Preface

Fungal cellular and molecular biology has entered an unprecedented phase of rapid growth and change. The availability of complete genome sequences, coupled with the advent of new genetic and molecular tools, has made possible analyses that were deemed unthinkable just a few years ago. In the current environment, it is advantageous to have access to books that synthesize and rationalize the new information gleaned from genomics with the accumulated literature from years of research in the field.

Our goal was to organize a book that will be a major work on the filamentous fungi, serving as the first point of reference for this important group of organisms. We envisioned producing a handbook for professional researchers and graduate students in the field, as well as a textbook for graduate and undergraduate courses. Although model organisms are covered in detail, we strove to represent the diversity of the fungal kingdom. The chapters in this book cover a variety of dimorphic and "obligate" filamentous fungal species, illustrating lifestyles adapted to diverse ecological niches. Chapters also provide comparisons to work with the yeasts *Saccharomyces cerevisiae* and *Schizosaccharomyces pombe*, as appropriate. Every effort has been made to incorporate new data from genomics-based approaches and to provide well-grounded evaluation of the literature.

We are indebted to the many authors who made this book possible. All took time out from already overextended schedules to write chapters that are comprehensive and capture the essence of their field. In particular, we would like to acknowledge the efforts of Dr. Rowland Davis, Professor Emeritus at UC Irvine. Rowland suffered a severe stroke, yet emerged from a coma and extended time on a ventilator (during which time he could not speak) to ask about his reference list and permission to republish forms for figures! Rowland, you are an inspiration to the rest of us.

We recognize Dr. Michelle Momany for her efforts during the early stages of organizing the book. She was instrumental in developing the original outline and contacting prospective authors. New administrative duties as department head prohibited her from continuing with the project.

We thank ASM Press for having the foresight to solicit a book on filamentous fungi. We are indebted to Senior Editor Gregory Payne for first discussing the idea for this book with one of us (Borkovich) and then for his patience and advice as we solicited and read chapters and worked with the authors to create the best possible book. We thank Senior Production Editor Ellie Tupper, whose attention to detail and editorial standards are unsurpassed and are reflected in the final product.

Lastly, we would like to acknowledge those scientists (and mentors) who have passed away in the last few years and whose work laid the foundation for the information described in many of the chapters of this book. Among these are John Fincham, Norman Giles, Edward Garber, David Perkins, Dorothy Newmeyer, David Stadler, and Robert Metzenberg. Their enthusiasm for science and the study of filamentous fungi lives on in their scientific "descendants."

Cellular and Molecular Biology of Filamentous Fungi
Edited by K. A. Borkovich and D. J. Ebbole

1

History and Importance to Human Affairs

JOAN W. BENNETT, ROWLAND DAVIS, AND CARLENE RAPER

The fungi have figured in folklore, myth, and art since ancient times. In 185 BCE, Nicander described a fungus as "the evil ferment of the earth." Centuries later, European herbalists speculated on the origin of such *earthy excrescences*, calling them bastard plants derived by spontaneous generation (Ramsbottom, 1953). Some believed fungi emanated from thunder. According to Ramsbottom, Caesalpinus described these organisms in 1583 as follows:

> Some plants have no seeds; these are the most imperfect, and spring from decaying substance; and they therefore have to feed themselves to grow. . . They are a sort of intermediate existence between plants and inanimate nature.

In the 18th century Linnaeus classified fungi as bona fide organisms belonging to a subgroup within the plant kingdom. Until a few decades ago, fungi were grouped with "cryptogams" (plants without flowers or seeds). Academics who studied them generally resided within Departments of Botany or Colleges of Agriculture. Now known to resemble animals more than plants, true fungi have been split off from other heterotrophic cryptogams such as the slime molds and Oomycota and are placed in a kingdom of their own (Barr, 1992; Baldauf and Palmer, 1993; Alexopoulos et al., 1996). Scientifically, they are studied primarily for their impact on human affairs and for what they can tell us about fundamental biological principles. In popular culture, many amateurs collect macrofungi for their food, hallucinogenic, tinder, or dye properties. A number of delightful books for popular reading are available, such as *The Romance of the Fungus World* (Rolfe and Rolfe, 1925); *Magical Mushrooms, Mischievous Molds* (Hudler, 1998); *Slayers, Saviors, Servants, and Sex. An Expose of the Kingdom Fungi* (Moore, 2001); and *Mr. Bloomfield's Orchard* (Money, 2002).

Fungi possess all the basic attributes of eukaryotes, including membrane-bound nuclei, chromatin, mitochondria, vacuoles, and cytoskeleton. Like plants, they grow in a polar manner, and walls, chemically different from those of plants, bind their cells. Physiologically, however, they resemble animals more than plants. They also encompass unique characteristics. Perhaps their single most distinct feature relates to nutritional strategy. Fungi, as heterotrophs, literally live in both their food and waste. Lacking chlorophyll, they generally use a variety of carbon and nitrogen sources to make virtually all the vitamins and amino acids necessary for life. They inhabit a broad spectrum of environmental niches spanning a wide range of food sources, temperature, and moisture. They travel primarily through spore dispersal. While vegetative fungal cells are essentially aquatic, their differentiated spores, whether vegetative or sexual, can survive dry, harsh environmental conditions over extensive periods of time. Fungal spores are found in the air at great heights all over the world.

Because of their nutritional versatility, fungi perform many essential roles in global ecosystems. As carbon recyclers, they figure importantly in biomass degradation and in helping plants forage nutrients through the formation of mycorrhizae (Isaac, 1992). On the other hand, many forms feed off crop plants. Fungal blasts, blights, and mildews have been known since the beginning of agriculture. Chestnut blight, Dutch elm disease, potato light blight, wheat rust, corn rust, rice blight, and coffee rust are all caused by various species of fungi. In fact, the vast majority of plant pathogens are fungi (Large, 1940; Money, 2007).

Several species attack animals as well. It is not widely appreciated that Agostino Bassi, an Italian scientist working well before Pasteur and Koch, proposed a microbial theory of disease based on his studies of a fungal disease of silkworms called muscardine. Following earlier work on sheep breeding and cheese production under such luminaries as Spallanzani and Volta at the University of Padua, Bassi spent several years studying muscardine. By 1835 he had identified the causative agent as a fungus similar to *Botrytis* that could transmit the disease through infection of its powdery spore mass from diseased insects to healthy ones. Ten years later, Bassi extended his contagion theory to human diseases such as cholera, gangrene, plague, rabies, typhus, and smallpox. He also published on the importance of chemical disinfection and the use of heat for sterilization.

Joan W. Bennett, Department of Plant Biology and Pathology, School Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ 08901. **Rowland Davis,** Department of Biological Sciences, Molecular Biology and Biochemistry, University of California, Irvine, CA 92697. **Carlene Raper,** Department of Microbiology and Molecular Genetics, University of Vermont, Burlington, VT 05405.

Pasteur later cited Bassi in several of his writings and is said to have kept a copy of Bassi's portrait in his office (Major, 1944; Porter, 1973). Unfortunately, most introductory microbiology books do not mention Bassi's groundbreaking contribution to germ theory.

While few fungi are obligate animal pathogens, some facultative species cause severe illness in humans, particularly in those who are immunocompromised. Among these are *Aspergillus fumigatus*, *Candida albicans*, *Cryptococcus neoformans*, and *Histoplasma capsulatum*. Up-to-date research on these animal pathogens as well as several plant pathogens is presented in this volume on filamentous fungi.

In addition to their ability to cause disease, many fungi damage materials useful to mankind by invading stored foods, fabrics, lumber, cellulose, and even plaster and cement. A few species have been identified as possibly related to "sick building syndrome." Others contaminate postharvest crops and produce toxic substances. Yet in truth, most fungi are harmless, even helpful to humankind. Sometimes their degradative powers can be harnessed for bioremediation (Bennett et al., 2001). They are also important to a number of industries in the processing of food, paper, alcohol, drugs, and dyes; in the production of enzymes, organic acids, and antibiotics; and, of course, in the harvesting and cultivation of edible mushrooms (Tkacz and Lange, 2004; An, 2005).

The fungal kingdom provides a diversity of approachable models for studying an array of biological phenomena. A general capacity for making most of the essential vitamins and amino acids permits culturing of many species on defined media under controlled conditions in the laboratory. Short, predominantly haploid life cycles with propagation dependent on either asexual or sexual spore disposal facilitate genetic studies. A unique capacity for heterokaryosis (the mitotic reproduction of different types of haploid nuclei within a common cytoplasm) eases analyses of genetic complementation. With such advantages, the fungi provide a wealth of model systems for basic research on eukaryotic gene regulation, mitochondrial inheritance, senescence, cell cycle control, metabolism, signal sensing, circadian rhythms, and population genetics (Maheshwari, 2005).

Notable among these model systems is the ascomycete *Neurospora crassa*. George Beadle and Edward Tatum used this fungus to investigate how genes control metabolism, the complex series of enzymatic reactions required for making life-sustaining molecules (reviewed by G. W. Beadle [1948]). Beadle teamed first with Boris Ephrussi on experiments with the genetically tractable fruit fly *Drosophila melanogaster* but soon found that organism too complex to complete the goal in mind. Learning from earlier studies by B. O. Dodge and C. C. Lindegren about the unique advantages of *N. crassa* (then known as *Neurospora sitophila*, a contaminant of bakeries and sugar cane processing), Beadle, a corn geneticist, engaged Tatum, a biochemist, to employ this fungus instead. Using a simple defined medium to isolate a variety of nutritionally deficient mutants (auxotrophs), Beadle and Tatum capitalized on *N. crassa*'s haploid nature and its capacity for heterokaryosis and meiotic recombination to promulgate their famous "one gene one enzyme" hypothesis. Why not choose humans for such a study? While metabolic pathways can be studied in humans, the latter are not ideal organisms for examining gene function. As George Beadle put it (in a gender-biased phrasing of the time), "His life cycle is too long, his offspring are too few, his choice of a mate is not often based on a desire to contribute to the knowledge of heredity, and it is inconvenient to subject him to a complete chemical analysis." (Beadle, 1948). Beadle and Tatum received the Nobel Prize for their pioneering study of *Neurospora*. It opened a whole new field of biochemical genetics that extended to other organisms and reveals striking commonality in metabolic pathways throughout the biological world.

For the most part, Beadle and Tatum confirmed their hypothesis that single genes encode single enzymes, but later studies revealed exceptions. Using the heterokaryon complementation test to determine whether two mutations reside in one or more genes, Fincham and colleagues discovered that two particular mutants defective for the production of NADP-glutamate dehydrogenase in *N. crassa* complemented one another yet the mutations responsible resided within a single gene (Fincham and Pateman, 1957). They showed that this enzyme is a homomultimer, constituted of multiple polypeptides, all encoded by the *gdh* gene. Such exceptions seem to be confined to multimeric proteins. Studies with *Neurospora* and another ascomycete, *Aspergillus nidulans*, demonstrated that genes of a given metabolic pathway are usually scattered, not clustered within operons as in bacteria—an early insight on differences in gene arrangement between eukaryotes and prokaryotes. Subsequent studies on gene regulation of metabolic pathways revealed regulatory genes that initiate a cascade of gene activity. For example, when nitrate is substituted for ammonia in the medium of *N. crassa*, the *nit-3* gene encoding nitrate reductase is induced. This transcriptional response requires the activity of two genes, first *nit-2*, and then *nit-4*, which is induced by the presence of nitrate. When nitrogen sufficiency is achieved, *nit-3* transcription is turned off indirectly by the *nmr* gene product which binds with glutamine to block the action of the *nit-2* gene product (Marzluf, 1997). Many such Rube Goldberg schemes have been worked out first in the fungi, including yeast (*Saccharomyces cerevisiae*). Comparable examples of gene regulation have been shown to exist in more complex eukaryotes.

The advantages of working with *Neurospora*, *Aspergillus*, and other filamentous fungi are clearly evident in formal genetic studies, and there are several excellent textbooks that provide reviews of classical fungal genetics (Esser and Kuenen, 1967; Fincham et al., 1979; Bos, 1996). Early work by B. O. Dodge and Carl and Gertrude Lindegren during the 1920s and 1930s had established *N. crassa* as an organism "with absolutely orthodox genetics" (Ryan and Olive, 1961; Davis, 2000). The asci of *N. crassa* contain octads of ascospores. Meiosis yields a linear tetrad in which the products of the first meiotic division remain in either the upper or lower halves of the tetrad; the products of the second division remain adjacent in each half, and sister spores remain adjacent. Robin Holliday, using the technique of tetrad analysis in *N. crassa*, developed an important model of DNA recombination. The rare aberrant ratios of 6:2 or 5:7 rather than the 4:4 ratio expected for segregation of two alleles of a single gene were explained as events of gene conversion. Holliday observed that gene conversion correlated positively with recombination and suggested that conversion took place not at single mutational sites but in conversion tracts (segments of chromosome). He posited that such conversion was a by-product of meiotic recombination, resulting in loss of information in one chromosome and its repair through use of the homologous chromosome as template during synapsis. Holliday thus proposed an innovative model of DNA strand exchange known as the Holliday junction (Holliday, 1964).

The foundations of mitochondrial genetics and mitochondrial function originated with studies involving the

yeast *S. cerevisiae* and the filamentous *N. crassa*. Both fungi have served significantly in our understanding of vacuolar function and the role that this organelle plays in nitrogen and phosphate storage and amino acid metabolism (Mitchell and Mitchell, 1952; Davis, 2000).

Since the earlier classical studies, fungal research has progressed rapidly with the advent of molecular biology. It is now possible to extract, manipulate, and amplify genes for reintroduction into most model fungi and thus determine cause and effect from genotype to phenotype. While such manipulations can apply to human cell cultures, they are not as easily manageable in the living, breathing human.

Application of the molecular toolbox to model fungal systems has advanced our understanding of a host of biological principles described in this volume. For example, genetic control of the eukaryotic cell cycle, first studied in depth in the yeast *S. cerevisiae*, was also probed in *A. nidulans* by Ron Morris and associates. They identified genes responsible for the mechanisms of nuclear migration and cellular growth that suggested comparable mechanisms for nuclear migration in developing neurons of the mammalian brain (Morris, 1975, 2000).

Nevertheless, *N. crassa* remains the dominant filamentous fungal model, in part because of the strong scientific community involved in its use (Davis, 2007). For example, finite mechanisms of gene silencing with parallels in other organisms have been elucidated in *N. crassa*. The first discovered is the premeiotic repeat induced point mutation (known as "RIP") phenomenon. It was discovered by inserting stretches of DNA identical to resident DNA into the genome and noting that both the introduced and resident copies become heavily mutated by methylation, thus destroying function (Singer and Selker, 1995). Other schemes of gene silencing, also discovered in *N. crassa*, involve RNA. Quelling, which is related to RNA interference in animals, occurs posttranscriptionally in DNA-transformed cells through the combined action of RNA-dependent RNA polymerase and other (dicer) components (Catalanotto et al., 2004; Fulci and Macino, 2007).

Details on the stages of meiosis have come from research with *Coprinus cinereus* (recently renamed *Coprinopsis cinerea*). Mimi Zolan and Pat Pukkila have taken advantage of a unique attribute of this basidiomycete. Its process of meiosis can be synchronized by an appropriate regime of light versus dark (Pukkila et al., 1985). Light sensing figures prominently in the discovery of the underlying mechanisms of circadian rhythms. Jay Dunlap, Jennifer Loros, and associates have led the way in a detailed molecular analysis of the numerous genes and proteins responsible for *N. crassa*'s physiological accommodation to the light-dark cycle that affects all organisms. Their work laid the groundwork for extended studies in other organisms such as the fruit fly and humans, in which numerous commonalities have been revealed (Bell-Pedersen et al., 1996; Dunlap, 1999).

Signaling and sensing are central to mate recognition among the fungi. An astonishing range of sexual expressions exists throughout the kingdom. Following Blakeslee's 1904 discovery of a sexual cycle with two mating types in the Mucorales, a host of studies defined a variety of sexual mechanisms in other species. Notable among these were the independent works of Kniep (1920) and Bensaude (1918), who first described an incompatibility system with multiple sexes in the mushroom-bearing basidiomycetes *Schizophyllum commune* and *Coprinus lagopus* (synonym *Coprinopsis cinerea*). John and Carlene Raper, Lorna Casselton, and their associates extended these studies leading to the molecular investigations included in this volume.

The fungi express seven different patterns of sexuality. Raper bemusedly speculated that such multifarious lifestyles suggest that Mother Nature used the fungi as a testing ground for all possible ways to accomplish sex. This wealth of sexual mechanisms provides fortuitous material for exploring the genetic and molecular controls of the sexual process. John Raper wrote a book called *Genetics of Sexuality in the Higher Basidiomycetes* over 40 years ago (1966), in which he aptly noted, "Perhaps the most important development in the evolution of the fungi was the emergence of the complex and interrelated features of incompatibility, heterokaryosis and the incorporation of the dikaryon as an integral phase of the sexual cycle." Joe Heitman, James Kronstad, John Taylor, and Lorna Casselton edited the recently published book, *Sex in Fungi* (2007), documenting the enormous progress made in this field since Raper's book. In light of more recent discoveries, the underlying mechanisms of sexual diversity, noted by Raper decades ago, involve molecules of ancient origin that figure prominently in development and sensing throughout the biological world.

We now know that the elaboration of multiple mating types (thousands in the Higher [Homo] Basidiomycetes) evolved from two genetic complexes regulating the two mating types in the Ascomycetes, Hemiascomycetes, and Hemibasidiomycetes. One set of genes encodes transcriptionally regulating homeodomain proteins comparable to other homeodomain proteins that regulate development and differentiation in many animals including worms, flies, and humans (Casselton and Kues, 2007). The other set of genes encode pheromones and pheromone receptors similar to molecules that regulate odor, taste, and sight in flies and mammals (Fowler and Vaillancourt, 2007). Bipolar mating type systems predominate in the Ascomycota, while the Homobasidiomycetes have numerous versions of these important regulator genes. Interestingly, the pheromone and receptor genes of the homobasidiomycete *S. commune* can be expressed in the hemiascomycete *S. cerevisiae* by using the yeast's native processing enzymes, thus indicating important connections between distantly related species (Fowler et al., 1999). Research with the model species *S. commune* and *Coprinopsis cinerea* provides unique opportunities for understanding how so many different versions of these genes function at the molecular level to detect compatible mates.

Not all fungi engage in sex. Among the currently defined 100,000 species, well over 17,000 have no known sexual state (Hawksworth et al., 1983; Hawksworth and Rossman, 1997). These "asexual" fungi are variously called anamorphic, mitosporic, "the fungi imperfecti," or Deuteromycetes. Before the use of nucleic acid characters in taxonomy, they posed serious challenges to classification (Reynolds and Taylor, 1993). They include many microfungi important in agriculture, industry, and medicine. *Aspergillus niger* is one such species. Pontecorvo and colleagues (1953) discovered a rare process of genetic recombination in this fungus, in which haploid nuclei occasionally fuse, form somatic diploids, and then proceed through a series of haploidizations. They called it parasexuality. Using *A. nidulans*, a species with a sexual phase that taxonomists and GenBank call *Emericella nidulans*, the Pontecorvo group demonstrated the value of parasexual analysis for mapping genes onto chromosomes, a method used for decades in mammalian cell genetics (Pontecorvo, 1956). This process also proved useful for genetic mapping in other asexual species capable of heterokaryosis, such as members of the antibiotic-producing penicillia (MacDonald, 1983) and aflatoxin-producing

species of *Aspergillus* (Bennett and Papa, 1988). Recombinant DNA manipulations, gene cloning, expression libraries, transcriptional profiling, and the sequencing of entire genomes have been a boon to genetic analysis of all fungi, but particularly to those lacking a sexual cycle (Bennett and Lasure, 1985, 1991; Prade and Bohnert, 2003; Goldman and Osmani, 2008).

Genome projects create databases that greatly accelerate the process of gene discovery across the biological world (http://www.genomesonline.org/). Not surprisingly, the power of entire genomes has proven irresistible to the mycological community. The last 10 years have seen an explosive growth in the number of fungal species that have genome projects (http://www.genomesonline.org/gold.cgi?want=Eukaryotic+Ongoing+Genomes). Genome projects have been particularly useful for well-developed genetic systems such as *N. crassa* (Borkovich et al., 2004) but also for poorly characterized nonsexual species such as *A. fumigatus* (Nierman et al., 2005). However, in general, our ability to exploit these voluminous in silico data has lagged behind our capacity to acquire them, and this increasing gap has highlighted the importance of experimental manipulations in biology.

This volume is a testament to the continuing robustness of fungal systems as a source of insight into all of the life sciences.

Rowland Davis actively and enthusiastically organized the early stages of planning this chapter, but because he suffered a serious stroke on May 11, 2008, he was unable to participate in the writing. J.W.B. and C.A.R. thank him for his inspiration but take responsibility for any errors of content and style in this final version.

Hyphal Structure

ROBERT W. ROBERSON, MARITZA ABRIL, MEREDITH BLACKWELL, PETER LETCHER, DAVID J. McLAUGHLIN, ROSA R. MOURIÑO-PÉREZ, MERITXELL RIQUELME, AND MAHO UCHIDA

Structure is a fundamental element of the physical world. It is so basic that we can often overlook its profound significance. Structure exists at all levels of organization, from atomic particles to the universe. There is a continuum of structured levels with a higher-level structure often composed of multiple copies of a lower-level structure. Concepts such as order, connection, morphology, recognition, organization, and function are all associated with the perception of structure. How structure originates, develops, matures, reproduces, evolves, reacts, and ultimately dies is the motivation underlying most approaches of inquiry and discovery in the sciences (Pullan and Bhadeshia, 2000).

The defining feature of filamentous fungi is the hypha. Hyphal growth provides the means for colonization of substrates, secretion of hydrolytic enzymes, nutrient assimilation, regulation of morphogenesis, and recognition of environmental signals. Hyphae also function as gametes in sexual reproduction in many fungi and differentiate into a variety of structures such as the paraphyses in ascomycete fruiting bodies; thick-walled, clampless skeletal and binding hyphae, cystidia, and setae in basidiomycete fruiting bodies; and infectious structures such as appressoria and haustoria.

Hyphal growth and differentiation are complex processes requiring the control of cell wall synthesis, polarized vesicle transport, exocytosis, endocytosis, turgor pressure, organelle positioning, and cytoplasmic migration and fusion. The result is a polarized system of growth giving rise to a tubular cell. The components that make up the cytoplasm of hyphae, and for that matter all cells, are assembled into a dynamic, interconnected, and structured unit that provides the foundation for growth and morphology. Indeed, all aspects of cellular behavior are supported by the underlying structure of the cytoplasm. The hyphal cytoplasm contains many of the organelles and subcellular inclusions found in other heterotrophic eukaryotic organisms. However, because of their mode of growth and diverse interactions with the ecosystem, hyphae also maintain a cytoplasmic structure and contain organelles and inclusions that are unique to the fungi. Some features show significant structural plasticity within the fungi themselves or are present only in certain fungal groups. Such features (e.g., Spitzenkörper, cytoskeletal order, septal structure, and nuclear division) are of particular importance in understanding aspects of hyphal behaviors and have been used as indicators of evolutionary relationships. Recently, a community level effort and a multigene approach have resulted in a stable phylogenetic classification of fungi to the level of order (Hibbett et al., 2007). As part of this effort, the Assembling the Fungal Tree of Life Structural and Biochemical Database (AFTOL, 2007) has been established as a developing repository of images and references to studies on the topic (Celio et al., 2006).

Much of our knowledge of hyphal structure has come from decades of intensive study of these cells by light microscopy (LM) and transmission electron microscopy (TEM). In the late 1950s and 1960s the work from several laboratories illustrated the utility of bioimaging methods in elucidating hyphal cytoplasmic structure. In 1957, Girbardt described cytoplasmic organization and behavior in living hyphae of *Trametes versicolor* (Basidiomycota) by using phase-contrast LM (Girbardt, 1957). This work was coupled to ultrastructural studies using TEM and three-dimensional reconstruction methods (Hawker, 1965; Bracker, 1967; Girbardt, 1969) providing an unprecedented view of hyphal structure. A few years later Grove and Bracker (1970) used LM and TEM to make a significant impact on understanding cytoplasmic order and emphasized its diversity among major fungal groups. These works and others paved the way

for further structural studies aimed at understanding hyphal growth, morphology, and fungal taxonomy and evolution (Kahn and Kimbrough, 1982; Kumar et al., 2007). The use of TEM for structural studies was strengthened in the late 1970s with the application of cryo-methods for ultrastructural investigations (Howard and Aist, 1979). When successful, ultrafast freezing and sub-zero degree dehydration significantly improves the preservation of many cell types and their subcellular structures compared to traditional preparation protocols, such as aqueous chemical fixatives and room temperature dehydration (Chandler and Roberson, 2009). As more researchers took advantage of these improvements, knowledge of fungal cellular structure grew rapidly (e.g., Howard, 1981; Vargas et al., 1993). The most recent advancement in ultrastructural research has been the application of electron tomography for high-resolution and three-dimensional analysis of internal cellular structures (Müller et al., 2000; Hohmann-Marriott et al., 2006). By the mid-1980s, the advancement in ultrastructural studies was supported greatly by the development of new tools for LM and live-cell imaging. Using high-resolution cameras, computer technology, and fluorescently conjugated molecular probes, the study of many structural components in space and time became possible (Spellig et al., 1996; Suelmann et al., 1997; Freitag et al., 2004; Mouriño-Pérez et al., 2006; Uchida et al., 2008).

Equipped with a better knowledge of cellular structure, and interfacing this with the strength of molecular biology, significant advancements can be made towards understanding the biology of a cell and organism. In this chapter, structural features of hyphae from diverse taxonomic groups are reviewed. Also addressed are characteristics of cytoplasmic order and selected organelles and features that are important in studies of hyphal growth and fungal phylogeny.

HYPHAL ORGANIZATION

The constitutive delivery of secretory vesicles from their sites of origin to the point of growth is carried out in a hyphal cytoplasm that maintains a highly polarized order (see also chapter 19). Hyphae maintain this polarity in order to sustain three main processes: synthesis of the cell wall, growth of the plasma membrane, and secretion of materials required for nutrition. The establishment and maintenance of cytoplasmic polarity is not unique to the fungal hypha. In fact, it is a fundamental characteristic of cell biology as evidenced by asymmetric cell division, cell motility, and the establishment of cell surface features (e.g., microvilli and flagella). The most obvious examples of cytoplasmic polarity found in most hyphae are the maintenance of the Spitzenkörper (i.e., the apical body) (see "Spitzenkörper" below) located at the growing apex of the cell and the alignment of most organelles and structures along the axis of growth. An example of polarized cytoplasmic order is illustrated in a hypha of *Neurospora crassa* (Ascomycota) and *Sclerotium rolfsii* (Basidiomycota) (Fig. 1).

The hyphal tip of most fungi can be partitioned into several regions based on cytoplasmic order. However, depending on the particular fungal taxon this order can vary. The apical dome, or region I (McDaniel and Roberson, 2000), begins at the tip of the cell and typically extends back 2 to 3 μm. This limited area is structurally simple; however, it is the site of highly active processes that are fundamental to hyphal growth and morphogenesis (e.g., vesicle motility, exocytosis, cytoskeletal dynamics, and cell wall biosynthesis). Mitochondria, occasionally smooth endoplasmic reticulum (ER), and in the Ascomycota, Woronin bodies are found in region I. As mentioned above, the primary structure at the apex of growing hyphae of septate fungi (i.e., Ascomycota and Basidiomycota) is the Spitzenkörper (Fig. 1 to 3). A structural equivalent of the Spitzenkörper is not common or has not been observed in hyphae or hypha-like cells (e.g.,

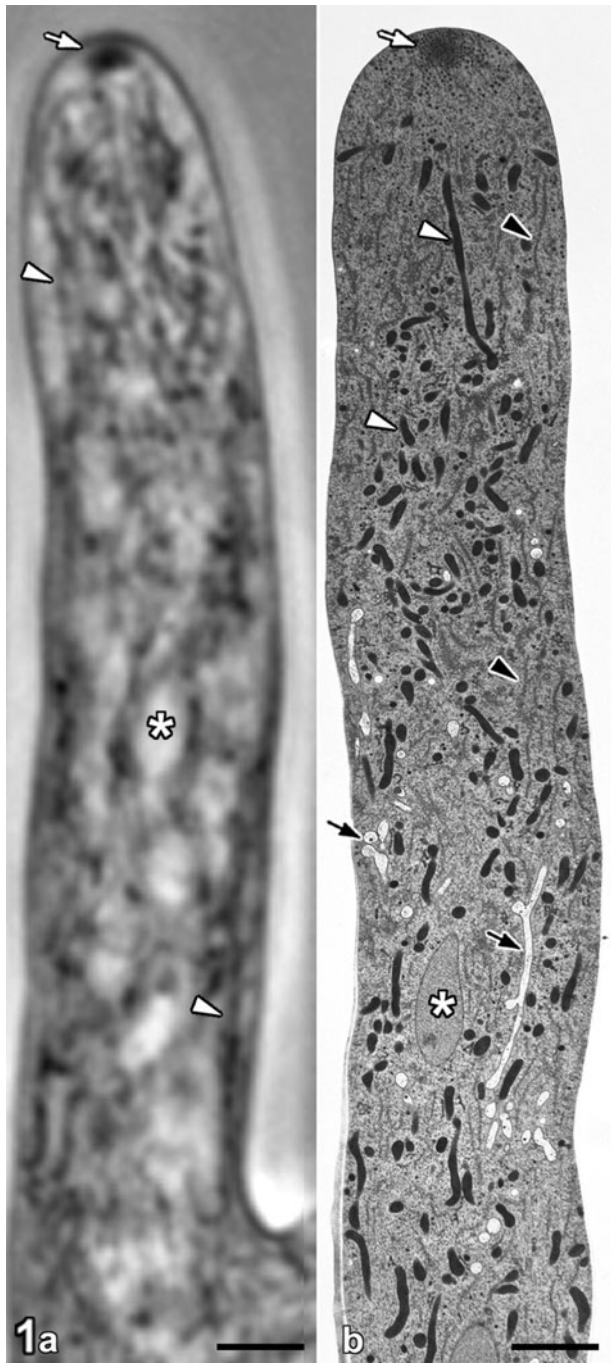

FIGURE 1 Cytoplasmic order of hyphal tip. (a) Phase-contrast light micrograph of *N. crassa* with Spitzenkörper (white arrow), mitochondria (arrowheads), and nucleus (asterisk). Scale bar, 4 μm. (b) Near-median TEM section through *S. rolfsii* cryofixed hypha illustrating Spitzenkörper (white arrow), mitochondria (white arrowheads), rough ER (black arrowheads), vacuoles (black arrows), and nucleus (asterisk). rhizoids) of the zygosporic fungi (e.g., Mucoromycotina) or the other relatively early diverging lineages. As a notable exception to this statement, Spitzenkörper have been identified in hyphae of *Allomyces macrogynus* (Blastocladiomycota) (Vargas et al., 1993), a zoosporic fungus that produces hyphae and rhizoids. In the fungi and fungus-like organisms (e.g., Oomycota) that lack Spitzenkörper, clustering of vesicles is seen near the apical plasma membrane. Although the arrangement of these vesicles appears to be less organized and complex than those of the Spitzenkörper of Ascomycota and Basidiomycota, there are characteristic patterns that are recognized. For example, in *Rhizopus* species and other members of the Mucorales (Mucoromycotina), a thin crescent-shaped band of closely packed vesicles is present just beneath the apical plasma membrane (Grove and Bracker, 1970). That Spitzenkörper are found only in the fungi, and primarily only in the mature hyphae of septate fungi, begs questions regarding its evolution and role in polarized growth.

Below the apical dome, the hyphal cytoplasm contains common eukaryotic inclusions and organelles including nuclei, cisternae and vacuoles, rough and smooth ER, mitochondria, cytoskeletal elements, vesicles, ribosomes, and Golgi equivalents. In the septate fungi, typically two subapical regions are recognized, regions II and III. Region II is the subapical zone just behind the apical dome, and in optimally growing hyphae, it can extend from 15 to 25 μm (Riquelme et al., 2002). In hyphae growing at less than optimal rates, the size of region II is reduced. Region III extends subapically behind region II until the first septum appears. The primary feature that differentiates region II from region III in both septate and aseptate fungi is the presence of nuclei, region II being devoid of nuclei.

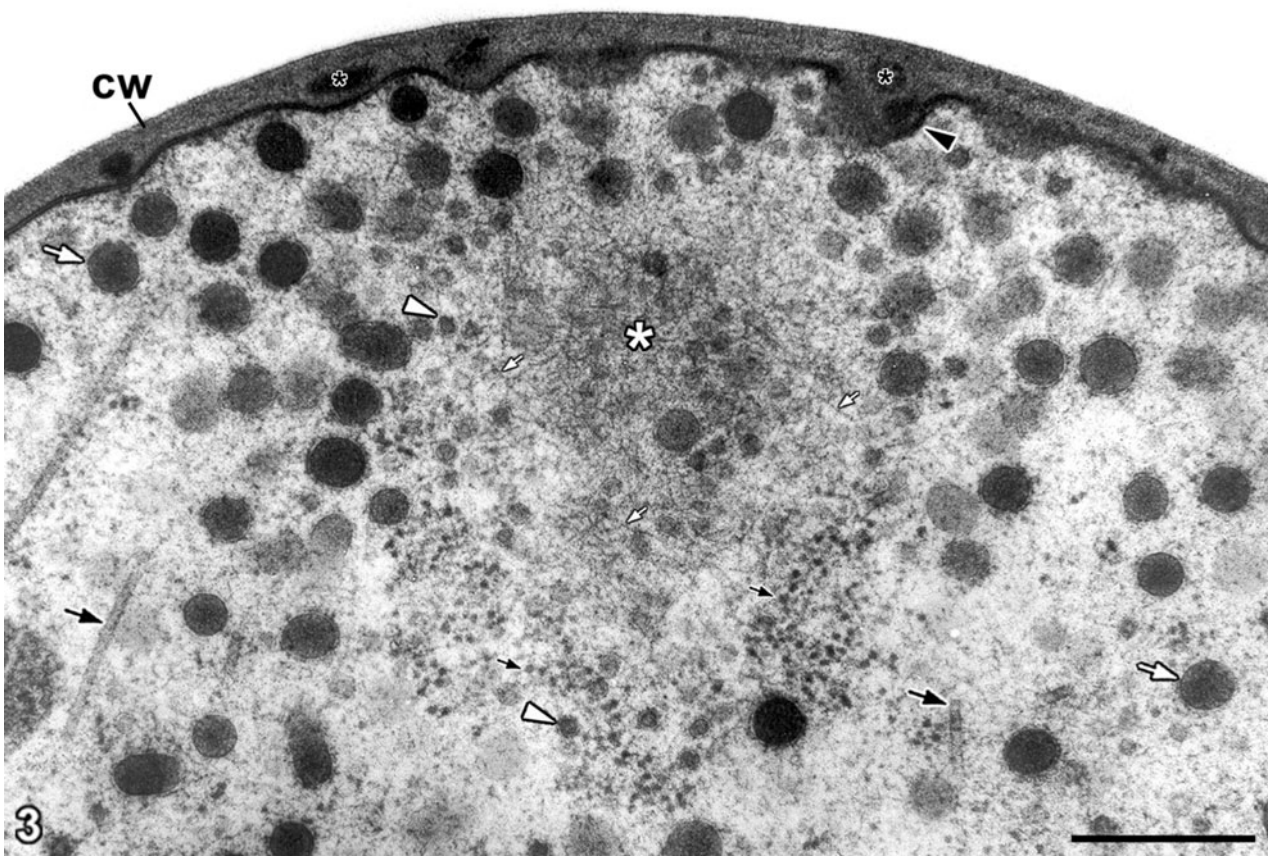

FIGURE 3 Near-median TEM section through hyphal tip of *Botrytis cinerea* (Ascomycota) illustrating structural components of the Spitzenkörper and surrounding cytoplasm. Shown are apical vesicles (white arrows); microvesicles (white arrowheads); central core (asterisk); MTs (black arrows); MFs (small white arrows); plasma membrane at sites of exocytosis (black arrowheads); ribosomes (small black arrows); cell wall (CW); cell wall inclusions (black asterisks). Scale bar, 200 nm.

Analogous to the hypha is the rhizoid, a filamentous structural feature of the thallus that occurs frequently among early-diverging zoosporic fungi. A rhizoid is a relatively short, thin somatic branch of a thallus, usually with determinate growth. It contains limited cytoplasm and lacks nuclei and Spitzenkörper. Rhizoidal elongation results from unipolar development of a zoospore cyst: the rhizoid develops as an extension of the zoospore cyst and ramifies over or within a substrate. Rhizoids are also found in certain members of zygospore-producing fungi, particularly parasites of invertebrate animals. The function of a rhizoid is similar to that of a hypha in that it accesses and transports nutrients to a developing reproductive body and anchors the organism to a substrate.

CELLULAR COMPONENTS: STRUCTURE, FUNCTION, AND ORGANIZATION

Spitzenkörper

The Spitzenkörper is a dense, spheroidal cluster of vesicles, cytoskeletal components, and signaling proteins found at the tips of most growing hyphae. It plays crucial roles in optimizing hyphal extension rates and in determining patterns of growth and morphogenesis by acting as a dynamic organizing center in the reception of secretory vesicles from subapical regions and orchestrating their delivery to the apical membrane (i.e., a "'vesicle supply center'") (Bartnicki-García et al.,1989; Riquelme et al.,1998). In the strict sense, the Spitzenkörper is a manifestation of the secretory pathway (see "Endomembrane System: Secretory and Endocytic Pathways," below). The Spitzenkörper is not bound by a membrane and can exhibit significant variability in size, shape, position, and behavior. These variations can occur between cells of the same species due to the natural dynamic pleomorphism of the Spitzenkörper and/or responses to endogenous and environmental signals that influence the numbers and types of vesicles that associate with it. The Spitzenkörper is an ephemeral structure, and its presence and absence are tightly correlated with rates of cell growth. It assembles as secondary and tertiary hyphal branches emerge (Riquelme and Bartnicki-García, 2004) and as germ tubes mature into hyphae (Araujo-Palomares et al., 2007).

In observations with phase-contrast microscopy of septate fungi, the Spitzenkörper typically appears as a dark body that partially or completely encloses a differentiated light central core (Fig. 1 and 2). Nine morphological patterns of Spitzenkörper organization have been described using phase-contrast microscopy (López-Franco and Bracker, 1996). Whether morphological patterns can be clearly articulated ultrastructurally and represent valid phylogenetic markers remains to be determined.

The most obvious component of the Spitzenkörper of the Basidiomycota and Ascomycota is a dense aggregation of secretory vesicles, the ultrastructural equivalent of the dark region seen with phase-contrast microscopy (Fig. 1 to 3) (Girbardt, 1969; Grove and Bracker, 1970; Howard, 1981). The Spitzenkörper central core contains substantially fewer vesicles and thus has a lower refractive index, giving rise to its phase-light appearance. Morphologically there are two categories of vesicles: the apical vesicles, also known as macrovesicles (70 to 100 nm in diameter), and smaller polyhedral microvesicles (30 to 40 nm in diameter). Although the arrangements of Spitzenkörper vesicles may appear to be disordered and random, spiral and linear patterns of vesicles have been observed. For example, Roberson and Fuller (1988) reported linear patterns of microvesicles associated with microfilaments (MFs), presumably filamentous actin. The Spitzenkörper is, in fact, enriched with actin MFs that are most concentrated within the core (Fig. 3) (Bourett and Howard, 1991). Microtubules (MTs) are also found associated with the Spitzenkörper (Fig. 3). A thin bed of ribosomes (Fig. 3) subtends the Spitzenkörper and appears to be a consistent feature in the Spitzenkörper of the Ascomycota.

Sites of exocytosis at the hyphal apex are rarely visualized when hyphae are prepared for electron microscopy using cryofixation methods, although exocytotic profiles are abundant in hyphae fixed with standard chemical methods (Howard and Aist, 1979). It is believed this is due to the high rate at which heat must be withdrawn from cells in order to achieve freezing without resolvable ice crystal damage, a process that requires fixing the cells within milliseconds (Chandler and Roberson, 2009). Figure 3 is a rare image of a cryofixed cell showing numerous sites of exocytosis at the apical plasma membrane. Spherical to ovoid inclusions within the cell wall are possibly the contents of vesicles just after exocytosis. This image suggests that vesicle fusion with the plasma membrane may occur in synchronized bursts of exocytosis.

Although, as mentioned above, Spitzenkörper are present in all growing hyphae of the Ascomycota and Basidiomycota, they are not common in other fungi. Thus far, Spitzenkörper have been confirmed in only one other fungal phylum, the Blastocladiomycota in *Allomyces* (Fig. 4 and 5) (Vargas et al., 1993). The *Allomyces* Spitzenkörper is unique both structurally and functionally. The most distinctive aspect of the *Allomyces* Spitzenkörper is its large (~3-μm) phase-light core (Fig. 4). Also, since there is no evidence for apical vesicles in *Allomyces*, the phase-dark region present in Fig. 4 is created primarily by closely associated mitochondria (Fig. 5). The ultrastructural equivalent of the phase-light area contains a granular-to-fibrous matrix with an irregular boundary in which MFs, microvesicles, and MTs are present (Fig. 5). The *Allomyces* Spitzenkörper is also set apart from those of the septate fungi in that it contains γ-tubulin and functions as an MT organizing center (MTOC) (Roberson and Vargas, 1994; McDaniel and Roberson, 1998). The interest in the diversity of structure and function of the *Allomyces* Spitzenkörper is amplified by the fact that members of the

Blastocladiomycota are zoosporic fungi. Unlike nonzoosporic fungi, they possess centrosomes rather than spindle pole bodies (SPBs) as their nuclear-associated MTOC. Indeed, this group of fungi may prove to be pivotal in understanding the evolution of the Spitzenkörper as fungi became adapted to a terrestrial lifestyle. Further investigations of zoosporic and aseptate hyphal fungi may result in additional evidence of diverse Spitzenkörper.

Nuclei

Interphase nuclei in filamentous fungi are structurally similar to those in other eukaryotic organisms. They have a nuclear envelope perforated by numerous nuclear pore complexes enclosing a ribosome-free nucleoplasm packed with chromatin of varying densities and containing one or two nucleoli (Fig. 6). An MTOC is associated with the cytosolic surface of the nuclear envelope, and in nonzoosporic fungi this is a SPB (Fig. 6 and 7a through d). In the zoosporic fungi the nuclear MTOC is a centrosome, and, as in animal cells, it is composed of a pair of barrel-shaped centrioles positioned at a 90° angle relative to each other and embedded in a pericentriolar matrix. *Basidiobolus* is a fungus of great interest, as it has a modified centrosomal MTOC yet has lost the ability to produce flagella (McKerracher and Heath, 1985). A diversity of SPB forms occur among the zygosporic fungi, which reflects their diverse evolutionary origins (Celio et al., 2006). In many Basidiomycota the SPB is modified into a globular form (Fig. 7c and d) from the plaque or disk-shaped structure characteristic of the Ascomycota, a form also present in some Basidiomycota (Pucciniomycotina) (Fig. 7a and b), reflecting shared ancestry. The shape of nuclei varies from approximately spherical in older, more quiescent cellular regions to elongate or pyriform in those regions where rapid cell growth or cytoplasmic motility is occurring. Nuclei are extremely malleable and able to pass through very small openings, such as septal pores, enabling their movement from one cell into another. Fungal nuclei range in size from 1 to 3 μm in diameter; except those of *Basidiobolus*, which can be up to 25 μm in length.

The number of nuclei per hyphal compartment varies depending on the fungal group. In the dikaryotic (n+n) Basidiomycota there are typically two nuclei per compartment after plasmogamy, and these are maintained in close proximity to each other (Fig. 6). Movement into new hyphal compartments may be achieved via the formation of a clamp connection during mitosis and cytokinesis. Free nuclear migration from one compartment to another is prevented by the complex septal dolipore apparatus (see "Septal Structure," below), unless there has been enzymatic breakdown of septa after plasmogamy. In the haploid Ascomycota, each hyphal

compartment can contain one to many nuclei; however, a large number of nuclei may be found in the apical compartment before septum formation. The nuclei are more or less free to move from one compartment to the other through a simple septal pore, unless it is plugged (see "Woronin Bodies," below). In the fungi that lack septa or have few septa, large numbers of nuclei are distributed throughout the cytoplasm. These fungi are considered coenocytic.

The history of the study of mitosis in filamentous fungi was reviewed by Aist and Morris (1999) (see also chapter 6). They described the considerable understanding of the structures involved in mitosis by 19th and early 20th century researchers who extrapolated from the results of light-microscopic studies of large meiotic nuclei to the smaller nuclei characteristic of mitotic divisions. A period of confusion in the understanding of fungal mitosis, which characterized the 1950s and 1960s, was followed by a series of studies using newly available ultrastructural methods to show that fungal mitosis was comparable to that in other eukaryotes, albeit with some features characteristic of fungi (Aist and Morris, 1999). These features include absence of a metaphase plate, a usually intact nuclear envelope during division, asynchronous separation of chromosomes in anaphase A, elongation of a narrow central spindle in anaphase B, and synchronized mitosis in haploid filamentous fungi (Fig. 7e and f).

The number of mitotic studies within a single phylum of fungi is limited, and generalizations based on these limited studies may prove to be unfounded (Celio et al., 2006). The best-studied phylum is the Basidiomycota, which shows considerable variation in the organization of the nuclear envelope during metaphase when a number of taxa are sampled. The structures may vary from an SPB loosely inserted in a pore in the nuclear envelope with a membranous cap at metaphase surrounding the SPB on its cytoplasmic face (Fig. 7e) without (Bourett and McLaughlin, 1986) or with perinuclear ER, to loss of the nuclear envelope with the retention of the membranous cap (Swann et al., 1999), to an intranuclear SPB with a more or less closed nuclear envelope, to an SPB lacking a membranous cap and tightly or loosely inserted in a polar fenestra (Fig. 7f) (Celio et al., 2007). In the Ascomycota the metaphase nuclear envelope is either intact, as in most basal phyla with the exception of the Chytridiomycota, or with a polar fenestra (Celio et al., 2006). The functional significance of these variations in membrane organization is unknown. However, astral MTs fail to form while membranous caps are present, and this suggests that they may regulate polar movements.

A benefit from studies that provide a more complete understanding of the variations in mitosis is that they can yield new insights into the mechanisms of nuclear division and challenge our present concepts. For example, it is usual to find that during mitosis the SPBs are approximately parallel to each other at each end of the spindle, but in *Kriegeria eriophori* (Basidiomycota) the poles may be perpendicular to each other during division with unknown implications for the mitotic mechanism (Swann et al., 1999).

Mitochondria

Like that of nuclei, the structure of fungal mitochondria is similar to that of other eukaryotic organisms (see chapter 14). They are bound by a double-unit membrane with the internal membrane having a much increased surface area that is manifested in elaborate invaginations (i.e., cristae) that extend into the mitochondrial matrix. Fungal mitochondria differ from other eukaryotes in that their shape is more elongate, they are larger organelles, and their plate-like cristae are arranged as lamellae that are parallel to the organelle's long axis. Mitochondria occur throughout the hyphal tip cytoplasm and can be particularly dense in numbers near the apex, where large amounts of ATP are required to sustain growth (Fig. 1, 2, 4, 5, and 8). They are typically aligned along the long axis of the hypha and are often seen in close proximity to MTs, rough ER, and Golgi equivalents. Mitochondria move mostly at bulk flow rates; however, they are capable of rapid saltatory motility in filamentous fungi via actions of MTs (Fuchs and Westermann, 2005) or actin MFs (Suelmann and Fischer, 2000) and their associated motors (Fig. 8).

Endomembrane System: Secretory and Endocytic Pathways

The endomembrane system is a cytoplasmic association of membranes that divide the cell into functional and structural organelles and compartments that together provide a means for the synthesis, breakdown, and transport of

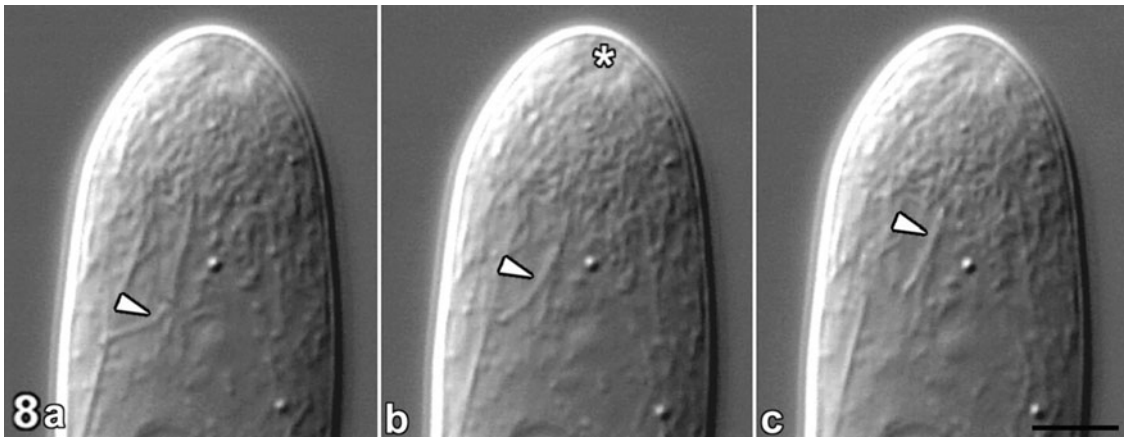

FIGURE 8 Differential interference contrast LM of *A. macrogynus* illustrating saltatory motility of a mitochondrion (arrowhead) presented over a 1.5-s period. The Spitzenkörper is indicated by an asterisk. Bar, 5 μm. Reprinted from *Fungal Genetics and Biology* (McDaniel and Roberson, 2000) with permission from the publisher.

materials out of, into, and within the cell. The components of the endomembrane system are connected by the intracellular movements of materials via vesicles or, less commonly, physical connections (e.g., nuclear envelope and rough ER). Below, we discuss briefly elements of the secretory and endocytic pathways. For a recent review on the protein constituents of each organelle please see Bourett et al. (2007).

Secretory Pathway

The outward secretory pathway starts with the synthesis of proteins at the rough ER and from there through the Golgi apparatus to the cell surface. The ER is thought of as a unified interconnected membranous network with distinct functional domains and morphologies that play essential roles in membrane and protein biogenesis. It is present in all regions of the hyphal tip cell. The network generally exhibits a gradient distribution with increasing abundance towards the hyphal apex (Maruyama and Kitamoto, 2007). Extensive profiles of rough ER are present in hyphal subapical regions. These are easily recognized ultrastructurally when viewed in cross section as thin sheets of ribosome-decorated membrane cisternae oriented along the growing axis of the hypha (Fig. 1b and 9a). Smooth ER is less common, although it can be found in region I in close association with the Spitzenkörper and in association with dolipore septa of the Basidiomycota (see "Septal Structure," below). This organelle is involved in the synthesis of lipids, further processing of proteins, carbohydrate metabolism, and detoxification of drugs and poisons. Increased amounts of smooth ER occur in hyphae grown under stress conditions and in the presence of certain growth inhibitors (for an example, see Roberson and Fuller, 1990).

The Golgi apparatus is involved in additional modifications of proteins delivered from the rough ER and in their packaging into transport vesicles. In most eukaryotic cells this organelle is composed of a group of flattened cisternae, or dictyosomes, that are layered one on top of the other in a manner similar to a stack of pita bread with each cisterna having distinct roles in protein modification. In fungi the structure of the Golgi apparatus is unique and appears as inflated tubular and often fenestrated cisternae that vary in shape from cup-like to planar bodies (Fig. 9a through e). Because of the structurally simplified nature of the fungal Golgi apparatus, Morré and others (1971) referred to individual organelles as Golgi equivalents. However, they have physiological functions typical of stacked Golgi cisternae of other organisms (Sewall et al., 1989). Recently, Hubbard and Kaminskyj (2008) reported the localization of a Golgi marker (CopA) tagged with green fluorescent protein (GFP) in *Aspergillus nidulans* (Ascomycota). They showed that Golgi equivalents are more abundant at hyphal tips than in subapical regions. Vesicles, mitochondria, and MTs are often observed in close association with Golgi equivalents (Fig. 9b through e).

Vesicles are small spherical bodies bound by a single-unit membrane with a cargo of proteins and glycoproteins. Vesicles are found throughout the hyphal cytoplasm. They are most highly concentrated in the apex of growing hyphae in the area identified as the Spitzenkörper by LM. Clouds of vesicles are also seen in small aggregations near the plasma membrane in region I of the hyphal tip and are referred to as satellite Spitzenkörper (López-Franco et al., 1995). Satellite Spitzenkörper form de novo and combine with the primary Spitzenkörper, and they may be involved in producing pulsed hyphal growth (López-Franco et al., 1994). As is the case for all eukaryotic cells, fungal vesicles provide an invaluable link in the packaging and delivery of goods to designated targets. As would be expected, vesicles are often associated with cytoskeletal elements (for examples, see Roberson and Fuller, 1988; Riquelme et al., 2002; and Zekert and Fischer, 2009).

There are several classes of fungal vesicles; some are found throughout the Fungi while others are found in specific taxa. The apical vesicles and microvesicles have been described previously (see "Spitzenkörper," above) and are both likely secretory vesicles, although little is known regarding their composition and distinct roles in tip growth. Bartnicki-García and coworkers (1978) isolated a population of vesicles termed chitosomes from fungal hyphae and showed that they possessed chitin synthase activity. Chitosomes are similar in appearance to microvesicles, but without confirming immunoelectron microscopy their relationship has remained unclear. However, recent localization of GFP-labeled chitin synthases to the Spitzenkörper core of *N. crassa* (Riquelme et al., 2007) represents a significant step in addressing this question. Microvesicles are sometimes coated with a dense fibrous network referred to as filasomes (Fig. 9f) (Howard, 1981). The fibrous coat of filasomes contains actin (Bourett and Howard, 1991; Roberson, 1992) and other actin-binding proteins and likely represents, in part, the cortical actin patches seen with epifluorescence imaging (see "MTs," below). Filasomes are most abundant in the cortex of the apical hyphal regions and may be the manifestation of non-clathrin-facilitated endocytosis. Studies of fungal genomes (Read and Kalkman, 2003) and live-cell imaging experiments using endocytic marker dyes (for an example, see Peñalva, 2005) support the view that endocytosis is common in filamentous fungi.

Endocytic Pathway

The inward endocytic pathway starts at the plasma membrane and is responsible for lipid and protein recycling and for uptake and breakdown of extracellular materials through an endosomal and lysosomal system. Components of the endocytic compartments in filamentous fungi have been difficult to identify due perhaps to a reduced and less complex endocytic system relative to mammalian cells (Bourett et al., 2007). Recent studies using the membrane-selective fluorescent vital dye FM4-64 to visualize the endocytic pathway have broadened our understanding of the structure and dynamics of the endocytic compartments in filamentous fungi (Fischer-Parton et al., 2000; Ashford and Allaway, 2007). Multivesicular bodies (MVBs) are common in fungi and other eukaryotic organisms. In mammalian cells these organelles may be involved in the transfer of materials from early endosomes to lysosomes (i.e., mature endosomes/vacuoles in fungi) (Piper and Katzmann, 2007). They are recognized with TEM as membrane-enclosed bodies (150 to 350 nm in diameter) containing smaller vesicle-like particles and are often associated with MTs (Fig. 9g). At the LM level, these organelles are likely the small spherical bodies exhibiting MT-dependent bidirectional saltatory motion (McDaniel and Roberson, 2000; Riquelme et al., 2002). They probably are also components of the endosomal structures visualized in a number of fungal species after FM-464 staining and GFP tagging of early endosome components (for examples, see Fischer-Parton et al., 2000; Peñalva, 2005; and Abenza et al., 2009).

Fungal vacuoles are motile, complex organelles with versatile functions and morphologies (Ashford and Allaway, 2007) (see chapter 15). Vacuoles are analogous to mammalian lysosomes, playing a primary role in the breakdown of materials. In the fungi they also function as storage compartments for biosynthetic precursors, calcium ions, and

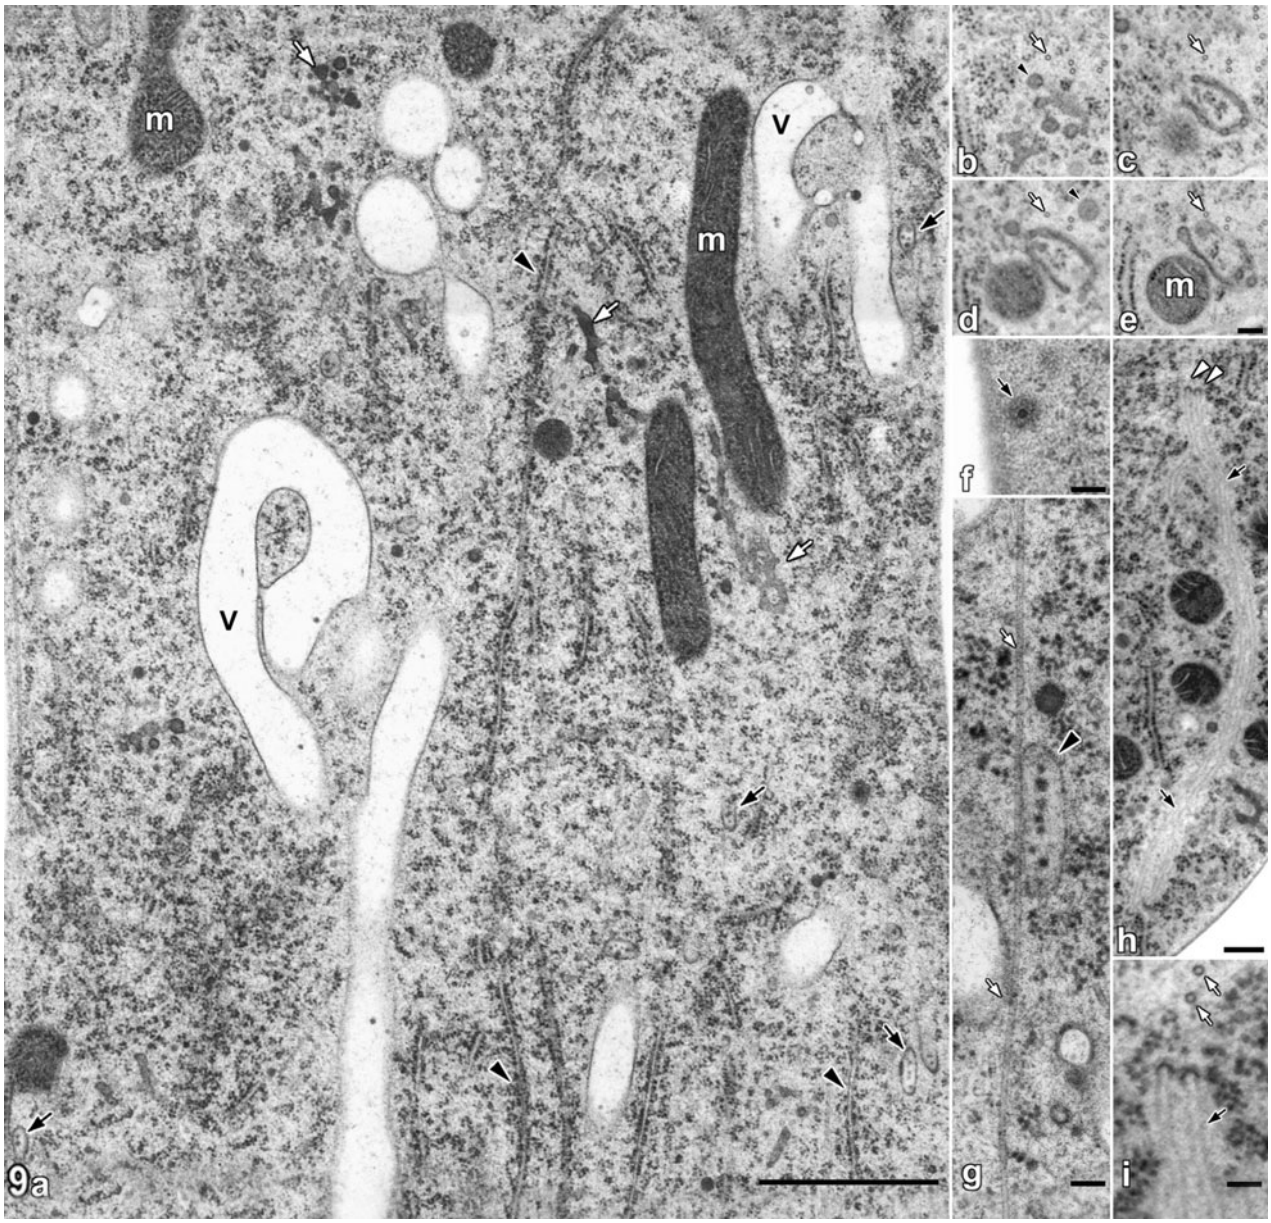

FIGURE 9 Elements of the endomembrane system and organelles viewed with TEM. phosphates; in pH and osmotic regulation; and in ion homeostasis and cytoplasmic detoxification (Veses et al., 2008). Furthermore, they are involved in membrane recycling, long-distance nutrient transport through the fungal body, and regulation of hyphal extension. The distribution and morphology of vacuoles vary among the fungal taxa and also from cell to cell within individuals, depending on physiological conditions and cellular function. In many growing hyphal tip cells the vacuole is viewed as a dynamic network of small tubular-to-flattened cisternae that are continuously or transiently linked with larger spherical-to-elongate cisternae that group in clusters or are solitary (for examples, see Roberson and Fuller, 1988; and Ashford and Allaway, 2007) (Fig. 9a, h, and i). In some cases, the hypha can

possess a cytoplasm that is dominated almost entirely by a single vacuole that maintains a small "slug" of cytosolic contents near the growing tip. MTs are commonly in close association with vacuoles (Fig. 9i). Observations with TEM have identified electron-dense fibrillar material coating the cytosolic surfaces of elaborate cisternae identified as vacuoles (Fig. 9h and i). Vacuolar content varies depending on cellular maturation and health. During optimal growth the luminal content ranges from being electron transparent to containing a fibrous/granular matrix. Small spherical inclusions and sometimes crystalline inclusions are also present. Under conditions of environmental stress or exposure to growth inhibitors, vacuoles increase in number and size and their lumen becomes more electron dense and filled with inclusions (Roberson and Fuller, 1990).

Cytoskeleton

Cells regulate their morphology, organize and support cytoplasmic components, interact with the environment, and control their movements and intracellular transport. These functions are fulfilled through the coordinated actions of the cytoskeleton (see chapter 17). The fungal cytoskeleton is composed primarily of two structural elements, the MTs and actin MFs, which extend throughout the cytoplasm, making connections with themselves and other cellular elements to form a continuous interconnected cytoplasmic system. Each cytoskeletal element has discrete mechanical and dynamic characteristics and performs specific and shared duties in the cell. Cytoskeletal function and behavior are direct results of the inherent characteristics of their proteins as well as the actions of hundreds of associated proteins that interact with the cytoskeleton and cytoplasmic components in highly regulated and precise ways. In many eukaryotes there is a third component of the cytoskeleton, intermediate filaments. However, their abundance and role(s) in creating a self-stabilizing structural framework in the fungal cytoplasm is apparently much reduced due to the contributions of the fungal cell wall and turgor pressure, and they will not be addressed here.

MTs

MTs are tubular structures built from subunits of α- and β-tubulin heterodimers. These heterodimers assemble end to end, forming 13 parallel protofilaments that bundle together to build the wall of the MT. MTs have an outer diameter of ~24 nm and a variable length. The lumen of the MT has a diameter of ~14 nm and is routinely described as "empty." However, there is clear evidence that dense particles and fibrous materials reside within the core of the MT, which may represent MT-binding proteins that regulate its assembly and disassembly (Garvalov et al., 2006).

Each αβ-tubulin dimer has a structural polarity that is manifested throughout the entire MT polymer. One end of the MT has β-tubulin exposed and is referred to as the plus end, while the α-tubulin end is the minus end. The plus and minus designations refer to the rate at which αβ-tubulin dimers add to the MT. In vitro studies show that in a solution of pure tubulin, dimers assemble at both ends of the MT but add faster to the plus end. In the cell, MT nucleation and organization are regulated by the MTOC (e.g., SPB and centrosome) through the interactions of the MT's minus end with another member of the tubulin family, γ-tubulin (Oakley and Oakley, 1989). γ-Tubulin monomers combine with other proteins to form hundreds of ring-shaped aggregates (i.e., the γ-tubulin ring complex) that are embedded within the matrix of the MTOC. Thus, a single γ-tubulin ring complex serves as a nucleation site for a single MT that is oriented with its minus end attached to the MTOC and its plus end extending into and interacting with the cytoplasm.

MTs occupy the cortical and central cytoplasmic hyphal regions (Fig. 10), with most studies indicating their abundance in the cell cortex. In the subapical hyphal regions MTs are primarily oriented parallel to the growing axis of the cell, often exhibiting a distinct helical curvature with variable pitches that outline nuclei and mitochondria. MTs have a tendency to intertwine with one another to form a loosely braided meshwork in the central cytoplasm. This arrangement is most obvious in large mature hyphae (Mouriño-Pérez et al., 2006) (Fig. 10) and less so in smaller hyphae and germ tubes. Oblique or transverse MT orientations are observed during branch formation and in association with the mitotic spindle. Cytoplasmic MTs are mostly solitary, although bundles of two to four sometimes occur (Fig. 9b through e and 10) and are likely bound together by Tau-like associated proteins and/or molecular motors, although this remains equivocal (Fischer, 2007). MT bundles are transient structures providing increased cytoplasmic support and the potential for generating contractile forces when MTs are arranged with opposite polarities (e.g., mitotic spindles). As mentioned above, MTs are often in close proximity to membrane-associated structures (Fig. 3 and 9b through e and g) and, occasionally, are juxtaposed to actin MFs (Vargas et al., 1993).

Dynamic instability is the primary behavior of MTs in eukaryotic cells. It is characterized by the rapid interconversion between assembly and disassembly of the MT plus end and provides a means for MTs to reassemble into different structural organizations during cell cycle, growth, and development. In hyphal regions I and II of septate hyphae, dynamic instability is visualized in GFP-tubulin strains (Uchida et al., 2008) as the anterograde growth of MTs, many of which enter the apical dome and interact with the Spitzenkörper and apical plasma membrane with their plus ends. After a brief pause, MTs undergo a catastrophic disassembly and shrink until rescued, and the cycle repeats. Fragmentation of MTs and their subsequent anterograde and retrograde movements have been reported in the hyphal cortex of *N. crassa* (Uchida et al., 2008). These actions suggest the presence of MT-severing proteins (e.g., katanin) and treadmilling or active MT transport within this fungus.

LM and TEM (Fig. 3 and 10) (Hohmann-Marriott et al., 2006; Freitag et al., 2004; Mouriño-Pérez et al., 2006) imaging reveals that MTs tend to converge within the apical dome. The apical convergence of MTs is most pronounced in hyphae of *A. macrogynus* (Blastocladiomycota) because, as mentioned above, the Spitzenkörper serves as an MTOC in this fungus (Roberson and Vargas, 1994; McDaniel and Roberson, 1998). The idea that the Spitzenkörper might be an MTOC in all fungi is a very provocative one, but repeated attempts to localize γ-tubulin to the Spitzenkörper of septate fungi have failed (R. W. Roberson and R. R. Mouriño-Pérez, unpublished results). Furthermore, results from live-cell studies of GFP-tubulin fungal strains provided no indication that MTs are nucleated at the Spitzenkörper (Uchida et al., 2008), which would be expected from an MTOC. Although this role has not been established for other Spitzenkörper, there are reports of MT nucleation from apical sites in germ tubes of the rust fungus *Uromyces phaseoli* (Basidiomycota) (Hoch and Staples, 1985) and during lateral branch formation in *N. crassa* (Mouriño-Pérez et al., 2006).

Actin MFs

Actin MFs are composed of subunits of identical globular actin monomers that assemble into two protofilaments,

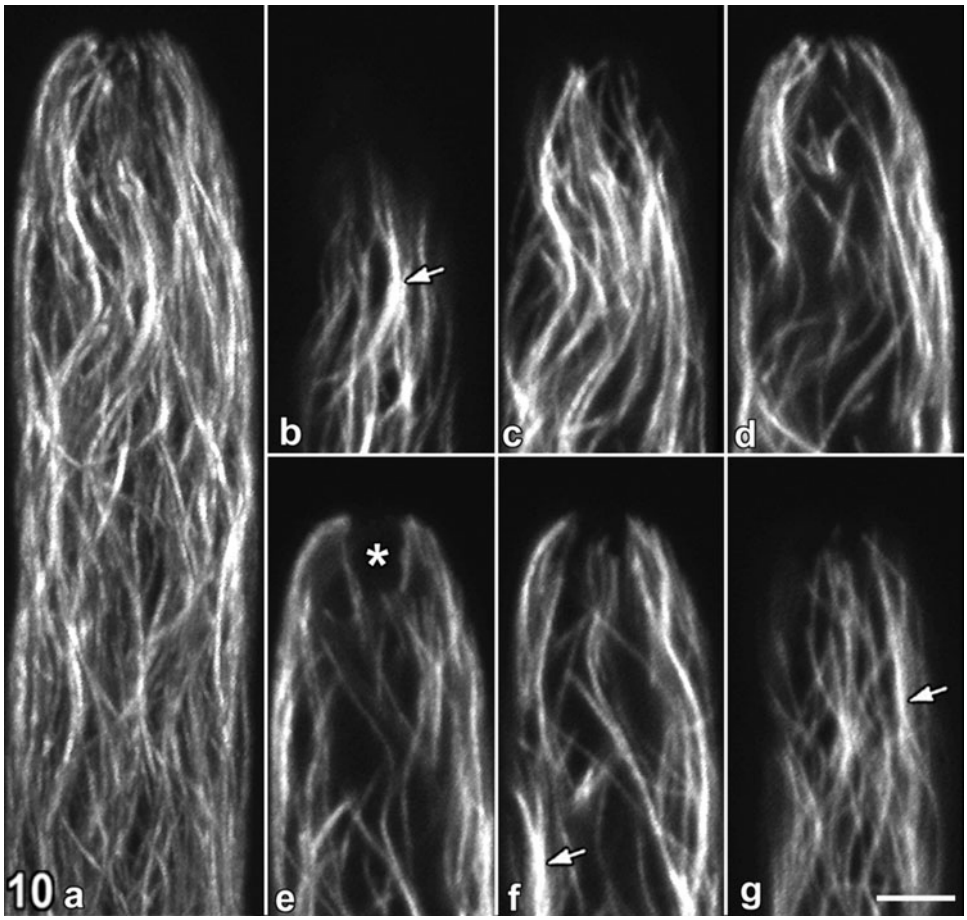

FIGURE 10 Immunofluorescence of MTs in hyphal cells of *S. rolfsii* visualized with confocal microscopy. (a) Reconstruction of six longitudinal optical sections through hypha. MTs are primarily oriented parallel to the growing hyphal axis exhibiting helical curvatures forming a loosely braided meshwork. (b through g) Optical serial sections. MTs are in close proximity to Spitzenkörper but at the time of cell fixation were not traversing Spitzenkörper (asterisk in panel e). MT bundles are indicated by arrows. Scale bar, 3 μm.

forming a left-handed helical filament. These short and flexible filaments are generally present in much higher numbers in the cytoplasm than MTs. Although actin is found throughout the cell, the highest density of actin filaments is in the cell cortex. The cortex is also the site for most MF nucleation. A single filament is about 7 nm in diameter and appears as a thin electron-opaque thread when viewed with TEM (Fig. 3). However, in fungal hyphae and other eukaryotic cells, actin MFs are visualized more often as complex networks and bundles. Like MTs, actin MFs are polar structures and are regulated through the interactions of many associated proteins.

Imaging of the actin cytoskeleton, including actin-associated proteins, reveals several distinct arrangements and distribution patterns in filamentous fungi. These include small spots or patches, longitudinal cables, and contractile rings associated with septum formation. At the LM level, the most obvious of these arrays are small cortical patches that are typically concentrated in a band located between 1 and 4 μm behind the growing tip of a mature hypha (Fig. 11) (Roberson, 1992; Srinivasan et al., 1996; Virag and Griffiths, 2004; Araujo-Bazán et al., 2008; Taheri-Talesh et al., 2008; Upadhyay and Shaw, 2008). Actin patches are excluded from the extreme hyphal tip and generally present in reduced numbers in the lower subapical hyphal areas. As noted previously, there is strong correlative evidence that filasomes are the ultrastructural equivalent of cortical actin patches. Araujo-Bazán and others (2008) have shown that endocytic proteins colocalize with actin cortical patches in mature hyphae of *A. nidulans*, supporting a spatially coupled mechanism of constitutive apical exocytosis and subapical endocytosis via filasomes/actin patches. In slower-growing germ tubes, the apical distribution of actin patches is less organized than in mature hyphae (Taheri-Talesh et al., 2008; Upadhyay and Shaw, 2008). In addition to cortical patches, a small apical aggregation or spot of actin has been reported in some fungi (Srinivasan et al., 1996; Taheri-Talesh et al., 2008) and corroborates EM data demonstrating a dense actin MF network associated with the Spitzenkörper (Fig. 3) (Bourett and Howard, 1991). In several fungi, proteins required for actin nucleation and organization (i.e., the polarisome) are found at the tips of growing hyphae (Knechtle et al., 2003; Harris et al., 2005) and some colocalize with the Spitzenkörper (Sharpless and Harris, 2002; Crampin et al., 2005).

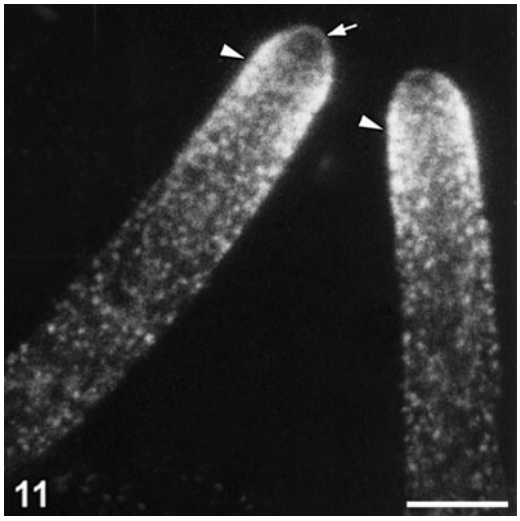

FIGURE 11 Immunofluorescence of actin in hyphal cells of *S. rolfsii* visualized with wide-field epifluorescence microscopy. Actin is localized as cortical patches in high numbers beneath apical domes (arrowheads). Actin spot was not observed at the apex (arrow) in these cells. Scale bar, 7 μm. Septal Structure

Hyphae are broadly distinguished as aseptate or septate. Aseptate hyphae are found in members of several phyla of early diverging lineages, including zoosporic and zygosporic fungi. Even so-called aseptate hyphae, however, may be separated into active and nonfunctional portions by adventitious septa, i.e., septa that are not associated with mitotic divisions. Hyphae that are said to be regularly septate have septations that form in conjunction with nuclear divisions. Septate hyphae are divided into compartments that enable a division of labor as the hyphae mature from the growing tip backwards. Perforate septa allow for the selective passage of cytoplasm and some organelles between the compartments during their maturation. Below is presented a limited discussion of hyphal septation in the context of phylogeny and function.

Chytridiomycota, an early diverging zoosporic lineage of fungi, have adventitious septa that cut off parts of the often extensive mycelial system or rhizoids found in some species. Members of the traditional groups known as Zygomycota are usually considered to be coenocytic. Recent molecular analyses including additional taxa of zygospore-forming fungi, however, indicate that the phylum as previously defined may not be monophyletic (White et al., 2006; Hibbett et al., 2007). Certainly, a comparison of morphology, including septal characters, supports these organisms as more diverse than originally accepted. For example, one clade of zygospore-forming fungi lacks regularly septate hyphae but often has adventitious septa (White et al., 2006). Another large clade of zygospore-forming fungi, however, is characterized by regularly septate, plugged hyphae, and the characteristic plugs are used to distinguish among some orders within this clade (White et al., 2006).

Regularly septate hyphae are taxonomically important markers in Ascomycota and Basidiomycota, and these phyla often are referred to as septate fungi. A simple central septal pore (Fig. 12a) is generally present in hyphal members of the Ascomycota. However, there is significant structural diversity, especially among structures occluding the pores, for members of this phylum (AFTOL, 2007). Examples of such plugs in Pezizomycotina include nonmembranous material, granular lamellate structures, non-membrane-bound subspherical occlusions with translucent finger-like extensions from the pore margin, and non-membrane-bound subspherical occlusions without translucent finger-like extensions. In addition to the non-membrane-bound structures, membrane-bound Woronin bodies (Fig. 12a) (see "Woronin Bodies" below) may block the pores of more mature compartments in certain ascomycete (Pezizomycotina) hyphae (AFTOL, 2007).

The dolipore septum present in most Basidiomycota is characterized by an inflated region surrounding the septal pore (Fig. 12b) (Celio et al., 2006). In addition, within some taxonomic groups (Agaricomycotina) membranous septal pore caps (parenthosomes) and associated structures are positioned in the cytoplasm near the pore (Lutzoni et al., 2004). Septal pore caps are derived from the ER and appear as simple membranous caps or caps with extensions that may be cupulate, reticulate, or tubular. The extensions may be smooth vesicular-tubular membranes or multiple saccules; the cap may be reticulate. The cap also may be imperforate, uniperforate, or multiperforate with small or large pores and may have uniform electron-transparent or electron-dense contents with internal layers (AFTOL, 2007). The septal pore apparatus prevents the movement of large organelles (e.g., nuclei) from one compartment to another and is often associated with clamp connections. The septal pore system is less complex in other members of the Basidiomycota, including the earlier-diverging lineages.

Septal pore caps in *Rhizoctonia solani* (Basidiomycota) contain a glycoprotein that is associated with the ER (van Driel et al., 2008). This protein is also found in non-membrane-bound plugs that block the septal pore and, thus, are involved in regulating cellular activity at the pore.

Woronin Bodies

Woronin bodies are small (150 to 500 nm in diameter) electron-dense organelles that are spherical, oblong, hexagonal, or rectangular and bounded by a single-unit membrane (Fig. 12a) (Momany et al., 2002) (see chapter 16). Early evidence indicated that Woronin bodies functioned only as septal plugs to prevent loss of cytoplasm in damaged hyphae (Trinci and Collinge, 1974). More recently, Jedd and Chua (2000) demonstrated that the Woronin body is a specialized type of peroxisome. The size and number of Woronin bodies per cell are variable; a number of up to seven may be characteristic of certain species (Soundararajan et al., 2004). In the past, Woronin bodies were defined on the basis of morphology and position near the septal pore of ascomycetes. However, organelles with structural characteristics similar to those of Woronin bodies have been identified in conidia, appressoria, penetration pegs, and apical cytoplasm of germ tubes and hypha (Momany et al., 2002; Riquelme et al., 2002; Soundararajan et al., 2004; Hohmann-Marriott et al., 2006). In order to determine the identity of presumptive apical Woronin bodies, Momany (2002) and her colleagues used antibodies to the *N. crassa* Woronin body matrix protein, Hex1, to study the organelles in germ tube cells of *A. nidulans*. They provided evidence that the presumptive organelles in cell apices were in fact Woronin bodies that later were transported to the region of the developing septum.

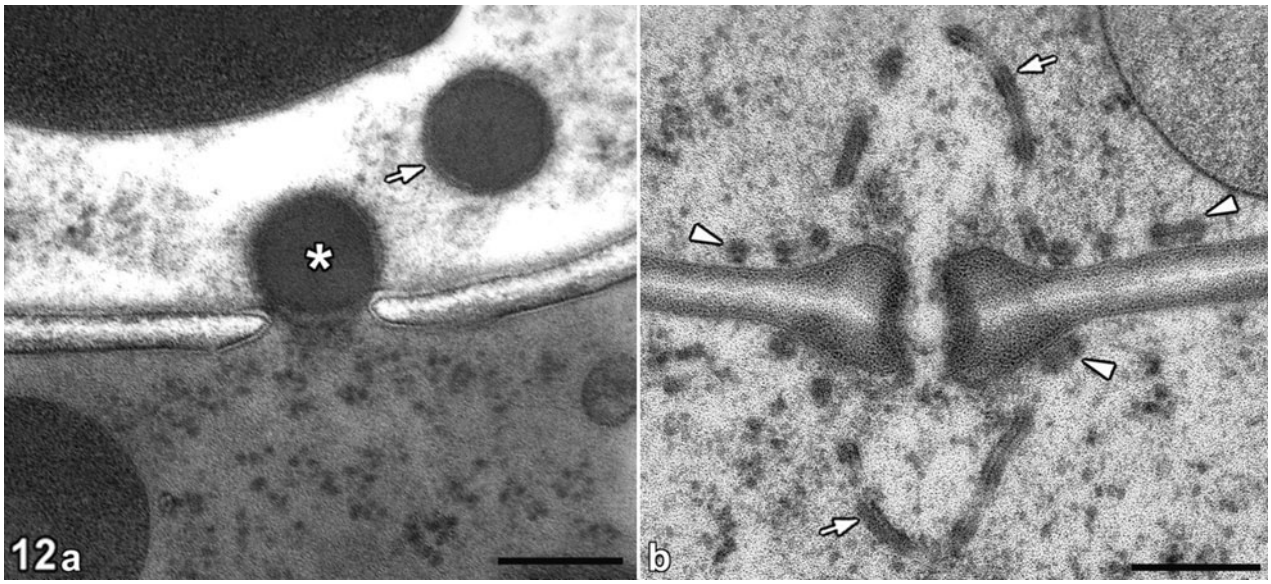

FIGURE 12 TEM of septal pore complexes. (a) Simple septal pore in a conidiation mutant of *Fusarium verticillioides* (Ascomycota). Woronin bodies are bound by a single-unit membrane (arrow). Note one of the Woronin bodies (asterisk) plugging the septal pore and the density difference between the cellular compartments above (apical) and below (distal) the cross wall. Scale bar, 300 nm. Courtesy of Beth Richardson and Tony Glenn. (b) Dolipore septal pore and septal pore cap (i.e., parenthosomes) (arrows) of *A. vulgare* (Basidiomycota) with the cap extending along the cross wall (arrowheads). Scale bar, 125 nm. APPLICATION OF CELLULAR STRUCTURE TO FUNGAL PHYLOGENETICS

Since the early 1960s the focus of some mycologists who acquire structural data has been to use selected cellular components as characters in taxonomic and evolutionary studies. Fine structure has been useful in distinguishing fungi from other organisms (Hawker, 1965; Heath, 1986; Sewall et al., 1989). More often, however, it has been applied to distinguish among fungal groups. Basidiomycete taxonomy benefited from early TEM studies of septa. The presence or absence of a dolipore septum provided the means of distinguishing single hyphae of ascomycetes and many basidiomycetes, and variation in septum structure provided new characters with taxonomic significance, especially in Agaricomycotina (McLaughlin et al., 1995; Celio et al., 2006). Characters derived from structures other than hyphae also have been important in mycology, and these include nuclear divisions used to distinguish some groups of fungus-like organisms from the monophyletic kingdom Fungi (for examples, see Heath, 1986; and Celio et al., 2006). TEM has been applied to fungi that cannot be cultured easily, including a number of obligate parasites of plants and animals, and has proved useful in some cases for observations on the morphology of very small fungi (Blackwell, 1994).

Newer methods to derive and analyze macromolecules have replaced structural fine detail in the minds of many systematists. Structure, however, remains important, especially when used in conjunction with sequence analyses that help to polarize evolutionary direction, a feat not usually possible with fine structure alone because the characters are often autapomorphic (i.e., confined to a single group). Characters shared by groups, synapomorphies, are needed to establish relationships.

SUMMARY

The ability to understand cytoplasmic structure can provide powerful insights into the biology of cells and organisms. This chapter has briefly reviewed the diversity of hyphal structures and presented examples of how bioimaging has contributed to a broader understanding of hyphal biology and phylogenetic relationships between fungal taxa. At the heart of polarized growth is the secretory pathway in which vesicles are targeted to sites of growth and subsequently fuse with the plasma membrane. In mature hyphae of the septate fungi, these events have given rise to the Spitzenkörper, a complex and dynamic structure that clearly influences hyphal growth and morphogenesis. Although there have been great advances in understanding the biology of the Spitzenkörper, profound questions still remain. For example, what are the unique characteristics of its three-dimensional structure, and are they applicable to phylogenetic analysis? What are the precise mechanisms of its function? Are the Spitzenkörper and polarisome one and the same? What are the processes regulating Spitzenkörper assembly and disassembly? These are complex questions that will require continued research using model organisms such as *A. nidulans*, *N. crassa*, and *Ashbya gossypii* (Ascomycota). However, it behooves us to apply our knowledge and efforts integratively and broadly so that a more complete understanding of hyphal growth among fungi can be realized. For example, what is the lineage of Spitzenkörper evolution? Are there specific advantages that the Spitzenkörper provides to growing septate hyphae that are absent from nonseptate hyphae? How common are Spitzenkörper in other, less-well studied taxa, such as hyphal members of the Chytridiomycota (e.g., *Spizellomyces punctatus* and *Monoblepharis insignis*) or zygosporic fungi

that manifest divergent characters towards the septate fungi (e.g., *Mortierella verticillata* [Mortierellales] and *Coemansia reversa* [Kickxellales])?

At the same time that some fungal biologists are asking questions about form and function, others are interested in the use of ultrastructural features as morphological traits that offer characters that support the results of molecular analyses in phylogenetic studies. The presence or absence of certain morphological characters (e.g., septa and Woronin bodies) already has been useful in defining higher taxa, especially since evolutionary polarity often can be established using stable phylogenetic trees based on DNA sequences. Ever-enlarging molecular databases, especially those of whole genomes, are allowing us to look for the genetic basis of many structural features, such as the presence or absence of Woronin body matrix proteins. This capability will allow us to understand the basis of these features not only in an evolutionary sense but also in a functional one. Collaboration among different types of fungal biologists including systematists is essential to understanding structure and how it applies to the study of the Fungi.

A Top-Down Systems Biology Approach for the Identification of Targets for Fungal Strain and Process Development

MACHTELT BRAAKSMA, ROBERT A. VAN DEN BERG,
MARIËT J. VAN DER WERF, AND PETER J. PUNT

For many years, filamentous fungi have been used for the industrial production of a large variety of metabolites and proteins. A well-known example of a fungal bioprocess is the production of the secondary metabolite penicillin by *Penicillium chrysogenum*, developed about 60 years ago (Ligon, 2004). Fungal production processes for other β-lactam antibiotics, as well as drugs such as hypolipidemic agents (e.g., lovastatin by *Aspergillus terreus*) (Tobert, 2003), have been developed since. Furthermore, many of the commercial biological production processes for organic acids are fungal bioprocesses, including the production of citric, gluconic, and itaconic acid by *Aspergillus* species or lactic acid by *Rhizopus oryzae* (Magnuson and Lasure, 2004). Filamentous fungi also play an important role in the industrial production of proteins and enzymes. In particular, *Trichoderma* and *Aspergillus* species, but also *Penicillium* and *Rhizopus* species, are used to produce a large number of different enzymes, e.g., (hemi)cellulases, xylanases, chitinases, amylases, proteases, and many more (see the list of commercial enzymes from the Association of Manufacturers and Formulators of Enzyme Products [AMFEP] at www.amfep.org). The first industrial fungal bioprocess for proteins dates back even further than that for penicillin. For instance, the product takadiastase appeared on the market in 1894 and is in fact fungal amylase produced by *Aspergillus oryzae* (Gwynne and Devchand, 1992).

Some of the above-mentioned production processes have been developed and optimized over a period of decades, like penicillin, citric acid, and amylase; others have been developed more recently and are still being optimized to reach viable commercial production levels. This is particularly true for production of nonnative proteins by use of genetically engineered fungal strains. This chapter discusses approaches to select targets for improvement of production processes, with a special focus on the application of functional genomics technologies as an unbiased approach towards target selection.

Machtelt Braaksma, Robert A. van den Berg, Mariët J. van der Werf, and Peter J. Punt, Microbial Production Processes, TNO Quality of Life, Zeist, The Netherlands.

OPTIMIZATION OF FUNGAL PRODUCTION PROCESSES

The development of a fungal production process starts with the selection of a strain that produces the compound of interest or with the construction of such a strain. Once this strain is available, production levels need to be increased in order for the process to become economically viable. Optimization of the fungal production process, or any bioprocess for that matter, can be achieved by an iterative cycle of strain improvement and/or process optimization (Fig. 1). Process optimization includes improving medium performance as well as identifying optimal environmental process parameters, such as pH, temperature, and aeration. Many techniques are available for process optimization: straightforward methods like the change-one-factor-at-a-time approach or more advanced methods using the experimental design approach, for which various design and optimization techniques are available (Kennedy and Krouse, 1999; Weuster-Botz, 2000). Many of these techniques rely on prior knowledge of components and environmental parameters likely to affect product yields. This obviously means that many more components and parameters are overlooked that could be beneficial to bioprocess performance, but about which no prior knowledge is available. Similarly, strain optimizations until now mainly include alleviating bottlenecks identified in case-by-case studies. Often only the obvious targets for metabolic engineering are addressed (van der Werf, 2005). In the case of protein production, targeting known putative bottlenecks at the posttranscriptional stage is a commonly applied approach of optimizing production levels, for instance by alleviating blockages

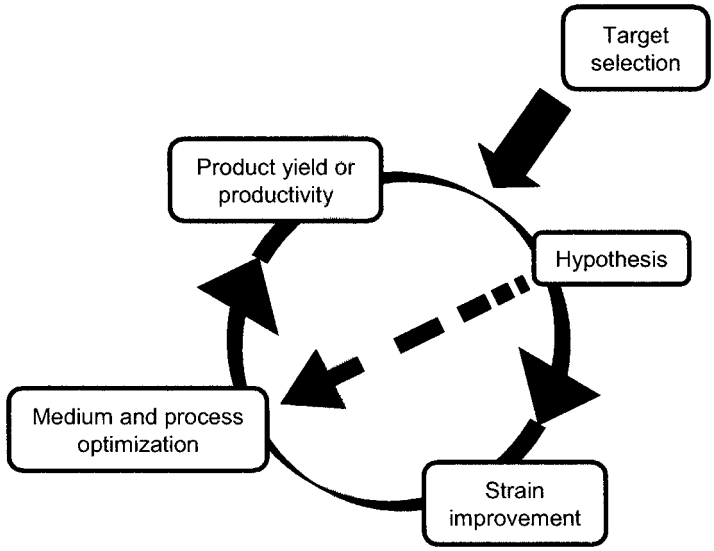

FIGURE 1 Iterative cycle of strain improvement and/or process optimization.

along the secretion pathway (Conesa et al., 2001) or by eliminating extracellular proteases (Braaksma and Punt, 2008). From the almost infinite number of genetic changes that can be introduced by overexpression or knocking out of genes, only those that are known from the current and generally limited knowledge of the metabolic pathway are selected to optimize product formation. Biological processes or interactions that are not currently known to be important for bioproduct formation or that are not yet known to exist are not taken into account.

In our research we aim at using a strain and process development approach which is not a priori hypothesis driven but relies on first acquiring data sets rich in information with regard to the bioprocess under study from functional genomics technologies and using these for target selection from the broadest possible ranges of expressed genes (transcriptomics), proteins (proteomics), or metabolites (metabolomics). In this chapter such a systems biology approach, based on the information gathered with functional genomics technologies and in combination with multivariate data analysis tools, is discussed as a method to achieve unbiased selection and ranking of targets for both strain improvement and bioprocess optimization.

TOP-DOWN SYSTEMS BIOLOGY

In systems biology the organism is studied as an integrated and interacting network of genes, proteins, and biochemical reactions. Principally, at its extreme, two approaches are recognized within systems biology: top-down and bottom-up systems biology (Bruggeman and Westerhoff, 2007). In bottom-up systems biology, biological knowledge is used as the starting point and a comprehensive mathematical model of the biological system under study is built. In fungal research metabolic stoichiometric or kinetic models and metabolic network topology models have been used for a systems-level investigation of mainly *P. chrysogenum* and *Aspergillus* species (David et al., 2006; Andersen et al., 2008a; Melzer et al., 2007; Gheshlaghi et al., 2007; Nasution et al., 2008). Similar to the more classical approaches for target selection, these methods require prior knowledge about the studied system. The models are built from known components only and demand an extensive knowledge of the individual parts of the model, and they exclude all components and reactions whose functions are not yet (fully) known.

In contrast, in top-down systems biology, data are used as the starting point and statistical data mining approaches are applied to come to a comprehensive understanding of the biological system. The principle behind top-down systems biology is that molecular components that respond similarly to changes in the experimental conditions are somehow functionally related. No other prior assumptions regarding the interactions of the studied molecular components are required. This allows the study of complex and relatively poorly characterized processes and strains, as extensive knowledge of the studied organism or process is not necessary. In this top-down systems biology approach there is also no a priori focus on specific biomolecules expected to relate to the biological question. Therefore, this approach also enables the discovery of previously unknown or unexpected relations between specific biomolecules and the biological process studied. Despite the potential of top-down systems biology, the great majority of scientists applying systems biology use a bottom-up systems biology approach. The reluctance towards top-down systems biology might relate to the risk of being overwhelmed by the enormous quantity of data that arise from functional genomics technologies such as metabolomics and transcriptomics. The challenge is to be able to extract relevant information from these data sets. Principally, the success of this approach depends on balancing three interlinked key factors: (i) definition of the biological question, (ii) experimental design, and (iii) the data analysis tool (Fig. 2). These three factors are discussed in more detail below.

THE BIOLOGICAL QUESTION

A clear definition of the biological question to be answered is the crucial starting point in any top-down systems biology research project, because only then can a suitable experimental setup and data analysis strategy be selected (van der

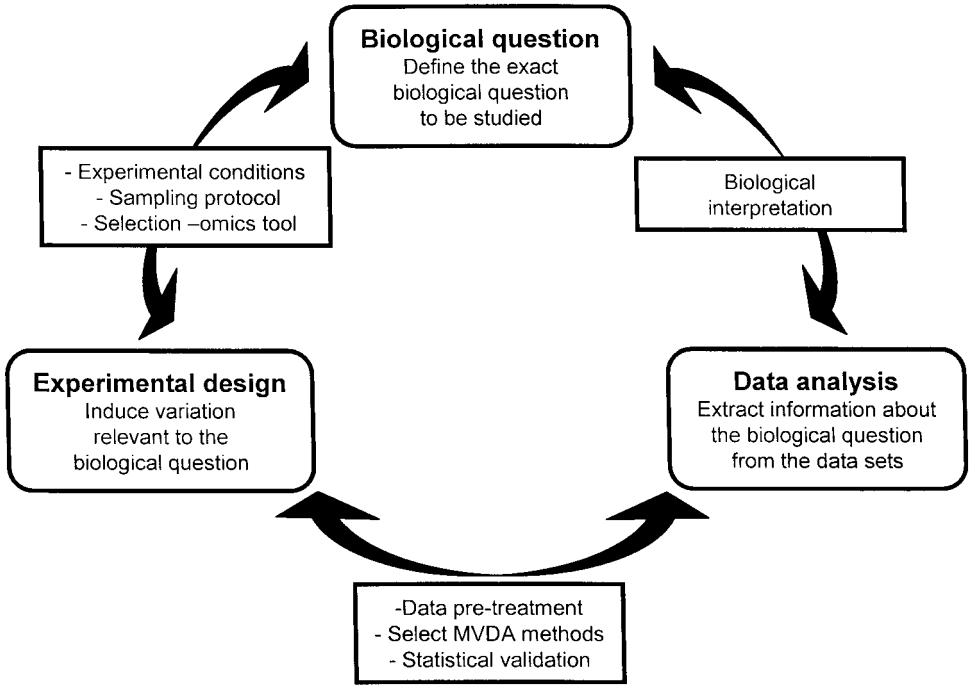

FIGURE 2 Key conditions and their relation to a successful systems biology study. In top-down systems biology, three interlinked factors are crucial for success: (i) the biological question, (ii) the experimental design, and (iii) data analysis.

Werf et al., 2005; Trygg et al., 2007). To explain this in more practical terms, two examples are given of ways to define the biological question in a study to gain more insight in the regulation of the proteolytic system of *Aspergillus niger*. First, when this problem is approached on a metabolic level, the biological question could be, "Which metabolites induce protease activity in *A. niger*?" On the other hand, when this problem is approached on a genetic level the biological question could be stated as, "Which transcriptional regulators are associated with protease activity in *A. niger*?" In the first case metabolite levels are the relevant biomolecules to be measured, in the second case transcript levels are to be determined, and in both cases protease activities will have to be determined. What is important is that the biological question be translated into a quantifiable biomolecule level, which can be measured at different biochemical levels (i.e., at the transcriptome, metabolome, or proteome level). In addition, it is often possible to specify a quantifiable phenotype that is relevant for the biological question, such as protease activity in this case. It is also very important to clearly define this phenotype. For instance, in the production of a biological compound or activity, among others, the following definitions of phenotypes could be chosen for improvement: concentration (in grams per liter) or activity (in units per liter); specific concentration or activity (in grams per gram dry cell weight or in units per gram dry cell weight); productivity (in grams per liter per hour or in units per liter per hour); specific productivity (in grams per gram dry cell weight per hour or in units per gram dry cell weight per hour). When reducing costs of nutrients is the key goal, one could also think of defining the phenotype as cost of nutrients per unit product (in U.S. dollars per gram of product) or cost of nutrients per unit productivity (in U.S. dollars per gram of product formed per liter per hour) (Kennedy and Krouse, 1999). The biological question and its translation into a practical format strongly influence the other key factors of a top-down systems biology study, i.e., experimental design and data analysis. The experimental setup should ensure that experimental conditions that induce variation relevant for the biological question are selected and that data analysis is able to extract the information relevant to the biological question from the functional genomics data set.

EXPERIMENTAL DESIGN

Based on the biological question, the experimental design of the top-down systems biology study should be aimed at generating large information-rich data sets in order for data analysis to extract relevant biological information from the data set. Not only experimental conditions for the experimental design should be considered, but also sampling, sample workup, and the functional genomics tool to be used to analyze the samples.

Experimental Conditions

The first step in establishing how to plan and conduct the experiments is to identify those parameters affecting the response of the phenotype. These parameters can be process type (batch, fed-batch, or continuous), environmental conditions such as pH and nutrients, or selected strains. In the case of using various mutant strains to induce variation in the data set (for an example, see Askenazi et al., 2003), one should keep in mind that each strain may have its own bottleneck, making identification of specific targets for a general improvement more complex. When a phenotype relevant to the biological question is available, the experimental conditions should be targeted to induce variation in

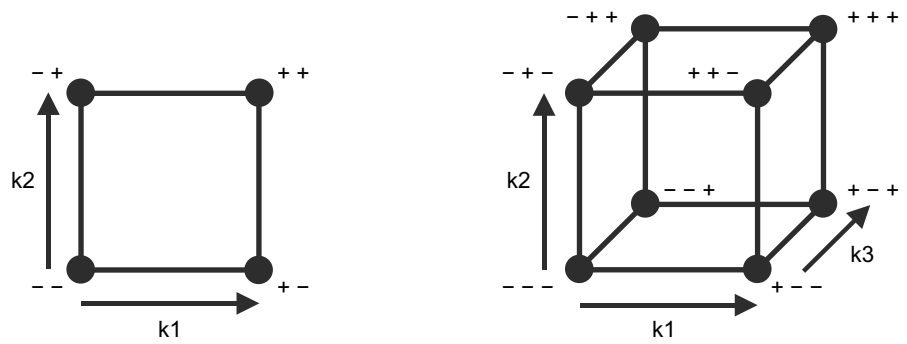
this phenotype. When it is unclear what experimental factors are involved in the induction of biological variation relevant to the biological problem, screening experiments need to be conducted to obtain more information regarding these experimental factors.

Traditionally, one of the most frequently used approaches to study which parameters affect biological responses is the change-one-factor-at-a-time approach, in which one independent variable is studied while all others are fixed at a specific level. An advantage of this simple and easy method is that any change in response can be attributed to a specific change. On the other hand, this change-one-factor-at-a-time approach has some serious drawbacks, perhaps the most important being that possible interactions between components are ignored. As a result, this approach frequently fails to find optimal conditions for experiments. Another disadvantage is the unnecessarily large number of experiments that are required when testing more than a few variables. Therefore, the change-one-factor-at-a-time method is acknowledged to have severe shortcomings and is more and more being replaced by statistics-based experimental designs, also called "Design of Experiments." For an initial screening of factors possibly related to the biological question, different types of experimental designs, so-called screening designs, are available, including the full factorial design (Lundstedt et al., 1998). In a full factorial design, every level of a factor is investigated at all levels of all other factors. Often the factors are investigated at two levels, requiring a number of runs equal to 2^k for k factors, which results in a large number of experiments when many factors are investigated (Fig. 3). When the factors are investigated at three or more levels, requiring 3^k runs in the case of three levels and n^k runs for n levels, the number of experiments rapidly becomes impracticable. To reduce the number of experiments without the loss of too much information, several experimental designs derived from the full factorial design are available. The most commonly used one is the fractional factorial design (Lundstedt et al., 1998; Trygg et al., 2006), which requires only n^{k-p} number of runs, with k as the number of investigated factors at n different levels, and p describing the size of the fraction of the full factorial used. With this type of design, three-way and higher interactions are ignored. Another useful screening tool is the Plackett-Burman design (Plackett and Burman, 1946; Weuster-Botz, 2000). This experimental design is a variation on the fractional factorial design, but instead of ignoring only higher interactions it considers all interactions between factors negligible. The downside of the last two designs is that when interactions between factors are not negligible, they are confounded with the estimated effects. This means that the estimated effects and those interaction effects cannot be distinguished from one another.

Based on this first phase, the main factors relevant to the biological question under study are selected for the final setup of experiments for the top-down systems biology study. In principle, statistical experimental designs for this phase can be any of the methods as described above. While in the screening phase the goal was to find out a little about many factors, in this phase the goal is to extract the maximum amount of information from the experiments, preferably in the fewest number of runs. Types of statistical experimental designs suitable for this phase of the study include central composite designs and Box-Behnken designs, which are both based on (fractional) factorial designs, or D-optimal designs, a computer-aided design method (Kennedy and Krouse, 1999; Trygg et al., 2006; Lundstedt et al., 1998). On top of that, response surface methodology can be applied to generate a data set with an evenly distributed variation. Response surface methodology is commonly used in industry for process optimization (Dobrev et al., 2007; Li et al., 2007). Based on a set of designed experiments, e.g., from a factorial design, a model that predicts the biological response to different levels of the various factors included in the study is built. In contrast, from such a model, conditions that will result in various levels of relevant biological response can be selected for the top-down systems biology study.

Selection of a Functional Genomics Tool

Selection of the functional genomics tool to be used in a top-down systems biology study depends on the level at which the biological phenomena relevant for the biological question occur. With transcriptomics the expression levels of mRNA under a given condition are examined. The transcriptome reacts very fast, within a few minutes, to environmental changes. This makes transcriptomics a very suitable tool to study the cell exposed to changing environmental conditions, such as the addition of toxic or chemical compounds (Arvas et al., 2006; Guillemette et al., 2007) or transfer from one medium to another (Yuan et al., 2006). However, mRNA levels do not directly correlate to the levels of the encoded protein, due to posttranscriptional regulation steps at the level of mRNA stability, processing, and



A. 2^2 full factorial design **B**. 2^3 full factorial design

FIGURE 3 Full factorial designs, with two factors (A) or three factors (B) investigated at two different levels.

translation. Therefore, transcriptomics is only an indirect approach to study the function of a cell. On the other hand, the proteome and the metabolome together determine the actual function of the cell (the phenotype) (Oliver, 2000).

The proteome, meaning all proteins present at a given moment under defined environmental conditions, gives an indication of which metabolic pathways occur under those conditions (Kim et al., 2007a), as many proteins are enzymes that catalyze biochemical reactions. In contrast to transcriptomics, quantitative proteomics is still far from being a comprehensive analysis tool, mainly due to the limited dynamic detection range and poor reproducibility of proteomic analysis. Because of this there is a very strong bias towards identifying only the more abundant proteins in a complex proteome sample. Nonetheless, to study posttranslational modifications of proteins, such as phosphorylation and glycosylation, proteomics is the most obvious tool (Fryksdale et al., 2002; Kim et al., 2007b).

The metabolome of the cell, i.e., all metabolites present in a cell at a certain moment, provides valuable information about the regulatory or catalytic properties of either mRNA or enzyme, as metabolites are downstream of all genome and proteome regulatory structures (Oldiges et al., 2007). As the metabolome is closest to the phenotype of a cell, it will be most relevant in order to understand biological functioning. Similar to what was noted above for proteomics, full coverage of the complete metabolome is not (yet) accomplished by the available analytical platforms, although some metabolomics platforms are approaching the ultimate goal of providing a universal platform for the comprehensive and quantitative analysis of microbial metabolomes (van der Werf et al., 2007).

Sampling Strategy

The sampling strategy is part of the experimental setup and describes when and how samples for the functional genomics analysis are collected. It embraces two main issues, namely, collecting the sample at a time point where the biological response relevant to the biological question is present and ensuring that levels of biomolecules remain unchanged from the moment of sampling. Concerning the first issue, if it is unknown beforehand which phases during the cultivation contain information related to the biological question, the sampling protocol should cover all possibly relevant growth phases and phase transitions (Trygg et al., 2007). At the same time, practical matters have to be considered as well. For instance, the sampling volumes can limit the number of obtainable samples, or the costs of sample analysis can influence the sampling strategy. In the case of continuous cultures, time issues are of no importance, but due to technical difficulties this fermentation technique is not as commonly applied in fungal research as it is in research involving other microorganisms. Besides, with the application of continuous cultures the approach is quite different, as time is no longer a factor, excluding longitudinal effects (e.g., induction or other perturbations during the fermentation process). In addition, it should be noted that although the process conditions are fixed during continuous cultures, changes in the production organism are frequently observed (Swift et al., 1998; Withers et al., 1995), making continuous cultures prone to transitions, albeit of a different kind.

The second issue relates to the high turnover of mRNA and metabolites (for proteins this is not so much of an issue), risking the introduction of unwanted changes in RNA or metabolite levels during sample harvesting or workup. In order to obtain samples that reflect the state of the cell under the environmental conditions at the time of harvesting, rapid sampling (Nasution et al., 2006) and immediate inactivation (quenching) of the cellular metabolism are a necessity. In the literature, the quenching methods used for filamentous fungi mainly include rapid filtration followed by immediate freezing of the cells (David et al., 2006) (mostly used for transcriptomics samples) or dilution of the cells in a methanol solution of −45°C (more often used for metabolomics samples) (Ruijter and Visser, 1996; Nasution et al., 2006; Kouskoumvekaki et al., 2008).

After quenching the cells, conditions should be maintained during sample workup in order to prevent changes in the metabolite composition or RNA levels due to residual enzymatic activity present in the samples. Extraction of RNA from mycelia is often accomplished by disruption of the cells by either grinding under liquid nitrogen with a mortar and pestle (Kimura et al., 2008; Foreman et al., 2003) or bead milling at temperatures of approximately 4°C (Andersen et al., 2008b), followed by a standard RNA isolation protocol. Extraction of proteins is done in a similar way, without the stringent control of temperature (Carberry et al., 2006). For fungal metabolomics samples, two methods in particular have been described for extracting metabolites from the cells. The first is boiling the cells in an ethanol-buffer solution and subsequent reduction of the volume by evaporation in a rotavapor (Nasution et al., 2006). The second is chloroform extraction at −45°C (Ruijter and Visser, 1996).

A final issue to consider as part of the sampling strategy is replicates. As the total variation in the data set is the sum of technical, uninduced biological, and induced biological variations, repeated measurements may be necessary to estimate the individual contributions of these various parts. However, in general the biological variation is much larger than the variation induced by sample workup or variation in the analytical method (van den Berg et al., 2006). This makes repeating the experimental procedure with identical samples not very worthwhile in most cases. Some biological replicates will have to be included in the experimental design to estimate the overall uninduced biological variation due to small differences between biological conditions or biological variability. In this way, the induced biological variation can be established, calculated on the basis of the differences between the experimental conditions.

Based on the various aspects of the experimental setup discussed above, it becomes clear that it is necessary to balance the demands from the biological question and the data analysis on one side with practical considerations on the other.

DATA ANALYSIS

After having generated data sets under several different conditions with hundreds or thousands of proteins, mRNAs, or metabolites, the remaining challenge is to extract information about the biological question from these enormous data sets. Multivariate data analysis (MVDA) tools are preferably used, as those tools take into consideration the intrinsic interdependency of the biomolecules. But before the data sets can be analyzed by MVDA tools, the data output from the various functional genomics methods often requires data pretreatment.

Data Pretreatment Methods

In addition to the specific preprocessing steps of the data output from the various genomic methods, such as deconvolution of data files generated by gas chromatography-mass spectrometry for metabolomics (van der Werf et al., 2005) or normalization of cDNA microarrays (Leung and Cavalieri, 2003), another critical step before applying MVDA tools is data pre-

treatment of the data sets. Data pretreatment procedures correct for the influence of factors such as the abundance of a biomolecule or the magnitude of the change, which are generally not a reflection of the importance of a biomolecule (van den Berg et al., 2006). Appropriate data pretreatment methods will articulate the *biological* information content and will consequently allow more relevant biological interpretation of the data set. Three classes of data pretreatment methods can be distinguished: centering, scaling, and transformation. The last two methods are always applied in combination with centering. In MVDA, mean centering and autoscaling are the two most commonly used data pretreatment methods. With mean centering, the average level of a biomolecule is subtracted from each individual experiment, thereby adjusting for differences in the offset between high-abundance and low-abundance biomolecules. With autoscaling, the values are subsequently divided by the standard deviation of each biomolecule, adjusting for disparities in increase/decrease differences between the various biomolecules. In addition to these two methods, range scaling holds great promise, as the mean centered values are not divided by a statistical measure for data spread, as is the case with autoscaling, but by a biological measure, namely, the biological range. The biological range is the difference between the minimal and maximal levels reached by a certain biomolecule in a set of experiments. In Fig. 4 the effect of data pretreatment on principal component analysis (PCA) results of a metabolomics data set of *Trichoderma reesei* is shown (van der Werf et al., unpublished data).

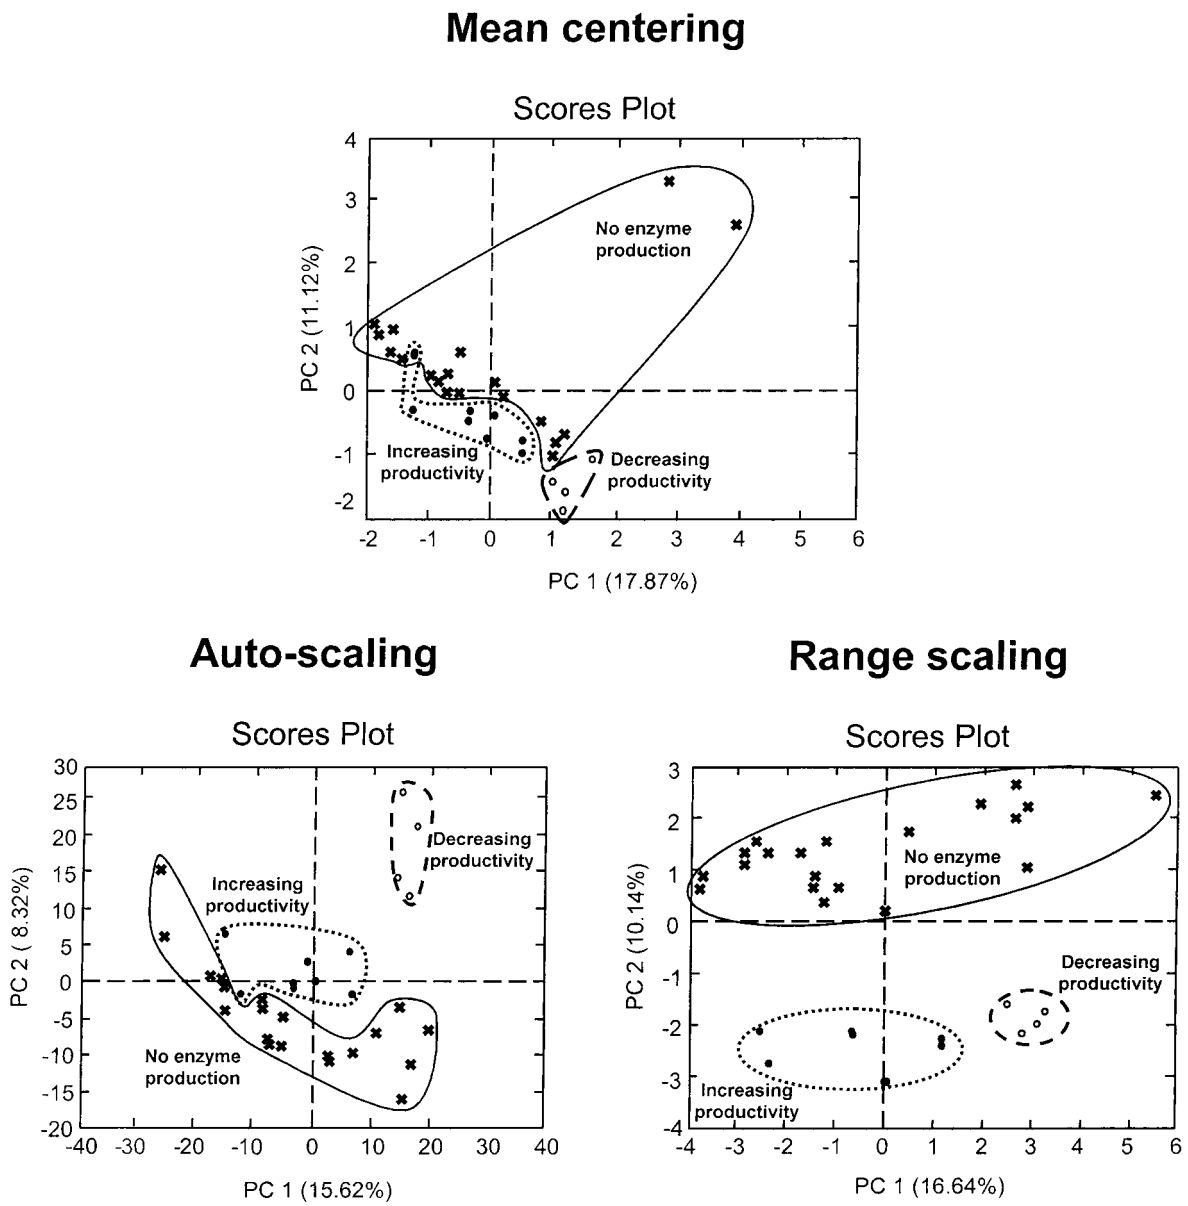


FIGURE 4 The effect of mean scaling, autoscaling, or range scaling of metabolomics data sets on PCA data results. The data sets are derived from research related to induction of cellulase activity in *T. reesei* (van der Werf et al., unpublished data). The metabolomes of three groups of samples (no enzyme production, increasing productivity, and decreasing productivity) were analyzed and pretreated with these three different approaches and subsequently analyzed by PCA.

With data pretreatment the biological information content in the data set is accentuated. In this particular case, it is range scaling that especially emphasizes the biological variation among the different biological groups. This data pretreatment method allows a clear separation of these different groups, whereas no grouping or a less obvious grouping is observed in the data sets when the other two methods are used.

MVDA Tools

Choices in data analysis strategy are influenced by the biological question, the characteristics of the experimental design, the behavior of the relevant biomolecules, and the dimensions of the data set. There are various MVDA methods that address different biological questions. In general, these methods can be divided in two main groups, namely, unsupervised methods and supervised methods. Unsupervised methods include PCA (Jackson, 1991; Jolliffe, 2002) or hierarchical clustering analysis (Eisen et al., 1998) that visualize relations/patterns in data sets without prior knowledge. Supervised methods, which include regression methods such as partial least squares (Geladi and Kowalski, 1986) and principal component regression (Mardia et al., 1979) or classification methods such as partial least squares discriminant analysis (Barker and Rayens, 2003) and principal component discriminant analysis (Hoogerbrugge et al., 1983) do the same as unsupervised methods while at the same time prior knowledge about one or more biological properties of the data set are taken into consideration. Discriminant methods are particularly suitable for samples with no quantifiable phenotype other than the presence or absence of a certain biological characteristic, e.g., morphological traits such as color or hyperbranching or certain environmental conditions or perturbations. For discriminant methods, this means that the samples are divided in (biological) groups, e.g., a group of samples from the wild-type strain and a group of samples from a mutant. Although each sample within such a biological group is designated as equal, there will always be biomolecules correlating to specific groups that are irrelevant to the biological question under study (so-called chance correlations). Therefore, when it is possible to express the phenotype as a numerical figure, this is preferred, as the risk of chance correlations is reduced when analyzing such data with regression methods. Regression methods find correlations between a numerical phenotype response and the biomolecule composition for the different samples in the data set. Regression methods are preferably applied to a set of experiments with large and evenly distributed variation in the biological response of interest.

In addition, validation of the data analysis results is of crucial importance, as it will provide an indication of the risk that correlations were found by chance due to the relatively low number of samples in relation to the large number of measured biomolecules. As multivariate statistical methods were developed for data sets containing many samples and few variables, this is a serious risk. Frequently applied data analysis validation strategies in top-down systems biology are cross validation, permutation, jackknifing, and bootstrapping (Rubingh et al., 2006; Westerhuis et al., 2008; Efron and Tibshirani, 1993). Based on the results of these validation steps, the reliability of the obtained models is established. Finally, a list of biomolecules can be obtained with the largest contribution to the model, i.e., those with the highest absolute regression factor. The biomolecules with the highest ranking are considered to be most relevant to the studied biological phenomenon.

Biological Interpretation

Based on the list of biomolecules identified by the MVDA tools as being important in relation to the question under study, targets for improvement of the production process have to be selected. There is a possibility with MVDA tools that biomolecules that do not show an unambiguous interaction with the specific biological question will be identified. Therefore, one of the first steps is to go back to the original data sets and examine fluctuation of the concentration of the biomolecule in relation to the studied phenotype. Moreover, not all biomolecules that exhibit an apparently strong interaction with the studied phenotype are biologically related to it. For that reason, as much information as possible should be acquired about the biological function of these biomolecules in the context of the question under study. From this knowledge, biological hypotheses will have to be formulated and new experiments will have to be set up to test them. For targets from transcriptomics studies, this can be quite straightforward, by either overexpression or deletion of the designated relevant genes, depending on a positive or negative correlation with the phenotype. On the other hand, several options for the ultimate improvement of the process are possible for targets identified in metabolomics studies. An easy way to increase product levels might be the addition or omission to the growth medium of a relevant metabolite identified by data analysis. This approach bears the risk that the transport of the compound into the cell will limit its suitability. More complex is the segue from a relevant metabolite identified by using metabolomics to a gene target for metabolic engineering. This requires knowledge about the metabolic pathway(s) involving the metabolite and its putative (allosteric) regulatory effects. Even then, it is not straightforward to translate this knowledge into a gene target. For instance, when a positive correlation between the product of interest and an intermediate in the biosynthesis route for the product is observed (an increase in the concentration of this intermediate correlates with elevated product levels), the enzyme converting the intermediate is not active enough and the corresponding gene should therefore be overexpressed. In another example, elevated product levels correlate with increased levels of an intermediate via a side reaction. Elimination of this competitive pathway by deletion of the corresponding gene should result in an increased flux through the biosynthetic pathway of interest and thus elevated levels of the desired product.

RESEARCH EXAMPLE: A TOP-DOWN SYSTEMS BIOLOGY APPROACH TO STUDY PROTEASE INDUCTION IN *A. NIGER*

At the Microbial Production Processes group of TNO Quality of Life, part of the internationally operating Netherlands Organization for Applied Scientific Research, filamentous fungi are developed as production hosts for heterologous proteins. For this application of filamentous fungi, degradation by proteases is acknowledged to be one of the key factors limiting heterologous protein yields. Besides classical approaches for strain development, such as screening for protease mutants and targeted disruption of known protease genes (Braaksma and Punt, 2008), a top-down systems biology approach was applied to further elucidate the proteolytic system and its regulation in *A. niger*. The ultimate goal is to identify new targets for further improvement of the fungal cell factory for heterologous protein production.

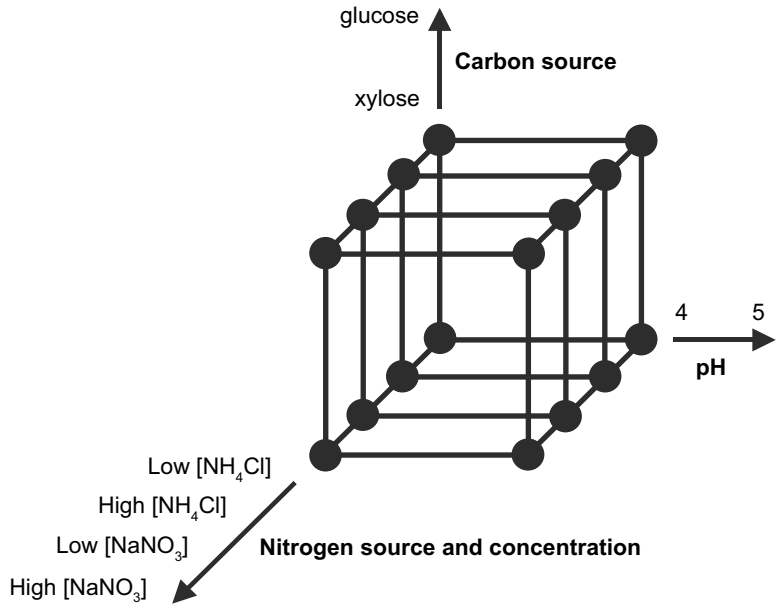

FIGURE 5 Full factorial design of the experiments for the top-down systems biology approach to study the regulation of the proteolytic system of *A. niger*. Four factors were varied at two different levels.

Approach

During the past decade, an advanced analytical platform has been developed at TNO that allows the comprehensive analysis of a broad range of metabolites (van der Werf et al., 2007). This metabolomics platform has been successfully applied for metabolomics studies of various microorganisms, including a study for metabolites linked to cellulase induction in *T. reesei* (van der Werf et al., unpublished data). This platform was therefore used to study the regulation of the proteolytic system of *A. niger*, with the specific biological question: "Which metabolites induce protease expression in *A. niger*?" In order to perform a top-down systems biology study, data sets in which the levels of protease activity varied were required. To this end, after an initial screening of conditions influencing protease activity in *A. niger* cultures, a series of experiments were performed according to a full factorial design involving four factors that were investigated at two levels (Braaksma et al., 2009). The four factors included were pH, carbon source, nitrogen source, and nitrogen concentration (Fig. 5). At different phases during growth, samples were collected and prepared for metabolome analysis (Braaksma et al., unpublished data). As it was not clear beforehand how to define the phenotype protease activity, several definitions were used and compared during the course of the research (Fig. 6). In the case where bioproduct formation occurs during the stationary phase, as is observed with protease activity, the specific activity, concentration, or productivity could be calculated from the actual biomass or the maximum biomass. Due to lysis, biomass levels might decrease significantly during the stationary phase, resulting in deceivingly high values for specific phenotypes, or further increase even when actual production has ceased.

The following example illustrates that having a well-thought-out experimental design beforehand (including the choice of functional genomics tools and sampling strategy) is crucial for a successful top-down system biology study. After the culturing experiments had been performed, the opportunity occurred to also perform transcriptomics analysis with a limited number of samples. This allowed investigation of transcriptional changes that are associated with protease expression in *A. niger*. As the experiments were not designed specifically for transcriptional analysis, the selection of samples to be used for RNA extraction and microarray analyses turned out to be the critical step. The response of transcript levels to environmental changes is preceded by regulation by metabolites, which make sampling at specific time points even more crucial for transcriptomics. The earliest samples in which protease activity was detectable were selected for the transcriptomics analyses. Due to this criterion, some of the selected samples were from a time point at which the carbon source was still present in the medium, while another set of samples were from times when the carbon source had been depleted. Unexpectedly, statistical data analysis of the results from the microarray revealed that variation in protease activity due to various growth conditions was actually dominated by variation due to the different biological time points of the samples. PCA showed that instead of clustering samples together based on similar protease levels, samples clustered based on whether the carbon source was still present or not. Knowledge not only of protease activity as phenotype but also of other measured culture parameters allowed identification of this effect. Based on these results, it was clear that additional microarray experiments using an experimental design with the explicit intent of applying transcriptomics would be preferred to study transcriptional changes associated with protease expression in *A. niger*.

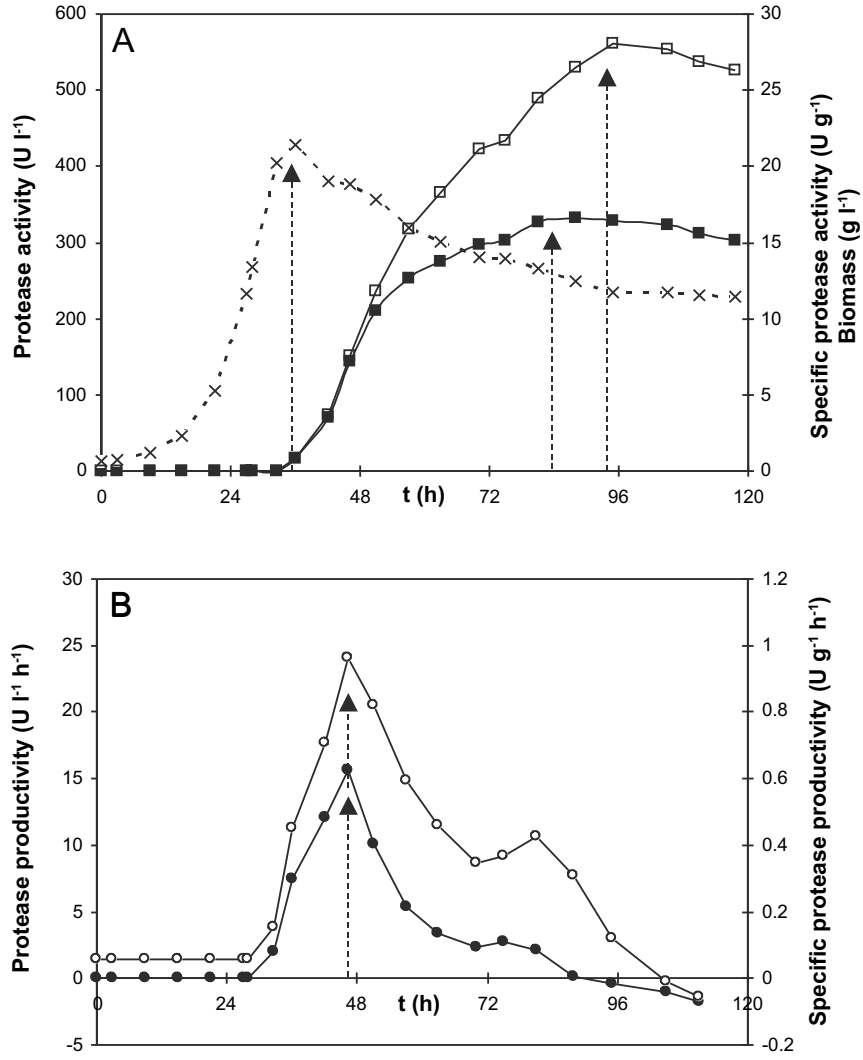

FIGURE 6 Representation of different protease phenotypes during a glucose-based batch culture. (A) Protease activity (■) and specific protease activity (□). (B) Protease productivity (●) and specific protease productivity (○). Time points at which the biomass (×) and each different phenotype reached its maximum value are indicated by upward arrows.

CONCLUSIONS

The available selection methods for relevant targets for fungal strain and process development, or for that matter any microbial production process, have been very successful in numerous cases. However, the exclusion of all biological processes or interactions that are not currently known to exist has been shown to hamper further improvement while using these approaches. Recently introduced functional genomics technologies in combination with MVDA tools enable an open and comprehensive top-down systems biology approach towards target selection. Nevertheless, the success of such an approach depends heavily on a systematic study covering all aspects, from a clear description of the biological question up to statistical data analysis. As this involves knowledge beyond the biologist expertise (e.g., biostatistics), the assistance of experts in other fields will be indispensable. Due to its unbiased nature, a successful top-down systems biology approach will provide a new boost in the ongoing cycle of bioprocess optimization.

Phylogenetics and Phylogenomics of the Fungal Tree of Life

JOSEPH W. SPATAFORA AND BARBARA ROBBERTSE

The past 2 to 3 decades have witnessed both the birth of molecular phylogenetics of fungi and its development into a fundamental tool for comparative biology of fungi. Phylogenetic trees, once restricted to studies on systematics, are now used throughout all disciplines of fungal biology and provide the evolutionary context for a broad suite of studies that include understanding the evolution of major life forms, description of complex biotic communities, and predictive experimental biology. This is especially true in the genomic era, where a rapid convergence of phylogenetics and genomics is occurring and is resulting in the emerging field of phylogenomics. Although a young field, phylogenomics has already garnered multiple definitions including the use of evolutionary relationships to predict homology and function of uncharacterized genes, and the construction of phylogenies based on genome-scale sampling of the maximum—or at least a large amount—of discrete orthologous sequence data. Here we provide a review of (i) the current status of fungal phylogenetics based on multigene phylogenies, (ii) current evolutionary hypotheses on the evolutionary relationships of organisms that are classified in the Kingdom Fungi, and (iii) the use of genome-scale sampling to infer evolutionary relationships of the fungi.

MOLECULAR SYSTEMATICS OF THE FUNGI

Since the first molecular phylogenetic studies of the Kingdom Fungi, rRNA genes have played a prominent role in inferring phylogenetic relationships of the kingdom (Bruns et al., 1992). This is largely based on the fact that rRNA genes are ubiquitously distributed across life and that these genes possess regions of nucleotide conservation, which allowed for the development of universal primers (Bruns et al., 1991). Thus, the collection and alignment of rRNA nucleotide data were relatively straightforward and resulted in an exponential increase of molecular phylogenetic studies of the Fungi throughout the 1990s (Lutzoni et al., 2004). Although these analyses were collectively based on a small set of data, numerous landmark discoveries that greatly advanced the field of fungal phylogenetics were made regarding the evolution of fungi and fungus-like organisms. These include, but are not limited to (i) the placement of the heterokont water molds (Oomycota) and slime molds (Myxomycota) outside the Fungi (Gunderson et al., 1987; Baldauf and Doolittle, 1997); (ii) recognition of a close evolutionary relationship between the Animal Kingdom and Fungi (Baldauf and Palmer, 1993); (iii) defining a monophyletic Fungi to include Chytridiomycota, Zygomycota, Basidiomycota, and Ascomycota (reviewed by Blackwell et al., 2006); (iv) characterization of the Chytridiomycota as comprising the early-diverging lineages of Fungi (James et al., 2000); (v) recognition of the arbuscular mycorrhizae (Glomeromycota) as a taxon distinct from the Zygomycota (Schüβler et al., 2001); and (vi) support for the monophyly of Ascomycota and Basidiomycota and their sister group relationship (Lutzoni et al., 2004).

