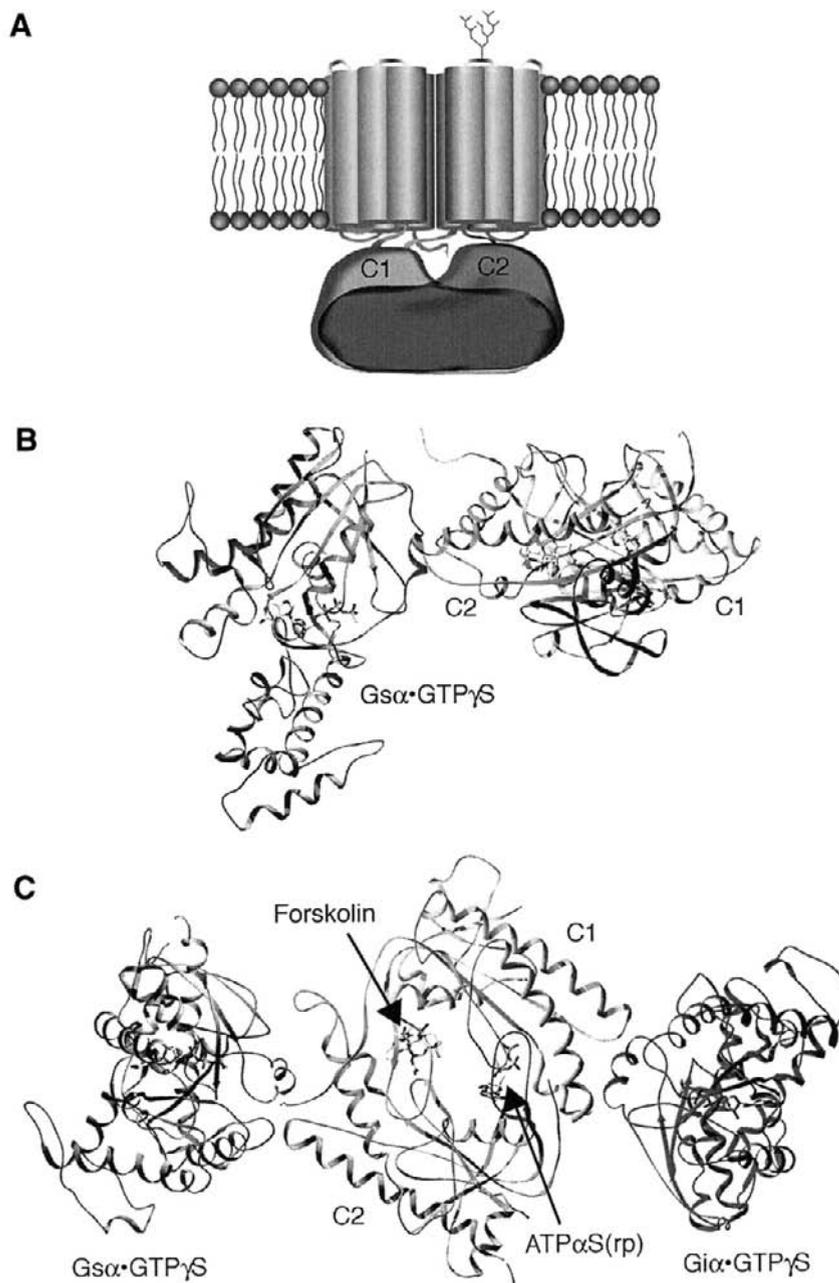

Figure 2 (A) This is an illustration of the membrane topology of a typical mammalian membrane-bound adenylyl cyclase. The 12-TM domain polypeptide also contains two large and homologous cytoplasmic domains each approximately 40 kDa in size. The C1 domain (lime green) and the C2 domain (sky blue) are represented by pseudosymmetrically related globular proteins. An asparagine-linked glycosylation site is also depicted in green. (B) This is an X-ray crystal structure of the stimulatory G protein, Gsα, bound to the catalytic core of adenylyl cyclase. GTPγS-activated Gsα (gray steel) is shown bound to the C1(lime green) and C2 domain (sky blue) of adenylyl cyclase in the presence of forskolin and substrate inhibitor, ATPαS(rp). Illustrations were generated using SwissPDBViewer [73] and rendered with POV-RAY™ using the coordinates for the Gsα-GTPγS·C1·C2·Fsk complex with ATPαS(rp) in the presence of Mn²⁺ and Mg²⁺ (PDB id: 1CJK)[26]. (C) Rotated view of the Gsα-GTPγS·C1·C2·Fsk structure in (B) and with Giα-GTPγS (PDB id:1GIA) modeled into the pseudosymmetrically related Gsα-binding site. Visible also is the diterpene activator forskolin and the substrate inhibitor, ATPαS(rp). Note the twofold pseudosymmetry in the C1·C2 complex.

mechanism of catalysis (Fig. 2C) [17,18]. The catalytic core of AC is composed of a heterodimer of the C1 and C2 domains, which are related to each other by a twofold pseudosymmetry (Fig. 2). Forskolin binds to a hydrophobic pocket at the interface of the two domains, while G proteins bind on the surface, contacting both domains. The active site of catalysis, where nucleotides bind, is also located at the interface of the C1 and C2 domains and is pseudosymmetrically related to the forskolin binding site. The residues in this active site that are responsible for coordinating the binding of the nucleotide as well as two magnesium ions are highly conserved across all isoforms of both AC and GC [25,26]. In a manner similar to DNA and RNA polymerases, RNA spliceosomes, and reverse transcriptases, ACs utilize the metals to both stabilize the transition state of the reaction and also to deprotonate the 3' hydroxyl moiety of the ribose ring of ATP [19]. This is a key step that is necessary for the nucleophilic attack on the alpha phosphate by the newly formed oxyanion. The products are cAMP and the leaving group in the reaction, pyrophosphate (PPi).

The structure of AC from *Trypanosoma brucei* was recently solved and shares a similar protein-fold to the mammalian forms [27]. In sharp contrast, the structure of the catalytic AC domain of the exotoxin from *B. anthracis* recently delineated by the Tang laboratory, portrays a highly divergent protein-fold and a completely different catalytic mechanism [28]. AC from *B. anthracis* utilizes the traditional catalytic triad consisting of histidine, serine, and aspartic acid residues to stabilize the transition state and deprotonate the 3'-OH.

Regulation

In invertebrates or vertebrates, neurotransmitter and hormonal regulation of ACs occurs primarily through heterotrimeric G proteins [29] (Table I and Fig. 3 for summary). G-protein-coupled receptor (GPCR) activation by these extracellular stimuli in turn leads to activation of bound G proteins by initiating the exchange of GDP for GTP. The α subunit of the stimulatory G protein ($G_s\alpha$) activates all nine membrane-bound isoforms of AC in a nucleotide-dependent fashion, preferring the GTP-bound form to the GDP-bound form by a factor of 10 [4,13,30,31]. $G_s\alpha$ activation of ACs is terminated by GTP hydrolysis to GDP, a reaction that is accelerated by RGS proteins [32,33]. The α subunits of the inhibitory family of G proteins, $G_{i1,2,3}$, G_o , and G_z [34–36], inhibit AC activity, as the name would indicate, in an isoform-dependent manner [3,4,13,30]. G_{i1-3} , $G_{o\alpha}$, and $G_z\alpha$ inhibit AC5 and AC6, and $G_{o\alpha}$ also inhibits AC1 and possibly AC8. For AC5 and AC6 $G_{i\alpha}$ -inhibition does not occur by competition with $G_s\alpha$; in fact, mutagenesis experiments suggest that $G_{i\alpha}$ binds to a site pseudosymmetrically related to the $G_s\alpha$ site, on the opposite side of AC (see Fig. 2C) [37]. $G\beta\gamma$ subunits are also important modulators of AC activity. They can potently stimulate the activity of AC2, AC4, and AC7, but in a manner that is dependent on

co-activation by $G_s\alpha$ [34,38]. $G\beta\gamma$ subunits are also potent inhibitors of AC1 and AC8 [34].

CaM is a ubiquitous Ca^{2+} sensor protein and is a potent activator of several mammalian membrane-bound AC isoforms: AC1 [39], AC8 [40], and perhaps AC3 [41]. The primary source of calcium ions is thought to be derived from capacitative entry through Ca^{2+} channels, rather than the G-protein-regulated and inositol triphosphate (IP3) sensitive release of Ca^{2+} from intracellular stores [42,43]. CaM is also implicated in the pathology of the bacterial exotoxins mentioned above, as it is the principal AC activator [44,45]. CaM activation of edema factor (EF; the exotoxin from *B. anthracis*) yields a catalytic rate 1000-fold higher than that of CaM-activated mammalian ACs.

CaM also inhibits AC1 and AC3 indirectly through the activity of CaM-dependent protein kinase II and IV (CaMKII, IV)[46,47]. Phosphorylation of AC1 and AC3 by CaM kinases inhibits cyclase activity by blocking the binding of activators. In this sense, posttranslational modification of ACs by phosphorylation is generally inhibitory and can also be caused by the PKA as well as protein kinase C (PKC). PKA supports a negative-feedback mechanism whereby the more cAMP that is produced by ACs, the more PKA is activated, and thus the more ACs that are phosphorylated and inhibited.

The effects of Ca^{2+} have also been shown to be quite inhibitory on AC5 and anthrax [48,49]. Low micromolar concentrations of Ca^{2+} , well below the toxic levels and certainly within the physiological dynamic range found in a cell, effectively and specifically inhibit these two isoforms. While all isoforms of AC are inhibited by higher concentrations (mM), the effect on these isoforms are consistent with levels derived from capacitative entry, similar to the CaM-dependent stimulatory effect.

The small molecule forskolin (isolated from the plant *Choleus forskohlii*) is a potent activator of all mammalian membrane-bound isoforms of AC except for AC9, which is weakly activated [50]. AC isoform-specific forskolin analogs have been discovered using structural-based drug design, and it has been hypothesized that endogenous forskolin-like molecules may exist [51]. While the binding site of forskolin is within the conserved catalytic domain, the stimulatory actions appear to be selective for the membrane-bound vertebrate and invertebrate forms [50].

In contrast, ACs are inhibited by a class of adenosine analogs known as P site inhibitors [52]. These small molecules act by binding to a conformation of the enzyme that closely resembles the product-bound state or the posttransition state [53,54]. Inhibition is enhanced with the presence of PPi. The potency of P-site inhibitors is therefore increased by higher levels of AC activity [53]. Several adenosine analogs have been developed that appear to display some isoform preference [51,55]. In addition, polyphosphorylated acyclic nucleosides (such as 9-(2-triphosphonyl-methoxyethyl) adenine, PMEApp) and foscarnet (phosphonoformic acid), also inhibit ACs [55,56]. Both drugs are used clinically as antiviral and antifungal agents and share a similar proposed mechanism of action as the P-site inhibitors on AC. It should be noted

Table I Summary of the Regulatory Properties of the Mammalian Adenylyl Cyclases*

AC isoform	Tissue distribution	G α s	G $\beta\gamma$	G α i	Protein kinases	Calcium	Forskolin	Notes
AC1	Brain, adrenal (medulla)	↑	↓	↓(G α o)	↑ PKC ↓ CaMKIV	↑ CaM	↑	
AC2	Brain, skeletal muscle, Lung (heart)	↑	↑*		↑ PKC		↑	
AC3	Brain, olfactory epithelium	↑			↑ PKC ↓ CaMKII	↑ CaM	↑	
AC4	Brain (heart, kidney, liver, lung, BAT, uterus)	↑	↑*		↑ PKC		↑	
ACS	Heart, brain, kidney, liver, lung, Uterus, adrenal, BAT	↑	↓	↓	↑ PKC α , ζ ↓ PKA	↓	↑	
AC6	Ubiquitous	↑	↓	↓	↑ PKC ↓ PKA	↓	↑	
AC7	Ubiquitous, High in brain	↑	↑*		↑ PKC		↑	
AC8	Brain, lung (testis, adrenal, uterus, heart)	↑				↑ CaM	↑	
AC9	Brain, skeletal muscle	↑						
sAC	Testis							↑ Bicarbonate

*G $\beta\gamma$ stimulation of AC isoforms is conditional upon G α co-activation.

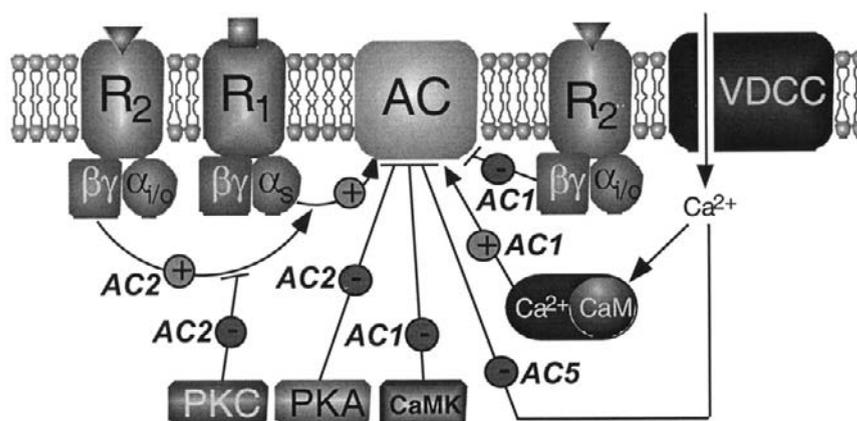

Figure 3 This is an illustration of the complex modes of regulation of membrane-bound mammalian adenylyl cyclase. Summarized are the stimulatory (green circles with pluses) or inhibitory (red circles with minuses) influences of hormone-receptor-mediated G-protein regulation, protein kinase regulation, and Ca²⁺ and/or CaM effects on AC activity. AC isoform-specific effects are demarcated in italics beside the stimulatory or inhibitory signs. For example, the G $\beta\gamma$ effects are inhibitory on the AC1 family of cyclases (AC1, AC8, and presumably AC3) and stimulatory on the AC2 family of cyclases (AC2, AC4, and AC7). The stimulatory effects of G $\beta\gamma$ are dependent on prior activation by G α s. Ca²⁺-CaM directly and potently activates the AC1 family of cyclases, whereas Ca²⁺ alone effectively inhibits the AC5 family of cyclase (AC5 and AC6). Not illustrated is forskolin, which activates all membrane-bound isoforms except AC9.

that the primary therapeutic target of these compounds is the mechanistically similar viral polymerases and transcriptases.

The lone soluble mammalian AC isoform (sAC) is as unique in overall structure as it is unique in regulation [6,7,57]. sAC activity is not affected at all by the classic AC modulators: G proteins, CaM, or forskolin [57]. Instead, it is activated *in vivo* as well as *in vitro* by bicarbonate ions [14]. Soluble forms of AC in prokaryotes are also sensitive to bicarbonate, suggesting that sAC is an evolutionarily conserved bicarbonate sensor [15]. The single TM domain AC in *Dictyostelium* is unique in the same way. It is regulated by

osmotic stress; however, it is not yet clear if it actually has intrinsic osmosensing activity [16]. Although the mechanisms of regulation of these isoforms are quite different, the sequence of the catalytic domains are similar and the putative catalytic residues are conserved.

Physiology

Adenylyl cyclases are studied in many systems and have been implicated in numerous physiological roles. At the least,

it is known that all mammalian AC isoforms are expressed in the central nervous system and in excitable tissues; but, for the most part, AC is expressed in nearly every tissue (see Table I). More precise patterns of expression have been difficult to obtain due to relatively low levels of expression as well as a general lack of highly specific antibodies. Exceptions in expression patterns do exist, most notably in sAC, which is most highly expressed in the testis [6].

The precise roles of specific AC isoforms have been difficult to assess because most cells express multiple isoforms. The specific contributions of these ACs have only recently been segregated from the remaining isoforms. Researchers have taken advantage of genetic mutations in AC or gene disruption using homologous recombination in mice. Several studies have investigated the function of AC in the *Drosophila* mutant *rutabaga* [58]. These mutants are deficient in a calcium-activated AC, which is quite similar to the mammalian AC1. Deficiency of this AC causes these flies to avoid a trained odor, indicating that AC1 is important in memory and learning [59]. Likewise, specific disruption of the AC1 gene in mutant mice or the spontaneous mutation of AC1 in the *barrelless* mouse, have a negative effect on long-term potentiation (LTP) [60,61]. AC1 and AC8 are both necessary for both late-LTP (L-LTP) as well as long-term memory (LTM) [62]. Knockouts of either AC gene by itself yields normal L-LTP and LTM; however, double knockout mice exhibit no L-LTP or LTM. This effect can be reversed by infusion of forskolin into the hippocampus, which may compensate the null AC1 and AC8 by producing cAMP through other AC isoforms.

AC3 has been demonstrated to be involved in transmitting olfactory responses in mice [63]. AC isoforms 2,3, and 4 are all present in olfactory cilia; however, it is interesting that a knockout of just AC3 is sufficient to completely ablate responses to odorants. It has also been shown that ACs are important in developing drug dependencies. Following chronic opiate treatment, several ACs are upregulated and become supersensitized to additional stimulation by either Gs α or forskolin. Specifically, AC1, AC5, AC6, and AC8 are sensitized, while AC2, AC3, AC4, and AC7 are not [64–66]. Depending on the system, upregulation of AC may or may not involve a transcriptional step.

Upregulation of AC isoforms is also important for cell differentiation. AC2, AC5, and AC6 are upregulated in differentiation of pluripotent PI9 cells. Additionally, upregulation of AC2, AC5, and AC8 accompany neuronal differentiation [67]. It is also interesting that ectopic expression of AC2 in NIH3T3 cells inhibits cell cycle progression [68]. One resulting hypothesis is that for cell differentiation to occur, upregulation of AC2 is necessary to induce a temporary arrest of cell proliferation.

Summary

Adenylyl cyclase is clearly an incredibly important molecule as it is intimately involved in the very complex

signaling pathways that regulate the numerous facets of life itself. The identification and characterization of ACs has come a long way since the initial discovery of cAMP nearly forty years ago, especially with recent advances applying molecular genetic and structural biology approaches. Nevertheless, many important questions still remain unanswered. For instance, what is the function of the 12-TM domain structure, other than localizing ACs to the membrane? Can the 12-TM structure support transport of molecules across the plasma membrane, as originally proposed when the first AC cDNA [39] was reported? Membrane-bound isoforms of ACs have recently been shown to homodimerize [69]. Although the relevance of AC dimerization is unknown, it is particularly intriguing with regard to the specter of heterodimerization. Heterodimers between different AC isoforms would add a new dimension to the already complex network of AC regulation. In any case, much more research is needed to more fully understand the precise regulation and physiological roles of ACs.

Guanylyl Cyclases

Ted D. Chrisman and David L. Garbers

*Cecil H. & Ida Green Center for Reproductive Biology Sciences,
Howard Hughes Medical Institute and Department of Pharmacology,
University of Texas Southwestern Medical Center, Dallas, Texas*

Receptor guanylyl cyclases and their ligands together with guanosine-3',5'-monophosphate (cGMP), and its effectors compose signal transduction pathways regulating essential tissue and cell functions. For example, cGMP is the documented second messenger for NO- and atrial natriuretic peptide (ANP)-induced vascular smooth muscle relaxation, and in the kidney cGMP mediates ANP-induced natriuresis and diuresis. Likewise, pathologic elevations of cGMP in intestinal mucosal cells result in severe diarrhea in response to secretion of a heat-stable peptide (Sta) from pathogenic strains of *Escherichia coli*; Sta is a potent agonist of a guanylyl cyclase in these cells. And disruption of the murine C-type natriuretic peptide (CNP) gene, a ligand for a chondrocyte guanylyl cyclase, results in dwarfism and early death, while disruption of a photoreceptor guanylyl cyclase results in cone-specific dystrophy in the mouse. Therefore, the various guanylyl cyclase/cGMP signaling pathways are physiologically important, but the relevance of the interactions with other signaling pathways has been less clear. Recently, cGMP signaling pathways have been shown to impact on signaling systems that regulate cell proliferation and differentiation.

Historic Perspectives

Guanylyl cyclases catalyzing the formation of cGMP and pyrophosphate (P~P) from MgGTP or MnGTP were identified in crude extracts of mammalian tissues shortly after the discovery of cGMP in rat urine [1]; importantly those studies established that the guanylyl cyclases were distinct from adenylyl cyclases implying different functions for each of the families of cyclases. Differences in subcellular distribution and kinetics of guanylyl cyclases in mammalian tissue homogenates prompted the suggestion that different forms of the cyclase exist rather than there being a differential

distribution of a single form of the enzyme. Several decades later through the use of recombinant DNA technology, the early speculations were confirmed, and two categories of guanylyl cyclases were identified through cloning: single-pass plasma membrane or particulate guanylyl cyclases (pGC) and cytosolic or soluble guanylyl cyclases (sGC). P~P has not been shown to signal, and thus cGMP is considered the second messenger following ligand activation and no initial signaling pathway other than the generation of cGMP has yet been firmly documented for any of the cyclases (Fig. 1).

Guanylyl Cyclases

Seven single-pass plasma membrane (pGC) and four cytosolic or soluble (sGC) guanylyl cyclase subunits have been identified in mammals. Many more (23 putative guanylyl cyclase genes) have been identified in *Caenorhabditis elegans*, and multiple-pass plasma membrane cyclases, similar to the mammalian membrane forms of adenylyl cyclase, have been reported in *Dictyostelium discoideum*, *Plasmodium falciparum*, *Paramecium tetraurelia*, and *Tetrahymena pyriformis* [1].

The seven mammalian pGCs (GCA through GCG) are expressed in many different tissues and cultured cells (Table I). The structurally similar 120- to 140-kDa proteins contain an amino terminal extracellular domain (BCD; the apparent ligand-binding domain is the least similar within the family), a single-pass transmembrane domain (TMD), a protein kinase homology domain (KHD; 30% homologous to protein kinase catalytic domains [2], and a carboxyl-terminal cyclase catalytic domain (CCD; the most conserved and the most highly similar to adenylyl cyclases [1]). Homodimeric plasma membrane cyclases appear to be preferentially expressed *in vivo* even though more than one cyclase is expressed

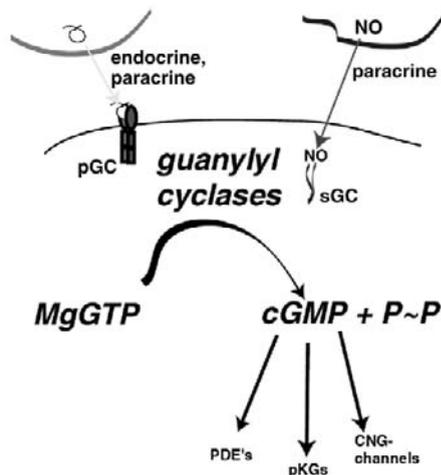

Figure 1 The two general forms of guanylyl cyclase found in mammals. The plasma membrane (pGC) forms exist as minimal homodimers and the soluble (sGC) forms exist as minimal heterodimers to display catalytic activity. The increased concentrations of cGMP found as a result of stimulation of these forms then acts on phosphodiesterases (PDEs) that are stimulated or inhibited by cGMP, ion channels (CNG) directly gated by cGMP, or on cGMP-dependent protein kinases (PKGs) to elicit a cell behavioral response.

simultaneously by a single cell. The minimum catalytic unit of the pGCs appears to be that of a homodimer [3] (Fig. 2).

The sGCs are heterodimeric proteins composed of subunit isoforms α (cti, 0.2, both 82 kDa) and β (pi, 70 kDa; 02, 76 kDa) and are expressed in many of the same cells and tissues as the pGCs (Table II). A heme moiety noncovalently bound to the β subunit amino terminus confers ligand (NO) sensitivity to the cyclase. Two human subunits, named 0.3 and ps are orthologs of rat oti and pi. The aipi heterodimer is more commonly found *in vivo* but aapi has been detected as well. The β subunit also contains a potential geranylgeranylation site [4] raising the possibility of plasma membrane localization of this form and the possibility therefore of NO-stimulated cGMP elevations at the level of the membrane. The minimum active mammalian soluble cyclase appears to be a heterodimer as expression of a or β subunits alone results in no detectable guanylyl cyclase activity while co-expression of various subunits produces high-soluble guanylyl cyclase activity. The studies of Sunhara *et al.* [5] and of Liu *et al.* [3] also support the existence of a dimer as the minimal unit for catalytic activity.

Guanylyl Cyclase Ligands

Ligands have been identified for some but not all mammalian GCs (Table II). Human ANP (28 amino acids), brain natriuretic peptide (BNP, 32 amino acids), and CNP (22 or 53 amino acids) compose a family of distinct and structurally similar oligopeptides having a highly conserved 17-member ring required for biological activity. ANP and BNP are endocrine ligands released from the heart that promote natriuresis, diuresis, and vasorelaxation by direct activation of GCA

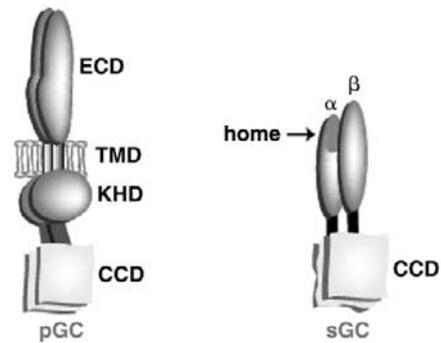

Figure 2 The general domain structure of the membrane forms (pGC) or the soluble forms (sGC) of guanylyl cyclase. BCD represents the extracellular ligand binding domain, TMD the transmembrane segment, KHD the protein kinase homology domain, and CCD the cyclase catalytic domain. The KHD appears to bind ATP as a regulatory molecule. For sGC, the subunits of the heterodimer have been arbitrarily named α and β . Heme binds to the amino terminal region, probably to the β subunit.

in the kidney, in vascular smooth muscle, or the adrenal gland. CNP, classified as a natriuretic peptide by virtue of its structure and the only known ligand for GCB, has no known tissue depots and only marginally mimics the vascular and renal actions of ANP and BNP. CNP is generally considered a paracrine ligand involved in regulation of cell proliferation and differentiation [6,7].

ANP, BNP, and CNP bind with near equal avidity to a third cell surface receptor, the natriuretic peptide clearance receptor (NPR-C). NPR-C has a BCD similar to GCA and GCB, a short cytosolic domain devoid of the KHD and CCD, and is expressed by most mammalian cells. Internalization of the peptide-receptor complex serves to remove or "clear" natriuretic peptides from the extracellular space thus buffering their effects on cell function. There is some evidence suggesting that NPR-C may also signal via a pertussis-toxin-sensitive pathway to inhibit adenyl cyclase [8].

GCC was identified initially as the receptor for the enterotoxin, Sta. Subsequently three mammalian ligands for GCC, guanylin, uroguanylin, and lymphoguanylin were isolated. All are small peptides with structural homology and sequence identity and expressed in the intestine and other tissues.

NO, the ligand for sGCs, has diverse actions on cardiovascular, renal, and immune cell function and is expressed by many cell types [1]. NO has effects similar to the natriuretic peptide signaling pathways in those cells where GCA, GCB, and sGC are expressed.

Extracellular ligands for GCE, GCF, and GCD have not been identified and remain orphan receptors. GCE and GCF (human RetGC-1 and RetGC-2), expressed in photoreceptors, are activated intracellularly by Ca^{2+} -free forms of guanylyl cyclase activating proteins (GCAPs) which bind to the coiled-coil region linking the KHD and CCD [9,10]. Although GCE and GCF may not require extracellular ligands based on these observations, the conservation of Cys within the BCD compared to the guanylyl cyclases with known ligands, and the conservation of the BCD across all vertebrates that have been studied suggests heavy evolutionary pressure

is being exerted to retain the BCD structure. One source for this pressure would be the need to recognize a ligand.

cGMP Effectors

At least three classes of cGMP-binding proteins amplify and mediate changes in intracellular cGMP levels in mammalian tissues: cGMP-dependent protein kinases (PKG), cyclic nucleotide-gated (CNG) ion channels, and cyclic nucleotide phosphodiesterases (PDE). The serine/threonine protein kinases PKG1 and PKG2 mediate most of the known effects of cGMP. The cytosolic PKG1 is the more widely distributed form, highly expressed in vascular smooth muscle, cerebellum, and platelets. Gene disruption of this kinase in the mouse results in vascular, intestinal, and erectile dysfunctions [1]. PKG2, abundant in intestine, bone, lung, and brain, contains a myristolated site and is localized to the plasma membrane, and gene disruption in the mouse results in resistance to Sta-induced diarrhea, intestinal secretory defects, and dwarfism [11].

The 11-gene PDE family functions to decrease signaling levels of both cGMP and cAMP and also provides a point at which both cGMP and cAMP signaling pathways can intersect. PDE5, -6, and -9 are cGMP-specific [12], cGMP-stimulated PDE-2 hydrolyzes both cGMP and cAMP, and PDE3A is a cGMP-stimulated, cAMP-specific family member.

Cyclic nucleotide-gated channels are ubiquitously expressed, the prototypical CNG channel being the photoreceptor, relatively nonselective cation channel.

Guanylyl Cyclases and Cell Growth Regulation

Although NO, ANP, and BNP appear to be important counterbalances to the renin/angiotensin/aldosterone axis in the cardiovascular system, there is considerable and convincing evidence that various guanylyl cyclases also regulate cell proliferation and differentiation. The molecular basis of such regulation remains principally at the descriptive level in that a number of growth factors, including serum, act rapidly to desensitize either GCA or GCB [1,13] and likewise, cGMP, possibly in the same manner as cAMP, inhibits growth factor activation of the MAP kinase pathway. Interestingly, this apparent adversarial relationship between various mitogens and the guanylyl cyclases appears to primarily involve the membrane forms of the enzyme [13]. In fibroblasts, whereas serum, basic fibroblast growth factor, or platelet-derived growth factor decrease CNP-stimulated GCB activity, they fail to alter the activity of NO-stimulated guanylyl cyclase [13]. Identification of the pathway by which the various mitogens, including serum, communicate with the membrane forms of guanylyl cyclase, in particular GCA and GCB, remains unknown.

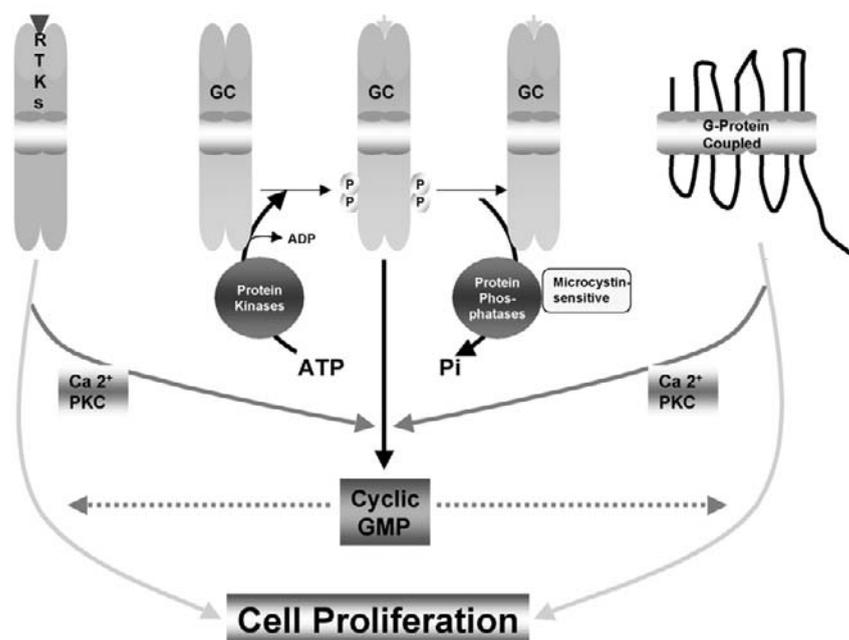

Figure 3 Schematic showing the adversarial relationship between various growth factor receptor signaling pathways and guanylyl cyclases A and B. By mechanisms not yet understood, various growth factors including serum act on receptor tyrosine kinase receptors or G-protein-coupled receptors to rapidly desensitize the ligand-stimulated forms of GCA or GCB. Both Ca²⁺ and protein kinase C (PKC) have been suggested as important components of the desensitization pathway. The dephosphorylation of the guanylyl cyclase receptor, leading in part or totally to desensitization, is mediated by a microcystin-sensitive protein phosphatase. Likewise, cGMP inhibits activation of the MAP kinase pathway in response to growth factors or serum. The subsequent rate of cell proliferation is dictated by whether the guanylyl cyclase or mitogen-stimulated pathways are dominant.

Both GCA and GCB appear to exist in a phosphorylated state in the absence of ligand, and it is the phosphorylated form that is most sensitive to the addition of ligand. Based on the work of Potter and Hunter [14], 6 principal sites of phosphorylation exist, all located within or just to the amino terminal side of the consensus protein kinase homology domain. A number of reports have suggested that dephosphorylation at these sites leads to desensitization of either GCA or GCB [14]. However, neither the protein kinase(s) nor the protein phosphatase(s) responsible for the apparent regulation of these receptors have been identified, although the protein phosphatase(s) responsible for dephosphorylation have been shown to be particularly sensitive to inhibition by microcystin [15,16] (Fig. 3). A significant number of reports suggest that activation of protein kinase C is one of the important upstream events that lead to desensitization of the natriuretic peptide receptors [14,17], where even the dephosphorylation of a single serine through activation of the protein kinase C pathway appears to desensitize GCB [18]. However, the recent work of Abbey and Potter [17] suggest that not only protein kinase C but also the other arm of the phospholipase C pathway (IPS/Ca²⁺) is capable of causing desensitization of GCB. Their work in A10 smooth muscle cells further suggests that it is the elevations of Ca²⁺ that are required for the desensitization. Interestingly, however, the degree of desensitization obtained through elevations of Ca²⁺ alone are not equivalent to those seen through activation of the phospholipase C pathway [17]. Identification of the guanylyl cyclase protein kinase(s) and phosphatase(s) now seems essential for the understanding of the mechanisms by which the various mitogens, acting through either G-protein-coupled or receptor tyrosine kinase receptors mediate a rapid and marked decrease in guanylyl cyclase activity, where Ca²⁺ or protein kinase C may often serve as upstream regulators.

Phosphodiesterase Families

Jennifer L. Glick and Joseph A. Beavo

Department of Pharmacology, University of Washington, Seattle, Washington

Introduction

The cyclic nucleotides are ubiquitous second messengers that regulate a large number of processes, including proliferation, chemotaxis, differentiation, contraction, gene transcription, and inflammation. These second messengers are produced and utilized by nearly all eukaryotes from amoebae to man. Regulation of the intracellular levels of cGMP or cAMP, both in the resting state and in response to stimuli, is therefore critical for the proper functioning and survival of many organisms. The levels of a cyclic nucleotide in the cell are determined by the relative rates of synthesis by the cyclases, adenylate cyclase, and guanylate cyclase and degradation by the phosphodiesterases (PDEs). Although the generation of cyclic nucleotide signals in many systems has been the subject of intense study, the understanding of the mechanism by which these signals are terminated by the PDEs is, in most cases, still in its infancy. This is curious as the cyclase and phosphodiesterase activities were discovered within a few years of one another [1,25].

“Cyclic nucleotide phosphodiesterase” was first described as a widely distributed enzyme that could catalyze the hydrolysis of cAMP and cGMP to their respective 5' monophosphates [2]. The initial studies of PDE activity used either tissue homogenates or partially purified preparations of these enzymes from various tissues. The characteristics of PDE activity from these studies varied greatly depending on the PDE source. It was unclear whether these differences were a consequence of the purification scheme of these enzymes (that is, the presence of different contaminating proteins) or of the existence of multiple forms of PDE. PDEs were therefore referred to in terms of the tissue from which they were purified (for example, rat liver PDE or bovine brain PDE). Later anion exchange chromatography experiments demonstrated the presence of several PDE activities in an individual tissue or cell type. These observations were later confirmed in

experiments by use of immunocytochemistry, immunoblotting, and *in situ* hybridization. With the purification of multiple enzymes to apparent homogeneity and more stringent characterization of their properties, PDEs were subsequently named according to their regulatory properties and substrate specificities (for example, calcium/calmodulin-stimulated PDE or cGMP-stimulated PDE). With the advent of molecular biology, there has been a virtual explosion of new information, including the cloning of the previously known and many new PDE genes, as well the identification of a number of new splice variants. Nucleotide sequence data for the PDEs have also allowed for the organization of them into gene families according to homology. As more data emerge regarding the distribution, characteristics, and roles of the many PDE isozymes, it is clear that the regulation of cyclic nucleotide signaling by PDEs is far more complex than could have been imagined when they were first studied in the 1960s.

The Gene Families

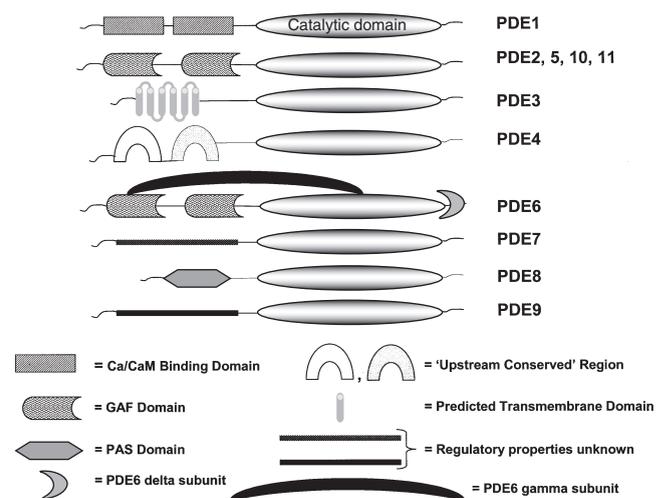

There currently exist 11 PDE gene families. The current nomenclature for a PDE contains, in order, two letters to indicate species, followed with a number indicating gene family, a letter to represent an individual gene, and finally a letter to identify the splice variant. For example, HSPDE7A1 represents *Homo sapiens* PDE gene family 7, gene A, splice variant 1. For a correlation between older and current PDE nomenclature, see Beavo *et al.* [3]. The kinetic properties, substrate specificities and drug sensitivities of these families (Table I) have been described extensively elsewhere [3,23,26,27] and will not be discussed at length here. In general, the phosphodiesterases share the same organizational structure. Each protein has an N-terminal domain that confers regulatory properties to the protein, followed by a more C-terminal ~270 amino acid catalytic domain and a

Table I Characteristics of the PDE Families

PDE family	Genes	# Splice variants	Regulatory domains, role	Phosphorylation	Substrate(s)	Commonly used inhibitors												
PDE1	1A, 1B, 1C	9	CaM, activation	PKA	cGMP, cAMP	KS-505												
PDE2	2A	3	GAF, activation	Unknown	cAMP, cGMP	EHNA												
PDE3	3A, 3B	1 each	Transmembrane domains, membrane targeting	PKB	cAMP	Milrinone												
PDE4	4A, 4B, 4C, 4D	>20	UCR1, UCR2, unclear	ERK, PKA	cAMP	Rolipram												
PDE5	5A	3	GAF, unclear	PKA, PKG	cGMP	Sildenafil, Dipyrimadole, Zaprinast												
PDE6	6A, 6B, 6C	1 each	GAF, activation	PKC, PKA	cGMP	Dipyrimadole, Zaprinast												
PDE7	7A, 7B	6	Unknown	Unknown	cAMP	None Identified												
PDE8	8A, 8B	6	PAS, unknown	Unknown	cAMP	None Identified												
PDE9	9A	4	Unknown	Unknown </tr <tr> <td>PDE10</td> <td>10A</td> <td>2</td> <td>GAF, unknown</td> <td>Unknown</td> <td>cAMP, cGMP</td> <td>None Identified</td> </tr> <tr> <td>PDE11</td> <td>11A</td> <td>4</td> <td>GAF, unknown</td> <td>Unknown</td> <td>cAMP, cGMP</td> <td>None Identified</td> </tr>	PDE10	10A	2	GAF, unknown	Unknown	cAMP, cGMP	None Identified	PDE11	11A	4	GAF, unknown	Unknown	cAMP, cGMP	None Identified

PDE11	11A	4	GAF, unknown	Unknown	cAMP, cGMP	None Identified												

short C-terminal tail. The sequence identity in the catalytic domain between genes is only about 35 percent, yet all PDEs possess the signature sequence H-D-X₂-H-X₄-N [4]. The substrate specificities of the different PDE families run the gamut from dual-specificity PDEs to those that are highly specific for either cAMP or cGMP. Further, the relative substrate specificity can vary even between members of a gene family. For example, within the PDE1 family, PDE1A2 has a K_m for cGMP that is approximately 20-fold higher than that for cAMP, yet PDE1C2 has a K_m that is equal for both. In addition to variation in specificity, the activity of a PDE toward one nucleotide may depend upon the concentration of the other. For instance, PDE2s hydrolyze cAMP and cGMP with relatively similar K_m values. However, the presence of a small amount of cGMP (which binds allosterically) stimulates the enzymes' catalytic activity toward cAMP several-fold [5]. To make things more complex, there are also PDEs for which the cyclic nucleotides are competitive inhibitors for one another. Cyclic AMP is a competitive inhibitor of cGMP hydrolysis by PDE10 [6], and cGMP is a potent competitive inhibitor of cAMP hydrolysis for PDE3 [7]. This variety and flexibility in substrate specificities of the PDEs makes them a family of enzymes with tremendous diversity, suitable for the fine tuning of many cyclic nucleotide-mediated signaling systems.

As mentioned above, most of the PDEs also possess domains within their N-termini that regulate the activity of the catalytic site (Fig. 1). The PDE1 proteins have two Ca²⁺/calmodulin binding domains, and binding of calmodulin to these PDEs stimulates their activity [8]. The PDE2, PDE5, PDE6, PDE10, and PDE11 proteins all have allosteric, cGMP-binding domains known to be part of the larger GAF domain family [9]. The consequence of binding of cGMP to these domains varies with the PDE. As discussed above, cGMP binding to PDE2 stimulates activity. For PDE5, binding of cGMP to this domain alters the protein's susceptibility to phosphorylation, but a direct effect on activity

**Figure 1** Domain organization of the PDE families.

has not been demonstrated. For further discussion of the GAF domains in PDEs, see Martinez, Tang *et al.* (Chapter 207) in this volume. The PDE3 family proteins have six predicted transmembrane segments in their amino terminal domains, consistent with the observation that PDE3 activity is at least partially membrane-associated. The PDE4 family, a large family of enzymes with four genes and many splice variants, is responsible for the majority of basal cAMP-hydrolyzing activity in most cells. For further discussion of the PDE4 family, see Conti (Chapter 71) in this volume. The N-terminus of PDE8 contains a PAS domain, a domain that generally is found in proteins that are involved in sensing and responding to the cellular environment (for example, redox state, light or energy levels) [10]. The PAS domains in many proteins bind small molecules such as heme, NAD, or chromophores and can also serve as a site for homodimerization. It will be interesting to see whether some small molecule also binds the PDE8 PAS domain, what effect that may have on activity,

and also whether the PAS domain of PDE8 serves to dimerize the protein. PDE7 and PDE9 have substantial N-terminal segments that bear no resemblance to known proteins. What role these portions of PDE7 and PDE9 have in the protein remains to be seen.

Thus, with great variation in nucleotide specificity and regulatory properties, the PDE superfamily comprises a complex set of enzymes that can provide cross talk between the cGMP and cAMP pathways, with Ca^{2+} /CaM dependent pathways, and allow the cell exquisite control of cyclic nucleotide dynamics.

Implications of Multiple Gene Families/Splice Variants

Another remarkable feature of the PDE superfamily is the expression and localization patterns of its members. Individual PDEs, within gene families, and even between splice variants, have unique expression patterns. For example, the PDE1 genes PDE1A, PDE1B, and PDE1C are all expressed in brain. However, *in situ* localization studies have shown that PDE1A is expressed primarily in the cortex, PDE1B in the striatum, and PDE1C in the cerebellum [11]. The expression pattern of PDE1C splice variants has been further broken down. PDE1C5 is highly expressed in testis; PDE1C1 is more generally distributed, found in heart, testis, cerebellum, and olfactory epithelium; and PDE1C2 is primarily expressed in the olfactory neuroepithelium.

The PDE3 genes provide another example of the complex localization of family members. PDE3A and PDE3B are generally found in distinct cell types, with PDE3A expressed in platelets and PDE3B in adipose cells and hepatocytes. Both are apparently expressed in vascular smooth muscle cells, although probably in different compartments. For further discussion of the PDE3 family, see Weston *et al.* (Chapter 72) of this volume.

The ability to produce multiple N-terminal variants allows for specific differential targeting of the PDE2 family members. The three PDE2A splice variants differ only at their extreme N-terminus. However, the PDE2A2 N-terminus contains a putative transmembrane domain, and the PDE2A3 variant contains an N-terminal myristoylation site, both of which probably allow for targeting to membrane compartments of the cell and are responsible for the membrane associated forms of PDE2 activity observed in tissue homogenates [12].

All of the above examples of differential localization of PDE genes/splice variants imply that each of these PDEs probably plays specialized roles in the regulation of cyclic nucleotide signaling in cells. Perhaps the definitive example of precise localization of a PDE to achieve specialized function is in the case of the PDE6 gene family. In the photoreceptor cells of the retina, a visual signal is generated through the activation of a cascade of proteins that ultimately result in the activation of PDE6. PDE6 rapidly hydrolyzes the cGMP in the cell, the resident cGMP-gated cation channels close,

and the cells become hyperpolarized. All of the proteins involved in this cascade, including PDE6, are expressed primarily in the retina and specifically targeted to the membrane disks of the photoreceptors. Although this PDE family is the first known and best characterized example of a highly specialized PDE, there are certainly others to follow. A prime candidate example is PDE1C2. As mentioned previously, PDE1C2 is highly expressed in the olfactory neuroepithelium. The other major PDE expressed there is PDE4A. However, expression of PDE1C2 is restricted to the cilia of the epithelium, where it co-localizes with adenylate cyclase III. PDE4A is not expressed in the cilia of the neurons, but rather throughout the remainder of the neuronal layer [13]. Clearly, in the olfactory neuroepithelium, PDE1C2 and PDE4A are playing different roles in regulating cAMP during olfaction.

Another demonstration of compartmentalization of PDE activities was accomplished by Dousa and colleagues while investigating the effects of cAMP-elevating agents on kidney mesangial cells. In these cells, mitogenesis and superoxide production are both stimulated through the production of cAMP. Rolipram (a PDE4-specific inhibitor) inhibited the production of superoxide in these cells while having no effect on mitogenesis. Likewise, cilostamide (a PDE3-specific inhibitor) inhibited mitogenesis while having no effect on superoxide production. These results indicate that these two PDEs have access to different cAMP pools within the cell [14].

The phenomenon of differential localization of PDEs speaks to the idea of compartmentalization of cyclic nucleotide signals. Compartmentalization was originally proposed to explain how a second messenger as ubiquitous as cAMP can mediate different effects within a cell [15,20]. The idea that there are different cyclic nucleotide “pools” available only to certain kinases, channels, exchange factors, or PDEs is a compelling one. However, the details of how these compartments are established are only beginning to emerge. For the cAMP-dependent protein kinases, differential localization is accomplished through their association with anchoring proteins, AKAPs. It is becoming increasingly clear that signaling “modules” are built through the association of receptors, mediators, and targets with each other, AKAPs, and other scaffolding proteins. To that end, in recent years the AKAPs have been shown to associate with receptors, channels, G proteins, and PDEs [16,18,28,29,30]. PDEs also may have their own scaffolding partners. Recently, it was shown that PDE4D5 interacts with RACK1, a WD-repeat protein that also serves as a scaffold for PKC, Src, and integrin [17]. In addition, PDE4D interacts with myomegalin, a protein that appears to target PDE4 to the Golgi and centrosomes of cells [18]. As better tools become available to investigate PDE targeting, we are likely to see more examples of this type of compartmentalization of PDE function.

PDE Inhibitors as Therapeutic Agents

The wide variety of PDE isozymes implies that PDEs have tremendous therapeutic potential. Indeed, some of the

oldest drugs man has known (for example, caffeine, ginseng) are PDE inhibitors! Some PDE inhibitors such as theophylline, papaverine, and dipyridamole were in fact used before their mechanism of action was known. However, with a new appreciation of the complexity of the PDE signaling systems and the availability of more sophisticated endpoint assays, a new generation of PDE-inhibiting drugs is being developed.

PDE inhibitors have long been known to have anti-inflammatory properties and have been used for the treatment of asthma, stroke, and chronic obstructive pulmonary disease (COPD). Early treatments for these diseases with PDE inhibitors have unfortunately been hampered by the side effect of emesis. Novel PDE4 inhibitors (Ariflo, GlaxoSmithKline; and Roflumilast, Byk Gulden) are now in clinical trial for the treatment of asthma and COPD with milder emetic side effects [19]. Milrinone, a PDE3 inhibitor that has been used to treat patients in congestive heart failure, has recently been shown *in vitro* to increase conductance of the CFTR transporter, indicating promise for the treatment of cystic fibrosis [20,31]. Cilostazol, also a PDE3 inhibitor, is currently being applied to the treatment of patients with intermittent claudication, and clinical trials suggest that cilostazol may also be useful in the prevention of restenosis after angioplasty [21,32]. Dipyridamole inhibits PDEs in platelets and is commonly used in combination with aspirin (ASA) to reduce clotting, despite the initial lack of clinical data demonstrating an added benefit of dipyridamole over ASA [22]. However, the recent European Stroke Prevention Study (ESPS2) clearly demonstrated an additive effect of dipyridamole and ASA in the prevention of second stroke [23]. Thus, dipyridamole will likely continue to be prescribed in combination with ASA. And finally, Viagra, a PDE5-specific inhibitor, has been used successfully for the treatment of male erectile dysfunction with minimal side effects.

The successful treatment of patients with specific PDE inhibitors is encouraging but not surprising given the specific, diverse distribution of many of the PDEs. In addition, the recent identification of the PDE8, PDE9, PDE10, and PDE11 should lead to the development of novel inhibitors with as yet unknown application. As we begin to fully appreciate the full complement of PDEs in a system of interest and how they are compartmentalized and regulated, new therapeutics (as well as novel application of older drugs) will no doubt be applied to a wide variety of disease states.

Where Do We Go from Here?

Although it is certainly possible that more PDEs exist that bear little resemblance in linear sequence to the currently known proteins, it is also certain that most if not all of the proteins responsible for the major PDE activities in tissues have been identified and their genes cloned. With the upcoming completion of the sequencing of multiple genomes, the identification of new PDE gene families by the "traditional" method of BLAST searching with current known sequences

is probably drawing to a close. One of the new challenges in the field lies in determining exactly how many PDEs exist. Many of the newly identified splice variants are based on EST searching or RACE from cDNA libraries. It is often difficult to distinguish alternative splicing from library construction artifacts or mis-splicing. It is therefore important to confirm the existence of these variants by using a variety of techniques, including RNase protection and immunoblotting. There are currently few good antibodies available for PDEs, especially the newly discovered ones. It will take the development of a full complement of good, sensitive antibodies specific for all PDEs and splice variants to accomplish this goal.

Another challenge in the field lies in the potential differences in PDE activities and their regulation *in vitro* versus '*in cellulo*.' Only a few of the PDEs have potent, highly selective, cell-permeable inhibitors. Therefore, current methods for studying PDE activity/regulation require either purification of the protein or overexpression in heterologous systems. Localization of PDEs is determined through subcellular fractionation or immunocytochemistry by using tissues that have been fixed and mounted to a slide. Little is known about how well these studies correlate to the situation in the cell. Removing a PDE from its native environment also removes it from other regulatory factors. It is possible that factors that mildly stimulate a PDE *in vitro* have much greater effects *in situ*. In addition, PDEs are also vulnerable to proteolysis in the *in vitro* assays, which can affect their activities. Two things are in great need. One is selective inhibitors for all the PDE families, preferably for the different splice variants as well. This need is exemplified by the discovery that the newest PDEs are insensitive to IBMX, which has been used for decades as a nonspecific PDE inhibitor. It is not clear whether the development of splice variant-specific PDE inhibitors is possible, but efforts in this area are under way. A second need is the accurate, sensitive, real-time measurement of PDE activity in live, intact cells. New techniques have already been developed for the real-time measurement of cyclic nucleotide levels in cells [24,50,51]. Although further refinement of these technologies is needed, the real-time measurement of cyclic nucleotide levels, combined with specific PDE inhibitors, will prove to be a powerful step in furthering the understanding of PDE functions in cells.

The cAMP-Specific Phosphodiesterases: A Class of Diverse Enzymes That Defines the Properties and Compartmentalization of the cAMP Signal

Marco Conti

Division of Reproductive Biology, Department of Gynecology and Obstetrics, Stanford University School of Medicine, Stanford, California

The second messenger cAMP generated by adenylyl cyclases either interacts with and activates intracellular effectors or is degraded and inactivated by phosphodiesterases (PDEs). Of the eleven PDE families thus far identified, three families of isoenzymes are specific for cAMP, including family 4, 7, and 8 (see chapter xx for the nomenclature). Given their high affinity for cAMP in the submicromolar to micromolar range, they are the primary enzymes involved in the inactivation of this cyclic nucleotide under resting or stimulated conditions, thus playing a critical role in signaling.

Isoenzymes that belong to the PDE4 family were the first to be identified on the basis of their pharmacological and biochemical properties. Indeed, rolipram, a PDE inhibitor developed in the fifties as an antidepressant that specifically targets PDE4, has been of tremendous value in dissecting the properties and functions of PDE4. Because of their potential therapeutic use in inflammatory disorders, drugs specific for PDE7 and PDES are also under development.

The cloning of the PDE4 genes by virtue of their homology with the *Drosophila* PDE [1] was soon followed by the identification of the other two families using either a strategy of complementation of yeasts deficient in phosphodiesterases for PDE7 [2], or database homologous searches for PDE8 [3]. It is now established that four genes code for the PDE4s, whereas two genes each encode the PDE7s and PDESs. The presence of multiple genes represents only a first layer of complexity in the cAMP-PDE enzymes, as multiple transcripts originate from these genes either by alternate splicing or the use of different promoters, greatly expanding the number of cAMP-PDE proteins expressed in mammalian cells. Although the number likely will be corrected upward, 15–18 different PDE4, 4 different PDE7, and potentially 6 PDE8 proteins thus far have been identified [4]. A total of 28 different proteins specifically hydrolyze cAMP in the cell (Fig. 1). Given this extreme heterogeneity, it has been proposed that cAMP-PDEs have a modular structure with

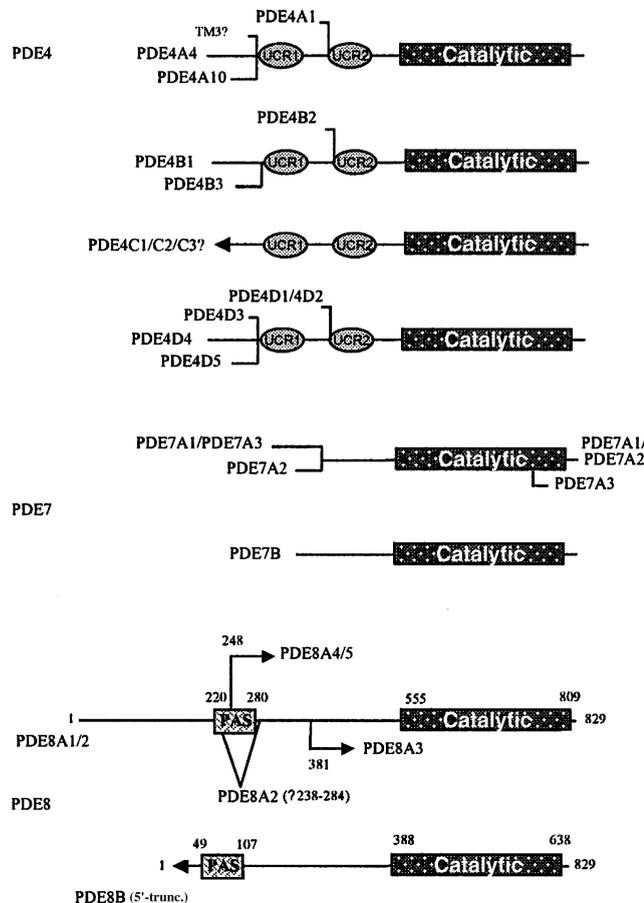

Figure 1 Schematic representation of the different cAMP-PDE expressed in human cells. The gene family is reported on the left. The open reading frame is indicated as a continuous line with the catalytic region indicated as a box. The point of divergence of a splicing variant is indicated by a bracket. The conserved UCR1 and UCR2 regions present in all PDE4 are designated as ovals. The PAS domain in PDE8 is indicated as a cross-hatched box.

different regulatory cassettes specific for each variant, and that cells use distinct cAMP-PDE proteins with subtle differences in their properties to adapt cAMP signaling to their specialized functions.

Structure of the cAMP-PDEs: Catalytic and Regulatory Domains

Cyclic AMP-PDEs are proteins with molecular weights ranging between 50 and 130 kDa and are composed of a catalytic domain surrounded by domains with regulatory functions. Deletion and site-directed mutagenesis, as well as analysis of sequence conservation, have defined the boundaries of the catalytic domain and mapped it to the carboxyl-terminus end of the cAMP-PDE. The structure of this domain in a PDE4 has been recently resolved at the atomic level, demonstrating a compact globular bundle of 17 helices subdivided in 3 subdomains that define a catalytic pocket [5]. Two metal ion binding sites are present in this pocket: one of

these metal binding sites is thought to be permanently occupied by Zn^{2+} , whereas binding of the second metal ion at the second site, likely Mg^{2+} , can be rapidly exchanged. Both metals are essential for substrate binding and for the catalytic activity of PDE4 and presumably for the other cAMP PDEs. Changes in affinity for Mg^{2+} follow posttranslational modification of PDE4 and may impact the hydrolytic capacity of the enzyme [6].

Domains flanking the catalytic domain of the cAMP-PDEs have been identified by different strategies and can roughly be divided into regulatory and targeting domains. Two regions highly conserved from worm and fly to mammals are present at the amino terminus of the PDE4 long forms and are termed upstream conserved regions 1 and 2 (UCR1/UCR2). These domains, signatures for PDE4, serve regulatory functions because a phosphorylation site for PKA has mapped to the amino-terminus end of UCR1. Yeast two-hybrid or pulldown assays have indicated that UCR1 and UCR2 interact with each other and that phosphorylation modulates this interaction [7].

Targeting domains have been identified in several PDE4s as well as at the aminoterminal of PDE7 (see the following). In addition, motifs corresponding to a PKA pseudosubstrate are present at the amino terminus of PDE7A1 and PDE7A2 [2]. Although their function has not been confirmed, they may play a role in the regulation of PKA. Finally, PDE8 contains a PAS domain likely involved in protein/protein interaction [3].

Subcellular Targeting of the cAMP-PDEs and cAMP Signal Compartmentalization

The cAMP PDEs are not uniformly distributed throughout the cell. Conversely, they are targeted to discrete compartments via mechanisms that are only partially known. This nonrandom distribution of PDEs is described, for instance, in the olfactory sensory neurons. The cAMP PDE 4A is present in the body of the neuron in a region surrounding the nucleus, whereas a PDE1 is targeted to the cilia, suggesting that the two enzymes control different cAMP pools [8].

Targeting domains have been identified in PDE4s, and in most instances they coincide with domains that mediate protein/protein interaction. The interaction of a PDE4D5 with RACK-1 [9], a scaffold protein initially identified as a PKC binding protein, is the best characterized, even though the significance of this interaction is unclear. The localization of PDE4D to the Golgi/centrosome structures is probably mediated by the PDE4 interaction with myomegalin, a large coiled-coil protein discovered by yeast two-hybrid screening [10]. Interestingly, in skeletal muscle where it is expressed at high levels, myomegalin colocalizes with PDE in a region where P adrenergic receptors, adenylyl cyclases, PKAs, and AKAPs are also localized [11,12]. A PDE4D3 is targeted to the centrosome or the perinuclear region through interaction with AKAP450 or mAkap, two scaffold proteins that also bind PKA (see the following). PDE4A5 binds to SH3 domain-containing proteins and is localized at the plasma membrane [13]. An additional mechanism of targeting may be

dependent on the direct interaction with the lipid bilayer, as the amino terminus of PDE4A1 is highly hydrophobic and is sufficient for membrane localization of this PDE isoform [14]. One of the splicing variants of PDE7, PDE7A2, contains a unique hydrophobic amino terminus which likely targets it to insoluble structures of the skeletal muscle [15].

The physiological consequence of this distribution of PDEs in different cell districts is still a matter of debate. However, in one case, it is clear that interaction of PDE with scaffold protein serves to create a signaling unit with PKA. The PDE4D3 variant co-immunoprecipitates with the RII regulatory subunit of PKA and with two AKAPs, indicating the presence of a PKA/PDE signaling complex organized on the AKAP scaffold [16,17]. AKAP350/450, also termed Yotiao, is a true signaling scaffold because it complexes PKA, a PDE, PP1, and in some cases, is anchored to receptors [18]. Given the rapid phosphorylation and activation of this PDE isoform by PKA, this colocalization allows the rapid termination of the cAMP signal in a discrete domain of the cell.

Regulation of cAMP-PDEs

The activity of cAMP-PDEs is tightly regulated and integrated in several signaling pathways. Two major mechanisms of regulation have been described. These include regulation by phosphorylation and regulation at the level of transcription/translation of the genes [19]. In addition, interaction with other proteins or with lipids may affect the conformation and activity of these enzymes, even though this area of research is in its infancy.

Regulation of cAMP PDEs by Phosphorylation: Feedback Regulation of cAMP

Using a thyroid cell line as a model of PDE regulation, it was demonstrated that TSH rapidly activates a PDE4D and that this activation is dependent on cAMP accumulation and mediated by PKA [4]. The phosphorylation sites in PDE4D3 have been mapped by site-directed mutagenesis and by phosphopeptide analysis. These data, together with experiments in intact cells, have established that a short-term feedback regulation of PDE4 is operating in the cell to dampen or maintain cAMP levels within a narrow range of concentrations. PKA phosphorylation sites are also present in PDE7, though their significance is unclear.

In addition to a PKA-mediated phosphorylation at the amino terminus, all PDE4s, except PDE4A, are phosphorylated by MAPK at a carboxyl-terminus site [20]. This phosphorylation decreases the activity of the long forms or increases that of the short forms. These effects are overridden by the PKA-mediated phosphorylation. It has been proposed that this regulation is a means to terminate the MAPK kinase activation.

Other kinases may use PDE4s as substrates, as an increase in PDE4A activity follows S6 kinase activation by GH or monocytic cell line activation by lipopolysaccharides (LPS) [13].

PDE4B may be the target of kinases functioning in the T-cell-receptor-activated pathway [13].

Regulation of cAMP PDE Expression During Cell Adaptation and Differentiation

In the seventies, it was observed that changes in cAMP produced an increase in PDE activity and that this increase required protein synthesis. The cloning of PDE4 provided the tools to demonstrate that the regulation of transcription of the PDE4D gene and mRNA accumulation are regulated by cAMP. In the Sertoli cell of the testis, FSH, which increases cAMP, produces more than a 100-fold increase in PDE4D mRNA and accumulation of PDE4D2 protein. This upregulation and consequent increase in cAMP hydrolysis contributes to the state of desensitization that follows hormonal stimulation [19]. Similar findings have been reported for T cells and several cell lines. PDE4B is subject to a similar cAMP-mediated regulation, even though both transcription and mRNA stabilization may contribute to the regulation of the corresponding mRNA [4]. This long-term feedback regulation of cAMP-PDE may play a particularly important role in neuronal cell adaptation and in gonadal cell function. This is inferred by recent observations on the phenotype of mice deficient in a PDE4 where several functions including fertility and behavioral effects follow inactivation of PDE4D [13,21].

An increase in PDE4 expression is also associated with the activation of other signaling pathways, including activation of T-cell receptors by mechanisms that are mostly unknown. In the same vein, PDE7 and PDE8 expression are induced by activation of T lymphocytes by CD3/CD28 antibodies [22]. This induction seems to be critical for the activation of these cells because PDE7 mRNA antisense treatment blocks replication and IL-2 production. PDE4B2 expression is induced in monocytes by LPS activation of the Toll-like receptor pathway [23], a regulation that may be critical for cytokine production, since PDE4 inhibitors block TNF- α production. These regulations in immune cells provide the rationale for the development of cAMP-PDE inhibitors for the treatment of inflammatory disorders.

The above summarized properties and regulations indicate that cAMP-PDEs play an important role in cAMP signaling as well as acting as integrators of multiple signaling pathways. Although much needs to be done to fully understand their functions, these PDEs should be regarded as homeostatic regulators of signaling.

Introduction

The mammalian PDE superfamily contains at least 11 functionally distinct, highly regulated, and structurally related gene families. PDE families differ in their primary sequences, substrate affinities and catalytic properties, sensitivity to effectors and inhibitors, responses to regulatory molecules, and cellular functions [1–5]. Intracellular cAMP and cGMP pools are tightly regulated and seem to be temporally, spatially, and functionally compartmentalized [6]. Most cells contain representatives of more than one PDE gene family (and different variants of the same family) but in different amounts, proportions, and subcellular locations. By virtue of their distinct intrinsic characteristics, their intracellular targeting to different subcellular locations, and their interactions with molecular scaffolds, cellular structural elements, and regulatory partners, different PDEs integrate multiple cellular inputs and modulate the intracellular diffusion and functional compartmentalization, as well as the amplitude, duration, termination, and specificity of cyclic nucleotide signals and actions [6–8]. PDEs are critical determinants of the unique cellular phenotypes (or “fingerprints”) that characterize cyclic nucleotide signaling pathways.

Some PDE families are rather specific for cAMP hydrolysis (PDEs 4,7,8); others are cGMP-specific (PDEs 5,6,9); some hydrolyze both cGMP and cAMP (PDEs 1,2,3,10,11).

This chapter will briefly discuss various aspects of the molecular diversity, structure/function, regulation, and functions of these dual-specificity PDEs.

The catalytic core of mammalian PDEs (~270 amino acids near the carboxy terminus) is more highly conserved among members of the same gene family than between different gene families [1,9]. This core contains common structural elements responsible for hydrolysis of cAMP and cGMP, as well as family-specific sequences responsible for differences in substrate affinities, catalytic properties, and sensitivities to family-selective inhibitors, such as SCH51866 and methoxymethyl-isobutylxanthine (PDE1), EHNA (erythro-9-(2-hydroxy-3-nonyl)-adenine) (PDE2), and milrinone, cilostazol, and cilostamide (PDE3) [1,9]. Selective inhibitors—that is, drugs that target individual PDE families with 10 to 100-fold greater potency than for other PDE families—are not yet available for the more recently identified PDEs 10 and 11, although dipyrindamole (IC₅₀, ~0.37 μM) is a potent inhibitor of PDE11.