In spite of these advancements, it became clear that rRNA data alone were limited in their utility and that many important phylogenetic questions pertinent to understanding the evolution of the Fungi would require additional genes and likely different types of genes, i.e., protein-coding genes (Liu and Hall, 2004; Lutzoni et al., 2004; Reeb et al., 2004). PCR and sequencing primers with fairly broad applicability were developed for several nuclear protein-encoding genes, with the first and second largest subunits of RNA polymerase II (*RPB1* and *RPB2*, respectively) and translation elongation factor 1-alpha (*TEF*) being the most widely used protein-coding genes in fungal systematics. These genes provided independent assessments of rRNA phylogenies and resulted in more robust tests of morphological and ecological evolution of the Fungi (Blackwell et al., 2006). These genes also provided the raw data that initiated the production of multigene phylogenies and arguably transformed the field of fungal phylogenetics from gene trees to species trees.

In order to advance the development of multigene phylogenies, the fungal systematics community created the Research Coordination Network Deep Hypha (Blackwell et al., 2006). The goal of the Deep Hypha Research Coordination Network was to accelerate the collection of multigene

Joseph W. Spatafora and Barbara Robbertse, Department of Botany and Plant Pathology, Oregon State University, Corvallis, OR 97330.

sequence data across the Fungal Tree of Life. This was achieved by the creation of the community-based "Assembling the Fungal Tree of Life" (AFTOL) Project, which promoted the collection of nucleotide sequence data for six loci—nuclear small subunit rRNA and nuclear large subunit rRNA, mitochondrial small subunit rRNA, *RPB1*, *RPB2*, and *TEF*—for a target set of taxa across the major orders and families of the Fungi (Lutzoni et al., 2004). AFTOL resulted in the collection of more than 5,000 publicly available sequences for more than 2,000 taxa and the development of additional primers for enhanced data collection across the Fungi. (Visit www.aftol.org for a complete list of sequences and primers managed by WASABI [Kauff et al., 2007].) Simultaneous with the rapid growth in the collection of multigene data sets was the dramatic development of algorithms for model-based phylogenetic analyses of complex nucleotide sequence datasets. Maximum likelihood and Bayesian analyses of large multigene data sets are now routine due to the development of faster and more powerful processors and readily available computer software packages with more efficient search algorithms (e.g., RAxML [Stamatakis, 2006]; GARLI [Zwickl, 2008]; MRBAYES [Ronquist and Huelsenbeck, 2003]; and PhyloBayes [Lartillot and Philippe, 2004]). Recent analyses of multigene sequenced data have resulted in enhanced phylogenetic resolution (Matheny et al., 2007; Hofstetter et al., 2007) and have demonstrated that the protein-coding genes *RPB1*, *RPB2*, and *TEF* possess higher levels of phylogenetic informativeness than rRNA genes (Townsend, 2007; Schoch et al., 2009). The convergence of our ability to collect relatively large amounts of multigene sequence data and our ability to rigorously analyze these data has resulted in our current and most accurate understanding of the evolution of the Fungi.

THE FUNGAL TREE OF LIFE

By the Fungal Tree of Life, we explicitly refer to the monophyletic Kingdom Fungi (Fungi) and all of its subgroups. For brevity's sake we will not discuss groups outside the Fungi (e.g., Oomycota), although they are important organisms at numerous levels and have traditionally been studied by mycologists. We also focus our discussion on higher-level systematics, emphasizing major clades of Fungi and patterns of fungal evolution. The Fungi currently comprises one subkingdom, six phyla, 10 subphyla, 35 classes, 12 subclasses, and 129 orders (Hibbett et al., 2007). These taxa collectively form a phylogenetic classification whereby all groups are based on phylogenetic analyses that revealed support for monophyletic groups (clades) of fungi (see Hibbett et al., 2007, for supporting studies). As such, some traditional groups were not inferred to be monophyletic and some taxa (e.g., Zygomycota) were not formally designated as a group, while others (e.g., Chytridiomycota) have a more restricted use. This classification will undoubtedly be modified over the years as new higher-level taxa are discovered, but the recognition of taxa based on the criterion of monophyly as revealed by explicit multigene phylogenetic analyses should provide a greater level of stability. Also, the names proposed for higher taxa by Hibbett et al. (2007) employ the rationale of autotypification as originally applied to the Ascomycota by Eriksson and Wynka (1997). That is, the names of higher taxa (e.g., class Sordariomycetes, subphylum Pucciniomycotina) are based on well-characterized and nomenclatural legitimate genera (e.g., *Sordaria* and *Puccinia*, respectively), thereby removing any taxonomic confusion or uncertainty associated with previous classifications (e.g., Pyrenomycetes and Urediniomycetes, respectively).

The Early-Diverging Lineages of the Fungal Tree of Life

The early-diverging lineages of the Fungal Tree of Life (Fig. 1) consist of zoosporic fungi formerly classified in the Chytridiomycota (James et al., 2006a), nonflagellated filamentous fungi of Zygomycota (White et al., 2006), and the Microsporidia (Keeling and Fast, 2002). Microsporidia are unicellular, intracellular parasites of animals, and their phylogenetic placement has been and continues to be controversial (Gill and Fast, 2006; Liu et al., 2006). They possess highly reduced genomes and relatively high rates of nucleotide substitution (Keeling and Slamovits, 2004). Consequently, there exist fewer clear-cut examples of shared orthologous genes with other taxa. For those genes that are clearly orthologous (e.g., rRNA genes), nucleotide positional homology is often difficult to assess due to the high rate of nucleotide substitution and significantly complicates DNA alignments and phylogenetic analyses. Historically Microsporidia were classified in the Protista, which has long been recognized as a taxon of convenience and not monophyletic. More recent phylogenetic analyses of protein-coding data support Microsporidia as a member of the early-diverging lineages of the Fungi (Keeling, 2003; James et al., 2006a) or as a sister group to the Fungi (Liu et al., 2006). Hibbett et al. (2007) classified Microsporidia as a member of the Fungi, which is consistent with either of the aforementioned placements. One of the more provocative hypotheses concerning the phylogenetic placement of Microsporidia is that of James et al. (2006b). In that study, which is based on five nuclear genes and one mitochondrial locus, Microsporidia, along with *Rozella*, a chytrid that is an intracellular parasite of other fungi, formed the earliest-diverging clade of the Fungi. Caution is advised here, however, as the grouping of these intracellular parasites may well be an artifact of long branch attraction driven by common molecular evolution processes (e.g., high rates of nucleotide substitution, reduced gene content, nucleotide biases, etc.). Consistent with this relationship being an analytical artifact, a more recent analysis of genome organization provided support for placement of Microsporidia among the zygomycetous fungi based on the presence and synteny of sex loci (Lee et al., 2008). Thus, the placement of both Microsporidia and *Rozella* remains elusive, and these two important taxa require additional research.

Although zoosporic (flagellated) fungi comprise a small number (<1,000) of known species of Fungi (Kirk et al., 2008), an accurate understanding of their phylogenetic relationships is essential to understanding early and pivotal events in the evolution of the kingdom. All zoosporic species of Fungi produce zoospores that possess a single smooth posterior whiplash flagellum with some polyflagellate exceptions. Until recently, zoosporic species of Fungi were classified in the Chytridiomycota sensu Barr (Barr, 1992). Phylogenetic analyses of multiple genes, however, have revealed that the Chytridiomycota does not form a monophyletic group (James et al., 2000, 2006a, 2006b). Rather, these fungi comprise a set of paraphyletic lineages that occupy much of the early-diverging branches of the Fungal Tree of Life (Fig. 1). These lineages include the genus *Rozella* (mentioned above), the Chytridiomycota, Neocallimastigomycota, and Blastocladiomycota, and the genus *Olpidium*. The Chytridiomycota represents the core chytrid clade, and most species produce zoosporangia with life cycles characterized by very limited if any hyphal growth. The majority of Chytridiomycota members are saprobic and occur in

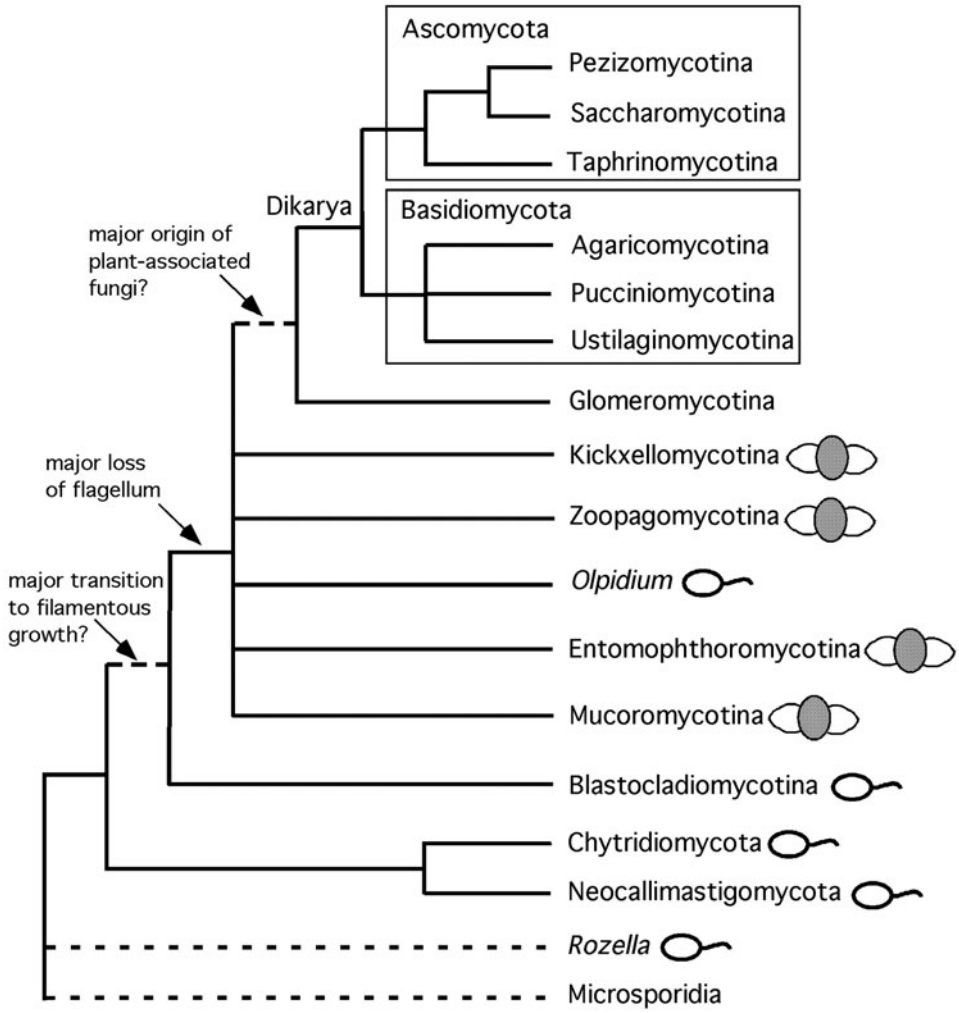

FIGURE 1 Fungal Tree of Life. Phylogenetic tree depicting the major phyla and subphyla of the Kingdom Fungi. Hypotheses for major morphological transitions are depicted along the backbone of the tree. Lineages of zoosporic and zygosporangium-producing fungi are shown along the right of the tree with the symbols of stylized zoospores and zygosporangia, respectively. Dashed lines represent early-diverging lineages of uncertain placement (e.g., *Rozella* and Microsporidia) or internal nodes that are resolved in cited studies but with <70% bootstrap values (e.g., Blastocladiomycota and Glomeromycota). Phylogenetic relationships are based on Lutzoni et al. (2004), James et al. (2006b), and Hibbett et al. (2007).

freshwater and terrestrial ecosystems, but a number of important pathogens do reside in this clade including the amphibian decline pathogen *Batrachochytrium dendrobatidis* and the potato pathogen *Synchytrium endobioticum*. It is a sister group to the Neocallimastigomycota, which includes fungi that produce polyflagellated zoospores. These fungi reside in the gastrointestinal system of ruminants, where they function in the breakdown of cellulosic material and are the only known example of obligate anaerobic fungi.

The Blastocladiomycota is the third major phylum of zoosporic fungi. These fungi produce copious amounts of filamentous hyphae and include examples of fungi with true alternations of generations (e.g., *Allomyces*). Other fungi may have an alternation of generations, e.g., *Saccharomyces cerevisiae*, but it is uncommon in Fungi. Current multigene phylogenies provide some support for the placement of Blastocladiomycota as a sister group to the remaining taxa of Fungi, but additional confirmation is needed (James et al., 2006a, 2006b). Finally, the genus *Olpidium*, a parasite of plant roots, is nested among the nonflagellated fungi traditionally classified in the Zygomycota and not with other "chytrids" (Fig. 1) (James et al., 2006b).

Our understanding of the phylogenetic relationships of the zoosporic fungi is central to one of the major questions concerning the Fungal Tree of Life, namely, the evolution of the flagellum. There is general consensus that the most recent common ancestor (MRCA) of Fungi possessed a flagellated stage in the life cycle, but there exist multiple hypotheses concerning the number of losses of the flagellum, which resulted in nonflagellated Fungi (e.g., Ascomycota and Basidiomycota). The work of Liu et al. (2006) supports a single loss of the flagellum during the evolution of the Fungi, whereas a study by James et al. (2006b), which sampled a larger number of taxa (e.g., *Rozella* and *Olpidium*)

and more genes, estimated multiple losses of the flagellum. Regardless, these rival hypotheses are consistent with a flagellated MRCA and the polarity of character state transition being ordered from flagellated to nonflagellated.

The remaining taxa of the early-diverging lineages of *Fungi* consist of species typically classified in the "Zygomycota" (Fig. 1). Most species grow as aseptate filaments, although septate hyphae are common in some groups (e.g., Trichomycetes of Kickxellomycotina), and they are characterized by gametangial copulation that results in the zygosporangium. Like the zoosporic fungi, zygosporangium-producing fungi do not form a monophyletic group. Rather, they form a paraphyletic grade, and the most accurate use of the term Zygomycota is currently under debate (White et al., 2006; Hibbett et al., 2007). For that reason the zygosporangium-producing fungi are classified in four monophyletic subphyla, Entomophthoromycotina, Kickxellomycotina, Mucoromycotina, and Zoopagomycotina, whose phylum level classification is *incertae sedis* (uncertain).

The Mucoromycotina comprises some of the best-studied species of zygosporangium-producing fungi including *Rhizopus* of the Mucorales, *Mortierella* (Mortierellales), and the mycorrhizal *Endogone* (Endogonales). As such, this clade may be thought of as the core clade of "Zygomycota." The remaining clades include the Entomophthoromycotina (Entomophthorales), a large group of insect pathogens, and the Zoopagomycotina (Zoopagales), which includes parasites and predators of amoebae, nematodes, and rotifers. Finally, the Kickxellomycotina includes an interesting assemblage of taxa that contains saprobes, mycoparasites (Kickxellales and Dimargaritales), and obligate symbionts of arthropod hindguts (Trichomycetes). While the zygosporangium-producing fungi do not form a monophyletic group, they do occupy a somewhat intermediate position between the zoosporic fungi and the Dikarya (Ascomycota plus Basidiomycota). rRNA data continue to dominate the currently available data for most zygosporangium-producing fungi (White et al., 2006), and a significant increase in protein-coding and genomic data is needed to resolve the evolutionary relationships of the zygomycete lineages and to develop a more complete understanding of the evolutionary origins of the nonflagellated terrestrial lineages of the Fungal Tree of Life.

Glomeromycota

The Glomeromycota represents one half of what is arguably the most successful symbiosis on the Earth. These fungi are the arbuscular mycorrhizae fungi that form endomycorrhizae with the majority of plant species on the planet (Smith and Reed, 2008). Previous evolutionary hypotheses considered these fungi to be members of the Endogonales (Mucoromycotina), but early rRNA phylogenies did not support this classification (reviewed by Redecker and Raab, 2006). Rather, these early studies suggested that the Glomeromycota (as Glomales) was a sister group to the Dikarya (Simon et al., 1993; Schüβler et al., 2001), resulting in the hypothesis that the MRCA to the Glomeromycota and Dikarya corresponded to the colonization of land by the green plant lineage. Consistent with this hypothesis are the numerous Rhynie Chert fossils of Glomeromycota associated with the earliest known land plants (Taylor et al., 2003) and that the majority of plant-associated fungi and mycorrhizae are members of the Glomeromycota plus Dikarya clade. The support for this relationship is tenuous, however, and multigene phylogenetic analyses have not contributed much to resolve this question (James et al., 2006b). Thus, we cannot discount the hypothesis that the Glomeromycota may not be a sister group to the Dikarya and that the plant associations and mycorrhizae characterized in the Glomeromycota and Dikarya may represent parallel origins of fungal-plant symbioses.

Dikarya

The subkingdom Dikarya comprises the majority of known fungal species (>95,000) and includes the phyla Ascomycota and Basidiomycota. It is diagnosed by the production of regularly septate hyphae and a dikaryotic nuclear state in the life cycle, although the extent to which it constitutes part of the life cycle varies greatly between the two phyla (Alexopoulos et al., 1986; Hibbett et al., 2007). Typically, the dikaryotic state is the long-lived, vegetative state in the Basidiomycota, but it is restricted to a short-lived ascogenous or sexual reproductive state in the Ascomycota. It is also among the Dikarya that multicellularity (fruit body production) occurs among the Fungi, likely as a product of independent evolutionary events within the Basidiomycota and Ascomycota.

The Basidiomycota comprises three subphyla: Pucciniomycotina, Ustilaginomycotina, and Agaricomycotina (Fig. 2). As previously mentioned, to avoid confusion between taxon names and informal names, each of these subphyla is named after a well-characterized genus (Hibbett et al., 2007). These subphyla, however, are ecologically and morphologically diverse and contain more than rusts, smuts, and mushrooms, respectively. The relationships of the three subphyla to one another are essentially unresolved, with the backbone of the Basidiomycota currently depicted as a trichotomy of these three taxa.

The Pucciniomycotina is the second largest subphylum of Basidiomycota and includes eight classes and 18 orders. While most researchers in fungal biology are familiar with the rust fungi (*Puccinia*), this subphylum also includes basidiomycetous yeasts (Sporidiobolales), smut fungi (Microbotryales), insect symbionts (Septobasidiales), and fungi formerly classified in Ascomycota (Mixiales) (Aime et al., 2006). Thus, the Pucciniomycetes is one of the more diverse clades of fungi and remains one of the more challenging experimental groups due to their often biotrophic nature and complex life histories.

The Ustilaginomycotina includes two classes and nine orders and the majority of plant pathogenic "smut fungi" (Begerow et al., 2006). It is in the Pucciniomycotina and Ustilaginomycotina that we see the production of teliospores, specialized spores in which karyogamy and meiosis occur and on which promycelia (modified basidia) are produced.

The Agaricomycotina comprises three classes (Tremellomycetes, Dacrymycetes, and Agaricomycetes) and 21 orders of fleshy, sporocarp-forming Basidiomycota (Hibbett, 2006). The Tremellomycetes is the earliest-diverging lineage of the Agaricomycotina and includes jelly fungi and species with both filamentous and yeast growth forms. These fungi include agents of wood decay, mycoparasites, and important human pathogens of increasing medical importance (e.g., *Cryptococcus* spp.). The Dacrymycetes also produce gelatinous sporocarps that tend to fruit from woody substrates, but it shares a more recent common ancestor with the Agaricomycetes than with the Tremellomycetes. The Agaricomycetes includes all of the fleshy basidiomycetes that are typically referred to as mushrooms, boletes, conchs, crusts, and puffballs. It represents the largest group of known Basidiomycota and arguably the most important group of fungi associated with forest ecosystems, including ectomycorrhizae, tree pathogens, and wood and litter decay. It also includes most of the species commonly

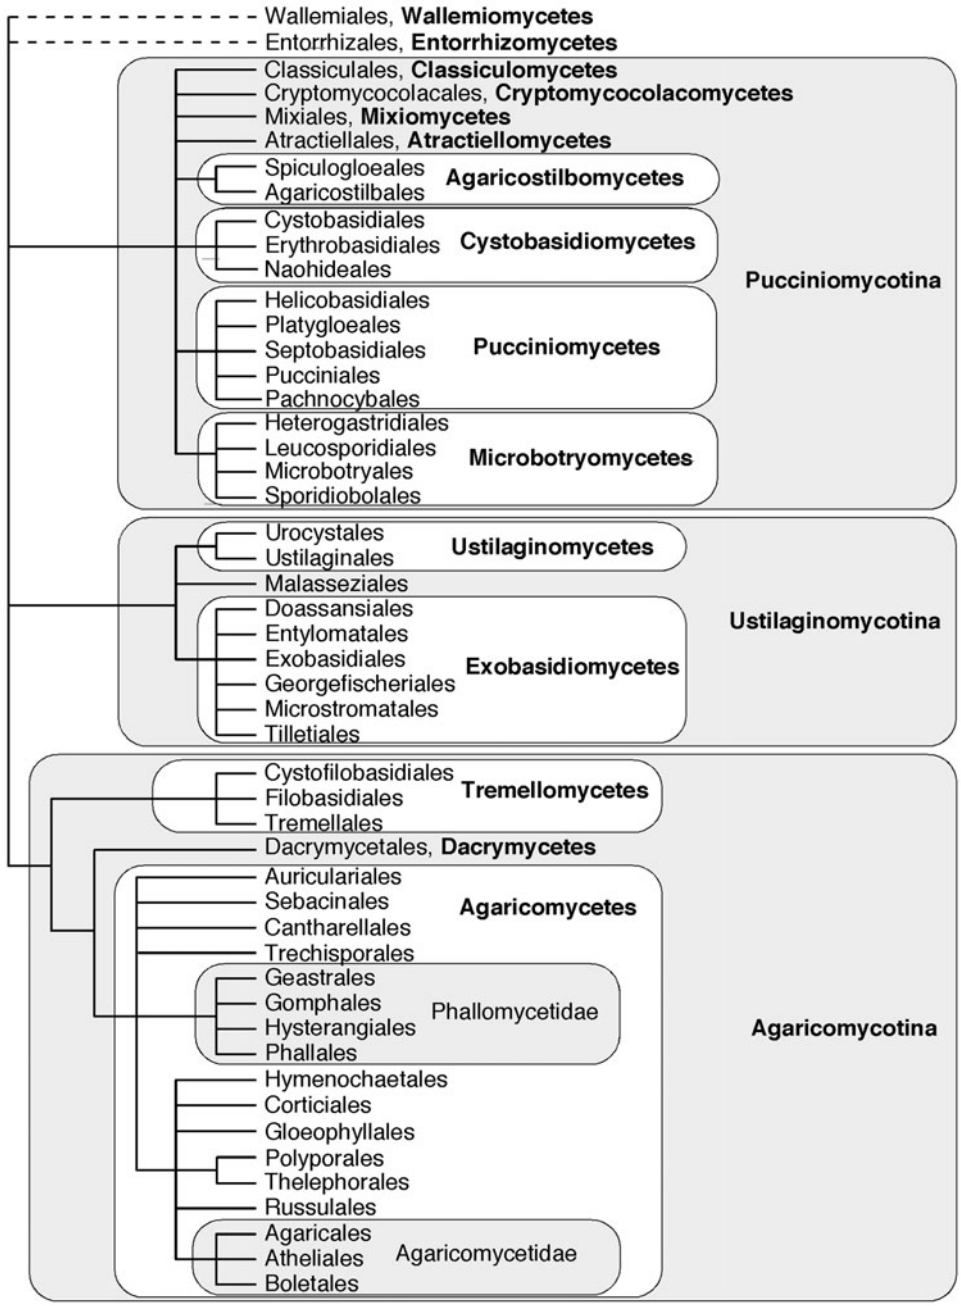

FIGURE 2 Phylogeny and classification of Fungi: Basidiomycota. Dashed lines indicate taxa that are of uncertain placement. Reproduced with permission from Hibbett et al., 2007.

cultivated in the commercial mushroom industry (e.g., Chinese black jelly mushroom [*Auricularia* spp.], button mushroom [*Agaricus bisporus*], shiitake mushroom [*Lentinula edodes*], oyster mushroom [*Pleurotus ostreatus*], etc.) and some of the more prized culinary mushrooms (e.g., chanterelles [*Cantharellus* spp.], porcini [*Boletus edulis*], and matsutake [*Tricholoma* spp.]). Some of the more characterized model organisms in terms of basidiomycete genomics, genetics, and cell biology (e.g., *Coprinopsis cinereus*) are also members of the Agaricomycetes.

Considerable advancements have been made in the understanding of morphological and ecological character evolution of the Basidiomycota as a function of multigene phylogenies. Septate basidia and repetitive spore germination are present in the Pucciniomycotina, Ustilaginomycotina, Tremellomycetes, Dacrymycetes, and Agaricomycetes and are likely ancestral for the Basidiomycota, with traditional (agaricoid) nonseptate holobasidia and basidiospore germination restricted to germ tube formation primarily confined to the Agaricomycetes (Hibbett, 2006). A saprobic ecology (e.g., wood and litter decay) is ancestral for most lineages with multiple independent derivations of ectomycorrhizae (James et al., 2006b; Matheny et al., 2006; Binder and Hibbett, 2006; Hibbett and Matheny, 2009). Finally, sporocarp morphology is a poor predictor of evolutionary relationships. This is perhaps the most dramatic impact of molecu-

lar phylogenetics, as many of the preexisting hypotheses regarding evolutionary relationships and their classifications were based on the sporocarp morphology (Hibbett and Binder, 2002; Matheny et al., 2006, 2007). Ancestral character state reconstructions of sporocarp morphology on robust molecular phylogenies have revealed that sporocarp morphologies are some of the more labile traits in fungal evolution (Hibbett, 2004). It appears likely that all major sporocarp morphologies (e.g., mushrooms, puffballs, conches, crusts, etc.) have been derived multiple times during the evolution of the Basidiomycota. Currently there are 11 major ordinal and/or supraordinal clades recognized within the Agaricomycetes, the majority of which include multiple sporocarp morphologies. (See Matheny et al., 2007, on Agaricomycetes systematics.)

Ascomycota

With more than 63,000 species, the Ascomycota is the largest phylum of Fungi (Kirk et al., 2008) and like the Basidiomycota includes three subphyla: Taphrinomycotina, Saccharomycotina, and Pezizomycotina (Fig. 3). Taphrinomycotina (~140 spp.) represents the earliest-diverging lineage of the Ascomycota and is a sister group to the Saccharomycotina plus Pezizomycotina clade. It includes four classes of morphologically and ecologically distinct fungi including plant pathogens (*Taphrina*, Taphrinomycetes), human pathogens (*Pneumocystis*, Pneumocystidiomycetes), fission yeasts (*Schizosaccharomyces*, Schizosaccharomycetes) and sporocarp-producing taxa (*Neolecta*, Neolectomycetes). Its monophyly has been debated for some time with early rRNA analyses resolving the group as a paraphyletic grade at the base of the Ascomycota, while other multigene analyses have supported its monophyly (Sugiyama et al., 2006). The most recent analyses of six genes and increased taxon sampling have provided additional support for its monophyly (James et al., 2006b; Spatafora et al., 2006), and it is recognized as a formal subphylum (Hibbett et al., 2007).

The Saccharomycotina are the "true yeasts" and include the model organism *S. cerevisiae* and important human pathogens such as *Candida albicans*. Few fungi have had a more pronounced impact on human civilization than *S. cerevisiae* due to its use in fermentation and the production of alcohols and leavened breads. While there is a single order (Saccharomycetales) and relatively few described species (~1,000 [Kirk et al., 2008]), environmental sampling of novel ecological niches such as beetle endosymbionts has revealed a staggering diversity of Saccharomycotina yeasts (Suh et al., 2005). This research has demonstrated that many tropical species of wood and fungus-inhabiting beetles possess obligate fungal endosymbionts that are members of the Saccharomycotina. The exact function of most of these fungi is unknown, but extrapolations from other fungal endosymbionts of insects suggest that they may play a role in fatty acid metabolism and/or the breakdown of noxious compounds. If this rate of species discovery continues, it is not unreasonable to assume that the Saccharomycotina may be one of the most species-rich clades of Fungi.

The Pezizomycotina are what most researchers in fungal biology refer to as filamentous fungi or filamentous ascomycetes, although it does contain a few species with yeast-like growth (e.g., *Symbiotaphrina*). It includes 10 classes (Fig. 3), 55 orders, and more than 60,000 species (Kirk et al., 2008). Importantly, classes of the Pezizomycotina include some of the better-studied model organisms such as *Neurospora* of the Sordariomycetes and *Aspergillus* and *Penicillium* of Eurotiomycetes. The relationships among the 10 classes of Pezizomycotina remain one of the more recalcitrant problems in fungal phylogenetics, but some patterns are emerging and statistically well-supported relationships do exist (Spatafora et al., 2006; Schoch et al., 2009). The earliest-diverging lineages of the phylum are Orbiliomycetes (e.g., *Orbilia*; nematode trappers and saprobes) and Pezizomycetes (e.g., *Ascobolus* and *Peziza*; saprobes and ectomycorrhizae), two classes of fungi that form cup-shaped sporocarps (apothecia).

The remaining classes form a monophyletic supraclass level clade, "Leotiomyceta," which is characterized by a basal polytomy and considerable morphological and ecological diversity (Lumbsch et al., 2005; Schoch et al., in press). Within the "Leotiomyceta," the Sordariomycetes (e.g., *Neurospora*) and Leotiomycetes (e.g., *Sclerotinia*) form a monophyletic group that primarily includes perithecial (flask-shaped) and apothecial fungi, respectively, but is united by the production of relatively thin-walled, unitunicate asci (Spatafora et al., 2006; Robbertse et al., 2006; Schoch et al., 2009). The Dothideomycetes (e.g., *Pyrenophora*) and Arthoniomycetes (e.g., *Arthonia*) form a monophyletic group that includes plant saprobes/pathogens and lichens, respectively, but is united by the production of thick-walled bitunicate asci (Schoch et al., 2006). Additional major classes of the "Leotiomyceta" include the Eurotiomycetes and Lecanoromycetes. The Eurotiomycetes (e.g., *Aspergillus* and *Penicillium*) represents one of the most morphologically and ecologically diverse classes of fungi, comprising saprobes, human pathogens, plant pathogens, mycorrhizae, lichens, and rock-inhabiting fungi. Its monophyly has been debated with analyses and arguments both in favor of (Lutzoni et al., 2004) and against (Liu and Hall, 2004) its monophyly and recognition as a class. More recent multigene analyses, however, have supported its monophyly and provide an excellent example of where increased taxon and character sampling confidently resolved a complex question in fungal phylogenetics (Geiser et al., 2006). Finally, the Lecanoromycetes (e.g., *Lecanora* and *Peltigera*) contains the vast majority of lichenized fungi. While a core set of families and orders are confidently placed in the class, the boundaries of the class are debatable, as are its relationships to the other classes of the "Leotiomyceta" (Miadlikowska et al., 2006; Hofstetter et al., 2007).

Like the Basidiomycota, molecular phylogenetics has provided increased insight into the ecological and morphological evolution of the Ascomycota. A saprobic lifestyle is supported as ancestral for the phylum, with multiple derivations of mycorrhizae, plant pathogens, animal pathogens, and lichens (James et al., 2006b; Schoch et al., in press). More than 98% of all known lichens are ascomycetes, and they account for approximately 25% of Pezizomycotina species diversity (based on estimated species numbers for Arthoniomycetes [~1,600] and Lecanoromycetes [~14,000] [Kirk et al., 2008]). The exact number of lichenization events is not fully resolved (Lutzoni et al., 2001; Schoch et al., in press), but increased taxon and character sampling supports all ascomycete lichens being restricted to the Pezizomycotina and at least two origins of lichenization within the subphylum (Lecanoromycetes and Arthoniomycetes). Prior to molecular phylogenetics, many of the evolutionary hypotheses and the resulting classifications of the Ascomycetes were based on sporocarp (e.g., apothecia, perithecia, cleistothecia, and pseudothecia), ascus (e.g., operulate, inoperulate, bitunicate, and unitunicate), and developmental (e.g., ascohymenial and ascolocular) characters (reviewed by

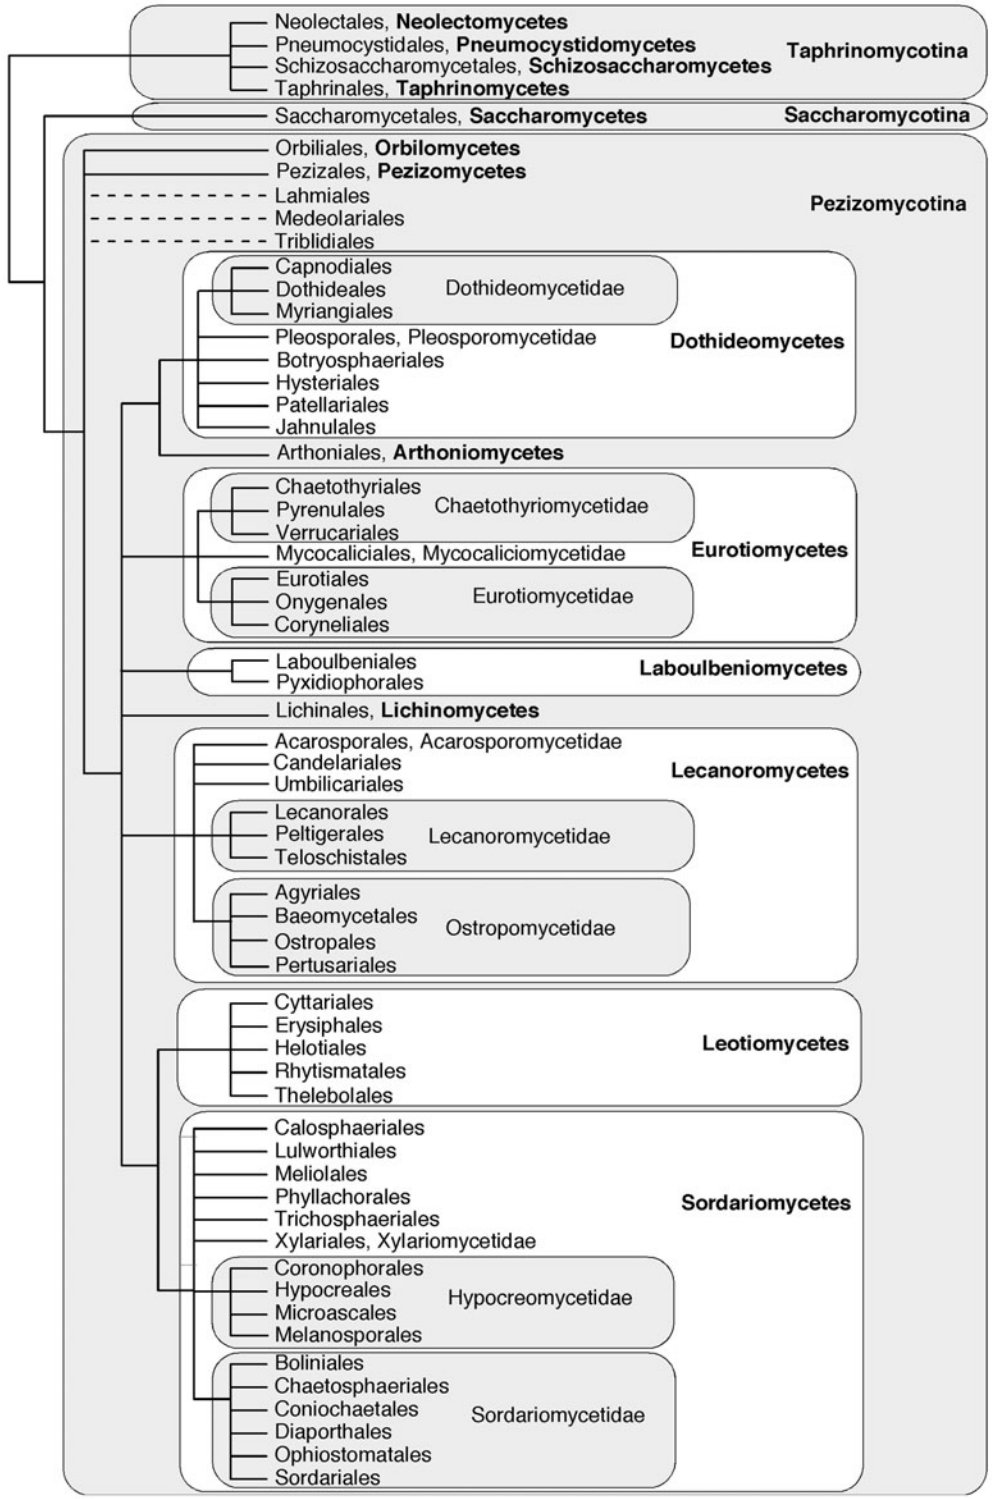

FIGURE 3 Phylogeny and classification of Fungi: Ascomycota. Dashed lines indicate taxa that are of uncertain placement. Reproduced with permission from Hibbett et al., 2007.

Spatafora et al., 2006). Most of these characters are not diagnostic of natural, monophyletic groups, and the classic names used to designate formal taxa (Discomycetes for apothecia, Pyrenomycetes for perithecia, Plectomycetes for cleistothecia, and Loculoascomycetes for pseudothecia) have been abandoned (Hibbett et al., 2007) and now refer to morphologies only. These characters either are ancestral and have been lost multiple times (e.g., the apothecium) or derived multiple times during the evolution of the Ascomycota (e.g., the cleistothecium), or are not diagnostic of a monophyletic group with equivocal explanations of character state gains and losses (e.g., bitunicate asci of

Eurotiomycetes and Dothideomycetes/Arthoniomycetes) (Schoch et al., in press). The names used in the formal higher classification of the Ascomycota are not, therefore, meant to impart morphologies but are clade designators based on resident genera (e.g., Sordariomycetes [*Sordaria*], Eurotiomycetes [*Eurotia*], etc.).

DATING THE FUNGAL TREE OF LIFE

One of the more elusive areas of research in fungal phylogenetics has been the calibration of the Fungal Tree of Life to geologic time (Taylor and Berbee, 2006). As we increase our understanding of the major groups of Fungi and their evolutionary relationships, we would like to place the Fungal Tree of Life into the context of the evolution of the Earth and its ecosystems and the origin and diversification of other major life forms (e.g., plants and animals). Part of the problem, however, is the paucity of fungal fossils that can be confidently assigned to a given lineage. Exceptions do exist and include >400 million-year-old Glomeromycota fossils (Taylor et al., 2003; Redecker et al., 2000), ~90 million-year-old mushrooms of the Agaricales (Hibbett et al., 1995), and ~100 million-year-old insect pathogens of the Hypocreales (Sung et al., 2008). The second major problem is that most data sets do not behave in a strictly clock-like fashion, and while advancements have been made to accommodate relaxed molecular clocks, no one methodology is universally accepted (e.g., r8s [Sanderson, 2003], PhyloBayes [Lartillot and Philippe, 2004], and BEAST [Drummond and Rambaut, 2007]).

The collective result is a very broad spectrum of dates for the last common ancestor of Animals and Fungi that has been estimated to be anywhere from 2.5 billion years old to 600 million years old depending on the calibration point(s) used (Heckman et al., 2001; Hedges and Kumar, 2004; Taylor and Berbee, 2006) (Fig. 4). Because most fungal fossils are found either associated with fossil plants or in terrestrial paleoecosystems with well-developed floras, it seems reasonable to postulate that the diversification of most extant lineages of Fungi is closely associated with the origin and diversification of land plants and terrestrial ecosystems (Taylor and Berbee, 2006).

PHYLOGENOMICS OF THE FUNGAL TREE OF LIFE

As stated previously, phylogenomics is a term used broadly with several definitions (Philippe et al., 2005; Delsuc et al., 2006). Here we focus on the use of genome-scale data sets in phylogenetic analyses. Currently there have been more genomes sequenced for Fungi than for any other kingdom of eukaryotes, and at the preparation of this text more than 100 genomes in different stages of annotation were publicly available (http://www.genomesonline.org/ and http://fungalgenomes.org/genome). The majority of these have been species of Ascomycota, with a more recent increase in the sampling of Basidiomycota with a particular emphasis on wood decay and plant and human pathogens. Many clades of Fungi are lacking sequence information for exemplar genomes, especially early-diverging lineages (e.g., zoospore and zygosporangium-producing fungi). This situation poses a significant problem with respect to taxon sampling and the error that undersampling can introduce into phylogenetic analyses (Baurain et al., 2007). This problem will be alleviated in due course, however, as genomic sequencing becomes less expensive and more widely available to basic fungal biology laboratories. Below we provide a brief review of some of the analytical issues such as ortholog discovery and inferring nodal support, and then we provide a brief review of published phylogenomic analyses of fungi.

ORTHOLOG DISCOVERY AND NODAL SUPPORT

Molecular phylogenetics is dependent on the analysis of orthologous genes, with the misinterpretation of paralogous copies leading to erroneous estimation of species trees from gene trees. The problem of paralogy is greatly exacerbated in genomic data, where many if not most of the genes are initially unknown and they are part of gene families characterized by complex patterns of gene loss and gene duplication. Furthermore, the assessment of orthology relies on well-annotated genomes, so any error intrinsic to a given genome annotation will be introduced into the initial stages of analysis and perpetuated. In an attempt to begin to unravel these complex patterns of homology, different algorithms and methodologies have been developed. Most methods and algorithms for estimating homology and orthologous groups of proteins have been applied to the annotations of genomes, not necessarily for the selection of phylogenetic markers.

Recently, Kuzniar et al. (2008) provided a comprehensive review of published programs and databases of ortholog identification in which the strengths and weaknesses of each are highlighted. Some of the major detection methods are informed by precompiled ortholog databases (COCO-CL [Jothi et al., 2006]; Orthostrapper [Storm and Sonnhammer, 2002]; LOFT [van der Heijden et al., 2007]; RIO [Zmasek and Eddy, 2002]), while others are ab initio programs, such as Inparanoid (Remm et al., 2001), Ortholuge (Fulton et al., 2006), MultiParanoid (Alexeyenko et al., 2006), and OrthoMLC (Li et al., 2003). Of the ab initio programs only the last two are capable of making ortholog predictions across multiple genomes, an attractive quality as phylogenetic analyses are inherently comparisons of multiple taxa. Furthermore, Markov clustering methodologies (van Dongen, 2000) are more applicable to automation than KOG (Tatusov et al., 2003), which relies on manual curation. These Markov clustering methods, however, make tradeoffs between sensitivity and specificity, resulting in different levels of false-positive and false-negative error rates (Chen et al., 2007). While these rates can be estimated with well-characterized genomes with high confidence in gene models and subsequent annotations, their application to the incorporation of newly sequenced genomes into phylogenetic analyses will likely involve examples of both false positives (inclusion of nonorthologous proteins) and false negatives (exclusion of orthologous proteins). Undoubtedly this field of research will undergo considerable maturation over the next several years.

Two important revelations that occurred early in the development of phylogenomic analyses were observable conflicts among individual gene trees and the difficulty in assessment of nodal support, or the statistical confidence, in a particular clade. Due to processes such as gene duplication, gene conversion, lineage sorting, and horizontal gene transfer, different genes can have evolutionary histories that are in conflict with one another and that do not accurately record the evolutionary history of the species. As genome-scale data are analyzed, it is inevitable that larger suites of genes with conflicting gene histories will be detected (Rokas et al., 2003). This pattern of conflict will likely become more apparent and will require informed choices of single-copy orthologous genes (Robbertse et al., 2006), application of accurate DNA and amino acid models of evo-

lution (Philippe et al., 2005; Liu et al., 2009), and scaleable tests for phylogenetic conflict (Kauff and Lutzoni, 2002).

In traditional phylogenetic analyses the most common measure of nodal support is the nonparametric bootstrap (Felsenstein, 1985), or bootstrap proportions (BPs), and the posterior probability (Ronquist and Huelsenbeck, 2003). The latter is generally considered to be a liberal statistic, and more emphasis is placed on the BP (Suzuki et al., 2002; Alfaro et al., 2003; Taylor and Piel, 2004). Importantly, BPs are not confidence intervals, and a node is typically considered well supported when it receives greater than 70 to 75% BP (Lutzoni et al., 2004). When applied to phylogenomic analyses, however, BPs are rarely below 70 to 75%, even though some of the nodes are unstable, i.e., in conflict across different data sets, and sensitive to taxon and character sampling (Rokas et al., 2003; Philippe et al., 2004, 2005; Robbertse et al., 2006; Fitzpatrick et al., 2006). This is particularly troubling as different methods of ortholog detection result in different sets of putative orthologous proteins (Chen et al., 2007), and, as previously mentioned, phylogenomic analyses in general suffer from inadequate taxon sampling. This situation is currently unresolved, and BPs should be viewed conservatively with any knowledge of how different taxon samplings, character samplings, and differences in analyses (e.g., characters coded as DNA versus amino acid) affect the BP of a given node.

GENOME-SCALE PHYLOGENETIC ANALYSES OF FUNGI

The first genome-scale phylogenetic analyses that included fungal sequences were performed by Rokas et al. (2003). This study analyzed 106 genes from eight taxa in the Saccharomycotina. The 106 individual gene trees resulted in more than 20 alternative topologies, whereas analyses of a concatenated alignment of all 106 genes produced a single well-supported topology that was inconsistent with the 20 alternative single-gene topologies in at least one inference. Jeffroy et al. (2006) analyzed the same 106 genes in the Rokas et al. (2003) study but expanded the taxon sampling to 14 Saccharomycetina species. Their analyses explained the incongruence among the single-gene trees as a result of compositional biases, saturation, and method of analysis. The latter analysis also provided strong support for the WGD (whole-genome duplication) and CTG (organisms translate CTG as serine instead of leucine) clades within Saccharomycotina.

Robbertse et al. (2006) produced the first study of a wider sampling of the Ascomycota. Their analyses included a concatenated alignment of 781 genes from 17 taxa (the Saccharomycotina [4 taxa], Pezizomycotina [10 taxa], Schizosaccharomycotina [1 taxon], and 2 Basidiomycota taxa as outgroup). Neighbor-joining and maximum likelihood analyses resulted in identical topologies, whereas the maximum parsimony analyses resolved the *Staganospora nodorum* (the only taxon representing the Dothideomycetes) differently. Uncertainty in the placement of *S. nodorum* was also found by Fitzpatrick et al. (2006) (Fig. 5); however, all higher taxa (e.g., classes) in which more than one taxon was sampled (e.g., Sordariomycetes, Eurotiomycetes, Leotiomycetes, etc.) were confidently resolved. Importantly, Robbertse et al. (2006) demonstrated the efficacy of analyses that combined ortholog discovery, protein alignments, and phylogenetic inference in a semi-automated computational pipeline. Expanding the sampling of fungal taxa, Fitzpatrick et al. (2006) inferred relationships between 42 species of Fungi (Pezizomycotina [17 species], Saccharomycotina [19 species], Taphrinamycotina [1 species], Basidiomycotina [4 species], and Zygomycotina [1 species]) using both supertrees analyses of 4,805 single-gene trees and analysis of a superalignment of 153 universally distributed orthologs. The consensus supertree reflected some artifacts, but a matrix representation with parsimony supertree and the phylogeny inferred from the concatenated alignment of 153 genes (Fig. 5) were highly congruent. The study identified two classes within the CTG clade of the Saccharomycotina that may correlate with sexual status. These analyses and others (Robbertse et al., 2006; Kuramae et al., 2006; Liu et al., 2009) supported the Leotiomycetes-Sordariomycetes sister group relationship to the exclusion of the remaining classes of the Pezizomycotina, resolving the homology of their unitunicate, inoperculate (poricidal) asci and demonstrating the plasticity of sporocarp morphology at the superclass level (Schoch et al., 2009).

In the first large-scale comparison of nuclear and mitochondrial genomic data, Liu et al. (2009) conducted a phylogenomic analysis using 113 nuclear genes and 13 mitochondrial genes involving taxa from which whole-genome or expressed sequence tag (EST) sequences were available. The sampling included taxa from the Pezizomycotina (16 taxa), Saccharomycotina (13 taxa), Taphrinamycotina (4 taxa), Basidiomycotina (10 taxa), Zygomycota (6 taxa), and Chytridiomycota (5 taxa) with the goal of testing the monophyly of the Taphrinomycotina. As a result of using EST data, the 113 nuclear gene data set had a proportion of missing data, with only one single protein represented for all 54 species and the average proportion of missing data being 25% per species. The authors concluded that the missing data did not affect the phylogenetic analysis significantly when using a large data set with a strong phylogenetic signal, but they did detect conflict between the nuclear and

FIGURE 4 Different calibration points change estimated divergence dates. Ascomycota split from Basidiomycota after the origin of two phyla not shown, the Chytridiomycota and Glomeromycota. In the top diagram we assumed that the 400 million-year-old fossil *Paleopyrenomycites devonicus* represents Sordariomycetes as indicated by the letter "S." This pushes the minimum age for the origin of the stem lineages of all five fungal phyla, including the Glomeromycota, to 1,489 million years ago, more than three times the age of the first fossil evidence of land plants. In the middle diagram we assumed that *P. devonicus* represents Pezizomycotina but not necessarily Sordariomycetes. Applying calibrations from plant and animal fossils in addition to assuming that *P. devonicus* represents Pezizomycotina gave an estimate of 792 million years ago for the origin of the fungal phyla, still almost twice the age of the first fossil evidence for vascular plants. In the bottom diagram, assuming that *P. devonicus* provided a minimum age for the Ascomycota, indicated by the letter "A," at 400 million years resulted in the estimate that fungal phyla had been established by 452 million years ago, roughly the age of the first land plants. In this scenario, however, the ages for the divergences among vertebrates are far too recent given fossil data. This discrepancy might result from using fossils from one kingdom (Fungi) to calibrate events in the same kingdom and another kingdom (Animalia), as discussed in the text. Reproduced with permission from Taylor and Berbee, 2006.

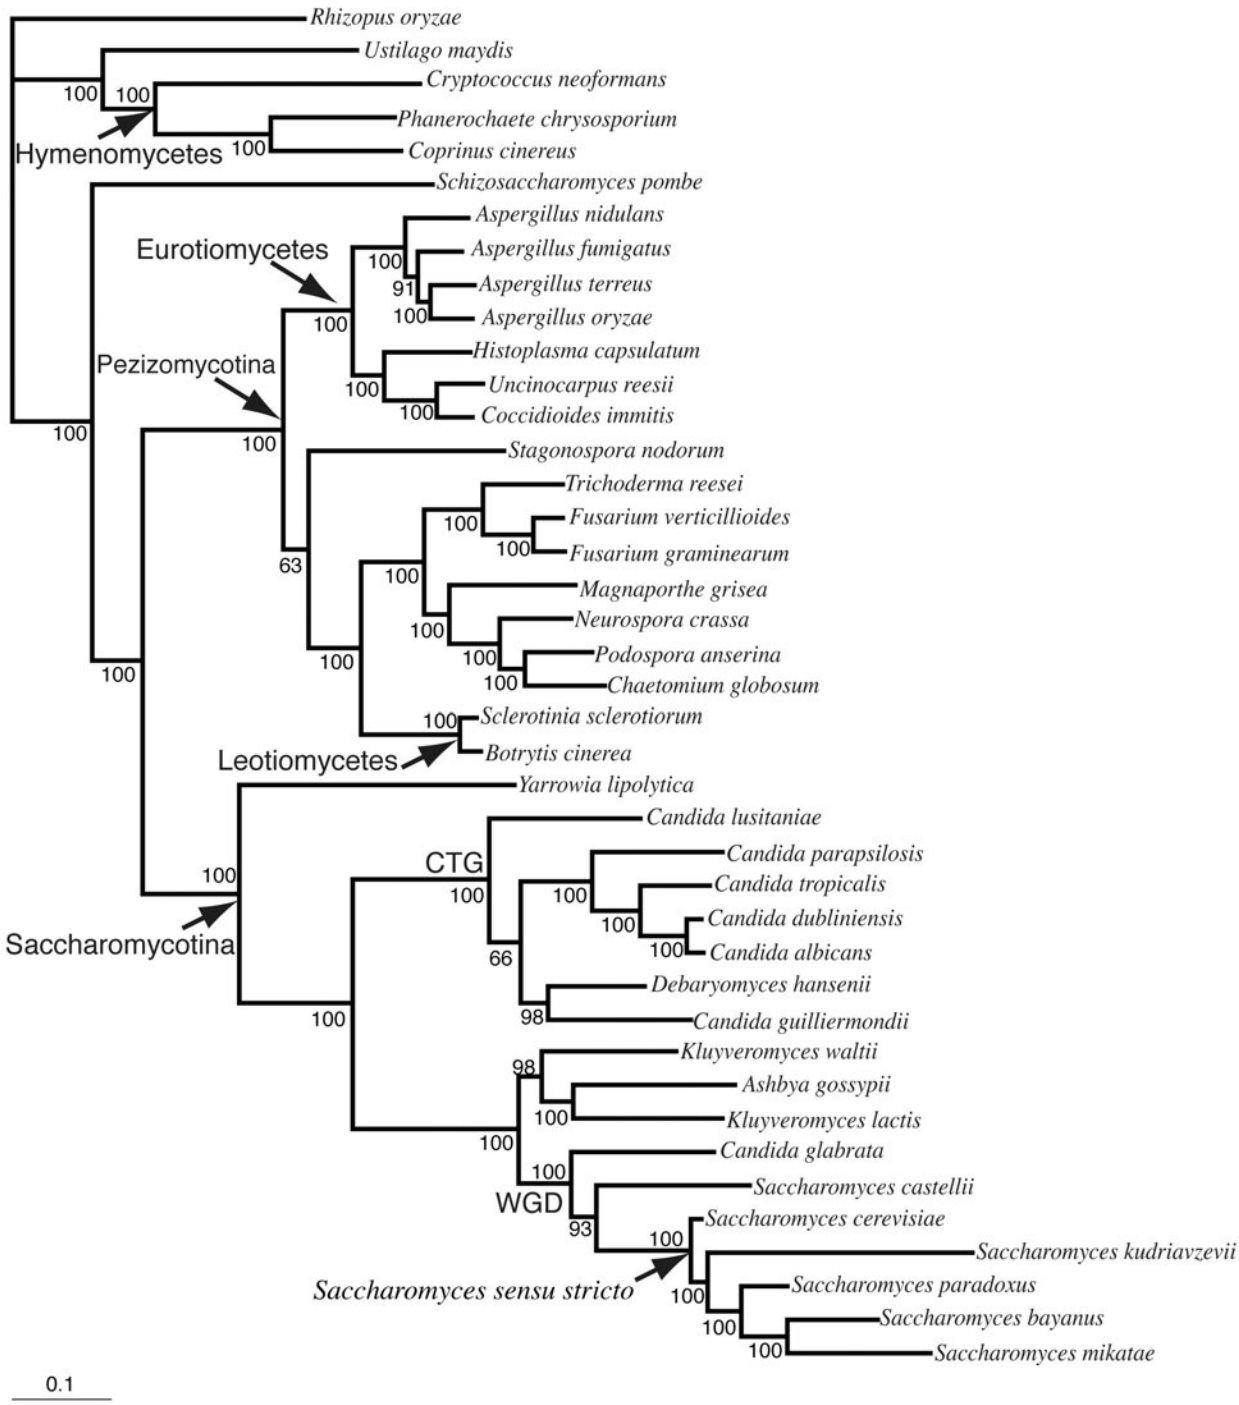

FIGURE 5 Maximum likelihood phylogeny reconstructed using a concatenated alignment of 153 universally distributed fungal genes. The concatenated alignment contains 42 taxa and exactly 38,000 amino acid positions. The optimum model according to ModelGenerator (Keane et al., 2006) was found to be WAG+I+G. The number of rate categories was 4 (alpha 5 0.83), and the proportion of invariable sites was approximated at 0.20. Bootstrap scores for all nodes are displayed. *Saccharomyces castellii* is found at the base of the WGD node. Reproduced with permission from Fitzpatrick et al., 2006.

mitochondrial data sets. The mitochondrial data of yeasts (Saccharomycotina) and fission yeasts (*Schizosaccharomyces*, Taphrinomycotina) were characterized by fast-evolving sequences, which resulted in patterns consistent with long-branch attraction. After they accommodated for fast-evolving positions, their analyses supported the Taphrinomycotina (using the following taxa as representatives: *Pneumocystis carinii*, *Saitoella complicata*, *Schizosaccharomyces pombe*, and *Taphrina deformans*) as monophyletic and as a sister group to the Saccharomycotina plus Pezizomycotina clade.

CONCLUSION

Multigene analyses have had a major impact on phylogenetic studies of the Fungi, resulting in our most thorough understanding of evolutionary relationships of the Kingdom to date (Blackwell et al., 2006; Hibbett et al., 2007). The advent of whole-genome sequencing and the inclusion of heterogeneous genomic sequence data (e.g., ESTs) has set the stage for addressing phylogenetic questions with the maximum amount of discrete, orthologous sequence data. Although the genome era provides an abundance of genes and sequence data, significant challenges remain in the assessment of orthology (Kuzniar et al., 2008) and in the analyses of problematic sequence data (e.g., saturated sites and fast-evolving positions [Jeffroy et al., 2006; Liu et al., 2009]) and heterogeneous supermatrices (Philippe et al., 2004; Delsuc et al., 2006).

Taxon sampling is currently the major limiting factor in genome-scale phylogenetic analyses, and attention and priority should be given to major clades of Fungi for which no genome data are available (e.g., Lecanoromycetes and Dacrymycetes). Finally, the application of new high-throughput sequencing technologies (e.g., Illumina, 454, etc.) to small eukaryotic genomes and cDNA libraries, while advancing broader taxon sampling of the Fungi, will diversify the types of sequence data available for phylogenetic analyses and likely require new analytical approaches.

Cellular and Molecular Biology of Filamentous Fungi
Edited by K. A. Borkovich and D. J. Ebbole

5

Signal Transduction Pathways

GYUNGSOON PARK, CAROL A. JONES, AND KATHERINE A. BORKOVICH

Most filamentous fungi spend at least a portion of their life cycle as free-living organisms and, as such, are exquisitely sensitive to changes in their environment. Furthermore, those fungi that can parasitize or live symbiotically with another organism must sense the presence of the host in order to ensure a productive association. Such sensing and integration of signals from multiple sources—from both the abiotic and biotic environment—require a complex web of signal transduction pathways.

This chapter covers major signal transduction pathways that have been characterized in multiple species of filamentous fungi. Since many of these systems are elaborated upon in subsequent chapters in this book, the coverage is broad and summarizes recurring themes. The signaling pathways included are monomeric and heterotrimeric GTP binding proteins, mitogen-activated protein kinases (MAPKs), protein kinase A/cyclic AMP (PKA/cAMP) signaling, two-component regulatory systems, calcium signaling, target of rapamycin (Tor) pathways and pH regulatory mechanisms. With the exception of two-component systems, related pathways are found in animals, where they also play fundamental roles. In general, the elements of these systems are found in all fungal species that have been sequenced; however, the number of genes representing each signaling protein class often varies. In spite of this conservation, several interesting variations in how pathway components are arranged or regulated have also emerged. Furthermore, accumulating evidence indicates that multiple pathways often cooperate to regulate the same function in the same species, resulting in more complex signal transduction networks.

GTP-BINDING PROTEINS

Monomeric GTPases

Monomeric GTP-binding proteins, included in the superfamily of Ras-related small GTPases, participate in various cellular processes in eukaryotes (for reviews, see Jaffe and Hall, 2005, and Weeks and Spiegelman, 2003). Small GTPases cycle between GDP-bound inactive and GTP-bound active forms. The switch from the GDP- to GTP-bound form upon signal sensing is mediated by a guanine nucleotide exchange factor (GEF) that is specific to the particular GTPase. Conversion back to the inactive GDP-bound form is facilitated by a GTPase-activating protein (GAP). Another regulatory factor, the guanine nucleotide dissociation inhibitor (GDI), inhibits dissociation of GDP from the GTPase and membrane binding in order to prevent autoactivation.

Within the Ras superfamily, Ras and Rho subfamily proteins have been the most frequently implicated in the regulation of signal transduction in yeasts and filamentous fungi. Most filamentous fungi have two Ras proteins (Ras1p and Ras2p), but only a single Ras protein (RasAp) has been identified in *Aspergillus nidulans* (Som and Kolaparthi, 1994; Weeks and Spiegelman, 2003). Functional analysis of Ras proteins in these filamentous fungi demonstrates that they participate in the regulation of conidiation, mating, and pathogenesis by mediating signal transduction either from a Gα subunit to a downstream cAMP-dependent PKA pathway or from a pheromone receptor to an MAPK cascade. In *Neurospora crassa*, a homologue of mammalian Rap (another member of the Ras subfamily) is implicated in mating (Ito et al., 1997).

Among Rho subfamily GTPases, Rho, Cdc42, and Rac-related proteins are universally present in filamentous fungi. These GTPases regulate polarized growth of fungal hyphae, multicellular development and pathogenicity through cytoskeleton reorganization and other regulatory functions (Sudbery, 2008). Homologues of *Saccharomyces cerevisiae* Rho1p, Rho3p, and Rho4p have been identified in several filamentous fungi and characterized for roles in cell integrity, septation, polarized hyphal growth, and pathogenicity (Martinez-Rocha et al., 2008; Rasmussen and Glass, 2005; Wendland and Philippsen, 2001). Although Cdc42 is highly conserved among yeasts and filamentous fungi, Rac is found in filamentous fungi but absent from yeasts. Results from studies in several filamentous fungi show that Cdc42 and Rac GTPases possess distinct and common essential functions during regulation of polarized growth and morphological development (Momany, 2005; Sudbery, 2008). Thus, deletion of genes for both

Gyungsoon Park, Carol A. Jones, and Katherine A. Borkovich, Department of Plant Pathology and Microbiology, University of California, 1415 Boyce Hall, 900 University Avenue, Riverside, CA 92521.

GTPases is lethal in fungi. In addition, accumulating evidence indicates that Cdc42 and Rac proteins can be regulated by Ras and then go on to activate downstream effectors, such as p21-activated kinases, in filamentous fungi (Chen et al., 2006; Vallim et al., 2005).

GEFs, GAPs, and GDIs control the activation state of their partner GTPase. The number of GEF and GAP genes found in the genomes of filamentous fungi is greater than that of small GTPases, suggesting the possibility of fine-tuning in the control of small GTPases (Borkovich et al., 2004). GAPs that inhibit the function of Rho1 have been identified in *Ashbya gossypii* and *N. crassa* (Vogt and Seiler, 2008; Wendland and Philippsen, 2000). Cdc24 and Cdc25-like proteins have been characterized as GEFs specific for Cdc42 and Ras-type GTPases, respectively, in several filamentous fungi (Muller et al., 2003; Nichols et al., 2007; Schink and Bolker, 2008). Most GEFs specific for Rho, Cdc42, and Rac-type GTPases in mammalian systems are distinguished by the presence of functional domains, such as the catalytic dbl homology, lipid-binding pleckstrin homology, and the zinc finger Fab1-YOTB/ZK632.12-Vac1-EEA1 domains, which are also found in GEFs from filamentous fungi (Rossman et al., 2005; Schink and Bolker, 2008). Functional characterization of these domains will reveal those that are important for temporal and spatial regulation of GEFs for small G proteins in filamentous fungi.

Heterotrimeric G Proteins

Heterotrimeric G proteins regulate numerous cellular processes during development and pathogenesis in filamentous fungi (for a review, see Li et al., 2007). Heterotrimeric G proteins, composed of α, β, and γ subunits, have universal roles as mediators, transferring signals from G-protein-coupled receptors (GPCRs) to downstream effectors in eukaryotes. In the inactive state, the complex of three subunits, with the Gα subunit in the GDP-bound form, is associated with a GPCR in the plasma membrane. When a ligand (signal) binds the GPCR, GDP is exchanged for GTP on the Gα subunit and the Gβγ and Gα subunits dissociate. Free Gα-GTP and Gβγ subunits can then regulate downstream effectors, such as enzymes, ion channels, and other regulatory proteins. After GTP hydrolysis on the Gα subunit, the GDP-bound Gα protein reassociates with the Gβγ dimer and GPCR, allowing a new cycle of signaling (Li et al., 2007).

In filamentous fungi, there are three different families of Gα subunits, termed Group I, II, and III (Li et al., 2007). Group I and III Gα subunits are highly conserved among many filamentous fungi. Group I proteins are involved in multiple pathways, including pheromone response and mating, nutrient sensing, and pathogenesis. Group III proteins have been demonstrated to function in sexual spore development and in nutrient sensing related to cAMP-dependent pathways. Compared to Group I and III subunits, Group II has less obvious roles in filamentous fungi (Kays and Borkovich, 2004). However, a Group II protein is required for optimal growth on poor carbon sources and plays a compensatory role during cell growth, sexual development, and asexual sporulation in *N. crassa* (Li and Borkovich, 2006).

Most filamentous fungi possess a single Gβ and Gγ subunit, although more than one subunit is present in the genomes of several fungi, such as *Rhizopus oryzae*, *Cryptococcus neoformans*, *Coprinus cinereus*, and *Podospora anserina* (Li et al., 2007). In aggregate, evidence suggests that Gβ subunits are required for complex formation and/or stabilization of Gα and Gγ proteins and regulation of MAPK- and cAMP-dependent pathways during mating and pathogenesis (Krystofova and Borkovich, 2005; Yang et al., 2002).

The genomes of filamentous fungi contain genes encoding proteins other than canonical Gβ subunits that can form complexes with G proteins to regulate signal transduction. For example, a Gβ-like RACK1 homologue has been demonstrated to interact with Gα and Gγ proteins to regulate cAMP levels during formation of the virulence factors melanin and capsule in *C. neoformans* and to participate in protoperithecium formation and cross-pathway control of amino acid synthesis in *N. crassa* (Muller et al., 1995; Palmer et al., 2006).

As mentioned above, heterotrimeric G proteins associate with, and are regulated by, GPCRs that are present on the plasma membrane (Fig. 1). GPCRs contain seven-transmembrane (7-TM) helices connected by intracellular and extracellular loops. At least nine classes of GPCR genes have been enumerated to date in filamentous fungal genomes (Li et al., 2007; Xue et al., 2008). GPCRs homologous to pheromone receptors from yeasts have been shown to regulate mating in both ascomycete and basidiomycete fungi (Li et al., 2007). A predicted GPCR similar to cAMP receptor-like proteins from the protist slime mold *Dictyostelium discoideum* was characterized for its role during fruiting body development in *N. crassa* and during vegetative growth and conidiation in *Trichoderma atroviride* (Brunner et al., 2008; Krystofova and Borkovich, 2006). Proteins related to the carbon-sensory GPCR Gpr1p from *S. cerevisiae* function during sensing of carbon sources and amino acids in *N. crassa* and *C. neoformans*, respectively (Li and Borkovich, 2006; Xue et al., 2006). The 7-TM protein PTH11 is required for virulence in the rice pathogen *Magnaporthe grisea* (Kulkarni et al., 2005). Filamentous fungi contain a large number of predicted GPCRs homologous to PTH11, but functions for these are currently unknown (Li et al., 2007). In addition, cellular roles have not yet been revealed for several other classes of predicted GPCRs in filamentous fungi, including microbial opsins, Stm1-related proteins, human mPR-like receptors, rat growth hormone releasing factor-related proteins, and proteins similar to *Arabidopsis thaliana* AtRGS1 (for reviews, see Li et al., 2007, and Xue et al., 2008).

An increasing number of studies implicate other proteins, in addition to GPCRs, that regulate Gα, Gβ, and Gγ subunits in filamentous fungi. As GAPs, regulator of G protein signaling (RGS) proteins accelerate the GTPase activity of Gα subunits and negatively control Gα protein-mediated signaling (Fig. 1). Many filamentous fungi have more than one RGS protein, and each RGS acts on one or more groups of Gα subunits during the regulation of conidiation, pathogenicity, and secondary metabolism (Liu et al., 2007; Segers et al., 2004; Yu, 2006).

Phosducin-like proteins (PhLPs) have been shown to regulate Gβγ in filamentous fungi and other eukaryotes (Kasahara et al., 2000; Seo and Yu, 2006). As observed in *Cryphonectria parasitica* and *A. nidulans*, loss of PhLP genes leads to phenotypes identical to those of mutants lacking Gβ subunits (Kasahara et al., 2000; Seo and Yu, 2006). The results from *C. parasitica* preceded later studies in mammals that established a role for PhLPs as chaperones that stabilize Gβ proteins, thereby facilitating formation of the Gβγ dimer (Kasahara et al., 2000; Seo and Yu, 2006).

MAPK SIGNALING PATHWAYS

MAPKs are serine/threonine protein kinases that are regulated by a variety of upstream factors, including Cdc42p, GPCRs, p21-activated kinases, and response regulators

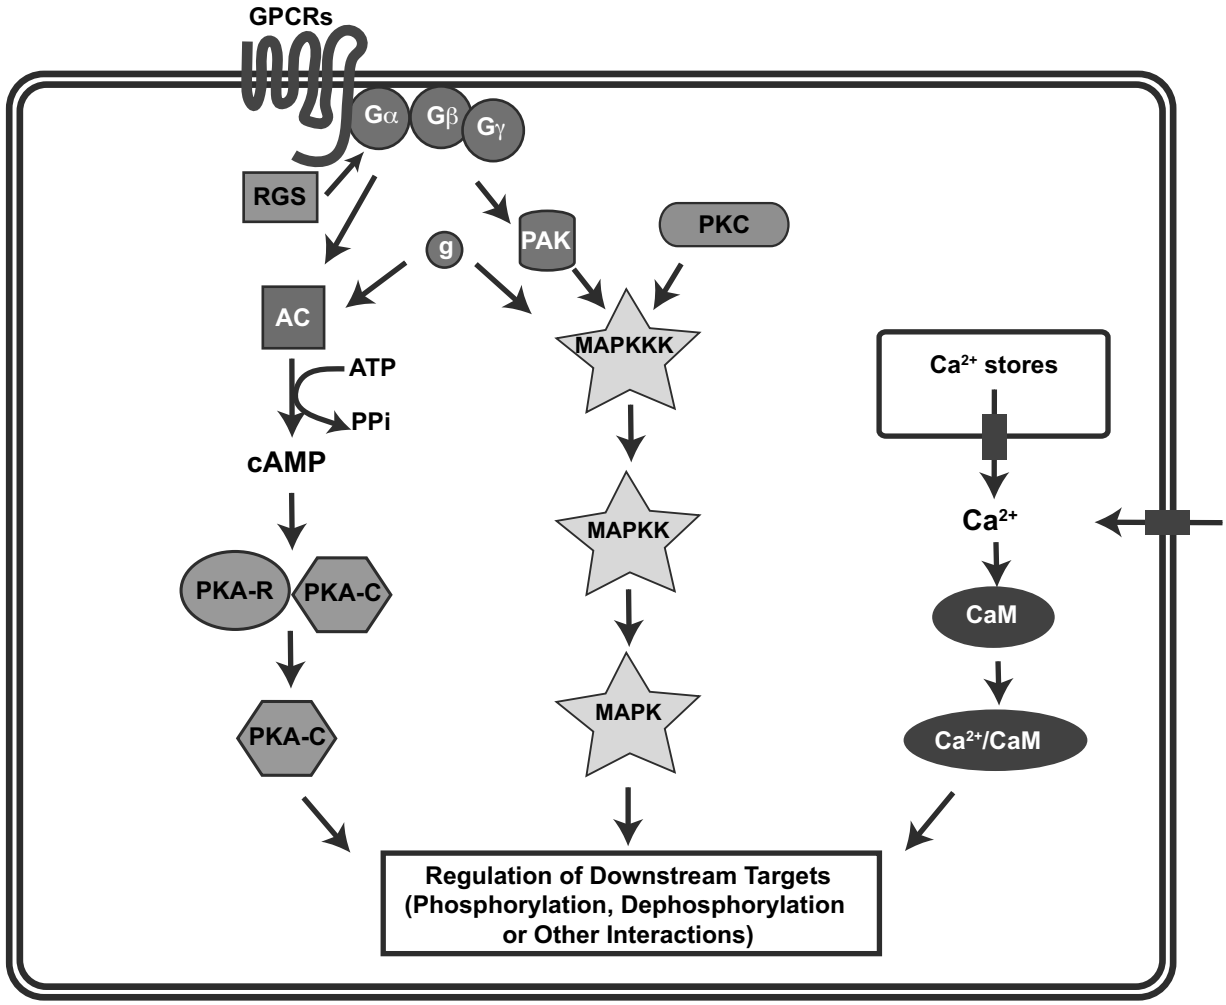

FIGURE 1 Overview of signal transduction pathways in filamentous fungi. Environmental signals are sensed by GPCRs or other unknown proteins, leading to regulation of downstream pathways. Activation of heterotrimeric and small G proteins can result in modulation of cAMP levels and MAPK pathways. In response to environmental signals, free Ca^{2+} transported into the cytoplasm from the external environment or from intracellular Ca^{2+} stores binds to the Ca^{2+} sensor calmodulin and other regulatory proteins. The Ca^{2+}-calmodulin complex regulates downstream targets, including the serine-threonine protein phosphatase calcineurin. Abbreviations: Gα, Gα subunit; Gβ, Gβ subunit; Gγ, Gγ subunit; g, small G proteins; PAK, p21-activated kinase; PKC, protein kinase C; AC, adenylyl cyclase; PKA-R, protein kinase A regulatory subunit; PKA-C, protein kinase A catalytic subunit; CaM, calmodulin.

from two-component regulatory systems (see below). MAPK modules operate in a three-tier, sequential phosphorylation cascade to regulate cellular processes. Within the MAPK module, the MAPK kinase kinase (MAPKKK) is first activated by phosphorylation. The MAPKKK then phosphorylates/activates the MAPK kinase (MAPKK), which in turn phosphorylates/activates the MAPK. The MAPK ultimately controls a variety of processes, including the cell cycle, mating, morphogenesis, and pathogenesis (Fig. 1). Three MAPK modules homologous to those involved in the pheromone response (Ste11p/Ste7p/Fus3p or Kss1p), osmoregulation (Ssk2/22p or Ste11p/Pbs2p/Hog1p), and cell wall integrity (Bck1p/Mkk1/2p/Slt2p) in *S. cerevisiae* are highly conserved in filamentous fungal genomes. Among the three cascades, the one that is most similar to Fus3p/Kss1p is the best characterized in filamentous fungi and has been shown to regulate the pheromone response, development, and pathogenicity (for a review, see Zhao et al., 2007). Hog1-like MAPK pathways have been implicated in the response to osmotic and oxidative stresses in many filamentous fungal species (for a review, see Zhao et al., 2007). However, roles for the Hog1p-related pathway in pathogenicity vary among filamentous fungi (Dixon et al., 1999; Segmuller et al., 2007). As observed in *S. cerevisiae*, the Slt2p-related MAPK cascade functions in the control of cell wall integrity in many filamentous fungi, although this is not the case in *Botrytis cinerea* and *Collectotrichum lagenarium* (Kojima et al., 2002; Rui and

Hahn, 2007). The Slt2p-related pathway also regulates vegetative growth, hyphal morphology, conidiation, and pathogenicity in several species (for a review, see Zhao et al., 2007) and has been recently shown to influence secondary metabolism in *N. crassa* (Park et al., 2008).

Many transcription factors that control gene expression in filamentous fungi are downstream targets of MAPKs. Ste12p-like transcription factors have frequently been implicated as downstream proteins controlled by the Fus3p/Kss1p-homologous MAPK (for a review, see Zhao et al., 2007). In *Ustilago maydis*, the high-mobility group domain transcription factor Prf1p is regulated by Fus3p/Kss1p-like MAPK (Kaffarnik et al., 2003). Finally, transcription factors homologous to Rlm1p in *S. cerevisiae* have been shown to function downstream of the Slt2p-like MAPK in *M. grisea* (Mehrabi et al., 2008).

Roles for Gβ subunits of heterotrimeric G proteins and the Ras GTPase as upstream regulators of Fus3p/Kss1p-related MAPKs have been demonstrated in several filamentous fungi during mating and pathogenesis (Lee and Kronstad, 2002; Wang et al., 2000). Overexpression of the Fus3p/Kss1p-like MAPK suppresses the mating defect of a Gβ mutant in *C. neoformans* (Wang et al., 2000). Both Ras2 and Ubc3 (MAPK) in *U. maydis* function in the pheromone response pathway, and constitutive activation of Ras2 induces pseudohyphal growth in the wild type but not in *fuz7* (MAPKK) and *ubc3* (MAPK) mutants (Lee and Kronstad, 2002). The Ste50p-related adapter protein physically interacts with the Ste11p-like MAPKKK and is required for activation of the Fus3p/Kss1p homologous MAPK in *M. grisea* and *U. maydis* (Klosterman et al., 2008; Park et al., 2006). Finally, response regulators from two-component regulatory systems have also been shown to regulate Hog1p-like cascades in filamentous fungi (Jones et al., 2007; Yoshimi et al., 2005; see below).

cAMP SIGNALING

cAMP acts as a second messenger that regulates signaling pathways in filamentous fungi and other eukaryotes. The enzyme adenylyl cyclase converts ATP to cAMP and pyrophosphate. Various proteins are implicated in the activation of adenylyl cyclase, including cyclase-associated protein, heterotrimeric G proteins, and small G proteins (Kozubowski et al., 2009; Lee et al., 2003). Intracellular cAMP binds to the regulatory subunits of PKA, and this association triggers dissociation of the regulatory and catalytic subunits, leading to activation of the freed catalytic subunits. Activated PKA then phosphorylates various protein targets that are critical for fungal growth, development, and pathogenesis (Kozubowski et al., 2009; Lee et al., 2003).

Perhaps the best-characterized function for the cAMP signaling pathway in both yeasts and filamentous fungi is nutrient sensing (Li et al., 2007; Xue et al., 2006). Sensing of carbon source or amino acids by a GPCR activates the coupled Gα subunit of a heterotrimeric G protein that in turn mediates transfer of the signal to adenylyl cyclase, leading to regulation of cAMP levels (Li and Borkovich, 2006; Xue et al., 2006). In addition to nutrient sensing, many cellular processes such as asexual sporulation, mating, pathogenesis, and secondary metabolism are also influenced by cAMP levels (Lee et al., 2003; Li et al., 2007; Shimizu et al., 2003). Finally, cross-talk between the cAMP-dependent pathway and MAPK cascades has often been observed, particularly during pathogenic development (for reviews, see Kozubowski et al., 2009, and Lee et al., 2003).

TWO-COMPONENT REGULATORY SYSTEMS

Two-component systems have been identified in bacteria, archaea, plants, protists, and fungi (Wolanin et al., 2002). Two-component regulatory systems are major signal transduction pathways in filamentous fungi (Fig. 2). "Two-component" refers to the two different protein domains present on proteins in this phosphorelay system: histidine kinase (HK) and response regulator (RR) domains. The HK is autophosphorylated (using ATP) in response to an environmental signal. The phosphate from the HK is then transferred to an RR domain present on either the same or a different protein. In filamentous fungi and yeasts, HKs are of the hybrid type, containing both HK and RR domains. In these systems, a histidine phosphotransferase (HPT) accepts phosphate from the RR domain on the hybrid HK (HHK). The phosphate on the HPT protein is ultimately transferred to an RR domain on a terminal RR protein. The phosphorylation status of the RR determines its regulatory effect on downstream effectors, such as MAPK cascades and/or gene transcription.

The sequenced genomes of several filamentous fungi reveal that most contain two or three RR protein-encoding genes, but only one for HPT proteins. The number of RR and HPT genes in filamentous fungi and yeasts is similar (Borkovich et al., 2004). However, the number of HHK protein genes in filamentous fungi is greater than that in sequenced yeasts (1 to 3) and ranges from 10 to 20. The HHKs of filamentous fungi have been categorized into 11 classes, according to the sensor domains present at the amino terminus (Catlett et al., 2003). Some of the HHKs contain one or more PAS (acronym for Per/Arndt [arcyl-hydrocarbon receptor nuclear translocator]/Sim [single-minded protein]) domains; PAS domains are thought to be involved in sensing redox potential, cellular oxygen, energy, and light and are found in proteins regulating hypoxia responses and circadian rhythms (Catlett et al., 2003; Taylor and Zhulin, 1999). GAF (acronym for cGMP phosphodiesterase/adenylyl cyclase/Fhl) domains bind to cyclic GMP and chromophores (Aravind and Ponting, 1997; Catlett et al., 2003). The phytochromes are known for their role in light sensing (Galagan et al., 2003). HAMP (acronym for HK, adenylyl cyclases, methyl-binding proteins, and phosphatases) domains are known to connect extracellular sensory and intracellular output domains in signaling proteins (Hulko et al., 2006).

In certain animal fungal pathogens, mutation of an HK or an RR component renders the strain avirulent (Du et al., 2005). This finding, along with the observation that two-component systems have not been found in any animal genome sequences, including those of humans, makes these pathways a potential target for the development of new antifungal agents (Wolanin et al., 2002).

The best-understood fungal two-component system is the Sln1p/Ypd1p/Ssk1p pathway in *S. cerevisiae* (Posas et al., 1996). When the HHK Sln1p becomes phosphorylated, it transfers its phosphate to the HPT protein Ypd1p and then onto the RR Ssk1p. When phosphorylated, Ssk1p is unable to activate the downstream MAPK pathway. When Sln1p is not phosphorylated, this leads to a buildup of Ssk1p in the unphosphorylated form and activation of the Ssk2p and Ssk22p MAPKKKs, ultimately leading to the phosphorylation of the Hog1p MAPK (Maeda et al., 1994). The Hog1p

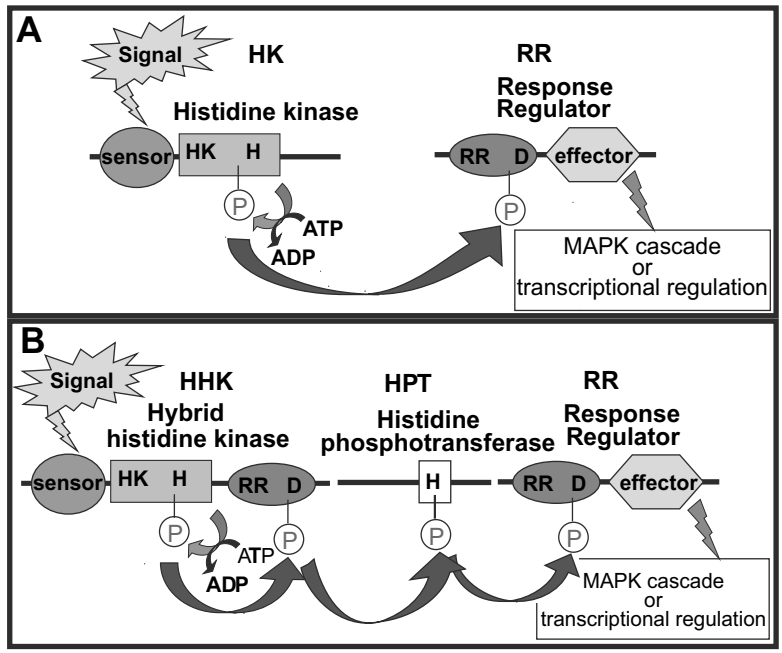

FIGURE 2 Two-component regulatory systems. (A) Two-component signaling pathway. In simple two-component signaling pathways the two components are an HK and an RR protein. The sensor domain(s) located at the N terminus of the HK protein senses environmental signals. In response to such a signal, a histidine residue (H) in the HK domain autophosphorylates, using ATP. The same phosphate (P) is then transferred to an aspartate residue (D) on the RR protein. The phosphorylation status of the RR determines how it regulates downstream pathways, such as MAPK cascades. Alternatively, the RR may act directly as a transcription factor. (B) Multicomponent phosphorelays. Multicomponent phosphorelays contain HHKs, possessing both an HK and an RR domain within the same protein. The sensor domain(s) of the HHK located at the N terminus senses an environmental signal(s) to regulate autophosphorylation of the HHK on a histidine residue in the HK domain. The phosphate is then transferred intramolecularly from the HK domain to an aspartate residue in the RR domain of the same HHK protein. The phosphorelay continues with transfer of the phosphate from the RR of the HHK to a histidine residue on an HPT. This same phosphate is then passed onto an aspartate residue on a terminal RR protein.

MAPK cascade regulates the expression of genes responsible for the synthesis of glycerol, a counter solute, which can help maintain internal osmolarity when the external environment is hyperosmotic (Maeda et al., 1994). The RR Skn7p, which is also regulated by the HHK Sln1p, has been found to be involved in cell wall assembly, regulation of the cell cycle, and the oxidative stress response (Brown et al., 1994; Morgan et al., 1997).

Mutation of certain two-component protein genes results in loss of osmotic and/or oxidative stress resistance in a variety of filamentous fungi. Filamentous fungi contain an HHK similar to Sln1p (the only HHK found in baker's yeast), but this protein has not been shown to regulate osmosensing. Instead, proteins similar to the HAMP domain-containing HHK OS-1 from *N. crassa* and RR Ssk1p homologues have been implicated in resistance to osmostress in several filamentous species. The HHK *os-1* or RR *rrg-1* (similar to *ssk-1*) from *N. crassa* and the *os-1*-like HHK, *fos-1*, from *Aspergillus fumigatus* all play a role in osmosensing (Clemons et al., 2002; Jones et al., 2007). In *N. crassa,* the RR *rrg-2* (similar to *S. cerevisiae skn-7*) is believed to regulate the oxidative stress response (Banno et al., 2007). In *C. neoformans* and *Candida albicans*, loss of the RR *ssk-1* yields both osmotic and oxidative stress phenotypes (Bahn et al., 2006; Chauhan et al., 2003). Of note, deletion of the RR *skn-7* results in sensitivity to hydrogen peroxide, but not to osmolarity in *C. albicans* (Singh et al., 2004).

A number of mutations in genes encoding proteins involved in two-component signaling, which are homologous to those involved in the *S. cerevisiae* osmotic stress response, have also been found to be important for virulence in filamentous fungi. Mutation of *fos-1* (the *os-1*-like HHK) from the lung pathogen *A. fumigatus* leads to a severe decrease in the level of virulence in mouse models (Clemons et al., 2002). The human pathogenic yeast *C. albicans* has three HHKs; deletion of any one HHK decreases virulence in mouse models (Selitrennikoff et al., 2001; Torosantucci et al., 2002; Yamada-Okabe et al., 1999). In addition, loss of the RR *ssk1* renders *C. albicans* avirulent (Du et al., 2005). Mutation of the HHK *tco-1* or the deletion of the RR *skn7* in *C. neoformans*, the causative agent of fungal meningitis, leads to reduced virulence (Bahn et al., 2005; Coenjaerts et al., 2006; Wormley et al., 2005). Mutation of two-component pathway genes has also been found to reduce virulence in plant pathogens. For example, mutation of the RR *rr-1* from *Fusarium graminearum* and deletion of Δ*bos-1* (*os-1*-like) from *Botrytis cinerea* significantly impaired the virulence of these organisms on their plant host (Goswami et al., 2006; Viaud et al., 2006).

Two-component pathways have also been implicated in resistance to fungicides. Iprodione, which is a dicarboximide fungicide, is used against plant pathogens such as *B. cinerea* (Ochiai et al., 2001; Pommer and Lorenz, 1995). The phenylpyrrole fungicide fludioxonil was recently approved for use on postharvest citrus (Kanetis et al., 2008). While *S. cerevisiae* is not sensitive to these fungicides, it is known that mutation of two-component (HK or RR) genes that control the osmotic stress response in fungicide-sensitive species can result in fungicide resistance (Motoyama et al., 2005; Zhang et al., 2002). Furthermore, the natural fungicide resistance of *S. cerevisiae* can be overcome by the introduction of the *os-1* HHK gene from *M. grisea* (Motoyama et al., 2005) or *Alternaria brassicicola* (Dongo et al., 2009). These results suggest that the OS-1 class of HHKs may play a direct role as a fungicide sensor in filamentous fungi.

CALCIUM SIGNALING

Environmental stresses or developmental cues promote Ca^{2+} transfer into the cell cytoplasm from the external environment or from intracellular stores (Fig. 1). Free calcium within the cell can act as a second messenger in eukaryotes. In filamentous fungi, calcium-mediated signaling is crucial for regulating stress responses, morphogenesis, and pathogenicity (Kraus and Heitman, 2003).

Calcium signaling pathway components are involved in regulation of intracellular free Ca^{2+} levels and Ca^{2+}-dependent signal transfer, leading to changes in gene expression. In eukaryotes, Ca^{2+} permeable channels, pumps, transporters, and phospholipase C (PLC) regulate the concentration of intracellular free Ca^{2+}. As shown in *N. crassa*, *M. grisea*, and *Aspergillus* spp., filamentous fungi possess multiple predicted Ca^{2+}-regulated channels, pumps, and transporter genes in their genomes (Bencina et al., 2009; Zelter et al., 2004). Since the number of these genes represents a significant proportion of the genome, calcium signaling holds promise as a major regulatory mechanism controlling cellular processes in filamentous fungi (Zelter et al., 2004).

In plants and animals, Ca^{2+} release into the cytoplasm is mediated by inositol triphosphate (IP_3) that binds to receptors on the surface of organelles containing intracellular calcium stores. IP_3 is synthesized by PLC. Fungal genomes lack apparent IP_3 receptors; however, filamentous fungi possess multiple PLC genes, and IP_3 is produced and involved in the activation of a Ca^{2+} channel in *N. crassa* (Silverman-Gavrila and Lew, 2002). The secondary messenger cAMP can also affect intracellular Ca^{2+} levels, through PKA-dependent activation of a Ca^{2+} channel, as shown in *A. niger* (Bencina et al., 2005).

Intracellular free Ca^{2+} exerts a major effect on downstream events through binding to the Ca^{2+} binding protein calmodulin (Chin and Means, 2000). In several plant and human pathogenic fungi, calmodulin is essential for full virulence, because it controls infection-related morphogenesis (Lee and Lee, 1998; Warwar et al., 2000). Ca^{2+}/calmodulin has been demonstrated to activate the serine-threonine protein phosphatase calcineurin (Fig. 1). Calcineurin is a heterodimer composed of catalytic and regulatory subunits, and the catalytic subunit is activated in response to stresses, as well as during fungal development and pathogenicity (Steinbach et al., 2006). Other known targets of Ca^{2+}/calmodulin in filamentous fungi include a kinase that regulates the circadian clock and a neutral trehalase that modulates conidiation (reviewed by Borkovich et al., 2004).

OTHER SENSORY PATHWAYS

Tor Pathway

As stated above, a GPCR/Gα/cAMP signaling pathway modulates nutrient sensing in filamentous fungi. Nutrient sensing is also regulated by the Tor kinase-mediated signaling pathway, which is highly conserved in all eukaryotes, from yeasts to humans (Rohde et al., 2008). Tor kinase is a member of the phosphatidylinositol 3-kinase superfamily and is inhibited by the antifungal agent rapamycin (Thomas and Hall, 1997). Treatment with rapamycin and nutrient deprivation lead to dramatic changes in cellular processes necessary for survival, and Tor signaling contributes to cell growth, translation, transcription, ribosome biogenesis, and autophagy in *S. cerevisiae* (Rohde et al., 2008). Under conditions of nitrogen starvation or rapamycin treatment, Tor kinase is inhibited, leading to dephosphorylation of a regulatory protein for PP2A-like protein phosphatase and activation of phosphatase activity (Beck and Hall, 1999). This leads to dephosphorylation and nuclear accumulation of the zinc-finger transcription factor, Gln3p, and expression of genes controlled by nitrogen catabolite repression (Beck and Hall, 1999). Accumulating evidence reveals coordination of Tor signaling with other pathways (Rohde et al., 2008). In particular, cAMP often regulates the same targets in parallel with Tor signaling in response to nutrient deprivation (Chen and Powers, 2006).

The observation that rapamycin inhibits the growth of several filamentous fungi suggests a role for Tor kinase in these organisms (Cruz et al., 1999; Dementhon et al., 2003). In contrast to *S. cerevisiae*, filamentous fungi appear to possess only one Tor kinase gene (e.g., *A. nidulans*, *P. anserina*, and *Fusarium fujikuroi* [Muthuvijayan and Marten, 2004; Pinan-Lucarre et al., 2006]). Accumulating evidence indicates that Tor signaling is required for filamentous development in dimorphic fungi and for expression of genes required for secondary metabolite biosynthesis in *F. fujikuroi* (Cutler et al., 2001; Teichert et al., 2006).

pH Regulation

Fungi can grow under a wide range of pH values due to the presence of the regulatory mechanisms that maintain intracellular pH homeostasis (Bencina et al., 2009). Intracellular pH level is regulated by a machinery that includes K^+ and Na^+/H^+ transporters, Ca^{2+}/H^+ exchangers, proton/nutrient transporters, and proton ATPases. Similarities in the V-type and F-type proton ATPase complexes observed in *Aspergillus* spp. and yeasts suggest a universal requirement for these ATPase complexes in fungal pH regulation (Bencina et al., 2009). In contrast, as demonstrated in *Aspergillus* spp., more cation/proton exchangers and P-type proton ATPases are present in filamentous fungi than in *S. cerevisiae*, suggesting more complex regulation of pH sensing in filamentous species (Bencina et al., 2009).

Regulation of gene expression by ambient pH has been extensively studied in the filamentous fungus *A. nidulans*. In *A. nidulans*, a zinc finger transcription factor, PacC, plays a major role in this regulation (for a review, see Penalva et al., 2008). PacC is in an inactive form under acidic conditions, and alkaline pH transforms PacC to an active form by triggering its proteolysis. The alkaline pH signal is thought to induce endocytosis of a plasma membrane complex that includes the 7-TM helix protein PalH (probable pH sensor)

and the arrestin protein PalF, resulting in an endosomal membrane complex on the surface of the endosome. In the endosome, the transferred signal activates the cysteine protease PalB to initiate proteolysis of inactive PacC that has been recruited to endosomal membrane by PalA, a component of the endosomal sorting complex required for transport. The first proteolysis generates a PacC form with an open conformation that is susceptible to further proteolysis. After a second round of proteolysis by the proteasome, the processed PacC transcription factor can activate genes expressed under alkaline conditions and repress genes expressed under acidic conditions (Penalva et al., 2008).

One of the important biological functions of PacC-mediated pH regulation in filamentous fungi is control of fungal pathogenesis, as demonstrated in phytopathogenic species. PacC-homologous transcription factors in these fungi have been demonstrated to regulate full fungal virulence in a positive or negative manner (Caracuel et al., 2003; Rollins, 2003; You et al., 2007).

We apologize to those whose work could not be cited here due to space limitations. We thank Gloria Turner, Sara Wright, James Kim, Patrick Schacht, and Alexander Michkov for helpful comments on the manuscript. Work on G protein signaling in the Borkovich laboratory has been funded by NIH grants GM48626 and GM086565 (to KAB).

Mitotic Cell Cycle Control

COLIN P. C. DE SOUZA AND STEPHEN A. OSMANI

During cell division, eukaryotic cells must faithfully pass on their genetic information to daughter nuclei. The eukaryotic cell cycle comprises two main events, DNA replication (S phase) and DNA segregation, which are generally separated by the so-called gap phases, G_1 and G_2. The period of time comprising G_1, S phase, and G_2 is called interphase, while the relatively short period of time in which the DNA is segregated is called mitosis. The cell cycle has been extensively studied at the ultrastructural, biochemical, and genetic levels in many model systems, from yeasts to human tissue culture cell lines. Model yeast systems have had an enormous impact on our current understanding of how the cell cycle works, and it is now clear that many cell cycle regulatory networks are conserved in humans. In addition, findings for filamentous fungi have also made significant contributions to the understanding of how the cell cycle is regulated. This chapter focuses on our current understanding of how control of the mitotic phase of the cell cycle is achieved in filamentous fungi.

FUNGAL MITOSIS

Survival of filamentous fungi requires exploration by rapid polarized growth to find nutritional requirements, as well as the production of large numbers of asexual and/or sexual spores that can lie dormant until suitable conditions trigger germination. These scenarios require rapid nuclear proliferation, and therefore, the cell cycle of filamentous fungi is completed within a relatively short time in comparison to a typical mammalian cell cycle, which takes close to 24 h. For example, in *Aspergillus nidulans* one cell cycle takes about 2 h, although nuclei are in mitosis for only 5 min (Bergen and Morris, 1983). These rapid nuclear divisions are orchestrated by the cell cycle machinery and must be coordinated with growth and development. In different fungal species, this can be achieved in different ways. For example, while the syncytia of both *Ashbya gossypii* and *A. nidulans* contain multiple nuclei, in *A. gossypii* nuclear divisions occur asynchronously, while in *A. nidulans* nuclear divisions occur in a parasynchronous manner (Gladfelter, 2006).

The mitotic spindle is the structure upon which eukaryotic chromosomes are segregated and is comprised of microtubules emanating from the spindle poles and connecting to the kinetochores of the chromosomes (Fig. 1). While nuclear envelope (NE) breakdown is a hallmark of higher-eukaryote mitosis, many fungi undergo a closed mitosis within an intact NE. Therefore, in many fungi, the NE can also be considered to be an important part of the mitotic apparatus. In fungi, the mitotic microtubule organizing center is the spindle pole body, while in mammalian cells the centrosomes perform this function. Microtubules are comprised of heterodimers of α- and β-tubulin and have a plus end and a minus end (Oakley, 2004). In a spindle, the minus ends are nucleated from the spindle pole bodies and attach to kinetochores, to form kinetochore microtubules. In addition, microtubules emanating from opposite poles interdigitate their plus ends to form interpolar microtubules. Mitosis is in large part achieved by the dynamic nature of microtubules, and indeed the different stages of mitosis, termed prophase, metaphase, anaphase, and telophase, are defined by the characteristic changes in microtubule organization which take place during mitotic progression. Many of these changes are orchestrated by microtubule motor proteins of the dynein and kinesin families.

Studies with filamentous fungi have had a large impact on our understanding of microtubule and motor protein function (for reviews, see Oakley, 2004; Fischer et al., 2008; Xiang and Fischer, 2004; and Xiang and Plamann, 2003; see also chapter 16). Many of these studies were carried out with *A. nidulans*, in which α- and β-tubulin mutants that affected microtubule function were first isolated (Oakley, 2004). This subsequently led to the cloning of the prototypical γ-tubulin (Oakley and Oakley, 1989), which is now known to have universal roles in nucleating microtubules not only from fungal spindle pole bodies but also from mammalian centrosomes. In addition, some of the first mutants encoding microtubule motor proteins were isolated in *A. nidulans*, and roles for such motor proteins have been well studied in other model fungal systems

Colin P. C. De Souza and Stephen A. Osmani, Department of Molecular Genetics, The Ohio State University, 805 Riffe Building, 496 W 12th Ave., Columbus, OH 43210.

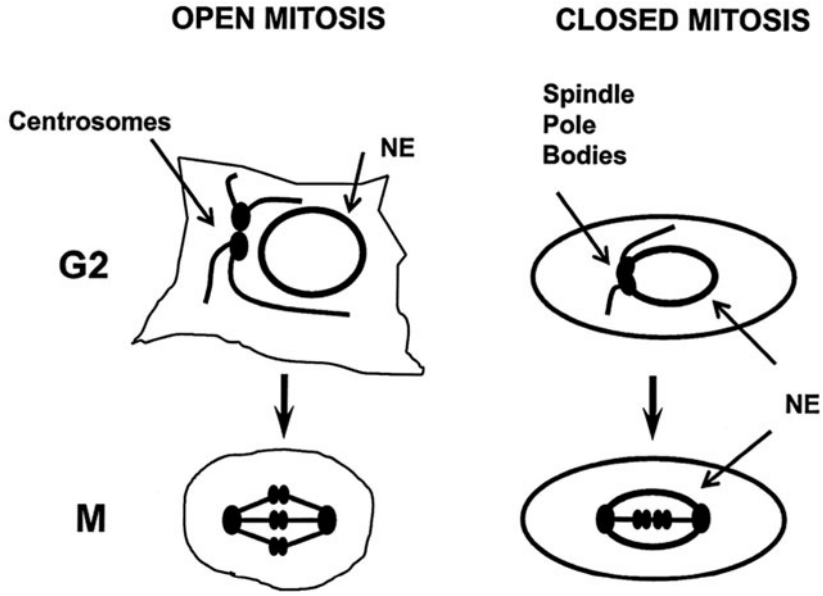

FIGURE 1 Schematic showing mammalian open mitosis and fungal closed mitosis. The NE breaks down during open mitosis so that microtubules nucleated from the cytoplasmic centrosomes can attach to kinetochores. During closed mitosis the spindle pole bodies are in the NE and nucleate spindle microtubules that attach to kinetochores within nuclei.

such as *Neurospora crassa* (Xiang and Fischer, 2004; Xiang and Plamann, 2003).

It has been known for quite some time that there are many variations in the structural features of fungal mitosis (Heath, 1980). Here we describe the more general features and discuss some variations in later sections. During interphase, microtubules are cytoplasmic and nuclear DNA is uncondensed. This is similar in mammalian cells and fungal cells, although while mammalian centrosomes are cytoplasmic, fungal spindle pole bodies are generally located within the NE (Fig. 1). By G_2, both the DNA and spindle pole bodies have been duplicated, although segregation of either has not occurred. Fungal spindle formation begins at the G_2/M transition, when cytoplasmic microtubules begin to depolymerize and nuclear microtubules form from the nuclear face of the spindle pole bodies and attach to the kinetochores. At this stage, prophase, DNA condensation also occurs and spindle pole body separation begins. Metaphase then follows, although in filamentous fungi a distinct metaphase plate is not formed. Chromosome segregation begins in anaphase A, with the dissolution of sister chromatid cohesion and their initial movement towards the spindle poles. Spindle elongation and segregation of the NE then occurs in anaphase B and telophase. However, it is important to note that because of the multinucleate nature of fungal hyphae, cytokinesis does not occur in every cell cycle, and when it does, cells do not typically physically separate.

It is the daunting job of cell cycle regulators to precisely orchestrate the dramatic morphological changes which take place during mitosis in both a temporal and a spatial manner. These regulators must also coordinate mitosis with the rest of the cell cycle such that mitosis and DNA replication alternate and occur once, and only once, each cell cycle. Also in the job description for the cell cycle regulator is the ability to engage checkpoints to prevent cell cycle progression in response to defects in DNA replication, genome integrity, or spindle function. The use of genetic screens in lower eukaryotes has defined many of these cell cycle regulatory mechanisms.

GENETIC APPROACHES TO IDENTIFY CELL CYCLE-SPECIFIC GENES

While by the early 1970s the morphological aspects of mitosis had been described for many organisms, including a vast array of filamentous fungi (for reviews, see Aist and Morris, 1999, and Heath, 1980), the genes regulating the cell cycle were unknown. Researchers with great foresight turned to the genetics of simple eukaryotes to identify mutants with cell cycle defects. Genetic screens performed with budding yeast by Leland Hartwell, fission yeast by Paul Nurse, and *A. nidulans* by Ron Morris aimed to identify temperature-sensitive cell cycle mutants. While the cell cycle status of such mutants was monitored by bud size in the case of *Saccharomyces cerevisiae* and cell size in the case of *Schizosaccharomyces pombe*, Morris scored the mitotic events of chromosome condensation and spindle formation in *A. nidulans* (Morris, 1976b). Mutants that arrested in interphase were termed "never in mitosis" (*nim*), while those which accumulated in mitosis were termed "blocked in mitosis" (*bim*). In addition, because these phenotypes were scored in multinucleate hyphae, mutants with defects in septation (*sep* mutants) and nuclear migration (*nud* mutants) were also identified. This screen identified 26 *nim* mutants, 9 *bim* mutants, 5 *sep* mutants, and 5 *nud* mutants (Morris, 1976b). Subsequent genetic analysis determined that multiple alleles of only some genes were identified, suggesting that the screen was not saturating. The cell cycle defects that resulted in a *nim* phenotype occurred in 23 genes, and those resulting in a *bim* phenotype occurred in 6 genes. While this screen laid the foundation for cell cycle analysis in the model filamentous fungus *A. nidulans*, it is important to recognize the pioneering work of Guido Pontecorvo and Etta Kafer and their colleagues, who helped

establish the genetic utility of this organism (Pontecorvo, 1953; Pontecorvo and Kafer, 1958).

The identification of *nim* and *bim* mutants proved to be of great value for the study of the cell cycle even before the establishment of molecular cloning allowed their identification. Several of these temperature-sensitive alleles caused a cell cycle arrest that was readily reversible upon return to permissive temperature (Bergen and Morris, 1983; Morris, 1976a; Oakley and Morris, 1983), allowing the generation of cell cycle synchronized populations. Further dissection of the cell cycle was possible by determining where in interphase *nim* mutants arrested. These studies utilized hydroxyurea (HU) to cause a reversible S-phase arrest and also defined the length of the different cell cycle phases in *A. nidulans* (Bergen et al., 1984).

In addition to the above and other genetic screens for temperature-sensitive mutants (Orr and Rosenberger, 1976a, 1976b), screens for aneuploidy-generating mutants (Upshall and Mortimore, 1984) and DNA damage-sensitive mutants (Shanfield and Kafer, 1969; Goldman and Kafer, 2004) have also identified genes important for cell cycle regulation in *A. nidulans*. The use of secondary genetic screens to identify cell cycle regulators has also been productive. These include screens for extragenic suppressors (De Souza et al., 2006; Holt and May, 1996; Kraus and Harris, 2001; McGuire et al., 2000; Wu et al., 1998), synthetic lethal interactions (Efimov and Morris, 1998), copy number suppressors (De Souza et al., 2003; Xiang et al., 1995, Ukil et al., 2008), and two-hybrid interactors (Davies et al., 2004; Osmani et al., 2003). Of these, screens to identify extragenic suppressors of *nim*, *bim*, or other temperature-sensitive mutants have been most utilized. We discuss some of the genes identified in these extragenic suppressor screens in subsequent sections of this chapter but would like to highlight one particular extragenic suppressor screen. This screen, performed by Berl Oakley's lab, was for extragenic suppressors of the *benA*33 β-tubulin mutant and led to the discovery of *mipB* (microtubule interacting protein), which encoded a new type of tubulin now known by its universal name, γ-tubulin (Oakley and Oakley, 1989). This landmark discovery paved the way for the discovery of γ-tubulin ring complexes, which are now known to be the microtubule nucleation sites within spindle pole bodies and centrosomes (reviewed by Job et al., 2003). Further analysis of *A. nidulans* γ-tubulin mutants, generated by alanine-scanning mutagenesis, has uncovered mitotic roles for this protein independent of its roles in microtubule nucleation (Jung et al., 2001; Prigozhina et al., 2004). This work highlights the importance of forward genetics for gene discovery.

GENOMIC APPROACHES FOR CELL CYCLE GENE IDENTIFICATION

Primary and secondary genetic screens have given great insight into cell cycle regulation in *A. nidulans* as well as other organisms. However, these screens have not identified all cell cycle regulators. For example, one notable omission from the Morris screen was the Cdk1 kinase, which was known to be essential for mitotic entry in other organisms. A reverse-genetic approach was used to isolate the gene encoding Cdk1, *nimX*^{Cdk1}. As this was done in the pregenomics era, *nimX*^{Cdk1} cloning was achieved by PCR using degenerate oligonucleotides (Osmani et al., 1994). Reverse genetics were further applied to generate temperature-sensitive alleles of *nimX*^{Cdk1} based on known temperature-sensitive point mutations identified in *S. pombe cdc2* (the prototypic Cdk1) (Osmani et al., 1994). This strategy worked because of the high level of sequence and functional conservation between Cdk1 orthologues and allowed the roles of *nimX*^{Cdk1} in both the G_1/S and G_2/M transitions to be defined.

The recent availability of the complete genomic sequence of *A. nidulans*, as well as many other filamentous fungi (Dean et al., 2005; Dietrich et al., 2004; Galagan et al., 2003, 2005; Kamper et al., 2006), has greatly streamlined gene manipulations such as deletion or tagging. Combined with improved gene-targeting techniques, these strategies will no doubt garner major insight into the cell cycle as well as other processes in filamentous fungi. However, we should avoid the temptation of using reverse genetics alone, as the most significant findings have, and will likely continue to, come from novel gene discovery.

The genomics era enables the use of global approaches to study gene function, as has occurred with great success in *S. cerevisiae* (http://www.yeastgenome.org/). The simplest application of genomic data is to identify fungal orthologues of proteins with known mitotic functions to study their function in filamentous fungi. This approach, however, has its limitations, not the least of which is the reoccurring finding that even highly conserved proteins can have quite different functions in yeasts and in filamentous fungi. However, there is currently great potential for targeted genomic approaches, such as targeting all protein phosphatases (Son and Osmani, 2009) or all protein kinases to define their roles in mitotic regulation. There is also an ongoing *N. crassa* large-scale deletion program (Colot et al., 2006), and it will be interesting to define what gene deletions cause defects in mitosis by using this unbiased approach. Proteomic approaches also have great power to identify new proteins that interact with mitotic regulators. Most secondary genetic screens, such as copy number suppressor and extragenic suppressor screens, tend to identify proteins that physically interact with the initial target protein. The biochemical equivalent of such screens is protein complex purification. The power of such approaches has recently been nicely demonstrated by purification of the VeA protein using a TAP-tag approach, which linked this global developmental regulator to the global secondary metabolism regulator LaeA (Bayram et al., 2008). An S-tag affinity approach has also been successfully employed to purify *A. nidulans* nuclear pore complex (NPC) proteins together with their associated proteins (Liu et al., 2009). This led to the discovery of two NPC proteins that were previously thought to be vertebrate specific and were not readily identifiable based on sequence homology alone. Compared to genetic screens, the affinity purification approach is very fast and has an advantage over genetic screens and 2-hybrid approaches as de facto proteins are known to physically interact, although not necessarily in a direct manner. Such approaches, in combination with targeted or genome-wide green fluorescent protein tagging and live cell imaging, has tremendous potential to revolutionize our understanding of fungal mitotic regulation and mitotic regulation in general.

REGULATION OF MITOTIC PROGRESSION THROUGH PROTEIN PHOSPHORYLATION

The work that defined the mechanism of mitotic regulation by the Cdk1 cyclin-dependent kinase in partner with mitotic B-type cyclins resulted in Paul Nurse, Leland Hartwell, and Tim Hunt being awarded a Nobel Prize in 2001. In addition to Cdk1/cyclin B, other classes of Cdks and cyclins have been demonstrated to drive different aspects of the cell cycle in humans. As a result, it has become clear that the regulation of protein phosphorylation through the cell cycle is at the heart of its regulation. In addition to Cdk1, other

classes of kinases are essential for mitosis, and work involving filamentous fungi has contributed to our understanding of protein phosphorylation during mitosis. As is the case for the Cdk family, simple eukaryotes generally only have one member of a mitotic protein kinase family, while multiple members are found in human cells. Regulators of mitotic phosphorylation include the mitotic kinases Cdk1/cyclin B, NIMA, Aurora, and Polo, as well as mitotic phosphatases.

Cdk1/Cyclin B

The role for Cdk1/cyclin B in promoting mitosis is universally conserved in eukaryotes (Fig. 2). To function, Cdk1 requires a cyclin binding partner. This complex is kept inactive in G_2 by Wee1 kinase-mediated inhibitory phosphorylations on adjacent threonine and tyrosine residues within the ATP-binding domain. Activation at the G_2/M transition is achieved by dephosphorylation of these residues by the dual-specificity Cdc25 phosphatase. The components of this regulatory network are present in the genomes of filamentous fungi, and in *A. nidulans*, *A. gossypii*, and *Ustilago maydis* experimental evidence suggests that these components function in an analogous manner (Harris, 2006; Helfer and Gladfelter, 2006; Perez-Martin et al., 2006). The *A. nidulans* orthologues of cyclin B (NIME) and Cdc25 (NIMT) were identified in Ron Morris's screen and subsequently cloned (O'Connell et al., 1992), while Cdk1 and Wee1 were found by reverse genetics (Osmani and Mirabito, 2004). However, in *A. nidulans*, activation of Cdk1 kinase activity alone is not sufficient to trigger mitotic entry.

NIMA

The phenotype of *nimA5* is one of the most strikingly reversible of all the *nim* mutants identified in *A. nidulans*. This mutation causes a late G_2 cell cycle arrest at restrictive temperature, which upon return to permissive temperature results in synchronous mitotic entry (Oakley and Morris, 1983). This defined *nimA* function as being essential for mitotic entry. Cloning of *nimA* by complementation of *nimA5* temperature sensitivity revealed that it encoded a protein kinase that was not a member of the Cdk family (Osmani et al., 1987, 1988b) but defined a new family of protein kinases. NIMA is tightly regulated during the cell cycle, and levels of both its mRNA and protein peak late in G_2, when its activity is maximal (Osmani et al., 1987, 1991a). Most surprising was the finding that at the *nimA5* G_2 arrest point, Cdk1/cyclinB was fully active (Osmani et al., 1991a). Therefore, NIMA has a role in promoting mitosis which is independent of Cdk1/cyclin B protein kinase activation. This role likely extends to other filamentous fungi, as *nimA* orthologues from *N. crassa* and *Magnaporthe grisea* can complement *A. nidulans nimA* mutants (Osmani et al., 1991a; Pu et al., 1995; Veneault-Fourrey et al., 2006). However, NIMA is itself regulated by protein phosphorylation and its full mitotic activity requires multiple phosphorylations which are dependent upon Cdk1/cyclin B (Ye et al., 1995). Therefore, mitotic entry in *A. nidulans* requires the coordinated activities of both NIMA and Cdk1/cyclin B (Fig. 3).

Insight into why *nimA* mutants arrest in G_2 with activated Cdk1/cyclin B came from study of the location of cyclin B. Although cyclin B normally accumulates in G_2 nuclei, it is excluded from nuclei in a *nimA* mutant G_2 arrest (Wu et al., 1998). This suggests a role for NIMA in allowing Cdk1/cyclin B access to its nuclear substrates. The identification of mutations in two different NPC proteins which suppress a *nimA1* G_2 arrest suggests that NIMA targets the NPC to facilitate nuclear entry of Cdk1/cyclin B (De Souza et al., 2003; Wu et al., 1998). We discuss in more detail how NIMA regulates changes in mitotic nuclear transport later in this chapter.

Further studies indicated that ectopic expression of NIMA was sufficient to promote the mitotic events of chromatin condensation and spindle formation, even in cells arrested either in S phase or without Cdk1 activity (Osmani et al., 1988a; Ye et al., 1995). The location of NIMA during the cell cycle is dynamic and fits nicely with its roles in regulating the NPC, chromatin condensation, and spindle function (De Souza et al., 2000, 2004). NIMA is cytoplasmic in G_2, and as cells enter mitosis, it becomes prominent at the nuclear periphery, where it displays a location similar to that of NPCs (De Souza et al., 2004). Following this, it enters the nucleus, where it has a role in phosphorylating the histone H3 serine 10 residue, an event implicated in chromatin condensation (De Souza et al., 2000). Subsequent to this, NIMA locates along the spindle in metaphase

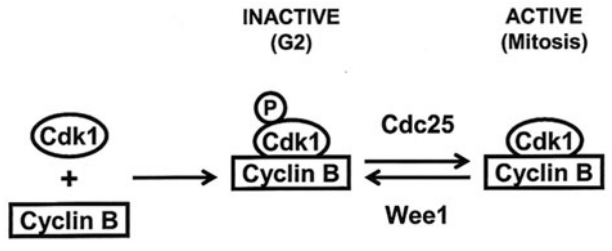

FIGURE 2 Regulation of Cdk1/cyclin B by tyrosine dephosphorylation. Cdk1/cyclin B activation requires dephosphorylation carried out by the Cdc25 phosphatase.

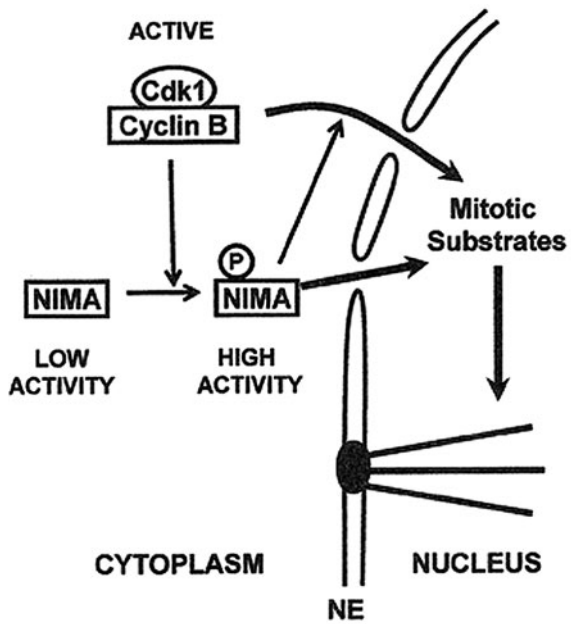

FIGURE 3 Mitotic entry requires both Cdk1/cyclin B and NIMA kinase activities in *A. nidulans*. Active Cdk1/cyclin B cannot enter the nucleus without NIMA activity. NIMA needs Cdk1/cyclin B-dependent phosphorylations to become fully active. Activation of both Cdk1/cyclin B and NIMA allows them to enter the nucleus and phosphorylate their nuclear substrates, thereby triggering mitosis.

and accumulates at the spindle poles late in mitosis before it is degraded during mitotic exit (De Souza et al., 2000). This dynamic location pattern suggests that NIMA has functions at different stages of mitosis and interacts with many proteins that may also be substrates. One of these interacting proteins is TINA, which was identified as a NIMA interacting protein in a yeast two-hybrid screen (Osmani et al., 2003). TINA locates to the spindle pole body during mitosis, and its deletion interferes with proper microtubule function at the spindle pole body, a function conserved in *S. pombe* (Toya et al., 2007).

Given the essential mitotic roles of the prototypic NIMA kinase in *A. nidulans*, there has been much interest in defining the mitotic roles of NIMA-related kinases in other organisms. Although the *S. cerevisiae* NIMA orthologue Kin3 is not essential, a temperature-sensitive allele has been generated which prevents phosphorylation of its mitotic substrates (Chen et al., 2002), causing lethality. In *S. pombe*, the Fin1 NIMA orthologue was identified in a genetic screen for mitotic mutants, and although not essential for mitosis, Fin1 does play roles during mitotic progression (Grallert et al., 2004; Grallert and Hagan, 2002; Krien et al., 1998, 2002). In human cells and other higher eukaryotes, NIMA-related kinases have been termed NEKs (acronym for NIMA-related kinase). Determining NEK function is complicated by the presence of 11 NEK genes, which in some cases encode splice variants (O'Regan et al., 2007). However, initial studies indicated that ectopic expression of *A. nidulans* NIMA or *S. pombe* Fin1 could induce mitotic events in human cells (Krien et al., 1998; Lu and Hunter, 1995; O'Connell et al., 1994), while expression of dominant negative NIMA constructs caused a G_2 arrest (Lu and Hunter, 1995; Lu and Means, 1994). This suggested that human NEKs have roles in mitotic regulation. Indeed, of the 11 human NEKs, four have been implicated in regulating mitotic events, while others have more specialized roles in regulating cilia function (O'Regan et al., 2007; Quarmby and Mahjoub, 2005).

The Aurora and Polo Mitotic Kinases

In addition to Cdk1 and NIMA, other kinases are involved in mitotic regulation. Of these, members of the Aurora and Polo kinase families have been most studied (Nigg, 2001). Although orthologues of these kinases are present in fungal genomes, to date little is known about their function. However, it would be expected that fungal Aurora and Polo kinases have functions in regulating mitosis, and this has been demonstrated in *A. nidulans* (Bachewich et al., 2005; C. P. De Souza and S. A. Osmani, unpublished observations).

Therefore, progression through mitosis requires a complex network of mitotic phosphorylations, which are primarily driven by the Cdk1, NIMA, Polo, and Aurora kinases. While fungal genomes generally encode only one of each of these mitotic kinases, higher eukaryote genomes encode multiple Cdks, NIMA-related kinases, Polo kinases, and Aurora kinases, which have functions in mitosis (Nigg, 2001; O'Connell et al., 2003; O'Regan et al., 2007; Petronczki et al., 2008). This likely reflects the increased complexity of cell cycle regulation in higher eukaryotes, along with specialized functions in different cell or organ types. Consistent with this, in mice, Cdk1 is sufficient to drive the cell cycles during embryonic development, but more specialized cell types require other Cdks (Santamaria et al., 2007). Not mutually exclusive to this is the likelihood that multiple roles can be performed by a single mitotic kinase in lower eukaryotes, but that in higher eukaryotes, these different roles are accomplished by distinct members of the kinase family.

Mitotic Phosphatases

Given that mitotic entry and progression are driven by phosphorylation, it stands to reason that there should exist phosphatases that dephosphorylate kinase substrates. Supporting this, *A. nidulans bimG* is a type I protein phosphatase whose mutation causes a mitotic arrest with elevated levels of phosphorylated proteins recognized by the MPM-2 phospho-specific antibody (Doonan and Morris, 1989). BIMG locates to the spindle pole bodies, nucleolus, and septa, suggesting it may dephosphorylate substrates at several different mitotically relevant locales (Fox et al., 2002).

Another phosphatase that regulates mitotic exit and cell division is the Cdc14 phosphatase, which is a component of the mitotic exit network/septation initiation network in budding and fission yeasts, respectively (Wolfe and Gould, 2005). Interestingly, in *Candida albicans*, Cdc14 locates to the bud neck during yeast-like budding but does not locate to septa during hyphal growth (Clemente-Blanco et al., 2006). Further, deletion of *C. albicans* Cdc14 causes defects in mitotic exit and morphogenesis. This suggests that Cdc14 has roles in mitotic exit in this organism but that these roles differ depending upon the developmental stage.

CELL CYCLE REGULATION THROUGH REGULATED PROTEIN DEGRADATION

As mitotic entry is primarily driven by phosphorylation regulated at the level of mitotic kinase activation, mitotic exit requires the inactivation of these kinases. Cells achieve this through the regulated degradation of either the mitotic kinases themselves or their regulatory subunits. For example, the defining characteristic of the prototypic Cdk1 cyclin binding partner, cyclin B, is its interphase accumulation followed by rapid degradation during mitotic exit (Murray et al., 1989; Potapova et al., 2006). Degradation of cyclin B completely inactivates Cdk1, as it no longer has a cyclin partner. Cyclin B is targeted for its proteasome-mediated degradation by ubiquitination carried out by the anaphase-promoting complex (APC) (Fig. 4). The degradation of NIMA is also required for mitotic exit (Pu and Osmani, 1995), and this is also regulated by the APC (Fig. 4) (Ye et al., 1998). While turning off kinases by degradation may seem like an all-or-nothing approach, it has become clear that such degradation is both temporally and spatially regulated. Filamentous fungal studies have contributed to this field of research, which is still a very topical area of biology.

As the *bim* mutants isolated in *A. nidulans* cause a mitotic arrest, it would be predicted that they code for functions required for mitotic exit. Of these mutants, the *bimE7* mutation gave the tightest mitotic arrest and was of particular interest, as it was shown to be able to override either an S-phase HU arrest, or a *nim*A5 G_2 arrest, and allow cells to enter mitosis (Osmani et al., 1988a). This indicated that BIME had a function in interphase as well as mitotic exit and suggested that its interphase function may be to keep NIMA activity below the threshold required for mitotic entry. The cloning of *bimE* revealed that it encoded a large protein, but its sequence did not shed much light on how it functioned (Engle et al., 1990). Subsequently, Marc Kirschner's lab biochemically purified *Xenopus* APC and found that it contained orthologues of not only BIME but also BIMA (Peters et al., 1996). This defined BIME and

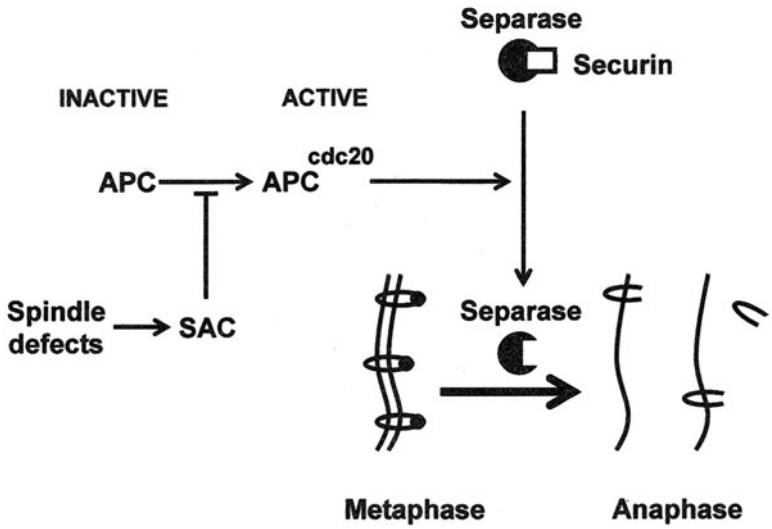

FIGURE 4 The APC regulates mitotic exit by triggering sister chromatid segregation. Cdc20 binds to and activates the APC. This allows the APC to ubiquitinate securin, targeting it for degradation by the proteasome. Securin degradation relieves inhibition of separase, which then degrades the Scc1 component of the securin ring complex. Spindle defects activate the SAC, which prevents Cdc20 binding to APC.

BIMA as components of the APC, consistent with the mitotic arrest caused by their loss of function. APC mutants have also recently been shown to arrest in late mitosis in *A. gossypii* (Gladfelter et al., 2007).

Additional studies have further explored the function of the *A. nidulans* APC components BIME^{APC1} and BIMA^{APC3} in interphase. Interestingly, while APC mutants can override a *nimA5* G_2 arrest, they cannot surpass the G_2 arrest caused by deletion of *nimA* (Ye et al., 1998). In addition, APC mutants cannot override a G_2 arrest caused by lack of Cdk1/cyclin B function (James et al., 1995; Lies et al., 1998). Therefore, both NIMA and Cdk1/cyclinB are required for mitotic entry, even in the absence of APC activity. Biochemically, loss of APC greatly increases Cdk1/cyclin B kinase activity (Ye et al., 1998). This increased Cdk1/cyclin B kinase activity presumably makes a *nimA5* G_2 arrest leaky, possibly by phosphorylation of NIMA5 protein. Morphological studies suggest that this leakiness may be manifested by the discontinuity of the NE observed in *nimA5 bimE7* double mutants (Osmani et al., 1991b). This would result in permeability of the NE, and the normal compartmentalization of Cdk1/cyclin B to the cytoplasm in a *nimA5* mutant (Wu et al., 1998) would be lost, allowing mitotic entry.

In addition to regulating levels of mitotic kinase activity, the APC also regulates sister chromatid dissolution during anaphase. It does this by targeting a protein called securin for degradation. This relieves the securin-mediated inhibition of a protease called separase, which in turn degrades Scc1, a component of the ring-like protein complex called cohesin, which holds sister chromatids together (Fig. 4) (Gruber et al., 2003). This elegant regulatory network, first defined in budding yeast (Uhlmann et al., 1999; Gruber et al., 2003), is also present in filamentous fungi, as indicated by the finding that *bimB* encodes the *A. nidulans* separase (May et al., 1992). In addition, other regulators of sister chromatid cohesion have been identified genetically in *A. nidulans*. One of the four subunits of the cohesin ring complex is encoded by *sudA*, which was identified as an extragenic suppressor of the *bimD6* temperature-sensitive mutation (Holt and May, 1996). The *bimD* gene encodes an orthologue of *Sordaria macrospora* Spo76 and human Pds5A/B, regulators of sister chromatid cohesion. Similar to the process that occurs in vertebrates, BIMD dissociates from chromatin during prophase (van Heemst et al., 2001). Interestingly, BIMD is also important for cell cycle regulation, as *bimD6* mutants transit the cell cycle faster than the wild type and BIMD overexpression leads to a G_1 arrest (van Heemst et al., 1999, 2001).

The APC is also targeted by cells to prevent mitotic exit in response to defective spindle formation by using a regulatory system called the spindle assembly checkpoint (SAC) (Fig. 4). This checkpoint was identified in budding yeast and monitors the attachment of microtubules to kinetochores (reviewed by Musacchio and Salmon, 2007). If microtubules are not correctly attached to all kinetochores in a bipolar manner, the SAC inhibits the activation of the APC (Fig. 4). This is achieved by the inhibitory binding of certain SAC proteins to APC activators such as Cdc20, thus inhibiting APC function. This is a universal mechanism in eukaryotes; components of the SAC are conserved in filamentous fungi, and mutants have been identified by both forward and reverse genetics in *A. nidulans* (Efimov and Morris, 1998; Prigozhina et al., 2004). Such SAC mutants display greatly enhanced sensitivity to drugs, such as benomyl, which interfere with spindle function and normally lead to SAC activation. These SAC mutants do not delay anaphase if correct microtubule attachments are not made and hence undergo lethal mitosis.

In general, the nuts and bolts view of mitotic regulation is that kinase activation triggers mitotic entry while the activation of protein degradation triggers mitotic exit. One study has revealed an unexpected relationship between these counteracting biochemical processes. In this work, rapid inactivation of the APC component BIMA^{APC3} in an asynchronous cell cycle population did not

cause a mitotic arrest as would be expected. Rather, rapid inactivation of $BIMA^{APC3}$ resulted in synchronous cell cycle oscillations of Cdk1/cyclin B and NIMA kinase activity (Ye et al., 1998). This indicates that $BIMA^{APC3}$ may be part of a cell cycle clock mechanism that can be reset upon its inactivation. Findings such as these are important, as we still do not understand how the cell cycle clock is regulated. For example, while the time taken to replicate or segregate DNA defines the length of S phase and mitosis, respectively, less is known about how the length of G_1 is regulated and almost nothing is known about how the duration of G_2 is controlled.

MODULATION OF NUCLEAR TRANSPORT DURING THE CELL CYCLE

Studies of cell cycle regulation utilizing filamentous fungi have provided new insights into how nuclear transport can be regulated in a cell cycle-specific manner. Nuclear transport occurs in a regulated manner through the aqueous channel of NPCs. These massive structures straddle the two membrane layers of the NE to provide a regulated conduit between the cytoplasm and nucleoplasm (Tran and Wente, 2006). During the transition from interphase to mitosis, transport of proteins to the nucleus has to be regulated. For instance, during interphase, microtubules form exclusively in the cytoplasm because tubulin is unable to transit the NPC. However, the mitotic spindle has to gain access to nuclear chromosomes in order to segregate them. How then does cytoplasmic tubulin gain access to nuclear chromosomes? In higher eukaryotes this problem is solved by NE breakdown during early mitosis. As the NE does not exist during such "open mitoses," there is no need to transport tubulin into the nucleus; the system is open. In the corn smut *U. maydis*, a similar process occurs whereby the genome is actively removed from the NE, allowing the mitotic spindle access to chromosomes in a form of open fungal mitosis (Straube et al., 2005). However, in many other fungi, including the model genetic organisms *S. cerevisiae*, *S. pombe*, *N. crassa*, *A. gossypii*, and *A. nidulans*, the NE persists during mitosis. These organisms therefore require a different mechanism to get tubulin into nuclei during mitosis. Little is currently known about these mechanisms. In *S. cerevisiae*, NPCs remain intact throughout mitosis, although protein-protein interactions between specific NPC proteins (Nups) change within the NPC structure (Makhnevych et al., 2003). This leads to changes in the transport properties of NPCs during mitosis (Makhnevych et al., 2003), but how this relates to tubulin transport is not known.

Work utilizing *A. nidulans* has uncovered a new type of mitosis-specific change in nuclear transport. In *A. nidulans*, tubulin released from cytoplasmic microtubules is unable to enter nuclei during interphase but can enter mitotic nuclei (Ovechkina et al., 2003). This demonstrates that a cell cycle-regulated mechanism for mitotic location of tubulin to nuclei, presumably involving cell cycle regulation of nuclear transport, exists in *A. nidulans*. Recent studies utilizing genetic analysis of NIMA-interacting genes have found this to be the case, but in a manner that was not anticipated.

The NIMA mitotic kinase interacts genetically with two components of the NPC, termed $SONA^{Gle2}$ and $SONB^{Nup98}$ ("SON" is an acronym for "suppressor of *nimA1*"), orthologues of highly conserved Nups found from yeasts to humans (De Souza et al., 2003; Wu et al., 1998). $SONB^{Nup98}$ is highly phosphorylated during mitosis in a NIMA- and Cdk1-dependent manner, indicating that it is mitotically regulated. Investigation of the location of $SONB^{Nup98}$ and $SONA^{Gle2}$ during mitosis found that they unexpectedly disassembled from NPCs at the G_2/M transition and returned back to NPCs during exit from mitosis (De Souza et al., 2004). These findings prompted studies of all the *A. nidulans* Nups, as well as other key nuclear transport proteins, revealing that NPCs partially disassembled during mitosis (De Souza et al., 2004; Osmani et al., 2006). Examination of the predicted location of these Nups within the NPC led to a new model for closed mitoses. In this model, Nups that are predicted to locate in the central transport channel, the so-called FG repeat Nups, as well as Nups located to the cytoplasmic and nucleoplasmic sides of the NPC structure, disperse from a core NPC structure specifically during mitosis (Fig. 5). The core NPC structure that remains at the NE during mitosis allows free diffusion of tubulin and

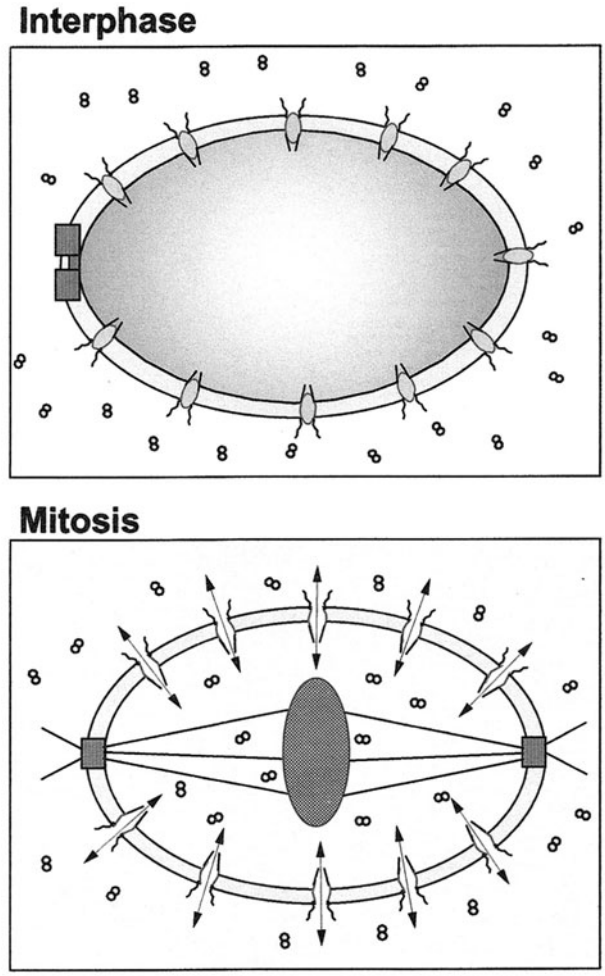

FIGURE 5 Schematic of interphase and mitotic *A. nidulans* nuclei. NPCs are embedded within the NE. During interphase, Nups occupy the central channel of NPCs, restricting diffusion. In mitosis, the NPCs partially disassemble such that the central channel is now open and the NE is permeable. This facilitates nuclear entry of tubulin, allowing spindle formation from the spindle pole bodies.

mitotic regulators into and out of nuclei (Osmani et al., 2006). In this partially open mode of mitosis, proteins localize within the cell depending on their respective binding affinities, similar to a mammalian open mitosis. Such mitosis-specific diffusion through the NE is consistent with prior studies showing that a reporter construct fused to a nuclear localization sequence is actively transported into nuclei during interphase but disperses from nuclei upon entry into mitosis (Suelmann et al., 1997). Therefore, opening of the NPC transport channel to allow diffusion between the cytoplasm and nucleoplasm provides the mechanism by which cytoplasmic tubulin gains access to nuclei, enabling formation of the nuclear mitotic spindle. During exit from mitosis, the core mitotic NPC structure acts as a prepore to which the dispersed Nups return and reestablish regulated nuclear transport and entry into G_1 (Fig. 5).

The genetic interaction between NIMA and Nups and the fact that these same Nups disperse from NPCs during mitosis suggest that NIMA plays a direct role to promote NPC disassembly. Several additional findings support this. As NIMA enters nuclei, it does so in a distinctive manner. Rather than seamlessly entering nuclei, as does tubulin, NIMA accumulates around the nuclear periphery during translocation, colocalizing with NPCs within the NE as described above (De Souza et al., 2004). Thus, NIMA is at the correct location at the right time to promote $SONB^{Nup98}$ phosphorylation and partial NPC disassembly. Importantly, as mentioned above, $SONB^{Nup98}$ is hyperphosphorylated during mitosis in a NIMA-dependent manner. Further, ectopic expression of NIMA promotes both the release of $SONB^{Nup98}$ from NPCs and the opening of the transport channel allowing diffusion of tubulin into nuclei (De Souza et al., 2004). Finally, dominant negative NIMA constructs accumulate at the nuclear periphery when overexpressed and delay entry into mitosis (De Souza et al., 2004). Therefore, NIMA is both necessary and sufficient to promote partial NPC disassembly and free diffusion into and out of nuclei to promote mitosis.

It is currently unclear whether other filamentous fungi, or other organisms in general, utilize partial NPC disassembly to regulate mitosis and what role NEKs may play if they do. However, similar to *A. nidulans*, some filamentous fungi that maintain an intact NE during mitosis have been demonstrated to display equilibration between the cytoplasmic and nuclear compartments specifically during mitosis. For instance, in the plant pathogens *Fusarium verticillioides* and *M. grisea*, the permeability of the NE changes dramatically during mitosis, allowing cytoplasmic proteins into mitotic nuclei (Bourett et al., 2002). In addition, cytoplasmic tubulin can enter the mitotic nuclei of *M. grisea* but not interphase nuclei (Czymmek et al., 2005). These mitotic changes in NE permeability may be mediated by partial NPC disassembly. In the case of *M. grisea*, this is particularly intriguing given that its NIMA orthologue is required for mitosis and can complement *A. nidulans nimA* mutants (Veneault-Fourrey et al., 2006).

Complete NPC disassembly has recently been demonstrated during mitosis in *U. maydis* yeast-like cells, which undergo a form of open mitosis (Theisen et al., 2008). Little is currently known about how NPC disassembly and reassembly are regulated during mammalian open mitosis, and these processes do not occur in model yeast systems. Therefore, model filamentous fungi such as *A. nidulans* and *U. maydis* provide unique opportunities to study mitotic regulation of the NPC.

THE LINKAGE OF CYTOKINESIS TO MITOTIC EXIT

Differential Regulation of Cytokinesis

As suggested by the fact that filamentous fungi often maintain many nuclei in a common cytoplasm, cytokinesis does not accompany every nuclear division. The process of cytokinesis during filamentous growth is generally achieved by the formation of a cross wall called a septum at a specific point in hyphae. In terms of how this relates to the cell cycle, this process is best understood in *A. nidulans*, for which genetic screens have been performed to isolate septation mutants (Harris et al., 1994; Morris, 1976b). During normal uninucleate conidial germination, septation does not occur in the first two or three cell cycles, resulting in either four or eight nuclei in the cytoplasm of a single germ tube (Fiddy and Trinci, 1976; Harris, 1997). However, following the third or fourth synchronous round of mitoses, a single septum asymmetrically forms, separating the resulting nuclei into two cellular compartments (Fig. 6A). Similar suppression of septation during the initial cell cycles also occurs during germination of *A. fumigatus* conidia (Momany and Taylor, 2000). Notably, when septation does occur, it is coordinated with the completion of mitosis, indicating that it is regulated by the cell cycle machinery. How septation is suppressed in early cell cycles and then induced in later rounds of mitosis is not well understood, although cell size

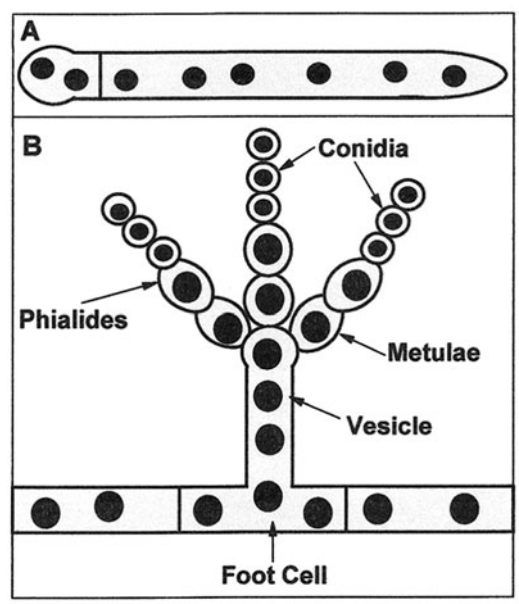

FIGURE 6 Septation is not always linked to nuclear division in *A. nidulans*. (A) A germling containing eight nuclei, which underwent its first asymmetric septation following the third mitosis. (B) Diagram of a conidiophore that has formed by growth of a multinucleate cell containing a stalk and vesicle. This cell originally formed by growth of a specialized aerial hypha termed the vesicle from the foot cell, in which multiple nuclear divisions occur without septation. Cytokinesis is linked to nuclear division during the formation of metulae and phialides as well as when uninucleate conidiospores form by budding from the phialide. Cytokinesis occurs through septation in hyphae, but by budding to form metulae, phialides and conidia.

TABLE 1 Cytokinesis and nuclear division in different *A. nidulans* cell types

Cell type	Cytokinesis and nuclear division
Early germling	Not linked
Hyphae	Linked
Foot cell	Specialized septa
Vesicle	Not linked
Phialides/metulae	Linked (pseudohypha-like budding)
Conidiospores	Linked (budding)

is thought to play an important role (Wolkow et al., 1996). Such suppression of septation in early cell cycles has been proposed to be a mechanism which subsequently accelerates polarized growth during the transition from germling growth to hyphal growth (Horio and Oakley, 2005). This is because the initial lack of septation generates a cytoplasm containing multiple nuclei increasing the biosynthetic capacity of a cell which is only growing in one direction at a single growth site. Consistent with this, the rate of growth of hyphal tips, driven by multiple nuclei, is some five times faster than the tip growth of small germlings (Horio and Oakley, 2005).

Further variations in the linkage of cytokinesis with nuclear divisions exist in other *A. nidulans* cell types (Fig. 6B and Table 1). The most dramatic variation occurs during *A. nidulans* asexual sporulation, in which cytokinesis is linked to every nuclear division, resulting in the formation of chains of uninucleate conidiospores in a budding-type process (Adams et al., 1998). Conidiospores are formed from a specialized cell called a phialide, which is part of a specialized structure called the conidiophore. The budding of conidiospores occurs by repeated mitotic nuclear divisions of the phialide nucleus such that one daughter nucleus remains in the phialide while the other enters the conidium and arrests in G_1 (Timberlake, 1990). Therefore, the phialide acts as a type of stem cell, which maintains its own identity and mitotic capacity while generating numerous other, mitotically inert, cells. It is likely that many of the genes that regulate hyphal septation are also involved in asexual budding, as mutants deficient in septation also abolish or greatly interfere with conidiation (Harris et al., 1994; Liu et al., 2003; Liu and Morris, 2000; McGuire et al., 2000). However, how these developmental changes in septation are integrated with the cell cycle machinery is not known.

Regulators of Septation

A septation initiation network has been described in the fission yeast *S. pombe* and is analogous to the mitotic exit network of budding yeast (Wolfe and Gould, 2005). These networks consist of a GTPase signaling cascade that coordinates septum formation and/or cytokinesis with the completion of each mitosis. Most components of an analogous pathway are present in filamentous fungi (Borkovich et al., 2004; Harris, 2008; Kim et al., 2006; Straube et al., 2005). Mutants in some of these components including *sepH*^{Cdc7}, *sidB*^{Sid2}, and *mobA*^{Mob1} compromise septation and conidiation in *A. nidulans* (Bruno et al., 2001; Kim et al., 2006). Interestingly, neither *sepH*^{Cdc7}, *sidB*^{Sid2}, nor *mobA*^{Mob1} is essential for colony formation or hyphal growth, while the fission yeast orthologues of these mutants are essential genes (Gould and Simanis, 1997). This likely reflects the essential nature of cytokinesis in uninucleate fission yeast in comparison to the multinucleate nature of filamentous fungi, such as *A. nidulans* (Kim et al., 2006).

Another cell cycle regulator which has been implicated in *A. nidulans* septation is *A. nidulans* Cdk1 (De Souza et al., 1999; Harris and Kraus, 1998; McGuire et al., 2000; Ye et al., 1999). High levels of Cdk1 activity induce early onset of septum formation in small cells and before the third round of mitosis (De Souza et al., 1999; Harris and Kraus, 1998). This has led to the proposal that a threshold level of Cdk1 activity is required to induce septation (Harris, 2001; Harris and Kraus, 1998). However, to date it has not been demonstrated that, during hyphal growth, Cdk1 activity is lower during the first and second rounds of mitosis than in the third, when the formation of the first septum is generally initiated. Therefore, it is still unclear how septation is suppressed until after the third mitosis in *A. nidulans* or how a single, asymmetric septum is formed (Fig. 6A). Cdk1 activity also interferes with cytokinesis in the basidiomycete *U. maydis*. During the yeast-like phase of its life cycle, *U. maydis* undergoes budding which differs from that of ascomycetous yeasts in that two distinct septa, rather than one, are formed in each budding event. Genetic manipulations that increase Cdk1 activity interfere with this budding process, resulting in chains of cells separated by septa (Sgarlata and Perez-Martin, 2005a, 2005b). Therefore, Cdk activity is important for the regulation of cytokinesis and septation in both the ascomycete and basidiomycete filamentous fungi.

Another interesting observation with regards to septation in *A. nidulans* is that DNA damage can inhibit septum formation (Harris and Kraus, 1998). Further, some mutants defective in septation are thought to indirectly prevent septation by causing genotoxic damage. In such mutants, the septation defects are suppressed when combined with DNA damage checkpoint-deficient mutants (Harris and Kraus, 1998; Wolkow et al., 1996). Therefore, filamentous fungi have a mechanism to prevent septation if DNA damage has occurred. This may help maintain multiple copies of the genome in one cellular compartment, which increases the chance of having at least one functional copy of an essential gene in each cell. For example, if DNA damage knocks out an essential gene in only one G_1 nucleus of a cell containing several nuclei, preventing septation ensures that no cells are generated which contain only a null allele of an essential gene. Potential mechanisms such as these suggest that filamentous fungi have evolved specialized checkpoint mechanisms regulating septation.

SYNCHRONY OF CELL CYCLE PROGRESSION IN MULTINUCLEATED CELLS

One of the intriguing aspects of syncytial, multinucleate fungi is how they coordinate cell cycle events such as mitosis between nuclei in a common cytoplasm. This can vary among different organisms, which utilize either synchronous, parasynchronous, or asynchronous modes of nuclear division (Gladfelter, 2006). For example, *A. nidulans* hyphae use a parasynchronous mode, in which mitosis occurs as a wave generally beginning at the hyphal tip and then spreading along the rest of the cell. In contrast, *N. crassa* and *A. gossypii* undergo asynchronous nuclear divisions, and therefore mitosis is "nuclear autonomous" in these organisms (Gladfelter et al., 2006; Serna and Stadler, 1978). As we have discussed above, the biochemical activities that regulate mitotic entry are conserved in different

filamentous fungi. How different organisms utilize these same activities but display such dramatically different modes of timing nuclear division has long been a mystery, but it is likely that cellular compartmentalization of mitotic regulators is important. As the mitotic apparatus is set up within the individual nuclei of a syncytium, the key may be in how these mitotic regulators gain access to nuclei. As we have described, the NE is permeable during *A. nidulans* mitosis, due to the partial disassembly of NPCs. In other organisms, NPCs may remain intact, as occurs in budding yeast (Makhnevych et al., 2003). In these organisms, modification of nuclear transport pathways is likely important for nuclear entry of mitotic regulators. One possibility is that modification of nuclear transport pathways can be modulated in a nuclear autonomous manner, whereas partial NPC disassembly, which is likely initiated in the cytoplasm, cannot. Given that partial NPC disassembly is unlikely to occur in a nuclear autonomous manner, it is not likely to be utilized by organisms undergoing asynchronous mitoses within a syncytium. Future studies will no doubt shed light on these and other possible mechanisms, such as nuclear autonomous activation of the APC and protein degradation, for temporally regulating asynchronous mitosis within syncytia.

Interestingly, while mitosis within *A. nidulans* syncytia is parasynchronous under optimal conditions, this synchrony breaks down when cells are grown on nutrient-poor media (Clutterbuck, 1970; Rosenberger and Kessel, 1967). Therefore, *A. nidulans* can change its mode of mitosis in response to environmental conditions that affect growth rate. If environmental conditions dictate slow growth, it may be more practical to divide one nucleus at a time, as this requires less energy than synchronously dividing multiple nuclei. It remains to be seen if such asynchronous *A. nidulans* mitoses are regulated by partial NPC disassembly or if another mechanism is utilized.

G_2 DNA DAMAGE AND SLOWED S-PHASE CHECKPOINTS

Eukaryotic cells utilize safeguard mechanisms to prevent cell cycle progression if DNA is not completely replicated or if DNA is damaged. Such mechanisms have been defined as cell cycle checkpoints, which, by stopping the cell cycle, allow cells time to complete replication or repair DNA damage before entering mitosis. Given the critical nature of such checkpoints, it is not surprising that mutations in many key cell cycle checkpoint genes have been identified in human genetic disorders, such as ataxia-telangiectasia and Nijmegen breakage syndrome (Lavin, 2007). Cell cycle checkpoints are therefore a crucial part of the DNA damage response and are integrated with detection of DNA damage and the activation of DNA repair pathways. Below is reviewed what is known about the cell cycle checkpoint branch of the DNA damage response in filamentous fungi. Readers are also referred to reviews on other aspects of the DNA damage response (Goldman et al., 2002; Goldman and Kafer, 2004).

As outlined above, activation of the Cdk1 kinase via dephosphorylation of its tyrosine residue is required for mitotic entry (Fig. 2). Most eukaryotic cells target this Cdk1-activating step to prevent mitotic entry if DNA is damaged or incompletely replicated (Jin et al., 1996; Rhind et al., 1997; Ye et al., 1997). A notable exception to this is the budding yeast *S. cerevisiae* (Amon et al., 1992; Sorger and Murray, 1992), which arrests at the metaphase-to-anaphase transition by inhibiting sister chromatid separation in response to DNA damage (Cohen-Fix and Koshland, 1997). This likely reflects the fact that this organism does not have a G_2 phase of the cell cycle, since spindle formation begins as DNA is replicated in S phase. However, in filamentous fungi and other organisms mutations that inhibit the tyrosine phosphorylation of Cdk1 cause defects in the G_2 DNA damage checkpoint. For example, in *A. nidulans*, strains in which the phosphorylatable threonine and tyrosine residues within Cdk1 have been mutated to nonphosphorylatable alanine and phenylalanine residues (Cdk1 AF mutant) fail to arrest in G_2 in response to DNA damage (Ye et al., 1997). The failure of the G_2 DNA damage checkpoint in such cells results in enhanced sensitivity to DNA-damaging agents. Mutations in the *ankA*^{wee1} kinase responsible for tyrosine phosphorylation of Cdk1 (Fig. 2) also cause checkpoint defects and DNA damage sensitivity (Ye et al., 1997).

The inability to phosphorylate Cdk1 on threonine and tyrosine also results in loss of the prolonged S-phase checkpoint that prevents mitotic entry if DNA replication is not completed (Ye et al., 1996). Therefore, *A. nidulans* Cdk1 AF and Δ*ankA*^{wee1} mutants inappropriately enter mitosis even if DNA replication is not completed. This results in sensitivity to low concentrations of the ribonucleotide reductase inhibitor HU, which interferes with DNA replication. In *U. maydis*, preventing tyrosine phosphorylation of Cdk1 also results in sensitivity to HU, suggesting that a similar prolonged S-phase checkpoint exists in Basidiomycetes (Sgarlata and Perez-Martin, 2005a).

In *A. nidulans*, completely inhibiting DNA replication by using high concentrations of HU revealed a second checkpoint that monitors DNA replication. In these studies, Cdk1 AF mutants inappropriately entered mitosis if replication was slowed but did not enter mitosis if replication was completely inhibited. Moreover, Cdk1 AF mutants displayed marked sensitivity to low concentrations of HU but no enhanced sensitivity to transient exposure to concentrations of HU that completely block DNA replication. This revealed a second checkpoint, termed the S-phase arrest checkpoint, which responds to a complete block in DNA replication. The S-phase arrest checkpoint can prevent mitosis even in the absence of Cdk1 tyrosine phosphorylation. Interestingly, loss of BIME^{APC1} function together with lack of Cdk1 tyrosine phosphorylation was found to negate the S-phase arrest checkpoint (Ye et al., 1996). This is likely because the loss of BIME^{APC1} function, together with activation of Cdk1, results in the accumulation of the active phosphorylated form of NIMA. Therefore, in these cells, Cdk1 and NIMA are both active, and this is sufficient to allow mitotic entry even without DNA replication. These studies provided further evidence of a role for the APC during interphase.

While Cdk1 tyrosine phosphorylation is crucial in preventing inappropriate mitotic entry in response to genomic defects, less is known about how cells know when to engage such checkpoints. To achieve this, stalled replication forks or damaged DNA must first be detected by the cell, and then pathways leading to Cdk1 tyrosine phosphorylation must be activated. To identify upstream regulators of Cdk1 tyrosine phosphorylation, the library of DNA damage-sensitive mutants available for *A. nidulans* was screened for sensitivity to low concentrations of HU. The rationale was that as Cdk1 tyrosine phosphorylation is required for both the G_2 DNA damage and prolonged S-phase checkpoints, regulators of Cdk1 tyrosine phosphorylation should be sensitive to both DNA damage and a slowed S phase. Of these

mutants, only the four mutant alleles of *uvsB* and two of *uvsD* displayed sensitivity to HU, in addition to their defined DNA damage sensitivities. These genes were subsequently cloned by complementation of their HU sensitivity, and sequencing indicated that UVSB was closely related to fission yeast Rad3, while UVSD displayed low homology to Rad26 (De Souza et al., 1999; Hofmann and Harris, 2000). Both *uvsB* and *uvsD* mutants failed to arrest in G_2 in response to DNA damage, indicating that they did indeed function in the G_2 DNA damage checkpoint, similar to their *S. pombe* orthologues (al-Khodairy et al., 1994; al-Khodairy and Carr, 1992). However, while Rad3 was known to be a member of the ATM-related (ATR) protein kinase family, orthologues of Rad26 were not known. Subsequently, the human UVSD/Rad26 orthologue ATR-interacting protein (ATRIP) was identified and shown to be phosphorylated by ATR as part of the checkpoint response (Cortez et al., 2001). Recently, *N. crassa uvs-3* was shown to be a member of the UVSD/Rad26/ATRIP family (Kazama et al., 2008). Further, *uvsD* can partially complement the HU sensitivity of *uvs-3* mutants, indicating functional conservation of this checkpoint in another filamentous fungus.

Another key player in cell cycle checkpoints is the ATM checkpoint kinase. ATM is related to the ATR checkpoint kinase but is thought to be more specific for the response to DNA double-strand breaks, whereas ATR responds to a wider range of genotoxic damage. Reverse genetics have been used to identify and delete the *A. nidulans* ATM orthologue, $atmA^{ATM}$, demonstrating that it is required for the proper checkpoint response to DNA double-strand breaks. Recently it has been shown that strains lacking both $uvsB^{ATR}$ and $atmA^{ATM}$ are not viable (Malavazi et al., 2008), although interestingly this is not the case in budding yeast (Morrow et al., 1995). More surprisingly, however, $atmA^{ATM}$ nulls also display defects in polarized hyphal growth (Malavazi et al., 2006). Findings such as these suggest that the cell cycle checkpoint machinery may be integrated with hyphal morphogenesis, although the mechanisms involved remain to be elucidated.

The MRN (Mre11, Rad50, and Nbs1) complex cooperates with ATM and ATR to generate signals that activate cell cycle checkpoints (D'Amours and Jackson, 2002; Lavin, 2007; Zhang et al., 2006). Consistent with this, mutants in the *A. nidulans* orthologues of these genes have defects in cell cycle checkpoints (Bruschi et al., 2001; Malavazi et al., 2005; Semighini et al., 2003). Of these genes, $scaA^{Nbs1}$ was identified in a screen for mutants sensitive to the DNA topoisomerase I inhibitor camptothecin, while $mreA^{Mre11}$ was subsequently identified in a two-hybrid screen using a $scaA^{Nbs1}$ bait (Bruschi et al., 2001; Semighini et al., 2003). Intriguingly, $sldI^{Rad50}$ was identified in a screen for genes which are synthetically lethal with the loss of function of the microtubule motor dynein (Malavazi et al., 2005).

Another interesting connection between the cell cycle and the DNA damage response comes from the finding that a mutation in $sonB^{Nup98}$, which encodes an NPC protein, causes DNA damage sensitivity (De Souza et al., 2006). Interestingly, this mutation is conditional in that mutants are not DNA damage sensitive at 32°C but display marked sensitivity at 42°C. At the same elevated temperature, this $sonB^{Nup98}$ mutation has also been shown to suppress a *nimA1* G_2 arrest (De Souza et al., 2003), and this was the way this mutation was first identified. However, despite this role in the G_2/M transition, $sonB^{Nup98}$ mutants were found to have an intact G_2 DNA damage checkpoint. Rather, the role for $sonB^{Nup98}$ in the DNA damage response may involve the MRN complex as the $sonB^{Nup98}$ mutant is synthetically lethal with $scaA^{Nbs1}$ mutants at 42°C but not at 32°C. This suggests that $SONB^{NUP98}$ plays a novel role in the DNA damage response and reveals a potential link between the cell cycle, NPCs, and the DNA damage response.

The Chk1 and Chk2 kinases are components of the signaling pathways that activate cell cycle checkpoints in response to the detection of DNA damage (Chen and Poon, 2008). The corresponding genes have recently been deleted in *A. nidulans*, and the roles of these kinases in the DNA damage response have begun to be characterized (Malavazi et al., 2008). Intriguingly, the *N. crassa* Chk2 orthologue, *prd-4*, was identified as a gene involved in the circadian system, revealing an interesting link between this clock system and the cell cycle (Pregueiro et al., 2006).

One interesting question with regard to checkpoint regulation within a fungal syncytium is whether a defect within a single nucleus can activate cell cycle checkpoints, such that all nuclei arrest. For example, if DNA damage occurs in only one nucleus, do other nuclei within the same cell arrest in G_2? Technology now exists to address such questions, using lasers to specifically elicit damage to a single nucleus within a syncytium.

VARIATIONS ON THE MODE OF MITOSIS WITHIN FUNGI

Filamentous fungi display stunning diversity in how the genome is physically segregated by the mitotic apparatus. For example, while many fungi maintain an NE around the spindle in a closed mitosis, basidiomycetes such as *U. maydis* strip the mitotic apparatus from the NE. Morphological differences such as these were readily identifiable in early studies of fungal mitosis using light or electron microscopy and have been elegantly described in the literature (Aist and Morris, 1999; Heath, 1980; O'Donnell and McLaughlin, 1984; Robinow and Caten, 1969). However, more-recently identified variations, such as the partial NPC disassembly during mitosis in *A. nidulans*, became apparent only by use of more modern tools, such as live cell imaging of fluorescently tagged proteins. It is likely that other mitotic variations await discovery. It is clear, however, that referring to mitosis as either open or closed has its limitations. For example, molecules at least a large as 250 kDa can defuse in and out of nuclei during *A. nidulans* mitosis (Osmani et al., 2006). Therefore, although the NE is intact, it is a partially open system.

Many of the mitotic variations described in filamentous fungi are variations on how the NE is segregated to generate two daughter nuclei during closed mitosis (Heath, 1980). The NE acts as a barrier between the nucleus and cytoplasm and as such keeps kinetochores in the nucleus away from cytoplasmic microtubules. In organisms undergoing closed mitosis, the mitotic spindle is formed by microtubules nucleated from the nucleoplasmic face of the spindle pole body. One advantage of undergoing closed mitosis is that it restricts the attachment of spindle microtubules to only those kinetochores within that nucleus. This is presumably highly advantageous in filamentous fungi that contain multiple nuclei within a syncytium, as it prevents internuclear spindles (see De Souza and Osmani, 2007, for a discussion of this topic). Therefore, multinucleate fungi tend to maintain their NE intact until at least metaphase, when all microtubule attachments have been made. Subsequent to this, however, there is

significant variation in how segregation of DNA and the NE are coordinated (Heath, 1980).

How the NE undergoes restriction and fission to generate two daughter nuclei during the closed mitoses of yeasts and fungi is still a complete mystery. Little is known about how NE fission is regulated or what the motor proteins involved are. Clearly NE fission has to occur after segregation of DNA on the mitotic spindle. In *A. nidulans*, there are many examples of mitotic mutants that enter mitosis but fail to undergo NE fission, generating polyploid nuclei surrounded by a single contiguous NE (Davies et al., 2004; De Souza et al., 1999; May et al., 1992; Pitt et al., 2004). In some cases, DNA appears to segregate, but examination of the NE reveals that it still connects the DNA masses. Therefore, DNA segregation can be uncoupled from NE fission, suggesting that although normally coordinated, these are distinct processes. Further, some mutants that fail to complete NE fission undergo subsequent rounds of DNA replication (De Souza et al., 1999; May et al., 1992; Pitt et al., 2004). One possibility is that this allows cells to increase their biosynthetic capacity, even without nuclear division. As long as such cells also have other nuclei which have normal haploid ploidy, they should be able to continue growth and eventually undergo asexual development.

Perhaps even more fascinating than the described mitotic variations among species are the mitotic variations which occur in different cell types within one organism. In fact, given that septation is mitotically linked but does not occur in every mitosis or cell type, all filamentous fungi display some mitotic variations during their life cycle. In some cases, specialized cellular structures are made to facilitate these mitotic variations, for example, the *A. nidulans* conidiophore. Another intriguing example of a specialized cell structure for mitosis is the clamp that is formed during the dikaryotic stage of many basidiomycetes (Iwasa et al., 1998; Scherer et al., 2006). As such dikaryons contain two genetically distinct nuclei, it is important that following mitosis the two new cellular compartments inherit one of each type of nucleus. The clamp helps cells achieve this by providing a small branch in which one nucleus undergoes mitosis while, at the same time, the other nucleus undergoes mitosis in the germ tube (Fig. 7). The formation of specialized septa then allows the successful generation of dikaryotic cells. Clearly, the spatial regulation of the cytoskeleton and septum formation by mitotic regulators is also important to facilitate this fascinating mode of mitosis. Additionally, it has been suggested that although basidiomycetes, such as *U. maydis*, undergo open mitosis in their yeast phase of growth, this is unlikely to occur during the dikaryotic phase (De Souza and Osmani, 2007). This is because such open mitoses would likely allow interference between the spindle apparatus of the different nuclei synchronously undergoing mitosis within the same cell. This leads to the interesting possibility that open and closed mitoses might occur in fungi in a developmentally regulated manner, as is known to occur in *Physarum polycephalum* (Solnica-Krezel et al., 1991; Tanaka, 1973).

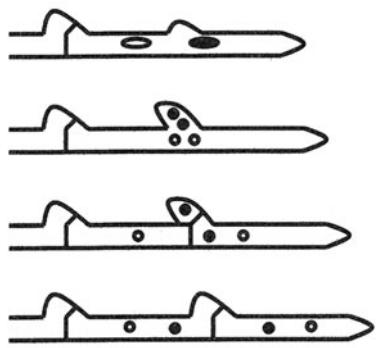

FIGURE 7 Schematic showing how development of a clamp and specialized septa help maintain the dikaryotic state of basidiomycete hyphae (adapted from Iwasa et al., 1998).

DEVELOPMENTAL CONTROL OF CELL CYCLE PROGRESSION IN MULTICELLULAR FUNGI

Many filamentous fungi have life cycles in which developmentally differentiated cell types form. Such changes are a prerequisite for sexual or asexual reproduction and are often involved in host cell invasion by pathogenic fungi (Gow et al., 2002; Steinberg, 2007). These developmental changes are initiated by environmental factors triggering different developmental and transcriptional programs (Adams et al., 1998; Borkovich et al., 2004; Steinberg, 2007). In *A. nidulans*, many of the transcriptional factors regulating asexual conidiophore development have been characterized (Adams et al., 1998). For example, mutation of the *brlA* transcription factor prevents asexual conidiophore formation, while inappropriate expression in vegetative cells can induce conidiospore formation when it normally would not occur (Adams et al., 1988). Such ectopic expression of *brlA* has been shown to induce the mRNA expression and increase activity of the Cdk1/cyclin B and NIMA mitotic kinases (Ye et al., 1999). This suggests that levels of these kinases are increased during asexual development, in a *brlA*-dependent manner. Consistent with this, Cdk1/cyclin B and NIMA kinase activities increase sixfold during conidiophore development (Ye et al., 1999). This provides strong evidence that components of the mitotic machinery are developmentally regulated. Interestingly, during asexual conidiophore formation, a second *brlA*-inducible cyclin, Pcl2, is involved in Cdk1 regulation in addition to $NIME^{CyclinB}$ (Schier and Fischer, 2002). Together, these studies indicate that during development, Cdk1 activity is increased and regulated by multiple cyclin binding partners. However, as Cdk1 AF mutants display many developmental anomalies such as septation in the stalk and vesicle (Ye et al., 1999), it is clear that this activity must still be correctly regulated by tyrosine phosphorylation.

Other Cdks, such as members of the Cdk5/Pho85 family, are not directly involved in cell cycle regulation but have roles in developmental regulation. In *A. nidulans*, this includes the PHOA and PHOB Pho85-like Cdks, which together with their PHO80 cyclin partner, are involved in the developmental switch between asexual and sexual reproduction in response to environmental stimuli (Bussink and Osmani, 1998; Dou et al., 2003; Wu et al., 2004). Further, the *U. maydis* Cdk5 together with its cyclin partner, Pcl12, has important roles in regulating morphogenesis and pathogenesis (Castillo-Lluva et al., 2007; Flor-Parra et al., 2007). Therefore, filamentous fungi utilize a more sophisticated Cdk-cyclin machinery to regulate developmental decisions that are not required in unicellular yeasts.

CELL CYCLE CONTROL AND PATHOGENESIS

Pathogenic fungi often undergo morphological changes during host invasion (Gow et al., 2002). Such morphological changes can entail switching between budding and filamentous modes of growth. In large part, this is achieved by

regulating septation and cytokinesis, which, as we have discussed above, are under cell cycle control. For example, at 25°C the nonpathogenic form of the dimorphic fungal pathogen *Penicillium marneffei* undergoes filamentous vegetative growth, in which cells are generally multinucleate. However, this organism is pathogenic at 37°C, where conidia germinate and form hyphae, which in turn produce arthroconidia. Arthroconidia are uninucleate cells that arise because nuclear division and septation have become coupled. Breakdown of the material between the double septa in these cells results in the formation of yeast-like cells that divide by fission (Canovas and Andrianopoulos, 2007). Clearly then, the regulation of cytokinesis and mitosis is important for the pathogenicity of this and other fungi.

Links between cell cycle regulators and pathogenicity have also been uncovered in the maize smut fungus, *U. maydis*, as recently reviewed (Perez-Martin et al., 2006). During the infection process, haploid yeast-like sporidia of opposite mating types arrest in G_2 and fuse to form the pathogenic filamentous dikaryon (Garcia-Muse et al., 2003; see also chapter 34). This G_2 cell cycle arrest is therefore important for pathogenicity (Perez-Martin et al., 2006). Further, links between Cdks and pathogenesis have been revealed by preventing Cdk1 tyrosine phosphorylation, which stops the initiation of pathogenic development, perhaps due to a failure of cells to arrest in G_2 (Sgarlata and Perez-Martin, 2005a). Notably, interfering with either *U. maydis* Cdk1 phosphorylation or levels of B-type cyclins at later stages of plant infection also decreases virulence (Garcia-Muse et al., 2004; Sgarlata and Perez-Martin, 2005a). In addition, specific cyclins and other cell cycle regulators are important for regulating the morphogenic changes in the opportunistic human pathogen *C. albicans*, although whether or not this is important for virulence remains controversial (reviewed by Berman, 2006, and Whiteway and Bachewich, 2007).

Infection caused by the rice blast *M. grisea* has been demonstrated to be tightly linked to the cell cycle (Veneault-Fourrey et al., 2006). In this organism, a mitosis occurs in which one daughter nucleus migrates into an infection structure called the appressorium. Inhibiting the cell cycle by drug treatment before this mitosis greatly affects appressorium development, whereas drug treatment after this mitosis has little effect. To investigate this further, Talbot and colleagues turned to molecular genetics and generated a version of the *M. grisea nimA* orthologue containing the equivalent mutation, which causes a G_2 arrest at the restrictive temperature in *A. nidulans*. This $MgnimA^{E37G}$ strain was defective in appressorium formation at a nonpermissive temperature, providing further evidence that mitosis is required for this process and subsequent plant infection by *M. grisea* (Veneault-Fourrey et al., 2006). Therefore, cell cycle events such as mitosis may be linked to pathogenicity if these events are a prerequisite for formation of an infectious structure such as the *M. grisea* appressorium. Interestingly, however, this is not the case in the closely related plant pathogen *Colletotrichum gloeosporioides*, in which appressorium formation is not dependent on mitosis (Nesher et al., 2008).

SUMMARY

Filamentous fungi provide rich and varied experimental opportunities to further our understanding of mitosis and its regulation. Until relatively recently, *A. nidulans* has been the workhorse of the filamentous fungi for studies of mitosis. This situation is largely a result of the pioneering work of Ron Morris, whose genetic screens laid the foundation for the isolation of many cell cycle-specific genes. Clearly, there is much still to be understood about mitotic regulation in humans as well as in filamentous fungi. Equally clear are the vast opportunities provided by other fungi whose varied biology provides unique experimental advantages for the study of various aspects of mitosis. As outlined in this review, areas of particular interest are how the cell cycle is coordinated with morphogenesis and/or pathogenicity and the molecular basis of synchronous versus asynchronous cell cycles within syncytia. *A. gossypii* and *N. crassa* provide unique model systems in which to define how such asynchronous mitoses are regulated within a common cytoplasm. Other areas primed for further insights are the dramatic structural changes that occur in nuclei, in addition to the intensively studied processes of chromosome condensation and spindle formation. Many of these changes, such as NPC disassembly, do not occur in model yeasts, and therefore model fungi such as *A. nidulans* and *U. maydis* provide excellent systems with which to study these processes. With the current availability of high-quality genome data and recent improvements in gene targeting and proteomic technologies for many filamentous fungi, we look forward to the next cycle of mitotic insights from these important and fascinating organisms.

Meiosis

CLAIRE BURNS, PATRICIA J. PUKKILA, AND MIRIAM E. ZOLAN

INTRODUCTION

In fungi that have a sexual cycle, meiosis is the process by which chromosomes recombine and haploid nuclei are generated. Meiosis consists of one round of DNA replication followed by two rounds of division (Fig. 1). The first division, termed reductional, separates homologs (thus reducing the ploidy of nuclei from diploid to haploid). The second division, termed equational, is like mitosis in that sister centromeres separate. The two divisions required by meiosis pose a number of problems that cells need to address. First, homologous chromosomes (homologs) need to find one another (pair). Second, each pair of homologs (each bivalent) must remain associated until the first division, and recombination plays an important role in this association between homologs. Third, the associations between sister chromatids (cohesion) must be modulated along the length of the chromosomes in specific ways through the two meiotic divisions. Filamentous fungi such as *Sordaria macrospora*, *Neurospora crassa*, and *Coprinus cinereus* (reclassified as *Coprinopsis cinerea* [Redhead et al., 2001]) have been and continue to be valuable organisms for the elucidation of meiotic processes, as reviewed previously (Pukkila, 1994; Zickler, 2006).

This chapter discusses the hallmarks of meiosis, crossover (chiasma) distribution, genes necessary for meiosis, and the transcriptional program of meiosis, with a focus on recent studies. A recent review, "*Neurospora* as a model fungus for studies in cytogenetics and sexual biology at Stanford" (Raju, 2009), is highly recommended as a complement to this chapter, which does not encompass the elegant studies described therein.

Pairing and Synapsis

Filamentous fungi display the interesting characteristic of maintaining haploid nuclei throughout mycelial development until nuclear fusion (karyogamy), which begins meiosis. Therefore, by definition, homologs cannot associate prior to karyogamy, and so any pairing must occur de novo and cannot be due to any premeiotic associations. Once karyogamy has occurred, nuclei proceed into the leptotene stage of meiosis. By the end of leptotene, homologous chromosomes have paired. In most organisms a proteinaceous structure, the synaptonemal complex (SC), forms between paired homologs (reviewed by Henderson and Keeney, 2005, and Page and Hawley, 2004), and formation of the SC, termed synapsis, begins to occur during zygotene. Pachytene is, by definition, the stage at which chromosomes are fully synapsed (Fig. 2).

While complete SC is found in most organisms, there are notable exceptions, including the fungi *Schizosaccharomyces pombe*, *Aspergillus nidulans*, and *Ustilago maydis* (Egelmitani et al., 1982; Fletcher, 1981; Olson et al., 1978; discussed by Zickler, 2006), suggesting that the structure is not absolutely required for meiosis and raising questions about its purpose (Page and Hawley, 2004). The SC is formed by the initial deposition of lateral/axial elements along chromosome axes, followed by the addition of transverse filaments perpendicular to the homolog axes, and central elements. Chromosomes condense during SC formation, and SC proteins play a role in this compaction (Page and Hawley, 2004). On exit from pachytene, the SC disassembles and nuclei enter diplotene. Synapsis differs from pairing in that it does not absolutely require homology and can occur between nonhomologous chromosomes (Page and Hawley, 2004).

Recombination and Crossover Formation

The formation of crossovers is essential for meiosis in most organisms that have been examined. For a pair of homologs to biorient on the metaphase I spindle and to separate in meiosis I, a stable association must form between them, and crossovers, in combination with cohesion between sister chromatids, form this association (Fig. 3).

Recombination begins with the formation of a DNA double-strand break (DSB). The break is then resected in the 5′-to-3′ direction on both strands, leaving single-stranded tails. One of these ends then invades the DNA duplex of a homologous chromatid, with an extreme bias (in meiosis) towards a nonsister (i.e., a chromatid of the homolog). Strand invasion leads to the formation of a D-loop. In crossover

Claire Burns, Department of Biology, Indiana University, Bloomington, IN 47405. **Patricia J. Pukkila,** Department of Biology, University of North Carolina, Chapel Hill, NC 27599. **Miriam E. Zolan,** Department of Biology, Indiana University, Bloomington, IN 47405.

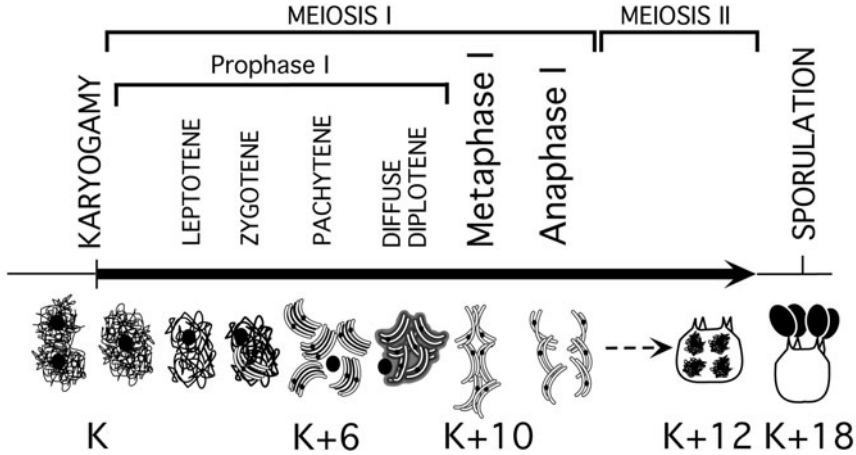

FIGURE 1 Progression and timing of meiosis in *C. cinereus*. Meiosis in *C. cinereus* is synchronous and begins directly after karyogamy (K). Homologs pair, condense, and synapse, and all meiotic cells are in pachytene 6 h postkaryogamy. After a further 2 to 3 h, homologs separate in the first meiotic division. Twelve hours after karyogamy, the second division has occurred, resulting in four meiotic products. Six hours subsequently, nuclei have migrated into basidiopores. Reproduced from the *EMBO Journal* (Celerin et al., 2000), with the permission of the publisher.

formation, the displaced loop anneals to the other single-stranded, resected end formed by the original DSB.

In *Saccharomyces cerevisiae*, DNA synthesis and ligation occur, forming a double Holliday junction that resolves as a crossover (Allers and Lichten, 2001); this is illustrated in Fig. 3. However, in *S. pombe*, a single Holliday junction intermediate generates a crossover (Cromie et al., 2006). Because this feature has been studied in only these two organisms, it is not known whether a single or double Holliday junction is the more common intermediate. In *S. cerevisiae*, the double Holliday junction then resolves to form a reciprocal crossover, which, in concert with cohesion, prevents precocious homolog separation (Fig. 3). Recombination, gene conversion, and postmeiotic segregation are thoroughly discussed elsewhere in this volume (chapter 8).

Cohesion and Divisions

The formation of a crossover alone is not sufficient to keep homologs together until the first meiotic division; sister chromatid cohesion is also required. Cohesion is mediated by the cohesin complex, which consists of four protein subunits that form a ring-like structure (see Watrin and Peters, 2006, for diagram). One popular model is that the ring structure "embraces" the two sister chromatids (Haering et al., 2008); this is depicted in Fig. 3. The presence of a crossover means that cohesion between original sister chromatids forces homologs to stay together (Fig. 3J). The separation of homologs and then of sister centromeres in two separate meiotic divisions necessitates the stepwise release of cohesin. At anaphase I, cohesin is released from the arms of the chromosomes but remains at the centromere (Revenkova and Jessberger, 2005). This allows homologs to separate. At the second division, centromeric cohesin is lost and sister centromeres separate. The meiotic cohesin complex contains a meiosis-specific subunit, Rec8. Rec8 associates with other proteins at the centromere that protect it from degradation at anaphase I (Wang and Dai, 2005).

The two meiotic divisions produce four haploid nuclei, which are sometimes followed by a postmeiosis mitosis, either before (as in *N. crassa*) or after (as in *C. cinereus*) spore formation. In *N. crassa*, eight ascospores are produced, in which each chromosome is derived from one of the eight DNA strands in the corresponding original pair of homologs (Raju, 1980). *C. cinereus* produces four basidiospores, each containing two nuclei (Kues, 2000).

Filamentous Fungi and Meiosis

Filamentous fungi have several advantages for the study of meiosis. First, the meiotic program and chromosome behavior in filamentous fungi are similar to those of more complex organisms. The genetic and cytological tractability of fungal systems allows genes to be well characterized, shedding light on the functions of conserved proteins. Second, unique aspects of development in filamentous fungi provide ideal conditions for analysis of certain meiotic events. Short fungal life cycles and the abundant production of meiotic cells facilitate analysis. For example, in *C. cinereus*, dikaryotic mycelia produce mushrooms within 1 to 2 weeks under the right conditions, and each mushroom contains approximately 10 million synchronous meiotic cells arrayed on the surface of hundreds of gills (Pukkila et al., 1984). The four products of meiosis (tetrads) can be recovered for analysis, and the linear arrangement of ascospores in some species (e.g., *N. crassa* [Raju, 1980]) is a direct consequence of the meiotic divisions, allowing further discernment of meiotic events. Third, the chromosomes of some filamentous fungi are particularly accessible for meiotic study, within intact cells or by surface spreads of meiotic nuclei (for examples, see Raju and Lu, 1970; Pukkila and Lu, 1985; Raju, 1992; Seitz et al., 1996; and Zickler, 2006).

The burgeoning publication of fungal genomes and increasing ease of transcriptomic and proteomic studies will facilitate identification of meiotic orthologs in fungi not traditionally associated with meiotic research. The wealth of data will allow us to build hypotheses regarding the conservation of meiosis as a process and that of the components

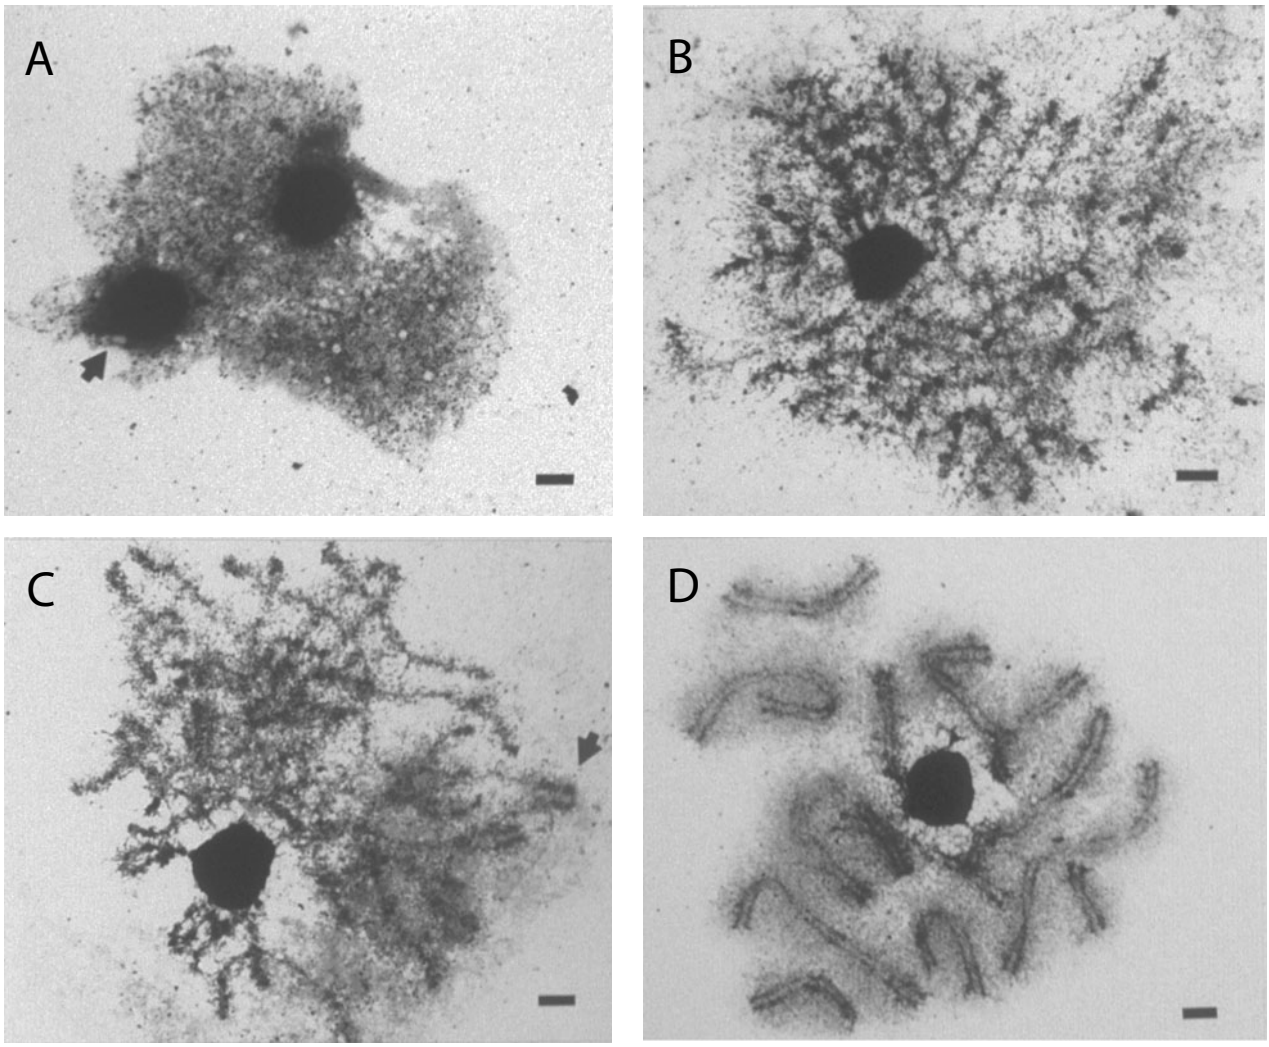

FIGURE 2 Electron microscopy of SC formation in *C. cinereus*. (A) At karyogamy, haploid nuclei fuse, and chromosomes are relatively uncondensed. Two nucleoli (dark structures indicated by an arrow) are apparent. (B) During leptotene, chromosomes condense and homologs start to pair. (C) During zygotene, chromosomes condense further and are paired along their length (note the pair in the upper right-hand corner of the image). The SC begins to form (arrow). (D) In pachytene, chromosomes are fully condensed, and homolog pairs are fully synapsed along their lengths. Scale bar, 1 μm. Reproduced from *Genetics* (Seitz et al., 1996), with the permission of the publisher.

and control of meiosis. For example, investigation of the *N. crassa* and *U. maydis* genomes shows interesting differences in orthologs of meiotic regulators (Borkovich et al., 2004; Donaldson and Saville, 2008). Meiotic regulation in *S. cerevisiae* and *S. pombe* is well characterized, with very little conservation of regulatory proteins (Honigberg and Purnapatre, 2003; Pawlowski et al., 2007). This highlights the drawbacks of concentrating research on a small number of organisms. Even within the relatively few other model systems widely used for the study of meiosis, such as *Mus musculus*, *Drosophila melanogaster*, *Caenorhabditis elegans*, and *Arabidopsis thaliana*, differences in their meiotic processes are observed. For example, in most organisms (including *C. cinereus*) recombination is required for SC formation, but SC can form independently of recombination in *D. melanogaster* and *C. elegans* (discussed by Henderson and Keeney, 2005). Fungal research is well placed for exploitation of rapid-sequencing technologies; the relatively small size of fungal genomes (as an example, the *C. cinereus* genome is about 1/100 the size of the mouse genome) allows generation of very large amounts of data. These data, from many different fungi, will hopefully allow us to move towards an understanding of general, conserved meiotic processes.

CHIASMA DISTRIBUTION IN FUNGAL CHROMOSOMES

Chiasmata, which are the sites of reciprocal genetic exchange between two of the four chromatids in a bivalent, are not distributed randomly in most organisms. A random distribution of chiasmata would result in bivalents containing 0, 1, 2, etc., chiasmata with frequencies predicted by the Poisson distribution. Nonexchange bivalents would be prone to exhibit nondisjunction (the failure of chromosomes to separate properly) at the first meiotic division.

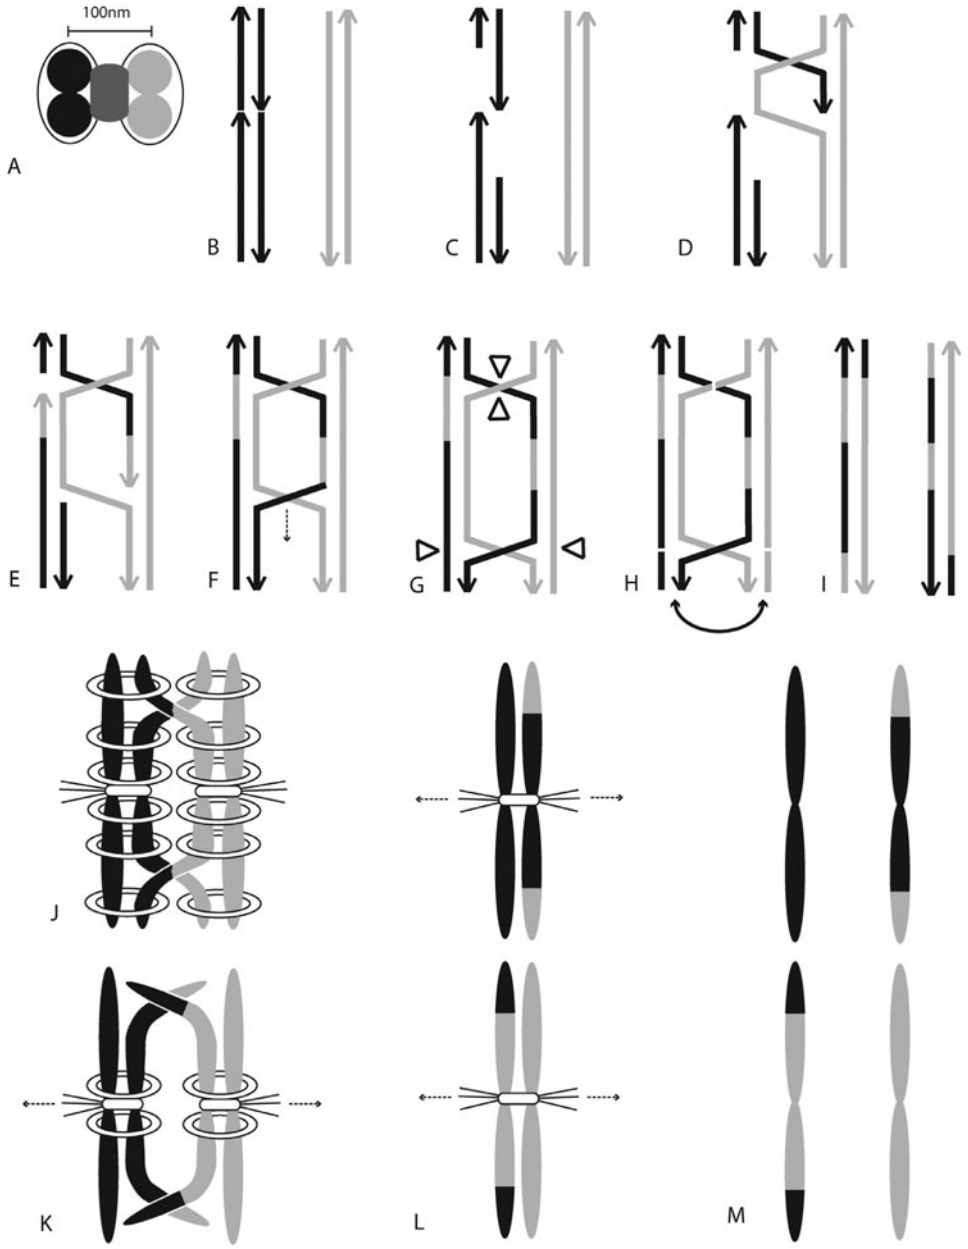

FIGURE 3 Formation of a crossover and its role in meiotic segregation. (A) The arrangement of sister chromatids and homologs, shown end-on. Sister chromatids (one pair in black and one pair in gray) are held together with cohesin (black ring). Homolog association is stabilized in many organisms by the SC (dark gray). This arrangement allows a sister from one homolog to interact with either sister from the second homolog. (B) Initiation of recombination. Spo11, a conserved protein, makes a DNA double-strand break, which is then resected in the 5′-to-3′ direction (C). To simplify, only one chromatid from each homolog is shown. Note that in panels B through I, both DNA strands are shown for the two chromatids. In panels J through M, all four chromatids are shown, each of which have two DNA strands (not shown), constituting eight strands in a pair of homologs. (D) The single strand invades a nonsister duplex, displacing a loop. The invading strand extends by replication, using the opposing duplex as template. The displaced loop may or may not be captured by the second single strand. If not captured, the invading strand and loop retract, and no crossover results. If captured, the second single strand expands, using the loop as a template (E). The invading strand is recaptured by the original sister, forming a double Holliday junction (F), which can then migrate (F and G). To resolve the junction, the DNA is nicked as shown by the arrows (G and H), forming a crossover (I). Note that the ends of the chromatids have exchanged, as represented by the different colors; this is a single crossover. (J) Crossovers are represented at the chromosomal level. Sister chromatids within homologs are shown, and chromosomes are compacted at this stage. Two crossovers are shown, as is typical in *C. cinereus*. Although the two crossovers are illustrated here as formed between the same chromatids, note that, due to the orientation illustrated in panel A, crossovers can and do form with either chromatid of the opposing homolog. Sister chromatids are held together by cohesin (rings), and this, combined with the crossover, is what holds homologs together while under tension at kinetochores. (K) Upon release of arm, but not centromere-associated, cohesin, homologs immediately begin to separate; this is the first meiotic division. For the second meiotic division, centromeric cohesin is released, allowing sister separation (L) and formation of the four meiotic products (M).

Sister chromatids would remain associated; sister centromeres would orient to one pole, but the bivalent would lack a connection between the homologs. The "balance of forces" necessary to orient the pairs of sister kinetochores to opposite poles would be impossible to establish without a connection between the homologs in the nonexchange bivalents. This situation could lead to meiotic arrest or to independent behavior of the two homologs. If they behave independently, one-half of the meioses will produce gametes aneuploid for the nonexchange chromosome.

Thus, it is not surprising that all organisms examined to date exhibit a nonrandom distribution of chiasmata. In particular, mechanisms exist in every organism that forms chiasmata to position these so that each bivalent contains at least one chiasma. However, beyond this generalization, there is a striking lack of uniformity in chiasma frequency per bivalent and in the location of chiasmata along the bivalents among all species in general and fungi in particular. Eukaryotes contain between 1 and 510 acrocentric, telocentric, metacentric, and/or holocentric chromosomes per genome (Boveri, 1887; Manton and Sledge, 1954). Fungi exhibit a narrower distribution of chromosome numbers and shapes in the genomes described to date, with a range of 3 to 20 mainly submetacentric chromosomes per genome (Gregory et al., 2007). Eukaryotes also exhibit a dramatic variation in DNA content (6.8 to 130,000 Mb/genome), while the range in fungi is again much narrower (6.8 to 795 Mb per genome [Gregory et al., 2007]). However, fungal genomes exhibit the **same** extremes in chiasma frequency per bivalent as are found in all eukaryotes (1 to 12 chiasmata per bivalent in fungi and 1 to 13 chiasmata per bivalent in all species [White, 1973]). These extremes are illustrated in Fig. 4, which compares two meiotic bivalents in prophase. The first (Fig. 4A) is from *S. cerevisiae* (Winzeler et al., 1998), and the second (Fig. 4B) is from *C. cinereus* (Stajich et al., unpublished data). The positions of all (or nearly all) the crossovers in *S. cerevisiae* and *C. cinereus* were determined by direct allelic variation scanning and simple sequence repeat mapping, respectively. Thus, an understanding of factors influencing the remarkably divergent chiasma distribution in experimentally tractable fungal model systems is likely to be highly relevant to other species of interest. Among the many ways that a specific chiasma distribution might have adaptive value, three appear to be the most relevant to understanding how specific chiasma distributions arise and are maintained. These three views of chiasma distribution are summarized here and considered in more detail in the following sections.

First, there appears to be a good correlation between sites of synaptic initiation and sites of chiasma formation. In fungi, there is a near-universal occurrence of subtelomeric sites of synaptic initiation. Several lines of evidence indicate that chiasmata also form at these subtelomeric sites. Taken together, these observations suggest that a key to understanding chiasma distribution in these species lies in understanding mechanisms that restrict synaptic initiation to particular chromosome regions (those that are clustered near the nuclear envelope during the "bouquet" stage).

Second, the placement of chiasmata relative to the centromere can have important physical consequences for chromosome shape. When chiasmata first become visible in diplotene, the bivalents are in an extended configuration, transcriptionally active, and flexible, and they can each lie flat in one plane. However, when chromosomes condense prior to the metaphase of the first meiotic division, the chiasmata define the boundaries of rigid loops that lie in planes perpendicular to each other, so the bivalents take on characteristic three-dimensional shapes. Since the kinetochores are attached to the spindle poles via microtubules, the chromatin between the kinetochores and proximal chiasmata on either side lies in the axial plane (parallel to the spindle microtubules). However, the distal chromatin (up to the next chiasma) forms a loop in the equatorial plane, followed by a loop in the axial plane, etc., in organisms with multiple chiasmata. Two extremes are illustrated at metaphase in Fig. 4. Very little chromatin lies in the axial plane in the *S. cerevisiae* bivalent with multiple proximal chiasmata (4A), while most of the chromatin lies in the axial plane in the *C. cinereus* bivalent with distal chiasmata (4B). Thus, the placement of the chiasmata has important consequences for orientation and shape of the bivalents on the meiotic spindle.

Third, chiasma localization influences the degree of linkage exhibited by adjacent markers. In some cases, the cosegregation of particular alleles in a haplotype segment

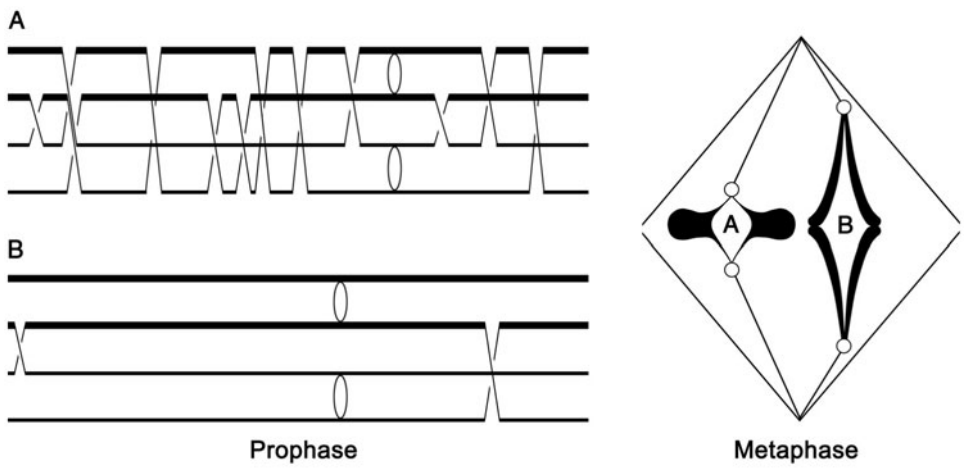

FIGURE 4 Variation in number of chiasmata per bivalent in fungi. (A) Meiotic bivalent from *S. cerevisiae* with 12 chiasmata diagrammed in prophase (left) and metaphase (right). (B) Meiotic bivalent from *C. cinereus* with two chiasmata diagrammed in prophase (left) and metaphase (right). Each chiasma results from a reciprocal exchange involving one chromatid from each homolog.

may be adaptive, while in others, the regular exchange in particular chromosome intervals may have selective value.

Subtelomeric Sites of Synaptic Initiation and Chiasma Formation in Fungi

Following the discovery by M. Moses of the SC in crayfish (Moses, 1956), fungi became favored material for cytological analysis because the relatively small size of fungal nuclei facilitated the serial sectioning and three-dimensional reconstruction of meiotic nuclei necessary to observe the assembly and structure of the SC (Gillies, 1972; Holm et al., 1981; Zickler, 1977). It was soon noted that synapsis initiated near chromosome ends, with the formation of patches of the tripartite, electron-dense SC near the nuclear envelope, where the chromosome ends were anchored. These patches then appeared to grow larger in a continuous fashion, with some interstitial sites of initiation noted also. Each initiation site was marked by a prominent electron-dense structure called a "recombination nodule" (RN) (Carpenter, 1975). Several lines of evidence indicate that synapsis initiates at sites where chiasmata will form. First, electron-dense material was observed to persist in regions initially marked by RNs, and the number and distribution of these regions corresponded to the number and distribution of chiasmata. Second, Maguire showed that the frequency of crossing-over within inversion heterozygosities in maize chromosomes was directly proportional to the frequency of homologous synapsis (via interstitial initiation) in the regions (Maguire, 1966; Maguire and Riess, 1994). Third, mutations that reduce the number of chiasmata also reduce the number of synaptic initiation sites (Zickler et al., 1992). Finally, mutations that abolish recombination in fungi also eliminate SC formation in most genetic backgrounds (Celerin et al., 2000; Keeney et al., 1997; reviewed by Zickler, 2006, and Zickler and Kleckner, 1999).

The occurrence of subtelomeric sites of synaptic initiation leads to an important prediction for the behavior of polyploid nuclei. As Loidl and Jones have pointed out (Loidl and Jones, 1986), switches in synaptic partners at the pachytene stage (when synapsis is complete) in these nuclei provide a record of the minimum number of independent sites that were used to initiate synapsis. In *C. cinereus*, analysis of triploid nuclei indicated that there are just over two sites per chromosome that can initiate synapsis (Pukkila et al., 1995). In *S. cerevisiae* tetraploid nuclei, despite a high overall recombination frequency (more than six chiasmata per bivalent), synaptic initiations were relatively infrequent. In fact, synapsis was initiated independently at more than one site in only one-half of the chromosome sets, producing an average of five quadrivalents per nucleus (Loidl, 1995). In both *S. cerevisiae* and in *C. cinereus*, the sites of independent synaptic initiation were usually subtelomeric, not interstitial. Recently, Kaback and collaborators (Barton et al., 2008) have used a new mapping technique and discovered that meiotic recombination rates are indeed elevated near the ends of *S. cerevisiae* chromosomes, as they are in *C. cinereus* (Stajich et al., unpublished). The similar levels of multivalent configurations in the two species despite the >3-fold difference in chiasma frequency raise the fascinating possibility of universal distinct properties of subtelomeric initiation sites in fungi in comparison to interstitial initiation sites. Further potential roles for the interstitial sites are considered below.

Chiasma Location and Chromosome Shape

Chiasmata can help to ensure proper chromosome disjunction by providing physical connections between homologous chromosomes. Since proper chromosome disjunction depends on the attachment of homologous centromeres to opposite poles at metaphase I, it is not surprising to learn that the location of these physical connections relative to the centromeres has important consequences for the efficiency of stable bipolar orientation of bivalents at metaphase I. In addition, the geometry of the spindle, the number of microtubules involved in pole-kinetochore attachments, the mechanisms of cohesin deposition around the centromeres (which must be maintained until metaphase II) and of deposition distal to the chiasmata (which must be released at metaphase I), the steps involved in signaling bipolar attachment of all bivalents (necessary to initiate anaphase I), and the physical properties of the surrounding nucleoplasm or cytoplasm are also variables that contribute to optimal chiasma localization.

The ways in which these variables interact to affect chiasma distribution is particularly obvious in plants and animals with large genomes and relatively small numbers of chromosomes (reviewed by White, 1973). For example, in the grasshopper *Stethophyma grossa*, with 13 acrocentric chromosomes, each bivalent in the male has a single proximal chiasma, so the bulk of the chromatin lies in the equatorial plane at metaphase I. In sharp contrast, the chiasmata in females are interstitial or distal, so the bulk of the chromatin lies in the axial plane with the narrow spindle surrounded by yolk masses (White, 1973). Sex-specific differences are also common in newts (Watson and Callan, 1963) and in plants such as *Lilium* and *Fritillaria* (Fogwill, 1958). The interplay of factors is clearly complex, since related species can show contrasting distributions in the two sexes. For example, in some newts, the males show localized chiasmata, while in others, the females display them (Watson and Callan, 1963). Interestingly, chiasma patterns in sex-reversed X-Y females are identical to those displayed in normal X-X females, suggesting the importance of the interplay of chromosome shape and spindle function (Wallace et al., 1997).

To date, analogous cytological studies have not been undertaken with fungi, since metaphase chromosome morphology using currently available techniques is poor. However, other lines of evidence point to the importance of chiasma location in proper disjunction of fungal chromosomes. Dawson and collaborators (Ross et al., 1996) used artificial "model chromosomes" and minichromosomes to examine the ability of a single chiasma at varying locations along the chromosome to promote proper disjunction. They observed that an exchange near a chromosome end was less likely to promote proper disjunction than an exchange closer to the centromere. It would appear that the many filamentous fungi that rely on one distal chiasma per arm must have mechanisms to insure that sister chromatid cohesion distal to the exchange is adequate to promote disjunction. In turn, this pattern of crossover distribution may facilitate bipolar orientation and subsequent anaphase onset, where very little "untangling" of chromatids would be required (Fig. 4B), in contrast to organisms that rely on multiple chiasmata (Fig. 4A).

Chiasma Location and Genetic Exchange

The occurrence of subtelomeric sites of crossing-over also makes an important prediction concerning relationships between genetic and physical maps. In many fungal species, the minimum map distance is 100 centimorgans (cM) $\times N$ (the haploid chromosome number), as predicted if there is usually a single reciprocal exchange (equivalent to 50 cM) per chromosome arm, plus varying levels of internal exchanges. In *C. cinereus*, the total map distance has been estimated to be 1,300 cM based on chiasma frequency (Holm

et al., 1981) and 1,346 cM based on a complete linkage map generated by using random amplified polymorphic DNA (RAPD) markers (Muraguchi et al., 2003). Since there are 13 chromosomes in *C. cinereus*, and since subtelomeric sites of synaptic initiation are the norm in this fungus (Holm et al., 1981), recombination hot spots and cold regions are predicted to occur in this species. The RAPD map is consistent with this prediction, since every chromosome showed a striking internal cluster of RAPD markers that were completely linked to each other. In fact, 91 of the 230 markers used fell into these clusters (3 to 18 markers per cluster). If the RAPD markers are randomly distributed in the genome, this result suggests that 40% of the *C. cinereus* genome experiences very little crossing-over. Recently, the prediction of subtelomeric hot spots and cold regions in the *C. cinereus* genome has been confirmed using a map based on simple sequence repeats. Stajich et al. (unpublished) found that nearly one-half of the crossovers occurred in subtelomeric hot spots. As predicted by the RAPD map, over one-half of the genome (53%) exhibited very little reciprocal exchange (3% of all exchanges).

In addition to the potential roles in synaptic initiation and chromosome shape described above, the potential adaptive value of genomes with large blocks exhibiting little genetic recombination together with other blocks exhibiting high rates of recombination deserves consideration. It has long been recognized that a reduced recombination rate would be advantageous when particular combinations of alleles at different loci provide a selective advantage (and/or other combinations provide a selective disadvantage) (Fisher, 1930; Kimura, 1956; Nei, 1967). Evidence that genes under such "epistatic selection" are in regions that are cold for recombination has also been obtained (Pal and Hurst, 2003).

The availability of a new set of genomic sequences together with anchored genetic maps from organisms with reduced recombination rates in comparison to the relatively small number of model systems analyzed to date should accelerate our understanding of how particular patterns of chiasma distribution along chromosomes arise and are maintained. Both the cold regions described above and hot spots are likely to be informative. For example, the mating type locus of *Cryptococcus neoformans* is flanked by two recombination hot spots (Hsueh et al., 2006). In addition to affecting the series of genome changes that enabled an ancestral tetrapolar mating system to evolve into the single complex MAT locus, the hotspots are undoubtedly instrumental in the spread of particular MAT loci to new genetic backgrounds. The molecular basis of the best-characterized fungal recombination hot spots is considered elsewhere in this volume (chapter 8).

GENES NECESSARY FOR MEIOSIS

How are conserved genes with roles in meiosis identified? Four methods have been employed. The first takes advantage of the growing number of fungal genome sequences now available, and genomic analyses, along with PCR-based approaches, have allowed the identification of a conserved core of meiotic genes (Table 1). Although a broad sampling of fungi is only currently in progress (J. Logsdon, personal communication), previous work shows that meiosis is certainly the ancestral state in fungi, as in all extant eukaryotes (Malik et al., 2008). Even though numerous fungi have no known sexual stage, their phylogenetic positions (Lobuglio et al., 1993) argue that if sex is not actually present it must have been lost in these lineages. In addition, population genetic data (for an example, see Burt et al., 1996; reviewed by Taylor et al., 1999) have shown that recombination is occurring even within putatively asexual lineages. Also, it was shown recently that Spo11 is required for homologous recombination in the *C. albicans* parasexual cycle (Forche et al., 2008); this is the only nonmeiotic role known for Spo11. Finally, in at least some cases the sexual stage may merely be cryptic to researchers; some species long thought to be asexual have recently been shown to have the hallmarks of sexual reproduction (Tzung et al., 2001; O'Gorman et al, 2009). Therefore, there is widespread conservation within fungi of core meiotic genes, and it will be interesting to determine the evolutionary and mechanistic relationships between meiotic sex and parasex, especially if they alternatively or coordinately adapt the same sets of proteins.

The second approach to the analysis of meiotic genes involves direct screens for meiotic mutants, either from wild-collected isolates or by laboratory mutagenesis. The analysis of wild strains of *N. crassa* (Leslie and Raju, 1985) showed that recessive mutations affecting meiosis are rampant in the wild. This is not unexpected in an organism that is not homothallic; if the meiotic genes are expressed only in the multinucleate or diploid phase, there will be no selection against mutations, since they will be complemented in the multinucleate or diploid phase.

There are numerous genes that will interfere with sporulation. For example, in *C. cinereus* a standard mutagenesis routinely yields about 1% survivors that form white mushrooms, indicating a defect in spore formation (Pukkila, 1994), but these are not always defective in meiosis (Kanda et al., 1989). Therefore, the absence of spore production does not necessarily indicate a defect in meiosis. Conversely, most meiotic mutants do cause defects in either spore formation or spore viability, although spore formation is usually more dramatically reduced in basidiomycetes (e.g., contrast *spo11* mutants in *S. macrospora* with those in *C. cinereus* [Celerin et al., 2000; Cummings et al., 1999; Storlazzi et al., 2003]). For *C. cinereus*, the failure of spore formation by meiotic mutants likely reflects both a regulatory coupling between successful completion of meiosis and spore development and also gene expression contributions from the haploid meiotic products to the developing spores.

The third method of identification of genes necessary for meiosis is to take advantage of the evolutionary and biochemical connections between meiosis and mitotic processes, most notably DNA double-strand break repair (reviewed by Cummings and Zolan, 1998; Goldman et al., 2002; and Pukkila, 1994). For example, by use of this approach, mutations in the genes encoding proteins of the conserved MRN complex (Mre11, Rad50, and Nbs1) have been found to disrupt meiosis in both filamentous fungi (Acharya et al., 2008; Gerecke and Zolan, 2000) and yeasts (Alani et al., 1990; Johzuka and Ogawa, 1995; Young et al., 2004; reviewed by Borde, 2007). The Rad51 protein, a eukaryotic homolog of the bacterial RecA protein, was shown to be required for meiosis in *A. nidulans* (van Heemst et al., 1997), and it associates with meiotic chromosomes in filamentous fungi with timing consistent with its role in meiotic recombination (Acharya et al., 2008; Tesse et al., 2003) (Fig. 5).

The fourth method for the identification of meiotic genes takes advantage of modern genomics to examine global patterns of gene expression. This approach and its contributions to date are summarized in the last section of this chapter.

TABLE 1 Some core meiotic genes and their functions and conservation among fungi[a]

Gene	Presence of orthologs in completed sequencing project for:												Protein function
	Sc	*Cg*	*Kl*	*Ca*	*Sp*	*Nc*	*Gz*	*Mg*	*An/f/o*	*Um*	*Cn*	*Cc*	
spo11	+	+	+	+	+	+	+	+	+	PA	+	+	Transesterase, creates DNA DSBs in meiotic chromosomes
Mre11	+	+	+	+	+	+	+	+	+	+	+	+	3′–5′ double-stranded DNA exonuclease and single-stranded DNA endonuclease, forms complex with Rad50 and Nbs1, required for DSB processing
rad50	+	+	+	+	+	+	+	PA	+	+	+	+	SMC protein, ATPase, forms complex with Mre11 and Nbs1
hop1	+	+	+	+	+	−	−	PA	+	PA	+	+	DNA binding protein that displays Red1-dependent localization to the unsynapsed axial-lateral elements of the synaptonemal complex; required for homologous chromosome synapsis and chiasma formation
hop2	+	+	+	+	+	−	−	PA	+	PA	+	+	Protein that localizes to chromosomes, preventing synapsis between nonhomologous chromosomes and ensuring synapsis between homologs; complexes with Mnd1p to promote homolog pairing and meiotic DSB repair
mnd1	+	+	+	+	+	−	−	PA	+	PA	+	+	With Hop2, functions after meiotic DSB formation, and required for stable heteroduplex DNA formation
dmc1	+	+	+	+	+	−	−	PA	+	PA	+	+	Meiosis-specific homolog of Rad51, has similar function but promotes interhomolog recombination
rad51	+	+	+	+	+	+	+	+	+	+	+	+	Forms helical filaments on single-stranded and double-stranded DNA and catalyzes homologous DNA synapsis and strand exchange
msh4	+	+	+	+	−	−	+	+	+	+	+	+	Forms a heterodimer with Msh5, interacts with Mlh1/Mlh3 heterodimer. Required for crossover recombination
msh5	+	+	+	+	−	+	+	+	+	+	+	+	Forms a heterodimer with Msh4, interacts with Mlh1/Mlh3 heterodimer. Required for crossover recombination
mer3	+	+	+	+	−	+	−	+	+	+	+	+	Meiosis-specific DNA helicase
rad21 (scc1)	+	+	+	+	+	+	+	+	+	+	+	+	Holds Smc1 and Smc3 heads together by binding N-terminal domain to Smc3 and C-terminal domain to Smc1, forming cohesin ring
rec8	+	+	+	+	+	+	+	+	+	+	+	+	Meiosis-specific paralog of Rad21

Meiosis-specific genes are in bold. Symbols and abbreviations: +, orthologs are present; −, orthologs are absent; PA, orthologs are putatively absent; *Sc*, *Saccharomyces cerevisiae*; *Cg*, *Candida glabrata*; *Kl*, *Kluyveromyces lactis*; *Ca*, *Candida albicans*; *Sp*, *Schizosaccharomyces pombe*; *Nc*, *Neurospora crassa*; *Gz*, *Gibberella zeae*; *Mg*, *Magnaporthe grisea*; *An/f/o*, *Aspergillus nidulans/fumigatus/oryzae*; *Um*, *Ustilago maydis*; *Cn*, *Cryptococcus neoformans*; *Cc*, *Coprinus cinereus*. Data are from Malik et al., 2008, and Malik and Logsdon (unpublished). See Malik et al. (2008) and references therein for a comprehensive survey of meiotic genes.

Comparative Studies of Meiosis in Filamentous Fungi

Studies of mutants in filamentous fungi have made substantial contributions to the analysis of the two core features of meiosis: the structure of meiotic chromosomes and the role of interhomolog crossovers in meiotic chromosome structure and behavior.

Meiotic Chromosome Structure Is Set up during Meiotic S Phase

The DNA replication that precedes meiosis (premeiotic S) is unique in that it is the critical time during which chromosomes are prepared structurally for interhomolog recombination (Forsburg, 2002). For some fungi, including *C. cinereus* and *N. crassa*, it has been documented that premeiotic S

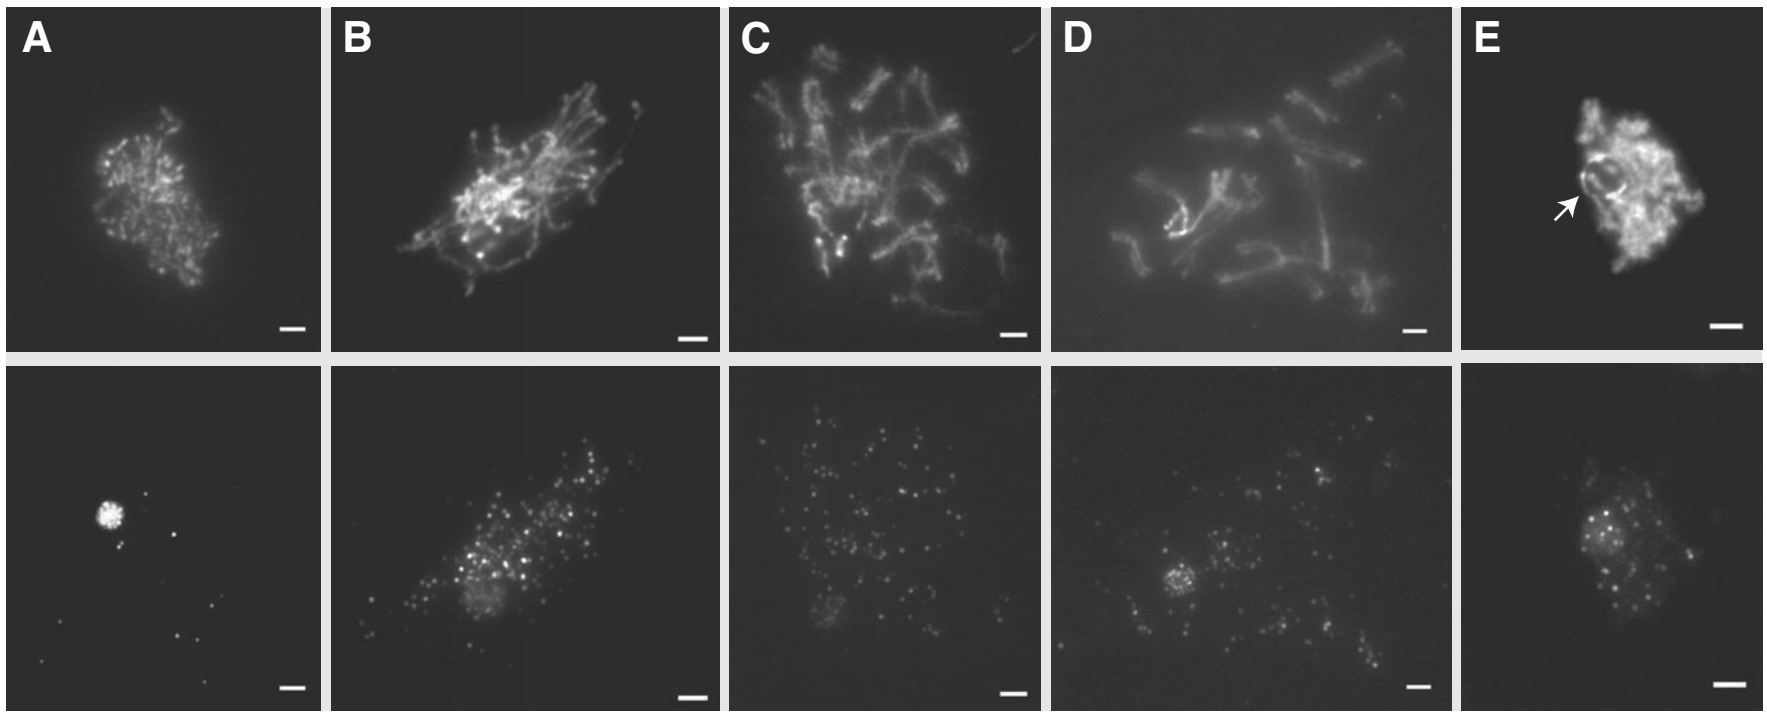

FIGURE 5 Time course of Rad51 association with meiotic chromosomes. Chromosome spreads were stained with DAPI (4′,6-diamino-2-phenylindole) (top panels) and antibody against *C. cinereus* Rad51 (bottom panel), which was detected using fluorescein isothiocyanate-labeled antirabbit antibody. (A) Preleptotene image taken 1 h after karyogamy (K+1). (B) Leptotene image taken at K+2. (C) Zygotene image taken at K+4. (D) Pachytene image taken at K+6. (E) Diplotene image taken at K+8. Arrows in panel E show ribosomal DNA, which does not synapse, within the nucleolus. Scale bars represent 2 μm for all images. All panels except panel A are reproduced from *Genetics* (Acharya et al., 2008), with the permission of the publisher.

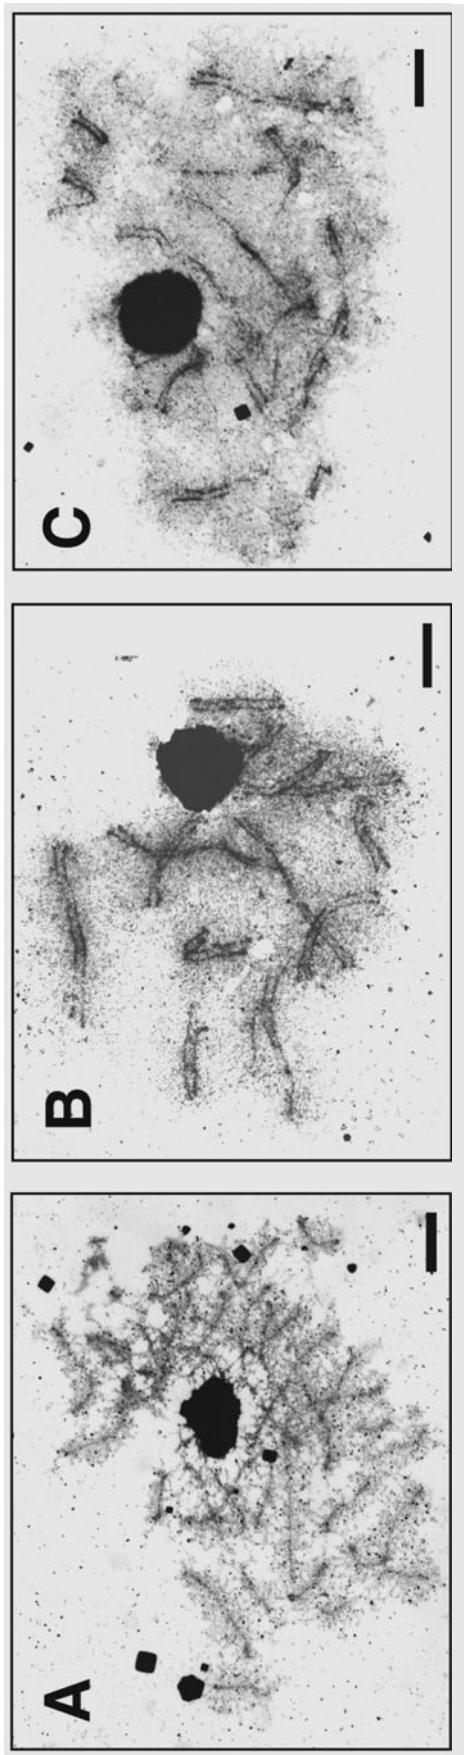

FIGURE 6 The *spo22-1/msh5-22* mutation suppressed synapsis defects of *spo11-1*. Surface spreads of meiotic chromosomes were stained with silver nitrate and photographed using transmission electron microscopy. (A) *spo11-1*; (B) *spo22-1/msh5-22*; (C) *spo11-1 msh5-22* double mutant. Scale bars represent 2 μm for all images. All images are reproduced from Merino et al. (2000), with the permission of the publisher.

occurs prior to karyogamy (Iyengar et al., 1977; Kanda et al., 1990). Therefore, events that are critical parts of prophase I actually occur before the diploid nucleus forms. In other fungi, the timing of premeiotic S is less clear; evidence now exists that in *Magnaporthe grisea* it occurs postkaryogamy (Farman, 2002).

The fundamental difference between a mitotic G_2 chromosome and a chromosome entering meiosis is seen in the relationship between the two sister chromatids (reviewed by Petes and Pukkila, 1995, and Zickler, 2006). Three features are particularly noteworthy. First, meiotic crossing-over is suppressed between sister chromatids except within the rRNA genes, which do not synapse (Fig. 5E) (Petes and Pukkila, 1995). Second, an increased need for sister chromatid cohesion is imposed by recombination. This is seen by recruitment of extra cohesin to double-strand break sites during mitosis (Strom et al., 2004; Unal et al., 2004) and by the suppression of cohesion defects by mutations that prevent recombination (Storlazzi et al., 2003, 2008). Third, cohesion must be maintained at the centromere during anaphase I, to allow sister chromatids to stay together through the first meiotic division (Fig. 3). The last step, the protection of cohesin at the centromere, is effected by the substitution of the mitotic cohesin component Rad21/Scc1 with a meiosis-specific paralog, Rec8 (Watanabe and Nurse, 1999). The association of Rec8 with other proteins allows it to escape cleavage at anaphase I (Fig. 3) (Kitajima et al., 2004; Watanabe and Kitajima, 2005).

A mutant of *C. cinereus*, initially called *spo22-1* (Kanda et al., 1990), has allowed an unusual insight into both the role of sister chromatids in meiosis and the requirement that sister chromatids impose for the activities of other meiotic genes. In *spo22-1*, premeiotic DNA replication is specifically inhibited (Kanda et al., 1990). Although it is not yet known whether replication initiates and then falters, cytogenetic data make it clear that there are functionally no sister chromatids in the *spo22-1* mutant (Pukkila et al., 1995). The *spo22-1* mutant has recently been shown to be an allele of *msh5*, one of the six eukaryotic *mutS* homologs in *C. cinereus* (Celerin et al., unpublished data). The gene *msh5* was initially identified as specifically required for crossover formation (Hollingsworth, 2008), and most models for its function place it in Holliday junction resolution (Snowden et al., 2004, 2008), in partnership with Msh4, with which it forms a dimer. However, Msh5 is also required early in meiosis for the specification of recombination sites as crossover sites (Borner et al., 2004); see Bishop and Zickler, 2004, for an excellent review. So far, its role in premeiotic DNA replication is known uniquely in *C. cinereus*. However, it is possible that other filamentous fungi, in which premeiotic S precedes karyogamy, will show a similar Msh5 dependency.

Role of Recombination Proteins

Meiotic recombination initiates with a DNA double-strand break made by the protein Spo11, which is homologous to archaebacterial topoisomerases (Keeney, 2007; Keeney et al., 1997) (Fig. 3). In the filamentous fungi examined, as well as in *S. cerevisiae* and mouse, the chromosomes of *spo11* mutants condense and can form complete axial cores (Fig. 6) (Baudat and de Massy, 2007; Bellani et al., 2005; Celerin et al., 2000; Keeney et al., 1997; Storlazzi et al., 2003) but essentially never form SC. Therefore, the dependency of synapsis on recombination articulated for *S. cerevisiae* (Alani et al., 1990; Padmore et al., 1991) seems to be true for the filamentous fungi. Spo11 requires the functions of other proteins for its break-forming activity, although whether for direct participation in the reaction or

because of prebreak effects on chromatin is not always clear (reviewed by Keeney, 2007). In *S. cerevisiae*, the protein Ski8, initially identified as required for degradation of nonadenylated mRNAs, is required for Spo11 function and interacts with it in yeast two-hybrid assays (Arora et al., 2004; Uetz et al., 2000). For *S. macrospora*, Tesse et al. (2003) showed that the Ski8 and Spo11 proteins are interdependent for localization to meiotic chromosomes and that *ski8* mutant phenotypes are similar to those in strains defective for *spo11* and can be similarly suppressed by irradiation-induced DSBs. An interesting aspect of this study was the analysis of an allelic series of loss-of-function mutants of *ski8*. These mutants were examined for their ability to form Rad51 foci, an indicator of recombinational activity. A direct correlation was seen between nuclei that had more Rad51 foci and those that progressed further in synapsis.

A result similar to that found for *ski8* mutants was seen in an allelic series of *rad50* mutants of *C. cinereus* (Acharya et al., 2008). In contrast to the situation for *S. cerevisiae*, DSB formation is not Rad50 dependent in *C. cinereus*, but DSB processing requires Rad50. The *rad50* alleles that form more Rad51 foci undergo significantly more synapsis and also increased stable homolog pairing. Therefore, the mechanistic link between recombination progression and homolog synapsis is conserved in filamentous fungi.

In *C. cinereus*, *msh5* mutations have been employed as tools for the examination of the links between recombination and synapsis. For example, both *spo11* and *rad50* mutants show significantly more synapsis when an *msh5* mutation is introduced (Fig. 6) (Merino et al., 2000; F. M. Kennedy, O. P. Savytskyy, and M. E. Zolan, unpublished data). Remarkably, when homolog pairing is assayed using fluorescence in situ hybridization, the *spo22-1/msh5-22* mutation completely suppresses the need for Rad50 (Kennedy et al., unpublished). These studies lead to two conclusions. First, the requirement for Spo11 activity in synapsis is replication dependent. Second, there are very few Rad51 foci formed in *msh5-22*; the level is not significantly different from that of the *spo11-1* mutant. Therefore, either the small number of Spo11-independent Rad51 foci indicates recombinational sites that are insufficient to promote synapsis in the presence of a sister (i.e., in the *spo11-1* single mutant) but are sufficient for synapsis in the absence of a sister chromatid, or the wild-type Msh5 protein prevents synapsis in the absence of recombination, and this block is removed in *msh5* mutant strains.

Transcriptional Regulation

The availability of ever-increasing numbers of fungal genomes, with concomitant tools such as microarrays, has allowed genome-wide analyses of transcription under many conditions (for a summary of early fungal array studies, see Breakspear and Momany, 2007). The areas of study discussed in that review include metabolism, symbiosis, pathogenesis, and development, which includes fruiting body production and conidiation but no scrutiny of meiosis. Transcriptional regulation of meiosis has been profiled in *S. cerevisiae* (Chu et al., 1998; Primig et al., 2000) and *S. pombe* (Mata et al., 2002), but data from filamentous fungi are scarce. Genes expressed in fungal fruiting bodies have been profiled by array analysis in few fungi, including *S. macrospora* (Nowrousian et al., 2005) and *Fusarium graminearum* (Qi et al., 2006), but to date specific investigation of meiotic transcription is limited to *U. maydis* (Zahiri et al., 2005) and *C. cinereus* (Burns et al., unpublished data).

Data from *U. maydis* identified only a small number of meiotically regulated transcripts. This is in contrast with the transcriptional studies in *S. cerevisiae* (Chu et al., 1998; Primig et al., 2000), *S. pombe* (Mata et al., 2002), and *C. cinereus*, which indicate that a large proportion of the genome is up- or down-regulated throughout meiosis and sporulation; this is unsurprising given the substantial biochemical and physiological changes required during a short time frame. Clustering of genes with similar expression profiles is indicative of coordinate function and regulation (Eisen et al., 1998). Gene clustering of meiotic and sporulation time course experiments identified successive waves of transcription, with seven or eight clusters (*S. cerevisiae*) or four clusters (*S. pombe*) describing stress and response to nutritional changes (induction of meiosis), premeiotic S and prophase I, meiotic divisions, spore formation, and spore maturation. Transcription data from gill tissue of *C. cinereus*, facilitated by the synchronous development of meiotic tissues in this organism, produce nine clusters that also exhibit transcriptional waves. This 15-h time course experiment encompasses data from prekaryogamy, meiotic S phase, meiotic prophase, meiotic divisions, and the formation of tetrads, but not sporulation.

The transcriptional profiles of meiotic progression in *C. cinereus* bear considerable similarities to those from *S. cerevisiae* and *S. pombe*. The most striking transcriptional change in all three fungi occurs after expression of prophase-I-specific genes, such as those involved in creating double-strand breaks, maintaining sister chromatid cohesion, and formation and resolution of crossovers. Subsequently, there is a wholesale downregulation of these meiotic genes and a concomitant switch to upregulation of genes associated with sporulation, such as those involved in production of energy reserves, spore budding, and metabolism of cell wall components such as hydrophobins.

Expression profiling studies, in concert with gene ontology analysis and comparison with orthologs from other organisms, are extremely important for discernment of timing and function of meiotic genes. Such approaches have been used successfully with *S. pombe* and *S. cerevisiae* to identify new genes involved in meiosis and sporulation (Enyenihi and Saunders, 2003; Gregan et al., 2005; Jordan et al., 2007; Martin-Castellanos et al., 2005; Rabitsch et al., 2001). Further scrutiny of meiotically expressed genes will aid discovery of poorly conserved genes, such as those for the SC. In addition, transcriptional profiling of meiotic mutants will further elucidate pathways and functions.

Regulation of Meiosis

One area ripe for further investigation is transcriptional control of meiosis in filamentous fungi. Extensive studies involving *S. cerevisiae* and *S. pombe* have revealed little similarity in the mechanisms of meiotic regulation, yet in both species meiosis is induced by nutritional restriction. In *S. cerevisiae*, the master regulator of early meiotic genes is IME1, via UME6, which binds to an upstream motif common to many of these genes. Subsequent gene expression is controlled by NDT80, and these genes again bear common upstream motifs (Chu et al., 1998; Primig et al., 2000). In contrast, no common motifs have yet been discovered in the upstream regions of coordinately expressed meiotic genes in *C. cinereus*. The IME1 equivalent in *S. pombe*, STE11, bears no resemblance to the *S. cerevisiae* protein yet has a similar role in responding to nutritional deficiencies (Mata et al., 2002). Neither of these proteins has orthologs in *C. cinereus*; the light-induced meiosis in *C. cinereus* deems this very unlikely.

Similarly, other fungi in which meiosis and sporulation are differently induced may also be likely to employ different regulatory mechanisms. Although these main regulatory

proteins have no C. *cinereus* orthologs, some other aspects of the regulatory machinery, such as cyclin-dependent kinases, are present. Intriguingly, Mre11, part of the meiotic complex that processes double-strand breaks, has been implicated in transcriptional regulation of further meiotic and sporulation genes in *S. cerevisiae* (Kugou et al., 2007); *mre11* expression in C. *cinereus* is unexpectedly slightly earlier than that of another complex member (*rad50*), and it is possible that further investigation could reveal a regulatory role. A number of putative transcription factors were identified in transcriptional profiling of C. *cinereus*; these may perform functions similar to those of the regulators from yeast species.

In addition, several filamentous fungi have orthologs of *S. pombe* Mei2, which has been shown to sequester meiotic transcripts in vegetative growth (Harigaya et al., 2006). Meiotic transcripts have also been shown to undergo regulated splicing in yeast meiosis (Juneau et al., 2007), indicating a further level of regulation; genes in *S. cerevisiae* have few introns, with meiotic genes containing a disproportionately high number. Meiotic genes in C. *cinereus* appear to contain a higher number of introns than other genes, and a number of RNA-splicing factors are expressed throughout prophase I, perhaps suggesting a level of intron-mediated regulation; this could be probed using high-density microarrays or next-generation sequencing approaches. Regulation of meiosis at the epigenetic level, manipulation of recombination hot spots, and targeted disruption of cohesion complex components are also exciting targets for future analyses of the meiotic process in filamentous fungi.

The C. cinereus research described was funded by NIH grant GM43930 (to M.E.Z.) and NSF grant EF 0412016 (to P.J.P.) and supported in part by the Indiana METACyt Initiative of Indiana University, funded in part through a major grant from the Lilly Endowment, Inc. We thank Sasha Savytskyy for assistance with microscopy images and Susan Whitfield for the production of Fig. 4.

DNA Repair and Recombination

P. JANE YEADON, HIROKAZU INOUE, FREDERICK J. BOWRING, KEIICHIRO SUZUKI, AND DAVID E. A. CATCHESIDE

To maintain the integrity of the genome, all organisms must continually monitor their chromosomes and repair any lesions. DNA damage can occur in many ways: through exposure to radiation, including UV and ionizing radiation (IR); as a result of the activity of chemical mutagens, such as methyl methanesulfonate (MMS); and during internal processes such as replication and recombination. Yet diversification of gene sequences by mutation and the subsequent shuffling of novel sequences into new combinations is required for evolution to occur, allowing species to adapt to environmental change and to develop new complexity and capabilities.

Recombination yielding genetic diversity occurs during the pachytene stage of meiosis (see chapter 7 in this volume), the reductional division that leads to the formation of sperm and eggs in mammals or the haploid spores of filamentous fungi. However, recombination can also occur in vegetative cells, where it is part of the armory of repair systems available to correct mutational damage.

Investigations using filamentous fungi have made major contributions to our understanding of the core biological processes of DNA repair and recombination, as certain model species provide particularly favorable opportunities for insight. The Ascomycete fungi, including the filamentous fungus *Neurospora crassa*, conveniently provide a full set of the products of a single meiosis packaged in spores inside a single ascus. Both *N. crassa* and *Sordaria fimicola* also have the advantage of spores that are ordered within the ascus, allowing convenient detection of marker segregation at the first or second division of meiosis, or in the subsequent mitotic division, which reflects a failure of repair of mismatches in heteroduplex DNA.

Analysis of *Neurospora* spores provided the first evidence that recombination is not explained just by breakage of homologous chromosomes at equivalent places and reciprocal exchange of the broken ends during repair of the breaks. Mary Mitchell (1955) found that instead of a 4:4 (Mendelian) segregation of allelic genes in a heterozygous cross, there was often a 6:2 segregation, as if one allele had been converted into the other. Further work with *Neurospora* nutritional mutants (Case and Giles, 1958a; Stadler, 1958; Murray, 1960) and with spore color markers in *Sordaria* (Olive, 1959; Kitani et al., 1962) and in *Ascobolus immersus* (Lissouba et al., 1962) contributed to the development of the first plausible molecular explanation for the events of meiotic recombination (Holliday, 1964). However, the demonstration that meiotic gene conversion occurs in *Saccharomyces cerevisiae* (Fogel and Hurst, 1967), a yeast species of economic importance commanding the resources for early determination of its genome sequence, has resulted in work with yeast leading the way to uncovering details of basic processes of recombination.

DNA REPAIR

The study of DNA repair began with the discovery of photoreactivation (Kelner, 1949) and UV-sensitive mutants in bacteria (Hill, 1958), followed by isolation and characterization of mutants with sensitivity to UV, IR, and chemical mutagens in both *Escherichia coli* and the yeast *S. cerevisiae*. Mutagen-sensitive yeast mutants were characterized by analysis of the degree of sensitivity to particular mutagens and of epistasis in double mutants (Game, 2000). Three major groups of mutants were identified, each with a different role in DNA repair: *excision repair*, which removes damaged DNA such as thymine dimers; *recombination repair*, which repairs DNA strand breaks; and *postreplication repair*, which fills DNA gaps after replication.

DNA repair in *Neurospora* (Schroeder et al., 1998) and *Aspergillus nidulans* (Kafer and May, 1998) appears more complex than in yeast. Early attempts to group six UV-sensitive *N. crassa* mutants (*upr-1*, *uvs-2*, *uvs-3*, *uvs-4*, *uvs-5*,

and *uvs-6*) as had been done in *S. cerevisiae* were unsuccessful. For example, the *N. crassa uvs-2* gene was initially thought to be involved in nucleotide excision repair (NER), because the mutant phenotype is similar to that of *S. cerevisiae* NER mutants. However, when *uvs-2* was cloned and sequenced, it was found to encode a homolog of *S. cerevisiae* Rad18, with both ring finger and zinc finger motifs (Tomita et al., 1993), indicating a role in postreplication repair (PRR) rather than NER. The *N. crassa mei-3* gene, whose mutants were originally characterized as mutagen sensitive and defective in meiosis (Newmeyer and Galeazzi, 1977, 1981), was found to be a homolog of *E. coli recA* and *S. cerevisiae RAD51* (Cheng et al., 1993; Hatakeyama et al., 1995). Since *uvs-6* is epistatic to *mei-3*, the gene products are in the same pathway of recombination repair. In addition, it has recently been shown that *uvs-3* is involved in damage checkpoint control (Kazama et al., 2008).

Since NER mutants with high sensitivity to UV were not found in fungi, early DNA repair mutants were mainly isolated as strains showing high sensitivity to MMS or other chemical mutagens. More recently, utilization of the *N. crassa* genome database (Galagan et al., 2003) has made it possible to identify additional DNA repair genes (Table 1) (Borkovich et al., 2004), but many of the phenotypes have yet to be characterized by experimentation.

NER Pathways in Filamentous Fungi

Discovery of a *mus-18* mutant sensitive only to UV suggested that *N. crassa* has two different NER systems (Hatakeyama et al., 1998; Ishii et al., 1998). The *N. crassa mus-38*, *mus-43*, and *mus-44* genes, homologs of *S. cerevisiae RAD1*, *RAD14*, and *RAD10*, respectively, are components of the NER pathway common to most other organisms (Hatakeyama et al., 1998; Sato et al., 2008), but *mus-18* forms part of a novel NER pathway (Ishii et al., 1991), and the redundancy in NER gives *N. crassa* high resistance to UV. *mus-18*, which encodes a UV damage-specific endonuclease (Yajima et al., 1995), although lacking in most higher organisms including *S. cerevisiae*, *Caenorhabditis elegans*, and *Drosophila melanogaster*, has homologs in many fungi including *Aspergillus*, *Coprinus*, and *Ustilago*.

PRR Pathways

Mutants belonging to the PRR pathway group are extremely sensitive to UV, mitomycin C, and MMS, but their sensitivity to hydroxyurea (HU), an inhibitor of ribonucleotide reductase, is similar to that of the wild type. *N. crassa uvs-2* and *mus-8*, induced by DNA damage, are homologs of *S. cerevisiae RAD18* and *RAD6* and encode a ubiquitin ligase (E3) and ubiquitin-conjugating enzyme (E2), respectively (Tomita et al., 1993; Soshi et al., 1996). In *S. cerevisiae*, these enzymes are recruited to a DNA lesion at which DNA polymerase is stalled and monoubiquitylate Lys164 of proliferating cell nuclear antigen, the DNA sliding clamp (Hoege et al., 2002). This is a key step of PRR and enhances the survival of cells with persistent unrepaired DNA damage by regulating the mechanisms of template switching and translesion DNA synthesis (TLS). *S. cerevisiae* Srs2, a 3′-to-5′ DNA helicase, dissociates Rad51-nucleoprotein filaments and prevents repair by the homologous recombination (HR) pathway, resulting in repair by TLS (Krejci et al., 2003, Veaute et al., 2003). In contrast, the *N. crassa* Srs2 homolog, Mus-50, has a different function, unraveling intertwined DNA during the recombination process (Suzuki et al., 2005). In *S. cerevisiae*, the Ubc13/Mms2/Rad5 complex extends the ubiquitin chain from the monoubiquitylated proliferating cell nuclear antigen with a noncanonical lysine 63-linked ubiquitin-chain (Hoege et al., 2002). *S. cerevisiae* Rad5 is a ubiquitin ligase (E3), essential for the polyubiquitylation, but the *N. crassa RAD5* homolog, *mus-41*, is not required for polyubiquitylation (Kawabata et al., 2007). The *mus-41* mutant is sensitive to UV and MMS, and *uvs-2* is epistatic to *mus-41*. *N. crassa* has Ubc13 and Mms2 homologs, Mus-46 and Mus-47, respectively. The single mutants, *mus-46* and *mus-47*, and the *mus-46 mus-47* double mutant are each equally sensitive to UV and MMS, and *uvs-2* is epistatic to both, suggesting a direct interaction of Mus-46 and Mus-47, which has been confirmed by a yeast two-hybrid assay (Kawabata et al., 2005).

Both filamentous fungi and mammals have a greater number of TLS polymerases than does *S. cerevisiae*. *N. crassa upr-1* and *mus-26*, mutants, which are UV sensitive but show low mutability (Sakai et al., 2002, 2003), are in the *uvs-2* subgroup. *upr-1* and *mus-26* are homologs of *S. cerevisiae Rev3* and *Rev7* and encode the catalytic subunit and associated protein of TLS polymerase ζ, respectively. Polymerase η, encoded by the human XP variant gene, is also a TLS polymerase. *Neurospora* and *Aspergillus* have several additional genes that appear to be TLS polymerase homologs (Borkovich et al., 2004), but the roles of these are not yet known.

Recombination Repair

Genes involved in recombination repair form two groups, differentiated by the phenotype. DNA double-strand breaks (DSB) are repaired by two major pathways: HR and nonhomologous end joining (NHEJ). These pathways are regulated by the same upstream process (Fig. 1).

HR Repair

N. crassa mei-3, *mus-11*, and *mus-25* mutants are sensitive to MMS, bleomycin, histidine, and IR and, except for *mus-11*, are also slightly sensitive to UV. Homologs are widely distributed from yeast to higher organisms and correspond to *S. cerevisiae RAD51*, *RAD52*, and *RAD54*, respectively (Borkovich et al., 2004). Despite the sequence similarity, phenotypes of the mutants vary between species for each homolog. For example, the *S. cerevisiae rad52* mutant is highly sensitive to many mutagens and sterile in homozygous crosses (Game, 1993; Shinohara and Ogawa, 1995), similar to the *N. crassa mus-11* mutant, but the vertebrate *RAD52* mutant is insensitive to mutagens and fertile (Rijkers et al., 1998), suggesting that Rad52 may have a different function in each organism. In *S. cerevisiae*, Rad52 removes the single-strand binding protein RPA to allow access to Rad51 (Haber, 1999). In addition, orthologs of the human *BRCA1* and *BRCA2* genes, which play important roles in homologous recombination, have not been found in lower eukaryotes, including *S. cerevisiae*, *N. crassa*, and *A. nidulans*.

As indicated above, sequence similarity between *N. crassa mei-3*, *mus-11*, and *mus-25* and their *S. cerevisiae* orthologs does not always signify functional similarity. These mutants are sterile in homozygous crosses, preventing assessment of their effect on meiotic recombination, and since the *Neurospora* vegetative cell is haploid and includes little repetitive DNA, mitotic recombination is a rare event. However, if DNA fragments with sequence homologous to part of the genome are transformed into the wild type, 3 to 10% of the transformants result from homologous integration. In contrast, if *mei-3*, *mus-11*, or *mus-25* mutants

[a]Genes identified by annotation in *A. nidulans*.

[b]*S. pombe* gene.

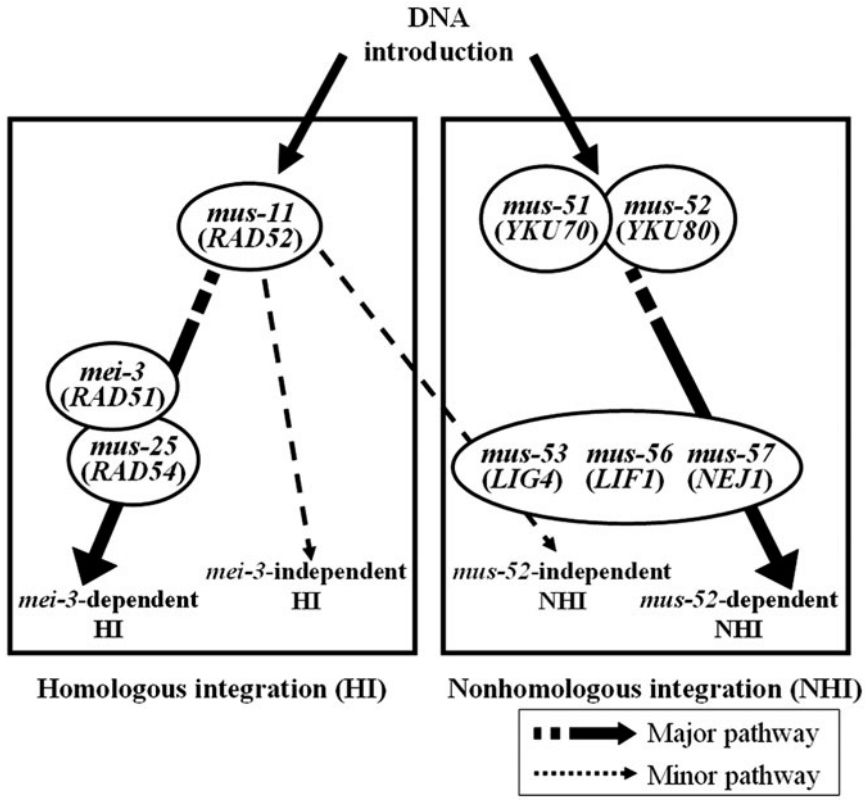

FIGURE 1 Pathways (major, thick arrows; minor, narrow dashed arrows) for integration of exogenous DNA into chromosomal DNA. Exogenous DNA is integrated into the chromosomes by two major pathways, *mus-11* dependent and *mus-52* dependent. The *mus-11*-dependent pathway has three branches. Two branches yield homologous integration (HI); one is *mei-3* dependent, and the other is *mei-3* independent. The third *mus-11* branch is *mus-52* independent but, like the major *mus-52*-dependent pathway, leads to nonhomologous integration (NHI). Both *mus-52*-dependent and *mus-52*-independent NHI pathways require *mus-53*, *mus-56*, and *mus-57*. The genes in parentheses represent *S. cerevisiae* homologs.

are used as the transformation host, homologous integration almost never occurs (Handa et al., 2000; Ishibashi et al., 2006). It seems likely, therefore, that these genes function in HR in *N. crassa*, as in *S. cerevisiae*.

NHEJ

NHEJ is the major pathway for repair of DSB in higher organisms, but among mutants showing high sensitivity to MMS or IR, NHEJ-defective mutants have not been found in fungi, suggesting the possibility of a backup system to NHEJ as in NER. However, NHEJ homologs of the human *KU70*, *KU80*, and *LIGIV* genes (*mus-51*, *mus-52*, and *mus-53*, respectively) have been identified in the *N. crassa* genome (Ninomiya et al., 2004; Ishibashi et al., 2006), and these mutants, like *mei-3* and *mus-25*, show significant sensitivity to MMS and bleomycin and slight sensitivity to UV.

When transforming DNA fragments share more than 1 kb of homologous sequence with the host genome, all transformants obtained in *mus-51*, *mus-52*, and *mus-53* mutants result from homologous integration, confirming that *mus-51*, *mus-52*, and *mus-53* function in NHEJ. This observation suggested a use for NHEJ-deficient mutant strains as hosts for efficient gene targeting/replacement experiments (Ninomiya et al., 2004; Ishibashi et al., 2006). This approach has also been successful with many other fungi (*A. nidulans*, *Aspergillus niger*, *Aspergillus oryzae*, *Aspergillus fumigatus*, *Magnaporthe grisea*, *Podospora anserina*, *Cryptococcus neoformans*, *Cryphonectria parasitica*, and *Candida glabrata*) and has been used for gene improvement and high-throughput gene knockout projects in fungi (Colot et al., 2006).

Transformation in the *N. crassa mei-3 mus-52* double mutant produces very few transformants, but all result from homologous integration, indicating the existence of a *mei-3*-independent minor homologous integration pathway (Ishibashi et al., 2006). Another minor pathway may be microhomology-mediated end joining (Fig. 1).

Regulation of Recombination Repair in *Neurospora*

mus-23, *uvs-6*, and *mus-45* mutants are highly sensitive to a range of mutagens, including MMS, IR, UV, histidine, HU, and 4-nitroquinoline 1-oxide (4NQO), and appear to be homologs of *S. cerevisiae MRE11*, *RAD50*, and *NBS1/XRS2*, respectively (Watanabe et al., 1997; Borkovich et al., 2004). Each of these mutants and all double-mutant combinations have the same sensitivity to mutagens; homozygous crosses are sterile, and a characteristic "stop-start growth" phenotype is also observed. This suggests that these three proteins form a complex, designated MRX/MRN. Double mutants carrying *mei-3* (HR) and *mus-51*, *mus-52*, or *mus-53* (NHEJ) showed similar sensitivity to that of *uvs-6* (*S. cerevisiae*

RAD50 homolog), and double mutants of *uvs-6* with *mei-3* (HR group) or *mus-51* (NHEJ group) also showed sensitivity similar to that of *uvs-6*. These results indicate that *uvs-6* is epistatic to *mei-3* and *mus-51* in MMS sensitivity, and since DSB are repaired by either HR or NHEJ, the UVS-6/MUS-23/MUS-45 complex regulates a process upstream of both recombination repair pathways (Fig. 1). Interestingly, mutation of *uvs-3* (described below) in any mutant of this group results in a synthetic lethal.

Checkpoint Control

Checkpoint control enables cells to coordinate DNA repair and the cell cycle following damage. In *Homo sapiens*, there are two interacting systems, ATR and ATM, that are involved in complex phosphorylation cascades. Mutants defective in checkpoint control are extremely sensitive to a range of mutagens. The *N. crassa uvs-3* mutant is sensitive to UV, IR, MMS, mitomycin C, and HU; homozygous crosses are barren, and hyphal growth shows a stop-start growth pattern (Schroeder, 1970; Newmeyer and Galeazzi, 1978). The spontaneous mutation rate is high but is not increased by mutagens (de Serres et al., 1980; de Serres, 1980; Inoue et al., 1981), and micronuclei are observed at high frequency (Kazama et al., 2008). The sequence of *uvs-3* suggests that it is a homolog of the human *ATRIP*, which functions in ATR checkpoint control (Kazama et al., 2008). Homologs are found in many other organisms, including Lcd1 in *S. cerevisiae*, Rad26 in *Schizosaccharomyces pombe*, and UvsD in *A. nidulans*. Phosphorylation of ATRIP is dependent on ATR. In the same epistasis group as *uvs-3*, the *N. crassa mus-9* gene is an ATR homolog and has a phenotype very similar to that of *uvs-3* mutants: high sensitivity to mutagens, genome instability, deficiency in induced mutagenesis, and a meiotic defect (Kazama et al., 2008). ATR homologs, such as Mec1 in *S. cerevisiae*, Rad3 in *S. pombe*, and UvsB in *A. nidulans*, are involved in cell cycle arrest, although only *MEC1* is essential for the process. *A. nidulans* and *N. crassa* ATR mutants are sterile in homozygous crosses, but *S. pombe rad3* mutants generate viable spores. A mutation in *mus-21*, a homolog of *S. cerevisiae ATM/TEL1*, is epistatic to *uvs-6* (an MRX member), and a double mutant with *uvs-3* or *mus-9* (ATR) is a synthetic lethal (Fig. 2). These relationships indicate that recombination repair is integrated into the phosphorylation cascade of *mus-21/ATM* damage checkpoint control. Further study of checkpoint mechanisms in fungi requires identification and analysis of other checkpoint-related genes such as Chk1, Chk2, and Rad53.

Others: MMS-Sensitive Mutants with Unusual Phenotypes

qde-3/mus-19

The MMS-sensitive *mus-19* mutant is an allele of the quelling-defective mutant *qde-3*. This gene is a member of the RecQ helicase family (3′-to-5′ DNA helicase) and is epistatic to *mei-3* and *uvs-2*, so *qde-3* has a function in both HR and PRR (Kato et al., 2004). *N. crassa* has two RecQ helicases, *qde-3* and *recQ2* (Pickard et al., 2003). QDE-3 is similar to *S. cerevisiae* Sgs1 and human BLM, while RecQ2 is similar to human RecQL5α. The *qde-3* mutant is sensitive to MMS, *N*-methyl *N*′-nitro-*N*-nitrosoguanidine (MNNG), camptothecin (CPT), and HU, while *recQ2* is much less sensitive. However, the *qde-3 recQ2* double mutant is more sensitive to MMS, MNNG, CPT, and HU than either single mutant, indicating that both RECQ homologs function in repair (Kato and Inoue, 2006). In homozygous crosses, *qde-3*, but not

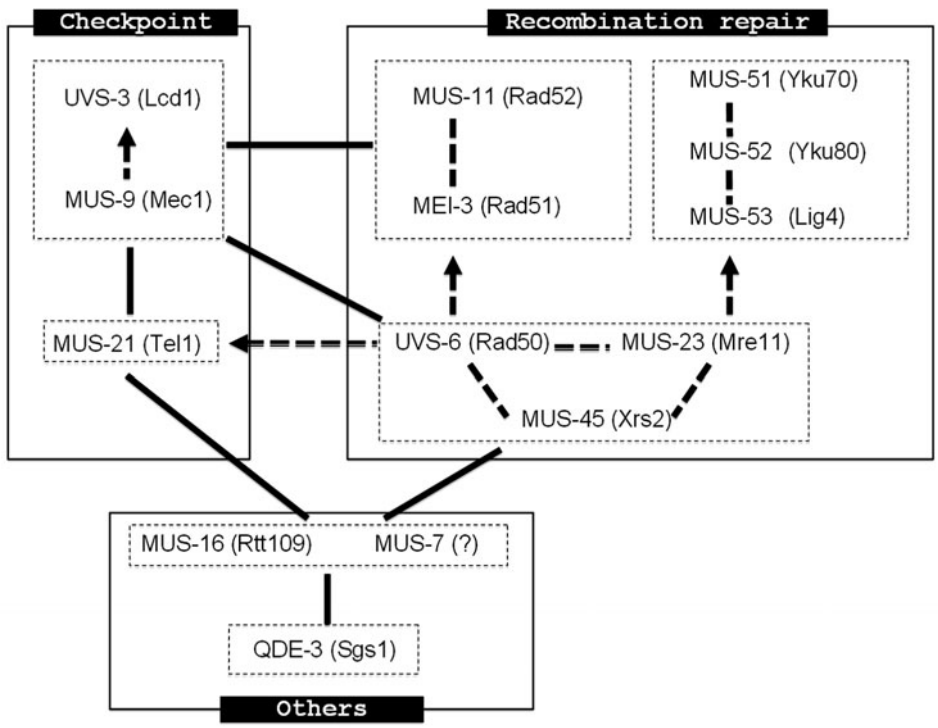

FIGURE 2 Epistatic and synthetic lethal relationships of mutagen-sensitive mutations in *N. crassa*. A solid line indicates a synthetic lethal relationship, and a dotted line indicates an epistatic relationship. Arrows indicate which mutation is epistatic.

recQ2, is sterile. *qde-3* has a high spontaneous mutation rate, as does the double mutant. Also, colony morphology is irregular and growth is unstable in the double mutant. The growth defect and the high spontaneous mutation rate of the double mutant are respectively suppressed by mutation in *mei-3* and *mus-52* (Kato and Inoue, 2006), suggesting that both RecQ homologs work downstream of *mei-3* in homologous recombination repair to maintain genome stability in *N. crassa*.

As noted above, *N. crassa mus-50* encodes a homolog of a 3′-to-5′ helicase, Srs2, and the *mus-50 qde-3 recQ2* triple mutant is lethal, indicating that at least one 3′-to-5′ helicase is necessary for survival (Suzuki et al., 2005). This lethality is suppressed by mutation in *mei-3*, *mus-11*, or *mus-25* (a homolog of *S. cerevisiae RAD54*). Genetic analysis shows that there are two independent pathways to repair strand breaks: one is dependent on QDE-3 and MUS-50, and the other is dependent on MUS-25 and RECQ2. Although there is no Srs2 homolog in the human genome, there are five RecQ homologs, each with an independent function. One behaves like Srs2 in *S. cerevisiae*, suggesting that during evolution, Srs2 has been functionally replaced by a duplicated RecQ homolog. Unlike *S. cerevisiae*, which has a single copy of each gene, *N. crassa* has two RecQ homologs and one Srs2 homolog, so filamentous fungi may be at an interesting stage in evolution.

mus-7 and *mus-16*

Mutants *mus-7* and *mus-16* are highly sensitive to MMS, ethyl methanesulfonate, 4NQO, HU, and CPT but less sensitive to UV, IR, and mitomycin C. DNA damaged by MMS generates DSB during DNA replication, and since IR also causes DSB, most mutants sensitive to IR also show high sensitivity to MMS. Thus, the sensitivity phenotype of *mus-7* and *mus-16* mutants is novel (Kafer, 1981; Inoue and Schroeder, 1988). These mutants are sterile in homozygous crosses, in contrast to mutants defective in base excision repair that remove alkylated bases generated by MMS. Epistasis analyses indicate that *mus-7* and *mus-16* mutants do not belong in any of the three major repair groups or in damage checkpoint control. MMS induces mutation at high frequency in both mutants, which also show chromosomal instability. The *mus-7* gene encodes a protein with no known motifs to provide clues to its function. A homolog in *S. pombe*, *mus-7*, has a similar phenotype (Yokoyama et al., 2007). Interestingly, the CPT sensitivity of *mus7* was suppressed by mutation in *top1* (topoisomerase 1). On the other hand, double mutants carrying *mus7* and *rqh1* (RecQ family gene defective) show higher sensitivity to MMS and CPT than either single mutant (Yokoyama et al., 2007). In *N. crassa*, the equivalent double mutant is lethal (Fig. 2). Although it has been reported that *S. cerevisiae MMS1* has no homolog in other organisms, it appears to be a functional homolog of *S. pombe* Mus7 and *N. crassa* MUS-7 (Hryciw et al., 2002). Like *N. crassa mus-7*, in comparison with the wild type, the *S. cerevisiae mms1* mutant is highly sensitive to killing by MMS or CPT and mildly sensitive to UV but no more sensitive to IR. *rad52* is epistatic to *mms1* for MMS and CPT sensitivity in *S. cerevisiae*, and the *mms1* mutant shows slow growth, abnormal morphology, and genomic instability. The *N. crassa mus-7 mus-11* double mutant grows more poorly with time (M. Yokoyama, A. Inamori, C. Ishii, S. Hatekeyama, and H. Inoue, unpublished data). Mus-7 is involved in replication-associated damage repair, and because of the lack of homology to other known repair proteins, further analysis may open a new area in research into DNA repair in addition to the known major repair pathways.

The *mus-16* mutation is lethal in combination with either *mus-21*, *mus-23*, or *qde-3*, and *mus-7* is epistatic to *mus-16* (Fig. 2), suggesting that both are in the same repair group. *N. crassa mus-16* is defective in acetylation of Lys56 of H3 (Yokoyama et al., unpublished), like the *S. cerevisiae* homolog Rtt109 (Schneider et al., 2006; Driscoll et al., 2007), indicating that some mutants defective in chromatin maintenance and modification also have a mutagen-sensitive phenotype. Such mutants may be useful for analysis of chromatin dynamics.

RECOMBINATION

Linkage and Crossing-Over

As far back as 1905, Bateson, Saunders, and Punnet demonstrated that some sweet pea genes were typically inherited together but sometimes segregated independently (Bateson et al., 1905). Subsequently, Morgan (1910, 1911) demonstrated that the degree of linkage of genes on the *D. melanogaster* X chromosome varied between different gene pairs. Linkage was assumed to reflect (Morgan, 1911) the likelihood that a chromosomal exchange, or crossover (Morgan and Cattell, 1912), would occur between genes and thus could be used as a measure of the distance separating that gene pair. Sturtevant (1913) used the relative frequency of crossovers between loci to plot the relative positions of six genes on a map of the *Drosophila* X chromosome, creating the first linkage map.

Creighton and McClintock (1931) demonstrated a correlation, predicted some 20 years earlier by Janssens (1909), between the number of chiasmata, visible connections between homologous chromosomes during meiosis, and the number of crossovers in *Zea mays*. Indeed, it has since been demonstrated that in most organisms, normal meiotic chromosome segregation is dependent on the occurrence of at least one such crossover in each bivalent (Baker et al., 1976).

Gene Conversion

One feature of the Ascomycetes that makes them ideal subjects for recombination studies is that all products from a single meiosis are retained in the ascus. Indeed, it was an ascomycete that provided the first indication that recombination was not always reciprocal. Lindegren (1953) found that segregation of mutations in *S. cerevisiae* did not always conform to the expected Mendelian ratio. Some asci contained three wild-type and one mutant or one wild-type and three mutant spores (6:2 and 2:6, respectively, in an eight-spored ascus) instead of the expected two wild-type and two mutant spores. This phenomenon was called "gene conversion," and although initially thought to be due to a rare and peculiar chromosomal aberration, it was soon found to be common among Ascomycetes.