Widely divergent N-terminal portions of PDEs contain information that determine responses of different PDEs to specific regulatory signals, such as binding sites for Ca²⁺/calmodulin and autoinhibitory domains (PDE1), membrane-targeting domains (PDEs 2,3), and sites for phosphorylation by cAMP-, cGMP- and Ca²⁺/calmodulin-dependent protein kinases, protein kinase B (PKB/Akt), and protein kinase C (PDEs 1,2,3,10,11) [1–5].

PDE2s contain two homologous, noncatalytic, cGMP-binding regions upstream of the catalytic core. These domains, conserved in PDE5, PDE6, PDE10, and PDE11 and a wide variety of proteins, are referred to as GAF domains (because of proteins containing these domains: cGMP-binding PDEs, *Anabena* adenylyl cyclase, and the *E. coli* transcriptional regulator, *fhl A*) [5,10]. In PDE2, PDE5, and PDE6, GAF domains bind cGMP with high affinity but with different functional consequences. Binding of cGMP to GAF domains results in allosteric activation of PDE2, enhances PKG-induced phosphorylation/activation of PDE5, and enhances interactions between PDE6 catalytic and inhibitory subunits and transducin. Functional consequences of interactions with GAF domains in PDEs 10 and 11 are unknown. Since the K_d for cGMP binding to the PDE10A GAF domains ($>9\mu\text{M}$) is much higher than physiological cGMP concentrations, cGMP binding is probably not the primary function of these GAF domains [5,10]. Other small molecules can bind GAF domains; for example, *fhl A* binds formate in an N-terminal region containing two GAF domains [11].

PDE1 (Ca²⁺/Calmodulin-dependent PDE)

Of the three PDE1 subfamilies (1A–C), PDE1A and PDE1B have higher affinity for cGMP ($K_m \sim 5\mu\text{M}$ and $2.7\mu\text{M}$, respectively) than for cAMP ($K_m \sim 113\mu\text{M}$ and $24\mu\text{M}$, respectively) [15], whereas PDE1C has high affinity for both cAMP and cGMP ($K_m \sim 1\mu\text{M}$). PDEs 1B and 1C hydrolyze cAMP and cGMP at similar rates, with V_{max} for cAMP by PDE1A twice that for cGMP [15]. There are five PDE1A [16,17], two PDE1B [17,18], and five PDE1C [15,19] splice variants; N-terminal, not C-terminal, diversity apparently accounts for functional and regulatory differences. Alternative splicing generates structural changes in calmodulin-binding domains, with PDE1A1 and PDE1C2 having greater affinity for calmodulin than PDE1A2 [20] or other PDE1C isoforms [15], respectively. *In vitro* phosphorylation of PDE1A1 and PDE1A2 by PKA [21,22], or PDE1B by calmodulin-dependent protein kinase II [23], renders the enzymes less sensitive to Ca²⁺/calmodulin. PDE1A possesses an N-terminal PEST recognition motif for m-calpain which generates an activated cleavage fragment that is independent of calmodulin [24] and could provide an alternative intracellular mechanism for cyclic nucleotide regulation.

PDE1s may mediate cross-talk between Ca²⁺, lipid, and cyclic nucleotide signals. Stimulation of CHO cells with PMA or agonists that activate lipid-signaling pathways, or transfection with specific PKC isoforms, rapidly induces PDE1 activity and expression [25,26]. In mammalian brain, PDE1 is relatively highly expressed, with distinct isozyme-specific distributions. PDE1B distribution in the striatum correlates with that of dopamine receptors, inferring a role in modulating dopamine-mediated cAMP signaling [27]. PDE1C2 and adenylyl cyclase AC3 colocalize to olfactory sensory neuronal cilia that extend to nasal epithelium, where they may regulate transient cAMP responses to odorants [27].

PDE1A upregulation has been implicated in developing tolerance to vasodilator effects of chronic nitroglycerin treatment [28]. Quiescent smooth muscle cells (SMCs) from intact normal human aorta express PDEs 1A and 1B, whereas proliferating SMCs in human arterial primary cultures and cultures from atherosclerotic lesions contain high levels of PDE1C(12).

In pancreatic islets [29,30] and cultured β -cell lines [31], PDE1, especially PDE1C, may regulate cAMP and glucose-induced insulin secretion, since PDE1 inhibition augments glucose-stimulated insulin release from β TC3 cells and exposure to glucose activates PDE1 [31].

PDE1 may be elevated in certain tumors [32]. PDE1B1 is induced in activated T cells and expressed in human lymphoblastoid cell lines but not in normal, quiescent, peripheral blood lymphocytes [33]. PDE1 inhibitors, 8-methoxymethyl-IBMX and vinpocetine, can attenuate IL-13 production and induce apoptosis of lymphoma cells [34], suggesting the potential for PDE1-targeted therapy of leukemia and inflammatory disorders.

PDE2 (cGMP-stimulated PDE)

Unique N-terminal regions in three variants of the single PDE2A gene, most likely generated via alternative exon splicing [4,35–41], may localize PDE2 to soluble (PDE2A1) and particulate (PDE2A2, PDE2A3) subcellular fractions. In general, PDE2A mRNA expression is similar in human [38], rat [42], and bovine [39] tissues, with relatively high levels in brain and intermediate levels in heart, liver, skeletal muscle, and pancreas.

PDE2 isoforms exhibit similar catalytic properties, hydrolyzing cAMP ($K_m \sim 30\mu\text{M}$) and cGMP ($K_m \sim 10\mu\text{M}$) at similar maximal velocities (100–160 $\mu\text{mol}/\text{min}/\text{mg}$) with positively cooperative kinetics. At physiological concentrations, cGMP is the preferred substrate and effector for PDE2, and can stimulate PDE2-mediated cAMP hydrolysis up to 50-fold with a $K_d \sim 0.35\text{--}0.5\mu\text{M}$. By interaction with non-catalytic cGMP-binding regions in the two GAF domains upstream of the catalytic domain [43], cGMP induces a conformational change and converts PDE2 from a ligand-free state, displaying low affinity for cAMP and positively cooperative or sigmoidal kinetics, to an activated high-affinity conformation, displaying classical Michaelis-Menton kinetics without any change in V_{max} , [36]. Because of this unique allosteric regulation, PDE2 is referred to as the cGMP-stimulated cAMP PDE. At higher concentrations, cGMP inhibits cAMP hydrolysis, due to competition at the catalytic site.

Physiologically, PDE2 is a locus for cross-talk between cAMP- and cGMP-signaling pathways and may play an important role in cells where cAMP and cGMP regulate opposing functions. Regulation of PDE2 by cGMP may be more important when intracellular cAMP is elevated, rather than in the basal state [4,36]. The relatively recent development of a selective PDE2 inhibitor, EHNA [44], has been

critical in elucidation of putative pathways regulated by PDE2s. However, although EHNA potently inhibits PDE2 (IC₅₀, ~0.8–2 μM, at least 50-fold less than for other PDEs), it also inhibits adenosine deaminase.

In heart and platelets of different animal species, effects of NO and cAMP and cGMP seem to be regulated by the interplay of different PDEs, especially PDE2, PDE3, and PDE5. In frog ventricular myocytes and human atrial myocytes, NO-induced activation of guanylyl cyclase increases cGMP, which can activate PDE2, resulting in increased hydrolysis of cAMP and decreased L-type channel Ca²⁺ current I_{ca} [45–48]. PDE2 may be located in the same subcellular compartment as PKA and the L-type channel [49], and might specifically regulate L-type channel phosphorylation. In rabbit platelets, nitrovasodilators and prostacyclins act synergistically to inhibit platelet aggregation via increased cAMP, generated by NO-induced activation of guanylyl cyclase, cGMP accumulation, and subsequent inhibition of cAMP hydrolysis by PDE3 [50]. In human platelets, however, although PDE3 may be important in the absence of nitrovasodilators or at low cAMP concentrations, increases in cAMP seem to be restricted by cGMP-induced activation of PDE2 [51]. [Stimulation by nitrovasodilators, via increases in cGMP, results in inhibition of PDE3 as well as activation of PDE2, resulting in net cAMP hydrolysis. Thus, clinical effectiveness of nitrovasodilators as platelet inhibitors, which could be compromised by activation of PDE2, may be enhanced by PDE2 inhibitors [50–52].

In cultured bovine adrenal glomerulosa cells, ANP inhibits ACTH-stimulated aldosterone secretion, presumably via cGMP-induced activation of PDE2 and hydrolysis of cAMP [53]. PDE2 may also be important in regulation of phytohemagglutinin-induced activation (but not by anti CD3) of the T-cell receptor [54], the hypoxic pressor response in rat lung [55], NO-induced inhibition of prolactin release from the pituitary gland [56], NaCl absorption by the rat thick ascending tubule [57], olfactory neuroepithelial signaling [58,59], and effects of NGF on cAMP-induced PC12 cell differentiation [60,61].

PDE3 (cGMP-inhibited cAMP PDE)

Both PDE3 subfamilies, PDE3A and PDE3B, generated from separate genes located on chromosome 11 and 12, respectively [62,63], hydrolyze cAMP and cGMP with high affinity (K_m values of ~0.1–0.8 μM) in a mutually competitive manner, with V_{max} for cAMP higher (~4–10-fold) than for cGMP [14,64]. Both are specifically inhibited by compounds such as milrinone, enoximone, and cilostazol [64].

PDE3A and B exhibit cell-specific differences in expression. PDE3B is relatively highly expressed in cells important in energy metabolism, such as white and brown adipocytes, pancreatic β cells, and hepatocytes [64–67]; PDE3A is highly expressed primarily in the cardiovascular system, for example platelets, smooth muscle, and cardiac myocytes [64,68]. Full-length PDE3s (Mw~135 kDa) are

found in association with membranes; smaller PDE3A forms are found in cytosolic fractions [68].

The structural organization of PDE3A and PDE3B proteins is identical [14] with the catalytic domain found in all PDEs located in the C-terminal portions of the molecules. The catalytic domains of PDE3A and B are highly conserved, except for an insertion of 44 unique amino acids that is not found in the catalytic domains of other PDE families and that also differs in, and thus distinguishes, PDE3A and B isoforms. PDE3A and B N-terminal portions are quite divergent, consisting of large hydrophobic regions containing 5 to 6 transmembrane helical segments and separated from the catalytic domain by a regulatory domain with consensus sites for phosphorylation by PKA and PKB [14,64].

Studies with specific, cell-permeable, PDE3 inhibitors (some of which are used in clinical situations [64,65]) suggest that PDE3s regulate several important physiological functions, including adipose tissue lipolysis, insulin secretion, platelet aggregation, vessel relaxation, cardiac function, oocyte maturation, and cell proliferation [14,64]. In intact cells, insulin/IGF-1 and cAMP-increasing agents activate (and presumably phosphorylate) PDE3s in adipocytes [14], hepatocytes [67,69], platelets [64], oocytes [70], and pancreatic β cells [71].

In adipocytes, insulin-induced phosphorylation and activation of membrane-associated PDE3B, via insulin receptor substrates (IRS)/phosphatidylinositol-3 kinase (PI3K)/PKB signaling pathways [72–77], is a major mechanism whereby insulin acutely antagonizes catecholamine-induced lipolysis and release of fatty acids. Activation of PDE3B leads to increased degradation of cAMP and consequent lowering of PKA activity, net dephosphorylation of hormone-sensitive lipase, and reduced lipolysis [78]. Protein phosphatase 2A catalyzes PDE3B dephosphorylation [79]. cAMP-elevating hormones also phosphorylate and activate PDE3 in adipocytes and several other cells, including platelets, as a feedback mechanism to limit excess production of cAMP.

Several studies suggest that reduced PDE3B gene expression in adipocytes is associated with insulin resistance. PDE3B activity and gene expression are decreased in adipose tissue from JCR: LA-cp rats, a strain that develops obesity, insulin resistance, and vasculopathy [80], and from obese, insulin-resistant, diabetic KKAY mice [81,82]. Administration of pioglitazone to KKAY mice increased adipocyte PDE3B expression and restored its responsiveness to insulin. Long-term incubation (~24 hr) of 3T3-L1 adipocytes with TNFα and ceramides results in increased lipolysis that is associated with downregulation of PDE3B; troglitazone reverses the effect on PDE3B [83]. Whether downregulation of PDE3B is important in development of TNFα-induced insulin resistance is not certain.

In pancreatic islets, insulinoma cells, and clonal β cells [30,31,71,84,85], PDE3, most likely PDE3B, seems to be important in regulation of insulin secretion. Activation of PDE3B by insulin-like growth factor I (IGF-1) [71] or leptin [88] attenuates insulin release stimulated by the cAMP-elevating hormone glucagon-like peptide 1 (GLP-1).

Selective PDE3 inhibitors increased plasma insulin in normal rats [86,87]. In pancreatic islets and insulinoma cells, they enhanced insulin secretion stimulated by glucose [30,84–86], indicating that PDE3-mediated control of cAMP may also be important for nutrient-stimulated release of insulin (although inhibition of the cAMP/PKA pathway has been reported not to adversely affect glucose-induced release [89,90]).

In hepatocytes, activation of PDE3B is thought to be important in the antiglycogenolytic actions of insulin and leptin [69,91]. In frog (*Xenopus laevis*) and murine oocytes and in intact rodents, specific PDE3, not PDE4, inhibitors blocked oocyte maturation [92,93]. In the frog oocyte, IGF-1-induced meiotic maturation is associated with PKB-induced activation of oocyte PDE3A and reduction in cAMP [70]. Taken together, these studies suggest that activation of PDE3B (perhaps via PI3-K/PKB-signaling) is important in counterregulatory actions of insulin, IGF-1, leptin, and other cytokines on certain cAMP-mediated processes.

PDE10

Two variants of the single PDE10 gene, PDE10A1 and PDE10A2, with unique N-termini but otherwise identical sequences, and several rat variants, PDE10A3, 10A4, 10A5, and 10A6, have been cloned and characterized [94–97]. PDE10 activities were detected in extracts of rat striatum and testis [98,99]; human PDE10A1 transcripts, in brain, testis, heart, kidney, lung, liver, and pancreas; PDE10A2 in brain, kidney, and placenta. Recombinant PDE10 hydrolyzes both cAMP ($K_m \sim 0.05\text{--}0.26 \mu\text{M}$) and cGMP ($K_m \sim 3\text{--}8 \mu\text{M}$), with V_{max} for cGMP \sim five-fold higher than cAMP. Since cGMP hydrolysis is potently inhibited by cAMP, PDE10 may serve as a cAMP-inhibited cGMP PDE *in vivo*, but characterization of PDE10 function(s) awaits development of specific inhibitors.

Two PDE10 N-terminal GAF domains, although similar to GAF domains in PDE2, PDE5, and PDE6, are probably not important in functional cGMP-binding [96]. The unique N-terminal region of PDE10A2 contains a consensus site for PKA phosphorylation, but effects of phosphorylation on activity in intact cells and *in vitro* are unknown.

PDE11

Several rat [100] and human [100–102] splice variants of the single PDE11 gene, with unique N-termini, have been cloned and characterized. Recombinant PDE11A hydrolyzes both cGMP and cAMP, with K_m values of $0.52 \mu\text{M}$ and $1.04 \mu\text{M}$, respectively [103]. With similar V_{max} values for both cAMP and cGMP, despite the two-fold higher affinity for cGMP, PDE11A may function as a genuine dual substrate PDE at physiologically relevant concentrations. PDE11A splice variants exhibit differences in V_{max} (PDE11A4 \gg PDE11A2 $>$ PDE11A3 \gg PDE11A1), and

in their sensitivities to inhibitors, some of which were two- to three-fold more potent against PDE11A3 than PDE11A4 [102], indicating that the N-terminus of PDE11A may affect the conformation of the protein and thus regulate catalytic activity. The splice variants possess different GAF domains in their N-terminal regions: PDE11A4, with two GAF domains; PDE11A3, one complete and one incomplete GAF domain; PDE11A2, one complete GAF domain; and PDE11A1, an incomplete GAF domain. Although PKA and PKG phosphorylate PDE11A4, but not other variants, it is uncertain whether phosphorylation occurs *in vivo* or serves a regulatory function [102].

PDE11A transcripts are highly expressed in prostate and testis, with moderate expression in salivary gland, pituitary gland, thyroid gland, and liver. PDE11A3 transcripts are specifically expressed in testis, whereas PDE11A4 is particularly abundant in prostate [102], suggesting a potential role for PDE11 in these tissues.

Conclusions

In general, dual-specificity PDEs seem to be regulators of many cyclic nucleotide signaling pathways, including proliferation of vascular smooth muscle (PDE1) [12,13], myocardial contractility and platelet aggregation (PDE2 and PDE3) [4,14], adrenal steroidogenesis (PDE2), and insulin/IGF-1 action (PDE3) [3,4,12–14]. In addition, because of their intrinsic characteristics and regulatory properties, dual-specificity PDEs can serve as a locus for cross-talk among Ca^{2+} , cAMP, and cGMP signaling pathways, since Ca^{2+} , calmodulin, and calmodulin kinase regulate PDE1, and since, depending on physiological cyclic nucleotide concentrations, cGMP can modulate intracellular cAMP concentrations by either stimulating or inhibiting cAMP hydrolysis by activating PDE2 or inhibiting PDE3. Little is known of intracellular functions of recently identified PDE10 and 11, but PDE10 might be expected to function as a cAMP-inhibitable cGMP PDE.

Phosphodiesterase-5

Sharron H. Francis and Jackie D. Corbin

*Department of Molecular Physiology and Biophysics,
Vanderbilt University Medical School, Nashville, Tennessee*

Introduction

Cyclic GMP-specific cGMP-binding phosphodiesterase (PDE5) is a class I PDE, and it is abundant in smooth muscle, platelets, Purkinje cells, and renal tissues. It is the pharmacological target for sildenafil citrate (ViagraTM), vardenafil (LevitraTM), and Fadalafil (CialisTM), all of which are treatments for male erectile dysfunction. It is also an emerging target for treatment of other disorders involving smooth muscle, such as pulmonary hypertension. PDE5 is dimeric; each 100-kDa monomer contains a catalytic domain and a regulatory domain that includes two GAF domains associated with the allosteric cGMP-binding function and a single phosphorylation site for either cGMP-dependent protein kinase (PKG) or cAMP-dependent protein kinase (PKA). The role of the allosteric cGMP-binding in enzyme regulation is poorly understood. There is no apparent homology between the allosteric cGMP-binding site(s) and the catalytic site; they have distinctly different analog specificities, and neither is homologous with the cyclic nucleotide-binding sites of PKA and PKG. There are three splice variants that differ at their amino-termini, and they are derived from a single gene. Expression of PDE5 is subject to long-term and developmental regulation. Phosphorylation of the single phosphorylation site requires binding of cGMP to the regulatory domain and results in activation of catalysis as well as increased cGMP-binding affinity at the allosteric sites. Increased phosphorylation occurs in intact cells when cGMP is elevated in response to atrial natriuretic peptide. PDE5 plays a central role in selectively controlling cGMP levels in numerous tissues through breakdown of cGMP at the catalytic site and binding of cGMP at the allosteric sites.

PDE5 has recently gained prominence with the realization that the activity of this enzyme in combination with that of guanylyl cyclases plays a key role in modulating cGMP levels in smooth muscle cells and therefore in determining

contractile tone in this tissue (Fig. 1). PDE5 is highly abundant in corpus cavernosum of the penis and is inhibited by several drugs that are highly effective for treatment of male erectile dysfunction. The demonstrated role of PDE5 activity as a major determinant in modulating cGMP signaling in numerous tissues has led to renewed interest in this enzyme and its potential as an important pharmacological target.

Gene Organization and Regulation of Expression

The single human PDE5 gene is located on chromosome 4q26, contains 23 exons, and encodes mRNA for three variants: PDE5A1, A2, and A3. These proteins, 100 kDa, 95 kDa and 95 kDa, respectively, share similar properties and have different amino-termini, a result of alternative mRNA splicing [1–4]. Alternative first exons arranged in the order A1-A3-A2 account for the three forms [5]. PDE5 mRNA is present in many tissues [3,4,6], but PDE5 protein level is relatively low in most tissues. PDE5 protein occurs in relative abundance in smooth muscle, platelets, and Purkinje cells and has been detected in proximal renal tubules, collecting renal ducts, and epithelial cells of pancreatic ducts [2,7]. It is by far the major cGMP-hydrolyzing PDE in penile corpora cavernosae of human, dog, and rabbit. PDE5A3 appears to predominate in smooth muscle, and its expression may only occur in smooth muscle [4,8]. PDE5A1 and PDE5A2 are co-expressed in a variety of tissues, but PDE5A2 is the major form found in most human tissues [4,9].

PDE5 is subject to long-term and developmental regulation [1,9–11]. Both cAMP and cGMP stimulate PDE5A promoter activity, and cAMP increases PDE5A2 expression [9,12]. PDE5A1 promoter contains multiple Sp1- and AP2-binding sequences and involves a portion of the first exon. PDE5A2 utilizes an intronic promoter located downstream from the

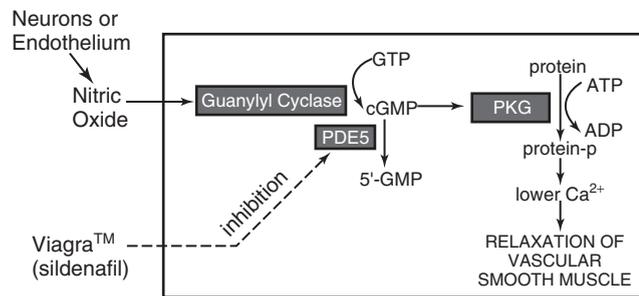

Figure 1 Nitric oxide and cGMP signaling in smooth muscle cells. Cyclic GMP level in smooth muscle cells is determined by the balance between the rate of cGMP synthesis by guanylyl cyclases and the rate of cGMP breakdown by phosphodiesterases (PDE). When cGMP is elevated, it binds to cGMP-dependent protein kinase (PKG) and activates that enzyme to bring about relaxation of smooth muscle. PDE5 is abundant in vascular smooth muscle and contributes to the downregulation of cGMP levels. Inhibitory agents such as sildenafil (Viagra™), Vardenafil (Levitra™), or tadalafil (Cialis™) that block catalytic activity of PDE5 enhance elevation of cGMP in response to stimuli that activate guanylyl cyclases.

first exon of PDE5A1. This promoter also contains sequences that bind Sp1 and AP2 transcription factors [5]. Several of the Sp1 sites are important for promoting PDE5A2 gene transcription and in providing for cGMP stimulation of transcription [13].

General Structure

PDE5 is a dimer of identical subunits each with $M_r \sim 100,000$ (Fig. 2). A regulatory domain is located in the amino-terminal portion of each monomer, and a catalytic domain occupies a more carboxyl-terminal region. The regulatory domain of PDE5 contains a phosphorylation site (Ser-92 in bovine PDE5A1 and Ser-102 in human PDE5A1) for PKG or PKA [14]. The regulatory domain binds cGMP at highly specific, allosteric binding sites that show kinetic heterogeneity [15]. The catalytic site is also highly specific for cGMP and, like all known PDEs, contains binding sites for divalent cation(s) that are required to support catalysis. The amino acid sequence of the PDE5 allosteric cGMP-binding region is not homologous with the catalytic site, and neither of these is homologous with cyclic nucleotide-binding sites in PKA, PKG, cyclic nucleotide-gated cation channels, or cyclic nucleotide-regulated guanine nucleotide exchange factors [16].

Phosphorylation of a single serine near the aminoterminal of PDE5 by PKG or PKA requires cGMP binding to the regulatory region and would be predicted to occur only when cellular cGMP is significantly increased and PKG is concomitantly activated (Fig. 3). PDE5 is phosphorylated in intact cells in response to stimuli that elevate cGMP. Elevation of cAMP does not mimic this. PDE5 is at least a ten-fold better substrate for PKG than for PKA. This preference results from a phenylalanine located at P⁺, which is a negative determinant for PKA. PKG has ~20-fold higher affinity for PDE5 regulatory domain as substrate ($K_m \sim 2.7 \mu\text{M}$) than

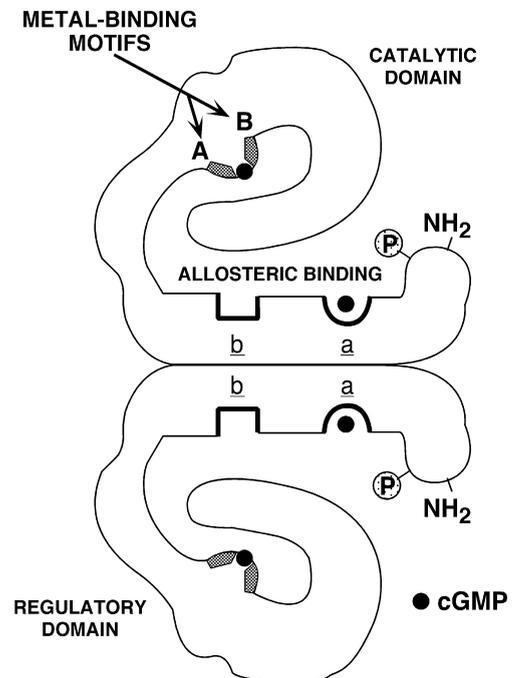

Figure 2 Working model of PDE5. The regulatory domain in the amino-terminal portion of PDE5 contains the phosphorylation site (Ser-102), two GAF domains (*a* and *b*) associated with allosteric cGMP-binding and the dimerization domain. Cyclic GMP binding to the isolated GAF domain *a* has been demonstrated, but whether the GAF domain *b* binds cGMP remains to be determined. The catalytic domain in the carboxyl-terminal portion of PDE5 contains a cGMP-binding substrate site and two Zn^{2+} -binding motifs (A and B), portions of which form a novel metal-binding site.

for the peptide containing the phosphorylation site ($K_m \sim 68 \mu\text{M}$), indicating that additional features in the PDE5 regulatory domain contribute to high-affinity interaction with PKG [17].

PDE5 Catalytic Domain

Catalytic domains of all mammalian PDEs include ~270 residues that are 25 to 50 percent conserved and contain 18 invariant amino acids [16,18]. PDE5 is highly specific for cGMP and exhibits a k_{cat} of 4.3 sec^{-1} and K_m of $1\text{--}6 \mu\text{M}$ for that nucleotide. Catalytic site affinity for cAMP is at least 100-fold lower than that for cGMP, but V_{max} for cAMP is actually higher than that for cGMP. Cyclic nucleotide analog specificity of the catalytic site differs from that for cGMP-binding to the regulatory domain, and the catalytic site tolerates more modifications to the cGMP molecule. Cyclic GMP analogs with modifications at the 2'-OH or at N1 and C2 are accommodated well at the catalytic site. High catalytic site affinity vardenafil and PDE5 inhibitors such as sildenafil, tadalafil which exhibit slight resemblance to cGMP, further indicate the promiscuous nature of this site. Recombinant PDE5 containing only the catalytic domain is monomeric, and the catalytic properties (K_m , V_{max} for cGMP, and IC_{50} for inhibitors) compare well to those of full-length PDE5, indicating that requirements for catalysis exist within a single catalytic domain [16,19].

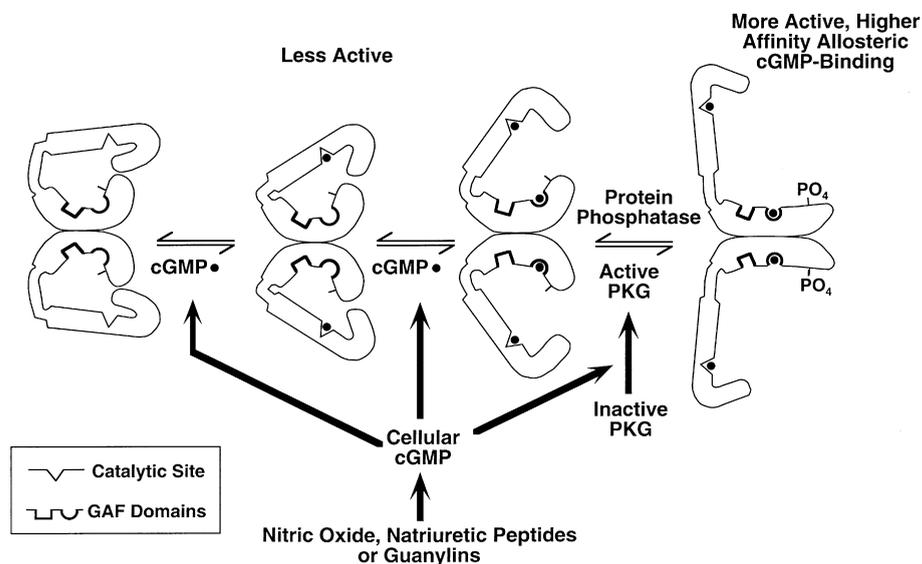

Figure 3 Working model of conformational changes that occur in PDE5. Upon elevation of cellular cGMP, cGMP interacts with its major intracellular receptors, PDE5 and PKG. For PDE5, evidence suggests that cGMP interacts first with the catalytic site where it is hydrolyzed. That initial interaction induces a conformational change in PDE5 to increase cGMP binding to the regulatory domain. The possibility that cGMP binding to the regulatory domain increases the affinity of the catalytic site for cGMP, and maximum catalytic activity is also increased. Cyclic GMP-binding to the regulatory domain produces yet another change in the amino-terminal portion of PDE5 to expose the serine that can be phosphorylated by PKG. Under these circumstances, PKG would be activated due to specific binding of cGMP to its allosteric sites. Evidence suggests that the phosphorylated PDE5 is the most active form and exhibits highest affinity for cGMP binding in the regulatory domain. Existence of each conformation is based on extensive biochemical studies.

Cloning of PDE5 cDNA led to identification of two conserved Zn²⁺-binding motifs (A and B) in catalytic domains of all mammalian PDEs. The importance of Zn²⁺ in catalytic function of PDEs was first demonstrated experimentally with PDE5. Zinc binds to PDE5 with high stoichiometry (~3 mol/mol PDE5 monomer), is not competed by 10,000-fold excess of either Mn²⁺ or Mg²⁺, and is effective at far lower concentration (submicromolar) than either Mn²⁺ or Mg²⁺ in supporting catalytic activity. Site-directed mutagenesis of PDE5 confirms the catalytic importance of residues in Zn²⁺-binding motifs A and B and reveals involvement of residues from each motif to form a novel Zn²⁺ binding site [20,21]. Two conserved downstream aspartates are also implicated as critical for efficient catalysis. Mutation of two other residues, Tyr-602 and Glu-775, causes marked changes in K_m for cGMP.

A variety of PDE inhibitors block catalysis by competing with cGMP at the catalytic site. The order of potency, in descending order, of some common PDE inhibitors for PDE5 is vardenafil, tadalafil ≥ sildenafil, zaprinast, dipyridamole, 3-isobutyl-1-methylxanthine (IBMX), cilostamide, theophylline, caffeine, rolipram [19]. PDE5 is the specific target of sildenafil citrate, a potent competitive inhibitor (IC₅₀ of 1–4 nM) marketed as ViagraTM. Affinity of sildenafil for PDE5 is 10- and 100-fold greater than that for PDE6 and PDE1, respectively, and much greater than that for other PDE families. Other commercialized compounds [LevitraTM (vardenafil), CialisTM (tadalafil)] have now been produced that inhibit PDE5 with equal or better potencies than sildenafil

and that show even stronger selectivity than sildenafil for inhibition of PDE5 compared to other PDEs [22,23].

Occupation of PDE5 catalytic site by cGMP, cGMP analogs, or inhibitors such as sildenafil increases cGMP binding to allosteric cGMP-binding sites in the regulatory domain (Fig. 3). This increases catalytic activity and also leads to exposure of the phosphorylation site, thereby allowing for phosphorylation, further activation of PDE5, and enhanced cGMP-binding affinity of the allosteric sites. Inhibitors such as sildenafil bind exclusively to the PDE5 catalytic site and do not compete with cGMP for binding in the regulatory domain sites [16,19].

PDE5 Regulatory Domain

Allosteric sites in unphosphorylated PDE5 bind cGMP with a K_d ~0.2–1.5 μM; affinity varies depending on conditions. Cyclic GMP binding is associated with one or two GAF domains comprised of ~110 residues each [29]. The GAF acronym derives from a group of apparently unrelated proteins that contain these ancient domains, bind diverse ligands, and share low amino acid sequence similarity: cGMP-binding PDEs, cyanobacterial *Anabaena* adenylyl cyclase, and *Escherichia coli* transcriptional factor *fh1A*. Whether both GAF domains in a single PDE5 monomer bind cGMP is not known. Two kinetically distinct cGMP-binding sites with ~four-fold difference in affinity exist in the enzyme. Over the years, much evidence has been presented and interpreted

as supporting the likelihood that cGMP binds to both GAF domains in PDE5. However, stoichiometry of cGMP binding to the regulatory region is best estimated at 1 mol cGMP per monomer. A recombinant protein containing only the more amino-terminal GAF domain of PDE5_a binds cGMP with an affinity similar to that of the high-affinity component in native and wild-type PDE5 [17]. It is clear that at least the cGMP-binding associated with the more amino-terminal GAF domain is a very stable and self-contained entity (Figs. 2 and 3).

Functional roles of allosteric cGMP-binding in PDE5 has been partly clarified (see below), but the biological advantage of having two GAF domains in most cGMP-binding PDEs (PDE2, PDE5, PDE6, PDE10, PDE 11) is a mystery [16]. Site-directed mutagenesis of residues in the more amino-terminal GAF or in both GAFs diminishes or compromises cGMP binding and causes a three- to four-fold increase in K_m of PDE5 for cGMP. Integrity of both GAFs and retention of cGMP binding by the regulatory domain influences exposure of the phosphorylatable serine for PKG or PKA action (Fig. 3). The phosphorylation in turn increases the affinity with which the regulatory domain binds cGMP, and the K_m for cGMP as substrate is lowered. Whether this latter effect results from phosphorylation alone or from a concomitant increase in the cGMP-binding affinity of the regulatory domain is not known.

Dimerization occurs through stable interactions located near or within the allosteric cGMP-binding sites. The nature of the contacts and the advantages of a dimeric enzyme are not known. Dimerization could contribute to stability or function of the cGMP-binding domains. It is clearly not required for catalytic function.

Concluding Remarks

Studies of PDE5 have provided major insights into molecular characteristics of that enzyme and have advanced our understanding of general properties shared by all members of the PDE superfamily. PDE5 has been successfully targeted for a widely marketed treatment for male erectile dysfunction. The success of sildenafil (ViagraTM) in this regard has renewed interest in PDEs as potential pharmacological targets. The relatively restricted expression of PDE5 along with its well-defined biochemical properties enhances its attraction as a target for future pharmacological interventions.

Structure, Function, and Regulation of Photoreceptor Phosphodiesterase (PDE6)

Rick H. Cote

*Department of Biochemistry and Molecular Biology,
University of New Hampshire,
Durham, New Hampshire*

Introduction

The remarkable single-photon sensitivity of the visual pathway in rod photoreceptors requires that a photon of light be converted into a cascade of biochemical reactions. This process starts with activation of the visual pigment molecule (rhodopsin, R^*). During the lifetime of one R^* , ~100 heterotrimeric G-proteins (transducin) can be catalytically activated per second. Each activated transducin (specifically, the GTP-loaded α subunit, α_t^* -GTP) then binds to and activates the effector enzyme, cGMP phosphodiesterase (PDE). The hydrolytic action of PDE rapidly reduces the cytoplasmic cGMP concentration, causing dissociation of cGMP from cyclic GMP-gated ion channels. A single R^* can suppress over 1 pA of current that normally flows through these plasma membrane channels in the dark. Termination of the rod photoresponse, along with modulation of photoresponse sensitivity during dark and light adaptation, requires biochemical reactions distinct from the excitation pathway described above. Cone photoreceptors have phototransduction pathways similar to rods, but the biochemical machinery of cone phototransduction must differ significantly to account for physiological differences in the light sensitivity and adaptational properties of cones. For reviews of rod and cone phototransduction, see [1–4].

Photoreceptor cells express a single type of PDE (classified as PDE6). In rods, the PDE6 holoenzyme consists of a catalytic heterodimer ($\alpha\beta$) to which two inhibitory γ subunits bind ($\alpha\beta\gamma_2$). Different classes of cone photoreceptors exist in mammalian retina, and each expresses cone-specific PDE6 catalytic (α') and inhibitory (γ') subunits. There is some evidence that PDE6 subunits—particularly the γ subunit—are expressed and function in nonretinal tissues [5,6], but the level of expression is low compared to photoreceptor cells (20 μ M). The PDE6 family is one of five families of PDEs that contain noncatalytic, cGMP-binding GAF domains (see Chapter 192 by Glick and Beavo, this volume). The catalytic and regulatory features of the PDE6 family make it uniquely suited as the central effector of the visual transduction pathway.

Structure and Subcellular Localization of Rod PDE6

The primary sequence of the catalytic subunits of PDE6 largely consists of highly conserved regulatory and catalytic domains along with a C-terminal sequence that is the site of posttranslational modifications conferring membrane attachment (Fig. 1). The N-terminal half of the sequence contains homologous GAFa and GAFb domains. The GAF domain

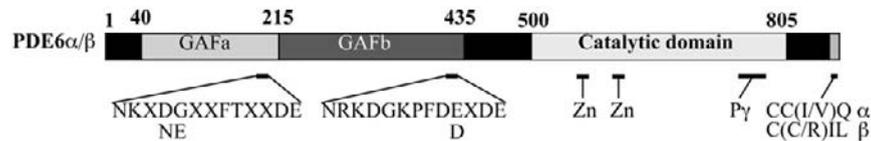

Figure 1 Domain organization of the catalytic subunits of rod PDE6. The bovine rod α (859 a.a.) or β (853 a.a.) subunit each contain two tandem GAF domains (blue and red), a catalytic domain (yellow), and unique C-terminal isoprenylation motifs (green). The consensus sequences for GAFa and GAFb represent amino acid identity [except for positions occupied by two (alternate shown below) or more (denoted by X) different residues]; sequence alignment was performed with human, bovine, mouse, dog, and frog α and β subunits. For the isoprenylation motifs, the frog sequences were omitted.

is a structural module responsible for binding allosteric regulatory molecules [ref. [7,8]; see review by Hurley, this volume]. Based on the crystal structure of the related PDE2 GAF domains [9] and amino acid sequence analysis of the known cGMP-binding phosphodiesterases (PDE2, PDE5, and PDE6), it is likely that the GAFa domains of PDE6 contain high-affinity cGMP binding sites (Fig. 1). An interaction site of the γ subunit with GAFa has been identified by cross-linking experiments [10]. The fact that the PDE6 holoenzyme has 4 GAF domains but only 2 high-affinity cGMP binding sites [11,12,13] raises intriguing questions about the function of the GAFb domains. Whereas 26% of the residues in GAFa are identical in known rod and cone PDE6 sequences, 60% of the GAFb amino acids are identical, including a unique 24 amino acid insert present in PDE6 GAFb but not in other GAF-containing phosphodiesterases.

Progress in elucidating the structure-function relationship of the catalytic domain of PDE6 has relied on its structural similarity to the PDE5 catalytic domain [14], the ability to express recombinant PDE5/cone PDE6 chimeras [15–17], and homology modeling of the catalytic domain based on the PDE4 crystal structure [18]. Two metal ion binding sites critical for catalysis are present in all PDE families [19,20], and substitution of PDE6-specific residues from this region into the PDE5 sequence partially restores PDE6 catalytic efficiency [17]. Using a similar approach, PDE6-specific residues near the catalytic pocket of the enzyme that interact with the Py subunit have been delineated [16,17,21].

The arrangement of the GAF and catalytic domains within the quaternary structure of PDE6 has been obtained at 2.8 nm resolution by using electron microscopy and image analysis of individual PDE6 molecules [22]. Three distinct domains, probably representing two GAF domains and the larger catalytic domain, were observed. The molecular organization of PDE5 was highly homologous. The isolated GAFa domain [23] or the catalytic domain [24] of PDE5 have been expressed and retain their ability to bind or hydrolyze cGMP, respectively. These results strongly suggest that individual domains fold into functional units that can interact to generate the final quaternary structure of the catalytic dimer.

Regulation of Rod PDE6 Catalysis by γ

The γ subunit has multiple sites of interaction with the PDE6 $\alpha\beta$ dimer and with the α_t^* -GTP subunit of transducin;

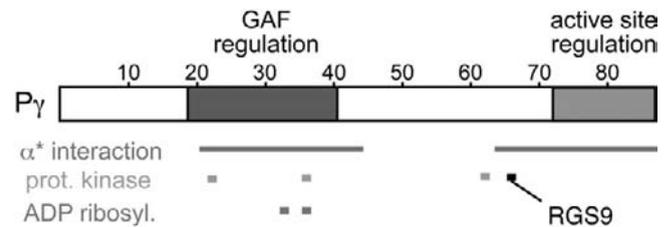

Figure 2 Sites of interaction and regulation of the inhibitory γ subunit of PDE6. The rod γ subunit (87 a.a.) binds to PDE6 at its central GAF interaction domain (red) and its C-terminal inhibitory domain (green). Two major sites of interaction with activated transducin α_t^* subunits are shown in green, and interaction with RGS9 at Val⁶⁶ is in black [50]. Phosphorylation sites are shown in orange. ADP ribosylation at either Arg³³ or Arg³⁶ is in purple [51].

in addition, it serves as a potential substrate for posttranslational modifications (Fig. 2). The C-terminus of γ binds at the entrance to the active site and physically blocks entry of substrate [16,17,25,26]. The central, polycationic region of γ also interacts with the catalytic dimer, and with 50-fold higher affinity than the C-terminal γ region [27]. Binding of this region of γ to the catalytic dimer enhances cGMP binding to PDE6. The combined interactions of the central and C-terminal domains of γ with PDE6 result in very high binding affinity of full-length γ [28]. Recent work has revealed two nonidentical γ binding sites on $\alpha\beta$, one of which is regulated by cGMP binding to the GAF domain [27].

Post-translational modifications of γ have been postulated as feedback mechanisms for PDE6 regulation (Fig. 2). Protein kinases present in rod outer segments can phosphorylate γ at Thr²² [29–31] or Thr³⁵ [31–33]. The primary effect of phosphorylation at either site is to markedly reduce γ interaction with activated transducin [29,31,33]. However, feedback regulation of PDE6 or transducin by phosphorylated γ is unlikely, based on the low stoichiometry of γ phosphorylation observed in the above-cited studies. Phosphorylation of γ at Thr⁶² in nonretinal tissue culture cells has been linked to regulation of the MAP kinase signaling cascade [6], suggesting that γ might be involved in regulating other signaling pathways in photoreceptor cells.

Catalytic Properties of Nonactivated and Activated PDE6

In rod outer segments, there is equimolar γ subunit relative to the PDE6 catalytic subunit concentration [34].

The very high ($K_D \sim 1 \text{ pM}$) binding affinity of γ for the catalytic dimer ensures that only 1 out of 2200 $\alpha\beta$ dimers lacks bound γ and are activated in the dark-adapted condition [35], in good agreement with electrophysiological estimates of spontaneous PDE6 activation [36].

Removing both γ subunits from the PDE6 catalytic dimer activates the enzyme more than 300-fold, with a catalytic constant (k_{cat}) of 5500 s^{-1} for bovine rod PDE6 [27,37] and close to 8000 s^{-1} for frog PDE6 [34,35]. The catalytic efficiency ($k_{\text{cat}}/K_M = 4 \times 10^8 \text{ M}^{-1}\text{s}^{-1}$) for cGMP approaches the diffusion-controlled limit. cAMP is a relatively poor substrate ($k_{\text{cat}}/K_M \sim 3 \times 10^6 \text{ M}^{-1}\text{s}^{-1}$), primarily because of its reduced affinity for the active site [27,35]. Under conditions tested to date, the GAF domains of PDE6 do not allosterically activate or inhibit the active site [27,38].

During visual excitation, PDE6 activation results from binding of α_t^* -GTP to the PDE6 holoenzyme, thereby releasing the inhibitory constraint of γ . However, the maximum extent of activation of cGMP hydrolysis ($k_{\text{cat}} = 4400 \text{ s}^{-1}$ for frog PDE6. [34,35,39,40]) is about half of the fully activated value. In combination with observations that full activation of the PDE6 holoenzyme requires a single α_t^* -GTP [41], it is likely that only one of the two catalytic sites on the PDE6 dimer is activated by transducin during phototransduction.

Roles of the GAF Domains in PDE6 Regulation

The GAF-containing PDE2, PDE5, and PDE6 families each utilize the GAF domain in a different manner. cGMP binding to PDE2 allosterically stimulates catalysis directly [42,43], whereas cGMP binding to PDE5 induces a conformational change enhancing phosphorylation of the enzyme that subsequently increases catalysis [44].

For PDE6, cGMP occupancy at the GAF domains enhances the affinity of γ for nonactivated PDE6 [31,41]; conversely, binding of γ to the PDE6 catalytic dimer enhances cGMP binding to the two nonidentical GAF domains [35,45]; conversely, binding of γ to the PDE6 catalytic dimer enhances cGMP binding to the two non-identical GAF domains [34,46]. This positive cooperativity of cGMP and γ binding serves to lower the basal catalytic activity of PDE6, and reduces cGMP metabolic flux in the dark-adapted state. Binding of cGMP to the GAF domains also serves to sequester a large majority of the total cellular cGMP, because the concentration of PDE6 is so large (see Chapter 195 by Francis and Corbin, this volume, for detailed discussion).

Upon transducin activation of frog PDE6, displacement of one γ subunit on PDE6 not only fully stimulates catalysis but also lowers cGMP-binding affinity at one GAF domain. Accelerated dissociation of cGMP at this site is accompanied by release of γ from the PDE6 holoenzyme. Rebinding of cGMP to PDE6 causes re-association of γ to the enzyme (see Fig. 8 of [34]).

It has been proposed that the primary purpose of the GAF domains is to release sequestered cGMP to assist guanylyl cyclase in restoring cytoplasmic cGMP levels during the

recovery phase of the photoresponse [13,47]. However, the kinetics of cGMP dissociation from the GAF domain are too slow, and the rates of cGMP hydrolysis by activated PDE6 too fast to allow bound cGMP to significantly affect cytoplasmic cGMP levels during recovery to the dark-adapted state.

A more likely role for the GAF domains is to regulate the state of association of γ to catalytic dimer [46]. Free γ has been shown to act in concert with RGS9 to accelerate inactivation of α_t^* -GTP [48,49]. Only when the GAF domains are unoccupied can γ dissociate from PDE6 and serve in this capacity [38,50]. Dissociation of cGMP (and hence γ) from PDE6 is likely only during prolonged light exposures when PDE6 is persistently activated and cytoplasmic cGMP levels remain low. This negative feedback mechanism involving cGMP, the GAF domains of PDE6, and the γ subunit acting as a GTPase accelerating factor for transducin could underlie the accelerated kinetics and reduced amplitude of the photoresponse characteristic of light-adapted rod photoreceptors.

Conclusion

The lifetime of activated rod PDE6 during rod phototransduction is a highly regulated process. Much work remains to fully describe the molecular events within the PDE holoenzyme and its interactions with transducin that precisely regulate the extent and duration of PDE6 activation. The interaction of PDE6 with other proteins such as the “ δ subunit” [51] or GARP2 [52] is poorly understood, but may represent novel mechanisms for regulating the subcellular localization or catalytic activity of PDE6. Finally, it is possible that cross-talk between the visual transduction pathway and as yet uncharacterized signaling pathways may be fundamental to a complete understanding of rod PDE6 regulation during daytime illumination conditions when rod photoreceptors are near or at response saturation.

The Complexity of Cyclic Nucleotides Signaling

Protein phosphorylation is the most common posttranslational mechanism for regulating cellular functions. Regulation by this covalent modification of proteins is not a simple on-off mechanism occurring homogeneously within cells. On the contrary, activation and inhibition of protein kinases and phosphatases are tightly controlled both in time and in space. The exact timing of signal kinetics, the quantitative determination of the speed of signaling molecule diffusion, and their precise location within living cells are necessary prerequisites to a better understanding of cell physiology and pathology [1]. Protein kinases and phosphatases are often discretely localized within the cell in close proximity to receptors and targets, and this location appears critical for speed and specificity of response. The finding that signaling components are highly organized at the plasma membrane, in the cytoplasm, and in the nucleus has led to the proposal of “signaling domains” [2], that is, specific compartments within the three-dimensional matrix of the cell where the signal is generated and/or specifically targeted. cAMP-mediated signaling, for example, complies with tight local control, and the structural basis for such compartmentation is being uncovered. In hippocampal neurons the presence of a macromolecular signaling complex including the β 2-adrenergic receptor, a G protein, adenylyl cyclase (AC), protein kinase A (PKA), the phosphatase PP2A, and the ultimate effector of the receptor, the L-type Ca^{2+} channel has been documented [3], and a highly localized signal transduction from the receptor to the channel has been demonstrated. A crucial role in the nucleation of such signaling domains is played by

A kinase anchoring proteins (AKAPs) [4], a family of functionally related proteins that anchor the regulatory subunit of PKA and possess unique targeting sequences that direct the PKA-AKAP complex to specific subcellular compartments. Within the “signaling domain” not only receptors, effectors and their ultimate targets are found in close proximity, but evidence is also accumulating that compartmentation involves the small diffusible molecules that act as intracellular second messengers and that second messenger limited diffusion can contribute to the efficiency and specificity of signal transmission [5].

The cyclic nucleotides cAMP and cGMP are freely diffusible intracellular second messengers that mediate specific responses to a staggering number of extracellular stimuli by activating downstream effectors, mainly the cAMP- and cGMP-dependent protein kinases (PKA and PKG, respectively). PKA and PKG in turn can potentially phosphorylate hundreds of different cellular targets. The enormous load of specific information that enters the cell and is funneled through these two second messengers is relayed to the final effector systems without any loss of informational detail. The issue raised is how a single molecule can generate the appropriate response to so many different stimuli. One possible way that cyclic nucleotides could expand their signaling capability enough to accomplish this task is by adopting multiple signaling codes. According to this view, transmission of information is not exclusively dependent on the amplitude of the response but can be frequency-dependent [6], similar to what has been shown for Ca^{2+} oscillations, or space-dependent [7]; that is, signal transmission can take place in restricted subcellular compartments, while other

signals are excluded. Several features of the cyclic nucleotides signaling cascades provide a potential molecular basis for such diversity in signaling modes [8]. First, intracellular cyclic nucleotide concentrations appear to be highly flexible and transient in nature because of a tightly controlled equilibrium of synthesis and breakdown. Second, both cyclases (the enzymes that make cyclic nucleotides) and phosphodiesterases (the enzymes that degrade cyclic nucleotides) exist in several isoforms with different tissue distribution, different intracellular targeting, specific regulation, and cross-talk with other signaling pathways. Third, Ca^{2+} , for which a frequency-encoded and a space-encoded mode of signaling has been clearly established, modulates both the synthesis and the breakdown of cyclic nucleotides by regulating, in an isoform-specific manner, both cyclases and phosphodiesterases [8].

A thorough and accurate analysis of the spatio-temporal aspects of cyclic nucleotides signaling appears to be crucial for our understanding of cell physiology [9,10]. So far, such analysis has been very difficult due to technical limitations. Lately, however, there have been methodological advances that allow monitoring of cyclic nucleotide in real time in live cells, thus opening the way to a detailed description in space and time of cAMP and cGMP biochemistry *in vivo*.

Methodological Advances

Traditionally, cyclic nucleotide concentration has been measured by immunoassay on cell lysates. Such a destructive method has several limitations: it is rather insensitive and often phosphodiesterase inhibition is necessary to achieve adequate sensitivity [11,12]; only the average concentration of the cyclic nucleotide in the cell population is recorded; the total, rather than the free cyclic nucleotide content, is detected; the temporal resolution is rather limited; any topographical information on the location of the response is cancelled out. A few attempts have been made to localize cyclic nucleotides in fixed tissue by immunocytochemistry [13] but accurate quantification is a problem, and time-courses are difficult to record.

Two nondestructive approaches have been pursued to monitor dynamically and in real time the levels of cyclic nucleotides in single live cells: (1) recombinant cAMP-cGMP sensitive channels, and (2) fluorescent probes sensitive to cAMP-cGMP and/or cAMP-cGMP dependent phosphorylation. The first method utilizes cyclic nucleotide-gated (CNG) ion channels genetically engineered to be especially sensitive to either cGMP [14] or cAMP [15]. One version of such methodology artificially introduces CNG channels into various cell types via the "patch-cramming" technique: an excised, inside-out membrane patch containing the channels is "crammed" into a recipient cell to measure cGMP concentration in the cytosol near the tip of the pipette [16]. The advantages of this approach are the possibility of easily calibrating the system and the minimal alteration or buffering of the intracellular level of cGMP. One limitation is that detection of the cyclic nucleotide level is confined to the

restricted area where the patch pipette is inserted. Also, given the relatively large size of the patch pipette, this approach is applicable only to relatively large cells (above about 40 μm in diameter). Alternatively, CNG channels have been used to study the membrane-localized, cAMP-signaling pathway by expressing the channel at the plasma membrane, where the adenylyl cyclase is known to reside, and by measuring either cAMP-induced currents [17] or cAMP-induced Ca^{2+} influx via Ca^{2+} -sensitive fluorescent dyes [18].

The second approach for real-time monitoring of cyclic nucleotide levels in live cells relies on imaging of cyclic nucleotide-activated protein kinases (or of their target peptides) that have been fluorescently labeled and are competent for fluorescence resonance energy transfer (FRET) [19]. FRET is a physico-chemical phenomenon whereby the excited state energy of a donor fluorophore is non-radiatively transferred to a nearby acceptor fluorophore. For FRET to occur, the following requirements must be satisfied: (1) substantial overlap between the emission spectrum of the donor and the excitation spectrum of the acceptor, (2) alignment relative to each other in space of the fluorophore transition dipoles, and (3) distance between donor and acceptor fluorophores within 1 to 10 nm. The efficiency of FRET decreases with the sixth power of the distance between the fluorophores [20], making FRET a phenomenon that is exquisitely suitable for detecting conformational changes.

Most FRET-based probes for cyclic nucleotides exploit either PKA or PKG as the natural sensors for cAMP and cGMP, respectively. They take advantage of the conformational change that results from binding of the cyclic nucleotide to the kinase and that leads to a change in the distance between the FRET-donor and acceptor fluorescent labels.

Inactive PKA is a heterotetramer made of a dimer of regulatory subunits (R_2) and two catalytic subunits (C). When cAMP levels rise, two molecules of the second messenger bind to each of the R subunits, thus inducing a conformational change that leads to dissociation of two active C subunits. The prototype FRET-based sensor for cAMP consists of a fluorescein-labeled C subunit and a rhodamine-labeled R subunit [21]. This probe requires *in vitro* labeling of purified C and R subunits and subsequent microinjection in the cell of interest, which limits its use only to a restricted number of applications. Moreover, this very laborious approach suffers from several limitations [22,23], including probe instability, nonspecific compartmentation, and some toxic effect on the injected cell. A variant of this sensor has been generated that is entirely genetically encoded and in which the donor and acceptor fluorophores are the blue (BFP) and green (GFP) variants of the green fluorescent protein [24]. When cAMP is low PKA is mainly in the holotetrameric conformation $\text{R-BFP}_2\text{C-GFP}_2$ and the two fluorophores are close enough to generate FRET. Upon excitation of BFP at its proper excitation wavelength (380 nm), part of its excited state energy is emitted as blue light (460 nm) and part is transferred to the nearby acceptor GFP, which in turn is excited and emits green light (510 nm). When cAMP levels increase, C-GFP subunits are released, the two fluorophores

diffuse apart, and FRET is abolished. In this condition excitation of BFP at 380 nm only generates emission of blue light and no green light is emitted. FRET can be conveniently measured as the ratio of donor to acceptor emission with the advantage of cancelling out fluorescence intensity variations due to probe concentration, optical path length, and excitation intensity [25]. More recently this probe was modified by changing the BFP-GFP couple with the more convenient mutants CFP-YFP [3].

Based on the same general principle, sensors for cGMP have been generated [26,27]. In the probe denominated “cygnet,” the cyan (CFP) and yellow (YFP) variants of the green fluorescent protein have been genetically fused to the amino- and carboxy-terminus of PKG, respectively. CFP and YFP act as donor and acceptor for FRET. The relatively large conformational change generated by cGMP binding to the PKG regulatory domain moves the donor CFP away from the acceptor YFP, thus reducing FRET.

Two other genetically encoded probes have been recently generated to monitor the cAMP dynamics in living cells. These two probes are also based on FRET between two mutants of GFP. Rather than directly probing cAMP levels, these sensors report the PKA-mediated phosphorylation of a substrate peptide. In the first case the two variants of GFP are joined by the kinase-inducible domain (KID) of the transcription factor CREB (cAMP-responsive element binding protein) [28]. The phosphorylation of KID by PKA decreases FRET among the flanking GFPs. The cAMP probe described by Zhang and coworkers is based on a similar principle. In this latter case the fusions of CFP, a phosphoamino-acid-binding domain (14-3-3 τ), a consensus substrate for PKA, and YFP results in a change of FRET dependent on PKA-mediated phosphorylation [29].

Functional Compartments of cAMP in Heart Cells

Mayer and coworkers [30] were the first to propose, more than 20 years ago, the existence of spatially restricted domains of cAMP. The hypothesis was formulated to explain a series of data obtained in cardiac myocytes. In particular, the authors found that the positive inotropic and lusitropic effects induced by β -adrenergic stimulation correlated with activation of a particulate, membrane-bound fraction of PKA; similar elevations of cAMP due to prostaglandin I resulted in the activation of a cytosolic form of PKA and in minimal functional consequences [31]. Similarly, stimulation of cardiac myocytes with glucagon-like peptide-1 (GLP-1) generates a rise in [cAMP]_i comparable to that elicited by isoproterenol, a β -AR agonist, but causes modest negative inotropy and no lusitropic effect, in sharp contrast with isoproterenol [32]. Moreover, in contrast to β_1 -AR, β_2 -AR stimulation fails to induce a cAMP-dependent phosphorylation of non-sarcolemmal proteins (such as phospholamban, or the myofilament proteins troponin I and C protein), but it does activate sarcolemmal L-type Ca²⁺ channels [33], suggesting a differential spatial organization of the PKA activated by the two β -ARs.

More convincing, yet indirect evidence, for localized domains of cAMP was provided by Jurevicius and Fishmeister [34]. In a series of elegant experiments carried out by whole-cell patch-clamp recordings of Ca²⁺ currents in frog heart cells they showed that a local stimulus of the β -adrenergic receptor causes a local activation of I_{Ca}, whereas local application of the adenylyl cyclase activator forskolin induces activation of I_{Ca} throughout the cell. The authors suggested that β -adrenergic stimulation generates a localized accumulation of cAMP sufficient to efficiently activate only nearby located Ca²⁺ channels, whereas nonspecific activation of AC induces a generalized rise of cAMP concentration [34]. Due to the experimental setup, the spatial resolution of these experiments was in the order of 20 μ m, making it difficult to anticipate the physiological relevance of such cAMP compartments in a 10 to 15 μ m wide mammalian cell. New insight into this issue came from experiments in which cAMP dynamics were monitored in real time in rat neonatal cardiac myocytes by using a FRET-based, genetically encoded sensor for cAMP [24]. In these cells, β -adrenergic stimulation generates multiple microdomains with increased concentration of cAMP in correspondence of the T tubular system (Fig. 1). T tubules in heart cells run along sarcomeric Z lines whose distance from one another is about 2 μ m. The local gradients of the second messenger spread for less than half such a distance, implying a range of action for cAMP as small as about 1 μ m [35].

Local control and limited diffusion of cAMP is not a prerogative of heart cells. In fact, in human embryonic kidney cells it has been demonstrated, by using recombinant cyclic nucleotide-gated channels as a cAMP sensor, that a uniform extracellular stimulus with PGE₁ initiates a transient increase in cAMP concentration near the plasma membrane and a sustained rise of the second messenger in the bulk cytosol [18], suggesting that spatially and temporally distinct cAMP signals can coexist within simple cells.

An important role in cAMP diffusional restriction seems to be played by phosphodiesterases, the cAMP degrading enzymes. In fact, PDE inhibition allows uniform spreading of the second messenger from the restricted microdomains along the T tubular network into the bulk cytosol [35] (Fig. 1). It is interesting that certain PDE inhibitors seem to cause “spill-over” of PGE₁-induced cAMP from the soluble into the particulate compartment of ventricular myocytes [7]. A reduction in the localized cAMP effects upon inhibition of PDE was observed also in the frog heart cells locally stimulated with isoproterenol [34], and a role for PDE in shaping the local cAMP response underneath the plasma membrane has been uncovered in embryonic kidney cells [18]. In support of the notion that PDE can control cAMP spreading is the finding that PDEs have also been found to be targeted to specific subcellular compartments [36] and in cardiac myocytes PDEs have been found to be anchored to AKAPs [31,37]. Alternative mechanisms, however, cannot be excluded. In the case of the β_2 -AR, in fact, local signaling has been suggested to result from the coupling of β_2 -AR to Gi proteins that may act locally, possibly through a protein phosphatase-dependent mechanism [38].

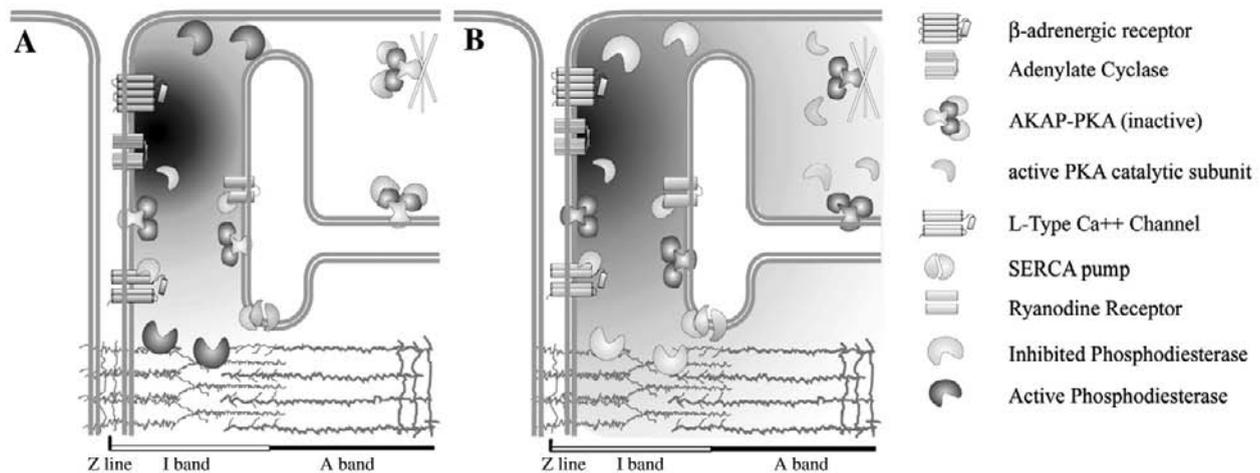

Figure 1 PKA, the main effector of cAMP, is a key regulator of excitation-contraction coupling in muscle cells. In the heart, sympathetic control of the frequency and strength of contraction is exerted by β -AR stimulation, activation of G proteins, and in turn activation of adenylyl cyclase and synthesis of cAMP. The second messenger activates PKA, which by phosphorylating L-type Ca^{2+} channels and the ryanodine receptor increases the amount of Ca^{2+} ions available for contraction of the sarcomere, and by phosphorylating phospholamban (PLB) it favors Ca^{2+} reuptake by the calcium pump SERCA-2. In heart cells, G proteins [44], AC [44], PKA [45], A kinase anchoring proteins (AKAPs) [37,45], the L-type Ca^{2+} channels [44], and the ryanodine receptor [46] have all been found within the T tubular network/junctional SR membrane, thus forming a “signaling domain” that provides a potential anatomical basis for the confined activation of the cAMP signaling pathway.

When the β -adrenergic agonist interacts with the β -AR, a series of G-protein-mediated changes leads to activation of adenylyl cyclase and synthesis of cAMP. The latter acts by means of PKA to phosphorylate the L-type Ca^{2+} channel, which increases the inward movement of Ca^{2+} ions through the membrane of the T tubule. These Ca^{2+} ions release more Ca^{2+} from the sarcoplasmic reticulum (SR) through the ryanodine receptor, and more Ca^{2+} is thus available for binding to sarcomeric proteins for contraction. PKA also activates phospholamban (PLB), thus increasing Ca^{2+} reuptake through the Ca^{2+} pump SERCA-2, located on the SR membrane. All the molecular elements involved in the β -adrenergic signaling pathway are clustered in the region of the T tubular network/junctional SR membrane. PKA itself is anchored in this area through binding to AKAPs [45]. Activation of the β -AR generates in these cells a localized increase of cAMP, which in turn activates a subpopulation of PKA that is confined within the same signaling domain [35] (panel A). Compartmentation of cAMP is due to the activity of phosphodiesterases. Indeed, inhibition of PDE allows homogeneous diffusion of cAMP in the cytosol [35] (panel B). The bars at the bottom of panels A and B indicate sarcomeric elements.

Spatio-temporal Aspects of Cyclic Nucleotides Signaling in Neurons

Although both cAMP and cGMP have been shown to be involved in the molecular processes that govern certain types of learning and memory and, in particular, in activity-induced synaptic plasticity [39,40], most of the spatiotemporal intricacies of cyclic nucleotide signaling in neural circuits still remain to be elucidated [41,42]. Some of the available data, however, point to an important role of the spatial organization of the second messenger in controlling the output. cAMP is involved in both short- and long-term synaptic changes, and functional compartmentation of the second messenger has been proposed as one of the possible mechanisms that control which effect, either short- or long-term, is put in place [42]. In the monosynaptic connection between sensory and motor neurons of the gill-withdrawal reflex in the marine snail *Aplysia* the generalized application of serotonin very rapidly produces (20 sec) a spatial gradient of free cAMP, with the higher concentration being recorded at the distal neuronal processes and the lower concentration at the cell body. On the contrary, only a very prolonged stimulation (2 hrs) is accompanied by translocation of the PKA catalytic subunit to the nucleus [43]. The interpretation of these results is that the observed gradients confine cAMP where it is

most needed for short-term plasticity, that is at the tip of the processes where most of the presynaptic terminals reside. The attenuation of the cAMP signal at the cell body could represent a safety mechanism to ensure that only repeated stimulation leads to active PKA C subunits entering the nucleus, activating transcriptional programs, and therefore generating long-term effects [43].