Mary Mitchell (1955) demonstrated that wild-type progeny arising from crosses between two *pdx* mutant strains of *N. crassa* did not result from abnormal segregation of entire chromosomes but from changes in a short chromosomal region, since markers flanking the *pdx* locus segregated normally. Mitchell demonstrated that this effect was not due to crossing-over, as no reciprocal double mutants were found in asci containing wild-type progeny. While the effect was not due to a crossover, crossing-over between *pdx* and a marker nearby was elevated in asci showing conversion. This was also observed at other loci in *Neurospora* (Case and Giles, 1958a, 1958b; Stadler, 1958; Murray, 1960) and *A. nidulans* (Pritchard, 1955). Gene conversion has also been demonstrated in *S. fimicola*

(Olive, 1959) and *A. immersus* (Lissouba et al., 1962). In *Sordaria*, as in *Neurospora*, gene conversion is associated with a local increase in crossing-over (Kitani et al., 1962).

PMS

Olive (1959) found, in addition to 6:2 and 2:6 ratios, also 5:3 and 3:5 ratios of spore color segregation in asci from *Sordaria*. Moreover, an additional class of abnormal asci, aberrant 4:4, was found in the same species (Kitani et al., 1962). Here, pairs of sister spores, which arose from a postmeiotic mitosis and thus should be genetically indistinguishable for spore color, were different. Segregation of the aberrant allele was not due to abnormal behavior of an entire chromosome, since the sister spores had identical flanking markers. Thus, the spore color mutation must have segregated during the mitotic division that follows meiosis, implying that the recombinant chromosome from which the spore pair derived was a heteroduplex (hDNA), a DNA molecule in which the two strands were not fully complementary. This is an example of postmeiotic segregation (PMS), which has also been observed in *S. cerevisiae* (Fogel et al., 1979) and in *N. crassa* (Case and Giles, 1964).

Models of Meiotic Recombination

The segregation patterns of parental DNA in recombinant chromosomes from yeasts and filamentous fungi as considered above stimulated Whitehouse (1963) and Holliday (1964) to formulate models of meiotic recombination, and aspects of both models remain valid to this day. While subsequent theoreticians built upon the foundations laid by Whitehouse and Holliday, common to each model was a single mechanism to account for all HR. However, it has recently become clear that this assumption was erroneous and that recombination, while thought to have a single mode of initiation, proceeds by at least three distinct pathways (reviewed by Baudat and de Massy, 2007; Cromie and Smith, 2007; and Lynn et al., 2007). Moreover, the relative contribution of each pathway to the total recombination quota varies from organism to organism.

Until recently it was thought that the DSB repair (DSBR) model (Szostak et al., 1983; Sun et al., 1991) could explain all recombination. In this model, a break in both strands of one homolog (Fig. 3B) is resected to generate single strands. Invasion of the homologous duplex by a 3′ end (Fig. 3C) and DNA synthesis, using the complementary

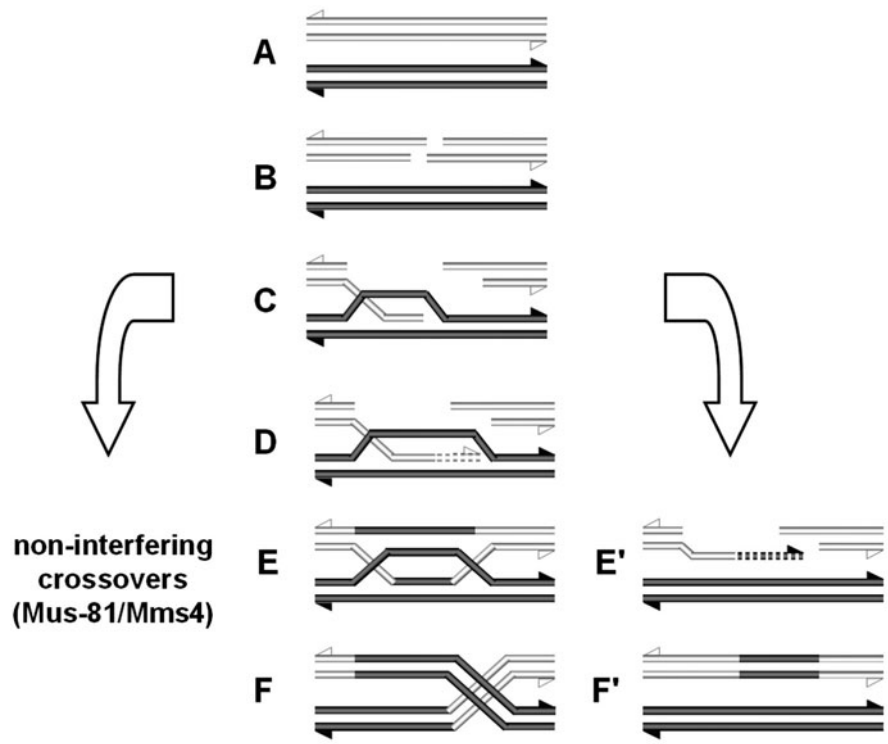

FIGURE 3 Models for meiotic recombination (after Baudat and de Massy, 2007). The central column depicts the generation of crossovers. All recombination is thought to be initiated by a break in both strands of the duplex (B). The 5′ ends are resected, and one of the 3′ ends invades the homologous duplex (C), where it is extended by DNA polymerase using the homolog as a template (D). The D loop formed by displacement of a strand of the invaded chromosome provides a template for repair of the second strand of the initiating chromosome (E). The ligation of ends forms two Holliday junctions that when resolved yield a crossover (F). Synthesis-dependent strand annealing is depicted on the right branch. Here, instead of ligation leading to paired Holliday junctions, the newly synthesized DNA ends are unraveled from the template to anneal one with the other (E′). The gap is closed and then ligated (F′). Only the initiating chromosome is converted, and there is no crossing-over. The left branch indicates the existence of a pathway yielding noninterfering crossovers, although details of the mechanism remain to be elucidated.

strand of the intact duplex as template, leads to the formation of a D loop that provides a template for repair synthesis of the second 3′ end (Fig. 3D). Ligation of the free ends produces paired Holliday junctions (Fig. 3E). Branch migration can give symmetric heteroduplex, and resolution of the two Holliday junctions in the same or opposite sense yields crossover (Fig. 3F) or noncrossover (Fig. 3F′) outcomes, each associated with conversion resulting from correction of mismatched bases in hDNA. The DSBR model explains the higher probability of conversion of the initiating chromosome but also suggests that one-half of the chromosomes with a conversion event should also have a crossover near the converted site, although most mitotic conversions (Pâques and Haber, 1999) and some meiotic conversions (Bowring and Catcheside, 1996) yield few associated crossovers. Moreover, since conversion events with and without a crossover are alternative outcomes of the resolution event, this model predicts that they should occur at the same time, but they do not (Allers and Lichten, 2001). These discrepancies led to the formulation of the synthesis-dependent strand annealing (SDSA) model.

The SDSA model (Nassif et al., 1994; Ferguson and Holloman, 1996; Pâques et al., 1998) accounts for the predominance of conversion of the initiating chromosome, a variable degree of association of conversion with crossing-over, and the differential timing of crossover and noncrossover events. In the current version of the SDSA model, following extension by repair synthesis, the invading strand is reannealed with the initiating duplex (Fig. 3E′) and no Holliday junction is formed, a circumstance that leads only to conversion of the initiating chromosome and no crossover. The finding that replication errors occurring during repair synthesis usually appear only on the initiating chromosome provides support for the SDSA model (Strathern et al., 1995; Pâques et al., 1998).

More recently, a third recombination pathway, which requires Mus81 and Mms4 and generates crossovers independently of the DSBR route, has been identified. The majority of crossovers in *S. cerevisiae* require the "ZMM proteins," comprising Zip1, Zip2, Zip3, Zip4/Spo22, Mer3, Msh4, and Msh5 (Borner et al., 2004). ZMM-dependent crossovers exhibit crossover interference (Sturtevant, 1913), the process that reduces the chance that crossovers will occur close together. *S. cerevisiae* ZMM mutants exhibit greatly reduced levels of crossing-over, and the residual Mus81/Mms4-dependent crossovers show no interference (de los Santos et al., 2003). Interestingly, all crossovers in *S. pombe* are Mus81/Mms4 dependent (Smith et al., 2003) and also lack interference (Munz, 1994). Crossovers in *A. nidulans*, which lack interference (Strickland, 1958), may also result from the Mus81/Mms4 pathway.

Initiation of Recombination

It is thought that all meiotic recombination in *S. cerevisiae* is initiated by SPO11-generated DSB (Keeney and Neale, 2006). SPO11-catalyzed DSB are also responsible for initiation of meiotic recombination in *Coprinus cinereus* (Celerin et al., 2000), *Sordaria macrospora* (Storlazzi et al., 2003), and *N. crassa* (Bowring et al., 2006). However, studies using filamentous fungi provide just a hint that SPO11 might not be required for the initiation of all recombination events. In *S. macrospora*, for example, knocking out *SPO11* reduces crossing-over about 10-fold across a large interval on chromosome 4 but does not abolish it (Storlazzi et al., 2003). In *N. crassa*, mutation of *spo11* seems to exhibit a variable effect on recombination, depending upon where in the genome one samples. Crossing-over is severely reduced in an interval on LG VII in an *N. crassa spo11* mutant, but at *his-3* on LG I there is no apparent reduction in either gene conversion or crossover frequency in homozygous pairings of three different *spo11* mutants. Since this lack of effect occurs at the target region of *rec-2*, now known to be an activator of recombination (see below), this raises the possibility that initiation here is independent of SPO11. However, since pairings of *N. crassa spo11* mutants exhibit an increased frequency of hyperploid spores, it is conceivable that the observed crossing-over occurs after meiosis in these partially diploid nuclei, and normal meiotic recombination is initiated exclusively by SPO11 (Bowring et al., 2006).

Polarity and Recombination Hot Spots in Filamentous Fungi

Polarity of conversion, a linear relationship between conversion frequency at a given site and its position in the locus, was first observed by Lissouba and Rizet (1960), working with a series of allelic spore color mutants in *A. immersus*, but has also been noted in *A. nidulans* (Siddiqi, 1962) and in *N. crassa* (Case and Giles, 1958a; Murray, 1963; Stadler and Towe, 1963). Shortly afterwards, conversion at *ARG4* of *S. cerevisiae* was shown to involve a tract of DNA sequence; if a site at the low end of the conversion gradient is converted, other sites towards the high end of the gradient are often converted along with it (Fogel and Mortimer, 1970).

Use of molecular techniques such as PCR and DNA sequencing have enabled analysis of recombination at the molecular level in *N. crassa*. The lesions defining *his-3* mutant alleles K1201, K504, K458, K874, K26, and K480 have been identified (Yeadon and Catcheside, 1999; Yeadon et al., 2001, 2002; Rasmussen et al., 2002), and the order of these sites on the physical map is the same as on the genetic map (Angel et al., 1970), confirming that polarity reflects relative physical position along a chromosome. Polarity indicates that recombination starts in a particular place and proceeds in a linear fashion. Supportive of this, studies with *N. crassa* using a large chromosomal inversion (Murray, 1968) showed that polarity is dependent on sequences near the gene within which recombination occurs, so recombination is presumably initiated within these sequences at a recombination initiation site, or hot spot.

It is likely that many recombination hot spots exist in *N. crassa*, as both allelic recombination and crossing-over occur at frequencies that vary with location in the genome. For example, gene conversion has been detected at high frequency at the *cot-1* and *lys-4* loci (P. J. Yeadon, F. J. Bowring, and D. E. A. Catcheside, unpublished data), and recombination is known to be an uncommon event in the vicinity of *am* (Bowring and Catcheside, 1998). The only well-characterized hot spot, however, is *cog*, centromere distal of the *his-3* locus (Bowring and Catcheside, 1991; Yeadon and Catcheside, 1995, 1998), although a similar site may exist in *A. immersus*.

ccf-2 in *Ascobolus*

The *A. immersus* conversion control factor *ccf-2* acts in *cis* at the adjacent *wI* locus (Lamb and Helmi, 1978; Helmi and Lamb, 1983). Three alleles are known, P, 91, and K; and crosses homozygous for P yield the highest gene conversion frequency in *wI*. The 91 and K alleles appear to act as partially dominant suppressors of recombination at *wI* (Lamb and Helmi, 1978). This factor appears to behave in a fashion similar to that of the *N. crassa* hot spot *cog*.

cog

cog has alleles with two phenotypes, high (cog^+) and low (*cog*) frequency recombination (Angel et al., 1970), influencing both allelic recombination in *his-3* and crossing-over between *his-3* and the centromere-distal gene, *ad-3* (Catcheside and Angel, 1974). Although cog^+ was previously thought to be completely dominant to *cog*, the alleles are actually codominant (Yeadon et al., 2004a). The genetic interval between *his-3* and *ad-3* is 15.5 centimorgans (cM) when cog^+ is homozygous, 7.5 cM when cog^+ is heterozygous, and only 1.4 cM if *cog* is homozygous. Likewise, two copies of cog^+ in a *his-3* heteroallelic cross yield approximately twice as many His^+ recombinants as a single copy in an otherwise identical cross. Thus, the *cog* alleles in a cross appear to operate independently of one another to initiate recombination events.

Sequences within the 900-bp *cog* region, defined by crossover mapping (Yeadon and Catcheside, 1995), show multiple strain-specific differences. However, the *cog* variant first found in Lindegren Y8743 (Angel et al., 1970) is the only naturally occurring cog^+ allele known (Yeadon and Catcheside, 1995, 1999), and *cog* variants present in Lindegren *A*, Emerson *A*, and St Lawrence 74*A* strains all appear to have the same low-frequency recombination and thus *cog* phenotype. Conservation of much of the *cog* region is known to be irrelevant, but a 10-bp sequence, ~3.4 kb from *his-3*, including two single-nucleotide polymorphisms (SNPs) is definitely required for the high-frequency recombination phenotype (Yeadon and Catcheside, 1998). Deletion of the entire *cog* region, with the exception of 60 bp in which the 10-bp sequence lies, does not substantially alter the cog^+ phenotype (A. Romsang, P. J. Yeadon, F. J. Bowring, and D. E. A. Catcheside, unpublished data), so this short motif may be sufficient for high-frequency recombination, at least at this chromosomal location.

N. crassa strains have been constructed in which 1.8 kb of native sequence between *his-3* and *cog* is replaced with a series of foreign sequences (Yeadon et al., 2002; Rasmussen et al., 2002), including the human *Herpes simplex thymidine kinase* (*TK*) gene. Analysis of recombinant progeny of *TK* heterozygotes indicates that recombination is initiated distal to the replacement region (Yeadon et al., 2001), which is located 1.2 kb proximal to the SNP motif required for high-frequency recombination. In addition, a peak in conversion close to the motif (Yeadon and Catcheside, 1998) suggests that the initiation site is at, or close to, the SNP motif (Yeadon et al., 2004b).

The series of insertion/replacement strains has been used to analyze recombination in crosses in which the distance between *cog* and *his-3* varies from 1.7 kb to nearly 6 kb. The frequency of His^+ progeny from heteroallelic crosses increases exponentially as the distance from *cog* declines (Yeadon et al., 2002), suggesting that recombination events are initiated at the same place and terminate in a stochastic fashion, one possible explanation for polarity. In organisms as diverse as *Drosophila* (Hilliker et al., 1994) and *S. pombe* (Grimm et al., 1994), a similar relationship between the distance separating markers and the chance of coconversion has been observed, so the distance that a recombination event travels may be a stochastic process in most organisms.

Data from both *S. cerevisiae* (Nicolas et al., 1989) and *S. pombe* (Gutz, 1971) suggest that the chromosome carrying the more active hot spot, on which conversion is more likely to be initiated, is usually the recipient of information. *N. crassa* is no exception, for the chromosome bearing cog^+ is almost always the one that is converted (Catcheside and Angel, 1974; Yeadon and Catcheside, 1998; Yeadon et al., 2001). This relationship is not simple, however, as conversion tracts in *N. crassa* can be very complex. Between *his-3* and *cog*, the sequences from different wild-type strains diverge by up to 3.4% (Yeadon and Catcheside, 1999), thus providing many silent markers for analysis of recombinant progeny. Use of these markers has shown that many conversion tracts at *his-3* are discontinuous, with patches of sequence from each parent (Yeadon and Catcheside, 1998), and similar although less complex events have been recorded at *am* (Bowring and Catcheside, 1998).

A Template-Switching Model for Recombination

TM429 is a *his-3* mutant generated in a cog^+ strain, in which the mutant allele is a translocation that separates the proximal end of *his-3* from *cog* (Catcheside and Angel, 1974). In a translocation heterozygote, therefore, a *his-3* allele proximal to TM429 lies on the opposite side of the breakpoint from *cog*. The frequency of His^+ spores from such a cross is low and unregulated by *rec-2* (see below), unless the intact chromosome also carries cog^+, so recombination can cross the translocation heterology provided it is initiated on the unbroken chromosome (Catcheside and Angel, 1974). Supportive of this, molecular analysis of His^+ progeny of a TM429 heterozygote showed that conversion can occur on both sides of the translocation breakpoint in individual progeny (Yeadon et al., 2001). It has also been observed that conversion tracts are often patchy in His^+ progeny of non-translocation homozygotes (Yeadon and Catcheside, 1998), even in the absence of mismatch repair (Koh and Catcheside, 2007). This suggests that if recombination is initiated by a DBS close to cog^+, the break is repaired by DNA synthesis that can use either the homologous chromosome or the initiating chromosome as a template and may switch from one to the other during repair, a template-switching variant of the SDSA model (Pâques and Haber, 1999; Yeadon et al., 2001). Like other SDSA models, a crossover can arise by resolution of single (Ferguson and Holloman, 1996) or double Holliday junctions (Pâques et al., 1998).

The Role of MMR in Recombination

Sequences that differ in the chromosomes involved in a recombination event, such as point mutations, insertions, and deletions, yield hDNA with mismatched bases (Modrich, 1991; Strand et al., 1993). The mismatch repair (MMR) pathway recognizes these and corrects them with variable degrees of efficiency, which may generate novel sequence combinations.

MMR in bacteria utilizes the MutS, MutL, and MutH proteins. MMR is initiated when a dimer of MutSp binds to a mismatch (Su et al., 1988), followed by the binding of MutLp dimer to the MutS-mismatch complex, increasing the stability of the complex (Grilley et al., 1989; Mankovich et al., 1989) and activating MutH endonuclease (Grafstrom and Hoess, 1987), which cleaves at the GATC site (Au et al., 1992). Since MutH cleavage is in the unmethylated strand, repair is targeted to the newly synthesized strand.

In *S. cerevisiae*, six *MutS* (*MSH1* through *MSH6*) and four *MutL* (*PMS1* and *MLH1 through MLH3*) homologs have been identified (reviewed by Pâques and Haber, 1999, and Borts et al., 2000). A heterodimer of MSH proteins recognizes the mismatch and an MLH protein heterodimer binds to the mismatch/MSH complex. The MSH and MLH proteins involved in each dimer depend on the nature of the mismatch, with MSH2/MSH3 recognizing small loops, insertions, and deletions, which are repaired with

the assistance of PMS1/MLH2, and single-base frameshift mutations, which utilize MLH1/MLH2 for repair. The MSH2/MSH6 heterodimer binds to small loops and single-base mismatches and recruits PMS1/MLH1 (Borts et al., 2000). Thus, all Mshp heterodimers involved in MMR include Msh2p, but only two of the three Mlhp repair heterodimers include Pms1p.

Mutations in *MSH2* and *PMS1* in *S. cerevisiae* increase PMS, as mismatches in hDNA remain uncorrected, and also have a mutator phenotype, increasing microsatellite instability and spontaneous mutation up to 1,000-fold (Strand et al., 1993). In addition, spores from MMR-deficient diploids show reduced viability compared to that of spores from wild-type crosses, to 60 to 80% in *S. cerevisiae* (Williamson et al., 1985) and 86% in *S. pombe* (Rudolph et al., 1999). Also in *S. pombe*, a *msh2*Δ (deletion) mutant exhibits abnormal meiotic chromosome structures, with linear elements frequently aggregated, a rare occurrence in the wild type (Rudolph et al., 1999).

N. crassa also has six *MutS* and four *MutL* homologs (Borkovich et al., 2004). Strains defective in *msh-2* (Koh and Catcheside, 2007) and *pms1* (L. Y. Koh and D. E. A. Catcheside, unpublished data) have been generated by repeat-induced point mutation (Selker, 1990), and subsequent *msh-2* deletion mutants have been made using the split-marker technique of Catlett et al. (2003), with the coding sequence replaced by the hygromycin resistance gene.

Both *msh-2*^{RIP} and *pms1*^{RIP} strains have a mutator phenotype, as the mitotic reversion rate of the *his-3* K458 allele is increased 20-fold in *msh-2* and *pms1* mutants compared to wild-type strains (Koh and Catcheside, 2007; Koh and Catcheside, unpublished). Moreover, although 85 to 95% of the spores from wild-type *N. crassa* crosses are viable, *msh-2*^{RIP} and *pms1*^{RIP} homozygotes yield 20 to 30% inviable colorless spores and only 60 to 70% of pigmented spores are viable.

In an analysis of 42 *N. crassa* octads from *msh-2*Δ homozygotes, the only examples of non-Mendelian segregation of mutant alleles were PMS (5:3 or 3:5), confirming that Msh-2 is required for MMR in *N. crassa*. In addition, conversion tracts in His$^+$ progeny of *msh-2*^{RIP} homozygotes are at least as patchy as in progeny of wild-type crosses (Koh and Catcheside, 2007). Thus, interruptions to conversion tracts cannot be due solely to patchy MMR, providing support for the template-switching hypothesis of recombination (Yeadon et al., 2001).

Sequence heterology at levels commonly found in *N. crassa* crosses prevents crossing-over in *S. cerevisiae*, although absence of Msh2 restores exchanges in the heterologous interval (Chambers et al., 1996). However, even in *N. crassa* crosses between strains of different wild-type origin, crossing-over between *his-3* and *ad-3* is unaffected by *msh-2*Δ, although the *lys-4* to *mat* interval is increased up to twofold in some crosses (Yeadon et al., unpublished). Also, the frequency of His$^+$ allelic recombinant spores in the progeny of *N. crassa msh-2*Δ homozygotes is 150 to 160% of that of otherwise isogenic wild-type diploids, and this effect is unchanged by SNPs within the *his-3* gene (Yeadon et al., unpublished). It thus seems that Msh-2 does not regulate recombination in the *his-3* region, although the effect on the *lys-4* to *mat* interval suggests that crossing-over here may be regulated by Msh-2. Since Msh-2 does not regulate *his-3* allelic recombination, the increase in His$^+$ progeny in *msh-2*Δ homozygotes suggests that the direction in which hDNA within *his-3* is repaired by Msh-2 shows bias toward restoration of the original mutant allele rather than toward gene conversion.

The *pms1*^{RIP} homozygotes show no obvious recombination phenotype, although recombination in *his-3* may be slightly increased, and the double homozygote has the same phenotype as the *msh-2*^{RIP} homozygote (Koh and Catcheside, unpublished), suggesting that, as in *S. cerevisiae*, Msh-2 and Pms-1 operate in the same pathway.

Msh-4 and Crossing-Over in *Neurospora*

MSH4 and MSH5, members of the same protein family as MSH2, are not involved in MMR but rather have a role in crossing-over (reviewed by Hoffmann and Borts, 2004). MSH4 and MSH5 are known to form a heterodimer, and mutation in either has been observed to yield the same phenotype in many organisms: increase in chromosomal nondisjunction and a reduction in crossing-over (Ross-Macdonald and Roeder, 1994; Zalevsky et al., 1999; Hollingsworth et al., 1995; Hunter and Borts, 1997). In addition, MSH4 localizes at synapsis initiation sites during yeast and mammalian meiosis (Novak et al., 2001; Neyton et al., 2004), and chromosome synapsis in *S. cerevisiae msh4* mutants is delayed and defective (Novak et al., 2001). Although MSH4/MSH5 is absolutely required for crossing-over in *C. elegans* (Zalevsky et al., 1999), crossovers occur at a reduced frequency in *S. cerevisiae msh4* mutants. These MSH4-independent exchanges do not show normal crossover interference but are distributed at random in the intervals in which they fall.

An ortholog of the highly conserved *MSH5* has been identified in *N. crassa* (NCU09384.1) by bioinformatic analysis (Borkovich et al., 2004), and the most likely *msh-4* candidate has been deleted (Conway et al., 2006). Deletion of *msh-4* is dominant, due to meiotic silencing of unpaired DNA (MSUD) (Shiu and Metzenberg, 2002), and mutants exhibit defects in meiosis; sporogenesis is delayed, and fertility is reduced to 20% of that of the wild type (Conway et al., 2006). Although *msh4*Δ reduces recombination in the *mat* to *lys-4* and *lys-4* to *ad-3* intervals, residual recombination occurs at about 30% of the wild-type frequency (S. Conway, P. J. Yeadon, F. J. Bowring, and D. E. A. Catcheside, unpublished data), suggesting that a ZMM protein-independent crossover pathway operates in *N. crassa* as it does in *S. cerevisiae* (see above). Whether these remaining crossovers lack interference cannot be determined in the *his-3* region, as the high frequency of gene conversion at both *his-3* and *lys-4* precludes measurement of interference by random spore analysis, and *msh4*Δ mutants do not yield full octads, preventing tetrad analysis of crossover distribution.

REGULATION OF RECOMBINATION

A number of genes that modulate recombination frequency in distinct genomic regions have been discovered in the filamentous fungi. These include genes that promote or suppress recombination and that act either in their immediate vicinity or at one or more remote loci.

Ascobolus Conversion Control Factors (*ccf* and *cv*)

A. immersus carries a number of conversion control factors that regulate gene conversion frequency in specific genomic regions. These fall into three classes, of which the first class, *ccf-2*, has been described above.

ccf genes in the second class act at specific but remote loci and comprise *ccf-3* and *ccf-4* (Helmi and Lamb, 1983). The *ccf-3E* allele increases conversion frequency at *wI* and is dominant to the *ccf-3*e allele. The action of the *ccf-4R* allele depends on the *ccf-2* and *ccf-3* alleles in a cross. When

ccf-3E is present, *ccf-4R* reduces recombination in *wI* only in the absence of *ccf-2(91)* (Helmi and Lamb, 1983).

A third class of *Ascobolus ccf* genes suppresses recombination at a nearby locus only when heterozygous. Crosses heterozygous for different pairs of *ccf-5* and *ccf-1* alleles show reduced gene conversion rates at the *w9* and *w62* loci, respectively (Emerson and Yu-Sun, 1967; Howell and Lamb, 1984; Lamb and Shabbir, 2002). Similarly, gene conversion at the *b1*, *b2*, *b4*, and *b6* loci is reduced in *cv1*, *cv2*, *cv4*, or *cv6* heterozygotes, respectively, and in addition to this effect, crossing-over between the *b4* and *b6* loci is reduced in *cv4* and *cv6* heterozygotes (Girard and Rossignol, 1974). The molecular bases of these effects on recombination have not been explored.

ss in *Neurospora*

ss is analogous to the *ccf-1*, *ccf-5*, and *cv* elements of *Ascobolus*. Catcheside (1981) found that recombination between *nit-2* alleles is influenced by the wild-type origin of the parental strains, with crosses of homozygous origin yielding higher allelic recombination frequencies than those where the two strains are from different backgrounds. This heterozygous suppression of recombination is due to a genetic element called *ss*, which is tightly linked to *nit-2*. Recombination is suppressed 2- to 20-fold depending upon the *ss* alleles present, but unlike *cog*, each *ss* allele does not operate independently; crosses homozygous for any *ss* allele yield more Nit^+ spores than those in which the *ss* alleles are heterozygous.

Neurospora rec Genes

The three known *N. crassa rec* genes, *rec-1*, *rec-2*, and *rec-3*, act *in trans* at specific regions of the genome (Fig. 4). Each dominant *rec-n*$^+$ allele was thought to produce a diffusible product (Catcheside, 1977) that reduces recombination in its target regions by about 1 order of magnitude. The *rec-1* gene acts at *his-1* on linkage group V (Jessop and Catcheside, 1965) and at *nit-2* on LGI (Catcheside, 1970), but not at 10 other loci tested (Catcheside and Austin, 1969). The *rec-2* locus, on LGV (Smith, 1968), modulates recombination in two intervals on LGI, *his-3* to *ad-3* (Angel et al., 1970; Catcheside and Corcoran, 1973) and *sn* to *arg-3* (Catcheside and Corcoran, 1973), and between *his-5* and *pyr-3* on LG IV (Smith, 1966).

In *rec-2*$^+$ hetero- or homozygotes, recombination between *his-3* alleles is reduced 30-fold when *cog*$^+$ is present and 4-fold in crosses homozygous for *cog*, dropping the recombination rate for both *cog* genotypes to the same low level (Angel et al., 1970). Recombination appears to be initiated at the 5′ end of *his-3* in the presence of *rec-2*$^+$, rather than at *cog*, which lies several kilobases 3′ of *his-3* (Catcheside and Angel, 1974; Yeadon and Catcheside, 1998), suggesting that initiation of recombination at *cog* is suppressed by *rec-2*$^+$ (Catcheside and Angel, 1974).

rec-3 regulates recombination at *am* on LG V (Catcheside, 1966) and at *his-2* on LG I (Catcheside and Austin, 1971). There are three known alleles, *rec-3*, *rec-3*^{L}, and *rec-3*$^+$. The *rec-3*$^+$ allele is dominant to both *rec-3* and *rec-3*^{L} at *his-2*, but at *am*, the effect of *rec-3*^{L} on recombination is intermediate between that of *rec-3* and *rec-3*$^+$ (Catcheside, 1974).

While the dominant allele of each *N. crassa rec* gene appears to suppress recombination at the target, it now appears that this is an artifact of another meiotic process. Genes that lack a homolog are silenced during meiosis in *N. crassa* by MSUD (Shiu and Metzenberg, 2002). The *rec-2* and *rec-2*$^+$ sequences lack homology, so in a heterozygous mating neither has a homolog with which to pair (F. J. Bowring and D. E. A. Catcheside, unpublished data). If MSUD is disabled in a *rec-2*$^+$/*rec-2* heterozygote,

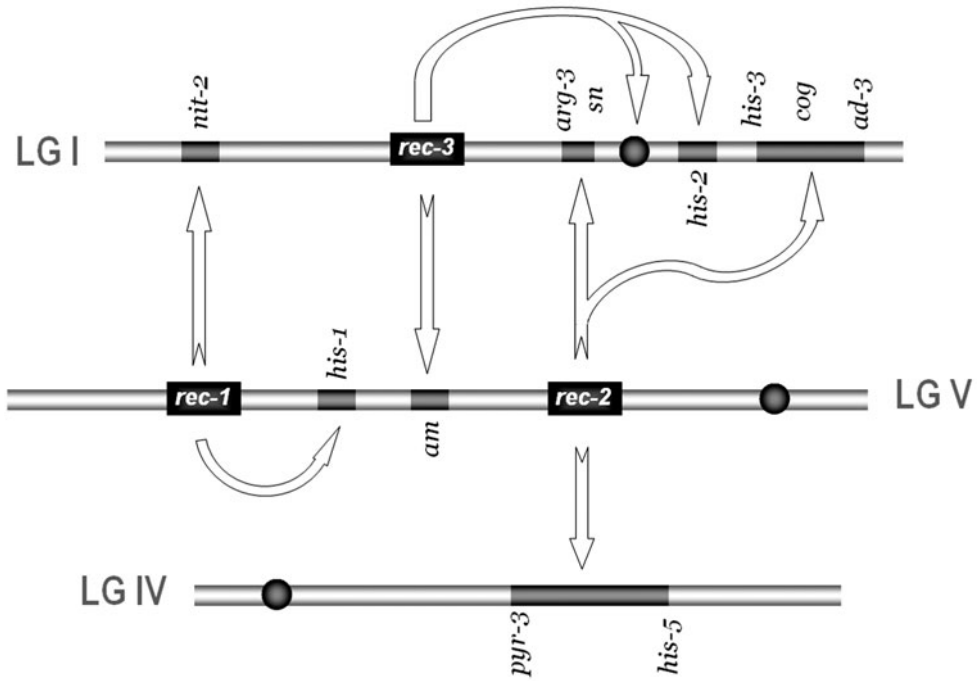

FIGURE 4 A partial linkage map of *Neurospora*, showing the locations of the known *rec* genes and the regions in which each *rec* gene influences recombination (arrow heads). Spheres represent the centromeres. The map is not to scale, and only part of each chromosome is shown.

recombination at *his-3* is substantially increased, although not quite to the level seen in a *rec-2* homozygote. Additionally, a *rec-2* deletion behaves, like *rec-2*$^+$, as a dominant suppressor of recombination.

Indeed, MSUD is responsible for the dominance of all three *rec* genes. In the absence of MSUD, recombination frequencies at *his-1* in *rec-1*$^+$/*rec-1* heterozygotes and at *am* in *rec-3*$^+$/*rec-3* heterozygotes are indistinguishable from those of *rec-1* and *rec-3* homozygotes, respectively (Bowring and Catcheside, unpublished). Thus, rather than *rec-n*$^+$ genes producing suppressors of recombination, the *rec-n* allele of each is an activator of recombination. Normal levels of recombination at the *rec-2* target near *his-3* have been observed in *spo11* mutants (see above), suggesting the tantalizing possibility that *rec* genes are a novel class of recombination initiators.

In addition to genes having a large effect on recombination, others having small effects are known in *N. crassa*. For example, both allelic recombination in *his-3* alleles and crossing-over in the vicinity varies at least twofold in crosses with the same *cog* and *rec-2* genotype (Yeadon et al., 2004a) depending on an unlinked factor in the genetic background. A similar effect is seen at the *nit-2* locus (Catcheside, 1970). It is not known if these genes of minor effect act locally or globally across the whole genome. It appears that *N. crassa* is highly polymorphic for genes with both large and small effects on recombination, suggesting there is selective advantage to the species in the ability to vary recombination frequency.

A and *B* Mating Type Factors in *Schizophyllum commune*

In *S. commune*, two unlinked factors, *A* and *B*, must both be heterozygous for a pair of strains to be compatible for mating (Simchen, 1967). The *A* factor is encoded at two linked loci, α and β (Raper et al., 1958, 1960), and recombination in the α to β interval is determined in the main by a single unlinked *rec* locus. In the presence of the dominant *rec*$^+$ allele, the frequency of recombination between α and β is reduced from an average of 15 to 4% (Simchen, 1967). There is also an effect of genetic background, as recombination frequencies vary from 1 to 8% in crosses including *rec*$^+$ and from 8 to 25% in the absence of *rec*$^+$.

There is a similar but independent system regulating recombination in the *B* factor. In addition, temperature has a differential effect on each regulatory system, suggesting that each *rec* gene product involved may have a different temperature optimum (Stamberg, 1968).

Sequence Heterology and Recombination

At the *b2* locus of *A. immersus*, sequence heterology has been used to infer details of recombination intermediates (Nicolas and Rossignol, 1989, and references therein). Recombination, and thus hDNA, is usually initiated at the end of the gene closer to the 1F1 mutation and extends towards A4 at the other end of the gene, but it can also be initiated elsewhere. Asymmetric hDNA is seen most often close to the initiator, declining towards the other end of the gene, while the gradient for symmetric hDNA is in the opposite direction.

Although extension of asymmetric hDNA is unaffected, heterology blocks extension of symmetric hDNA. Close to the initiator, mismatches in *b2* reduce both kinds of hDNA, perhaps by interfering with the strand invasion step that occurs immediately after initiation (Nicolas and Rossignol, 1989). Similarly, naturally occurring mismatches close to *cog* may interfere with strand invasion (Yeadon et al., 2004a), and mismatches within *his-3* appear to reduce the chance of resolution of a recombination intermediate between the mutant alleles (Yeadon et al., 2004a).

In *N. crassa*, heterozygosity for *TK* inserted between *cog* and *his-3* has no effect on allelic recombination in *his-3* (Yeadon et al., 2004a). These data suggest that recombination initiated at *cog*, after strand invasion and before resolution of the recombination intermediate, may involve only DNA synthesis and thus extension of asymmetric hDNA, also unaffected by heterology in *A. immersus* (Nicolas and Rossignol, 1989). In *A. immersus*, however, such large heterologies increase crossing-over, which tends to occur between the initiator and the heterology, suggesting it may block the migration of Holliday junctions and force their resolution (Nicolas and Rossignol, 1989). In contrast, heterozygosity for *TK* does not stimulate crossing-over in the *his-3* region of *N. crassa* but reduces the *his-3* to *ad-3* genetic interval by 50%. Some of the reduction in crossing-over is due to deletion of a novel crossover hot spot in the region replaced by *TK* (see below), but the heterology has an additional effect, which may not be confined to the heterologous region alone (Yeadon et al., unpublished).

A Novel Crossover Hot Spot near *his-3* in *Neurospora*

Using a *Neurospora* cross maximized for sequence heterology in the *his-3* region, high-density SNP analysis and partial sequencing of 150 octads were used to locate crossovers between *his-3* and *ad-3*. Crossovers appeared to have a nonrandom distribution, most falling close to *his-3* or more than 40 kb distal, and all those in which the location was determined flanked regions showing gene conversion and/or PMS. More crossovers than expected occurred within a 200-bp region that falls within the native sequence removed in the deletion/replacement strains described above (Yeadon et al., 2002).

The 200-bp sequence has been deleted in several strains to enable comparisons between crosses that are isogenic apart from the deletion. The deletion decreases crossing-over in the distal *his-3* to *ad-3* interval, increases recombination in the *his-3* to *lys-4* interval, and increases conversion in *his-3* more than would be expected (Yeadon et al., 2002) as a result of decreasing the distance from *cog* by 200 bp (Yeadon et al., unpublished). We conclude that the 200-bp sequence includes a motif that is a preferred site for termination of recombination events, so that when it is deleted, fewer events terminate between *his-3* and *cog*, lowering the crossover frequency in this interval. Conversely, more events reach *his-3* (so more conversion occurs), and more extend past *his-3*, thus increasing the frequency of crossovers in the proximal *lys-4* to *his-3* interval.

CONCLUSION

The availability of sequenced genomes for a number of filamentous fungi together with the development of efficient gene targeting techniques makes reverse genetics, previously very difficult with these organisms, relatively easy. Research into DNA repair and recombination can now proceed apace by deletion of each annotated gene with a predicted role in these processes, enabling us to move beyond understanding individual repair systems to an understanding of more complex networks. However, deletions alone will not be enough. As considered above, the location and type of a mutation can yield a novel phenotype. Moreover, epigenetic control of DNA metabolism will undoubtedly play a part in DNA repair and recombination.

Thus, the isolation of mutants sensitive to mutagens remains an indispensable tool if we are to develop a comprehensive understanding of DNA repair and recombination.

It is now clear that there are several pathways by which recombination occurs, that yeast does not contain them all, and that pathways present only in other species need to be investigated in detail. The filamentous fungi have greater genetic complexity than yeast and are more similar to complex organisms such as mammals. The filamentous fungi will continue to provide efficient model systems for such investigation.

Chromatin Structure and Modification

ZACHARY A. LEWIS AND ERIC U. SELKER

Chromatin is the substrate for virtually all DNA-mediated processes in eukaryotic cells. The basic unit of chromatin is the nucleosome, which is composed of ~146 bp of DNA wrapped around a protein core composed of histones H2A, H2B, H3, and H4 (Luger et al., 1997). The core histones are subjected to extensive posttranslational modification, which can influence interactions of nucleosomes with each other or with nonhistone chromatin proteins (Bhaumik et al., 2007; Jenuwein and Allis, 2001; Kouzarides, 2007). Replacement of the core histones with histone variants also contributes to the assembly of functionally distinct chromatin domains (Henikoff et al., 2004), while chromatin remodeling can further modulate chromatin structure (Cairns, 2007; Smith and Peterson, 2005). In addition, some organisms carry out methylation of cytosine bases in DNA to yield 5-methylcytosine (Klose and Bird, 2006). Ultimately, all of these processes contribute to the establishment of local chromatin environments that promote or inhibit various DNA-templated processes. In general, histones and chromatin modifiers are quite conserved, but there is some variation, even among the fungi. In this chapter, what is known about chromatin structure in the filamentous fungi is discussed. This information is compared to what is known for other eukaryotes (e.g., the extensively characterized budding yeast *Saccharomyces cerevisiae*), and exciting areas for future research are highlighted.

HISTONES

In budding yeast, transcription of the core histones is tightly regulated and is primarily restricted to the S phase of the cell cycle (Gunjan et al., 2005). Replication-dependent incorporation of newly synthesized histones occurs immediately behind the replication fork and involves the trimeric chromatin assembly factor 1 (CAF-1) (Krude and Keller, 2001). Components of CAF-1 are conserved in filamentous fungi and likely participate in replication-dependent chromatin assembly as well (Borkovich et al., 2004). CAF-1 can also serve as a scaffold to mediate interaction of proteins behind the replication fork. For example, the meiosis-specific recombinase Lim15/Dmc1 interacts with the large subunit of CAF-1 in *Coprinus cinereus* (Ishii et al., 2008). This interaction likely facilitates chromatin assembly following recombination. The genomes of many eukaryotes contain multiple copies of each histone gene. While transcription of some histone genes is restricted to S phase, others are transcribed throughout the cell cycle (Takayama and Takahashi, 2007). Notably, a distinct set of histone chaperones that occur in filamentous fungi catalyzes replication-independent histone deposition outside S phase (Borkovich et al., 2004; Henikoff and Ahmad, 2005; Tagami et al., 2004). Despite tight regulation of histone gene transcription, even budding yeast carries out replication-independent histone deposition at some regions of the genome (Green et al., 2005). Replacement of histones in this fashion serves to alter chromatin structure in one of two ways. Histones that have undergone posttranslational modification can be replaced by those that have not, or the canonical histone proteins can be replaced by histone variants.

The full complement of histone genes has been characterized for *Neurospora crassa* (Hays et al., 2002). *N. crassa* encodes a single gene for three of the canonical histones H3, H2A, and H2B, plus two copies of the canonical H4 protein, a single homolog of the centromere-specific H3 variant H3v/CENH3, and one H2A variant, H2Az. *N. crassa* also encodes a divergent H4 variant that is probably a pseudogene. Like other eukaryotes, the *hH3* and *hH4.1* genes are divergently transcribed from a shared promoter. *hH2A* and *hH2B* are also divergently transcribed. Independent inactivation of either *hH4.1* or *hH4.2*, which encode identical proteins, does not noticeably perturb growth. BLAST searches of the *Magnaporthe grisea*, *Aspergillus nidulans*, and *Fusarium graminearum* genomes suggest that the number and organization of histone genes are conserved in these fungi. In contrast, BLAST searches of the basidiomycete *C. cinereus* genome suggest that it has multiple copies of both *hH3-hH4* and *hH2A-hH2B* gene pairs. Table 1 details the complement of predicted histone genes found in the genome sequences of *N. crassa* and *C. cinereus* (http://www.broad.mit.edu/science/data#).

The functions of the H3 and the H2A variants are not currently established for filamentous fungi. Like its homologs in yeast, plants, and animals, the H3 variant is

[b]These sequences were identified by performing BLAST searches of the *C. cinereus* genome sequence, using the corresponding *N. crassa* histone protein sequences as the query sequence.

presumably involved in centromere function, serving as the site of kinetochore assembly (Black and Bassett, 2008). The function of the H2A variant H2Az is not well understood in any organism. In yeast, this protein localizes to promoter regions and acts to prevent spreading of heterochromatin (Eirin-Lopez and Ausio, 2007). Similarly, H2Az appears to antagonize DNA methylation in plants (Zilberman et al., 2008). In *Drosophila* and mammals, H2Az also localizes to heterochromatic regions and may be important for heterochromatin formation or function (Zlatanova and Thakar, 2008). It is possible that H2Az has evolved different functions in different eukaryotic lineages. Investigation of H2Az function in filamentous fungi is an exciting area for future research.

Higher eukaryotes encode two noncentromeric histone H3 proteins (Henikoff and Ahmad, 2005). Canonical H3 is expressed during S phase and incorporated into chromatin in a replication-dependent manner. In contrast, the histone variant H3.3 is transcribed outside S phase and is incorporated into histones in a replication-independent manner. Fungi encode a single canonical H3, which belongs to the H3.3 group based on amino acid sequence. As mentioned above, however, work with budding yeast revealed that distinct groups of histone chaperones can catalyze deposition of this H3 protein in replication-dependent or -independent fashions (Green et al., 2005), and both sets of chaperones are present in the genome sequences of filamentous fungi (Borkovich et al., 2004). Thus, nonreplicative histone replacement may serve to erase preexisting chromatin marks in filamentous fungi as well.

The linker histone H1 is currently the most extensively characterized histone in filamentous fungi, but much is still unknown about the function of this protein. Study of plant and animal H1 has been primarily carried out in vitro because higher eukaryotes encode multiple linker histones, which complicates in vivo depletion studies. Indeed, the human genome encodes 11 H1 variants (Izzo et al., 2008). The genomes of *S. cerevisiae* and *Tetrahymena thermophila* possess single H1 genes, but the encoded proteins have rather different structures from those in higher eukaryotes. Thus, it is not clear if these proteins are functionally equivalent to their counterparts in higher eukaryotes. The fission yeast *Schizosaccharomyces pombe* lacks an obvious homolog of H1. Like budding yeast, several ascomycete genomes contain single *hH1* genes, yet the H1 proteins encoded by these fungi are structurally more similar to those of higher eukaryotes (Barra et al., 2000; Brosch et al., 2008; Folco et al., 2003; Ramon et al., 2000). BLAST searches of the *C. cinereus* genome reveal three putative H1 proteins, suggesting that basidiomycetes may be more complex than their ascomycete counterparts. *A. nidulans*, *N. crassa*, and *Ascobolus immersus* strains harboring inactive copies of *hH1* are viable, indicating that H1 does not perform essential functions in these fungi. Deletion of the *hho*A gene from *A. nidulans* produced no observable phenotypes (Ramon et al., 2000). An *A. immersus* strain harboring a MIP-silenced copy of *H1* produced three observable phenotypes, an overall increase in nuclease accessibility, DNA hypermethylation, and a decrease in lifespan (Barra et al., 2000) (see "Silent Chromatin and DNA Methylation" below for an explanation of MIP). In *N. crassa*, mutants lacking H1 exhibited transcriptional derepression of the gene encoding pyruvate decarboxylase (*cfp*), and a transcriptional fusion of the *cfp* promoter to the *hygromycin phosphotransferase* (*hph*) gene produced elevated *hph* expression in the *hH1* mutant (Folco et al., 2003). No effects on DNA methylation were observed. It is possible that H1 acts as a sequence-specific transcriptional repressor in fungi, but more-detailed analysis of H1 is required to determine the specific function of this histone.

HISTONE MODIFICATIONS

Posttranslational modification of histone proteins by acetylation and methylation was first described in 1964 (Allfrey et al., 1964). Acetylated histones supported higher rates of RNA synthesis than did unacetylated histones, suggesting that posttranslational modification of the histone proteins could produce functionally distinct chromatin domains. Indeed, the identification of histone modifications and their functions has been an intense and fruitful area of investigation. The expanding list of modifications now includes acetylation, methylation, phosphorylation, ADP-ribosylation, deimination (arginine to citrilline), proline isomerization, ubiquitylation, and sumoylation (Bhaumik et al., 2007; Jenuwein and Allis, 2001; Kouzarides, 2007; Latham and Dent, 2007). Some representative modifications that occur within the N-terminal tail domains of H3 and H4 are shown in Fig. 1. Many histone "marks" are reversible, a feature that contributes to the dynamic nature of the chromatin fiber. Further complexity results from the fact that lysine residues can be mono-, di-, or trimethylated, and each state may have distinct functional consequences. Similarly, monomethylated, symmetrically dimethylated, and asymmetrically dimethylated forms of arginine have been identified. Genetic and biochemical studies have led to the identification of many of the enzymes that establish these modifications, as well as those that reverse them.

Modification of histones may impact nuclear processes through at least two mechanisms. (i) The modifications themselves can influence interactions between nucleosomes, thus promoting or inhibiting the assembly of higher-order chromatin structures. (ii) Alternatively, the modifications can create binding sites for protein complexes that directly

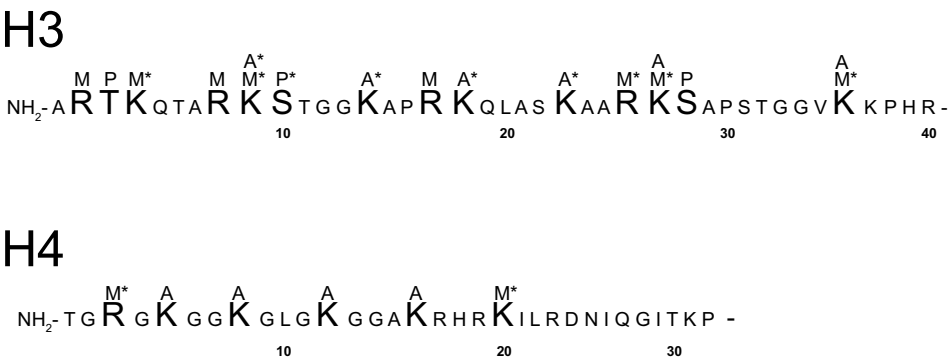

FIGURE 1 Covalent modifications of the H3 and H4 N-terminal tails. The amino acid sequence of the N-terminal tails of H3 and H4 is shown. Some of the modified residues are shown in larger font, and modification of these residues by acetylation (A), methylation (M), or phosphorylation (P) is indicated above the respective amino acids. The modifications highlighted by an asterisk have been characterized in filamentous fungi.

catalyze DNA-templated reactions or complexes that further modify chromatin structure. Indeed, several protein domains that recognize and bind specific histone modifications have been identified, supporting the hypothesis that a "histone code" consisting of chromatin marks and proteins that read them serves to link chromatin structure and function (Jenuwein and Allis, 2001; Taverna et al., 2007).

Histone modifications can be loosely grouped into "active marks," which facilitate processes such as transcription, recombination, and DNA repair, and "repressive marks," which tend to inhibit these processes. Identification of modified residues and their functions has progressed more rapidly for H3 and H4, in part because H3 and H4 are more conserved than H2A and H2B. Indeed, antibodies that specifically recognize modifications of H3 or H4 can be used experimentally in a wide range of eukaryotic species. Furthermore, studies have shown that the functions of several histone modifications are conserved across eukaryotic kingdoms (Kouzarides, 2007). Modifications of H2A and H2B have also been identified, and some of these modifications appear to act in conserved pathways (e.g., ubiquitylation of H2B plays a conserved role in transcription in yeast, plants, and humans) (Weake and Workman, 2008). In general, transcriptionally active chromatin contains hyperacetylated histones and H3 methylated at K4, K79, and K36. Conversely, silent chromatin contains hypoacetylated histones and H3 methylated at K9 (Bhaumik et al., 2007; Kouzarides, 2007).

Fungi are excellent models to elucidate the function of histone modifications. Unlike higher eukaryotes, the genomes of many fungi have, or are predicted to have, single enzymes that catalyze a specific histone modification. For example, whereas methylation of H3 K9 is catalyzed by at least four separate enzymes in mammals (Lall, 2007), a single protein appears to be responsible for all detectable H3 K9 methylation in *N. crassa* (Tamaru and Selker, 2001; Tamaru et al., 2003). Despite this advantage, our understanding of chromatin modifications and their functions in filamentous fungi is in its infancy.

In eukaryotes, virtually all histone lysine methylation is performed by enzymes that contain a SET domain (Bhaumik et al., 2007). The only known exception is methylation of H3 K79, which is catalyzed by a non-SET domain protein, DOT1. DOT1 homologs are present in filamentous fungi, as are a number of SET domain proteins (Adhvaryu et al., 2005; Borkovich et al., 2004; Brosch et al., 2008; Palmer et al., 2008; Tamaru and Selker, 2001). Analysis of H3 and H4 from *N. crassa* revealed that H3 is methylated at lysines 4, 9, 27, 36, and 79, whereas H4 is methylated at lysine 20 (Adhvaryu et al., 2005; Tamaru and Selker, 2001). It is unlikely that this list is complete, since detection of these modifications relied on commercially available antibodies. In filamentous fungi, H3 K9 methylation, which is a component of silent heterochromatin, represents the most extensively characterized histone modification (discussed below). Initial examination of H3 K4 and K36 methylation indicates that these modifications have conserved functions in transcription (Adhvaryu et al., 2005).

CHROMATIN AND TRANSCRIPTION

In yeast, animals, and plants, H3 K4 methylation is associated with expressed genes (Bhaumik et al., 2007; Kouzarides, 2007). Chromatin immunoprecipitation experiments in *N. crassa* indicated that H3 dimethyl K4 associates with at least three expressed genes, namely, *mtr*, *hH4*, and *pcna* (Adhvaryu et al., 2005; Honda and Selker 2008; Tamaru et al., 2003). Similarly, in *A. immersus* H3 dimethyl K4 is found in expressed genes but is absent from these genes when they are silenced by DNA methylation (Barra et al., 2005). Chromatin immunoprecipitation followed by hybridization to a high-resolution microarray covering *N. crassa* LGVII confirmed that H3 dimethyl K4 resides within genes (Lewis et al., 2009). Indeed, nearly 45% of LGVII genes were enriched for H3 dimethyl K4, while this modification appeared to be excluded from heterochromatin domains (Fig. 2).

In *S. cerevisiae*, methylation of H3 K36 is enriched within the 3′ regions of transcribed genes, where it recruits the histone deacetylase (HDAC) Rpd3 (Carrozza et al., 2005; Keogh et al., 2005). Why would a mark associated with active transcription recruit a protein associated with transcriptional repression? It turns out that deacetylation by Rpd3 prevents RNA polymerase II transcript initiation at cryptic promoters that reside within coding sequences. H3 K36 methylation may serve a similar function in filamentous fungi. Adhvaryu and colleagues inactivated the gene encoding SET2 in *N. crassa* and demonstrated that this enzyme catalyzes methylation of H3 K36 (Adhvaryu et al., 2005). *set-2* mutants exhibited defects in sexual and asexual

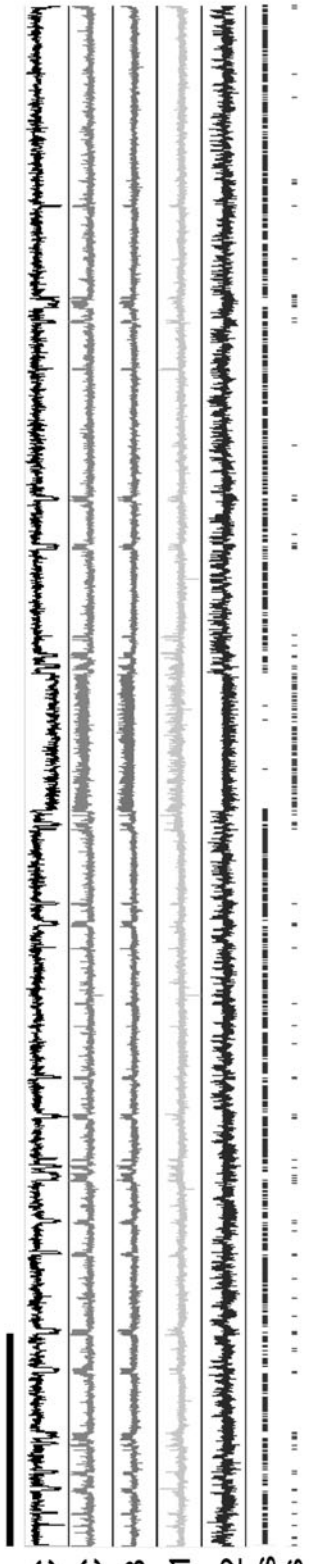

FIGURE 2 Chromatin modification profile for *N. crassa* LGVII. The base composition of LGVII is shown as the moving average of %GC at the top of the plot. The distribution of DNA methylation (5mC), H3 trimethyl K9 (H3K9me3), HETEROCHROMATIN PROTEIN-1 (HP1), and H3 dimethyl K4 (H3K4me2) is shown for LGVII. The positions of predicted open reading frames (genes) and repeats are also indicated. The scale bar on the top left indicates 0.5 Mb.

development, suggesting that SET-2 activity is important for expression of genes involved in these developmental pathways. Introducing a mutant histone harboring a K36-to-L substitution reproduced the set-2 phenotype. Notably, chromatin immunoprecipitation assays demonstrated that K36 methylation was enriched in the 3′ region of the *mtr* gene, suggesting that K36 methylation may serve similar functions in budding yeast and filamentous fungi.

Changes in the position of individual nucleosomes can expose or mask regulatory sites within a DNA molecule (Cairns, 2007). This process, called chromatin remodeling, is often observed within eukaryotic promoters and can even include complete ejection of nucleosomes from the chromatin fiber. Such chromatin remodeling is frequently correlated with changes in transcription. Indeed, many promoter-associated chromatin domains adopt an "open" conformation following activation of transcription. Changes in chromatin structure from a closed to an open conformation may result from transcription. Alternatively, remodeling of promoter nucleosomes may represent a distinct, regulated event that occurs prior to transcription. Several elegant studies have addressed these possibilities by examining nucleosome remodeling at inducible promoters in species of *Aspergillus*.

In *A. nidulans*, expression of the divergently transcribed *niaD* and *niaA* genes requires induction by nitrate (mediated by NirA) and derepression in the absence of ammonium (mediated by AreA). Within the *niaD-niaA* promoter, a nucleosome-free region containing binding sites for AreA is flanked on either side by positioned nucleosomes (Muro-Pastor et al., 1999). Activation of transcription results only when induction by nitrate is accompanied by loss of repression (i.e., the absence of ammonium). Induction of transcription results in remodeling of the entire nucleosome array in a manner that depends on AreA. Importantly, these changes occur in the absence of the activator NirA, indicating that transcription is not required to induce chromatin remodeling.

Similarly, disruption of an ordered nucleosome array at the *alcA* and *alcR* promoters occurs following transcriptional induction and requires the transcriptional activator AlcR (Mathieu et al., 2000). Since deletion of the *alcA* TATA box produced a dramatic reduction in the rate of transcription but did not inhibit the AlcR-dependent changes in nucleosome position, the authors concluded that chromatin remodeling and transcriptional activation occur in a stepwise fashion at the *alcA* promoter.

Several studies have explored the relationship between histone acetylation and chromatin remodeling. For example, analysis of the bidirectional *prnD-prnB* promoter from *A. nidulans* revealed that the ordered pattern of nucleosomes observed under repressed conditions was perturbed by treatment with the HDAC inhibitor trichostatin A (TSA) (Garcia et al., 2004). Moreover, induction of *prnD-prnB* transcription is accompanied by increases in acetylation of H3 K9 and K14 in addition to rearrangement of nucleosomes at the promoter (Reyes-Dominguez et al., 2008). Chromatin remodeling at the promoter does not require acetylation of these residues, however, since mutant strains lacking the GcnE or AdaB components of the SAGA histone acetyltransferase (HAT) complex display normal induction of transcription and normal nucleosome remodeling at the promoter. The authors speculate that perhaps acetylation of other residues in H3 or acetylation of H4, H2A, or H2B by additional HATs could be required for chromatin remodeling upon transcriptional activation.

Similarly, AreA-dependent acetylation of H3 K9 and K14 is associated with chromatin remodeling at the *niaD-niaA* promoter (Berger et al., 2008). Under certain nutrient conditions, however, NirA can induce chromatin remodeling that is not dependent on increased acetylation of H3 K9 and K14. This suggests that acetylation is not required for all chromatin remodeling at this promoter or alternatively, acetylation of other lysine residues on H3, H4, H2A, or H2B may be important for NirA-mediated chromatin remodeling at *niaD-niaA*.

Although involvement of SAGA was not required for remodeling at the *A. nidulans prnD-prnB* promoter, studies of the light-induced *albino-3* gene in *N. crassa* uncovered an essential role for histone acetylation at this promoter (Grimaldi et al., 2006). Light-induced transcription at the *N. crassa al-3* promoter was accompanied by an increase in acetylation of H3 K14, dependent on the WC-1 transcriptional activator. Moreover, *N. crassa* strains expressing a mutant H3 protein with a K14-to-Q substitution display reduced gene activation in response to light, suggesting that acetylation of this residue is required for normal transcription induction. Lastly, light-induced acetylation at the *al-3* promoter and light-induced transcription of the *al-3* and *vivid* genes were abolished in a mutant strain lacking the *N. crassa* Gcn5 homolog NGF-1.

Nucleosome position is determined by DNA sequence, the occupancy of DNA binding proteins, and the activity of chromatin remodeling enzymes (Schnitzler, 2008). Indeed, the *A. nidulans* CCAAT binding factor AnCF and its binding site are both required to organize a nucleosome-free region within the *amdS* promoter (Narendja et al., 1999). Similarly, two DNA sequence motifs within the *Hypocrea jecorina cbh2* promoter are required to properly position nucleosomes at this promoter (Narendja et al., 1999).

The chromatin remodelers that catalyze the dramatic changes in nucleosome organization at the *Aspergillus* promoters described above have yet to be identified. In *N. crassa*, however, knockout mutants for 19 predicted ATP-dependent chromatin-remodeling enzymes have been created (Belden et al., 2007). One of these enzymes, named CLOCKSWITCH (CSW-1), is required for normal functioning of the circadian clock. Binding of CSW-1 to the promoter of the *frequency* (*frq*) gene occurs in a circadian fashion. Light-induced and circadian-cycle-regulated expressions of *frq* are respectively mediated by two *cis*-acting elements within the promoter, the light response element and the clock box (C-box) (Froehlich et al., 2002). Light induction produces a change in micrococcal nuclease accessibility near the light response element (Belden et al., 2007). Likewise, a change in micrococcal nuclease accessibility is observed near the C-box over the course of a circadian cycle. These circadian changes in the *frq* promoter were reduced, but not abolished, in the *csw-1* mutant strain. The authors conclude that CSW-1 acts to negatively regulate binding of the transcription factor WC-2 to the C-box by remodeling chromatin at this promoter element. Interestingly, circadian and light-regulated chromatin rearrangements at the *frq* promoter persist in the *csw-1* mutant strain, indicating that multiple chromatin-remodeling enzymes act on the *frq* promoter.

Histone acetylation is typically associated with transcriptional activation, while removal of acetyl groups by HDACs is frequently involved in transcriptional repression. Eukaryotic genomes encode multiple HDACs that fall into four categories (Brosch et al., 2008; de Ruijter et al., 2003). Class I and II HDACs are homologs of *S. cerevisiae* RPD3 and HDA1, respectively. Homologs of the *S. cerevisiae* NAD^+-dependent HDAC SIR2, called sirtuins, constitute the class III HDACs. Lastly, class IV HDACs, which are absent from fungi, include HD2 of plants and HDAC11 in mammals.

A. nidulans RpdA and HosA were the first HDACs identified in filamentous fungi (Graessle et al., 2000), followed shortly by identification of their respective homologs HDC2 (Brosch et al., 2001) and HDC1 (Baidyaroy et al., 2001) in *Cochliobolus carbonum*. Mutants lacking HDC1 displayed reduced virulence, abnormal conidium production, reduced growth rates on carbon sources other than glucose, and a ~50% reduction in global HDAC activity (Baidyaroy et al., 2001). Surprisingly, the reduced growth rates were correlated with a decrease in expression of several extracellular depolymerases. Loss of expression did not result from derepression of the carbon catabolite repressor CREA. Why HDC1, a presumed transcriptional repressor, is required for transcription activation is not clear, but this represents an interesting question to address in future studies. Similarly, studies with *Ustilago maydis* also revealed a role for the RPD3 homolog Hda1 in both repression and activation of genes, as well as an essential role for this protein in teliospore development (Reichmann et al., 2002; Torreblanca et al., 2003).

S. cerevisiae HOS3 has sequence features attributed to both Class I and Class II enzymes and therefore cannot readily be grouped into either of these classes (Brosch et al., 2008). While HOS3 homologs have not been identified in plant or animal systems, HOS3 homologs HosB and HDC4 were identified in *A. nidulans* and *C. carbonum*, respectively (Trojer et al., 2003). Homologs are also present in the genome sequences of other ascomycetes and several basidiomycetes, suggesting that this group of HDACs is specific to fungi (Brosch et al., 2008). Like HOS3 in budding yeast (Carmen et al., 1999), the HDAC activity of *A. nidulans* HosB was highly resistant to HDAC inhibitors TSA and HC-toxin (Trojer et al., 2003).

Interestingly, the HDAC inhibitor HC-toxin is a secondary metabolite (SM) produced by *C. carbonum*. Other filamentous fungi such as *Alternaria brassicicola* also produce SM HDAC inhibitors. It is possible that HOS3 family HDACs are upregulated in response to exposure to these inhibitors. This is not the only mechanism of self-protection, however. *C. carbonum* apparently produces an extrinsic factor that serves to protect its normally sensitive HDACs from HDAC inhibitors (Baidyaroy et al., 2002).

Trojer and colleagues identified the class II HDACs HdaA from *A. nidulans* and HDC3 from *C. carbonum*. Analyses of chromatography fractions containing HDAC activity from wild-type and *hdaA* mutant strains indicated that HdaA accounts for the majority of HDAC activity in *A. nidulans*, while RpdA accounts for most of the remaining activity (Tribus et al., 2005; Trojer et al., 2003). In addition, these analyses demonstrated that HosA and an NAD^+-dependent activity, likely due to a SIR2 homolog, also contribute to the overall HDAC activity under standard laboratory growth conditions (Trojer et al., 2003). The contributions of these enzymes are minor relative to those of HdaA and RpdA. The authors also demonstrate that HdaA, HosA, and RpdA are all present in high-molecular-mass complexes. Strains that lack HdaA are sensitive to oxidative stress, which correlated with decreased transcription of the catalase *catB* gene and reduced activity of the CatB enzyme (Tribus et al., 2005). These effects on *catB* transcription are presumably indirect but are not currently understood at the molecular level.

Notably, more recent work revealed that HdaA is involved in repression of telomere-proximal SM clusters in *A. nidulans* (Shwab et al., 2007). Examination of SM gene expression in mutants lacking *A. nidulans* HosB or the SIR2 homolog HstA revealed no effects, but a triple mutant lacking HdaA, HosB, and HstA showed enhanced SM gene transcription relative to the *hdaA* mutant alone. These data suggest that the deacetylases work in concert to regulate genes from at least two telomere-linked SM clusters. Furthermore, chromatin immunoprecipitation experiments with *Aspergillus parasiticus* revealed that ordered expression of genes within the aflatoxin gene cluster is accompanied by acetylation of H4 (Roze et al., 2007). Taken together, these data suggest that an antagonistic relationship between HATs and HDACs is important for the coordinated regulation of SM genes in filamentous fungi.

Histone arginine methylation has been shown to positively and negatively regulate transcription in eukaryotes (Bedford 2007; Bedford and Richard, 2005). The genomes of *A. nidulans* and *N. crassa* each encode three predicted protein arginine methyltransferases (PRMT) (Borkovich et al., 2004; Trojer et al., 2004). The *A. nidulans* and *N. crassa* proteins RmtA/PRMT1, RmtB/PRMT3, and RmtC/PP-2 most closely resemble higher-eukaryotic PRMT1, PRMT3, and PRMT5, respectively. Notably, RmtB and PRMT3 lack an N-terminal Zn-finger domain that is present in PRMT3 homologs in higher eukaryotes. Functional analysis of the *A. nidulans* PRMTs revealed that all three proteins methylate histone substrates in vitro (Trojer et al., 2004). RmtA specifically methylates H4, RmtB methylates H4, H3, and H2A, and RmtC methylates H4 and H2A. The authors further demonstrated that all three PRMT proteins methylate H4 R3 and RmtB methylates H3 R26. The list of substrate residues is likely incomplete since antibodies were available only for methylated H4 R3, H3 R17, and H3 R26. Examination of histones isolated from *A. nidulans* revealed that methylation of H4 R3 and H3 R26 occurs in vivo but H3 R17 methylation does not. Moreover, in vitro methylation of H4 R3 by RmtA is inhibited when histones are first acetylated by the p300 HAT. Similarly, methylation of H3 by RmtB inhibits subsequent acetylation of histones by recombinant p300. In contrast, methylation of H4 by RmtB enhances acetylation by p300. Also, acetylation of H3 and H4 does not inhibit the methyltransferase activity of RmtB. Future studies that examine the function of these PRMT proteins in vivo will advance our understanding of the role of histone arginine methylation in filamentous fungi and in other eukaryotes.

SILENT CHROMATIN AND DNA METHYLATION

Heterochromatin is typically rich in repeated sequences and often comprises important structural domains, such as centromeres and telomeres. With respect to heterochromatin, the filamentous fungi are more similar to higher eukaryotes than to the budding yeast. Heterochromatin formation and maintenance in *S. cerevisiae* relies on a complex of Sir proteins (Rusche et al., 2003), only one of which, the NAD^+-dependent HDAC Sir2, is conserved in higher eukaryotes (Dali-Youcef et al., 2007). In contrast, H3 methylated at K9 is a mark for heterochromatin in the fission yeast *S. pombe*, plants, and animals but is absent from budding yeast (Grewal and Jia, 2007). Methylation of H3 K9 has been documented in several filamentous fungi (Barra et al., 2005; Palmer et al., 2008; Tamaru and Selker, 2001). In addition, the protein that reads this mark, HETEROCHROMATIN PROTEIN-1, is also absent from budding yeast but is present in the genomes of higher eukaryotes and filamentous fungi (Brosch et al., 2008; Freitag et al., 2004). Similarly, many genetically tractable model organisms such as budding yeast, fission yeast, *Drosophila*, and *Caenorhabditis elegans* lack readily detectable DNA methylation, which is a common feature of heterochromatin and repeated sequences in plants, animals, and some filamentous fungi (Suzuki and Bird, 2008). Thus, filamentous fungi are particularly attractive model systems to investigate heterochromatin formation and function due to their similarity to higher eukaryotes and their genetic tractability.

Much of our understanding of heterochromatin in filamentous fungi has emerged from the study of DNA methylation. The first methylated sequences identified in a fungal genome were a pair of tandemly arranged 5S rRNA pseudogenes in *N. crassa* (Selker and Stevens, 1985). These 5S rRNA pseudogenes are highly divergent and are rich in AT base pairs relative to other *N. crassa* 5S rRNA sequences. The discovery and subsequent characterization of the premeiotic genome defense system repeat-induced point mutation (RIP) revealed that these duplicated sequences were, in fact, relics of this process (Selker and Stevens, 1985). RIP operates exclusively during the sexual phase of the life cycle. After fertilization but prior to nuclear fusion, duplicated sequences within each haploid genome are detected and both copies are littered with C-G to T-A transition mutations. In the vegetative phase of the life cycle, products of RIP exhibit dense nonsymmetrical DNA methylation of most remaining cytosines (Selker et al., 1993a). In contrast, virtually all DNA methylation in animals occurs at symmetrical CpG dinucleotides and much of the methylation in plants occurs at symmetrical CpG or CpHpG (H=C, A, T) sites (Suzuki and Bird, 2008).

Similar to the situation in *N. crassa*, DNA methylation is targeted to sequence duplications in the ascomycete *A. immersus* by a RIP-like process termed methylation induced premeiotically (MIP) (Colot et al., 1996; Rossignol and Faugeron, 1995; Selker, 1997). In *A. immersus*, duplicated sequences detected during the premeiotic phase of sexual reproduction are heavily methylated, yet the primary DNA sequences remain unaltered. Thus, the DNA methylation established by MIP silences expression of duplicated sequences, but unlike what is observed with RIP, mutation of duplicated sequences does not occur.

The catalytic domains of both prokaryotic and eukaryotic cytosine DNA methyltransferases (DNMT) are composed of 10 highly conserved amino acid sequence motifs (Goll and Bestor, 2005), which led to the identification of two putative DNA methyltransferases from *A. immersus*. Masc1, the first DNMT homolog discovered in fungi, is the founding member of a family of fungus-specific DNMTs (Malagnac et al., 1997). Interestingly, Masc1 is required for MIP and for normal sexual development but is not required for maintenance of preexisting DNA methylation. These data suggest that Masc1 acts as a de novo DNMT during sexual development, while at least one maintenance methyltransferase acts to propagate preexisting methylation patterns during vegetative growth. Identification of the proposed maintenance methyltransferase(s) in *A. immersus* has proven difficult, however. Masc2, a second putative DNMT from *A. immersus*, exhibits C-5 DNMT activity in vitro, but mutant strains that lack this protein exhibit normal DNA methylation during vegetative and sexual phases of the life cycle (Malagnac et al., 1999). Additional work is necessary

to elucidate the proteins and mechanisms that contribute to the overall pattern of DNA methylation in this fungus.

In *N. crassa*, all DNA methylation within vegetative tissue requires the DNMT DIM-2 (Kouzminova and Selker, 2001). The DIM-2 protein is similar to *A. immersus* Masc2, and these proteins belong to a family of eukaryotic DNMTs that includes MET-1 from *Arabidopsis thaliana* and DNMT1 from mammals (Colot and Rossignol, 1999; Goll and Bestor, 2005). The finding that DIM-2 is responsible for all vegetative DNA methylation in *N. crassa* is notable for two reasons. First, this suggests that DIM-2 is capable of performing cytosine methylation at both symmetric and asymmetric sites. This is a unique feature of DIM-2, since animal and most plant methyltransferases exhibit strict substrate specificity (Goll and Bestor, 2005). Second, this observation revealed that DNA methylation is not essential in *N. crassa* (Kouzminova and Selker, 2001). In fact, the *dim-2* mutant displays apparently wild-type growth under all conditions that have been examined. This stands in contrast to the situation in plants and animals, where DNA methylation is essential for normal development.

One proposed mechanism of RIP involves cytosine methylation followed by deamination to produce C-to-T transition mutations (Galagan and Selker, 2004). Initial analysis of strains that lack DIM-2, however, revealed that RIP occurs normally in these strains. Searches of the *N. crassa* genome sequence revealed a second DNMT, which resembles *A. immersus* Masc1. Genetic analysis demonstrated that this DNMT homolog is required for RIP (Freitag et al., 2002). Hence, the protein was named RIP DEFECTIVE (RID). In contrast to *A. immersus* Masc1, RID is not required for sexual development, indicating that this is not a general function of RID/Masc1 family DNMTs.

Experimental analysis of DNA methylation and RIP in organisms other than *N. crassa* and *A. immersus* is in its early stages. The current data suggest that the filamentous fungi are a heterogeneous group with respect to both DNA methylation and RIP. DNA methylation of transposable elements or multiple-copy transgenes has been experimentally verified in a handful of fungi, including *M. grisea* (Nakayashiki et al., 2001), *Schizophyllum commune* (Mooibroek et al., 1990), and *C. cinereus* (Freedman and Pukkila, 1993). Searches of the genomic and expressed sequence tags (EST) data available for many filamentous fungi reveal that homologs of RID/Masc1 are widespread within the filamentous ascomycetes, but obvious homologs are not present in the genomes of the basidiomycete *C. cinereus* or of the yeasts *S. pombe* and *S. cerevisiae*. Although DNA methylation has not been detected in *A. nidulans*, its genome contains a single DNMT homolog that belongs to the RID/Masc1 family. Analysis of this gene, which was named *DNA methyltransferase homolog A* (*dmtA*), revealed an essential role in sexual development, similar to the case for Masc1 (Lee et al., 2008). The essential function(s) that DmtA and Masc1 perform is unknown. While DNA methylation has not been detected within *A. nidulans*, it is possible that trace amounts of transient DNA methylation are restricted to a few nuclei within the reproductive tissue. Alternatively, these proteins may have a function that does not require DNMT activity.

DNMTs of the DIM-2 family are found in several phylogenetically diverse species, including several ascomycetes such as *N. crassa*, *M. grisea*, and *F. graminearum*, as well the basidiomycete *C. cinereus*. In order to generate a more complete understanding of DNA methylation in fungi, experimental evidence of in vivo DNMT activity must be demonstrated for these predicted enzymes. It will also be important to better characterize the distribution of methylated cytosine within fungal genomes.

Currently, the genomic distribution of DNA methylation is best defined in *N. crassa*. Genomic analyses of DNA methylation clearly demonstrated an intimate association between RIP and DNA methylation. The first genome scale study to determine which sequences are methylated involved purification of methylated DNA by methylated DNA affinity chromatography (Selker et al., 2003). This study identified methylated sequences from all seven *N. crassa* chromosomes. Notably, virtually all of these sequences displayed hallmarks of RIP. More recently, analysis of the distribution of DNA methylation was performed by methylated DNA immunoprecipitation followed by hybridization to high-resolution DNA microarrays covering LGVII at 100-bp resolution (Lewis et al., 2009). DNA methylation on this chromosome was highly correlated with the presence of AT-rich DNA that had undergone the RIP process (hereafter referred to as "RIP'd") (Fig. 2). Notably, dense DNA methylation was detected within a large (~350-kb) centromeric domain, as well as in over 40 additional domains ranging from 0.5 to 20 kb. These included short domains adjacent to each telomere. All methylated domains exhibit hallmarks of RIP, reinforcing the earlier, less detailed study. No significant methylation was detected within genes, suggesting that this fungus does not rely on DNA methylation to regulate expression of functional coding sequences. Studies designed to address the function of DNA methylation in *N. crassa* and *A. immersus* showed that DNA methylation inhibits transcription elongation, but they did not reveal a role for DNA methylation at promoters. DNA methylation within the *mtr* and *am* promoters of *N. crassa* and the promoters of an *hph* reporter and the *met-2* gene in *A. immersus* did not inhibit transcription initiation, in contrast to the situation in mammals (Barra et al., 2005; Rountree and Selker, 1997). DNA methylation within the coding regions of these genes inhibited transcription elongation in both of these fungi, however.

Association of DNA methylation with sequences targeted by RIP and MIP is consistent with a mechanism that involves establishment of DNA methylation during the sexual phase of the life cycle, followed by maintenance methylation during vegetative growth. At least in *N. crassa*, however, it is clear that RIP'd DNA is a *cis*-acting signal for DNA methylation (Miao et al., 2000; Selker et al., 1993b; Selker and Stevens, 1987; Singer et al., 1995). Indeed, analysis of a series of RIP'd alleles of the *am* gene revealed that *N. crassa* performs both maintenance and de novo methylation (Selker et al., 2002; Singer et al., 1995). Whereas no methylation was detected in lightly RIP'd alleles of *am* during vegetative growth, moderately RIP'd sequences were methylated following RIP but did not support de novo methylation when unmethylated copies were reintroduced by transformation. In contrast, heavily RIP'd sequences were methylated following RIP and triggered de novo methylation when unmethylated copies were reintroduced by transformation. Dissection of sequences that are sufficient to target DNA methylation suggested that cooperative recognition of AT-rich sequences, potentially by an AT-hook domain protein, directs DNA methylation (Miao et al., 2000; Selker et al., 1993b; Tamaru and Selker, 2003).

Although the protein(s) that recognizes RIP'd DNA has not been identified, studies with *N. crassa* have uncovered a direct link between histone modification and DNA methylation. The SET domain protein DIM-5 is required for all detectable DNA methylation in this fungus (Tamaru

and Selker, 2001). DIM-5 most closely resembles *S. pombe* Clr4 and animal SUVAR 3–9 proteins but is unique in that it lacks the N-terminal chromo domain that is present in these proteins. In contrast to *dim-2* strains, which display no defects in growth or development, *dim-5* mutants display reduced growth rates and exhibit defects in sexual development. The specific cause of these growth defects is currently unknown but may result from problems with chromosome segregation and genome stability, as observed for *S. pombe* and *D. melanogaster* strains that harbor mutations in their respective DIM-5 homologs (Grewal and Jia, 2007; Peng and Karpen, 2008). In *N. crassa*, tandem repeats of transforming DNA have been reported to be unstable in a *dim-5* mutant, suggesting that H3 K9 methylation may serve to prevent mitotic recombination between repeated sequences (Chicas et al., 2005).

DIM-5 catalyzes mono-, di-, and trimethylation of H3 K9 in vitro, but trimethyl H3 K9 is the predominant product, both in vitro and in vivo (Tamaru et al., 2003; Zhang et al., 2003). In *S. pombe* and animals, methylated H3 K9 is recognized and bound by the chromo domain protein HP1 (Bannister et al., 2001; Grewal and Jia, 2007; Lachner et al., 2001). *N. crassa* encodes a single HP1 homolog, which is required for DNA methylation (Freitag et al., 2004). Cytologically, HP1 localizes to three or four distinct heterochromatic foci in wild-type cells, and proper localization requires DIM-5. While the chromo domain of HP1 directly binds H3 methylated at K9, a C-terminal chromo shadow domain interacts directly with a tandem pair of PXVXL-related motifs found in the N-terminal domain of DIM-2 (Freitag et al., 2004; Honda and Selker, 2008). Thus, HP1 serves to link methylated H3 K9 and DNA methylation. High-resolution analysis of the distribution of trimethyl H3 K9 and HP1 across LGVII revealed that both exhibit extensive colocalization with DNA methylation (Fig. 2) (Lewis et al., 2009). All regions that were enriched for trimethyl H3 K9 were enriched for DNA methylation, indicating that methylation of H3 K9 is sufficient to trigger DNA methylation. HP1 associates with domains of H3 K9 methylation but exhibits a complex localization pattern, indicating that dynamic binding of HP1 or accessory proteins contribute to the steady-state distribution of the protein. Notably, the distribution of trimethyl H3 K9 is largely unaffected in mutants that lack DNA methylation or HP1. Therefore, the pathway for heterochromatin formation appears to be largely unidirectional in *N. crassa*. In addition, DNA methylation was restored at all LGVII heterochromatic domains following depletion and subsequent reintroduction of the H3 K9 methylation machinery. Together, these data suggest that RIP'd DNA is sufficient to direct H3 K9 methylation de novo and that heterochromatic domains in *N. crassa* are defined molecularly by RIP'd DNA, H3 K9 methylation, HP1, and DNA methylation.

Although the molecular events downstream of H3 K9 methylation are becoming clear, the signals that direct DIM-5 to regions of RIP'd DNA are not yet well defined. In *S. pombe*, the RNA interference (RNAi) pathway is involved in the establishment of H3 K9 methylation by Clr4 at pericentric heterochromatin and works in concert with other pathways to target K9 methylation at the silent mating type locus (Grewal and Jia, 2007). Similarly, components of the RNAi machinery are important for some DNA methylation in plants (Henderson and Jacobsen, 2007). In *N. crassa*, however, the RNAi pathway is not involved in maintenance or de novo DNA methylation (Borkovich et al., 2004; Chicas et al., 2005; Freitag et al., 2004). Also, H3 K9 methylation and HP1 localization do not require the RNAi pathway.

Treatment of *N. crassa* with the HDAC inhibitor TSA leads to loss of some DNA methylation, indicating that HDAC activity is required for DNA methylation of some, but not all methylated regions in this fungus (Selker, 1998). Indeed, two of the four acetyl coenzyme A-dependent HDACs of *N. crassa* are required for normal DNA methylation (K. M. Smith, J. Dobosy, G. R. Green, D. A. Anderson, and E. U. Selker, unpublished data). It will be important to identify the protein(s) that recognize RIP'd DNA to gain a complete understanding of heterochromatin formation in *N. crassa*.

In *A. immersus*, DNA methylation is associated with dimethyl H3 K9 rather than trimethyl K9 (Barra et al., 2005). The enzyme that performs this modification has not been identified. In addition, it is not known if DNA methylation can direct K9 methylation in this fungus. H3 K9 methylation has also been described in *Aspergillus fumigatus*, a filamentous fungus that lacks DNA methylation (Palmer et al., 2008). *A. fumigatus* strains that lack ClrD, a homolog of DIM-5, display defects in growth and development, similar to *N. crassa dim-5* mutants. In addition, *clrD* mutants display increased sensitivity to 6-azauracil, suggesting that transcription is impaired in these strains. Interestingly, *clrD* mutants show reduced mono- and trimethyl H3 K9, whereas dimethyl K9 levels appear to be unaffected, suggesting that multiple H3 K9 methyltransferases are present in *A. fumigatus*. A complete understanding of H3 K9 methylation in the fungi awaits more-detailed analyses of the genomic localization and the proteins responsible for this modification.

CONCLUSIONS

The investigation of chromatin structure and function in the filamentous fungi has been fruitful, but much remains unknown. Important functions for chromatin in transcription, gene silencing, and genome defense have been uncovered. It will be interesting to determine how histone variants, chromatin remodeling, and chromatin modifications impact additional biological processes in filamentous fungi. For example, the role of chromatin structure in DNA repair and recombination is largely unknown for this group. Also, it will be interesting to determine if changes in chromatin structure accompany development or pathogenesis. The complete genome sequences available for many fungi allow high-resolution mapping of the distributions of modified histones, histone variants, and nonhistone chromatin proteins, which should provide some clues to their functions. Future genetic, biochemical, and molecular studies are necessary as well. Together, these analyses will provide a more complete understanding of chromatin structure and function in filamentous fungi.

Transposable Elements and Repeat-Induced Point Mutation

A. JOHN CLUTTERBUCK AND ERIC U. SELKER

Fungi have relatively compact genomes. While a plant or animal may contain 30,000 genes in a genome of about 4,000 Mb, a typical filamentous fungus contains about 10,000 genes in a haploid genome of 40 Mb or less. The compact nature of fungal genomes probably reflects selection for small nuclear and cell volumes, compatible with wind-dispersed asexual spores, narrow hyphae, and in some cases passage of nuclei through septal pores. Not surprisingly, fungi appear to be adept at controlling "selfish DNA," such as transposable elements (TEs). In most fungi examined, TEs comprise no more than 3% of the genome, implying effective TE repression and destruction mechanisms. Touchon and Rocha (2007) found that genome size in bacteria was the main factor correlating with insertion sequence abundance. The high TE content of *Laccaria bicolor* (Martin et al., 2008), accompanying a genome approximately twice the size of that in most filamentous fungi, and the paucity of TEs in *Saccharomyces cerevisiae* suggest that this correlation applies to fungi as well.

The first discovered, and probably most potent, genome defense mechanism is called repeat-induced point mutation (RIP). Although RIP was initially found in the filamentous fungus *Neurospora crassa*, other fungi show evidence of a mechanism similar or equivalent to RIP, as discussed in this chapter. RIP in *Neurospora* is first briefly described, and then, what is known about the distribution and condition of TEs in this and other filamentous fungi is summarized. Recent reviews (Daboussi and Capy, 2003; de Lima Fávaro et al., 2005) have given broad coverage to many aspects of TEs in filamentous fungi, including their use as analytical tools and in population or taxonomic studies, which are not updated here. Instead, this chapter concentrates on the impact of RIP on TEs.

RIP

RIP was discovered as a result of a detailed analysis of progeny from crosses of *N. crassa* transformants (Selker, 1990). It was found that duplicated sequences, whether native or foreign, and whether linked or unlinked, were frequently subjected to numerous polarized transition mutations (GC to AT) in the haploid genomes of the special premeiotic binucleate cells of the ascogenous tissue resulting from fertilization (Fig. 1) (Cambareri et al., 1989, 1991; Foss et al., 1991; Selker et al., 1987; Selker and Garrett, 1988). Experiments in which the stability of a gene was tested when it was unique in the genome or else combined with an unlinked copy demonstrated that RIP is not simply repeat *associated*; it is clearly repeat *induced* (Selker and Garrett, 1988). In a single passage through the sexual cycle, up to ~30% of the GC pairs in duplicated sequences can be mutated in *N. crassa* (Cambareri et al., 1989, 1991). A likely mechanism for generation of C→T transitions is methylation of cytosines followed by spontaneous or enzymatic deamination and DNA replication (Selker, 1990). The putative deamination step might be catalyzed by a DNA methyltransferase (DMT) or similar enzyme. Consistent with this possibility, one of two putative DMTs predicted from the *N. crassa* genome sequence is involved in RIP (Freitag et al., 2002). Progeny from homozygous crosses of mutants with defects in this gene, *rid* (RIP defective), do not show RIP activity. Mutants defective in *rid* do not have any obvious defects in DNA methylation in vegetative hyphae or in fertility, growth, or development. While methylation has not been documented in the sexual phase of the life cycle, most sequences affected by RIP are found to be methylated in vegetative hyphae. The *Neurospora* DMT DIM-2, which was identified genetically (Foss et al., 1993), is necessary for vegetative DNA methylation but is not required for RIP (Kouzminova and Selker, 2001).

All indications are that every sizable duplication (greater than ~400 bp for tandem duplication or ~1,000 bp for unlinked duplication) in *Neurospora* is susceptible to RIP. Nevertheless, duplications escape RIP at some frequency (typically less than 1% in one passage through the sexual cycle for a tandem duplication or approximately 50% for an unlinked duplication). Even duplications of chromosomal segments containing numerous genes are sensitive to RIP (Bhat and Kasbekar, 2001; Perkins et al.,

A. John Clutterbuck, Faculty of Biomedical and Life Sciences, University of Glasgow, Glasgow G12 8QQ, Scotland, United Kingdom. **Eric U. Selker,** Institute of Molecular Biology, University of Oregon, Eugene, OR 97403-1229.

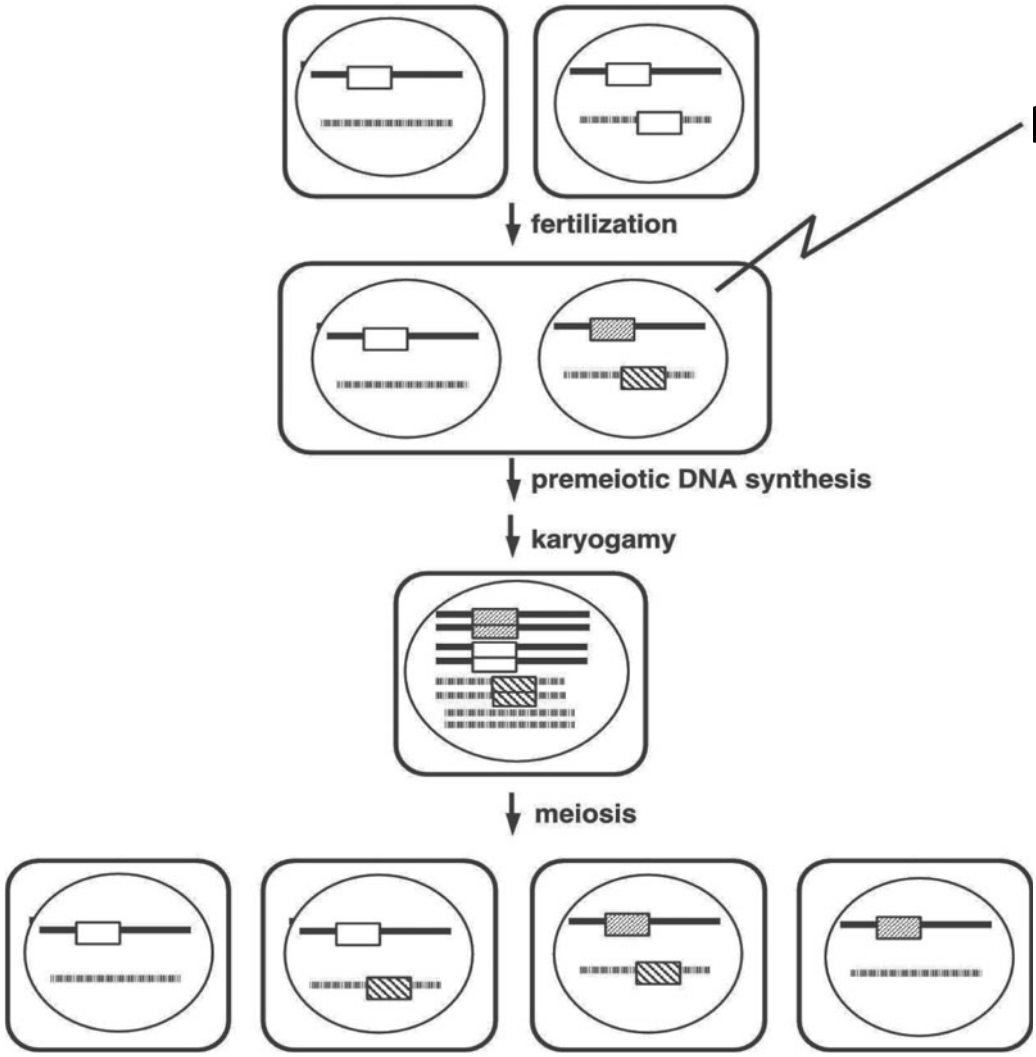

FIGURE 1 Diagram of RIP in *Neurospora*. Two haploid strains of opposite mating type are illustrated, one containing an unlinked duplication (open boxes). For clarity, only two chromosomes are shown. The lightning bolt indicates the time that RIP occurs, and the filled boxes indicate new alleles created by RIP. The four possible combinations of chromosomes in the meiotic progeny are represented below. In cases in which an essential gene was duplicated, only the left-hand two products would be expected to be viable. Unlinked gene-sized duplications pass through a cross without being discovered and mutated by RIP at an appreciable frequency (~50%), but direct duplications of the same sequences rarely survive untouched. Most products of RIP are left methylated at remaining cytosines.

1997). The existence of RIP has raised the question of whether *Neurospora* can utilize gene duplications to evolve. The *N. crassa* genome sequence revealed gene families, but tellingly, virtually all paralogues were found to be sufficiently divergent that they should not trigger RIP (Galagan and Selker, 2004). Exceptions include the rRNA gene cluster and genes with relatively short regions of similarity, such as an unlinked pair of histone H4 genes. Thus, RIP may indeed limit evolution in *Neurospora* (Galagan and Selker, 2004).

RIP has been demonstrated experimentally, using multicopy transgenes, in a few other filamentous ascomycetes: *Podospora anserina* (Graia et al., 2001; Bouhouche et al., 2004; Arnaise et al., 2008), *Magnaporthe oryzae* (*M. grisea*) (Ikeda et al., 2002), and *Leptosphaeria maculans* (Idnurm and Howlett, 2003), but no evidence of RIP was found in *Sordaria macrospora* (Le Chevanton et al., 1989; Walz and Kück, 1995). It is clear that RIP does not follow an identical pattern in all fungi: whereas RIP in *N. crassa* is intense enough to reduce the C+G content of the most affected elements to below 30% and widespread enough for unmutated TEs to be absent from the sequenced genome (Galagan et al., 2003), in *M. grisea* and *P. anserina* RIP is described as "light" or "mild" (Ikeda et al., 2002; Graia et al., 2001), and in *P. anserina* it was observed only in late-maturing ascospores. In both *N. crassa* and *P. anserina*, the majority of mutated cytosines were found in CpA dinucleotides, but in *M. grisea*, the preferred context for RIP was (A/T)pCp(A/T).

Interestingly, some fungi show what appear to be milder genome defense systems that are similar to RIP. The most

notable example is MIP (methylation induced premeiotically) in *Ascobolus immersus*, a process that, like RIP, detects linked and unlinked sequence duplications during the period between fertilization and karyogamy, but relies exclusively on DNA methylation for inactivation (Barry et al., 1993; Faugeron et al., 1990; Goyon et al., 1996; Goyon and Faugeron, 1989; Malagnac et al., 1999; Rhounim et al., 1992; Rossignol and Faugeron, 1994). The sensitivity of MIP in *Ascobolus* to tandem and unlinked duplications appears to be equivalent to that of RIP in *Neurospora* (Goyon et al., 1996).

DNA methylation in vegetative mycelia has been reported for apparent relics of RIP in *M. grisea* (Ikeda et al., 2002) and *P. anserina* (Graia et al., 2001), as in *N. crassa*, but was not found in *L. maculans* (Idnurm and Howlett, 2003), and no more than trace quantities of 5-methylcytosine have been found in *Aspergillus* species (Antequera et al., 1984; Gowher et al., 2001).

TEs IN FILAMENTOUS FUNGI

The genomes of *Neurospora* and other filamentous fungi show a large variety of sequences homologous to TEs found in other organisms. In a 2003 review of TEs in filamentous fungi, Daboussi and Capy (2003) list 67 individually named elements, to which many more could now be added. These include two new categories of class II DNA transposons: *Helitrons* and *Polintons* (Kapitonov and Jurka, 2001, 2006). Most fungal elements have been discovered accidentally or by searching for elements of a particular class. The discovery of TE sequences in *Neurospora* was facilitated by the fact that nearly all of them have been subjected to RIP and are found methylated in the vegetative mycelium. In a preliminary characterization of methylated sequences in *N. crassa*, Selker et al. (2003) compiled a list of 32 named TEs, as well as some unidentified fragments. Many more relics of RIP were discovered when the whole genome was sequenced (Galagan et al., 2003). In *M. grisea*, the distribution of members of 13 TE families was studied in bacterial artificial chromosome end sequences (Thon et al., 2004). A search for TEs in the large (65-Mb) genome of the mycorrhizal basidiomycete *L. bicolor*, using a variety of techniques, revealed that 21% of the genome is accounted for by such elements (Martin et al., 2008). Similarly, Clutterbuck et al. (2008) reported systematic surveys for TEs by comparing repetitive sequences in the genomes of *Aspergillus nidulans*, *Aspergillus fumigatus*, and *Aspergillus oryzae* (Galagan et al., 2005) with known elements listed in Repbase (Jurka et al., 2005). The wealth of elements found makes it impractical to give them individual names, so new elements are named by their superfamily, a family number, and species abbreviation, e.g., the *A. fumigatus* element *Mariner-6_AF*. More recently Wicker et al. (2007) have proposed a unified classification and code-naming system for all TEs.

Most filamentous fungal genomes surveyed contain a wide variety of elements from known TE superfamilies, each fungus containing its own unique set of elements. Among class I retrotransposons, *Gypsy*-superfamily long-terminal-repeat (LTR) elements are common, and many species contain more than one such family. *Copia* superfamily LTR elements also occur in many species. All *Copia* elements in *A. nidulans* and *A. fumigatus* are degenerate (Clutterbuck et al., 2008), and while it has been suggested that *Copia* elements are underrepresented in filamentous fungi (de Lima Fávaro et al., 2005), they are abundant in *Microbiotrium violaceum* (Hood et al., 2005), *L. bicolor* (Martin et al., 2008), and *Aspergillus niger* strain CBS513.88 and its derivatives (Braumann et al., 2007). *LINE*-like, non-LTR retrotransposons, e.g., "*I*" elements, are also common.

Class II DNA transposons are most frequently represented by multiple *Mariner* families of *Pogo* and *Tc1/Mariner* clades; *MUDR (MULE)*, *hAT*, *Helitron*, and *Polinton* DNA elements are also found in some species. *Mariner* elements generally encode only a single transposase, but some "*long mariners*" found in *A. fumigatus* and *A. oryzae* are distinguished by the presence of one or more additional open reading frames (Galagan et al., 2005). The *A. nidulans* genome includes four putative *MUDR* families, one of these being the "*MATE*" (*DNA-3_AN*) element (Aleksenko and Clutterbuck, 1997), fragments of which confer autonomous replication on AMA1 plasmids in *Aspergillus* and *Penicillium*. The basis of this phenomenon is unknown, but the ability of this element to enable plasmid replication suggests the occurrence of a replicative stage in the parent transposon. *Helitron* elements are characterized by an encoded helicase that is believed to function in replication by a rolling-circle mechanism (Kapitonov and Jurka, 2001). They were found in the *A. nidulans* genome (Galagan et al., 2005; Clutterbuck et al., 2008) and homologues of the *A. nidulans* element are abundant in *Neosartorya fischeri*, which is noted for its relatively high TE content (Fedorova et al., 2008). The *L. bicolor* genome also contains many *Helitron* fragments (Martin et al., 2008). *Polintons* may contain multiple genes, characteristically including DNA polymerase B (Kapitonov and Jurka, 2006). Representatives were found in two fungi: the soybean rust *Phakopsora pachyrhizi* and the arbuscular mycorrhizal fungus *Glomus intraradices*.

Intact elements with full open reading frames, e.g., the 15 near-identical copies of *Mariner-6_AN* (the largest *Mariner* family in Fig. 2A), can be considered to be potentially mobile. Most degenerate elements are probably immobile. However, if abundant copies of similarly deleted elements are found, this suggests that these are nonautonomous elements that have lost their transposase functions but can spread passively using the transposases of related, intact elements. For example, *A. nidulans* contains two families comprising 192 nonautonomous *hATN* elements (Fig. 2B), although only two fragments of intact *hAT* elements remain in the genome. Other examples of nonautonomous elements occur in many classes, the most prominent being *SINEs* (related to *LINEs*) and *MITEs* (deleted *Mariners*). The *A. oryzae* genome contains *SINE* elements with homology to the 5′ half of 5S rRNA, which appear to be new to fungi but are also present as fragments in other aspergilli (Galagan et al., 2005). The origin of a nonautonomous *Helitron-N1_AN* by deletion and adoption of a new 3′ end has been traced in detail (Cultrone et al., 2007).

Another distinctive class of TE fragments consists of solo LTRs, presumed to result from excision of the internal sequences of LTR retrotransposons by recombination between their terminal repeats. The frequency of such solo elements may reflect the recombination potential of their host genome. Interestingly, the homothallic species *A. nidulans* contains 505 solo LTRs from known or unknown retroelements (Fig. 2B), while *A. fumigatus* and *A. oryzae* have only 150 and 186, respectively, although all these species have numerous LTR retrotransposons (Clutterbuck et al., 2008). Since no fruiting bodies were observed, these fungi have long been assumed to be asexual, but the recent discovery of heterothallic sexual reproduction in *A.*

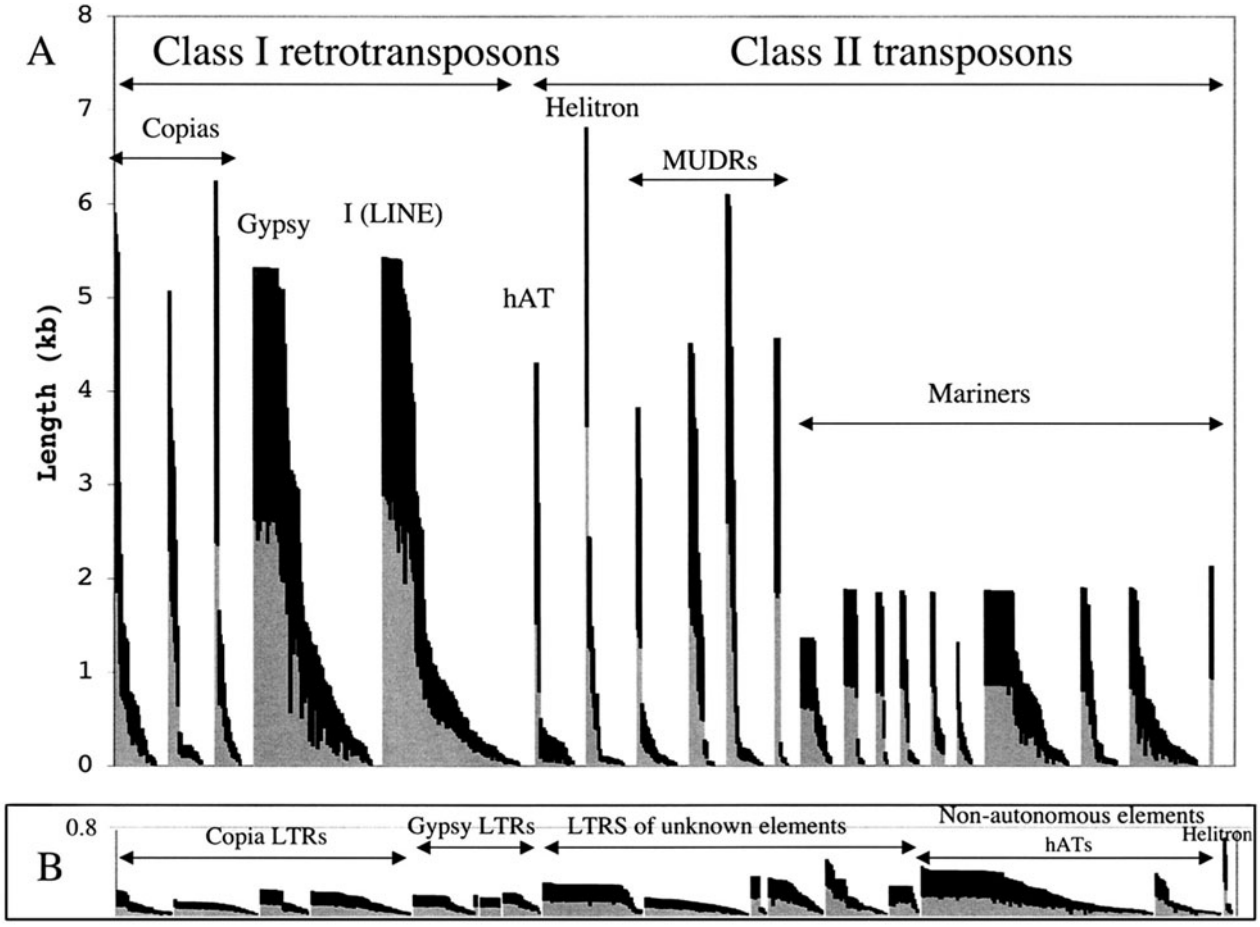

FIGURE 2 Graphic list of TEs in *A. nidulans*. Each vertical line represents one element, elements being ranked by length within families. In each element the black, upper portion of the line represents A+T content while the gray lower part represents C+G; the predominance of A+T in some elements is suggestive of the action of RIP. (A) Long elements and their fragments. (B) Small elements, including solo LTRs and nonautonomous elements.

fumigatus (O'Gorman et al., 2009) puts this assumption in doubt for other "asexual" fungi.

GENOMIC DISTRIBUTION OF TES

The distribution of TEs in fungal genomes suggests that there are a limited number of innocuous genomic locations. TEs can damage their hosts by insertion into functional coding or regulatory sequences; Daboussi and Capy (2003) list numerous instances of this, the resulting mutations often being the first evidence of the existence of a novel TE. They also cause genome rearrangement by homologous recombination between unlinked elements of the same family. It has been noted that chromosomal rearrangement breakpoints in the lineages of the three *Aspergillus* species analyzed often coincide with regions of TE clusters (Galagan et al., 2005). Similarly, blocks of conserved synteny between *M. oryzae* (a member of the *M. grisea* complex) and *N. crassa* are separated by TE clusters in *M. oryzae* (Thon et al., 2006). Aberrant excision, involving interaction between two copies of an element, as described by Hua-Van et al. (2002), can cause local chromosome rearrangements. Comparative synteny maps of three aspergilli (Galagan et al., 2005) suggest that this has been a common evolutionary event and could explain the puzzling reshuffling, without dispersal, of gene clusters, e.g., of the quinate catabolism genes (Giles et al., 1991; see also chapter 26).

Centromere sequences fail to compile in most genome projects because they consist of highly repetitive material, and contigs abutting centromeres generally end in a cluster of very AT-rich TE fragments, although adjacent regions of *A. nidulans* are mostly TE-free. Telomeres may also be excluded from fungal genomes sequences, although in this case it is because the terminal contigs are too short to be accepted by the compiler (Clutterbuck and Farman, 2008). Clustered relics of TEs are frequent within 100 kb of telomeres, but the short subtelomeric domains in *A. nidulans* are TE-free (Clutterbuck and Farman, 2008). It seems likely that these segments, although variable and probably subject to RIP, cannot be interrupted without damage to the host. It is noteworthy in this context, however, that extensive segments of fungal genomes appear to be nonessential

(Takehashi et al., 2006). Connelly and Arst (1991) described a viable deletion of what is now known to be a 270-kb telomeric segment of *A. nidulans* chromosome III containing 10 TE fragments and 96 putative (autocalled) genes. Thus, primary TE insertion sites may often be in nonessential distal regions of chromosomes, but other TE cluster regions could be the result of chromosomal rearrangements in which TEs have participated.

Of the three *Aspergillus* species analyzed by Clutterbuck et al. (2008), *A. fumigatus* has the most numerous full-length TEs, possibly correlated with the lowest level of genome rearrangement in its ancestry (Galagan et al., 2005). Fifty-five percent of TEs in this species are found in tight clusters, an appreciable proportion of which can be interpreted as the result of "nesting," i.e., the invasion of resident elements by new ones. In virtually all these cases, the invaded element has reduced C+G content compared to the invader. The commonest of these invaders in *A. fumigatus* are *Gypsy-1_AF* elements, and analysis of flanking regions of nonnested, i.e., scattered, *Gypsy-1_AF* insertions gives some support to the hypothesis that they preferentially insert into AT-rich areas, since in all cases the flanking 100 bp has an A+T content of >50% and in most cases >60%.

Despite the prominence of TE clusters, 45% of *A. fumigatus* elements are scattered throughout the genome. Typical of these are *Mariner* elements, many of which are young, full-length copies that have evidently managed to insert between genes without damage to the host. Li Destri Nicosia et al. (2001) reported a failure to find any cases of TE insertion as a cause of spontaneous mutation in the *A. nidulans niaD* gene. This suggests that all *A. nidulans* elements are very effectively repressed or that TEs have evolved to avoid insertion into active genes. Evidence of TE target site choice has been found mainly for eukaryote retroelements; this was reviewed by Bushman (2003) and earlier by Craig (1997). The *S. cerevisiae Ty3* element represents a classic example, in which this element preferably inserts close to polymerase III transcription initiation sites (Chalker and Sandmeyer, 1992). A related recent investigation (Dai et al., 2007) revealed that phosphorylation directs the integration of *Ty5* into heterochromatin. A precise target site preference is also shown by the majority of intact copies of the *LINE* element *I-1_AF* in *A. fumigatus*, which are inserted at the same site in the LTRs of *Afut2_AF* elements (Galagan et al., 2005; Clutterbuck et al., 2008).

LIFE AND DEATH OF TEs

The origins of novel TEs are generally unknown, but evolution of LTR retrotransposons can often be traced within the host organism. Class II DNA transposons more commonly fall into discrete families of near-identical elements. Population studies regularly show variation in TE content or location between isolates, and reservoirs of active elements may exist within the species; a good example of this is the finding of an active *Neurospora Tad* element in an African population, when laboratory strains and other wild isolates contained only defective remains (Kinsey and Haber, 1989). Another example is the *Copia*-like *ANiTa1* element found in the genome of *A. niger* industrial strain CBS513.88 and its derivatives (Braumann et al., 2007). In these strains most *ANiTa1* copies are young in appearance, but none with intact internal sequences are found in the ATCC 1015 strain sequenced by the Broad Institute. The presence of members of the same TE superfamilies in a wide range of plants, animals, and fungi implies that horizontal gene transfer must have occurred, and while suggestive evidence of this is abundant, final proof is rare (Daboussi and Capy, 2003).

Daboussi and Capy (2003) listed a considerable number of TEs that have demonstrated mobility. A recent addition to this list is the *Aft1* (*Mariner-1_AF* in Repbase) element of *A. fumigatus* (Hey et al., 2008). Mobility in the wild is indicated by *Aft1* site polymorphism in *A. fumigatus* strains, and in the laboratory, evidence of mobility consists of *Aft1* excisions from a plasmid reintroduced into its parent strain. The rarity of such events contrasts with the proliferation of *Fusarium Fot1* elements introduced into a naïve *Aspergillus* host (Li Destri Nicosia et al., 2001). Similarly, Ikeda et al. (2002) introduced the *M. grisea MAGGY* element into a strain that did not previously contain it, resulting in the generation of 15 to 20 copies in different progeny strains derived from a single transformant.

The pattern of bursts of activity for new elements, to give a limited number of copies that are then apparently repressed, suggests copy-number-dependent, family-specific autorepression. A number of repression systems are partially understood (for reviews, see Slotkin and Martienssen, 2007, and Maxwell and Curcio, 2007; see also chapters 9, 11, and 12). One remarkable mechanism for repression of class I LTR retrotransposons reported in *Schizosaccharomyces pombe* employs a CENP-B centromere binding protein homologue, apparently derived from the transposase of a class II *Mariner* element (Cam et al., 2008). The *S. pombe* CENP-B homologues act by aggregating their target sites at the ends of LTR retrotransposons into heterochromatic clusters. It appears that "domestication" (or "exaption") of *Mariner* transposase for this function has occurred separately in *S. pombe* and mammals but has not occurred in other organisms (Casola et al., 2008).

Stress may cause release from repression and allow resumption of transposition (Daboussi and Capy, 2003). A recent example from fungi is the heat shock activation of DNA transposons in *Ophiostoma ulmi* (Bouvet et al., 2007). Transposition activation by stress can be seen as a panic measure: from the perspective of the element, it might lead to release of free elements potentially available for horizontal transfer to a safer host. From the perspective of the host organism, transposon activation can lead to random chromosomal rearrangements, and it has recently been demonstrated that a proportion of stress-induced rearrangements, although not shown to be related to TE activity, may confer resilience to the initial stress (Coyle and Kroll, 2008).

Older TE families have evidently suffered from destruction (e.g., by RIP) as well as repression. In addition, Fig. 2 shows that a large proportion of recognizable elements are fragmented; aberrant transposition is one TE-specific mechanism of fragmentation (Hua-Van et al., 2002), but at present there is little indication that the majority of fragmentation is the result of anything other than the destructive processes suffered by the rest of the genome.

EXTENT OF DAMAGE OF TEs BY RIP

A striking feature of some of the TE sequences illustrated in Fig. 2A is their low C+G content, presumably due to the action of RIP. Daboussi and Capy (2003) list a number of fungi in which RIP has been either observed experimentally or deduced from the presence of numerous C→T transitions in repeated genomic elements. Sequences that resemble known relics of RIP have been reported in a variety of filamentous ascomycetes, including *A. nidulans*, *A. fumigatus*, and *A. oryzae* (Clutterbuck, 2004; Galagan et al., 2005; Montiel et al., 2006; Hey et al., 2008; Clutterbuck et al., 2008), *A. niger*

and *Penicillium chrysogenum* (Braumann et al., 2007), and *Colletotrichum cereale* (Crouch et al., 2008). Depletion of C+G content of repetitive genomic sequences can best be followed where a number of near-identical, undamaged copies of the element can be used to compile a consensus, with which other, C+G-depleted copies, can be compared. *"MATE"* (*DNA-3_AN*) elements (Clutterbuck, 2004) are represented by two nearly identical 6.1-kb copies, a third incompletely sequenced copy, and two more copies that differ individually from the consensus by a few transversions and 263 and 306 C→T transitions respectively (counting replacements on both strands). This suggests that RIP has operated here.

A survey of TE samples in 28 filamentous ascomycete genomes, backed up by genome scans for C+G-depleted tracts (A. J. Clutterbuck, unpublished data), shows that C+G depletion is subphylum-wide. Of course, genomic data do not tell us whether the mechanisms involved are specific to repeats, at what stage in the life cycle they occur, nor whether the process is still active in any species. The data do, however, show that depletion can be more extreme than is apparent from experimental studies of RIP. The resulting heavily mutated sequences will usually be unrecognizable as TEs, but in some cases a consensus sequence can still be constructed, for example, for the *A. oryzae Mariner1-AO* element, which shows C+G content of just 17.5% (Clutterbuck et al., 2008). It has been noted that the *A. oryzae* genome includes numerous stretches of DNA with A+T content of >90% (Machida et al., 2005). This is a statistic that varies from 0.001 to 2.2% in the species surveyed, with *N. crassa* and *A. nidulans* being near the high and low ends of the range, at 0.5 and 0.04%, respectively. The preferred context for C→T transitions also appears to vary; while CpA dinucleotides are the most frequently affected in *N. crassa* and its relatives, CpG dinucleotides appear to be most commonly mutated in many species, and the central tracts of degraded TEs can be completely devoid of this dinucleotide (Clutterbuck, unpublished). Cytosines flanked on the 3′ side by pyrimidines are generally less affected than those adjacent to purines. In *A. nidulans* and *A. fumigatus*, CpY dinucleotides are hardly diminished at all, while in other species either CpC or CpT dinucleotides approach CpR dinucleotides in depletion frequency.

Homologues of the *N. crassa rid* gene are present in all *Aspergillus* species whose genomes have been sequenced to date, as well as in other filamentous fungi (Galagan and Selker, 2004). The *rid* homologue in *A. nidulans*, *dmtA*, is essential for completion of sexual reproduction (Lee et al., 2008), although, like *rid* in *Neurospora*, its deletion does not affect vegetative growth. Consistent with the expectation that RIP would only occur premeiotically, as in *N. crassa* (Fig. 1), Ikeda et al. (2002) found that high levels of RIP in *M. grisea* were found only in isolates that were sexually fertile under laboratory conditions. The sexual status of many ascomycetes is unknown, but the absence of sexuality cannot be assumed from failure to observe it. Many studies, e.g., on *Penicillium* and *Aspergillus* species (LoBuglio et al., 1993; Geiser et al., 1996) indicate that sexual and apparently asexual species are closely related. The facility to detect mating-type genes in wild populations, including the determination of homothallic or heterothallic status, and the distribution of opposite mating types in heterothallics (O'Gorman et al., 2009, plus supplementary information online [see O'Gorman et al., 2009]), can be expected to lead to increased detection of sexuality. While the frequency of sexual reproduction, or indeed the time since it last occurred in a species, may be important for the observation of C+G depletion in TEs, it is also clear that the extent of such observation will depend greatly on the quantity and age of TEs in each species, i.e., on the unique history of TE incursion and proliferation in each species.

FINAL COMMENTS

TEs represent a genome component that, with rare exceptions, is of no value to the host organism and can be detrimental. Like other genomic components, TEs provide a record of the evolutionary processes to which they were subjected, but unlike most genomic components, their turnover is rapid and the record they leave is largely one of decay, including defeat by the defense mechanisms of the host. RIP is the most potent genome defense system known in eukaryotes. It is perhaps surprising that RIP is apparently unique to filamentous ascomycetes, but genome defense mechanisms appear to be unusually labile in evolution (for an example, see Hammond et al., 2008; see also chapter 12), perhaps because they have to be retailored to meet each new emergency encountered by the host. Moreover, RIP carries costs for the host, the most significant of which is probably that it limits the evolution of gene families.

Meiotic *trans*-Sensing and Silencing in *Neurospora*

RODOLFO ARAMAYO AND ROBERT J. PRATT

Sexual reproduction is good for organisms and can be beneficial for the propagation of transposable elements (TEs) that could use this developmental stage to "jump" and "infect" pristine genomes. While the mobilization of the elements themselves is mutagenic, their abundant presence in genomes of sexual, especially Metazoan organisms, suggests either that their presence brings benefits or that removing them is just too costly for the organism. Evidence suggests that in fact TEs may not always be detrimental, as they probably contribute to aspects of genetic diversity and/or chromosome stability (Pardue and DeBaryshe, 2003). This widely accepted dogma states that the genomic landscape is shaped largely by the ongoing battles waged between genetic programs contributing "constructively" to the stable inheritance of a species' DNA and the exquisitely regulated expression of its genes and the invasive, parasitic genetic elements such as transposons (Hickey, 1993). We think it is reasonable to say that these past battles largely shaped the genome of many organisms including that of *Neurospora crassa*, an organism that exhibits a very rigorous and diverse set of genome defense programs. Studying the biology of these genome defense mechanisms in *Neurospora* will certainly help us understand how different organisms dealt with the evolutionary forces aiming at shaping the different genome's architecture through time.

At the center stage of all sexual reproduction is meiosis, a complex molecular process during which the controlled genetic exchange of genes and gene segments between genomes of organisms belonging to the same species occurs. From an engineering point of view, meiosis places a set of paternal and maternal chromosomes into the same cellular compartment and then proceeds to break down their gene combinations into smaller parts, recombining and reassembling them into new, possibly never before seen chromosome combinations. The genome products of meiosis now have the ability to reconstitute metabolic pathways, organelles, tissues, and organs by using their newly acquired gene assemblies. This process has profound implications especially for complex adaptation traits and phenotypes produced and composed of a great many different genes. A simple explanation of why meiosis has proven to be nondeleterious to the maintenance of these complex processes might be that, despite its ability to literally shred the genome into pieces, it might also have developed molecular mechanisms that ensure that the basic pieces that constitute the different pathways and/or processes are present on both genomes. What is likely to be a primordial form of such checkpoint mechanisms is exemplified by meiotic *trans*-sensing and silencing, processes found and discovered in *N. crassa*.

Before delving into the complexities of meiotic silencing, we think it is important to remind the reader that before any genetic exchange can take place between the chromosomes participating in meiosis, these molecules must first physically pair. The term "pairing" has, unfortunately, different meanings. To make things worse, the term is sometimes used interchangeably with "synapsis," a word that has a more restricted meaning. We thus find it necessary to define these terms. We find at least four different kinds of chromosome "pairing" in meiosis (Cook, 1997). First is the cohesin-dependent pairing that results from the duplication of the strands of DNA after premeiotic DNA replication. Second is the long-distance pairing or "alignment or coalignment or juxtaposition" that is observed at leptotene, where each duplicated pair searches for its (duplicated) homolog. Third is the short-distance pairing or synapsis that is seen at zygotene, where the building of the synaptonemal complex draws the homologs even closer together so that by pachytene they lie in close register with one another. Fourth is the single-stranded DNA (ssDNA)-ssDNA complementary pairing or "complementary base-pair pairing" that precedes the recombination that takes place between two DNA duplexes that must lie within nanometers of each other.

In general, our understanding of all homology-sensing mechanisms is rather poor. So is our understanding of the connections between the meiotic long-distance pairing, meiotic *trans*-sensing, and recombination. The process of meiotic long-distance pairing must involve *trans*-sensing between chromosomal segments, but the relationship between these kinds of sensing and that of the *trans*-sensing that activates meiotic silencing is unknown. For the sake of simplicity, we therefore consider the *trans*-sensing that

Rodolfo Aramayo and Robert J. Pratt, Department of Biology, Texas A&M University, College Station, TX.

is involved in the early evaluation of every chromosomal DNA segment and the one involved in meiotic silencing as being the same. The *trans*-sensing between the genomes participating in meiosis occurs concomitantly with the coalignment of homologous chromosomes and requires extensive searching and satisfaction of stringent molecular homology criteria before recombination is allowed. The perceived absence of such an equivalent DNA segment as "sensed" by this meiotic "*trans*-sensing" mechanism triggers in many organisms the establishment of unique chromatin architectures such as those mediated by histone modifications and specialized nonhistone proteins early in meiosis (Ivanovska and Orr-Weaver, 2006; Prieto et al., 2004). In *Neurospora*, the lack of a homologous region triggers, we think, the destruction of RNA molecules with homology to the "nonhomologous" region. This uses core components of the RNA silencing pathways found in other organisms. At the molecular level the only well-understood homology-sensing process is recombination, a process whose final product appears relatively late in meiosis. Importantly, not only does homology sensing play a critical role in blocking ectopic recombination, but also its absence can clearly have catastrophic consequences for the organism (Bourc'his and Bestor, 2004). Perhaps it is therefore not surprising to find that the same molecular mechanisms used by many types of cells to recognize and suppress viruses, retrotransposons, and insertion sequences have been either adapted from, or adapted to, meiotic mechanisms optimized to maintaining genome integrity. One such example is meiotic silencing.

A WORD ABOUT *NEUROSPORA* BIOLOGY

Understanding meiotic silencing in *Neurospora* requires knowledge about the life cycle of *N. crassa* (reviewed by Davis and de Serres, 1970) (Fig. 1). *N. crassa* is a heterothallic filamentous fungus with two nonswitching mating types, *A* and *a*. It grows vegetatively as a multinucleate mass of interconnected hyphal cells called mycelia. Asexual reproductive development involves the production of aerial hyphae from which conidiophores form chains of terminal asexual spores called conidia. Conidia can germinate to form a new mycelial network, thus completing the vegetative cycle. Under poor nitrogen and low-temperature (i.e., 25°C) conditions, sexual development is activated. From these sexually competent tissues and at discrete locations hyphal knots are formed and later develop into female structures called protoperithecia. Special receptor hyphae called trichogynes emanate from the protoperithecia to search for male cells of the opposite mating type. Fertilization occurs by the fusion of the trychogyne and a male cell (i.e., plasmogamy). Following fertilization, the male- and the female-derived nuclei coexist in a heterokaryotic tissue and divide mitotically until they are sorted into dikaryotic tissue, in which each cell compartment

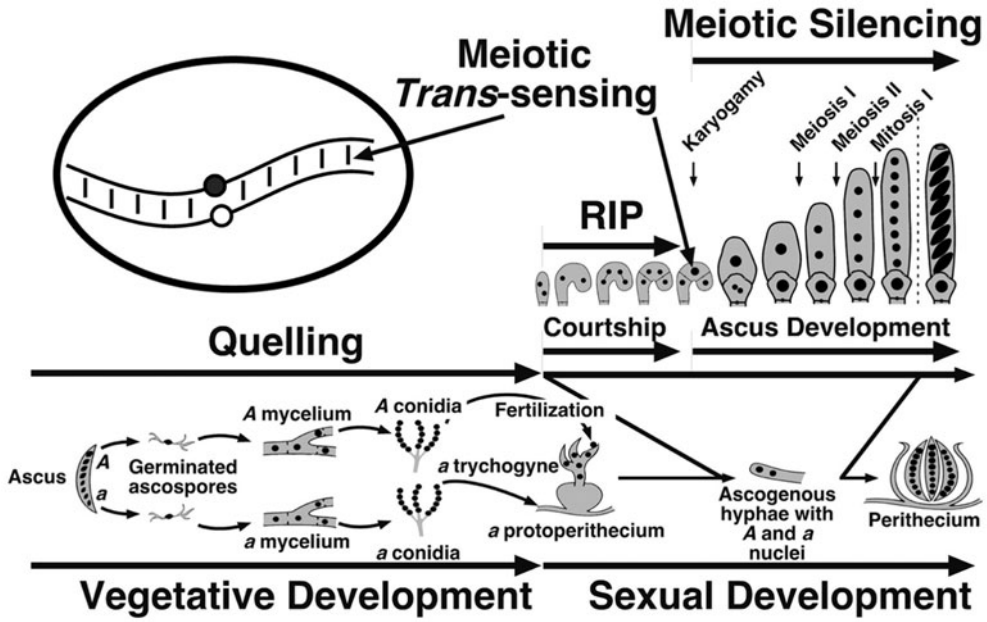

FIGURE 1 Genome defense mechanisms in the life cycle of *N. crassa*. *Neurospora* has two mating types, *A* and *a*. Sexual spores (ascospores) are formed when strains of opposite mating type mate and undergo sex. Germinated ascospores form mycelia from which asexual spores (conidia) are produced. Mating occurs when, in response to nitrogen starvation, a strain (either A or *a*) forms a protoperithecium (female element) that is fertilized by a male element of the opposite mating type to initiate perithecium development. After fertilization, the male- and the female-derived nuclei coexist in a heterokaryotic tissue and divide mitotically until they are sorted into a dikaryotic tissue (dikaryotic cells contain only one nucleus of each mating type). The nuclei then pair and undergo a series of synchronous mitoses until the tip of the hyphal cell in which they reside bends to form a hook-shaped cell called a crozier. One crozier will originate one ascus, containing eight ascospores. The time and places in the life cycle where quelling, RIP, meiotic *trans*-sensing, and meiotic silencing occur are indicated. Homologs pair inside the only diploid nucleus present in the zygote, immediately after karyogamy. The oval representing a diploid nucleus shows only one pair of chromosomes in the process of sensing. (Adapted from *Chromosome Research* **15:**633–651, 2007.)

contains only one nucleus of each mating type. The nuclei then pair and undergo a series of synchronous mitoses until the tip of the hyphal cell in which they reside bends to form a hook-shaped cell called a crozier. There, the two nuclei undergo a coordinated mitosis yielding, after septum formation, a uninucleate basal or antepenultimate cell, a uninucleate lateral or tip cell, and a dinucleate penultimate ascus mother cell that contains one nucleus of each mating type. It is in this ascus mother cell that karyogamy, meiosis, and postmeiotic mitosis take place. After the first mitosis, the resulting eight nuclei inside the ascus are then compartmentalized, resulting in an ascus cell that contains eight haploid spores arrayed in an order that reflects their lineage (Raju, 1980, 1992). One perithecium may contain up to 200 developing asci. Ascospores are then forcefully ejected from the beak of the perithecium. These ascospores, after ejection, continue to mature for a few days, after which they can be readily germinated following brief exposure to high temperature (~60°C for 40 min). Germinated ascospores produce vegetative mycelia, thus completing the sexual cycle. Because *Neurospora* is hermaphroditic in nature, strains of either mating type can act as either females or males. The ability to perform directional crosses adds to the already impressive power of *Neurospora* genetics. Meiotic segregation and recombination can be studied in *Neurospora* by analyzing individual asci (tetrads) or random spores ejected from numerous asci (Davis and de Serres, 1970; Perkins, 1966; Perkins, 1988).

GENOME DEFENSE IN *NEUROSPORA*

Genomes like that of *N. crassa* have developed a number of complex defenses to preserve their integrity (Borkovich et al., 2004; Galagan et al., 2003). At least four distinct but potentially interrelated mechanisms are known: DNA methylation, quelling, repeat-induced point mutation (RIP), and meiotic silencing by unpaired chromatin/DNA (Fig. 1). During haploid vegetative growth, AT-rich elements that invade the genome may be detected and densely methylated (Freitag et al., 2001; Miao et al., 2000; Romano and Macino, 1992; Singer et al., 1995). Multicopy elements can also activate quelling, a posttranscriptional silencing mechanism (Cogoni, 2001; Cogoni and Macino, 1999b; Cogoni and Macino, 2000; Pickford et al., 2002). Once activated, quelling produces diffusible signals (i.e., small interfering RNAs [siRNAs]) that block the propagation of the repeated element by RNAi-mediated degradation of its transcript (Catalanotto et al., 2002). If nuclei containing repeated DNA elements enter the sexual phase of the life cycle, the sequences are subjected to RIP (Freitag et al., 2002; Selker, 1990, 1997). In this process, GC-to-AT transition mutations are introduced into the duplicated sequences, presumably by unrepaired deamination of methylated cytosines. Many of the remaining, nonmutated cytosine bases are kept methylated by DIM-2, a DNA methyltransferase responsible for all known cytosine methylation in *Neurospora* (Kouzminova and Selker, 2001). Additionally, these sequences can be associated with trimethylated histone-H3, lysine-9 (H3K9me3) heterochromatin and transcriptionally repressed (Rountree and Selker, 1997; Tamaru et al., 2003). Remaining elements are scrutinized during meiosis by *trans*-sensing, which identifies the unsuccessful pairing of discrete DNA regions due to the presence of a heterologous region or the presence of a deletion on the opposite chromosome (i.e., the lack of a homologous region). This failure to "sense" a homologous region triggers an RNAi-mediated silencing mechanism that has been termed MSUD (meiotic silencing of unpaired DNA) (Shiu et al., 2001). Unfortunately, the acronym MSUD (maple syrup urine disease) is most commonly used to refer to a human disorder that abnormally affects the metabolism of amino acids and has been in use since 1975 (Wendel et al., 1975). To avoid further contamination of the scientific literature, we highly discourage its use.

Unlike quelling and RIP, there is no direct evidence that meiotic silencing is effective in preventing the spread of repeated elements in meiosis. The lack of active transposable elements in this organism and the fact that meiotic silencing can be detected in all laboratory strains tested as well as in many other isolates of this organism from nature suggest the possibility that meiotic silencing's true function/mechanism still remains to be discovered. One thing is clear, whatever that role might be, it must be related to some aspect of symmetry evaluation in meiosis. Based on what we know at this moment, however, the idea of meiotic silencing can be best explained in the context of a transposable infection (Fig. 2A). Imagine sex between two haploid parents (parents *A* and *a*), one of which was infected by a transposable element in the previous vegetative cycle. For simplicity, our discussion focuses on only one pair of homologous chromosomes (*Neurospora* has seven). These pairs of homologous chromosomes will first undergo premeiotic DNA replication, generating sister chromatids attached along their length by cohesin. The participating parental nuclei will then fuse at karyogamy, generating a diploid nucleus. Early in meiosis these homologous chromosomes will first *trans*-sense (i.e., evaluate their degree of mutual identity) and then synapse with each other, a process characterized by the distinct formation of a proteinaceous structure called the synaptonemal complex, which forms between the homologs (reviewed by Raju, 1980; and Zickler, 2006). In our model, the new transposable element, along with all of the other regions on the homologous chromosome, will undergo *trans*-sensing with the regions on the homolog. However, the transposable element will fail to detect a homologous region at the allelic location on its homolog and will be identified and tagged as unpaired DNA or chromatin. In *Neurospora* this would have a meaningful consequence, because the detection of this unpaired chromatin/DNA would trigger meiotic silencing. This would result in the production of a signal, perhaps siRNAs or Piwi-interacting RNAs (piRNAs), that would now target any transcript(s) from this unpaired region and from any other homologous region(s) of the genome for destruction. Once activated, meiotic silencing continues to occur as homologous chromosomes separate at the end of meiosis I, as sister chromatids separate at meiosis II and until after the first mitosis. It is at this stage, when each nucleus is enveloped in a membrane that signals the start of the process of cellularization, when the nuclei are encapsulated into individual ascospores, that meiotic silencing stops and silencing is reset.

By using these silencing mechanisms, *Neurospora* can protect its genome from parasitic nucleic acids during all stages of its life cycle. Perhaps providing evidence for the combined effectiveness of these strategies, there is only one known functional transposable element in *Neurospora*, and this is present in only 1 of more than 300 wild isolates of *Neurospora* from around the world (Kinsey, 1989; Kinsey and Helber, 1989). Attesting to the functionality of these mechanisms, when this transposable element was introduced into laboratory strains of *Neurospora*, its copy number was repressed in a quelling-dependent manner (Nolan et al., 2005) and existing duplications were inactivated by RIP (Cambareri et al., 1994). Similarly, it is clear that other transposable elements

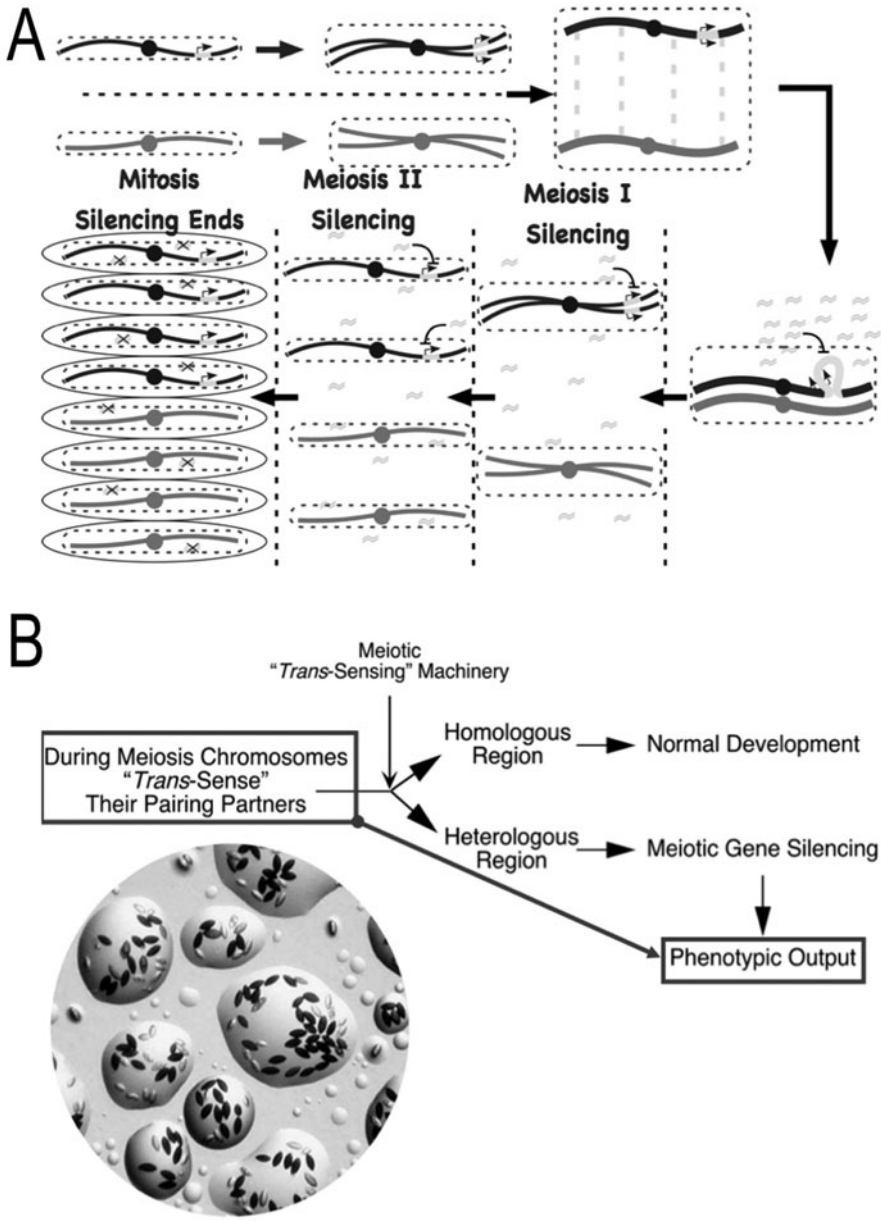

FIGURE 2 Meiosis, meiotic *trans*-sensing, and meiotic silencing. (A) Homologous chromosomes are represented by the squiggly lines contained inside the dashed rectangles. The temporal stage during which the prekaryogamic events occur inside the haploid A and *a* nuclei is represented by the horizontal dashed line. The stages where cell division occurs are indicated by vertical lines. The active comparison between chromosomal regions that occurs during meiotic *trans*-sensing and recombination is represented by the vertical dashed lines connecting the homologous chromosomes participating in the process. The clear region located on one chromosome represents a transposable or an insertion element. The small squiggly lines represent a hypothetical diffusible signal containing the sequence information from the unpaired region. Meiotic silencing uses this sequence information to silence homologous regions. (B) Depiction of the close connection seen in *Neurospora* between meiotic *trans*-sensing and silencing. The resultant phenotypic output, which may or may not reveal the result of meiotic gene silencing, can be detected by the use of appropriate reporters, which, according to their nature can affect the color and/or the shape of the ascospores product of the cross. The close temporal and developmental connection between meiosis and spore formation makes of *Neurospora* one of the most, if not the most powerful model system available for studying the molecular mechanisms behind meiotic *trans*-sensing. See the text for more details.

have tried their luck in *Neurospora* and failed, as evidenced by the presence of their RIP-mutagenized relics in the genome (Selker, 1990). Given this extensive "genome paranoia," it is not surprising that duplicated elements of any sort, including paralogous genes, are rare in *Neurospora* (Borkovich et al., 2004; Galagan et al., 2003).

THE DISCOVERY OF MEIOTIC SILENCING

The study of mutants affecting sexual development in *Neurospora* started in 1935 (Dodge, 1935, 1946). In 1972 and 1975 female and male sterile mutants, respectively, of *N. crassa* were identified (Mylyk and Threlkeld, 1974; Vigfusson and Weijer, 1972; Weijer and Vigfusson, 1972). These studies were then followed in 1975 by what is perhaps the earliest description of a *Neurospora* meiotic mutant, *meiotic-1* (*mei-1*), by David Smith (Smith, 1975). In 1978, Thomas Johnson published an elegant study on the isolation and characterization of perithecial development mutants in *N. crassa* (Johnson, 1978), a study that was followed by a report by A. M. DeLange in 1980, describing an exhaustive search for meiotic mutants (DeLange and Griffiths, 1980a, 1980b). In all these early studies, the key signature for meiotic mutants of *Neurospora* was, invariably, the production of white ascospores. These were interpreted as being the result of irregular segregation of chromosomes during meiosis. The rule was as follows: white or hypohaploid ascospores are aborted aneuploid products of meiosis, while reciprocal hyperhaploid ascospores develop normal black pigmentation and have good germination and viability (Smith, 1975). Concurrently with the search for meiotic mutants, the development of DNA-mediated transformation for *Neurospora* (Case et al., 1979) opened the way for the discovery of RIP (Selker, 1990). Hints of the instability of repeated sequences in *Neurospora* came from the strikingly different behavior observed for tandem duplications during the vegetative and the sexual phases of the life cycle. During vegetative growth, tandem duplications tend to be relatively stable. Duplications resulting from integration of transforming DNA by homologous recombination are lost at low but detectable frequency. In contrast, these same repeats are not stable in the sexual phase of the life cycle. Because the primary transformants were generally heterokaryotic (i.e., carried both transformed and untransformed nuclei), it was a common laboratory practice to obtain homokaryotic transformants by crosses prior to their characterization. Results from these crosses were not always clear. The transformation markers participating in these crosses were commonly observed to give a non-Mendelian inheritance, whose explanation was attributed to be the result of RIP mutagenesis of the transformation-generated repeats (Case, 1986; Case et al., 1979; Dhawale and Marzluf, 1985; Kim and Marzluf, 1988; Selker, 1990). The discovery of RIP opened a new and arguably very convenient way to inactivate genes in *Neurospora*, but unfortunately, it also obscured the identification and delayed the discovery of meiotic *trans*-sensing and silencing in *Neurospora*, because mutants in genes that might have been good targets for silencing could not have been obtained by crosses.

The discovery of meiotic *trans*-sensing and silencing was the result of the generation of an *Ascospore maturation-1* (*Asm-1*) deletion mutant of *Neurospora* by standard gene replacement and not by RIP (Aramayo and Metzenberg, 1996). We determined that the product of *asm-1*$^{+}$ (ASM-1) is an abundant nuclear protein essential for the formation of aerial hyphae, the development of protoperithecia, and the maturation of the ascospores (Aramayo and Metzenberg, 1996; Aramayo et al., 1996). Strains carrying deletion alleles of *Asm-1* do not form aerial hyphae but instead form "stunted" hyphae, a phenotype that resembles the one observed for the equivalent mutant of *Aspergillus nidulans* (Breakspear and Momany, 2007; Busby et al., 1996; Dutton et al., 1997; Miller et al., 1991, 1992; Wu and Miller, 1997). They are also female sterile, as revealed by their inability to form protoperithecia. A DNA fragment carrying both the promoter and coding region of the gene integrated at an ectopic location can readily complement these vegetative phenotypic defects. Obviously, the ectopically located complementing fragment can direct the production of wild-type transcripts and protein products and complement the deletion defect. These observations clearly established that *Asm-1*$^{\Delta}$ deletion alleles are recessive to the inserted complementing fragment, a property these alleles share with frameshift mutant alleles of the gene (e.g., *asm-1*^{fs}).

Despite the fact that both *Asm-1*$^{\Delta}$ deletion alleles and *asm-1*^{fs} frameshift alleles have the same vegetative mutant phenotype, these alleles have strikingly different genetic behavior in meiosis. During sexual development, the spores that inherit recessive, loss-of-function alleles of *Asm-1* cannot mature, whereas spores containing wild-type alleles mature normally. This was established by observing that in *asm-1*$^{+}$ × *asm-1*^{fs}, spores that carry the *asm-1*^{fs} allele do not mature, whereas those inheriting wild-type versions of the gene do. Given that the gene product of *Asm-1* is a protein that carries all the signatures of a DNA binding protein, we postulated that ASM-1 is a transcription factor required for the expression of genes involved in ascospore maturation. That is, its gene product is not required for meiosis I and II or mitosis I and II, but it is required to jump-start the system only after cellularization. This would explain the spore-specific requirement of the gene product.

Surprisingly, we observed that in *asm-1*$^{+}$ × *Asm-1*$^{\Delta}$ crosses, the *Asm-1*$^{\Delta}$ deletion allele was ascus dominant. That is, all spores within the ascus fail to develop, including the ones carrying the *asm-1*$^{+}$ allele. The behavior of *Asm-1*$^{\Delta}$ alleles was both puzzling and apparently contradictory, as the gene was being dominant by being absent. These observations were originally regarded to be the result of genetic "haploinsufficiency," a genetic term that describes a diploid phenomenon by which the product of a single functional allele of a gene is unable to confer a wild-type phenotype to the organism. Of course, if this were the case with *Asm-1*$^{\Delta}$ and the developmental deficiency observed were in fact due to haploinsufficiency, then a cross containing any two functional copies and the deletion would remedy the spore maturation defect. This could be tested by isolating a strain carrying the deletion allele and a functional copy of the gene inserted ectopically and then crossing it to a wild-type strain [i.e., *asm-1*$^{+}$ × *Asm-1*$^{+}$ (ectopic)]. However, even in this case a crop of immature spores was also observed. These results could not be easily reconciled with the idea that the dominance of *Asm-1*$^{\Delta}$ was due to haploinsufficiency (Aramayo and Metzenberg, 1996). Rather, they suggested that the unpaired copies of the gene were in fact misbehaving.

But how could genes be dominant by being absent in the homologous chromosome? The apparent genetic contradiction was resolved by the discovery of the connection between this phenomenon and RNA silencing (Shiu et al., 2001). Metzenberg and colleagues demonstrated that the meiotic silencing of unpaired DNA appears to be posttranscriptional because mutations in an RNA-dependent RNA polymerase (RdRP) gene, *Suppressor of ascus dominance-1* (*Sad-1*), suppress the ascus dominance exerted by unpaired copies of

Asm-1 or other reporter genes (Shiu et al., 2001). In light of this observation, in an *asm-1*$^{+}$ × *Asm-1*$^{\Delta}$ cross, what is really happening is that the unpaired wild-type allele is exerting its dominance by producing an abnormal diffusible product as a result of its failure to pair with its partner in the homologous chromosome. Further experiments demonstrated that pairing of the *Asm-1* gene, regardless of where it occurs, is essential for its normal expression and ascus development, and it was postulated that paired alleles could "sense" (i.e., *trans*-sense or undergo meiotic *trans*-vection) the presence or absence of their partners in homologous chromosomes (Aramayo and Metzenberg, 1996). Furthermore, failure to sense an intact and appositionally localized copy on the homologous chromosome caused silencing of copies positioned elsewhere in the genome, regardless of their own pairing status (Lee et al., 2004; Shiu et al., 2001). Meiotic *trans*-sensing and meiotic silencing are two highly interrelated but different mechanisms that together scan and control the integrity of the genomes that participate in meiosis.

INDUCTION AND DETECTION OF MEIOTIC SILENCING

Chromosomes appear to "sense" the presence of homology and/or identify small regions of nonidentity within their homologs in early meiotic stages. If the regional identities are equivalent above a certain threshold, development proceeds normally. If not, meiotic *trans*-sensing machinery is activated and targets homologous sequences in the genome, regardless of their own pairing status (Fig. 2B). Some of the quantitative and qualitative aspects of the sensing threshold have been addressed experimentally, and at least two types of silencing (i.e., *cis-* and *trans-*) have been described (see below) (Lee et al., 2004). Quantitatively, the following observations have been made. (i) Given one small loop and one large loop of unpaired DNA, both carrying the same identical length of DNA homologous to a set of paired reporter genes, the large loop will silence more efficiently than the smaller one. (ii) Given two loops of identical size, but one carrying twice as much DNA homologous to a set of paired reporter genes, this more homologous loop will silence more efficiently than the one carrying the same amount of homologous DNA. (iii) The silencing signal produced by an unpaired loop is confined to the unpaired region and does not "spread" to neighboring regions (e.g., paired reporter genes can be located next to a region of unpaired DNA without being significantly perturbed). (iv) The canonical promoter of a gene need not be present in the loop of unpaired DNA for a gene to be silenced. (v) Meiotic silencing does not affect the ability of a promoter to direct transcription at a later developmental time (Kutil et al., 2003; Lee et al., 2003, 2004; Pratt et al., 2004).

In theory, to detect meiotic silencing, any gene whose gene product is required for the completion of meiosis, the reestablishment of mitosis, the cellularization, and/or maturation of the ascospores can be used. Similarly, genes whose gene products are essential structural components of the ascus would work. However, experimentally it is easier to assay meiotic silencing by performing crosses in which a reporter gene, typically a native gene required for ascospore morphology or color, is unpaired. Importantly, the use of genes whose sexually specific gene products have already completed their function before or at karyogamy is not recommended, as they would escape silencing, as would any gene products that either are not expressed or are dispensable for sexual development, unless, of course, they are fused to a fluorescent marker like green fluorescent protein (*gfp*$^{+}$).

The ratio of ascospores with mutant and wild-type phenotypes can be determined using reporters whose silencing results in an abnormal spore phenotype. An example with the reporter gene *Roundspore* (*Rsp*) and the meiotic silencing component *Sad-1* is shown in Fig. 3. In crosses between wild-type strains and strains carrying recessive loss-of-function alleles of *Rsp*, e.g., a single-nucleotide insertion creating a frameshift (*rsp*^{fs}), the *Rsp* alleles from both parents detect sufficient homology by *trans*-sensing so as not to trigger meiotic silencing (Fig. 3A). In this cross the "normal" expression of the only functional allele of *Rsp* (i.e., *rsp*$^{+}$) remains unaltered. The gene product produced by this allele produces enough mRNA and protein to confer a "wild-type" phenotype to the developing genotypically heterozygous diploid ascus cell. All of the ascospores have a spindle-shaped morphology. As expected, crosses homozygous for the recessive loss-of-function allele of *Rsp* (i.e., *rsp*^{fs}) produce asci containing eight round ascospores (Fig. 3B). No functional *Rsp* gene product is present in this situation. In contrast, if the *rsp*$^{+}$ alleles participating in this cross cannot sense their partners on the opposite homologous chromosome, for instance, when the mating strain carries deletion alleles of *Rsp* (i.e., *Rsp*$^{\Delta}$), all ascospores have a round or ovoid morphology. This situation triggers *cis*-meiotic silencing (Fig. 3C), a process that requires the participation of SAD-1 and that of other gene products involved in the process. As a result, silencing of *rsp*$^{+}$ is effective in the ascus. Therefore, unlike alleles carrying point mutations, deletion alleles of *Rsp are* ascus dominant and their behavior violates Mendelian law (at least at the level of phenotype), since all ascospores appear to be mutant, even those that contain functional *rsp*$^{+}$.

It should be noted that, similarly to deletion alleles, some RIP alleles (mutant alleles generated through RIP mutagenesis) exhibit dominant behavior in meiosis. Significant sequence deviation between homologous alleles, as opposed to deletions or insertions, is also sensed and can trigger repression. The degree of identity that is required to escape *trans*-sensing and avoid triggering meiotic silencing suggests that the *Neurospora* system has very stringent standards for defining homology (Pratt et al., 2004). This has been assessed by crossing strains carrying wild-type alleles of meiotic reporter genes with strains carrying varying degrees of mutation (generated by RIP) in the homologous locus. The mutated alleles, if sufficiently different, would confer a dominant phenotype by triggering meiotic silencing and repressing the wild-type gene. Amazingly, as little as 6% sequence divergence (or 94% identity) could trigger low detectable silencing, yet a slight increase of identity to 97% (or 3% divergence) prevented significant silencing (Pratt et al., 2004). Furthermore, the methylation status of the RIP-mutated alleles shifted the sequence identity threshold, such that methylated mutant alleles were detected as having worse identity to the wild-type allele than unmethylated ones (Pratt et al., 2004). This suggests that either the 5-methylcytosines contribute to heterology as a "fifth base" or their effects on chromatin structure (by recruitment of methylated DNA binding proteins, etc.) impact on homology recognition. These contributions are not mutually exclusive, and thus, both may contribute to identification and pairing. We therefore refer to deletion and RIP alleles as indels and homologous inducers of meiotic silencing, respectively. Similarly, if a wild-type strain is crossed to a partner containing an ectopic copy of *Rsp* (e.g., by directed insertion at the *his-3* locus), the ectopic allele will be unpaired and will trigger the silencing of all *Rsp* alleles

regardless of whether the other alleles are themselves paired or unpaired. Again round ascospores are produced (Fig. 3D). We refer to the type of silencing where paired regions must be silenced as *trans*-silencing.

In *Neurospora*, testing the involvement of genes in meiotic silencing is not straightforward. The diploid nature of the meiotic cell makes it difficult to identify recessive alleles in genes involved in the process. In addition, the meiotic lethality observed in crosses homozygous for loss-of-function alleles complicates the conceptually simple experiment of assaying meiotic silencing in the complete absence of the candidate gene's gene product (e.g., *Sad-1* [Fig. 3E]). The best known experiments that can be done are to assay the degree of meiotic silencing in crosses heterozygous for the candidate gene (e.g., *Sad-1* [Fig. 3F]). In this situation, the *cis*-silencing is expected to significantly decrease the amounts of transcript and protein below that which is expected from a single functional gene. According to this logic, if there is enough active SAD-1 protein in heterozygous crosses (probably synthesized before the *sad-1*$^+$ gene is silenced) to allow meiosis to proceed, but not enough to maintain fully functional meiotic silencing machinery, we should then be able to determine the involvement of *sad-1*$^+$ in meiotic silencing. The suppression of meiotic silencing or the "silencing the silencer" strategy has been widely used in the identification of several components of meiotic silencing. Once meiotic silencing is activated, the process is dominant. It should be noted, however, that not all loss-of-function alleles of meiotic silencing components are equally dominant, perhaps as a result of their involvement in different steps of the meiotic silencing pathway. Ultimately, the output of these experiments is, by convention, a percentage of wild-type ascospores. For reporter genes, the stronger the silencing, the lower the percentage of ascospores or asci with a wild-type phenotype. For suppressors, the stronger the suppression of silencing, the higher the percentage of ascospores or asci with a wild-type phenotype. It should always be kept in mind that these numbers represent the output of two events, meiotic *trans*-sensing and meiotic silencing, and the relative contribution of each to this percentage is still unclear. For example, one can imagine that once induced, meiotic silencing is always 100% effective within an ascus. If so, the output is a direct measure of the efficiency of meiotic *trans*-sensing or of the frequency at which unpaired DNA is detected. The converse is also potentially true; unpaired DNA is always detected but the efficiency of meiotic silencing varies. Additionally, of course, the output could be a combination of both efficiencies.

At what level is the known meiotic machinery involved at this level of homology sensing? Recent data suggest that the stable long-distance pairing (i.e., alignment), short-distance pairing (i.e., synapsis), recombination, and segregation steps of chromosome pairing in meiosis are all dispensable for meiotic silencing. Mutations in *spo-11*, *ski-8*, *Msh-4*, *mei-1*, *Mei-2*, and *mei-3*, which cause severe defects or eliminate synapsis and/or recombination, do not abrogate gene-specific silencing despite global asynapsis (R. J. Pratt and R. Aramayo, unpublished data). *spo-11* and likely *ski-8* mutants fail to stably align their chromosomes (Bowring et al., 2006; Tesse et al., 2003). This suggests that *trans*-sensing and the triggering of meiotic silencing may occur during an earlier, unstable chromosome alignment stage of meiosis upstream of mechanisms guiding synapsis. Very little is understood about these early events in chromosome recognition; but it is conceivable that the mechanisms involved in this *trans*-sensing use features of homology recognition mechanisms present in all organisms. Alternatively, *trans*-sensing could occur through a novel parallel independent pathway, perhaps through a mechanism similar to programmed DNA elimination in ciliates (discussed below).

RNAi AND MEIOTIC SILENCING

A role for RNAi has been strongly inferred by the identification of genes required for *Neurospora* meiotic silencing. RdRPs have been identified as essential components of RNAi in several organisms, and a separate RdRP, QDE-1, has been shown to be essential for quelling, the vegetative RNAi silencing process (Cogoni and Macino, 1999a). Further screens for meiotic silencing factors identified two other additional RNAi-related genes: one coding for an Argonaute-like protein, *Suppressor of meiotic silencing-2* (*Sms-2*) (Lee et al., 2003); and the other coding for a Dicer-like protein, *Suppressor of meiotic silencing-3* (*Sms-3*) (Alexander et al., 2007; D. W. Lee and R. Aramayo, unpublished data). Several other *Sms* mutants have also been identified (R. J. Pratt, D. W. Lee, and R. Aramayo, unpublished data). In addition, the posttranscriptional gene silencing nature of meiotic silencing was confirmed using transgene reporters. Only regions containing homology to the reporter transcript result in silencing when unpaired (Lee et al., 2004). Based on these observations, a model for RNAi's involvement in meiotic silencing was postulated (see Fig. 2 in Lee et al., 2003).

The *Sad-1*, *Sms-2*, and *Sms-3* orthologs in the fission yeast *Schizosaccharomyces pombe* (Rdp1, Ago1, and Dcr1, respectively) constitute the main RNAi pathway in this organism (Volpe et al., 2002). The RNAi pathway in *S. pombe* is essential for normal chromosome biology, including heterochromatin formation (e.g., histone H3K9 methylation) and normal centromere and telomere functions (Martienssen et al., 2005). In contrast, strains carrying loss-of-function mutations in any of the components of the meiotic silencing pathway (i.e., *Sad-1*, *Sms-2*, or *Sms-3*) of

FIGURE 3 Meiotic silencing in *Neurospora*: detection and suppression. Simplified views of the genetic composition of the participants in, and of the predicted phenotypic outputs of, several different crosses are presented using *Rsp* as a reporter gene. (A) In crosses where the diploid is *sad-1*$^+$/*sad-1*$^+$ *rsp*$^+$/*rsp*$^{\text{frameshift (fs)}}$, silencing of the reporter gene *Rsp* is not activated due to the lack of unpaired chromatin/DNA. As a result, the sole functional copy of *Rsp* can complement the heterozygous *Rsp* condition, which results in the production of wild-type spindle-shaped ascospores. This observation establishes that the product of *Rsp* acts before cellularization and that all spores, regardless of their individual genotypes, are spindle shaped. (B) As expected, in crosses where the diploid is *sad-1*$^+$/*sad-1*$^+$ *rsp*^{fs}/*rsp*^{fs}, all spores are round, which establishes that it is the product of *Rsp* that controls spore shape. (C to F) A box represents the diploid stage. Inside it, only one homologous chromosome pair is depicted with the *Sad-1* and the *Rsp* loci indicated. A predicted ascus product of the cross is shown to the right of the diploid cell. Arrows represent SAD-1 activity, and bars represent silencing. The thickness of these lines represents relative levels of silencing or activity. (C) Unpaired *rsp*$^+$ resulting in *cis*-silencing. (D) Unpaired ectopic *rsp*$^+$ resulting in *trans*-silencing. (E) In the absence of functional product of *Sad-1*, development stops at the pachytene stage of meiosis I. This makes the evaluation of the presence or absence of silencing by use of *Rsp* impossible. (F) The dominance of the *Rsp*$^{\Delta}$ allele can be suppressed in crosses heterozygous for *Sad-1*. See the text for details.

Neurospora do not have a discernible vegetative phenotype. In addition, whereas DNA methylation in *Neurospora* requires a histone H3K9-specific methyltransferase, this activity is independent of RNAi (Freitag et al., 2004), and there is no evidence that transcriptional repression accompanies meiotic silencing (Lee et al., 2004). However, all of the genes required for meiotic silencing in *Neurospora* are also required for fertility (Lee et al., 2003; Shiu et al., 2001; Lee and Aramayo, unpublished), indicating that components of the meiotic RNA silencing pathway are required for the completion of sexual development and/or meiosis and that these processes are intimately codependent.

A MODEL FOR MEIOTIC RNA SILENCING

Once identified, regions of nonhomology are predicted to produce some form of aberrant RNA, which is converted into double-stranded RNA (dsRNA) by the action of the RdRP SAD-1 (Fig. 4). The presence of dsRNA triggers the initiation step of the pathway, which could involve the

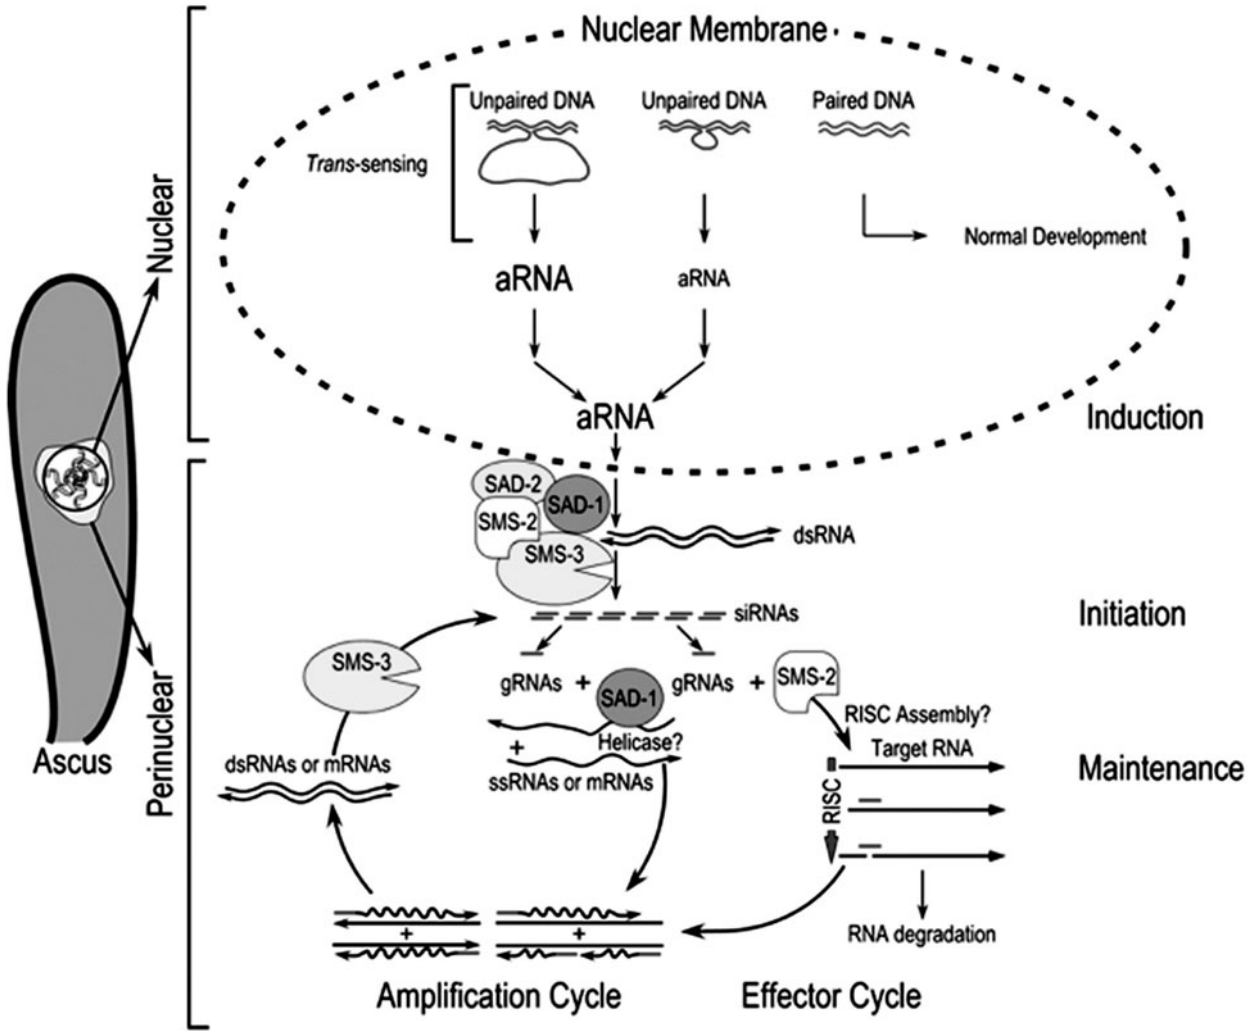

FIGURE 4 A model for meiotic silencing. An ascus at the pachytene stage of meiosis I is presented. Inside this cell, the meiotic nucleus, delineated by its nuclear membrane, apparently remains intact and is surrounded by a perinuclear structure that supports the attachment of components of the meiotic silencing apparatus. Inside the nucleus unpaired DNA (not paired DNA) induces meiotic silencing of homologous regions. The degree of unpairing determines the strength of the induction step, which presumably involves the synthesis of aberrant RNA (aRNA) and its conversion to double-stranded RNA (dsRNA) by the SAD-1 RdRP. The presence of dsRNA triggers the initiation of the meiotic RNA silencing process, which is composed of the following steps: the conversion of the dsRNA trigger into siRNAs via the SMS-3 Dicer (initiation step); the use of guide RNAs (gRNAs) as primers and single-stranded RNA (ssRNA) as a template by SAD-1 RdRP to generate dsRNA (amplification cycle); the incorporation of the gRNAs generated by both the initiation step and the amplification cycles into the RNA-inducing silencing complex (RISC), to direct the endonucleolytic cleavage of mRNA or ssRNA (effector cycle). It is possible that SAD-1 and SMS-2 maintain the silencing by participating in complexes related to the RdRP and the RNA-induced transcriptional silencing complexes detected in *S. pombe*, respectively.

conversion of the dsRNA trigger into siRNAs, although the presence of small RNAs with homology to the target sequence have not yet been observed. This step is predicted to be executed by the SMS-3/DCL-1 Dicer, because it is required for meiotic silencing (Borkovich et al., 2004; Catalanotto et al., 2004; Galagan et al., 2003; Lee et al., 2003). The maintenance of silencing probably involves amplification, also through SAD-1, and degradation of the target mRNAs via an RNA-induced silencing complex, of which the Argonaute-like protein SMS-2 is predicted to be an essential component, as in other conserved RNAi pathways (Lee et al., 2003). The lack of detectable siRNA-like molecules may be due to their rapid utilization and turnover, which may also contribute to the lack of silencing "memory" once sporulation is complete and homolog interactions are over (Lee and Aramayo, unpublished). Interestingly, the SAD-2 protein is also required for meiotic silencing, but its role appears to be to anchor or recruit the SAD-1 RdRP to the cytoplasmic face of the nuclear periphery (Shiu et al., 2006). This indicates that SAD-1's RdRP activity is required outside the nucleus, perhaps to screen RNAs as they transit nuclear pores as a sort of quality check. In any case, RdRP activity is likely a downstream effector of meiotic silencing and not a component of the *trans*-sensing mechanism that must necessarily be nuclear. An "RNA quality" monitoring system, however, implies that deficient pairing triggers production of aberrant transcripts to alert the system and hence that proficient recognition and pairing suppresses this transcription. Determining any role(s) for aberrant transcription in meiotic silencing awaits further analyses.

MEIOTIC SILENCING, A COMMON THEME IN MEIOSIS?

In the meioses of *Neurospora*, worms, and mice, gene expression from DNA that lacks a pairing partner is silenced. This meiotic silencing by unpaired DNA was first observed in *N. crassa* when it was shown that expression of a gene required for the maturation of sexual spores required proper meiotic pairing (Aramayo et al., 1996). These observations were reminiscent of the *trans*-vection phenomena previously observed in *Drosophila* (Lewis, 1954). Further investigations suggested that, rather than gene expression being activated or repressed by pairing, gene expression was being prevented by unpairing, probably by triggering an RNAi-like silencing mechanism acting on homologous mRNAs (Lee et al., 2003, 2004; Shiu et al., 2001).

Since then, meiotic silencing by unpaired chromatin/DNA has been discovered in both worms and mouse. Here, unpaired chromatin/DNA is associated with specific histone modifications and transcriptional silencing (Baarends et al., 2005; Bean et al., 2004; Turner et al., 2005). In worms, unpaired chromatin/DNA is imprinted and regains transcriptional activation at a slower rate than paired regions due to its ability to retain chromatin signatures related to silencing longer in the zygote (Bean et al., 2004). In mouse, meiotic silencing might be related to the meiotic sex chromosome inactivation observed during male spermatogenesis (Handel, 2004). The role of this inactivation is controversial but has been proposed as a mechanism for imprinting the paternal X chromosome for preferential inactivation in the murine placental tissues and marsupial embryos (Huynh and Lee, 2005; Okamoto et al., 2005). In both mouse and worms, there is a strong correlation between homologous and nonhomologous synapsis and transcriptional repression (Bean et al., 2004; Turner et al., 2005, 2006). In addition to the silencing of these large chromosomal regions, smaller unpaired regions in mouse spermatogenesis also seem to invite heritable epigenetic modifications and may be mechanistically related to the meiotic silencing phenomena observed in *Neurospora* (Herman et al., 2003; Rassoulzadegan et al., 2002, 2006).

While there are differences in the known properties of these phenomena, there is one key underlying theme: they all seem to identify regions of unpaired chromatin/DNA and target them for silencing. These silencing phenomena are considered epigenetic, because they result in a heritable, yet reversible, mutant phenotype in progeny that contain genes with a wild-type DNA sequence. By studying meiotic silencing in the genetically amenable and fast-growing filamentous fungus *N. crassa*, we expect to shed light on the properties and mechanisms of these and other potentially related epigenetic phenomena.

EVOLUTIONARY CONSERVATION AND FUNCTION OF MEIOTIC SILENCING

The ancient origins of meiotic silencing in all of its current manifestations are likely grounded in RNAi-mediated genome defense mechanisms. The role of RNAi in genome defense has been identified in many organisms. It is likely that the recognition of linear sequence heterology in meiosis, crucial for productive recombination, is also (and perhaps originally) a component of genome defense. The meiotic processes that we observe today may be partly a combined product of escalating warfare between genomes and invasive elements, with homolog recognition originating as a friend-or-foe assessment. Such *trans*-sensing and its connection to the meiotic recombination machinery are very poorly understood; but this *trans*-sensing could be related either to RNAi processes or to a separate process that has adapted RNAi mechanisms as the effector process in some organisms.

Although meiotic silencing is evident in highly diverse organisms, it appears to be absent in many as well, including yeast, flies, and at least some plants. Fission yeast, for example, seems to have all of the RNAi components required, albeit a minimal set, and has no meiotic silencing (A. Klar and R. Aramayo, unpublished data). However, recombination in this organism occurs without synapsis. Conversely, budding yeasts have synapsis but no RNAi components and no meiotic silencing (Anantharaman et al., 2002; Aravind et al., 2000). In *Drosophila,* synapsis is absent only in males, but there is no evidence for meiotic silencing in either sex, and an RdRP seems to be missing from the fly RNAi toolkit. Similarly, there are no obvious RNAi-related RdRPs encoded in mammalian genomes, yet mammals have both synapsis and meiotic silencing. However, meiotic silencing in mammals, as defined by meiotic sex chromosome inactivation and MSUC (meiotic silencing by unpaired chromatin), appears to be largely an adaptation of DNA repair pathways and, apparently, mechanistically quite distinct from RNAi. It remains to be determined, however, if the widespread antisense transcription observed in the mammalian transcriptome replaces the roles played by RdRPs in other organisms (Katayama et al., 2005). Finally, there are flowering plants, which have multiple isoforms of all RNAi components and full synaptonemal complex formation—but no clear demonstration as yet for meiotic silencing (V. Chandler, personal communication). A related phenomenon in plants, paramutation, is an interallelic, *trans*-sensing epigenetic process that requires an RdRP, *mop-1* (Chandler et al., 2000; Chandler and Stam,

2004). Paramutation may have originated from meiotic silencing but adapted later to operate in mitotic tissues.

The absence of either an RdRP or a synaptonemal complex may select against meiotic RNAi silencing or select for adaptation of a non-RNAi related mechanism. As mentioned for flies, the loss of meiotic synapsis could predispose for a further loss of meiotic silencing, if unsynapsed chromatin can be targeted for repression by this process. Similarly, loss of synapsis in fission yeast could have caused the loss of a mechanistic link between RNAi and meiotic silencing. The loss of an RdRP, on the other hand, would not cripple RNAi-related mechanisms but might decrease their sensitivity to endogenous substrates such as unpaired DNA.

Irrespective of the effector response in meiotic silencing, all sexually reproducing organisms must utilize some aspects of *trans*-sensing to detect homology between chromosomes while also creating a barrier to heterologous pairing. A number of transvective processes have been identified in diverse species—operating either within or outside meiosis. In many cases, these processes either have been determined or are predicted to have a mechanistic link to RNAi (Alleman et al., 2006; Herman et al., 2003; Rassoulzadegan et al., 2006; Wu and Morris, 1999). Genomic DNA elimination in *Tetrahymena* is a dramatic example of a *trans*-sensing process that involves RNAi (for a more informative review of this complex process, see Mochizuki and Gorovsky, 2004). These ciliates have two nuclei that share one cytoplasm: a transcriptionally inactive, diploid micronucleus and a transcriptionally active, polyploid macronucleus. The macronuclear DNA is a fragmented and amplified version of the micronucleus in which all repetitive DNA elements, including transposons, have been deleted (reviewed by Matzke and Birchler, 2005; and Mochizuki and Gorovsky, 2004). After conjugation, meiosis, and genome mixing, the old macronucleus is destroyed and a new macronucleus arises from a new, genetically mixed micronucleus—but any sequence not present in the old macronucleus is eliminated during new macronuclear maturation. The recognition process—a *trans*-sensing process between two separate nuclei—involves production of small, scanning RNAs from micronuclear transcription that are proposed to "scan" the old macronuclear genome. Those with homology (e.g., encoding essential loci) are degraded, whereas those with no homology (e.g., repetitive elements) are then used to guide elimination of homologous sequences in the new macronucleus. This results in a fragmented genome in which all repetitive elements have been eliminated, and the remaining gene-encoding sequences are amplified and transcribed during vegetative growth. The elimination-targeting mechanism is highly related to RNAi-mediated transcriptional silencing in plants and *S. pombe*, but ciliates have clearly found a more permanent way to silence the targets—by deleting them. It is interesting to consider that related genome-scanning mechanisms may be at work in meiotic *trans*-sensing.

From a genome protection perspective, it makes sense that organisms have developed a molecular mechanism like meiotic silencing to check the integrity of the genomes participating in meiosis. Meiotic silencing allows prevention of the expression of novel insertions (e.g., transposons) without necessarily affecting the regulation of adjacent genes. From an evolutionary perspective, however, meiotic silencing could also participate in speciation. Genomes evolving significant differences in genes required for germ cell/spore viability or meiotic progression could trigger *trans*-sensing alerts and meiotic silencing, leading to reproductive isolation from each other. In this context, Shiu et al. (2001) showed that mutations in *Sad-1*-RdRP significantly increased interbreeding efficiencies among various *Neurospora* species, indicating that a component of the species barrier in this organism is meiotic silencing (Shiu et al., 2001). Genomes could also accumulate a series of mutations or duplications in regions that house genes that are not required for meiosis without consequences to fertility. Heterochromatic regions of genomes, for example, may have become transposons "traps" partly because they are regions which transposons can invade without creating a meiotic silencing consequence. Heterozygous (novel) insertions would be recognized by *trans*-sensing and repressed to prevent further spread, but unless the genomic neighborhood housed meiotic loci that would be affected by any potential spreading of the repression, there would be no consequence to fertility. Duplications of genes involved in development, considered a major source of evolutionary complexity, would also be allowed.

The study of meiotic *trans*-sensing and meiotic silencing is therefore important not only from a mechanistic perspective (i.e., to understand how chromosomes pair and how homologous regions are detected) but also from an evolutionary point of view. Meiotic silencing may be another reproductive fitness test in the assessment of genomes that are brought together by sexual reproduction, and its potential role in genome evolution merits consideration.

We apologize for the exclusion, due to limited-space considerations, of information pertinent to organisms other than those included here. We also thank our colleagues and members of the Aramayo Lab for helpful discussions and/or the sharing of data unpublished at the time of this writing: Dong Whan Lee, Ana Victoria Suescun, Alexis Brown, Ryan Millimaki, and Aldrin Lugena. This work was supported by U.S. Public Health Service Grants GM58770 to R.A.

12

Mycoviruses

DONALD L. NUSS

Viruses of fungi (mycoviruses) were discovered much more recently than viruses of plants and animals and, with few exceptions, remain less well studied. This is understandable when one considers the modest economic importance of mycovirus infections, the relatively small size of the fungal research community, and the fact that the majority of mycovirus infections are asymptomatic. However, the last several decades have witnessed an increased interest in mycoviruses and a significant acceleration in the pace of mycovirus research. This has been driven, in part, by increased reports of mycovirus-mediated phenotypic changes in their fungal hosts that are considered to be fundamentally interesting and of potential practical value. Interest has been further stimulated by technical advancements in mycovirus molecular biology that have demonstrated the utility of mycoviruses as tools for probing mechanisms underlying fungal biology and for manipulating the fungal host. Complementary advances in the genomics of filamentous fungi are providing experimental systems with the rare capacity for facile genetic manipulation of both virus and eukaryotic host. This chapter provides a brief overview of viruses associated with filamentous fungi while highlighting recent developments in mycovirus molecular biology that illustrate the potential utility of mycoviruses for fundamental research and practical applications.

BRIEF OVERVIEW OF MYCOVIRUSES OF FILAMENTOUS FUNGI

Viruses of filamentous fungi, with the exception of the double-stranded DNA (dsDNA) rhizidioviruses isolated from the aquatic fungus *Rhizidiomyces* (Dawe and Kuhn, 1983), have genomes composed of RNA and are accommodated primarily within six taxonomic families: *Totiviridae*, *Partitiviridae*, *Chrysoviridae*, *Reoviridae*, *Narnaviridae*, and *Hypoviridae* (Table 1). Members of the family *Totiviridae* form icosahedral virions of approximately 40 nM in diameter that contain a single 4.6- to 7-kbp dsRNA (Wickner et al., 2005). The single genomic RNA encodes a capsid protein and an RNA polymerase protein that consists of the capsid protein fused with an RNA-dependent RNA polymerase (RDRP) domain as a result of a −1 ribosomal frameshift. Viruses of related genera within the family are found in the protozoan hosts *Giardia*, *Trichomonas*, and *Leishmania*.

Members of the family *Partitiviridae* also form small icosahedral virions, but the genome consists of two dsRNAs (1.4 to 2.2 kbp) that are individually packaged (Ghabrial et al., 2005a). One dsRNA encodes the capsid protein, and the second dsRNA encodes the RDRP. Viruses of two related genera of the *Partitiviridae* infect plants.

The family *Chrysoviridae* was originally listed as a genus of the family *Partitiviridae*. Members of this family also form 30- to 35-nm virion particles, but the genome consists of four unrelated, separately encapsidated dsRNAs of 2.4 to 3.6 kbp in size (Ghabrial et al., 2005b). Similar to what occurs for members of the *Partitiviridae*, the capsid protein and RDRP of members of the *Chrysoviridae* are encoded on separate dsRNAs. The functions of the proteins encoded by the other two dsRNAs have not been determined.

Reoviruses that infect fungi are organized within the genus *Mycoreovirus* of the extensive family *Reoviridae* (Mertens et al., 2005). Members of this genus contain 11 or 12 segments of dsRNA (732 to 4,127 bp) that are packaged within a large, ~80-nm, double-shelled spherical virus particle. Hosts for viruses constituting the 12 genera of the family *Reoviridae* include plants, animals, invertebrates, and lower eukaryotes.

Members of the families *Narnaviridae* and *Hypoviridae* are found only in fungal hosts and are distinguished by the absence of a capsid protein and, consequently, the inability to form true virions. The family *Narnaviridae* is comprised of the genus *Narnavirus*, which is restricted to viruses that infect *Saccharomyces cerevisiae*, and the genus *Mitovirus*, which contains viruses of filamentous fungi (Buck et al., 2005). The mitovirus genome consists of a 2.3- to 2.7-kb single-stranded RNA (ssRNA) that encodes a single protein containing RDRP motifs. Mitoviruses are associated with mitochondria, and the coding strand employs mitochondrial codon usage.

Confirmed members of the family *Hypoviridae* infect only the chestnut blight fungus *Cryphonectria parasitica* and are related phylogenetically to the potyviruses, a large group of

Donald L. Nuss, Center for Biosystems Research, University of Maryland Biotechnology Institute, Rockville, MD 20850.

TABLE 1 Primary mycovirus taxonomic families[a]

Family	Nature of genome	Genome size	Genome configuration	Virion[b]	Morphology (size in nm)
Totiviridae	dsRNA	4.6–7 kbp	1 segment	+	Icosahedral (40)
Partitiviridae	dsRNA	1.4–2.2 kbp	2 segments	+	Icosahedral (30–35)
Chrysoviridae	dsRNA	2.4–3.6 kbp	4 segments	+	Icosahedral (30–35)
Reoviridae	dsRNA	0.7–4.1 kbp	11 or 12 segments	+	Isometric (80)
Narnaviridae	ssRNA	2.3–2.7 kb	1 segment	−	Ribonucleoprotein complex
Hypoviridae	ssRNA	9–13 kb	1 segment	−	Pleomorphic membrane vesicles

[a]The unassigned genus *Rhizidovirus* contains dsDNA viruses from the aquatic fungus *Rhizidiomyces* (Dawe and Kuhn, 1983), and the genus *Barnavirus* contains the ssRNA, 4-kb, 1-segment, bacilliform virus particle found in the cultivated mushroom *A. bisporus* (Wright and Revill, 2005).

[b]+, virions are formed; −, no virions are formed.

ssRNA plant viruses (Nuss et al., 2005). Hypoviruses were originally classified as dsRNA viruses due to the prominence of dsRNA found in extracts of infected *C. parasitica*. Subsequent cloning, sequence analysis, and development of an infectious hypovirus cDNA clone demonstrated that the hypovirus coding strand is infectious, a defining characteristic of ssRNA viruses (Shapira et al., 1991; Choi and Nuss, 1992). Hypovirus genetic information consists of a single linear RNA of 9 to 12.7 kb that encodes one polyprotein (species CHV3 and CHV4) or two polyproteins (species CHV1 and CHV2) (Hillman and Suzuki, 2004). Hypovirus RNA replication is associated with pleiomorphic membrane vesicles of 50 to 80 nm in diameter. While the six taxonomic families described above accommodate the majority of mycoviruses, a growing list of recently characterized mycoviruses remains unclassified (Table 2) (Marquez et al., 2007; Kwon et al., 2007). Additional adjustments to the current taxonomic structure will be required as more mycovirus sequences become available.

Mycovirus infections share several features that are distinctive from plant and animal viruses. Perhaps the most significant difference is that the life cycle of mycoviruses is not punctuated by an extracellular transmission phase. Mycoviruses are not infectious in the classic sense. Mycovirus infections cannot be initiated by exposing uninfected hyphae to cell extracts prepared from an infected strain. Rather, mycoviruses are transmitted by cytoplasmic mixing following hyphal fusion (anastomosis) or through asexual spores. Mycovirus infections are also persistent. In this regard, the absence of capsid proteins for members of two mycovirus taxonomic families, *Hypoviridae* and *Narnaviridae*, is likely related to the persistent nature and intracellular confinement of mycovirus life cycles. Most mycoviruses lead secret lives, causing no obvious symptoms in their fungal hosts.

TABLE 2 Examples of mycovirus-mediated alteration in fungal host phenotype[a]

Symptom	Fungus	Plant host	Disease	Mycovirus family	Reference
Thermal tolerance	*C. protuberata*	*D. lanuginosum* and tomato	NA	Unclassified	Marquez et al., 2007
Reduced mycotoxin production	*F. graminearum*	Wheat	Scab disease of small grain	Unclassified; potexvirus-like genome	Kwon et al., 2007
Hypovirulence	*Diaporthe perjuncta*	Stone fruits	Diaporthe disease of stone fruit	Unclassified; tombusvirus-like	Moleleki et al., 2003
Hypovirulence	*Ophiostoma ulmi*, *Ophiostom a novo-ulmi*	Elm trees	Dutch elm disease	*Narnaviridae* (genus *Mitovirus*)	Buck and Brasir, 2002.
Hypovirulence	*Sclerotinia homoeocarpa*	Turfgrass	Dollar spot disease	*Narnaviridae* (genus *Mitovirus*)	Deng et al., 2003
Hypovirulence	*Rhizoctonia solani*	Potato	Rhizotonia disease	Unclassified	Lakshman et al., 1998
Hypovirulence	*Helminthosporium victoriae*	Oats	Victoria blight	*Totiviridae* and *Chrysoviridae* coinfection	Jiang and Ghabrial, 2004
Hypovirulence	*Rosellina necatrix*	Apple	White root rot	*Reoviridae*	Wei et al., 2003
Hypovirulence	*H. mompa*	Fruit trees	Violet root rot	*Endornavirus*	Osaki et al., 2006
Hypovirulence	*C. parasitica*	American chestnut	Chestnut blight	*Hypoviridae*, *Reoviridae*, *Narnaviridae* (genus *Mitovirus*)	Hillman and Suzuki, 2004

[a]Only mycoviruses for which the nucleotide sequence has been determined are listed. NA, not applicable.

However, exceptions to this general feature, discussed in the next section, include host phenotypic changes that are fundamentally interesting and of potential practical value.

SYMPTOMS ASSOCIATED WITH MYCOVIRUS INFECTIONS

Efforts to understand the cause of symptoms associated with severe dieback disease, La France disease, of the cultivated mushroom *Agaricus bisporus* led to the discovery of the first mycovirus in 1962 (Hollings, 1962). Symptoms associated with mycovirus infections remain a significant economic consideration to the cultivated mushroom industry due to the cost of hygienic precautions implemented to prevent virus epidemics and the emergence of new virus diseases such as MX virus (Rao et al., 2007). Interestingly, the majority of the symptoms associated with mycovirus infections have been viewed as having potential utility and quite often influence interactions between the fungal host and other organisms (Table 2). For example, the ability of the endophytic fungus *Curvularia protuberata* to confer heat tolerance to the panic grass *Dichanthelium lanuginosum* collected from geothermal soils in Yellowstone National Park was shown to require the presence of a mycovirus, subsequently named the Curvularia thermal tolerance virus (Marquez et al., 2007). Moreover, the virus-infected endophytic fungus, but not the virus-free fungus, was able to confer heat tolerance to tomato.

Most reports of mycovirus-associated symptom expression involve an alteration in the interaction between plant pathogenic fungi and their plant host. These infections generally result in reduced fungal virulence, termed hypovirulence, although cases of increased virulence have been reported (Nuss and Koltin, 1990). The best-characterized examples of hypovirulence (Table 2) primarily involve fungal members of the Ascomycota, and two basidiomycetes, *Rhizoctonia solani* and *Helicobasidium mompa*. The major taxonomic classes of mycoviruses are represented among the viruses that are associated with the hypovirulence phenotype, which also includes a number of interesting unclassified mycoviruses. Hypovirulence is often accompanied by additional symptoms. For example, the reduced-virulence phenotype exhibited by the FgV-DK21 virus-infected scab disease pathogen of small grains, *Fusarium graminearum*, is accompanied by reduced mycelium growth, increase pigment production, and, most interestingly, a significant reduction in the production of trichothecene mycotoxins (Kwon et al., 2007). Hypovirulence has not yet been reported for fungal pathogens of animals or humans.

The properties of mycovirus infections present technical challenges in demonstrating cause and effect relationships between mycovirus infection and symptom expression. It is often difficult to cure a fungal strain of a mycovirus infection. The reintroduction of a mycovirus into a cured strain is hampered by the absence of an extracellular phase in the mycovirus life cycle. The use of anastomosis to reintroduce mycovirus into a cured strain is complicated by the transmission of a mixture of cytoplasmic material. These technical problems have been overcome for one group of mycoviruses, the hypoviruses responsible for hypovirulence of the chestnut blight fungus *C. parasitica*. Not only did the development of an infectious full-length hypovirus cDNA clone allow the conclusive demonstration that the hypovirus genetic information was responsible for hypovirulence and associated symptoms, but it also provided the means for addressing the mechanisms underlying mycovirus-mediated alterations of fungal host phenotype and gene expression.

THE HYPOVIRUS-*C. PARASITICA* EXPERIMENTAL SYSTEM

The primary elements of the hypovirus-*C. parasitica* experimental system consist of full-length hypovirus cDNAs and a genetically manipulatable fungal host (Fig. 1). Hypovirus infections of *C. parasitica* can be initiated by installing the hypovirus cDNA, under the control of a fungal gene promoter and terminator flanking elements, into the host chromosome (transformation) (Choi and Nuss, 1992). The hypovirus cDNA-derived transcripts produced in the resulting "transgenic hypovirulent" strains are transported to the cytoplasm, translated, and used as a template to initiate hypovirus RNA replication. Replication occurs in association with cytoplasmic vesicles that can be purified from the fungus for in vitro analysis of viral RNA synthesis (Fahima et al., 1993). This process results in a replicating hypovirus RNA trimmed of all nonviral vector nucleotides (Chen et al., 1994a). Alternatively, infection can be initiated by electroporation-mediated introduction of the coding strand transcript generated in vitro from the viral cDNA (transfection) (Chen et al., 1994b). Both protocols require the production of cell wall-free spheroplasts from virus-free *C. parasitica*. The transformation protocol employs a selectable marker to allow isolation of resulting transgenic hypovirulent strains. After transfection, the regenerated hyphal structures anastomose, forming cytoplasmic networks through which the replicating hypovirus RNA can migrate. This allows efficient recovery of transfection-initiated hypovirulent strains without reliance on marker selection.

Progress in developing the hypovirus reverse genetics system has been accompanied by advances in *C. parasitica* molecular biology and genomics. DNA-mediated transformation of *C. parasitica* spheroplasts is very efficient, yielding several thousand stable transformants per microgram of transforming DNA (Churchill et al., 1990). Since *C. parasitica* is haploid and asexual spores are uninucleate, gene disruption and elimination of heterokaryons are quite efficient. The efficiency for homologous recombination has recently been increased from ~5 to 85% with the development of a *C. parasitica* mutant strain containing a disruption of the KU80 gene that encodes a key component of the nonhomologous-end-joining DNA repair pathway (Lan et al., 2008). The *C. parasitica* genome was recently sequenced by the U.S. Department of Energy Joint Genome Institute Community Sequencing Program (http://www.jgi.doe.gov/CSP/index.html). Finally, *C. parasitica* has been shown to support the replication of members of five virus families: *Hypoviridae*, *Reoviridae*, *Narnaviridae*, *Partitiviridae*, and *Chrysoviridae* (reviewed by Hilman and Suzuki, 2004), thus providing a rich resource for approaching fundamental issues of virus-host interactions.

MECHANISMS UNDERLYING MYCOVIRUS-MEDIATED MODULATION OF FUNGAL HOST PHENOTYPE AND GENE EXPRESSION

There has been a growing appreciation in contemporary virology research for the connection between virus-mediated symptom expression and alterations in cellular regulatory processes. In this regard, efforts to understand hypovirus-mediated symptom expression revealed alterations in several cellular signal transduction pathways and, in the process, provided the first link between G-protein signaling and fungal virulence.

The suggestion that hypovirus infection may alter one or more cellular regulatory pathways is derived from the

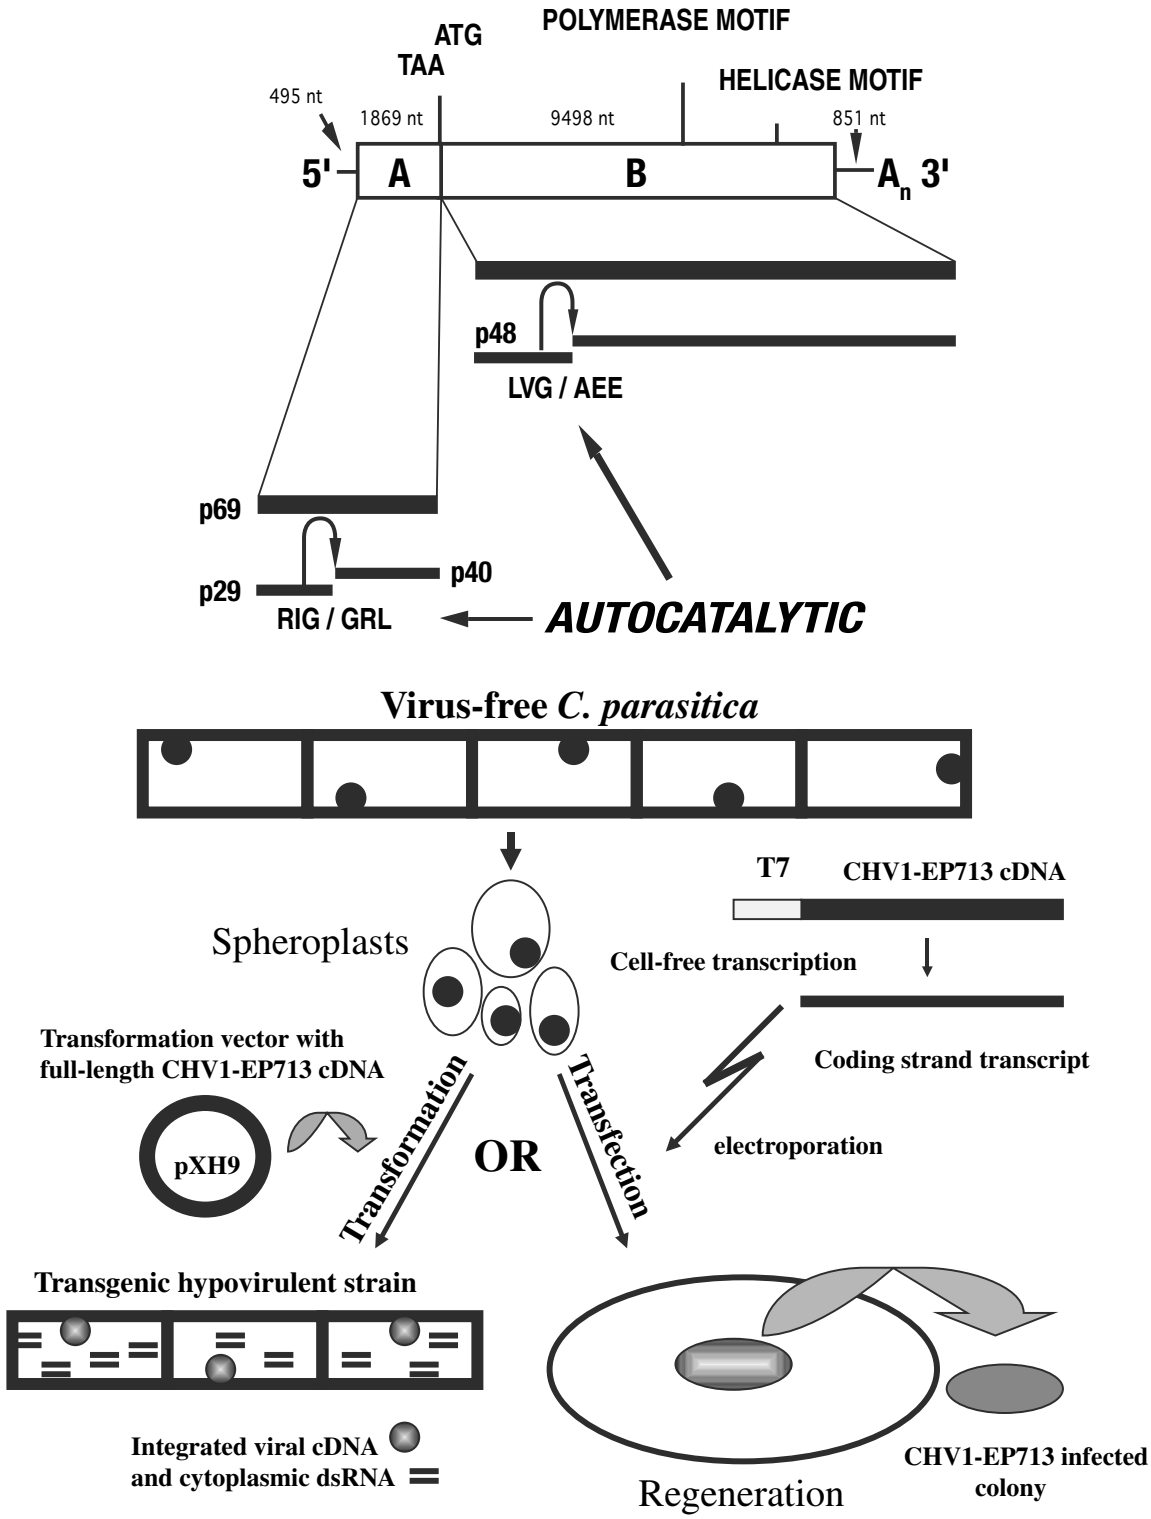

FIGURE 1 Hypovirus CHV1-EP713 genome organization, expression strategy, and reverse genetics. (A) The coding strand RNA of prototypic hypovirus CHV1-EP713 consists of 12,712 nucleotides (nt), excluding the poly(A) tail. The 5′-proximal coding domain, open reading frame A (622 codons), encodes two polypeptides, p29 and p40, that are released from a polyprotein, p69, by an autocatalytic event mediated by p29. Expression of open reading frame B (3,165 codons) also involves an autoproteolytic event in which a 48-kDa polypeptide, p48, is released from the N-terminal portion of the encoded polyprotein. Adapted with permission from Shapira et al., 1991. (B) Diagram illustrating the basic elements of the *C. parasitica* transformation (left) and transfection (right) protocols. Parallel horizontal bars (=) indicate hypovirus dsRNA. Adapted with permission from Nuss et al., 2002.

persistent, noncytopathic nature of hypovirus infections and the constellation of phenotypic changes that result from hypovirus infection, e.g., reduced pigment production, reduced asexual sporulation, reduced virulence, and loss of female fertility (reviewed by Nuss, 2005). The first experimental evidence supporting this view appeared in a report describing the reduced accumulation of the Gα subunit CPG-1 in hypovirus-infected *C. parasitica* and the substantial reduction in virulence that resulted from transgenic cosuppression of *cpg-1* expression (Choi et al., 1995). The importance of G-protein signaling in *C. parasitica* virulence was confirmed by targeted disruption of *cpg-1* (Gao and Nuss, 1996). Hypovirus-mediated reductions in the accumulation of both CPG-1 and the cognate Gβ subunit were subsequently shown to be regulated at the posttranscriptional level (Dawe et al., 2003). Transcriptional profiling studies on hypovirus-infected and G-protein subunit null mutant *C. parasitica* strains, using an expressed sequence tag-based microarray representing approximately 2,200 *C. parasitica* genes, identified a subset of G-protein-regulated, hypovirus-responsive genes (Dawe et al., 2003). These included a homologue of the yeast transcription factor Ste12. Subsequent analysis of the *cpst12* null mutant resulted in the identification of a subset (47) of Cpst12-regulated, hypovirus-responsive genes, providing a link between hypovirus-mediated modifications in cellular signaling and changes in the host transcriptional profile (Deng et al., 2007). A role for G-protein signaling in pathogenesis has now been established for most animal and plant pathogenic fungi (Li et al., 2007). Hypovirus-mediated alterations of calcium/calmodulin/inositol triphosphate-dependent (Larson et al., 1992) and mitogen-activated protein kinase signaling cascades (Park et al., 2004) have also been reported. The availability of the *C. parasitica* genome sequence will greatly facilitate future studies of the influence of hypovirus infection on host regulatory pathways and gene expression and allow a more precise understanding of their contribution to virus-mediated symptom expression.

FUNGAL ANTIVIRAL DEFENSE MECHANISMS

Animals and plants have elaborate mechanisms for defense against virus infection involving combinations of innate and adaptive responses that include RNA silencing, interferon production, and antibody production. Antiviral defense mechanisms currently identified in fungi include a self/nonself recognition system that presents barriers to the major mode of mycovirus transmission and an RNA recognition system that targets mycovirus RNA for destruction.

Vegetative Incompatibility

Vegetative incompatibility is a self/nonself recognition system that controls the ability of many fungi to undergo vegetative fusion events (anastomoses) that lead to cytoplasmic mixing and heterokaryon formation (reviewed by Glass and Kaneko, 2003; see also chapter 20). In the absence of an extracellular phase to their life cycle, mycoviruses rely on anastomosis as a major avenue for horizontal transmission. This has led to the long-held proposal that the genetic control of vegetative incompatibility may have evolved as a barrier to cytoplasmic infections by viruses, senescence plasmids, or transposable elements (Caten, 1972).

The vegetative incompatibility (*vic*) system in *C. parasitica*, which is controlled by at least six genetic loci with two alleles at each locus (Cortesi and Milgroom, 1998), clearly reduces transmission of mycoviruses between individuals in the laboratory (reviewed by Milgroom and Cortesi, 2004). High levels of *vic* diversity are thought to impose barriers to the spread of hypoviruses through wild *C. parasitica* populations, thereby reducing biocontrol efficacy. However, as noted by Milgroom and Cortesi (2004), low levels of *vic* diversity do not guarantee successful hypovirus spread through natural *C. parasitica* populations, indicating the influence of other contributing factors.

RNA Silencing

In fungi, mechanisms underlying RNA silencing, or RNA-mediated, sequence-specific suppression of gene expression, have been elucidated primarily through studies with *Neurospora crassa* (chapter 9). Since microRNAs, small RNAs that are produced in plants and animals from genome-encoded RNA hairpins and are involved in development and cellular regulation, have not been detected in fungi (Cerutti and Casas-Mollano, 2005; Nakayashiki et al., 2006), fungal RNA silencing has been portrayed as having originated as an ancient defense mechanism against invasive nucleic acids and viruses. Indeed, transposon silencing has been demonstrated in *N. crassa* (Nolan et al., 2005). However, the absence of a mycovirus experimental system has limited the use of *N. crassa* to examine whether RNA silencing also provides antiviral defense in fungi. Recent studies with hypovirus- and reovirus-infected *C. parasitica* and *Aspergillus* mycoviruses have demonstrated that RNA silencing also serves as an antiviral defense mechanism in fungi.

Viruses of plants and a growing number of animal viruses have been found to encode proteins that suppress host RNA silencing pathways (reviewed by Voinnet, 2005). Similarities between hypovirus-encoded protein p29 (Fig. 1) and the plant potyvirus-encoded suppressor of RNA silencing, HC-Pro (Choi et al., 1991), and reports that p29 could act in *trans* to increase the accumulation of homologous hypovirus RNA as well as heterologous mycoreovirus RNA (Sun et al., 2006) stimulated predictions that p29 might be a mycovirus-silencing suppressor. Segers et al (2006) tested this prediction and showed that p29 suppressed RNA silencing both in *C. parasitica* and in a heterologous plant system. Direct evidence that RNA silencing serves an antimycovirus role was subsequently provided by the demonstration that disruption of one of two *C. parasitica* dicer genes, *dcl-2*, the homologue of *N. crassa* dicer gene *dcl-2* (chapter 9), increased susceptibility to infections by hypovirus CHV1-EP713 and reovirus MyRV1-9B21 (Segers et al., 2007).

Hammond et al. (2008) observed that infection by *Aspergillus* virus 1816 resulted in suppression of inverted repeat transgene (hairpin) silencing. These authors also detected small RNA derived from *Aspergillus* virus 341 by Northern analysis, but only in an *A. nidulans* argonaute mutant strain, indicating that virus-derived small RNAs (vsRNAs) are present at a low level in some mycovirus-infected wild-type *Aspergillus* strains.

Details of vsRNA biogenesis in fungi are beginning to emerge. Zhang et al. (2008) demonstrated that hypovirus-derived vsRNAs accumulated in wild-type and *dcl-1* mutant *C. parasitica* strains, but not in the *dcl-2* mutant strain that was previously shown to have increased susceptibility to hypovirus infection. Cloning and sequence analysis of the hypovirus vsRNAs showed that they were produced from both positive and negative viral RNA strands in a 3:2 ratio and in a nonrandom distribution along the viral genome. A significant portion (>50%) of the hypovirus-specific vsRNAs were found to contain a 3′ terminal mismatch with the viral RNA sequence. In most cases, the mismatch

consisted of a single or double adenosine. Similar terminal mismatches, which may result from the addition of non-template-encoded residues, have not been reported for vsRNAs generated from plant or animal virus RNAs. It will be interesting to see whether small-interfering RNAs generated in uninfected fungi also contain 3′-terminal mismatches when that information becomes available.

Consistent with the requirement of C. *parasitica dcl-2* for biogenesis of hypovirus vsRNAs, Zhang et al. (2008) reported that *dcl-2* transcript accumulation increased 10- to 15-fold in response to hypovirus or mycoreovirus infections, while the expression of *dcl-1* increased only modestly (2-fold). Interestingly, *dcl-2* transcript levels were found to be superinduced (35-fold) following infection by a mutant hypovirus that lacked the p29 suppressor of RNA silencing. In this regard, Choudhary et al. (2007) recently showed that the production of hairpin dsRNA in *N. crassa* results in induction of both argonaute *qde-2* and dicer *dcl-2* expression. Interestingly, Hammond et al. (2008) observed no change in *A. nidulans* argonaute (*rsdA*) or dicer (*dclB*) transcript levels after infection by any of three *Aspergillus* mycoviruses.

The prospects for using mycovirus experimental systems for elucidating mechanisms underlying the induction and suppression of antiviral RNA silencing are promising due to simplified RNA silencing pathways and the evolutionary position of fungi relative to plants and animals. Additionally, the C. *parasitica*/mycovirus experimental system takes advantage of a highly tractable eukaryotic host that is the natural host to a constellation of well-characterized viruses with different replication strategies representing five different virus taxonomic families and a facile hypovirus reverse genetics capability. In this regard, a novel role for the C. *parasitica* dicer DCL-2 in viral RNA recombination was recently reported (Zhang and Nuss, 2008).

PROSPECTS FOR ENGINEERING MYCOVIRUSES TO MANIPULATE THE FUNGAL HOST

The concept of engineering mycoviruses to manipulate the phenotypic traits of the fungal host has, in fact, been reduced to practice. The installation of a full-length infectious hypovirus cDNA copy into C. *parasitica* chromosomal DNA has provided a novel means of hypovirus transmission not observed in nature (reviewed by Nuss, 2005). In contrast to hypovirus RNA, which is not transmitted to ascospores, the hypovirus cDNA copy that is present in the nucleus of transgenic hypovirulent strains is inherited by a portion of the ascospore progeny, followed by generation of cytoplasmically replicating viral RNA. Because of allelic rearrangement at the vegetative incompatibility loci during meiosis, the hypovirulent ascospore progeny represent a spectrum of different *vic* types. The prediction that this novel mode of transmission will facilitate cytoplasmic spread of hypoviruses in natural C. *parasitica* populations is currently being tested.

The hypovirus transfection and transformation protocols have provided the means to extend hypovirus host range, allowing the engineering of hypovirulent strains of four fungal species that are closely related to C. *parasitica* (Chen et al., 1994b) and two fungal tree pathogens in separate genera (Sasaki et al., 2002). It has also been possible to engineer chimeras of mild and severe hypovirus isolates to fine-tune the interaction between C. *parasitica* and its plant host (Chen et al., 2000).

The potential for using mycoviruses to manipulate fungal phenotype extends past hypovirulence. The ability of Curvularia thermal tolerance virus-infected *Curvularia protuberata* to confer heat tolerance in tomato as well as the natural panic grass host provides a prime example (Marquez et al., 2007). The reduced production of trichothecene mycotoxins by the *F. graminearum* virus FgV-DK21 provides another (Kwon et al., 2007). Clearly, many exciting opportunities for engineering mycoviruses as tools for studying and manipulating fungal hosts are anticipated with advances in the development of corresponding mycovirus reverse genetics and fungal transformation protocols.

SUMMARY

Mycoviruses are now known to be widely distributed throughout the kingdom Fungi. Although most mycovirus infections appear to be asymptomatic under laboratory conditions, the effect of these persistent virus infections on the fungal host over time in nature is not well understood and deserves more intense scrutiny. Detailed molecular characterizations have, justifiably, been conducted primarily for those mycoviruses that cause interesting phenotypic changes in the fungal host, e.g., hypovirulence. These analyses are revealing an increasing number of unclassified viruses, exposing the need for significant adjustments to the current mycovirus taxonomic structure. Advances made with the hypovirus-C. *parasitica* experimental system have demonstrated that, similar to viruses of plants and animals, mycoviruses have utility for elucidating host function and manipulating host phenotype. It is anticipated that the development of similar capabilities for other mycoviruses will provide access to a rich repertoire of biological interactions for fundamental and practical application.

Mitochondria and Respiration

FRANK E. NARGANG AND JOHN C. KENNELL

Mitochondria are double-membrane-bound organelles that are divided into four subcompartments: the mitochondrial outer membrane (MOM), the intermembrane space (IMS), the mitochondrial inner membrane (MIM), and the matrix. Mitochondria grow by the incorporation of newly synthesized material into existing organelles that eventually divide. They contain their own DNA (mtDNA), which specifies a few proteins involved in oxidative phosphorylation. However, the vast majority of proteins in mitochondria are encoded by nuclear genes, synthesized on cytoplasmic ribosomes, and imported into the organelles. Many crucial cellular activities, such as the biogenesis of iron-sulfur clusters, apoptosis, and calcium homeostasis, involve mitochondria. However, the best-known function of mitochondria is ATP production via cellular respiration. This chapter covers the functions of mitochondria in filamentous fungi.

CYTOLOGY AND INHERITANCE

Confocal microscopy images of mycelia stained with mitochondrion-specific dyes reveal mitochondria as elongated tubes that are densely packed in a parallel orientation at the growing tip of hyphal cells. Mitochondria in subapical regions are more sparsely distributed and tend to be shorter and more rod-shaped. While branched mitochondria are common in yeast (Okamoto and Shaw, 2005), they are not readily detected in filamentous fungi (Hickey et al., 2004). Mitochondria are highly dynamic and readily move from cell to cell through septal pores. Movement is directed by interactions with actin filaments and/or microtubules, depending on the organism (Boldogh and Pon, 2006; Fuchs et al., 2002). Images of cytoplasmic flow following anastomosis show that mitochondria are rapidly transferred through the fusion pore with the direction of flow thought to be related to differences in the turgor pressure between hyphal cells involved in fusion (Hickey et al., 2002). The use of potentiometric dyes, such as rhodamine 123, provides a measure of the MIM potential, and staining intensities of growing hyphal cells show that mitochondria at the growth tip are highly active. While this appears to reflect the high energy demands associated with apical growth, one study suggests that mitochondria at the growing tip consume little oxygen and may play a role in calcium sequestration (Levina and Lew, 2006).

In fungi that have morphologically distinct gametes (i.e., anisogametic), mitochondria are inherited via the maternal parent. In heterothallic filamentous ascomycetes that develop fruiting bodies, the parent that forms the sexual fruiting body contributes mitochondria to the ascogenous cell. Although mitochondria of the conidial parent are generally excluded, several incidences of paternal mtDNA transmission have been reported (reviewed by Yan and Xu, 2005). The most direct mechanism of transmission would seem to occur via leakage of the male mitochondria into the sexual hypha, the trichogyne. An alternative route may also occur during the development of the fruiting body in perithecium-forming fungi (Griffiths, 1995). Crosses between strains that are vegetatively compatible versus those that are incompatible showed that the rates of paternal inheritance of mitochondrial plasmids (mt plasmids) (described below) was 10-fold higher among compatible strains, suggesting that plasmids enter the maternal tissue via fusion of cells destined to form the ascogenous cell, rather than via fusion of conidia and the trichogyne (Debets and Griffiths, 1998). Furthermore, studies with *Aspergillus nidulans* showed that cytoplasms of compatible parents mix prior to the formation of the cleistothecia, whereas those of incompatible parents do not (Bruggeman et al., 2003).

THE ELECTRON TRANSPORT CHAIN

Mitochondrial respiration occurs via transfer of electrons from reduced electron carriers to molecular oxygen. This is accomplished using an electron transport chain housed in the MIM (Fig. 1). Four large enzyme complexes are involved in the transfers, and three of these (complexes I, III, and IV) have the ability to couple electron transfer to the pumping of protons across the MIM from the matrix to the IMS. Complex V, the ATP synthase, utilizes the energy stored in the proton gradient to synthesize ATP. Most current information on these complexes has come from studies

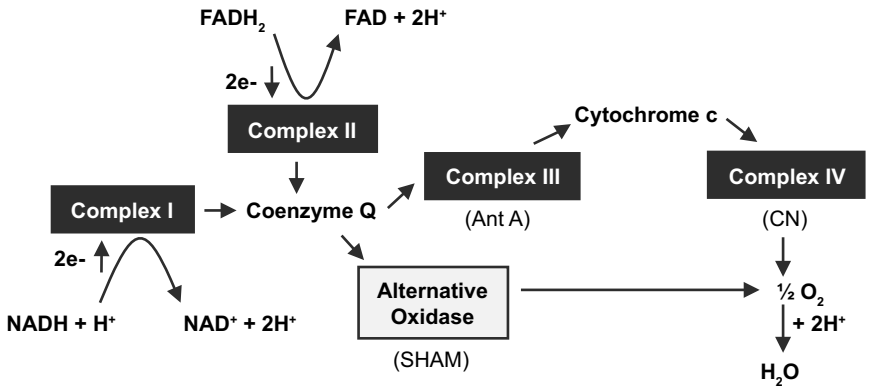

FIGURE 1 Electron transport chain. Electrons from the reduced electron carriers NADH + H^+ and $FADH_2$ are extracted by complex I and complex II, respectively, and transferred through the electron transport chain in the direction of the arrows. Complex IV uses the electrons to reduce molecular oxygen to water. The four large enzyme complexes are shown as black boxes. The pathway that ends at complex IV is referred to as the cytochrome-mediated electron transport chain (cmETC) in this chapter. At coenzyme Q (the ubiquinone/ubiquinol pool) the path to oxygen may branch in organisms capable of producing AOX. Complexes I, III, and IV are sites where electron transfer is coupled to proton pumping. The cmETC refers to the path of electrons from complex I to oxygen via complex IV since cytochromes *b* and c_1 (found in complex III), cytochrome *c*, and cytochromes *a* and a_3 (found in complex IV) are involved in electron transfer via this path. Chemicals mentioned in the text that inhibit electron flow are shown in parentheses under the enzymes that they affect (Ant A, antimycin A; CN, cyanide; SHAM, salicylhydroxamic acid).

on mammalian tissues or from *Saccharomyces cerevisiae*. However, *S. cerevisiae* does not contain complex I, and *Neurospora crassa* has provided a useful model for the study of the structure and function of this complex.

Respiratory Complex I

Complex I has NADH:ubiquinone oxidoreductase activity and couples the transfer of electrons to the pumping of protons from the matrix to the IMS. The *N. crassa* enzyme contains at least 39 protein subunits as well as flavin mononucleotide and eight to nine iron sulfur clusters. Seven of the subunits are encoded on mtDNA. The enzyme exists as an L-shaped structure with the membrane arm integrated into the MIM and a peripheral arm associated with the membrane arm that protrudes into the matrix (Marques et al., 2005; Videira and Duarte, 2002). Although the location of all subunits within the complex is not known with certainty, it has been predicted (Duarte and Videira, 2007) that 16 subunits exist in the membrane arm and 23 subunits are in the peripheral arm (Fig. 2). It has been shown that in *N. crassa* the enzyme is not essential for growth but is required for successful completion of the sexual phase (Duarte et al., 1998).

Work with *N. crassa* showed that large and small intermediates of the membrane arm assemble independently and then join to yield the fully assembled subcomplex. Based on the assembly phenotypes of several complex I subunit mutants, it has recently been suggested that the large intermediate of the membrane arm itself is first formed from two other smaller subcomplexes (Duarte and Videira, 2007). The peripheral arm also assembles independently, and when both arms are complete, they associate to form functional complex I (Nehls et al., 1992; Tuschen et al., 1990). Examination of complex assembly in knockout mutants lacking specific subunits revealed that the loss of certain subunits has no effect on the assembly of the other subunits of the complex, while loss of other subunits leads to assembly defects (Schulte, 2001; Videira, 1998). As expected, the loss of a protein subunit required for assembly of one arm of the enzyme normally does not affect assembly of the other arm. However, there are exceptions to this rule. In *N. crassa*, an acyl carrier protein traditionally associated with fatty acid synthesis is also a subunit of the complex I peripheral arm. Loss of acyl carrier protein results in defects in assembly of both the peripheral and membrane arms, although the mechanism by which the membrane arm is affected is not well understood (Schneider et al., 1995; Schulte, 2001). Similarly, loss of an 11.5-kDa subunit of the membrane arm leads to defects in assembling both the membrane and peripheral arms. It was suggested that the 11.5-kDa protein may participate in connecting the two arms of the complex and that subunits of the peripheral arm might degrade or aggregate when it is absent (Marques et al., 2005, 2007).

Recently, it has been shown that *N. crassa* complex I mutants are more resistant than wild-type strains to phytosphingosine (Castro et al., 2008), a drug that was previously shown to induce apoptosis-like death in *A. nidulans* (Cheng et al., 2003). Interestingly, mutants affecting other respiratory complexes were more sensitive to the drug, and it was suggested that complex I plays a direct role in apoptosis. Furthermore, it has been shown that caspase cleavage of the 75-kDa subunit of complex I in mammals is necessary for various changes that occur in mitochondria during apoptosis (Ricci et al., 2004). Additional relationships between fungal and mammalian apoptosis are evident from studies of other mitochondrial proteins. A mutant of the *N. crassa* homologue of the mammalian apoptosis-inducing factor was also more resistant to phytosphingosine than the wild type. A deletion of the gene encoding the *N. crassa* AMID-like protein, another protein known to be involved in mammalian apoptosis, resulted in increased sensitivity to

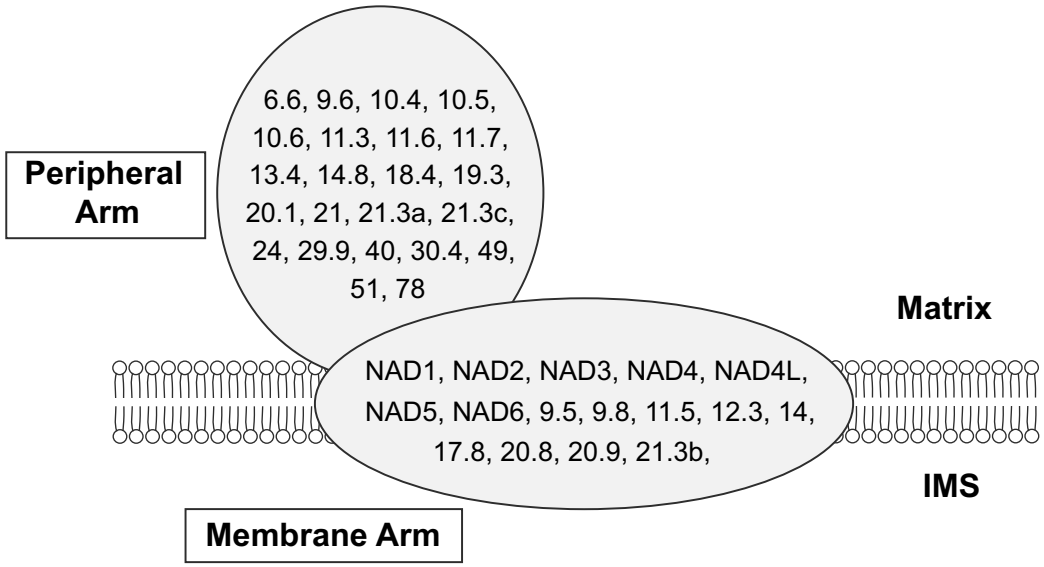

FIGURE 2 Predicted placement of subunits in the peripheral or membrane arms of *N. crassa* complex I (Duarte and Videira, 2007). The seven mitochondrially encoded subunits are referred to as NAD proteins but may be called ND proteins in some other references. The subunits encoded within the nucleus are referred to according to their molecular mass in kilodaltons.

phytosphingosine (Castro et al., 2008). These findings suggest that filamentous fungi can serve as useful models for apoptosis in higher organisms.

Alternative NADH or NADPH Dehydrogenases

In addition to complex I, fungi and plants also contain single polypeptide dehydrogenases, which oxidase either NADH, NADPH, or both [symbolized as NAD(P)H]. They donate electrons to the electron transport chain but are incapable of proton pumping. In *N. crassa* there are four such enzymes. NDE1 [NAD(P)H dehydrogenase external 1] is an NADPH dehydrogenase (Melo et al., 2001), while NDE2 uses both NADH and NADPH as substrates (Carneiro et al., 2004). Both enzymes are anchored to the MIM by a single membrane-spanning domain with their catalytic activity present in the IMS. Thus, these enzymes oxidize substrates external to the matrix. NDE3 also oxidizes both NADH and NADPH and is found as a soluble protein in both the mitochondrial IMS and the cytosol (Carneiro et al., 2007). The fourth enzyme of this class in *N. crassa* is NDI1 [NAD(P)H dehydrogenase internal 1]. This protein was found to be a peripheral membrane protein on the inner side of the MIM that oxidizes NADH within the matrix (Duarte et al., 2003). The existence of these enzymes likely explains why *N. crassa* mutants with nonfunctional complex I are still viable. Triple knockouts of *nde1*, *nde2*, and *nde3* are also viable, suggesting that there are other systems in *N. crassa* that oxidize cytoplasmic pools of NAD(P)H (Carneiro et al., 2007).

Double mutants of *ndi-1* and any subunit of complex I that eliminates its activity are lethal, since both systems of oxidizing matrix NADH are nonfunctional. Although single *ndi-1* mutants have no effect on vegetative growth, germination from both conidia and ascospores is much slower than that from wild-type spores (Duarte et al., 2003). Double mutants of either *nde-1* or *nde-3* and complex I are viable. Since NDE2 is active in the IMS, it was surprising that *nde-2*/complex I double mutants were inviable. It was suggested that *N. crassa* may be capable of exchanging matrix and external NADH so that NDE2 may complement the activity of complex I (Carneiro et al., 2004). Taken together these results indicate that the single-enzyme NAD(P)H dehydrogenases play an important role in the growth and development of *N. crassa*.

THE MITOCHONDRIAL GENOME

Fungal mitochondrial genomes are AT-rich DNAs that map as circular molecules. However, several studies suggest that fungal mtDNAs are actually long, concatenated linear molecules (reviewed by Nosek and Tomaska, 2003). True monomer-length linear mitochondrial genomes have also been found in a number of ascomycetes, and a variety of telomeric structures have been identified. These include covalently closed terminal hairpins and tandemly repeated sequences of 739 bp or larger. Although common in plants, segmented mtDNAs are rare in fungi. Thus far, the only segmented genome identified is in the chytridiomycete *Spizellomyces punctatus*, which is composed of three circular molecules (Laforest et al., 1997).

The sizes of fungal mtDNAs reported to date range from 18 to >150 kb (reviewed by Bullerwell and Lang, 2005; Hausner, 2003; and Kennell and Cohen, 2003). The size extremes fall between the average size of animal mtDNAs and the lower limit of plant mtDNAs. Despite the size differences, most fungal mitochondrial genomes encode the same set of 13 polypeptides found in animal mitochondrial genomes (Burger et al., 2003). The set includes apocytochrome *b*; cytochrome oxidase subunits 1, 2, and 3; complex I (NADH dehydrogenase) subunits 1, 2, 3, 4, 4L, 5, and 6; and ATPase subunits 6 and 8. In addition, many fungal mitochondrial genomes also encode ATPase subunit 9 and a ribosomal protein (*rps3*; [Bullerwell et al., 2000; Bullerwell and Lang, 2005]). Notably, *Saccharomyces* and *Schizosaccharomyces* species have lost the genes for NADH dehydrogenase. The genes carried on *N. crassa* mtDNA are

TABLE 1 *N. crassa* mitochondrial genes[a]

Gene	Product	Subunit of:
nad1	NAD1	Complex I
nad2	NAD2	Complex I
nad3	NAD3	Complex I
nad4	NAD4	Complex I
nad4L	NAD4L	Complex I
nad5	NAD5	Complex I
nad6	NAD6	Complex I
cob	COB	Complex III
cox1	COX1	Complex IV
cox2	COX2	Complex IV
cox3	COX3	Complex IV
atp6	ATP6	Complex V
atp8	ATP8	Complex V
atp9	ATP9	Complex V
rnl	25S rRNA	Ribosome
rns	19S rRNA	Ribosome
rps3 or *S5*	Ribosomal protein S3	Ribosome
28 tRNAs	28 tRNAs	

[a]Data from Kennell et al., 2004, and Cahan and Kennell, 2005. In some references the *nad* genes and NAD proteins are referred to as *nd* and ND, respectively.

shown in Table 1 as representative of a "typical" filamentous fungus.

Although the genetic code used in the expression of mitochondrial encoded genes can differ both within and between fungal phyla, filamentous ascomycete species annotated to date use the codon UGA to specify tryptophan, rather than a stop codon. In addition to protein-encoding regions, mitochondrial genomes also encode large and small rRNAs as well as a minimal set of tRNAs needed for translation. Interestingly, chytridiomycete fungi have lost a large number of tRNAs and presumably import the necessary tRNAs from the cytoplasm. In other fungal phyla, mtDNAs occasionally lack a few tRNAs necessary to accommodate all codons represented among mitochondrion-encoded genes. In this case, either the tRNAs are imported or tRNAs having U residues at the third anticodon position may undergo a superwobble to read all four nucleotides in the third codon position (Rogalski et al., 2008). In addition to rRNAs and tRNAs, several ascomycetes encode a gene for the mitochondrial RNase P RNA subunit (*mpB*) (Bullerwell and Lang, 2005).

The standard set of fungal mitochondrial genes resembles that of animals and is believed to represent independent gene loss in the two lineages from a common protist ancestor (Bullerwell and Lang, 2005). What differentiates fungal from animal mtDNAs is the amount of noncoding regions and tolerance of selfish genetic elements such as mobile introns and plasmids (see below). The intron content of fungal mtDNAs varies widely, constituting from zero to over 50% of individual genomes. Mitochondrial introns fall into two discrete classes, group I and group II, which differ in both structure and splicing mechanism (see below). Fungal mtDNAs also contain a variety of repetitive sequences. These repetitive elements are variable in length but are usually less than 100 bp. The majority are palindromes that have conserved secondary structures, such as "G+C clusters" in *Saccharomyces* spp. (de Zamaroczy and Bernardi, 1986), "double-hairpin elements" in *Allomyces macrogynus* (Paquin et al., 2000), and "PstI palindromes" and "CG-rich palindromes" in *N. crassa* (Cahan and Kennell, 2005; Yin et al., 1981). The number of repeats within the mtDNA of a particular species varies depending on the strain examined (Cahan and Kennell, 2005). Smaller, nonpalindromic repeats have also been detected; for example, there are 124 copies of an 11-bp repeat in the 100-kb genome of *Podospora anserina* (Koll et al., 1996). The distribution pattern of many of these elements suggests that they are mobile (Cahan and Kennell, 2005; Paquin et al., 2000). Fungal mitochondria also can harbor extrachromosomal DNA plasmids (described below), and plasmid-derived sequences are commonly detected in mtDNAs.

MITOCHONDRIAL SELFISH GENETIC ELEMENTS

Mobile Introns

The study of fungal mitochondrial introns has been an active area of research that has yielded a number of significant findings. Notably, the study of mechanisms of splicing and intron mobility of group I and group II introns was initially carried out with *S. cerevisiae* and was later expanded to other fungi, plant mitochondria and chloroplasts, and more recently to bacteria. Among the findings described below and elsewhere is speculation that these elements evolved in the RNA world (Gilbert and de Souza, 1999) and played an important role in the evolution of organelle and nuclear genomes alike. For instance, it is increasingly accepted that group II introns were ancestors of spliceosomal introns (reviewed by Lambowitz and Zimmerly, 2004, and Rodriguez-Trelles et al., 2006). Recently, it was suggested that the introduction of mobile group II introns into the primordial eukaryotic cell via the alphaproteobacterial ancestor of mitochondria could have provided the driving force that led to the evolution of the nuclear membrane (Lopez-Garcia and Moreira, 2006; Martin and Koonin, 2006).

Group I Introns

Among the first group I introns identified were those found in fungal mtDNA. A recently developed algorithm is able to separate group I introns into six categories based on conserved intron core sequences (Lang et al., 2007). In vitro studies show that group I intron RNAs are ribozymes, capable of self-catalysis; however, in vivo, group I introns are commonly associated with proteins that facilitate splicing. In some cases, the mitochondrial proteins involved in splicing are bifunctional and are involved in other essential functions. In *N. crassa*, a mitochondrial tyrosyl-tRNA synthetase has adapted to function in group I intron splicing (Akins and Lambowitz, 1987). The synthetase protein, encoded by the nuclear *cyt-18* locus, both aminoacylates mitochondrial $tRNA^{Tyr}$ and promotes group I intron splicing by stabilizing the catalytically active RNA structure (Caprara et al., 1996; Mohr et al., 1992). Molecular and biochemical studies, coupled with the crystal structure of the CYT18-group I intron RNA, demonstrate that the protein binds to the intron by using a surface that is separate and distinct from that which binds $tRNA^{Tyr}$ (Paukstelis et al., 2008). Comparative genomic analysis suggests that the adaptation of CYT-18 protein that created a separate domain associated with splicing evolved during or after the divergence of the subphylum Pezizomycotina from Saccharomycotina

(Paukstelis and Lambowitz, 2008). The evolution of a new binding site associated with group I splicing also appears to have occurred with an intron-associated gene, I-AniI, of *Aspergillus*, whose intron open reading frame (ORF) product also participates in intron mobility (Caprara and Waring, 2005). Another host factor involved in group I intron splicing was identified in *N. crassa*—the product of the *cyt-19* gene (Mohr et al., 2002). In this case, the CYT19 protein functions as an ATP-dependent RNA chaperone to facilitate both group I and group II intron splicing. CYT19 is an RNA helicase (i.e., DExH/D-box protein) that appears to destabilize inactive structures that act as kinetic traps in RNA folding (Halls et al., 2007).

In addition to secondary and tertiary structural characteristics, group I introns can also be distinguished by ORFs contained within the intron. Most commonly, ORFs associated with group I introns encode endonucleases that are involved in intron mobility. The endonucleases typically recognize a 15- to 45-bp DNA sequence of an intronless allele of the gene in which they reside. The transposition event is therefore site specific and described as "homing." Insertion of group I introns/homing endonuclease genes is initiated by a double-stranded cut in the recipient allele catalyzed by the endonuclease. This stimulates the double-strand break repair response of the host, and the donor allele is used as a template for DNA synthesis, resulting in a copy of the intron being inserted into the recipient allele.

There are four families of homing endonucleases (HEs), two of which have been found in fungal mtDNAs, i.e., "LAGLIDADG" and "GIY-YIG," with the letters indicating conserved amino acid sequences (Chevalier and Stoddard, 2001). The LAGLIDADG HEs can also be further divided according to whether they have one or two motifs (Haugen et al., 2005). The HE ORFs either are freestanding in the intron or can be in frame with the upstream exon. In the latter case, a proteolytic cleavage may be involved to liberate the active protein (van Dyck et al., 1998). Homing endonuclease genes are believed to be independent selfish genetic elements in their own right (reviewed by Haugen et al., 2005), and their association with group I (and group II) self-splicing introns was a beneficial union for both parties, as the intron minimized damage to the host by splicing the element out of RNAs prior to translation while the HE facilitated mobility.

Several intron-encoded HEs are bifunctional and participate in splicing (called maturases), like the aforementioned I-AniI gene. HEs that have maturase activity are more likely to be retained, as they enable host genes to be properly spliced. However, there are many examples of intron-encoded genes that are truncated or absent altogether. These introns are presumed to have lost the ability to transpose (Haugen et al., 2005) and are usually dependent on proteins encoded by another intron (Henke et al., 1995) or by host factors (Lambowitz and Perlman, 1990) for splicing. It is interesting that most filamentous ascomycetes contain a group I intron in the large rRNA gene (*rnl*). Rather than encoding an HE as is the case in yeasts, the intron carries a gene for protein subunit 3 of the small ribosome (*rps3*). By carrying an essential host gene, the intron is maintained and thus is highly conserved.

Group II Introns

Group II introns were initially identified in fungal mtDNAs and the organellar genomes of plants (Michel et al., 1989). While they have a broad distribution, group II introns occur infrequently in fungal mitochondrial genomes. They can be divided into three families, based on predicted secondary structure (types IIA, IIB, and IIC) with fungal mitochondrial group II introns belonging to IIA (Toro et al., 2007). Like group I introns, they are ribozymes, but splicing is protein assisted in vivo. The group II splicing mechanism is similar to that of spliceosomal introns, supporting the hypothesis that group II introns are the predecessors to nuclear spliceosomal introns (Pyle and Lambowitz, 2006).

Mitochondrial group II introns also contain ORFs that encode proteins involved in mobility and/or splicing. These group II intron-encoded proteins are multifunctional and display a remarkable number of biochemical activities. For instance, those found in fungal mitochondria function as a reverse transcriptase (RT), an RNA maturase, a DNA binding protein, and an endonuclease (reviewed by Lambowitz and Zimmerly, 2004). Since their initial identification in fungal mitochondria and chloroplasts of higher plants, group II introns have been detected in both eubacteria and archeabacteria. Although rare in the archaea, group II introns are surprisingly common in both gram-positive and gram-negative bacteria, occurring in approximately 25% of genomes that have been sequenced (Toro, 2003).

Unlike the DNA-mediated transposition of group I introns, group II mobility occurs via an RNA intermediate and involves reverse splicing of the liberated intron RNA into the DNA of the intronless allele, followed by the reverse transcription of inserted intron RNA. This process is site specific and typically involves an H-N-H (his-asn-his) HE domain of the intron-encoded protein, which defines a third family of HEs. The specificity for the insertion site is primarily dictated by sequences in the intron RNA. This makes it possible to target mobile group II introns to insert into different sites in DNA simply by modifying intron RNA sequences. Programmable gene-targeting vectors, called "targetrons," have been developed and can be used in bacteria for targeted gene disruption (reviewed by Lambowitz et al., 2005). These vectors can also be used to knock in genes by the introduction of a cargo gene into a specific domain of the intron. Efforts are under way to use targetrons in eukaryotic genomes. If successful, they could become an important tool for use in genetic engineering and gene therapy (Pyle and Lambowitz, 2006; Toro et al., 2007).

mt Plasmids

Fungal mitochondria frequently contain extrachromosomal DNAs (and in some cases RNAs), and these genetic elements can be divided into two distinct groups: (i) plasmid-like mitochondrial elements (plMEs) that derive from the mitochondrial genome and (ii) naturally occurring, autonomously replicating plasmids that have little or no homology to mtDNA. Members of the first group are circular, oligomeric DNAs that are homologous to regions of the mitochondrial genome (reviewed by Hausner, 2003). The second group contains "true" plasmids, which exist in several forms that can be classified based on their structure (linear or circular) and by the types of nucleic acids directly involved in their replication: DNA, RNA, or retroplasmids (i.e., those that have both RNA and DNA replicative forms; reviewed by Griffiths et al., 1995).

plMEs Derived from mtDNA

The most thoroughly studied group of plMEs are the so-called p^- mtDNAs that define one class of the *petite* respiratory-defective mutants of *S. cerevisiae*. The p^- mtDNAs are deleted forms that retain anywhere from 35 bp to approximately one-third of the wild-type mitochondrial genome (Dujon, 1981). The portion that remains is amplified back up

to the size of the wild-type mtDNA as a series of tandem repeats. Since p^- strains lack significant portions of mtDNA, they are dependent on fermentative pathways of energy production for survival. Some of these p^- mtDNAs are hypersuppressive and rapidly replace wild-type mtDNA in a population. They are thought to have a replicative advantage over wild-type mtDNA molecules (MacAlpine et al., 2001).

plMEs are detected in several obligate aerobes, such as *Aspergillus*, *Neurospora*, and *Podospora* species. Interestingly, they are usually detected only in strains that have mitochondrial defects associated with either nuclear or mitochondrial mutants. Consequently, strains containing plMEs are associated with growth defects, such as a "ragged" phenotype in *Aspergillus amstelodami*, a "stop-start" phenotype in *N. crassa*, and senescence in *P. anserina*. Multimeric plMEs have also been detected in the plant pathogens *Ophiostoma novo-ulmi* and *Cryphonectria parasitica*, where they are associated with degenerative disease and hypovirulence, respectively (Abu-Amero et al., 1995; Monteiro-Vitorello et al., 1995). The mechanisms associated with the formation of mtDNA-derived elements appear to vary between host genera.

In *P. anserina,* plMEs form during senescence, which for this fungus is a genetically programmed phenomenon (see below). As cultures age, multimeric circular DNAs accumulate and are associated with a concomitant deletion of regions of the mtDNA. Collectively called senDNAs, the most common type (α-senDNA or plDNA) has a monomer length of 2.5 kb and corresponds precisely to the first intron of the mitochondrial *cox1* gene. It is thought to be produced either by reverse transcription of the *cox1* pre-mRNA or by excision of the intron from the mtDNA (Jamet-Vierny et al., 1997; Sainsard-Chanet et al., 1993). Additional DNAs (e.g., β- or γ-senDNAs) are often detected in presenescent cultures, and these vary in both size and extent. Members of each class of senDNA share a common core sequence and appear to derive from recombination between short direct repeats of the mitochondrial genome (Cummings et al., 1985; Osiewacz and Scheckhuber, 2002). It was originally believed that senDNAs were responsible for mitochondrial impairment and growth decline, yet subsequent studies showed that some strains undergo senescence without the accumulation of senDNAs and that senDNAs were found to persist in some long-lived mutant strains (Silar et al., 1997; Silliker and Cummings, 1990), indicating that other mechanisms are likely involved (Jamet-Vierny et al., 1999). The prevailing view is that these senDNAs play a role in accelerating senescence but are not the causal agents (Osiewacz and Scheckhuber, 2002).

Several different plasmid-like mitochondrial elements have been found in *N. crassa*. Like the *petite* and senDNAs, they are multimeric DNAs that derive from relatively short regions of the mtDNA. It has been speculated that they originate from recombination events (Almasan and Mishra, 1990; Gross et al., 1989) or as a consequence of DNA repair due to stalled replication associated with the high-copy-number PstI palindromes (Hausner et al., 2006a). Some plMEs share a core consensus sequences, yet collectively they lack conserved regions that might serve as replication origins and appear to propagate by a rolling-circle method of replication (Hausner et al., 2006b). Interestingly, several plMEs contain the promoter sequence of the large rRNA gene (Gross et al., 1989; Hausner et al., 2006b) and are abundantly transcribed, and it has been hypothesized that the transcripts serve as primers for second-strand synthesis. Although the *Neurospora* plMEs arise in respiratory-deficient or UV-sensitive strains, it has been shown that they can be transferred to wild-type strains via anastomosis and propagated (Hausner et al., 2006b).

Naturally Occurring Plasmids

Naturally occurring, or true mt plasmids show no significant homology to mtDNA and replicate independently. They are widely distributed in filamentous fungi, and in *Neurospora* species it has been estimated that >50% of natural isolates contain one or more types of mt plasmid (Arganoza et al., 1994; Griffiths, 1995). In organisms other than filamentous fungi, mt plasmids occur infrequently. Although they are found in *Pichia* species, they have not been detected in other yeasts (Blaisonneau et al., 1999). They also show limited occurrence among basidiomycetes and have not been reported in zygomycete or chytridiomycete species.

The linear mt plasmids that use DNA or RNA in their mode of replication have an evolutionary relationship with cytoplasmic mycoviruses and may have been introduced into mitochondria recently, while the origin of linear and circular retroplasmids is thought to precede that of mitochondria (i.e., they arose prior to the introduction of the alphaproteobacterium-like organism into the primitive eukaryotic cell). Thus, they have been described as "molecular fossils," which are defined as contemporary genetic elements that are ancient in origin and provide insight into the evolutionary past (Maizels and Weiner, 1993). At first glance, mt plasmids seem to be similar to their bacterial counterparts, yet they differ in several important ways: (i) mt plasmids are more like bacteriophages in that they encode their own polymerase(s); (ii) while plasmid sequences are commonly detected within the mitochondrial chromosome, mt plasmids do not encode integrase genes and integration is not part of the replication cycle; (iii) mt plasmids do not provide an obvious selective advantage to their host (except in rare instances); and (iv) despite their widespread occurrence and potential as vehicles of transmitting genetic information, mt plasmids have not successfully been employed as vectors due to the inability to readily transform mitochondria.

Linear double-stranded DNA (dsDNA) mt plasmids that use a direct DNA replication mode are the most common type of plasmid in fungal mitochondria. They range in size from 2 kb to almost 10 kb and are described as "invertrons" because they have terminal inverted repeats and contain a 5′ covalently-linked terminal protein (Sakaguchi, 1990). The prototypical fungal linear DNA plasmid contains two large ORFs, one on each strand, directed inward from the terminal repeat. One ORF encodes a bacteriophage-like DNA-dependent DNA polymerase (DdDp), which is similar to those encoded by protein-primed bacteriophages phi29 and PRD1. The other ORF encodes a T7-bacteriophage-like single-subunit DNA-dependent RNA polymerase (similar to nucleus-encoded mitochondrial RNA polymerases [Kempken, 1995b]). Many variations in size and internal organization exist, including plasmids that have a single large ORF encoding a DdDp or a DNA-dependent RNA polymerase, such as the pLm9 and pLm10 of *Leptosphaeria maculans* (Lim and Howlett, 1994). Single-ORF-encoding linear invertrons are often paired with a plasmid that encodes the other polymerase, suggesting that the two plasmids are dependent upon each other. In some instances, mitochondrial invertrons encode small ORFs of unknown identity that are typically found between the regions encoding the polymerases (Klassen and Meinhardt, 2007).

Circular DNA mt plasmids are covalently closed dsDNAs that replicate using a DdDp. They are approximately 5 kb in length and have a single long ORF that encodes a DdDp. The prototype is the LaBelle plasmid of *Neurospora intermedia* (Li and Nargang, 1993; Pande et al., 1989) which is 4.1 kb in length and encodes a 1,151-amino-acid ORF that shows similarity to virus-like family B DNA polymerases (Li and Nargang, 1993; Schulte and Lambowitz, 1991). The mechanism of replication is only partly understood; the LaBelle plasmid appears to be transcribed by the host mitochondrial RNA polymerase (Nargang et al., 1992) and following translation, the plasmid DdDp is thought to associate with the plasmid DNA and initiate DNA synthesis (Schulte and Lambowitz, 1991). The site of initiation of DNA synthesis and the nature of the primer are unknown. However, two-dimensional gel electrophoresis analysis of a circular DNA plasmid of *C. parasitica* (pCRY1) showed that the plasmid exists as discretely sized concatenated circular molecules with a varying amount of linear DNAs, suggesting that the plasmids replicate via a rolling-circle mechanism (Monteiro-Vitorello et al., 2000).

Plasmids classified as retroplasmids are dsDNAs that encode an RT or RNA-dependent DNA polymerase) and replicate via an RNA intermediate. Prototypic circular retroplasmids are the Mauriceville and Varkud plasmids of *Neurospora* species. These plasmids are covalently closed circular DNAs of approximately 3.6 kb and have 97% sequence identity, despite occurring in different species (Akins et al., 1988; Nargang et al., 1984). Both plasmids have a single large ORF that encodes a 725-amino-acid protein that has RT activity (Kuiper and Lambowitz, 1988; Kuiper et al., 1990). In vitro studies have demonstrated that the Mauriceville RT can initiate DNA synthesis without a primer (Wang and Lambowitz, 1993), which suggests that it may have a direct evolutionary relationship with RNA-dependent RNA polymerases. Strains containing Mauriceville or Varkud grow normally, but upon repeated vegetative transfer, they often become senescent. Presenescent cultures contain variant forms of the plasmids that contain cDNA copies of mitochondrial tRNAs (often along with other sequences) that appear to result from a template-switching event during plasmid replication (reviewed by Galligan and Kennell, 2007). Also included in this group is the VS plasmid of *N. intermedia*. It is a small (880-bp) dsDNA that does not encode any large ORFs. It appears to replicate via reverse transcription, using the RT encoded by the Varkud plasmid, and is thus considered to be a satellite plasmid (Kennell et al., 1995). Notably, the VS RNA transcript is a ribozyme and shows highly efficient RNA cleavage and ligation activity (Saville and Collins, 1990, 1991; Zamel et al., 2004). Only one other circular retroplasmid has been reported outside *Neurospora* species thus far: pThr1 of *Trichoderma harzianum* (Antal et al., 2002).

There are also linear dsDNA retroplasmids, whose prototypes are pFOXC2 and pFOXC3 of *Fusarium oxysporum*. These plasmids are 1.9-kb dsDNAs characterized by a "clothespin" structure having a terminal hairpin at one end and telomere-like repeats at the other containing a 5′-linked protein (Kistler et al., 1997; Walther and Kennell, 1999). The pFOXC plasmids contain a single large ORF that encodes an RT and are the first linear genetic elements shown to replicate via reverse transcription (Walther and Kennell, 1999). In vitro studies show that the pFOXC-RT has a loose specificity for primers, a characteristic that is likely to play a role in the addition of terminal repeats (Simpson et al., 2004). The existence of a plasmid that encodes an RT and has telomere-like ends suggests that it may have an evolutionary relationship to telomerase. A linear retroplasmid that has two terminal hairpins has been detected in *Rhizoctonia solani* (Katsura et al., 2001). Reviews of the replication cycle, phylogeny, and evolutionary significance of mitochondrial retroplasmids have been published recently (Galligan and Kennell, 2007; Hashiba and Nagasaka, 2007).

There are numerous reports of RNA elements being associated with mitochondria. Though they are formally classified as mitoviruses, they can also be considered plasmids based on their structural similarities to linear mt plasmids and lack of an extracellular form. The prototypical mitochondrial RNA plasmid is a 2.7-kb dsRNA found in *C. parasitica*, strain NB631 (Polashock and Hillman, 1994). It has a single ORF that encodes an RNA-dependent RNA polymerase believed to be involved in its replication. Other mitochondrial dsRNAs have been reported in *O. novo-ulmi* (Doherty et al., 2006; Hong et al., 1999), as has one in the basidiomycete *Helicobasidium mompa* (Osaki et al., 2005).

Surveys of *Neurospora* isolates show that more than one plasmid type can exist within an individual isolate, and in one case, seven different plasmid types were detected in a strain of *N. intermedia* (Yang and Griffiths, 1993b). Plasmids can recombine to form chimeric variants (even those of different types) indicating that they coexist within the same mitochondrion (Griffiths and Yang, 1995; Maas et al., 2007).

As expected of genetic elements that reside in mitochondria, mt plasmids are inherited maternally, yet they are also known to exploit alternative mechanisms of transmission, such as paternal inheritance (May and Taylor, 1989; Yang and Griffiths, 1993a) and transmission via anastomosis of fungal cells. Surveys of various filamentous fungal genera indicate that highly similar plasmids can be found in distantly related fungi, which implies that these elements are horizontally transmitted in nature (Arganoza et al., 1994; Griffiths, 1995). In laboratory experiments, mt plasmids are readily transmitted between vegetatively compatible strains (Debets et al., 1994) and have also been shown to overcome incompatibility barriers (Baidyaroy et al., 2000; Collins and Saville, 1990). Plasmid transfers between different species of *Neurospora* (Griffiths et al., 1990) and even between closely related fungal genera (Kempken, 1995a) have been reported. A thorough review of the inheritance mechanisms of fungal mt plasmids has been published (Griffiths, 1995).

MITOCHONDRIAL GENE EXPRESSION

Early studies involving *S. cerevisiae* showed that transcription of fungal mitochondrial genes utilizes a nucleus-encoded mitochondrial RNA polymerase, which is composed of two subunits, a catalytic core subunit (Masters et al., 1987) and a sigma-like specificity factor (Jang and Jaehning, 1991). The polymerase shows high similarity to single-subunit T3/T7-like RNA polymerase and appears to have replaced the multisubunit bacterial polymerase associated with the ancestral mitochondrial genome (Gray et al., 1998). The specificity factor binds to the core polymerase, creating a holoenzyme that recognizes the mitochondrial promoter, which in yeast is a nine-nucleotide consensus sequence. In *N. crassa*, the mitochondrial promoter consensus sequence differs slightly from yeast and is less conserved (Kennell and Lambowitz, 1989; Kubelik et al., 1990). Promoters are dispersed throughout the genome—the 78-kb mtDNA of *S. cerevisiae* contains 11 promoters on one strand and 1 promoter on the other

(Dieckmann and Staples, 1994)—and primary transcripts are most commonly multigenic and often terminate following a tRNA. Most mitochondrial genes appear to be constitutively expressed, and differential levels of RNA expression depend on the strength of the promoter. Interestingly, developmental regulation of several mitochondrial genes was reported in *N. crassa* during conidial germination; however, regulation appears to involve the recruitment of RNAs to the ribosome and is not dictated by the level of transcription (Bittner-Eddy et al., 1994).

Numerous processing events are required to generate mRNAs, several of which are transcript specific, while others, such as those that occur at the 3′ end of mRNA precursors, are performed by RNA endonucleases that cleave at conserved sequences (Min and Zassenhaus, 1993). The 5′ ends of tRNAs are cleaved by a mitochondrial RNase P (Miller and Martin, 1983; Morales et al., 1992), and 3′ ends are cleaved by a specific endonuclease (Chen and Martin, 1988) with CCA residues being added posttranscriptionally by a tRNA nucleotidyltransferase (Chen et al., 1992). Modification of nucleotides of tRNAs appear to occur in the nucleus, cytoplasm, and mitochondrion. In some lower fungi, the 5′ ends of certain tRNAs are edited (Forget et al., 2002; Laforest et al., 1997). As described above, RNA splicing of group I and group II introns involves intron-encoded maturase proteins as well as nucleus-encoded gene products. RNA turnover appears to play a role in the regulation of mitochondrial gene expression, with intergenic spacer regions cleaved from primary transcripts being rapidly turned over (Margossian and Butow, 1996). Some enzymes involved in RNA stability have been shown to be transcript specific (Dieckmann and Staples, 1994). While transcription, RNA processing, and degradation play a role in controlling the expression of certain mitochondrial genes, most regulation appears to occur during translation. In yeast, the synthesis of mitochondrial gene products is typically regulated by inner-membrane-bound translational activator proteins (Fox, 1996; Poyton and McEwen, 1996), and a similar example is known in *N. crassa* (Coffin et al., 1997). These proteins interact with both the ribosomes and the 5′ untranslated regions of mitochondrial mRNAs or help tether the synthesis of hydrophobic mitochondrial gene products to the inner membrane (Green-Willms et al., 1998). Many of these translational activators are mRNA specific, which may be necessary to provide individual control over gene products to coordinate the proper assembly of the large respiratory chain complexes.

IMPORT OF PROTEINS INTO MITOCHONDRIA

The large number of different proteins that are found in mitochondria (probably about 1,000 for fungi) and the limited coding capacity of mtDNA emphasize the fact that most mitochondrial proteins are encoded by nuclear genes, translated in the cytosol, and imported into the organelle. Incoming proteins must also be sorted to the correct mitochondrial compartment for proper function. These processes are achieved by multisubunit translocases housed within the MOM and MIM. Although *S. cerevisiae* has been the dominant organism in the field since the mid-1990s, several important contributions have come from studies with *N. crassa*. Here we attempt to define the basic import process and briefly summarize the literature while pointing out contributions that have involved filamentous fungi—almost entirely *N. crassa*.

The term "precursor" or "preprotein" is used for mitochondrial proteins before they reach their final destination and conformation within the mitochondrion. The precursors of many mitochondrial proteins carry an N-terminal extension referred to as a "targeting sequence" or a "presequence," which is ultimately removed from the protein. Presequences usually contain hydroxylated and positively charged amino acids, lack negatively charged amino acids, and are capable of forming an amphipathic helix that presents the positively charged residues on one face and hydrophobic residues on the other (von Heijne, 1996). For precursors without presequences, the mitochondrial targeting information is found within the mature protein sequence.

Early studies using *N. crassa* showed that translation of precursor proteins on cytosolic ribosomes was not directly coupled to their import into mitochondria. Rather, they are released from ribosomes into the cytosol and interact with the mitochondrial import apparatus in a posttranslational fashion (Hallermayer et al., 1977; Harmey et al., 1977). However, there may also be certain proteins or conditions that favor cotranslational import (Ahmed et al., 2006; Lithgow, 2000; Verner, 1993).

Complexes Used for Import of Proteins into Mitochondria

The import complexes found in both the MOM and the MIM are shown and defined in Fig. 3 and its legend. The nomenclature for import complexes and their components was unified in 1996 (Pfanner et al., 1996). Complexes are referred to in capital letters (e.g., TOM). Proteins of the complexes use the same letters, with only the first letter capitalized (e.g., Tom). Numbers following the letters designate the molecular mass in kilodaltons of a specific protein (e.g., Tom40). A somewhat confused nomenclature has arisen for those complexes and subunits discovered since the unification. This is most evident for the SAM or TOB complex (see below), and the alternate names for its components are listed in Table 2. In this chapter, we use the SAM complex terminology. Another nomenclature discrepancy has developed with respect to the import motor associated with the TIM23 complex. One view sees the motor as a complex that is separate from the TIM23 complex and refers to it as the PAM (preprotein translocase-associated motor) complex. A different view is that the motor is simply part of the TIM23 complex. Here we refer to the PAM complex, but we also give the most common alternate names for subunits of the complex.

The TOM complex

Preproteins are recognized and bound on the outer surface of the MOM (cytosolic side) by specific receptors in the TOM complex and are subsequently routed through the TOM complex translocation channel or pore. Precursors are kept in an import-competent state through interaction with chaperones and other factors in the cytosol (reviewed by Neupert, 1997, and Neupert and Herrmann, 2007). The TOM complex of the MOM is the entry point for almost all mitochondrial proteins into the organelle. The holo-TOM complex, which can be isolated following solubilization of mitochondria in the mild detergent digitonin, consists of seven subunits (Fig. 3). Stronger detergents remove Tom70 and Tom20 and give rise to the core TOM complex (Ahting et al., 1999). All the subunits of the TOM complex are held in the membrane by a single membrane-spanning domain with the exception of Tom40. Computer predictions and circular dichroism studies (Ahting et al., 2001; Becker et al., 2005) have shown that Tom40 exists as a β-barrel in the MOM.

The TOM complex from *N. crassa* has been visualized by electron tomography (Ahting et al., 1999, 2001;

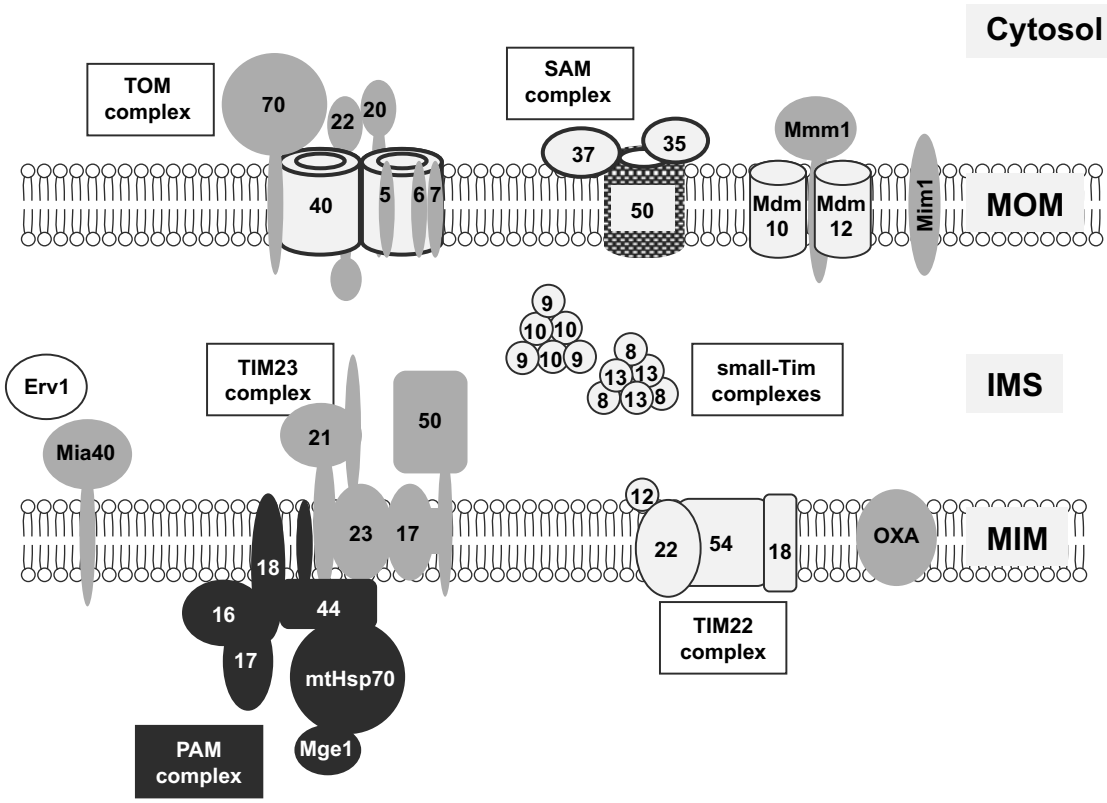

FIGURE 3 Complexes and proteins involved in import of proteins into mitochondria. Subunits of each complex are shown with a number representing their molecular mass. The TOM complex (translocase of the outer mitochondrial membrane) is the entry point for the majority of mitochondrial proteins. The SAM complex (sorting and assembly machinery) is also known as the TOB (topogenesis of β-barrel proteins) complex (see Table 2). The SAM complex is responsible for the insertion of β-barrel proteins into the outer membrane following their import through the TOM complex into the IMS. Further assembly of β-barrel proteins requires the action of Mdm12 and Mmm1. Tom40 additionally requires the action of Mdm10 and Mim1. The two TIM complexes (translocases of the inner mitochondrial membrane) were named for the Tim22 and Tim23 proteins originally identified as components of the respective complex. Precursors of the carrier family (such as the ATP/ADP carrier) and a few other proteins with an even number of membrane-spanning domains and no cleavable presequence are inserted into the MIM by the TIM22 complex. Precursors with cleavable targeting signals are recognized as substrates by the TIM23 complex and translocated into the matrix. However, some TIM23 substrates contain stop-transfer signals that halt movement into the matrix and result in partitioning into the MIM. The PAM complex (presequence translocase associated motor) binds the N terminus of presequence-containing preproteins as they enter the matrix. Through cycles of interaction with mtHsp70, the precursor is drawn into the matrix. Two complexes composed of six small Tim protein subunits, either three subunits of Tim8 plus three of Tim13 or three of Tim9 plus three of Tim10, exist in the IMS. These complexes chaperone precursors en route to either the SAM complex or the TIM22 complex through the IMS. The OXA (cytochrome oxidase assembly) complex "exports" a small class of matrix targeted precursors back into the MIM from the matrix. It is also involved in the insertion of mitochondrial translation products into the MIM. The Mia40 and Erv1 proteins form a disulfide relay system that is responsible for trapping a class of small precursors with a twin cysteine motif into the IMS. Further details are given in the text.

Künkele et al., 1998a). Purified preparations of the holo-TOM complex were seen to contain structures with two or three pores, while the core complex contained mostly two-pored structures (Fig. 4). When purified from mitochondria by using the detergent octylglucoside, the complex contained only Tom40 and gave images containing only one pore (Ahting et al., 2001). Comparison of the *S. cerevisiae* wild-type complex with the complex isolated from strains lacking Tom20 revealed that the presence of Tom20 correlated with the existence of the three-pored structure (Model et al., 2002). The pores within the TOM complex structure have been estimated to be about 20 to 26 Å in diameter by both electron microscopic analysis and size exclusion studies (Ahting et al., 1999, 2001; Hill et al., 1998; Künkele et al., 1998a; Schwartz and Matouschek, 1999).

Tom40 is the major component of the TOM complex pore (Hill et al., 1998; Künkele et al., 1998a, 1998b). The gating characteristics of the TOM core complex and purified Tom40 from *N. crassa* have been compared by electrophysiological analysis. The presence of the non-Tom40 components of the core complex reduced the energy needed for transitions between different conductance states of the pore. Examination of core complex isolated from mutant strains lacking one of Tom5, Tom6, or Tom7 showed no

TABLE 2 Alternate names for the SAM complex and its components

Name used in this chapter	Synonyms
SAM complex (sorting and assembly machinery)	TOB complex (topogenesis of β-barrel proteins)
Sam50	Tob55, Omp85
Sam37	Mas37, Tom37, Metaxin 1 (mammalian)
Sam35	Tob38, Tom38, Metaxin2 (mammalian)

differences from the wild type, suggesting that Tom22 and/or some combination of the smaller Tom components is required for the effect (Poynor et al., 2008).

The cytoplasmic domains of Tom70, Tom22, and Tom20 act as receptors for mitochondrial precursor proteins. The C-terminal domain of Tom20 contains a series of alpha helices that form a groove for binding presequences through hydrophobic interactions via a dynamic mechanism that allows recognition of a wide range of mitochondrial presequences (Abe et al., 2000; Saitoh et al., 2007). Tom22 is required for maintaining TOM complex organization (van Wilpe et al., 1999) and has been shown to interact with Tom20, where it assists with the binding of precursors (Mayer et al., 1995; Yamano et al., 2008) and promoting their passage from the receptor to the translocation pore (Kiebler et al., 1993). Tom70 is the usual receptor for hydrophobic precursors with multiple membrane-spanning domains and internal targeting signals that are destined for the MIM (Ryan et al., 1999; Söllner et al., 1990; Young et al., 2003). Such proteins include members of the carrier family like the ATP/ADP carrier. Though the precursors that interact with Tom70 are fairly specialized, when Tom70 is absent, Tom20 is able to fulfill its function.

There appears to be some variability between yeast and *N. crassa* with respect to the function of the three small components of the TOM complex. In yeast, Tom5 was found to play an important role in the transfer of precursors from the receptors to the translocation channel (Dietmeier et al., 1997), but no effect on import was seen in *N. crassa* strains lacking the protein (Schmitt et al., 2005). In yeast, Tom6 is thought to promote the association of receptors with Tom40, while Tom7 has the opposite function and decreases stability of receptor/Tom40 interactions (Alconada et al., 1995; Dekker et al., 1998; Hönlinger et al., 1996). In *N. crassa*, both proteins increase complex stability (Sherman et al., 2005). Tom7 and the IMS domain of Tom22 may form part of a site for binding precursors on the inner side of the TOM complex (Esaki et al., 2004).

The SAM Complex and Assembly of β-Barrel Proteins

The SAM complex (Fig. 3; Table 2) is responsible for the insertion of β-barrel proteins into the MOM. The currently known β-barrel proteins of the MOM are Tom40, porin, Sam50, Mdm10, and Mmm2. The SAM complex contains three core components Sam50, Sam35, and Sam37 (Kutik et al., 2007; Milenkovic et al., 2004; Neupert and Herrmann, 2007; Waizenegger et al., 2004). Sam50, predicted to be a β-barrel protein itself, is the core of the complex and forms what appears to be an insertion channel (Paschen et al., 2003). In *N. crassa*, three different versions of Sam50 occur as the result of alternative splicing (Hoppins et al., 2007). In yeast, Sam35 and Sam37 are peripheral membrane proteins on the cytosolic side of the MOM, but the mammalian homologue of Sam37 (metaxin 1) appears to be anchored in the MOM by a single membrane-spanning domain (Abdul et al., 2000; Armstrong et al., 1997).