Conclusions

In the last decades it has become clear that signal transduction does not rely on stochastic events but rather on the sophisticated organization of molecular interactions that are precisely regulated both in time and space. Cyclic nucleotides are key players in the relay of intracellular signals, and are bound to be subject to the same strict control. The fine description of cAMP and cGMP dynamics has been hampered in the past by the lack of adequate technology for real-time monitoring of the levels of these second messengers in live cells. The recent development of imaging-based methodologies that allow single cell analysis and very high spatial and temporal resolution will certainly be crucial in our understanding of cAMP and cGMP biochemistry *in vivo*. At present, the large majority of the data available on the spatio-temporal

aspects of cyclic nucleotide signaling refers to cAMP, and although some evidence for subcellular heterogeneity in cGMP has been presented in the past, no direct single cell data on this topic have yet been published (at the moment this manuscript was submitted). Certainly, in the coming years we can expect to see the uncovering of a finely detailed map of the molecular mechanisms that orchestrate both cAMP and cGMP signal transduction.

Introduction

Cyclic nucleotides bind to specific proteins in cells and are thereby sequestered into different functional compartments. Some of the bound cyclic nucleotide serves to activate target proteins such as protein kinases or ion channels while another portion is bound to sites in other proteins and therefore inactive for stimulating protein kinases or ion channels. Sequestration into or release from such inactive sites could be modulated in response to certain stimuli. In order for sequestration to be physiologically relevant, cyclic nucleotide-binding proteins should have ample affinity and be present in sufficient amounts to bind a significant portion of the total cellular cyclic nucleotide. Moreover, the sequestration should be a regulated process. These conditions appear to be met for cGMP binding to the allosteric (noncatalytic) sites of phosphodiesterase-5 in penile corpus cavernosum or of phosphodiesterase-6 in retina.

It is usually emphasized that extracellular signals modulate levels of cyclic nucleotides in cells by regulation of the activities of adenylyl and guanylyl cyclases. Changes in concentrations of signals presented to cells are thus critical determinants for rate of formation of cAMP or cGMP. Rate of loss, or inactivation, of cAMP or cGMP also contributes importantly to determining the cellular concentration of these nucleotides, but this aspect has been studied much less. There are at least three possible routes of loss of active cellular cyclic nucleotides. These are illustrated for cGMP in Fig. 1.

First, loss of cellular cAMP into the extracellular space can occur by efflux such as through leakage or specific transport processes [1,2]. This energy-dependent transport process for cAMP and cGMP may involve an organic anion transport process that utilizes multidrug resistance proteins in some tissues [3–5]. The rate of cyclic nucleotide efflux appears to be dependent on intracellular cyclic nucleotide levels and independent of direct signal regulation. Furthermore, loss of cyclic nucleotides by hydrolysis greatly exceeds that achieved by efflux [1,6–9].

Second, loss of cyclic nucleotides through degradation by cAMP and cGMP phosphodiesterases (PDEs) has been widely investigated [10–16]. PDEs have been shown to be regulated by a variety of signaling pathways [10–16]. See several chapters in this volume for additional information on specific PDE families.

Third, sequestration of cyclic nucleotide, which is the focus of this chapter, is also a possible route of loss of the cytoplasmic, active pool of cyclic nucleotide. In contrast to loss of cyclic nucleotide by either efflux or degradation, this process would be largely reversible.

Physiological sequestration of second messengers and other signaling agents is not a new concept. For example, Ca²⁺ sequestered in cardiomyocyte sarcoplasmic reticulum is unavailable to stimulate contraction of heart muscle until its release due to depolarization of the cardiomyocyte [17]. Compartmentalization and regulated trafficking of protein kinases and myriad other proteins among plasma membrane, cytoplasm, nucleus, and other organelles is commonplace.

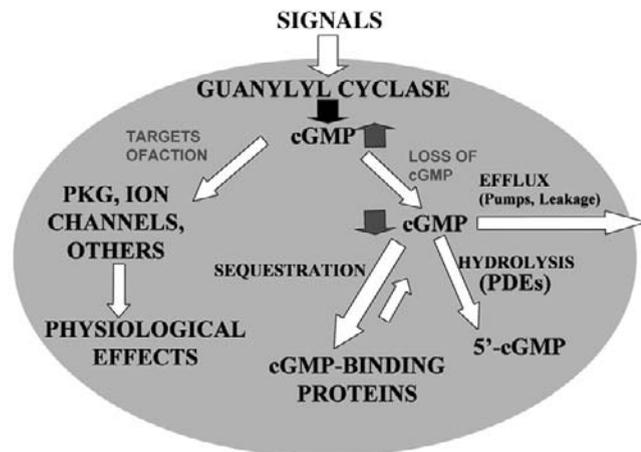

Figure 1 Routes of formation and loss of cGMP in cells.

Likewise, there is increasing evidence for compartmentalization of cAMP into subcellular microdomains that impose diffusional restriction on the nucleotide [18,19]. A portion of the cellular cyclic nucleotide pool can be bound as inert forms to certain cellular proteins. As such, this pool is diffusionaly restricted and less available for degradation or efflux, but upon dissociation, this cyclic nucleotide can join the pool of free cyclic nucleotides or traffic among cyclic nucleotide-binding proteins. Thus, some proteins could act as sinks for cyclic nucleotides, not only providing for inhibition of action by sequestration but also as a source of active cyclic nucleotide after release by certain stimuli.

Localization of cyclic nucleotide-binding proteins to particular compartments within cells would concentrate both the proteins and bound cyclic nucleotide within these locales [18]. Compartmentalization of cyclic nucleotides with their target proteins such as PKA and PKG, or with PDEs, almost certainly occurs and is likely to be physiologically advantageous. Co-localization of cyclic nucleotides with PDE activity could also be brought about evolutionarily by fusing noncatalytic cyclic nucleotide-binding domains with catalytic domains responsible for cyclic nucleotide hydrolysis. This would effectively concentrate the cyclic nucleotide in the microenvironment of the catalytic site. Upon dissociation from the binding site, the nucleotide would most likely be hydrolyzed rather than reentering the active pool.

Conclusive evidence for sequestration of cAMP into inactive pools by cellular proteins has not been demonstrated. Type I regulatory subunit (R subunit) of PKA occurs in stoichiometric excess of catalytic subunit (C subunit) in some tissues [20]. This R subunit contains bound cAMP. However, the apparent excess of R subunit in some cases could be an artifact, since the instability of free C subunit makes quantification difficult. If excess R subunit is conclusively demonstrated, it might act as a buffer to dampen cAMP responses or act as a reservoir for cAMP. R subunit is in slight excess of cAMP in unstimulated rat heart [18].

Cellular sequestration of cGMP in certain instances seems entirely plausible. Of particular emphasis is the likelihood

that cGMP could be sequestered by a group of cGMP-binding phosphodiesterases (PDEs) (PDE2, PDE5, PDE6, PDE10, PDE11) that contain noncatalytic GAF domains. Several of these families of PDEs (PDE2, PDE5, PDE6) degrade cGMP or cAMP at catalytic sites and have been shown to bind cGMP at noncatalytic (allosteric) sites associated with the GAF domains. These binding sites provide the potential for sequestration of cGMP away from its targets such as cGMP-dependent protein kinase (PKG) and cyclic nucleotide-gated channels. Some signals could cause release of this latent form of cGMP for stimulation of certain pathways, or alternatively, they could release the nucleotide near the catalytic site for its efficient breakdown and contribute to negative feedback regulation of the cGMP pathway. If sequestration of cGMP by a cGMP-binding PDE is to be physiologically meaningful, the affinity of cGMP for this PDE should be high. Furthermore, the stoichiometric amount of this PDE should be significant relative to the level of cGMP itself. There should also be mechanisms for modulating the affinity state of the cGMP-binding sites of the PDE. Whether the levels of PDE2, PDE10, or PDE11 are sufficient or capable to bind a significant amount of total cGMP in any cell has not been investigated [21–24]. It should be emphasized that cellular sequestration by any of the cGMP-binding PDEs would be enhanced by appropriate co-compartmentalization with cGMP production. This also applies to cGMP-gated channels, although it is unlikely that number and affinity of binding sites of these proteins are sufficient to bind a significant portion of total cGMP in most cells.

Sequestration of cGMP in Rod Photoreceptor Cells by PDE6

Cyclic GMP is the primary intracellular second messenger for visual transduction and is present in high concentrations in photoreceptor cells. Light stimulation activates PDE6 more than 100-fold, causing free cytoplasmic cGMP to drop to sub-micromolar levels. Recovery of the dark-adapted level of cGMP is aided by PDE inactivation in concert with guanylyl cyclase activation. cGMP-gated cation channels in the plasma membrane close in response to the light-induced decrease in cGMP, resulting in hyperpolarization of the cell (for reviews, see [25, 26]).

Sequestration of cGMP is central to this pathway, since the dark-adapted level of cytoplasmic cGMP (2–4 μM) inferred from electrophysiological studies [27,28] is less than 10 percent of total cGMP concentration (60 μM) in the signal-transducing outer segment portion of the photoreceptor [29]. Both PDE6 holoenzyme ($\alpha\beta\gamma_2$) and the cGMP-gated channel bind cGMP and could sequester it [30,31]. However, the relative number of cGMP-binding sites and the affinity with which each protein binds cGMP (Table I) indicate that the cGMP-gated ion channel plays a minor role in sequestration of cGMP in the outer segment.

PDE6 is present in high concentrations (20 μM holoenzyme concentration) in rod outer segments [30,32]. Two high-affinity

Table I Calculated Intracellular Concentrations in Frog Rod Outer Segments

Component	concentration ¹ (μM)	[cGMP site] (μM)	Binding affinity (μM)	[cGMP] bound ³ (μM)
PDE6 (high affinity)	20	40	0.06	39.0
Low affinity		75	7.0	18.4
cGMP-gated channel	1	4	30 ²	0.3
cGMP	Total: 60 free: 2.3			

1. Concentrations in the rod outer segment are referenced to the cytoplasmic volume (see text).
2. The cited value is the half-maximal activation constant for this binding reaction.
3. Bound and free values were estimated using EQCAL (Elsevier Biosoft) and assuming non-interacting, non-cooperative binding.

cGMP-binding sites per holoenzyme are occupied in the inactive PDE6 [34], binding two-thirds of total cellular cGMP in amphibian rod outer segments [35]. A second class of cGMP-binding sites with 100-fold lower affinity has been detected [35]. Assignment of this binding to the second GAF domain within each catalytic subunit of PDE6 is largely based on the fact that no other high-abundance cGMP-binding protein has been reported in photoreceptors. Together, the high- and low-affinity sites sequester 95 percent of total cellular cGMP, bringing the free cGMP into the low micromolar range (Table I).

Light activation of PDE6 causes a sub-second decline in free cytoplasmic cGMP to sub-micromolar levels, causing closure of cGMP-gated ion channels in the plasma membrane. Notably, total extractable cGMP is decreased only approximately 50 percent (to approximately 30 μM). Activation of PDE6 converts one of its high-affinity cGMP-binding sites to a lower affinity that allows for rapid dissociation of this cGMP. The other high-affinity site on PDE6 undergoes a more modest loss in affinity, and cGMP probably remains bound to this site—and therefore protected from hydrolysis—during excitation and recovery [33,36–38]. Termination of the photoreponse requires inactivation of PDE6 catalysis by its γ subunit, restoration of the second high-affinity binding site on PDE6, acceleration of cGMP synthesis by guanylyl cyclase, and rebinding of cGMP to the cGMP-gated channel and to both sites on PDE6.

The functional significance of light-induced changes in the amount of sequestered cGMP is unknown. One hypothesis is that cGMP released from light-activated PDE6 could elevate cytoplasmic cGMP and assist guanylyl cyclase during the recovery phase of the response [35,36]. However, sequestered cGMP that is released upon illumination will be quickly hydrolyzed and is unlikely to contribute to restoring free cGMP levels during recovery [37]. A more plausible hypothesis is that cGMP release from activated PDE6 serves as a negative feedback mechanism to inactivate PDE6 during bright light adaptation of photoreceptors [33]. Cyclic GMP dissociation from PDE6 exerts an allosteric effect on inhibitory γ subunit [33,38,39], causing γ to accelerate transducin GTPase (in concert with RGS9; [37,40,41]). In this view, cGMP-binding sites on activated PDE6 would respond

to a persistent reduction in free cGMP levels (that is, bright, continuous illumination) by releasing bound cGMP, causing transducin to more rapidly inactivate itself and allow the γ subunit to inhibit PDE6 once more. This is consistent with the speeded recovery of the photoreceptor light response under conditions of bright light adaptation.

In summary, cGMP sequestration by PDE6 meets the criteria for physiological relevance: (1) concentrations of PDE6 cGMP-binding sites and cGMP in photoreceptor cells are comparable, (2) GMP-binding to PDE6 is regulated, and (3) affinity of the cGMP-binding sites is sufficient for quantitatively significant cGMP binding in these cells. Cyclic GMP binding by PDE6 is likely to serve multiple functions in regulating the signal transduction in photoreceptors. In the dark-adapted state, PDE6 binding of cGMP maintains free cytoplasmic cGMP at the low levels needed for opening a small fraction of cGMP-gated ion channels in the plasma membrane. Following light activation, release of cGMP from PDE6 may shorten the lifetime of excitation and provide a mechanism for adapting photoreceptor cells to sustained illumination.

Sequestration of cGMP by PDE5

PDE5 was the first recognized mammalian cyclic nucleotide receptor other than PKA and PKG [42,43]. It is highly specific for hydrolysis of cGMP at a single catalytic site on each subunit, and it contains two potential cGMP-binding sites (GAF domains) in the regulatory domain of each subunit [44,45] with an average cGMP-binding affinity of about 200 nM. Phosphorylation of PDE5 by PKG at Ser-92 (bovine enzyme) increases cGMP-binding affinity ten-fold [46,47] and also stimulates the catalytic activity of the enzyme [47]. Furthermore, occupation of the catalytic site of bovine PDE5 by cGMP or cGMP analogs stimulates binding of cGMP to the allosteric sites, which in turn stimulates phosphorylation at Ser-92 [43,48]. It follows from these reciprocal, allosteric effects that elevation of cGMP in cells would initiate PDE5-mediated negative feedback by stimulation of both cGMP breakdown at its catalytic site and sequestration of cGMP at its allosteric sites. These two mechanisms for lowering free

Table II Calculated Intracellular Concentrations in Rabbit Corpus Cavernosum

Cell conditions		Free [cGMP] nM ²	Bound [cGMP] nM ²	
[cGMP] nM	PDE5		To PDE5	To PKG
Basal	Unphospho-	7	6.7	4.0
Elevated	Unphospho-	23	20.0	11.0
Elevated	Phospho-	8	41.1	4.5
Basal	Phospho-	2	14.2	1.4

1. Basal total cGMP concentration 18 ± 4 nM. Nitric oxide-stimulated cGMP concentration, ~ 54 nM. Total PDE5 concentration (referenced to cGMP binding sites), 188 ± 6 nM. Total PKG concentration (referenced to cGMP binding sites), 58 ± 6 nM. Calculations based on specific enzyme activity of pure proteins, and intracellular water of 0.5 g per g tissue.

2. Calculated assuming the following K_D values: PKG=100 nM (from K_m of PKGI α at 20°C), unphospho-PDE5=200 nM at 0°, phospho-PDE5=30 nM, using EQCAL and assuming noninteracting, noncooperative cGMP binding.

cGMP levels should diminish cGMP binding to PKG or other cGMP receptor proteins.

In order for sequestration of cGMP to play a significant role in modulating the free cGMP levels in PDE5-regulated signaling pathways, the number and affinity of cGMP-binding sites must be sufficient to buffer cGMP, and the rate of binding/sequestration must be faster than the rate of loss via hydrolysis. At least in some tissues, these conditions appear to be met. In rabbit corpus cavernosum smooth muscle cells (Table II), PDE5 allosteric binding site concentration is more than five times higher than basal cGMP [49]. The binding affinity of these sites is great enough (even for the unphosphorylated PDE5) to sequester a significant portion of cGMP, even after elevation of this nucleotide by various agents. Loss of active cellular cGMP by this sequestration could be quantitatively meaningful since loss of total cellular cGMP by PDE5 catalytic breakdown of this nucleotide is calculated to require about 16 sec [49].

Under basal intracellular conditions, most cGMP molecules would be bound to PDE5 or PKG given the high affinities of these two proteins for cGMP. Using the K_D value of 200 nM that we determined for unphospho-PDE5 [48,50], PKG K_D for cGMP of 100 nM [51], and the intracellular values of 188 nM PDE5, 58 nM PKG and 18 nM for cGMP (Table II), we used EQCAL (Elsevier Biosoft) to calculate free cGMP and bound cGMP under various conditions.

Figure 2 summarizes our model for regulation of cGMP signaling pathways by sequestration of this nucleotide by allosteric sites of PDE5. In the basal condition (low cGMP, unphosphorylated PDE5), both PDE5 and PKG contribute to binding about half of the total cellular cGMP (free concentration = 7 nM). A three-fold increase in total cGMP levels by guanylyl cyclase activation initially would cause corresponding increases in free cGMP and the amount bound to both PKG and PDE5. Increased PKG activation resulting from cGMP binding might phosphorylate PDE5, enhancing ten-fold its binding affinity at the noncatalytic binding sites. This would immediately reduce the free cGMP and reverse

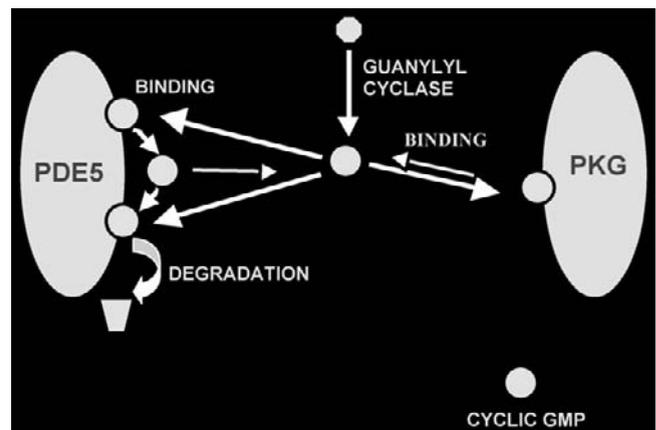

Figure 2 Proposal for regulation of some signaling pathways by sequestration of cGMP by allosteric sites of PDE5.

PKG activity to its basal state. If PDE5 dephosphorylation were relatively slow, free cGMP levels as well as PKG bound to cGMP might both drop several-fold lower than their basal values (Table II). In summary, cGMP elevation would cause increased sequestration, resulting in dampening of the cGMP signal and facilitating termination of this signal.

The process described above could be part of a concert of negative feedback processes for cGMP that have evolved for fine regulation of cGMP signaling in a number of tissues: (1) increased PDE5 catalytic activity due to mass action of elevated cGMP, (2) increased cGMP binding to PDE5 allosteric sites due to mass action of elevated cGMP, (3) increased PDE5 catalytic activity due to phosphorylation and activation of PDE5 by activated PKG [50], and (4) increased cGMP binding to PDE5 allosteric sites due to this phosphorylation. A fifth possible process is direct stimulation of the PDE5 catalytic site by allosteric cGMP binding to the enzyme, which would be predicted by the principle of reciprocity [52]. A final possibility is that concentrating cGMP near the catalytic site by its release from proximal

cGMP-binding sites could increase efficiency of cGMP hydrolysis. The presence of such an array of mechanisms for negative feedback of the cGMP pathway suggests that cells cannot readily tolerate excessive activation of PKG or other target proteins. Thus, for both PDE5- and PDE6-containing cells, sequestration may act to (1) buffer cGMP levels in the basal state and (2) act as negative feedback regulator to prevent overstimulation and accelerate response termination of the signaling pathway.

Introduction

cAMP-dependent protein kinase (PKA) is one of the best characterized members of the large protein kinase superfamily. The catalytic subunit serves as a structural prototype for the entire family. The inactive holoenzyme comprises a regulatory (R) subunit dimer and two catalytic subunits. Binding of cAMP to the R subunits unleashes the active C subunits. The structure of the C subunit is described and correlated with its function. The structure of the dimerization/docking domain of RII α and the cAMP binding domains of RI α and RII β are also described and correlated with the dynamic properties of the R subunits.

cAMP-dependent protein kinase (PKA) was one of the first protein kinases to be discovered [1], the first to be sequenced [2], the first to be cloned [3], and the first protein kinase for which a crystal structure was solved [4]. It thus serves in many ways as a prototype for the entire protein kinase superfamily, which represents approximately 2 percent of the human genome. cAMP is an ancient stress response signal; for example, it is a universal indicator of glucose deprivation. Whereas in bacteria, the cAMP second messenger is linked to the catabolite gene activator protein, in mammals it is linked primarily to the activation of PKA. PKA is ubiquitous in mammalian cells and regulates many diverse pathways.

The inactive holoenzyme complex consists of a regulatory (R) subunit dimer and two catalytic (C) subunits. Binding of cAMP to the R subunits unleashes the active C subunits, thus allowing them to phosphorylate a variety of protein substrates, both cytosolic and nuclear [5,6]. In addition to serving as inhibitors of PKA activity and receptors for cAMP, the R subunits also serve as adapters that tether the C subunit to specific cellular locations by binding to A kinase anchoring proteins (AKAPs) [7]. PKI, another inhibitor of the C subunit that is independent of cAMP [8], also contributes to trafficking of the free C subunits between the cytoplasm and

the nucleus [9]. The inhibitors of PKA activity are both modular and multifunctional proteins. A review of PKA structure thus must include the diverse set of proteins that contribute overall to PKA regulation. The structures of the C subunit and its inhibitors, both the R subunits and PKI, are described here.

Catalytic Subunit

In mammals three isoforms of the C subunit have been identified: α , β , and γ [3,10,11]. The C α subunit is expressed constitutively in all cells, whereas expression of C β is tissue specific and especially prominent in brain. C γ is found primarily in testes. Several splice variants of both C α [12] and C β [13] also exist; all differ in the first exon. In the primary form of C α , β , and γ , exon I codes for 14 amino acids that include an N-terminal myristylation site [14]. The other C subunit splice variants are typically not myristylated. In addition to co-translational myristylation, the C subunit is phosphorylated posttranslationally at two essential sites [15]. Phosphorylation at Thr197 in the activation loop is essential for efficient catalysis [16]. Phosphorylation at Ser 338 is essential for stability and is very likely to be an important part of the maturation of the initial transcript into an active enzyme [17]. Phosphorylation at Ser10 [18] and deamidation of Asn2 [19] are other posttranslational modifications that have been identified.

Catalytic Properties

The C subunit is a highly concerted enzyme; all its energy is focused on transferring the γ -phosphate of ATP to an appropriate substrate protein [20]. There are two general recognition motifs for PKA substrates [21]: Arg-Arg-X-Ser/Thr-Hyd and Arg-X-X-Arg-X-X-Ser/Thr-Hyd, where X is any residue and Hyd is a hydrophobic residue. The mechanism

for catalysis has been carefully defined by Adams [22]. Pre-steady state kinetics established that the actual rate of phosphoryl transfer is very fast ($>500/s$) whereas the k_{cat} is only 20/sec. For PKA, the k_{cat} correlates, in general, with the release of ADP and the conformational changes that allow for its release [23]. The K_m for the heptapeptide, kemptide (Leu-Arg-Arg-Ala-Ser-Leu-Gly), is 10–20 μM ; however, this K_m does not reflect a true binding affinity. The K_d (200–300 μM) more accurately reflects affinity [24].

Structure

Multiple forms of the C subunit have been crystallized, and these structures provide a molecular understanding of nucleotide binding, peptide binding, and conformational flexibility [4,25–27]. The C subunit comprises a highly conserved core containing a smaller ATP binding domain (residues 40–126) that is dominated by β structure and a larger, mostly helical lobe (residues 127–300) that provides a docking site for peptides/proteins as well as several essential residues that contribute to catalysis (Fig. 1). The adenine ring of ATP is buried at the base of the cleft between the two lobes, and the peptide docks to the surface of the large lobe at the edge of the cleft. This core is conserved in all protein kinases that phosphorylate Ser, Thr, or Tyr [28].

In PKA, as seen in Fig. 2, the core is flanked by 40 additional residues at the N-terminus that begin with a myristoyl moiety attached to the N-terminal Gly. This is followed by an amphipathic helix that is anchored by hydrophobic interactions to both the small and large lobe of the core [29]. The core is followed by a 50 residue “tail” that is anchored to the large lobe (residues 301–318), has a flexible anionic “gate” that draws basic peptides to the active site cleft, and terminates

with a hydrophobic motif at the C terminus (Phe-Ser-Glu-Phe) [30,31]. This hydrophobic motif is anchored to a hydrophobic pocket on the small lobe and probably helps orient the C-helix into its active conformation.

CONSERVED CORE

As recognized initially by Hanks and Hunter [32], the conserved kinase core consists of a set of sequence motifs that span the entire core (Fig. 1). Although affinity labeling provided clues about the roles of some of these motifs [5,33,34], the first crystal structure revealed the unique architecture that brings most of these conserved motifs to the active site cleft where they contribute primarily to the binding of ATP and phosphoryl transfer [35]. The detailed characterization of the C subunit is reviewed in Johnson *et al.* [36].

SMALL LOBE

In general, the small lobe is more “loosely” structured than the large lobe. One of the most essential features of this enzyme is the glycine-rich loop that links β strands 1 and 2. In most of the crystal structures, this loop is disordered or ordered poorly [31]. Only in the ternary complex where ATP, or an ATP analog, and an inhibitor peptide, PKI (5–24), are bound [26,37] and in a recently solved aluminum fluoride complex that mimics a transition state intermediate, is the tip of the loop firmly anchored [38].

The hydrogen bond between the backbone amide of Ser53 and the γ -phosphate of ATP is probably the driving force for catalysis [39]. The two other essential residues in the small lobe are Lys72 in β strand 3, which anchors the α - and β -phosphates of ATP, and Glu91 in the C helix, which interacts with Lys72. All crystal structures of the C subunit so far have been of the active, fully phosphorylated protein.

Figure 1 Structure and sequence of the catalytic subunit of PKA. A ribbon diagram of the mouse C subunit bound to ATP and an inhibitor peptide PKI(5-24) is on the left [26]. β strands are in green; α helices are yellow. PKI(5-24) is red. Conserved residues are indicated as red balls, phosphorylation sites as purple balls. On the right is the sequence with the same color coding.

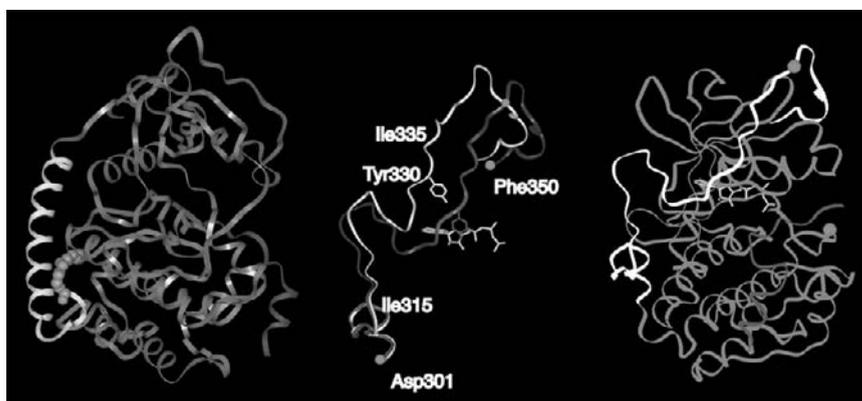

Figure 2 The N and C terminal tails of the catalytic subunit. The structure of the myristylated N terminus (residues 1–40) was observed in the mammalian C subunit (left); this structure represents an open conformation. On the right is a structure of a ternary complex of the recombinant C subunit with the C terminal tail highlighted in white. In the center is shown the conformation of the C terminal tail in an “open” and “closed” conformation. Tyr330 in the closed conformation forms a nucleation site by interacting with the ribose of ATP, the linker through Glu127, and the P-3 Arg through a water molecule. Replacement of Tyr330 with Ala leads to significant loss of activity. In the absence of ATP, the tail tends to be disordered.

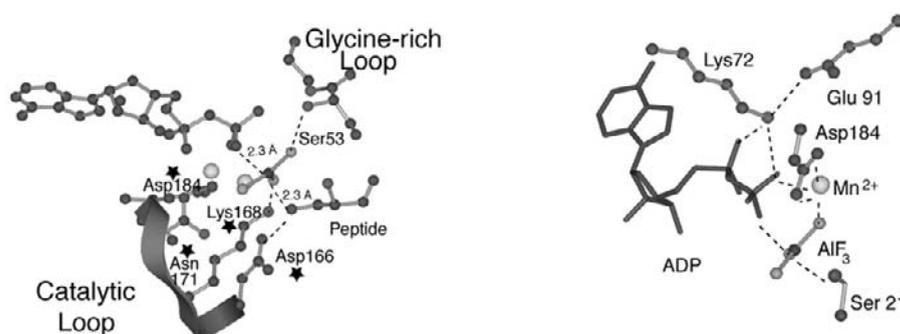

Figure 3 Aluminum fluoride complex mimics a transition state intermediate. On the left is the active site cleft in the presence of MgATP and PKA (5-24) [26]. On the right is the convergence of active site residues in a complex of C subunit with ADP, AlF_3 , and a substrate peptide. This structure reveals how many of the conserved residues cluster around the active site cleft and contribute to the transfer of the γ phosphate of ATP to the peptide substrate. Conserved residues are highlighted with a yellow dot.

Phosphorylation decreases the K_M (ATP) 50-fold and increases the rate of phosphoryl transfer from 500s^{-1} to 20s^{-1} [16]. For many other protein kinases the proper orientation of the C helix is dependent upon phosphorylation of the activation loop in the large lobe [40]. Most likely, this is also true for the C subunit when the protein is unphosphorylated.

LARGE LOBE

Most of the conserved residues in the large lobe are localized on a β sheet that is anchored firmly through hydrophobic interactions to the large lobe (Fig. 3). The catalytic loop linking β strands 6 and 7 contains 3 conserved residues; Asp166 and Asn171 are universally conserved whereas Lys168 is conserved in all Ser/Thr specific kinases. Although Asp166 is positioned to be a catalytic base, it contributes only minimally to phosphoryl transfer and is thought to be used

primarily for orienting the peptide hydroxyl moiety rather than contributing significantly to the nucleophilic properties of the attacking group [41]. Asn171 binds to the second metal ion that interacts with the α and γ phosphates of ATP. It also hydrogen bonds to the backbone carbonyl of Asp166, thereby stabilizing the backbone of the catalytic loop. The magnesium-positioning loop, residues 184–187, links β strands 8 and 9. Asp184 binds the activating Mg ion that bridges the β and γ phosphates of ATP. β strand 9 is followed by the activation loop, which is positioned for optimal phosphorylation by the phosphorylation of Thr197. When expressed in *E. coli*, Thr 197 can be autophosphorylated. However, Thr197 is also an excellent substrate for PDK1 [42], and in mammalian cells it is more likely that the C subunit is phosphorylated by a heterologous protein kinase, not by autophosphorylation [43]. Thr197 is followed by the P+1 loop, named because three residues (Leu198, Pro202, and Leu205) fold inward

and form a docking site for hydrophobic P + 1 residue. In fact, however, this loop can be more appropriately referred to as the peptide-organizing loop, since almost every residue contributes to some aspect of peptide recognition. Gly200 and Thr201 are essential and conserved in all Ser/Thr protein kinases. Gly200 abuts the backbone of the P-site residue and forms a hydrogen bond to the P + 1 backbone amide. In contrast, the side chain of Thr201 interacts directly with catalytic loop residues, where it is wedged between and hydrogen bonds to the side chains of Lys168 that positions the γ -phosphate of ATP and Asp166 that positions the hydroxyl acceptor in the peptide substrate. The bridging role of Thr201 is seen most clearly in the structure of ADP, AlF_3 , and a substrate peptide (Fig. 3) [38]. Glu203 in PKA provides a docking site for the P-6 Arg and Tyr204 hydrogen bonds to Glu230, a primary recognition site for the P-2 Arg. The aromatic ring of Tyr204 also contributes to peptide binding.

Protein Kinase Inhibitor

PKI contains a 20 residue inhibitor domain that binds to the free subunit ($K_d = 2$ nM). In solution, PKI, which contains 75 amino acids, is mostly disordered with the exception of two helical regions [44]. The first helical region provides high-affinity binding for PKI to the C subunit [8]. This amphipathic helix precedes the consensus site, which for PKI contains an Ala at the P site. The high-affinity binding of PKI requires ATP. While the consensus site segment of PKI binds to the active site cleft region, the high-affinity binding of PKI requires the amphipathic helix that docks to a hydrophobic pocket composed of Tyr²³⁵-Pro-Pro-Phe-Phe [25]. The second helix in the C subunit lies in the region that harbors the nuclear export signal [9].

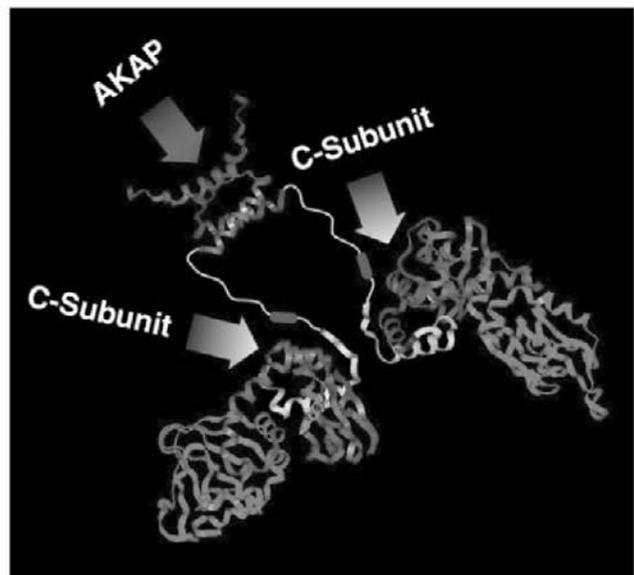

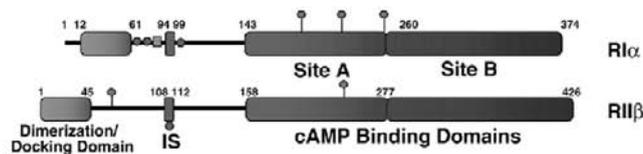

Figure 4 Domain organization of the regulatory subunits. The modular organization of RI and RII is shown on the left and a model of the subunit showing a flexible linker is on the right. Figure on the left is done by Ashton D. Taylor.

Regulatory Subunits

As seen in Fig. 4, the R subunits are modular proteins that are multifunctional and highly flexible [45]. There are two major isoforms, types I and II, with α and β subtypes in each class. RI α and RII α are expressed in most mammalian tissues whereas the expression of the β isoforms is more tissue specific. There are also unique isoform distribution patterns: RI α is expressed predominantly in growing and transformed cells and RII α predominates in differentiated cells [46]. The isoforms are clearly not functionally redundant. The only R subunit that is essential is RI α . Deletion of RI α is embryonically lethal and leads to cardiac defects [47]. Knockouts of other isoforms give unique phenotypes but are not lethal, and RI α tends to compensate when other R subunits are deleted [48]. For example, deletion of RII β gives a lean phenotype with a resistance to alcohol toxicity [47,49]. Myxomas and Carney disease are caused by premature stop codons in RI α [50].

Clearly, there is still much to be learned about the physiological importance of the PKA isoforms. RI α requires ATP and 2 Mg^{2+} ions to form a tight complex with the C subunit [51]; the high-affinity binding of ATP (60 nM) and C (0.2 nM) are synergistic. Type I holoenzyme is activated at lower levels of cAMP than type II holoenzyme [52,53]. RII binding to the C subunit is independent of $MgATP$; instead RII subunits are autophosphorylated at the consensus inhibitor site by the C subunit.

Molecular Architecture

All mammalian R subunits share the same organization. At the N-terminus is a dimerization/docking domain that locks the enzyme into a stable dimer. In the RI subunits the two protomers are actually linked by a disulfide bond [54].

Figure 5 Structures of the regulatory subunits. On the left is the structure of the cAMP-binding domains of RI α [61] and RII β [62]. On the right is the dimerization/docking domain of RI α .

This is followed by a flexible and variable linker region that also contains a pseudo-substrate inhibitor site. In the absence of cAMP, this inhibitor site binds to the active site cleft of the C subunit, thus blocking access of other substrates. At the C-terminus lie two stable, tandem cAMP-binding domains. In RI α the first cAMP-binding domain also contributes to the docking of the C subunit [55]. Domain A thus shuttles between two conformations: a C bound form associated with the holoenzyme and a cAMP-bound conformation. The second cAMP-binding domain serves as a gatekeeper and regulates access of cAMP to site A [56].

cAMP is an ancient signaling molecule that has been conserved from bacteria to man. The cAMP-binding domain that serves to shield the cyclic phosphate from solvent and from phosphodiesterases is also ancient [57]. In bacteria the cAMP-binding domain is linked to a DNA-binding domain in the catabolite gene activator protein, whereas in mammals it is linked to protein kinase activation and is also found in cyclic nucleotide gated channels [58] and in a cGMP exchange factor, EPAC [59]. The highly conserved phosphate-binding cassette that surrounds the cyclic phosphate is the recognition motif for this [57]. One side of this motif interacts with cAMP while the other side interacts with the rest of the domain and is the heart of an extended network of interactions that reach to both the C-subunit docking site and the B domain [60]. Although the motif and the overall domain are highly conserved in RI and RII, the network of interactions (Fig. 5) that lead to the cooperative binding of cAMP and the release of the catalytic subunit are remarkably different in RI α and RII β [61,62].

The D/D domains are composed of a very stable four-helix bundle (Fig. 4), but once again there are striking differences between RI and RII [63]. The AKAP-binding surface is formed at the dimer interface, and dimerization is essential for AKAP binding. An amphipathic helix from the AKAP docks to this dimer interface [64].

Dynamics

In the absence of C subunit, the region that links the D/D domain to cAMP-binding domain A is quite mobile, as

demonstrated by time-resolved fluorescence anisotropy [65]. Even in the holoenzyme the linker remains quite mobile. Small angle X-ray scattering reveals a highly asymmetric structure [66]. Hydrogen/deuterium exchange in the presence and absence of C-subunit and in the presence and absence of cAMP has provided a glimpse of the dynamic network that links cAMP binding to the release of the C-subunit [60].

Cyclic GMP-Dependent Protein Kinase

Thomas M. Lincoln

*Department of Pathology,
University of Alabama at Birmingham,
Birmingham, Alabama*

Introduction

The emergence of nitric oxide (NO) signaling between cells in biological systems over the past two decades has opened up new fields of exploration in such areas as vascular biology and neuroscience. Because NO signaling involves one of the more established intracellular signaling molecules, namely cyclic GMP, there has been a renewed interest among investigators to learn more about this signaling pathway. In this review, I will highlight one major player in the cyclic GMP signaling pathway, the cyclic GMP-dependent protein kinase (PKG). Although this particular protein kinase was among the first half-dozen protein kinases discovered more than 30 years ago, its role in biological systems is still not as well-defined as some of the more recently discovered protein kinases. I will review a few of the earlier seminal findings regarding the function of this enzyme and examine more thoroughly information that has come to light recently.

Biochemical and Molecular Biology of PKG Isoforms

Up to two genes in the genomes that have been studied to date encode cyclic GMP-dependent protein kinase [1,2]. In vertebrates, the products of the genes are termed the type I and the type II cyclic GMP-dependent protein kinase (referred to hereafter as PKG-I and PKG-II, respectively). In the mammalian tissues studied, PKG-I seems to be the more widely expressed form and is present at easily measured levels in

smooth muscle cells, platelets, cerebellar Purkinje cells, and cardiomyocytes [3–6]. Other cells contain measurable but lower levels of the enzyme, and these include endothelial cells, leukocytes, and many endocrine-secretory cells. Still other cells do not appear to express measurable levels of PKG-I, and these include erythrocytes and skeletal muscle myocytes. PKG-II was first discovered in intestinal epithelial cells, where it is highly expressed and localized to the particulate fractions of these cells [7,8]. The presence of PKG-II has been confirmed in brain tissue [9], juxtaglomerular cells [10], and chondrocytes through molecular and genetic studies [11].

PKG is a member of the serine/threonine kinase branch of protein kinases and is a member of the group of cyclic nucleotide-dependent protein kinases. The protein kinases in this group have as their distinguishing feature an N-terminal regulatory component (either a domain of the enzyme or a separate subunit) that binds with high affinity to either cyclic AMP or cyclic GMP. The PKG members bind cyclic GMP on their regulatory domain with an affinity approximately 20–50 times that of cyclic AMP, whereas the cyclic AMP-dependent protein kinases (PKA) bind cyclic AMP to their regulatory subunits with the greater affinity [12,13]. The catalytic domain of the PKG members reside in the C-terminal half of the protein. The PKG isoforms can be divided into four regions: (1) an extreme N-terminal domain consisting of a leucine/isoleucine zipper dimerization motif and an autoinhibitory sequence (the autoinhibitory sequence contains serine and threonine residues that undergo phosphorylation that modulates activity of the enzyme once the enzyme has been activated by the binding of cyclic GMP [12–15]);

(2) tandem, high-affinity cyclic GMP binding sites probably created through the duplication of the DNA sequences encoding specific amino acid residues in this region [16]; (3) a catalytic domain having homology with all members of the entire protein kinase family; and (4) an extreme C-terminal region with unknown function.

PKG-I is expressed in cells as two isoforms that are derived by the alternate mRNA splicing for the first two exons encoding the N-terminal region of the enzyme [3–6]. The smaller of the two forms (PKG-I α) has the first exon expressed as the N-terminal region and is the form most abundant in platelets, most vascular smooth muscle cells, and cerebellum. The larger of the two forms (PKG-I β) expresses the second exon in the protein and is abundant in vascular and nonvascular smooth muscle cells. However, there appears to be much variability in the expression of these two isoforms even in the same cell type (e.g., aortic smooth muscle cells). Furthermore, mRNA levels usually appear more abundant for the I β isoform in cells where the level of I α protein may be more than twice that of the I β protein [17–19]. These results imply that the I α mRNA may be more unstable than the I β , but there are few studies to date published on regulation of the expression of the mRNAs encoding these enzymes.

The concentration of cGMP necessary for half-maximal activation of the purified PKG-I α isoform has been measured at approximately 0.1 μ M, while the concentration of cGMP necessary for half-maximal activation of the purified I β isoform is 1 to 2 μ M. This is despite both isoforms' having identical sequences that encode the two tandem cGMP binding sites. The reason given for this functional difference is that the N-terminal domain encoding the I β isoform contains an autoinhibitory domain that is either "more efficient" at inhibiting the holoenzyme or has a higher affinity for inhibiting the catalytic domain of the holoenzyme [20]. Predictably, therefore, PKG-I α is activated at lower cGMP levels in the cell than PKG-I β . Corbin and colleagues have in fact shown that PKG-I exists as a partially-activated PKG especially after autophosphorylation [13,15]. The two cGMP-binding sites have different affinities for cGMP, and it has been shown that occupation of the high-affinity cGMP-binding site confers partial activation to PKG-I [13–16,20]. Upon elevation of cGMP in the cell, occupation of the second, lower-affinity binding site leads to further activation of the enzyme and autophosphorylation. The role of autophosphorylation of PKG-I has been investigated. Early studies suggested that autophosphorylation may prevent reassociation of regulatory and catalytic domains of PKG, similar to the role of autophosphorylation of the PKA regulatory subunit II. However, it is now clear that autophosphorylation may serve a more complex role for PKG and may somehow stabilize the activated enzyme in the active state even after the dissociation of cGMP. This mechanism has been shown to be operational for the calmodulin-activated protein kinase, CAM Kinase II, where the kinase remains active even after dissociation of the active calcium-calmodulin complex [21]. The molecular regulation of CAM kinase II in this fashion has been suggested to be the basis for synaptic facilitation and of memory and learning

in the nervous system. For PKG, it is possible that autophosphorylation is a mechanism to maintain PKG activity and relaxation of the smooth muscle cell even after elevated NO and cGMP have dissipated and returned to baseline levels.

There may be different functional roles for PKG-I α and I β , at least in smooth muscle cells. There has been speculation that PKG-I β , with its lower "affinity" for cGMP, may serve to buffer cGMP concentrations in the cell. This seems unlikely given the importance of PKG-I β in intracellular calcium regulation (see below). An attractive hypothesis for the functionally different roles of PKG-I isoforms is based on the fact that the sequence difference between the two enzymes is only at the N-terminus. In PKA, the N-terminus of the regulatory subunit determines what targeting proteins PKA binds to in the cell, the AKAPs (A kinase anchoring proteins) [22]. Hence, it has been suggested that the different N-terminal domains of PKG-I allow the kinases to bind to different targeting proteins in the cell. Experimental evidence for this hypothesis has recently been provided and demonstrates that PKG-I α appears to localize to the perinuclear regions of smooth muscle cells [23,24] whereas PKG-I β is more widely distributed in smooth muscle cells [25]. Functionally, the different subcellular distribution could affect which isoform of PKG regulates intracellular calcium mobilization, for example. The PKG-I β isoform, but not PKG-I α , has been shown to bind to a protein termed IRAG [for inositol (1,4,5) P₃-receptor-associated cGKI substrate] [26]. The function of the IRAG protein is to compartmentalize PKG-I β with the inositol 1,4,5-trisphosphate (IP₃) receptor in the endoplasmic reticulum (ER) compartment of the smooth muscle cell. PKG has been shown to catalyze the phosphorylation of the IP₃ receptor, and its localization with this substrate is necessary for phosphorylation [27,28]. The role of IP₃ receptor phosphorylation has not been unequivocally defined although there is speculation that PKG-dependent phosphorylation regulates calcium release from the ER [26,28].

Binding proteins specific for PKG-I α have also been described, and these include a male germ cell 42 kDa protein [29] and the myosin light chain phosphatase binding subunit (MBS) [30]. Of these two potential targeting proteins, the binding to MBS has been most extensively characterized. Surks *et al.* [30] have shown that PKG-I α , but not PKG-I β or Type II PKG, binds via the leucine zipper domain to MBS. As a consequence of PKG binding, the MBS is phosphorylated, resulting in the activation of the phosphatase. In contrast to PKG, both Rho-kinase A and protein kinase C (PKC)-catalyzed phosphorylation of MBS lead to the inhibition of the phosphatase activity [31,32]. Therefore, multisite phosphorylation mechanisms regulate the phosphorylation of myosin light chain and hence contractility in smooth muscle cells. The concepts of PKG-dependent regulation of smooth muscle contractility will be addressed again below. The purpose of this discussion here is to illustrate the importance of the N-terminal domains of PKG-I in targeting the kinase to subcellular compartments.

Other studies have suggested that various PKG isoforms bind to cytoskeletal compartments. PKG-binding proteins

such as myosin [33], vimentin [34], and actin-binding proteins [24,25] have been reported, but except for VASP the physiologic significance is unknown. Recently, fluorescent indicators have been used to determine the localization of PKG in cells. In HEK-293 and A549 epithelial cells, PKG was found to be localized with the best-characterized PKG substrate to date, VASP [24]. VASP is an actin-binding protein that is widely expressed and preferentially localized to focal adhesions of cells [35,36]. The precise anchoring protein for PKG in focal adhesions is not known, however.

PKG-II, as stated earlier, has a different distribution compared with PKG-I. PKG-II was first identified in intestinal epithelial cells as a phosphorylated protein. Since then, PKG-II has been cloned from brain and epithelial tissues. PKG-II clearly is the key kinase that regulates intestinal chloride transport due to phosphorylation and activation of the CFTR [37–39]. PKG-II has also been shown to inhibit renin release from the juxtaglomerular cells in the kidney [10,40]. PKG-II exists as a homodimer, is N-terminally myristoylated and anchored in the cell membrane, and has tandem cGMP-binding sites like the PKG-I isoforms, although differences in activation mechanisms exist [41,42]. The sequence homology between PKG-I and PKG-II is approximately 50 percent overall, but the PKG-II isoform possesses unique cGMP-binding properties and activation by cGMP compared with PKG-I. PKG-II also has a very low affinity for cAMP and therefore does not appear to be cross-activated by cAMP in the cell. These findings suggest that drugs may be devised that could selectively target PKG-II and PKG-I in the cell, thus providing better insight into the roles of these two isoforms of PKG in cell function.

Physiologic Roles of PKG

Both PKG-I and PKG-II have been genetically deleted in mice and the phenotypes of the knockout mice studied. PKG-I deficient mice demonstrate a loss of NO-dependent relaxation of smooth muscle and acquire hypertension at approximately four weeks of age [43]. The animals also demonstrate abnormalities in platelet function [44]. These phenotypic properties are predictable based on the known roles for cGMP in relaxing vascular and nonvascular smooth muscle, inhibiting platelet adhesion and activation, and relaxing cavernosal smooth muscle in the penis. The animals succumb at an early age apparently due to digestive and colorectal dysfunction. Recently, Wegener *et al.* [45], using PKG-I conditional knockout animals, demonstrated a clear role for PKG in mediating the negative inotropic actions of NO and cGMP in mouse heart. The role of NO and cGMP in regulating cardiac contractility has been the subject of much controversy over the past two decades, in part because the antiadrenergic effects of muscarinic agonists have been difficult to distinguish from those related directly to cardiomyocyte cGMP, such as the inhibition of voltage-gated Ca^{2+} channels. This study provides a rather conclusive role for PKG in directly mediating the actions of cardiomyocyte cGMP.

PKG-II deficient mice show predictable changes in salt and water absorption from intestinal epithelium but also produced an unexpected phenotype of dwarfism. Lack of PKG-II causes the epiphyses of the long bones to close and harden prematurely, suggesting that PKG-II is required for chondrocyte proliferation and matrix production.

The classic roles of PKG in cell function were established in smooth muscle and platelets. Cyclic GMP was identified as the intracellular mediator of nitrovasodilator-drug dependent smooth muscle relaxation, and then shown to mediate epidermal growth factor receptor (EDRF) (that is, NO)-dependent relaxation. Many studies in the 1980s and 1990s established that PKG mediated relaxation by diverse mechanisms. Many of the details of the mechanisms responsible for smooth muscle relaxation have been reviewed elsewhere and will not be repeated here [5,6,46]. However, what should be emphasized is that smooth muscle cell relaxation can be accomplished by a number of very different mechanisms. For example, active contraction of the VSMC is achieved and regulated by two pathways: increases in cytosolic free calcium with the activation of myosin light chain kinase (MLCK), and activation of the rho-rho kinase pathway preventing myosin light chain dephosphorylation by inhibition of myosin light chain phosphatase [47,48]. The latter pathway constitutes the mechanism of calcium-sensitization of smooth muscle [49]. PKG has been shown to catalyze the phosphorylation of proteins that regulate both pathways. For example, PKG-dependent phosphorylation of protein components of calcium-activated potassium channels (K_{Ca} channels) leads to the activation of this channel and hyperpolarization of the cell [50–54]. Hyperpolarization inhibits calcium entry into the cell and hence allows less MLCK activation. PKG also catalyzes the phosphorylation of components of the calcium-sequestering mechanism in smooth muscle cells such as phospholamban [23]. Phospholamban phosphorylation leads to its dissociation from and the activation of the endoplasmic reticulum (ER) Ca-ATPase pump. Not only does this mechanism decrease cytosolic free calcium levels, it loads up the ER (or sarcoplasmic reticulum, the SR) with calcium. More calcium is then available for release near the plasma membrane compartment, where it activates K_{Ca} channels [55]. The increases in the number of “calcium sparks” by PKG is a novel mechanism for regulation of cytosolic calcium levels. Furthermore, the PKG-dependent phosphorylation of the SR calcium release channel, the IP_3 receptor, could contribute to calcium sparks and relaxation by either increasing calcium release toward the plasma membrane or by inhibiting calcium release, thus allowing greater filling of the SR with calcium for release through the ryanodine receptor [27,56,58]. What seems to be the case is that in different types of smooth muscle cells, the regulation of intracellular calcium levels relies on any one of these diverse mechanisms more than the others. Hence, cGMP-dependent regulation of K_{Ca} channels, for instance, might be more important in the relaxation of one type of smooth muscle compared to another. Nonetheless, each calcium-lowering pathway has apparently evolved the

capacity to be regulated by cGMP/PKG-dependent protein phosphorylation. The occurrence of redundant mechanisms controlling cytosolic calcium in smooth muscle apparently provides evolutionary or selective advantage to the cell and organism to prevent excessive calcium accumulation and contractile activity in the cell.

The role of PKG in regulating smooth muscle myosin light chain phosphatase activity followed earlier findings demonstrating that cGMP produced calcium desensitization in smooth muscle cells [49,59,63]. The detailed mechanism by which PKG activates the phosphatase is still uncertain, but it is clear that phosphorylation of the MBS due to PKG localization and phosphorylation of the protein is necessary [30]. The reports of PKG-dependent activation of myosin light chain phosphatase, which is a Type I serine/threonine protein phosphatase, follow other reports in which cGMP and PKG have been implicated in protein phosphatase regulation in the nervous system. In Purkinje cells, a protein substrate for PKG, originally discovered in Paul Greengard's laboratory and termed the G-substrate, is an inhibitor of protein phosphatase 1 [64] and protein phosphatase 2A [65] when phosphorylated. DARPP-32, an inhibitor for protein phosphatase 1 when phosphorylated by PKA, is also phosphorylated by the NO/cGMP/PKG pathway [66], thereby suggesting that both cAMP and cGMP signaling pathways regulate DARPP-32 activity.

In addition to serine/threonine protein phosphatase regulation, protein tyrosine phosphatases have also been reported to be regulated by PKG. In smooth muscle, PTP-1, a soluble form of protein tyrosine phosphatase, is both phosphorylated and activated by NO/cGMP/PKG [67]. The role of the NO/cGMP signaling pathway in smooth muscle cell proliferation has been extensively studied, but specific mechanisms by which PKG regulates proliferation are unknown. Perhaps the regulation of protein tyrosine phosphorylation by phosphatases contributes to the antiproliferative actions of NO and cGMP.

A final mechanism for cyclic nucleotide-dependent smooth muscle relaxation is the regulation of thin filaments and particularly the phosphorylation of small heat shock protein HSP-20 and HSP-27 [68–70]. HSP-20 is a actin-binding protein in smooth muscle whose phosphorylation is catalyzed in the intact tissue by PKA and PKG. Tissues deficient in HSP-20 are less sensitive to cyclic nucleotide-dependent relaxation, thus suggesting an important role for HSP-20 in active relaxation [71,72]. It is interesting that PKG not only catalyzes the phosphorylation of HSP-20 but also induces its expression in VSMC [73].

PKG has been implicated in the regulation of MAP kinase pathways, gene expression and transcriptional activity, and in the regulation of VSMC phenotypic modulation. Although these findings have been reviewed recently and will not be discussed here [5,46], one newer role for cGMP/PKG signaling is in tumor cell apoptosis. It has been known that the nonsteroidal, antiinflammatory sulindac derivatives have potent anticancer activity [74,75]. One derivative, exisulind, induces apoptosis in cells derived from a number of different

tumors, and in clinical studies exisulind prevents colorectal polyp formation in patients with familial adenomatous polyposis. Exisulind exerts its actions on tumor cells by inhibiting the type V cGMP phosphodiesterase (PDE-V) [76,77]. PDE-V, which is also the target for sildenafil (trade name, Viagra), is a specific cGMP phosphodiesterase that when phosphorylated by PKG hydrolyzes cGMP at a high rate. Exisulind produces sustained inhibition of PDE-V in tumor cells, leading to increases in cGMP and activation of PKG. PKG promotes the phosphorylation of β -catenin either through direct catalysis of phosphorylation of the protein or through activation of other kinase pathways that lead to β -catenin phosphorylation. When phosphorylated in response to PKG activation, β -catenin is targeted for ubiquitination in the cytoplasm of the tumor cell. β -catenin combines with T-cell factor (TCF) to form a transcriptional complex that activates gene expression in tumor cells, resulting in resistance to apoptosis. By virtue of its phosphorylation by PKG activation, anti-apoptotic pathways are apparently turned off while pro-apoptotic pathways are turned on (e.g., caspase genes), leading to tumor cell death [78,79]. The pro-apoptotic effects of PKG may be dependent on activation of the c-Jun NH₂-terminal kinase (JNK) pathway [78–80]. Clearly, the roles for PKG in regulating gene expression, cell growth and differentiation, and apoptosis are only beginning to be uncovered.

Concluding Remarks

The family of protein kinases is huge, with some estimates of the number of gene products expressed in cells that belong to this family at around 5 percent. And protein phosphorylation, being the important and widespread regulator of cell function that it is, is a major area of interest in every biological process. As already mentioned, PKG was perhaps the fourth protein kinase discovered, following phosphorylase kinase, casein kinase, and PKA. Yet until about 15 years ago, understanding and solving the roles of PKG in biological function lagged the understanding of most other kinases' roles because upstream pathways leading to PKG activation were not well-defined. This changed rather dramatically with the uncovering of the biological role of NO. Now it seems that PKG has many important roles in various biological processes—even more than could be imagined by those investigators that began studying PKG from the time of its discovery. As discussed here, PKG plays a central role in smooth muscle cell contraction (e.g., blood pressure regulation, erectile function, gastrointestinal motility), smooth muscle cell gene expression in diseases such as atherosclerosis, salt and water absorption, skeletal growth, cardiac contractility, memory and learning, and tumor apoptosis. In the world of fruit flies and honey bees, whether the insects are a “stay-at-home couch potatoes” or “active food foraging providers” seems to depend on whether or not PKG is expressed (the food foragers express PKG and the couch potatoes don't) [81,82]. While I suspect that there is not any message for humans in these findings, one predication is that there will continue to

be active pursuit of therapeutic agents that interact with the PKG pathway. With PKG involvement in so many different biological processes, and with losses in its expression or activity correlated with human diseases, new agents directed to enhance PKG expression or activity may find their way into future therapies.

Inhibitors of Cyclic Nucleotide-Dependent Protein Kinases

Wolfgang R. G. Dostmann

*Department of Pharmacology,
University of Vermont, College of Medicine,
Burlington, Vermont*

Introduction

Inhibitors of cyclic nucleotide-dependent protein kinases have served as valuable tools in identifying the pivotal roles of cAMP-dependent protein kinase (PKA) and cGMP-dependent protein kinase (PKG) in cellular biology by allowing the elucidation of basic molecular mechanisms of kinase structure and function and the dissection of the specific roles for each kinase in intracellular signaling. The remarkably similar multidomain structures of PKA and PKG simultaneously provide an opportunity and pose a challenge for the design of potent and selective inhibitors. A set of inhibitors now available target one of three distinct regions found in all subforms of cyclic nucleotide-dependent protein kinases: the cyclic nucleotide binding sites, the ATP-binding domains, and the peptide/substrate binding regions. This review will present the apparent experimental advantages and pitfalls of each inhibitor class and will provide a guide for identifying the inhibitor best suited for a given experiment, whether a reconstituted enzyme assay or intact cell or tissue preparation is involved.

The cyclic nucleotide-dependent protein kinases PKA and PKG, primary targets for the second messengers cAMP and cGMP, respectively, have served as rosetta stones in our understanding of a vast number of intracellular signaling mechanisms ranging from smooth muscle cell relaxation

to neuronal synaptic plasticity (for reviews see [1–7]). Therefore, the search for potent inhibitors of these kinases has been extensively investigated ever since their discoveries. However, the structural similarities of PKA and PKG have posed a formidable obstacle in the design of selective inhibitors that specifically target cyclic nucleotide-dependent protein kinases and show little inhibitory potency to other more distant Ser/Thr-kinase relatives.

The domain structures of PKA and PKG dictate key target sites for putative inhibitors. Figure 1 compares the domain structures of PKA and PKG and defines three distinct classes of inhibitors and their various sites of actions. The regulatory components of cyclic nucleotide-dependent protein kinases each harbors two tandem cyclic nucleotide binding sites that allow allosteric and cooperative control of kinase activity (for reviews see [1,6,7]). A particular class of cAMP/cGMP derivatives, (R_p)-phosphorothioates, are the only known inhibitors that bind to the cyclic nucleotide binding sites [8–10]. Although their mode of action is still not completely understood, studies have indicated that the binding of these derivatives fails to induce the conformational changes essential for releasing catalytic activity [11,12]. The catalytic components of cyclic nucleotide-dependent protein kinases contain two target sites for inhibitors: the ATP-binding site and the substrate-binding site. Compounds mimicking ATP represent a diverse class of inhibitors, as has been known for

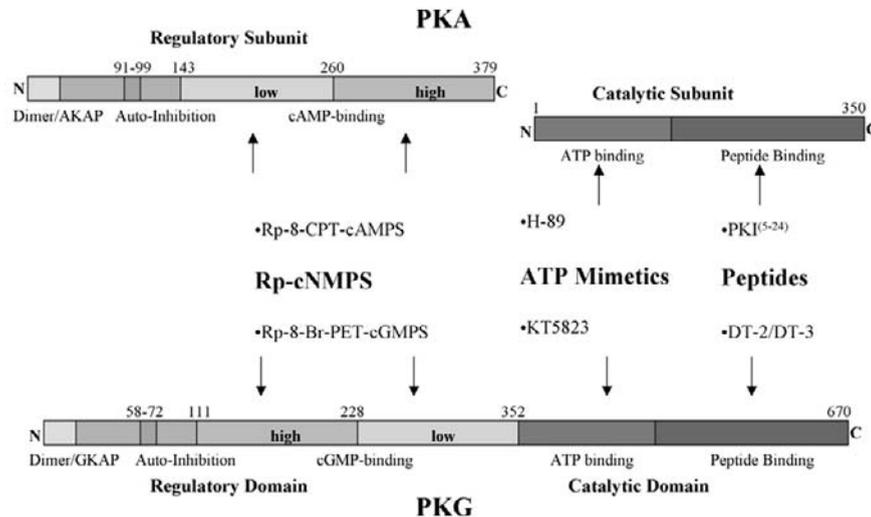

Figure 1 Domain structures of PKA and PKG with target sites for inhibitors and prominent inhibitor examples. Rp-cNMPS denotes (R_p)-diastereomers of cAMP/cGMP phosphorothioate derivatives.

all other major families of protein kinases [13,14]. In contrast, peptide inhibitors designed to block the substrate-binding site of PKA have been relatively straightforward [15–17]. PKA contains a well-defined substrate consensus sequence [18] that serves as an ideal template for peptide inhibitor design [19]. However, selective PKG peptide inhibitors have long remained elusive, partly because the sequence requirements for PKG inhibition do not follow a classic consensus sequence and the kinase appears to nonspecifically favor positively charged amino acids [18,20–26]. Only recently has a new class of potent and cell membrane permeable PKG peptide inhibitors based on combinatorial peptide libraries emerged [27–29].

Cyclic Nucleotide Binding Site-Targeted Inhibitors

The cyclic-nucleotide binding sites of PKA and PKG show remarkable sequence similarity with respect to the recognition motif of the nucleotide phosphodiester (FGE...RAA and FGE...RTA for all PKA and PKG isoforms, respectively). The crystal structures of PKA RII β [30] and RI α [31] revealed the architecture of the cyclic nucleotide binding pocket with an invariant arginine situated at its base. It is thought that chelation of the phosphate moiety by the invariant arginine is the first step in cAMP binding. The discovery that sulfur substitution of the axial exocyclic phosphate oxygen (Rp-) of cyclic nucleotides resulted in inhibitors of PKA and PKG, while cyclic nucleotide analogs carrying the equivalent apical sulfur substitution (Sp-) act as kinase agonists [8,32–35], prompted the synthesis and subsequent analysis of an entirely new class of cyclic nucleotide analogs [9,10,36–40] in an effort to identify selective and isozyme-specific inhibitors (for a comprehensive overview and a complete list of references visit www.biolog.de). Tables I and II give examples of PKA- and PKG-specific Rp-cyclic nucleotide phosphorothioates (Rp-cNMPS). These studies revealed that the competitive

binding of Rp-cAMPS to both cAMP-binding sites in the PKA holoenzyme is thought to prevent dissociation of the regulatory subunits [11,12]. Likewise, it is believed that binding of Rp-cGMPS and analogs to PKG are unable to induce the conformational change needed to expose the enzyme's catalytic cleft.

Recent studies have demonstrated that Rp-cAMPS analogs can function as partial agonists dependent on the presence of MgATP and enzyme concentration [11,41]. These findings raise questions concerning the usefulness of inhibition constants when dealing with Rp-cAMPS analogs. However, this phenomenon is not observed for PKG partly because the holoenzyme complex does not dissociate into regulatory and catalytic subunits. Another important finding is that the sulfur substitution in Rp-cNMPS increases the relative lipophilicity and hence cell-membrane permeability compared to their cNMP counterparts [42], (see also: www.biolog.de/logkw.html). In addition, Rp-cNMPS exhibits complete resistance to phosphodiesterases [43]. These properties have markedly contributed to the diverse applications that cyclic nucleotide binding site-targeted inhibitors have enjoyed in intracellular signaling research [10]. It should be noted that Rp-cGMPS derivatives [37,38], in particular Rp-8-Br-PET-cGMPS, as a PKG inhibitor with high selectivity, low toxicity, and superior membrane permeability, has gained supremacy in its class [39].

ATP Binding Site-Targeted Inhibitors

Synthetic protein kinase inhibitors that are competitive with ATP and specific for PKA and/or PKG represent a structurally diverse group of small ligand compounds [44,45]. Polycyclic aromatics, such as Isoquinolinesulfonyl and Naphthalenesulfonyl compounds ("H-series"), and naturally occurring molecules, such as staurosporine analoga ("K-series"), have served primarily as valuable inhibitors of

Table I Potencies of Selected Cyclic Nucleotide-Dependent Protein Kinase Inhibitors

PKA inhibitors	K _i /IC ₅₀ (μ M)	Isoform selectivity	Comments	Refs.	PKG inhibitors	K _i /IC ₅₀ (μ M)	Isoform selectivity	Comments	Refs.