The assembly of β-barrel precursors has been intensively studied in both yeast and *N. crassa* with a focus on the assembly of the Tom40 precursor (Model et al., 2001; Rapaport and Neupert, 1999; Taylor et al., 2003). As shown in Fig. 5, a newly synthesized 40-kDa precursor binds to receptors on the cytosolic side of the TOM complex and is subsequently translocated through the pore of the complex. Studies involving both *N. crassa* and yeast demonstrated that as the precursor emerges from the TOM complex to the IMS side of the outer membrane, it associates with the Tim8/Tim13 or Tim9/Tim10 complex (Hoppins and Nargang, 2004; Wiedemann et al., 2004). Presumably these complexes act as chaperones to guide the precursor to the SAM complex. The incoming Tom40 precursor then associates with the SAM complex, resulting in the formation of a 250-kDa intermediate known as assembly intermediate I. This association is transient, and the SAM complex inserts Tom40 into the outer membrane. Insertion of β-barrel proteins into the MOM is dependent on a specific sorting signal that occurs in the last predicted β-strand of the proteins. Interestingly, the receptor for the signal is Sam35, which resides on the cytosolic side of the MOM. It is thought that Sam35 is closely associated with the

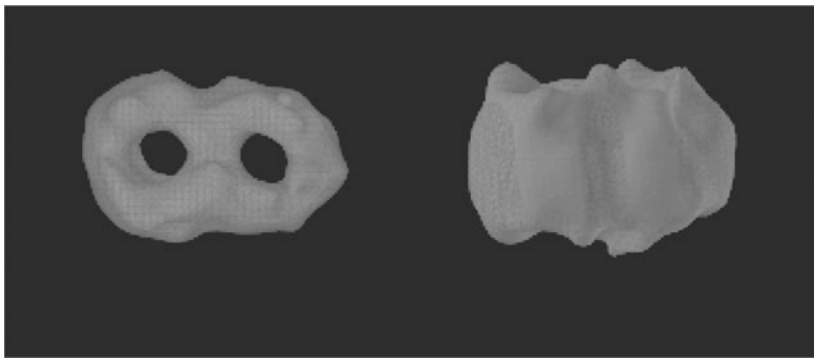

FIGURE 4 Electron tomographic image of the purified *N. crassa* TOM core complex. The stain-filled pits are assumed to be pores through which preproteins cross the MOM. (From Ahting et al., 1999.)

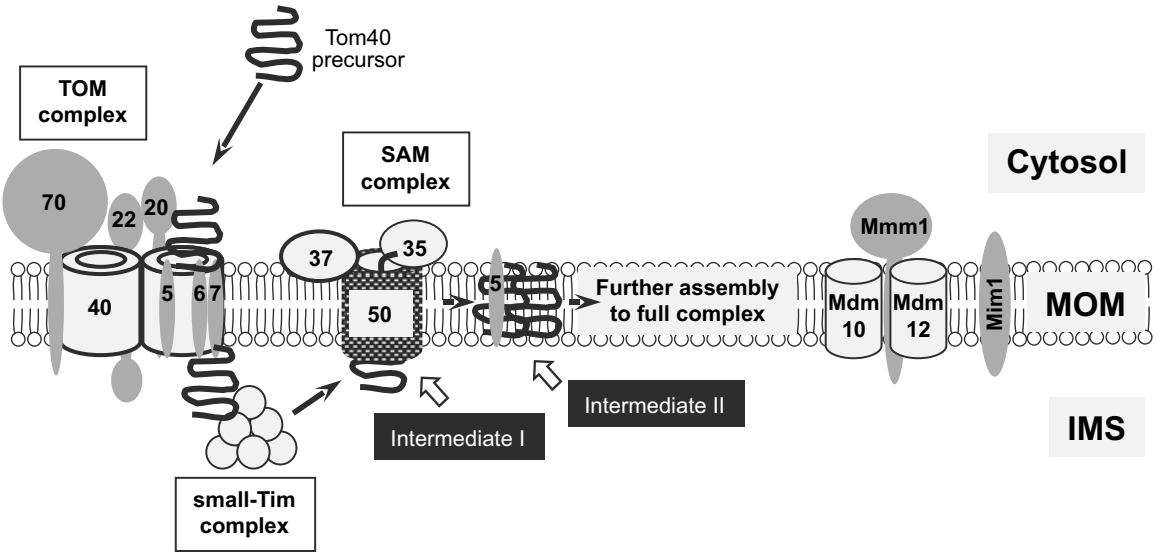

FIGURE 5 Steps in assembly of Tom40 into the TOM complex. Following synthesis in the cytosol, a Tom40 precursor is recognized by the TOM complex and imported into the IMS. The precursor then interacts with one of the small-Tim complexes that chaperone the precursor to the SAM complex. The precursor interacts with the SAM complex and forms assembly intermediate I. The SAM complex inserts the precursor into the membrane, where it associates with a preexisting Tom40 molecule and a molecule of Tom5 to give assembly intermediate II. Further assembly gives the fully formed TOM complex. The Mdm10, Mdm12, Mmm1, and Mim1 proteins are also required for efficient assembly of Tom40 at steps following interaction with the SAM complex.

membrane domains of Sam50 and that the β-signal extends through the SAM complex to interact with Sam35. Interaction of the β-signal with Sam35 results in a change in the conductance and increase in size of the SAM complex channel so that several β-strands of the incoming precursor could insert at the same time. These data suggest that the insertion of β-barrel proteins into the channel occurs with the precursor in at least a partially folded conformation followed by lateral release from the channel into the membrane (Kutik et al., 2008). The steps up to and including membrane insertion of Tom40 serve as a general model for the assembly of all β-barrel proteins into the MOM (Kutik et al., 2008; Paschen et al., 2003). Following insertion, there are different pathways for further assembly depending on the particular β-barrel protein. For Tom40, insertion is followed by association with another Tom40 subunit and a Tom5 subunit to form a 100-kDa intermediate known as assembly intermediate II. Further interactions with additional TOM complex subunits give rise to the fully assembled 400-kDa TOM core complex. However, additional proteins are needed for efficient assembly of Tom40 and other β-barrel proteins.

Three proteins originally described for their roles in mitochondrial distribution and morphology (mdm) or maintenance of mitochondrial morphology (mmm) have now been shown to be involved in β-barrel assembly pathways. The Mdm10, Mdm12, and Mmm1 proteins were known to exist in a complex, and the absence of any one of them resulted in altered mitochondrial morphology in yeast (Boldogh et al., 2003). Altered mitochondrial morphology was also shown for *mmm1* mutants in *N. crassa* (Prokisch et al., 2000). However, Mdm12 and Mmm1 have now been shown to be required for efficient assembly of all β-barrel proteins (Meisinger et al., 2007), while Mdm10 is specifically required for efficient assembly of Tom40 into the TOM complex (Meisinger et al., 2004). Since β-barrel precursors in mutant strains lacking these proteins are able to form interactions with the SAM complex, it is thought that the requirement for these proteins occurs at later steps in the assembly pathway. It seems likely that the defects in mitochondrial morphology associated with the loss of any of these three proteins are a secondary effect that is revealed as a result of interruptions in the β-barrel assembly pathway (Meisinger et al., 2007). Another protein named Mim1 (or Tom13) also plays a role in the assembly of Tom40 into the TOM complex at a point after association with the SAM complex (Becker et al., 2008; Ishikawa et al., 2004; Waizenegger et al., 2005).

Import Complexes Found in, or Associated with, the MIM

The vast majority of the work on the TIM23, TIM22, PAM, and OXA complexes as well as the IMS oxidative folding pathway has been done using *S. cerevisiae* with few contributions coming from filamentous fungi. Nonetheless, for completeness, the function of these complexes is summarized here briefly. The work is described in several recent general reviews (Bohnert et al., 2007; Bolender et al., 2008; Gakh et al., 2002; Koehler, 2004; Kutik et al., 2007; Milenkovic et al., 2007; Neupert and Herrmann, 2007) and in more specific reviews given in the appropriate sections. References to original work are cited only for recent work not covered in reviews or for examples of studies that have involved filamentous fungi.

The TIM23 Complex and the PAM Complex

Preproteins destined for the matrix emerge on the IMS side of the TOM complex as they cross the MOM. Further

translocation is initiated by the TIM23 complex (Fig. 3), which contains Tim50, Tim23, Tim21, and Tim17. Tim50 interacts with the incoming precursor and passes it to the translocation channel. The channel appears to be formed by Tim23, but Tim17 is involved in channel gating (Martinez-Caballero et al., 2007). In a membrane potential-dependent reaction, the positively charged presequence of the preprotein is moved through the Tim23 channel (Krayl et al., 2007). Tim21 has been proposed to connect the TOM and TIM23 complexes and may assist in releasing the precursor from the TOM complex. Movement of the remaining portion of the preprotein through the channel requires the PAM complex (also known as the motor segment of the TIM23 complex). Tim50 plays another important role by interacting with Tim23 when no preproteins are present to prevent leakage of protons from the IMS to the matrix through the Tim23 pore.

The PAM complex (Fig. 3) contains Tim44, Pam18 (also called Tim14), Pam16 (also called Tim16), Pam17 mtHsp70, and Mge1. Tim44 binds to the matrix side of the TIM23 complex and recruits the ATP bound form of the mtHsp70 chaperone to the site (Schiller et al., 2008). The incoming precursor is then bound by mtHsp70-ATP resulting in hydrolysis of the ATP molecule and the formation of an mtHsp70-ADP complex that is tightly bound to the precursor. This complex is released from Tim44, allowing a new mtHsp70-ATP complex to bind. The Mge1 protein associates with the mtHsp70-ADP complex and stimulates release of the precursor and ADP from mtHsp70. This cycle is repeated until the precursor is translocated into the matrix. Hydrolysis of ATP by mtHsp70 is regulated by Pam18 (Tim14) and Pam16 (Tim16). Pam17 is thought to stabilize an association between the Pam16 (Tim16) and Pam18 (Tim14) subunits. The presequence of incoming precursor proteins is removed upon its entrance into the matrix by the matrix processing peptidase. Tam41 (also called Mmp37), though not a component of the complex, was reported to be required to maintain the integrity of the TIM23 complex.

There is debate as to how the energy gained from hydrolysis of ATP by mtHsp70 is actually used to drive translocation into the matrix (Neupert and Brunner, 2002; Pfanner and Truscott, 2002). The ratchet model suggests that spontaneous unfolding of the portion of the precursor still on the cytosolic side of the MOM would allow sliding of the precursor back and forth within the TOM and TIM23 pores. However, since mtHsp70 binds to the precursor as it enters the matrix, this would prevent backsliding and impart a net vectorial movement into the matrix as the more-C-terminal regions of the precursor are progressively bound by mtHsp70. The power stroke or active-pulling model suggests that mtHsp70 exerts a pulling force on the precursor via conformational changes that occur when ATP is hydrolyzed. The entropic pulling model suggests that entropy loss as the result of excluded volume effects upon the binding of mtHsp70 to incoming precursors drives movement (De Los Rios et al., 2006).

Several proteins destined for the IMS or the MIM also use the TIM23 pathway to reach their destinations. In these cases, the presequence is followed by a stop-transfer signal that arrests translocation of the precursor in the TIM23 complex and results in its lateral insertion into the MIM. The presequence is also removed from these preproteins by matrix processing peptidase resulting in an integral MIM protein. Some of these proteins undergo further cleavage by an inner membrane peptidase that removes the stop-transfer signal from the mature peptide (Gakh et al., 2002). This results in a final IMS location for the imported protein. It has been suggested that a TIM23 complex associated with the PAM complex, but without the Tim21 protein, accomplishes translocation into the matrix, whereas the membrane portion of the TIM23 complex with Tim21, but without the PAM complex, inserts precursors into the inner membrane (Chacinska et al., 2005; van der Laan et al., 2007). However, other studies concluded that the TIM23 membrane complex and the PAM complex were always associated, regardless of the type of preprotein being imported. In this study, different conformations of the entire complex were detected depending on the nature of the precursor being imported (Popov-Celeketic et al., 2008).

Oxidative Folding Drives Import of Small IMS Proteins

Many small proteins destined for the IMS, including the small Tim proteins (Fig. 3), contain characteristic twin cysteine motifs and use an oxidative-folding, disulfide relay system to drive their import (reviewed by Hell, 2008, and Stojanovski et al., 2008). When these proteins enter the IMS from the TOM complex, they interact with an oxidized form of the Mia40 protein. Mia40 catalyzes the formation of intramolecular disulfide bonds within the proteins, converting them to an oxidized folded state that conformationally traps them in the IMS. Mia40 is reduced as a result of the reaction, and the Erv1 protein reoxidizes Mia40 so that its catalytic function is restored. Reoxidation of Erv1 is accomplished by passage of its electrons to molecular oxygen or oxidized cytochrome *c*.

The TIM22 Complex

The TIM22 complex (Fig. 3) imports the carrier proteins (such as the ATP/ADP carrier) as well as TIM complex subunits with multiple membrane-spanning domains to the MIM (reviewed by Jensen and Dunn, 2002, and Rehling et al., 2004). These hydrophobic proteins are chaperoned across the IMS by the small Tim protein complexes (Tim8-Tim13 and Tim9-Tim10) and bound by a Tim9-Tim10-Tim12 complex associated with the TIM22 complex on the IMS side of the MIM. Tim22 is the pore-forming component of the complex and mediates the insertion of the precursor protein into the MIM in the presence of membrane potential. Tim54 and Tim18 are thought to be involved in TIM22 complex assembly. A role for Tim54 in the assembly of the Yme1p protease complex of the MIM has also been demonstrated (Hwang et al., 2007).

OXA Translocase

A number of nucleus-encoded proteins are known to be imported into the matrix via the TIM23 pathway but then "exported" back into the MIM. For many of these proteins the insertion is catalyzed by the Oxa1 translocase (Fig. 3) of the MIM (reviewed by Bonnefoy et al., 2008, and Stuart, 2002). Oxa1 is also involved in the insertion of mitochondrially translated proteins into the MIM. In *S. cerevisiae* it has been shown that mitochondrial ribosomes interact with Oxa1 to facilitate insertion of proteins in a cotranslational manner. Work with *N. crassa* demonstrated that the protein probably exists as a homotetrameric complex in the MIM (Nargang et al., 2002). Oxa1 is essential for viability in both *N. crassa* (Nargang et al., 2002) and *P. anserina* (Sellem et al., 2005).

COORDINATION OF NUCLEAR AND MITOCHONDRIAL GENOMES

Since proper formation of mitochondria requires the expression of a small number of genes within the organelle and a large number of genes in the nucleus, it has long been thought that there must be systems of communication to ensure that mitochondrial biogenesis occurs in a regulated fashion. The term "retrograde regulation" has been used to describe the signaling from mitochondria that influences the expression of nuclear genes. Although some of the earliest reports on mitochondrial to nuclear signaling were from work with *N. crassa* (Barath and Kuntzel, 1972a, 1972b), retrograde signaling has been most intensively studied in *S. cerevisiae*, where many genes functioning in various retrograde pathways have been described (reviewed by Butow and Avadhani, 2004).

AOX as a Model for Retrograde Regulation

Alternative oxidase (AOX) is a nucleus-encoded protein that represents an excellent model for retrograde regulation because its expression is often influenced by the functional status of the standard cytochrome-mediated electron transport chain (cmETC) (Fig. 1). AOX is found in several species of fungi and yeasts (but not *S. cerevisiae*), protists, bacteria, and animals as well as in all green plants (Chaudhuri et al., 2006; Finnegan et al., 2004; Joseph-Horne et al., 2001; McDonald and Vanlerberghe, 2006; Rhoads and Vanlerberghe, 2004). AOX transfers electrons directly from ubiquinol to oxygen. When both the AOX and cmETC pathways are fully or partially functional, a branched pathway is formed (Fig. 1). The AOX is not sensitive to the same inhibitors that act on the cytochrome-mediated electron transport chain such as cyanide (inhibits complex IV) or antimycin A (inhibits complex III). Thus, AOX is often described as the cyanide-insensitive or cyanide-resistant respiration pathway. AOX is inhibited by compounds such as salicylhydroxamic acid and *n*-propylgallate.

Electron transfer via the AOX pathway bypasses the last two proton-pumping sites of the cmETC. Thus, the energy that normally would have been used to create a proton gradient and synthesize ATP is lost as heat. This makes the alternative pathway inefficient in terms of energy conservation. However, under conditions where mutations or inhibitors have blocked one of the later steps of the standard respiratory pathway, recycling of electron carriers and ATP production via proton pumping at complex I can continue via the AOX (Fig. 1). Thus, one function of the AOX may be to provide an escape mechanism from inhibitors of the latter portion of the cmETC so that the negative effects of naturally occurring molecules like sulfide and cyanide might be avoided (Joseph-Horne et al., 2001; McDonald and Vanlerberghe, 2004).

AOX has been observed in many filamentous fungi and has been studied in detail with respect to its expression in a few species. In 1953, cyanide-insensitive respiration in the cytochrome aa_3 and *b* deficient (*poky*) mutant of *N. crassa* was reported (Tissieres et al., 1953). Subsequently it was shown that this alternative pathway of respiration was present in the mitochondria of *poky* and that the AOX and cmETC form a branched pathway (Lambowitz et al., 1972). It was also demonstrated that the *N. crassa* enzyme could be induced not only by growth in the presence of the cmETC inhibitors cyanide and antimycin A, but also by chloramphenicol, ethidium bromide, and oligomycin (Bertrand et al., 1983; Edwards et al., 1974, 1976; Lambowitz and Slayman, 1971). Chloramphenicol inhibits mitochondrial protein synthesis and results in a reduction of complexes I, III, and IV, which contain mitochondrially encoded components. Ethidium bromide inhibits mitochondrial transcription so that it also reduces the level of complexes containing components encoded by mtDNA. Induction by oligomycin is likely due to inhibition of electron transport that occurs with the buildup of the proton gradient that cannot be dissipated due to inhibition of ATP synthase. In addition to *poky*, other mutations affecting the cmETC also resulted in AOX expression (Bertrand et al., 1983; Li et al., 1996) as did growth in copper-deficient medium (Schwab, 1973), since Cu is a constituent of complex IV. Taken together, these observations suggest that any condition resulting in a reduction of the function of the cmETC induces AOX in *N. crassa*.

The regulation of AOX expression has been of considerable interest since its discovery. Transcription of nuclear DNA was shown to be required for the appearance of AOX activity (Edwards and Unger, 1978). Nuclear run-on assays and quantitative PCR have shown that there is a low level of constitutive transcription of the *N. crassa* gene (Chae et al., 2007a; Tanton et al., 2003). However, the near-total absence of cyanide-insensitive respiration or AOX protein in uninduced cells suggests a mechanism of posttranscriptional control that prevents expression of the mRNA. Induction of the AOX occurs quite rapidly. A 1-h exposure of growing cells to antimycin A increased the rate of AOX transcription about sevenfold (Tanton et al., 2003). Longer exposure to antimycin A led to about a 17-fold increase in transcript levels (Chae et al., 2007a). AOX activity was detected after about 30 min following addition of chloramphenicol or ethidium bromide to growing cultures (Edwards et al., 1974, 1976).

N. crassa mutants unable to express AOX were originally isolated by using selection schemes centered on the inability of strains lacking AOX to grow in the presence of antimycin A (Bertrand et al., 1983; Edwards et al., 1976). These screens led to the identification of two genes required for AOX production, known as *aod-1* and *aod-2* (for alternative oxidase deficient). Using a monoclonal antibody developed against the *Sauromatum guttatum* AOX protein, it was shown that most *aod-1* mutants still produced AOX protein, whereas *aod-2* mutants did not. This led to the hypothesis that *aod-1* was the structural gene for AOX while *aod-2* encoded a factor required for AOX expression (Bertrand et al., 1983; Lambowitz et al., 1989). When the *N. crassa aod-1* gene was cloned, it was shown that the level of the *aod-1* message was severely reduced in an *aod-2* mutant, supporting the hypothesis that *aod-2* was involved in controlling the transcription or stability of the *aod-1* mRNA (Li et al., 1996). A second AOX structural gene (*aod-3*) was discovered in *N. crassa* by homology searches (Tanton et al., 2003) after the completion of the *N. crassa* genome sequence (Galagan et al., 2003). However, conditions leading to expression of *aod-3* have not been identified, and the gene clearly plays no role under conditions where *aod-1* function is required, since strains containing mutations affecting the *aod-1* gene do not grow in the presence of antimycin A (Descheneau et al., 2005; Tanton et al., 2003).

The cloning of *aod-1* allowed the development of a reporter system screen to select specifically for regulatory mutants unable to induce *aod-1* expression. Use of this system led to the discovery of four additional genes (*aod-4*, *aod-5*, *aod-6*, and *aod-7*) required for *aod-1* expression (Descheneau

et al., 2005). Thus, a total of five putative AOX regulatory loci may exist, and since the mutant screen was not saturated, there may be a very complex pathway(s) controlling production of the enzyme. Recently, two of the potential regulatory genes (*aod-2* and *aod-5*) were identified as zinc cluster transcription factors necessary for the expression of *aod-1*. Electrophoretic mobility shift assays demonstrated that the two factors bind as a heterodimer to the AOX induction motif (AIM) found about 170 bases upstream from the start of the structural gene coding sequence (Chae et al., 2007a).

The AIM sequence is typical of those recognized by zinc cluster transcription factors (MacPherson et al., 2006) and contains two directly repeated CGG triplets separated by 7 bp (Chae et al., 2007b). The AIM was found to be conserved in other species of the order Sordariales but was not detected in more distantly related fungi known to express AOX, so that the mechanism for regulation of expression of AOX may vary among filamentous fungi and other organisms (Chae et al., 2007a). The current challenge in *N. crassa* is to identify the signal(s) that activates the AOX transcription factors and to determine the identity of the other potential members of the signal transduction pathway.

In *Magnoporthe grisea* the alternative pathway is induced following exposure to the fungicide SSF-126 [(E)-2-methoxyimino-*N*-methyl-2-(2-phenoxyphenyl) acetamide], a complex III inhibitor (Mizutani et al., 1995). Nuclear run-on assays showed that the AOX was also transcribed constitutively in this species (Yukioka et al., 1998a), although exposure of cells to SSF-126 increased the rate of transcription. Since SSF-126 was shown to result in the generation of reactive oxygen species (ROS), and since hydrogen peroxide also induced transcription of AOX, it was suggested that ROS may act as an AOX induction signal in *M. grisea*. The constitutively expressed transcript was thought to be actively degraded by a factor sensitive to cycloheximide. AOX-deficient mutants affecting the structural gene have been isolated in *M. grisea*, and potential regulatory elements in the promoter region have been identified, but these have not been directly tested for a role in production of the transcript (Yukioka et al., 1998b).

M. grisea is a plant pathogen that causes rice blast disease. Quinol oxidation inhibitors, acting at complex III of the cmETC, are a major class of fungicides used to combat *M. grisea* and other fungal plant pathogens. Unexpectedly, the fungal AOX does not provide an escape from the action of these inhibitors, except possibly in the later stages of infection. It is thought that plant antioxidants released during infection may reduce ROS, which seem to be required for AOX induction in these pathogenic species (reviewed by Fernandez-Ortuno et al., 2008).

Candida albicans contains two AOX genes, named *AOX1a* and *AOX1b*. Although the *AOX1a* transcript could not be detected on Northern blots, a reporter gene fused to its promoter showed constitutive expression. Expression of *AOX1b* was dependent on the growth phase and could be induced by cyanide, antimycin A, paraquat (*N*,*N*′-dimethyl-4-4′-bipyridinium dichloride), hydrogen peroxide, and menadione. Interestingly, although an *aox1a* mutant strain was capable of inducing AOX (presumably from *AOX1b*) following a short treatment with antimycin A, growth of the strain in the presence of potassium cyanide or antimycin A was severely reduced. There was virtually no growth of an *aox1b* mutant or a double *aox1a aox1b* mutant in the presence of these inhibitors. It was also shown that in cells deleted for the CaSLN1 gene, which encodes a histidine kinase, AOX activity and protein levels were slightly reduced under normal conditions and slightly increased in the presence of antimycin A. This suggested that the histidine kinase may be involved in the regulation of AOX expression in this species (Huh and Kang, 2001). It has recently been reported that erythroascorbic acid stimulates AOX production in *C. albicans* as well as having a general stimulating effect on respiration (Huh et al., 2008). The mechanisms involved are not yet understood. The activity of MnSOD has also been found to influence *C. albicans* AOX expression, probably via its effect on mitochondrial ROS levels (Hwang et al., 2003). Finally, it has been suggested that AOX plays a role in the pH-controlled transition between yeast and hyphal forms of *C. albicans* (Konno et al., 2006).

AOX in *P. anserina* and Its Relationship to Senescence

As described below, *P. anserina* is unusual among filamentous fungi in that it has a limited life span and undergoes senescence after a strain-specific period of growth. Senescence is associated with rearrangements in the mtDNA that lead to a gradual decline in mitochondrial function in this obligate aerobic organism. As in other organisms, *P. anserina* expresses AOX in response to impairment of the standard electron transport chain by mutations (Borghouts et al., 2001; Dufour et al., 2000). Interestingly, the decline in electron transport caused by the effects of the natural senescence mechanism on the cmETC complexes does not result in the induction of AOX (Borghouts et al., 2001). Two possible explanations for this observation were suggested. First, the organism may have a mechanism that prevents AOX induction during senescence, since the degeneration of mtDNA that occurs results in the loss of mitochondrial genes, including those for complex I. Thus, the AOX activity would have no purpose during senescence, because the ability to create a proton gradient and synthesize ATP via complex I would not exist even if the AOX were in place. Second, it was shown that transcription of *P. anserina* AOX was reduced when the growth medium was supplemented with copper (Borghouts et al., 2001; Stumpferl et al., 2004). Since the cytoplasmic copper concentration in cells undergoing senescence is thought to increase (Averbeck et al., 2001; Borghouts et al., 2001, 2002), this may have a negative effect on AOX expression.

There appears to be a low level of constitutive transcription of the AOX gene in wild-type strains, which can be increased severalfold in mutants affecting the cmETC (Borghouts et al., 2001; Dufour et al., 2000). However, different results have been reported as to whether or not the protein is expressed in noninduced cultures (Borghouts et al., 2001; Gredilla et al., 2006; Lorin et al., 2001; Sellem et al., 2005; Stumpferl et al., 2004). Unlike what has been seen in many organisms, transcript levels of AOX were not induced by ROS in *P. anserina*, as judged by examination of AOX following growth in the presence of hydrogen peroxide or paraquat (Borghouts et al., 2001). In fact, a reduction in transcript levels was seen. It was not known if transcript production was repressed or if these compounds decreased transcript stability.

Long-lived strains of *P. anserina* that carry mutations affecting the cmETC have been isolated (Belcour and Vierny, 1982; Schulte et al., 1988). As a result of the cmETC respiratory defects, AOX is induced in such strains. For example, studies with a mutant lacking a functional complex IV of the cmETC due to a disruption in the nucleus-encoded

COX5 subunit of the complex showed that AOX was induced, ROS production was reduced, mtDNA rearrangements were eliminated, and life span was dramatically increased (Dufour et al., 2000). Since it is thought that ROS may play a role in inducing senescence, and since an inverse correlation between ROS and AOX levels was observed in plants (Maxwell et al., 1999; Purvis, 1997; Wagner and Moore, 1997), it was conceivable that respiration via AOX in *P. anserina* could have accounted for all the phenotypic properties of the mutant. However, it has now been shown that there is no direct link between AOX levels, ROS, and life span in *P. anserina*, since overexpression of AOX in the *cox5* mutant strain severely decreased the life span and returned ROS production to wild-type levels (Lorin et al., 2001). Similar observations were made when AOX was overexpressed in a mutant lacking cytochrome c_1 and complex III function (Sellem et al., 2007). In addition, inactivation of the gene encoding AOX did not affect the life span of an *oxa1* mutant which was characterized by decreased levels of complexes I and IV, strongly induced AOX levels, and an increased life span (Sellem et al., 2005).

Other investigations of AOX and life span in *P. anserina* have focused on copper metabolism. The effects of cellular copper depletion were examined in a mutant affecting a transcription factor called *GRISEA*, which is required for expression of a copper permease (Borghouts et al., 2001). These mutant cells were also found to have an increased life span, and this was related to several events in the cell. Complex IV of the standard electron transport chain was reduced about fivefold in the mutant due to its use of copper as a cofactor. The *SOD2* gene, encoding mitochondrial Mn-SOD2, was not expressed because it requires *GRISEA* for transcription. Finally, AOX was induced in these cultures most likely because of the reduction in complex IV activity. It was suggested that ROS levels would be decreased due to respiration via the AOX and that this would result in a longer life span (Borghouts et al., 2001; Gredilla et al., 2006).

The following model has been suggested as an explanation for the relationship between respiratory characteristics and senescence (Lorin et al., 2006; Scheckhuber and Osiewacz, 2008). Loss of function of the cmETC leads to induction of AOX and decreased ROS. Such strains have dramatically increased longevity but also grow more slowly than wild-type cells—probably due to the presence of only one coupling site for ATP production. Overexpression of AOX results in increased ROS, increased growth rate, and decreased longevity relative to cmETC mutants expressing normal levels of AOX. Thus, the data can be explained by an inverse relationship between ROS levels and longevity, although all factors involved in ROS generation and management are probably not yet understood.

SENESCENCE

Filamentous fungi are generally considered immortal. *P. anserina* is an exception to this rule, as it has a defined vegetative-growth life span (Osiewacz and Scheckhuber, 2002). The senescent syndrome involves a series of events that ultimately affect mitochondrial genome stability and function. Among natural isolates of *Neurospora* species, senescence is primarily detected in strains having mt plasmids that have a propensity to integrate into the mtDNA and is rarely observed in laboratory strains. Yet, like *Podospora*, interactions between nuclear and mitochondrial genetic systems play an important role in senescence, and plasmid-free nuclear senescent mutants that affect mtDNA stability have also been identified. Regardless of its initial cause, senescence in filamentous fungi invariably involves mitochondrial dysfunction and, in most cases, is associated with rearrangements or deletions of mtDNA. The term senescence was initially used to describe the growth of *P. anserina* (Rizet, 1953) and has since been applied to any filamentous fungal culture that shows an initial period of constant vegetative growth before growth slows and stops altogether. Senescence has been documented in several filamentous fungi, but most investigations have been conducted with *Podospora* or *Neurospora* (reviewed by Bertrand, 2000, and Griffiths, 1992).

Non-Plasmid-Related Senescence

While the life span of *P. anserina* strains is a cytoplasmically controlled trait, specific nuclear genes play a role in controlling the onset of senescence (Marcou, 1961; Tudzynski and Esser, 1979). In addition to the GRISEA transcription factor, which influences the rate of senescence in *P. anserina* (described above), other nuclear genes are known to modulate life span (Rossignol and Silar, 1996). For example, deletion of the nuclear gene encoding a dynamin-related protein involved in mitochondrial fission results in a markedly increased life span in *Podospora* that correlates with a severe reduction of senDNA amplification as well as an increased resistance to the apoptosis inducer etoposide (Scheckhuber et al., 2007). In *Neurospora*, two nuclear gene mutants, *natural death* or *nd* (Sheng, 1950) and *senescent* or *sen* (Navaraj et al., 2000), have been shown to cause senescence. The mtDNA of presenescent cultures of both *nd* and *sen* have large deletions and/or gross rearrangements caused by intramolecular recombination events, suggesting that the products of the nuclear nd^+ and sen^+ genes are involved in mtDNA recombination or repair, although it has also been suggested that the product of the *sen* gene could play a role in protein import (Maheshwari and Navaraj, 2008).

Plasmid-Induced Senescence

Studies of *Neurospora* strains that contain the Kalilo linear mtDNA plasmid revealed that repeated vegetative transfer leads to growth defects and senescence (reviewed by Griffiths, 1992). Senescence has also been associated with the linear DNA plasmid Maranhar of *N. crassa* (Court et al., 1991) and variant forms of the Mauriceville and Varkud family of circular retroplasmids (Akins et al., 1986). Curiously, plasmid-associated senescence has not been detected for other plasmid families, such as circular plasmids with a DNA-based replication mode, linear retroplasmids, or RNA plasmids, nor has it been reported in organisms other than *Neurospora* species. While there are plasmid- and strain-specific differences, plasmid-associated senescence generally involves the integration of autonomously replicating forms of the plasmid into the mtDNA. A single integration event may disrupt an essential gene, or multiple integration events, followed by homologous recombination, can lead to large deletions of the mitochondrial genome. Once formed, the defective mtDNAs appear to overtake cultures and exhibit "suppressivity" toward wild-type mtDNAs, to the point that intact (functional) mtDNAs become scarce. This is similar to the behavior of several mitochondrial mutants, such as the "stopper" mutants of *N. crassa* (reviewed by Bertrand, 2000).

One possible explanation for the suppressive effect is that the mtDNAs with large deletions may have a replicative advantage over wild-type DNAs. However, this seems unlikely, as some integrations probably increase the size of the mtDNA. Furthermore, there is one report of senescence in a strain containing a variant form of the Mauriceville

plasmid that was found to be associated with impairment of mitochondrial protein synthesis due to plasmid overreplication but showed no evidence for plasmid integration (Stevenson et al., 2000). This demonstrates that altered mtDNAs are not a prerequisite for suppressivity. The phenomenon of suppressivity as it relates to takeover of cultures by mitochondrial mutations in *N. crassa* has been reviewed previously (Kennell et al., 2004)

In *P. anserina*, an mt plasmid appears to have different effects depending on nutritional status. The linear DNA plasmid pAL2-1 originally was reported to extend longevity in strains in which it had integrated into the mtDNA (Hermanns et al., 1994; Hermanns and Osiewacz, 1996), though later studies found the plasmid to have a neutral effect (van der Gaag et al., 1998). More recently, the pAL2-1 plasmid was shown to decrease life span when cultures were grown on media containing low levels of glucose (i.e., calorie restriction [Maas et al., 2004]). One way to reconcile these contradictory reports is that the integration of the pAL2-1 into the mtDNA interferes with programmed senescence and thus would appear to increase longevity, while as an autonomously replicating element the plasmid has little effect unless strains are subjected to calorie restriction, which extends life span and unmasks the senescence-inducing effect. Interestingly, a recent report found evidence of a cryptic retroplasmid in *N. intermedia* strains that appears to attenuate or suppress senescence in Kalilo strains (Maas et al., 2007). In summary, there appears to be a large range of molecular events that can lead to senescence, but all involve eventual effects on mtDNA and/or mitochondrial function.

Vacuoles in Filamentous Fungi

EMMA JEAN BOWMAN AND BARRY J. BOWMAN

Major contributions of filamentous fungi to the ecosystem include degradation of detritus by saprotrophic fungi, support of plant growth by mycorrhizal fungi, and invasion of humans and major crop plants by pathogenic fungi. Although the fungal vacuole plays a critical role in all of these functions, we are only just beginning to understand what specific genes and proteins are involved, how they are regulated, and the molecular mechanism of their action in formation of this organelle.

Investigators are in good agreement that the vacuole is a dynamic organelle, enclosed by a single membrane, with a variety of structural forms: small vesicles, tubules, and large vesicles. It is an acidic compartment as a consequence of the activity of the vacuolar H^+-translocating ATPase (V-ATPase) in the membrane. It contains high concentrations of basic amino acids, polyphosphate, hydrolytic enzymes, and divalent cations. It has a presumed role in nitrogen and phosphate storage, solute transport, regulation of cellular amino acid metabolism, recycling of macromolecules, osmoregulation, and cytosolic ion and pH homeostasis. The vacuole is an important organelle.

STRUCTURE OF THE VACUOLE

The Vacuolar System as a Motile Tubular Complex

The old textbook view of vacuoles as large round organelles changed to a dynamic picture of connected tubules, vesicles, and some large vesicles as the result of work by Anne Ashford and her colleagues (Shepherd et al., 1993; Cole et al., 1998). Using the ectomycorrhizal fungus *Pisolithus tinctorius*, they observed four zones of vacuolar morphology from the growing hyphal tip: (i) the apical zone, which has few or no vacuoles; (ii) the subapical zone with small ovoid-spherical vacuoles; (iii) the nuclear zone, where tubular vacuoles predominate; and (iv) the basal zone, where large spherical vacuoles are most common. (Fig. 1 through 3 in Hyde et al., 2002, show fine examples of these zones.) The parts appear to form a continuous vacuolar system with numerous small tubes connecting small vesicles, large vesicles, and highly tubulated regions. Most striking is the active nature of the vacuolar system in living hyphae. Tubules extend, retract, fuse with each other and with spherical vacuoles, and can deform (reversibly) into small vesicles. Vesicles may sprout small tubules and appear to slide along larger tubules.

Such a dynamic pleiomorphic tubular vacuolar structure has been documented in many other filamentous fungi, including *Paxillus involutus* (Tuszynska et al., 2006), *Phanerochaete velutina* (Darrah et al., 2006), *Phialocephala fortinii* (Saito et al., 2006), *Gigaspora margarita* (Uetake et al., 2002), *Aspergillus oryzae* (Shoji et al., 2006a), *Neurospora crassa* (Hickey et al., 2004), and several members of the oomycete genus *Saprolegnia* (Allaway et al., 1997).

Visualizing the Vacuolar Complex

The vacuolar structure described above is the product of live-cell imaging in microscopes utilizing fluorescent dyes that accumulate in vacuoles and green fluorescent protein (GFP)- or red fluorescent protein (RFP)-tagged proteins targeted to vacuoles or vacuolar membranes. Both fluorescent microscopes and confocal laser scanning microscopes are widely used. Delights of the live-imaging technology are movies showing the dynamic vacuolar system in action. Examples are included on a CD-ROM produced for educational purposes, which can be obtained from www.fungalcell.org (Hickey and Read, 2003).

The dye preferred by at least two research groups is Oregon green 488 carboxylic acid diacetate (carboxy-DFFDA) 6 isomer (catalog no. 06151; Invitrogen-Molecular Probes, Eugene, OR), which accumulates specifically in the lumen of both tubular and spherical vacuoles (Cole et al., 1998; Hickey et al., 2004). The dye diffuses into cells, where it is colorless and nonfluorescent until esterases cleave off the acetate groups to yield the fluorescent, amine-reactive carboxy-DFFDA. Cole and colleagues (Cole et al., 1997) proposed that in *P. tinctorius* the dye crosses the vacuolar membrane via a nonspecific anion transporter and becomes trapped there. Supporting this hypothesis, probenecid, an anion transport inhibitor, prevented uptake of the carboxy-DFFDA from the cytosol to the vacuolar system.

Emma Jean Bowman and Barry J. Bowman, Department of Molecular, Cell, and Developmental Biology, University of California, Santa Cruz, CA 95064.

Other fluorescent dyes from Molecular Probes are also suitable for staining fungal vacuoles. Earlier studies used 6-carboxyfluorescein diacetate (6-CFDA); it works well but is being replaced by its more stable derivative, carboxy-DFFDA. Kitamoto and coworkers (Shoji et al., 2006a) have used 7-amino-chloromethyl coumarin (CMAC), which is converted to a cell-impermeant conjugate with glutathione and accumulates in fungal vacuoles via glutathione pumps. Another useful dye is FM4-64 because it labels plasma membranes, endosomal membranes, and vacuolar membranes in a progressive manner. Commonly used as an indicator dye for endocytosis, FM4-64 beautifully illuminated the endosomal/vacuolar systems of *A. oryzae* (Shoji et al., 2006a) and *N. crassa* (Hickey et al., 2004) but labeled only plasma membranes and vacuoles in dead or damaged cells in *P. tinctorius* (Cole et al., 1998).

More recently, investigators have been visualizing the vacuolar system with probes containing marker proteins tagged with GFP and RFP. The availability of complete genome sequences for *A. oryzae* and *N. crassa* greatly facilitated these studies. Genes for proteins targeted to the vacuole have been obtained by PCR and cloned into GFP and RFP vectors for transformation to *A. oryzae* and *N. crassa*.

Kitamoto and his colleagues initiated the studies with GFP and RFP in vacuoles of filamentous fungi. Based on studies with *Saccharomyces cerevisiae*, they constructed a strain of *A. oryzae* expressing the fusion protein of carboxypeptidase Y, a protease in the vacuolar lumen, and enhanced GFP (CPY-EGFP) (Ohneda et al., 2002). Unexpectedly, the fluorescence of CPY-EGFP was weak and unclear in cells grown on acidic medium (pH 5.5, which is optimal for growth) but appeared in the lumen of vacuole-

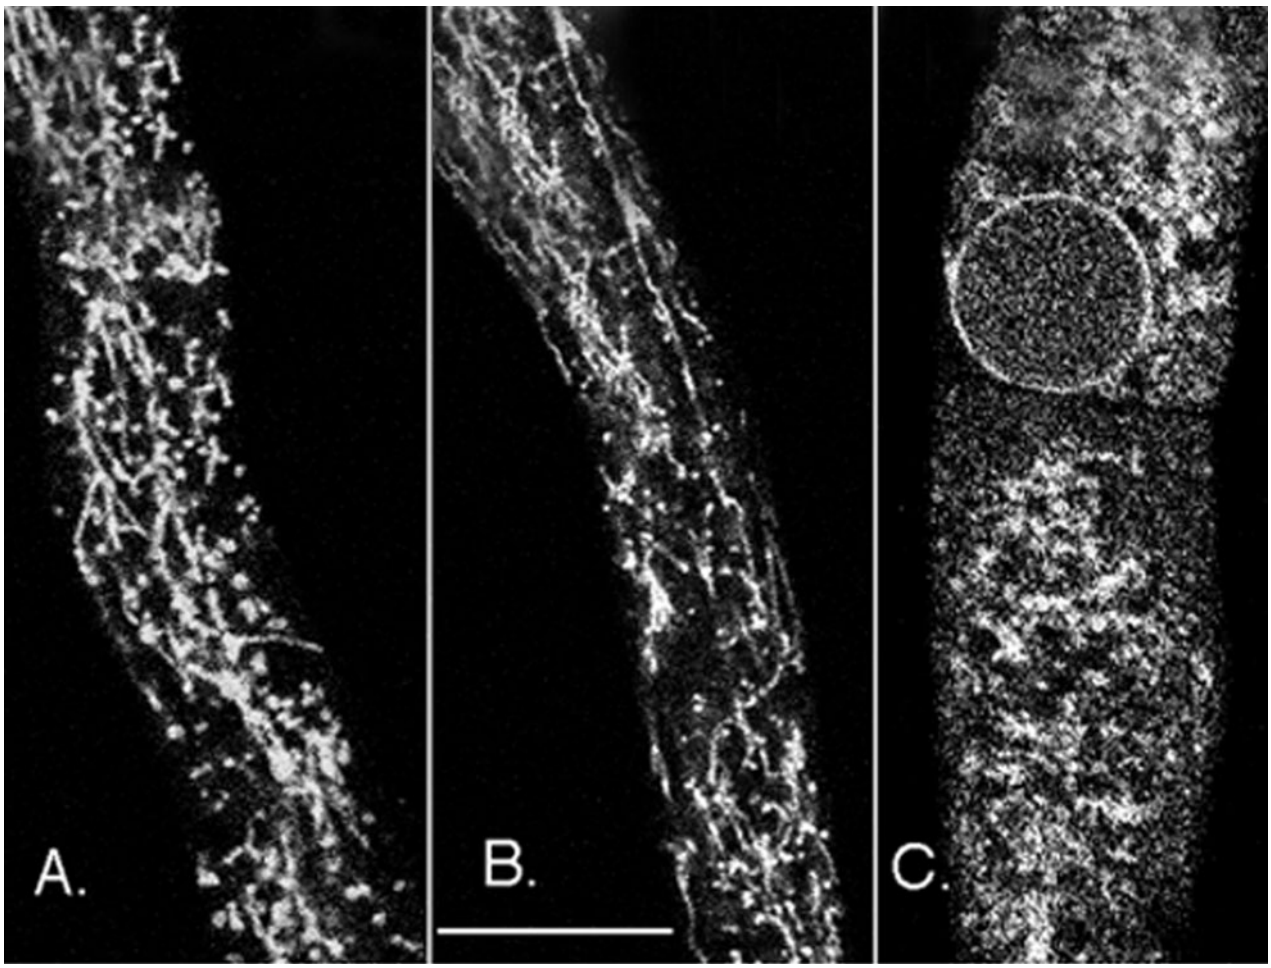

FIGURE 1 Visualizing the vacuole with RFP and GFP. RFP (dsRED) or GFP was fused to proteins predicted to be in the membrane of the vacuole, using the plasmids pMF272 or pMF334 constructed by M. Freitag (Oregon State University, Corvallis). By transformation into *N. crassa,* the recombinant genes were targeted to the *his-3* locus. Images were obtained by confocal microscopy (B. Bowman and E. J. Bowman, unpublished results). (A) RFP dsRED was fused to the N terminus of the CAX protein. (B) RFP dsRED was fused to the N terminus of the VAM-3 protein. In panels A and B the region shown is approximately 100 μm behind the hyphal tip. The vacuolar system consists of tubules and small vesicles. (C) GFP was fused to the C terminus of the A subunit of the V-ATPase (encoded by *vma-1*). The region shown is approximately 2 mm behind the hyphal tip. In this older part of the hypha, the fluorescence is localized to the membrane of a large vacuole and to many small vesicles. In this strain the vacuole appears as a network of tubules and small vesicles nearer the hyphal tip (not shown), as in panels A and B. The bar represents 10 μm, and the scale is the same for all panels.

like structures grown on medium of alkaline pH (8.0). Apparently, EGFP fluorescence is sensitive to low pH. A subsequent paper was more satisfying. Vam3p is a tSNARE protein located on the vacuolar membrane in *S. cerevisiae*. Shoji et al. (2006a) examined vacuolar membranes in strains of *A. oryzae* expressing the fusion protein EGFP-AoVam3p and saw the dynamic, pleiomorphic structure that has become a hallmark of the vacuolar system in filamentous fungi as described above. Thus, AoVam3p became the first protein to be localized on membranes of tubular vacuoles. Beautiful confocal images of the vacuolar membrane system in *N. crassa* are obtained by using fusion proteins between GFP or RFP and VAM-3, proteins involved in calcium transport, such as CAX, and subunits of the V-ATPase (Fig. 1).

A Cautionary Note

Because it is dynamic and flexible, the fungal vacuolar system is subject to variation and change induced by the experimenter. The cells are surprisingly fragile and must be handled with extreme care to avoid damage and artifactual findings. Damage can result from high concentrations of dyes, excessive light intensity, too-long exposure to light, oxygen deprivation, and rough handling of samples. Signs that cells have been perturbed include slowing of hyphal growth, narrowing of the hyphal tip, retraction of the Spitzenkörper from the tip, and changes in organelle morphology (Hickey et al., 2004; Cole et al., 1998). The vacuolar system in particular responds to insult by forming many spherical vesicles with a range of sizes.

Complications in assessing the condition of a sample come from natural variation in the material. Vacuolar form and motility vary with the age of the culture, growth conditions, and the location within the culture (Cole et al., 1998; Ohneda et al., 2002; Shoji et al., 2006a). Furthermore, experimental treatments such as addition of inhibitors may affect growth and morphology of the vacuolar system in the same way as damage does (Hyde et al., 1999, 2002; Tuszynska et al., 2006). When feasible, showing that a response is reversible is desirable.

Another View of the Vacuole

For biochemical studies in vitro, vacuoles can be isolated from filamentous fungi as a pure organellar fraction of round vesicles, approximately 0.2 to 2 μ in diameter. Cramer et al. (1983) developed the original procedure for *N. crassa* in the early 1980s. Cells are grown for 14 to 15 h in aerated liquid culture and lysed in 1 M sorbitol by the action of glass beads in a BeadBeater (BioSpec Products), and vacuoles are then separated from other cell fractions by differential centrifugation. The vacuoles, behaving like osmometers, become very dense and pellet with mitochondria. Centrifugation on a sucrose gradient separates mitochondria from vacuoles, which pellet under a 60% sucrose solution. To isolate vacuolar membranes, the pelleted dense vacuoles are lysed by suspension in a low-osmotic solution (1 mM Tris-HCl, pH 7.5) and then the light vacuolar membranes are pelleted at high speed (Bowman and Bowman, 1997).

After viewing the tubular vacuolar system by microscopy, one might anticipate a large yield of vacuoles and vacuolar membranes from such a preparation. Instead, from a typical cell fractionation procedure we obtain ~200 mg of mitochondrial protein, 20 mg of plasma membrane protein, and 2 mg of vacuolar membrane protein. This is a reminder that the dense tubular vacuolar system occurs only near the growing tips of hyphae, while large spherical vacuoles predominate behind them. The structure of vacuoles in a mass of mycelium grown in the lab, in liquid or on plates, remains to be investigated. Similarly, results from in vitro and in vivo studies should be compared with caution.

MAINTENANCE AND BIOGENESIS OF THE VACUOLAR SYSTEM

Microtubules

For filamentous fungi, the study of formation and biogenesis of the vacuole is a nascent research area. In 1993, Steinberg and Schliwa proposed that all organellar formation and movement in *N. crassa* were microtubule-dependent processes (Steinberg and Schliwa, 1993). Hyde et al. (1999) observed the effects of microtubule inhibitors on the structure of the vacuolar system of *P. tinctorius* visualized with carboxy-DFFDA. The antimicrotubule drug oryzalin largely eliminated the tubular vacuolar system, replacing it with spherical vacuoles. Upon removal of the microtubule inhibitor, the tubular vacuolar system re-formed. Antiactin drugs had little effect on the morphology and motility of the majority of the vacuolar system, but they did cause "massed tubules" at and just behind the tip, possibly because growth was inhibited and tubules piled up as mass flow continued. Electron microscope pictures of freeze-substituted material consistently showed a close alignment of microtubules and vacuoles. Taken together, these results pointed to microtubules, but not microfilaments, as important for determining vacuolar morphology and motility (Hyde et al., 1999).

GTPases

Dynamin-like proteins, which are GTPases, have been implicated in the formation of the interconnected vacuolar system of filamentous fungi. In *P. tinctorius* GTPγS induced a dramatic increase in tubular vacuoles in the first five cells. (Typically, tubular vacuoles are primarily in the first cell in this fungus.) The change was reversible and prevented by preincubation with GDPγS. This behavior was consistent with the action of a dynamin-like protein (Hyde et al., 2002).

A molecular approach was taken in the study of *Aspergillus nidulans*. Kitamoto and his group began choosing homologs of *S. cerevisiae* genes known to be involved in vacuolar biogenesis to evaluate their functions in filamentous fungi. Deletion of the *vps*A gene (*S. cerevisiae* homolog *VPS1*), which encodes a protein related to dynamin, led to severe alterations in the structure of the vacuolar system of *A. nidulans*. Vacuole-like structures, identified by staining with the vacuolar dye 6-CFDA in the disruptant strain, were highly fragmented rather than large and spherical as in the wild-type strain (Tarutani et al., 2001). Deletion of the *ava*A gene (*S. cerevisiae* homolog *VAM4/YPT7*), which encodes a small GTPase in the Rab family, elicited a similar phenotype, i.e., highly fragmented vacuoles (Ohsumi et al., 2002). If Vam4p is fixed in the GDP-bound state by mutation in *S. cerevisiae*, it loses its function in homotypic vacuolar fusion. A strain with the comparable mutation in the *ava*A gene produced highly fragmented vacuoles, consistent with a role for the GDP-bound form of the enzyme in preventing activity. For both of the *A. nidulans* genes the authors suggested that the small vacuole-like compartments might be intermediates in vacuolar biogenesis (Tarutani et al., 2001; Ohsumi et al., 2002). Interestingly, although both *A. nidulans* genes had functions similar to those of their yeast homologs, neither one was able to rescue its respective *S. cerevisiae* deletion strain.

Late Endosomal Markers

Data from other deletion strains led to more complex interpretations (Tatsumi et al., 2007). An *S. cerevisiae* strain lacking Vps24p, a marker protein for late endosomes, grows normally and has intact vacuoles because an alternative route for vacuolar biogenesis is available. In contrast, the homologous deletion in *A. oryzae* resulted in a strain (Aovps24) that grew poorly and contained fragmented and aggregated vacuoles, much like the two *A. nidulans* strains described above. Late endosomal and vacuolar functions appeared to be functionally fused in the *A. oryzae* mutant. Strains with three other late endosomal markers (again by homology to *S. cerevisiae*) fused to EGFP were constructed and examined by confocal microscopy. The EGFP signal appeared as static dot-like structures near vacuoles that were stained by FM4-64 (an endomembrane system dye) but not by CMAC (a vacuolar dye), suggesting an endosomal location only. Expression of the dsRED- and EGFP-tagged late endosomal markers in the Aovps24 strain did not label dispersed dot-like structures but aggregated bodies previously identified as fragmented vacuoles. Thus, the fragmented vacuoles behaved like hybrid organelles with features of both late endosomes and vacuoles. Maybe AoVps 24 is required for the functional separation of these two compartments. The data can be interpreted as evidence for a late endosomal function in vacuolar biogenesis (Tatsumi et al., 2007).

Vacuolar Membrane Marker

AoVam3p was the first protein shown to locate on the membrane of tubular vacuoles in filamentous fungi (Shoji et al., 2006a). The yeast homolog, Vam3p, is a vacuolar membrane syntaxin that regulates vesicular traffic to vacuoles and the homotypic fusion between vacuoles. As anticipated, the fusion protein of EGFP-AoVam3p localized to small punctate structures in the apex, tubular vacuoles behind the apex, and the membrane of large vacuoles further back, like a typical vacuolar network in *A. oryzae*. Surprisingly, it also colocalized with FM4-64. Sequence analysis revealed equal similarity of AoVam3p to two *S. cerevisiae* proteins, Vam3p and Pep12p. (Pep12p is a tSNARE in the late endosome/prevacuolar compartment.) In the absence of a second homolog in *A. oryzae*, it is possible that AoVam3p has the functions and cellular locations of both proteins. Time-lapse imaging of EGFP-AoVam3p for a short period showed multiple changes in vacuolar structure, consistent with a role for the protein in mediating fusion of small vesicular and tubular structures with large spherical vacuoles (Shoji et al., 2006a).

How filamentous fungi form their unique, variable, and vibrant vacuolar system is just beginning to be studied and understood. One lesson from the experiments above is that understanding the biogenesis of the vacuolar system in *S. cerevisiae* cannot be transferred directly to filamentous fungi and that additional studies are essential.

FUNCTIONS OF THE VACUOLAR SYSTEM

Storage of Nitrogen and Phosphorus Compounds

Fungal vacuoles serve as storage reservoirs for high levels of phosphorus and nitrogen in the form of basic amino acids and polyphosphate (polyPi), respectively. R. H. Davis used *N. crassa* in a classic analysis of basic amino acid metabolism and its regulatory role in fungi. The amino acid story and its partner polyamine story are covered in chapter 24 of this volume, and we do not discuss it further here.

The history of polyPi in fungal vacuoles has elements of mystery. What does it do in the vacuole, what form does it take, and how does it get there? Early studies suggested that polyPi served as a counterbalance to the positive charges in the vacuole. Extracts of isolated vacuoles of *N. crassa* were found to contain millimolar concentrations of ornithine (18.1 mM), arginine (13.6 mM), histidine (1.9 mM), and lysine (1.8 mM), as well as spermidine (2.5 mM), Mg^{2+} (2.7 mM), Na^{+} (1.5 mM), and K^{+} (0.7 mM). The polyphosphate-P level (36.7 mM) was sufficient to counterbalance about one-half of the total positive charges (Cramer and Davis, 1984). As a counterion for neutralization of basic amino acids (and other positive ions), the polyPi allows cells to store both P and N compounds in a small volume.

PolyPi was once thought to occur in the form of granules in living cells, but the picture changed with improvements in sample preparation for electron microscopy. Electron microscopic analysis of growing cells of *P. tinctorius*, prepared by anhydrous freeze substitution, showed dispersed phosphorus, largely balanced by potassium ions in large spherical and tubular vacuoles (Cole et al., 1998). X-ray microanalysis of the same samples showed colocalization of phosphorus with potassium. Similar results were obtained with *P. tinctorius* associated with *Eucalyptus pilularis* as an ectomycorrhiza: the polyPi was concentrated in vacuoles of the fungus in dispersed form, not in granules (Ashford et al., 1999).

More recently Saito et al. (2006) used an innovative enzymatic method to localize polyPi in the dark root fungal endophyte, *P. fortinii*. The probe consisted of the recombinant polyPi binding domain of *Escherichia coli* exopolyphosphatase (PPBD) linked to Xpress tag, which could be visualized in confocal microscope images as a fluorescent signal by using anti-mouse Xpress conjugated with Alexa 488 or in transmission electron micrographs as gold particles conjugated with goat anti-mouse-immunoglobulin G antibody interacting with the PPBD mouse-anti-Xpress antibody complex. Again, the polyPi occurred in dispersed form in the fungal vacuoles, with tubular vacuoles appearing to contain less polyPi than spherical or elongated vacuoles.

A new insight into the importance of polyPi storage comes from a study of the corn smut fungus, *Ustilago maydis* (Boyce et al., 2006). Infection of corn by the fungus depends on a morphological transition from budding to filamentous growth. Mutants that limited polyPi accumulation in the vacuole favored the transition to the filamentous form, yet the resultant hyphae had reduced virulence in maize seedlings. One interpretation of these results is that vacuolar polyPi levels play an important part in mediating both morphogenesis and infectivity in this pathogenic fungus.

Vacuolar Calcium

Fungal vacuoles also act as reservoirs for divalent cations, including Ca^{2+}, Zn^{2+}, and Fe^{2+}, to prevent them from reaching toxic levels in the cytosol. In *S. cerevisiae* over 95% of the cellular Ca^{2+} has been reported to be in the vacuole (Eilam et al., 1985). Purified vacuoles of *N. crassa* were found to contain only 0.3 mM Ca^{2+} ions (Cramer and Davis, 1984), and calcium did not colocalize with phosphorus in X-ray microanalysis of *P. tinctorius* (Cole et al., 1998). Electrophysiological experiments demonstrated that the vacuole of *N. crassa* accumulates high concentrations of Ca^{2+} (300 μM) and that this reservoir is largely responsible for maintenance of low concentrations of Ca^{2+} in the cytosol (0.1 μM) (Miller et al., 1990). No calcium was detected in vacuoles of a mutant strain with an inactivated *cax* gene that encodes a putative Ca^{2+}/proton exchanger in the vacuolar membrane (Zelter et al., 2004). Yet the *cax* mutant is not sensitive to high concentrations of Ca^{2+} in the medium. A second *N. crassa* mutant, *nca-2*, is defective

in the homolog of a CaATPase (Pmcp) in the vacuolar membrane of yeast. The *nca-2* mutant retains normal, possibly elevated, levels of vacuolar Ca^{2+} but is sensitive to high amounts (200 mM) of Ca^{2+} in the medium (Abreu, 2003; B. J. Bowman, unpublished results). The phenotypes of the *cax* and *nca-2* mutants suggest that additional components are involved in mediating proper cytosolic Ca^{2+} levels. Because of the universal importance of Ca^{2+} as a signaling molecule, it is important to pursue the question of how the vacuole regulates cellular distribution of Ca^{2+} in a filamentous fungus.

Transport of Solutes

Filamentous fungi that are associated with plants as mycorrhizae or as endophytes are believed to supply nutrients to the plant. That transport of nutrients such as polyPi along the hypha to the plant occurs via the dynamic vacuolar system is a logical and attractive hypothesis. Retrograde transport of carbon compounds from the plant to the fungus could also utilize the vacuolar system. The nature of filamentous growth itself requires the constant translocation of new material to the growing tip. Cytosolic streaming is vigorous and must contribute to growth. Because of its orientation and constant flux, the vacuolar system is a likely conduit as well.

From the Kitamoto lab comes other evidence suggesting that the structure of the vacuolar system points to a role in transport (Shoji et al., 2006a, 2006b). Using the strain of *A. oryzae* that expressed EGFP-AoVam3p to label the vacuolar system (see above), the researchers observed an increase in the amount of tubular vacuolar structure in hyphae that extended onto a glass surface compared to the amount seen in hyphae growing on medium. Perhaps the increased tubular vacuoles served to transport nutrients to the hyphae not in contact with the medium. In mature hyphae, the EGFP fluorescence filled the lumen of the large vacuoles, as though the membrane protein had been internalized. An attractive hypothesis was that the vacuoles degrade cytosolic material by microautophagy (see below) in old vacuoles and recycle it via transport through the tubular connections in the vacuolar system to growing regions of the mycelium.

A detailed study by Darrah et al. (2006) generated the first direct evidence that the tubular vacuolar system functions in transport by following the movement of carboxy-DFFDA through the vacuolar system of *P. velutina*. The researchers monitored the dye's progress by using the technique of fluorescence recovery after photobleaching. They concluded that longitudinal transport through the dynamic, interconnected vacuolar system did occur, over distances of millimeters or even centimeters, and that solute movement could be described by a diffusion model. Moreover, these workers noted that diffusion through the vacuolar system could permit movement of solutes in both directions, thus counteracting the force of mass flow in the cytosol.

Degradative Enzymes

In the wild, filamentous fungi are important agents of recycling, and degrading litter is a major activity. Fungal vacuoles are well known for their high contents of hydrolytic enzymes (Klionsky et al., 1990). Although many of these enzymes have been extensively studied in *S. cerevisiae*, they have to date received much less attention in filamentous fungi. During our efforts to identify subunits of the V-ATPase in *N. crassa*, we isolated an abundant vacuolar protein that proved to be the homolog of proteinase A, the product of the *PEP4* gene in *S. cerevisiae*. Because proteinase A is at the top of an activation cascade, yeast cells containing Pep4p null mutations are deficient in at least three proteases. Inactivation of the *pep-4* gene in *N. crassa* resulted in phenotypes different from those of the mutants in yeast. The *N. crassa* mutant strains were not sporulation deficient, and they were not deficient in protease B and carboxypeptidase Y. Instead, the activities of the other proteases in the *pep-4* mutants were higher than in the wild type, as if the loss of proteinase A was compensated by higher levels of other proteases (Vázquez-Laslop et al., 1996). However, in *Aspergillus niger*, inactivation of the *pepE* gene, which encodes the homolog of *S. cerevisiae* proteinase A, gave a different result. The mutant strain was not deficient in sporulation, but it did exhibit reduced levels of activity for three proteases, similar to the *S. cerevisiae* proteinase A mutant strain (van den Hombergh et al., 1997).

While investigating the incompatibility reaction (described below) in *Podospora anserina*, Paoletti et al. (2001) characterized the homolog of proteinase B, a vacuolar protein involved in autophagy in *S. cerevisiae*. The proteinase B homolog was also purified in *A. niger* (Frederick et al., 1993).

Autophagy

One of the most fascinating and far-reaching roles of the vacuolar system in filamentous fungi is the involvement in autophagy. The process of autophagy has an essential role during starvation, cell differentiation, cell death, and aging in all eukaryotic organisms (Reggiori and Klionsky, 2002; Levine and Klionsky, 2004; Klionsky et al., 2007). One of two cellular pathways for the turnover of proteins and organelles, autophagy takes place in lysosomes of mammals and vacuoles of fungi, both of which have a range of hydrolases capable of degrading all cellular constituents. (The other pathway, proteasome-mediated degradation, is not discussed here.) Microautophagy involves uptake of cytosolic material directly at the vacuolar membrane and is poorly understood. In macroautophagy, bulk cytoplasm or cytosolic organelles are first sequestered in double-membrane vesicles called autophagosomes. The autophagosomes dock with vacuoles and fuse with them. In both sorts of autophagy the membrane vesicles and their contents are released into the vacuole and broken down by vacuolar hydrolases.

Thoroughly studied in *S. cerevisiae*, autophagy has received less attention in the filamentous fungi. However, the basic phenomenon has been demonstrated by using orthologs of marker proteins for autophagy in *S. cerevisiae*. In *S. cerevisiae*, Atg1p is required for the formation of preautophagosomes, and Atg8p moves from the cytoplasm to autophagosomes and to autophagic bodies in the vacuole upon induction of autophagy (Reggiori and Klionsky, 2002). When autophagy was induced by nitrogen starvation in *P. anserina*, the fluorescent GFP-PaAtg8 fusion protein localized to perivacuolar bodies and to the vacuolar lumen (Pinan-Lucarré et al., 2003, 2005). Starvation also induced transcription of two genes involved in autophagy (Pinan-Lucarré et al., 2003). Similar results were obtained with *A. oryzae*. Fusion proteins of EGFP-AoAtg8 and DsRed2-AoAtg8 localized in dot structures similar to preautophagosomes under normal growth conditions and transferred into vacuoles under starvation conditions or following addition of the inhibitor rapamycin, which is convincing evidence that autophagy was induced (Kikuma et al., 2006).

As proposed for other organisms (Levine and Klionsky, 2004), autophagy plays an important role in the differentiation and development of filamentous fungi. Strains of *A. oryzae* with AoAtg8 deleted, which did not accumulate

DsRed-2 from the cytosol in their vacuoles (an indication that autophagy did not occur), were deficient in the differentiation of aerial hyphae and in conidial germination. Furthermore, EGFP-AoAtg8 localized to vacuoles in swollen conidia, germlings, and germ tubes even under nutrient-rich conditions. These (and other) results point to a role for autophagy in differentiation and development (Kikuma et al., 2006). Autophagy also affected differentiation in *P. anserina*. Inactivation of two genes involved in autophagy led to deficiencies in pigmentation, differentiation of aerial hyphae, and development of perithecia (Pinan-Lucarré et al., 2003).

The phenomenon of nonself recognition in filamentous fungi is often associated with autophagy. Also referred to as cell death by incompatibility, vegetative incompatibility, heterokaryon incompatibility, or programmed cell death, it is the subject of chapter 20 in this volume. Cells of growing filamentous fungi fuse with each other to form a mycelial network. However, when two cells that differ genetically at specific loci called *het* or *vic* loci fuse, they undergo cell death by incompatibility. We mention it here because the vacuolar system is intimately involved. As cells of *P. anserina* or *N. crassa* begin to die, the vacuolar system undergoes a morphological change from the tubular network to round vesicles (Pinan-Lucarré et al., 2005; Glass and Kaneko, 2003). The vacuoles fuse into larger vacuoles and then collapse or burst. Because vacuolization is a common feature of cell death by incompatibility, it is likely that vacuolar membrane permeability or rupture releases lytic enzymes and acidifies the cytoplasm, causing cell death in filamentous fungi (Pinan-Lucarré et al., 2007). Destruction of the heterokaryotic cell can be complete within 30 min after hyphal fusion (Glass and Koneko, 2003).

The cause-and-effect relationship between autophagy and cell death by incompatibility is not yet clear. A 2003 study (Pinan-Lucarré et al., 2003) involving *P. anserina* reported that autophagy was induced during cell death by incompatibility. Two genes involved in the autophagic process in *S. cerevisiae* were upregulated during incompatibility, and a GFP-PaATG8 fusion protein accumulated in vacuoles in response to either nitrogen starvation or induction of the incompatible reaction in a self-incompatible strain. A later paper (Pinan-Lucarré et al., 2005) showed that cell death by incompatibility could be experimentally separated from autophagy in *P. anserina*. Deletion of either the PaATG1 gene, involved in early autophagy, or the PaATG8 gene blocked the formation of autophagosomes but failed to prevent cell death or the accompanying vacuolization that is characteristic of both autophagy and cell death by incompatibility. In fact, cell death by incompatibility was accelerated in the deletion mutants, as if autophagy played a protective role.

As suggested by Pinan-Lucarré et al. (2007), the vacuole probably functions both in cell death by incompatibility and in autophagy. The inside-out destruction of the vacuole could be necessary for the induction of cell death by incompatibility, and intact vacuoles could be needed for autophagy to function in turning over cytoplasmic constituents and shielding neighboring cells from destruction.

THE FUNGAL VACUOLE AS A MODEL ORGANELLE FOR STUDIES OF THE V-ATPase

V-ATPases

Discovered in the early 1980s, V-ATPases are large multisubunit enzymes found in all eukaryotic cells. They are present on many components of the endomembrane system and on plasma membranes of specialized cells (Forgac, 2007; Kane, 2006). They have cellular roles in multiple physiological processes, and a number of diseases are associated with their malfunction. V-ATPases were first identified and characterized on vacuolar membranes of fungi and plants. Due to the availability of extensive molecular biology tools and a large number of investigators, *S. cerevisiae* became the premier model organism for investigating the V-ATPase. Later, animal systems became preeminent because of the involvement of V-ATPases in diseases. The filamentous fungus *N. crassa* also served as one of the major model systems for the identification and analysis of the enzyme.

Vacuolar Function and the V-ATPase

The fungal vacuole is an acidic compartment, providing an environment favorable for maturation and activity of hydrolytic enzymes. An electrochemical gradient of protons drives the transport of molecules across the membrane. The V-ATPase in the vacuolar membrane is the driving force for both of these functions. Large enough to be readily seen in an electron micrograph, V-ATPase molecules thickly decorate the vacuolar membrane of *N. crassa* (Fig. 2). *N. crassa* is a favorable model system for study of the V-ATPase because of the ease and economy of growing large numbers of cells, the availability of a procedure for isolating clean vacuolar membranes, and the density of the enzyme on vacuolar membranes.

Structure and Mechanism of the V-ATPase

V-ATPases are composed of two domains that form a ball-and-stalk structure, similar to, but larger than, the related F_OF_1 ATP synthase in membranes of mitochondria, chloroplasts, and bacteria (Forgac, 2007; Kane, 2006; Venzke et al., 2005). The proton-translocating domain of the enzyme, named V_0, contains six types of subunits embedded in the membrane, with a reported stoichiometry of $a_1,c_{4-5},c'_1,c''_1,d_1,e_1$. ATP is hydrolyzed within the V_1 domain of the enzyme, a roughly globular structure connected to V_0 by at least two stalks. V_1 contains eight subunits with a stoichiometry of $A_3B_3CDE_2FG_2H_{1-2}$. Like the F-type ATPase, the V-ATPase functions as a rotary motor. In current models, hydrolysis of ATP by the "motor" (primarily the A and B subunits) drives the rotation in the membrane of the "rotor" (subunits D,F,c,c′,c″, and d). The remaining subunits connect and stabilize the complex structure (Fig. 3). One difference between the subunit content of V-ATPases of fungi and higher eukaryotes has been found. Subunit c′ is present in all fungi but not in other organisms (Chavez et al., 2006; Forgac, 2007).

Genes Encoding V-ATPase Subunits

The first published sequences for subunits of the V-ATPase were for *Daucus carota* and *N. crassa* (Bowman et al., 1988a, 1988c; Zimniak et al., 1988). Today it is known that 14 genes encode the 14 subunits of the V-ATPase in *N. crassa*, making it likely that all the V-ATPases in the cell have the same structure. By contrast, higher eukaryotes express multiple isoforms of some subunits: four for a, two for B, E, H, and d, and three for C and G, making the total number of possible isoform combinations in the enzyme enormous (Forgac, 2007). Most of the isoforms in mammals are expressed in different tissues or in some cases on different membranes within a cell. Even in *S. cerevisiae*, two genes encode one of the subunits, the 100-kDa subunit a of the V_0 sector of the enzyme. The two isoforms localize

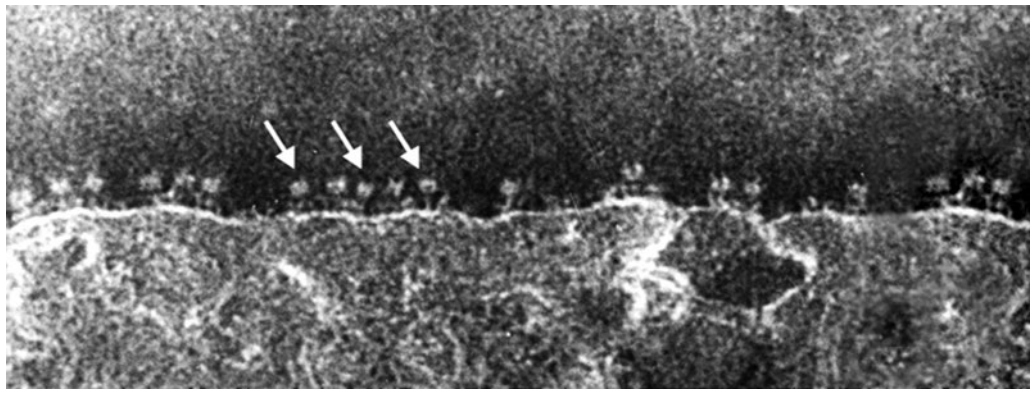

FIGURE 2 Electron micrograph of the V-ATPase in vacuolar membranes. Vacuolar membranes were isolated from *N. crassa*, negatively stained, and examined by transmission electron microscopy as described previously (Dschida and Bowman, 1992). A few of the V-ATPases are indicated by arrows. The globular head is 12 nm wide and is attached to the membrane by a 3-nm-wide stalk.

either to the vacuolar membrane or to the Golgi membrane, and both forms can partially substitute for each other (Manolson et al., 1994).

We have named the genes in *N. crassa* as follows. *vma-1*, *vma-2*, *vma-5*, *vma-8*, *vma-4*, *vma-7*, *vma-10*, and *vma-13* encode the V_1 subunits A, B, C, D, E, F, G, and H, respectively. *Vph-1*, *vma-3*, *vma-11*, *vma-16*, *vma-6*, and *vma-9* encode V_0 subunits a, c, c′, c″, d, and e. The *vma/vph-1* genes have relatively short, multiple introns (two to six introns), which tend to cluster near the ends of the coding region and may be important for high levels of expression (Bowman and Bowman, 2000; Chavez et al., 2006). The genes in *N. crassa* are scattered throughout the genome, raising the question of whether their transcription is regulated in a coordinated manner. This is an interesting point, because variability in numbers of V-ATPase subunits can have severe effects on vacuolar acidification in yeast (Rizzo et al., 2007). Expression levels of all the genes have not been determined, but at least three *vma* genes seem to be transcribed at levels that reflect the relative amount of gene product found in the cell (Wechser and Bowman, 1995). Furthermore, the upstream sequences of four *vma* genes share features with constitutively expressed housekeeping genes (Hunt and Bowman, 1997; Wechser and Bowman, 1995).

Bafilomycin and Concanamycin, Specific Inhibitors of V-ATPases

The most significant contributions from filamentous fungi to the study of V-ATPases resulted from the fortuitous discovery that bafilomycin specifically inhibits V-ATPases of fungi, plants, and animals (Bowman et al., 1988b). The bafilomycins and the related concanamycins are macrolide antibiotics with 16- or 18-membered lactone rings, isolated from *Streptomyces* species (Bowman et al., 1988b; Dröse et al., 1993). Their contribution to the study of V-ATPases is threefold. (i) Sensitivity to these inhibitors was the initial criterion used to identify V-ATPases in multiple organelles and organisms. Currently they are used to investigate numerous cellular processes. (ii) Bafilomycin and concanamycin spawned a new area of drug discovery,

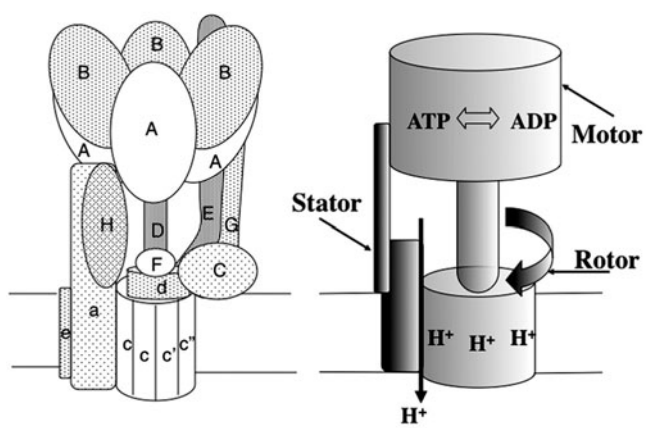

FIGURE 3 Two models of the V-ATPase. As shown on the left, the V-ATPase is composed of 14 different types of subunits, some of which are present in multiple copies. The diagram is modified from the model of the *N. crassa* V-ATPase in Venzke et al. (2005). The model on the right shows the major functional domains. The rotor portion of the enzyme is composed of subunits D, F, d, c, c′, and c″. The A and B subunits form the ATP binding sites and constitute the motor domain. It is not known for certain which subunits form the stator domain.

in which the major targets were V-ATPases involved in osteoporosis and cancer (Bowman and Bowman, 2005; Boyd et al., 2001). (iii) Analysis of mutants resistant to bafilomycin and concanamycin led to a better understanding of the structure and mechanism of the V-ATPase (Bowman et al., 2006).

For reasons that are not clear, mutant strains with an altered V-ATPase that were resistant to bafilomycin or concanamycin in vivo could only be isolated in filamentous fungi. Attempts to isolate resistant mutants in *S. cerevisiae* failed, as did our first attempts with concanamycin as the selective agent in *N. crassa* (Bowman et al., 1997). Selection with bafilomycin was successful. A hallmark of fungal strains with an inactivated V-ATPase gene is the inability to grow at alkaline pH (Nelson and Nelson, 1990). Similarly, wild-type strains cannot grow on medium buffered to pH 7.5 and containing bafilomycin or concanamycin (0.2 to 1.0 μM). We mutagenized *N. crassa* conidia with UV light and selected for strains that were able to grow on medium buffered to pH 7.5 and containing bafilomycin. While a number of conidia germinated, only the strong growers showing wild-type hyphal morphology proved to contain an altered V-ATPase gene (Bowman and Bowman, 2002). In vitro analyses of V-ATPase activity and isolation of the mutated gene confirmed these were V-ATPase mutants: the K_i for inhibition of the enzyme by bafilomycin was increased, and *vma-3*, the gene encoding the proteolipid subunit c in the V_0 domain, was mutated. We named the strains bfr (bafilomycin resistant) strains.

Because bafilomycin and concanamycin have similar structures, we expected the V-ATPases in the bfr strains to be resistant to concanamycin. They were not. However, by subjecting bfr strains to UV mutagenesis and selecting for strains growing at pH 7.5 in the presence of concanamycin, we isolated ccr strains (concanamycin resistant) that were resistant to both inhibitors in vivo and in vitro. The ccr strains all had additional mutations in the *vma-3* gene (Bowman et al., 2004). Altogether we have isolated 55 independent bafilomycin/concanamycin-resistant strains that have amino acid changes at 12 different sites, all in the c subunit of the V-ATPase. Site-directed mutagenesis targeted another 12 residues (Bowman et al., 2006). The increase in resistance to bafilomycin among all the mutants ranged from 2-fold to 450-fold; the increase in resistance to concanamycin ranged from no effect to 97-fold. We hypothesize that both inhibitors bind the same region of subunit c but that concanamycin, which is slightly larger, may have more contact points and bind more tightly.

One goal of the mutagenesis studies was to identify the binding site(s) of bafilomycin and concanamycin on the V-ATPase to determine how the inhibitors act. Subunit c is a highly conserved hydrophobic protein with four predicted membrane helices, an evolutionary duplicate of the two-helix subunit c in F-type ATPases (Mandel et al., 1988). We constructed a model of the arrangement of the V-ATPase helices based on the crystal structure of the c-subunit ring of the F-type ATPase (Stock et al., 1999). Most of the residues implicated in binding bafilomycin/concanamycin clustered together in this model. Positions of the residues supported a model in which the drug-binding site is a pocket formed by helices 1, 2, and 4. We hypothesized that the drugs inhibit by preventing the rotation of the c subunits in the V-ATPase rotor mechanism (Bowman et al., 2004).

We also hoped to generate a good model for the structure of c subunits of the V-ATPase. Our modeling efforts were greatly facilitated by the publication of a crystal structure for the homologous subunits of the V-ATPase in the bacterium *Enterococcus hirae* (Murata et al., 2005). The new model shows the positions of the residues that confer resistance to bafilomycin and concanamycin in a 10-membered subunit c ring. Ten of the 11 mutation sites that confer the highest degree of resistance are closely clustered. They form a putative drug-binding pocket at the interface between helices 1 and 2 on one c subunit and helix 4 of the adjacent c subunit. The excellent fit of the *N. crassa* sequence to the *E. hirae* structure and the degree to which the structural model predicted the clustering of these residues suggest that the folding of the eukaryotic polypeptides is very similar to that of the bacterial protein (Bowman et al., 2006).

Phenotype of V-ATPase Null Mutants

Inactivation of *vma* genes has a myriad of effects on vacuolar function, growth rate, and development. After publishing our conclusion that *vma-1* was an essential gene (Ferea and Bowman, 1996), we stumbled upon a null strain by letting cultures growing from spores in liquid medium sit on the benchtop for 2 weeks. One tube showed weak mycelial growth in the lower half of the medium. (*N. crassa* is a fast-growing fungus. Wild-type strains reach the surface overnight and produce abundant conidia within 4 days.) The rescued mycelium proved to be an authentic *vma* null strain (Bowman et al., 2000). generated by the process of repeat-induced point mutation (see chapter 10 in this volume).

Disruption or replacement of *vma* genes encoding different V-ATPase subunits gives almost identical phenotypes (Bowman et al., 2000; Chavez et al., 2006). Many functions attributed to vacuoles are lost. Vacuoles contribute to pH homeostasis, and *vma* null strains grow poorly in acidic medium (the optimum pH is 5.5 to 5.8), weakly in more acidic medium, and not at all in basic medium (pH 7.2 and above). Vacuoles store large amounts of basic amino acids; *vma* mutant cells have one-fifth the amount of acid-soluble arginine found in wild-type cells. Vacuoles store potentially toxic divalent cations; the presence of 4 mM Zn^{2+} in the medium inhibits growth of *vma* null strains by 85% but does not affect the wild type. As mentioned above, the finding that Ca^{2+} in the medium is less toxic to V-ATPase mutants in *N. crassa* (50% inhibition by 100 mM Ca^{2+} versus 13% inhibition of wild-type growth) than to mutants in *S. cerevisiae* needs to be explained. Vacuoles have a role in osmotic homeostasis, and vacuoles do not pellet as dense organelles in *vma* mutants, apparently having lost the capacity to behave like osmometers. The phenotypes of *vma* null strains provide strong evidence for the involvement of vacuoles in these various processes.

The most severe consequences of inactivating the V-ATPase are on growth and development. The primary effect appears to be on the control of tip elongation and morphology. We measured growth as the increase in colony diameter on an agar surface. The *vma-1* (encodes catalytic subunit A) null strain grew at 0.5 mm/h, eight times slower than the wild type (4.2 mm/h). In the slowly advancing mutant strain, branching is primarily dichotomous and frequent, resulting in a crowded growth front that often looks layered. Aerial hyphae are short and rare. By comparison, the wild type grows mainly by apical extension, producing side branches at less frequent intervals, and forms aerial hyphae that result in a cottony appearance. *vma* null strains cannot differentiate conidia (asexual spores) or form perithecia (female fruiting bodies). However, they can act as a male and contribute a nucleus in a fertile sexual cross.

Fewer than 1% of the spores carrying a *vma* null mutation germinate. We constructed heterokaryons between *vma-1* null mutants of opposite mating types and a helper strain. The heterokaryons grew normally, indicating that the *vma* mutation is recessive. The helper strain contributes to perithecial development but not to ascus and ascospore development. Crossing two *vma* null strains to each other resulted in arrest of ascus development in meiotic prophase (Bowman et al., 2000). The V-ATPase clearly has a prominent and essential role in morphogenesis and development of *N. crassa*. However, little is known about the mechanisms that the vacuole employs to mediate these functions in filamentous fungi.

We have found some interesting differences in the phenotypes of different *vma* mutants. For example, two mutant alleles of *vma-1* (which encodes the A subunit) were generated by repeat-induced point mutation. One of these, named *pvn1*, has a stop codon at amino acid residue 130 (of a total of 607) and is unlikely to make a polypeptide, while the second, *pvn2*, has only four amino acid changes and produces a membrane-bound protein detectable on a Western blot (E. J. Bowman, unpublished results). No V-ATPase activity was detected in membrane fractions from either strain, and both had the phenotype of the *vma* null mutants described above for almost all characteristics (Bowman et al., 2000). However, it was surprising that growth on 1 M sorbitol induced conidiation in the *pvn2* mutant. Although not detectable in vitro, perhaps a very low level of V-ATPase activity was present and accounted for the ability to conidiate. We speculated that sorbitol could desiccate the culture and induce a stress response, which might include upregulating expression of V-ATPase genes. More unexpected was the difference in ascospore viability; *pvn-2* spores germinated as well as the wild type. This could result from a low level of V-ATPase activity, or because the presence of the protein product, even though inactive, is required for spore germination.

vma-11 mutant strains, which are either defective in, or completely lacking, the c′ subunit, have a less severe *vma* null phenotype (Chavez et al., 2006). These strains grow slightly better than the other *vma* null strains. The "extra" growth is inhibited by concanamycin, suggesting that some V-ATPase activity is present. Subunit c′ occurs in V-ATPases of fungi but not other organisms. Perhaps even in fungi it is not completely essential or can be replaced by an extra copy of the closely related c subunit. Like *pvn-2*, the *vma-11* mutants produce conidia when grown on 1.5 M sorbitol. However, *vma-11* strains with nonsense mutations or with complete deletion of the gene exhibit very low levels of ascospore germination (Chavez et al., 2006). A functional V_0 rotor domain (an assembled cluster of c, c′, and c″ subunits) may be critical for ascospore germination. *vma-11* and *vma-16* mutant strains produce few viable ascospores, and despite extensive efforts, a viable spore with an inactivated *vma-3* gene has never been recovered.

Role of the V-ATPase in Vacuolar Morphogenesis

Inactivation of a V-ATPase gene changes the structure of the vacuolar system in *N. crassa*. It was reported that vacuoles in a *VMA* null strain of *S. cerevisiae* are normal (Yamashiro et al., 1990). This was not the case in the *vma-1* null strain of *N. crassa*. Compared with wild-type vacuoles, which are spherical, the vacuoles in the mutant were irregular, often misshapen, and frequently multilamellar (Bowman et al., 2000). This is interesting in view of fascinating recent studies involving *S. cerevisiae*, examining the role of the V-ATPase in regulating vacuolar fusion and fission (Baars et al., 2007). The results from Andreas Mayer's lab show that homotypic fusion of vacuoles requires the physical presence of the V-ATPase (at least the V_0 part) but not H^+-translocating activity. Fission, however, does require V-ATPase pump activity. The investigators propose that vacuolar morphology results from an equilibrium of competing fission and fusion reactions, with the ratio of the rates determining the outcome. Vacuolar morphology was visualized with FM4-64 in deletion strains lacking Vma1p, Vma3p, and Vma6p (Baars et al., 2007). They contained one enlarged vacuole/cell, suggesting that fusion was dominant. By analogy, we suggest that similar processes determine the structure of vacuoles in the *vma-1* null strain of *N. crassa*.

V-ATPase and Autophagy

In *S. cerevisiae*, the V-ATPase plays an essential role in autophagy (Reggiori and Klionsky, 2002). The breakdown of engulfed material by vacuoles requires normal acidification of the vacuole, both to provide the acid pH that is optimal for degradative enzymes and to facilitate the autocatalytic cleavage and activation of proteinases A and B. These proteases initiate a proteolytic cascade that leads to the activation of most vacuolar hydrolases. The V-ATPase achieves the acidification. The contribution of the V-ATPase to autophagy in filamentous fungi has not yet been investigated. Such studies will indicate whether the vacuole plays a conserved function in regulating autophagy in yeasts and filamentous fungal species.

SUMMARY

The former image of the vacuole as the junkyard of the cell in filamentous fungi has been replaced by a picture of a constantly changing, multifunctional meshwork of vesicles and tubules. The vacuolar system is highly variable in appearance at different locations within the mycelium and in response to different growth conditions. We know almost nothing about what controls and regulates the structure of the vacuole. Is it as functionally compartmented as it is structurally diverse? Although we have a good idea of what the vacuolar contents are, we are comparatively ignorant as to how they get there, how they are stored, how they are used, and how they are moved about. The nature of tip growth necessitates the transport of materials over long distances in the mycelium; however, the role of vacuoles in polarized growth has been largely ignored. Our understanding of autophagy in filamentous fungi is primitive, yet we suspect that it plays a critical role in recycling resources to support tip growth.

Several labs are introducing new approaches to study the dynamic behavior of the vacuolar system of filamentous fungi. One example is the work by Darrah et al. (2006), in which fluorescence recovery after photobleaching and mathematical modeling are combined to determine the connectivity of membranous compartments in vivo. Other methods are being developed by Watkinson et al. (2005). Using a combination of photon counting scintillation imaging and stable-isotope nuclear magnetic resonance, this group's goals are to observe how a transport system develops and is altered and to follow nitrogen in a mycelial network growing in a "realistic soil."

Molecular approaches similar to that pioneered by the Kitamoto group to take advantage of genome sequence data from filamentous fungi should facilitate rapid progress in understanding vacuolar structure and function. Homologs of *S. cerevisiae* genes with known functions in vacuolar biogenesis, autophagy, and ion transport are excellent candidates for

identifying the genes involved in these processes in filamentous fungi. Genetic studies of strains with selected genes deleted either singly or in combination with others will allow us to evaluate their roles in the cell. Confocal laser scanning microscopy of fusion proteins with GFP and RFP or other tags will reveal the cellular locations of these proteins. We can anticipate finding novel adaptations in how filamentous fungi use these genes and their products to support their unique lifestyle.

One of the most fascinating questions about the vacuolar system is whether it is structurally and functionally compartmentalized. Are endocytic and lysosomal functions in separate vesicles or membrane segments? Are calcium and arginine enclosed together or in specialized vacuoles? Do forward transport and retrograde transport occur simultaneously in the same tubule? Are the three vacuolar calcium transporters in the same or different regions of the vacuolar complex? Can autophagosomes fuse with any region of the vacuolar system? Methods used by Valkonen et al. (2007) might be applied to such questions. Using fluorescence lifetime imaging microscopy in combination with Foerster resonance energy transfer, these authors were able to demonstrate for the first time the spatial and functional separation of two SNARE proteins on the plasma membrane in a filamentous fungus.

In addition to being intriguing for their contribution to unique growth habits, the vacuoles of filamentous fungi have been valuable as model systems, especially in two areas. First is their role in arginine metabolism: the compartmentalized storage, the regulation of cytosolic concentrations, and the mobilization in times of need (chapter 24). Second is their contribution to the discovery of V-ATPases and to studies of the structure and function of this major class of enzymes. The investigations performed in recent years demonstrate that the vacuole is a dynamic organelle with many important roles in metabolism, growth, and development. Although it is the most visible organelle in fungal hyphae, the vacuole has not yet received the attention it deserves.

Peroxisomes in Filamentous Fungi

LEONARDO PERAZA-REYES, ERIC ESPAGNE, SYLVIE ARNAISE, AND VÉRONIQUE BERTEAUX-LECELLIER*

Peroxisomes are single membrane-bound organelles present in most eukaryotic organisms. They are normally round and small ($\leq$1 μm), but they can be considerably larger and can adopt elongated or branched shapes. Peroxisomes typically contain a number of oxidoreductases that produce hydrogen peroxide (H_2O_2) (hence their name) as well as enzymes for reactive oxygen species (ROS) disposal. They are implicated in several metabolic functions that vary not only between organisms but also with cell and environmental pressures. They are highly dynamic and act in close association with other organelles.

Peroxisomes are involved in the regulation of diverse developmental processes, such as female/male gametophyte recognition during the fertilization of flowering plants (Boisson-Dernier et al., 2008) and neuronal differentiation and migration during brain development in mammals (reviewed by Faust et al., 2005). Moreover, as illustrated in plants, peroxisomes provide an important source of diverse signaling molecules (Nyathi and Baker, 2006). In humans, peroxisomes are required for various developmental events and deficiencies result in multiple severe anomalies that are often lethal (Steinberg et al., 2006; Wanders and Waterham, 2006). Despite significant research using various model organisms, peroxisome function is not completely understood, in particular, their impact on development. In this respect, filamentous fungi have been increasingly used as model organisms to study peroxisomes. In this chapter, we present an overview summarizing the current knowledge of the function of peroxisomes in filamentous fungi.

PEROXISOME DYNAMICS IN FUNGI

Peroxisomes are present in most major fungal groups. The main exceptions are the groups of anaerobic fungi that are also devoid of true mitochondria, such as Microsporidia (Cavalier-Smith, 1987). Similarly, there is no conclusive evidence for their existence in the rumen fungi Neocallimasticales, whose microbody-like organelle, the hydrogenosome, is now recognized as derived from mitochondria (Embley et al., 2003). The recognition of these lineages as fungi (James et al., 2006) indicates that their peroxisomes were lost secondarily, which is further supported by the existence of orthologs of some *pex* genes in microsporidian genomes (Fedorov and Hartman, 2004).

Peroxisome Assembly, an Overview

Peroxisome formation among diverse eukaryotic organisms shares a common basic biogenetic process mediated by a number of conserved proteins known as peroxins (for which the Pex acronym has been adopted [Distel et al., 1996]). Proteins controlling peroxisome dynamics are classified according to their involvement in three major processes (Table 1): (i) biogenesis of peroxisome membranes and insertion of peroxisomal membrane proteins (PMPs), (ii) peroxisome matrix protein import, and (iii) peroxisome division and inheritance.

Both peroxisome membrane and matrix proteins are synthesized in the cytosol and are sorted to peroxisomes to be inserted into the membrane or translocated to the peroxisome matrix, respectively. Three proteins are known to control the biogenesis of the peroxisome membrane and the insertion of PMPs (Table 1), and most cells lack detectable peroxisome membranes if any of these peroxins are absent (reviewed by Fujiki et al., 2006). In contrast, absence of the peroxins implicated in the import of the peroxisome matrix proteins results in (empty) peroxisomal remnants. The latter process relies on a larger set of peroxins (Fig. 1). Pex5 and Pex7 are the soluble receptors recognizing peroxisome matrix proteins in the cytosol (by means of their PTS1 or PTS2 targeting sequences, respectively), whereas the docking site at the peroxisome membrane is provided by the peroxins Pex14, Pex13, and, in yeasts, Pex17p (the docking complex). These proteins, together with RING finger domain-containing PMPs Pex2, Pex10, and Pex12, form a larger complex known as the importomer; this complex probably constitutes the translocator for peroxisome matrix proteins. In *Saccharomyces cerevisiae*,

TABLE 1 Predicted peroxins of *P. anserina*[a]

Peroxin	*P. anserina* coding sequence	Characteristic	Main function(s)	Comments[a]
Biogenesis of peroxisome membranes and peroxisomal membrane protein insertion				
PEX3	Pa_7_8080	PMP	Peroxisome membrane anchor of PEX19, importomer linking in *P. pastoris*	M, F
PEX16	Pa_1_21920	PMP, intraperoxisomal in *Y. lipolytica*	PMP targeting, peroxisome proliferation in *Y. lipolytica*	
PEX19	Pa_2_10100	CAAX box	Receptor/chaperone of PMPs	M, F
Peroxisome matrix protein import				
PEX1	Pa_1_6740	AAA-type ATPase	Peroxisome dislocation of Pex5p	A, ER, F
PEX2	Pa_1_2750	PMP, RING finger domain	Importomer protein	A, ER, F
PEX4	Pa_1_9240	E2 ubiquitin conjugation enzyme	Monoubiquitination of Pex5p	A, ER, F
PEX5	Pa_1_18440	Tetratricopeptide repeats, WxxxF/Y motifs	PTS1 receptor, PTS2 coreceptor (plants and mammals)	A, ER, F
PEX6	Pa_1_9330	AAA-type ATPase	Peroxisome dislocation of Pex5p	ER, F
PEX7	Pa_6_3500	WD-40 repeats	PTS2 receptor	F
PEX8	Pa_7_9670	Leucine zipper motive	Importomer linking protein	
PEX9			ORF incorrectly identified	
PEX10	Pa_1_4170	PMP, RING finger domain, E3 ubiquitin ligase	Importomer protein, polyubiquitination of Pex5p	M, A, ER, F
PEX12	Pa_3_3790	PMP, RING finger domain	Importomer protein	M, F
PEX13	Pa_1_4570	PMP, Src homology 3 domain	Importomer (docking) protein, membrane anchor of PEX14	F
PEX14	Pa_4_8910	PMP, PxxP-motif	Importomer (docking) protein, membrane anchor of receptors	A, F
PEX14/17	Pa_3_5160	Pex14-N-term conserved region	Predicted docking protein in filamentous fungi	
PEX15		PMP	Membrane anchor of PEX6 in *S. cerevisiae*	
PEX17		PMP	Docking protein in *S. cerevisiae*	
PEX18		WxxxF/Y motifs	PTS2 coreceptor in *S. cerevisiae*	
PEX20	Pa_4_7290	WxxxF/Y motifs	PTS2 coreceptor	
PEX21		WxxxF/Y motifs	PTS2 coreceptor in *S. cerevisiae*	
PEX22		PMP	Membrane anchor of PEX4	
PEX22-like	Pa_6_4620	1 predicted TM segment	Predicted peroxin	
PEX26	Pa_7_1760	PMP	Membrane anchor of PEX6 in *Homo sapiens*	
Peroxisome division/proliferation				
PEX11	Pa_4_9300	PMP	Peroxisome proliferation/division	F
PEX11B	Pa_4_7960	3 predicted TM segments	Predicted peroxin	
PEX11C	Pa_7_5380	No predicted TM segments	Predicted peroxin	
PEX23	Pa_4_3500	PMP dysferlin motifs	Peroxisome proliferation; protein import?	F
PEX23-like	Pa_2_660	No predicted TM segments	Predicted peroxin	
PEX24	Pa_2_620	PMP	Peroxisome size and number; protein targeting?	F
PEX25		PMP	Peroxisome size and number	
PEX27		PMP	Peroxisome size and number	
PEX28	Pa_2_620	PMP	Peroxisome size and number; *S. cerevisiae* Pex28p ortholog of *Y. lipolytica* Pex24p	
PEX29		PMP	Peroxisome size and number	
PEX30	Pa_4_3500	PMP, dysferlin motifs	Peroxisome number negative regulator; *S. cerevisiae* Pex30p ortholog of *Y. lipolytica* Pex23p	
PEX31		PMP, dysferlin motifs	Peroxisome size negative regulator	
PEX32		PMP, dysferlin motifs	Peroxisome size negative regulator	

[a]Abbreviations: M, marker peroxin, present in all peroxisome-containing organisms and absent from organisms devoid of peroxisomes (Schluter et al., 2006); A, ancient peroxin, present in the common ancestor of peroxisome-containing organisms (Gabaldon et al., 2006); ER, peroxin presenting similarity to an ER-associated degradation pathway protein; F, peroxins present in major taxa of Fungi (see the text).

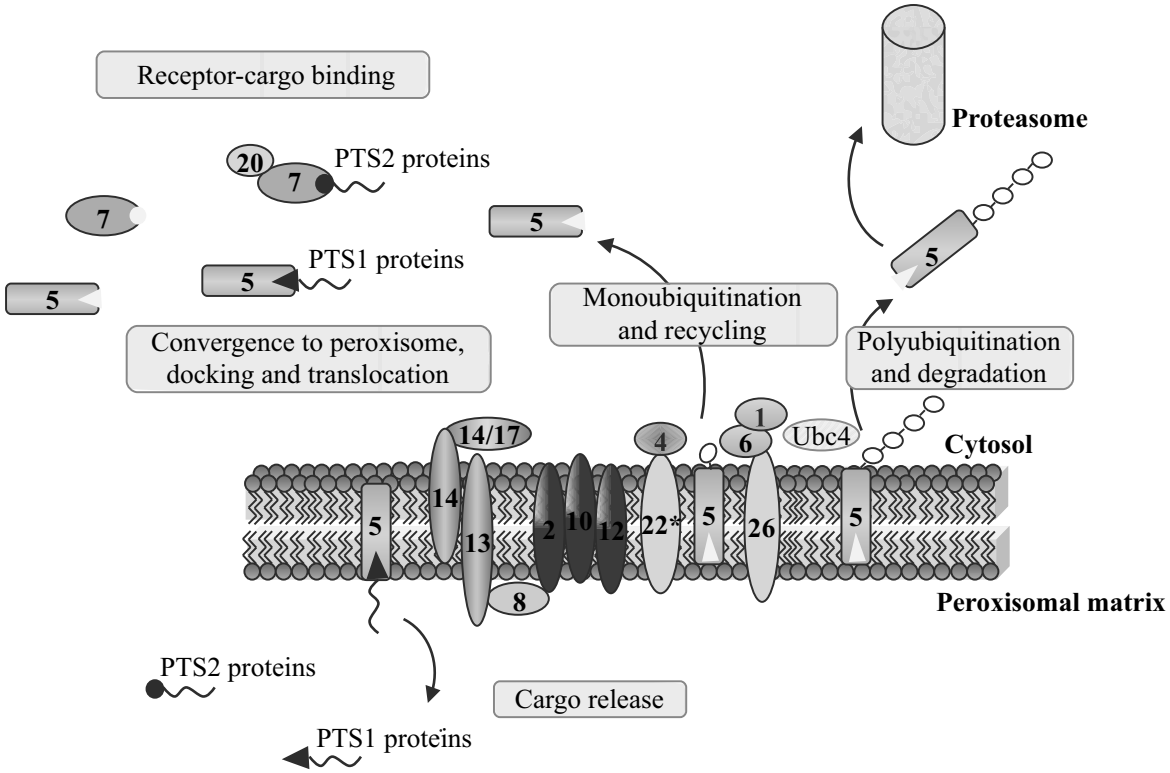

FIGURE 1 Schematic representation of the putative peroxisome matrix protein import pathway in filamentous fungi. The recognition of the peroxisomal matrix proteins by Pex5 and Pex7 receptors occurs in the cytosol (Pex5 and Pex7 recognize PTS1 and PTS2, respectively); the cargo-receptor complexes then dock at the peroxisomal membrane (where both import pathways converge) and are then translocated. These last processes require the importomer, which is composed of two subcomplexes linked by Pex8: the docking complex (formed by Pex14, Pex13, and Pex14/17) and the RING finger complex (formed by Pex2, Pex10, and Pex12). After cargo release in the peroxisomal matrix, Pex5 receptors are either monoubiquitinated (by Pex4) or polyubiquitinated (by Ubc4). The release of the Pex5 ubiquitinated form requires Pex1 and Pex6, AAA-type ATPases anchored in the peroxisomal membrane by Pex26. When polyubiquitinated, Pex5 receptors are then degraded by the proteasome; when monoubiquitinated, they are recycled back to engage in another round of import. The asterisk in "Pex22*" denotes that in filamentous fungus genomes a Pex22-like protein is usually present rather than a true Pex22 ortholog (see also Table 1).

Pex8p is the peroxin bringing the docking and RING finger complexes of the importomer together (Agne et al., 2003). Peroxisome matrix proteins are translocated together with their receptor Pex5 or Pex7; after cargo release in the peroxisome matrix, these receptors are cycled back to the cytosol to be reutilized in additional rounds of import. Export of Pex5 is dependent on a ubiquitination activity that marks the receptor for recycling (after Pex4-mediated monoubiquitination) or degradation (after Ubc5/6-mediated polyubiquitination). The ubiquitinated receptors are released from the peroxisome membrane by an AAA-type ATPase-heteromultimeric complex formed by Pex1 and Pex6 and anchored to the peroxisome membrane by Pex26 (reviewed by Platta and Erdmann, 2007).

The Formation of Fungal Peroxisomes

Peroxin genes have a eukaryotic origin. There is a highly conserved array of peroxins (Table 1), which likely represent the essential core of peroxisome biogenesis factors of early eukaryotes. Notably, a large proportion of the most ancient peroxins exhibits similarity to proteins of the endoplasmic reticulum (ER)-associated degradation pathway, suggesting a common evolutionary origin for peroxisomes and the ER (Gabaldon et al., 2006; Schluter et al., 2006). With the exception of Microsporidia, which lack most *pex* genes (Schluter et al., 2006), fungi from all major taxa for which a genome sequence is available (Chytridiomycota, zygomycetes, Ascomycota, and Basidiomycota) also contain orthologs of Pex6, 7, 11, 13, 23, and 24 (Kiel et al., 2006; our unpublished observations). Consequently, these proteins probably reflect the essential peroxisome biogenesis proteome of the last common ancestor of fungi. As exemplified for *Podospora anserina* (Table 1), peroxin proteomes of present-day fungi are rather more complex. The analysis of the peroxin distribution among phylogenetically diverse fungi (see below) indicates that this was probably also true for early fungi and that many peroxin genes were replaced and/or recruited during the course of fungal evolution (for exhaustive analyses of fungal peroxins see Kiel et al., 2006, and Kiel and van der Klei, 2009).

In fact, some of the key components required for peroxisome assembly have so far been characterized only in fungi. In some cases, such as the importomer bridging protein Pex8, there is no known ortholog beyond fungi (Kiel et al., 2006; Rayapuram and Subramani, 2006). In contrast, some highly conserved peroxins were lost and/or replaced in the course of fungal evolution; this is the case for some peroxins implicated in the export of receptors. Pex4 is absent from some basidiomycetes, and its anchoring protein, Pex22, is absent from most filamentous fungi. The role of Pex22 in some taxa may be fulfilled by a Pex22-like protein. Similarly, the mostly ubiquitous Pex6-anchoring peroxin, Pex26, is absent from some basidiomycetes and saccharomycetes; however, in the latter group, this has been possibly replaced by Pex15. Another Saccharomycotina-exclusive protein is the docking component Pex17p, but a gene putatively encoding the PEX14/17 hybrid peroxin is present in the genome of most filamentous fungi (Kiel et al., 2006; L. Peraza-Reyes, unpublished observations).

The Dynamics of Peroxisomes in Filamentous Fungi

The ER is now known to play an important role in the biogenesis of peroxisomes (reviewed by Titorenko and Mullen, 2006); however, the population of peroxisomes in a cell is largely controlled by the division of preexisting peroxisomes. Peroxisome division proceeds by three mechanistically different events: peroxisome elongation, constriction, and fission (exhaustively reviewed by Fagarasanu et al., 2007). One of the most conserved peroxins implicated in peroxisome division is Pex11. This protein is required for the proliferation and elongation of peroxisomes and is present in different isoforms in filamentous fungi, along with other proteins implicated in peroxisome proliferation such as Pex23 (Table 1) (Kiel et al., 2006). The archetypical Pex11 protein is indeed implicated in peroxisome proliferation (Kiel et al., 2005; Hynes et al., 2008), but whether additional isoforms are involved in peroxisome dynamics remains to be established. Nevertheless, in other eukaryotes it is common to observe different organism-specific Pex11 isoforms controlling the proliferation of peroxisomes in response to different stimuli, in specific cellular types or in distinct peroxisomal subtypes (Schrader and Fahimi, 2006; Orth et al., 2007, and references therein). The presence of these Pex11 and Pex23 protein families in filamentous fungi possibly reflects some peroxisomal specialization toward the filamentous lifestyle.

Organelle distribution and movement in cells normally require coordination between the actin and microtubule elements of the cytoskeleton. Peroxisomes are highly dynamic organelles in fungi. Their movement and segregation in the budding yeast *S. cerevisiae* require an active interplay with the cytoskeleton, whereas in the fission yeast *Schizosaccharomyces pombe*, their distribution seems to be independent of the cytoskeleton and instead depends on their interaction with mitochondria (Jourdain et al., 2008). In *S. cerevisiae*, *Yarrowia lipolytica*, and plants, peroxisomes are associated with the actin cytoskeleton, whereas they interact with microtubules in mammalian cells (Schrader and Fahimi, 2006; Chang et al., 2007, and references therein). We would expect the peroxisome distribution in hyphae to depend largely on their association with the cytoskeleton, due to polarized growth of filamentous fungi, but this area has not been sufficiently studied. Preliminary experiments with *P. anserina* show that peroxisome movement and distribution in asci are not drastically affected by microtubule-disrupting drugs (V. Berteaux-Lecellier and D. Zickler, unpublished observation). However, this is not necessarily true for other fungi. In many aspects, peroxisome division and positioning parallel those of mitochondria. The mitochondria-cytoskeleton association is rather divergent in filamentous fungi; for example, in fungi such as *Aspergillus nidulans*, mitochondrial movement does not require functional microtubules, whereas in others, such as *Neurospora crassa*, this movement is mainly microtubule dependent (Westermann and Prokisch, 2002). It would be interesting to determine if a partitioned cytoskeleton association is also observed for fungal peroxisomes.

A PEROXISOME-RELATED ORGANELLE OF FILAMENTOUS FUNGI: THE WB

Hyphae are the major mode of cellular organization in fungi, and in most species these filamentous cells are compartmentalized by perforate septa that allow intercellular cooperation and communication. Due to the syncytial growth of filamentous fungi, the wounding of hyphae can lead to a severe loss of cytoplasm and subcellular organelles if the plasma membrane or a nearby septum is not rapidly sealed. Woronin bodies (WBs) are highly specialized peroxisome-related organelles that are unique to filamentous fungi and function to seal the septal pore in response to cellular damage (Trinci and Collinge, 1974; Markham and Collinge, 1987) (Fig. 2). In addition, WBs are also required for efficient pathogenesis (see "Peroxisomes in Predatory and Pathogenic Fungi" below for details), survival during nitrogen starvation (Soundararajan et al., 2004), and conidiation (Simon et al., 2005) in various fungi. Since their discovery by Michael S. Woronin (Woronin, 1864), WBs have been observed by electron microscopy in a variety of euascomycetes and now have been identified in more than 142 species of filamentous fungi (Markham and Collinge, 1987; Würtz, 2007). They appear to be hexagonal to spherical electron-opaque structures bound by a single membrane and have been reported to be between 100 and 750 nm.

The WB was first purified from *N. crassa*, and this allowed the identification of a key WB-associated protein, HEX-1 (Jedd and Chua, 2000; Tenney et al., 2000). Induced hyphal wounding in *hex-1* mutants of *N. crassa*, *Aspergillus oryzae*, and *Magnaporthe grisea* leads to substantial macroscopic bleeding (Jedd and Chua, 2000; Tenney et al., 2000; Soundararajan et al., 2004). Analysis of the HEX-1 crystal structure reveals the existence of three intermolecular interfaces promoting the formation of a three-dimensional protein lattice. Consistent with these data, self-assembly is disrupted by mutations in intermolecular contact residues (Yuan et al., 2003). Production of this assembly-defective HEX-1 mutant protein results in aberrant WBs, which possess a soluble noncrystalline core. This mutant allele also fails to complement an *hex-1* deletion in *N. crassa*, demonstrating that the HEX-1 protein lattice is required for WB function.

HEX-1 possesses a functional peroxisome-targeting signal (PTS1), suggesting that WBs are related to peroxisomes (Jedd and Chua, 2000; Managadze et al., 2007). Expression of *N. crassa* GFP-HEX-1 in wild-type mycelia stains WBs and peroxisomes in a targeting signal-dependent manner (Managadze et al., 2007). The *hex-1* deletion mutant grows normally with oleate as the sole carbon source, a clear indication that WBs are not associated with the peroxisomal pathway of fatty acid β-oxidation (see "Ubiquitous Functions" below for details) and thus are not presumably associated with peroxisomal metabolism. In *N. crassa*, nearly all peroxisome assembly mutants are defective in WB biogenesis (Managadze et al., 2007; Liu et al., 2008). Using the *N. crassa*

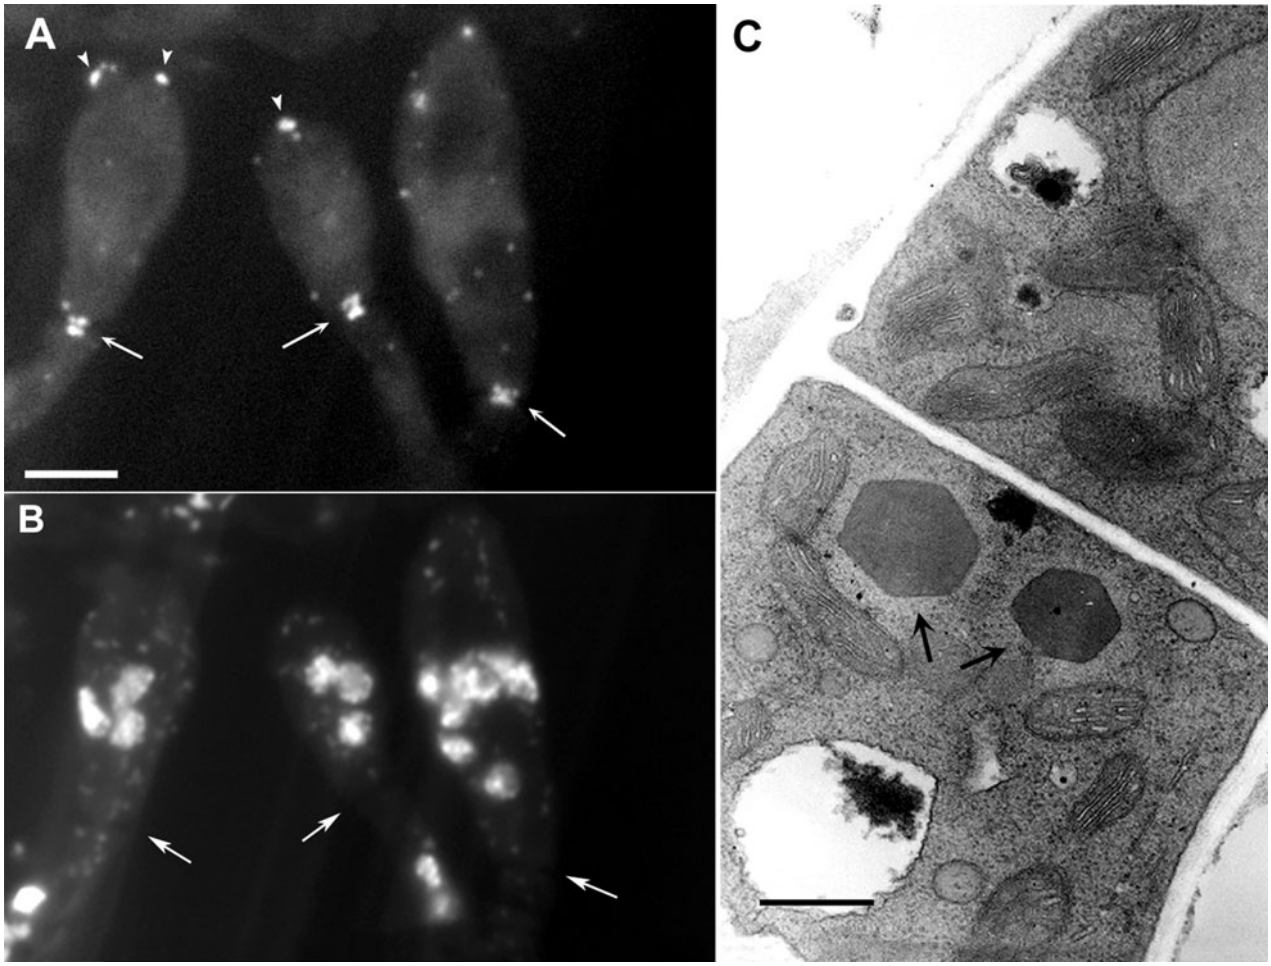

FIGURE 2 Woronin bodies. The WB is a specialized peroxisome of filamentous fungi that function in sealing the septal pores that communicate hyphal compartments. (A) *P. anserina* WBs delimiting apical cells of paraphysae are indicated by arrows; note the recently formed WBs at the tip of the cell (arrowheads). (B) Corresponding DAPI (4′,6-diamidino-2-phenylindole)-stained micrograph. Arrows indicate the positions of the septal pores. (C) In fungi like *N. crassa*, the WB structural lattice is reflected by the hexagonal shape that WBs adopt. In the image, two WBs (arrows) before plugging a septal pore are shown (note that the septal pore is not in the same plane as WBs and is not visible here). *P. anserina* WBs were stained by anti-hex1 antibody, a kind gift from G. Jedd. The transmission electron micrograph in panel C was done by Jorge Sepulveda and L. Peraza-Reyes, courtesy of Wilhelm Hansberg's laboratory (UNAM, Mexico). Scale bars, 5 μm (panels A and B) and 500 nm (panel C).

Δpex14 mutant, impaired in peroxisomal import, Managadze et al. (2007) have shown that HEX-1 remains cytosolic and that WBs are not formed. Furthermore, subcellular fractionation studies demonstrate that PEX14 is not localized to WBs in appreciable amounts, but rather is associated with peroxisomes. Together these observations suggest a transient peroxisomal residence of HEX-1 en route to WBs.

Liu et al. (2008) have recently shown that fungal peroxisomes create WBs through a process that couples the self-assembly of HEX-1 in the peroxisomal matrix with the assembly of the Woronin sorting complex (WSC), a PMP22/MPV17-related peroxisomal membrane protein, at the peroxisomal membrane. HEX-1 crystals are formed but fail to associate with the peroxisomal membrane in *wsc* mutants and instead move randomly in the matrix. In a wild-type strain, as the formation of the HEX-1 crystal proceeds in the peroxisomal matrix, WSC interacts with HEX-1 and keeps the HEX-1 crystal bound to the peroxisomal membrane. The HEX-1 crystal is then tightly surrounded by the peroxisomal membrane as a result of the WSC-HEX-1 interaction. This should ultimately lead to WB budding off. Organelle sizes and their WSC membrane content increase simultaneously with the entrance of HEX-1 into the peroxisomal matrix. Moreover, Liu et al. (2008) have shown that WSC overproduction promotes a cellular cortical association of peroxisomes in the absence of HEX-1. All these observations have led to the suggestion that WSCs have a dual function in WB morphogenesis and inheritance: the sorting of HEX-1 to a defined region within peroxisomes and the cellular cortical association of the resulting WB.

WBs are formed in the apical regions of the growing hyphae of filamentous fungi and are then transported from the apex to the basal regions (Momany et al., 2002). The spatial localization of *hex-1* gene expression has been examined, and WB formation has been directly observed, using time-lapse confocal microscopy, by Tey et al. (2005). The results show that apex-localized gene expression is a key determinant of spatially restricted WB assembly.

VPS1, DNM1 (dynamin-related proteins), and FIS1 (involved in DNM1 function) promote membrane constriction and fission in various intracellular compartments, such as peroxisomes (Hoepfner et al., 2001; Koch et al., 2004; Kuravi et al., 2006) or mitochondria (Mozdy et al., 2000; Hoppins et al., 2007). In *N. crassa*, the deletion of the corresponding genes showed that nascent WBs are less apparent and that the HEX-1 lattice in mature WBs is generally smaller than those observed in the wild-type control (Liu et al., 2008). On the other hand, if HEX-1 is heterologously expressed in the *S. cerevisiae vps1 dnm1* double-deletion strain, formation of WBs is almost completely blocked (Wurtz et al., 2008). Thus, WB formation in the *N. crassa* double-mutant strain may be affected more than that in single mutants, and at least, DNM1 and VPS1 may be required for the differentiation of WBs from peroxisomes (Liu et al., 2008).

Sordaria macrospora PRO40 (Masloff et al., 1999) (essential for the formation of fruiting bodies and thus for the sexual life cycle) and its *N. crassa* ortholog, SO (Fleissner et al., 2005) (necessary for hyphal fusion and female fertility), define a class of proteins present only in filamentous ascomycete fungi that appear to be involved in the response to hyphal injury. Moreover, partial colocalization of PRO40 with HEX-1 has been described in *S. macrospora* (Engh et al., 2007). However, the integrity of WBs is not affected in *pro40* mutant strains. In *N. crassa*, the SO protein localizes to septal plugs and contributes to, but is not essential for, septal plugging (Fleissner and Glass, 2007). Further investigations are required to determine whether the endogenously expressed SO/PRO40 protein is present in WBs. If this turns out to be the case, a novel function for WBs in fruiting body formation may be envisaged.

PEROXISOME METABOLISM

The recent completion of several fungal genomes has provided a new way of studying the peroxisomal proteome. The two well-characterized peroxisome targeting signals, PTS1 and PTS2 (Neuberger et al., 2003; Maynard et al., 2004; Petriv et al., 2004), have been used to perform in silico searches of proteins that might be imported into the peroxisomal matrix (Emanuelsson et al., 2003; Galagan et al., 2005). Peroxisomes were previously thought to contain almost 50 enzymes, but current data suggest that the peroxisome matrix contains nearly 200 proteins in yeast and *Arabidopsis* (Kal et al., 2000; Kamada et al., 2003) and in *P. anserina* (V. Berteaux-Lecellier and O. Lespinet, personal communication). However, in vivo studies are still required to confirm the peroxisomal location of these newly identified proteins. The known peroxisomal enzymes are involved in various anabolic or catabolic pathways, some of which are ubiquitous, whereas others are more specific. In fact, peroxisomes are highly dynamic organelles whose content varies not only between organisms but also in function of the cell type. This is nicely illustrated in plants, where peroxisomes have been given different names based on their main activity in the cell; in germinating seeds, peroxisomes have been called glyoxysomes because of their involvement in the glyoxylate cycle, converting lipids into sucrose. At the start of photosynthesis, peroxisome metabolism plays an important role in photorespiration, and peroxisomes have thus been described as "leaf peroxisomes" (Hayashi and Nishimura, 2003). Here we mention the main metabolic peroxisomal functions of fungi, with emphasis on those that are particular to, and have been characterized more fully in, filamentous fungi. For detailed information on more general pathways, such as fatty acid β-oxidation and the glyoxylate cycle, the reader is advised to consult chapter 22.

Ubiquitous Functions

Ubiquitous functions for peroxisomes include the well-known peroxisomal fatty acid β-oxidation pathway. This pathway, together with the mitochondrial β-oxidation pathway, allows filamentous fungi to grow on various fatty acids (Maggio-Hall and Keller, 2004; Klose and Kronstad, 2006; Hynes et al., 2008; Boisnard et al., 2008). The peroxisomal pathway converts fatty acids into acetyl coenzyme A (acetyl-CoA), an important intermediary within cellular metabolism. Acetyl-CoA is required for several biosyntheses, and its ratio is tightly regulated (Schrader and Fahimi, 2008). Acetyl-CoA is further metabolized by the glyoxylate cycle within peroxisomes, to ultimately form carbohydrates (for further details, see chapter 22), which are used for various reactions in the cell. Moreover, mutant analyses in various fungus species suggest that the peroxisomal β-oxidation pathway is a source of acetyl-CoA in the synthesis of melanin (see "Peroxisomes in the Maturation and Germination of Fungal Spores" and "Peroxisomes in Predatory and Pathogenic Fungi" below; see also Kimura et al., 2001; Ramos-Pamplona and Naqvi, 2006; and Boisnard et al., 2008, and references therein). The peroxisomal β-oxidation of some fatty acids leads to pimelic acid formation, a biotin precursor (vitamin H or B7 [Ohsugi et al., 1988]). Consistent with this observation, peroxisomal biogenesis mutants altered for the peroxisomal β-oxidation pathway are auxotrophic for biotin (Hynes et al., 2008; V. Berteaux-Lecellier, A. Panvier-Adoutte, and M. Picard, unpublished data).

Beyond their role in β-oxidation, filamentous fungus peroxisomes are also involved in several other metabolic pathways, such as purine and amino acid metabolism. Some of these pathways require oxidase activities (acyl-CoA oxidase, D-amino-acid oxidase, urate oxidase, etc.); thus, normal peroxisomal metabolism constantly produces H_2O_2. Free radicals and derived species have important roles in signal transduction (Burdon, 1995; Lander, 1997; Bolwell, 1999; Aguirre et al., 2005; Jamet-Vierny et al., 2007); however, they are also highly corrosive. Therefore, peroxisomes contain antioxidant enzymes (like peroxidases and catalases) to regulate the level of ROS. Interestingly, a codistribution in peroxisomes of some H_2O_2 scavenger and producer enzymes is observed in filamentous fungi. The first step of peroxisomal fatty acid β-oxidation is usually performed by the acyl-CoA oxidase. This reaction produces enoyl-CoA and H_2O_2 (for further details see chapter 22); H_2O_2 is reduced to H_2O by catalase. Although both of these enzymes are located in peroxisomes in *A. nidulans* (Valenciano et al., 1996; Kawasaki and Aguirre, 2001), *N. crassa* peroxisomes contain an acyl-CoA dehydrogenase instead of acyl-CoA oxidase (and therefore do not produce H_2O_2 during fatty acid β-oxidation); no peroxisomal catalase has been detected (Thieringer and Kunau, 1991; Schliebs et al., 2006).

It is highly probable that peroxisome biogenesis defects disturb ROS homeostasis. Peroxisome impairment might have a significant impact on cell physiology, due to the

important role of free radicals in cell signaling. However, aside from the involvement of peroxisomal ROS in leaf senescence (del Rio et al., 1998), the mechanisms involved in the peroxisomal control of cell fate remain poorly described.

Specific Functions

Plants, yeasts, and filamentous fungi display a wide spectrum of peroxisomal activities, mainly due to the existence of peroxisome-specific functions.

Only a few filamentous fungi produce penicillin, one of the most used antibiotics: most notably, *A. nidulans* and *Penicillium chrysogenum* (Brakhage, 1997; van den Berg et al., 2007). The biosynthesis of this secondary metabolite is catalyzed by three enzymes and is a compartmentalized process (Brakhage, 1997; van der Lende et al., 2002). In particular, three pieces of evidence support the involvement of peroxisomes in penicillin biosynthesis. First, there is a clear positive correlation between penicillin production and the number of organelles per cell (Müller et al., 1991; Valenciano et al., 1998; Kiel et al., 2005). Second, the last step of penicillin biosynthesis (carried out by an acyltransferase, IAT) takes place in peroxisomes (Müller et al., 1991; Valenciano et al., 1998; van der Lende et al., 2002). Third, if the IAT putative peroxisomal targeting signal is removed, the enzyme remains in the cytosol and is still active in vitro. However, the mutant no longer produces penicillin (Muller et al., 1992). Interestingly, IAT is synthesized as a proenzyme, which has to be self-processed to be functional in vivo (Garcia-Estrada et al., 2008). This occurs inside peroxisomes, where both the pH value and the concentration of enzyme are presumably optimum for efficient self-processing. To further investigate the importance of peroxisomes in penicillin biosynthesis, studies relating to its production in various peroxisomal mutants should prove informative. However, attempts to obtain stable peroxisomal mutants in *P. chrysogenum* have been unsuccessful (Kiel et al., 2004) and true peroxisomal assembly mutants in *A. nidulans* have not been studied thus far for their capacity to produce penicillin (De Lucas et al., 1997; Hynes et al., 2008).

Methylotrophy is restricted to a limited number of microorganisms, and only a few yeast species are able to use methanol as a sole carbon and energy source (Yurimoto et al., 2005). In these yeasts, alcohol oxidase, which is localized in peroxisomes, catalyzes the first step of methanol assimilation and yields formaldehyde, a cytotoxic compound that can be either oxidized or assimilated (van der Klei et al., 2006). A set of genes involved in methanol utilization has recently been identified in the *P. anserina* genome (Espagne et al., 2008), and most of the genes have been shown to produce transcripts. If methylotrophic yeasts are shifted to a medium with methanol as the sole carbon source, a significant increase in peroxisomal size and number is observed (van der Klei et al., 2006), reflecting the intense methanol assimilation process occurring in the peroxisomal matrix. *P. anserina* growth on methanol results in fewer peroxisomes than on normal media; moreover, the peroxisomes are less dynamic and are mainly circular and clustered. In contrast to methylotrophic yeasts, these peroxisomes do not significantly increase in size. Thus, despite the presence of the enzymes required for methanol assimilation, overall findings indicate that *P. anserina* is not likely to be a true methylotroph. *P. anserina* grows on methanol-containing medium, but it appears to assimilate methanol poorly, and this leads to a highly vacuolated mycelium, strongly suggesting that the putative methanol assimilation pathways are rather involved in the detoxification of C1 compounds (Yurimoto et al., 2005).

PEROXISOMES IN THE REGULATION OF CELL MORPHOGENESIS AND DIFFERENTIATION

Filamentous fungi generate various cellular types to colonize different niches or to invade appropriate hosts. Also, these cell types are generated to ensure survival in hostile environments and to reproduce by either sexual or asexual processes (see chapters 33 to 36 of this book). Differentiation into various cell types implicates a rearrangement in the cell physiology. This is observed for peroxisomes, for which we observe variation in number and size during the course of fungal development. In growing hyphae, peroxisomes are mainly round or elongated and are regularly distributed throughout cells. In addition, peroxisome numbers can be significantly increased with substrates whose metabolism requires peroxisomal function, such as oleic acid (Valenciano et al., 1996). In *P. anserina*, the number, size, and localization of peroxisomes have been shown to vary largely during sexual development progression (Fig. 3). The size and distribution of peroxisomes in ascogonia (female sexually differentiated hyphae) are like those in growing hyphae. After fertilization, peroxisome numbers are particularly low in dikaryotic crozier cells (there are one to five), but peroxisome numbers increase after karyogamy. In the young growing asci (meiocytes), more than 100 peroxisomes can be observed, mostly concentrated at the tip of the cell. In mature asci, peroxisomes again appear to be randomly distributed and they do not seem to proliferate until ascospore formation, during which their numbers increase dramatically in the newly delimited ascospores (Berteaux-Lecellier et al., 1995; Peraza-Reyes et al., 2008a). Similarly, peroxisome numbers in the macroconidia of *Fusarium graminearum* are significantly greater than those observed in any vegetative developmental stage. This peroxisomal increase is correlated with high transcript levels for genes encoding many proteins implicated in peroxisome function, such as peroxisomal β-oxidation enzymes and peroxisome biogenesis and transport (Seong et al., 2008).

Fungal Dimorphism and Hyphal Morphology

Hyphal and mycelial morphology of most studied fungal mutants defective in peroxisomal function is not, or only slightly, affected under "nutrient-rich" growth conditions. In most cases, the observed deficiency is limited to a reduced growth rate; thus, studies implicating peroxisomes in the direct control of hyphal morphogenesis are limited. Nonetheless, peroxisomes play an important role in modulation of the morphogenic transitions that take place between the vegetative states of some dimorphic fungi, as well as in the establishment of their hyphal shape. One documented example is the dimorphic transition of the saprophytic yeast *Y. lipolytica*. This ascomycete displays various cell morphologies, ranging from yeast cells to septate hyphae, and some peroxins are required for the establishment of the hyphal morphology (Titorenko et al., 1997; Titorenko and Rachubinski, 1998). Moreover, the absence of a protein that controls peroxisome inheritance, Inp1p, induces filamentation under circumstances where normally a yeast form would prevail (Chang et al., 2007). The precise role of peroxisomes in the control of *Y. lipolytica* dimorphism has yet to be clearly established; however, they seem to participate in regulating the polarization of cells in an intricate manner with the endomembrane system and the secretory pathway of the cell.