AGC-type protein kinases, notably PKC [44–50]. In fact, the inhibitory potency against PKC is a defining property of most ATP-site inhibitors of the above series. However, a subset of compounds, including the H-series H89 and KT5720 and the K-series H8 and KT5823, are moderately specific inhibitors for PKA and PKG, respectively (see Tables I and II). The relatively simple chemical modifications of isoquinoline-derivatives in particular produced a wealth of selective protein kinase inhibitors with potential for clinical applications [45,50]. In addition, the cell-membrane permeability of these compounds further amplified their versatility in

dissecting signaling pathways involving protein kinase signaling. However, concerns regarding toxicity and reports of problems using *in vivo* conditions, specifically with KT5823 as specific PKG inhibitors, have questioned their usefulness in intact cell preparations [51–53] (for a detailed discussion see: www.biolog.de/ti1003.html).

Recently it was observed that the natural product balanol inhibits protein kinases of the AGC-subfamily with high potency [54,55]. The crystal structure of balanol in complex with the catalytic subunit of PKA [56] confirmed a structural peculiarity of most ATP-site targeted inhibitors: the molecules

satisfy essential interaction within the ATP-binding site but utilize unique interactions with the enzyme, thus gaining selectivity and specificity. It has been shown that analogs of balanol display variability in protein kinase inhibition, and the structural determinants of their protein kinase selectivity can now be elucidated with computational methods [57–59].

Peptide Binding Site-targeted Inhibitors

The observation that relatively short peptides corresponding to the regulatory subunit's autophosphorylation site were effective substrates for PKA [60] and the discovery of protein kinase inhibitor (PKI) [15,61] prompted a comprehensive search of PKA inhibitory peptides [15–17,19,62–65] and presented a prime example for the concept of “consensus sequences” [18,66,67]. However, full appreciation of the intricate structural web existing between kinase and inhibitor occurred only after the crystal structure of the catalytic subunit of the PKA:PKI adduct was solved [68]. Peptides derived from PKI isoforms α and β [69–71], namely PKI^{5–24} and PKI^{10–22}, are still the most potent and, more important, the most selective PKA inhibitors known today (Tables I and II). However, their use in intact cell studies is limited, for example in patch-clamp techniques, due to their inability to cross the plasma membrane. Unfortunately, fusion peptides of PKI^{15–22} with membrane translocation signal (MTS) peptides derived from Antennapedia-homeo domain or *HIV-1* tat [28,72] showed a profound loss in PKA selectivity (W. Dostmann, unpublished results).

Attempts to identify PKG-selective inhibitor peptides based on the auto-inhibitory domain of the enzyme or *in vivo* substrates have been tedious at best, due to the lack of a well-defined consensus sequence [20–24,73,74]. Only a relative preference for basic residues surrounding the phosphate acceptor site has been established [18,21,22,24–26]. Various synthetic peptides have been used with limited success to analyze and optimize the sequence requirements for PKG substrates and inhibitors [75–79]. Recently, the identification of selective inhibitors of PKG by a novel peptide library screen specifically designed to select for tight binding peptides was reported [27–29]. Cellular internalization of the peptides was accomplished by N-terminal fusion to the membrane translocation sequences from either the HIV-1 Tat protein [47–59], DT-2 or the *Drosophila* Antennapedia homeo-domain [43–58], DT-3 [29,80]. A surprising finding is that these fusion peptides result in an extraordinary synergism with respect to PKG inhibition (Tables I and II). It was shown that DT-2 and DT-3 effectively inhibit NO-induced vasodilation, further emphasizing the central role for PKG in the modulation of vascular contractility [80]. These results suggest that the cell membrane permeability of DT-2 and DT-3, combined with enormous PKG selectivity, will significantly advance our experimental ability to dissect PKG-mediated intracellular pathways from PKA and other kinases.

Conclusions

R_p-phosphorothioate derivatives of cAMP and cGMP competitively inhibit cyclic nucleotide-dependent protein kinases by ‘freezing’ the enzymes in their inactive holoenzyme states. A large pool of derivatives, moderate selectivity and cell membrane permeability are regarded as their advantages as tools in intact cell studies. However, partial antagonism and limited potencies restrict their versatility. ATP-analogs are a highly resourceful group of protein kinase inhibitors. Cell membrane permeability and limited selectivity highlight their advantages and disadvantages, respectively. Peptide-derived inhibitors present the most potent and selective group of PKA and PKG blockers. Low cell membrane permeability remains their main obstacle in cellular research. Recently, a subset of PKG-selective peptide inhibitors employing MTS sequences as a means of membrane translocation has overcome this problem.

Introduction

The cyclic nucleotide-dependent protein kinases cAMP and cGMP-dependent protein kinases (PKA and PKG) are closely related enzymes, with approximately 50 percent sequence identity. These two kinases have similar substrate specificities; in particular, both show a strong preference for Arg residues at positions (−3) and (−2) of peptide substrates. The crystal structure of PKA revealed multiple contacts between these substrate Arg side chains and the enzyme. There are differences in specificity between the two enzymes particularly at the (+1) site, with PKA having a higher preference for hydrophobic residues. However, hydrophobic residues at the (+1) site are only found in approximately 40 percent of PKA substrates, possibly because the phosphorylation sites must be hydrophilic enough to be located on the surface of the protein. Although PKG is more stringent in its requirement for residues at the (−1), (+2) and (+3) positions than PKA, there is substantial overlap in specificity, and the two kinases are expected to share some substrates, as is the case for the cystic fibrosis transmembrane conductance regulator.

The cAMP and cGMP-dependent protein kinases (PKA and PKG, respectively) belong to subgroup 1 of the AGC group of Ser/Thr protein kinases, the group that also contains protein kinase C (PKC) [1]. Early studies on PKA specificity over 25 years ago established that residues in the local

phosphorylation site sequence were the primary specificity determinants (reviewed in [2]). Synthetic peptides corresponding to these sites were effective substrates. They have been used extensively to study the substrate specificity of protein kinases and have proved effective to measure PKA and PKG [3] activities in many systems. More recently synthetic peptides have been exploited as substrates in high-throughput screening for inhibitors and activators of protein kinases, including PKG [4]. This chapter focuses primarily on new developments in our understanding of the similarities and differences in the recognition of peptide substrates by PKA and PKG and the identification of important residues in enzyme substrate recognition.

Peptide Substrate Recognition

The catalytic domains [1] of PKA and PKG1 share 48 percent sequence identity; the strongest similarity is found in the central part of the catalytic domain, containing the majority of the substrate-binding residues as well as those involved in catalysis. We can therefore expect that the PKG catalytic domain will have a structure similar to the crystal structure of PKA [5–7]. The PKA crystal structures show the binding of a peptide inhibitor or substrate to PKA [5–9]. By examining these and other structures, we identified a constellation of 20 PKA residues (called acceptor loci)

Table I Acceptor Loci (Residues) in the Substrate-Binding Cleft of PKA, PKG1 α , and PKG1 β

Acceptor loci	PKA (Swiss-Prot # P17612)	PKG1 α (Swiss-Prot # Q13976)	PKG1 β (Swiss-Prot # P14619)	Substrate side chain subsite(s)
1	Gly 52	Gly 368	Gly 384	(-1)
2	Ser 53^a	Gly 369	Gly 385	(-1)/(+2)
3	Phe 54	Phe 370	Phe 386	(+2)
4	Leu 82	Thr 399	Thr 415	(+2)
5	Gln 84	Gln 401	Gln 417	(+2)
6	Glu 127	Glu 444	Glu 460	(-3)
7	Phe 129	Trp 446	Trp 462	(-3)
8	Ser 130	Thr 447	Thr 463	(-3)
9	Asp 166, catalytic Asp	Asp 483, catalytic Asp	Asp 499, catalytic Asp	(0)
10	Glu 170	Glu 487	Glu 503	(-3)/(-2)
11	Phe 187	Phe 504	Phe 520	(+1)/(+2)
12	pThr 197	pThr 516	pThr 532	(+3)
13	Leu 198	Phe 517	Phe 533	(+1)/(+3)
14	Thr 201	Thr 520	Thr 536	(-2)
15	Pro 202	Pro 521	Pro 537	(+1)

17	Tyr 204	Tyr 523	Tyr 538	(-2)
18	Leu 205	Val 524	Val 539	(+1)
19	Glu 230	Glu 549	Glu 565	(-2)
20	Tyr 330	Phe 651	Phe 667	(-3)

^aWhere the acceptor loci differ between PKA and PKG, the residues are shown in **bold**. Phosphothreonine, pThr.

predicted to interact with the side chains of peptide substrates between subsites (-3) and (+3) (the specificity determining residues in the phosphorylation site sequence are notated -n to +n, depending on their position on the N or C-terminal side of the phosphorylation site, 0; Table I). Other important peptide substrate enzyme interactions can occur outside the subsites (-3) and (+3) [6] but are not considered here for reasons of brevity. Although acceptor loci determine specificity, historically, residues in substrate phosphorylation site sequences that facilitate peptide substrate binding have been called specificity determinants, and for this reason acceptor loci are used here to notate contact residues on the kinase surface. A substrate Arg at (-3) (see Table I) binds to acceptor loci 6,7,8,10, and 20, plus the 3'-OH and 4'-OH of the ATP ribose moiety. An Arg at (-2), however, binds to acceptor loci 10,16,17, and 19 (acceptor locus 16 corresponding to Glu203 is diagnostic of the AGC group of protein kinase subfamily). The substrate (-3) and (-2) Arg residues make more contacts with the PKA catalytic core than any other substrate side chains, and this accounts for the strong specificity-determining role of Arg at these two positions. The only other subsite approaching this number of interactions is the (+1) hydrophobic pocket comprising acceptor loci 11,13,15, and 18. Acceptor locus 18 (Leu205) is situated at the end of this pocket, facilitating optimal binding to Leu or Ile residues (Val is suboptimal at this subsite). Acceptor loci 1,4, and 13 are located in

the (-1), (+2), and (+3) side chain pockets, respectively, and suggest a modest preference for hydrophobic residues at these subsite pockets.

Comparison of Kinase Substrate Acceptor Loci

Due to the similarities in the acceptor loci, PKA and PKG share strong substrate specificity for Arg residues in peptide substrates at (-3) and (-2) positions [2]. By contrast, members of the PKC subgroup have an additional strong specificity for Arg or Lys at the (+2) position [10]. Of the 20 PKA acceptor loci, 13 are shared with PKG1 (Table I), whereas seven are different (2,4,7,8,13,18, and 20). The key difference appears to be acceptor locus 18 at the bottom of the (+1) pocket; the acceptor locus 18 of PKG is a Val, whose side chain is too short to contact a Leu residue bound at (+1). Thus, unlike PKA, a (+1) Val or Leu would make the same number of contacts with PKG. These differences in acceptor loci residues dictate the overall differences in the substrate specificities of PKA and PKG.

Optimum Recognition Sequences

Extensive studies of PKA over the past 30 years have identified a large number of substrates, in fact the largest

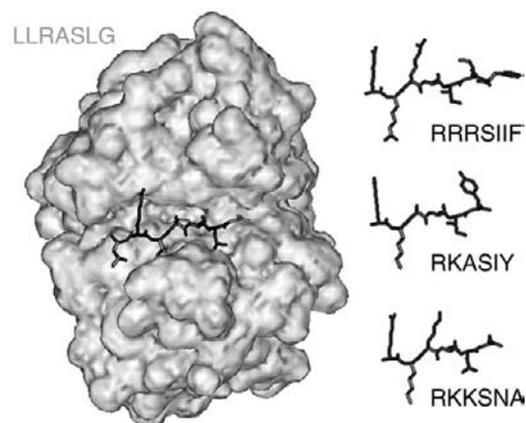

Figure 1 Surface structure of the catalytic domain of PKA with the “Kemptide” substrate (LRRASLG) bound. The structures of peptides representing the optimized recognition sequences for PKA (RRRSIIIF [12], RKASIIY [13]) and PKG (RKKKSNA [13]) are illustrated.

number for any protein kinase thus far; the number of phosphorylation sites currently listed in PhosphoBase [11] is 165, including redundancies such as entries for the same protein from different species. The results of oriented degenerate peptide library experiments have enabled estimates to be made of the optimal substrate sequence for protein kinases. The optimum recognition sequence for PKA [12], RRRSIIIF (phosphorylation site underlined), is consistent with conclusions derived from both inspection of the acceptor loci and the early synthetic peptide studies using the Kemptide (LRRASLG). Optimal substrate sequences for PKA, RKASIIY- and PKG, RKKKSNA-have also been studied by using peptide libraries on cellulose paper [13]. The binding of the “Kemptide” substrate to PKA together with the structures of the optimized peptide substrates for PKA and PKG are illustrated in Fig. 1. Examination of substrate sequences for PKA (Table II) shows that specificity (for Arg) is strong at (–3) and (–2), but the specificity is broad at other positions, particularly at (+2) and (+3). Only a minority of substrate sequences conform reasonably well to the peptide library motif (e.g., RRNSIILT, RKVSLAP, RRGSVPI, RRDSLFLV, and RRQSVLV). The consensus sequence inferred from known PKA substrates would be RR(R/S)SLSS. Our structural analysis and the peptide library results indicate that the (+1) site should strongly favor hydrophobic residues, however, less than 40 percent of sites in known substrates contain hydrophobic residues at this position. There are a number of smaller residues [Gly, Ala, Ser, and Pro (GASP)] found at (–1), (+1), (+2), and (+3) in substrate sequences, which would be expected to make few, if any, contacts with the enzyme. The presence of these small residues accounts for the wide range of PKA substrate phosphorylation site sequences. This raises the question of whether within the cell the AKAPs (A kinase anchoring proteins) [14] may increase the probability of PKA binding by these suboptimal sequence-containing substrates, and therefore compensating for this suboptimal recognition, as well as localizing the substrate to a signaling complex.

Table II Abundance of Particular Residues in PKA and PKG Substrate Phosphorylation Sites (PhosphoBase), LIMVF, Leu/Ile/Met/Val/Phe; GASP, Gly/Ala/Ser/Pro

Subsite	Residue	PKA	PKG	
(–3)	Arg	65.4	69.7	
	Lys	16.7	6.1	
(–2)	Arg	56.4	45.4	
	Lys	16.4	42.1	
(–1)	Arg	12.7	24.2	
	Leu	9.7	16.2	
(0)	LIMVF	23.0	42.4	
	GASP	35.2	12.1	
	(0)	Leu	19.4	6.1
		LIMVF	36.9	24.2
		Ser	13.9	6.1
	(0)	GASP	29.4	27.3
Arg		7.9	15.1	
(0)		LIMVF	12.4	18.2
	Ser	14.5	12.1	
	Ala	19.1	21.2	
(0)	GASP	38.6	37.4	
	(0)	LIMVF	15.8	9.1
		Pro	6.1	18.2
	(0)	GASP	32.9	24.2
Glu		7.0	27.3	

One reason the optimal recognition sequence defined by peptide library experiments is not more highly represented in substrates is that it is rather hydrophobic and therefore difficult to accommodate in an exposed loop of a protein where the phosphorylation site would usually be located. The protein substrate’s function also needs to be taken into account. Phosphorylation is required to induce structural and functional changes in the substrate, and these might not necessarily be compatible with a single highly conserved phosphorylation site sequence motif. Substitution of one or more hydrophobic residues in the motif by smaller residues such as Ser, Ala, Gly, or Pro would render the peptide less hydrophobic and increase the probability that the phosphorylation site is in a loop region. In addition, the smaller residues may facilitate structural changes in the substrate triggered by the phosphorylation event that are essential for altering protein function. The major implication of these considerations is that the binding of Arg at (–3) and (–2) provides the bulk of the interactions needed to bind the substrate to PKA, and this permits considerable flexibility in accommodating surrounding residues. A further reason for sequence diversity in local phosphorylation site sequences for PKA is that they may have a kinetic function in signaling, determining the order in which protein substrates are phosphorylated, that otherwise could not be achieved if there was a common

conserved optimum motif [15]. By contrast, the peptide library motif for PKC α (RRRSLRK) [10,16] is more hydrophilic and therefore a better guide for PKC substrates such as MARCKS [17].

Comparison of PKA and PKG Specificity

Despite its close similarity to PKA, PKG is more restricted in its known substrates, with 33 phosphorylation sites listed in PhosphoBase. Some of these phosphorylation sites are common to both PKA and PKG. The consensus motif based on substrate sequences of PKG is R(R/K)(R/L)S(R/A)AE (Table II). Although largely similar to the PKA substrates, the PKG substrates show distinct differences. The (-2) site has a similar preference for Arg and Lys, whereas in PKA, Arg is heavily favored over Lys. The (-3) specificity is basically equal in PKA and PKG, despite the substitution of the acceptor locus 20 of PKA (Tyr to Phe) resulting in a loss of the acceptor group for the Arg side chain. PKG is more specific at the (-1), (+2), and (+3) sites than PKA, and Gly, Ala, Ser, and Pro occur more rarely at (-1) and (+3) positions. The moderate preference for hydrophobic residues at (+1) of PKA is not observed with PKG. Indeed the most dramatic differences in specificity between PKA and PKG were observed in peptide analogs (LRRRRF-aminoalcohol) containing α -substituted alcohols. PKG is able to phosphorylate the hydroxyl group in these peptide analogs in either the equivalent of a D or L-amino acid configuration, whereas PKA has a strict requirement for the L-configuration [18]. The PKG Val acceptor site 18 for the (+1) subsite is likely to explain its capacity to phosphorylate different isomers. The highest preference at (+1) is for Arg or Ala. PKG does display some preference for Arg/Leu, Ala/Ser, and Glu at (-1), (+2), and (+3), respectively. In summary, the specificity of PKG is narrower when compared to PKA, and a correspondingly smaller number of substrates have been identified. The additional specificity constraints for PKG may mean that anchoring proteins play less of a role in PKG signaling.

Overlapping substrate motifs for PKA and PKG suggest that there will be phosphorylation sites that the two protein kinases have in common, as is the case with RRL⁷³⁷SLVP from the cystic fibrosis transmembrane conductance regulator [19,20]. By contrast, RTL⁷SVSS from glycogen synthase is a substrate for at least eight different protein kinases, including PKA, but not PKG [11,21] possibly because the Ser residues at both (+2) and (+3) do not provide favorable contacts for PKG. The results show how two protein kinases such as PKA and PKG, with considerable sequence similarity, nevertheless exhibit significant diversity in substrate recognition properties.

Conclusion

The use of synthetic peptide analogs and peptide libraries has played a critical role in revealing the major specificity

determinants in PKA and PKG substrate phosphorylation site sequences. Crystal structures of PKA with peptide substrates and inhibitors bound to the enzyme have provided a road map to understanding the important acceptor loci residues on the kinase surface responsible for peptide substrate binding. Molecular modeling of these structures has allowed us to identify important similarities and differences in PKA and PKG substrate specificity.

Introduction

The cAMP- and cGMP-kinases (PKA and PKG, respectively) belong to the ACG-subclass of Ser/Thr-specific protein kinases and generally prefer the phosphate acceptor residue preceded by a row of basic residues. S is the favored phosphate acceptor also when taking into account the 12-fold higher frequency of S over T in eukaryotic proteins. Based on an extensive body of work with peptide substrates *in vitro* (see Chapter 80, this volume) and mapping of phosphorylation sites in physiological substrates *in vivo*, PKA is well known to phosphorylate substrates with the general motif R(R/K)X(S/T) [1–6], whereas the consensus for PKG substrates is (R/K₂₋₃)(X/K)(S/T) and includes more basic residues than the PKA consensus [7]. However, considerable overlap of sites phosphorylated by both kinases is observed *in vivo*. By analysis of physiological substrates (Table II), the preference for PKA in the P⁻³ and P⁻² positions is RR≥RK>>KR≥KK, and there are weaker preferences for small residues (S, G, P) at P⁻¹, for a basic residue (R) at P⁻⁴ to P⁻⁷, and for a hydrophobic residue (F, I, L, V) at P⁺¹ [8]. Substrate specificity of PKG is similar to that of PKA, but in physiological substrates (Table III) a stronger preference for R>>K at P⁻³ (at position P⁻² K=R), a slight preference for basic or neutral residues (K, R, S) in P⁻⁴, and an increased frequency of neutral and hydrophobic residues (S, V, A) at P⁻¹ and (S, L, A) at P⁺¹ is observed (this chapter).

Here we present data on the total availability of PKA and PKG consensus sites in the human proteome, estimate

frequencies of phosphorylation of different motifs, and attempt to give an overview of physiological substrates of both kinases that meet a set of eligibility criteria. However, mechanisms whereby the phosphorylation event alters function of each individual substrate and thereby regulates its physiological role are not included in this short overview.

Abundance of PKA and PKG Phosphorylation Sites in the Human Proteome

We have searched available protein databases (January 2002), including all translated and indexed sequences from the full draft of the human genome, with all the permutations of the canonical PKA and PKG motif, (R/K)(R/K)X(S/T). A little more than 35,000 motifs were found in human proteins, which is approximately 15 percent of all motifs identified (Table Ia). Based on the total abundance of canonical motifs (phosphorylated and nonphosphorylated) in a limited set of approximately 100 substrates for PKA in which the phosphorylation sites have been mapped, Shabb estimated the probability of phosphorylation of permutations of the canonical sequence, which was RRXS (0.8) > RRXT, RKX(S/T) (0.5–0.3) > KKX(S/T), KRX(S/T) (<0.2) [8]. A similar analysis of frequency of PKG phosphorylation (this chapter, from substrates listed in Table III) shows that probability of phosphorylation *in vivo* by PKG is estimated as R(R/K)XS (0.7) > RKXT (0.5) > KRXS, RRXT (0.3) > KKXS (0.2).

Table I Abundance of PKA and PKG motifs^a

a. Frequency and probability of phosphorylation of canonical substrate sequences			
Consensus	Homo sapiens	Estimated phosphorylated motifs of PKA ^b	Estimated phosphorylated motifs of PKG ^c
RRXS	7078	5662	5096

		TQAKRKKS	0

^aAll available human protein sequences including predicted proteins translated from the full draft of the human genome were analyzed (January 2002: 54687 sequences in the International Protein Index (IPI) version 2.4 at EMBL-European Bioinformatics Institute, Hinxton, Cambridge, UK, which provides a minimally redundant yet maximally complete set of human proteins assembled from SWISS-PROT, TrEMBL, RefSeq and Ensembl, see (<http://www.ebi.ac.uk/IPI/IPhelp.html>).

^{b,c}Probability for the motif being phosphorylated by PKA^b ([8]) or PKG^c (this study) *in vivo*.

^dPreferred *in vivo* motifs according to [8].

^eHigh-affinity peptides [9,10,17]. The authors acknowledge the kind help of Dr. Paul Kersey at EBI with searching IPI.

Using these probabilities, we estimate that PKA, PKG, or both can phosphorylate approximately 15,000 sites in the human proteome *in vivo*. When both frequency of different sites and probability of phosphorylation are taken into account, RRXS followed by RKXS stands out as the most abundant *in vivo* sites for both kinases (Table Ia). Notably, however, this analysis also predicts phosphorylation of significant numbers of substrates with less prevalent motifs such as K(R/K)X(S/T) with lower affinity but which may be physiologically relevant especially in contexts where kinase and substrate are colocalized [8]. In contrast, preferred substrates defined by more detailed analysis of physiological substrates (Tables II and III) or by *in vitro* phosphorylation of generations of peptide libraries with PKA and PKG are clearly less abundant due to their more restricted motifs (Table Ib). High-affinity substrates such as LRRASLG (Kemptide, [9]) and RAERRASI [7] for PKA and TQAKRKKS for PKG [10] used *in vitro* enzyme assays were not found in the human proteome.

Physiological Substrates

General criteria for identification of physiological substrates of protein kinases were originally outlined by Krebs and Beavo [11], recently reviewed by Shabb [8], and can be summarized thus:

1. The target protein should be phosphorylated stoichiometrically and dephosphorylated by phosphatase *in vitro* at significant kinetic rates.
2. Functional properties of the substrate should change in correlation with the degree of phosphorylation.
3. Phosphorylation of the substrate should be demonstrated *in vivo* or in intact cells with accompanying functional changes.
4. The cellular levels of protein kinase should correspond to the extent of phosphorylation of the substrate.
5. The *in situ* phosphorylation sequence should be identified (new, adds stringency).

^a Site-directed mutagenesis.

^b Potential phosphorylation site because the serine residue meets the consensus sequence

With the present level of available technologies such as deletion and mutation mapping of the site and mass spectrometry, current consensus is that the primary evidence to consider is that *in vivo* phosphorylation occurs in response to elevated cAMP or cGMP (criteria 3–5), and this takes priority over *in vitro* mapping of PKA and PKG sites (typically the method of use in older literature) where a pitfall is that less stringent phosphorylations may occur. However, application of these criteria excludes phosphorylations occurring *in vivo* that are either silent (that is, no functional change) or whose function has not yet been mapped. Conversely, substrates implicated in physiological pathways but where the precise mechanism or site has not yet been identified are also excluded.

Here we present a comprehensive list of PKA substrates that meet the above eligibility criteria identified through review of the literature (Table II). This list is based on a recently published review by Shabb [8], and has been revised by adding new published data, bringing the number of identified and listed physiological substrates of PKA that meet the eligibility criteria to 116 and the number of analyzed motifs to 162. Furthermore, we present a corresponding list of 29 PKG substrates, representing 38 analyzed motifs, that have been identified by systematic literature search and application of the same set of criteria (Table III). It is interesting that 13 of those motifs are also phosphorylated by PKA (Tables III and II), indicating at least 30 percent overlap in substrates. During these searches we also revealed a number of potential substrates that do not fulfil

a convincing combination of the general criteria yet. Furthermore, the discrepancy between the identified substrates that meet the criteria (Tables II and III) and the estimated number of substrates (Table I) indicates that more than 99 percent of human PKA and PKG substrates are still unidentified, and this constitutes a major task to address in the future.

Concluding Remarks

The specificity of a substrate is determined not only by the primary sequence, but also by several other factors that affect the degree of phosphorylation of a given target. The tertiary structure of the substrate affects function and kinetics of the kinase, such as for example the catalytic subunit of cAMP-kinase that in part acquires its substrate specificity from the conserved F at position P11⁻¹[12]. The organization of the microenvironment around a phosphorylation event has a clear impact. In that respect, anchoring proteins (AKAPs, GKAPs) play an important role by locating PKA and PKG in close vicinity to their substrates and demonstrate how low-affinity substrates may become physiologically relevant.

Effects of cGMP-Dependent Protein Kinase Knockouts

**Franz Hofmann, Robert Feil,
Thomas Kleppisch, and Claudia Werner**

Institut für Pharmakologie und Toxikologie, TU München, München, Germany

Both mammalian cGMP-dependent protein kinase genes, cGKI and cGKII, have been inactivated in mice. The major phenotypes observed in cGKI knockout mice are decreased life span, impaired relaxation of vascular, visceral, and penile smooth muscle, disturbed platelet function, and altered neuronal functions. cGKII knockout mice have a normal life span, decreased longitudinal bone growth, decreased intestinal chloride secretion, and altered renin secretion.

Cyclic GMP-Dependent Protein Kinases: Genes and Knockouts

Cyclic GMP-dependent protein kinases (cGKs) are serine/threonine kinases which are activated by the second messenger cGMP. Two cGK genes, cGKI and cGKII, have been identified in mammals. The amino terminus (approximately amino acids 1–100) of cGKI is encoded by two alternatively used exons, resulting in the production of two cGKI isoforms, cGKI α and cGKI β . To generate cGKI and cGKII gene targeted mouse lines, the exon encoding part of the ATP-binding site in the catalytic domain (cGKI) or the first part of the cGMP-binding pocket (cGKII) was destroyed by homologous recombination in embryonic stem cells. These strategies resulted in loss-of-function mutants of the cGKII gene [1] and of the cGKI gene with complete inactivation of both the I α and I β isozyme [2]. Since cGKI-null mutants have a decreased viability (most animals die until six weeks of age), a conditional cGKI mouse line was generated in which the ATP-binding site encoding exon was flanked by loxP sequences allowing for Cre-mediated tissue-specific inactivation of the cGKI gene [3].

Vasorelaxation and Hypertension

Nitric oxide (NO) and atrial natriuretic peptide (ANP) stimulate cGMP synthesis and relax small arteries and arterioles resulting in a decreased blood pressure. Targeted inactivation of the NO-synthase III (NOS III), ANP, or ANP receptor gene causes hypertension (reviewed in reference [4]). Juvenile (4 to 5 weeks old) cGKI knockout mice have an elevated blood pressure [2] indicating that the anti-hypertensive effects of NO and ANP are at least in part mediated by activation of cGKI. Potential *in vivo* targets for cGKI are the Ca²⁺-activated K⁺ (BK_{Ca}) channel [5] and IRAG [6], a protein involved in the intracellular calcium release mechanism. Phosphorylation of these two proteins could reduce the cytosolic calcium concentration, thereby leading to vasorelaxation. Vascular smooth muscle cells (VSMCs) isolated from wild-type mice endogenously express cGKI α , cGKI β , and IRAG. NO/cGMP inhibited noradrenaline-induced Ca²⁺-transients in wild-type but not in cGKI-deficient VSMCs. Interestingly, the defective Ca²⁺ regulation in cGKI-deficient VSMCs can be rescued by transfection of the cGKI α isozyme, but not the β isozyme [7]. These results suggest that cGKI α relaxed smooth muscle by decreasing the cytosolic Ca²⁺ level. The role of cGKI β in VSMCs is unclear at present, but may be more related to the cGKI effects on smooth muscle proliferation, differentiation, and gene expression [8]. The results described above do not preclude the possibility that cGKI decreases vessel tone by additional Ca²⁺-independent mechanisms including the activation of myosin phosphatase [9], of phosphorylation of RhoA [10], and of telokin [11] resulting in dephosphorylation of the myosin light chains without affecting the cytosolic calcium level. Blood pressure

may be regulated also by cGKII via inhibition of renin secretion [12].

The interpretation of the pathophysiology of the conventional cGKI knockout animals was complicated by the finding that 7-week-old, cGKI-null mutants had a normal or only slightly elevated blood pressure [2] indicating that the lack of cGKI can be bypassed in older animals. However, cGKI-null mutants develop multiple phenotypes with increasing age including infections and inflammation [13], which are known to induce massive NO synthesis. High concentrations of NO can increase cGMP levels to extreme values in vascular smooth muscle [5]. Thus, it is tempting to speculate that the apparent "normalization" of blood pressure in older cGKI-null mutants may be due to crossactivation of cAMP-dependent protein kinase by the high cGMP levels that are potentially generated in these diseased mice [5]. Furthermore, cGMP levels should be increased in cGKI knockout animals since the cGMP hydrolysing phosphodiesterase 5 (PDE 5) is not phosphorylated in cGKI-deficient VSMCs [14]. It has been suggested that *in vivo* activation of PDE 5 requires phosphorylation by cGK [15].

Further analysis of the cGKI-null mutants was limited by their low viability and by the fact that the cGKI gene was inactivated in the germline and thus in every cell of these mice. Therefore, it was difficult to study the role of cGKI in adults and whether the age-related hypertension of these mice reflected a function of cGKI in VSMCs, endothelial cells, or other cell types such as cardiomyocytes. To overcome these limitations, a mouse line has been generated which allows the conditional inactivation of the cGKI gene in somatic cells [3]. Cardiomyocyte-specific cGKI mutants are fully viable and can be studied throughout adulthood. The combined analysis of conventional and cardiomyocyte-specific cGKI knockout mice demonstrated that cGKI mediates the negative inotropic effect of cGMP in the juvenile as well as in the adult murine heart [3]. In line with results obtained in older NOS III knockout mice [16,17], the NO/cGMP/cGKI pathway does not appear to be involved in the negative inotropic action of acetylcholine [3].

Platelet Function

NO is of major importance for the homeostasis of platelet-endothelium and platelet-platelet interactions by inhibiting the adhesion of platelets to injured endothelium, platelet activation, and aggregation [18]. *In vitro* and *in vivo* studies with cGKI-deficient platelets proved that these effects are mediated by activation of cGKI [19]. Platelet adhesion and aggregation during ischemia/reperfusion of the microcirculation was analyzed by intravital video microscopy in wild-type mice infused with cGKI-deficient platelets and cGKI-deficient mice infused with wild-type platelets. These experiments clearly showed that platelet cGKI but not endothelial or smooth muscle cGKI is essential to prevent intravascular adhesion and aggregation of platelets after ischemia, probably by inhibiting the activation of the platelet fibrinogen receptor, glycoprotein IIb-IIIa [19].

Gastrointestinal and Urogenital Function

Both cGKI and cGKII knockout mice show severe gastrointestinal malfunctions. cGKI-deficient mice have disturbed bowel movement leading to delayed passage of food [2]. Apparently, NO-dependent relaxation of stomach smooth muscle is disturbed leading to an increased tonus of the pylorus [2,20]. At present it is not clear whether or not the lack of cGKI in a subpopulation of the interstitial cells of Cajal [21] contributes to the motility defect. Deletion of the cGKII gene abolished CFTR-mediated intestinal water secretion after stimulation of particulate guanylyl cyclase by guanylin or the heat-stable toxin from *Escherichia coli* [1]. This disturbance is confined to the small intestine. Ion transport was normal in the colon of cGKII-deficient mice [22].

Deletion of the cGKI gene impaired the NO/cGMP-induced relaxation of penile smooth muscle leading to erectile dysfunction, but did not affect the motility and fertility of sperm [23]. Furthermore, the NO/cGMP-dependent relaxation of urinary tract smooth muscle is abolished in cGKI-null mutants [24].

Nervous System

Over the past few years a number of neuronal functions of cGKs have been identified. All three cGKs are expressed in specific brain regions of mammals. Analysis of naturally occurring *Drosophila* variants in food-searching behavior, combined with the introduction of transgenes and transposable P elements into the *Drosophila* genome, led to the identification of the *foraging* gene as the *dg2* gene, which encodes cGKII [25]. Behavioral analysis of the cGKII knockout mice revealed increased anxiety and increased consumption of alcohol at first contact [26]. cGKII is expressed in the amygdala and basal forebrain, structures thought to be involved in anxiety and addiction.

cGKI α is expressed in dorsal root ganglia and cerebellar Purkinje cells, whereas cGKI β predominates in the hippocampus and olfactory bulb. Deletion of the cGKI gene led to impaired pathfinding of sensory neurons in the spinal cord and to a substantial reduction of nociceptive flexion reflexes [27], suggesting that cGKI α is required for the correct guidance of sensory neurons during development. The production of the cGKI and cGKII knockout mouse lines has also allowed to test whether or not these protein kinases are involved in hippocampal long-term potentiation (LTP) [28,29] and cerebellar long-term depression (LTD) [30]. These analyses showed that hippocampal LTP was not affected in juvenile (4 to 5 weeks old) conventional knockout mice lacking cGKI, cGKII, or both enzymes [31]. However, LTP was impaired partially in adult (at least 3 months old) mutants, in which the cGKI gene was inactivated specifically in the hippocampus. In agreement with the conventional cGKI knockout mice [31], LTP was unchanged in juvenile hippocampus-specific cGKI mutants (TK, RF, and FH, unpublished data). These phenotypes suggest that cGKs may regulate discrete neural functions in an age-dependent manner.

Preliminary experiments with Purkinje cell-specific cGKI mutants support the hypothesis that cGKI is an essential part in the regulation of LTD in the cerebellar Purkinje cells.

Bone

The particulate guanylyl cyclases, GC-A and GC-B, which generate cGMP upon binding of peptide ligands (ANP, BNP, and CNP) are expressed abundantly in mouse tibial epiphysis and vertebrae [32]. Cultivation of mouse tibia in the presence of BNP induced a significant increase in total bone length. Transgenic mice overexpressing BNP exhibited skeletal overgrowth that was restricted to bones with endochondral ossification [32]. cGKI and cGKII are expressed in the growth zones of bones [1]. The deletion of cGKI had no apparent effect on the growth of the skeleton. In contrast, cGKII-deficient mice are dwarfs, having limbs 16–30% shorter than normal [1]. Targeted expression of CNP in the growth plate chondrocytes failed to rescue the skeletal defect of the cGKII knockout mice, suggesting that cGKII plays a critical role in the CNP-mediated endochondral ossification [33].

Outlook

Taken together, the analysis of cGK-deficient mice has demonstrated the physiological relevance of these protein kinases as major mediators of cGMP signaling in diverse organs and tissues. cGKI plays an important role for cardiovascular and gastrointestinal homeostasis and has discrete functions in the central and peripheral nervous system. cGKII regulates longitudinal bone growth, intestinal ion transport, and renin release in the kidney, and it may be involved in the generation of complex behaviors like anxiety and addiction. In the future, the combined analysis of conventional and conditional cGK knockout mice and of cGK-deficient primary cells will further advance our understanding of the specific functions of cGKI α , cGKI β , and cGKII in the mammalian body in health and disease. These studies may also help to develop new strategies for the treatment of cardiovascular, gastrointestinal, skeletal, and neuronal disorders.

Cyclic Nucleotide-Regulated Cation Channels

Martin Biel and Andrea Gerstner

*Department Pharmazie-Zentrum für Pharmaforschung,
Ludwig-Maximilians-Universität München,
München, Germany*

Introduction

Cyclic nucleotides exert their physiological effects by binding to four major classes of cellular receptors: cAMP- and cGMP-dependent protein kinases [1], cyclic GMP-regulated phosphodiesterases [2], cAMP-binding guanine nucleotide exchange factors [3], and cyclic nucleotide-regulated cation channels. Cyclic nucleotide-regulated cation channels are unique among these receptors because their activation is directly coupled to the influx of extracellular cations into the cytoplasm and to the depolarization of the plasma membrane. Two families of channels regulated by cyclic nucleotides have been identified, the cyclic nucleotide-gated (CNG) channels and the hyperpolarization-activated cyclic nucleotide-gated (HCN) channels [4–7]. The two channel classes differ from each other with regard to their mode of activation. CNG channels are opened by direct binding of cAMP or cGMP. In contrast, HCN channels are principally operated by voltage. These channels open at hyperpolarized membrane potentials and close on depolarization. Apart from their voltage sensitivity, HCN channels are also activated directly by cyclic nucleotides, which act by increasing the channel open probability.

General Features of Cyclic Nucleotide-Regulated Cation Channels

Structurally, both CNG and HCN channels are members of the superfamily of voltage-gated cation channels. Like other

subunits encoded by this large gene family, CNG and HCN channel subunits are believed to assemble to tetrameric complexes. The proposed structure and the phylogenetic relationship of mammalian CNG and HCN channel subunits is shown in Fig. 1 (see also Table I for recent nomenclature). The transmembrane channel core consists of six α -helical segments (S1–S6) and an ion-conducting pore loop between the S5 and S6. The amino- and carboxy-termini are localized in the cytosol. CNG and HCN channels contain a positively charged S4 helix carrying three to nine regularly spaced arginine or lysine residues at every third position. In HCN channels, as in most other members of the channel superfamily, the S4 helix functions as “voltage-sensor” conferring voltage-dependent gating [8,9]. In CNG channels, which are not gated by voltage, the specific role of S4 is not known.

CNG and HCN channels reveal different ion selectivities. CNG channels conduct both Ca^{2+} and monovalent cations with permeability ratios $P_{\text{Ca}}/P_{\text{Na}}$ ranging from about 2 to 25 depending on the respective channel type and the cyclic nucleotide concentration [10,11]. By providing an entry pathway for Ca^{2+} , CNG channels control a variety of cellular processes that are triggered by this cation. In contrast, HCN channels are not permeable to Ca^{2+} . These channels pass Na^+ and K^+ ion with a relative permeability ratio $P_{\text{Na}}/P_{\text{K}}$ of about 0.15 to 0.25 [12–14].

In the carboxy-terminus, CNG and HCN channels contain a cyclic nucleotide-binding domain (CNBD) that has significant sequence similarity to the CNBDs of most other

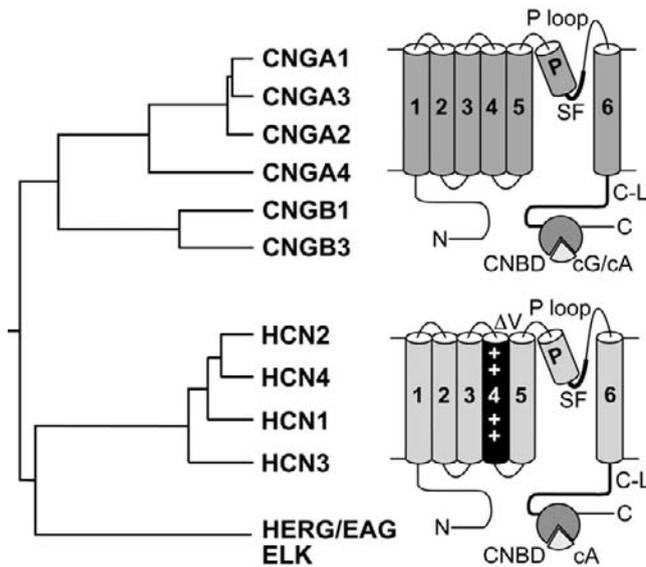

Figure 1 Phylogenetic tree and structural model of cyclic nucleotide-regulated cation channels. The CNG channel family comprises six members, which are classified into α subunits (CNGA1-4) and β subunits (CNGB1 and CNGB3). A “CNGB2” subunit does not exist. The HCN channel family comprises four members (HCN1-4). The channels are distantly related to EAG/HERG and ELK K^+ channels [49]. CNG and HCN channels share a common transmembrane topology, consisting of six transmembrane segments (1–6), a pore loop, and a cyclic nucleotide-binding domain (CNBD). The pore loop comprises the pore helix (P) and an uncoiled strand of 4 to 5 amino acid residues forming the selectivity filter (SF). CNG channels are activated *in vivo* by binding of either cAMP (cA) or cGMP (cG), depending on the channel type. HCN channels activate on membrane hyperpolarization (ΔV) and are enhanced by binding of cAMP. The positively charged amino acid residues in the S4 segment of HCN channels are indicated by “+” symbols. CL, C-linker involved in activation gating of CNG and HCN channels.

Table I Adopted Nomenclature for Cyclic Nucleotide-Regulated Ion Channel Subunits [5,48]

Adopted nomenclature	Previous designations
CNGA1	CNG1/CNG α 1/RCNC1
CNGA2	CNG2/CNG α 3/OCNC1
CNGA3	CNG3/CNG α 2/CCNC1
CNGA4	CNG5/CNG α 4/OCNC2/CNGB2
CNGB1	CNG4/CNG β 1/RCNC2
CNGB3	CNG6/CNG β 2/CCNC2
HCN1	HAC2/BCNG1
HCN2	HAC1/BCNG2
HCN3	HAC3/BCNG4
HCN4	HAC4/BCNG3

types of cyclic nucleotide receptors (Fig. 2). In CNG channels, the binding of cyclic nucleotides to the CNBD initiates a sequence of allosteric transitions that lead to the opening of the ion-conducting pore [15]. In HCN channels, the binding of cyclic nucleotides is not required for activation. However, cyclic nucleotides shift the voltage-dependence of

channel activation to more positive membrane potentials and thereby facilitate voltage-dependent channel activation [12–14]. Despite the fact that the CNBDs of HCN and CNG channels show significant sequence homology, the two channel classes reveal different selectivities for cyclic nucleotides. HCN channels display an approximately ten-fold higher affinity for cAMP than for cGMP whereas CNG channels select cGMP over cAMP [4,5].

CNG Channels

CNG channels are expressed in retinal photoreceptors and olfactory neurons and play a key role in visual and olfactory signal transduction [16]. CNG channels are also found at low density in some other cell types and tissues such as brain, testis, and kidney (for recent compilation of tissue expression see [17]). Although the function of CNG channels in sensory neurons has been unequivocally demonstrated, the role of these channels in other cell types remains to be established. Based on phylogenetic relationship, the six CNG channels identified in mammals are divided in two subfamilies, the α subunits (CNGA1-4) and the β subunits (CNGB1 and CNGB3) (Fig. 1). CNG channel α subunits (with the only exception of CNGA4) form functional homomeric channels in various heterologous expression systems. In contrast, β subunits do not give rise to functional channels when expressed alone. However, together with CNGA1-3 they confer novel properties (e.g. single channel flickering, increased sensitivity for cAMP and L-cis diltiazem) that are characteristic of native CNG channels [4]. The physiological role and subunit composition are known for three native CNG channels: the rod and cone photoreceptor channel and the olfactory channel. The CNG channel of rod photoreceptors consists of the CNGA1 subunit [18] and a long isoform of the CNGB1 subunit (CNGB1a [19]). The cone photoreceptor channel consists of the CNGA3 [20] and the CNGB3 [21] subunit. CNG channels control the membrane potential and the calcium concentration of photoreceptors. In the dark both channels are maintained in the open state by a high concentration of cGMP. The resulting influx of Na^+ and Ca^{2+} (“dark current”) depolarizes the photoreceptor and promotes synaptic transmission. Light-induced hydrolysis of cGMP leads to the closure of the CNG channel. As a result the photoreceptor hyperpolarizes and shuts off synaptic glutamate release. Mutations in CNG channel genes have been linked to retinal diseases. Mutations in the CNGA1 [22] and CNGB1 [23] subunits have been identified in the genome of patients suffering from retinitis pigmentosa. The functional loss of either the CNGA3 [24,25] or the CNGB3 [26] subunit causes total color blindness (achromatopsia) and degeneration of cone photoreceptors.

The CNG channel expressed in cilia of olfactory neurons consists of three different subunits: CNGA2 [27,28], CNGA4 [29,30], and a short isoform of the CNGB1 subunit (CNGB1b) [31,32]. The channel is activated *in vivo* by cAMP, which is synthesized in response to the binding of

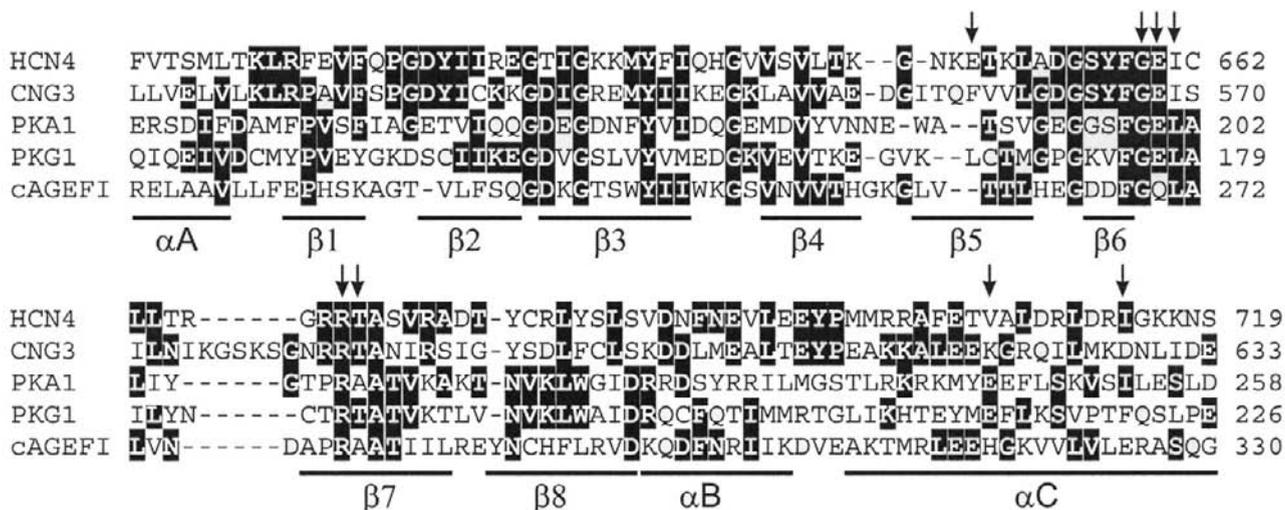

Figure 2 Amino acid sequences of CNBDs of cyclic nucleotide-binding proteins. Residues identical in at least two sequences are highlighted by a black background. Amino acids that are supposed to interact with cyclic nucleotides in CNG channels are indicated by arrows [50]. HCN4 (human HCN4, accession NP_005468), CNG3 (bovine CNG3, accession Q16281), PKA1 (cAMP binding site 1 of bovine cAMP-dependent protein kinase, α -catalytic subunit, accession P00517), PKG1 (cGMP-binding site 1 of bovine cGMP-dependent protein kinase type I α , accession P00516), cAGEF1 (human cAMP-GEF1, accession NP_006096).

odorants to their cognate receptors. The olfactory CNG channel is thought to conduct almost exclusively Ca^{2+} under physiological ionic conditions [33]. The resulting increase in cellular Ca^{2+} activates a Ca^{2+} -activated Cl^- channel, which further depolarizes the cell membrane. Ca^{2+} is not only a permeating ion of the olfactory CNG channel, it also represents an important modulator of this channel. By forming a complex with calmodulin that binds to the CNGA2 subunit, Ca^{2+} decreases sensitivity of the CNG channel to cAMP [34]. The resulting inhibition of channel activity is the principal mechanism underlying odorant adaptation [35].

HCN Channels

A cation current that is slowly activated by membrane hyperpolarization (termed I_h , I_f , or I_q) is found in a variety of excitable cells, including neurons, cardiac pacemaker cells, and photoreceptors [36]. The best understood function of I_h is to control heart rate and rhythm by acting as “pacemaker current” in the sinoatrial (SA) node [37]. I_h is activated during the membrane hyperpolarization following the termination of an action potential and provides an inward Na^+ current that slowly depolarizes the plasma membrane. Sympathetic stimulation of SA node cells raises cAMP levels and increases I_h by a positive shift of the current activation curve, thus accelerating diastolic depolarization and heart rate. Stimulation of muscarinic receptors slows down heart rate by the opposite action. In the brain I_h fulfills diverse functions: it controls the activity of spontaneously spiking neurons (“neuronal pacemaking” [36]), it is involved in the determination of resting potential [36], in photoreceptors it provides rebound depolarizations in response to pronounced hyperpolarizations [36], it is involved in the

transduction of sour taste [38], and it is involved in the control of synaptic plasticity [39].

HCN channels represent the molecular correlate of the I_h current [5–7]. In mammals, the HCN channel family comprises four members (HCN1–4) that share about 60 percent sequence identity to each other and about 25 percent sequence identity to CNG channels. The highest degree of sequence homology between HCN and CNG channels is found in the CNBD. When expressed in heterologous systems all four HCN channels generate currents displaying the typical features of native I_h : (1) activation by membrane hyperpolarization, (2) permeation of Na^+ and K^+ , (3) positive shift of the voltage-dependence of channel activation by direct binding of cAMP, and (4) channel blockade by extracellular Cs^+ . HCN1–4 mainly differ from each other with regard to their speed of activation and the extent by which they are modulated by cAMP. HCN1 is the fastest channel, followed by HCN2, HCN3, and HCN4. Unlike HCN2 and HCN4, whose activation curves are shifted by about +15 mV by cAMP, HCN1 is only weakly affected by cAMP (shift of less than +5 mV). Site-directed mutagenesis experiments have provided initial insight into the complex mechanism underlying dual HCN channel activation by voltage and cAMP. Like in other voltage-gated cation channels, activation of HCN channels is initiated by the movement of the positively charged S4 helix in the electric field [8,9]. The resulting conformational change in the channel protein is allosterically coupled by other channel domains to the opening of the ion-conducting pore. Major determinants affecting channel activation are the intracellular S4–S5 loop [40], the S1 segment [41], and the extracellular S1–S2 loop [41]. The CNBD fulfills the role of an auto-inhibitory channel domain. In the absence of cAMP the cytoplasmic carboxy-terminus inhibits HCN channel gating by interacting with the channel

core and thereby shifting the activation curve to more hyperpolarizing voltages [42]. Binding of cAMP to the CNBD relieves this inhibition. Differences in the magnitude of the response to cAMP among the four HCN channel isoforms are largely due to differences in the extent to which the CNBD inhibits basal gating. It remains to be determined whether the inhibitory effect of the CNBD is conferred by a direct physical interaction with the channel core domain or by some indirect pathway. There is initial evidence that the so-called C-linker, a peptide of about 80 amino acids that connects the last transmembrane helix (S6) to the CNBD, plays an important role in this process [43] (Fig. 1). The C-linker was also shown to play a key role in the gating of CNG channels, suggesting that the functional role of this domain has been conserved during channel evolution [15].

HCN channels are found in neurons and heart cells. In SA node cells, HCN4 represents the predominantly expressed HCN channel isoform [44,45]. In mouse brain all four HCN isoforms have been detected [46,47]. The expression levels and the regional distribution of the HCN channel mRNAs vary profoundly between the respective channel types. HCN2 is the most abundant neuronal channel and is found almost ubiquitously in the brain. In contrast, HCN1 and HCN4 are enriched in specific regions of the brain such as thalamus (HCN4) or hippocampus (HCN1). HCN3 is uniformly expressed throughout the brain, however at very low levels. HCN channels have also been detected in the retina and some peripheral neurons such as dorsal root ganglion neurons [45].

Introduction

In 1998 two independent groups identified a novel family of cAMP-binding proteins, Epacs or cAMP-GEFs [1,2]. These highly conserved and rather ubiquitously expressed proteins serve as guanine nucleotide exchange factors (GEFs) for the small GTPases Rap1 and Rap2 and as such induce signal transduction pathways independent from protein kinase A (PKA). One process among others that is controlled by Rap is integrin-mediated cell adhesion [3].

The Epac Family

In humans the Epac (exchange protein directly activated by cAMP) family consist of two members, Epac1 and Epac2 (Fig. 1). Epac1 has in its N-terminal part a DEP (dishevelled, egl-10, pleckstrin) domain, responsible for membrane localization, followed by a cAMP-binding site that closely resembles the cAMP-binding domains in PKA and cyclic nucleotide gated ion channels (Fig. 2). The C-terminal part consists of the REM domain and the catalytic domain. These domains closely resemble similar domains in GEFs for other members of the Ras family, such as Sos and RasGRP. The CDC25-homology domain mediates the exchange of guanine nucleotides bound to the target GTPase in the case of

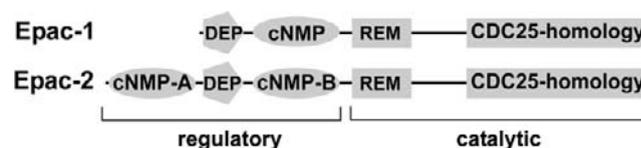

Figure 1 Domain organization of Epac. The regulatory and the catalytic part of the protein are indicated. Dishevelled, egl-10, pleckstrin (DEP) cyclic nucleotide binding domain (cNMP), Ras exchange motif (REM), CDC25 homology domain (CDC25 homology).

Epac Rap1 and Rap2. The REM domain is responsible for the stabilization of the CDC-25 homology domain [4] but is not directly involved in the catalysis of nucleotide exchange. Epac2 has in addition a second N-terminal cAMP domain.

The cAMP-Binding Domain of Epac Closely Resembles Those of PKA and Channels

Sequence comparison between various cAMP-binding sites as well as the crystal structure of cAMP-binding sites of PKA in the presence of cAMP identifies various consensus sequences specific for cAMP-binding, including the phosphate binding cassette (PBC) [5]. These motifs are all present in the cNMP-binding domain of Epac1, as well as in the second cNMP-binding domain of Epac2 (Fig. 2)

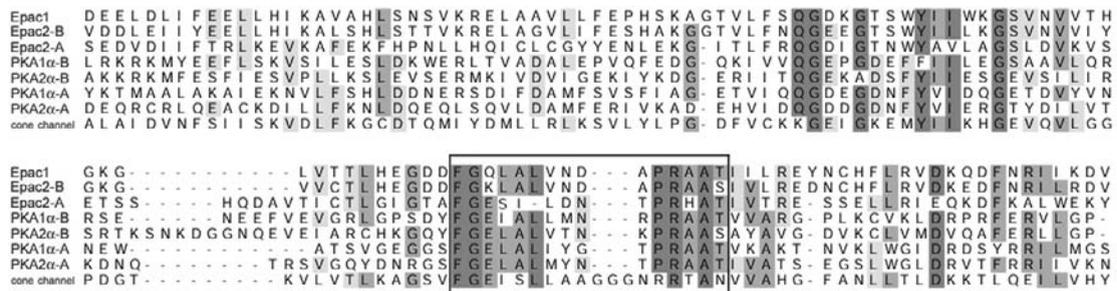

Figure 2 The phosphate binding cassette (PBC) is clearly conserved in Epac. The PBC is marked by a box. All sequences shown are human.

Epac Is Conserved Through Evolution

In higher organisms two Epac proteins, Epac1 and Epac2 (Fig. 1), are found, which show strong sequence homology not only among species (human Epac2 and mouse Epac2) but also between each other (human Epac1 and human Epac2) (Fig. 3). The major difference between Epac1 and Epac2 is an additional N-terminal cNMP-binding domain. In lower organisms only one Epac is present that is more related to Epac2, due to its additional putative cNMP-binding domain. However, this domain is less conserved and lacks PBC, which makes cAMP binding to these domains highly unlikely. Note also that sequence conservation is strongest in the CDC25 homology domain, which mediates the catalytic activity, and in the more C-terminal cNMP binding domain, which is the (main) regulatory element. A minor role in regulation for the first cNMP-binding domain fits the biochemical data (see below).

Properties of Epac

In vitro experiments have shown that in the absence of cAMP, Epac is unable to increase intrinsic exchange of nucleotide on the small GTPase Rap1. However, cAMP accelerates the exchange activity by at least two orders of magnitude, proving the responsiveness of Epac to cAMP. By using isothermal titration calorimetry, the affinity of cAMP has been determined for each of the single domains of Epac1 and Epac2, as well as for the whole regulatory domain of Epac2 (Table I). These data indicate that there is no significant cooperativity in cAMP binding to the two cAMP-binding sites in the regulatory part of Epac2 [6]. In addition, deletion of the first cAMP-binding domain from Epac2 does not abolish the requirement of cAMP for activity [6]. The second cAMP-binding domain, which is conserved in the domain structure of Epac1 and Epac2, is therefore sufficient to maintain the inactive state of Epac2 in the absence of cAMP. This is in agreement with the relative low conservation of the first cAMP domain between species (see above).

The value of half maximal activity (IC_{50} -value) of Epac was determined by measuring the concentration dependency

of cAMP-induced activation of Epac. For Epac1 an IC_{50} value of 40 μ M is found (H. Rehman, unpublished data). This value reflects the affinity of cAMP for full-length Epac, and is clearly lower than the affinity of cAMP for the separate regulatory domain. This implies that the presence of the catalytic part of the protein reduces the cAMP affinity. Apparently, a conformational change induced by cAMP binding “consumes” parts of the binding energy.

Expression and Subcellular Localization of Epacs

Epac1 is expressed in a large number of tissues tested but most notably in kidney, ovary, thyroid, heart, and brain, where it is confined to the septum and the thalamus of the neonatal brain. Epac2 is predominantly expressed in the cerebral cortex, the hippocampus, the habenula, and the cerebellum of the brain and in the adrenal gland [2]. Subcellularly, Epac 1 is attached to membranes through its DEP domain [6], and an Epac-GFP fusion protein is located predominantly in the prenuclear region, where Rap1 and Rap2 are also located (F. J. Zwartkruis, unpublished observation).

Cellular Function of Epacs

Epacs mediate the activation of Rap1 and Rap2 by receptors that elevate the levels of cAMP. However, the biological effects are still unclear. A number of reports indicate cAMP-mediated but PKA-independent events that may be mediated by Epac. For instance, the following events have been noted: (1) cAMP-induced translocation of CFTR-like chloride channels in renal cells [7], (2) cAMP regulation of Glut-1 translocation to plasma membrane through PI3-kinase-dependent and PKA-independent signaling pathways [8], (3) cAMP-induced calcium influx in PBL cells [9], (4) cAMP-induced activation of PKB in thyroid cells [10], and (5) cAMP-induced transcription in glioma cells [11].

cAMP-induced Epac-mediated regulated secretion in pancreatic B-cells [12,13] is the only effect directly assigned to Epacs, but a role for Rap in this process was not established.

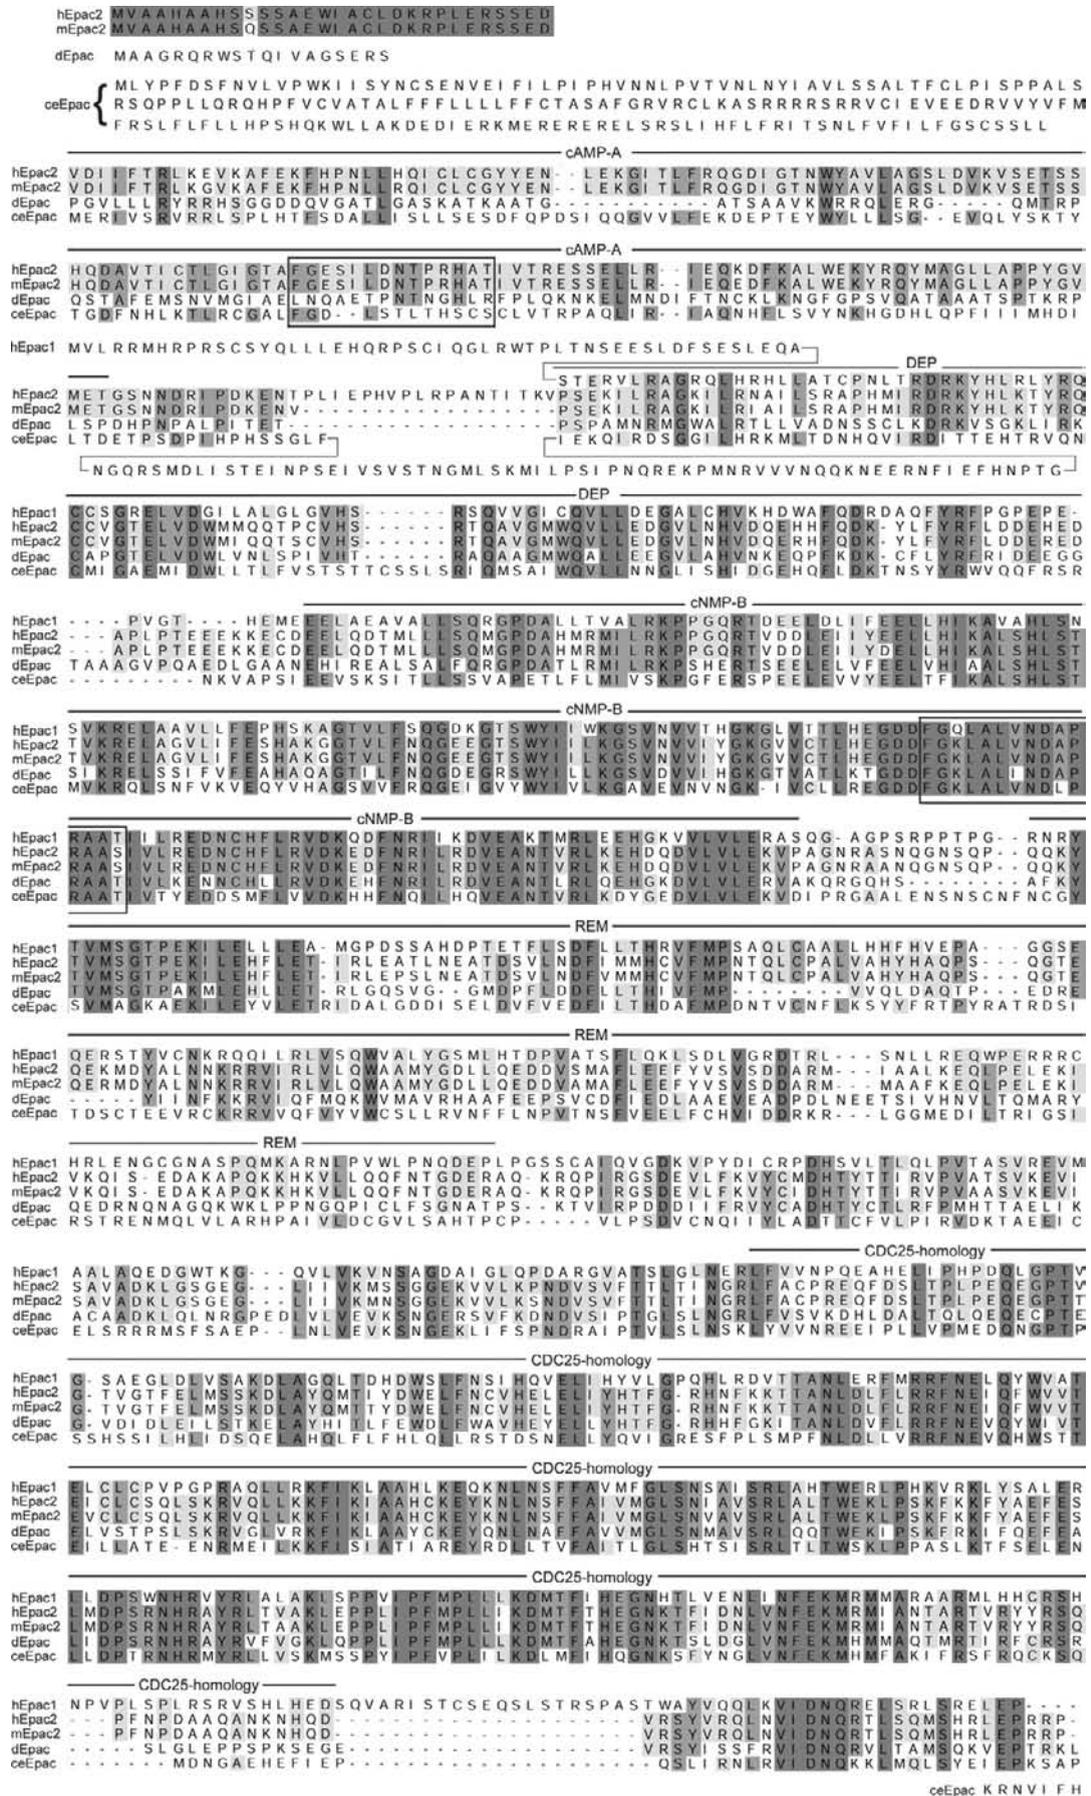

Figure 3 Sequence alignment of Epac from various species. The variable N-terminus is excluded from the alignment and given as sequence only. Domains are indicated according to Fig. 1 by bars over the sequence. The conserved phosphate binding cassette (PBC) is highlighted by boxes in both cNMP binding domains (h, *homo sapiens*; m, *mus musculus*; d, *Drosophila melanogaster*; ce, *Caenorhabditis elegans*).

Table I Affinities of cAMP Binding Domains

Epac1	Epac2		
	cAMP-A	cAMP-B	RD
4 μ M	90 μ M	1 μ M	80 μ M ; 0.5 μ M

Rap1 has been implicated in a variety of cellular functions, most notably in the regulation of ERK activity. However, these effects are mediated by PKA and Epacs are not involved. Whether this implies that a different pool of Rap1 is activated by PKA or that Rap1 is not involved in this process at all is still a matter of debate, although we favor the second alternative.

Introduction

The GAF domains are one of the largest and most widespread of the small-molecule binding domains [1]. They are distantly related to PAS domains, another superfamily with a similar fold [1]. The acronym GAF was coined from the first three protein families in which they were identified: cyclic cGMP-specific and -regulated cyclic nucleotide phosphodiesterases, *Anabaena* adenylyl cyclase, and *E. coli* transcription factor *FhlA* [2]. Over 890 GAF domain containing proteins have now been identified in a non-redundant database [3]. They are involved in many signal transduction pathways, protein regulation, and sensory systems [1,2]. This review will focus on the structure and function of cyclic nucleotide binding GAF domains found in PDEs and also include a short discussion of several others to which they are related.

cAMP and cGMP are used as second messengers in many cellular signal transduction pathways. The intracellular levels of cyclic nucleotides are determined by the relative activities of adenylyl and guanylyl cyclases, the enzymes that catalyze their synthesis, and cyclic nucleotide phosphodiesterases (PDEs), which hydrolyze 3',5' cyclic nucleotides to their respective inactive 5'-nucleotide monophosphates. Eleven PDE families have been identified in mammalian tissues [4]. PDEs are nearly all homodimers with monomer molecular

weights ranging from 50 to 135 kDa. The PDEs constitute the major pathway for the elimination of the cyclic nucleotide signal from the cells to precisely maintain their levels within a narrow range.

PDEs are multidomain proteins with a C-terminal conserved catalytic domain and one or more N-terminal regulatory segments. The regulatory segment from five of the PDE families (PDE2, 5, 6, 10, 11) contain one or two GAF domain modules. For the first three families, cGMP-binding to at least one GAF domain in the regulatory segment modifies the PDE's catalytic activity. In PDE2, cGMP bound to the GAF domain stimulates the V_{max} by more than ten-fold [5–8]. For PDE5A, cGMP binding to GAF A stimulates the phosphorylation by PKG of a Ser just N-terminal to GAF A [9] and increases the catalytic activity.

In rod and cone photoreceptor cells, the catalytic activity of PDE6 is inhibited by binding of a small 9 kDa inhibitory gamma subunit whose affinity is regulated by binding of cGMP to the regulatory segment. The apparent binding affinity of frog rod $P\gamma$ for PDE6 was 28 pM in the presence of cGMP and 16-fold weaker with the GAF sites unoccupied [10]. Unlike PDE2A and 5A, there is no evidence for this enzyme showing direct cooperativity between the GAF domains and catalytic sites. cGMP binding by GAF A does not act allosterically on the catalytic domain. Instead, it binds the central polycationic region of $P\gamma$ and increases the affinity of

the C-terminal region for the catalytic site [11]. In turn, binding or dissociation of cGMP to GAF A may also influence the interaction with transducin or its cognate GAP protein, RGS9. A photoactive peptide containing the polycationic region of P γ cross-linked to two residues in GAF A [12]. There is circumstantial evidence for gamma-like subunits associated with PDE5A in lung [13].

Two more recently discovered and less well-characterized PDE families, PDE10A and PDE11A, are homologous to PDE 2, 5, and 6 in their regulatory segment and contain GAF domains; however, careful binding studies have not yet been reported. A preliminary study suggests that PDE10A lacks a high-affinity cGMP binding site but may contain a low affinity site [14]. One unique structural feature of this family is the presence of splice variants that contain truncated GAF domains in the N-terminal region. These tissue-specific splice variants have been postulated mostly from Northern blot or RT-PCR data, and their existence as active proteins in the cell is not yet fully confirmed [15–18]. However, a genomics study of the PDE11A gene shows separate promoters for both splice variants with an incomplete GAF A (PDE11A3) or GAF B domain (PDE11A1) [19]. It is interesting that a similar series of structures have been seen in a PDE family from Trypanosomes [20,21]. The initial studies of PDE11A1 suggest that neither cAMP nor cGMP are allosteric effectors [18]. However, the splice variant tested lacked the GAF A of the full-length enzyme (PDE11A4) and has an incomplete GAF B. PDE11A4, with both GAF A and B, had no significant cGMP or cAMP binding activity in another preliminary study [17]. A “half-a-PAS” splice variant has been reported for PDE8A, the only PDE to contain a PAS domain [22].

Atomic Structure

The first atomic structure of a GAF domain came recently from a structural genomics project for signal transduction domains. A hypothetical GAF protein, YKG9, from the yeast genome was characterized at high resolution. However, yeast do not make cGMP and this protein did not bind the nucleotide [23]. The first atomic structure of a PDE GAF domain, in this case with bound cGMP, was recently determined (Martinez *et al.*, PNAS). The dimeric regulatory segment of mouse PDE2A, containing both the GAF A and B domains, was determined at 2.9 Å resolution. GAF A and B have very similar folds to YKG9. Although both the catalytic and GAF domains of PDEs bind cyclic nucleotides, and some homology exists, their folding structures are quite different and they appear to be examples of convergent evolution. For example, the catalytic domain of PDE4 is a bundle of 17 alpha helices in three subdomains [24], whereas the GAF domain is a beta sheet packed on the back side with two to four alpha helices and on the other side with a mixture of short alpha helices and loops that form the sides of the ligand-binding pocket [23]. In addition, the zinc-binding motif of the catalytic domain [25] is not present in the GAF domain.

These two new GAF domain structures from PDE2A can now be compared with that of YKG9. The overall folds of the three GAF domains with known structure are very similar, with the yeast variant having an additional N-terminal helix compared to the PDE2A GAF A. Yeast YKG9 (PDB 1F5M, monomer A) is distantly related to PDE2A GAF A with 136 C α atoms superimposing within 4.0 Å and a sequence identity of 10 percent, and to GAF B with 130 equivalent C α atoms that superimpose within an r.m.s deviation of 3.3 Å and a sequence identity of 16 percent.

In PDE2A, GAF A and B are connected through short linkers of several residues to a 32 residue long connecting helix of nine turns (Fig. 1). Unexpectedly, GAF A is engaged in numerous inter-subunit interactions, whereas the GAF B domains are well separated. The first five turns of the connecting helix also provide inter-subunit contacts but afterwards diverge. This occurs after C386, a residue that appears (at this somewhat limited resolution) to form a disulfide bond. A C386S mutant has an essentially identical structure. Therefore, the presence or absence of this disulfide bond has little effect on conformation. Whether this disulfide is integral to the activation or positive cooperativity of PDE2A remains to be determined. GAF A has a surprising, completely different dimer interface than the YKG9 dimer, with contacts from a completely different set of secondary structure elements. Recently, the overall shapes of the bovine PDE6A/B and PDE5A have been visualized at 28 Å resolution from uranyl-stained electron microscopy images [26]. These data show that both PDEs are dimers with the N-terminal regions interacting, which is clearly consistent with the dimerization interface between GAF A domains elucidated at higher resolution in PDE2A. An intriguing finding is that the dimerizing connecting helices that separate GAF A and B in PDE2A appear in the micrographs to be holes surrounded by connections of electron density. Although this could be an artifact of the low resolution and/or the uranyl acetate negative stain, the sequence of the PDE2A connecting helix is poorly conserved among the GAF PDEs.

In the 2.9 Å resolution crystal structure of PDE2A, electron density was found for a molecule of cGMP bound to GAF B. The binding site corresponds to the PAS pocket, showing the conservation of ligand binding function. It is interesting that the cGMP is completely buried, along with three bound waters. This strongly suggests that the protein must also exist in another more open state in which the initial binding occurs. The most distinctive feature of cGMP, its 3',5' cyclic phosphate group, has no side chain contacts. Two backbone amides (I458, Y481, A459) and a water make hydrogen bonds to the exocyclic oxygens of the phosphate. In addition, the positive end of the helix dipole of helix α 3 points directly at the negatively charged phosphate group. The guanine ring and ribose group make a total of six polar contacts and two hydrophobic contacts. One residue, D439, makes both a side chain contact (to the N2 nitrogen) and a backbone amide contact (to the O6 carbonyl). We believe this residue is a main specificity determinant for cGMP over cAMP.

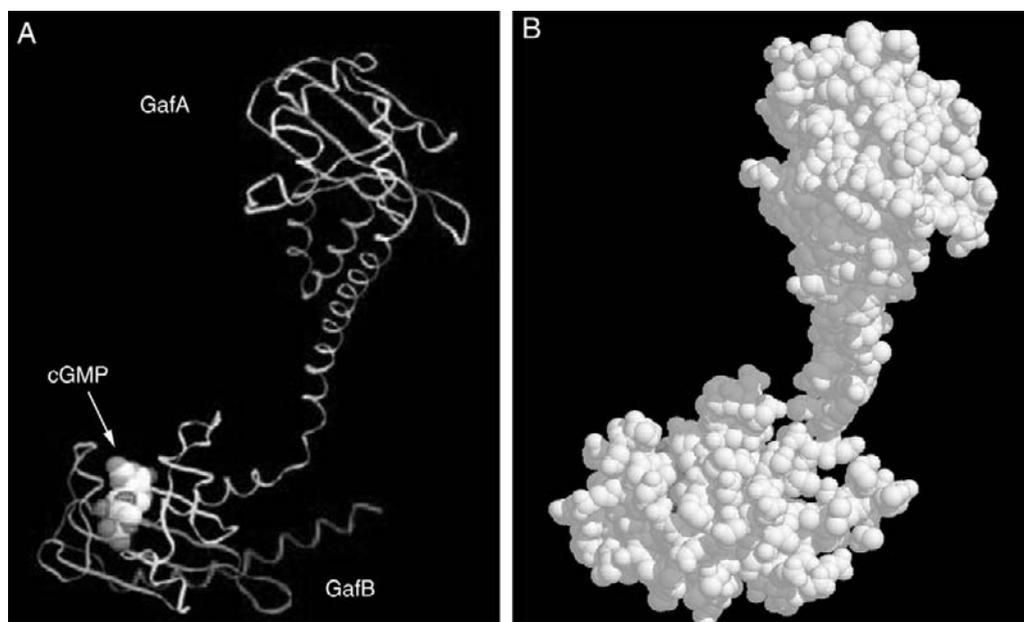

Figure 1 Structure of the PDE2A GAF A/GAF B monomer plus cGMP. Shown on the left is a ribbon structure of the monomer with a space-filling model of cGMP bound to GAF B. Shown on the right is a full space-filling model of both. Notice that the cGMP is almost completely buried. Less than 1 percent of the molecule is exposed to solvent. Presumably therefore the protein must go through some other conformation in order to bind the cyclic nucleotide.

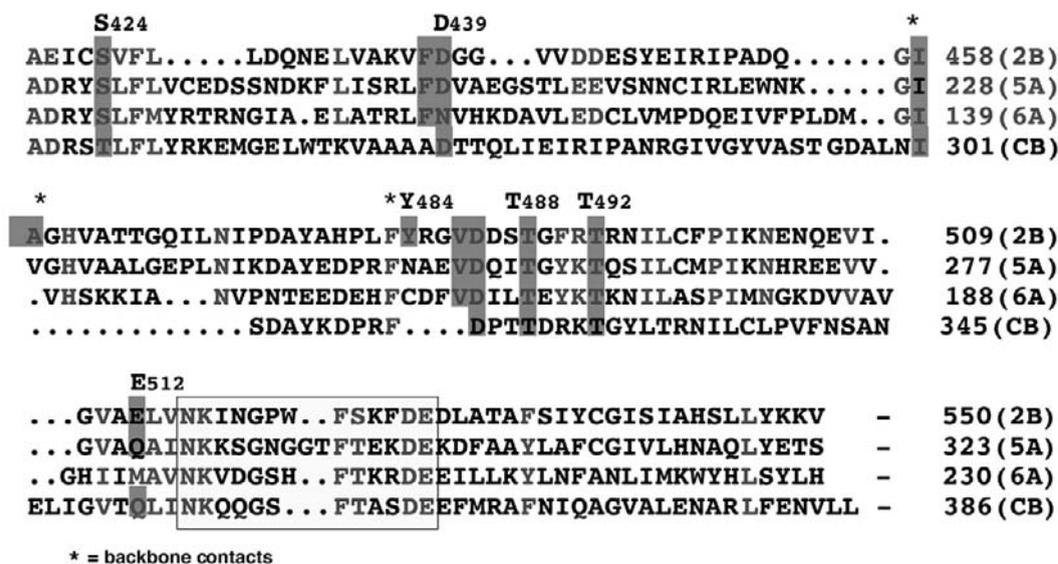

Aside from this work, published cGMP binding to individual PDE GAF domains have only been done for PDE5A, which shows binding to the GAF A domain [23,27]. A comparison of the 2A GAF B structure to the 5A GAF A sequence suggests that the binding motif is SX(13-18)FDX(18-22)IAX(21)[Y/N]X(2)VDX(2)TX(3)TX(19)[E/Q]. The [Y/N] and IA are backbone contacts not expected to be conserved. It is a theoretical possibility that PDE2A GAF A and PDE5A GAF B may be able to form additional cGMP binding sites, but the poor conservation of the motif and biochemical data suggest otherwise. Given the variety of ligands bound by PAS and GAF domains, it raises the intriguing possibility of unknown small molecule ligands regulating GAF PDEs. PDE6 is the PDE whose stoichiometry of cGMP is best documented, one 1 cGMP/monomer. The binding motif is best conserved in GAF A.

Although the YKG9 structure has no bound ligand and does not bind cGMP [23], it does contain a buried pocket with a volume of 590 Å³ corresponding to the location of the cGMP-binding site of our GAF domain. A structural superposition of YKG9 onto GAF B shows approximately 11 ordered waters, which are scattered about the volume occupied by the cGMP molecule in PDE2A GAF B. It is of possible significance that the YKG9 GAF pocket contains a buried acidic cluster (E132, D149, and D151). This may imply that YKG9 could bind an as yet unknown, positively charged ligand. One of these residues (D149) superimposes with E512 in PDE2A GAF B, the only charged residue buried in that GAF pocket.

The PDE2A GAF A+B structure does not suggest an obvious explanation for the activation mechanism of PDE2A.

In a recent paper, a cAMP-activated cyanobacterial adenylyl cyclase was enzymologically characterized and shown to contain GAF A and GAF B domains, like PDE2A. Binding of cAMP but not cGMP to this domain activated the cyclase. However, the organization of the cyclase differed in that it also contains a PAS domain interspersed in between GAF B and the cyclase domain [28]. Although the overall sequence homology of the cyanobacterial and mammalian GAF domains is not particularly high, it appears that the key residues necessary for binding in PDE2A GAF B are present (Fig. 2). Substitution of the mammalian PDE2 GAF A/GAF B domain cassette into the cyanobacterial cyclase amazingly allowed a fully functional cyclase to be formed, but one that now could be activated by cGMP. These data strongly suggest that the GAF domains function as a general, highly conserved, cyclic nucleotide switch for activating adjacent catalytic domains. In this case two organisms that are over two billion years removed from each other in evolution can utilize the other's GAF domain structural motif. The intervening PAS domain in the adenylyl cyclase apparently does not block this mechanism. This result argues against an intramolecular association between the GAF A and B assembly and the catalytic domain of either enzyme. More likely, binding of cGMP creates a conformational change in GAF B that is transmitted mechanically to the catalytic domain. This may involve a loop that blocks the active site. Alternatively, if the catalytic domains contact each other, the active site may be partially occluded in the inactive form by the opposite domain. A third possibility is conformational change within the active site itself.

In nearly all PDE GAF domains, as well as in the adenylyl cyclase *cyaB1* of *Anabaena*, there is a conserved

* = backbone contacts

Figure 2 Comparison of cNMP binding GAF domain sequences. Clustal W sequence alignment of the four GAF domains known to bind cyclic nucleotide. Gaps were further aligned by eye. 2B, mouse PDE2A GAF B; 5A, human PDE5A GAF A; 6A, human PDE6A GAF A; and CB, Anabaena Adenylyl Cyclase GAF B. Notice that in this alignment nearly all of the major cGMP contact points (shading) present in the PDE2A GAF B crystal structure are present in all of the other GAF domains that bind cyclic nucleotide. Backbone contacts are shown by asterisks. The original GAF domain signature sequence NKxxxFxxDE sequence found in the PDE GAF domains is also present in the Anabaena cyclase.

N[KR]X_nFX₃DE motif (Fig. 2) [29]. This motif straddles a loop on the other side of the beta sheet and approximately 17 Å from the cGMP binding pocket in PDE2A GAF B. Nevertheless, point mutations in the N[KR]X_nFX₃DE motif of GAF A, but not GAF B, of PDE5 greatly weaken cGMP binding [30]. In the structure of both GAF A and GAF B of PDE2, a salt bridge appears to be present between the K and D residues. This suggests that this motif may be important for conformation, or for a conformational change upon cGMP binding. Similar mutations in the Asp of this motif in GAF B but not GAF A of Anabaena AC disabled cAMP-dependent activation of cyclase activity [28].

The first crystal structures of GAF domains have solved many questions regarding regulation of the proteins but have also raised many questions. There may well be other ligands for each of the non-cGMP binding GAF domains in PDE2, PDE5, PDE6, and possibly the poorly characterized PDE10 and PDE11. What is the role of the GAF domains that don't bind cGMP? Do they serve only as dimerization domains for the holoenzyme? Is the common regulatory mechanism hinted at by the Anabaena cyclase/ratPDE2 chimera also conserved among the five GAF PDE families, yet affects the catalytic domain of three different PDE in such different ways? Ultimately, crystal or NMR structures will be needed for the various PDE domains with and without bound ligands to visualize the conformational changes that occur upon binding. Structures of the full-length holoenzymes and possibly also chimeras may also be required. Since these small molecule-binding GAF domains are intimately involved in regulation of so many different enzymes, they are also likely to become good targets for drug development.

Acknowledgments

cAMP Signaling in Bacteria

Introduction and Significance

Our understanding of cyclic AMP (cAMP) signaling in bacteria has resulted primarily from studying the *Escherichia coli* catabolite gene activator protein (CAP), also known as the cAMP receptor protein (CRP). CAP is a 45 kDa homodimer that positively regulates the expression of over 150 genes [1]. Transcriptional activation of RNA polymerase by CAP requires that CAP bind cAMP, undergo an allosteric conformational change, and bind to a specific DNA sequence near the polymerase binding site.

Kolb *et al.* [2] write that “[t]he title of paradigm has been awarded to CRP on many occasions and for many of its functions.” This is well-deserved. CAP is one of the most studied transcriptional regulators [3]. The conformational change of CAP upon cAMP binding has become an important paradigm for allostery [4]. The CAP DNA-binding domain contains a helix-turn-helix motif conserved in a large number of DNA-binding proteins; CAP is a founding member of this “First Family” of DNA-binding proteins, which include the homeodomain and the “winged helix” subfamilies [5,6]. The cAMP-binding domain is homologous to the regulatory subunit of cAMP-dependent protein kinases and the cyclic nucleotide binding domains of cyclic nucleotide-gated channels [7,8]. This homology to CAP has furthered our understanding of cyclic nucleotide-gated channels [8,9].

Background and History

In an environment containing glucose and other carbon sources, *E. coli* metabolizes glucose while metabolism of

other sources is inhibited. Upon glucose depletion, the enzymes that metabolize the remaining carbon sources are induced. This phenomenon has been called the “glucose effect” or “catabolite or glucose repression” and was studied extensively by Jacques Monod over 60 years ago [10,11]. This effect is mediated by cAMP. *E. coli* growing in glucose-containing media have low cAMP levels; but once glucose is removed, cAMP concentrations increase rapidly [12]. Furthermore, exogenously added cAMP also relieves glucose repression [13,14]. Glucose indirectly inhibits adenylate cyclase, which synthesizes cAMP from ATP [15]. CAP was discovered over thirty years ago and was shown to bind to cAMP and mediate its effects [16,17].

The CAP-cAMP complex structure was originally determined in the absence of the amino acid sequence from a 2.9 Å resolution isomorphous map [18]. The amino acid sequence was subsequently incorporated into the structure [19], which was later refined to 2.5 Å resolution [20] and most recently to 2.1 Å resolution [21]. Each subunit folds into two domains, a large (residues 1–130) N-terminal cAMP-binding domain and a small (residues 140–209) DNA-binding domain. The residues between the two domains form a hinge that accommodates movement of one domain relative to the other.

The cAMP conformation when bound to CAP was a matter of disagreement. In the crystal structure, the cAMP molecules, which are among the best-ordered parts of the structure, are in an *anti* conformation. Just as unambiguously, and approximately when the CAP-cAMP structure was initially solved, a *syn* conformation for the cAMP was inferred from NMR experiments [22]. This apparent paradox was not resolved for 15 years, as discussed below.

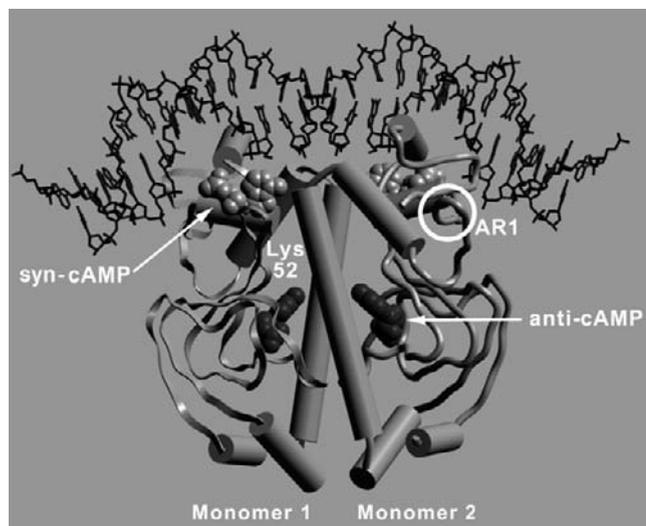

Figure 1 The cAMP-CAP-DNA dimer crystal structure [25]. The activating region 1 and Lys52 are labeled in the respective monomers where each is closer to the viewer. The *anti* and the *syn* cAMP molecules are shown as dark and light gray, respectively.

The crystal structure of CAP-cAMP complexed with a 30 base-pair DNA was solved initially at 3 Å resolution [23] and subsequently refined to 2.5 Å resolution [24]. The DNA in the complex is bent by 90°, which results almost entirely from two 40° kinks. A second CAP-DNA crystal form using a 46 base-pair DNA was solved at 2.2 Å resolution (Fig. 1) [25]. In this crystal form the DNA ends are disordered and unencumbered by crystal packing forces. The second crystal form structure confirms the major results of the original structure.

Transcriptional Regulation by CAP

The architecture of CAP-dependent promoters is amazingly varied. CAP can be either an activator or a repressor, and it can act alone or with other factors. CAP-binding site positions vary considerably among promoters. CAP can stimulate transcription alone when the DNA-binding sites are centered at -41.5 , -61.5 , and -70.5 , as in the *gal*, *lac*, and *malT* promoters, respectively [26]. When the CAP site(s) is (are) further upstream, CAP cooperates with other transcriptional activators, such as MalT and AraC [27,28]. CAP represses transcription of itself and adenylate cyclase [29,30]. An example more reminiscent of eukaryotic systems is a set of CytR-regulated promoters: CytR repression requires two CAP dimers bound exactly 53 base-pairs apart. CytR binds to this nucleoprotein complex, disrupting transcription activation by CAP [31]. It is beyond the scope of this review to discuss the different mechanisms of CAP action at various promoters. However, these few examples offer a sampling of many ways *E. coli* uses CAP in transcription regulation.

Several CAP regions that are involved in transcriptional activation, and that presumably contact RNA polymerase,

have been identified (Fig. 1). One such contact site, activating region 1 (AR1), is a surface-exposed loop (residues 158–162). Positive control mutations—that is, mutations that disrupt transcription activation but do not affect DNA-binding—have been found in AR1 [32–34]. An elegant experiment using heterodimers—one monomer has mutations in AR1, while the other has a mutation that alters the DNA sequence it recognizes—explored which activation loop is required at different promoters [35,36]. Zhou *et al.* demonstrated that when CAP is centered at -61.5 , a functional AR1 is essential in the downstream subunit but dispensable in the upstream subunit; the reverse is the case when CAP is centered at -41.5 . Suppressors of AR1 mutations map to a second surface-exposed loop containing Lys52 [37]. However, suppression only occurs when the CAP site is centered at -41.5 . By studying RNA polymerase alpha subunit deletion and point mutants, it has been shown that the C terminus contains a CAP contact site, when CAP binds at -61.5 but not at -41.5 [38]. Promoter architecture thus plays an important role in determining the exact nature of the CAP-polymerase interaction.

CAP Permits Differential Gene Regulation at Different cAMP Concentrations

Bacteria have two major pathways to control transcription of a global network of genes in response to environmental stimuli and signals. One is to use a transcription factor such as CAP that responds to a signal and undergoes a conformational change, allowing it to bind DNA specifically and thereby regulate gene expression. The other pathway is to use alternative sigma factors, which recognize different promoter sequences, thereby providing the cell with an easy way to turn on a gene family in response to a signal [39]. For example, alternative sigma factors are involved in response to heat shock, sporulation, and flagellar synthesis. Why does *E. coli* use binding to CAP, and not the induction of an alternative sigma factor, in response to cAMP? The answer appears to lie in the flexibility of CAP in regulating gene expression, a flexibility that an alternative sigma factor would be incapable of achieving.

The use of an alternative sigma factor is a digital response. By using a different sigma factor, the cell can turn on and off a whole set of genes in unison. This type of response is critical for discrete changes in developmental or environmental states, such as sporulation or heat shock, or when the cell requires a complex cellular machine, such as flagella, where it is most efficient to produce all the components together.

As noted above, *E. coli* employs CAP in multiple ways; accordingly, the response of CAP to cAMP is analog. The regulation of the expression of different operons can be turned on or off at different cAMP concentrations, with different thresholds for a cAMP response. The threshold is set by adjusting the DNA sequence to change the affinity of the DNA for CAP-cAMP, so that different cAMP concentrations lead to differing affinities for various promoters. For example,

the cAMP-CAP affinity for the *lac* promoter is about an order of magnitude higher than for the *gal* promoter [40]. CAP binds to a consensus sequence 450 times better than to the *lac* site, which is one of the strongest *in vivo*; no natural site is even close in binding affinity to that of the consensus site [41]. This is presumably because a consensus site will always be bound at all physiological cAMP concentrations, and hence no regulation would be possible at promoters containing a consensus-binding site [42].

What advantage does setting different cAMP thresholds at different promoters confer on the cell? Some carbon sources cost more energy to metabolize than others. Therefore, the cell will resort to certain metabolites at different levels of glucose depletion and hence different cAMP concentrations. Similarly, in the presence of multiple nonglucose carbon sources, the cell can utilize its metabolites most efficiently.

A Second cAMP-Binding Site in a CAP Monomer

Various experiments have shown that cAMP binding to CAP induces a conformational change in CAP [4]. It has been observed, with several conformational probes, that CAP has a biphasic dependence on cAMP concentration. These probes—which include proteolytic digestion rates, Cys178 modification, tryptophan fluorescence, fluorescence of an extrinsic probe, and DNA affinity—display two cAMP concentration-dependent behaviors. One set of behaviors is seen up to approximately 200 micromolar cAMP concentrations and the other at millimolar concentrations [43–45]. These observations have been explained by the presence of three conformational states: free cAMP, and CAP dimers with one and two molecules bound, respectively. However, the structure of CAP bound to a 46 base-pair DNA revealed a second cAMP molecule bound to each protein monomer (Fig. 1) [25]. This second cAMP molecule was in the *syn* conformation, and resolved the long-standing discrepancy between NMR and crystallographic observations on the cAMP conformation bound to CAP. Crothers and Steitz [46] postulated the existence of a second cAMP-binding site, when they suggested that at the millimolar concentrations in which the NMR experiments were done there was “a second weakly bound and rapidly exchanging cAMP which is in the *syn* conformation.” The presence of a second cAMP-binding site in each monomer suggests that the experiments showing the biphasic dependence on cAMP concentration be reinterpreted in terms of a new model involving three conformational states: free CAP, CAP with two cAMP molecules bound to the *anti* binding site, and CAP with two cAMP molecules bound to the *anti* and two to the *syn* binding sites.

Whether the *syn*-cAMP binding site is physiologically relevant remains unresolved. *In vivo*, does the cAMP concentration near CAP reach the millimolar concentrations necessary for physiological relevance? Alternatively, is *syn*-cAMP binding an artifact only observed *in vitro*?

Perspectives and Conclusions

Great strides have been made in understanding the molecular mechanism of action by CAP and its response to cAMP; however, many questions remain. Despite extensive efforts to crystallize apo-CAP, its structure has not been determined. The nature of the conformational changes that occur upon cAMP binding has been the subject of speculation and investigation [4,21,47]. Recent progress has included both the crystal structure solution of a transcription factor in the CAP family, CooA, without its effector CO [48], and a low-resolution NMR apo-CAP structure [49]. However, a high-resolution apo-CAP structure would be invaluable.

Over the past two decades, structural biology has contributed a great deal to understanding transcription and its regulation. RNA polymerase structures have provided a wealth of information about the basic mechanisms of transcription. Meanwhile, progress in solving the structures of a large number of transcription factor DNA-binding domains bound to their specific sites has elucidated how transcriptional regulators bind DNA elements within promoters. Structural biology has only begun to address how transcriptional regulators, once bound to DNA, interact with the basic transcription apparatus. Understanding the molecular mechanism of CAP activation is an attainable goal and will provide a useful model for transcription activation in general. The structures of both RNA polymerase and the entire CAP protein are known, including the CAP regions thought to contact RNA polymerase. In addition, since there is no chromatin in prokaryotes, issues of DNA accessibility and chromatin remodeling are not relevant for transcription activation by CAP. Solving the prokaryotic DNA-CAP-polymerase structure would make an enormous contribution to understanding transcription activation even in eukaryotes.

Acknowledgments

The author is supported by a special fellowship from the Leukemia and Lymphoma Society. I wish to acknowledge A. K. Aggarwal for support and encouragement. I am grateful to K. Borden, S. Garges, and D. Possen for helpful comments on the manuscript.

Cyclic Nucleotide Signaling in *Paramecium*

Jürgen U. Linder and Joachim E. Schultz

Department of Pharmaceutical Biochemistry,
Pharmaceutical Institute, University of Tübingen,
Tübingen, Germany

Introduction

The unicellular protozoan *Paramecium* uses both cyclic nucleotide second messengers, cAMP and cGMP, for signal transduction. Contrary to mammalian cells, in which cyclic nucleotide formation is under hormonal control, the primary input in *Paramecium* appears to be membrane potential and ion currents. Studies showed that regulation of cyclic nucleotide levels takes place at the site of formation, that is, by direct modulation of adenylyl cyclase (AC) and guanylyl cyclase (GC) activities. Molecular analyses revealed that the architecture of the respective cyclase enzymes differs from their mammalian congeners, leading to new concepts for the coupling of signals to second messenger generation. This chapter concentrates on the features of *Paramecium* AC and GC. Events downstream of cyclic nucleotide formation will be discussed only briefly, as they have been investigated to a much lesser extent. See Fig. 1 for a summary.

cAMP Formation and Adenylyl Cyclase

In the 1980s regulation of cAMP levels in *Paramecium* has been investigated by exposing cells to sudden changes of the extracellular ion milieu [1]. Increases in cAMP content are strictly dependent on hyperpolarization, e.g. elicited by a dilution of external K^+ . Upon an eight-fold dilution of K^+ cAMP levels increase up to four-fold within 5 to 10 seconds and then decline to a new steady-state level within few minutes. This behavior has the properties of an adaptive response.

cAMP formation is strictly coupled to a K^+ -conductance by which K^+ -ions exit the cell upon dilution [2] because (1) specific K^+ -channel blockers such as tetraethylammonium or Cs^+ abolish the cAMP response; (2) the cAMP response correlates with the K^+ concentration that the cells have been adapted to prior to the stimulus; upon dilution from 16 mM K^+ in the equilibration buffer where the K^+ resting conductance is high, the increase in cAMP is maximal whereas upon dilution from 1 mM K^+ in the equilibration medium where the resting conductance is low, the cAMP response is negligible; (3) The mutant *restless* which cannot control its K^+ resting conductance [3], shows an exaggerated cAMP response even when cells are adapted to low external K^+ .

Subsequently the stimulation of cAMP formation has been investigated biochemically via purification of *Paramecium* AC [2,4]: *Paramecium* AC activity is exclusively membrane-bound and requires detergents for solubilization. AC activity is high in ciliary membranes (0.5 nmol cAMP/(mg·min)) and increases to 25 μ mol/(mg·min) upon purification to homogeneity. *Paramecium* AC is a 97 kDa protein with ion pore-forming properties: upon reconstitution into black lipid bilayers an intrinsic cation-specific conductance of 320 ± 60 pS has been observed. The pore displays a slight preference for K^+ and is impermeable to tetraethylammonium. The unique bifunctional property of the *Paramecium* enzyme as an ion channel-AC suggests that the AC activity is regulated by an intrinsic K^+ -conductance. This AC may be involved in setting the resting membrane potential and thus behaves like a biological ammeter. Such a view is compatible with the observation that cAMP formation upon K^+ -dilution is

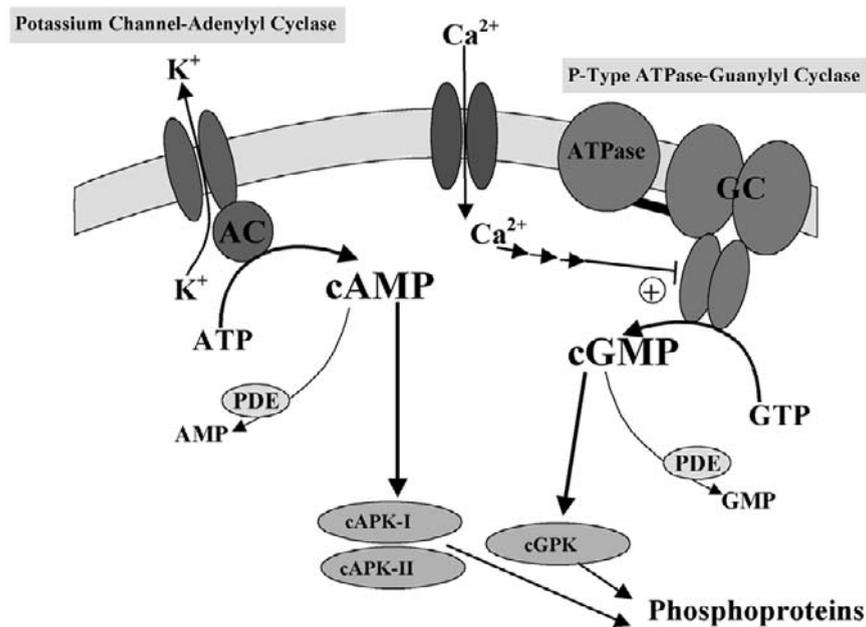

Figure 1 Overview of cyclic nucleotide signaling in *Paramecium*. PDE: cyclic nucleotide phosphodiesterase; cAPK/cGPK: cyclic AMP/GMP-dependent protein kinase; AC/GC: adenylyl/guanylyl cyclase. The light grey ribbon represents the cell membrane with incorporated channels and integral membrane domains. The P-type ATPase-like domain of *Paramecium* GC is connected by a cytosolic peptide linker to the GC-domain. The *Paramecium* AC most likely consists of a K^+ -channel and a catalytic domain with a yet unknown multimeric composition.

dependent on the K^+ resting conductance set by adaptation to the respective equilibration buffer (see above).

Recently we cloned a cDNA from *Paramecium* coding for a 98 kDa protein consisting of three domains (unpublished): an N-terminal ion channel domain linked to an AC catalytic domain and a single C-terminal tetratricopeptide unit. Thus the predicted protein correlates with the previous physiological and biochemical data. The functional properties of the protein have yet to be established.

Some chemoattractants cause hyperpolarization and thus elicit a transient cAMP response [5], e.g. L-glutamate. However, hyperpolarization brought about by addition of NH_4^+ or acetate ions has no effect on cAMP levels. Currently, it is unclear whether the response to L-glutamate is via stimulation of AC or via inhibition of cAMP-phosphodiesterase.

Guanylyl Cyclase and cGMP Formation

Paramecium contains a membrane-bound GC activity about 10 percent of which localize to ciliary membranes [6,7]. Soluble, that is cytosolic, GC activity has never been detected. Ca^{2+} -ions play a prominent role in the regulation of the protozoan GC as removal of Ca^{2+} greatly diminishes activity [4,8]. The inhibition is specifically relieved by readition of Ca^{2+} ions. Sr^{2+} is less effective and Ba^{2+} ions fail to reactivate [8]. The Ca^{2+} -dependence of the GC *in vitro* fits reasonably well the boost-like increase of cGMP levels *in vivo* upon a stimulated Ca^{2+} influx. One route by which

Ca^{2+} can enter *Paramecium* is a depolarization-activated, voltage-gated Ca^{2+} channel activated e.g. by an increase of extracellular K^+ . Channel inactivation is rapid within a few milliseconds, and the global cGMP content rises only by about 45 percent under these conditions [9]. In contrast, a depolarization caused by Ba^{2+} -addition results in a more sustained Ca^{2+} -entry and a substantial, yet short-lived increase in cGMP [9]. Mutants with defects in the depolarization-activated Ca^{2+} conductance show altered cGMP responses. *Pawn* mutants, which lack the depolarization-gated Ca^{2+} -influx, do not display a significant cGMP increase upon treatment with Ba^{2+} [9,10]. On the other hand, *dancer* cells in which the Ca^{2+} channel is very slowly inactivating after opening, show a sustained cGMP response toward Ba^{2+} -depolarization and, in contrast to the wild-type, cGMP levels in *dancer* cells rise three-fold upon a K^+ -depolarization [11]. An alternate route of Ca^{2+} entry is activated by chemical hyperpolarization, e.g. by the drug amiloride, which itself does not affect GC activity *in vitro* [12]. Upon amiloride addition cGMP-levels increase 6 to 30-fold within 10 to 20 sec, dependent on extracellular Ca^{2+} . *Pawn* mutants show an identical cGMP-response to amiloride, suggesting that the hyperpolarization-activated conductance is physically distinct from the depolarization-gated Ca^{2+} -channel opened by Ba^{2+} .

The molecular architecture of *Paramecium* GC has been elucidated via a homology-cloning approach [13]. A 7.2 kb cDNA was obtained coding for a 280 kDa integral membrane protein of two domains. The N-terminal domain of 155 kDa is similar to P-type ion transport ATPases and is

joined by a cytoplasmic linker to the C-terminal 115 kDa guanylyl cyclase domain. The calculated topology of the GC domain is identical with that of mammalian membrane-bound ACs (see previous chapters). It contains two sets of six transmembrane helices, which are linked to the two catalytic subdomains, called C1a and C2. The C1a subdomain contains the crucial amino acids required for substrate recognition and transition state stabilization and the C2 subdomain contains the two metal-cofactor binding aspartates. Thus the functions of C1a and C2 in *Paramecium* GC are inverse compared to mammalian ACs, where C1a binds Mg^{2+} and C2 takes over the other functionalities. The P-type ATPase-like domain contains ten transmembrane helices and harbors the invariant DKTGT(L/I)T signature motif of this class of transporters. However, several crucial deviations from functionally characterized consensus motifs indicate that this domain is not an active transporter but probably has adopted a new, as yet unrecognized function [13].

Due to the unorthodox genetic code in use in *Paramecium* a heterologous expression of the GC requires that the expression cassettes are adjusted to universal codon usage [13]. This way, a specific GC activity of up to 1 nmol cGMP/(mg·min) is detected in Sf9 cells expressing the C-terminal GC-domain. Cells expressing the holoenzyme yield about 0.5 nmol cGMP/(mg·min). A Western blot revealed, however, that in Sf9 cells the holoenzyme is cleaved into two large polypeptides.

The C1a and C2 catalytic subdomains of the *Paramecium* GC can be individually expressed in *E. coli* as soluble proteins, as previously demonstrated for the C1a and C2 domains of the mammalian ACs [14–16]. Alone the affinity-purified subdomains are inactive, yet a mixture of C1a and C2 reconstitutes a robust GC activity [17]. This system was then used for a further characterization of the catalyst. Based on x-ray and mutagenesis data from the mammalian AC/GC enzymes [18–20], Glu1681 and Ser1748 of *Paramecium* C1a were predicted to be key residues for GTP substrate specificity. Indeed mutation of both residues that specify the ATP substrate in the mammalian ACs, i.e. E1681K and S1748D, converts the *Paramecium* GC-C1a/C2 heterodimer into a specific AC [17].

Taken together the *Paramecium* GC is a unique protein assembly wherein an ion pump-like domain is fused to a classical mammalian AC domain in which the substrate specificity was modified during its evolution.

Downstream of Cyclic Nucleotide Formation

Intracellular levels of cyclic nucleotides reflect the balance between synthesis by the cyclases and hydrolysis by phosphodiesterases (PDE). In *Paramecium* PDE activity is high [21]. So far, the regulation of PDE activity has not been investigated in sufficient detail. However, the sharp rise and rapid fall in cGMP levels upon Ba^{2+} -depolarization vividly demonstrates the highly dynamic equilibrium of cGMP-formation and hydrolysis. Indeed it is estimated that the cellular cGMP turns over every two seconds in *Paramecium* [22].

The only known primary effectors for cyclic nucleotides in *Paramecium* are cAMP- and cGMP-dependent protein kinases. Two forms of cAMP-dependent protein kinases, cAPK-I (70 kDa) and cAPK-II (220 kDa), have been partially purified [23–25]. Both forms contain a single catalytic (C) and regulatory subunit (R). They differ in their R-subunits, which are subject to autophosphorylation *in vitro* [26]. The cloned subunit of cAPK-I has up to 38 percent identity to known R-subunits from other unicells and mammalian tissues. In agreement with the molecular weight of the protozoan cAPK-I an N-terminal dimerization region is missing. This explains RC-dimer composition in contrast to the R_2C_2 tetrameric structure in mammals [27]. Further, a cGMP-dependent protein kinase (cGPK) has been partially purified and correlated to a single 77 kDa protein [28]. It appears to autophosphorylate *in vitro* and uses ATP as well as GTP as phosphoryl donors. Numerous proteins appear to be phosphorylated in *Paramecium* in a cGMP and/or cAMP-dependent manner *in vitro* whose identity and function largely remains to be identified [29,30]. Some work has concentrated on a 29 kDa dynein light chain that is a substrate for cAMP-dependent phosphorylation *in vitro* and appears to be a component of the 22S axonemal dynein [31–34]. It has been suggested that this protein may regulate dynein function in *Paramecium* as hyperpolarization increases swimming speed and cAMP formation and because phosphorylation of the 29 kDa protein regulates microtubule translocation *in vitro*. It is interesting that the cAMP response to hyperpolarization is rather transient whereas the increase in swimming speed clearly extends to longer periods of time, demonstrating a lasting signal transduction.

With the advance of several genome projects targeting protozoans of the parvkingdom of Alveolata, including *Tetrahymena* and the apicomplexan parasites *Plasmodium* and *Cryptosporidium*, it is noteworthy that similar cGMP and cAMP signal transduction machineries seem to exist in all members of this parvkingdom, among those several of extremely high pathogenic potential. The studies with *Paramecium* may, therefore, turn out to be a valuable starting point for investigating signal transduction in this group of protozoans [35].

Cyclic Nucleotide Signaling in Trypanosomatids

Roya Zoraghi* and Thomas Seebeck

*Institute of Cell Biology, University of Bern,
Bern, Switzerland*

Introduction

The trypanosomatids (order: kinetoplastida) include the causative agents of human sleeping sickness and of the cattle disease nagana in Sub-Saharan Africa (*Trypanosoma brucei*), a host of diseases of camels, water buffaloes, and horses (*T. evansi*, *T. equinum* and *T. equiperdum*); Chagas disease in South and Middle America (*T. cruzi*); and Kala Azar (*Leishmania donovani*) and a host of other human Leishmanial infections worldwide.

Cyclic nucleotide signaling in parasitic protozoa has lately become an attractive field of research, not at the least because many experimental approaches have been greatly facilitated by the advanced stage of several of the genome projects (e.g. *T. brucei*: <http://parsun1.path.cam.ac.uk>; *T. cruzi*: <http://www.dbm.fiocruz.br/TcruziDB>; *Leishmania major*: <http://www.ebi.ac.uk/parasites/leish.html>).

Cyclic Nucleotide Signaling, Cell Proliferation, and Differentiation

During *in vitro* differentiation of *T. brucei* from bloodstream forms to the insect stage (procyclics),¹ two peaks of adenylyl cyclase (AC) activity were observed. The first peak

occurred 6–10 hr after triggering differentiation, before the first cell division. A second peak was observed when the cells emerged from the first division and before they began to proliferate [1,2]. However, an independent study using a different trypanosome strain found no involvement of cAMP in differentiation *in vitro* [3]. During animal infections, the intracellular cAMP levels of the trypanosomes increased from the early stages of the infection to the peak of parasitaemia and then decreased as differentiation from long slender to short stumpy forms began [4,5].^{2,3} These early observations were recently corroborated by *in vitro* experiments [6]. When cultured bloodstream form trypanosomes reached a threshold density, they secreted a low-molecular-mass factor (SIF: stumpy-inducing factor), which induced an increase in intracellular cAMP. This increase was followed by cell cycle arrest, and resulted in a high efficiency of differentiation to stumpy forms. Membrane-permeable cAMP analogs and the PDE inhibitor etazolate mimicked SIF activity, indicating that SIF acts via cAMP and that the elevated intracellular cAMP is a signal for differentiation. Similarly, membrane-permeable cAMP analogs, PDE inhibitors, or the inactivation of specific PDEs by RNA interference were shown to elevate intracellular cAMP and to concomitantly inhibit proliferation of cultured bloodstream forms of *T. brucei* [7,8].

*Current address: Dept. of Molecular Physiology and Biophysics, Vanderbilt University, Nashville, TN 37232-0615.

¹Procyclics: proliferative form of *T. brucei* adapted to the environment of the tsetse fly midgut.

²Long slender forms of *T. brucei*: proliferative form of the trypanosomes in the blood of mammalian hosts.

³Short stumpy forms of *T. brucei*: long slender forms eventually differentiate into short stumpy forms, which are pre-adapted to survival in the tsetse fly vector. Short stumpy forms do no longer proliferate and have a limited lifetime in the mammalian bloodstream.

In *T. cruzi*, increased cAMP was also found to downregulate cell proliferation. High intracellular cAMP levels inhibited DNA, RNA, and protein synthesis [9]. Fetal calf serum, which is mitogenic for *T. cruzi*, was shown to decrease intracellular cAMP [10].

However, increased cAMP appears to play a role in differentiation of *T. cruzi*. Prior to differentiation to metacyclic forms, the intracellular cAMP levels increased four-fold.⁴ In agreement with these findings, exogenous cAMP, cAMP analogs, and the PDE inhibitor papaverine induced differentiation *in vitro* [11]. In *T. cruzi*, the steady-state level of the mRNA of an unidentified gene, TC26, was elevated during differentiation to metacyclics or after induction by exogenous cAMP analogs. In a strain of *T. cruzi* that was unable to undergo differentiation, TC26 was not expressed [12]. Recent advances in the *T. cruzi* genome project have demonstrated that TC26 represents a family of repetitive elements.

In *L. donovani*, cAMP and PDE inhibitors blocked the transformation from the intracellular amastigote stage to the extracellular promastigote form.^{5,6} In *L. tropica*, caffeine was shown to increase intracellular cAMP levels and to reduce proliferation [13]. Yet binding of a specific component of human serum, C-reactive protein, to the surface of *L. mexicana* promastigotes induced differentiation to the amastigote form, possibly through a cAMP mediated signaling cascade [14].

Individual Components of the Cyclic Nucleotide Signaling Pathways

Cyclases

In striking contrast to the situation in higher organisms, the very small genomes of *T. brucei* and *T. cruzi* (about 40 Mbp) contain a large number of genes for different adenylyl cyclases [15,16]. In *T. brucei*, two types of AC genes can be discerned in terms of their genomic organization. Each telomeric VSG expression site contains a number of expression-site associated genes (ESAGs), one of which is always an AC [17].⁷ All other AC genes (GRESAGs, genes related to ESAG4) are scattered throughout the genome and are present either as single copy genes or as small gene families.

⁴Metacyclic forms: the mammalian-infective forms of *T. brucei* and *T. cruzi*, which are deposited by the respective insect vectors in the blood of the mammalian host.

⁵Amastigote: intracellular, nonflagellated forms of *T. cruzi* and *Leishmania ssp.*, which replicate within mammalian host cells.

⁶Promastigote: extracellular, flagellated forms of *T. cruzi* and *Leishmania ssp.*

⁷VSG (variable surface glycoprotein) of *T. brucei*: a tightly packed layer of single type of such a protein covers the entire surface of *T. brucei*. The genome contains several hundred genes for different VSGs. Only one of these is active at any given time, and activation switches stochastically between individual genes with a low frequency.

All ACs from *T. brucei* [18–21], *T. cruzi* [16], *L. donovani* [22], and *T. equiperdum* [23] for which sequence information is available exhibit a similar predicted structure. A short N-terminal leader sequence is followed by a large extracellular domain that bears no significant similarity to other proteins or among the different trypanosomal ACs. This putative extracellular receptor domain is connected via a single transmembrane helix to the intracellular catalytic domain [24]. The catalytic domains are strongly conserved, not only between kinetoplastid ACs, but also between the kinetoplastid and mammalian ACs [25,26] and are presumably activated by dimerization [22,24,26]. The AC activity of *T. brucei* is insensitive to agents known to activate mammalian cyclases, such as GTP or GTP analogs, forskolin, or cholera and pertussis toxins [1]. The AC activity in bloodstream form *T. brucei* can be transiently activated by Ca²⁺, whereas no such effect could be detected in procyclic form [27].

The overall structure of the trypanosomal ACs is reminiscent of that of the mammalian membrane-bound receptor guanylyl cyclases [28]. The large number of different trypanosomal ACs, all with different N-terminal (extracellular) domains, and their structural similarity with the receptor guanylyl cyclases suggest that the trypanosomal ACs may serve as extracellular receptors [15]. As trypanosomatids contain neither G-protein-coupled receptors nor heterotrimeric G proteins (see below), the ACs may serve as enzyme-linked receptors in an alternative paradigm for chemical sensing. The functional correlate to the structural similarity between trypanosomal ACs and the metazoan receptor GCs might be reflected by the vertebrate GC-D olfactory neurons. In this subpopulation of the olfactory receptor neurons, membrane-bound receptor GCs serve as olfactory receptors, instead of the G-protein coupled receptors expressed in the majority of olfactory receptor neurons [29].

Cyclic Nucleotide-Specific Phosphodiesterases

In *T. brucei*, PDE activity in lysates of bloodstream forms was first demonstrated over 20 years ago [30]. More recent work has now identified at least two different PDE families in *T. brucei*. TbPDE1 is coded for by a single-copy gene and represents a class I PDE with an unusually high K_m for its specific substrate, cAMP (Kunz *et al.*, submitted). This PDE is not essential for proliferation of *T. brucei* in culture, nor for the infection of the tsetse fly vector [31]. Three members of a second class I family of cAMP-specific PDEs of *T. brucei* have recently been identified and characterized (TbPDE2A [7]; TbPDE2B: [7a] TbPDE2C [8]). They share highly conserved catalytic domains but differ in their N-terminal regulatory regions [15], each of which contain one or two GAF domains [32]. All TbPDE2 family members characterized so far are highly specific for cAMP and exhibit a low K_m , and their activity is not affected by cGMP. Several broad-spectrum PDE inhibitors such as the methyl-xanthines are completely inactive toward the TbPDE2 enzymes. Dipyrindamole, trequinsin, sildenafil, and ethaverine inhibit the recombinant enzymes and block

proliferation of bloodstream trypanosomes in culture [7]. RNA interference experiments confirmed that inactivation of TbPDE2 family members is lethal to bloodstream trypanosomes in culture [8], suggesting that this PDE family might constitute an interesting drug target.

Two kinds of cAMP-specific PDE activities were detected in *T. cruzi*. One enzyme was a soluble, cAMP-specific PDE with a K_m of 40 μM , and it exhibited full activity at pH 8.0 and in the presence of 5 mM Mn^{2+} . The enzymatic activity was not Ca^{2+} dependent, and was not inhibited by theophylline and caffeine [33]. A second PDE activity was purified by affinity chromatography on a brain calmodulin-Sepharose column. Activation required micromolar concentrations of Ca^{2+} , and activity was blocked by EGTA and by calmodulin inhibitors [34].

A cAMP PDE activity was also detected in *L. tropica* and *L. donovani*, which required Mg^{2+} for full activation [35]. A cAMP-specific PDE activity from *L. mexicana* was recently characterized [36]. This PDE activity was found both in the cytoplasm and on the outer cell surface. It was identified as a 60 kDa protein on SDS-PAGE, exhibited an unusually high K_m of 277 μM for cAMP, and required Mg^{2+} for maximal activity. Based on its high K_m , the enzyme might represent a class II PDE, or it may represent the leishmanial homolog of TbPDE1 of *T. brucei*.

Protein Kinase A

In *T. brucei*, three genes were predicted to code for different catalytic subunits of PKA homologs [37]. The single-copy gene of a regulatory subunit of PKA has recently been identified and characterized. Although the overall sequence organization of the protein is well conserved with respect to its mammalian homologs, the PKA holoenzyme from *T. brucei* could only be activated by cGMP but not by cAMP. When expressed as recombinant proteins, both cyclic-nucleotide-binding domains of the regulatory subunit did bind cGMP, and this binding was not competed by cAMP [38]. The K_d s for cGMP binding to both of the domains were in the 10 μM range, and its physiological significance remains to be established.

In *T. cruzi*, both the regulatory and catalytic subunits of PKA have been purified from cultured cells. The putative catalytic subunit appeared to be similar to the bovine heart PKA catalytic subunit and cross-reacted with an antibody against the bovine enzyme. The putative regulatory subunit inhibited the catalytic subunit of bovine heart PKA, and this inhibition could be reversed by cAMP. Reconstitution experiments with the two purified proteins resulted in a holoenzyme with an activity similar to that of bovine heart PKA holoenzyme. The molecular weight of the reconstituted holoenzyme suggested a tetrameric structure [39,40].

A presumptive catalytic subunit of PKA was purified from *L. donovani*. Its activity could be inhibited by the regulatory subunit of bovine heart PKA, and the inhibition could be reversed by cAMP. A heat-stable porcine heart PKA inhibitor also inhibited its activity [41].

Cyclic Nucleotides and Host Parasite Intervention

In the bloodstream of the host, *T. brucei* cells are faced with a massive antibody response. As a potential countermeasure, they have acquired a mechanism for active disaggregation when agglutinated by VSG-specific antibodies [42]. The disaggregation mechanism is energy-dependent, does not result in the proteolysis of the bound antibody, and does not involve the shedding of VSG from the cell surface. The mechanism is modulated by PKA and cAMP. This suggests that a cAMP-signaling cascade might be triggered by antibody binding to the VSG coat. This cascade eventually results in the evasion of *T. brucei* from the onslaught of the host's anti-VSG antibody response.

Infection of mammalian cells by *T. cruzi* involves the mobilization of intracellular Ca^{2+} and the elevation of cAMP in the host cells. Parasites that lack the oligopeptidase B required to trigger the Ca^{2+} release in the host cell are still able to induce the elevation of cAMP in the host cell, and to infect them, albeit more slowly [43]. In addition, cGMP was also shown to play a role in modulating macrophage susceptibility to *T. cruzi* infection. Increasing the intracellular cGMP level in macrophages resulted in a marked increase in the number of parasites associated with the cells and in the percentage of infected cells. Similar pretreatments of the parasites had no effect on the host-parasite interaction [44]. The first step of the invasion of *T. cruzi* into its host cells consists in the adhesion to the host membrane. Attachment of infective trypanosomes to host muscle cell sarcolemma resulted in the rapid inhibition of parasite AC activity and significantly reduced intracellular levels of cAMP in the parasite [45].

L. tropica and *L. donovani* secrete a soluble factor that inhibited mammalian AC activity whereas it had no effect on the AC activity of the parasite [46]. cAMP was reported to modulate the intracellular superoxide dismutase activity in *L. donovani*, resulting in a reduction of parasite survival in the intraphagolysosomal environment [47].

Concluding Remarks

The current state of the study of cyclic nucleotide signaling in trypanosomatids still is very patchy. Nevertheless, the available results already provide a glimpse on the contours of the larger picture. One important conclusion that already can be drawn from the available data is that the trypanosomatids differ widely from their mammalian hosts in some, though not all, aspects of their cyclic nucleotide signaling pathways. Although some enzymes involved in these pathways, such as the PDEs that were investigated in great detail in mammals, can similarly be detected in trypanosomatids, amazing differences are seen with others. No G-protein-coupled receptors, heterotrimeric G proteins, or G-protein-activated adenylyl cyclases were found in trypanosomatids. The structure of their adenylyl cyclases, of which they express a large number of different isoenzymes, is entirely

different from that of their mammalian counterparts, and it closely resembles mammalian receptor guanylyl cyclases. In trypanosomatids, the receptor adenylyl cyclases may replace the G-protein-coupled receptors of higher eukaryotes as the major sensory system.

Such novel structures in old pathways might result from the evolutionary adaptation of the trypanosomatids to their parasitic lifestyles, or from the evolutionary distance between them and their mammalian and insect hosts. The three groups of organisms are evolutionarily far apart; the trypanosomatids are among the oldest of the extant eukaryotes, whereas insects and mammals represent much more recent developments. They also might simply reflect a degree of evolutionary diversity that has remained largely undiscovered and unexplored due to an overly narrow focusing of contemporary cell biological studies to a very small number of model organisms such as man, mice, or *Drosophila*.

Studying the parasite-specific wrinkles of cyclic nucleotide signaling pathways not only is a fascinating challenge for the adventurous scientific mind, but it also holds great promise from a practical standpoint. For many of the major parasitic diseases, the current state of the art of chemotherapy is deplorable. The identification of new signaling molecules that differ significantly between the cyclic nucleotide signaling pathways of hosts and parasites might open up a treasure trove of new potential drug targets, not only for trypanosomatid-caused diseases, but just as well for many other protozoal diseases such as malaria, toxoplasmosis, or amebiasis.

However, the pharmacology of the PDEs, a class of enzymes that are similar between mammals and trypanosomatids, has been highly developed for the human enzymes. PDE inhibitors are currently on the market or in the pipelines as medication for an increasing number of clinical applications, and potency as well as isoenzyme and subtype specificity are ever increasing. This extensive know-how on developing inhibitors for mammalian PDEs could and should be applied to their homologs from trypanosomatids and other protozoal pathogens, possibly resulting in an assortment of effective and highly selective antiparasitic compounds.

Cyclic Nucleotide Specificity and Cross-Activation of Cyclic Nucleotide Receptors

Clay E. S. Comstock and John B. Shabb

*Department of Biochemistry and Molecular Biology,
University of North Dakota School of Medicine and Health Sciences,
Grand Forks, North Dakota*

The homologous cAMP- and cGMP-dependent protein kinases (PKA and PKG) are generally believed to be activated relatively specifically by cAMP and cGMP. Certain physiological and pathophysiological conditions may exist in which elevation of one cyclic nucleotide may lead to cross-activation of the opposing kinase [1–3]. This chapter summarizes the current evidence supporting cAMP and cGMP cross-activation and the structural basis for cyclic nucleotide specificity of the cyclic nucleotide dependent protein kinases. The interaction of cyclic nucleotides with other eukaryotic cyclic nucleotide receptors is also discussed.

cAMP Cross-Activation of PKG

Though there is some evidence for cAMP cross-activation of PKG in gastric smooth muscle [4], the physiological paradigm for this type of cross-activation is vascular smooth muscle relaxation. In one line of experiments, doses of cyclic nucleotides sufficient to relax pig coronary arteries correlate with their potencies for PKG activation but not PKA activation [5]. Consistent with this, a mere twofold elevation of intracellular cAMP in this same tissue is sufficient to cause vasorelaxation and activation of both PKA and PKG [6]. A second and more frequently tried line of evidence correlates the pharmacological inhibition of PKG with the disruption of cAMP-induced functions such as vasorelaxation [7], phosphorylation of the IP₃ receptor in rat aorta [8], gating of the

L-type Ca²⁺ channel in rabbit portal vein myocytes [9], and gating of the Ca²⁺-activated potassium (BK_{Ca}) channel in porcine coronary artery myocytes [10]. A third experimental approach demonstrates that cAMP reduces vasopressin-induced Ca²⁺ mobilization in primary cultures of rat aortic myocytes, but not in myocytes depleted of PKG [11]. This last experimental model suggests cAMP-induced vascular smooth muscle relaxation is mediated solely by PKG. Other models suggest, however, that cAMP can also relax vascular smooth muscle through PKA activation [7,9]. The latter is further supported by the observation that PKG I-deficient mice still undergo cAMP-induced smooth muscle relaxation even though these mice already suffer severe vascular and intestinal disregulation [12].

Although the affinity of PKG for cAMP is 50- to 100-fold lower than its affinity for cGMP [13], two factors may make PKG susceptible to cAMP activation in the cell. First, the concentration of cAMP is estimated to be fivefold higher than cGMP in some tissues [5]. Second, autophosphorylation of PKG improves its affinity for cAMP *in vitro* [13–15]. For example, autophosphorylation at Ser-79 of the bovine type IP isoform of PKG results in a three- to fourfold increase in basal kinase activity and a twofold decrease in its K_a for cyclic nucleotides [16]. Though *in vivo* autophosphorylation at this site has not been determined directly, replacement of Ser-79 with aspartic acid to mimic the effect of autophosphorylation results in a mutant kinase with constitutive activity when expressed in CV-1 cells [17].

cGMP Cross-Activation of PKA

The best evidence for the cross-activation of PKA by cGMP is from studies with intestinal epithelial cell lines. The *Escherichia coli* heat-stable enterotoxin causes supraphysiological accumulation of cGMP and increased Cl^- permeability in the human intestinal T84 cell line, which expresses little or no PKG, but plenty of PKA [18]. Inhibitors of PKA activation also suppress increased Cl^- secretion in T84 cells upon stimulation with cGMP analogs or guanylin, an endogenous guanylyl cyclase activator peptide [19]. Similarly, induction of Cl^- conductance in the human colonic carcinoma cell line, Caco-2, by cAMP or cGMP analogs is suppressed by the PKA inhibitor PKI₅₋₂₄ but not the PKG inhibitor KT5823 [20]. Other studies suggest that cGMP-dependent activation of PKA may also occur during porcine carotid artery relaxation [21] and during atrial natriuretic peptide-induced testosterone production in mouse Leydig cells [22].

The cross-activation of PKA may occur indirectly through cGMP inhibition of the cAMP-specific phosphodiesterase PDE3. Treatment of rat small intestine synaptosomal preparations with inhibitors of PKA, but not PKG, block the NO-induced release of bombesin-like immunoreactivity (BLI), considered to be important in enteric smooth muscle contractility [23]. Treatment with trequinsin, a blocker of PDE3, results in increased cAMP and mimics the NO-induced release of BLI. The effects of trequinsin and NO are not additive suggesting that the two agents act through a common mechanism.

Molecular Basis for cAMP/cGMP Selectivity of PKA and PKG

Central to the theme of cyclic nucleotide-dependent protein kinase cross-activation is the degree to which the cyclic nucleotide-binding domain (CNBD) can select for the appropriate cyclic nucleotide. The typical CNBD contains about 124 residues and is characterized by three α -helices, an eight-stranded anti-parallel (β -barrel), and a half-dozen invariant residues. Three invariant glycines are critical for proper folding of the β -barrel, an invariant glutamic acid forms a hydrogen bond with the ribose 2'-OH, and an invariant arginine interacts electrostatically with the cyclic phosphate of the cyclic nucleotide. The importance of these residues in cyclic nucleotide-binding has been demonstrated by site-directed mutagenesis of the type I α regulatory subunit (RI α) of PKA, which contains two CNBDs termed the A and B domains (summarized in [24]). The contribution of the sixth invariant residue, an alanine, to high affinity cyclic nucleotide binding is not fully understood, though its mutagenesis destroys cAMP-binding activity [25]. Since all of these signature residues are present in cAMP- or cGMP-selective CNBDs, they are not involved in cyclic nucleotide selectivity.

The characteristic RAA and R(S/T)A motifs found in cAMP- and cGMP-selective CNBDs, respectively, have been identified as cAMP/cGMP selectivity determinants.

The middle residues in each motif are bracketed by the invariant Arg and Ala residues described above. Mutagenesis of the first Ala in the RAA motif in the A and B domains of RI α increases its affinity 200-fold for cGMP with minor effects on cAMP affinity [26–28]. Likewise, mutation of Ser/Thr residues to Ala in the R(S/T)A motif in the A and B domains of PKG I α [29], PKG I β [30], and PKG II [31] reduces their affinities for cGMP relative to cAMP. These site-directed mutagenesis studies along with cyclic nucleotide analog studies [32–34], molecular modeling [35,36], and determination of the structure of the RI α cAMP-binding domains [37] all support the interpretation that the selectivity of cGMP-binding domains is due to hydrogen bonding between the 2-amino position of cGMP and the Ser/Thr side chain.

Whereas cGMP selectivity can be explained in a large part by a single ligand-receptor interaction, identification of residues responsible for selective, high-affinity cAMP-binding has met with limited success. The RI α structure suggests that aromatic stacking between the A domain Trp-260 or the B domain Tyr-371 and the purine moiety of cAMP may contribute to cAMP/cGMP selectivity. Mutagenesis studies, however, demonstrate that Tyr-371, though important for general high-affinity cyclic nucleotide binding, does not affect cAMP/cGMP selectivity [38]. Other residues in the binding pocket close to the 6-position of the cyclic nucleotide have been implicated as potential selectivity determinants. A likely candidate is the peptide backbone carbonyl group of Asn-372, in the B domain of RI α . Mutagenesis of Asn-372 suggests that it contributes modestly to the cAMP selectivity in RI α (Comstock and Shabb, unpublished).