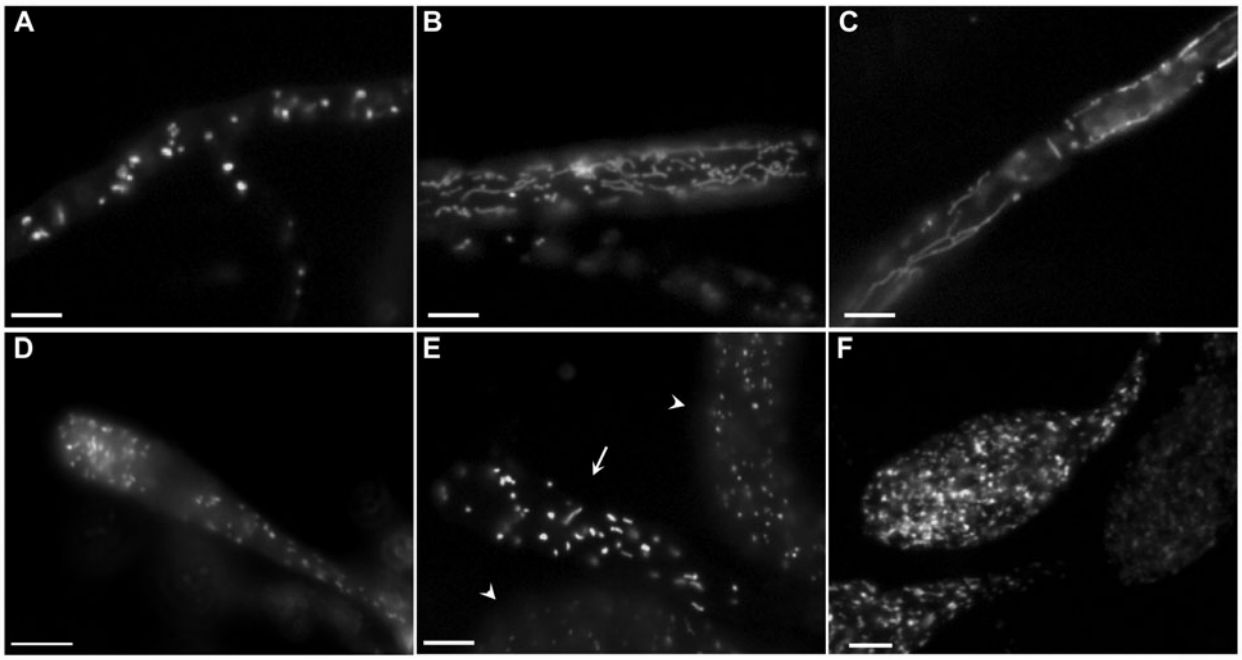

FIGURE 3 Peroxisome dynamics in filamentous fungi. Peroxisomes are highly dynamic organelles in filamentous fungi. They are typically round (A), but their number, form, and distribution can vary according to specific metabolical mycelial demands (A to C); during the formation of differentiated cells, such as during ascus development (panel D: observe the accumulation of peroxisomes at the growing apex of an ascus); between different cell types (panel E: compare the peroxisome shape in paraphysae [asexual cells present in fruiting bodies], shown by an arrow, and in asci, shown by arrowheads); and during spore formation (panel F: note the high peroxisome number resulting from the intense peroxisome proliferation occurring during ascospore formation). Images show peroxisomes of *P. anserina*. Peroxisomes were stained by the GFP-SKL reporter system (Ruprich-Robert et al., 2002); images were done in collaboration with D. Zickler. Scale bars, 5 μm.

Dimorphism in fungi may be related to the infective behavior of some pathogenic fungi. The maize pathogen *Ustilago maydis* normally adopts a unicellular yeast form when saprophytic and switches to the hyphal shape in order to infect its host. Fatty acids induce filamentation in in vitro cultures (Klose et al., 2004) and have a different effect on the growth pattern of induced mycelia. Interestingly, the peroxisomal multifunctional β-oxidation enzyme (Mfe2) of this fungus is required for the dimorphic transition induced by some but not all fatty acids. Moreover, in some situations in which the absence of Mfe2 does not impede filamentation, it reduces the branching of hyphae and, *in planta*, the infective hyphae of the *mfe2* mutants are virtually unbranched. These observations suggest that specific modified fatty acids, whose formation depends on the peroxisomal β-oxidation pathway, promote the dimorphic transition of this fungus and modulate its mycelial morphogenesis (Klose and Kronstad, 2006).

Asexual Cell Differentiation Processes

Developmental processes have energetic and metabolic demands different from those of vegetative growth and commonly require particular regulatory molecules. In fungi, some of these molecules can be in the form of fatty acid-derived secondary metabolites (Tsitsigiannis and Keller, 2007) or ROS (Aguirre et al., 2005), which could conceivably be formed or modified in peroxisomes. Similarly, peroxisome metabolism may contribute to the generation of key intermediary metabolites such as acetyl-CoA for energetic and biosynthetic purposes.

Conidium formation in *M. grisea* is drastically affected if peroxisome formation is defective. In this fungus, formation of aerial hyphae and conidia is largely diminished in mutant strains in which *pex6* has been deleted (Wang et al., 2007). At least some of these deficiencies can be explained by the reduced capacity of the mutant strains to supply peroxisomal acetyl-CoA, as mutant strains defective for the *pth2* gene, coding for a peroxisomal carnitine acetyltransferase, also show decreased conidiogenesis (Bhambra et al., 2006). Nevertheless, the conidiation default observed in the latter strains occurred to a lower extent, indicating that peroxisomal function is required for additional tasks (Wang et al., 2007). In the closely related saprophytic fungus *N. crassa*, functional peroxisomes are also required during conidiogenesis; however, the outcome of the peroxisomal dysfunction appears to be different, as mutants defective for the docking peroxin PEX14 are unable to form macroconidia from aerial hyphae (Managadze et al., 2007). In contrast, conidiation of *Colletotrichum lagenarium*, another sordariomycete, is not affected by peroxisomal dysfunction. In this pathogen, the number of conidia formed in the absence of isocitrate lyase (Asakura et al., 2006) or in *pex6* mutants with defective

peroxisome biogenesis (Kimura et al., 2001) is not affected. This complexity reflects the multiple mechanisms that fungi have evolved to control conidiogenesis.

An absence of functional peroxisomes in eurotiomycete fungi also results in different conidiation phenotypes. *P. chrysogenum* strains defective for *pex5* do not produce conidia (Kiel et al., 2004), whereas in *A. nidulans* conidia are formed but in significantly reduced numbers. In fact, the conidiation phenotype in *A. nidulans* is common to several mutants in which import of PTS1 proteins is affected. The effect was much less drastic in the absence of the PTS2 import pathway, and conidiation occurred normally in the absence of PexK (Pex11) (Hynes et al., 2008).

Asexual spore formation in *A. nidulans* and *N. crassa* is unaffected in the absence of isocitrate lyase activity, similar to what has been observed in the basidiomycete *Coprinopsis cinerea* (Flavell and Fincham, 1968; King and Casselton, 1977); consequently, the conidiation defects of peroxisomal mutants are not the consequence of a disrupted glyoxylate cycle. These ascomycete developmental deficiencies may result from defective WB formation; however, loss of HEX-1 only slightly affects development in *N. crassa* (Jedd and Chua, 2000; Tenney et al., 2000) and *A. nidulans* (Hynes et al., 2008), and no conidiation defects were observed in *M. grisea* (Soundararajan et al., 2004). This indicates that an absence of WBs influences conidiogenesis, but it is not the main cause of developmental deficiencies in these fungi. Interestingly, loss of HEX-1 in *N. crassa* abolishes cyclic conidiation induced by oleic acid in a wild-type strain; therefore, WB-mediated septal plugging may be implicated in coordinating periodic conidiation, which is controlled by the circadian clock of this fungus (Managadze et al., 2007).

Development of *A. nidulans* is controlled by fatty acid-derived oxylipin factors. These secondary metabolites, termed Psi factors, are derivatives of oleic, linoleic, and linolenic acids, and the proportions of their differently hydroxylated forms influence the ratio between sexual and asexual development (reviewed by Tsitsigiannis and Keller, 2007). In this fungus, oleic acid reduces the conidiation of a wild-type strain and induces the formation of cleistothecia (sexual fruiting bodies). Interestingly, this cleistothecial induction was not observed in a *pexF* (*pex6*) mutant, which could indicate that the peroxisomal metabolism influences oxylipin Psi factor formation (Hynes et al., 2008).

Sexual Development

The sexual development of some fungi takes place in large multicellular fruiting bodies, leading to the coordinated differentiation of numerous cell types. The development of these structures frequently occurs when mycelia have exhausted external resources, such that the metabolism of the emerging fruiting bodies becomes largely dependent on the reserve compounds of preexisting vegetative cells (Poggeler et al., 2006; Wosten and Wessels, 2006; see also chapter 33). Peroxisomal metabolism may play a major role in channeling nutrients from preexisting to newly differentiated cells of the developing fruiting bodies. The regulation of glyoxylate cycle enzymes in some fungi is in agreement with this assumption. In the ectomycorrhizal fungus *Tuber borchii*, the transcripts of genes encoding isocitrate lyase and malate synthase are much more abundant in fruiting bodies than in the vegetative mycelium. Moreover, metabolic resources of this ascomycete are relocated during fruiting-body development, and the lipids present in the vegetative hyphae of unripe fruiting bodies are mobilized to ripe ascospores upon maturation (Abba et al., 2007). However, in the basidiomycetes *Fomitopsis palustris*, *C. cinerea*, and *Schizophyllum commune*, the glyoxylate cycle appears to be regulated in an opposite manner, and glycolysis, together with the tricarboxylic acid cycle, seems to be the major pathway sustaining fruiting-body development (Cotter et al., 1970; Schwalb, 1974; Moore and Ewaze, 1976; Yoon et al., 2002). It is important to note that the lifestyle and fruiting-body constitution in these fungi differ; thus, these differences must reflect the diverse ways that fungi have developed to sustain fruiting-body development. Differentiation processes in *U. maydis*, culminating in sexual development, take place inside fungus-induced plant tumors and lead to the formation of diploid teliospores. The development of these teliospores is significantly delayed in the absence of the β-oxidation multifunctional enzyme (*mfe2*). Development in *U. maydis* is tightly connected to the virulence process; thus, it is possible that this developmental delay also reflects the lower proliferative efficiency *in planta* of the mutant strains (Klose and Kronstad, 2006).

A. nidulans produces few small cleistothecia in homozygous crosses of strains defective for the PTS1 peroxisome matrix import pathway (Hynes et al., 2008). A similar phenotype is observed in *P. anserina* mutants lacking the PTS1 receptor. However, in *P. anserina*, but not in *A. nidulans*, the lack of PTS2 receptor PEX7 acts as a partial suppressor of the *pex5* phenotype, suggesting that it is more detrimental to mislocalize a subset of peroxisomal matrix proteins than the complete matrix proteome in *P. anserina*. *P. anserina pex5* mutants also display a maternal effect during sexual development; i.e., the defect is observable in homozygous or heterozygous crosses whenever the *pex5* mutant is used as a female partner (Bonnet et al., 2006). These observations suggest that the incorrect compartmentalization of peroxisomal proteins affects the development of the maternally derived enveloping tissues of the fruiting bodies. Interestingly, this phenotype is not the consequence of a defective fatty acid β-oxidation pathway (Boisnard et al., 2008). The absence of PEX14 in *N. crassa* suggests an additional earlier peroxisomal role in protoperithecia development, as mutant strains defective for this peroxin are female sterile (Managadze et al., 2007). Remarkably, this phenotype is not observed if *P. anserina* lacks the corresponding peroxin (Peraza-Reyes et al., 2008b), suggesting fundamental differences in the physiology of even closely related fungi.

In addition to the fruiting-body constitution, peroxisomes also participate in differentiation processes taking place in the fertile portion (*centrum*) of these structures. *P. anserina* strains lacking the PTS receptors PEX5 and PEX7 exhibit abnormal formation of asci, resulting in ascospores with uneven numbers of nuclei or spores with no nuclei. The extent of this defect is considerably less in the absence of PEX7 than PEX5; moreover, *Δpex5* mutant also displays a maternal effect (Bonnet et al., 2006). The second *centrum* developmental event in which peroxisomes are involved in *P. anserina* is the transition from the prekaryogamy mitotic phase to the karyogamy and meiotic phase. PEX2 was the first protein shown to be required for this transition. Indeed, the mutation in *pex2* was found fortuitously when searching in mutant strains defective for ascospore formation (Simonet and Zickler, 1972), exposing one of the first developmental roles for peroxisomes (Berteaux-Lecellier et al., 1995). The phenotype of the *pex2* mutant is observed only in homozygous crosses and is characterized by an extended proliferation of crozier dikaryotic cells in which karyogamy never takes place and, consequently, ascospores are never formed (the *pex2* mutant phenotype is illustrated

in Fig. 11D of chapter 33). Nuclear fusion itself is presumably not affected in this mutant, as in vegetative cells it is normal (Berteaux-Lecellier et al., 1995); thus, it is likely that a prekaryogamy event required for the initiation of meiosis is impaired in these mutants. Moreover, this peroxisomal involvement may be specific to the differentiation of crozier/ascus cells in filamentous fungi, as the yeast *Pichia pastoris pex2* mutant (Waterham et al., 1996) can undergo the entire sexual cycle and form ascospores. Interestingly, so far the only proteins that have been implicated in this meiotic progression are all members of the *P. anserina* peroxisome RING finger complex; the same phenotype was observed in the absence of the other two RING finger peroxins, PEX10 and PEX12, but not in the absence of PEX5, PEX7, or PEX14 or in strains lacking both PEX5 and PEX7 (Bonnet et al., 2006; Peraza-Reyes et al., 2008b).

Likewise, none of the reported *A. nidulans* peroxin mutants (the orthologs of *pex1*, *3*, *5*, *6*, *7*, *11*, and *13)* display a similar phenotype (Hynes et al., 2008). This introduces the possibility of a bifunctional role for the peroxisome RING finger complex; however, so far, it has not been possible to dissociate discernible functions in peroxisome biogenesis and sexual development for the proteins of the RING finger complex (Peraza-Reyes et al., 2008b; our unpublished results). Moreover, there exist extragenic suppressors that partially restore the peroxisome assembly and developmental defects of cells defective for PEX2 (Ruprich-Robert et al., 2002; Boisnard et al., 2003; our unpublished data), indicating that in the presence of a defective RING finger complex there are alternative ways of restoring peroxisome biogenesis and sexual development. This also suggests that the role of the peroxisome RING finger complex in fungal development is not related to the classic peroxisome-matrix function/pathway and might reveal new unexpected functions for fungal peroxisomes.

Peroxisomes in the Maturation and Germination of Fungal Spores

The high number of peroxisomes in both *F. graminearum* macroconidia and *P. anserina* ascospores (Berteaux-Lecellier et al., 1995; Seong et al., 2008; see also under "Peroxisomes in the Regulation of Cell Morphogenesis and Differentiation" above for details) suggests a specific involvement of peroxisomes during spore maturation and germination. Spore maturation usually requires the incorporation of pigments such as melanin in the cell wall to make it stronger (Gomez and Nosanchuk, 2003). In filamentous fungi, melanin is produced by the dihydroxynaphthalene melanin biosynthesis pathway, either from malonyl-CoA or acetyl-CoA precursors (Langfelder et al., 2003; Ramos-Pamplona and Naqvi, 2006; Coppin and Silar, 2007). *P. anserina* peroxisomal assembly mutants have, to a different extent, ascospores that are less pigmented than wild-type ascospores (Berteaux-Lecellier et al., 1995; Bonnet et al., 2006; Peraza-Reyes et al., 2008b; Boisnard et al., 2008). Similarly, in plant pathogenic fungi, melanization of another fungal structure, the appressorium, is defective in peroxisome biogenesis mutants (Ramos-Pamplona and Naqvi, 2006; Kimura et al., 2001). Therefore, impairment of the peroxisomal fatty acid β-oxidation pathway that produces acetyl-CoA might account for this altered melanization. In line with this hypothesis, defects in melanization have also been observed in mutants affected in the peroxisomal β-oxidation pathway (Wang et al., 2007; Boisnard et al., 2008; see also "Peroxisomes in Predatory and Pathogenic Fungi" below for details). However, in the maize pathogenic fungus *U. maydis*, the teliospores formed by an *mfe2* mutant only display a delayed melanization (Klose and Kronstad, 2006), suggesting the existence of alternative sources for melanin precursors. Interestingly, such metabolites might be obtained from the host plant.

Beyond their impairment in melanization, ascospores from all *P. anserina* peroxisomal assembly mutants, along with the *fox2* (*U. maydis mfe2* ortholog) mutant strains, display a low germination frequency, suggesting a link between either β-oxidation or ascospore pigmentation and the germination process (Berteaux-Lecellier et al., 1995; Bonnet et al., 2006; Peraza-Reyes et al., 2008b; Boisnard et al., 2008). In fact, when *fox2* mutant ascospores are directly ejected onto the germination medium, the germination rate almost reaches that of the wild type (Boisnard et al., 2008). Thus, the fragility of less-pigmented ascospores rather than defects in the peroxisomal β-oxidation pathway is responsible for this germination impairment, at least for *P. anserina fox2* mutants. In *U. maydis*, the germination rate of the teliospores formed by the *mfe2* mutant is not affected, even if their melanization is delayed (Klose and Kronstad, 2006). Moreover, *A. nidulans* peroxisome assembly mutant ascospores, for which no defect in melanization has been reported, germinate efficiently (Hynes et al., 2008). Altogether these data show that peroxisomal fatty acid metabolism is not the only energy source required for the initiation of germination.

Ascospore germination studies of *P. anserina* peroxisomal assembly mutants and *fox2* mutant suggest that peroxisomes may also become involved in germination. Here, the growth rate of the germinative hyphae is reduced and gives rise to a spindly mycelium (Berteaux-Lecellier et al., 1995; Bonnet et al., 2006; Boisnard et al., 2008). This phenotype disappears for *pex2* mutant ascospores if glucose is added to the germination medium (Berteaux-Lecellier et al., 1995). The glucose requirement during germination is in accordance with *F. graminearum* microarray studies that showed that some of the most up-regulated genes associated with spores and spore germination are those involved in carbohydrate utilization and gluconeogenesis (Seong et al., 2008). Moreover, a phenotype similar to that of *P. anserina* ascospores is observed during the germination of *Aspergillus* conidia; this phenotype is delayed in *A. nidulans pex* mutants (Hynes et al., 2008) or when *A. fumigatus* isocitrate lyase and malate synthase mutants germinate under conditions resembling those faced after phagocytosis (Olivas et al., 2008). Moreover, if glucose is added to the medium, the germination rate of *A. fumigatus* conidia almost reaches that of the wild type (Olivas et al., 2008). Together these data suggest that the peroxisomal β-oxidation pathway and the glyoxylate cycle are required for the step following germination initiation, probably because they provide acetyl-CoA and carbohydrates to generate glucose for the further biosynthesis of cellular materials. Furthermore, intense degradation of trehalose has been observed during germination of *A. nidulans* conidia (Fillinger et al., 2001). Together, these data support the notion that peroxisomes are required under particular circumstances and that other carbon sources, notably trehalose, are required during conidial germination.

The importance of the glyoxylate cycle in spore germination is underscored by the *N. crassa* isocitrate lyase mutant phenotype (Flavell and Fincham, 1968; Gainey et al., 1992). In the absence of this key enzyme of the glyoxylate cycle, sexual spores fail to germinate or do not develop further than the germ tube state; however, *N. crassa* isocitrate lyase mutant conidia have no germination defect (Flavell and Fincham, 1968; Armitt et al., 1976). Moreover, neither the loss of isocitrate lyase activity nor peroxisome assembly

defects in *A. nidulans* lead to a defect in ascospore or conidium viability (Armitt et al., 1976; Gainey et al., 1992; Hynes et al., 2008).

The overall findings indicate that the peroxisome metabolic requirements for spore maturation and germination not only vary between sexual and asexual spores but also vary among filamentous fungi. Their specific requirements for these processes probably rely on the availability of external metabolites, which in turn is highly dependent on the fungus life cycle.

PEROXISOMES IN PREDATORY AND PATHOGENIC FUNGI

Many fungi are pathogenic to plants or animals. These fungi usually develop specialized structures to parasitize their host. For example, *Arthrobotrys oligospora*, a nematophagous fungus, differentiates, in the predacious phase, into three-dimensional adhesive networks (trap cells) to capture living nematodes (Barron, 1977). Studies performed with this fungus and other predatory fungi have shown that unusual peroxisomes are implicated in their developmental programs (Veenhuis et al., 1984; Dijksterhuis et al., 1994). During the transition from the saprophytic to the predatory stages, several cellular transitions occur and two classes of peroxisomes are observed: classical peroxisomes, which are present in vegetative hyphae in limited numbers, and electron-dense bodies that proliferate in trap cells from the initiation of trap development to the penetration of the host tissue (Dijksterhuis et al., 1994). These organelles are probably peroxisomes, as they contain catalase and D-amino-acid oxidase activities; however, they also possess unique attributes. Indeed, these organelles, like peroxisomes, are formed from a specialized region of the ER, but the major pathway for peroxisome production in the cell, by division of preexisting peroxisomes, is never observed. In addition, these bodies are surrounded by a thicker membrane and their electron density is high. These organelles are transitory and disappear by autophagy during the first stages of nematode infection, as soon as the mycelium has penetrated the cuticle and begun colonization of the host (Veenhuis et al., 1989; Dijksterhuis et al., 1994). The results of these cytological studies present an initial confirmation of a link between peroxisomes and fungal development. These unusual peroxisomes presumably play a crucial role in the initial stages of nematode infection. However, due to an absence of further studies, such as those investigating peroxisomal mutant pathogenicity, their role remains poorly understood.

A link between pathogenic development and peroxisomal function is also observed in phytopathogenic fungi, in which strains mutated for genes encoding peroxisomal proteins are less pathogenic than the wild type. The reported data strongly suggest that peroxisomes are implicated in pathogenesis, by producing precursors of the gluconeogenesis pathway via the glyoxylate cycle. Peroxisomes can also produce precursors for cell wall or melanin biosynthesis (Thines et al., 2000; Kimura et al., 2001; Asakura et al., 2006).

Mechanisms for the penetration and colonization of the host plant are well documented in fungi, such as the rice pathogen *M. grisea* (Talbot, 2003; Caracuel-Rios and Talbot, 2007) and *C. lagenarium*, the causal agent of cucumber anthracnose (Agrios, 2004). To penetrate their host plant, these fungi develop a specialized infection structure called the appressorium (Emmett and Parbery, 1975). The appressorium is a heavily melanized, dome-shaped single-cell structure that accumulates glycerol to a very high concentration. This allows, by hydrostatic turgor pressure, the production of a substantial invasive force required to perforate the leaf cuticle (Howard et al., 1991). The differentiation of this structure is accompanied by a rapid mobilization of lipid bodies, which are broken down by cytosolic triacylglycerol lipases generating fatty acids and glycerol (Thines et al., 2000). In *M. grisea*, this lipolysis and the associated release of glycerol appear to be the major source of turgor pressure generation (Wang et al., 2007).

Fungal growth requires carbohydrates for the biosynthesis of complex structural polysaccharides, such as glucans and chitin, to synthesize the cell wall. In the absence of external carbohydrates (i.e., during the first stages of infection), the peroxisome glyoxylate cycle may compensate by synthesizing glucose from lipids, which may explain their role during infection. Consistent with this idea, *C. lagenarium* mutant strains defective for the enzyme isocitrate lyase show a decreased frequency of host lesions, probably the consequence of a defect in the cell wall. This weakness in the cell wall may account for an increased sensitivity to the host defense responses (Asakura et al., 2006). Studies of various pathogenic fungi have shown that the glyoxylate cycle is also required at the beginning of the infection state, presumably due to the lack of a carbon source in the host environment (Lorenz and Fink, 2001; Idnurm and Howlett, 2002; Wang et al., 2003). However, the phenotype associated with the interruption of this cycle, at least in *C. lagenarium*, is not as drastic as when peroxisome biogenesis is hampered, suggesting that peroxisomes might have another role during the pathogenic cycle.

Fatty acids that are liberated by lipolysis are metabolized by β-oxidation—mostly peroxisomal β-oxidation—in the appressorium, generating acetyl-CoA. *M. grisea* mutant strains with knockout mutations in the genes encoding the peroxisomal β-oxidation multifunctional enzyme (Δ*mfp1*) or the peroxisomal carnitine acetyltransferase (Δ*pth2*), which are unable to export acetyl-CoA from the peroxisome to the cytoplasm, had a significant reduction in their ability to penetrate the plant cuticle and to colonize the host tissue. In addition, in the maize pathogenic fungus *U. maydis*, which does not produce true melanized appressoria, the infectious hyphae of the *mfe2* mutant are defective for the peroxisomal β-oxidation multifunctional enzyme. This mutant has virtually no branches, and its infective mycelium is less extended than the one from the wild type (Klose and Kronstad, 2006). These overall data highlight the importance of the cellular concentration of acetyl-CoA, first produced by the peroxisomal fatty acid β-oxidation pathway. Acetyl-CoA must then be exported from peroxisomes to the cytosol and other cellular compartments, to be used as a substrate in several metabolic and biosynthetic pathways to contribute to the host infection process (Bhambra et al., 2006; Wang et al., 2007).

The loss of virulence observed in the *M. grisea* Δ*mfp1* and Δ*pth2* mutant strains is accompanied by a decrease in the appressorium melanization. As described above ("Peroxisomes in the Maturation and Germination of Fungal Spores"), the dihydroxynaphthalene melanin biosynthesis pathway requires cytosolic precursors such as malonyl- or acetyl-CoAs. Disappearance of melanin is observed in the *M. grisea pex6* knockout mutant (see below). In this mutant strain, some peroxisomal enzymatic pathways, like β-oxidation, might be impaired due to the mislocalization of most peroxisomal proteins in the cytosol (Wang et al., 2007); this may partially account for the altered melanization process. However, a decrease in melanization does not appear to be the primary

reason for the loss of pathogenicity in these mutants, because addition of a melanin biosynthesis intermediate failed to restore the formation of lesions *in planta* and appressorium turgor pressure generation is normal in the Δ*pth2* mutant (Bhambra et al., 2006).

The above findings indicate that the role of peroxisomes in the infection process is complex and probably not restricted to the β-oxidation and glyoxylate pathways. The developmental regulation of the peroxisome number and of their enzymatic activities in pathogenic fungi suggests an important role for peroxisomes in the infectious developmental process. Moreover, in addition to the weak colonization of host plant tissue, Δ*pex6* appressoria are formed abnormally and with a low frequency (Wang et al., 2007), suggesting that peroxisomes are required at various stages of appressorium development.

It has recently become clear that appressorium formation in *M. grisea* is the consequence of a developmental process linking cell cycle progression and autophagic cell death (Veneault-Fourrey et al., 2006; Veneault-Fourrey and Talbot, 2007). Indeed, the appressorium appears to require the recycling of components produced by autophagy of preexisting cells. Peroxisome-produced acetyl-CoA could be a key component during this cell-remodeling process (Bhambra et al., 2006; Wang et al., 2007).

The multitude of functions fulfilled by the peroxisomal compartment is highlighted by the need for functional WBs (see "A Peroxisome-Related Organelle of Filamentous Fungi: the WB" above for details on WBs) in the formation of a functional appressorium in *M. grisea* (Soundararajan et al., 2004). Moreover, peroxisomes play also a part in spore formation and asexual developmental of this fungus (Wang et al., 2007). Thus, peroxisomes have diverse functions in the developmental process. The next challenge will be to better understand the link between peroxisomes and these developmental processes.

CONCLUDING REMARKS

To date, fungi have provided invaluable model organisms for studying peroxisome formation and function. Various yeasts have played a major role in the identification of several proteins implicated in peroxisome assembly and dynamics, as well as in the understanding of their function at the molecular and cellular levels. However, research into yeast developmental processes is limited; thus, filamentous fungi have been of great importance in revealing the developmental impact of peroxisomal function.

Peroxisomes provide fungi with a metabolic versatility that allows them to effectively colonize diverse habitats. In addition, they have been shown to be required for the execution of a number of developmental processes. Hence, the adaptability they provide is not limited to the capacity to effectively assimilate and metabolize diverse sources of carbon and nitrogen but also entails a metabolic relocation implicated in the modulation of cell fate. Furthermore, their involvement in developmental processes can vary between different fungal species, even when closely related phylogenetically. Thus, these fungal organelles appear to be adaptable and capable of adopting diverse roles with different physiological impacts. Interestingly, their plasticity extends far beyond the metabolic spectrum, as is nicely illustrated in fungi by the WB, a peroxisome-derived specialized organelle required for the filamentous lifestyle. In spite of the progress made in understanding peroxisome function in fungi, a detailed picture of how peroxisomes affect several other metabolic and developmental processes remains elusive. Further innovative approaches are required to fully understand the function of this organelle in fungi.

We are much indebted to D. Zickler (IGM, Orsay) for her collaboration with cytological studies, to W. Hansberg (UNAM, Mexico) for his kind gift of the transmission electron micrograph, and to G. Jedd (TLL, Singapore) for his generous gift of the anti-hex1 antibody. Our work is supported by the CNRS, the University Paris Sud-11, and grants from the ANR (National Research Agency, no. ANR-05-BLAN-0385-01). L.P.-R. was supported by a postdoctoral fellowship from ELA (European Leukodystrophy Association) Research Foundation.

The Cytoskeleton in Filamentous Fungi

XIN XIANG AND BERL OAKLEY

In eukaryotic cells, dynamic polymers such as microtubules and actin filaments are important cytoskeletal elements that not only function as tracks for intracellular transport but also generate forces to make cell polarization/motility, organelle positioning, mitosis, and cytokinesis possible. Genetic tractability, coupled with the development of advanced imaging techniques, has made fungi excellent model systems for studying the cytoskeletal machinery. Currently, much of our knowledge of the functions and regulation of the cytoskeleton in fungi has been generated by research on several genetic model systems, including both the budding and fission yeasts and several filamentous fungi. In this chapter, our discussions are focused on the microtubule and actin cytoskeletons of filamentous fungi, including the motor proteins that are integral to cytoskeletal function. Relevant results from yeasts are discussed to provide background and context. The classical literature on the electron microscopy and immunofluorescence microscopy of the fungal cytoskeleton is not reviewed here. This has been ably and comprehensively reviewed by Heath (Heath, 1994a, 1994b, 2000). The emphasis is instead on more recent data from live-cell imaging as well as genetic and molecular genetic studies.

Filamentous fungi grow almost exclusively by polarized extension of the hyphal tip (Harris and Momany, 2004). To maintain such a highly polarized growth pattern, not only do cell wall precursors need to be continuously transported to the hyphal tip, but multiple nuclei and other organelles also need to be positioned properly within the elongating hyphae. It has been shown that both the microtubule and the actin cytoskeletons play roles in polarized growth of hyphae, and how these cytoskeletal elements function to support hyphal growth and organelle distribution in elongated hyphae is a topic of great interest.

THE MICROTUBULE CYTOSKELETON

A typical microtubule is a hollow tube composed of 13 protofilaments. The microtubule's building blocks, α-tubulin and β-tubulin heterodimers, are arranged in a head-to-tail fashion in protofilaments, which gives the microtubule its inherent polarity with β-tubulins terminal at the plus end and α-tubulins at the minus end (Nogales et al., 1999). It is worth pointing out that early experiments done by Morris and coworkers with the filamentous fungus *Aspergillus nidulans* led to the first discovery of genes for these tubulin subunits (Oakley, 2004). The microtubule plus ends are highly dynamic, with alternate growing and shrinking phases (Desai and Mitchison, 1997). Many proteins, such as the classic microtubule-associated proteins (MAPs) and microtubule plus end tracking proteins (+TIPs) are found to modulate the plus end dynamics in vivo (Carvalho et al., 2003; Howard and Hyman, 2003; Akhmanova and Hoogenraad, 2005). The minus ends are generally attached to microtubule-organizing centers (MTOCs).

In most fungi, the major MTOC is the spindle pole body (SPB), which is generally associated with, and often embedded in, the nuclear membrane (Jaspersen and Winey, 2004). SPBs contain γ-tubulin, which was first discovered in *A. nidulans* and is required for nucleation of microtubule polymerization (Oakley and Oakley, 1989; Oakley et al., 1990, Wiese and Zheng, 2006). Results from mutational analysis of *A. nidulans* γ-tubulin suggest that it also carries out additional functions essential for mitotic regulation and the organization of cytoplasmic microtubules (Jung et al., 2001b; Prigozhina et al., 2004). In filamentous fungi such as *A. nidulans*, microtubules are arranged longitudinally within the hyphae and microtubule nucleation occurs predominantly at SPBs. Thus, between any two nuclei it is likely that there are microtubules with mixed polarity, but in a region between the first nucleus and the hyphal tip, all microtubules seem to extend from the SPB towards the hyphal tip, suggesting that the dynamic plus ends of microtubules are at the hyphal tip and that there is no major MTOC at the tip (Han et al., 2001; Horio and Oakley, 2005; Sampson and Heath, 2005). However, the existence of minor MTOCs in addition to the SPBs is not excluded (Konzack et al., 2005). In the dimorphic fungus *Ustilago maydis*, there are also nonnuclear MTOCs activated at different stages of the cell cycle (Straube et al., 2003), and in *Allomyces macrogynus* (Chytridiomycota), there is a prominent apical MTOC (McDaniel and Roberson, 1998). Recent advances

in live-cell imaging have allowed microtubule dynamics to be observed in several other filamentous fungi, including *Neurospora crassa*, and the application of electron tomography may provide further insights into microtubule organization in various fungal species (Freitag et al., 2004; Czymmek et al., 2005; Mouriño-Pérez et al., 2006; Hohmann-Marriott et al., 2006; Uchida et al., 2008).

In filamentous fungi, the microtubule cytoskeleton is essential for nuclear division, nuclear distribution, and transport of other organelles (Oakley and Morris, 1980, 1981; McDaniel and Roberson, 2000; Xiang and Plamann, 2003; Xiang and Fischer, 2004; Steinberg, 2007a, 2007b). Microtubules form mitotic spindles that are essential for chromosomal segregation during nuclear division. Microtubules almost certainly serve as tracks for the movement of vesicles, organelles, and RNA particles in the cytoplasm, and microtubule motor proteins are important for these intracellular transporting events (Xiang and Plamann, 2003; Steinberg, 2007a; Wedlich-Soldner et al., 2002a, 2002b; Becht et al., 2006; Soldati and Schliwa, 2006). The function of microtubules in rapid hyphal tip growth is likely related to the long-distance transport of cell wall precursors and polarity factors to the hyphal tip region (Horio and Oakley, 2005; Taheri-Talesh et al., 2008; Seiler et al., 2006; Vogt and Seiler, 2008) and to the communication with the actin cytoskeleton for maintaining directional hyphal growth (Fischer et al., 2008a, 2008b). Microtubules are also required for localizations of proteins in the septation initiation network (Kim et al., 2006a). In addition, dynamic microtubules may interact with the cortex to provide pushing or pulling forces directly on nuclei for nuclear positioning, as in yeasts (Finley and Berman, 2005; Tran et al., 2001; Maddox et al., 1999; Yeh et al., 2000; Daga et al., 2006). For microtubules to fulfill their cellular functions, the proper organization of the network is critical, and this also depends on proteins including microtubule motor proteins (Steinberg, 2007b).

MICROTUBULE MOTOR PROTEINS

Cytoplasmic Dynein

Cytoplasmic dynein, a multisubunit complex, is a minus-end-directed microtubule motor that plays a variety of roles in mitosis and in transport of cargoes such as vesicles, organelles, proteins, and mRNAs. The organization of the motor is different from that of the other motor protein families, kinesins and myosins (Vale, 2003; Sakato and King, 2004; Roberts et al., 2009), but the yeast dynein is a processive motor (meaning that it takes consecutive steps along a microtubule without falling off the track) and takes mainly 8-nm steps just like a plus-end-directed conventional kinesin (Reck-Peterson et al., 2006). The dynein heavy chain, which is a huge protein with a mass of about 500 kDa, is responsible for ATP-dependent motility. It contains an N-terminal tail that binds to other subunits of the dynein complex and a C-terminal motor unit comprising six AAA (acronym for ATPase associated with cellular activities) domains and a microtubule-binding stalk located between AAA4 and AAA5 (Pfister et al., 2006). Fungal dynein heavy chains show significant sequence similarity with mammalian dynein heavy chains, but interestingly, fungal dynein heavy chains are shorter due to a truncation at the C terminus (Vallee and Hook, 2006). Another interesting phenomenon is that in the dimorphic fungus *U. maydis*, the dynein heavy chain is encoded by two separate genes and synthesized as two polypeptides with the splitting point before the microtubule-binding site (Straube et al., 2001). Many other proteins involved in the in vivo function of cytoplasmic dynein have been discovered. They include proteins in the cytoplasmic dynein complex (Pfister et al., 2006); its accessory complex, dynactin (Schroer, 2004); and homologs of LIS1 (a product of the human disease lissencephaly gene) (Morris et al., 1998; Vallee and Tsai, 2006).

In fungal hyphae, cytoplasmic dynein is important for nuclear distribution and the positioning of organelles including endosomes (Xiang and Plamann, 2003; Xiang and Fischer, 2004; Steinberg, 2007a; Finley et al., 2008). It also plays nonessential roles during mitosis in spindle assembly, accurate chromosomal segregation, and spindle elongation (Efimov and Morris, 1998; Inoue et al., 1998; Li et al., 2005b; Fink et al., 2006a). In addition, dynein in filamentous fungi also participates in organizing the microtubule network by regulating microtubule dynamics and by providing force for transporting microtubules (Han et al., 2001; Fink et al., 2006b; Steinberg, 2007b). Finally, it has been found in *A. nidulans* that dynein loss of function causes an abnormal positioning of septa (Liu and Morris, 2000).

Mutants in the cytoplasmic dynein pathway have been isolated in *A. nidulans* as *nud* (acronym for nuclear distribution) mutants and in *N. crassa* as *ropy* mutants that exhibit nuclear clustering and hyphal growth phenotypes (Morris et al., 1998; Xiang and Plamann, 2003). Cloning of the *nud* and *ropy* genes in *A. nidulans* and *N. crassa* identified many components of the cytoplasmic dynein complex and the dynactin complex. Several genes encoding novel proteins important for dynein function were first identified in filamentous fungi, including NUDF (a homolog of mammalian LIS1 involved in neuronal migration), NUDE/RO11 (homologs of mammalian NudE/Nde1 and Nudel/Ndel1), and NUDC (a homolog of mammalian NudC and NudCL) (Osmani et al., 1990; Xiang et al., 1995; Minke et al., 1999; Efimov and Morris, 2000; Aumais et al., 2001; Vallee and Tsai, 2006; Zhou et al., 2006). The discovery of these fungal proteins as components in the dynein pathway has a great impact on studies in higher eukaryotic systems, especially studies on neuronal migration (Morris et al., 1998; Tsai and Gleeson, 2005; Vallee and Tsai, 2006). It should be pointed out, however, that not all proteins in dynein and dynactin complexes are essential for dynein's function in nuclear distribution. For example, loss of a dynactin component, p25, does not cause a nuclear distribution defect in *N. crassa* but a defect in vesicle positioning (Lee et al., 2001). In addition, loss of the 8-kDa dynein light chain in *A. nidulans* affects dynein function only at high temperatures (Liu et al., 2003).

In filamentous fungi, dynein and its regulators accumulate at the dynamic microtubule plus ends (Fig. 1), and the accumulation of dynein at the plus end depends on dynactin and kinesin-1 (Han et al., 2001; Zhang et al., 2003; Lenz et al., 2006). A similar localization has also been observed in budding yeast, where dynein at the plus ends of astral microtubules may be delivered to the Num1-containing regions of the cell cortex, where it exerts force to move the mitotic spindle (Lee et al., 2003; Sheeman et al., 2003; Miller et al., 2006). Spindle movement in *A. nidulans* may use the same mechanism, because the Num1 homolog ApsA in *A. nidulans* is also a cortical protein and is important for spindle movement (Xiang and Fischer, 2004; Veith et al., 2005). In *U. maydis*, premitotic nuclear migration toward the bud is dynein dependent, and the force exerted by dynein on the spindle pole body may also be involved in breaking the nuclear envelope for open mitosis (Straube et al., 2005).

Whether plus end dynein functions in interphase nuclear movement towards the hyphal tip is a question that needs to be addressed (Xiang and Fischer, 2004). Dynein at the microtubule plus end is involved, possibly indirectly through other +TIPs, in promoting microtubule dynamics (Carminati and Stearns, 1997; Han et al., 2001; Carvalho et al., 2003). It is possible that microtubule dynamics facilitates the interaction between a microtubule end and the cell cortex for pulling and/or pushing the nuclei around and the less dynamic microtubules in the dynein mutants could be a problem for nuclear migration. This notion is supported by the observations that the microtubule-destabilizing drug benomyl suppresses the nuclear distribution defect in the dynein mutants in *A. nidulans* and does so more dramatically in *Ashbya gossypii* (Willins et al., 1995; Alberti-Segui et al., 2001). However, loss of other +TIPs, such as the CLIP-170 homolog CLIPA or the Dis1/XMAP215/Stu2 homolog ALPA in *A. nidulans*, also causes microtubules to be less dynamic but does not produce an obvious nud phenotype (Efimov et al., 2006; Enke et al., 2007). Thus, dynein in *A. nidulans* may affect interphase nuclear migration through other mechanisms. Recent data suggest that dynein regulators such as NUDF and NUDC may be present at the SPB (Helmstaedt et al., 2008), but it remains to be determined whether they regulate dynein function at SPB to influence nuclear migration.

In filamentous fungi, the localization of cytoplasmic dynein to the dynamic microtubule plus ends is important for its function in retrograde transport of cargoes, especially early endosomes, inside the elongated hyphae (Steinberg, 2007a, 2007b). This was first demonstrated in *U. maydis* hyphae, where plus-end dynein is important for endosome loading and their subsequent transport towards the microtubule minus end (Fig. 2) (Lenz et al., 2006). Recently, green fluorescent protein (GFP)-Rab5A-labeled early endosomes have also been shown to undergo dynein-dependent retrograde movement in *A. nidulans* (Abenza et al., 2009). Given that dynein-mediated retrograde transport is crucial for the integrity of many cells, especially neurons (Chevalier-Larsen and Holzbaur, 2006), it is important to dissect the general regulatory mechanisms involved, and filamentous fungi are excellent model systems for these studies.

Kinesins

The genomes of most filamentous fungi analyzed to date contain 10 different kinesin-coding genes, except for the *A. nidulans* genome, which contains 11 kinesin genes (Schoch et al., 2003; Xiang and Plamann, 2003; Rischitor et al., 2004; Schuchardt et al., 2005; Galagan et al., 2005; Wortman et al., 2009). These kinesins belong to the kinesin-1, kinesin-3, kinesin-4, kinesin-5, kinesin-6, kinesin-7, kinesin-8, and kinesin-14 families (Lawrence et al., 2004; Schoch et al., 2003; Xiang and Plamann, 2003; Rischitor et al., 2004; Schuchardt et al., 2005). Here the discussion is focused on several kinesins that have been studied in filamentous fungi.

Kinesin-1

Kinesin-1 is a conventional kinesin that forms dimers and moves toward the plus ends of microtubules (Vale, 2003; Schliwa and Woehlke, 2003). Fungal kinesin-1 proteins show interesting differences in composition, structure, and properties relative to homologs in higher eukaryotes, and the reader is referred to reviews discussing these topics (Xiang and Plamann, 2003; Adio et al., 2006a). Although not essential for viability, fungal kinesin-1 proteins support vesicle trafficking important for rapid hyphal tip extension

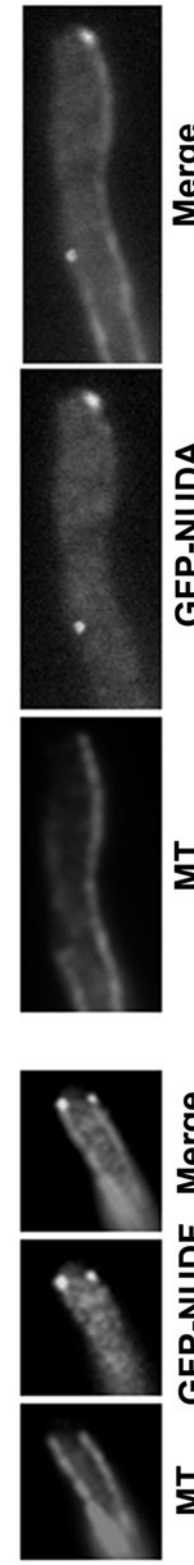

FIGURE 1 Microtubule plus end localization of GFP-labeled cytoplasmic dynein heavy chain (NUDA) and NUDF/LIS1. Microtubules (MT) are stained by an anti-α-tubulin antibody. This figure is a modified version of Fig. 2 from Han et al., 2001, with permission from Elsevier Ltd.

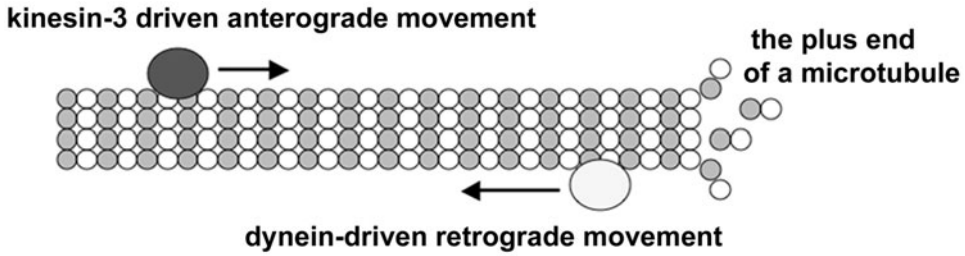

FIGURE 2 Diagram showing that early endosomes move bidirectionally along a microtubule. While the anterograde movement towards the microtubule plus end is driven by kinesin-3, the retrograde movement away from the plus end is driven by dynein (Lenz et al., 2006; Abenza et al., 2009; Zekert and Fischer, 2009).

(Xiang and Plamann, 2003; Requena et al., 2001; Schuchardt et al., 2005), and they may also play a role in microtubule organization (Straube et al., 2006). As a plus-end-directed motor, kinesin-1 is, surprisingly, also important for retrograde endosome movement from the hyphal tip (Steinberg, 2007a, 2007b; Abenza et al., 2009). This most likely results from a role for kinesin-1 in transporting cytoplasmic dynein to the plus end of microtubules, where dynein interacts with early endosomes for their retrograde transport (Zhang et al., 2003; Lenz et al., 2006; Steinberg 2007a, 2007b; Abenza et al., 2009). Finally, a kinesin-1 null mutant also exhibits a nuclear-distribution defect, although not as severe as that displayed by a dynein null mutant (Requena et al., 2001; Xiang and Fischer, 2004), and this may also be related to the role of kinesin-1 in the microtubule plus-end localization of dynein (Zhang et al., 2003).

Kinesin-3

Kinesin-3 proteins, members of the Unc104/KIF1 family, are mostly monomeric but can dimerize to become processive motors in the presence of high local protein concentration (Vale, 2003). Filamentous fungi including *A. nidulans* and *N. crassa* contain two members of the kinesin-3 family (Schoch et al., 2003; Xiang and Plamann, 2003; Rischitor et al., 2004). However, *U. maydis* contains a single kinesin-3, Kin3, which drives the anterograde transport of endosome-marker-containing vesicles toward the microtubule plus end close to the hyphal tip (Fig. 2) (Steinberg, 2007a). In *U. maydis*, kinesin-1 and kinesin-3 may both participate in transporting materials to the hyphal tip for hyphal growth, and this role becomes essential for polarized growth in the absence of an actin-based motor, myosin-V (Schuchardt et al., 2005). In *N. crassa*, the two kinesin-3 proteins, Nkin2 and Nkin3, play roles in the movement of mitochondria (Fuchs and Westermann, 2005). Specifically, Nkin2 is important for mitochondria to interact with microtubules in vitro and for mitochondrial movement in vivo. Nkin3, which is nonprocessive (Adio et al., 2006b), does not apparently associate with mitochondria in wild-type cells but can mediate mitochondrial motility in cells lacking Nkin2 (Fuchs and Westermann, 2005). Thus, the two kinesin-3 proteins may act redundantly to ensure proper mitochondrial transport. In *A. nidulans*, the UncA kinesin-3 transports vesicles toward the hyphal tip, and interestingly, it interacts preferentially with a special microtubule track apparently containing detyrosinated α-tubulin (Zekert and Fischer, 2009).

Kinesin-5

Kinesin-5 family members play roles in mitosis, and the founding member of this family is BimC in *A. nidulans* (Enos and Morris, 1990). At restrictive temperatures, the *bimC4* mutant exhibits a block in spindle-pole separation and forms monopolar rather than bipolar spindles (Morris, 1975; Enos and Morris, 1990). Interestingly, despite this block in spindle assembly, further rounds of DNA replication do not seem to be prevented, and thus, the *bimC4* mutant cell contains an abnormally large nucleus that is most likely polyploid (Enos and Morris, 1990). In *Saccharomyces cerevisiae*, the kinesin-5 proteins Cin8 and Kip1 also play important roles in spindle assembly mainly by pushing the spindle poles apart and maintaining a bipolar spindle (Saunders and Hoyt, 1992; Roof et al., 1992). Motors in the BimC (kinesin-5) family, such as Eg5 and Cin8, are homotetramers that most likely cross-bridge antiparallel microtubules and use their plus-end-directed motility to produce a force to move apart the spindle poles (Kapitein et al., 2005; Hildebrandt et al., 2006; Krzysiak and Gilbert, 2006). Remarkably, recent results have shown that Cin8 can also disassemble microtubules from the plus ends, which could be used as a mechanism for the length regulation of kinetochore microtubules to ensure proper chromosome congression (Gardner et al., 2008b).

Kinesin-7

Kinesin-7 proteins are plus-end-directed motors that are important for organizing the microtubule network in fungi. The *A. nidulans* KipA protein is involved in orienting microtubules so that growing microtubules merge at the center of fast-growing tips, which is important for directional hyphal growth (Konzack et al., 2005). It was observed in the *kipA* mutants that microtubule plus ends are able to reach the hyphal tip but exhibit continuous lateral movements. This may cause mislocalization of the vesicle supply center, or the Spitzenkörper (Reynaga-Peña, et al., 1997; Harris et al., 2005) near the center of the growing tip, and consequently a loss of hyphal directionality, which may explain why hyphae lacking KipA grow in curves (Konzack et al., 2005).

In both *S. cerevisiae* and *Schizosaccharomyces pombe*, the kinesin-7 proteins Kip2 and Tea2 transport the yeast homologs of CLIP-170 (the prototype of +TIPs), Bik1 and Tip1, respectively, to the microtubule plus end (Carvalho et al., 2004; Busch et al., 2004). Since Bik1 promotes microtubule growth in *S. cerevisiae*, the discovery that Kip2 transports Bik1 to the microtubule plus end provides the best explanation for the requirement of Kip2 for promoting microtubule growth (Carvalho et al., 2004). Both Kip2 and Bik1 are in the dynein pathway of spindle orientation and are important for dynein localization to the microtubule plus end (Sheeman et al., 2003; Carvalho et al.,

2004; Miller et al., 2006). *A. nidulans* KipA is also a +TIP, and a KipA rigor mutant protein (defined as one that cannot be detached from the microtubule track) decorates along microtubules, suggesting that KipA may move to the microtubule plus end by using its own motor activity (Konzack et al., 2005). However, KipA does not apparently play a critical role in dynein-mediated nuclear migration in *A. nidulans*. In *A. nidulans*, the CLIP-170 homolog CLIPA is also a +TIP and plays a redundant role with NUDE in targeting NUDF to the microtubule plus end (Efimov et al., 2006). KipA obviously enhances accumulation of CLIPA at the microtubule plus end at a higher temperature, consistent with a role for kinesin-7 in transporting CLIP-170 homologs in fungi (Carvalho et al., 2004; Busch et al., 2004). At a lower temperature, however, CLIPA accumulation at the plus end is independent of KipA (Efimov et al., 2006). It remains to be determined whether CLIPA may associate with the plus end, like CLIP-170, by binding to another +TIP, EB1 (end-binding protein 1), which exchanges rapidly at the plus end (Bieling et al., 2008; Dixit et al., 2009). How a temperature change affects the mechanisms of CLIPA localization also remains to be addressed.

In *S. pombe*, the CLIP-170 homolog Tip1 interacts with a cell end marker, Tea1, whose interaction with the formin For3p via Tea4 is important for localized actin assembly to ensure growth directionality (Martin et al., 2005b; Basu and Chang, 2007). The roles of the cell end marker proteins may be conserved between *A. nidulans* and *S. pombe*, as the cell end marker TeaA (Tea 1 homolog) in *A. nidulans* is also required for maintaining growth directionality (Takeshita et al., 2008). Although KipA does not seem to play a role in transporting TeaA to the microtubule plus end, it is important for proper localization of TeaA at the cortex, suggesting that other factors transported by KipA may be required for maintaining the proper localization of TeaA (Takeshita et al., 2008). A role for KipA in maintaining TeaA localization may explain why both *kipA* and *teaA* mutants exhibit curved hyphal growth, and it will be important to identify KipA cargoes in *A. nidulans* that are involved in maintaining TeaA localization and directional hyphal growth.

Kinesin-8

Kinesin-8 is a special family of kinesins that exhibit both plus-end-directed motility and kinesin-13-like depolymerase activity (Gupta et al., 2006; Varga et al., 2006). In *A. nidulans*, the kinesin-8 protein, KipB, is required for spindle positioning during mitosis, timely anaphase progression, and accurate chromosomal segregation (Rischitor et al., 2004). In both yeasts and mammalian cells, a role for kinesin-8 proteins in chromosome segregation has also been documented, which may be closely related to a function for kinesin-8 in modulating the kinetochore microtubules for bipolar chromosome attachment (West et al., 2002; Sanchez-Perez et al., 2005; Tytell and Sorger, 2006; Stumpff et al., 2008). In *A. nidulans*, KipB localizes to cytoplasmic, astral, and mitotic microtubules and moves along microtubules toward the plus ends (Rischitor et al., 2004). In *S. cerevisiae*, Kip3 functions in the Kar9 pathway of spindle orientation (Miller et al., 1998, 2006), and moves towards the microtubule plus ends, where it acts to prevent microtubule growth, thereby preventing the spindle orientated by the Kar9 pathway from being pushed back towards the mother cell (Gupta et al., 2006). *A. nidulans* KipB is important for mitotic spindle positioning, most likely also because of its function as a depolymerase at the microtubule plus end (Rischitor et al., 2004). KipB, however, is not required for interphase nuclear migration (Rischitor et al., 2004). Thus, dynein-dependent interphase nuclear migration may involve proteins other than those involved in spindle positioning such as KipB and ApsA (Rischitor et al., 2004; Veith et al., 2005; Xiang and Fischer, 2004).

Kinesin-14

Kinesin-14 proteins are in the Kar3/ncd family, contain a motor domain at their C terminus, and are minus-end-directed motors (Walker et al., 1990; Endow et al., 1994). In *A. nidulans*, the kinesin-14 family member is KlpA and deletion of its gene causes a suppression of the *bimC4* mutant phenotype, suggesting that KlpA and BimC play opposite roles in spindle assembly (O'Connell et al., 1993). This result is remarkably similar to that obtained from an independent study involving *S. cerevisiae*, whereby the loss of Kar3 suppresses the mitotic defect caused by loss of function of the kinesin-5 proteins Cin8 and Kip1 (Saunders and Hoyt, 1992). Thus, while kinesin-5 motors push the spindle poles apart, the kinesin-14 motors may counterbalance the force and pull the poles closer. Despite the role in antagonizing the kinesin-5 motors during spindle assembly, neither KlpA nor Kar3 is essential for mitosis. Nevertheless, several additional interesting functions of kinesin-14 proteins have been recently revealed in fungi. For example, a C-terminal deletion mutant of a kinesin-14, pkl1, is synthetically lethal with a γ-tubulin mutant in *S. pombe* (Paluh et al., 2000). In *A. nidulans*, a *klpA* null mutation, *klpA1*, significantly increases the cold sensitivity of three γ-tubulin mutant alleles. In synchronized cells, *klpA1* causes a transient inhibition of bipolar spindle formation and this effect is obviously exacerbated by the *mipAD123* γ-tubulin mutation, as many spindles never become bipolar in the double mutant. Thus, KlpA and γ-tubulin may play overlapping roles in the establishment of spindle bipolarity (Prigozhina et al., 2001).

Recent studies also indicate that the Kar3 protein, although originally thought of as being a minus end depolymerase (Endow et al., 1994), actually is targeted to the microtubule plus end by one of its light chains, Cik1, and acts as a depolymerase at the plus end (Sproul et al., 2005). In vivo results are consistent with this finding. For example, in mating yeast cells, Kar3 localizes to plus ends of overlapping microtubules, where it functions with Bik1 to drive nuclear congression by plus end capturing and depolymerization (Molk et al., 2006). Kar3 also plays a role in cross-linking spindle microtubules, which may be important for stabilizing anaphase spindles (Gardner et al., 2008a). In *S. pombe*, kinesin-14 klp2p also localizes to the microtubule plus end and organizes the bipolar arrays of microtubules with the microtubule bundler, ase1p (Janson et al., 2007).

THE ACTIN CYTOSKELETON

The actin cytoskeleton is essential for polarized growth of many cell types, including filamentous fungi (Seiler and Plamann, 2003; Harris and Momany, 2004; Fuchs et al., 2005). In filamentous fungi, the actin cytoskeleton and its myosin motors are important for the delivery of cell membrane and cell wall components to the growing hyphal tip and to the septum. The actin cytoskeleton may also participate in positioning mitochondria and Golgi equivalents in *A. nidulans* (Suelmann and Fischer, 2000; Hubbard and Kaminskyj, 2008). The organization of actin structures in filamentous fungi is probably similar to that in yeasts, where

three main types of actin structures can be found: actin patches, actin cables that emanate from the polarized growth sites (although actin cables are not as obvious as in yeasts), and septum-associated actin rings (Moseley and Goode, 2006; Harris et al., 1994; Torralba et al., 1998; Upadhyay and Shaw, 2008).

Actin cable formation in both budding and fission yeasts requires formin proteins that nucleate actin polymerization and are critical for actin cable elongation at the barbed ends that connect to the bud tip (Feierbach and Chang, 2001; Evangelista et al., 2002; Sagot et al., 2002a, 2002b; Pruyne et al., 2002; Moseley and Goode, 2006). Actin cables are most likely made of bundles of short filaments in both yeasts, and formin-mediated subunit insertion between the barbed end and the cell cortex may push other filaments in the bundle to move in a retrograde direction (Kamasaki et al., 2005; Martin and Chang, 2006; Buttery et al., 2007). The functional significance of retrograde actin flow is not clear, and whether this happens in filamentous fungi remains to be determined. It is interesting that in both yeasts, formins associated with the cell cortex (Bni1 in *S. cerevisiae* and For3 in *S. pombe*) may get released from the cortex and remain attached to the ends of the released actin filaments that undergo retrograde movements (Martin and Chang, 2006; Buttery et al., 2007).

Unlike the budding and fission yeasts, where two (Bni1 and Bnr1) and three (For3p, Cdc12p and Fus1) formins are found, respectively, filamentous fungi such as *A. nidulans* and *N. crassa* contain a single formin (Harris et al., 1997; Harris and Momany, 2004; Borkovich et al., 2004). The formin SepA in *A. nidulans* localizes to the hyphal tip and septa, where it organizes the formation of actin cables and septum actin rings, respectively (Sharpless and Harris, 2002). The fungus *A. gossypii*, which grows as filamentous hyphae but is evolutionarily close to *S. cerevisiae*, contains three formins, AgBnr1, AgBnr2, and AgBni1, but only AgBni1 is essential for hyphal growth. AgBni1 locates to hyphal tips and is required for forming actin cables for polarized transport of secretory vesicles (Schmitz et al., 2006). AgBni1 is similar to some other formins in that it may also be activated by Rho-family GTPases to release a self-folding-based autoinhibition, and a constitutively active form of AgBni1 changes the hyphal growth pattern in an interesting way. In cells expressing the active form of AgBni1, symmetric divisions of hyphal tips (tip splitting) can often be observed in young hyphae, a phenomenon that can only be seen in more mature wild-type hyphae, which undergo much more rapid elongation (Schmitz et al., 2006). Thus, a fine regulation of formin activity is important for maintaining the normal hyphal growth pattern, and too much formin activity may drive the formation of a much more robust actin cable system that would deliver too much material to maintain the growth of a single hyphal tip (Schmitz et al., 2006).

Formins are components of the polarisome complex involved in polarized growth (Sheu et al., 1998; Moseley and Goode, 2006). In *A. nidulans*, homologs of polarisome components such as Spa2 and Bud6 are also present, but they may function at different sites. While the Spa2 homolog SpaA seems to function only at the hyphal tip, the Bud6 homolog is detected only at the septum (Virag and Harris, 2006). The Spa2 homologs in several other fungi have also been studied. Spa2 in filamentous fungi such as *A. gossypii* is not essential for polarity establishment but is required for maximal polar growth (Knechtle et al., 2003), but in *Candida albicans*, it is important for polarity establishment and maintenance (Zheng et al., 2003). In *U. maydis*, Spa2 is important for morphogenesis and localizes to the hyphal tip, and this localization seems to be influenced by the small GTPase Rac1 but not by the integrity of the microtubules and the actin cytoskeleton (Carbo and Perez-Martin, 2008). Finally, studies of *A. gossypii* suggest that Spa2 and Bni1 but not Bud6 may be associated with Spitzenkörper, the vesicle supply center, during fast growth of hyphae (Kohli et al., 2008).

There may be interesting differences between filamentous fungi and yeasts in the temporal regulation of cytokinesis and polarized growth, two processes that require formin activity. Formins at the cytokinesis site are required not only for forming the actin ring (Tolliday et al., 2002) but also for the assembly of actin cables that can be used for the delivery of membrane and wall components for septation (Moseley and Goode, 2006). In *S. cerevisiae*, polarized bud growth occurs only early in the cell cycle, and the formin Bni1 and other polarisome components that were initially localized to the bud tip are targeted later during the cell cycle to the bud neck for cytokinesis (Moseley and Goode, 2006). In contrast, polarized hyphal growth in filamentous fungi occurs continuously regardless of cell cycle stages (Riquelme et al., 2003; Horio and Oakley, 2005), and SepA localizes to the hyphal tip and to the septum simultaneously (Sharpless and Harris, 2002). It is possible that subtle differences in formin regulation may have evolved to account for this difference. In addition, *C. albicans*, in which the yeast-hyphal transition occurs, may be well suited for studying how formins are regulated in these two different stages (Martin et al., 2005a; Li et al., 2005a; Rida et al., 2006).

The actin-patch-associated Arp2/3 complex is critical for formation of branched actin filaments (Pollard, 2007). Arp2/3 and its activators are conserved in filamentous fungi, but their functions require more study (Harris and Momany, 2004; Borkovich et al., 2004). In budding and fission yeasts, Arp2/3 and their activators are involved in the formation of endocytic actin patches that mediate endocytosis (Kaksonen et al., 2003; Galletta et al., 2008). The endocytic internalization machinery in *A. nidulans* appears to be similar to that in the budding yeast (Araujo-Bazán et al., 2008). Interestingly, in *A. nidulans*, the actin patches and, by inference, the sites of endocytosis are located primarily in a collar ringing the tip region that is spatially coupled to the site of exocytosis (Fig. 3) (Araujo-Bazán et al., 2008; Taheri-Talesh et al., 2008; Upadhyay and Shaw, 2008). Whether the Arp2/3 complex and its activators are used for both endocytosis and exocytosis or whether only the formin-mediated actin cables are important for exocytosis will need to be clarified.

Other actin regulators such as capping proteins are also conserved. Capping proteins function to block the addition and dissociation of actin monomers to and from the barbed end (Cooper and Sept, 2008). While the capping proteins are also involved in Arp2/3-mediated endocytosis in the budding yeast (Kim et al., 2006b), their roles in filamentous fungi remain to be defined. One interesting point is that capping proteins are also components of the vertebrate dynactin complex in which they cap the barbed end of the actin-related protein 1 (Arp1) filament (Schroer, 2004), but they are not essential for the spindle orientation function of the yeast dynactin complex (Moore et al., 2008). Functions of capping proteins in filamentous fungi will need to be determined. This will be interesting especially since the Arp1 pointed-end proteins are essential for dynein function in filamentous fungi, but not in the budding yeast (Lee et al., 2001; Clark and Rose, 2006; Moore et al., 2008; Zhang et al., 2008). Finally, the actin-binding protein tropomyosin is

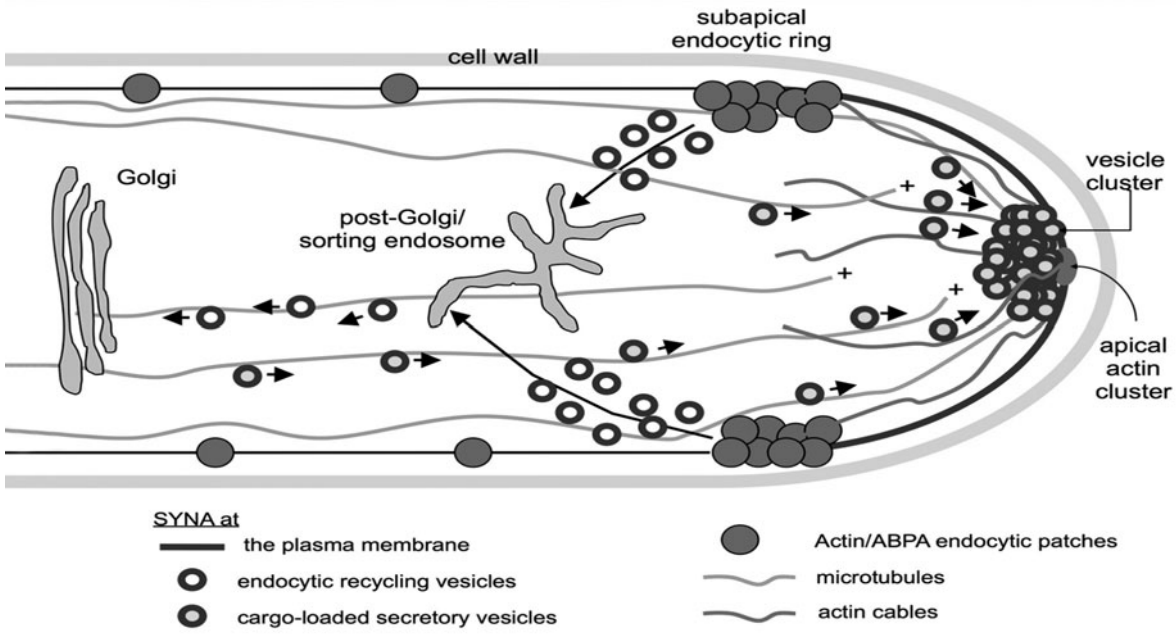

FIGURE 3 Model for tip growth in *A. nidulans*. The Spitzenkörper is not specifically labeled but includes (but is not necessarily limited to) the vesicle cluster and the apical actin cluster as well as the apical SSOA patch, SECC, and apical SEPA, which are not shown. Secretory vesicles containing components necessary for tip growth are transported toward the tip along microtubules powered by kinesin molecules (data not shown). The plus ends of microtubules are extremely dynamic. In some cases, they transiently contact the vesicle cluster. In such cases, the secretory vesicles could be transferred directly from microtubules to the cluster. In other cases, secretory vesicles presumably fall off the microtubule as the plus end disassembles, and they are transported to the vesicle cluster by myosin molecules (not shown) on actin cables. Vesicles fuse with the plasma membrane, releasing their contents, and the components of the membranes of the secretory vesicles (here represented by SYNA) become incorporated into the plasma membrane. As the tip grows, the ring of actin/ABPA endocytic patches moves forward, removing SYNA and other vesicle membrane components from the plasma membrane and incorporating them into endocytic vesicles for recycling. Although we do not have direct evidence, information from other systems and from M. Peñalva, J. Rodríguez, and J. Abenza (personal communication) indicates that these vesicles move to the post-Golgi sorting endosome by mechanisms that are not yet defined. From this compartment, SYNA-containing membranes move away from the tip on microtubules, powered by dynein, to be eventually incorporated into Golgi body-derived secretory vesicles containing cell wall biosynthetic enzymes and wall precursors. This figure and its legend are from Taheri-Talesh et al., 2008, with permission from the American Society of Cell Biology.

associated with the actin filaments in fungi and its acetylation may play a regulatory role in myosin-actin interaction (Pearson et al., 2004; Skoumpla et al., 2007).

ACTIN MOTORS: MYOSINS

Myosins are a diverse superfamily of actin motor proteins that play various cellular roles (Sellers, 2000). In filamentous fungi such as *A. nidulans* and *N. crassa*, four families of myosins have been found, including myosin-I, myosin-II, myosin-V, and the fungus-specific chitin synthases with myosin motor domains (Xiang and Plamann, 2003; Borkovich et al., 2004; Galagan et al., 2005; Wortman et al., 2009).

Myosin-I

Myosin-I, a single-headed motor, may participate in actin assembly through its interaction with the Arp2/3 complex (Higgs and Pollard, 2001). While a linker protein may be involved in the association of myosin-I with Arp2/3 in other cell types (Jung et al., 2001a), fungal myosin-Is are special in that their tails contain domains similar to that in the well-known Arp2/3 activator WASp, which may allow fungal myosin-Is to activate Arp2/3 directly (McGoldrick et al., 1995; Lechler et al., 2000; Evangelista et al., 2000; Lee et al., 2000; Higgs and Pollard, 2001). Consistent with this notion, synthetic lethality studies with yeasts have also suggested complementary functions of fungal myosin-Is and WASp homologs (Lechler et al., 2000; Evangelista et al., 2000; Lee et al., 2000).

The myosin-I from *A. nidulans*, MYOA, is required for initiating polarized growth, secretion, and septal wall formation (McGoldrick et al., 1995; Osherov et al., 1998). Consistent with these roles, wild-type GFP-MYOA localizes to the hyphal tip and septum (Yamashita et al., 2000). MYOA also plays a role in endocytosis, and this role was first revealed by an analysis of phosphorylation mutants of MYOA (Yamashita and May, 1998). Whether or not the motor activity of myosin-Is is involved in their cellular activities is an important question. In *A. nidulans*, a *myoA*

mutant that only contains 1% of its normal actin-activated ATPase activity and has no detectable in vitro motility can support polarized growth, suggesting that MYOA's function may be structural and not related to motility (Liu et al., 2001). Given the known interactions between fungal myosin-Is and Arp2/3, it is likely that MyoA is mainly required for organizing the actin patches in *A. nidulans* for polarized growth and endocytosis. It is important to note, however, that in *S. cerevisiae*, the myosin-I motor activity and actin nucleation are both required during endocytic internalization (Sun et al., 2006).

In *C. albicans*, the myosin-I CaMyo5 is also required for hyphal formation, which is similar to the situation in *A. nidulans* (Oberholzer et al., 2002). GFP-CaMyo5 co-localizes with cortical actin patches at both the bud and hyphal tip, and the null mutant forms random buds and also exhibits a depolarized distribution of the cortical actin patches. Interestingly, strains with specific mutations/deletions in CaMyo5 that exhibit depolarized actin patches are able to undergo hyphal growth, suggesting that CaMyo5 play distinct roles in actin patch distribution and polarized growth (Oberholzer et al., 2002, 2004).

Myosin-II

Myosin-II is the classic myosin, and its family members are involved in cytokinesis in both budding and fission yeasts (Moseley and Goode, 2006; Wu et al., 2006a). Myosin-II in *S. cerevisiae* also plays a role in retrograde actin flow in actin cables (Huckaba et al., 2006). Surprisingly, in the absence of a localized formin, yeast myosin-II localized at the bud neck may help to orientate actin cables for supporting polarized growth (Gao and Bretscher, 2009). The functions of myosin-IIs in filamentous fungi remain to be studied.

Myosin-V

Myosin-V is required for organelle transport in many organisms. In the budding yeast, where intracellular trafficking mostly depends on the actin cytoskeleton, one Myosin-V, Myo2p, drives transport of secretory vesicles, lysosomes, peroxisomes, and mitochondria, while the other myosin-V, Myo4p, has been implicated in the transport of endoplasmic reticulum and RNA-containing particles (Bretscher, 2003). In contrast to budding yeast, filamentous fungi use both microtubules and actin filaments for vesicle/organelle transport and for supporting polarized growth at the hyphal tip (Xiang and Plamann, 2003; Horio and Oakley, 2005; Fischer et al., 2008a, 2008b; Taheri-Talesh et al., 2008). The role of myosin-V in hyphal tip growth has been studied in *U. maydis*, which is a plant pathogen (Weber et al., 2003; Schuchardt et al., 2005). A GFP-Myosin-V fusion protein localizes to the hyphal apex as well as to the septa. However, myosin-V is not essential for hyphal tip growth or septation, but it is essential for conjugation tube formation. The defect in polarized hyphal growth is more pronounced after the mutant hyphae penetrate the plant epidermis (Weber et al., 2003). In the absence of kinesin-1 or kinesin-3, myosin-V becomes essential for hyphal growth (Schuchardt et al., 2005). In *S. pombe*, the myosin-V Myo52 has an important role in septum deposition and cell division (Mulvihill et al., 2006). However, myosin-V is not essential for septation in filamentous hyphae (Weber at al., 2003). Thus, filamentous fungi may utilize additional mechanisms for transporting cell wall materials to the septation site. Finally, Myo2p in *S. cerevisiae* moves the preanaphase mitotic spindle toward the bud neck by translocating the plus ends of astral microtubules along actin cables (Hwang et al., 2003; Miller et al., 2006). Whether this happens in filamentous fungi needs to be determined.

Chitin Synthases with Myosin Motor Domains

Remarkably, genes encoding chitin synthase with a myosin motor domain have been found in filamentous fungi (Fujiwara et al., 1997). In *A. nidulans*, CsmA and CsmB are class V and VI chitin synthases that contain a myosin motor domain. *csmA* or *csmB* single null mutants are viable, and the mutants show similar defects in polarized growth and cell wall integrity (Takeshita et al., 2002, 2005, 2006). However, the *csmA csmB* double null mutant is not viable, suggesting that the two proteins play important roles in polarized chitin synthesis (Takeshita et al., 2006). CsmA and CsmB both localize to actin-rich sites such as the hyphal tip and septa, and the myosin motor domains in both proteins are important for their interactions with actins, as evidenced by in vitro cosedimentation assays (Takeshita et al., 2005, 2006). Analyses of mutations in the myosin motor region in CsmA support the conclusion that this region is important for CsmA localization and function (Takeshita et al., 2005). In *U. maydis*, class V myosin chitin synthase (Mcs1) proteins localize to polar growth sites in both yeast-like cells and hyphae (Weber et al., 2006). The Mcs1 deletion mutant has no apparent hyphal growth defect, but mutant hyphae lose growth polarity after entering plants, and thus, this myosin chitin synthase is essential during early plant infection (Weber et al., 2006). In *Colletotrichum graminicola*, chitin synthase with a myosin motor domain is important for both polarized hyphal growth and plant pathogenicity (Werner et al., 2007).

INTERACTIONS BETWEEN THE ACTIN AND MICROTUBULE CYTOSKELETONS

Hyphal growth in filamentous fungi needs both microtubule and actin cytoskeletons, and thus, it would be important to understand how these two systems interact to coordinate vesicle transport towards the hyphal tip. It has recently emerged that the dynamic plus ends of microtubules play an important role in the interactions between these two systems, and +TIPs that associate with the plus ends are the critical factors (Carvalho et al., 2003; Akhmanova and Hoogenraad, 2005; Wu et al., 2006b; Basu and Chang, 2007; Fischer et al., 2008a, 2008b). Some of the +TIPs affect the directionality of growth in *S. pombe* and in *A. nidulans* (Basu and Chang, 2007; Fischer et al., 2008a, 2008b). For example, AlpA, the *A. nidulans* homolog of Dis1/XMAP215, and KipA, the *A. nidulans* homolog of Kip2/Tea2, accumulate at the microtubule plus ends and affect the growth directionality of the hyphae (Konzack et al., 2005; Enke et al., 2007). These +TIPs may affect the growth directionality by affecting the ability of plus ends to search for and capture targeting sites for the delivery of vesicles carrying membrane and wall materials. For example, a +TIP such as AlpA, which promotes the growth and dynamicity of microtubules, may facilitate such a delivery process (Enke et al., 2007).

A key discovery made with *S. pombe*, which has rod-shaped cells, is that the cell end protein Tea1 is delivered from the microtubule plus end to the cortex, where it interacts with the formin For3 to regulate actin assembly and polarized tip growth, and the Tea1-For3 interaction is mediated by Tea4, a protein that also gets delivered to the cell cortex by the microtubule plus end (Feierbach et al., 2004; Martin, 2005b). These results suggest that the microtubule

plus ends may direct the local assembly of actin cables. This idea is strongly reinforced by recent studies done in physically bent *S. pombe* cells, where microtubule plus ends contact cortical regions at the cell sides to induce formin-dependent polar growth at ectopic sites (Terenna et al., 2008; Minc et al., 2009). But surprisingly, polarized growth at these new sites depends on EB1, a +TIP, but not on the Tea1-Tea4 pathway (Minc et al., 2009). Recent studies with *A. nidulans* suggest that the cell end proteins are conserved in filamentous fungi (Takeshita et al., 2008; Fischer et al., 2008a, 2008b), and it is possible that general mechanisms of microtubule-plus-ends-directed local actin assembly may also be used in filamentous fungi. It is also important to note that filamentous hyphae undergo not only hyphal tip extension but also side branching, and how microtubule-actin interaction is involved in branching remains an interesting question.

How vesicles transported through microtubules get delivered to the actin cables is also an important question. In the budding yeast, myosin-V interacts with the microtubule plus end through EB1, and Kar9 mediates this interaction (Miller et al., 2006). While the interactions among these proteins in yeast are required for spindle positioning, it is remarkable that the connection between myosin-V and EB1 through another +TIP, melanophilin, has been found in vertebrate cells, and in this case, the interactions may be used for cargo delivery to the actin cytoskeleton from the microtubules (Wu et al., 2005, 2006b). Moreover, myosin-V may diffuse along microtubule tracks to obtain cargoes (Ali et al., 2007). It remains to be determined whether these and/or additional mechanisms operate in filamentous fungi and exactly how these events are regulated for directional transport of cellular materials during hyphal growth. Finally, it also remains to be determined whether in elongated hyphae of filamentous fungi, microtubule motors may transport factors that affect the actin cytoskeleton.

Projects on fungal cytoskeleton in the authors' labs are supported by the National Institutes of Health grants GM069527 (to X.X.) and GM031837 (to B.O.), and the Uniformed Services University of the Health Sciences intramural grant R071GO (to X.X.).

Cellular and Molecular Biology of Filamentous Fungi
Edited by K. A. Borkovich and D. J. Ebbole

17

The Cell Wall of Filamentous Fungi

NIR OSHEROV AND ODED YARDEN

The fungal cell wall performs multiple functions. It plays a significant role in development and integrity of the fundamental architecture required for survival and proliferation of the filamentous fungus. Also, the cell wall protects the fungus from abrasion, screens out poisons, and, by restricting inflation of the cytoplasm, allows the cell to become highly pressurized. It also serves as a scaffold for proteins that protect the inner polysaccharide layers and provide a dynamic interface with the surroundings. Fungal cell turgor ranges from 1 to 10 atm (Money, 1999). In comparison, the air in a car tire is compressed to a pressure of 2 atm. Generation of a cell wall and high turgor allow fungi to penetrate mineral and organic resources (Money, 1999). As the fungal cell wall is an essential structure of amazing complexity, it is not surprising that the fungal cell devotes a major fraction of its energetic output to its manufacture and upkeep. It accounts for 15 to 30% of the cellular dry weight (Nguyen et al., 1998). In the yeast *Saccharomyces cerevisiae* at least 20% of all genes are directly and indirectly involved in maintaining the cell wall (De Groot et al., 2001).

In addition to several comprehensive books covering this topic (Ruiz-Hererra, 1991; Gow and Gadd, 1995), several excellent reviews have been published in recent years describing the cell wall in yeast (Klis et al., 2006, 2007a; Ruiz-Herrera et al., 2006) and in filamentous fungi (Klis et al., 2007a; Latgé, 2007); its carbohydrate composition and biosynthesis (Bernard and Latgé, 2001; Adams, 2004; Latgé et al., 2005; Bowman and Free, 2006; Lesage and Bussey, 2006); cell wall proteins (CWPs) (De Groot et al., 2005; Dranginis et al., 2007; Richard and Plaine, 2007); the cell wall integrity pathway (Levin, 2005); and the cell wall as an antifungal target (Beauvais and Latgé, 2001; Selitrennikoff and Nakata, 2003; Nimrichter et al., 2005). This chapter provides a concise introductory overview describing the molecular composition and organization of the cell wall in the filamentous fungi. The major differences between the cell wall of the filamentous fungi and that of the better-studied yeast are stressed. Finally, take-home points regarding its dynamic structure and the many unanswered questions concerning its function are presented.

Smith Faculty of Agriculture, Food and Environment, The Hebrew University of Jerusalem, Rehovot 76100, Israel.

THE MOLECULAR ORGANIZATION OF THE FUNGAL CELL WALL: AN OVERVIEW

To be strong yet pliant, the fungal cell wall is engineered as a composite material. It incorporates a mix of cross-linked fibers (the polysaccharides glucan and chitin) and matrix components (primarily proteins and mannans) (Fig. 1). It therefore resembles strong man-made composites, such as reinforced concrete (made of mesh and mortar) or carbon-fiber reinforced plastics (made of fibers such as fiberglass or para-aremid synthetic fiber [Kevlar], embedded in epoxy glue).

The main fibrous component of the cell wall is glucan, a polymer of glucose. Glucan can be found in long β-1,3 or short β-1,6-linked chains forming the main bulk (30 to 60%, dry weight) of the cell wall and in α-1,3 glucan. β-1,3 glucans have a coiled spring-like structure that confers elasticity and tensile strength to the cell wall. β-1,6 glucan acts as a flexible glue by forming covalent cross-links to β-1,3 glucan and chitin and to cell wall mannoproteins (Kollar et al., 1997; Shahinian and Bussey, 2000; Kapteyn et al., 2000; Lowman et al., 2003; Sugawara et al., 2004). α-1,3 glucan is amorphous in structure and forms an alkali-soluble cement within the β glucan and chitin fibrils (Beauvais et al., 2005; Grün et al., 2005). Chitin, the second cell wall fiber, is a long-chain β-1,4-linked polymer of *N*-acetylglucosamine, a derivative of glucose. It forms microfibrils that are stabilized by hydrogen bonds. Chitin provides tensile strength to the cell wall and composes ~2% of the total cell wall dry weight in yeast, and 10 to 15% in filamentous fungi (Roncero, 2002; Klis et al., 2002). The absence of chitin and most glucans from plant and mammalian species makes these components of the fungal cell wall potential and actual targets for antifungal drugs (Gooday, 1977; Beauvais and Latgé, 2001; Selitrennikoff and Nakata, 2003; Nimrichter et al., 2005; Latgé, 2007).

The matrix components gluing the fibers together are mainly mannans and proteins. Mannans are polymers of

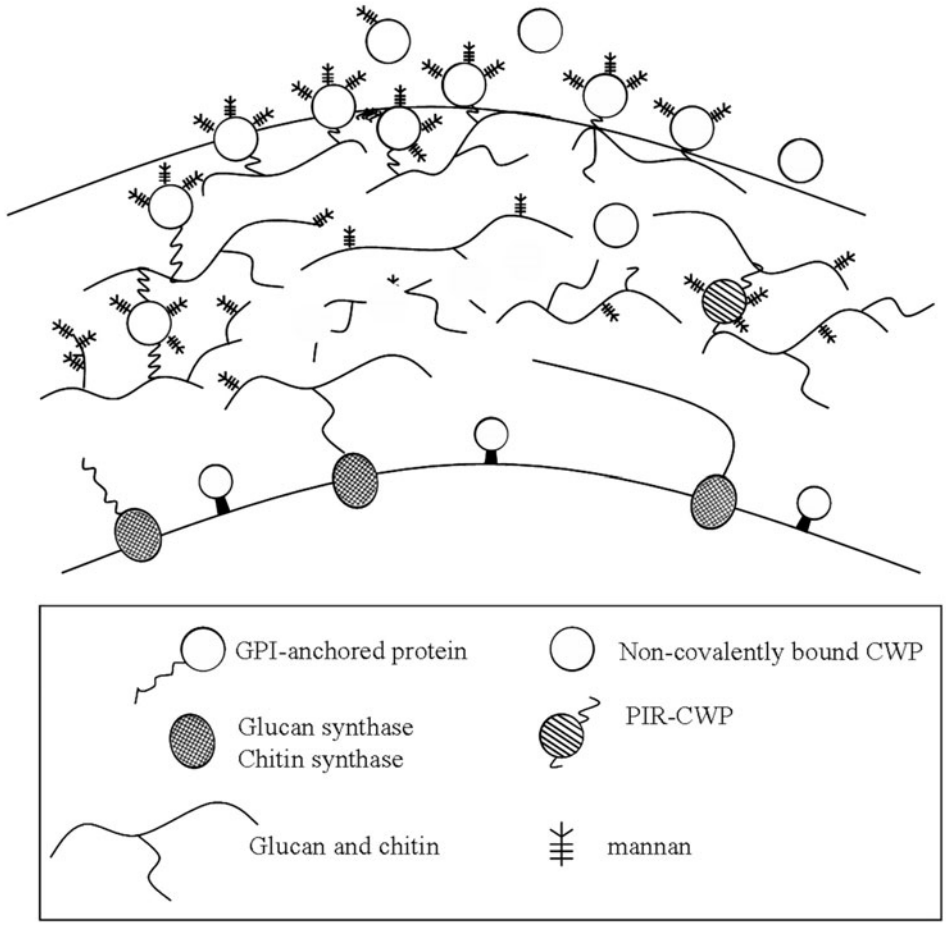

FIGURE 1 Structure and schematic representation of the architecture of a prototypical fungal cell wall. The outer layer contains high levels of different types of mannoproteins. The inner layer is made mainly of polysaccharides (β-glucans and chitin) and small amounts of proteins. The plasma membrane contains enzymes involved in β-glucan and chitin biosynthesis.

mannose and can be found as α-1,6 or α-1,2 or α-1,3/β-1,2 mannan chains either attached directly to glucans or covalently attached to proteins via asparagine (N-linked) or serine/threonine (O-linked) amino acid residues (Cutler, 2001; Shibata et al., 2007). They comprise 10 to 20% of the dry weight of the cell wall (Lesage and Bussey, 2006). The amount of glycoproteins in the cell wall is variable, between 10 and 40%, whereas the actual polypeptide content is about 4% (Klis et al., 2002; De Groot et al., 2007).

Cell wall composition has been studied most extensively in the yeasts *S. cerevisiae* (Kollar et al., 1997), *Schizosaccharomyces pombe* (Sugawara et al., 2004), and *Cryptococcus neoformans* (James et al., 1990; Vaishnav et al., 1998). In the filamentous fungi, detailed cell wall composition studies have been performed mainly with *Aspergillus fumigatus* (Fontaine et al., 2000), *Fusarium oxysporum* (Schoffelmeer et al., 1999), and *Neurospora crassa* (Bartnicki-Garcia, 1968), as well as in the dimorphic plant and human pathogens *Ustilago maydis* (Ruiz-Herrera et al., 1996) and *Candida albicans* (Lowman et al., 2003).

Cell wall composition varies extensively among the fungal orders. This variability is best viewed through the eyes of evolution; all fungal cell walls, including those of the distant chytrids, contain a branched polysaccharide of β-1,3/1,6 glucan that is linked to chitin via a β-1,4 linkage (Fig. 2A). This is likely the basic composition of an ancient ancestral fungal cell wall that has been further modified and decorated in the various fungal orders. For example, α-1,3 glucan appeared in the Ascomycetes and Basidiomycetes, and following their bifurcation, β-1,6 glucan was added to the former and xylose to the latter order (Ruiz-Herrera et al., 1996; Kollar et al., 1997; Vaishnav et al., 1998). Within the Ascomycetes, additional distinct differences have developed between the yeasts and filamentous fungi: the yeast *S. cerevisiae* contains β-1,6 glucan, whereas filamentous fungi such as *A. fumigatus* contain linear α-1,3/1,4 glucan and galactomannan with galactofuran side chains (Kollar et al., 1997; Fontaine et al., 2000) (Fig. 2B). The cell walls of the filamentous fungi contain higher levels of chitin than do those of yeasts (~15% versus 2 to 3%). The most likely reason for this difference is that being cylindrical and under high turgor pressure, the cell wall of filamentous fungi needs to increase its rigidity. Filamentous fungal cell walls also differ from those of the yeasts in their attachment to embedded proteins and mannans: in the yeast *S. cerevisiae* mannan chains are only found attached to CWPs, whereas in *A. fumigatus*, mannan chains are also found directly linked to glucans (Lesage and

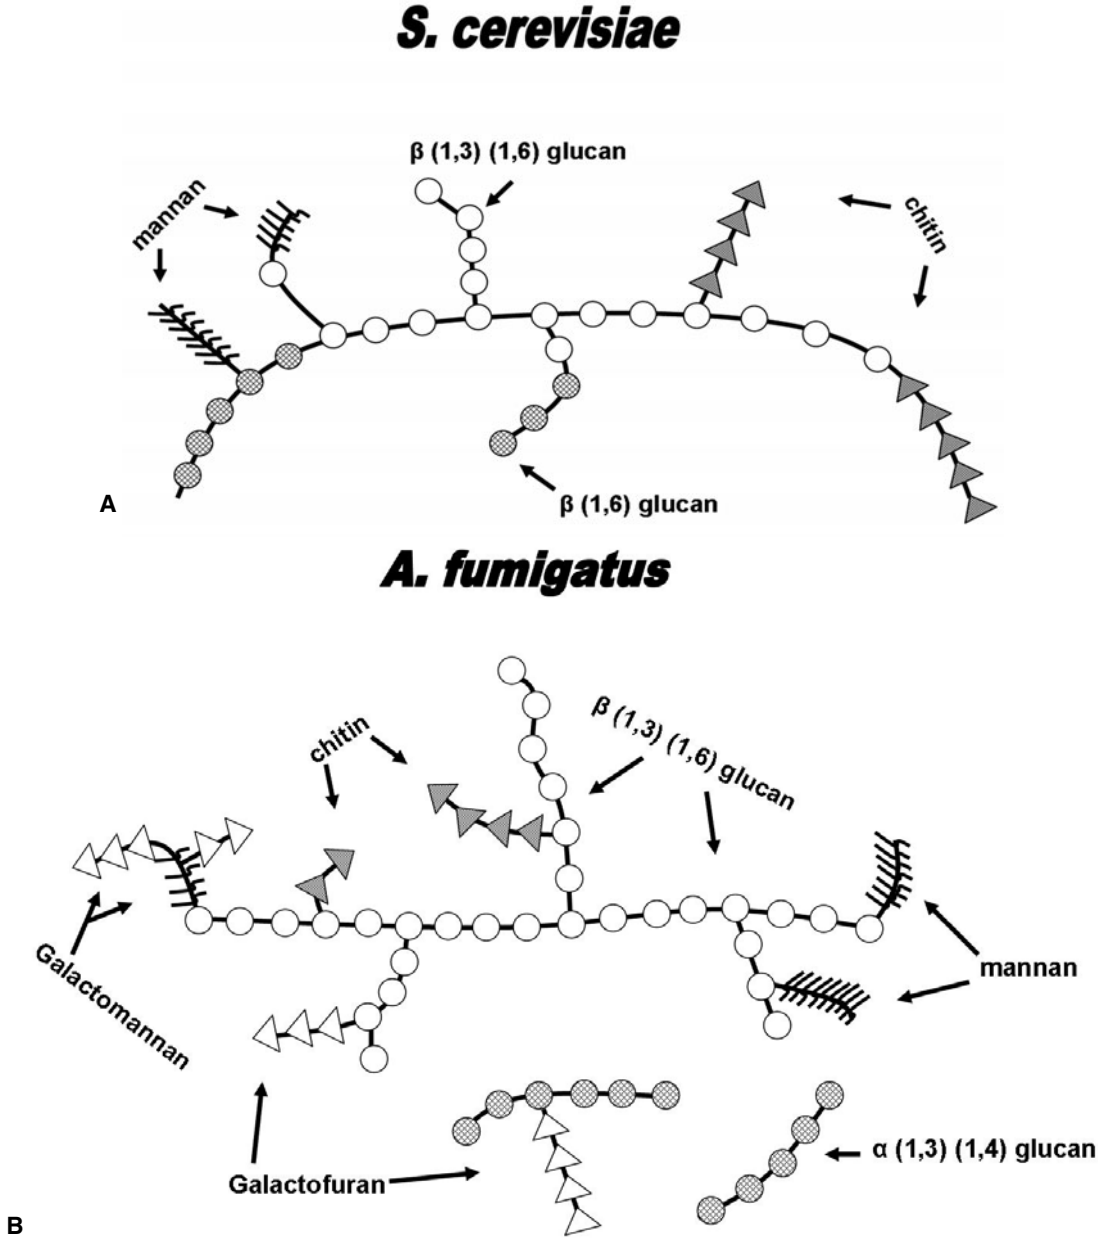

FIGURE 2 Comparison between the cell wall carbohydrate composition of a yeast (*S. cerevisiae*) (A) and a mold (*A. fumigatus*) (B). Both contain a branched polysaccharide of β-1,3/1,6 glucan that is linked to chitin via a β-1,4 linkage. However, only *S. cerevisiae* contains β-1,6 glucan, whereas *A. fumigatus* contains α-glucans and galactomannans that are not found in yeast.

Bussey, 2006; Latgé, 2007). Differences in the cell wall composition of yeast and filamentous fungi may have arisen because of differing evolutionary pressures; the filamentous fungal cell wall is adapted to extremely rapid deposition and growth at the hyphal tip and an ability to penetrate hard surfaces (Collinge and Trinci, 1974). In contrast, in yeast growth is largely isotropic and therefore slower, and it is usually confined to surfaces. This may explain why mutations in secretory and transport-related genes in yeast usually result in less severe phenotypic consequences than in filamentous fungi; the morphological complexity of the latter makes slight disturbances in homeostasis more obvious than they are in yeast (Whittaker et al., 1999; Seiler and Plamann, 2003).

MOLECULAR APPROACHES TO THE STUDY OF THE CELL WALL

The fungal cell wall in both yeasts and filamentous fungi is studied by various techniques that are addressed in this section. They include (i) the chemical analysis of carbohydrate composition; (ii) microscopic analysis (electron, light, and immunofluorescence); (iii) biochemical separation and identification of CWPs; (iv) use of cell wall biosynthesis

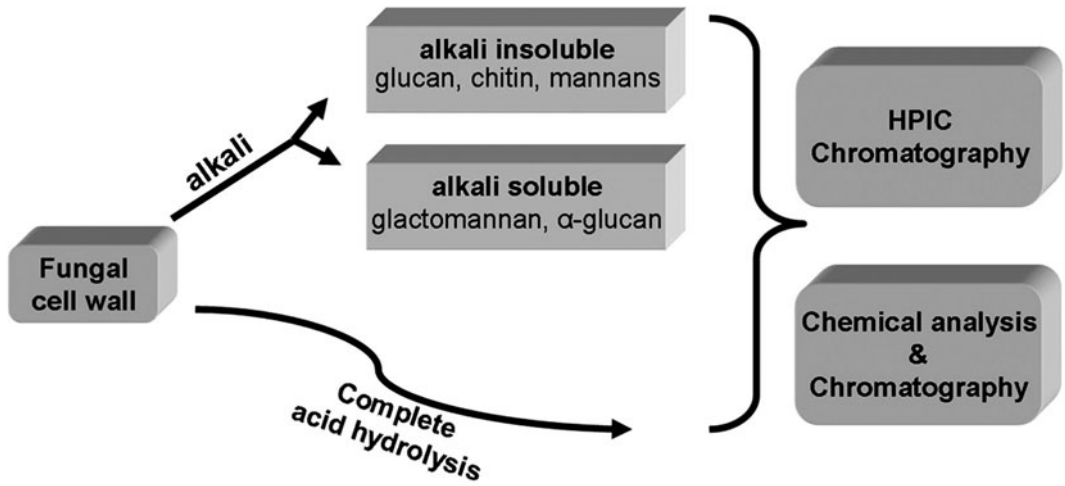

FIGURE 3 Schematic outlining the basic methods used to analyze the carbohydrate composition of the cell wall. Either the entire cell wall or alkali-digested soluble and insoluble fractions are completely digested by acid hydrolysis and analyzed by high-performance anion-exchange chromatography (HPIC) or chemical analysis and chromatography.

inhibitors and cell wall mutants; and (v) genomics, transcriptomics, and proteomics.

Chemical Analysis of Carbohydrate Composition

Chemical analysis has established the carbohydrate composition of the cell wall. The carbohydrate composition of the cell wall can be analyzed by two basic chemical methods (Fig. 3). The first is by complete acid hydrolysis of the carbohydrate chains into monomers (glucan to glucose, chitin to glucosamine, mannan to mannose, etc.) that are subsequently quantified by high-performance anion-exchange chromatography or enzymatic/spectrophotometric analysis (François, 2006). The advantage of this approach is that it is fast and can be adapted to perform high-throughput screening of mutants or to analyze changes in cell wall composition under various growth conditions (Ram et al., 1994; Dallies et al., 1998; Aguilar-Uscanga and François, 2003). The disadvantages are that it provides only the total levels of chitin, glucan, and mannan in the cell wall. Because complete carbohydrate hydrolysis is performed, it is impossible to identify the nature of the linkages between the different polymers and their subtypes.

The second, more traditional approach, involves solubilizing the cell wall in hot NaOH and separating the alkali-soluble and alkali-insoluble fractions. In *S. cerevisiae* the alkali-soluble fraction contains mainly mannans and some glucans. The alkali-insoluble fraction is then dissolved in cold acid to yield acid-insoluble (mainly β-1,3-glucan and chitin) and acid-soluble (β-1,3 glucan and β-1,6 glucan) fractions (Catley, 1988). Essentially the same method is used in *S. pombe* cell wall analysis (Pérez and Ribas, 2004). In *A. fumigatus* the alkali-insoluble fraction contains mostly β-1,3 glucan, chitin, some β-1,4 glucan, and galactomannan, and the soluble fraction contains α-1,3 glucan and some galactomannan (Bernard and Latgé, 2001).

Further fractionation is achieved by using specific endoglycosylhydrolases such as chitinase, β-1,3-glucanase, α-1,3-glucanase, and β-1,6-glucanase and by using acetolysis to internally cleave mannan chains (Bernard and Latgé, 2001; Magnelli et al., 2002; Pérez and Ribas, 2004; Magnelli et al., 2005). Finally, the carbohydrate linkages in the different fractions can be analyzed by specific carbohydrate chemistry methodologies (Kollar et al., 1997; Fontaine et al., 2000). The advantages of this approach are the ability to perform a complete carbohydrate analysis of the cell wall. The drawbacks include the time-consuming nature of the approach, the high degree of expertise needed to perform the analysis, and the lack of standardization in the field.

Microscopic Analysis

Microscopic analysis has established the layered structure of the cell wall and identified the spatial organization of its chemical and protein constituents. Traditionally, transmission electron microscopy or scanning electron microscopy (SEM) has been used to analyze the cell wall layers and their constitution (Osumi, 1998; Kaminskyj and Dahms, 2008). In most fungi, there are two layers; an electron-dense outer layer, and a light inner layer (Klis et al., 2007a). Numerous lines of evidence suggest that in yeasts such as *S. cerevisiae* and *C. albicans* and in filamentous fungi such as *N. crassa* and *F. oxysporum*, the dark outer layer is enriched in mannoproteins, whereas the inner translucent layer is composed primarily of glucan and chitin (De Groot et al., 2005). This can be shown by using proteases or glucanases to specifically remove the outer and inner layers of the cell wall, respectively (Kopecka et al., 1995; Koch and Rademacher, 1980; Zlotnik et al., 1984; Schoffelmeer et al., 1999; De Groot et al., 2005).

SEM has been used to monitor the construction of the cell wall following its removal by cell wall-degrading enzymes and has revealed that glucan is extruded from the plasma membrane as small particles that gradually coalesce into cross-linked fibrils (Osumi, 1998). Unlike transmission electron microscopy and SEM, atomic force microscopy, which uses a nanometer-wide tip to scan the specimen surface, can be performed on living cells. It has been used to probe (i) yeast cells during enzymatic cell wall removal, revealing a gradual roughening of the cell surface as mannans

were removed, exposing the underlying polysaccharide fibrils (Ahimou et al., 2003); and (ii) germinating *Aspergillus* spores, revealing the uncoating of the hydrophobic outer layer of proteins (collectively known as hydrophobins) that keep dormant spores dry (Ma et al., 2006).

Light microscopy and immunofluorescence (IF) are in widespread use for the analysis of CWPs and carbohydrates (Molina et al., 2000; De Groot et al., 2005). Antibodies used for IF interact specifically either with a CWP epitope or with a tagged epitope (i.e., *c*-Myc, 6HIS, FLAG, V5, etc.) engineered into the protein (Bates et al., 2007; Levdansky et al., 2007). Two main drawbacks to antibody-based IF are the need to fix the cells prior to staining and the limited penetration of the antibody inside the cell wall. Green fluorescent protein tagging of CWPs has also been used and in contrast to antibody-based methods can be used to visualize living cells. However, the large size of green fluorescent protein can cause artifacts, such as defective transport and mislocalization of the CWPs (Ram et al., 1998; Rodríguez-Peña et al., 2000; Pardini et al., 2006; Waterman et al., 2007). Various dyes and reagents are used for carbohydrate staining: β glucan stains with aniline blue (Shedletzky et al., 1997), and chitin stains with calcofluor white (CFW) or wheat germ agglutinin (Roncero et al., 1988). Carbohydrate-specific monoclonal antibodies specific towards mannan, galactomannan (Platelia Candida or Aspergillus antibody tests; Bio-Rad Laboratories), β-1,3 glucan, and α-1,3 glucan (Rappleye et al., 2007; Wheeler and Fink, 2006) have also become commercially available. However, a complete library of monoclonal antibodies specific to the different fungal glycosidic linkages needs to be developed. Such libraries, coupled with high-throughput methods, have revolutionized the study of plant cell walls (Moller et al., 2007).

Biochemical Separation

Biochemical separation has identified numerous CWPs. CWPs are relatively difficult to analyze (Yin et al., 2008). They are cross-linked to cell wall polysaccharides and are frequently glycosylated and of heterogenous size. CWP preparations are also easily contaminated with leaked cytosolic proteins (Klis et al., 2006).

Traditionally, the cell wall is first purified and then subjected to several steps of extraction: sodium dodecyl sulfate detergent washes to remove noncovalently bound proteins (e.g., secreted proteins), β-mercaptoethanol or preferably dithiothreitol extraction to remove additional noncovalently bound proteins and proteins covalently bound through cysteine residues, mild alkali extraction to remove glucan-bound proteins with internal repeats, and finally, hydrogen fluoride or glucanase treatment to extract glucan-bound glycosylphosphatidylinositol (GPI)-anchored proteins (Yin et al., 2008). Subsequently, the protein fractions are separated on a two-dimensional gel based on size and electrophoretic mobility and then fragmented proteolytically. The resulting peptides are analyzed by mass spectrometry (MS) to reveal their identities (Ebanks et al., 2006). However, this method is relatively hard to master technically, and because the CWPs are glycosylated to differing degrees, the individual protein spots are often fuzzy. Newer, more robust techniques include CWP extraction and proteolysis as described above, followed by liquid chromatography (instead of two-dimensional gel). Resolved peptides are fragmented by tandem MS (liquid chromatography/MS/MS), and the MS/MS spectra are searched against a fungal genome database to identify the corresponding CWPs (Yin et al., 2005). Recently, protein extraction has been simplified using "wall protein shaving." Intact fungal cells are incubated in the presence of proteases to digest accessible cell surface proteins. Because proteolytic enzymes are unlikely to permeate the plasma membrane of intact cells, this releases peptides that are associated specifically with the cell surface. Released peptides can be subsequently analyzed by MS, enabling the identification of cell surface proteins (Eigenheer et al., 2007).

Cell Wall Biosynthesis Inhibitors

Cell wall biosynthesis inhibitors are used to identify and characterize cell wall mutants. Testing for altered susceptibility to cell wall-damaging agents is commonly used to identify cell wall mutants in fungi. The most commonly used compounds are CFW and Congo red, which interfere with chitin synthesis; caspofungin and nikkomycin Z, which inhibit glucan and chitin synthesis, respectively; yeast killer toxin, which binds to a cell wall β-glucan receptor, forming lethal pores in the plasma membrane; Zymolyase, which degrades the β-1,3 glucan network; and less specific compounds such as sodium dodecyl sulfate, caffeine, and hygromycin B (Ram and Klis, 2006). Typically, mutants disturbed in the synthesis of glucan and chitin, mannosylation of mannoproteins, and GPI-anchor biosynthesis are hypersensitive to CFW and Congo red (Ram and Klis, 2006). In the filamentous fungi, *Aspergillus* mutants defective in glucan synthesis (Damveld et al., 2005a), CWP O-mannosylation (Shaw and Momany, 2002), and the cell wall stress response (Damveld et al., 2005b; Ronen et al., 2007) all exhibit CFW sensitivity.

CFW, yeast killer toxin, and caspofungin have also been used in mutant screens to identify genes that encode cell wall biosynthetic enzymes and structural CWPs involved in susceptibility (Brown et al., 1993; Bulawa et al., 1986; Ram et al., 1994; Lussier et al., 1997; Markovich et al., 2004; Hill et al., 2006). However, it is important to note that not all cell wall mutant phenotypes arise from mutation in genes directly involved in the cell wall. They can also arise because of defects in the cytoskeleton, in intracellular trafficking, and even in protein metabolism (Lussier et al., 1997; Pagé et al., 2003; Markovich et al., 2004). This is because the cell wall is a highly complex structure requiring the seamless integration of multiple cellular pathways and systems. Damage to any one of these can indirectly damage the cell wall.

Cell wall mutants can be analyzed using all of the above-described methods (microscopy, biochemistry, and inhibitors). For example, microscopic analysis of the *A. fumigatus* β-1,3 glucanosyltransferase Δ*gel2* deletion mutant revealed decreased melanization of the outer surface of conidia, and biochemical analysis of the cell wall showed an increase in chitin and a reduction in galactomannan (Mouyna et al., 2005).

Genomics and Transcriptomics

As described above, proteomic analysis has advanced considerably in recent years. More recently, genomics and transcriptomics approaches have emerged for analysis of the cell wall of filamentous fungi.

Genomic Analysis

To date, the genomes of 56 fungal species have been sequenced, including 35 species of dimorphic and filamentous fungi. It is now possible to identify approximately 50 to 100 putative CWPs in each of these species based on sequence

homology and conserved motifs, to reconstruct in silico cell wall carbohydrate biosynthesis pathways, and to select subsets of genes for further mutational analysis. Notable examples of genomic mining in filamentous fungi include the detection of all putative GPI-anchor-encoding genes in several species of filamentous fungi (De Groot et al., 2005) and the identification and analysis of repeat-containing putative CWPs in *A. fumigatus* (Levdansky et al., 2007).

Transcriptomics

The use of microarrays has revolutionized the analysis of the response of fungi to cell wall damage as well as the identification of genes transcribed during cell wall expansion/alteration during development. Notable examples of microarray studies involving the filamentous fungi include the transcriptional response of *C. albicans*, *A. fumigatus*, and *Aspergillus niger* to antifungal drugs (Liu et al., 2005; da Silva Ferreira et al., 2006; Meyer et al., 2007).

Efforts are under way to integrate different genome-wide analyses into one shared database. This type of data mega-clustering can reveal unexpected connections between biological processes and differentiate between novel and known effects in the analyzed experiments. One such database, with the acronym SIMBA (http://acgt.cs.tau.ac.il/simba/), is currently under development for the yeast *S. cerevisiae* (Tanay et al., 2005).

SYNTHESIS OF THE CELL WALL POLYSACCHARIDES

In filamentous fungi, growth and cell wall assembly occur mainly at hyphal apexes (Ruiz-Herrera, 1991). This is unlike the process observed in yeast, where extension occurs at bud tips, followed by intercalary growth. The carbohydrate polymers comprising the cell wall are synthesized de novo at hyphal tips by membrane-associated enzymes that are transported as inactive forms within vesicles to the tip region. Once incorporated into the plasma membrane, the active biosynthetic enzymes extrude the carbohydrate polymers through the membrane. This is followed by polymer cross-linking events and modifications performed by extracellular proteins. The mechanistic features of many aspects of polymer synthesis, extrusion, and assembly are still relatively uncharacterized.

Synthesis of Chitin, a Primary Cell Wall Component

The substrate for chitin synthase isozymes is UDP-*N*-acetylglucosamine (UDP-glcNAc), which is synthesized from fructose-6-phosphate by the Leloir pathway (Leloir and Cardini, 1953). In their pioneering work, Glaser and Brown (1957) used *N. crassa* when first describing cell-free chitin synthase activity. Since then, it has become evident that chitin synthases can be transported in vesicular organelles called chitosomes (Bartnicki-Garcia, 2006; Sietsma et al., 1996) and, based on in vitro experiments, some are activated by proteolysis (Bartnicki-Garcia, 2006).

The *N. crassa chs-1* gene was the first chitin synthase to be cloned from a filamentous fungus (Yarden and Yanofsky, 1991), following *CHS1* of *S. cerevisiae* (Bulawa et al., 1986). In time, it has become apparent that in contrast to the three chitin synthase genes found in yeasts (Cabib et al., 2001) filamentous fungi have multiple chitin synthase-encoding genes, the number of which can vary from 1 to over 20, and three classes of chitin synthases (designated III, V, and VI) are unique to filamentous fungi (Latgé, 2007; Choquer et al., 2004; Riquelme and Bartnicki-Garcia, 2008). A kinesin/myosin motor-like domain has been shown to be an integral part of one of one of these (class V), and the activity of these chitin synthases is associated with their binding to actin (Takeshita et al., 2005). Inactivation of some chitin synthase-encoding genes in various fungi results in no observable change in fungal phenotype, suggesting at least some redundancy in chitin synthase-encoding genes (Munro and Gow, 2001). Furthermore, the degree of overlapping functions of different chitin synthase classes in different fungal species remains unclear. The fact that the regulation of chitin synthases is complex and apparently involves various pathways (including the protein kinase C [PKC], osmotic stress, calcineurin and the cell wall integrity pathway) adds to the difficulty in dissecting the nature of chitin synthesis (Munro et al., 2007).

Synthesis of β-1,3 Glucan, the Major Cell Wall Component

The major polysaccharide core of the fungal cell wall is comprised of β-1,3 glucan. The substrate for β-1,3 glucan synthesis is UDP-glucose that is produced from glucose-6-phosphate by the activity of phosphoglucomutase and a uridylyltransferase. The synthesis of the β-1,3 glucan polymer is carried out by a glucan synthase protein complex, comprised of at least two proteins: the β-1,3 glucan synthase catalytic subunit (FKS) and a regulatory subunit (RHO) (Mazur and Baginsky, 1996; Qatoda et al., 1996). The number of genes encoding β-1,3 glucan synthases varies among different species, yet at least among filamentous ascomycetes analyzed so far, one FKS orthologue is apparently essential (Bernard and Latgé, 2001; Lesage and Bussey, 2006; Latgé, 2007). FKS (designated FK506-sensitive, as it was originally cloned by complementation of a mutant that was hypersensitive to the calcineurin inhibitor FK506 [Parent et al., 1993]) is a transmembrane protein that harbors a highly conserved hydrophilic signature motif (Douglas, 2001). The regulatory subunit is a Rho GTPase, whose activity is regulated by conformational changes that alter its GDP/GTP binding state as well as geranylgeranylation (required for transport and membrane attachment). The RHO subunit is maintained in an inactive form during vesicular transport and activated upon arrival at the plasma membrane (Abe et al., 2003).

There is evidence that in situ, β-1,3-linked glucans branch through β-1,6 linkages from the main β-1,3 glucan chain (Fontaine et al., 2000). β-1,6-Linked glucans play a pivotal role in cell wall assembly in yeast, where they interconnect all other wall components into a lattice (Klis et al., 2002). In sharp contrast, β-1,6-linked glucans are not found in a number of filamentous fungi, including *N. crassa* and *A. fumigatus*. Nonetheless, potential homologues of some yeast genes involved in β-1,6 glucan synthesis and transport have been discovered in some filamentous fungi (Borkovich et al., 2004), yet their roles have yet to be determined.

Regulation of Cell Wall Assembly

The synthesis of chitin and glucan is not sufficient for producing an intact and functional cell wall. Additional structural elements (notably galactomannans), once linked with glucan, contribute considerably to the integrity of the cell wall (Damveld et al., 2008). The biosynthesis of mannan and its galactofuran side chains has yet to be studied in depth (Bernard and Latgé, 2001), as is the function of various transglycosylases (glucanosyltransferases) involved in glucan modification and decoration. In addition to the biosynthetic and polymer-modifying enzymes, degradative

enzymes likely play important roles in the regulation and remodeling of the fungal cell wall. Spore germination, the formation of new hyphal branches, and conidial separation all require digestion of preexisting walls. Thus, specific members of the large families of chitinases and glucanases that have been identified in fungi are anticipated to play important roles in cell wall synthesis and remodeling (Adams, 2004; Seidl, 2008).

The orchestration of cell wall component biosynthesis and assembly involves both hierarchical and integrative modes of regulation. These include the transcriptional, translational, and posttranslational regulation of the gene and gene products involved in substrate synthesis, structural polymer biosynthesis, surface signaling, polarity, and secretion.

On the one hand, much progress has been made in the analysis of the basic physical components of the fungal cell wall. Yet many of the final stages of assembly and the dynamic changes that the cell wall undergoes have yet to be elucidated. Furthermore, even though links between cell wall biosynthesis and central signal perception and transduction pathways have been established (see "The Cell Wall Integrity Pathway" below), the comprehension of cell wall biosynthesis, at all its levels, is far from saturated.

COVALENTLY AND NONCOVALENTLY LINKED CWPs

CWPs Form the Interface between the Fungus and the Environment

CWPs perform diverse roles in the lives of fungi. They strengthen the polysaccharide cell wall polymers by cross-linking them, and by forming an outer coat, they protect them from hydrolytic degradation. In some cases, this protein coating masks the polysaccharides from recognition by the immune system (De Groot et al., 2005; Wheeler and Fink, 2006; Rubin-Bejerano et al., 2007). Also, CWPs mediate interactions with the environment, including adhesion and tissue invasion, biofilm formation, flocculation, and mating (Yin et al., 2008).

There are several categories of CWPs based on their mode of attachment to the cell wall (Fig. 1). CWPs are either covalently or noncovalently linked to cell wall polysaccharides. Covalently attached CWPs include (i) GPI-anchored CWPs, covalently linked to the β-1,3/1,6 glucan core through a trimmed form of their GPI anchor (Kollar et al., 1997) and (ii) alkali-sensitive linkage proteins including proteins with internal repeats directly linked to the β-1,3 glucan network through glutamine residues (Ecker et al., 2006). In both *S. cerevisiae* and *C. albicans*, they are proposed to function as cell wall cross-linkers and structural stabilizers (Martínez et al., 2004; Yin et al., 2005). Although members of this family have been identified in silico in several filamentous fungi including *N. crassa* and *M. grisea*, they have not been studied to date (De Groot et al., 2005). Noncovalently bound detergent-extractable CWPs often include proteins of cytosolic origin and secreted proteins. They are apparently bound by electrostatic interactions to the charged side chains of mannosylated proteins (De Groot et al., 2005).

GPI-Anchored CWPs

Most CWPs in yeast and filamentous fungi are GPI anchored. GPI-anchored proteins have been identified in silico by use of specially developed software (De Groot et al., 2003; Eisenhaber et al., 2004). These proteins contain a predicted N-terminal signal peptide and a C-terminal GPI anchor attachment site. Based on these analyses, there are predicted to be between 60 to 120 GPI-anchored-protein-encoding genes in the genomes of various ascomycetes (De Groot et al., 2003; Eisenhaber et al., 2004). GPI-anchored CWPs have also been identified recently in the basidiomycete mold *C. neoformans* (Eigenheer et al., 2007).

The GPI-anchored genes can be classified as those encoding (i) CWPs that are involved in cell wall biogenesis and remodeling including transglucosylases (Gas/Crh/Phr/GEL family), chitinases, and glycosyl hydrolases; (ii) CWPs with diverse enzymatic activities such as the lysophospholipases and proteases; (iii) adhesins (*ALS/FLO*) and hydrophobins; and (iv) with at least half of the genes in this category, proteins of unknown function, e.g., the Sps2/Ecm33 family, MP-1 family, CFEM-motif containing proteins and numerous conserved hypothetical genes (De Groot et al., 2005; Latgé, 2005).

Based on sequence homology, there is some functional overlap between GPI-anchored-protein-encoding genes in the genomes of ascomycete yeast and filamentous fungi, in particular for cell wall-modifying and -degrading enzymes. However, major differences exist even among closely related species. For example, 26% of *A. fumigatus* GPI-anchored-protein-encoding genes have no *A. nidulans* orthologues (our unpublished findings). This suggests that this class of fungal genes has rapidly diversified to meet the specific environmental needs of each species.

Only a small fraction of the GPI-anchored-protein-encoding genes in filamentous fungi have been studied by gene deletion (Latgé et al., 2005). In most cases, deletion results in no discernible phenotype or in subtle changes, such as altered germination rates, reduced adhesion, or changed susceptibility to cell wall-disrupting agents (for examples, see Bailey et al., 1996; Bernard et al., 2002; Damveld et al., 2005a; and Romano et al., 2006). There may be several reasons for these results, including (i) gene redundancy (especially for adhesins and cell wall-modifying enzymes that are found in large gene families) (Hoyer et al., 2007; Mouyna et al., 2005; Pardini et al., 2006); (ii) limited interaction of the gene product with specific external determinants (for example, the *C. albicans ALS3* adhesin specifically binds to buccal epithelial cells, but not to fibronectin-coated plastic [Zhao et al., 2004]); and (iii) expression under narrowly defined conditions (for example, *C. albicans* expresses a different set of GPI-CWPs in hyphal or yeast forms [De Groot et al., 2004]). In agreement with this last hypothesis, the actual number of GPI-anchored proteins isolated from the fungal cell wall under nutrient-rich conditions is far lower than the numbers predicted by in silico identification. Only 12 GPI-anchored proteins have been isolated from the cell wall of *S. cerevisiae* and *C. albicans*, and 8 such proteins have been isolated in *A. fumigatus* (Bruneau et al., 2001; De Groot et al., 2004; Yin et al., 2005).

Sequence Features Affecting Localization of Fungal GPI-Anchored Proteins

Fungal GPI-anchored proteins are either retained and localized to the plasma membrane or released and covalently bound to cell wall glucans. Early analysis of yeast suggested that retention of GPI-anchored proteins to the plasma membrane occurs primarily when two basic amino acids are found upstream of the GPI anchor site. However, results obtained with *C. albicans* suggest that the picture is not

clear-cut: the presence of long serine and threonine-rich regions, which are characteristic of many GPI proteins, favors targeting to the cell wall and may even override the plasma membrane-retaining effect of the two basic amino acids (Frieman and Cormack, 2004). Also, some of the GPI proteins containing membrane-retaining basic motifs have been nevertheless identified in the cell wall of *C. albicans* (De Groot et al., 2004). Therefore, the rules governing the differential localization of GPI proteins to the plasma membrane or cell wall have yet to be identified. This can be done by analyzing the localization patterns of a large number of these proteins. Additionally, the expression patterns of GPI proteins, under various growth conditions and at different time-points, need to be elucidated.

Several lines of evidence also suggest that at least in *A. fumigatus*, some GPI proteins are attached to the cell wall loosely, with no covalent linkages to β-glucan. The strongest line of evidence, based on MS analysis of the GPI-anchored acid phosphatase PhoAp, did not show that the C terminus of this protein was covalently bound to an oligosaccharide (Latgé et al., 2005). This might also be true for other fungi, since the identification of the chemical linkages between the protein and the polysaccharide, which remains the ultimate proof of such covalent linkages, has been assessed only for the *S. cerevisiae* GPI-anchored proteins Cwp2 and TIP1 (Van der Vaart et al., 1996; Fujii et al., 1999).

THE CELL WALL INTEGRITY PATHWAY

The cell wall serves as a major barrier between the organism and the environment. Thus, compromising the integrity of this structure leads to catastrophic consequences to the affected fungus. To orchestrate the establishment, growth, and maintenance of the fungal cell wall and to react to potential damage to the cell wall, a network of components involved in regulating cell wall integrity has evolved. This network, called the cell wall integrity (CWI) pathway, contains sensors, signal transducers, messenger molecules, regulators, and structural components.

In yeasts, members of the multiple Rho-type GTPase gene family regulate polarized growth by reorganization of the actin cytoskeleton and through signaling pathways that control the expression of cell wall biosynthetic genes. Rho1 is considered to be the master regulator of CWI in yeasts and has been the one most extensively studied, along with other components (reviewed by Levin, 2005). Rho proteins reside at the plasma membrane (this association is aided by the fact that they are C-terminally prenylated). Like other G proteins, Rho proteins cycle between the active GTP-bound state and the inactive GDP-bound state. The Rho protein cycle is regulated both by GTPase-activating proteins and guanosine nucleotide exchange factors acting in opposing directions. The Rho proteins receive their initial stimulus from transmembrane cell surface sensors, some of which are linked with additional signal transduction pathways. Thus, some components of the CWI pathway interface with Tor kinase signaling, Ca^{2+} signaling, phosphatidylinositide signaling, and sphingoid base signaling (Levin, 2005). Together, these components coordinate changes in the actin cytoskeleton, cell wall maintenance, expansion, and polarized secretion. Known effectors for Rho1 include PKC, β-1,3 glucan synthase, formins, transcription factors, and exocytosis components (reviewed by Levin, 2005).

Overall, the backbone of the CWI pathway in filamentous fungi (Fig. 4) appears to resemble that found in yeasts (Levin, 2005). Thus, Rho-type GTPases and PKC have been found to be involved in morphogenesis and cell wall (including septal) biosynthesis, remodeling, and fungal pathogenesis (Guest et al., 2004; Rasmussen and Glass, 2005; Martínez-Rocha et al., 2008; Teepe et al., 2007). Furthermore, the filamentous fungal CWI pathway has been found to activate chitin synthesis as well as genes encoding α-1,3 glucan synthases (Damveld et al., 2005b), via a conserved transcription factor (Damveld et al., 2005a). The latter does not occur in *S. cerevisiae* and *C. albicans*, as these yeasts lack the genes encoding the α-1,3 glucan synthases. The CWI pathway functions in concert with other sensing, transducing, and regulatory networks. This is exemplified in cases where the CWI pathway is activated following the activation of the calcineurin pathway or following the activation of the high-osmolarity mitogen-activated protein kinase pathway (in *S. cerevisiae*) or when cell wall inhibitory compounds are applied (respectively discussed by Harel et al., 2006; Bermejo et al., 2008; and Meyer et al., 2007). One method for the identification of additional CWI pathway components (such as the recently identified UDP-galactopyranose mutase) involves using reporter genes linked to cell wall stress-induced promoters (Damveld et al., 2008). *S. cerevisiae* clearly serves as an invaluable model for identification of CWI pathway components. Nonetheless, filamentous fungi do not necessarily have obvious homologues to all the identified yeast components and differences from the yeast model have been reported (Fujioka et al., 2007). Furthermore, the composition and morphological complexity of cell walls in filamentous fungi promise to yield novel regulatory and structural constituents of the CWI pathway. Examples of this complexity have already been demonstrated in cases where mitogen-activated protein kinase pathways act in both concerted and overlapping manners in the regulation of hyphal fusion and sexual reproduction, as well as in an interactive manner with additional pathways in the regulation of hyphal elongation/branching, as well as other developmental and metabolic pathways (Maerz et al., 2008; Park et al., 2008).

THE CELL WALL AS AN ANTIFUNGAL TARGET

The requirement of a functional cell wall for survival, growth, development, and pathogenicity of fungal species makes it an attractive target for antifungals. The fact that some of the constituents of the fungal cell wall are not present in potential hosts makes this target even more appealing on the basis of a desirable therapeutic index. As such, the fungal cell wall has been a constant focus of antifungal drug screening procedures. Compounds affecting a multitude of cellular processes can have various effects on the cell wall, yet only a few specifically affect cell wall biosynthetic components (Ruiz-Herrera, 1991). This section focuses on compounds affecting specific constituents of the fungal cell wall.

CHS Inhibitors

Chitin synthase (CHS) inhibition is mainly based on utilizing analogues of the CHS substrate UDP-*N*-acetylglucosamine. The two major groups of peptide nucleoside antibiotics used to inhibit CHS are polyoxins and nikkomycins (Dähn et al., 1976; Endo and Misato, 1969; Müller et al., 1981; Graybill et al., 1988). This group of competitive CHS inhibitors includes natural products of *Streptomyces* spp. and their derivatives that inhibit CHS in various fungi. As the active site of the membrane-associated CHSs faces the cytoplasm, the efficacy of the substrate ana-

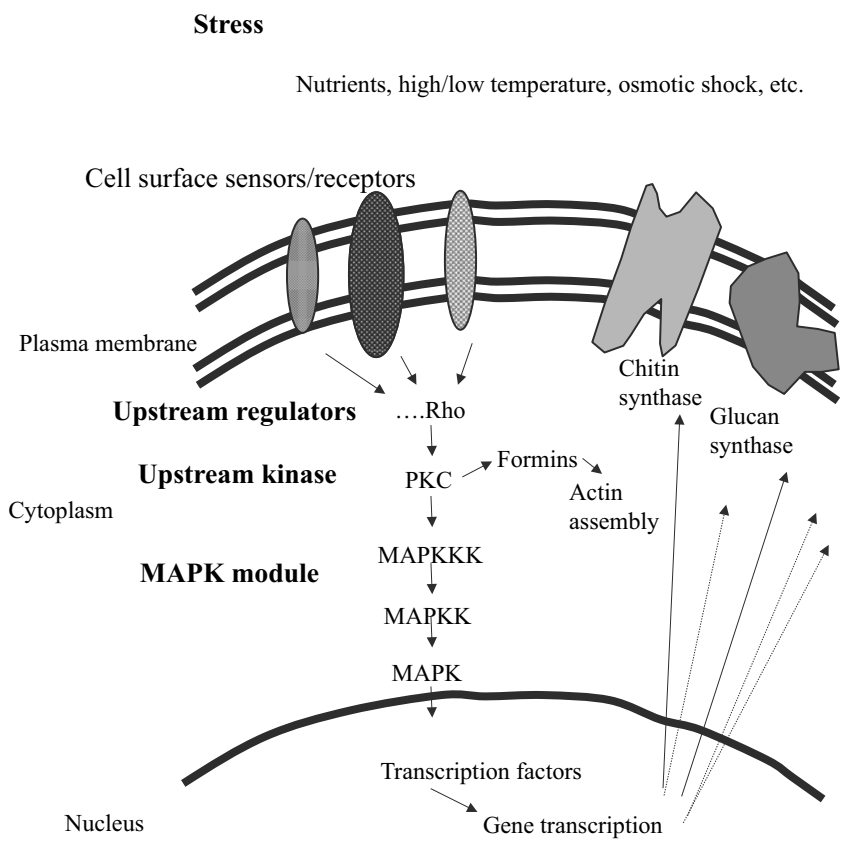

FIGURE 4 Outline of the fungal cell wall integrity pathway. Activation of the pathway involves perception of external signals (including stress- and nutrition-related cues) by membrane-associated sensors and signal transducers, intracellular transducers and messenger molecules, regulators, and structural components (including cytoskeletal proteins and cell wall biosynthetic enzymes). The pathway can also be activated via internal cues linked with other signaling pathways.

logues depends on their ability to enter the fungal cell. Differences in drug metabolism and specific CHS structure can also influence the degree of inhibition efficacy (Munro and Gow, 2001). As some plant pathogenic fungi are known to be sensitive to polyoxins, these compounds have been used (though to a limited degree) in agricultural practice (Cohen, 1987; Worthington, 1988). Overall, even though both polyoxins and nikkomycins can be effective CHS inhibitors in vitro, their limited efficacy in vivo (presumably on the basis of uptake and delivery limitations) has resulted in their restricted use as antifungals. Nonetheless, nikkomycins were effective in the treatment of murine histoplasmosis, and the combined use of nikkomycins with other antifungals (Li and Rinaldi, 1999) provides additional options for harnessing CHS inhibition as part of antifungal drug therapy programs.

GS Inhibitors

Two classes of glucan synthase (GS) inhibitors, the glycolipid papulacandins and the lipopeptide echinocandins, have been developed. They are noncompetitive inhibitors of GS, encoded by the essential *FKS1* gene (Beauvais and Latgé, 2001). Their precise mode of action is not well understood because of the difficulty in isolating active GS subunits. Interestingly, the echinocandins highlight differences between the cell walls of yeasts and filamentous fungi. They lyse and kill yeast cells but are only fungistatic to aspergilli, causing lysis of the hyphal tips and the formation of compact ball-like colonies (Bowman et al., 2002). Synthetic analogues of the echinocandins (but not of papulacandins) have been produced by several drug companies (caspofungin/Cancidas™ [Merck], FK 463/Micafungin™ [Fujisawa], and LY303366/Anidulafungin™ [Lilly]) and are used to treat invasive aspergillosis and disseminated candidiasis. Their clinical efficacy is similar to that seen for existing front-line antifungals from the polyene and azole families (Denning, 2003). The possibility of combining echinocandins with other antifungals is being actively investigated in animals (Ostrosky-Zeichner, 2008).

Mannosylation Inhibitors

Pradimicins are antifungal compounds that damage the cell wall of yeast and filamentous fungi by binding to terminal mannose residues, resulting in cell wall and membrane deformation and apoptosis (Walsh and Giri, 1997). Interestingly, in yeast, deletion of the mannosylated cell wall stress sensor *SLG1* increased resistance to pradimicin, suggesting that these compounds have a specific cell wall target (Hiramoto et al., 2005). The pradimicins were effective in curing fungal infections in animal studies, but their development for use in humans was discontinued because of liver toxicity (Walsh and Giri, 1997).

Cell Wall-Specific Antibodies

Antibodies have been developed both for identifying and diagnosing mold infections and for antifungal therapy (Nimrichter et al., 2005). For example, the Platelia enzyme-linked immunosorbent assay uses a monoclonal antibody that recognizes the galactofuranose side chains of *Aspergillus* galactomannan and galactomannoproteins released from the cell wall during infection. Monitoring of high-risk patients with Platelia can identify *A. fumigatus* infection before the onset of clinical symptoms, leading to early, more effective antifungal treatment (Mennink-Kersten et al., 2004).

A human recombinant antibody (Mycograb) recognizing the cell wall-associated heat shock protein Hsp90 of *C. albicans* has been produced and tested for antifungal activity and therapy. It is active against several yeast species and acts synergistically with amphotericin B and other antifungal drugs (Matthews et al., 2003). Mycograb is currently being used in clinical trials (Pachl et al., 2006), representing an excellent example of the use of cell wall ligands as new therapeutic agents against fungal infections.

Identification of Novel Cell Wall Targets

In principle, any essential, conserved, and well-characterized CWP involved in cell wall construction or host-pathogen interaction can serve as the target for the development of novel antifungals. For example, the *GAS/PHR/GEL* β-1,3 transglucosylases, which generate new branches of β-1,3 glucan, are promising drug target candidates: transglucosylase gene deletion in both yeast and filamentous fungi results in stunted growth, reduced virulence, and increased antifungal susceptibility (Beauvais and Latgé, 2001; Mouyna et al., 2005). Similarly, β-1,3 glucanases and chitinases, which degrade glucan and chitin, respectively, and enable plasticization and cell wall expansion, may also be potential drug targets. However, too little is known about their biochemistry and function to enable drug development.