Another RI α B domain residue that may contribute to recognition of the 6-amino group is Ile-368. Conversion of Ile-368 to Tyr increases the affinity three- to fourfold for N⁶-modified cAMP analogs [39]. The only fully converted cGMP-sensitive, cAMP-dependent protein kinase is a chimera where both of the cAMP-binding domains of RI α have been replaced by the cGMP-binding domains of PKG I [40].

Other Cyclic Nucleotide Receptors

Although cross-activation events are usually mediated by protein kinases, the potential involvement of other cyclic nucleotide receptors must be considered. For example, the homomeric expression of the olfactory cyclic nucleotide-gated (CNG) ion channel α subunit is more sensitive to cGMP than to cAMP [41,42]. However, heteromeric association with its β subunit tends to equalize the channel's affinity for cAMP and cGMP [43,44] suggesting that either cyclic nucleotide can act as its physiological ligand.

The CNBDs of the CNG ion channels are homologous to those found in the protein kinases. Like the kinases, mutagenesis of the invariant Arg in the ion channels results in reduced affinity for cGMP [45]. Substitution of the Thr in the R(S/T)A motif to an Ala in photoreceptor and olfactory CNG ion channels results in a reduction of cGMP-responsiveness

without affecting cAMP-induced channel activation [41]. Other mutagenesis [46,47], molecular modeling [48], and analog studies [49] suggest that the 2-amino group of cGMP may not always interact with the CNG ion channel R(S/T)A motif, but may, under certain conditions, bind cyclic nucleotides in a conformation distinct from that found with the protein kinases.

The recently identified cAMP-binding protein EPAC (exchange protein directly activated by cAMP) or cAMP-GEF (guanine-nucleotide exchange factor) [50,51] represents a new family of CNBD-containing proteins. Preliminary characterization of EPAC-1 cyclic nucleotide selectivity has been done [52]. Further studies of this and other cyclic nucleotide receptors should continue to shed light on the complex interrelationships of intracellular cyclic nucleotide signaling pathways.

Cyclic Nucleotide Analogs as Tools to Investigate Cyclic Nucleotide Signaling

**Anne Elisabeth Christensen and
Stein Ove Døskeland**

University of Bergen,
Bergen, Norway*

Introduction

Early after the discovery of the two naturally occurring cyclic nucleotide monophosphates (cNMPs) cAMP and cGMP, the lipophilic analog N⁶, 2'-O-dibutyryl cAMP was synthesized [1] and used to elicit cAMP responses in intact cells. Several hundred cNMP analogs have since been synthesized. See [2] for a review.

The effects of cAMP in vertebrates appear to be mediated mainly through activation of cAMP-dependent protein kinase isozyme I (cA-PKI) and cA-PKII, but also through activation of small GTPase exchange factors [3,4] and direct binding to ion channels [5,6]. Specialized extracellular cAMP receptors exist on the surface of *Dictyostelium discoideum* [7], and bacteria have a cAMP receptor [8] acting as a catabolite gene activator protein (CAP). The known receptors of cGMP are the cG-kinases (types I α , I β , and II) and ion channels [5], but cGMP can also bind directly to allosteric sites on cyclic nucleotide phosphodiesterases and thereby modulate their action [9]. In the first section of this chapter we will give guidelines and examples of the use of cNMP analogs. In the second section we will describe the chemistry and some properties of commonly used cNMP analogs.

Use of cNMP Analogs: Guidelines and Examples

Activating cNMP Analogs

In order to pinpoint the receptor responsible for a given cyclic nucleotide effect, a dominant positive form of the receptor (not readily available for most cNMP receptors) can be introduced by transfection or by microinjection into cells. The alternative is to use cNMP analogs activating the cNMP receptor. The analog approach does not depend on artificially overexpressed gene products and can be used when transfection or microinjection is not applicable, e.g. in blood platelets. An additional advantage of cNMP analogs is that they generally can be removed by washing the cells and act within minutes, rather than hours or days.

A major problem has been to discriminate between cAMP effects mediated through the EPAC (exchange protein directly activated by cAMP) family of cAMP-regulated GTP exchange factors, cA-PKI and cA-PKII, since all commercially available analogs that activate EPAC also activate cA-PKI and cA-PKII [10]. Recently, novel 2'-O-modified cAMP analogs have been synthesized that have about three orders of magnitude higher affinity (relative to cAMP) for EPAC than for the R subunits of cA-PKI or cA-PKII (Table I), and show EPAC

Table I Relative Affinities of Some EPAC-1 Selective cAMP Analogs

cA analog	Rel. aff. EPAC	Rel. aff. RI: $\sqrt{(AI)(BI)}$	Rel. aff. RII: $\sqrt{(AII)(BII)}$	EPAC/RI	EPAC/RII
cA	1.0	1.0	1.0	1.0	1.0
8-CPT-cA	65	2.57	1.01	25.3	64.3
2'-O-Me-cA	0.12	0.0048	0.0052	24.8	23.3
8-CPT-2'-O-Me-cA	4.6	0.0089	0.0028	517	1626

The table lists the analog affinity for the single cNMP binding site of EPAC-1, and the average affinity for site AI and BI of the RI subunit of cA-PKI and for site AII and BII of cA-PKII. The two right-hand columns give the preference for binding to EPAC relative to RI and RII. The data are from [35].

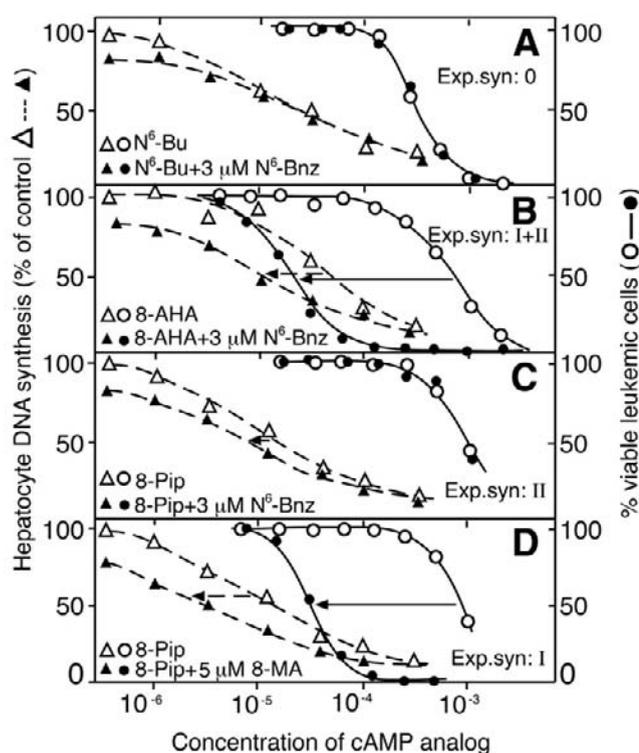

Figure 1 Effects of cAMP analog pairs selected for synergistic activation of cA-PKI and cA-PKII. Panel A shows that the two analogs N^6 -benzoyl-cAMP and N^6 -butyryl-cAMP (see Table III and Figure 2 for details of analog structure) fail to synergize in affecting hepatocyte DNA replication (Δ , \blacktriangle) or leukemic cell apoptosis (\circ , \bullet), as expected from lack of synergistic activation of either cA-PKI or cA-PKII (Table II). Panel B shows that N^6 -benzoyl-cAMP synergized strongly with 8-aminohexyl-amino-cAMP, indicating that either cA-PKI or cA-PKII or both isozymes were able to induce the observed effects. Panel C shows that N^6 -benzoyl-cAMP combined with 8-piperidino-cAMP, which only synergize for activation of cA-PKII (Table I), failed to synergize in induction of leukemic cell death but had a weak synergy in inhibiting hepatocyte DNA replication. Panel D shows that 8-piperidino-cAMP combined with 8-methylamino-cAMP, which selectively synergize for activation of cA-PKI (Table IIB), were strongly synergistic for leukemic cell death induction and moderately so for inhibition of hepatocyte DNA replication. The conclusion is that leukemic cell death can be induced by cA-PKI only, whereas hepatocyte DNA replication can be induced to a moderate extent by activation of cA-PKII, to a higher extent by cA-PKI, and in full by combined activation of cA-PKI and cA-PKII.

selectivity in intact cells [11]. N^6 -modified cAMP analogs such as N^6 -monobutyryl-cAMP and N^6 -benzoyl-cAMP appear to activate cA-PKI and cA-PKII without activating EPAC [11a,35]. Such analogs do not bind to the retinal rod ion channel [12] and discriminate better than 8-Br-cAMP against cGMP-kinases [13].

No single cAMP analog is capable of selectively activating either cA-PKI or cA-PKII, but this can be achieved by analog pairs [9,14]. Examples are given in Fig. 1, where the end-point was either inhibition of hepatocyte DNA replication or induction of leukemic cell death by apoptosis [14]. The theoretical background for the approach is that the two cAMP-binding sites of cA-PKI (AI, BI) and cA-PKII (AII, BII) can be distinguished by cNMP analogs, and that both site A and B must be occupied in a given isozyme to achieve biologically relevant activation [15]. cNMP analogs preferring site AI and BI will therefore synergize in activation of cA-PKI, whereas AII- and BII-preferring analogs will activate cA-PKII synergistically (Table II). Synergistic activation is weaker for cG-PK [9,13], but N^2 -substituted cGMP analogs can discriminate between the α and the β forms of cG-PKI [9]. The cyclic nucleotide-gated ion channels are less well characterized with respect to cNMP analog specificity; the photoreceptor channel was 30 times more sensitive to 8-Fl-cGMP (a fluorescein derived analog) than to cGMP itself [16]. Presumably, use of a battery of cGMP analogs, including 8-Fl-cGMP and analogs with cG-PK specificity, should allow a conclusion of whether an ion channel or cG-PK is responsible for a certain biological phenomenon.

Inhibitory cNMP Analogs

Considering the high latent energy of the cyclic phosphate bond it is no surprise that this part of the cNMP molecule is essential for biological action and that even minor modifications of the cyclic phosphate, as when either the axial (Sp) or equatorial (Rp) oxygen is replaced by sulphur, may interfere with activation. Sp-cNMPS analogs are generally agonistic, with the notable exception of the rod photoreceptor cGMP-gated cation channel, for which Sp-8-Br-PET-cGMPS

Table IIA Relative Affinities of Selected cN-analogs to cA-PK Binding Sites

cA analog	Rel. aff. AI	Rel. aff. BI	Rel. aff. AII	Rel. aff. BII
cA	1.0	1.0	1.0	1.0
N ⁶ -Bu-cA	3.6	0.093	0.71	0.041

Sp-5,6diCl-cBIMPS	0.022	0.13	0.034	14

Table IIB Predicted Synergy between Pairs of cN-analogs

cA analog	Predicted synergy cA-PKI	Predicted synergy cA-PKII
$x + y$	$\frac{\sqrt{(A^x + A^y)(B^x + B^y)}}{\sqrt{(A^x)(B^x)} + \sqrt{(A^y)(B^y)}}$	$\frac{\sqrt{(AII^x + AII^y)(BII^x + BII^y)}}{\sqrt{(AII^x)(BII^x)} + \sqrt{(AII^y)(BII^y)}}$
N ⁶ -Bu-cA + N ⁶ -Bnz-cA	1.0	1.1
8-AHA-cA + N ⁶ -Bnz-cA	2.8	2.9
8-Pip-cA + N ⁶ -Bnz-cA	1.0	4.4
8-Pip-cA + 8-MA-cA	3.2	1.0
N ⁶ -BC-cA + Sp-5,6diCl-cBIMPS	1.3	8.3

Panel A shows the affinity of selected cAMP analogs for the binding sites of cA-PKI (AI, BI) and cA-PKII (AII, BII). Data are from Øgreid *et al.* [36] or the authors' unpublished data. Panel B shows the formulas to predict synergy between analog pairs for activation of cA-PKI or cA-PKII. Numbers above 1.0 signify synergism. For details of cAMP analog structures, see Table III and Figure 2.

is an antagonist [17]. The Rp-cNMPS analogs are generally antagonistic or partially agonistic, with the exception of the cGMP-gated cation channel, where Rp-cGMPS analogs such as Rp-8-Br-cGMPS are agonists [18].

For practical purposes the comparative use of Rp-8-Br-cAMPS, Rp-cAMPS, and Rp-8-Br-cGMPS may be useful. Since these analogs must be used at high concentrations (0.1–1 mM in the extracellular medium) to be able to compete efficiently with cAMP or cGMP in the cell, it is important to test them against submaximal concentrations of the cNMP receptor activator. If Rp-8-Br-cAMPS is the more efficient inhibitor one can suspect that cA-PKI is the main mediator; whereas when Rp-cAMPS is the better inhibitor cA-PKII is more likely; and if Rp-8-Br-cGMPS is the most efficient inhibitor one can suspect cG-PK involvement. Further proof of cyclic nucleotide protein kinase involvement can be obtained by use of cell-permeable inhibitors directed against the kinase moiety of these enzymes, either broadly acting ATP antagonists [19] or more specific peptide inhibitors (Chapter 79 by Dostmann, this volume). If applicable, dominant negative forms of RI or RII (with deficient cAMP-binding sites) can be introduced by transfection or microinjection to further prove cA-PK involvement.

Chemistry and Properties of Cyclic Nucleotide Analogs

Cyclic AMP and cGMP are composed of four rings: the cyclic phosphate, the ribose, and a substituted aromatic purine double ring (pyrimidine and imidazole). The structure of most cNMP analogs can be described (Table III) as variously substituted derivatives of purine riboside-3',5'-cyclic monophosphate (cPuMP), shown in Fig. 2A. The parent cAMP and cGMP molecules are virtually unable to penetrate cell membranes by diffusion and are readily broken down by cyclic nucleotide phosphodiesterases. Most cNMP analogs that are synthesized for use in cell biology have enhanced lipophilicity (Table III) and improved resistance toward cyclic nucleotide phosphodiesterase attack.

The imidazole ring of cPuMP has been subjected to a number of substitutions at the 8 position. Substituent charge, hydrogen bonding potential, hydrophobicity, and bulk determine the specificity toward cAMP-binding sites type A and B of cA-PKI and cA-PKII [20]. Bulky 8-substituents will force the cNMP molecule into a *syn* conformation about the torsion angle between C4-N9 of the purine ring and the O1'-C1' of the ribose ring (Fig. 2A). This will deter cN binding to the

Table III Compounds Resulting from Substitution of cPUMP (fig. 2A)

8-Br-cG	OH	NH ₂	=O	Br	1.2	+
8-CPT-cG	OH	NH ₂	=O	Chloro-phenyl-thio	27	+
8-Fluo-cG	OH	NH ₂	=O	Fluo	–	+

Compounds resulting from substitution of cPUMP (Fig. 2A). For numbering of substituents, see Fig. 2A. 8-Fluo-cGMP is 8-[[2-(Fluoresceinylthioureido)amino]ethyl]thio]-cGMP. The lipophilicity data are adapted from [2] and www.biolog.de.

E. coli CAP protein that binds cAMP in the *anti*-conformation [21] and to the surface cAMP receptor of *Dictyostelium* [22], but not to cA-PK [23] and cG-PK, which bind cAMP in the *syn* conformation. 8-azido-cAMP can be used to photo-affinity label cA-PK in broken cell preparations [24]. This compound may not work in intact cells, since it is labile in a reducing environment, where it quickly decomposes to 8-NH₂-cAMP [25]. 8-Fluo-cAMP and 8-NBD-cAMP are both useful fluorescent cAMP analogs (for more information, see www.biolog.de). 8-Cl-cAMP is slowly metabolized intracellularly to toxic 8-Cl-AMP and 8-Cl-adenosine, and its antitumor properties [26,27] may be related to this fact [28,29]. The 7-deaza-cAMP molecule has intact ability to bind to cA-PK, but is metabolized to the highly toxic [30] compound 7-deaza-adenosine (tubercidine).

Most pyrimidine ring substituents are in the 6 or 2 position, in which cAMP and cGMP differ (Table III). The introduction of an electron-withdrawing group (-Cl, -CF₃) in position 2 will enhance binding to site B of cA-PK, but decrease binding to cG-PK [13,31]. The introduction into cGMP of certain bulky NH-substituents in 2-position can greatly enhance the specificity of binding to cG-PKI α compared to cG-PKI β [9]. The introduction of bulky hydrophobic NH-substituents in 6-position will produce molecules with preference for site A of cA-PK, low affinity for cG-PK, and resistance to degradation by cyclic nucleotide phosphodiesterases.

Modification of the purine ring structure itself has resulted in compounds with enhanced affinity for site B of cA-PKII (such as Sp-5,6-diCl-cBIMPS; Fig. 2B) or cG-PKI (such as

8-Br-PET-cGMP; Fig. 2C). Fluorescent analogs can also be produced by ring extension, as in 1,N⁶-etheno-cAMP [32].

The ribose moiety of cAMP and cGMP is tolerant to modification regarding binding to the *Dictyostelium* surface receptor [22] and EPAC (Table I), but not regarding binding to cA-PK and cG-PK. The 2'-O-butyryl-substituents give at least 1000-fold decreased binding activity but are useful to enhance membrane penetration. Since the butyrate is removed quickly by ubiquitous esterases in the cell, the parent compound will be formed intracellularly (trapping effect).

In the cyclic phosphate moiety the equatorial (Rp) or axial (Sp) oxygen (O) can be substituted with a sulphur (S) (see also Fig. 2B and 2E). This modification greatly increases the stability toward phosphodiesterases. Sp-cAMPS and Sp-cGMPS and their derivatives are used as hydrolysis-resistant agonists of cA-PK and cG-PK. It is interesting that Sp-8-Br-PET-cGMPS is an antagonist for the retinal type ion channels and an activator of cG-PK [17]. Rp-cAMPS and Rp-cGMPS and their derivatives act as partial agonists or pure antagonists for cA-PK and cG-PK. Rp-8-Br-cAMPS is an excellent inhibitor of cA-PKI, whereas Rp-cAMPS preferentially inhibits cA-PKII. Rp-8-Br-cGMPS is an antagonist of cG-PK and an activator of the retinal cGMP-gated ion channel [18]. The ability of cNMP analogs to penetrate cell membranes is highly improved [33] by masking the cyclic phosphate charge by esterification (cNMP-acetoxymethyl ester, e.g. Sp-cAMPS-AM, Fig. 2E) or coupling to a coumarin derivative. The cNMP-AM analogs will be trapped intracellularly due to esterase cleavage of the AM ester. The coumarin

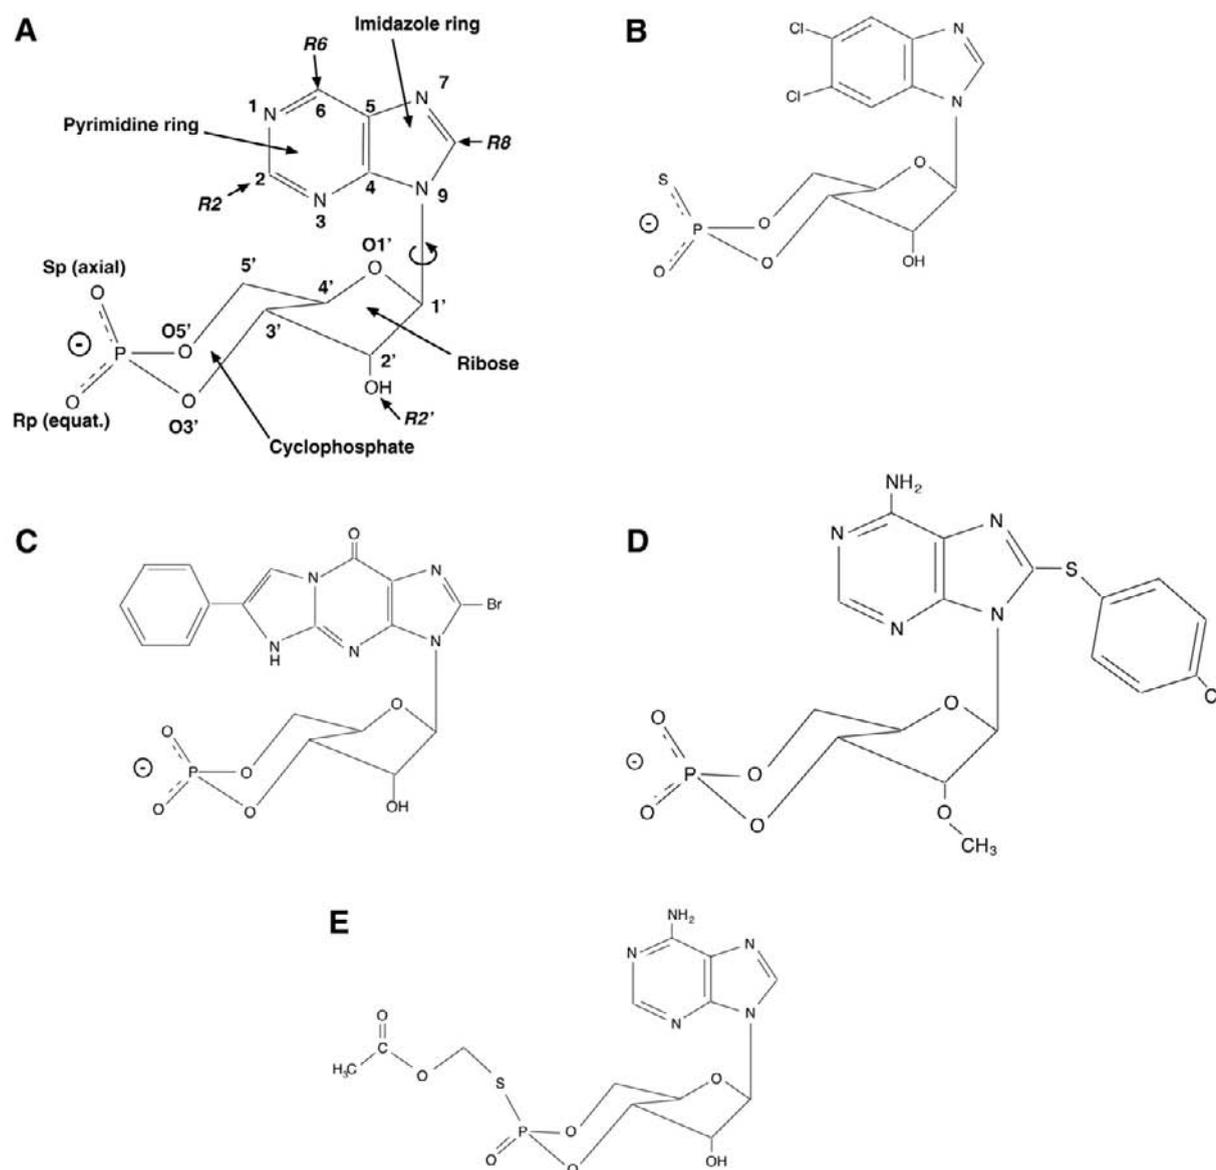

Figure 2 The structure of some cyclic nucleotide analogs. Panel A shows the structure of cyclic purine monophosphate (cPuMP), which can be considered the backbone of cAMP, cGMP, and the other analogs listed in Table III. The most common sites for substitution are indicated (R_2' , R_2 , R_6 , and R_8). Panel B shows Sp-cAMPS with modified pyrimidine ring (Sp-5, 6-di-chloro-cBIMPS), panel C shows 8-Br-cGMP with a phenyl-etheno extension of the pyrimidine ring, panel D shows 8-CPT-cAMP with a modified 2'-position (8-CPT-2'-O-Me-cAMP), and panel E shows the acetoxymethyl-modified Sp-cAMPS.

derivatives are caged, and in principle they are immediately converted to the active parent compound upon irradiation. Other modifications of the cyclic phosphate ring are replacements of the O_3' and O_5' by NH [22].

Future Developments

Currently available cNMP analogs have proven to be very useful tools in cell biology. There is nevertheless room for considerable progress regarding both the synthesis of more specific and potent analogs with improved pharmacokinetic properties and mapping of the cNMP receptors. An interesting novel approach is to synthesize polymer-linked

cNMPs to simultaneously occupy two binding sites in the same receptor complex [34].

Acknowledgments

We are grateful to Dr. Erik Maronde for critically reviewing the manuscript.

Signal Transduction by G Proteins—Basic Principles, Molecular Diversity, and Structural Basis of Their Actions

Lutz Birnbaumer

*Laboratory of Signal Transduction,
National Institute of Environmental Health Sciences,
Research Triangle Park, North Carolina*

Introduction

Cells do not live in isolation and respond to extracellular stimuli either with specific tasks such as neurotransmission, activation of substrate uptake, fatty acid release, or with adaptive changes that ensure homeostatic cohabitation with other cell types as is needed in multicellular organisms to ensure better survival (stress responses). Extracellular cues include nutrients, intoxicants, and of course, signaling molecules such as autacoids, growth factors, and hormones. Signaling molecules are either membrane-permeant (e.g., steroid hormones) or -impermeant (peptide hormones, biogenic amines) for which cells have evolved separate response mechanisms. For membrane-permeant signals, receptors are for the most part intracellular, cytosolic, or nuclear, and the changes they elicit are frequently modulations of gene expression with direct participation of the receptor in the regulatory complex that transcribes response genes. For membrane-impermeant signals, nature has evolved a repertoire of mechanisms by which binding of the ligand to its receptor on the cell surface leads to intracellular changes in one or more enzymatic activities and to activation or inhibition of regulatory signaling pathways. In many instances the action(s) of a receptor involve promotion or disruption of

multimeric protein complexes. Some of the signaling pathways activated by receptors in response to membrane-impermeant ligands are wholly cytosolic or submembranous; others affect nuclear gene expression. The process by which the extracellular ligand-receptor interaction leads to changes inside the cell is commonly referred to as “signal transduction”—the ligand is the extracellular signal whose message is transduced into an intracellular signal of a different chemical nature.

Among the signals generated in this way are second messengers, such as ions entering through ligand-gated ion channels; signaling molecules derived from the receptor itself, such as the cytosolic domain of Notch; products of the activation of the receptors' intrinsic enzymatic activities, such as cGMP formed by the guanylyl cyclase activity of ANF and guanylin receptors; tyrosine phosphorylation, first of self and then of proteins recruited to the phosphorylated receptor, as happens when epidermal growth factor (EGF), platelet-derived growth factor (PDGF), insulin, or nerve growth factor (NGF) bind to their respective homodimeric receptors; and sequential serine/threonine phosphorylation, also first of self (receptor II phosphorylating receptor I) and then of cytosolic transducing proteins such as R-SMADs by phosphorylated receptor I, as it happens in response to interaction of the transforming growth factor β (TGF β) and

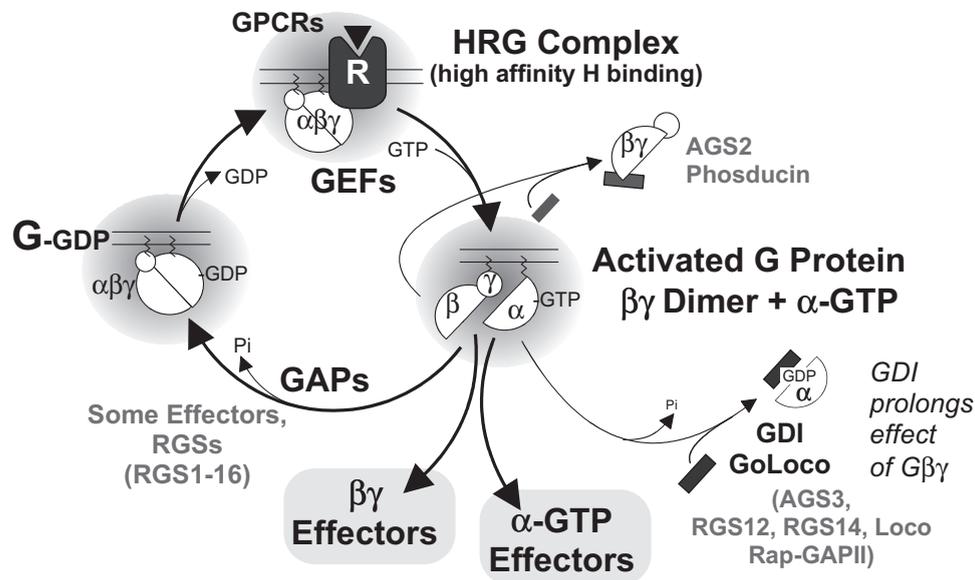

Figure 1 Hormone receptor complexes act as guanine nucleotide exchange factors (GEFs) to catalyze activation of the trimeric G protein with formation of α -GTP plus $\beta\gamma$, both of which modulate effector functions. Spontaneous decay of α -GTP to α -GDP can be modulated by GTPase activating proteins (GAPs) such as RGSs and some effectors, and by activators of G protein signaling (AGSs) that tilt the balance between effects through α -GTP versus those through $\beta\gamma$.

bone morphogenic protein (BMP) superfamily of signaling molecules with their heteromeric receptors. In the case of R-SMADs, their phosphorylation exposes a nuclear localization signal as well as a heterodimerization domain, leading ultimately to translocation into the nucleus and changes in gene expression. For general references see [1].

The use of heterotrimeric G proteins as signal transducers constitutes a completely different type of signal transduction process. In this case evolution has led a structurally related superfamily of receptors that recognize peptide and protein hormones, neurotransmitters, autacoids, and sensory signals such as light, odor, and taste, to acquire the ability to recruit and regulate the intrinsic signaling capacity of a large family of structurally related heterotrimeric regulatory GTPases (Fig. 1). This chapter deals with the mechanism of activation/deactivation and the action of the heterotrimeric G proteins responsible for transducing receptor activation signals into cellular responses. Activation of a G protein by a receptor, first proposed by Rodbell and collaborators to be a two-step process in which a GTP-dependent transducer regulates an enzyme or amplifier without clear knowledge of the number of molecular components involved [2], is now known to be a multistep process that includes GDP/GTP exchange and subunit dissociation of the $\alpha\beta\gamma$ G protein, followed by spontaneous deactivation—hydrolysis of the activating GTP to GDP—and reassociation of the separated members in preparation for reactivation by a new round of GDP/GTP exchange promoted by the activating hormone receptor (HR) complex (bottom panel of Fig. 1). As shown in this figure, the basic cycle is affected by modulators of G-protein signaling, the RGSs, which increase the rate at which α -GTP deactivates and the AGS2- and AGS3-type modulators which sequester

either α -GDP or $G\beta\gamma$ and thereby bias signaling through α -GTP versus signaling through $G\beta\gamma$ (see the following sections).

Ras, the Prototypic Regulatory GTPases

As the name indicates, regulatory GTPases are proteins that bind and hydrolyze GTP. Their regulatory power lies in the fact that their conformation differs when occupied by GTP or GDP. They are also referred to as molecular switches. Due to their intrinsic GTPase activity they carry a built-in inactivating timer that prevents the GTP state from being long-lived. The crystal structure of the 180 amino acid regulatory GTPase *ras*, in its GTP- and GDP-liganded forms, shows two principal regions that differ in the GTP state as compared to the GDP state, referred to as switch I and switch II [3]. Switch I, amino acids 32 through 40, is a large loop connecting α -helix 1 ($\alpha 1$) to β -strand 2 ($\beta 2$). Mutations in this region interfere with activation of several of the downstream effectors of *ras*. Switch II, amino acids 60 through 75, changes conformation even more drastically than switch I, to the extent that upon binding of GTP, amino acids 66 through 74 rearrange into a well-ordered α -helix ($\alpha 2$). Switches I and II are required for activation of downstream effector(s) by *ras*-GTP, the activated form of *ras*. *Ras*-GDP appears to be neutral. Mutations of Gln-61, (at the start of switch II after $\beta 3$), and of Gly-12 (at the base of $\alpha 1$), reduce the intrinsic GTPase activity of *ras* prolonging the life span of the activated GTP state. As is the case for most, if not all regulatory GTPases, the *ras* GTPase is under regulation of two types of proteins, a GEF or guanine nucleotide

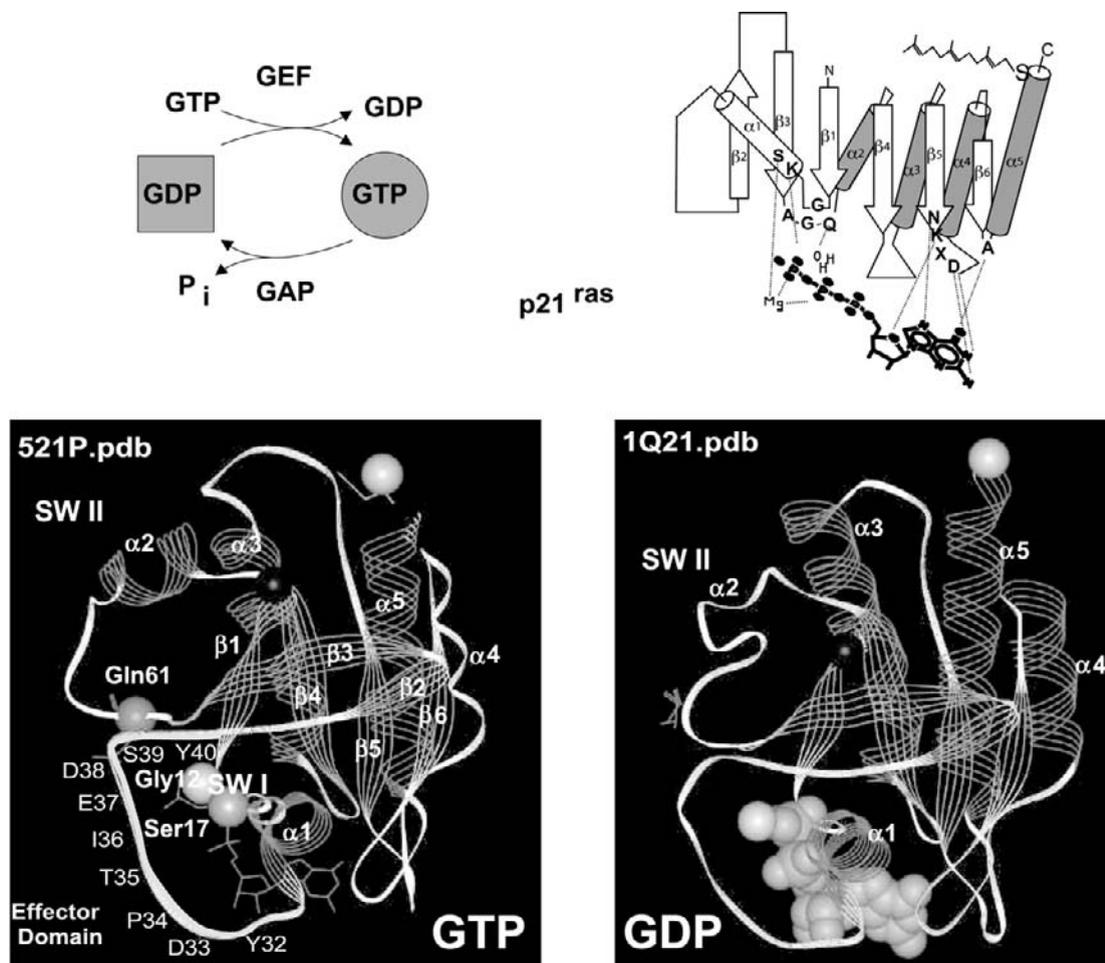

Figure 2 Model of the crystal structure of *ras* in its GTP and GDP states (PDB accession #521P and 1Q21) highlighting secondary structures (α -helices and β -strands as well as switch 1 (effector domain) and switch 2 regions). Bottom left illustrates the basic GTPase regulatory cycle and its two principal modulators: GEFs, responsible for activation, and GAPs, responsible for deactivation of the regulatory GTPases. The bottom right diagram is a two-dimensional representation of the three-dimensional features of the basic GTPase fold found in all regulatory GTPases.

exchange factor, responsible for promoting the transition of *ras*-GDP to *Ras*-GTP, and several GAPs or GTPase activating proteins, which, as their name indicates, shorten the life span of *ras*-GTP by increasing the catalytic efficacy of its intrinsic GTPase (see [4,5], and references therein). SOS (son of sevenless) and *ras*-GAP1, are the prototypes of *ras* GEF and *ras* GAP, respectively. Mutation of Ser-17 to Asn-17, roughly in the middle of $\alpha 2$, interferes with the nucleotide exchange reaction and locks *ras*-GDP in an inactive conformation in which it may still bind to proteins regulated by *ras*-GTP, but without affecting their activity. By reason of occupying the site to which *ras*-GTP should bind to activate effectors, Asn-17 *ras* interferes with signaling by wild-type *ras*-GTP and is referred to as a dominant negative form of *ras* [6]. Figure 2 depicts *ras* in its GTP and GDP conformations and highlights the locations of Gly-12 (G12), Ser-17 (S17), and Gln-61 (Q61), as well as switch I (in blue) and switch II. The upper left panel of Fig. 2 presents this basic GTPase cycle in schematic form with GEF and GAP regulating the life-times of the GTP and GDP states. The upper right panel is a schematic two-dimensional representation of the

main three-dimensional features of this regulatory GTPase (adapted from reference [3])

Heterotrimeric G Proteins

Trimeric G proteins are responsible for transducing the effects of the seven-transmembrane superfamily of receptors, and are regulatory GTPases which, while more complex than *ras*, nevertheless preserve the basic features of the *ras*-type regulatory GTPases. G proteins activated by seven-transmembrane receptors are α , β , γ trimers, of which the α subunit is the GTPase-bearing subunit. The β and γ subunits form a dimer that exists either free or in association with α -GDP. G β and G γ have never been found isolated as individual proteins.

Subunit Structure

α -Subunits were crystallized in the laboratories of Paul Siegler at Yale University and of Steven Sprang at

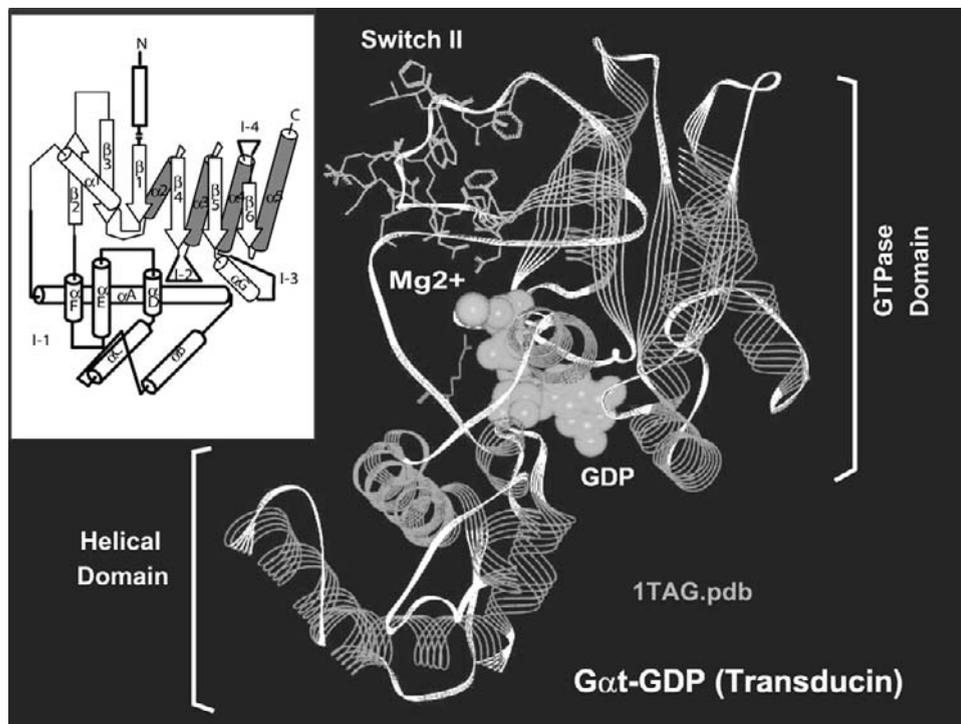

Figure 3 Crystal structure of an α subunit of a heterotrimeric G protein in its GDP state (PDB #1TAG) Its GTPase domain is oriented in the same way as *ras* in Fig. 2. Atoms of amino acid side chains of switch II two are displayed as sticks; space-filling CPK atoms were used to represent GDP. Mg is a cyan ball. Upper right inset: Two-dimensional diagram of three-dimensional features of heterotrimeric G-protein α subunit. Additions to the *ras* structure are in heavy lines. GTPase and helical domains are highlighted.

the University of Texas at Dallas, in collaboration with Heidi Hamm and Alfred Gilman, respectively [7,8]. From a structural viewpoint, α subunits of heterotrimeric G proteins are made up of a *ras*-like GTPase domain and a helical domain with 6 α -helices (αA through αF) inserted in the center of what would be switch I of the *ras* (Figs. 3 and 5). In its GDP-liganded form, $G\alpha$ s have a disorganized switch II region and exhibit high affinity for $G\beta\gamma$. $G\alpha$ -GDPs are therefore found associated with $G\beta\gamma$ s as heterotrimers. $G\beta\gamma$ locks GDP into its binding site on $G\alpha$, causing its dissociation rate to drop by a factor of 10 [9]. At the same time, $G\beta\gamma$ also shields the switch II region from interacting with possible effectors (Fig. 5). Consequently, activation of a heterotrimeric G protein requires two events: (1) exchange of GTP for GDP, and (2) dissociation of $G\beta\gamma$ from $G\alpha$. Subunit dissociation has not been measured in intact cells in an unequivocal way, but it is readily seen *in vitro*. Dissociation exposes the regulating surface of $G\alpha$ -GTP and allows for effector regulation with direct involvement of switch II ([10]; PDB accession #1CS4). The converse also applies. That is, $G\beta\gamma$ is a signaling molecule able to regulate effector functions and its association with $G\alpha$ -GDP resulting in occlusion of the signaling surface of its $G\beta\gamma$.

The structure of $G\beta\gamma$ deserves separate comment ([11,12]; Figs. 4 and 5). $G\beta$ is a seven-bladed propeller of which each blade is made up of four anti-parallel β -strands running from the center to the periphery. The innermost β -strand runs

parallel to the axis of rotation of the propeller. The next two change pitch to approach the orientation of the outermost, which runs along the periphery of the propeller and is coplanar with the circle described by the rotating propeller. Blade seven is made up of three β -strands contributed by the very C terminus of $G\beta$ and a fourth (outermost) “zipping” β -strand recruited from the sequence immediately preceding those that create blade I. Preceding the zipping β -strand is an extended N terminus with a long α -helix that interacts with the $G\gamma$ by forming a coiled-coil. $G\beta\gamma$ dimers have so far been crystallized only in association with $G\alpha$ subunits or with a retinal regulatory protein, phosducin, but not in isolation. Conformational changes in $G\beta$ that occur upon dissociating from $G\alpha$, if they occur, have not been observed as yet.

LIPID MODIFICATIONS

$G\alpha$ and $G\beta\gamma$ subunits engaged in signal transduction are membrane bound by virtue of lipid modifications. $G\beta\gamma$ dimers are anchored to membranes through a C15 or C20 polyisoprene attached to the Cys of a C-terminal CAAX motif. Posttranslational processing not only attaches the polyisoprene, but also removes the last three amino acids and methylates the new C terminus. Prenylation is not necessary for association of $G\gamma$ with $G\beta$, but is required for association of $G\beta\gamma$ to $G\alpha$ -GDP and for regulation of effector, e.g., adenylyl cyclase. Further, prenylation contributes to the association of the $G\gamma$ dimer to membranes.

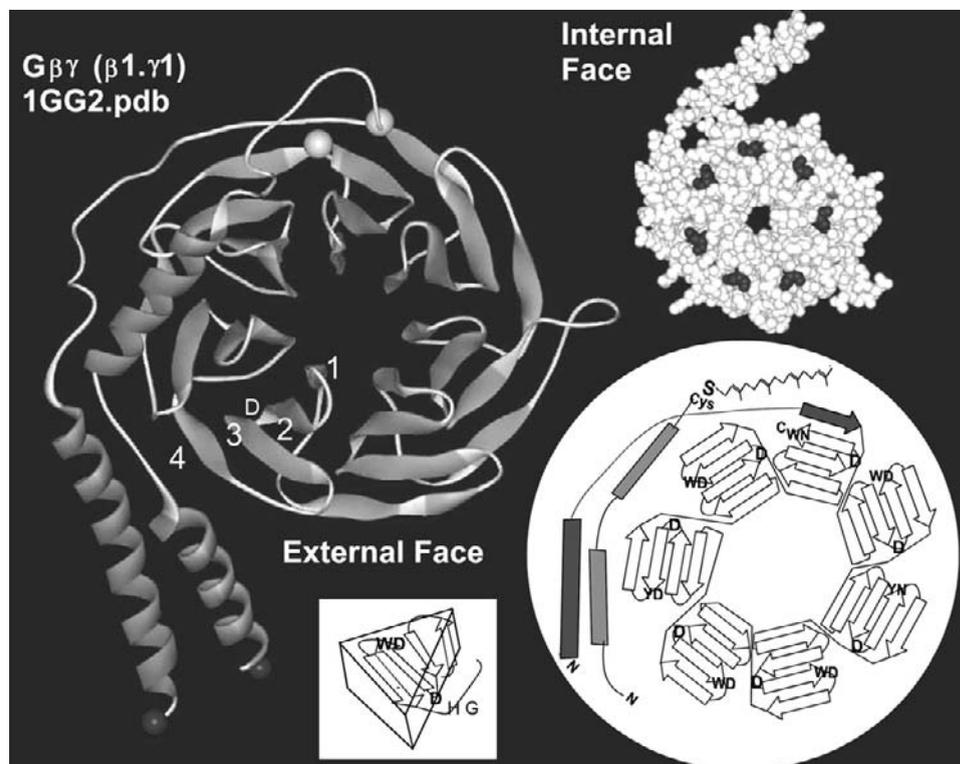

Figure 4 View of a seven-bladed $G\beta$ propeller from the “external” side determined by its orientation when complexed with α -GDP. Upper right inset: CPK representation of the same propeller viewed from the side facing α -GDP in its trimeric form. Blue: Conserved aspartic acids (D) present in each propeller blade. Bottom right: Two-dimensional diagram of the three-dimensional features of a $G\beta$ propeller highlighting the “zipping,” outermost β -strand of blade seven, and location of conserved D residues shown in blue in the space-filling representation of the model. Note the γ coiled-coil interaction of the γ subunit with the N terminus of the $G\beta$ subunit.

Most $G\alpha$ subunits engaged in signal transduction are palmitoylated near their N terminus. Palmitoylation facilitates their anchoring to the plasma membrane. $G\alpha$ subunits of the G_i / G_o family are also myristoylated at N-terminal glycines (Gly-2 of the primary transcript). $G\alpha$ myristoylation increases affinity for $G\beta\gamma$ dimers. Removal of myristic acid by Gly-2 to Ala-2 mutation renders $G_i\alpha$ subunits inactive as inhibitors of adenylyl cyclase. Some but not all nonpalmitoylated $G\alpha$ subunits fail to localize to membranes and are found in the cytosol. Lipid modification of $G\alpha$ and $G\gamma$ subunits are therefore essential for their normal biological activity (Reviewed in reference[13]).

Molecular Diversity of G Proteins

Each of the subunits that make up a heterotrimeric G protein is encoded by a family of structurally homologous genes. There are 16 $G\alpha$ (one with two splice variants), 5 $G\beta$, and 11 $G\gamma$ genes, raising the theoretical possibility of close to 1000 distinct heterotrimers. $G\alpha$ subunits are the longest of the three subunits, ranging from 350 to 390. Their sequence similarities vary from almost identical when $G_{i1}\alpha$ is compared to $G_{i3}\alpha$ (86% identical) to up to 60% different when $G_{s\alpha}$ is compared to $G_{16\alpha}$. Amino acid sequence alignments

show $G\beta$ s to be structurally a very closely related family with $\beta 1$ -4 being 350 amino acids long and differing by no more than 17% in their amino acid sequence. $G\beta 5$ with 395 amino acids, exhibits the same degree of similarity, differing primarily by a 45-amino acid N-terminal extension. $G\gamma$ s are the shortest (68–75 amino acids) and are the most diverse, differing in amino acid sequence between 40 and 65%. GGL ($G\gamma$ -like) domains of RGS 6, 7, 9, and 11 (for RGS see below) constitute an additional group of $G\gamma$ subunits that interact with the atypical N-terminal extension of $G\beta 5'$.

The actual number of G-protein isoforms in any given cell is much lower than 1000 for two reasons: (1) there is no cell known that expresses all G-protein subunit genes, and (2) there are structural limitations that do not allow all $\beta\gamma$ dimers to form, e.g., while $\beta 1$ interacts with $\gamma 1$, $\gamma 2$, and $\gamma 3$, $\beta 3$ does not interact with $\gamma 1$ or $\gamma 2$, but partners with $\gamma 4$. Vice versa, $\gamma 1$ partners with $\beta 1$ but not with either $\beta 2$ or $\beta 3$; and $\gamma 2$ partners with $\beta 1$ and $\beta 2$, failing to do so with $\beta 3$. The complete spectrum of permissible interactions among the 5 β subunits and 11 γ subunits still needs to be worked out. One $G\beta$, $G\beta 5$, interacts preferentially with the GGL domain of 6, 7, 9, and 11. It is quite possible that even for biochemically permissible interactions there may be $\beta\gamma$ dimers that never form because they are not co-expressed in the same cell.

Note that the internal face of G β shields the switch II of G α subunit from being accessible to effectors. Blue balls, N-terminal α carbons; brown balls, C-terminal α carbons; gray balls on G β , α carbons of conserved aspartic acids.

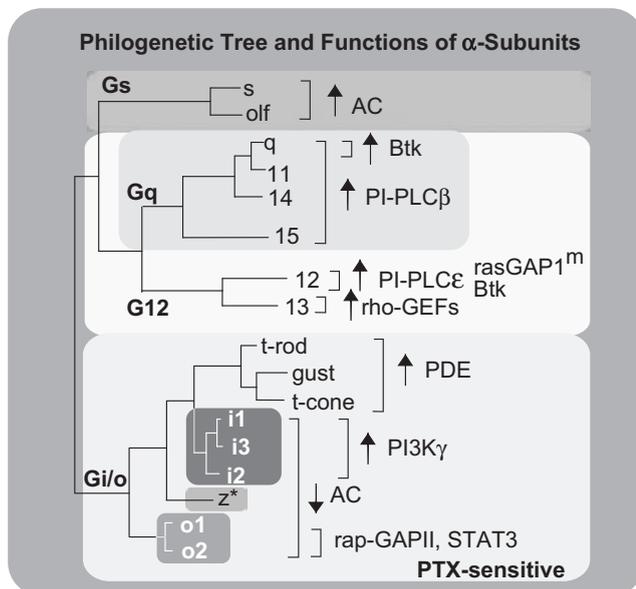

Figure 6 Phylogenetic analysis of G-protein α subunits reveals structural subdivisions that have functional correlates.

G proteins are named after their α subunit. This has its origin in the fact that for the first two G proteins discovered, Gs and transducin (Gt), it was established that the major (then sole) signaling function resided in their α subunits.

G α_s activates adenylyl cyclases (ACs), and G α_t subunits activate visual phosphodiesterase (PDE, a tetramer of one α , one β , and two inhibitory γ s). Activation of visual PDE results from the association of α t-GTPs with the PDE γ s, thereby suppressing their inhibitory effects on PDE $\alpha\beta$. A phylogenetic tree of G-protein α subunits (Fig. 6), clusters their sequences into four subfamilies: Gs, Gq, G12/13, and the pertussis toxin (PTX)-sensitive G α subunit subfamily. The latter includes three α subunits that play roles in light and taste perception, plus the α subunits of the Gi/Go family. PTX-sensitive α subunits not only show higher sequence similarity to each other than to the remaining α subunits, but as their name indicates, they are substrates for the ADP-ribosyl-transferase activity of the S1 subunit of pertussis toxin. The ADP-ribosylated amino acid is a Cys at position -4 from their C termini. PTX uncouples this group of G proteins from activation by receptors by virtue of creating of a steric hindrance to the G-protein::receptor interaction. Included in this structural group is the α subunit of Gz (α_z), which lacks a Cys at -4 from the C terminus and is PTX-insensitive. It is functionally a Gi, its closest structural homologue. As illustrated in Fig 6, and in more detail in Fig. 7, α subunits modulate the activity of a large and diverse group of enzymes, including ACs, phospholipase C β s (PLC β s), phosphatidylinositol 3-OH kinases (PI3Ks), as well as type 6 visual and type 3 gustatory PDEs and a Rho-GEF for regulation of cytoskeletal remodeling. An analysis of the evolution of the

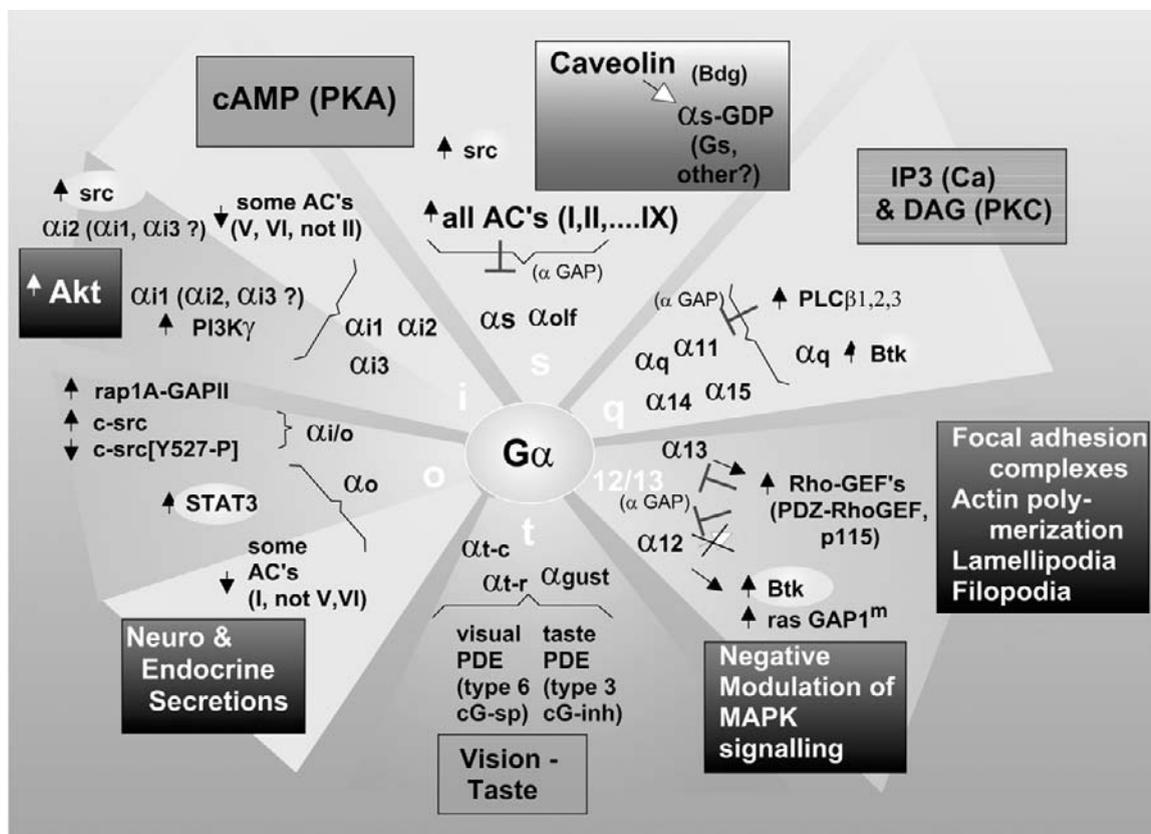

Figure 7 Effectors of activated α subunits. This figure shows the different signaling systems affected by α subunits at the periphery, with ever increasing detail toward the center. —|, inhibition.

intron-exon structure of G protein α subunits (Fig. 8) clusters the genes into the same groups: Gs, Gq/11, G12/13, and Gi/o and G-taste/vision. This type of analysis places Gz in the Gi/Go group solely on the basis of open reading frame sequence similarity, but shows no similarity in its intron-exon organization to those of any G protein as it has only three exons (two coding) instead of the eight to nine exons of the Gi/o family of α subunits. The loss of introns is highly suggestive of reactivation of a pseudogene with attendant chance mutation of the Cys at -4 from the C terminus.

Both $G\alpha$ subunits and $G\beta\gamma$ dimers modulate, positively or negatively, a diverse set of cellular functions. In some instances, the effects of $G\beta\gamma$ dimers are in concert with those of α subunits, in others regulation of effector by $G\beta\gamma$ is unrelated to regulation by a $G\alpha$. It is not clear at this time whether effectors distinguish $G\beta\gamma$ isoforms. As illustrated on Fig. 9 the gamut of $G\beta\gamma$ effectors is as complex and as diverse as that of the α subunits. Among the regulated functions worth mentioning are inhibition of type 1 AC, but co-stimulation with $G\alpha$ of type 2 and type 4 ACs; stimulation of type 3 $PLC\beta$ independently of co-existing stimulation by the Gq/11 group of α subunits; co-stimulation with $G\alpha i2$ (possibly also $\alpha i1$ and $\alpha i3$) of $PI3K\gamma$; and co-stimulation of $PI3K\beta$ with tyrosine-phosphorylated p85, the regulatory subunit of PI3K. *In vitro* reconstitution experiments in which $PI3K\beta$ was incubated with $G\beta\gamma$ and a tyrosine-phosphorylated peptide corresponding to the

tyrosine-phosphorylated sequence of p85, showed that stimulation by each was three to fivefold, but became 100-fold when the tyrosine-phosphorylated peptide and the $G\beta\gamma$ were added together. This type of cross-dependence on dual inputs is highlighted in Figs. 7 and 9. $G\beta\gamma$ also modulates, sometimes positively and sometimes negatively, a variety of ion channels and thereby provides a nexus between regulation of second messenger formation by enzymes and regulation of cell excitability by voltage, which it can augment (activation of potassium channels) or dampen (inhibition of presynaptic Ca^{2+} channels) (Fig. 9).

In conclusion, signal transduction by G proteins is the result of structurally similar receptors activating structurally very similar G proteins, which then regulate positively or negatively the activity of a diverse gamut of structurally unrelated cellular functions that affect intracellular levels of cAMP, inositol tris-phosphate (IP3), Ca^{2+} , diacylglycerol (DAG), and phosphatidyl inositol 3 phosphates (PIP3s) as well as ion channel activity and formation of lamellipodia and filopodia and the attendant cytoskeletal changes. Moreover, because second messengers such as cAMP, DAG, and Ca^{2+} affect protein kinases, it is unlikely that there is a cellular function that in one way or another is not under the controlling or modulatory influence that emanates from activation of heterotrimeric G proteins. Indeed, as indicated in Figs. 7 and 9, cellular responses included are the PI3K-PDK-Akt-NF. κ B anti-apoptotic response of cells to extracellular

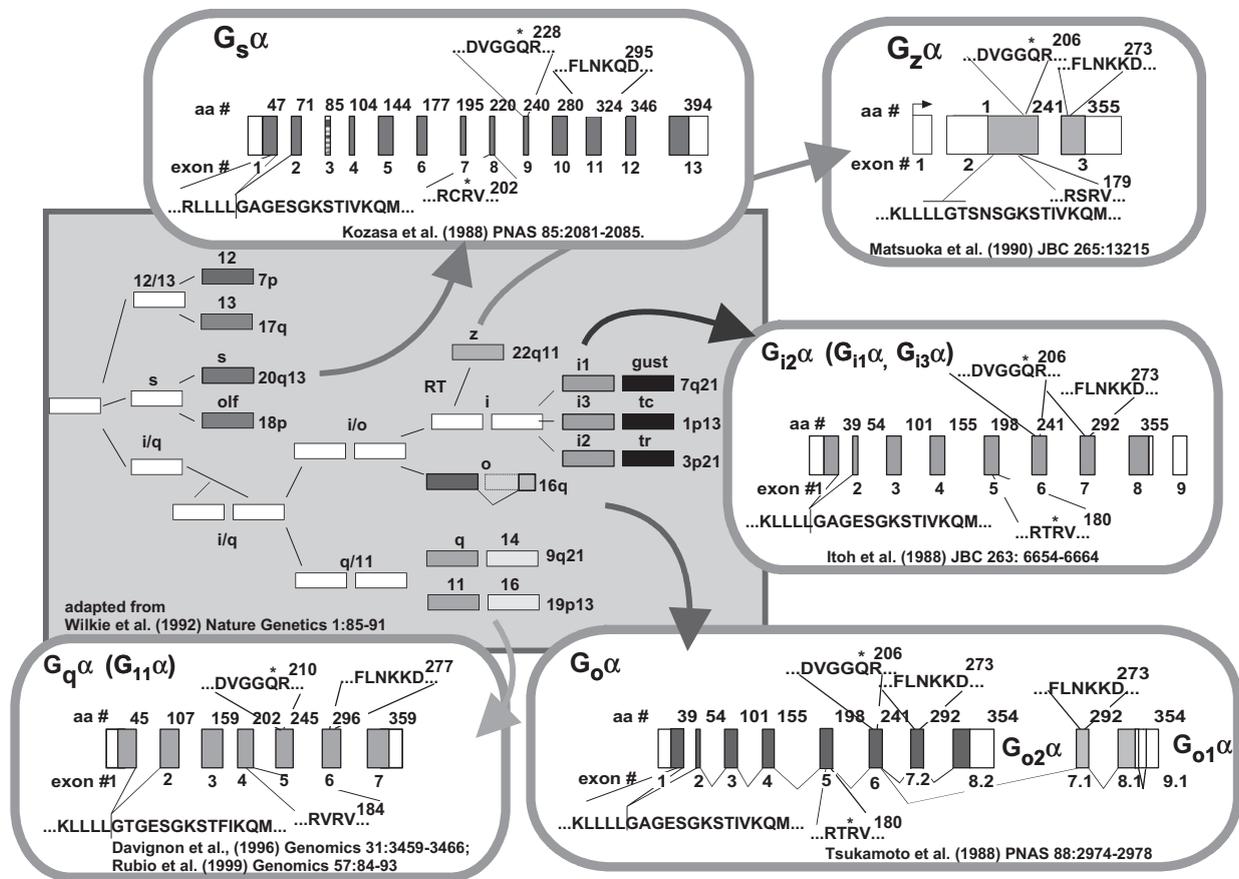

Figure 8 Analysis of the intron-exon structure and sequence similarities among proteins encoded in the exons, allow for development of model for the evolution of α subunit genes in which a series of gene duplications, loss of one intergenic region including most of the exons of the downstream gene followed by rescue of a pseudogene lead to the present day G-protein α subunits. The general layout of this figure was adapted from a similar layout in reference [26]. (Adapted from Wilkie *et al.*, *Nat. Genet.*, 1, 85–91, 1992. With permission). signals and the effects of $G\beta\gamma$ on dynamin, Golgi vesiculation, and vesicle budding.

Mechanism of G-Protein Activation by Receptors and Modulation of Activity

Receptors acting through heterotrimeric G proteins are referred to as GPCRs or G-protein-coupled receptors. They play the role of GEFs in the regulatory GTPase cycle. Ligand binding to GPCRs, all of which belong to the rhodopsin superfamily of seven-transmembrane receptors, has as its final effect the GDP-GTP exchange with attendant subunit dissociation into $G\alpha$ -GTP plus $G\beta\gamma$ (Fig. 1). The final effect of a hormone acting through a GPCR on any given cell depends on the type of G protein activated by the receptor, and the repertoire of effectors, i.e., regulatable enzymes, ion channels, and other affected molecules in the target cell.

MECHANISM OF ACTIVATION OF A G PROTEIN BY A RECEPTOR

At the molecular level, activation of a G protein by a rhodopsin-like receptor is still poorly understood. This is because of lack of knowledge of which amino acids of the receptor make contact with which amino acids of the G protein. In contrast, the regions of each molecule important for productive interaction are well known, as are some of the kinetic and molecular state changes that occur when a receptor under the influence of an activating ligand, i.e., agonist, interacts with and activates a G protein. Thus, binding of an agonist to a GPCR in the absence of guanine nucleotide (GTP or GDP), as can be done *in vitro* with purified membranes, has two consequences: (1) a shift of the equilibrium between two states of the receptor, from being mostly in state I (inactive) characterized by having low affinity for agonist as well as for the G protein(s), to mostly in state II (active) having higher affinity for the activating ligand, and (2) the stable association of the agonist-receptor complex to the G protein. The latter causes the G protein to reduce its affinity for GDP. Bound GDP, or prebound [3 H]GDP, will thus dissociate under these conditions. Mg ion has to be present if the receptor is to cause GDP dissociation. Addition at this point of GTP or a GTP analog such as $GTP\gamma S$ or GMP-P(NH)P, leads to its binding in place of GDP and to the activation of the G protein as seen by stimulation of the activity of an effector such as adenylyl cyclase or visual phosphodiesterase. For most of the cases where this has been studied, a high concentration of Mg ion, about 50 mM, mimics the action of the agonist-activated receptor. With a purified G protein, incubation with Mg ion and $GTP\gamma S$ or GMP-P(NH)P leads not only to accumulation of $G\alpha$ -bound guanine nucleotide, but also to subunit dissociation, i.e., formation of $G\alpha$ - $GTP\gamma S$ plus free $G\beta\gamma$. Dissociation is evident in several ways, the easiest being by a shift in sedimentation velocity from that corresponding to an approximate M_r of 100,000 protein ($G\alpha\beta\gamma$) to that of two co-sedimenting proteins of an approximate M_r of 50,000 ($G\alpha$ - $GTP\gamma S$ + $G\beta\gamma$). M_r s of α subunits are in the 40,000–50,000 range and those of $G\beta\gamma$ complexes are also approximately 50,000.

In intact membranes, where activation of a G protein of the $\alpha\beta\gamma$ type by agonist occupancy of a receptor can be measured in terms of stimulation of the activity of an effector, e.g., adenylyl cyclase, phospholipase C, visual phosphodiesterase, or an inwardly rectifying potassium channel, the net effect of receptor activity is thus facilitation of the activation of the G proteins by Mg ion. This comes about as a consequence of a receptor-induced shift in the apparent K_m for Mg ion from high millimolar to low micromolar. In other words, a receptor appears to act by reducing the concentration of Mg required for activation of the G protein by GTP from being above physiologic to being below physiologic. Free cytosolic Mg is in the order of 0.5 mM. The effect of glucagon (receptor) shifting the concentration of Mg ion required for activation of liver Gs, (the stimulatory regulatory component of adenylyl cyclase) by $GTP\gamma S$, is illustrated in Fig. 10.

STRUCTURAL DETERMINANTS

At the molecular level, mutational analysis has shown that amino acids in the third intracellular loop of GPCRs are involved in the ability of a GPCR to activate a G protein. Swapping intracellular loops between receptors of different G-protein preference, such as between M1 and M2 muscarinic receptors, or β and $\alpha 1$ adrenergic receptors, also points to the third intracellular loop as responsible for defining G-protein specificity. Further, most of the receptor mutations that are of the gain-of-function type are in the distal (C-terminal) end of the third intracellular loop. It is not known, however,

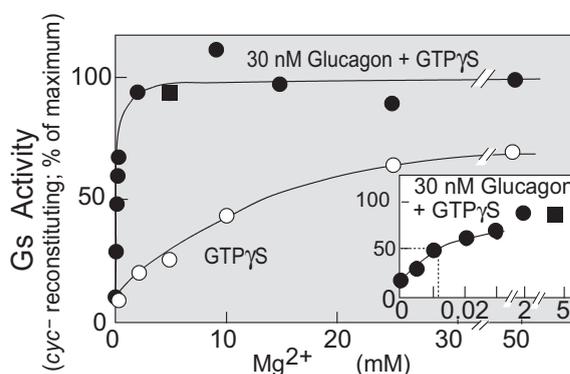

Figure 10 GPCRs reduce the concentration of Mg ion required for G-protein activation by GTP. The results of a three-step reaction are shown. In the first step (not shown), the adenylyl cyclase enzyme of liver membranes was inactivated by treatment with *N*-ethyl maleimide, leaving an intact receptor-G-protein system in its natural membrane environment. The second step tested for the effect of varying Mg ion on GDP/GTP γ S exchange in the absence and presence of the hormone glucagon. In the third step, the $G\alpha$ -GTP γ S complexes formed were extracted and quantified in a standard reconstitution assay. This figure shows the effect of the glucagon-activated receptor on the Mg required for G-protein activation. Note that (1) hormone was not necessary for Gs activation as long as high enough (supraphysiologic) Mg was present during incubation with GTP γ S, and (2) that in the presence of the hormone, the Mg required to activate Gs was approximately 1000-fold lower than in its absence. Inset: Same as main panel but with an expanded Mg concentration scale. (Adapted from Iyengar, R. and Birnbaumer, L., *Proc. Natl. Acad. Sci. USA*, **79**, 5179–5183, 1982. With permission).

why some mutations are activating and others inactivating. Moreover, it is also not known whether these amino acids actually contact the G protein, and if so, which G-protein subunit (for further discussion see references [14–17,141]).

Mutational analysis and sequence swapping experiments with G protein α subunits indicate that receptors interact with the very C terminus of the G protein α subunit. Indeed, swapping as few as three of the last ten amino acids between two α subunits can lead to a switch in the type of receptor that activates the G protein. The C terminus is not the only region of interaction of an α subunit with a receptor. Multiple sites have been identified by mutational analysis, including the $\alpha 3\beta 5$ and $\alpha 4\beta 6$ loops of the GTPase domain (Figs. 2 and 12; references [16] and [18]). The α subunit C terminus and the $\alpha 3\beta 5$ and $\alpha 4\beta 6$ loops are part of the same face of the molecule presumed to be immediately juxtamembranous. Receptors not only interact with the α subunit of a trimeric G protein. Free $G\alpha$ subunits are not recognized by receptors; they are only recognized in the context of the heterotrimer. In agreement with this conclusion, injection of subunit specific antisense oligonucleotides, or subunit specific antibodies, leads to loss of receptor-mediated effector regulation, not only upon suppressing $G\alpha$ but also either $G\beta$ or $G\gamma$ subunits, all in a gene-specific manner. It has been shown that in pituitary cells the M4 muscarinic receptor activates a Go G protein of subunit composition $\alpha 01\beta 3\gamma 4$, while the somatostatin receptor activates a Go of subunit composition $\alpha 02\beta 1\gamma 3$. It follows that receptors “proofread” the subunit subtypes that make up the particular trimer with which they enter in contact. Figure 5 shows that only one of the two faces of the $G\beta$ propeller is exposed to the milieu, while the other one faces the switch II region of the α subunits. The exposed face and the sides of the propeller are therefore available for interaction with a receptor. In turn, because the receptor interacts with $G\beta$ and $G\gamma$, it can reasonably be expected that receptors may affect the $G\beta\gamma$ interaction with $G\alpha$. One model, based on these considerations, as well as the results shown in Fig. 10, is that while the interaction of the receptor with the C terminus of $G\alpha$ is essential for selection of the type of $G\alpha\beta\gamma$ that will be activated through the GDP-GTP exchange reaction, the “activating” effect of the receptor may in fact be mediated by the $G\beta\gamma$. In this sense the $G\beta\gamma$ dimers would have a receptor dependent GEF activity. Thus, while $G\beta\gamma$ alone prevents GDP dissociation by acting as guanine nucleotide dissociation inhibitor (GDI), the $G\beta\gamma$ receptor complex has GEF activity facilitating binding of GTP to its site on α . Artificial “bending” of the N terminus, mimicking what $G\beta\gamma$ might do if it were acting as GEF, does indeed lead to an apparently constitutively active G protein [19]. It has been speculated that $G\beta\gamma$ may be the site of action of Mg ion [20]. If so, the role of receptor would be simply to promote binding of Mg ion to $G\beta\gamma$. Mg ion would then be responsible for changing the activity of $G\beta\gamma$ from GDI to GEF.

Regardless of the final outcome regarding the events responsible for G-protein activation by a receptor at the sub-molecular level, the overall reaction for a receptor activating

a G protein is facilitation of the action of Mg ion to promote GDP-GTP exchange, followed by dissociation of the trimer into $G\alpha$ -GTP plus $G\beta\gamma$.

RGSS OR REGULATORS OF G-PROTEIN SIGNALING

As there are receptors that by virtue of their GEF activity promote activation of the heterotrimeric G proteins, there are also GAPs that accelerate the GTPase activity of activated, GTP-liganded $G\alpha$ subunits. Two types of $G\alpha$ GAPs have been identified. One type are the RGSs. RGSs accelerate GTPase activity by 100-fold or more and exhibit $G\alpha$ subunit selectivity. Sixteen RGSs are known and many of them are multidomain, multifunction proteins, and thus not only affect the $G\alpha$ subunits but also aid in the organization of multicomponent “signaling complexes” [21]. The second type of GAPs are some of the effectors regulated by the α subunits. GAP activities of effectors increase k_{cat} of the $G\alpha$ -GTP complexes by 10- to 20-fold only. In both instances, increased GTP hydrolysis ensures not only prompt turn-off of the signaling protein, but also a faster approach to equilibrium, therefore increasing the rate at which responses to an extracellular stimulus can be obtained. Indeed for RGS proteins, faster on/off rates of the regulated function may be a primary *raison d'être*. In contrast, when effectors act as GAPs, the primary purpose may be to ensure that they are indeed affected by the activated α -GTP complex. The intrinsic GTPase activity of $G\alpha$ subunits is very low, in the order of 4–8 per s, giving them a rather long half-life, ensuring that they “find” their effector(s) while still in their GTP state. Once the effector has been found and the receptor message is delivered, the recipient of the message “kills” the messenger through activation of its deactivating mechanism. Thus, continued stimulation of effector, if this is desirable, requires continued presence of receptor agonist and constant reactivation of the G protein. Figure 11, illustrates the effect of GAPs on accelerating the rate at which equilibrium is established in a simple on/off reaction, such as binding of a hormone H to its receptor R. The three panels show: (1) the basic rate at which a bimolecular reaction reaches equilibrium; (2) the effect of increasing the k_{off} rate on the rate at which equilibrium is reached, expressed as HR formed in absolute concentrations; and (3) the fact that while the number of complexes at equilibrium decreases with increasing values of k_{off} , the rate at which equilibrium is reached increases with increases in k_{off} . It follows that, given the low intrinsic GTPase activity of $G\alpha$ subunits, the need for a rapid response can only be satisfied by both existence of a GAP and a very high concentration of reactants so that the amplitude of the read-out signal (regulated effector) is large enough upon activation of only a small fraction of the GTPase. This is, in fact, the case with the activation of transducin (heterotrimeric G protein) by rhodopsin. The GTPase of transducin is stimulated by RGS9, a GGL RGS. This ensures that the physiological rapid turn-off occurs within a tenth of a second as opposed to having a half-life 10 s ($t_{1/2} = \ln 2/k_{off} = 10$ s, where k_{off} corresponds to published intrinsic GTPase activity of $G\alpha$ subunits of 4 per min) [22]. However, to ensure that sufficient

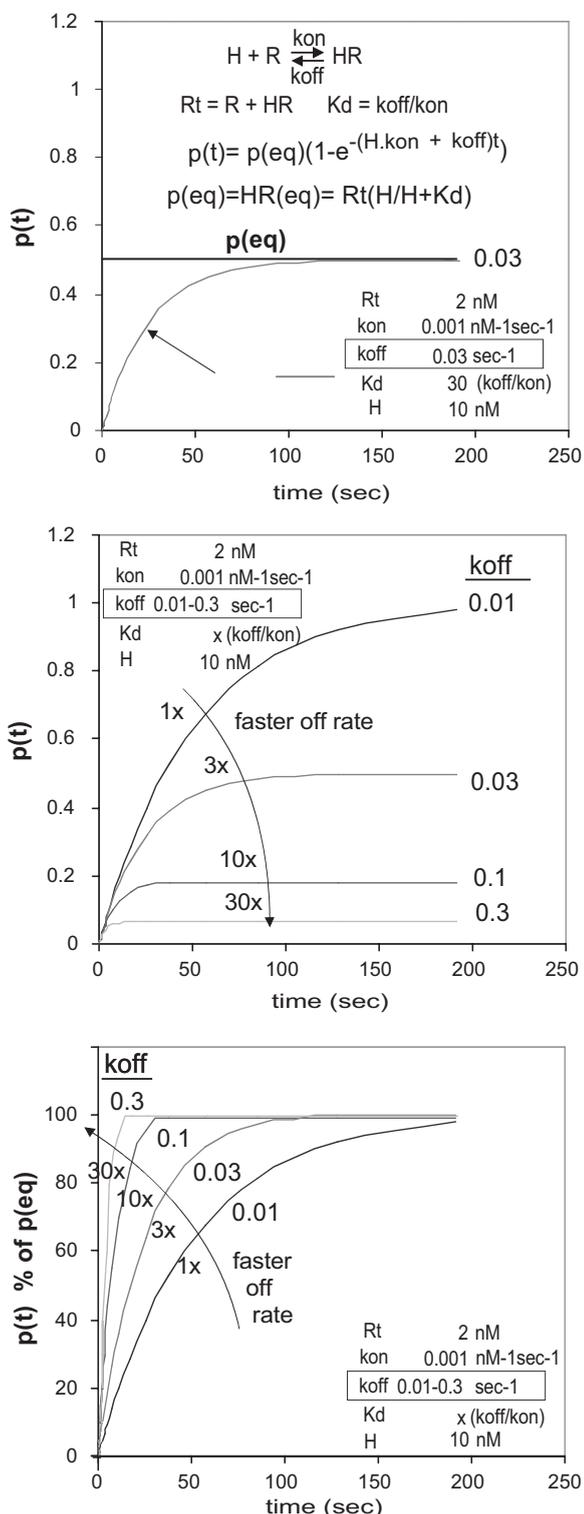

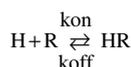

Figure 11 Approach to equilibrium of a reversible bimolecular reaction,

$HR = 0$ at t_0 . These panels illustrate the effect of increasing the k_{off} rate, equivalent to the effect of introducing a GTPase-activating RGS into a regulatory GTPase cycle.

active transducin will be formed, Mother Nature endowed the visual system with the highest known concentrations of receptor (rhodopsin; 40% of disk membrane protein) and regulated G protein (transducin; 10% of disc protein).

Other Forms of G-Protein Modulation: ASGs or Activators of G-Protein Signaling—the GoLoco domain

As described above, the free $G\alpha$ -GTP and the $G\beta\gamma$ released upon G-protein activation, are both active regulators of effector systems. RGSs and effectors acting as GAPs shorten the lifetime of the active $G\alpha$ with formation of $G\alpha$ -GDP. Due to the high affinity of $G\alpha$ -GDP for $G\beta\gamma$, a GAP activity not only accelerates deactivation of $G\alpha$ -regulated effectors, but also that of the $G\beta\gamma$ -regulated effectors from which $G\beta\gamma$ is sequestered by $G\gamma$ -GDP. ASGs, or activators of G-protein signaling, were uncovered in a search for molecules that potentiate the effect of α factor in baker's yeast [23]. α Factor acts by activating an $\alpha\beta\gamma$ heterotrimeric G protein and initiating a $G\beta\gamma$ -mediated cascade of reactions that leads to growth arrest and preparation for mating to the opposite mating type. One of the ASGs, AGS3, was found to potentiate $G\beta\gamma$ signaling by binding preferentially to $G\alpha$ -GDP and to do so via a domain found in unrelated proteins and referred to as GoLoco. In mammalian systems, GoLoco domains act as they do in yeast. They bind preferentially to GDP-liganded $G\alpha$ subunit of the G_i / G_o type, thus prolonging $G\beta\gamma$ signaling. In addition to AGS3, proteins with a GoLoco domain include several RGSs and Rap-GAPII. This hints at a role that transcends its direct function of binding the GDP forms of G_i / G_o and involves participation in integration of multicomponent signaling pathways (see reference [24] for recent review).

Even though they were identified in the same type of bioassay, AGS1, AGS2, and AGS3 differ in their mode of action. AGS1 (also Rasdex1) is a ras-related protein that appears to act as a GEF, whereas AGS2 interacts with $G\beta\gamma$ and AGS3 binds to α -GDP. Why a $G\beta\gamma$ -interacting protein (AGS2) would enhance the effectiveness of either a $G\beta\gamma$ or a $G\alpha$ -GTP remains to be determined. Another $G\beta\gamma$ -interacting protein, phosducin, serves to attenuate the action of transducin in the retina. The existence of $G\beta\gamma$ - and $G\alpha$ -interacting proteins (RGSs, GoLoco proteins, phosducin, and non-GoLoco ASGs) points to the fact that fine-tuning of the basic regulatory G-protein cycle is required for proper cell homeostasis. These fine-tuning mechanisms are therefore responsible for the ultimate ability of a cell to live a productive life that is in concert with the needs of the whole organism.

In Memoriam

This chapter is written 32 years after the first data on the GTP requirement in hormonal stimulation of liver adenylyl cyclase (then adenylyl cyclase) were obtained in Martin Rodbell's laboratory where I was a postdoctoral fellow. It was then that we made the proposal that receptors may be acting on adenylyl cyclase through a signal transducer

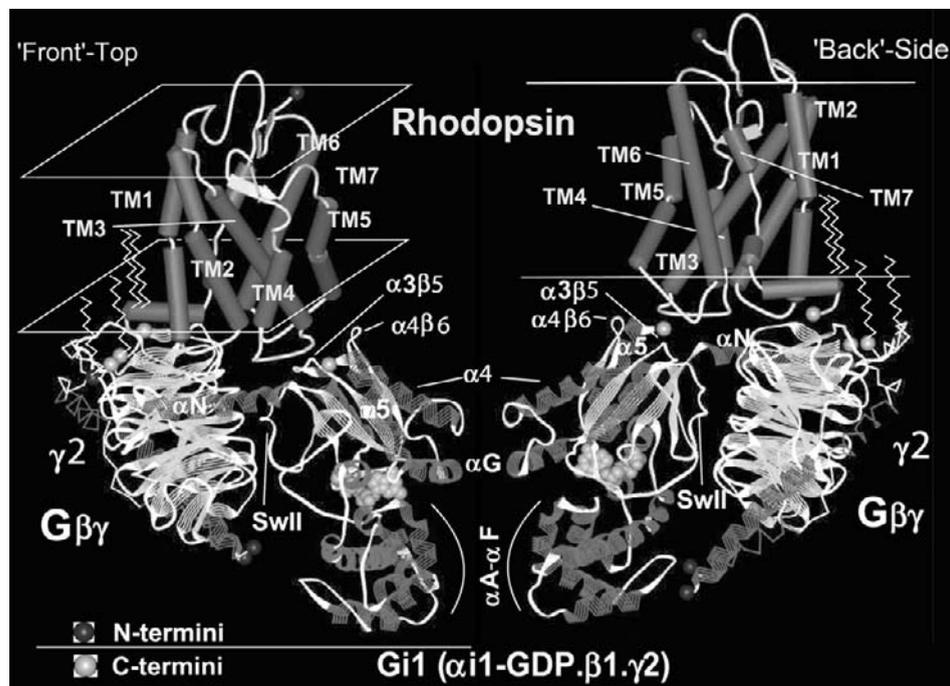

Figure 12 Model of orientation of a $G\alpha$ subunit with respect to both the inner plane of the plasma membrane and a membrane-embedded GPCR. This is based on the crystal structures of bovine rhodopsin (PDB accession #1F88) and the GDP-occupied G_i1 trimer (PDB accession #1GG2). The molecules are shown in a near-docking situation with receptor in its “inactive” conformation and the G protein with GDP bound to it. Two views are shown and the main structural features are annotated. Vertical zigzag lines denote the α subunit N-terminal myristylation and/or palmitoylation and the γ subunit C-terminal polyisoprenylation. Positions of lipids are approximate because the modified N- and C-terminal amino acids were not resolved in the crystal structure of G_i1 . Double zigzag approximately 13 amino acids after the TM7 of rhodopsin denotes double palmitoylation of the C terminus at that position. Single and double palmitoylation of GPCR C termini is a common but not universal feature of GPCRs.

driven by GTP—in some unknown way (Fig. 12). Two great thinking minds of that era are no longer with us. Martin Rodbell passed away in 1998 [25], as did Michael (Mickey) Schramm on June 8, 2002. Mickey visited often in the late 1960s, and fed us ideas that were incorporated into our thinking without us even realizing it. Seldom, if ever, have we properly given credit to Mickey’s influence on our thinking. Better late than never, goes the saying, but I wish I would have done it earlier. While life is destined to end, our task as researchers dedicated to extracting nature’s secrets never ends. Even though 32 years have passed, the mystery of signal transduction through G proteins has not been fully resolved, as the recent discoveries of RGS and AGS proteins demonstrates. While looking forward to new discoveries, we should also remember those that contributed in major ways to the way we think today. This chapter was written with the idea of introducing signaling through G proteins to the next generation of investigators. I hope not to have failed too badly.

Genetic Analysis of Heterotrimeric G-Protein Function

Juergen A. Knoblich

*Research Institute of Molecular Pathology (I.M.P.),
Vienna, Austria*

Introduction

For a surprisingly long time, the yeast *Saccharomyces cerevisiae* has been the only organism in which signaling by heterotrimeric G proteins has been analyzed genetically. More recently, mutants affecting G-protein function have also been analyzed in *C. elegans* [1–3], *Dictyostelium* [4,5], and *Drosophila* [6] and have yielded some quite unexpected results. In this chapter, I want to first summarize the results obtained in yeast and then focus on more recent experiments that have revealed a function for heterotrimeric G-proteins in cell polarity in *Drosophila*. The beautiful experiments done in *C. elegans* and *Dictyostelium* are summarized in other chapters (see the contributions by Julie Ahringer and Peter Devreotes) and will not be reviewed here.

Signaling by Heterotrimeric G Proteins in Yeast

In response to the pheromone α -factor, yeast cells polarize their actin cytoskeleton and extend a process called “shmoo.” α -factor binds to a seven-transmembrane receptor in the plasma membrane and activates the only heterotrimeric G protein present in the yeast genome, Gpa1 [7]. G-protein activation leads to polarization of the actin cytoskeleton, arrest of the cell cycle, and a transcriptional response in the nucleus. In mutants affecting the β -subunit (Ste4) or the γ -subunit (Ste18) of the heterotrimeric G-protein complex, no response to α -factor can be detected, whereas in mutants affecting the α -subunit the signaling pathway is constitutively activated.

Thus, signal transduction occurs via the free G $\beta\gamma$ subunit, but the GTP-bound G α subunit does not seem to play a role [7]. It is interesting that the defects observed in G β mutants can be rescued by a G α -G β -fusion protein in which G α and G $\beta\gamma$ are covalently linked but can still undergo conformational changes [8], indicating that the $\beta\gamma$ -subunit does not have to physically separate from the α -subunit for signaling to occur.

The best studied signal transduction cascade that operates downstream of the heterotrimeric G protein involves the protein kinases Ste11, Ste7, and Fus3 (Fig. 1A). Upon G-protein activation, Ste11 phosphorylates Ste7, which in turn phosphorylates Fus3 and induces its translocation into the nucleus. Fus3 belongs to the MAP-kinase family of protein kinases and therefore this cascade of protein kinases is the prototype of a so-called MAP-kinase cascade. Activation of the MAP-kinase cascade occurs in two ways: First, G $\beta\gamma$ binds and activates the protein kinase Ste20 when released from the α -subunit and Ste20 initiates MAPK-signaling by phosphorylating its most upstream member, Ste11. Second, all kinases of the cascade bind to the scaffold protein Ste5. Ste5 can bind to free G $\beta\gamma$ and therefore G-protein activation recruits the whole kinase cascade to the site of receptor activation. Thus, G-protein signaling in yeast involves the relocalization of downstream signaling components to the site of G-protein activation by direct binding to free G $\beta\gamma$.

Although the Map-kinase cascade transduces a signal into the nucleus, the most important downstream target for polarizing the actin cytoskeleton is the guanine exchange factor Cdc24 (Fig. 1A). Cdc24 binds free G $\beta\gamma$ through the

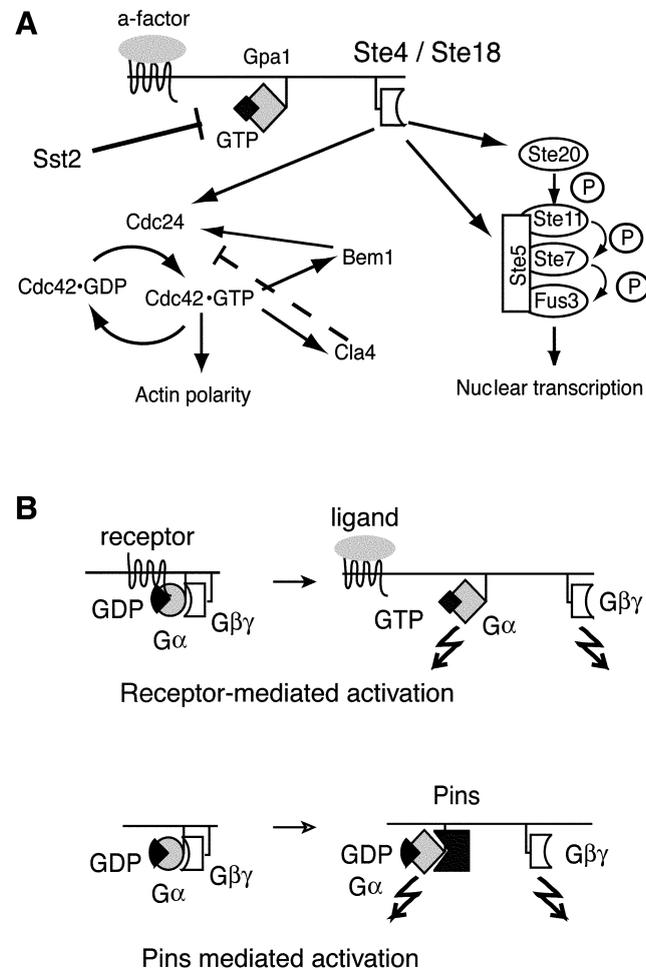

Figure 1 Outline of G-protein signaling in yeast (A) and *Drosophila* (B).

adaptor protein Far1 [9,10]. In the absence of α -factor, Far1 shuttles between the cytoplasm and the nucleus and sequesters Cdc24 in the nucleus [11,12]. Upon α -factor exposure, however, Far1 binds to free G $\beta\gamma$ and the trimeric complex is assembled, leading to an accumulation of Cdc24 at the site of receptor activation. Once it is localized, Cdc24 binds the adaptor protein Bem1 and this association stabilizes the cortical localization of the protein. Cdc24 is an exchange factor that catalyzes GDP/GTP exchange on the small G-protein Cdc42. Cdc42, in turn, is a well-characterized modulator of the actin cytoskeleton, and it is the local activation of Cdc42 by Cdc24 that is thought to polarize the actin cytoskeleton toward the site of α -factor exposure.

Two feedback loops have been shown to operate downstream of the G proteins. In its GTP bound form, Cdc42 can directly bind to Bem1 and recruit this adaptor protein to the cell cortex [13]. Bem1 in turn recruits Cdc24, which generates more Cdc42 and therefore amplifies the signal. Activated Cdc42 also recruits the protein kinase Cla4, which will phosphorylate Cdc24 at a site that is needed for it to bind to Bem1 [14]. This phosphorylation event will eventually terminate the signal and allow the signal transduction cascade to return to its inactive state. Thus, positive and negative

feedback loops that operate downstream of the G-proteins both amplify and terminate the signal that is initially generated by receptor activation.

Regulation of signaling also occurs at the level of the G protein itself. The protein Sst2 is required for yeast cells to recover and reenter the cell cycle after exposure to α -factor. Sst2 directly binds to the G-protein α -subunit. It contains a so-called RGS (regulator of G-protein signaling) domain that enhances the rate of GTP hydrolysis and therefore increases the rate of G-protein inactivation. RGS proteins were also found in higher eukaryotes and represent an evolutionarily conserved protein family that acts as GAPs for heterotrimeric G-proteins [15].

Heterotrimeric G-Protein Function in *Drosophila*

A genetic analysis of heterotrimeric G-protein function in *Drosophila* has recently revealed another important protein family that regulates G-protein activity by direct interaction. *Drosophila* neural precursor cells called neuroblasts divide asymmetrically along the dorso-ventral axis. Before division, a protein called Inscuteable localizes to their apical cell

cortex and establishes an axis of polarity that is used during mitosis for correct apical-basal spindle orientation and for asymmetric localization of protein determinants to the basal cell cortex [16]. Upon cytokinesis, these determinants are inherited by only one of the two daughter cells and ensure its correct cell fate. Inscuteable binds to a protein called Pins and recruits it to the apical cell cortex. Pins in turn recruits the heterotrimeric G protein $G\alpha_i$ through its C-terminal GoLoco domains, and both proteins are required for establishing an axis of polarity [17]. Thus, Inscuteable and Pins are adaptors that function by polarizing the distribution of heterotrimeric G-proteins.

Besides localizing the G proteins, Pins and its vertebrate homologs AGS-3 [18] and LGN [19] also seem to regulate their activity. Binding of Pins or just its GoLoco domains to $G\alpha_i$ induces the release of the $\beta\gamma$ -subunit *in vitro* without the need for receptor activation [6]. $\beta\gamma$ -release seems to occur in the GDP-bound form, since Pins does not induce nucleotide exchange and only binds the GDP-form of the G protein. In fact, GoLoco domains inhibit nucleotide exchange, suggesting they function as GDIs (GDP dissociation inhibitors) for heterotrimeric G-proteins [20]. The structural basis for these activities was recently revealed by X-ray crystallography [21]. GoLoco domains bind a region on $G\alpha$ that overlaps the $G\beta\gamma$ -binding domain and induce a conformational change that precludes coincident $G\beta\gamma$ interaction. In addition, they interact with the α - and β -phosphates of $G\alpha$ -bound GDP and inhibit its dissociation from the G protein. Thus, GoLoco domains represent a novel class of G-protein regulators that activate G proteins via a nonclassical mechanism that involves neither a seven transmembrane receptor nor GDP/GTP exchange on the α -subunit.

The function of heterotrimeric G-proteins in *Drosophila* has been addressed genetically. The *Drosophila* genome contains one of each of the major classes of $G\alpha$ -subunits, $G\alpha_i$, $G\alpha_o$, and $G\alpha_s$. $G\alpha_s$ mutants die for unknown reasons but do not show defects that can be associated with a lack of PKA activity or defects in any of the major developmental signaling pathways [22]. Mutants in $G\alpha_o$ have defects in heart development because epithelial polarity in cardiac precursors is not correctly established [23]. Mutants in $G\alpha_i$ have not been generated, but the function of this G protein was addressed by mutating the associated β -subunit [6]. Based on sequence similarity, $G\beta_{13F}$ is the common *Drosophila* homolog of vertebrate $G\beta_{1-4}$. $G\beta_{13F}$ binds to $G\alpha_i$, and in its absence $G\alpha_i$ can no longer be detected. Presumably, a homeostasis mechanism degrades $G\alpha_i$ in the absence of its associated β -subunit, ensures that cells contain equal amounts of $G\alpha$ and $G\beta$, and prevents the accumulation of free $G\alpha_i$ in $G\beta_{13F}$ mutants. Besides the defects in asymmetric cell division mentioned above, these mutants have defects in gastrulation. This phenotype resembles the one described for *concertina*, the *Drosophila* homolog of $G\alpha_{13}$. Whether $G\alpha_{13}$ is also degraded in $G\beta_{13F}$ mutants cannot be addressed due

to the lack of a good antibody, but this results suggests that both $G\alpha_i$ and $G\alpha_{13}$ use $G\beta_{13F}$ for signal transduction in *Drosophila*.

Conclusions

Together with genetic results obtained in *C. elegans* and *Dictyostelium* (reviewed in the chapters by Devreotes and Ahringer in this volume), these experiments tell us that heterotrimeric G proteins—besides their well-studied function in hormone and neurotransmitter signal transduction—have an important role in cell polarity. To exert this role, G proteins may not always be activated by classical mechanisms involving seven-transmembrane receptors. Unconventional G-protein activators have been identified, and their further analysis may reveal more widespread functions that might change some of the classical textbook views on the role of this important protein family.

Heterotrimeric G Protein Signaling at Atomic Resolution

David G. Lambright

*Program in Molecular Medicine and Department of Biochemistry and
Molecular Pharmacology, University of Massachusetts Medical School,
Worcester, Massachusetts*

Introduction

Heterotrimeric G proteins (subunits $G_{\alpha\beta\gamma}$) mediate a variety of physiological responses, including sensory perception, hormone action, polarization, chemotaxis, and growth control [1–3]. In the conventional paradigm for G-protein signaling, ligand-bound (or light-activated) heptahelical receptors catalyze release of GDP from the G_{α} subunit, resulting in a complex between the receptor and the nucleotide free $G_{\alpha\beta\gamma}$ heterotrimer. Association of GTP with G_{α} triggers release from the receptor and dissociation of G_{α} GTP and $G_{\beta\gamma}$. Depending on the particular signaling pathway, either G_{α} GTP or the released $G_{\beta\gamma}$ subunits interact with downstream effectors until the G_{α} subunit is deactivated by GTP hydrolysis. Although the G_{α} subunit possesses an intrinsic GTP hydrolytic activity, regulator of G protein signaling (RGS) domains, present in a variety of modular proteins, accelerate the rate of GTP hydrolysis [4].

Crystallographic studies of two different G-protein signaling pathways, involving the visual G protein transducin (G_t) as well as the hormone activated G proteins that stimulate (G_s) and inhibit (G_i) adenylyl cyclase (AC), reveal a highly conserved structural basis for heterotrimer assembly, activation by nucleotide exchange, and deactivation by GTP hydrolysis. The various structures explain a wealth of biochemical and cell biological data accumulated over the years and provide a springboard for mutational analyses aimed at dissecting structure-function relationships for the myriad

diverse biological responses mediated by G proteins. The most salient observations are highlighted below. Interested readers are encouraged to consult the cited references for in-depth discussion of particular structures.

Architecture and Switching Mechanism of the G_{α} Subunits

As illustrated in Fig. 1A, the G_{α} subunits share a conserved architecture with a Ras-like domain, consisting of a core six stranded β sheet ($\beta 1$ – $\beta 6$) surrounded by five helices ($\alpha 1$ – $\alpha 5$), and a helical domain comprising a long helix (αA) enveloped on three side by five shorter helices (αB – αF) [5]. Compared with monomeric GTPases, the helical domain of the G_{α} subunits represents an insertion within the $\alpha 1/\beta 2$ loop (known as the “effector binding loop” in Ras). Consequently, the Ras-like and helical domains are connected by two extended strands, one joining $\alpha 1$ of the Ras-like domain to αA of the helical domain and the other traversing from αF of the helical domain to $\beta 2$ of the Ras-like domain. In all of the G_{α} GDP and G_{α} GTP structures determined to date, the $\alpha D/\alpha E$ loop of the helical domain engages the Ras-like domain, thereby capping the nucleotide binding site [5–10]. In contrast, the ribose and phosphate moieties of the nucleotide are partially exposed in monomeric GTPases, particularly in the GDP-bound conformation in which the $\alpha 1/\beta 2$ loop is highly flexible. Consistent with the structural observations,

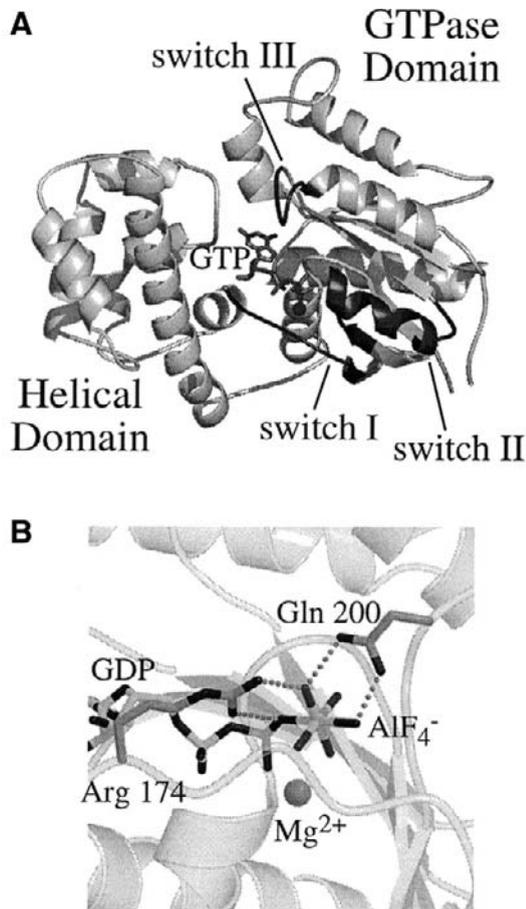

Figure 1 Active and transition states of a G_{α} subunit. (A) Structure of the active form of $G_{i\alpha}$ bound to $GTP\gamma S$, a poorly hydrolyzeable GTP analog. The conformational switch regions, deduced by comparison with the inactive (GDP-bound) form, are highlighted in dark gray. The Mg^{2+} ion is represented as a dark gray sphere. (B) Structure of AlF_4^- activated $G_{i\alpha}GDP$.

the G_{α} subunits bind GDP with high affinity in the absence of Mg^{2+} whereas monomeric GTPases require Mg^{2+} for high-affinity binding, exhibiting rapid rates of nucleotide release in the presence of EDTA [11]. As an obvious consequence of the conserved domain architecture in the G_{α} subunits, intrinsic as well as receptor-catalyzed GDP release necessarily involves a transition to an “open” intermediate in which the helical domain has rotated away from the Ras-like domain.

Structural changes between the GDP-bound (inactive) and GTP-bound (active) conformations are localized to three nonconsecutive conformational switch regions corresponding to the first linker strand (switch I), a region extending from the C-terminus of $\beta 3$ to the C-terminus of the $\alpha 2/\beta 4$ loop (switch II), and the $\beta 4/\alpha 3$ loop (switch III) [6,9]. In the GDP-bound structures, the switch regions are either disordered [9] or adopt a relaxed conformation stabilized by crystal contacts [6]. In the GTP-bound form, the γ phosphate is detected by direct hydrogen bonding interactions with the side chain hydroxyl of the invariant threonine residue in the RxxxT motif of switch I and the backbone NH group of the invariant glycine residue in the DxxGQ motif of switch II.

The conformation of switch III is indirectly coupled to the nucleotide state by a hydrogen-bonding interaction between the side chain carboxylate of an invariant glutamate residue in switch III and a main chain NH group in switch II. The active conformation is further stabilized through Mg^{2+} coordination by the side chain hydroxyl of the invariant threonine residue in switch I and through an extensive hydrophobic/ionic interface between the $\alpha 2$ helix of switch II and the $\alpha 3$ helix. Finally, the zipping of the $\beta 2$ and $\beta 3$ strands, resulting in two additional hydrogen bonds in the GTP-bound form, suggests cooperativity in the switching mechanism.

Insight into the GTP Hydrolytic Mechanism from an Unexpected Transition State Mimic

Aluminum fluoride (AlF_4^-) binds to $G_{\alpha}GDP$ near the binding site for the γ phosphate of GTP, inducing a conformational change that results in artificial activation of $G_{\alpha}GDP$ and dissociation from $G^{\beta\gamma}$. Crystal structures of the $GDP \cdot AlF_4^-$ -bound forms of $G_{i\alpha}$ [7] and $G_{t\alpha}$ [8] revealed an unexpected finding. Although the conformation of all three switch regions closely resembles that of the GTP-bound form, AlF_4^- does not mimic the tetrahedral geometry of the γ phosphate but rather adopts an octahedral geometry with four fluoride ligands arranged in an equatorial plane and two axial ligands consisting of an oxygen from the β phosphate of GDP and a water molecule (Fig. 1B). The bound aluminum fluoride interacts with and orders the side chains of two critical residues previously implicated in GTP hydrolysis, namely the arginine of the switch I RxxxT motif and the glutamine of the switch II DxxGQ motif. These observations led to the hypothesis that AlF_4^- activates $G_{\alpha}GDP$ by approximating the expected stereochemistry of the pentavalent intermediate for GTP hydrolysis. This notion is strongly supported by the remarkable observation that AlF_4^- also binds to and stabilizes complexes of both Ras and Rho GTPases bound to their respective GAPs [12,13].

$G_{\beta\gamma}$ with and without G_{α}

Parallel crystallographic studies revealed the stunningly beautiful structure of the $G_{\beta\gamma}$ heterodimer alone [14] and in complex with $G_{\alpha}GDP$ [15,16]. The seven distinctive WD repeats of G_{β} fold into a seven bladed β propeller in which each blade consists of a four stranded antiparallel β sheet (Fig. 2A). It is interesting that the WD repeats do not coincide precisely with the individual blades of the propeller, but rather each repeat begins with the outer strand of one blade and extends through the inner three strands of the next blade. G_{γ} possesses an N-terminal helix, which forms a parallel coiled coil with the N-terminal helix of G_{β} , followed by an internal helix and a region of coil that extends across the bottom of the G_{β} propeller. Although G_{γ} has well-defined secondary structure, it is devoid of intramolecular interactions characteristic of tertiary structure and thus could not

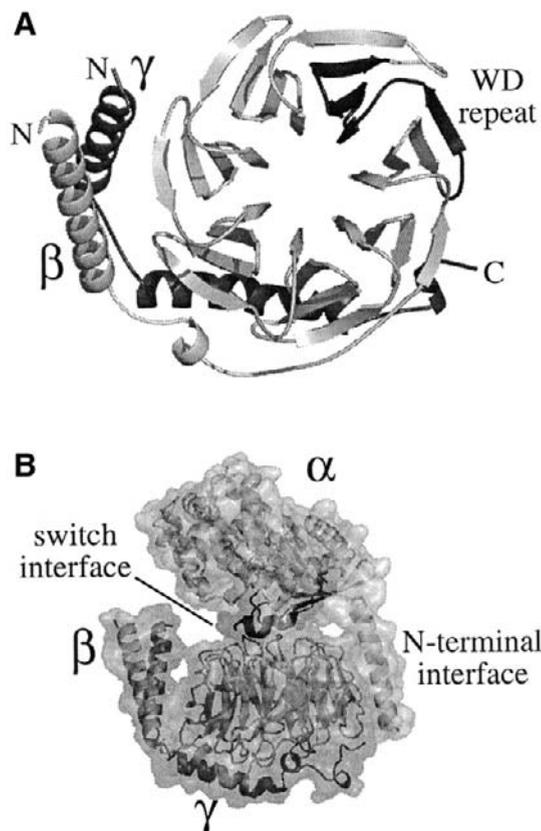

Figure 2 Structure of a heterotrimeric G protein. (A) Ribbon rendering of G $\beta\gamma$ with the γ subunit and one of the WD repeats in the β subunit shown in dark gray. (B) Heterotrimeric complex of a G α /G $\beta\gamma$ chimera and the unprenylated form of G $\beta\gamma$.

adopt a properly folded structure in the absence of G β . Indeed, roughly half of the residues in G γ are buried in an extensive hydrophobic interface with G β , a finding that explains the unusually high stability of the G $\beta\gamma$ heterodimer.

The interaction between G α GDP and G $\beta\gamma$ occurs at two distinct interfaces (Fig. 2B). The most extensive interface involves the switch I and II regions of G α , which contact residues from the loops and turns at the top of the G β propeller. The second interface forms between the N-terminal helix of G α and the side of G β . In the complex with G $\beta\gamma$, the switch regions of G α adopt a well-ordered conformation that is incompatible with the active conformation of G α GTP. In contrast, it appears that the interaction with the N-terminal helix of G α would not be directly influenced by the state of the bound nucleotide, consistent with a residual low-affinity interaction between G α GTP and the released G $\beta\gamma$ subunits.

Phosducin and G $\beta\gamma$

The first insight into how phosducin engages G $\beta\gamma$ and promotes membrane dissociation came from the crystal structure of a phosducin complex with an unprenylated form of retinal G $\beta\gamma$ [17]. Phosducin contains two domains,

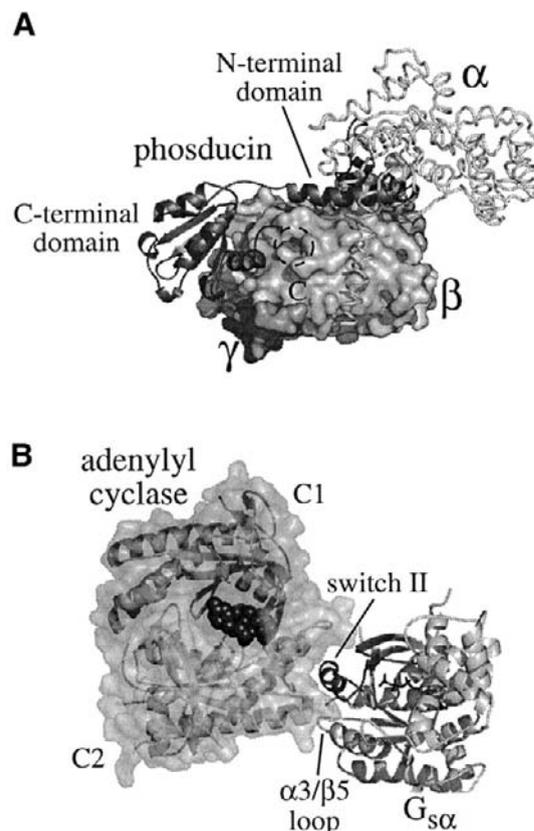

Figure 3 Regulatory and effector complexes with phosducin and adenylyl cyclase. (A) Structure of the unprenylated G $\beta\gamma$ (light surface) in complex with retinal phosducin (dark ribbon). For comparison, the G α /G $\beta\gamma$ chimera from Fig. 2B is overlaid as a light coil. A dashed circle denotes the location of the proposed binding cavity for the farnesyl moiety. (B) Structure of an active adenylyl cyclase C1-C2 heterodimer (ribbons and semitransparent surface) bound to forskolin (dark spheres) and GS α GTP γ S (ribbons). The active site is located to the left of the forskolin-binding site. Note that the interaction epitope of GS α comprises the switch II region and the α 3/ β 5 loop.

a small N-terminal helical domain composed primarily of hydrophilic residues and a C-terminal domain with a thioredoxin-like fold (Fig. 3A). The N-terminal domain interacts with the top of the G β propeller, overlapping extensively with the epitope for interaction with the switch regions of G α , whereas the thioredoxin domain contacts the side of G β at a site distinct from the N-terminal epitope for G α . These observations explain why the interaction of G $\beta\gamma$ with phosducin and G α is mutually exclusive. Furthermore, electrostatic calculations indicate that the presence of phosducin's thioredoxin-like domain introduces a substantial negative electrostatic potential near the prenylation site at the C-terminus of G γ , thereby destabilizing the association with acidic membranes. Finally, the interaction with phosducin's N-terminal domain perturbs the conformation of three loops at the top of the G β propeller. A subsequent structure of phosducin bound to farnesylated G $\beta\gamma$ suggested that the conformational changes in G β open a pocket of appropriate dimensions to accommodate the hydrophobic farnesyl group of G γ [18].

$G_{S\alpha}$ and Adenylyl Cyclase

Adenylyl cyclase (AC) consists of two hexahelical transmembrane domains, each followed by a similar cytoplasmic domain referred to as C1 and C2. Expressed independently, the isolated C1 or C2 domains form soluble but inactive homodimers. When mixed, the C1 and C2 homodimers spontaneously equilibrate to form catalytically active heterodimers that retain the ability to be stimulated by $G_{S\alpha}$ GTP and inhibited by $G_{i\alpha}$ GTP [19]. The structure of a C1-C2 heterodimer in complex with the GTP-bound form $G_{S\alpha}$ and forskolin, a plant terpenoid that activates AC, provided the first glimpse of how a GTP-bound G_{α} subunit recognizes and activates a downstream effector [20]. The inactive C2 homodimer binds two molecules of forskolin at symmetrical sites located at the dimer interface [21]. In contrast, the pseudo-symmetrical C1-C2 heterodimer binds a single forskolin molecule at an analogous site (Fig. 3B). The ATP-binding site is located at a pseudo-symmetrical site analogous to the second forskolin site in the C2 homodimer. The switch II region and $\alpha 3/\beta 5$ loop of $G_{S\alpha}$ contact the C1-C2 domains at a location remote from the active site, thereby inducing a domain rotation that brings key catalytic and ATP-binding residues into register.

Filling in the GAP

RGS domains present in a variety of modular proteins accelerate GTP hydrolysis for G_{α} subunits [4]. The underlying structural basis was established by the crystal structure of the helical RGS domain of RGS4 in complex with $G_{i\alpha}$ GDP and AlF_4^- [22]. In contrast to GAPs (GTPase-activating proteins) for Ras and Rho GTPases, which supply an “arginine finger” analogous to the catalytic arginine in switch I of G_{α} , RGS proteins promote GTP hydrolysis by engaging the switch I and II regions so as to reorient the catalytic arginine and glutamine residues of $G_{i\alpha}$ to stabilize the pentavalent intermediate (Fig. 4A).

Visual Fidelity

Structures of the $\text{GTP}\gamma\text{S}$ -bound and AlF_4^- activated forms of $G_{i\alpha}$ in complex with RGS9 and/or the inhibitory subunit of the retinal phosphodiesterase ($\text{PDE}\gamma$) provided further insight into the cooperative mechanism of effector recognition and RGS stimulation of GTP hydrolysis in the visual system [23]. $\text{PDE}\gamma$ forms a predominately hydrophobic interface with residues in the switch II/ $\alpha 3$ cleft of $G_{i\alpha}$, consistent with mutational data. This interaction sequesters C-terminal residues of $\text{PDE}\gamma$ implicated in $\text{PDE}\alpha\beta$ inhibition. RGS9 engages the switch I and II regions of $G_{i\alpha}$ in a manner analogous to that observed for RGS4 and $G_{i\alpha}$. As shown in Fig. 4B, a small interface between $\text{PDE}\gamma$ and a unique loop of RGS9, near the critical asparagine residue involved in positioning the catalytic glutamine of $G_{i\alpha}$,

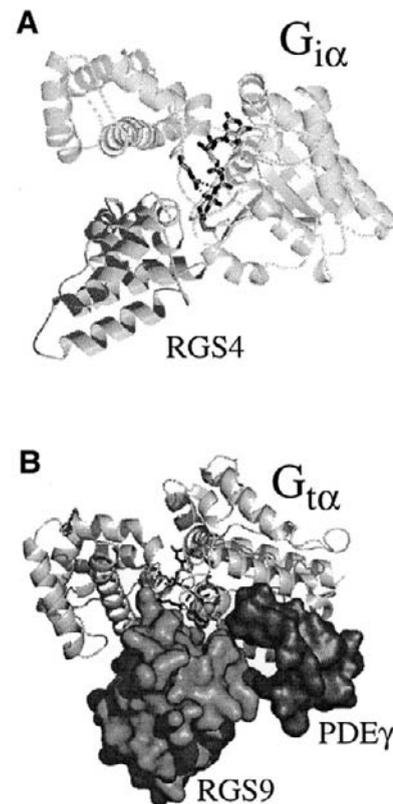

Figure 4 RGS and effector complexes with G_{α} subunits. (A) Structure of RGS4 (dark ribbon) bound to AlF_4^- activated $G_{i\alpha}$ GDP (light ribbon). Also shown are the conserved arginine and glutamine residues in the switch regions as well as $\text{GDP}\cdot\text{AlF}_4^-$. (B) Structure of AlF_4^- activated $G_{i\alpha}$ GDP (ribbons) bound to $\text{PDE}\gamma$ (dark surface) and RGS9 (light surface). couple the maximal GAP activity of RGS9 to the interaction of $G_{i\alpha}$ with $\text{PDE}\gamma$, thereby enhancing the fidelity of visual signal transduction.

What Structures May Follow

Clearly the most important unresolved structural question is how an activated receptor engages a heterotrimeric G protein so as to catalyze nucleotide exchange on the G_{α} subunit. The resolution of this question requires the crystal structure of a complex between a ligand-bound or light-activated receptor and the nucleotide free form of a G-protein heterotrimer. Only then can we claim to have glimpsed the conversion of extracellular signals into intracellular second messengers at atomic resolution.

In Vivo Functions of Heterotrimeric G Proteins

Stefan Offermanns

*Pharmakologisches Institut, Universität Heidelberg,
Heidelberg, Germany*

Introduction

The transmembrane signaling system, which uses heterotrimeric G proteins to couple heptahelical receptors to various effectors, operates in all cells of the mammalian organism and is involved in many physiological and pathological processes. The main properties of individual G proteins are determined by the identity of their α -subunits. To elucidate the role of G-protein-mediated signaling processes in the intact mammalian organism, almost all known genes encoding G-protein α -subunits have been inactivated by gene targeting in mice (Table I). So far, no mouse line was reported carrying targeted mutations of G β - or G γ -genes. This short review summarizes the main phenotypical changes observed in mice lacking G protein α -subunits.

Development

Various G α -deficient mouse models have pointed to the involvement of G-protein-mediated signaling pathways in certain developmental processes. For example, lack of G α_{13} results in embryonic lethality at about midgestation due to a defect in angiogenesis [1]. Mice deficient in both G α_q and G α_{11} suffer from a defect in heart development and die *in utero* (see below). In addition, signaling through G $_q$ class members has also been implicated in the proliferation and/or migration of craniofacial neural crest cells [2]. The complete loss of G α_s in mice homozygous for an inactivating G α_s mutation leads to embryonic lethality before embryonic day 10 [3]. It is interesting that heterozygotes show varying phenotypes depending on the paternal origin of the intact allele; these are probably caused by genetic

haploinsufficiency and/or tissue-specific imprinting of the maternal G α_s allele [4].

Central Nervous System

In the central nervous system (CNS), many mediators and neurotransmitters function through G-protein-coupled receptors to modulate neuronal activity or morphology. Neurotransmitters that induce an inhibitory modulation typically act on receptors that are coupled to members of the G $_{i/o}$ family, whereas G $_q$ - and G $_s$ -family members are primarily involved in excitatory responses.

The G-protein G $_o$ is highly abundant in the mammalian nervous system and has been shown to mediate inhibition of neuronal (N-, P/Q-, R-type) voltage-dependent Ca $^{2+}$ channels via its $\beta\gamma$ -complex, thereby reducing the excitability of the cell. G α_o -deficient mice suffer from tremors and have occasional seizures [5,6]; severely abnormal motor behavior can be observed in these animals (<http://www.anes.ucla.edu/~lutzb/realmice.htm>) as well. In addition, G α_o -deficient mice appear to be hyperalgesic when tested in the hot plate assay [6]. The latter finding is consistent with the observation that opioid receptor-mediated inhibition of Ca $^{2+}$ currents in dorsal root ganglia (DRG) from G α_o -deficient animals was reduced by about 30 percent compared to those in wild type DRGs [6].

G $_z$, a member of the G $_{i/o}$ -family of G proteins, shares with G $_{11}$, G $_{12}$, and G $_{13}$ the ability to inhibit adenylyl cyclases but has a rather limited pattern of expression, being found in brain, adrenal medulla, and platelets. G α_z -deficient mice exhibit altered responses to a variety of psychoactive drugs. Cocaine-induced increases in locomotor activity were more pronounced, and short-term antinociceptive effects of

Table I Phenotypical Changes in Mice Lacking α -Subunits of Heterotrimeric G-Proteins

morphine were altered [7,8]. In addition, behavioral effects of catecholamine reuptake inhibitors were abolished in G α_z -deficient mice [7], indicating that G α_z is involved in signaling processes regulated by various neurotransmitters.

G α_{olf} is expressed in various regions of the CNS, including olfactory sensory neurons and basal ganglia. G α_{olf} -deficient mice exhibit clear motoric abnormalities such as hypermotoric behavior [9]. Recent data indicate that G α_{olf} is critically involved in dopamin(D₁)- and adenosine(A_{2A})-receptor-mediated effects in the striatum [10,11].

The two main members of the G α_q family, G α_q and G α_{11} , are widely expressed in the central nervous system. Mice lacking G α_q develop an ataxia with clear signs of motor coordination deficits, and functional defects could be observed in the cerebellar cortex of G α_q -deficient mice [12]. In addition,

lack of G α_q resulted in defective cerebellar and hippocampal long-term depression (M. Kano *et al.*, unpublished; [13]).

Immune System

Mice lacking G α_{i2} develop a lethal, diffuse inflammatory bowel disease that resembles in many aspects ulcerative colitis in humans [14]. In subsequent studies, dramatic changes in the phenotype and function of intestinal lymphocytes and epithelial cells have been described that are likely to be due to defective lymphocyte homing in enteric epithelia [15]. On a cellular level, G α_{i2} may be involved in the regulation of T-cell function and trafficking. These processes are regulated through chemoattractant and chemokine

receptors that show a predominant coupling to G_i -type G-proteins. In addition to the colitis, many $G\alpha_{i2}$ -deficient mice develop colonic adenocarcinomas, which are probably secondary to colonic inflammation [14].

Heart

The $G\alpha_q/G\alpha_{11}$ -mediated signaling pathway appears to play a pivotal role in the regulation of physiological myocardial growth during embryogenesis. This is demonstrated by the phenotype of $G\alpha_q/G\alpha_{11}$ -double deficient mice that die at embryonic day 11 due to a severe thinning of the myocardial layer of the heart [2]. Adult cardiomyocytes are terminally differentiated post-mitotic cells that respond to stimulatory signals with cell growth rather than proliferation. Myocardial hypertrophy in the adult heart following mechanical stress depends on $G\alpha_q/G\alpha_{11}$ -mediated signaling as demonstrated by the absence of a hypertrophic response in adult mice with cardiomyocyte-specific $G\alpha_q/G\alpha_{11}$ deficiency [16].

Inhibition of L-type Ca^{2+} channels in the heart through muscarinic M_2 receptors was found to be abrogated in hearts lacking $G\alpha_o$ as well as $G\alpha_{i2}$ [5,17]. This unexpected finding suggests that both G proteins may regulate this downstream signaling event in a complex fashion.

Sensory Systems

Odors, light, and many tastants act directly on G-protein-coupled receptors. The G protein G_{olf} is centrally involved in the transduction of odorant stimuli in olfactory cilia, and $G\alpha_{olf}$ -deficient mice exhibit dramatically reduced electrophysiological responses to all odors tested [9]. Since nursing and mothering behavior in rodents is mediated a great deal by the olfactory system, most $G\alpha_{olf}$ -deficient pups die a few days after birth due to insufficient feeding, and rare surviving mothers exhibit inadequate maternal behavior. In contrast to the olfactory epithelium, the vomeronasal organ, which detects pheromones, expresses receptors that are coupled to $G_{i/o}$. Absence of $G\alpha_o$ results in apoptotic death of receptor cells that usually express $G\alpha_o$ [18].

Rod-transducin ($G_{t,r}$) and cone-transducin ($G_{t,c}$) play well-established roles in the phototransduction cascade in the outer segments of retinal rods and cones, where they couple light receptors to cGMP-phosphodiesterase. In mice lacking $G\alpha_{t,r}$, the majority of retinal rods does not respond to light anymore, and these animals develop mild retinal degeneration with age [19]. The light response is transferred from the receptor cell to bipolar cells of the retina. In mice lacking $G\alpha_o$, modulation of ON bipolar cells in response to light is abrogated, indicating that G_o is critically involved in the tonic inhibition of these cells mediated by metabotropic glutamate (mGluR6) receptors [20].

Among the four taste qualities—sweet, bitter, sour, and salty—bitter and sweet tastes appear to signal through heterotrimeric G-proteins. Gustducin is a G protein mainly

expressed in taste cells, and $G\alpha_{gust}$ -deficient mice show impaired electrophysiological and behavioral responses to bitter and sweet agents [21]. The residual bitter and sweet taste responsiveness of $G\alpha_{gust}$ -deficient mice could be further diminished by a dominant-negative mutant of gustducin- α , suggesting the involvement of other G proteins related to $G\alpha_{gust}$ [22].

Hemostasis

Hemostasis is a complex process involving platelet adhesion and aggregation as well as formation of fibrin through the coagulation cascade. Platelet activation results in a rapid shape-change reaction immediately followed by secretion of granule contents, as well as inside-out activation of the fibrinogen receptor, integrin $\alpha_{IIb}\beta_3$, leading to platelet aggregation. Most physiological platelet activators act through G-protein-coupled receptors, which in turn activate $G_{i2/3}$, G_q , G_{12} , and G_{13} . In platelets from $G\alpha_q$ -deficient mice, the effect of various platelet stimuli on aggregation and degranulation was abrogated, demonstrating that $G\alpha_q$ -mediated phospholipase C activation represents an essential event in platelet activation [23]. However, platelet shape change can still be induced in the absence of $G\alpha_q$, indicating that it is mediated by G proteins other than G_q , most likely G_{12}/G_{13} [24]. The defective activation of $G\alpha_q$ -deficient platelets results in a primary hemostasis defect, and $G\alpha_q$ ($-/-$) mice are protected against platelet-dependent thromboembolism.

The role of G proteins of the $G_{i/o}$ family in platelet activation has recently been elucidated. Platelets contain at least three members of this class, G_{i2} , G_{i3} , and G_z . ADP, which is released from activated platelets and functions as a positive feedback mediator during platelet activation, induces platelet activation through the G_q -coupled $P2Y_1$ receptor as well as through the G_i -coupled $P2Y_{12}$ purinergic receptor. The general importance of the G_i -mediated pathway is indicated by the fact that responses to ADP but also to thrombin were markedly reduced in platelets lacking $G\alpha_{i2}$ [25]. In contrast to ADP or thrombin, epinephrine is not a full platelet activator *per se* in murine platelets. However, it is able to potentiate the effect of other platelet stimuli. In platelets from $G\alpha_z$ -deficient mice, epinephrine's potentiating effects were clearly impaired, while the effects of other platelet activators appeared to be unaffected by the lack of $G\alpha_z$ [7]. Thus, members of the G-protein families G_q , G_{12} , and $G_{i/o}$ are involved in processes leading to platelet activation.

Conclusions

Mouse models lacking almost all known genes encoding G-protein α -subunits have been generated, and they provide a first insight into the biological roles of G-protein-mediated signaling pathways. To overcome embryonic lethality or complex phenotypes of some $G\alpha$ null mutations and to understand the degree of functional redundancy of closely

related G proteins researchers have begun to cross individual mutants and to generate mouse lines that allow for the conditional inactivation of genes in a time- and tissue-specific manner. These approaches will soon provide more detailed views on the functions of G-protein-mediated signaling pathways in the developing and adult mammalian organism.

Regulation of G Proteins by Covalent Modification

Jessica E. Smotrys and Maurine E. Linder

*Department of Cell Biology and Physiology,
Washington University School of Medicine, St. Louis, Missouri*

Introduction

G proteins are subject to a number of covalent modifications that affect their subcellular localization, protein-protein interactions, and regulation. The first modifications known were those catalyzed by bacterial toxins. The discovery of ADP-ribosylation of G-protein α subunits by cholera and pertussis toxins provided significant insights into G-protein function and is discussed in detail in another chapter in this volume (Chapter 100 by Di Girolamo and Corda). Regulation of G-protein activity by phosphorylation is also covered in a separate chapter (Chapter 99 by Luttrell and Luttrell). Other posttranslational modifications of G-protein subunits that have been reported include deamidation of $G_{\alpha\alpha}$ [1,2] and ADP-ribosylation of G_{β} by a cellular ADP-ribosyltransferase [3]. Here we focus on the covalent modification of G proteins by lipids. All G_{α} subunits are fatty acylated by amide-linked myristate and/or thioester-linked palmitate. All G_{γ} subunits are modified at the C-terminus by a farnesyl (C15) or geranylgeranyl (C20) isoprenoid. Two themes have emerged concerning the role of lipid modifications in G-protein signaling. First, by conferring membrane affinity, they have a role in properly positioning G proteins at the plasma membrane, where they must reside in order to interact with receptors and effectors. Once the G protein is in place, lipids further affect G-protein signaling by modulating protein-protein interactions. This chapter will focus on the latter role, as subcellular localization is discussed elsewhere (Linder, Volume 1, Chapter 60).

Separating the roles of lipid modification in membrane affinity from protein affinity is challenging. *In vivo*, mutation of lipid modified residues often results in mislocalized G protein. Defects in signaling can be attributed to the mislocalization, making it difficult to assess additional roles of the lipid modification. Scientists have turned to *in vitro* methods to study effects of lipid modification on affinity between proteins. However, due to the hydrophobic nature of the proteins involved, detergents must often be present in the assays. Detergents at concentrations above the critical micelle concentration (CMC) form micelles. Lipid modifications mediate association with the micelles, concentrating proteins at the micelle surface. Thus, an apparent change in affinity could reflect the ability of lipid-modified proteins to cluster at the micelle surface. The use of soluble effector domains, lipidated peptides, and x-ray crystal structures have allowed more definitive analysis of lipid effects on protein interactions.

N-Terminal Acylation of G_{α}

As presented in Table I, fatty acids are found singly or in combination on G_{α} subunits. N-myristoylation is a cotranslational modification of G-protein subunits of the $G_{i\alpha}$ subfamily [4]. Myristic acid is added through an amide linkage to a glycine residue exposed after removal of the initiator methionine. The enzyme that catalyzes this modification, N-myristoyltransferase, is associated with ribosomes in mammalian cells [5].

All G-protein α subunits with the exception of $G_{i\alpha}$ and gustducin are substrates for palmitoylation [4]. Palmitate is linked through a labile thioester bond to one or more cysteine residues near the N-terminus of G_{α} . Palmitoylation of G-protein α subunits is believed to occur at the plasma membrane. In contrast to N-myristoylation, palmitoylation is a reversible and regulated modification. This topic is explored in a separate chapter (Chapter 106 by Wedegartner).

Acylation and Subunit Interactions

In the inactive state, G_{α} forms a high-affinity complex with $G_{\beta\gamma}$. The crystal structure of this complex reveals that the lipid-modified termini of G_{α} and G_{γ} are proximal to each other [6,7]. Although the crystallized proteins lacked lipid moieties, it is predicted that the lipids extend away from the protein complex and into nearby membrane. *In vitro*, myristoylated $G_{o\alpha}$ has higher affinity for $G_{\beta\gamma}$ than the nonmyristoylated form [8]. Studies with $G_{i\alpha}$ suggest that this apparent increase in affinity is due to interactions of the myristoylated subunit with detergent micelles, rather than direct interaction of the fatty acid with $G_{\beta\gamma}$ [9].

The N-terminal modifications found on $G_{s\alpha}$ are also important for subunit interactions. $G_{s\alpha}$ is palmitoylated on Cys3 and contains an additional unidentified hydrophobic moiety at the N-terminus [10]. $G_{s\alpha}$, which has both modifications (purified from liver or Sf9 insect cells), has higher affinity for $G_{\beta\gamma}$ than $G_{s\alpha}$, which lacks the modifications (Sf9 $G_{s\alpha}$ treated with palmitoyl esterase or purified from *E. coli*) [10,11]. The relative contributions of the modifications cannot be determined from these experiments. Detergent at concentrations above the CMC is present in the assays, and the effect of lipidation may be indirect.

Interaction of G_{α} with Effectors

Activated $G_{s\alpha}$ and $G_{i\alpha}$ work to stimulate and inhibit membrane-bound adenylyl cyclase (AC), respectively. The lipid modifications found on these subunits are important for this activity. The unidentified modification on $G_{s\alpha}$ supports high-affinity binding to AC, independent of the presence of palmitate [10,12]. It is not clear whether this modification directly binds AC or increases affinity by concentrating the G protein at membranes. It is clear, however, that the myristoyl group on $G_{i\alpha}$ directly affects affinity for AC independently of membrane localization [13]. Myristoylation was required for $G_{i\alpha}$ to interact with a soluble domain of AC in an assay free of micelles or membranes. It is unknown whether the myristoyl group has a binding site on AC or affects the conformation of $G_{i\alpha}$ to mediate its interaction with the effector [13]. In contrast to N-myristoylation, palmitoylation does not appear to have an important role in promoting G_{α} -effector interactions [10,14].

Palmitoylation and Signal Downregulation

Activation of receptors increases palmitate turnover on $G_{s\alpha}$ and $G_{i\alpha}$ [4]. This may serve to regulate the amount of G_{α}

at the plasma membrane [15], although this has been controversial [16], and also to modify interactions with $G_{\beta\gamma}$ as mentioned previously in the section on acylation and subunit interactions. In addition, palmitoylation may be involved in signal down-regulation through effects on interactions with regulators of G-protein signaling (RGS), which stimulate the intrinsic GTPase activity of G_{α} subunits. Palmitoylated $G_{z\alpha}$ has reduced affinity for its RGS protein G_z GAP [17]. This same phenomenon was observed with other G_{α} -RGS pairs and is not due simply to the hydrophobicity of the palmitate moiety, since myristoylation of $G_{z\alpha}$ has the opposite effect and promotes interaction with G_z GAP. Thus, depalmitoylation after G-protein activation may be important for returning the G protein to the inactive state [17].

C-Terminal Modification of G_{γ}

All known G_{γ} subunits contain C-terminal CaaX motifs, where C is Cys, "a" is an aliphatic residue, and X is the C-terminal amino acid (Table I). These motifs direct prenylation of the cysteine residue, proteolysis of the three C-terminal residues (-aaX), and carboxymethylation of the C-terminal prenylated cysteine [18]. G_{γ} is modified with farnesyl or geranylgeranyl depending on the identity of the C-terminal amino acid. Most G_{γ} subunits are geranylgeranylated; $G_{\gamma 1}$, $G_{\gamma c}$, and $G_{\gamma 11}$ are farnesylated. Prenylation occurs in the cytoplasm, and subsequent processing steps are likely to take place at the endoplasmic reticulum [19,20].

Prenylation and Subunit Interactions

Prenylation of G_{γ} is not required for the assembly of $G_{\beta\gamma}$ dimers [21]. However, like G_{α} fatty acylation, prenylation promotes interaction of $G_{\beta\gamma}$ with G_{α} [22]. The type of prenyl group attached affects the affinity of the interaction for many G_{α} subunits. Generally, G_{γ} modified with the more hydrophobic geranylgeranyl group displays higher apparent affinity for G_{α} . This is likely to be an indirect effect due to enhanced association with the membrane surface. For example, changing the prenyl group from farnesyl to geranylgeranyl on $G_{\gamma 1}$ increases affinity of $G_{\beta 1\gamma 1}$ for both membranes and G_{α} [23].

Prenylation and Receptor Coupling

Prenylation is essential for receptor-G-protein coupling. Farnesylated peptides corresponding to the C-terminus of G_{γ} inhibit coupling to rhodopsin, suggesting that the prenyl group is directly involved in binding to receptor [24]. The type of prenyl moiety with which the peptides are modified influences the ability of the peptide to stabilize activated rhodopsin, a measure of affinity. Farnesylated peptides have greater affinity for rhodopsin than either geranylated (C10) or geranylgeranylated peptides [25]. Since the observed affinity does not correlate with hydrophobicity, this is suggestive of a specific binding site on rhodopsin that

Table I Lipid Modifications of Heterotrimeric G Proteins

Subunit	Lipid modifications	Modified sequence ^a
$\alpha_i, \alpha_o, \alpha_z$	N-Myr, S-palm	H ₂ N-MGC-

^amodified residues are in boldface

^b“a” is an aliphatic residue, additional processing includes proteolysis of the three C-terminal residues and carboxymethylation of the prenylated cysteine

preferentially recognizes farnesylated G_γ . However, in assays of rhodopsin-stimulated GTP γ S binding, geranylgeranylated $G_{\beta\gamma}$ dimers are more effective than their farnesylated counterparts, arguing against a specific farnesyl binding site on rhodopsin [23,26]. How the prenyl moiety functions in receptor recognition requires further investigation.

Prenylation and Effector Interactions

Prenylation and primary sequence of G_γ are both important determinants of $G_{\beta\gamma}$ effector activation. Similar to receptor coupling, the same $G_{\beta\gamma}$ complex is more effective in activating phospholipase C β (PLC β) or AC when G_γ is geranylgeranylated than when farnesylated [27]. In the case of PLC β activation, there is evidence that the prenyl group is not simply promoting effector activation indirectly through membrane interactions, but is directly mediating protein-protein interactions. Peptides corresponding to the C-terminus of G_{γ_2} inhibit activation of PLC β by $G_{\beta\gamma}$ in a prenylation-dependent manner. A fluorescence-based binding assay demonstrated a direct interaction of the prenylated peptide with PLC β_2 [28]. Precedence for prenyl-binding sites in proteins is provided by the structure of prenylated Cdc42, a Rho family GTPase, bound to Rho-GDI, a guanine nucleotide dissociation inhibitor, which regulates interaction of Rho family members with membranes. In this structure, the C-terminal geranylgeranyl group on Cdc42 inserts into a hydrophobic pocket formed by Rho-GDI [29].

A second mechanism for prenylation-dependent effector interactions is suggested by the structure of the $G_{\beta\gamma}$ -phosducin complex. Phosducin binds tightly to free $G_{\beta\gamma}$ extracting it from membranes and preventing its reassociation with G_α . Phosducin induces several local conformational changes in G_β that are not seen in the structures of free $G_{\beta\gamma}$ or the heterotrimer, including the opening of a pocket between blades 6 and 7 [30,31]. Based on their structure of farnesylated $G_{\beta\gamma}$ with phosducin, Loew *et al.* proposed that the farnesyl group is sequestered in the crevice [30]. $G_{\beta\gamma}$ may undergo a similar conformational change when bound to effectors.

Consistent with this model, mutations in G_β that perturb the putative prenyl binding pocket exhibit reduced potency in effector activation assays [32].

Carboxymethylation of G_γ

Methylation of the C-terminal prenylated cysteine residue is of interest because it is the only step in the post-translational processing of G_γ that is reversible and thus has the potential to be regulated. Methylation affects protein properties by neutralizing the negative charge on the C-terminal carboxylate ion. The effects of methylation on $G_{\beta\gamma}$ have only been studied for the farnesylated $T_{\beta\gamma}$ [33,34]. The most significant effect observed was that on effector interactions [34]. $T_{\beta\gamma}$ activation of phosphoinositide-3-kinase and PLC β , assayed in phospholipid/detergent micelles, was strongly dependent on methylation. Demethylated $T_{\beta\gamma}$ binds to phospholipid/cholate micelles, albeit less well than its methylated counterpart [9,34]. This suggests that the effect of methylation on effector interactions is not simply due to membrane affinity, but may involve direct protein contacts.

Conclusions

Lipid modifications found on G_α and $G_{\beta\gamma}$ modulate interactions with membranes and other proteins, playing an essential role in signal transduction. There is evidence for prenyl-binding sites on receptors and the effector PLC β , and a direct role for myristate in binding of $G_{i\alpha}$ to AC. How these modifications mediate these protein interactions awaits additional structural studies with lipidated proteins. Novel roles for lipid modifications in protein interactions will surely be revealed in the future.

Note Added in Proof

The unknown hydrophobic modification on α_s (Table I) has been identified as amide-linked palmitate at Gly2.

G protein-coupled receptors (GPCRs) represent the largest class of cell surface receptors and govern a multiplicity of intracellular signaling mechanisms, fulfilling a wide range of critical physiological and cell-specific actions. This vast signaling potential of GPCRs, however, leaves cell-specific transduction pathways vulnerable to profound alterations when G-protein coupled receptors are aberrantly expressed out of their cellular context or persistently activated by either mutagenesis or excess availability of their ligands. This review covers some of the mechanisms that GPCRs modulate in order to stimulate normal and pathological cell proliferation, including the communication between heterotrimeric G proteins and guanine-nucleotide exchange factors for the Ras and Rho families of small GTPases, signaling cassettes regulating the activity of members of the MAP kinase superfamily, and more recent findings that identify a number of G-protein-independent effectors. We also explore the emerging role of scaffolding molecules in physically organizing the components of each transducing pathway downstream of GPCRs. These organizing molecules are likely to provide cell specificity to GPCR-driven signaling by preventing inappropriate cross-talk in physiological contexts, and may be one of the missing components that allow aberrantly expressed GPCRs or ectopic activation of their targets to cause cell transformation.

Introduction

The family of G-protein-coupled receptors (GPCRs) encompasses the largest group of transmembrane proteins implicated in signal transmission. Also known as heptahelical receptors, these molecules are sensitive to large variety of ligands, including peptide and nonpeptide neurotransmitters, hormones, growth factors, odorant molecules, and light. Such a wide spectrum of sensitivity is reflected in the number of genes that encode GPCRs in animal genomes, including *Drosophila* (1 percent of total genes), *Caenorhabditis elegans* (more than 5 percent of all genes), and even humans, where more than 2 percent of human genes are responsible for over 1,000 proteins with heptahelical structure [1,2]. Numerous GPCRs have been implicated in physiology and in the progression of hereditary diseases [3] and this link has transformed the investigation of new therapeutic drugs: GPCRs and the signaling pathways that they control have become a major focus among pharmaceutical firms [1,2,4].

Heptahelical receptors are called G-protein-coupled receptors because of their well-studied signaling relationship to heterotrimeric G proteins (α , β , and γ subunits). GPCRs become stabilized in an active conformation upon ligand-binding, allowing them to catalyze the exchange of GDP for GTP bound to the G-protein α subunit. $G\alpha$ and $G\beta\gamma$ subunits subsequently activate effector proteins such as

adenylyl and guanylyl cyclases, phosphodiesterases, phospholipase A₂ (PLA₂) and C (PLC), and phosphatidylinositol-3 kinases (PI3Ks). These downstream molecules modulate the synthesis of various second messengers such as cAMP, cGMP, diacylglycerol, IP₃, PIP₃, and arachidonic and phosphatidic acid and can also lead to increases in cytosolic [Ca²⁺] through the opening or closing of a variety of ion channels. Although much work has been focused on the signaling relationship between GPCRs and trimeric G proteins, recent findings suggest that heptahelical receptor activation can direct biochemical responses that are independent of heterotrimeric G proteins (reviewed in [5]).

In this review we will attempt to give a sense of the multiplicity of classical and novel signaling systems that transmit heptahelical receptor-induced changes in cell behavior. We emphasize that the complexity of known GPCR-initiated signals is likely not to exist in one single cell type; that the signaling pathways available to GPCRs in a particular tissue are much more limited. However, because of the vast signaling potential of GPCRs, these critical cell-specific transduction pathways are in danger of being overridden by dysregulated mechanisms that are sensitive to heptahelical receptors. Thus, we will also focus on mechanisms that enforce GPCR signaling fidelity to physiological pathways as a barrier against GPCR-induced pathological outcomes such as cell transformation.

Heptahelical Receptors and Tumorigenesis

GPCRs can promote tumor formation in two different ways: through the stimulation of unregulated growth of cancer cells and by the recruitment of nascent blood vessels to tumor sites. Both tumor-promoting activities have received a great deal of attention since they suggest that drug-induced blockade of specific receptors might allow for the selective inhibition of cell growth or blood vessel formation in particular tumor types, and that such approaches would provide a mechanistic handle that could be exploited in the treatment of neoplastic diseases.

Growth factors such as thrombin, lysophosphatidic acid (LPA), bombesin, vasopressin, bradykinin, substance K, acetylcholine receptor agonists, angiotensin II, and many others induce cell division by binding to their cognate GPCRs in many different cell types (reviewed in [6–8]). The heptahelical protein encoded by the *mas* oncogene was the first clue of a connection between cancer and GPCRs. Unlike other oncogenes, the *mas* gene product does not contain any activating mutations when compared to other heptahelical receptors and requires ligand-binding for its transforming ability. This observation taken together with other findings showing that ectopic expression of serotonin 1C and muscarinic m1, m3, and m5 receptors transforms mouse cells in an agonist-dependent fashion [9,10] suggested that endogenous GPCRs can be tumorigenic in the presence of excess ligand and do not require to be mutated to be transforming.

The role of cellular GPCRs in tumorigenesis is an area of active research, and many heptahelical receptors, and their ligands, are coopted by tumors to support cell proliferation (Table I). For example, GPCR ligands such as bombesin, gastrin-releasing peptide (GRP), neuromedin B (NMB), bradykinin, cholecystokinin (CCK), galanin, neurotensin (NT), and vasopressin are secreted by small cell lung cancer cells (SCLC). These tumors also express the GPCRs sensitive to these agonists and thus use heptahelical receptors to stimulate their own proliferation in an autocrine or paracrine fashion (see [11] for an extensive review). A variety of neuropeptide receptors and their ligands play a role in the progression of colon adenomas and carcinomas, gastric hyperplasia and cancer, prostate cancer, and pancreatic hyperplasia and carcinoma (reviewed in [8,11]). Thus, ectopic expression of GPCRs allows tumor cells to override the heptahelical receptor-driven physiological pathways that are intrinsic to their original cell type and use the unchecked potential of GPCR-controlled signaling mechanisms to drive cell proliferation.

Ligand-dependence, however, is by no means an absolute requirement. Mutagenesis can cause GPCRs to become transforming even in an agonist-independent fashion, as is the case for α_{1b} adrenergic receptors [12]. Moreover, constitutively activating mutations do occur in nature. For example, 30 percent of hyperfunctioning human thyroid adenomas and a minority of differentiated thyroid carcinomas contained constitutively active TSH receptors [13], again linking GPCRs to human cancer. Hyperomorphic mutations have also been detected in other GPCR such as LH receptors, which can cause hyperplastic growth of Leydig cells in a form of familial male precocious puberty [14], and Ca²⁺-sensing G protein linked receptors, which can cause autosomal dominant hypercalcemia [15] and may be involved in certain cancers [16].

Genes that encode heptahelical receptors are also present in the genome of several DNA viruses, including the human cytomegalovirus (HCMV) [17], herpes virus saimiri (HVS) [18], and the Kaposi's sarcoma associated herpesvirus (KSHV) [19]. These receptors, such as the HCMV-encoded GPCRs, have a high degree of homology to chemokine receptors [20] and may help virally infected cells escape detection by the immune system. Moreover, viral GPCRs can also function in paracrine or autocrine fashion, encouraging inappropriate cell behaviors such as pathological cell proliferation. For example, the HVS-GPCR contributes to fatal lymphoproliferative diseases caused by HVS infection, such as leukemias and lymphomas, in several nonhuman primates [18].

Another way in which cellular and viral GPCRs can promote tumorigenesis is by promoting the development of blood vessels that support tumor growth. A variety of G-protein-coupled receptors, including those binding sphingosine-1 phosphate, LPA, PAF, thrombin, IL-8, GRO α - γ , MCP-1, and SDF-1, have been implicated in tumor-induced angiogenesis and vasculogenesis [21]. The sphingosine-1-phosphate (S1P) receptor S1P₁/EDG-1 is a particularly interesting example

Table I G Proteins and G Protein-Coupled Receptors in Tumorigenesis

Activating mutations	
<i>a) G proteins</i>	
$G\alpha_s$	Thyroid toxic adenomas, thyroid carcinomas, growth hormone-secreting pituitary adenomas, McCune-Albright syndrome
$G\alpha_{i2}$	Ovarian sex cord tumors, adrenal cortical tumors
<i>b) G protein-coupled receptors</i>	
TSH receptor	Thyroid adenoma, thyroid carcinoma
FSH receptor	Ovarian sex cord tumors, ovarian small cell carcinoma
LH receptor	Leydig cell hyperplasia, male precocious puberty
CCK-B receptor	Colorectal cancer
Ca ²⁺ -sensing receptor	Autosomal-dominant hypocalcemia, neoplasms
Autocrine and paracrine activation	
Neuromedin B receptor	Small cell lung carcinoma
Neurotensin receptor	Prostate cancer Small cell lung carcinoma
Gastrin receptor	Gastric cancer Small cell lung carcinoma
Cholecystokinin receptors	Pancreatic hyperplasia, pancreatic carcinoma, Gastrointestinal cancer Small cell lung carcinoma
Vasopressin receptors	Small cell lung carcinoma
Virally encoded G protein-coupled receptors

because of its interactions with receptor tyrosine kinases [22]. This GPCR was originally cloned from endothelial cells and supports G_i -dependent cell migration and Rac activation in human embryonic kidney (HEK) cells [22,23] and mouse embryonic fibroblasts (MEF) [24]. It is interesting that MEF derived from EDG $-/-$ animals not only exhibit deficits in S1P-directed Rac activation and cell migration but also in that elicited by other mitogens such as PDGF [25,26]. Previous data showing that the enzyme that makes S1P, sphingosine kinase, is stimulated by growth factors such as PDGF [27] led to a transactivation model in which S1P generated by PDGF receptor stimulation activated the EDG-1 receptor in a paracrine or autocrine way. Since cell migration is essential for blood vessel formation, this signaling relationship between the S1P₁/EDG-1 and the PDGF receptors might be a critical step in angiogenesis, including that promoted by tumors.

Viral GPCRs have also been implicated in pathological blood vessel formation. The KSHV-GPCR is a constitutively active G_q -coupled receptor and has been shown to be transforming when overexpressed in murine fibroblasts [19]. Recent work has shown that the KSHV-encoded GPCR can appropriate signaling pathways that are normally active in cell proliferation and use them to stimulate the inappropriate expression of VEGF [28,29] and promote cell survival [30], thus participating in the hyper-angiogenic response that characterizes Kaposi's sarcoma lesions.

G-Protein Signaling in Cancer

A minimum of ten of the seventeen $G\alpha$ subunits have been described to have transforming potential (reviewed in [31]), including members of the four trimeric G-protein classes: G_{12-13} , G_q , G_i , and G_s . In many cases, these proteins are similar to heptahelical receptors in that they stimulate carcinogenesis in their intact form when they are overexpressed outside their normal cellular context. However, mutations that inhibit the basal GTPase activity of two of these $G\alpha$ subunits, $G\alpha_s$ and $G\alpha_{i2}$, have been described in several tumors types.

Oncogenic mutations of $G\alpha_q$ family members have not been found in human cancers, and research carried out with laboratory-generated active forms of these proteins have yielded contradictory data. It seems that, depending on cell type, activated $G\alpha_q$ is transforming when expressed at low levels [32] but can lead to apoptosis when present at high levels [31]. It is interesting that highly transforming receptors, such as serotonin-1C, muscarinic m1 and α_1 -adrenergic receptors, are coupled to G_q , and that the KSHV-GPCR, a constitutively active G_q -coupled receptor, has been implicated in Kaposi sarcoma progression [19], suggesting that parallel pathways emanating from G_q receptors may be necessary in addition to the activation of the $G\alpha_q$ subunit itself.

Examples of transforming G-proteins include the *gcp*, *gip2*, and *gsp* oncogenes. The *gcp* gene was simultaneously

identified as an oncogenic sequence present in Ewing's sarcoma and as a transcript that induces strong transformation of NIH 3T3 cells [33,34]. *gip* turned out to be a wild-type $G\alpha_{12}$ subunit, belonging to the $G\alpha_{12/13}$ family. This result has been consistent with subsequent findings: increased expression of G_{12-13} subunits has been detected in many human cancers, but it is interesting that no mutations have been found. For example, breast, colon, and prostate adenocarcinoma-derived cell lines express elevated levels of wild-type $G\alpha_{12/13}$ (reviewed in [35]). The *gip2* oncogene is a constitutively active mutant of $G\alpha_{12}$. This mutation has been found in human ovarian sex cord stromal tumors and adrenal cortical tumors [36], although how often $G\alpha_{12}$ mutations occur in these cancer types remains a point of controversy. Fibroblast transformation resulting from transfection of *gip2* has been suggested to result from the derepression of the Ras-ERK1/2 pathway after cAMP/PKA inhibition [37]. However $G\alpha_{12}$ can also stimulate the Ras-ERK1/2 cascade via Rap1 inhibition [38] or stimulation [39], depending on the cellular context, and by stimulating the release of $\beta\gamma$ G-protein subunits [40]. The *gsp* oncogene codes for a GTPase-deficient mutant of $G\alpha_s$ and is found in thyroid toxic adenomas (30 percent), thyroid carcinomas (10 percent), growth hormone-secreting pituitary adenomas, and McCune-Albright syndrome. It is interesting that responses to *gsp* expression are cell-type specific. Increases in cAMP and activated PKA resulting from the presence of this oncogene can inhibit Raf1 and prevent transformation in some cells [41]. By contrast, the presence of *gsp* and the same downstream second messengers can inhibit cell growth in other cell types such as PC12 and thyroid cells [41–43].

gsp illustrates the importance of cellular context in regard to the transformation potential of GPCRs and G-proteins. Cell types that express the small GTPase Rap1 and the downstream kinase B-Raf, such as PC12 and thyroid cells, are predisposed to ERK activation in response to cAMP increases [42,43]. Thus the availability of the transforming ERK pathway to *gsp* depends on the organization of the signaling pathways present in a particular cell type. The cell type dependence of *gsp* transformation is only one specific case of a more general phenomenon. For example, the ERK pathway belongs to the MAP kinase group of related signaling cascades that are downstream of GPCRs, and many of these transduction pathways can be regulated as “signaling cassettes” to provide cell-type specific responses after heptahelical receptor stimulation.

A Matrix of MAPK Cassettes Links GPCRs to Biological Outcomes

Many intracellular cascades have been found to mediate GPCR cell growth effects. A major contributor to this function is a group of highly related proline-targeted serine-threonine kinases, generally known as MAP kinases (MAPKs). Although new members of this group have been recently discovered, we will focus on the three best-known classes of

MAPKs: the extracellular signal-regulated kinases (ERKs), the c-Jun N-terminal kinases (JNK), and the p38 kinases. These molecules are phosphorylated by a family of proteins known as the MAP kinase kinases (MAPKKs), which are, in turn, themselves phosphorylated by the MAP kinase kinase (MAPKKK) class of proteins. Under physiological conditions, there is great specificity among the MAP kinases in a particular cascade, with only a very limited number of proteins at each step. For example, in the ERK cascade the MAPKKK Raf-1 will not phosphorylate a MAPKK other than MEK1 or MEK2, two isotypes that perform the same function in that specific MAP Kinase pathway. Thus, MAP kinase molecules such as ERK are downstream of phosphorylation cascades, forming separate and parallel signaling cassettes.

G-protein coupled receptors can signal to a variety of MAPKKKs that are linked to MAP kinases, including those of the ERK, JNK, and p38 pathways. After activation, members of the MAPKs translocate to the nucleus, where they regulate the expression of genes that play a key role in physiological and pathological cell growth. These signaling molecules affect gene transcription by phosphorylating transcription factors that control the synthesis of these critical mRNAs [44]. Each MAP kinase signaling cassette has a different range of intracellular targets and is therefore able to induce different cellular responses such as cell proliferation, apoptosis, and migration. Much work has been done on the essential molecular events that GPCRs use to regulate the function of the MAPKs, and this research has provided insights into the underlying biochemistry that GPCRs use to govern a wide range of biological events.

ERK Cassette

Many GPCR agonists stimulate p42 and p44 MAPK (MAPK/ERK1/2) in multiple cell contexts (Fig. 1) (reviewed in [45]). Research focusing on the molecular mechanisms regulating this signaling cassette has revealed an assortment of cell-specific signaling cascades. These include the recognition of tyrosine kinases, PI-3 kinases, and PKC as possible downstream targets for GPCRs.

Tyrosine kinase inhibition reduces both the activation of ERK1/2 by GPCRs [46] and the rapid tyrosine phosphorylation of the adapter molecule Shc, a posttranslational modification that induces Shc-GRB2 complex formation [47]. These findings provided the first clue of a tyrosine kinase link between GPCRs and the Ras-ERK cassette. A subset of nonreceptor tyrosine kinases (NRTKs) and receptor tyrosine kinases (RTKs) have been suggested as mediators of this response. Src or Src-like kinases can phosphorylate Shc upon stimulation of β -adrenergic receptors, or $\beta\gamma$ subunits [48]. NRTKs such as Csk, Lyn, Btk, Pyk2, and Fak have been implicated in signaling to mediate the ERK cassette by $G\alpha_i$ and $G\alpha_q$ -coupled receptors in many cell contexts (reviewed in [49,50]). The variety of tyrosine kinases mediating the activation of the ERK cascade is a reflection of the multiplicity of cellular contexts in which this transduction

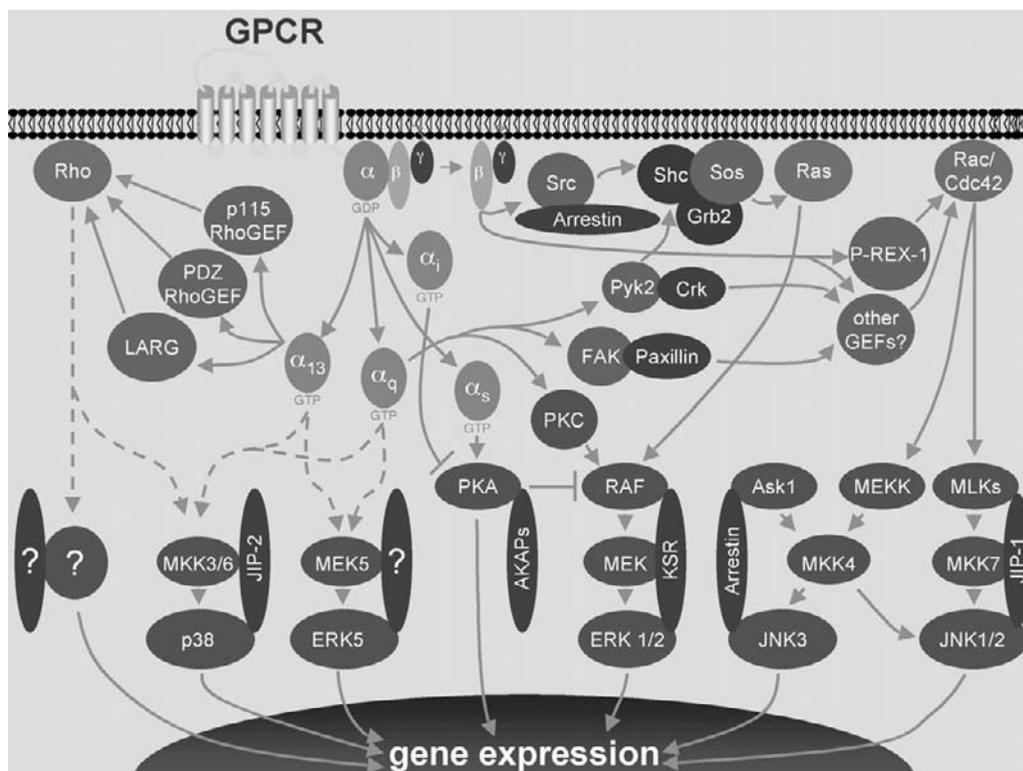

Figure 1 Signaling pathways connecting G-protein-coupled receptors to gene expression are embedded in scaffolding complexes. A multiplicity of signal transduction cascades can link G-protein-coupled receptor stimulation to nuclear events. Thus, aberrant expression of heptahelical receptors, or their cognate ligands, can lead to the activation of a large variety of biochemical routes that can promote neoplastic transformation. Under physiological conditions, scaffolding molecules ensure signal fidelity by physically linking multiple members of signaling cascades to proper subcellular locales and preventing inappropriate crosstalk between related pathways. Arrows represent positive stimulation; dashed lines, functional interactions where precise mechanisms are yet to be elucidated (see text for details).

pathway is involved and its modular nature. Thus, multiple tyrosine kinases in separate pathways may converge in the same signaling cascade to perform different functions.

The protein and lipid kinases of the PI3K family are also essential for GPCR signaling to ERKs. PI3K γ activity is stimulated upon binding to G $\beta\gamma$ subunits and upon stimulation PI3K γ activates by signaling to tyrosine kinases that phosphorylate Shc, leading to increases in ERK activity [51]. The PI3K β isoform can also mediate GPCR-directed signaling to the ERK cassette [52]. In this mechanism, it is possible that PI3K activates Rac and PAK in combination with Ras to stimulate Raf kinase activity [53]. The variety of pathways stimulated by PI3K γ and β is an example of the complex mechanisms by which GPCRs can activate the ERK cascade. It is interesting that these pathways all converge on the ERK cassette, impinging on the MAPKKK Raf-1 and suggesting that although the GPCR-driven signals mediated by PI3 kinase and tyrosine kinases are complex, they are fundamentally ordered, as they all “plug-in” to a canonical mechanism leading to ERK activation.

G α_q -coupled receptors can also use alternative mechanisms to activate the ERK pathway. These variations include signaling cascades that are mediated by protein kinase C, signals that are transmitted by Ras, and transduction

pathways that require the function of both Ras and PKC. Which mechanism functions in a given case depends strongly on the cell type and the extracellular stimulus given. Examples of this specificity include the second messengers that are synthesized in response to G q , such as diacylglycerol and elevated levels of intracellular Ca $^{2+}$, that can stimulate Ras through the guanine nucleotide exchange factors (GEFs) RasGRF and RasGRP (also called CalDGEF). These two GEFs are expressed only in certain tissues and stimulate only Ras and Ras-related GTPases (reviewed in [49]). By contrast, the mechanism by which PKC stimulates ERK activity is not yet completely elucidated, since direct phosphorylation of Raf does not seem to be sufficient to fully activate MEK and MAPK [54]. PKC may also modulate other molecules that regulate the interaction between Ras and Raf.

The consistent theme in GPCR signaling to ERK1/2 is that there is a complex matrix of transduction pathways that are ultimately integrated by a canonical set of three kinases (Raf, MEK, and ERK). This multiplicity of known signaling links that impinge on one cascade is unlikely to coexist in one single cell type but represents the summation of the different mechanisms by which GPCRs can connect to ERK in many cell types. In order to prevent pathological responses,

it is critical for GPCRs to activate ERK in a controlled fashion, restricting its duration and intensity by cell-specific pathways that can ensure the fidelity of each signaling step. There is always potential, however, for GPCRs to inappropriately stimulate the ERK cassette via signal transduction pathways that are extraneous to cellular context. For example, overexpression of gastrin receptors in cancer cells leads to an activation of c-Src and, in turn, the ERK pathway. Thus, inappropriate c-Src activation may contribute to the transforming effects of gastrin receptors. When mechanisms of ERK activation are placed out of their normal cellular context, they are likely to be disregulated and, given the transforming potential of the ERK cascade, likely to contribute to tumor progression. Thus ensuring cell-specific signal transduction with respect to the ERK cassette is a critical aspect of proper GPCR physiology.

JNK Cassette

The detailed mechanisms by which GPCRs stimulate the MAP kinase cassette that terminates in the c-Jun NH₂-terminal kinase (JNK) remain to be fully elucidated. This molecule, also known as stress-activated protein kinase (SAPK), has sequence similarity to ERK1/2, but is activated by GPCRs through distinct pathways. The most important difference in how these two MAP kinase cassettes are regulated is that whereas ERK1/2 stimulation often depends on Ras, the JNK cassette is downstream of the small G proteins Rac and Cdc42. Constitutively active mutants of Rac and Cdc42, for example, can stimulate JNK activity [55], and these two small G-proteins also mediate the activation of JNK by free G $\beta\gamma$ dimers and by G α_{12} , G α_{13} , G q , and G i [49,50,56]. Little is known about how GPCRs activate JNK beyond these general constraints, but recent work greatly advanced the field by identifying the first GEF known to be responsive to G $\beta\gamma$ and PI-3-kinase, P-REX [57]. This GEF, however, was purified from neutrophils and it remains to be seen whether P-REX or similar GEFs stimulate Rac in response to G $\beta\gamma$ in other cell types.

Another area that remains unclear is how G α_{12} /G α_{13} stimulates Rac1/Cdc42 and the downstream JNK cassette. Current candidates that might mediate this effect include two Rac/Cdc42 GEFs, Tiam1 and Dbl, and two Ras GEFs, which may also catalyze Rac GTP exchange, Ras-GRF1 and Ras-GRF2. Further, the nonreceptor tyrosine kinases PYK2 and FAK that are stimulated by stress-fiber and focal complex formation can also stimulate the JNK cassette by interacting with the adaptor proteins Crk [58] or paxillin [59]. Crk and paxillin can, in turn, stimulate GEFs for Rac and Cdc42 (reviewed in [49]).

Still, many of the open questions concerning the activation of the JNK kinase pathway are in the end questions about how Rac and Cdc42 respond to GPCRs. The question of which Rac effectors stimulate the JNK pathway is also an important, outstanding issue. Here again, the presence of a variety of mechanisms impinging on the JNK cassette reflects the general theme of GPCR-signaling complexity and the

exquisite cell specificity that is possible from such a wide range of alternative biochemical routes.

p38 Cassette

The p38 MAP kinases, like the JNK family, are stimulated by cellular stress and membrane-bound receptors [60]. There are presently four p38 MAPKs known: p38 α (CSBP-1), p38 β , p38 γ (ERK6/SAPK3), and p38 δ (SAPK4) [61].

Although the GPCRs and agonists that elicit increased activity from the p38 family of MAP kinases have been the focus of much investigation, there is no clear picture of the downstream mechanisms directly controlling p38 kinases. There have been some reports showing that G α_q and $\beta\gamma$ dimers stimulate p38 α [62] and that two NRTKs, BTK [63] and Src [64], are involved in this mechanism. Receptors that couple to G α_q can also stimulate the p38 α , p38 γ , and p38 δ isoforms [65]. Recent work indicates that G α_q mediates p38 activation through the MKK3 and MKK6 MAPKKs [66]. Further, research using electrophysiological techniques suggest that p38 MAP kinases are downstream from G₁₃ [67], and it has been proposed that this heterotrimeric G protein can initiate the activity of the p38 pathway by stimulating Ask, a MAPKKK for this cascade [68]. It is expected that the use of novel techniques, such as RNA interference or the generation of knockout animals for molecules acting upstream of p38, will enable the molecular dissection of the mechanisms by which GPCRs and other cell surface receptors activate each member of the p38 family of MAPKs.

G-Protein-Independent Signaling

It has now become evident that the extent of heptahelical receptor signaling reaches beyond signal transduction pathways that are downstream of G α and G $\beta\gamma$ subunits. Recent work suggests that GPCRs interact with a wide range of signaling molecules besides heterotrimeric G proteins. Molecules containing protein-protein interaction domains such as the PDZ, SH2, and SH3 motifs, as well as polyproline-containing regions, have been reported to directly interact with GPCRs (reviewed in [69]).

These specialized domains could serve GPCRs as cell-specific bypasses from trimeric G-proteins to activate intracellular signaling in some cellular contexts. Several signaling proteins containing these protein-protein interaction motifs have been shown to bind heptahelical receptors. For example, the PDZ domain interacts with proteins containing a C-terminal S/TxV(L/I) sequence common in GPCRs. SH2-containing molecules such as the adaptor Grb2 and the SH2-containing tyrosine phosphatase SHP (reviewed in [69]) have been reported to bind to the β_2 -adrenergic and AT_{1A} receptors, respectively. Other domains that have been reported to bind GPCRs are the polyproline-binding domains, such as SH3, WW, and EVH domains [5,70]. For example, metabotropic glutamate receptors (mGluRs) interact with a class of molecules that harbor Enabled/VASP

homology (EVH)-like domains, such as Homer (1a-c, 2, and 3), which binds mGluRs through a C-terminal polyproline sequence (PPXXFP) (reviewed in [69]).

This expanded view of GPCR signaling, combined with emerging results showing that the *frizzled*, *smoothed*, and *Dictyostellium* cAMP receptors elicit biological responses that are independent of heterotrimeric G proteins, suggests a reevaluation of the “G protein-coupled receptor/heterotrimeric G protein associated effector” concept of heptahelical receptor function. Thus, some workers prefer terms other than “GPCR” in order to avoid using a designation that suggests a more limited range than the vast array of signaling cascades that these receptors actually control. Alternative terms include serpentine, seven-transmembrane, or heptahelical receptors [71]. Such a wide range of signaling possibilities requires strict organization among the signaling molecules that are downstream of GPCRs. One emerging example of how these downstream cascades can be physically organized intracellularly is a variety of scaffolding molecules that tether multiple components of signal transduction pathways in specific configurations.

GPCR Effectors Are Organized by Scaffolding Molecules

Heptahelical receptors stimulate physiological cell growth via a variety of tightly regulated signaling modules. In the past decade, scaffolding proteins have emerged as general regulatory mechanisms ensuring the fidelity of intracellular pathways. These proteins bind components of signaling pathways, physically organizing them to enable physiological responses. The prototypical signaling scaffold is the yeast protein Ste5p, which binds the components of the yeast MAP kinase cascade leading to the mating response after activation of the pheromone GPCR [72–75] and has been suggested to maintain the signaling fidelity of this cascade [76]. Ste5p is particularly important to the mating pathway of yeast because unlike multicellular organisms, MAP kinase cascades share most of their components such as the PAK-like kinase Ste20p and the MEKK-like protein Ste11p [77–80]. Like scaffolds in multicellular organisms, however, Ste5p is expressed in a specific cell type: the haploid yeast cell. Thus Ste5p allows a generalized MAP kinase module to elicit a specialized physiological response in a particular cellular context.

Several scaffolds binding a variety of signaling pathways have now been described in multicellular organisms. These include the various MAP kinase pathways organized by scaffolding proteins such as kinase suppressor of RAS (KSR) and c-Jun terminal kinase interacting protein family (JIPs), the cAMP dependent cascades that rely on the A-kinase anchoring proteins (AKAPs) for tethering, and the multiple cell signals downstream of proteins that bind molecules of the β -arrestin class. In many cases, overexpression of these scaffolding proteins will inhibit cell transformation, suggesting that these molecules play an important role in

restricting the propagation of signaling events and preventing signal transduction cascades from causing pathological cell proliferation. Although there are very few published reports directly connecting G-protein-coupled receptors to these organizing molecules, we can expect that the relevance of scaffolding proteins to GPCR-induced transformation will become increasingly apparent in the foreseeable future because of their fundamental role in maintaining the integrity of biochemical routes connecting cell surface receptors to the nucleus.

KSR

KSR was first cloned in RAS suppressor screens by using *Caenorhabditis elegans* and *Drosophila* [81–83]. However, recent work has shown that KSR function is required for proper signaling between RAF-1 and ERK in both *Drosophila* [84,85] and *C. elegans* [86]. In these invertebrate systems, ablation of KSR by either RNAi [85] or mutation [86] prevented the efficient activation of MEK and ERK by constitutively active Ras. An intriguing finding is that overexpression of KSR has similar negative effects on preventing Ras-V12-induced tumorigenesis in *Drosophila* imaginal discs [84]. Roy *et al.* [85] have observed that wild-type KSR overexpression can only stimulate the ERK pathway if all other components binding KSR are concomitantly transfected; they suggest that the mechanism by which the overexpressed scaffolding protein prevents efficient signaling to ERK is through a stoichiometric excess of KSR isolating signaling components from each other.

The murine form of KSR was cloned concurrently with its invertebrate homologs [83,87]. Experiments in mammalian systems have paralleled results obtained in *Drosophila* and *C. elegans*. Transfection studies in NIH3T3 cells showed that KSR overexpression blocks RAS-induced transformation [88]. Moreover, KSR knockout mice are resistant to polyomavirus middle T-induced tumor formation [89], a finding that parallels results obtained with *Drosophila*. Mammalian KSR has been reported to bind $\beta\gamma$ subunits, preventing ERK activation [90]. This result is particularly interesting because it is the first known link between the KSR scaffold and G-protein-coupled receptors. Further work remains to elucidate the physiological role of $\beta\gamma$ subunit/KSR interactions and its effects on GPCR signaling to the ERK pathway.

JIP/IB Family of Scaffolding Molecules

The JIP/IB family of scaffolding proteins consists of three mammalian homologs JIP/IB-1, JIP/IB-1b, and JIP/IB-2 [91–93]. These molecules bind members of the mixed-lineage group of MAPKKK's (MLK) that have been reported to activate both JNK and p38 [94,95]. In addition, both IB1/JIP1 and IB2/JIP-2 have been found to bind the JNK MAPKK, MKK7 [93,96], and IB2/JIP-2 has also been reported to bind the p38 MAPKK MLK3 [97] and p38 γ [98].

JIP-1 was originally described as an inhibitor of the JNK pathway that could block JNK-dependent cell growth and transformation [91]. Soon thereafter IB1, an alternatively transcribed isoform of JIP-1, was found in insulin-secreting cells [92]. Like KSR, the overexpression of JIP proteins inhibits the transmission of signals through the JNK pathway. However, the physiological function of this set of protein scaffolds seems to be to temper the activity of the JNK pathway, since cells derived from JIP-1 +/- heterozygous mice or cells depleted of endogenous JIP-1 with antisense RNA have augmented JNK activity [99–101]. These large increases lead to enhanced apoptosis in IL-1 β /TNF α /IFN-treated pancreatic β cells. In fact, a mutation in the human *IB1/JIP-1* gene has recently been linked to adult onset diabetes [100]. An emerging property of these scaffolding proteins is their ability to bind certain GDP exchange factors that activate the small G-proteins Rho and Rac. The Rho exchange factor p190RhoGEF binds JIP-1 through its phosphotyrosine binding domain (PTB) in neuronal and PC12 cells [102]. Recent work describes the binding of IB2/JIP-2 to the RAC exchange factor TIAM and the RAC/RAS exchange factor RAS-GRF1, thereby physically linking known activators of RAC to components of the p38 pathway, which have previously been reported to be downstream of this small GTPase [97]. TIAM is phosphorylated in response to the G-protein-coupled receptor ligands LPA, endothelin-1, bombesin, and bradykinin [103], and this protein modification is required for the proper localization of TIAM after LPA stimulation [104]. Thus, the JIP scaffolding proteins might link G-protein-coupled receptors to the JNK and p38 pathways by physically interacting with the small GTPase exchange factors activated by heptahelical receptors.

AKAPs

cAMP signaling was the first second messenger described [105,106]. Production of this nucleotide is controlled by adenylyl cyclases, a class of enzymes that are mostly controlled by heptahelical receptors coupling to G proteins of the G_s class [107]. The best described target of cAMP is protein kinase A (PKA), a tetrameric enzyme that becomes activated upon binding to this nucleotide [108]. Activation of PKA does not occur randomly; instead a class of scaffolding proteins, the A kinase anchoring proteins (AKAPs), localizes PKA to specific sites of action [109]. These scaffolding proteins cannot be grouped together by homology, and are defined as AKAPs solely in terms of their capacity to bind PKA.

A common theme among AKAPs, besides their ability to bind PKA, is their multifunctional nature. A growing number of large, multivalent proteins that bind the PKA holoenzyme have been described. These proteins often serve as scaffolds for other signal transduction pathways or exhibit other functions in addition to binding PKA. For example, AKAPs now include proteins such as gravin, a protein that was first identified in patients with the autoimmune disease myasthenia gravis, and also binds protein kinase C (PKC) [110] and

three orthologous members of the WASP family of proteins that interact with the ARP2/3 actin polymerization unit WAVE1-3 [111] and respond to RAC signals [112,113]. Moreover, recent evidence suggests that WAVE3 and gravin function as tumor suppressors [114–116], and it is probable that more of these PKA-binding proteins will be shown to function as tumor suppressors.

One reason AKAPs might serve as tumor suppressors is that the G_s/cAMP pathway often serves as an inhibitor of cell proliferation. For example, PKA phosphorylates RAF-1 at serines 43, 259, and 621 [117]. Phosphorylation at serine 259 is critical for PKA-dependent inhibition of RAF-1 kinase activity *in vitro* and blocks RAF-1-dependent *in vivo* activation of ERK in COS cells. In addition, mutation of serine 43 to alanine blocked the ability of RAF-1 to bind RAS in response to cAMP increases. Thus, proper organization of cAMP signaling to PKA in the correct subcellular compartment may be critical in preventing other mitogenic pathways such as the PKC or ERK cascades from becoming overactive and promoting inappropriate cell proliferation.

Arrestin

G-protein coupled receptors are phosphorylated by the G-protein-coupled receptor kinase (GRK) family of proteins after ligand binding [118]. The scaffolding protein arrestin subsequently interacts physically with heptahelical receptors. Although this molecule has been primarily implicated in targeting GPCRs for endocytosis, arrestin has been also shown to couple GPCRs to the activation of Src-like kinases. This process apparently involves the formation of large multiprotein complexes that can include components of the MAPK and JNK cassettes [119,120]. For example, an arrestin-tethered multimolecular complex has been described in the Rac/Cdc42 independent activation of the JNK cassette MAPKKK ASK1 by G α_{12} [68]. It is interesting that arrestin only binds the neural-specific JNK3 isoform, suggesting that this scaffold enforces cell-type specificity in the activation of the JNK pathway by heptahelical receptors.

Conclusion: GPCR Biology Requires Both Signal Integration and Separation

The essential molecular events that GPCRs use to govern such a wide range of biological events seem elusive because of their apparent complexity. Classical second messenger-generating systems are now understood to be only a subset of the mechanisms that GPCRs use in physiological and pathological contexts. At first glance, this “brave new world” of complexity looks like a highly interconnected meshwork wherein signals derived from a GPCR can travel to any of a wide variety of end-points (Fig. 1). From our current standpoint, we cannot predict with any confidence which signaling pathway, of the many possible routes, will be activated by a heptahelical receptor. Yet this situation is not the case in biology: usually GPCR stimulation in a given context will

produce a repeatable result. Moreover, an emerging concept derived from recent studies with MAP kinases and other targets of GPCRs is that scaffold proteins are organizers and keepers of specificity. It may be as important to keep signals separate between closely related cascades, such as the MAP kinases, as it is to integrate them in a coordinated response.

Although physiological functions of GPCRs, including phenotypic differentiation and cell survival or death, most likely result from the integration of a complex network of signaling cassettes, it is probable that pathology induced by GPCRs, such as cancer or tissue hypertrophy, results from the breakdown of signal separation between targets downstream of these receptors. Recent advances in our understanding of GPCR-driven intracellular signaling networks and how they are organized by scaffolding proteins will provide a more global view of the general systems by which these receptors exert their numerous physiological roles and will elucidate their role in many pathological conditions. This new understanding may also point to novel approaches for pharmacological treatment of a variety of disease processes.

Signaling through G_z

Jingwei Meng and Patrick J. Casey

Department of Pharmacology and Cancer Biology,
Duke University Medical Center, Durham, North Carolina

General Properties

Tissue Distribution

G_z is a member of the G_i subfamily that contains a 41 kDa α subunit $G\alpha_z$ that possesses several properties that set it apart from other $G\alpha_i$ proteins [1–4]. First, the tissue distribution of $G\alpha_z$ is quite restricted, being found primarily in brain, retina, adrenal medulla, and platelets; expression is virtually undetectable in other tissues [4,5]. In adult rat brain, $G\alpha_z$ is expressed mainly in the hippocampus and, at modest levels, in the cerebellum and neocortex. $G\alpha_z$ is expressed in large neurons, such as cholinergic interneurons, but not striatal neurons [6]. During development of the mouse peripheral nervous system, $G\alpha_z$ is expressed at high levels in the superior cervical ganglion, dorsal root ganglion, and trigeminal ganglion; however, expression appears to be downregulated when mice reach the age of three weeks, except in the superior cervical ganglion. In the mouse central nervous system, expression of $G\alpha_z$ peaks at around the third postnatal week in whole brain; however, in the cerebellum the peak is observed around birth [7]. These findings suggest a possible role for G_z signaling in development of the nervous system.

Biochemical Properties

One of the more intriguing properties of $G\alpha_z$ that was noted when the protein was first studied is that the intrinsic rate of GTP hydrolysis by $G\alpha_z$, 0.05 min^{-1} , is quite low compared with most other G-protein α subunits [3]. This relatively weak GTP hydrolysis activity may be a result of a Ser substitution of the second Gly in a conserved GAGES sequence among G-protein α subunits [8]. This slow rate of GTP hydrolysis by $G\alpha_z$ suggests that it may participate in longer-duration signaling events than other $G\alpha_i$ proteins.

In addition, RGS (regulator of G-protein signaling) or RGS-like molecules (discussed in the section on RGS proteins) may play crucial roles in regulating G_z signaling due to their ability to enhance the slow GTP hydrolysis rate. The rate of GDP dissociation from $G\alpha_z$ is extremely slow and almost completely suppressed at Mg^{2+} concentrations greater than $100 \mu\text{M}$ [3]. Arachidonate and other unsaturated fatty acids selectively inactivate $G\alpha_z$ *in vitro* via a mechanism involving binding of negatively charged acidic lipid micelles to the nucleotide-free form of $G\alpha_z$ [9]. However, the biological significance of this unique lipid effect remains to be established.

Covalent Modifications

Unlike other members of the $G\alpha_i$ subfamily, $G\alpha_z$ lacks a consensus Cys residue near the carboxyl-terminus that is the site of modification by PTX-catalyzed ADP-ribosylation [3,4,10]. This makes $G\alpha_z$ a candidate for PTX-insensitive signaling processes. Another distinct property of $G\alpha_z$ is that $G\alpha_z$ can be phosphorylated both *in vitro* and in cells. Treatment of platelets with phorbol 12-myristate 13-acetate, thrombin, or a thromboxane A_2 analogue (U46619) activates protein kinase C (PKC). PKC activation both *in vitro* and *in situ* via permeabilized and intact platelets promotes rapid and stoichiometric phosphorylation of $G\alpha_z$ but has no effect on other members of the G_i subfamily, including $G\alpha_{i1}$, $G\alpha_{i2}$, $G\alpha_{i3}$, and $G\alpha_o$, or members of G_s subfamily [11]. Site-directed mutagenesis of potential PKC consensus sites revealed that Ser¹⁶ and Ser²⁷ of $G\alpha_z$ are responsible for nearly 80 percent of the total phosphorylation [12]. This PKC-mediated phosphorylation is effectively inhibited by the presence of $\beta\gamma$ complex, and phosphorylated $G\alpha_z$ has markedly reduced its ability to interact with the $\beta\gamma$ complex [13], suggesting that a $\beta\gamma$ contact site is around the amino-terminus of $G\alpha_z$.

near Ser²⁷. RGSZ1 (discussed in the section on RGS) is a G_z-selective RGS. Phosphorylation of Gα_z renders the α subunit much less susceptible to RGSZ1 action [14]. Taken together, PKC-mediated phosphorylation of Gα_z is thought to increase the strength and duration of G_z signaling by both preventing RGSZ1-enhanced GTP hydrolysis and re-formation of an α-βγ complex, although this hypothesis has not yet been directly tested.

Localization of Gα_z to the plasma membrane requires two lipid modifications: myristoylation Gly² during protein translation and palmitoylation on Cys³. Prevention of myristoylation by substitution of Ala for Gly² decreases palmitoylation on Cys³, but palmitoylation can be rescued by overexpression of βγ complex, suggesting that membrane association triggers a palmitoylation event [15,16]. Substitution of Ala for Cys³, which prevents palmitoylation, does not affect myristoylation during translation, suggesting that myristoylation, an irreversible modification, directly affects the cellular localization of Gα_z, while palmitoylation, a reversible modification, is more important for the interaction between Gα_z and its possible effectors and regulators [15,17].

Receptors That Couple to G_z

Many receptors that couple to G_i proteins can also activate G_z if the receptors are overexpressed in cells. In reconstituted lipid vesicles, nucleotide exchange of Gα_z is stimulated when m2-muscarinic receptors are activated [18]. In HEK293 cells, expression of either A₁-adenosine, α₂-adrenergic, or D2-dopamine receptors together with wild-type Gα_z confers PTX-insensitive inhibition of adenylyl cyclase in response to receptor activation [19,20]. Opioid receptors, including μ, δ, and κ opioid receptors, have also been reported to couple to several members of the G_i subfamily, including Gα_z [21–23]. Clues to a receptor that preferentially couples to G_z have recently come from the analysis of Gα_z knockout mice (discussed in the section on Gα_z knockout mice). Mice lacking Gα_z have decreased platelet aggregation and impaired inhibition of cAMP formation in response to epinephrine [24]. Since evidence indicates that the ability of epinephrine to promote platelet activation is mainly due to its ability to inhibit adenylyl cyclase via α_{2A}-adrenergic receptors [25], and the epinephrine response is lost even though the platelets still contain their normal complement of Gα_i proteins, it seems that α_{2A}-adrenergic receptors preferentially couple to G_z in platelets. This preferential coupling was further confirmed in experiments with PC12 cells expressing wild-type Gα_z. When these cells are challenged with cAMP analogue or nerve growth factor (NGF), treatment with a specific agonist to α_{2A}-adrenergic receptors, UK14304, attenuates PC12 cell differentiation; such an effect is not observed in these cells in the absence of Gα_z expression [26]. This pathway is discussed further in the section on effectors of G_z signaling.

Regulators of G_z Signaling: RGS Proteins

RGS proteins act as negative regulators of G-protein signaling by binding to, and enhancing GTP hydrolysis of, G-protein α subunits. Several RGS proteins that have been identified (at least 20 are known in mammals) selectively act on members of the G_i subfamily, including G_z. These include GAIP [27], RGS4 [28], and RGS10 [29]. In addition, an RGS protein identified through both biochemical and interaction-cloning approaches, termed RGSZ1, selectively acts on Gα_z but not on other members of G_i subfamily [14,30]. It is not clear whether these specific RGS proteins function only as negative regulators of G-protein signaling, or whether they can also function as effectors of G proteins or as adaptors linking Gα_z to other signaling pathways. Hints at such a process have arisen from studies indicating that RGSZ1 binds to the stathmin family member SCG10 and inhibits its microtubule disassembly functions, suggesting that RGS proteins have a broader role in cellular signaling [31].

Effectors of G_z Signaling

Although the cellular processes controlled by G_z activation are not well understood, activated Gα_z does possess an ability to inhibit some subtypes of adenylyl cyclase, a property shared with other members of the G_i subfamily [20,32]. Since expression levels of other members of the Gα_i subfamily are much higher than that of Gα_z, it is widely believed that the ability of Gα_z to inhibit adenylyl cyclase activity is largely masked and Gα_z has other unique, and presumably important, cellular functions. In this regard, stable expression of mutationally activated Gα_z can transform Swiss3T3 and NIH3T3 cells by stimulating mitogenic pathways. It is interesting that this stimulation is apparently unrelated to the ability of Gα_z to inhibit adenylyl cyclase [33].

Quite recently, potential clues to additional functions of Gα_z have emerged from yeast two-hybrid screens such as the one that resulted in the identification of RGSZ1 as a specific regulator of Gα_z. Two additional molecules were also identified in this screen that selectively interacted with mutationally activated Gα_z. These molecules were Rap1GAP, a GTPase-activating protein for the Ras-like monomeric G protein Rap1, and a transcriptional coactivator termed Eya2. There is emerging evidence that the interaction of Gα_z with each of these molecules has direct functional consequences. Eya2 interacts with transcription factors of Six family; this interaction results in a translocation of Eya2 from the cytosol to the nucleus. Expression of constitutively active Gα_z blocks this process by competing with Six4 in an activation-dependent manner [34].

The physical interaction between Gα_z and Rap1GAP blocks the ability of RGS proteins to stimulate GTP hydrolysis of the α subunit, and also attenuates the ability of activated Gα_z to inhibit adenylyl cyclase. In addition, co-precipitation assays revealed that Gα_z, Rap1GAP, and Rap1 could form a stable complex [35]. In cell-based studies,

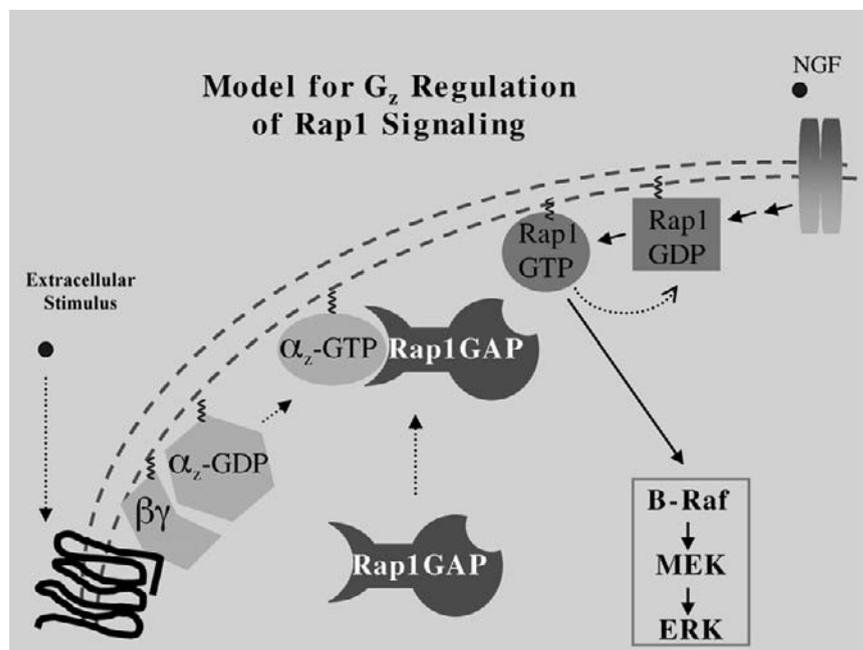

Figure 1 Model for Rap1GAP involvement in G_z signaling in neuronal cells. In the model shown, activation of Rap1 by elevated cAMP or NGF binding to its receptor leads to activation of a MAP kinase cascade that triggers cell differentiation. Concurrent activation of G_z by ligation of an appropriate G-protein-coupled receptor leads to recruitment of Rap1GAP to the membrane with subsequent downregulation of Rap1 signaling.

activated forms of $G\alpha_z$ were able to recruit Rap1GAP from a cytosolic location to the plasma membrane. Experiments in PC12 cells demonstrate that Rap1 activation, ERK phosphorylation, and cell differentiation induced by either cAMP analogue or NGF treatment were all blocked by either transfection of constitutively-activated $G\alpha_z$ or receptor-mediated G_z activation [26]. Based on these findings, a model has proposed in which receptor-mediated activation of G_z results in recruitment of Rap1GAP to the plasma membrane, where it can effectively downregulate Rap1 signaling (Fig. 1).

$G\alpha_z$ Knockout Mice

$G\alpha_z$ knockout mice have been generated by two independent groups [24,36]. $G\alpha_z$ null mice are viable and no major phenotypes associated with loss of $G\alpha_z$ have yet been described. As already noted in the section on receptors that couple to G_z , however, one group has reported that platelet aggregation in response to challenge with epinephrine and collagen is impaired in the $G\alpha_z$ knockouts [24]. Furthermore, both groups have reported that $G\alpha_z$ knockout mice exhibit abnormal responses to certain psychoactive drugs, including a pronounced increase in locomotor activity in response to cocaine administration and a reduction in the analgesic effects of morphine.

One particularly intriguing phenotype of the $G\alpha_z$ null mice was a complete loss of the antidepressant effects of catecholamine reuptake inhibitors, suggesting that the signaling

pathways invoked by antidepressant drugs of the norepinephrine reuptake inhibitor class are mediated primarily through G_z [24]. The physiological effects of this class of drugs are thought to be mediated at least in part through increased neurogenesis at the expense of cell differentiation [37,38]. The afore-mentioned findings that activation of G_z attenuates PC12 cell differentiation may provide a link between these observations. It is tempting to speculate that G_z signaling plays an important role in cell fate determination of neuronal cells. In this scenario, treatment with antidepressant drugs leads to increases in circulating norepinephrine that binds to G_z -coupled receptors, and subsequent activation of G_z leads to suppression of signaling pathways that promote cell differentiation and thereby allow cell proliferation associated with neurogenesis. In $G\alpha_z$ knockout mice, treatment with this class of antidepressant drugs cannot lead to activation of G_z and its downstream effectors, resulting in increased cell differentiation without further neurogenesis.

Summary

Although the precise role(s) of G_z in cellular signaling remain to be established, accumulating evidence points to the involvement of G_z in platelet function and, what is especially interesting, neurogenesis. It is intriguing to speculate that G_z may play a crucial role in determining cell fate during early brain development and later in neurogenesis in adulthood. Through subtle but extremely important actions,

G_z could participate in such critical brain functions as learning and memory [39,40].

Effectors of $G\alpha_o$ Signaling

Prahlad T. Ram, J. Dedrick Jordan, and Ravi Iyengar

Mount Sinai School of Medicine, New York, New York*

Introduction

Heterotrimeric G proteins transduce signals through a wide variety of intracellular signaling pathways. Signaling pathways activated by G proteins vary depending on the identity of the specific alpha subunits. Direct effectors of the $G\alpha_o$ subunit are largely unknown, but recent work using yeast two-hybrid analysis [1] and screening a cDNA expression library [2] has yielded exciting new data and helped identify proteins that directly interact with $G\alpha_o$ and may serve as effectors. Some of the direct effectors identified by these methods include the GTPase activating protein for the small G protein Rap (Rap1-GAP), the GAP from the large G protein $G\alpha_z$ (G_z -GAP), the regulator of G-protein signaling 17 (RGS-17), and the G-protein regulated inducer of neurite outgrowth (GRIN). In addition to the direct effectors, some of the signaling pathways that are activated downstream from $G\alpha_o$ have also been identified. These include mitogen activated protein kinase 1,2 (MAPK 1,2) [3], the nonreceptor tyrosine kinase Src [4,5], signal transducer and activator of transcription 3 (Stat3) [5], and phospholipase C (PLC) [6]. In this chapter we will detail the direct effectors as well as the other downstream signaling pathways activated by $G\alpha_o$.

Heterotrimeric G proteins comprise α , β , and γ subunits. In the inactive state the $G\alpha$ subunit is bound to GDP and the $G\beta\gamma$ dimer, and this trimeric complex is associated with the receptor. Upon activation there is an exchange of GDP for GTP on the $G\alpha$ subunit and a dissociation from the $\beta\gamma$ dimer. The GTP bound $G\alpha$ is then able to bind and activate its effector molecules, as is the $\beta\gamma$ dimer in certain instances. The downstream signal specificity is dependent on the identity of the $G\alpha$ subunit. There are currently four families of $G\alpha$ subunits: $G\alpha_s$, which activates adenylyl cyclase (AC); $G\alpha_i$, which inhibits AC of which $G\alpha_o$ is a member; $G\alpha_{q/11}$,

which activates phospholipase C; and finally $G\alpha_{12/13}$. Although the α subunits may activate some overlapping downstream signaling pathways, there are substantial differences between the individual members. Within the family of subunits, whereas the α subunits share common downstream targets they also associate with the common receptors that lead to their activation. A more detailed review of the richness of diversity among G-protein-coupled receptors, downstream targets, and physiological processes regulated by the various families of $G\alpha$ subunits has recently been published [7].

Of all the members of the $G\alpha$ subunits one of the more difficult to understand functionally has been $G\alpha_o$. $G\alpha_o$ was identified from bovine brain extract and is one of the most abundantly expressed proteins in the brain, making up almost 1 percent of the membrane proteins [8]. $G\alpha_o$ is present at high levels in the growth cones of neurons, and observations suggest a role for $G\alpha_o$ in regulation of neurite outgrowth [9,10]. Although $G\alpha_o$ is most abundantly expressed in the brain, other tissues have also been shown to express $G\alpha_o$, including the adenohypophysis, heart, kidney medulla, olfactory epithelium, and chromaffin cells [11].

$G\alpha_o$ is a member of the $G\alpha_i$ family of G proteins and has about an 80 percent homology to $G\alpha_{i1}$, but it does not appear to inhibit several forms adenylyl cyclase activity [12]. Early studies suggested a role for $G\alpha_o$ in coupling opiate and dopaminergic signals to the inhibition of voltage-sensitive calcium channels in neurons [13]. $G\alpha_o$ has also been shown to couple the f-met-leu-phe (FMLP) receptor to PLC in HL-60 leukemia cells [14], the muscarinic receptor to PLC in *Xenopus* oocytes [15], and the α_2 receptor to MAPK 1,2 in CHO cells [3]. Most $G\alpha$ subunits contain an intrinsic GTPase domain that hydrolyses the GTP to GDP, thereby inactivating the GTP-bound $G\alpha$. Mutation of this intrinsic GTPase domain results in a constitutively active $G\alpha$ subunit. The GTPase deficient $G\alpha_o$ subunit (Q-205-L)

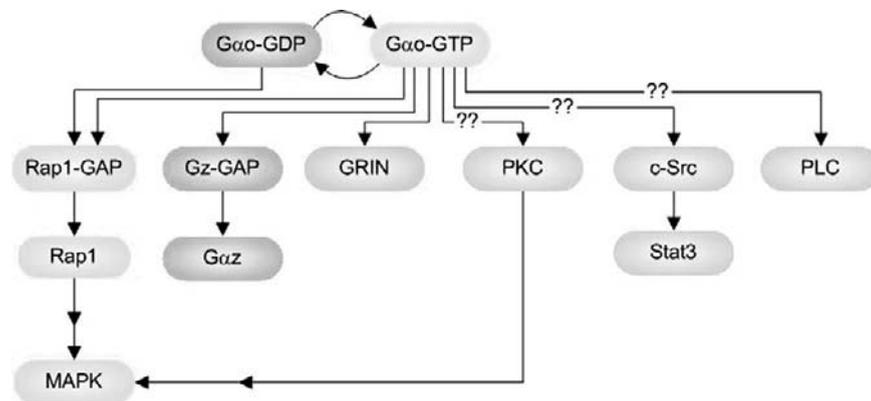

Figure 1 Effector pathways regulated by $G\alpha_o$. $G\alpha_o$ in the active GTP-bound or inactive GDP-bound state can regulate diverse signaling molecules. Not all pathways are likely to be present in all cell types. The regulation of multiple pathways allows for an increased complexity in the biological response to $G\alpha_o$ signaling.

has been used to identify physiological effects of $G\alpha_o$ (Q-L) expression in heterologous systems such as in *Xenopus* oocytes and mouse fibroblast cells [16,17]. This constitutively active mutant has also been a very useful tool to delineate and identify $G\alpha_o$ -activated signaling pathways and putative direct effectors. The direct effectors and signaling pathways activated by $G\alpha_o$ are shown in Fig. 1.

By using yeast two hybrid we have identified proteins that can interact with $G\alpha_o$, and the concomitant use of either the inactive or the active $G\alpha_o$ subunit has allowed the identification of binding partners that can preferentially bind to either the inactive or the active $G\alpha_o$ subunit [1]. A chick dorsal root ganglia (DRG) neuron library was used for the two-hybrid analysis. The reason for using the chick DRG was that this is a model system in which the effects of activating $G\alpha_o$ have been well characterized [18]. The direct binding partners identified from the DRG neurons included Rap1GAP, Gz-GAP, RGS17, and GRIN3 [1]. One of the interesting aspects of this study was that Rap1-GAP binds the inactive or GDP- $G\alpha_o$ preferentially over the active or GTP- $G\alpha_o$. In addition, the interactions between $G\alpha_o$ and Rap1GAP lead to a change in Rap1 activity, whereby the binding of $G\alpha_o$ and Rap1GAP relieves the inhibitory effect of Rap1GAP on Rap1, leading to the activation of Rap1 [1]. The sequestration of a negative regulator to activate a third molecule was a novel finding in signaling via G-protein-coupled receptors.