SUMMARY, OPEN QUESTIONS, AND FUTURE RESEARCH

The broad spectrum of functions that the fungal cell wall performs is clearly reflected in its complexity. Though rich in seemingly inert constituents, the cell wall is an extremely active part of the fungal cell. Even though many cell wall components have been characterized to various extents, our understanding of cell wall biosynthesis is far from complete. The mechanism by which cell wall polysaccharides are extruded and the significance of the variations in cell wall constituents in different fungi are just examples of questions yet to be answered. Although regulatory networks that affect cell wall synthesis and maintenance have been identified, the comprehensive signaling machinery involved and the associations between different pathways have yet to be elucidated. The significance of the cell wall as a target for antifungals has long been appreciated, yet the number of successful drugs developed is very small. Lastly, important progress has been made in the analysis of the cell wall. However, our still-inadequate levels of understanding concerning the fundamental features of the cell wall, as well as our limited current capabilities in harnessing our knowledge for relevant applications in medicine, agriculture, and industry, provide us with many challenges for the future.

Cellular and Molecular Biology of Filamentous Fungi
Edited by K. A. Borkovich and D. J. Ebbole

18

Hyphal Growth and Polarity

STEVEN D. HARRIS

The filamentous fungi inhabit a diverse array of ecological niches. This capacity presumably reflects several intrinsic features of fungal biology, such as their metabolic versatility and their ability to tolerate environmental stress. Of these features, one of the most important is undoubtedly the ability to form highly polarized hyphae that enable filamentous fungi to rapidly and efficiently colonize new substrates. With the exception of flagellated zoospores formed by chytrids (Taylor et al., 2004), fungi do not generate cells that are motile. The formation of polarized hyphae thus seems to be an ingenious solution to the problems that would arise from an otherwise sessile lifestyle (for example, escape from local environments that have been depleted of nutrients). Accordingly, it is no surprise that polarized hyphal growth is the defining characteristic of filamentous fungi. It should be noted that hyphal growth is not an exclusive property of fungi; other organisms, including the bacterial actinomycetes and the alga-related oomycetes, also employ hyphae as a means of growth (for examples, see Chater and Chandra, 2006; and Gow, 2004). Even higher plants and animals form highly polarized structures (e.g., plant pollen tubes and animal axons) that superficially resemble hyphae (Cheung and Wu, 2008; Arimura and Kaibuchi, 2007). Nevertheless, no group of organisms has resorted to hyphal growth to the same extent as fungi have. Although it is not possible to pinpoint the exact evolutionary origins of hyphal growth in fungi, it is clear that only a subset of species within the Chytridiomycota, which is currently recognized as the most ancestral fungal phylum, grow by forming hyphae (James et al., 2006). By contrast, all subsequent fungal phyla (i.e., Zygomycota, Ascomycota, and Basidiomycota) almost uniformly exhibit polarized hyphal growth (note that for the purpose of this argument, yeast growth is considered to be a modified form of hyphal growth). Because most of these fungi are terrestrial, whereas chytrids are primarily aquatic, it is tempting to speculate that polarized hyphal growth played an important role in allowing fungi to adapt to a terrestrial lifestyle.

Steven D. Harris, Department of Plant Pathology and Center for Plant Science Innovation, University of Nebraska, Lincoln, NE 68588-0660.

Hyphal growth encompasses several different morphogenetic processes. Foremost among these is the establishment and maintenance of a stable axis of polarized growth. As a result, cell surface expansion and cell wall deposition are confined to a discrete location that ultimately becomes the hyphal tip. The formation of additional polarity axes in subapical regions, the original spore, or in some cases even from a growing tip, generates branches or secondary hyphae, which ultimately results in a differentiated mycelium consisting of multiple hyphae (Fig. 1). The importance of polarized axis formation in enabling hyphal growth has been amply documented using genetic, physiological, molecular, and cell biological tools and is also supported by computational studies (summarized by Harris, 1997; Bartnicki-Garcia, 2002; Momany, 2002; Harris, 2006; and Steinberg, 2007). Another critical process underlying hyphal growth is septum formation. Septa are formed via a cytokinetic mechanism that resembles cell division in animal cells (summarized by Harris, 2001; and Walther and Wendland, 2003). However, instead of separating, hyphal cells remain attached and the division site is marked by a cross wall (i.e., the septum). Although septum formation is not required per se for the formation of polarized hyphae or for hyphal growth, mutant analysis suggests that septa are needed to form a differentiated mycelium (Harris et al., 1994). Recently, it has become apparent that hyphal anastomosis is also an integral feature of hyphal morphogenesis and colony development (summarized by Glass et al., 2004; see also the following chapters). Whereas hyphae at the advancing edge of a mycelial colony tend to avoid one another, those in interior regions appear to engage in chemotropic interactions and subsequently undergo hyphal fusions. In some cases, even germinating conidia are capable of anastomosis (Gabriela Roca et al., 2005). Like septum formation, hyphal anastomosis is not necessary for hyphal growth. However, by permitting the exchange of nutrients and presumably signals as well, this process clearly contributes to the formation of a fully functional mycelium.

Because of its importance to the lifestyle of filamentous fungi, there is considerable interest in characterizing the mechanisms underlying hyphal growth. In a practical sense, this likely reflects increased interest in understanding fungal interactions with humans and plants. For example,

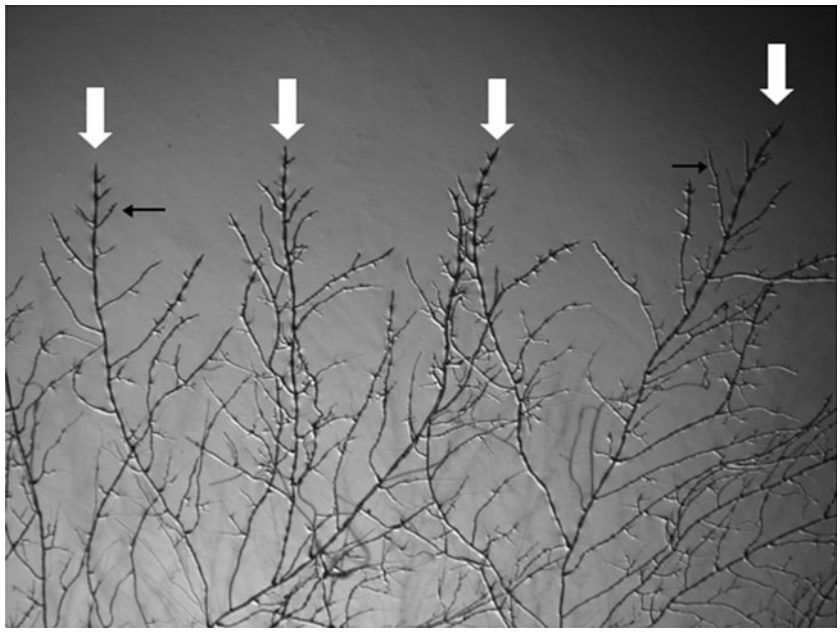

FIGURE 1 Organization of growing hyphae at the edge of a mycelial colony. Shown is the advancing edge of an *N. crassa* (strain FGSC9716) colony growing on Vogel's minimal medium supplemented with histidine. Thick white arrows indicate dominant extending hyphae. Thin black arrows show examples of secondary lateral branches. Note that branch emergence is suppressed in the immediate vicinity of hyphal tips.

while polarized hyphal growth is not generally recognized as a determinant of fungal virulence, it has been demonstrated that defects in hyphal morphogenesis do compromise the virulence of both human and plant pathogens (e.g., Nichols et al., 2004; Castillo-Lluva et al., 2007). Furthermore, recent studies suggest that the precise regulation of polarized hyphal growth appears to influence the outcome of fungal interactions with plants (Rittenour and Harris, 2008). As a result of the interest in understanding hyphal growth, a reasonably large number of proteins have been identified as playing key roles in the establishment and maintenance of hyphal polarity, septum formation, or hyphal anastomosis (summarized by Harris, 2006). Much of this effort has been guided by the so-called "yeast paradigm," which despite its limitations, has yielded valuable insight into hyphal morphogenesis (Harris and Momany, 2004). Although a coherent picture of the mechanisms underlying hyphal growth has yet to emerge, the rapid development of new tools and resources for manipulating filamentous fungi suggests that we will not have to wait much longer for this to happen. This chapter summarizes the progress achieved toward understanding the organization of fungal hyphae and the cellular systems involved in hyphal morphogenesis. Particular attention is paid to the mechanisms that have been implicated in the regulation of polarized growth and septum formation in filamentous fungi. Finally, the intriguing question of how morphogenetic regulatory systems may have evolved in the fungal kingdom is briefly addressed.

ORGANIZATION OF FUNGAL HYPHAE

Apical Dominance

As a general rule, fungal hyphae grow solely by tip extension (i.e., cell surface expansion and cell wall deposition are confined to the immediate hyphal apex). This mode of growth presumably reflects the importance of apical dominance, whereby the growing tip is dominant and appears to suppress the formation of other tips (i.e., lateral branches) in its general vicinity (Rayner, 1991). At a physiological level, apical dominance presumably reflects the exclusive targeting of cellular resources (i.e., vesicles laden with precursors required for cell surface expansion and cell wall deposition) to the hyphal tip at the expense of potential branching sites. Accordingly, branch sites would only become active once they are a sufficient distance from the growing tip. This would generate the stereotypical growth pattern of a fungal mycelium, with hyphae radiating outwards from the colony center and new hyphae arising via the formation of lateral branches (Fig. 1). It is not too difficult to imagine that the absence of apical dominance would lead to a disordered mass of hyphae growing in random directions. In fact, it might be instructive to consider apical dominance as performing the same role as the bud site selection system in the yeast *Saccharomyces cerevisiae*. Individual yeast cells exhibit one of two budding patterns depending on their mating type (Chant, 1999). Disruption of the mechanisms that specify these patterns do not perturb growth per se, but cells bud in a random fashion that alters colony formation and function (for an example, see Vopalenska et al., 2005). By analogy, apical dominance might represent a process that uses positional information to enable the directed growth of hyphae.

Despite its presumed importance, little is known about the mechanisms that may impose apical dominance on a hypha. In principle, any signaling molecule that exhibits a biased localization at growing hyphal tips could suppress branch formation and thereby promote apical dominance. Tip-high calcium and ion gradients are well known in filamentous fungi (Jackson and Heath, 1993; Robson et al., 1996), and it has been previously suggested that calcium could play a role in maintaining a single dominant hyphal

tip (Schmid and Harold, 1988). More recently, it has become apparent that reactive oxygen species (ROS), primarily superoxide, accumulate at hyphal tips and are seemingly involved in the enforcement of apical dominance (Semighini and Harris, 2008). Furthermore, studies involving several fungi, including *Aspergillus nidulans*, *Magnaporthe grisea*, and *Epichloe festucae*, implicate NADPH oxidase (Nox) and its associated regulators in the generation of ROS at hyphal tips (Tanaka et al., 2006; Egan et al., 2007; Takemoto et al., 2007; Semighini and Harris, 2008). An appealing, but still somewhat speculative model is that localized ROS generated by Nox triggers the formation of a calcium gradient at hyphal tips, as has been demonstrated in plant root hairs (Foreman et al., 2003). Indeed, as shown in *Arabidopsis thaliana*, ROS and calcium may act via feedback loops to mutually reinforce their respective gradients (Takeda et al., 2008). The net effect would be the generation of a positional signal that specifies the dominant axis of hyphal polarity.

Although apical dominance appears to be a characteristic feature of fungal hyphae, it has also become clear that it is not the only means of hyphal extension. Within the phylum Saccharomycotina (i.e., hemiascomycetes), both *Ashbya gossypii* and *Geotrichum candidum* form hyphae that undergo regular and repeated apical branching (split tips) (Heath et al., 2003; Philippsen et al., 2005). In these hyphae, apical dominance is presumably temporarily suspended to allow the simultaneous formation of two adjacent hyphal tips. Notably, the filamentous fungi within the Saccharomycotina do not possess obvious homologues of Nox and it is unclear whether they accumulate ROS at hyphal tips. Because they do possess apparent homologues of the yeast bud site selection markers (e.g., Bud8 [http://agd.vital it.ch/Ashbya_gossypii/geneview?db=core;gene=ACL193C]), it is tempting to speculate that they might be used to mark the tip and to regulate apical dominance in these fungi. An even more striking variation from the theme of apical hyphal extension is observed in the ryegrass mutualist *E. festucae*. Because this fungus must coordinate its growth with leaf cells in its grass host, it undergoes intercalary hyphal growth (Christensen et al., 2008). Specifically, ROS accumulation at hyphal tips appears to prevent the tip from extending, and growth is instead limited to internal hyphal segments demarcated by septa.

The Hyphal Tip Cell

Most filamentous fungi form multicellular hyphae that are compartmentalized by septa. Because it contains the extending hyphal tip, the apical compartment is known as the hyphal tip cell. This cell typically possesses a Spitzenkörper at the hyphal tip and displays asymmetric organization of vacuoles and endomembranes (i.e., endoplasmic reticulum [ER] and Golgi bodies) (Fig. 2). The Spitzenkörper, which was first described by Girhardt (1957) and has been extensively characterized by Bartnicki-Garcia and colleagues (Bartnicki-Garcia, 2002), is a dynamic structure of variable composition and shape. It is known to contain vesicles of different sizes, as well as microfilaments, microtubules, ribosomes, and possibly Woronin bodies (summarized by Harris et al., 2005). Although Spitzenkörper morphology can vary widely among different fungi, or even at different times in the same hyphal tip (Lopez-Franco and Bracker, 1996), it is almost always associated with hyphal tips undergoing active extension. Furthermore, mathematical models coupled with recent experimental observations strongly support the view that the Spitzenkörper determines the direction and rate of hyphal extension (Bartnicki-Garcia et al., 1995; Riquelme et al., 1998; Konzack et al., 2005). Nevertheless, a precise molecular description of what goes on in the Spitzenkörper has yet to emerge. At the very least, it appears to function as a vesicle supply center where exocytic vesicles transported from the hyphal interior on microtubules are transferred to microfilaments for localized distribution at the hyphal tip. In addition, results from microscopy studies suggest that the

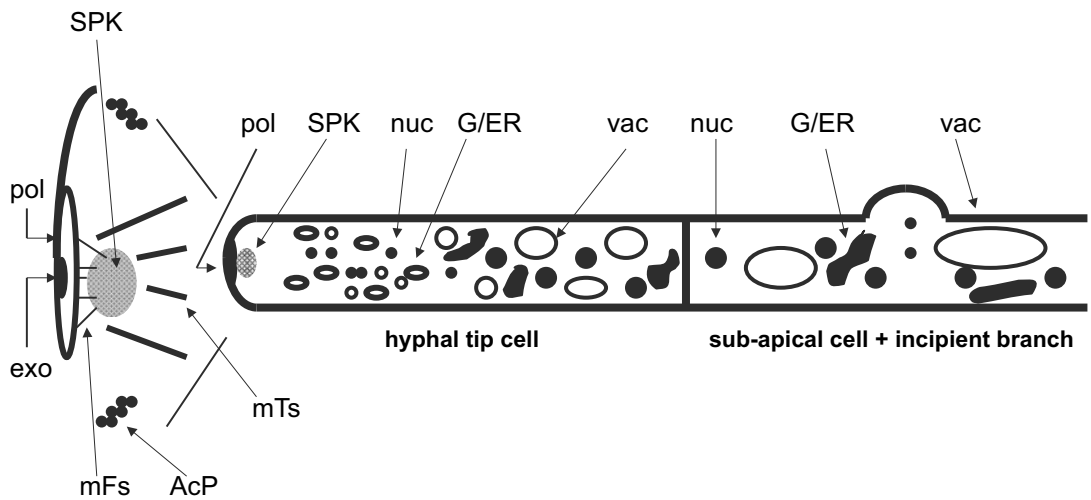

FIGURE 2 The organization of hyphal tip cells and subapical cells is shown through a schematic depiction of an extending hypha. Note the asymmetric organization of the hyphal tip cell, whereas the subapical cell remains uniformly organized until a new tip (i.e., the incipient branch) is formed. In hyphal tip cells, nuclei (nuc) exhibit a gradient of mitosis, with condensed mitotic nuclei located proximal to the tip. In addition, vacuoles (vac) and endomembranes (G/ER) are more fragmented near the tip. Finally, the tip also houses the Spitzenkörper (SPK) and the polarisome (pol). The enlarged depiction of the hyphal tip shows the exocyst (exo), microtubules (mTs), actin filaments (mFs), and actin patches (AcP). In the subapical cell, mitosis is blocked until a new branch emerges. At that time, nuclei proximal to the branch site resume mitosis. See the text for further details.

Spitzenkörper might also serve as a microfilament-organizing center (Harris et al., 2005).

The development of imaging probes that permit real-time localization studies has provided further insight into the organization of the hyphal tip cell. For example, the localization of chitin synthases in *Neurospora crassa* has revealed that endomembranous structures are organized in an asymmetric manner, with globular bodies in distal regions appearing to fragment into smaller vesicles as they approach the tip (Riquelme et al., 2007). The distribution of vacuoles is also asymmetric, as larger vacuoles appear to be primarily confined to the distal regions of tip cells. Finally, the presence of tip high calcium and ion gradients defines an additional asymmetry in tip cells (Jackson and Heath, 1993; Robson et al., 1996).

Nuclei in the hyphal tip cell are mitotically active and divide in a manner that appears to be coordinated with cellular growth. The term "duplication cycle" has been used to draw an analogy between the cell cycle of the hyphal tip cell and that of uninucleate yeasts *S. cerevisiae* and *Schizosaccharomyces pombe* (Fiddy and Trinci, 1976; Harris, 1997). Although nuclear division is coupled to the doubling of cytoplasmic volume during the duplication cycle of hyphal tip cells, the mechanisms that link either of these events to polarized hyphal growth, if any, remain to be determined. This stands in sharp contrast to yeasts such as *S. cerevisiae*, where regulatory interactions between cyclin-dependent kinases (Cdks) and Rho GTPase modules enforce tight coordination of polarized growth with cell cycle progression (summarized by Yoshida and Pellman, 2008). A further complication in determining whether nuclear division is coupled to morphogenesis in hyphal tip cells is the observation of two seemingly distinct patterns of mitosis in these cells (summarized by Gladfelter, 2006a). In one pattern, as best exemplified in *A. nidulans*, the tip cell possesses a limited number of nuclei (typically 8 to 24) and mitosis proceeds in a parasynchronous wave starting from the tip (Clutterbuck, 1970). In the alternate pattern, as seen, for example, in *A. gossypii*, the tip cell is populated with many nuclei (often >50) and mitosis occurs in a completely asynchronous manner, such that individual nuclei divide regardless of the mitotic status of their neighbor (Gladfelter et al., 2006). At first glance, the former pattern would appear to be more conducive to the imposition of a global regulatory mechanism that coordinates morphogenesis with nuclear division, but this still remains to be tested.

Subapical Hyphal Cells

Subapical hyphal cells, also known as intercalary cells, are those cells in a hypha that are not located at the tip (i.e., they are bounded by septa at either end). In addition to their position, there are notable features that distinguish these cells from hyphal tip cells (Fig. 2). First, they possess no obvious asymmetry; there is no Spitzenkörper, and vacuoles and endomembranes appear to be uniformly distributed. Indeed, in many fungi, such as *Candida albicans* and *Ustilago maydis*, subapical cells contain little cytoplasm at all and are largely filled with vacuoles (Barelle et al., 2003; Steinberg and Fuchs, 2004). Second, nuclei present in subapical cells typically undergo cell cycle arrest. The nature of this arrest is not well understood, though it has been shown in *C. albicans* that it occurs in G_1 and is lifted when subapical cells attain a critical cytoplasmic volume (Barelle et al., 2003; Barelle et al., 2006). Perhaps the most important role of subapical hyphal cells is the generation of new hyphal tips, which typically happens as part of a normal morphogenetic program that produces lateral branches from a primary hypha. The mechanisms that underlie the formation of a new hyphal tip from subapical cells remain poorly understood. However, several important steps are likely to be involved (Seiler and Plamann, 2003). For example, the site of branch emergence must be specified. In some fungi (i.e., *A. gossypii*), lateral branches emerge adjacent to preexisting septa, suggesting that septation itself may provide a marker (Wendland, 2003), whereas branch sites appear to be stochastically determined in other fungi (i.e., *A. nidulans* [Trinci, 1978; Walther and Wendland, 2003]). In addition, a new Spitzenkörper must be generated and the morphogenetic machinery must be targeted to the branch site. Localized calcium fluxes have been implicated in this step, though their precise role has yet to be determined (Grinberg and Heath, 1997; Virag and Griffiths, 2004). Finally, the cell cycle arrest that is characteristic of subapical cells must be lifted to allow resumption of nuclear division. In *C. albicans*, this appears to be triggered by passage though a G_1 cell size control (Barelle et al., 2006). The relevance of this observation to other filamentous fungi is a key issue that requires further study.

THE MORPHOGENETIC MACHINERY

Actin Cytoskeleton

The organization of the actin cytoskeleton has been extensively studied in numerous filamentous fungi. Classical studies reliant upon immunofluorescence microscopy and recent studies using green fluorescent protein (GFP)-based probes have both revealed a similar pattern: actin filaments found at the immediate hyphal tip (and occasionally in association with the Spitzenkörper) are subtended by a belt of actin patches (for examples, see Harris et al., 1994; Bruno et al., 1996a; Torralba et al., 1998; Wendland and Philippsen, 2001; Cheng et al., 2001; Pearson et al., 2004; Harris et al., 2005; Taheri-Tahesh et al., 2008; and Upadhyay and Shaw, 2008). Mobile actin patches are also observed in distal regions of the hyphal tip cell (Taheri-Tahesh et al., 2008; Upadhyay and Shaw, 2008). An additional actin-based structure, the contractile actin ring, transiently appears in hyphal tip cells during septum formation (Harris, 2001). Results from genetic, molecular, and chemical analyses emphasize the importance of the actin cytoskeleton to hyphal morphogenesis (Torralba et al., 1998; Virag and Griffiths, 2004; Araujo-Bazan et al., 2008). The complete absence of actin filaments does not abolish growth per se but does block polarized hyphal growth and also prevents septum formation (Harris et al., 1994; Torralba et al., 1998). In particular, emerging evidence strongly implicates actin patches as sites of endocytosis and suggests that by analogy to yeast, a "comet tail" of highly branched actin filaments might drive vesicle internalization (Upadhyay and Shaw, 2008; Araujo-Bazan et al., 2008). Although direct evidence is still lacking, it seems likely that longer unbranched actin filaments (i.e., actin cables) mediate the localized transport of exocytic vesicles at the immediate hyphal tip (A. Virag and S. D. Harris, unpublished results). Finally, the essential function of the contractile actin ring during septum formation remains unknown. However, the analogous structure in both *S. pombe* and *S. cerevisiae* is known to provide a spatial landmark that recruits the machinery needed for deposition of the septal cell wall (Vallen et al., 2000; Vjestica et al., 2008).

Two general types of actin filament nucleating proteins are widely conserved in eukaryotes: the formins and Wiscott-Aldrich Syndrome protein (WASp). In general, formins nucleate actin cables and contractile actin rings, whereas

WASp directs the formation of branched actin filaments (summarized by Pollard, 2007; and Chhabra and Higgs, 2007). The underlying biochemical mechanisms have been extensively described in both yeasts and animals (Moseley and Goode, 2006; Pollard, 2007). Among filamentous fungi, formins have been characterized in *C. albicans*, *A. gossypii*, and *A. nidulans* (Harris et al., 1997; Sharpless and Harris, 2002; Li et al., 2005; Martin et al., 2005; Schmitz et al., 2006). *C. albicans* possesses two formins that apparently exhibit distinct localization patterns; Bni1 localizes to hyphal tips, and Bnr1 localizes to septa (Li et al., 2005; Martin et al., 2005). Nevertheless, neither is required for polarized hyphal growth or for the formation of septa in hyphae (the double *bni1 bnr1* mutant phenotype remains unknown). By contrast, despite the existence of two apparent homologues, *A. gossypii* Bni1 is required for the establishment of hyphal polarity (Schmitz et al., 2006). It localizes to hyphal tips, where it nucleates actin cables that appear to mediate localized vesicle delivery. Unlike *C. albicans* or *A. gossypii*, *A. nidulans* possesses only a single formin, SepA (note that all sequenced Pezizomycotina genomes possess only a single annotated formin [S. D. Harris, unpublished result]). Notably, *sepA* mutants can form hyphae, though they exhibit defects in the maintenance of hyphal polarity and cannot undergo septation because of failure to form the contractile actin ring at septation sites (Harris et al., 1997; Sharpless and Harris, 2002). An important implication of this phenotype is that polarized hyphal growth can occur in the absence of any formin-mediated actin nucleating activity. Because chemical inhibitor studies show that actin filaments are required for polarized hyphal growth (for an example, see Torralba et al., 1998), WASp-mediated nucleation of branched actin filaments presumably enables polarity establishment to occur in *sepA* mutants. Although WASp homologues have not yet been subjected to functional studies in members of the Pezizomycotina, analysis of the *C. albicans* homologue, Wal1, supports the existence of distinct formin- and WASp-mediated pools of actin filaments (Walther and Wendland, 2004; Martin et al., 2005).

Several different types of actin-associated proteins are known to modulate the stability and dynamics of actin filaments (for examples, see Kreis and Vale, 1995; and Moseley and Goode, 2006). These include filament bundling proteins, such as fimbrin and alpha-actinin, as well as proteins that disassemble or sever filaments, such as ADF/cofilins or gelsolin. Annotation of the *A. nidulans* and *N. crassa* genome sequences has revealed that filamentous fungi possess a larger complement of these proteins than do yeasts (Borkovich et al., 2004; Harris et al., 2009), which further underscores the greater complexity of actin filament dynamics in hyphae. In *A. nidulans*, recent results highlight the important role of fimbrin (FimA) in the establishment of hyphal polarity (Upadhyay and Shaw, 2008). In particular, FimA localizes to actin patches, where it mediates endocytosis by presumably bundling branched actin filaments. Notably, alpha-actinin (AcnA in *A. nidulans*) has a role in polarized hyphal growth and septum formation that is independent from that of fimbrin (A. Virag and S. D. Harris, unpublished results). These observations seemingly imply the existence of distinct pools of actin filaments that are bundled in a different manner, with one pool (regulated by FimA) supporting endocytosis and the other (regulated by AcnA) directing exocytosis.

Filamentous fungi possess a large repertoire of myosins that include members of multiple classes, including a novel class (class VI) composed of hybrid myosin/chitin synthases that are involved in polarized hyphal growth and septum formation (see chapter 16 for further details). The class I myosins (i.e., MyoA in *A. nidulans* and Myo5 in *C. albicans*) are required for the establishment of hyphal polarity and localize to hyphal tips (McGoldrick et al., 1995; Oberholzer et al., 2002), where MyoA might serve as a scaffold for WASp-dependent actin filament nucleation (Liu et al., 2001). Class V myosins (e.g., Myo5 in *U. maydis* and Myo2 in *C. albicans*) have also been implicated in polarized hyphal growth and localize to hyphal tips (Weber et al., 2003; Woo et al., 2003), where it has been suggested that they might mediate vesicle transport between the Spitzenkörper and the cell surface.

Microtubule Cytoskeleton

In fungal hyphae, cytoplasmic microtubules typically exist as longitudinal arrays oriented parallel to the axis of hyphal extension (Grove and Bracker, 1970; Howard, 1981; Hoch and Staples, 1983). It is generally thought that these microtubules originate from microtubule-organizing centers associated with nearby nuclei (summarized by Xiang and Fischer, 2004). Localization of microtubule plus-end binding proteins in *A. nidulans* and *U. maydis* shows that these microtubules extend into the hyphal tip and appear to make cortical contacts (Han et al., 2001; Zhang et al., 2003; Schuchardt et al., 2005). Nevertheless, recent evidence suggests that the tip region also harbors microtubule nucleation sites (Straube et al., 2003; Konzack et al., 2005), though the relationship between these sites and the Spitzenkörper remains unclear at this time. Upon entry into mitosis, cytoplasmic microtubules are depolymerized so that tubulin can be shuttled into nuclei to enable construction of the mitotic spindle (Riquelme et al., 2003; Ovechkina et al., 2003; Sampson and Heath, 2005). However, at least in *A. nidulans*, intact cytoplasmic microtubules are maintained at the hyphal tip, where they allow tip extension to continue as mitosis proceeds (Horio and Oakley, 2005). One possibility is that the tip-associated nucleation sites organize this particular pool of microtubules.

Two specific roles have been attributed to cytoplasmic microtubules in support of polarized hyphal growth. First, it is generally accepted that microtubules provide "tracks" for the long-range transport of vesicles from the interior regions of hyphae to the tip (summarized by Steinberg, 2007). Second, microtubules have been strongly implicated in positioning the Spitzenkörper within the hyphal tip, such that in their absence, hyphae cannot extend in a directed manner and exhibit irregular growth patterns (Riquelme et al., 1998; Konzack et al., 2005; Takeshita et al., 2008). Indeed, the latter phenotype (i.e., bent, curved, or kinked hyphae) is typically observed when microtubules are eliminated by mutations or chemical perturbations. However, emerging evidence highlights a far more fundamental role for microtubules in polarized hyphal growth. For example, the ability to sustain rapid hyphal tip extension rates in *A. nidulans* is dependent upon the presence of intact cytoplasmic microtubules (Horio and Oakley, 2005). In their absence, hyphae extend at a slower rate, characteristic of germlings. In addition, it has also been demonstrated that microtubules become essential for the establishment of hyphal polarity under conditions that compromise actin filament formation (i.e., *sepA* mutations in *A. nidulans* [Virag et al., 2007]).

Filamentous fungi possess an extensive set of microtubule-based motor proteins (see chapter 16 for further details). Plus-end-directed kinesins are largely responsible for anterograde transport towards the hyphal tip, whereas minus-end-directed dyneins mediate retrograde transport from the tip (summarized by Steinberg, 2007). In *U. maydis*,

the complete set of 10 kinesins have been characterized (Schuchardt et al., 2005), and as many as 7 kinesins may be involved in polarized hyphal growth. Results from this study suggest the existence of considerable redundancy among kinesins and dyneins and also emphasized the point that myosins and kinesins may act in parallel to mediate vesicle transport to the hyphal tip. In *A. nidulans*, the kinesin KipA is required for the localization, but not the transport, of the cell end markers TeaA and TeaR at the hyphal tip (Takeshita et al., 2008). These markers are part of a hyphal tip-anchoring complex that associates with sterol-rich membrane domains and maintains the position of the Spitzenkörper. Thus, in addition to vesicle transport, kinesins also mediate the ability of microtubules to ensure that hyphae extend in a directed manner.

Vesicle Trafficking

Polarized hyphal growth is driven by localized cell surface expansion and cell wall deposition at the hyphal tip. The precursors needed to support these processes are delivered to the tip in vesicles via exocytosis. The volume of vesicles undergoing transport to the tip is potentially staggering, given that hyphae are capable of extension rates as high as 7.5 mm/h (Lopez-Franco et al., 1994). Simultaneously, excess membrane material, along with other factors, such as possible landmark proteins, are presumably retrieved from the hyphal tip and recycled via endocytosis. Several recent studies have clarified the specific roles of exocytosis and endocytosis in polarized hyphal growth, and they have also revealed where these events occur in relation to the hyphal tip (Taheri-Tahesh et al., 2008; Upadhyay and Shaw, 2008; Araujo-Bazan et al., 2008).

The vesicle supply center model of hyphal tip extension in based on the premise that the radial distribution of vesicles from the Spitzenkörper is sufficient to generate the characteristic shape of the hyphal tip (Bartnicki-Garcia, 2002). According to this model, a gradient of exocytic vesicles would be delivered to the hyphal tip, with the peak immediately anterior to the Spitzenkörper. However, the actual site of vesicle delivery may be far more discrete than this model implies. In *S. cerevisiae*, Sec3 is a well-characterized exocyst component that provides a positional landmark for polarized exocytosis (Finger et al., 1998). The *A. nidulans* homologue of Sec3, SecC, localizes to a small region at the apex of the hyphal tip (Taheri-Talesh et al., 2008). Assuming that SecC shares a landmark function in common with yeast Sec3, this result considerably narrows the zone in which exocytic vesicles would presumably fuse with the plasma membrane. Furthermore, it has become increasingly apparent that exocytosis is spatially coupled to endocytosis at hyphal tips in a manner that resembles neuromuscular junctions and mating yeast cells (Gundelfinger et al., 2003; Valdez-Taubus and Pelham, 2003). Studies with *A. nidulans* reveal that several established markers for endocytosis, including FimA, AbpA (homologue of *S. cerevisiae* Abp1), AmpA (= *S. cerevisiae* Rvs167), and SlaB (= *S. cerevisiae* Sla2), colocalize with actin patches in a collar immediately behind the hyphal apex (Upadhyay and Shaw, 2008; Araujo-Bazan et al., 2008). Notably, vesicles that fuse with the plasma membrane at the site marked by SecC appear to be recycled by endocytosis at this collar (Taheri-Talesh et al., 2008). Other *A. nidulans* proteins potentially involved in specification of the endocytic zone include MesA and the septins (Westfall and Momany, 2002; Pearson et al., 2004). The presence of an endocytic zone immediately posterior to the exocytic zone provides an efficient mechanism for the retrieval of membrane material and cell surface proteins so that they can be recycled. A growing body of evidence supports the notion that a tip growth apparatus that encompasses the Spitzenkörper and other components, such as the polarisome, functions to maintain the coupling of endocytosis to exocytosis in rapidly growing hyphae (Araujo-Bazan et al., 2008; Taheri-Talesh et al., 2008). Because the tip growth apparatus is not observed in germlings, at least in *A. nidulans*, its formation apparently coincides with the transition to rapid hyphal extension.

The importance of exocytosis in supporting rapid hyphal tip extension is widely accepted. The dynamic kinesin-mediated transport of vesicles into the hyphal tip has been observed in *N. crassa* (Seiler et al., 1999). Furthermore, genetic screens for *A. nidulans* or *N. crassa* mutants defective in hyphal morphogenesis have consistently identified functions implicated in the formation and transport of exocytic vesicles. For example, in *A. nidulans*, mutations that compromise coatomer function or disrupt organization of the Golgi body prevent the formation of a stable polarity axis (Whittaker et al., 1999; Shi et al., 2004; Yang et al., 2008). In addition, a comprehensive *N. crassa* screen identified several functions required for exocytosis (i.e., coatomers and exocyst components) as being essential for polarized hyphal growth (Seiler and Plamann, 2003). On the other hand, support for the importance of endocytosis in rapid hyphal tip extension has only recently emerged. A significant advance was the demonstration that the lipophilic dye FM4-64, which monitors bulk membrane internalization, is recycled to the hyphal tip, where it labels the Spitzenkörper (Fischer-Parton et al., 2000). This observation suggested that endocytosis is involved in organizing the hyphal tip. Genetic analyses of *U. maydis* and *A. nidulans* support this notion. An *U. maydis* mutant with a defective endosomal t-SNARE exhibits morphological phenotypes that are suggestive of a failure to maintain hyphal polarity (Wedlich-Soldner et al., 2000; Fuchs et al., 2006). In *A. nidulans*, mutations affecting SlaB or FimA cause dramatic defects in the establishment of hyphal polarity (Upadhyay and Shaw, 2008; Araujo-Bazan et al., 2008). As an aside, despite its apparent importance to polarized hyphal growth, mutations that affect endocytosis are vastly underrepresented in the large collections of morphogenetic mutants that have been generated in *N. crassa* and *A. nidulans* when compared to mutations that disrupt exocytosis. The basis for this discrepancy is unknown, but one possibility is that endocytosis is essential for hyphal growth and is not as robust a process as exocytosis.

The source of exocytic vesicles that are transported to the hyphal tip is generally presumed to be the Golgi body. However, the location and nature of the Golgi body in filamentous fungi remain somewhat confusing issues. *C. albicans* hyphae possess discrete ER and Golgi complexes that are physically separated; the ER is largely confined to the cell body, whereas Golgi complexes are exclusively found near the hyphal tip (Rida et al., 2006). By contrast, other filamentous fungi such as *N. crassa* and *A. nidulans* contain endomembranous compartments that may in fact be contiguous ER and Golgi bodies (summarized by Markham, 1995). Recent evidence obtained using GFP-labeled probes predicted to reside in these compartments (i.e., chitin synthases and sialyltransferase) further suggests that they are motile and fragment into vesicles as they approach the tip (Riquelme et al., 2007; Hubbard and Kaminskyj, 2008). This would be consistent with the cisternal maturation model of Golgi transport, whereby a single Golgi compartment undergoes maturation from early to late as defined by its resident glycoprotein-modifying enzymes (the alternate "traditional" model posits the existence of distinct early,

middle, and late compartments [summarized by Malhotra and Mayor, 2006]). This would also imply that exocytic vesicles might originate from sites that are far more proximal to the hyphal tip than previously thought. A final observation that further underscores the complexity of vesicle dynamics in filamentous fungi is the likely existence of different Golgi complexes. Distinct populations of exocytic vesicles are found in the Spitzenkörper (summarized by Harris et al., 2005): a class of larger vesicles (70 to 90 nm) known as apical vesicles, which presumably mediate bulk secretion, and a class of smaller vesicles (30 to 40 nm) known as chitosomes, which appear to possess chitin synthase activity. This distinction appears to exist at the level of Golgi complexes as well; GFP-labeled chitin synthases localize to Golgi complexes different from those labeled with conventional Golgi markers (Riquelme et al., 2007).

REGULATION OF POLARIZED GROWTH

Ras- and Rho-Related GTPases

Monomeric GTPases possess a universally important role in the regulation of growth and cellular morphogenesis in eukaryotes (Ridley, 2001; Hall, 2005), including fungi. Extensive analyses of *S. cerevisiae* and *S. pombe* have implicated both Ras- and Rho-related GTPases in the control of cell proliferation and morphogenesis (Chang and Philips, 2006; Garcia et al., 2006; Park and Bi, 2007). In both yeasts, the Rho-related GTPase Cdc42 sits at the nexus of the signaling pathways that regulate polarized growth. It is locally activated by cell-type-specific positional landmarks and in turn activates several effectors that recruit the morphogenetic machinery to enable cell surface expansion and cell wall deposition. In addition, as originally observed in animal cells (summarized by Chant and Stowers, 1995), yeast GTPases are apparently linked in a regulatory cascade (i.e., Ras → Cdc42 → Rho) that drives polarized growth (Chant, 1999; Pruyne and Bretscher, 2000). The characterization of Ras- and Rho-related GTPases in filamentous fungi is still in its infancy. Nevertheless, important differences from the model yeasts have already emerged.

The first Ras homologue characterized in filamentous fungi was RasA from *A. nidulans* (Som and Kolaparthi, 1994). Genetic analyses suggest that RasA acts in parallel with protein kinase A to regulate the germination of conidiospores and also has additional roles in the regulation of development (Fillinger et al., 2002). Notably, constitutively activated RasA (i.e., RasA-GTP) triggers prolonged isotropic expansion of the spore and inhibits the establishment of hyphal polarity (Som and Kolaparthi, 1994; Osherov and May, 2000). The basis of this phenotype still remains unknown, but it likely reflects an inability to spatially and temporally coordinate growth signals with morphogenesis. Subsequent to the identification of RasA, Ras homologues have been characterized in several filamentous fungi (for examples, see Alspaugh et al., 2000; Lee et al., 2002; Ha et al., 2003; Park et al., 2006; and Bluhm et al., 2007), and like RasA, most of these are homologues of *S. cerevisiae* Ras1 or Ras2 that function to coordinate morphogenesis with growth and/or development (often as upstream regulators of mitogen-activated protein [MAP] kinase signaling modules). For example, Ras function is required in several dimorphic fungi to enable the switch from yeast-like growth to filamentous hyphal growth (Alspaugh et al., 2000; Lee and Kronstad, 2002; Muller et al., 2003).

Filamentous fungi possess an additional Ras homologue that appears to have a more intimate role in morphogenesis than RasA. These proteins share homology with *S. cerevisiae* Rsr1, which couples bud site selection to polarity establishment in yeast (Park and Bi, 2007). *A. gossypii* Rsr1 (AgRsr1) is required for the maintenance of a stable polarity axis (Bauer et al., 2004). A*grsr1* mutants exhibit slow colony growth and produce misshapen hyphae that are often kinked or bent. This morphology results from the frequent pausing of hyphal extension followed by reinitiation along a different axis from the one that was previously used. AgRsr1 localizes to the hyphal tip, where it appears to organize actin filaments by stabilizing the polarisome. *C. albicans* Rsr1 (CaRsr1) has also been implicated in the regulation of hyphal guidance (Hausauer et al., 2005). In addition, CaRsr1 mediates the ability of *C. albicans* hyphae to reorient their growth direction in response to external environmental cues such as electrical fields (galvanotropic growth) or surface contours (thigmotropic growth) (Brand et al., 2008). The only other predicted Rsr1 homologue to be characterized is *A. fumigatus* RasB. Remarkably, *rasB* mutants cannot maintain a stable axis of hyphal polarity and undergo frequent branching from the hyphal tip (Fortwendel et al., 2005). Whether this reflects a role in stabilization of the polarisome remains to be determined. Nevertheless, at least in those filamentous fungi that belong to the Saccharomycotina and Pezizomycotina, Rsr1 seemingly promotes directed hyphal extension as part of a spatial regulatory mechanism that responds to internal and external cues.

In animal cells, Cdc42 and the closely related GTPase Rac1 act in a sequential manner to generate cell polarity (Chant and Stowers, 1995). Homologues of Cdc42 have been identified and characterized in a diverse array of filamentous fungi (for examples, see Boyce et al., 2001; Scheffer et al., 2005a; Chen et al., 2004; and Virag et al., 2007). Moreover, unlike the yeasts *S. cerevisiae* and *S. pombe*, filamentous fungi also possess a Rac1 homologue (Boyce et al., 2003; Chen and Dickman, 2004; Mahlert et al., 2006; Virag et al., 2007; Rolke and Tudzynski, 2008; Tanaka et al., 2008). The relative importance of Cdc42 and Rac1 in the regulation of polarized hyphal growth appears to vary between different fungi. Within the Saccharomycotina, Cdc42 clearly has the predominant role in promoting hyphal polarity (Park and Bi, 2007). Neither *A. gossypii* nor *C. albicans cdc42* mutants are capable of generating polarized hyphae (Wendland and Philippsen, 2001; Ushinsky et al., 2002); the *A. gossypii* mutant forms swollen spores with a disorganized actin cytoskeleton. The localization of *C. albicans* Cdc42 to the polarisome (it may also associate with the Spitzenkörper) is consistent with the notion that it acts via multiple effectors to locally organize the morphogenetic machinery (Crampin et al., 2005). By contrast, the *C. albicans* Rac1 homologue is completely dispensable for hyphal growth except under conditions where cells are embedded in a matrix (Bassilana and Arkowitz, 2006). In addition, *C. albicans* Rac1 and Cdc42 share no functional overlap. Thus, Saccharomycotina Rac1 homologues appear to affect hyphal growth only under specific circumstances.

Outside the Saccharomycotina (i.e., in the Pezizomycotina or the Basidiomycetes), both Rac1 and Cdc42 are involved in polarized hyphal growth, though their relative contributions vary quite considerably. For example, in *U. maydis*, Rac1 is necessary and sufficient for the formation of dikaryotic hyphae, whereas Cdc42 is only needed for cell separation following septum formation (Mahlert et al., 2006). However, because a *rac1 cdc42* double-deletion mutant is only capable of isotropic growth, *U. maydis* Rac1 and Cdc42 share at least one function required for the establishment of hyphal polarity. In *E. festucae* and the related grass

pathogen *Claviceps purpurea*, deletion of *rac1* severely compromises hyphal extension and triggers massive hyperbranching (Rolke and Tudzynski, 2008; Tanaka et al., 2008). By contrast, other than a modest hyperbranching phenotype, deletion of *C. purpurea cdc42* does not dramatically alter hyphal morphology (Scheffer et al., 2005a). Unlike these fungi, Cdc42 does have a prominent morphogenetic function in *A. nidulans*, where it is required for normal hyphal morphology and for the formation of lateral branches (Virag et al., 2007). Furthermore, *A. nidulans* Cdc42 localizes to a surface crescent at the hyphal tip, and genetic analyses suggest that it likely acts upstream of the polarisome. Although *A. nidulans* Rac1 has no apparent role in hyphal morphogenesis under normal conditions, it can function as a substitute of Cdc42 and, as observed in *U. maydis*, a *cdc42 rac1* double-deletion mutant is inviable (Virag et al., 2007). In the dimorphic human pathogen *Penicillium marneffei*, Rac1 localizes to septation sites and is involved in septum formation (Boyce et al., 2003). In addition, it also localizes to hyphal tips, where it acts in coordination with Cdc42 to maintain normal hyphal morphology (Boyce et al., 2005a). Collectively, these observations suggest that there is no general consensus regarding the relative roles of Cdc42 and Rac1 in polarized hyphal growth. Presumably, at least one of these GTPases must localize to the hyphal tip to organize the actin cytoskeleton and the vesicle trafficking machinery. Thereafter, their precise functions in morphogenesis and development have probably evolved in response to specific ecological challenges faced by different filamentous fungi.

Filamentous fungi typically possess additional Rho GTPases besides Cdc42 and Rac1 (i.e., Rho1-4) (for an example, see Borkovich et al., 2004). However, the function of these GTPases is generally not that well characterized. As initially established in yeast, Rho1 homologues likely contribute to hyphal morphogenesis as regulatory subunits of β-(1-3)-glucan synthase (for an example, see Qadota et al., 1996). Biochemical studies with *A. fumigatus* and *C. albicans* demonstrate that Rho1 copurifies with the glucan synthase complex (Kondoh et al., 1997; Beauvais et al., 2001), and genetic analyses show that *rho1* mutations compromise cell wall integrity (Guest et al., 2004). Rho1 impacts additional morphogenetic pathways in *S. cerevisiae* (i.e., activation of the formin Bni1 and regulation of exocyst function [Park and Bi, 2007]); thus, it is likely that the aberrant hyphal morphologies observed in fungal *rho1* mutants are not solely due to defective regulation of glucan synthases. Among the other Rho GTPases found in filamentous fungi, initial insight into the function of Rho3 and Rho4 has been obtained. In *A. gossypii*, Rho3 acts to maintain polarisome stability at hyphal tips as a downstream effector of the signaling protein Boi1/2 (Knechtle et al., 2006). In the absence of Rho3, hyphal polarity is transiently lost. However, unlike the *rsr1* mutant described above, *rho3* mutants reestablish hyphal polarity along the previously existing axis, thereby suggesting that positional cues are not lost. *C. albicans* Rho3 is also required for normal hyphal morphogenesis (Dunkler and Wendland, 2007). Rho4 is a unique Rho GTPase that is not conserved in *S. cerevisiae* (yeast Rho4 is a paralogue of Rho3). Characterization of *N. crassa* Rho4 shows that it is absolutely essential for the formation of the contractile actin ring at septation sites (Rasmussen and Glass, 2005). In addition, Rho4 contributes to hyphal morphogenesis by regulating microtubule organization and stability (Rasmussen et al., 2008). Preliminary observations suggest that Rho4 performs similar functions in *A. nidulans* (H. Si and S. D. Harris, unpublished results).

In *S. cerevisiae* and *S. pombe*, Ras and Rho-related GTPases function in a coordinated manner to direct cellular morphogenesis. For example, Ras acts upstream of Cdc42 in both yeasts (for examples, see Chang et al., 1994; and Mosch et al., 1996), and antagonistic interactions between Cdc42 and Rho1 have been described in *S. cerevisiae* (Gao et al., 2004). Although similar relationships undoubtedly exist in filamentous fungi, only a limited number of examples have so far been demonstrated. These include the observation that the effects of Ras1 on hyphal morphology and branch formation are mediated in part by Cdc42 in *P. marneffei* (Boyce et al., 2005a). Moreover, in the plant pathogen *Colletotrichum trifolii*, Ras1 regulates hyphal morphology by activating Rac1, which in turn controls MAP kinase activation and ROS production (Chen and Dickman, 2004). More extensive analysis is clearly needed to investigate the functional relationships between these GTPases in filamentous fungi. Furthermore, it would not be surprising to find that these relationships vary between different fungi as a function of their lifestyle and evolutionary history.

GEFs and GAPs

The activity of monomeric GTPases is controlled by a set of proteins that determine their GTP-binding status and regulate their association with membranes (Rossman et al., 2005; Tcherkezian and Lamarche-Vane, 2007). Guanine nucleotide exchange factors (GEFs) are positive regulators that activate monomeric GTPases by exchanging GDP for GTP. GTPase-activating proteins (GAPs) are negative regulators that boost the intrinsic GTP hydrolysis rate of GTPases and thus facilitate conversion back to a GDP-bound state. By virtue of their ability to determine where and when Ras and Rho-related GTPases are active, GEFs and GAPs play a key role in the coordination of morphogenesis with growth and development. For example, several studies with *S. cerevisiae* demonstrate that Cdc42 GEFs (e.g., Cdc24) and GAPs (e.g., Rga1, Rga2, and Bem3) are dually regulated by Cdks to coordinate bud emergence with cell cycle progression (McCusker et al., 2007; Sopko et al., 2007; Knaus et al., 2007). In addition to GEFs and GAPs, Rho dissociation inhibitors also down-regulate Rho-related GTPases by extracting them from membranes while they are in a GDP-bound state, such that they can no longer be accessed by GEFs for reactivation (Dovas and Couchman, 2005).

The deepest insight into the roles of GEFs and GAPs in polarized hyphal growth comes from studies of Cdc42 regulation in *C. albicans*. As might be expected for a positive regulator of Cdc42, *C. albicans* strains with reduced levels of Cdc24 have defects in polarized hyphal growth similar to those of *cdc42* mutants, and like Cdc42, Cdc24 also localizes to hyphal tips (Bassilana et al., 2005). By contrast, the Cdc42 GAP Rga2 appears to be excluded from hyphal tips (Zheng et al., 2007). Notably, the Hgc1-Cdc28 Cdk complex associates with and inactivates Rga2 to enable localized activation of Cdc42 and germ tube emergence. These observations show that hyphal growth in *C. albicans* is dependent upon the concerted regulation of both Cdc42 GEFs and GAPs. Cdc24 mutants have also been characterized in *A. gossypii* and *N. crassa*; in both cases the establishment of hyphal polarity is abolished, and at least in *A. gossypii*, the actin cytoskeleton remains depolarized (Wendland and Philippsen, 2001; Seiler and Plamann, 2003). Mutations affecting Cdc42 GAPs have not been generated in other filamentous fungi (note that the *A. gossypii* Rho1 GAP Bem2 has been shown to regulate the establishment and maintenance of hyphal polarity [Wendland and Philippsen, 2000]). However, given the prevailing view that negative

regulation of Cdc42 (or possibly Rac1) plays a critical role in breaking cellular symmetry, it seems reasonably likely that they will be intimately involved in hyphal morphogenesis.

The role of Ras GEFs and GAPs in polarized hyphal growth has also been addressed to a limited extent. In *U. maydis*, Sql2 is a likely GEF for Ras2, although its deletion does not adversely affect hyphal morphogenesis (Muller et al., 2003). However, two different Ras GAPs have been implicated in the regulation of polarized hyphal growth. *C. albicans* Bud2 specifies the use of normal branch sites (i.e., adjacent to septa) through its predicted ability to promote GTP cycling of Rsr1 (Hausauer et al., 2005). In *A. nidulans*, the Ras GAP GapA localizes to hyphal tips, where it presumably down-regulates RasA to permit normal actin organization and hyphal growth (Harispe et al., 2008). In addition, the loss of GapA allows germinating spores to initiate isotropic expansion in the absence of a growth signal. The analysis of *gapA* and *rasA* mutants in *A. nidulans* suggests that active Ras interferes with the formation of a stable axis of hyphal polarity. Accordingly, it seems likely that Ras GAPs will be key determinants that coordinate growth with polarized hyphal growth.

Protein Kinases

Several different classes of protein kinases have been implicated in the regulation of polarized hyphal growth in filamentous fungi. In many cases, particularly for dimorphic fungi such as *C. albicans*, *U. maydis*, and *C. neoformans*, MAP kinases have a vital role in the signaling pathways that coordinate morphogenesis with growth conditions under both normal and adverse conditions. Fungal MAP kinases have been extensively reviewed elsewhere (for an example, see Bahn et al., 2007) and are thus not considered here. However, two other classes of protein kinases that do have a more direct role in hyphal morphogenesis, the p21-activated kinases (PAKs) and the nuclear Dbf2-related kinases (NDRs), merit further attention. The PAKs are well-known effectors of Cdc42 and Rac GTPases (Arias-Romero and Chernoff, 2008), whereas NDRs are AGC family kinases that in some cases function downstream of PAKs (Hergovich et al., 2006).

Two PAKs, Ste20 and Cla4, both of which were initially characterized in *S. cerevisiae*, are involved in polarized hyphal growth. In *C. albicans*, Ste20 functions as a MAP kinase activator (i.e., a MAPKKKK) that is required for hyphal formation under some conditions (Leberer et al., 1996). Cla4 is also required for hyphal growth; *cla4* mutants produce short malformed germ tubes that fail to grow into long hyphae (Leberer et al., 1997). Both Ste20 and Cla4 possess CRIB domains that mediate interactions with Cdc42 that are necessary for the yeast-to-hyphal switch in *C. albicans* (Su et al., 2007). As in *C. albicans*, *A. gossypii cla4* mutants produce short hyphae that fail to undergo the transition to rapid hyphal growth and apical branching (Ayad-Durieux et al., 2000). In addition, *A. gossypii* Cla4 localization to hyphal tips correlates with this transition. Thus, in the Saccharomycotina, Cla4 is not needed per se for the formation of polarized hyphae, but hyphae cannot achieve their maximal extension rates in its absence. Recent results suggest that a hyphal tip-localized paxillin homologue (i.e., Pxl1) might be a Cla4 substrate that mediates hyphal maturation in *A. gossypii* (Knechtle et al., 2008).

In other filamentous fungi, Cla4 homologues have also been shown to affect hyphal morphogenesis. Deletion of *C. purpurea cla4* prevents the formation of a stable axis of hyphal polarity and results in compact, hyperbranched mycelial colonies (Rolke and Tudzynski, 2008). In this fungus, as well as in *U. maydis*, compelling evidence suggests that Cla4 is a downstream effector of Rac1 and that the Cla4 CRIB domain mediates their interaction (Mahlert et al., 2006; Rolke and Tudzynski, 2008). In other fungi (e.g., *M. grisea* and *C. neoformans*), Cla4 does not have as important a role in maintaining hyphal polarity but is involved in morphogenetic processes such as hyphal branching and cell fusion (Li et al., 2004; Nichols et al., 2004). In these cases, the "division of labor" may be more equitably split between the two PAKs, such that polarized hyphal growth would only be severely compromised by simultaneous deletion of both *cla4* and *ste20*. Nevertheless, Ste20 alone does regulate polarity maintenance in *C. neoformans* as well as spore germination in *P. marneffei* (Nichols et al., 2004; Boyce and Andrianopoulos, 2007). Ultimately, it seems likely that no common theme will emerge for the respective roles of different PAKs in hyphal morphogenesis. Although PAK activity is undoubtedly necessary for polarized hyphal growth, the relative functions of Ste20 and Cla4 in a given filamentous fungus presumably reflect its lifestyle and evolutionary history.

In the model yeasts, NDRs regulate mitotic exit (*S. cerevisiae* Dbf2), septum formation (*S. pombe* Sid2), and polarized growth (*S. cerevisiae* Cbk1 and *S. pombe* Orb6) (summarized by Hergovich et al., 2006). Though numerous genetic and physical interactions have been documented, the mechanisms by which yeast NDRs affect polarized growth are not known. One possibility, as recently suggested for *S. pombe* Orb6, is regulation of Cdc42 GAPs (Das et al., 2007). Far less is known about the roles of NDR kinases in hyphal morphogenesis, though one family member, Cot1 (=Cbk1/Orb6) has been implicated in polarized hyphal growth in several filamentous fungi (e.g., *N. crassa*, *A. nidulans*, *C. trifolii*, and *C. purpurea* [Yarden et al., 1992; Chen and Dickman, 2002; Scheffer et al., 2005b; Johns et al., 2006]). In these fungi, deletion of Cot1 results in the loss of hyphal polarity and triggers excessive formation of lateral branches. *N. crassa* COT-1 has been localized to the plasma membrane as well as to the cytoplasm, where it exhibits a vesicular/reticulate localization pattern (Gorovits et al., 2000; Seiler et al., 2006). A somewhat similar staining pattern was observed for *A. nidulans* Cot1, with occasional localization to the hyphal tip also noted (Johns et al., 2006). Detailed genetic analyses of *N. crassa* have shown that COT-1 functionally interacts with POD-6, a member of the GCK subfamily of Ste20 kinases (i.e., Ste20 kinase homologues with no CRIB domain) (Seiler et al., 2006). Furthermore, this interaction apparently contributes to polarized hyphal growth in a dynein/kinesin-dependent manner, because localization of both COT-1 and POD-6 is disrupted by mutations affecting microtubule motors. In addition, the loss of dynein function readily suppresses defects caused by *cot-1* mutations in *N. crassa* (Bruno et al., 1996b). When considered in light of the known functions and interactions of *S. pombe* Orb6, the characterization of *N. crassa* COT-1 seems to suggest that NDR kinases may participate in defining the zone of polarized growth at hyphal tips. However, further investigation in a broader range of filamentous fungi will be needed to obtain a deeper understanding of how these kinases regulate polarized hyphal growth. In particular, it will be important to determine how NDR and PAK kinases function relative to each other as well as to the monomeric GTPases that regulate hyphal morphogenesis.

Positional Markers

Polarized hyphal growth can be distilled down to a relatively simple task: organize the morphogenetic machinery so that vesicles carrying the components needed for cell surface expansion and cell wall deposition are targeted to a discrete

location that defines the hyphal tip. Although several monomeric GTPases and protein kinases have been implicated in the localized recruitment of the morphogenetic machinery, a key unanswered question is how these signaling components are locally activated. In other words, what is the nature of the positional markers, if any, that define the hyphal tip? Perhaps the best-known positional markers in fungi are those that specify the pattern of bud site selection in *S. cerevisiae* (Chant, 1999; Chang and Peter, 2003). However, with a few notable exceptions (Bud3 and Bud4/Int1), these markers are not that well conserved in organisms other than yeast and its immediate relatives (Gale et al., 2001; Wendland, 2003; Harris and Momany, 2004). Thus, filamentous fungi presumably employ an alternate mechanism to generate positional signals at the hyphal tip. At this time, there appear to be two reasonable possibilities. First, homologues of the complex used to mark cell ends in *S. pombe* are conserved in *A. nidulans* and are necessary for directed hyphal extension (Takeshita et al., 2008). In this complex, TeaR (= *S. pombe* Mod5) functions as a membrane-associated receptor for TeaA (= *S. pombe* Tea1), which is delivered on the plus end of microtubules and likely facilitates localized actin filament formation by recruiting the formin SepA. If the formation of this complex is disrupted, hyphae exhibit meandering growth because of failure to properly position the Spitzenkörper at the hyphal tip. Furthermore, the localization of both TeaR and TeaA at hyphal tips is dependent upon the presence of intact sterol-rich membrane domains (SRDs). Previous results show that these domains, which are defined by filipin staining and presumably represent aggregates of sphingolipid- and sterol-rich lipid rafts, localize to hyphal tips and are needed for polarized hyphal growth (Martin and Konopka, 2004; Pearson et al., 2004; Li et al., 2006; Alvarez et al., 2007). Collectively, these observations suggest an attractive mechanism whereby SRDs confined to the hyphal tip are able to locally organize the actin and microtubule cytoskeleton to maintain a stable axis of hyphal growth. Nevertheless, it remains to be determined how the SRDs are themselves generated in the correct location. In addition, because *teaR* and *teaA* mutants can still produce polarized hyphae, this mechanism cannot account for the initial establishment of a polarity axis during spore germination or hyphal branching.

A second possible mechanism for the positional marking of polarized growth sites in fungal hyphae is the use of tip high gradients of calcium and/or ROS (Jackson and Heath, 1993; Semighini and Harris, 2008). The likely role of these gradients in enforcing apical dominance presumably reflects their ability to mark the hyphal tip as the zone of active growth. By analogy to *Arabidopsis* root hairs, calcium and ROS could conceivably generate interdependent gradients that promote calcium influx only at the apex of the hyphal tip (Takeda et al., 2008). Because of its ability to modulate Cdc42 signaling (i.e., by binding to the GEF Cdc24 [Miyamoto et al., 1991]), calcium could subsequently trigger monomeric GTPase signals that locally recruit and activate the morphogenetic machinery.

It is also worth noting that positional landmarks may not be needed for the establishment of hyphal polarity or even for its subsequent maintenance. Whereas yeast cells possess obvious landmarks that can provide a template for a new polarity axis (for example, bud scars or birth scars in *S. cerevisiae* or the old end of *S. pombe* cells), no such marker has yet been identified for a filamentous fungus. Furthermore, although fungal hyphae display well-known tropisms (i.e., thigmotropism and galvanotropism [Brand et al., 2007]), examples of environmental cues that generate a polarity axis during spore germination or lateral branching have not yet been described. This does not imply that such a phenomenon does not exist, as, for example, the host surface undoubtedly plays some sort of role in directing the axis of spore polarization in plant pathogenic fungi (for an example, see Hardham, 2001). Nevertheless, there is sufficient reason to believe that spores undergoing isotropic expansion can generate a polarity axis at a random site. Clear precedence for this has emerged from studies of *S. cerevisiae*, where intertwined feedback loops can amplify initially stochastic fluctuations in Cdc42 levels to break cellular symmetry in the absence of any known positional landmark (Ozbudak et al., 2005). A key premise underlying "stochastic polarization" in yeast is the coupling of localized exocytosis at the polarization site to endocytosis in flanking regions (Wedlich-Soldner et al., 2003; Marco et al., 2007). Because the recently described tip growth complex of *A. nidulans* essentially provides a mechanism for accomplishing this (Taheri-Talesh et al., 2008), the maintenance of a stable polarity axis in rapidly extending hyphae may not necessarily require the presence of a positional landmark. If a similar complex exists on germinating spores (the tip growth complex has been observed only in mature hyphae), the initial establishment of hyphal polarity may also be independent of any landmark.

When considering the identity of positional markers that might influence the specification of a polarity axis during hyphal morphogenesis, the possible roles of nuclei cannot be ignored. Although spore polarization is apparently not dependent upon nuclear division in filamentous fungi (for an example, see Harris, 1999), anecdotal observations do suggest that nuclei are capable of determining the number and position of germ tubes that emerge from swollen spores. For example, a handful of *A. nidulans* mutants produced large multinucleate spores that eventually yielded germ tubes (i.e., *fimA* and *swoA* mutants shifted to permissive temperature [Momany et al., 1999; Upadhyay and Shaw, 2008]). Notably, when these spores polarize, they often generate multiple germ tubes that emerge simultaneously. However, if nuclear division is blocked, the resulting swollen uninucleate spores produce only a single germ tube (H. Tedford and S. D. Harris, unpublished observations). It has also been demonstrated that nuclear signals play a critical role in specifying septation sites in *A. nidulans* (Wolkow et al., 1996). Thus, nuclei could potentially facilitate the generation of a positional landmark that specifies a polarity axis. One context in which this might be important is in spores that have already produced one germ tube. In this case, the second germ tube is highly biased towards the opposite hemisphere of the spore (i.e., the bipolar germination pattern [Harris et al., 1999]). Assuming that nuclear division precedes the emergence of the second germ tube, astral microtubules emanating from the poles of a mitotic spindle aligned along the primary polarity axis could conceivably deposit a membrane marker that ensures the second germ tube emerges at a ~180° angle relative to the first.

SRDs

The possible role of SRDs in the regulation of polarized hyphal growth has drawn considerable interest over the past few years. As previously noted, these domains are defined by filipin staining and presumably represent aggregates of sphingolipid- and sterol-rich lipid rafts that localize to hyphal tips (Alvarez et al., 2007). The importance of lipid rafts in highly polarized growth has been amply documented in animals (e.g., neurons [Guirland et al., 2004]). SRDs have also been described in the model yeasts and implicated

in the formation of polarized mating projections (Proszynski et al., 2006) as well as in cytokinesis (Takeda et al., 2004). Their relevance to polarized hyphal growth is based upon two sets of observations. First, SRDs localize to hyphal tips in several filamentous fungi, including *C. albicans*, *C. neoformans*, *A. nidulans*, and *Fusarium graminearum* (note that, at least in *A. nidulans*, they also localize to septa) (Martin and Konopka, 2004; Nichols et al., 2004; Pearson et al., 2004; Rittenour and Harris, 2008). Second, disruption of SRD organization and/or formation destabilizes existing polarity axes and likely blocks the formation of new ones (Cheng et al., 2001; Martin and Konopka, 2004; Pearson et al., 2004; Li et al., 2006). These effects are triggered by chemical treatments (myriocin, filipin, and ketoconazole) and mutations (e.g., *A. nidulans aurA*, *mesA*, *barA*, and *basA*) that affect the synthesis of sphingolipids and sterols. Because these same treatments and mutations also disrupt the organization of the actin cytoskeleton at hyphal tips (Pearson et al., 2004; Li et al., 2006), it seems likely that SRDs function in some manner to regulate actin filament formation. As characterized in *A. nidulans*, one potential mechanism by which SRDs presumably accomplish this is by recruitment of the TeaR-TeaA complex to hyphal tips, which in turn promotes localization of the formin SepA (Takeshita et al., 2008). Nevertheless, other fungal proteins known to associate with lipid rafts (i.e., GPI-anchored proteins and superoxide dismutase [Siafakas et al., 2006]) are likely components of SRDs, where they too could influence polarized hyphal growth by regulating recruitment of the morphogenetic machinery.

Septins

The septins are GTP-binding proteins that form higher-order structures involved in diverse aspects of cellular morphogenesis (Weirich et al., 2008). They were first identified and characterized in *S. cerevisiae*, where they are required for cytokinesis and regulate bud morphology (Longtine et al., 1996). Subsequent studies have shown that the septins are broadly conserved in fungi and animals. They can be assigned into seven distinct subgroups, five of which are represented in fungi, including one that appears to be specific to the filamentous fungi (Pan et al., 2007). The role of septins in polarized hyphal growth remains an area of active investigation, but insights have emerged from several different studies (Douglas et al., 2005). During the yeast-to-hyphal transition in *C. albicans*, a septin band forms at the base of the emerging germ tube and a septin cap appears at its tip (Warenda and Konopka, 2002). As the germ tube elongates, these structures then disappear prior to the organization of a septin collar within the germ tube itself. Ultimately, the collar splits into two rings, between which the primary septum is deposited. Genetic analyses demonstrate that two of the *C. albicans* septins (Cdc3 and Cdc12) are essential, whereas deletion of two others (Cdc10 and Cdc11) adversely impacts hyphal morphogenesis (Warenda and Konopka, 2002). Based on these observations, it seems likely that the septin band facilitates germ tube emergence possibly by marking the polarization site and recruiting the morphogenetic machinery. Once the germ tube has formed, the septin ring is required for septum formation. Notably, the fifth *C. albicans* septin, Sep7, controls the stabilization of the septin ring and prevents the recruitment of components needed for septum degradation (*sep7* mutants form hyphae in which cells separate due to degradation of the primary septum [Gonzalez-Novo et al., 2008]). Additional observations implicate the septin ring in the regulation of hyphal extension. Prior to formation of the ring, the septin cap likely directs exocytosis to the hyphal tip in a process mediated in part by binding of Cdc11 to the exocyst component Sec3 (Li et al., 2007; Sinha et al., 2007). Once the cap disappears and the septin ring forms, Cdk-dependent (i.e., Ccn1-Cdc28) phosphorylation of Cdc11 weakens its affinity for Sec3, thereby ensuring that the exocyst continues to target exocytosis to the hyphal tip and not to the incipient septation site. This transition may in fact mark the point of hyphal maturation in *C. albicans*.

Compared to *C. albicans*, much less is known about septin function in other filamentous fungi. *A. gossypii* septins localize to the hyphal tip and branch sites as discontinuous rings (Helfer and Gladfelter, 2006). Mitosis occurs in an asynchronous manner in *A. gossypii* (Gladfelter, 2006a), and septin ring localization appears to be a key determinant that specifies zones of mitotic activity (Helfer and Gladfelter, 2006). This is based on the observations that mitotic nuclei are predominantly found adjacent to septin rings and that mitosis occurs at random sites in a septin mutant. By providing a scaffold for the localized recruitment of factors that promote mitosis, the septins presumably ensure a ready supply of nuclei to support the extension of active hyphal tips in *A. gossypii*. A correlation between septin localization and lateral branching has also been noted in *A. nidulans* (Westfall and Momany, 2002). In this case, the septin AspB (=Cdc3) exhibits premitotic localization to incipient branch sites and persists at the base of the branch, while adjacent nuclei enter mitosis. The ability of septins to coordinate branching with mitosis in divergent filamentous fungi that employ different modes of mitosis (i.e., asynchronous versus parasynchronous) suggests that this is a universal feature of these proteins. Genetic analysis of *A. nidulans* and *U. maydis* has revealed additional roles for septins in hyphal morphogenesis and septum formation, as well as in developmental processes (Westfall and Momany, 2002; Boyce et al., 2005b).

Although a great deal remains to be learned about the function of septins in polarized hyphal growth, they rightfully deserve their label as crucial determinants of cell morphology in filamentous fungi (Gladfelter, 2006b). As scaffolds capable of recruiting multiple regulators, they seemingly play a key role in the temporal and spatial coordination of both branch formation and septation with mitosis. In addition, based on their known functions in *S. cerevisiae*, septins could conceivably promote compartmentalization of the cell surface at hyphal tips (Lindsey and Momany, 2006). For example, they might act as "fences" to define the boundaries of SRDs. Finally, limited evidence already suggests that septins likely determine patterns of hyphal morphogenesis. This includes their apparent role in regulating the maturation of *C. albicans* hyphae (Sinha et al., 2007). Moreover, in *A. nidulans*, the asymmetric localization of AspB on the apical side of completed septa raises the possibility that they act as markers that specify the overall polarity of a growing hypha (Westfall and Momany, 2002). Future studies will undoubtedly uncover additional regulatory functions for septins in fungal hyphae. Nevertheless, it will soon be necessary to begin the search for relevant septin-associated proteins that mediate these functions.

ROLES OF THE SPITZENKÖRPER AND POLARISOME IN POLARIZED HYPHAL GROWTH

Localization and Composition of the Polarisome

In *S. cerevisiae*, a group of proteins consisting of Spa2, Bud6, and Pea2 localize to a cell surface crescent at the incipient

bud site and cosediment as a 12S complex upon sucrose density gradient centrifugation (Sheu et al., 1998; summarized by Sudbery and Court, 2007). This complex, which was termed the polarisome, is thought to mediate the formation of actin filaments by the formin Bni1 in response to Cdc42 signals. Besides activating Bni1 at the incipient bud site, Cdc42 has also been implicated in the recruitment of Spa2 (Rida and Surana, 2005). In turn, both Spa2 and Bud6 are known to facilitate Bni1 function; Spa2 promotes stable localization of Bni1, whereas Bud6 stimulates Bni1 actin-nucleating activity (Ozaki-Kuroda et al., 2001; Sagot et al., 2002). The function of Pea2 relative to Cdc42 and Bni1 remains a mystery. In addition to their roles in the regulation of actin filament formation, Spa2 and Bud6 are involved in other aspects of cellular morphogenesis in *S. cerevisiae*. For example, Spa2 interacts with numerous proteins, including the MAP kinase Slt2, the Rab GAPs Msb4/Msb4, and the Cdc42 effectors Gic1/Gic2 (for examples, see Sheu et al., 1998; Jaquenoud and Peter, 2000; van Drogen and Peter, 2002; and Tcheperegine et al., 2005), thereby suggesting that it provides a scaffold for multiple steps of cellular morphogenesis. Bud6 has an additional role in microtubule capture at the cell cortex (Segal et al., 2000). These functions are presumably independent of Spa2 and Bud6 association with each other in the context of the polarisome, though this has not been demonstrated. Accordingly, the polarisome may consist of additional components that transiently interact with these core components.

The conservation of the polarisome in other fungi is a subject that retains considerable interest. Homologues of Spa2, Bud6, and Bni1 have been characterized in *C. albicans*, *A. gossypii*, and *A. nidulans*. At this time, a general consensus for the function or localization of the polarisome in growing hyphae has yet to emerge. In *C. albicans*, both Spa2 and Bud6 localize to a surface cap at hyphal tips that likely corresponds to the polarisome, whereas Bni1 appears as a spot that subtends the cap (Crampin et al., 2005; Martin et al., 2005). As outlined in more detail below, growing evidence suggests that this spot is in fact the Spitzenkörper. Deletions of *spa2*, *bud6*, or *bni1* all lead to similar morphological defects and a failure to maintain hyphal polarity (Zheng et al., 2003; Li et al., 2005; Martin et al., 2005; Song and Kim, 2006). Somewhat similar localization patterns are seen in *A. nidulans* (Sharpless and Harris, 2002; Virag and Harris, 2006); SepA (=Bni1) localizes to the surface cap and the subtending spot, whereas SpaA (=Spa2) appears as a small surface crescent (an identical SpaA localization pattern was reported in *A. niger*, as well; Meyer et al., 2008). Deletion of *sepA* or *spaA* compromises the maintenance of hyphal polarity, though the defects are far more severe in *sepA* mutants (Sharpless and Harris, 2002; Virag and Harris, 2006). Notably, unlike what occurs in *S. cerevisiae*, SepA localization is not dependent upon SpaA in *A. nidulans* hyphae. In *A. gossypii*, Bni1 forms a crescent at the surface of hyphal tips that does not appear to overlap with Spa2, which localizes to a central spot just behind the tip (Knechtle et al., 2003; Schmitz et al., 2006). Genetic analyses demonstrate that Bni1 is absolutely essential for the establishment of hyphal polarity in *A. gossypii*. By contrast, Spa2 is needed for hyphae to attain normal extension rates and to generate the proper branching pattern.

What, then, can be inferred about the function and localization of the polarisome in fungal hyphae? First, it is not yet apparent that the polarisome, as defined in *S. cerevisiae*, even exists. Spa2 and Bni1 do not display extensive colocalization in those filamentous fungi that have been examined, and as observed in *A. nidulans*, formin recruitment may occur independent of Spa2 (Crampin et al., 2005; Philippsen et al., 2005; Virag and Harris, 2006). Less is known about Bud6, but limited evidence from *A. nidulans* suggests that Bud6 and formins are likely to be functional partners (Virag and Harris, 2006). Ultimate proof for the conservation of the polarisome in filamentous fungi will require biochemical and proteomic evidence similar to that used to reveal its existence in *S. cerevisiae*. At the very least, it seems plausible that an analogous structure is present as a surface cap at hyphal tips, where it mediates formin-dependent nucleation of actin filaments in response to Cdc42 signals.

Relationship between the Spitzenkörper and Polarisome

The localization of the *A. nidulans* formin SepA to a dynamic spot just behind the hyphal tip strongly suggested that it might be a component of the Spitzenkörper (Sharpless and Harris, 2002). This was subsequently confirmed when it was shown that SepA colocalizes with the FM4-64-labeled spot that is typically used to define the Spitzenkörper (Harris et al., 2005). Parallel studies with *C. albicans* demonstrated that the formin Bni1 and the myosin regulatory light chain Mlc1 also localized to the Spitzenkörper (Crampin et al., 2005). These observations are consistent with the notion that the Spitzenkörper functions as an actin-organizing center.

The localization of SepA to both the polarisome (surface cap) and the Spitzenkörper (subtending spot) suggests a possible functional relationship between these entities. Even in *C. albicans*, where they are spatially distinct objects that coexist in hyphae, but not in yeast cells or pseudohyphae (where the Spitzenkörper is not found), it was still suggested that the Spitzenkörper could plausibly be a "hyperactive" polarisome (Sudbery and Court, 2007). One possible explanation for their relationship is based on the mechanisms underlying formin-mediated nucleation of actin filaments. The *S. pombe* formin For3 nucleates short filaments at the cell tip that are then released and carried into the cell interior along actin cables (Martin and Chang, 2006). These movements are dependent upon the presence of actin filaments and require the C-terminal FH2 domain of For3. Based on this precedent, it is conceivable that the SepA spot could represent an accumulation of formins that have been transported along actin filaments that originated from the cell surface cap. In accord with this idea, the SepA spot disappears when actin filaments are eliminated by treatment with cytochalasin A, whereas localization at the cell surface remains (Sharpless and Harris, 2002). In addition, the C-terminal half of SepA, which houses the FH2 domain implicated in actin nucleation, is required for SepA localization to the spot (Sharpless and Harris, 2002).

Perhaps it is more appropriate to view the polarisome and Spitzenkörper as components of the larger tip growth apparatus (Taheri-Talesh et al., 2008). Localization of the polarisome, consisting at the very least of a formin plus Bud6, to the surface cap may ensure the formation of actin filaments that are used to transport exocytic vesicles stored in the Spitzenkörper. Formins delivered to the Spitzenkörper along the same actin filaments may be recycled back to the cap by diffusion or by transport along microtubules. Other multiprotein complexes implicated in localized exocytosis within the tip growth apparatus (i.e., the exocyst) may also display colocalization with the Spitzenkörper, depending on the dynamics of their individual components. The functional relationships between these complexes and the Spitzenkörper may be choreographed by Cdc42, which

also localizes to the surface cap in *A. nidulans* (note that the polarisome and exocyst are known Cdc42 effectors).

EVOLUTION OF MORPHOGENETIC MECHANISMS IN FUNGI

Conservation of Genes Required for Highly Polarized Growth

The availability of a large number of annotated fungal genome sequences has ushered in a new era whereby comparative genomic approaches can be employed to make inferences regarding the evolution of morphogenetic mechanisms in fungi. A particularly interesting issue is the relationship between highly polarized cell types in fungi (i.e., hyphae) and their opisthokont relatives in the animals (i.e., neurons and other migratory cells). Does this mode of growth require specific adaptations to the morphogenetic and/or regulatory machinery that are not required in less polarized cell types? A cursory comparison of the genes implicated in polarized hyphal growth with those needed for polarized morphogenesis of yeast cells suggests that this might be true. For example, filamentous fungi possess extra GTPase modules (e.g., Rac1) and microtubule motor proteins (e.g., kinesins) that are involved in polarized hyphal growth and are either absent or poorly conserved in yeast but are well conserved in neurons (for examples, see Harris and Momany, 2004; and Schuchardt et al., 2005). Additional examples include the role of ROS generated by Nox complexes in the maintenance of apical dominance in hyphae and neurons (Ibi et al., 2006; Semighini and Harris, 2008). Whether these examples reflect selection for mechanisms that enable highly polarized growth remains to be determined. Nevertheless, a more systematic analysis that is informed by bioinformatics approaches would seem to be warranted. From a practical viewpoint, this would reveal the extent to which genetically tractable model filamentous fungi such as *A. nidulans* and *N. crassa* could be used to model neurodegenerative disorders such as ataxia telangiectasia (Malavazi et al., 2006).

The Origins of Polarized Hyphal Growth

It is widely accepted that the Chytridiomycetes represent the most ancestral fungal phylum (James et al., 2006). Chytrids are largely aquatic fungi that produce motile zoospores that are capable of amoeboid movement (Longcore at al., 1999). In addition, certain chytrids (i.e., the monocentric chytrids) do not produce hyphae and in many respects appear to be morphologically similar to animal cells (Taylor et al., 2004). The Zygomycetes represent another basal fungal phylum that likely originated on multiple separate occasions from the chytrids (James et al., 2006). Notably, the Zygomycetes are terrestrial fungi that grow solely by hyphal extension (though they share certain polarized cell types with chytrids, such as rhizoids). Thus, at face value, it would appear that early fungi exhibited diverse morphologies that bear some similarity to their closest animal relatives in the Protozoa. However, the commitment to a terrestrial lifestyle may have selected for polarized hyphae as the dominant form of growth. The recent completion of annotated genome sequences for a chytrid, *Batrachochytrium dendrobatidis* (http://www.broad.mit.edu/annotation/genome/batrachochytrium_dendrobatidis), and two zygomycetes (*Rhizopus oryzae* and *Phycomyces blakesleeanus* [http://www.broad.mit.edu/annotation/genome/rhizopus_oryzae/MultiHome.html and http://genome.jgi-psf.org/Phybl1/Phybl1.home.html]) should make it possible to use comparative genomic approaches to test this hypothesis regarding the origins of hyphal growth. Two relevant observations have already emerged from a preliminary annotation of these genome sequences (S. Harris, unpublished results). First, the *B. dendrobatidis* genome possesses reasonably well-conserved homologues of proteins implicated in animal cell migration (i.e., talin, vinculin, and parvin) that are missing from *R. oryzae* or *P. blakesleeanus*. Second, despite their ancestral position in the fungal phylogeny, the chytrids and zygomycetes appear to exhibit increased complexity in terms of the gene content devoted to morphogenesis. For example, whereas *A. nidulans* and *N. crassa* each possess only a single formin, *R. oryzae* possesses at least eight distinct formin homologues. Furthermore, *R. oryzae* harbors increased numbers of annotated Ras/Rho-related GTPases (70 versus 27), Rho GEFs (23 versus 5), and Rho GAPs (34 versus 7) compared to *A. nidulans*. Although numerous explanations for this paradox are possible, these differences suggest that commitment to polarized hyphal growth might have introduced a "morphological bottleneck" that ultimately triggered the loss of genes needed for alternate forms of growth.

What Are the Minimal Requirements for a Functional Hypha?

The use of polarized hyphae as means of vegetative propagation is not a unique attribute of the filamentous fungi. Organisms within the animal (e.g., oomycetes) and bacterial (e.g., streptomycetes) kingdoms generate branched hyphae that closely resemble those produced by fungi. Additional cell types in plants (e.g., moss protonema) also bear considerable morphological similarity to hyphae. Accordingly, hyphal growth is likely a convergent solution to the common problem of nutrient acquisition across variable habitats. This raises an interesting question: is it possible to define a minimal set of functions required for polarized hyphal growth? It seems likely that components of the morphogenetic machinery that enable localized cell surface expansion and cell wall deposition would be universally important for hyphal growth. For example, even in Streptomyces, the tropomyosin-like protein DivIVA is required for normal hyphal morphogenesis (Fiardh, 2003). However, a more interesting challenge will be to determine whether regulatory functions, such as GTPases, as well as proteins involved in calcium and ROS signaling, are also universal components of the minimal gene set needed for hyphal growth.

The comparative analysis of morphogenesis in *S. cerevisiae* and *A. gossypii* provides potentially informative insight into the minimal requirements for polarized hyphal growth. Although these fungi are closely related members of the Saccharomycotina, *S. cerevisiae* grows as yeast and pseudohyphae (though it is capable of forming hypha-like filaments in response to mating pheromone), whereas *A. gossypii* is capable of hyphal growth only. This difference in growth form does not reflect large differences in their respective gene sets, as ~95% of *A. gossypii* genes are orthologues of *S. cerevisiae* genes (summarized by Philippsen et al., 2005). As might be expected, genes that are obviously important for polarized growth, such as Cdc24, Cdc42, Rho1, and Rho3, are as important for hyphal growth in *A. gossypii* as they are for morphogenesis in *S. cerevisiae*. However, genetic analyses have also identified homologues of *S. cerevisiae* genes that have strikingly different morphological phenotypes when deleted in *A. gossypii*. For example, despite the presence of two Bnr1 homologues, deletion of Bni1 is lethal in *A. gossypii* due to a failure in polarity establishment, whereas the analogous *S. cerevisiae* mutant is viable and capable of forming a bud (Schmitz et al., 2006). This difference presumably reflects a greater role for formin-nucleated actin cables in supporting

hyphal growth. Other examples of genes with seemingly different roles in polarized hyphal growth compared to their established function in yeast budding include the Ras GTPase Rsr1, the polarisome component Spa2, the PAK kinase Cla4, and the paxillin Pxl1 (Ayad-Durieux et al., 2000; Knechtle et al., 2003; Bauer et al., 2004; Knechtle et al., 2008). Based on these results, it seems possible that *A. gossypii* achieves hyphal growth by merely rewiring the genetic networks that underlie cellular morphogenesis in *S. cerevisiae*. According to this hypothesis, significant changes in gene content might not be necessary to generate polarized hyphae from a nonhyphal cell type.

The analysis of hyphal morphogenesis in *A. gossypii* highlights one additional puzzle. *A. nidulans* and *N. crassa* possess many genes that have critical roles in polarized hyphal growth (e.g., *A. nidulans mesA* and *barA* and *N. crassa pod-2* and *pod-3*) and that are either absent or poorly conserved in *A. gossypii* (Seiler and Plamann, 2003; Pearson et al., 2004; Li et al., 2006). However, in contrast to the mutant phenotypes in *A. nidulans* or *N. crassa*, the absence of these genes in *A. gossypii* in no way limits the ability of this fungus to generate hyphae capable of impressive extension rates. Other examples of functions that are required for efficient hyphal extension in *A. nidulans* but are apparently dispensable in *A. gossypii* include components of the TeaA/TeaR and Nox complexes (Takeshita et al., 2008; Semighini and Harris, 2008). The dispensability of these functions in *A. gossypii* implies that they are not part of the minimal gene set required for polarized hyphal growth. On the other hand, the importance of these functions in *A. nidulans*, and presumably other members of the Pezizomycotina, suggests that they confer some sort of selective advantage. It is not clear what this might be, but it might relate to the ability to form lateral branches, engage in hyphal anastomosis, or produce complex developmental structures.

SUMMARY AND MODELS

The importance of understanding the molecular mechanisms underlying polarized hyphal growth cannot be understated. Because filamentous fungi continue to pose a significant threat to human health and food security, there is considerable interest in the identification of novel targets that will limit fungal growth and thus the capacity to cause disease. As an essential function required for any filamentous fungus to colonize a human or plant host, specific features of polarized hyphal growth will likely provide attractive targets for this purpose. In addition, fungal hyphae share their highly polarized lifestyle with neurons and other migratory cells. It seems likely that at some level, the mechanisms that support this lifestyle will also be shared. The genetic tractability of filamentous fungi such as *A. nidulans* and *N. crassa* affords a tremendous opportunity to elucidate these mechanisms and to acquire insight that might be relevant to neurological disorders and other motor diseases.

Up to now, most of what is known about polarized hyphal growth has been obtained through the use of complementary genetic and microscopic approaches (summarized by Harris et al., 2005). The use of increasingly sophisticated microscopy techniques has revealed the subcellular organization of hyphal tip cells and, in particular, emphasized the role of the Spitzenkörper in polarized hyphal growth. The recent characterization of the hyphal tip apparatus in *A. nidulans* provides an outstanding example of the power of this approach (Taheri-Talesh et al., 2008). The identification and genetic analysis of mutants defective in hyphal morphogenesis date back to the original *Neurospora* mutant screens of Beadle and Tatum (summarized by Mishra, 1977). Over the intervening years, a sizable number of morphological mutants have been characterized, not only in the model fungi *A. nidulans* and *N. crassa*, but also in human and plant pathogens (summarized by Harris, 2006). Originally, these mutants were primarily identified using forward genetics, whereby mutants were generated and subjected to detailed phenotypic analysis before the affected genes were cloned by complementation. The availability of annotated genome sequences combined with the advent of functional genomic tools has, at least in the short term, triggered greater use of reverse genetic approaches aimed at mutating homologues of genes implicated in the polarized growth of yeasts or animal cells.

What has been learned so far? Perhaps the least surprising lesson is that polarized hyphae are not a modified yeast cell (unlike pseudohyphae). Genetic analyses of *N. crassa* and *A. nidulans* have generated a long list of genes needed for hyphal morphogenesis; in many cases, *S. cerevisiae* homologues of these genes, if present at all, have no known role in polarized growth (Harris and Momany, 2004; Harris 2006; Harris et al., 2009). Even *A. gossypii* possesses genes that are required for polarized hyphal growth yet are dispensable in *S. cerevisiae* (for example, Bni1 [Schmitz et al., 2006]). These differences presumably reflect the greater demands that highly polarized growth places on the morphogenetic machinery in hyphae compared to yeast cells (e.g., the long-range transport of vesicles and organelles along microfilament and microtubule tracks). Accordingly, given the current emphasis on the use of reverse genetic approaches, it would seem prudent to avoid sole reliance upon the so-called yeast paradigm. For example, homologues of proteins implicated in neuronal morphogenesis or cell migration would be attractive candidates for genetic analysis.

Another notable lesson that has become apparent is the intricately structured organization of the hyphal tip (Taheri-Talesh et al., 2008). Besides the Spitzenkörper, the hyphal tip also houses complexes such as the polarisome and exocyst. There are undoubtedly many additional complexes that localize to the tip, which should perhaps be viewed as a dynamic assemblage of complexes that function in an integrated manner to drive hyphal extension. Furthermore, exocytic vesicle delivery appears to be confined to the extreme apex of the hyphal tip, whereas flanking regions comprise endocytic zones where surface components are retrieved and recycled for subsequent reuse. The striking similarity between the organization of hyphal tips and that of the neurological synapse lends further credence to the notion that neurons and hyphae share common mechanisms for polarized growth.

What should be done next? It has been argued that the first step towards understanding the molecular basis of a specific cellular process is to assemble a "parts list" (for an example, see Pollard, 2003). At this point, many of the components involved in polarized hyphal growth have been identified. Although genetic and proteomic approaches are still needed to identify additional proteins, efforts to organize these components into functional modules must also be initiated. The construction of protein interaction networks (via yeast two-hybrid analysis, affinity purification, or protein complementation analysis) and genetic interaction networks (via synthetic genetic arrays) has yielded unprecedented insight into the functional modules that control cellular morphogenesis in *S. cerevisiae* (Boone at al., 2007). Similar approaches could also be used with *A. nidulans* or *N. crassa* to characterize the interaction networks that underlie polarized hyphal growth. The resulting information

would provide a framework for subsequent attempts to investigate the biochemical mechanisms that drive the establishment and maintenance of hyphal polarity. In addition, comparison of the "morphogenesis networks" from filamentous fungi and yeasts might shed light on how changes in network architecture impact cell shape in fungi.

Another key objective is to obtain a detailed understanding of how the hyphal tip is organized. The continued use of GFP-based probes to characterize protein localization and colocalization patterns within the tip will provide needed insight into the composition and dynamic behavior of the different complexes that comprise the hyphal tip apparatus. In addition, it is likely that the plasma membrane within the tip region is demarcated into distinct domains that differ in sterol and phospholipid composition. The identification of these domains would enable the characterization of their presumptive roles in organizing the tip. Finally, high-resolution electron tomography permits three-dimensional reconstruction of cellular structures at a nanoscale level. This approach has already offered a tantalizing glimpse into the organization of the *A. nidulans* hyphal tip (Harris et al., 2005). It is not unreasonable to envision these "fungal computerized axial tomography scans" providing an exquisitely detailed and quantitative picture of hyphal tip organization. Notably, the use of quantitative microscopy as a tool for the phenotypic analysis of morphological mutants has proven to be an effective approach for a systems-based analysis of morphogenesis in yeast.

Several models have attempted to provide a mechanistic basis for understanding polarized hyphal growth based on previous microscopy-based studies (summarized by Steinberg, 2007). The steady-state model is based on the notion that cell wall polymers are assembled at the immediate hyphal apex but are not cross-linked until they are displaced laterally (Sietsma and Wessels, 1994). Accordingly, the cell wall at the immediate apex remains plastic and responsive to internal turgor pressure, which in turn drives extension of the hypha. A major weakness with this model is the conflicting evidence regarding the necessity of turgor pressure for hyphal extension (Steinberg, 2007). The vesicle supply center model is founded on the role of the Spitzenkörper in polarized hyphal growth (Bartnicki-Garcia, 2002). The Spitzenkörper is thought to serve as a vesicle distribution hub in the hyphal tip. The release of vesicles in a radial manner coupled to the forward movement of the Spitzenkörper generates a gradient of exocytosis that leads to the typical hyphoid shape of filamentous fungi. On the other hand, if the Spitzenkörper remains in a fixed position, ovoid shapes characteristic of yeast cells are produced. Although well supported by experimental observations and mathematical models, recent evidence suggests that certain features of this model may need to be reconsidered (for example, the exocytic zone at the hyphal apex is much smaller than would be predicted by the model [Taheri-Talesh et al., 2008]). It has been suggested that a combination of the steady-state and vesicle supply center models may best account for hyphal morphogenesis (Steinberg, 2007). Nevertheless, the amoeboid model, which posits that forces generated by the cytoskeleton promote hyphal extension, cannot be excluded (Heath and Steinberg, 1999). Notably, *N. crassa* protoplasts can form cytoplasmic extensions that resemble pseudopodia from migrating animal cells (Steinberg, 2007). This observation, coupled with the conservation of a limited number of proteins implicated in animal cell migration, suggests that amoeboid movements might have a previously unforeseen role in hyphal extension.

Steinberg (2007) and Taheri-Talesh et al. (2008) have proposed updated models for polarized hyphal growth that incorporate observations from more recent molecular studies. Key elements of these models include the roles of (i) SRDs in directing the localization of the polarisome at the hyphal tip, (ii) formins in promoting the assembly of actin filaments anchored at the hyphal tip, (iii) myosins in the microfilament-based transport of vesicles to a discrete exocytic zone at the apex of the tip, (iv) actin patch-mediated endocytic retrieval of cell surface components from sites flanking the apex, and (v) microtubule-based transport of vesicles to and from the tip region. Both turgor pressure and forces generated by the cytoskeleton are proposed to drive the tip forward, and the tip itself likely houses a highly structured but dynamic apparatus that coordinates localized exocytosis with endocytosis.

Although these models account for much of what is known about the extension of mature hyphae, they still do not address the key issue of how hyphal polarity is initially established; that is, what is the key event(s) that breaks the symmetry of a swollen spore or a subapical hyphal cell? It might be tempting to consider specific proteins (e.g., proteins analogous to the *S. cerevisiae* bud site selection markers) or membrane domains (e.g., domains such as the SRDs implicated in recruitment of cell end factors in *A. nidulans*)

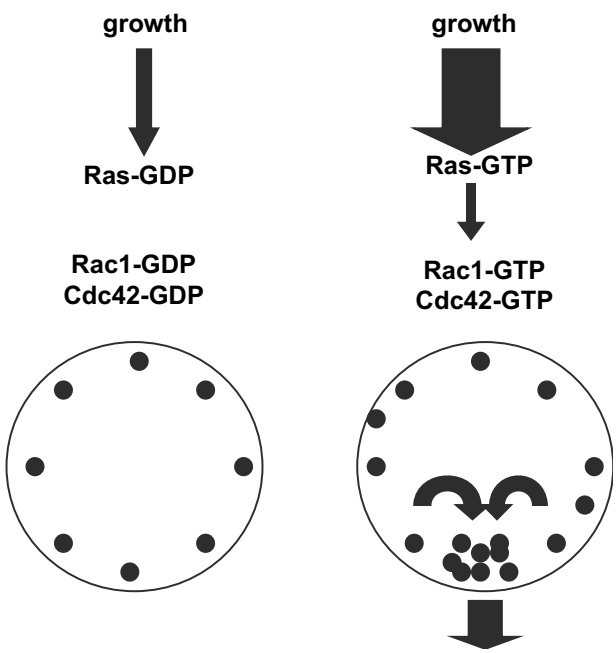

FIGURE 3 Model for the coordination of polarity establishment with growth by monomeric GTPases. (Left) Prior to receiving a strong growth signal (e.g., glucose), Ras is in an inactive GDP state that is unable to activate Rac1 or Cdc42. As a result, the latter GTPases (dots) are uniformly distributed. (Right) Upon reception of a strong growth signal, activated Ras (i.e., Ras-GTP) triggers the activation of Rac1 and Cdc42. Stochastic fluctuations in Rac1-GTP and/or Cdc42-GTP levels lead to local asymmetries in what was initially a uniform distribution. Feedback loops reinforce these asymmetries until a threshold is reached at a given site that then becomes the dominant polarity axis (black arrow). Both endocytic recycling of surface components and enhanced Rac1/Cdc42 GAP activity at nonpolarization sites likely play a key role in reinforcing the polarity axis.

as sources of positional information that initiate a polarity axis, but there is no reason that this event could not simply be a stochastic process. For instance, random fluctuations in local activity of a monomeric GTPase could be amplified by feedback loops, leading to asymmetries in membrane organization that enable recruitment of cell end factors, the polarisome, and other components of the hyphal tip apparatus (Fig. 3). Attractive candidates for the GTPase "trigger" are Rac1 and/or Cdc42. The emerging role of these GTPases as downstream effectors of Ras1 in fungi coupled with their known ability to coordinate the morphogenetic machinery suggests that they may define a signaling nexus that links the commitment to form a polarity axis to growth conditions (Fig. 3). Future experiments that exploit genomic and proteomic tools will undoubtedly provide new insights that test the validity of this hypothesis and reveal the key symmetry-breaking event(s) that lead to polarized hyphal growth.

Hyphal Fusion

NICK D. READ, ANDRÉ FLEIßNER, M. GABRIELA ROCA, AND N. LOUISE GLASS

Filamentous fungi in the Ascomycete and Basidiomycete groups grow by hyphal tip extension, branching and fusion to make an interconnected, supracellular network of hyphae that is the hallmark of these organisms (Buller, 1933; Read, 2007). Hyphal anastomosis also occurs in Zygomycetes (Griffin and Perrin, 1960), where it apparently is not a common phenomenon (Gregory, 1984), and in arbuscular mycorrhizal fungi, which are members of the Glomeromycota (Giovannetti et al., 1999, 2001). Species within the Oomycota, which undergo hyphal tip growth and branching but which are more closely related to algae and are members of the Kingdom Stramenopila, also undergo hyphal fusion (Stephenson et al., 1974).

Hyphal fusion occurs at a number of stages during the life cycle of filamentous fungi, particularly during (i) colony initiation, (ii) mature colony development, and (iii) sexual development. A wide range of important roles are performed by hyphal fusion during the life cycle. This chapter focuses on hyphal fusion in filamentous ascomycete and basidiomycete species, with emphasis on the model ascomycete fungus, *Neurospora crassa*. It reviews the different types of hyphal fusion, its mechanistic basis, and the varied functions that it serves, and it compares hyphal fusion with processes of cell fusion in fungi and other eukaryotic species. Hyphal fusion has also been recently reviewed by Glass et al. (2000, 2004), Roca et al. (2005a), Glass and Fleißner (2006), Read and Roca (2006), and Fleißner et al. (2008).

HYPHAL FUSION DURING DIFFERENT STAGES OF THE LIFE CYCLE

Hyphal Fusion During Colony Initiation

Hyphal fusion between spores and spore germlings during colony initiation is very common. It is most often observed between conidia and conidial germlings and has been demonstrated in over 73 ascomycete species (Roca et al., 2005a). Hyphal fusion has also been observed between ascospore germlings and between urediospore germlings (Read and Roca, 2006).

Tulasne and Tulasne (1863) first illustrated fusions between conidia and conidial germlings in a variety of species. An important early experimental study of fusion between germinating conidia was performed by Köhler (1930). He described fusion between germinating conidia of the same or different species via small hyphal bridges ("Fusionshyphen"), which were significantly narrower than germ tubes. Numerous other papers subsequently showed images of fused conidia and conidial germlings in culture (Hay, 1995), in asexual reproductive structures (Mesterhazy, 1973), or on host plants (Latunde-Dada et al., 1999). However, it was not fully appreciated until recently that fusion between conidia/conidial germlings involves the formation and interaction of specialized hyphae, which are different from germ tubes and which have been termed "conidial anastomosis tubes" (CATs) (Roca et al., 2003, 2005a, 2005b).

The initial characterization of CATs was made in the plant pathogen *Colletotrichum lindemuthianum* (Roca et al., 2003) and the saprotrophic species *N. crassa* (Roca et al., 2005b). They were shown to have the following combination of characteristics which distinguishes them from conidial germ tubes.

1. CATs are usually thinner and shorter than germ tubes and exhibit determinate growth. Germ tubes differentiate into vegetative hyphae of the mature colony (Fig. 1A through D) (Araujo-Palomares et al., 2007; Roca et al., 2005b). However, it is often not possible to define CATs on the basis of their width alone, and this is a problem particularly when identifying CATs that arise from germ tube tips (Fig. 1B) or as germ tube branches (Fig. 1C).
2. CATs are unbranched, while germ tubes undergo branching (Araujo-Palomares et al., 2007; Roca et al., 2005b).
3. CATs in *N. crassa* can arise directly from conidia, from germ tube tips or as subapical branches of germ tubes (Roca et al., 2005a, 2005b) (Fig. 1A through D).

Read, Fungal Cell Biology Group, Institute of Cell Biology, University of Edinburgh, Rutherford Building, Edinburgh EH9 3JH, United Kingdom. **André Fleißner,** Institut für Genetik, Technische Universität Braunschweig, Spielmannstraße 7, 38106 Braunschweig, Germany. **M. Gabriela Roca,** Fungal Cell Biology Group, Institute of Cell Biology, University of Edinburgh, Rutherford Building, Edinburgh EH9 3JH, United Kingdom. **N. Louise Glass,** Department of Plant and Microbial Biology, University of California, Berkeley, CA 94729-3102.

4. CAT induction is dependent on conidial density. In *N. crassa*, the optimum conidial density is $\sim 10^6$ conidia ml^{-1} (Roca et al., 2005b). Germ tube formation in *N. crassa* is not dependent on conidial density over the range of 10^2 to 10^6 conidia ml^{-1} (H.-C. Kuo and N. D. Read, unpublished data).
5. CATs home towards each other, while germ tubes tend to avoid one other. CAT homing has been most unambiguously demonstrated using optical (laser) tweezer micromanipulation (Fig. 1D). When the relative position of two CATs exhibiting chemotropic growth towards each other is changed by micromanipulation with optical traps, both CATs readjust their direction of growth back towards each other to make contact and fuse at their tips (Fleißner et al., 2005; Roca et al., 2005a; Wright et al., 2007).
6. CATs are under separate genetic control from germ tubes. A growing number of mutants have been isolated that are inhibited at specific stages of CAT fusion but undergo conidial germination and germ tube formation (Table 1).
7. CATs function in interconnecting conidial germlings and are believed to allow the young colony to act as a cooperative individual. Germ tubes, on the other hand, function in colony establishment.

How consistent these features of CATs are in other species will need to be carefully assessed in the future. Some species of filamentous fungi seem to lack CATs (for example, Craven et al. reported that *Alternaria alternata* does not form CATs [Craven et al., 2008]). We are not aware of any published illustrations of CAT fusion between conidial germlings in the model species *Magnaporthe oryzae* or *Aspergillus nidulans*. However, CAT formation in some species may require specific conditions (e.g., nutritional factors or conidial density) that are not commonly used experimentally.

Hyphal Fusion in a Mature Colony

A filamentous fungal colony is morphologically complex and contains a variety of different hyphal types (Bistis et al., 2003). Leading hyphae and their branches at the periphery of a colony typically grow outward, exhibit a subapical branching pattern, and tend to avoid each other (Buller, 1933). Hyphal anastomosis does not normally occur in this peripheral zone of an *N. crassa* colony (Hickey et al., 2002). Behind this peripheral zone, hyphal fusion occurs extensively to produce the characteristic interconnected state of the mature colony (Fig. 1E). Hyphal anastomosis is initiated by the formation of specialized "fusion hyphae," which arise as branches from established hyphae and branches in this part of the colony. Although fusion events are frequent within a colony, they are not uniformly distributed. Another type of hyphal fusion also occurs in mature colonies of nematophagous fungi, such as *Arthrobotrys oligospora*, where hyphal fusion is important for the formation of a range of specialized nematode-trapping structures. These traps can take the form of simple rings, constricting rings, or net-like structures (Barron, 1977; Read and Roca, 2006).

In *N. crassa,* vegetative hyphal fusion in a mature colony has been described in detail using time-lapse confocal microscopy (Hickey et al., 2002). The process can be conveniently divided into three phases: precontact, postcontact, and postfusion (Glass et al., 2000, 2004; Hickey et al., 2002; Read and Roca, 2006), as described below.

Precontact Phase

During the precontact phase in *N. crassa*, the fusion hyphae are induced and grow ("home") towards each other. The proximity of fusion hyphae to other hyphae often results in the initiation of new positively chemotropic hyphal tips that are fusion competent (Buller, 1933; Hickey et al., 2002; Köhler, 1929). The fusion hyphae in *N. crassa* can often be recognized as morphologically distinct from other hyphae. They always appear to be hyphal branches and can vary from being short, peg-like structures to reasonably long and often dichotomously branched hyphae (Hickey et al., 2002).

Fusion hypha formation is associated with the development of a Spitzenkörper. The Spitzenkörper is a complex organelle and protein assemblage predominated by secretory vesicles that is found in growing hyphal tips or at sites of branch initiation (Harris et al., 2005; Virag and Harris, 2006), and which is associated with polar and directional growth of hyphae (Bracker et al., 1997; Gierz and Bartnicki-Garcia, 2001; Girbardt, 1957; Grove and Bracker, 1970; Riquelme et al., 1998). During the precontact phase, the fusion hypha Spitzenkörper shares features in common with the Spitzenkörper of a growing vegetative hypha. The secretory vesicles within the Spitzenkörper can be readily stained with the membrane-selective dye FM4-64 (Fischer-Parton et al., 2000; Hickey et al., 2005). By use of this marker dye, the Spitzenkörper was stained in fusion hyphae of *N. crassa* and its behavior was monitored (Hickey et al., 2002). The formation of a new Spitzenkörper was found to precede a new fusion hypha at its site of emergence, and the positive chemotropic reorientation of fusion hyphal tips towards each other was associated with the Spitzenkörper in these tips positioning themselves towards the opposing tips (the localization of the Spitzenkörper in the growing tip was coincident with the direction of homing).

Postcontact Phase

Hyphal fusion in *N. crassa* usually results from "tip-to-tip" contact between two fusion hyphae or from "tip-to-side" contact between a fusion hypha and another hypha (Buller, 1933; Hickey et al., 2002). When the hyphal tips involved in fusion are very short branches, they are often referred to as "pegs" (Buller, 1933). During the postcontact phase, hyphal tips that will fuse cease extension growth and often undergo isotropic growth, which results in swelling of their tips (Hickey et al., 2002). This is accompanied by the adhesion of the two hyphae to each other and the digestion of their intervening cell walls. The Spitzenkörper persists during this period, suggesting that it provides secretory vesicles for wall synthesis during hyphal tip swelling and for the delivery of extracellular adhesives and cell wall-degrading enzymes during cell wall degradation and fusion pore formation (Hickey et al., 2002).

Postfusion Phase

The onset of the postfusion phase is marked by the fusion of the plasma membranes of the two anastomosing hyphae. This results in the formation of a "fusion pore" through which cytoplasm and organelles, including nuclei, flow. Fusion is often associated with dramatic alterations in the bulk flow of cytoplasm and organelles and facilitates their rapid mixing between the fused hyphae. The fusion pore increases in diameter following fusion, and one or two septa commonly form in its vicinity (Hickey et al., 2002). The Spitzenkörper persists at the site of fusion pore formation

and presumably continues to function in providing secretory vesicles containing cell wall-degrading enzymes and proteins associated with fusion pore formation and membrane merger. The Spitzenkörper disappears once the fusion pore is fully formed (Hickey et al., 2002). During the post-contact and postfusion phases, the persistence of the Spitzenkörper within a fusion hypha is a marked behavioral difference compared to that in a vegetative hypha, in which the Spitzenkörper characteristically disappears after hyphal growth has ceased (Girbardt, 1957).

Hyphal Fusion during Fertilization and in Sexual Development

In members of the Ascomycota and Basidiomycota, hyphal fusion occurs during mating-cell fusion and during the formation and maintenance of the dikaryon during the sexual phase of the life cycle. Mating-cell fusion commonly involves the fusion between a compatible hypha and a spore (microconidium or conidium in the Ascomycota and oidium in the Basidiomycota), which acts as a male fertilizing agent (or spermatium) in outbreeding species. In the Ascomycota, a fertile receptive hypha, the trichogyne, is often produced and grows out from the ascogonium of an unfertilized fruiting body. These trichogynes show positive chemotropism towards sex pheromones released by conidia (or microconidia) of opposite mating type (Fig. 1G) (Bistis, 1981; Kim and Borkovich, 2006). Mating cell fusion in some ascomycete species occurs in the absence of conidium-trichogyne fusion, but the precise mechanism(s) involved are poorly understood. In the Basidiomycota, monokaryotic hyphae of basidiomycete species show positive chemotropism towards sex pheromones released by oidia of opposite mating type (Bistis, 1970; Webster, 1980). Alternatively, compatible monokaryotic hyphae of opposite mating type can fuse in the absence of male oidia (Webster, 1980).

The dikaryotic phase is a feature of filamentous ascomycete and basidiomycete species, where nuclei of opposite mating type (in outbreeding species) or two genetically identical nuclei (in inbreeding species) are involved in the formation and proliferation of binucleate cells. In many ascomycete and basidiomycete species, dikaryotic cells are formed and maintained by specialized hyphae called crozier and clamp cells, respectively (Fig. 2A and B).

In *N. crassa* and related ascomycete species, ascogenous hyphae grow out from the ascogonium as a branched hyphal network that is mostly multinucleate (Beckett, 1981; Zickler et al., 1995). A hook-shaped crozier forms at the tip of an ascogenous hypha. Two nuclei within the crozier go through a simultaneous mitotic division and undergo septation across the two mitotic spindles to produce a uninucleate terminal cell and a binucleate penultimate cell, while the fourth nucleus remains in the multinucleate compartment of the ascogenous hypha (Fig. 2A). The two nuclei (the so-called "prefusion nuclei") in the penultimate cell undergo karyogamy. This cell becomes the ascus mother cell and subsequently grows out and develops into the ascus. Meanwhile, the terminal cell grows back and fuses with the subtending ascogenous hypha, allowing the nuclei in these two compartments to pair up. In *N. crassa*, the two nuclei that subtend the ascus also undergo karyogamy (Raju, 1980). In other species, these two nuclei maintain the dikaryotic state; this process is repeated as a result of further croziers forming as branches from the dikaryotic subtending cell (Berteaux-Lecellier et al., 1998; Read and Beckett, 1996). Other patterns of karyogamy have been described in other ascomycete species (e.g., in *Neotiella rutilans*) and have been reviewed by Read and Beckett (1996).

Clamp cells are found at the septa of dikaryotic hyphae of many basidiomycete species. Clamp cell formation is initiated from the apical hyphal compartment and involves the formation of a backward-growing hyphal branch at a site that is just forward of the site of the future septum. The hypha continues to grow back and forms a hook-like structure. Concomitantly, the two genetically different nuclei of the dikaryotic apical hyphal compartment divide and a septum forms at the base of the clamp cell in which one of the nuclei becomes trapped (Fig. 2B). Another septum is formed within the apical hyphal compartment, leaving the nucleus of the other mating type in the newly formed subapical hyphal compartment while keeping together two genetically different nuclei in the apical compartment. A subapical peg is typically formed in response to the presence of the backward-growing clamp cell, and the two fuse, resulting in the two solitary nuclei becoming united in the subapical hyphal compartment. This process is repeated at regular intervals to maintain binucleate hyphal compartments along the dikaryotic vegetative hypha (Badalyan et al., 2004; Buller, 1933; Todd and Aylmore, 1985). Within sexual fruiting bodies, little is known about hyphal fusion between somatic hyphae, although it has been reported in the sexual primordia of various basidiomycete species (Van der Valk and Marchant, 1978; Williams et al., 1985).

FIGURE 1 *N. crassa*. (A) Conidial anastomosis tubes (CATs) (c) that have formed directly from macroconidia (s) and fused with each other. Note that the germ tubes (g) are wider than the CATs. Bar = 5 μm. (From M. G. Roca, C.E. Jeffree, and N. D. Read, unpublished data.) (B) CATs (c) that have formed from germ tube (g) tips, grown towards each other, and made contact. Bar = 5 μm. (From Roca, Jeffree, and Read, unpublished.) (C) CATs (c) that have formed subapically from germ tubes (g) and have fused. Bar = 5 μm. (From Roca et al., 2005b, with permission.) (D) The CAT homing assay. The two conidia had germinated, and their CATs were homing towards each other (0 min). The left-hand germling was repositioned (here shown 4 min after repositioning). The CAT tips then changed their orientation to home back towards each other (15 and 21 min) before making contact (25 min) and subsequently fusing (not shown). The left-hand conidium remained trapped throughout the entire 25-min period without apparent inhibition of CAT growth, homing, or fusion. The position of the trap in the germ tube (g) is represented by the crosshair in the circle. Note that the germ tube is significantly wider than either CAT. Bar = 10 μm. (From Wright et al., 2007, with permission.) (E) Hyphal fusion in a mature colony that has resulted in a complex interconnected hyphal network. Bar = 100 μm. (From K.M. Lord and N. D. Read, cover image for 2008 issues of *Fungal Biology Reviews*, with permission.) (F) A comparison of the morphology of anastomosis between fusion hyphae in a mature wild-type colony (note fusion pores [asterisks]) and a fusion mutant (*soft*) in which fusion does not occur. Hyphae imaged by confocal microscopy after staining with calcofluor white M2R. Bar = 10 μm. (From Fleißner et al., 2005, with permission.) (G) Trichogyne that has homed towards, and wrapped around, a macroconidium (arrow) of opposite mating type. Bar = 20 μm. (From H.C. Kuo, C.E. Jeffree, and N. D. Read, unpublished data).

[a]Nomenclature and gene names according to *N. crassa*.

[b]"Male fertile" means that the mutant can be taken through a cross if used as a male, but not as a female. "Ascospore lethal" means that, even if used as a male, ascospore progeny bearing the indicated mutated gene cannot be recovered through a cross. "Perithecia not formed" indicates that mating cell fusion occurs, but subsequent sexual development from the protoperithecium is blocked when the mutant is used as a female. "Ascus dominant" indicates that mating cell fusion occurs, but subsequent sexual development from the protoperithecium is blocked when the mutant is used as a female or a male.

[c]TF, transcription factor.

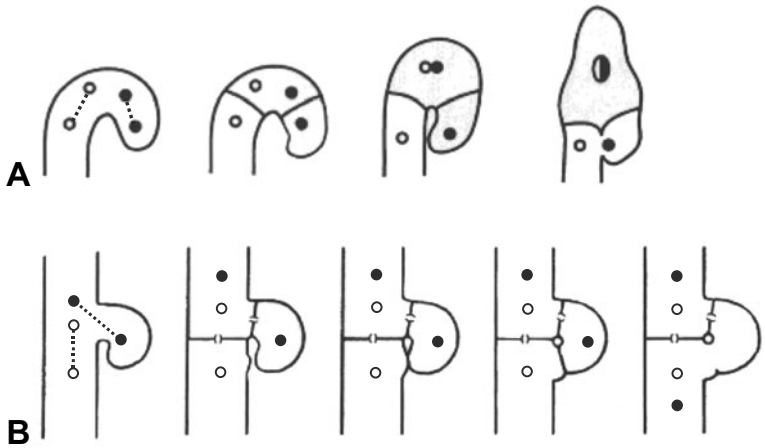

FIGURE 2 (A) Diagram of crozier cell fusion in a typical ascomycete species. (B) Diagram of clamp cell fusion in a basidiomycete species. See "Hyphal Fusion in a Mature Colony" for details.

MECHANISTIC BASIS OF VEGETATIVE HYPHAL FUSION

Induction

CAT induction probably involves an extracellular CAT inducer produced by ungerminated conidia. Evidence for this comes from observations that CAT formation is dependent on macroconidial concentration (Roca et al., 2005b), CATs form when conidia are close together, and culture filtrates can induce CAT fusion (Leu, 1967). CAT induction may involve a form of quorum sensing (i.e., a mechanism whereby cells sense their density by detecting extracellular molecules secreted by the population) (Miller and Bassler, 2001). In *Venturia inaequalis*, germling fusion via CATs was found to be frequent when conidia were in close proximity. Fusion was not observed between two isolated conidia mounted close to one another (Leu, 1967). However, when multiple conidia were placed close to one another under the same conditions, numerous germling fusion events were observed. Fusion between isolated conidial pairs in *V. inaequalis* was induced by the addition of culture filtrates from the same or different isolates. The observed fusion induction was apparently species specific, because culture filtrates of *Venturia pirina* did not induce fusions between *V. inaequalis* conidia. The identity of the self-signaling inducer is unknown.

The composition of the growth medium can affect fusion frequency among conidial germlings, and this may relate to the frequency of CAT induction. In *Leptosphaeria coniothyrium*, *Sclerotinia fructigena*, *Botrytis* sp., *Fusarium* sp., and *N. crassa*, the frequency of germling fusion was reduced on rich organic media (such as 1% malt or potato dextrose agar), but fusion was frequent when these media were diluted (Köhler, 1930; Laibach, 1928). In contrast, the frequency of germling fusion in *V. inaequalis* was found to be significantly greater on complete medium than on basal medium or water agar (Leu, 1967). It is not clear whether a nutrient or another factor in the medium is causing these inhibitory or stimulatory effects.

CAT induction in *N. crassa* requires a putative transmembrane protein (HAM-2) (Xiang et al., 2002) and the NRC-1/MEK-2/MAK-2 mitogen-activated protein (MAP) kinase pathway (see below); strains containing mutations in the genes encoding these proteins do not form CATs (Roca et al., 2005b). Furthermore, phosphorylation of MAK-2 increased during the period when CAT formation/hyphal fusion is most prolific (Pandey et al., 2004). In *Saccharomyces cerevisiae*, stimulation of the pheromone response pathway required for mating cell fusion results in activation of a transcription factor, Ste12 (Errede and Ammerer, 1989), which regulates the expression of genes involved in polarized growth, cell adhesion, cell wall breakdown, and membrane merger (Cross, 1988; Gammie et al., 1998; Heiman and Walter, 2000) (see "Chemoattraction" below). In *N. crassa*, a strain containing a deletion of the *ste12* ortholog, *pp-1*, is very similar in phenotype to the *nrc-1*, *mek-2*, and *mak-2* mutants, fails to form CATs, and is defective in germling fusion and hyphal fusion in mature colonies (Li et al., 2005; J. Li, A. Fleißner, and N. L. Glass, unpublished observations) (Table 1). CAT induction may also involve a filamentous-ascomycete-specific WW domain protein called SOFT (SO) because *so* mutants produce fewer CATs than the wild type (Fleißner et al., 2005).

Much less is known about what makes hyphae in the subperipheral region of the mature colony competent to undergo fusion, but the process involves the induction of specialized fusion hyphae (see "Hyphal Fusion in a Mature Colony" above). It is not known whether this is primarily regulated by a program of gene expression that is specific to this region of the colony or whether environmental factors are important in initiating the expression of hyphal fusion genes. However, an unknown self-signaling inducer is involved. This inducing compound seems to be produced by the tips of fusion hyphae because the close proximity of a fusion hyphal tip to a trunk hypha in *N. crassa* can induce the formation of a new fusion hypha in its vicinity (Buller, 1933; Hickey et al., 2002). It is not unreasonable to postulate that the same molecule may function as both the CAT and fusion hypha inducer.

As indicated in "Hyphal Fusion in a Mature Colony" above, nematode traps produced by nematophagous fungi result from hyphal fusion. They can be induced by the presence of nematodes, and Pramer and Stoll (1959) coined the term "nemin" to describe the inducer. Nordbring-Hertz et al. (1989) later showed that di- and tripeptides containing valine were very effective in inducing traps under nutrient-poor conditions.

Chemoattraction

A key feature of CATs or fusion hyphae is that they are attracted towards one other. In *N. crassa*, when the relative

position of two conidial germlings showing mutual attraction is changed by micromanipulation using optical tweezers, the CAT tips of both germlings adjust their growth towards each other to make contact and undergo fusion (Fleißner et al., 2005; Roca et al., 2005b; Wright et al., 2007) (Fig. 1D). These observations provide compelling evidence for a diffusible chemoattractant released from CAT tips and for a chemoattractant receptor located at the CAT tips. However, as with the CAT/fusion hypha inducer(s) (see "Induction" above), the identity of the chemoattractant is unknown. It is possible that the inducer and chemoattractant are the same self-signaling ligand. In *S. cerevisiae*, both the induction of the formation of mating cell protuberances (shmoos) and chemotropic interactions associated with mating are regulated by the secretion of peptide sex pheromones (**a**-pheromone or α-pheromone) that bind to their cognate G-protein-coupled receptors (Ste3p or Ste2p, respectively) in a cell of the opposite mating type (Cross, 1988; Elion, 2000).

The process of vegetative hyphal fusion between compatible cells in filamentous fungi involves the fusion of genetically identical cells (i.e., self fusion), in contrast to mating-cell fusion in *S. cerevisiae*, which involves the fusion of two genetically nonidentical cells (i.e., nonself fusion). The best-studied example of chemoattraction between genetically identical cells in eukaryotes is found in the slime mold *Dictyostelium discoideum*, in which extracellular cyclic AMP (cAMP) acts as a chemoattractant that results in aggregation of amoebae (Manahan et al., 2004). The discovery that the *N. crassa* genome encodes three G-protein-coupled receptor-like proteins that resemble *Dictyostelium* cAMP receptors (Borkovich et al., 2004; Galagan et al., 2003) suggested the possibility that cAMP may serve a similar chemoattractant role in filamentous fungi. However, cAMP plays no apparent role as a CAT chemoattractant in *N. crassa*, because a *cr-1* mutant lacking cAMP was shown to undergo CAT homing after optical tweezer-based micromanipulation (Roca et al., 2005b).

In *S. cerevisiae*, the interaction of **a** or α-pheromone with Ste3p or Ste2p, respectively, results in the disassociation of a heterotrimeric G-protein (Gα=Gpa1p, Gβ=Ste4p, and Gγ=Ste18p). Interaction between Gβγ and Ste20p activates a MAP kinase cascade (Ste11p-Ste7p-Fus3p) (Cross, 1988; Elion, 2000). Although mating-cell fusion in *N. crassa* involves a similar interaction of cognate pheromones and G-protein-coupled receptors (Li et al., 2007), mutations in *N. crassa* genes encoding the sex pheromones (*mfa-1* and *ccg-4*), the pheromone receptors (*pre-1* and *pre-2*), and heterotrimeric G-proteins (*gna-1*, *gnb-1*, and *gng-1*) do not affect vegetative hyphal fusion, as assessed by heterokaryon tests and germling fusion assays (Kim and Borkovich, 2004, 2006; Li et al., 2007). However, strains containing deletion mutations in *mak-2* (the *N. crassa* ortholog of *FUS3*) and *nrc-1* (the *STE11* ortholog) are unable to undergo germling or hyphal fusion in mature colonies (Pandey et al., 2004; Roca et al., 2005b) (Table 1). Furthermore, conidia of *mak-2* and *nrc-1* mutants do not attract wild-type CATs, indicating that neither of these mutants produces chemoattractant (Table 1) (Roca et al., 2005b). We have recently found that MAK-2-green fluorescent protein (GFP) localizes to the tips of CATs undergoing chemotropic homing towards each other (A. Fleißner, M. G. Roca, N. D. Read, and N. L. Glass, unpublished observations). These studies indicate that the MAK-2 MAPK pathway is required both for the initiation of fusion and for chemotropic interactions. Recent data indicate that a strain containing a deletion mutation of the predicted MAPKK in the MAK-2 MAP kinase pathway, termed *mek-1*, is also vegetative-fusion defective (Maerz et al., 2008) (Table 1). Interestingly, the vegetative-fusion defects of *mak-2* and *nrc-1* mutants are suppressed by mutations in *cot-1* (Maerz et al., 2008); *cot-1* encodes a protein kinase of the NDR Ser/Thr protein kinase family, which is required for hyphal tip elongation in *N. crassa* (Yarden et al., 1992). The requirement of the MAK-2 MAP kinase pathway for vegetative hyphal fusion is also conserved in other filamentous ascomycete fungi. For example, in *A. nidulans*, a mutant disrupted in the MAPKKK *nrc-1* homolog, *ste*C, fails to form heterokaryons (Wei et al., 2003).

In addition to genes encoding components of the MAK-2 MAP kinase pathway, an *N. crassa* locus called *soft,* which encodes a filamentous ascomycete-specific WW domain protein, is required for vegetative hyphal fusion (Fig. 1F) (Fleißner et al., 2005; Wilson and Dempsey, 1999). *so* mutants form CATs, but these fail to show chemotropic interactions (Table 1; Fig. 3), suggesting that *so* mutants are impaired both in the production/secretion and/or reception/transduction of a chemoattractant signal (Fleißner et al., 2005). Functional SO-GFP is found in the cytoplasm in hyphae, but upon injury, SO-GFP localizes rapidly to septal pore plugs. SO-GFP localization was shown to be Woronin body (*hex-1*) independent. Importantly, *so* mutants show a decrease in efficiency of septal plugging upon injury (Fleißner and Glass, 2007). In the homothallic filamentous ascomycete species *Sordaria macrospora*, strains containing mutations in the *so* ortholog (*pro40*) are also defective in vegetative hyphal fusion (Rech et al., 2007); Pro40, like SO, localizes to septal pore plugs (Engh et al., 2007). Similarly, mutations in *so* orthologs in plant pathogens such as *Fusarium oxysporum* and *Alternaria brassicicola* also resulted in mutants that fail to undergo vegetative hyphal fusion (Craven et al., 2008; Prados Rosales and Di Pietro, 2008) (see "Hyphal Fusion and Plant Pathogenesis" below).

In *N. crassa,* the *ham-2* (acronym for hyphal anastomosis) locus encodes a putative transmembrane protein (Xiang et al., 2002); *ham-2* mutants fail to undergo both germling and hyphal fusion in mature colonies (Table 1; Fig. 3). Similar to the *mak-2* and *nrc-1* mutants described above, *ham-2* mutants fail to attract wild-type CATs, suggesting that HAM-2 is required for chemoattractant production/secretion and/or reception/transduction (Roca et al., 2005b). In *S. cerevisiae*, mutations in the *ham-2* ortholog, *FAR11*, result in mutants that prematurely recover from G_1 growth arrest following exposure to pheromone (Kemp and Sprague, 2003). Far11p was shown to interact with five other proteins (Far3p, Far7p, Far8p, Far9p, and Far10p). Homologs of genes encoding *FAR3* and *FAR7* are lacking in *N. crassa* (Glass et al., 2004). Preliminary data show that mutations in *N. crassa* homologs of *Far*8 and *Far9/10* (*ham-3* and *ham-4*, respectively) result in mutants displaying phenotypes similar to the *ham-2* mutant, including a block in vegetative hyphal fusion (A. Simonin, C. G. Rasmussen, M. Yang, and N. L. Glass, unpublished results). In *S. macrospora*, strains containing mutations in the *ham-2* ortholog (*pro22*) results in mutants that show a dramatic reduction in fusion frequency and fail to develop mature fruiting bodies (Rech et al., 2007). The predicted *N. crassa* HAM-3 protein shows significant similarity to proteins of the striatin family. The striatin family of proteins act as scaffolding proteins that organize signaling complexes; for example, formation of a complex between striatin and the

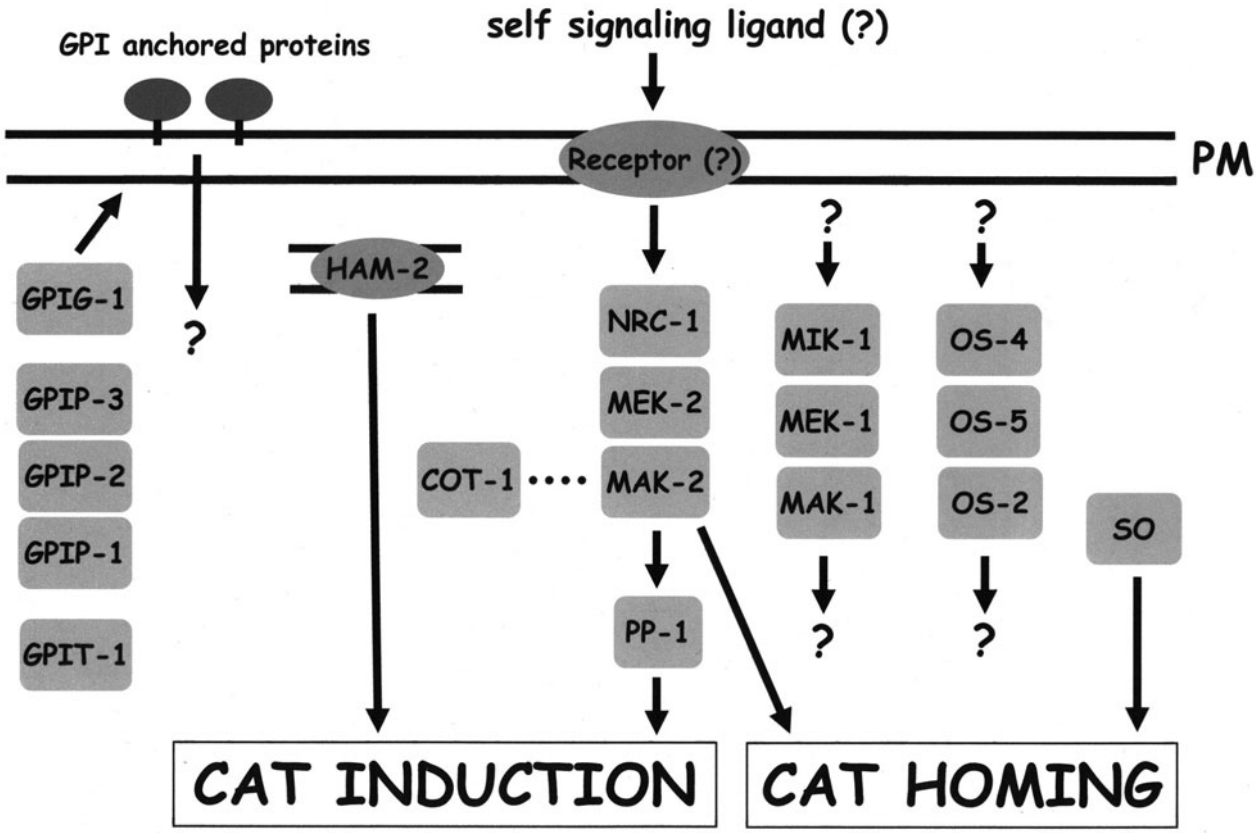

FIGURE 3 Working model of the signaling involved during vegetative hyphal fusion in *N. crassa* (see the text for details). The self-signaling ligand and receptor responsible for the process of self-fusion are unknown. GPIG1, GPIT1, GPIP1, GPIP2, and GPIP3 are involved in the GPI protein anchoring pathway (Bowman et al., 2006). It is not known which stage(s) of vegetative hyphal fusion these proteins regulate. HAM-2 is a predicted transmembrane protein (Xiang et al., 2002), although it is not known which cellular membrane it is associated with. NRC1-MEK2-MAK2 (Li et al., 2005; Maerz et al., 2008; Pandey et al., 2004; Roca et al., 2005b), MIK1-MEK1-MAK1 (Maerz et al., 2008), and the OS4-OS5-OS2 (Maerz et al., 2008) are three MAP kinase pathways, and PP1 (Li et al., 2005) is the transcription factor predicted to be at the base of the MAK2 pathway. Upstream elements of the MAK1 and OS2 MAP kinase pathways and the stage(s) of vegetative hyphal fusion that they regulate are unknown. Mutations in *cot-1* suppress the vegetative hyphal fusion defect of *mak-2* (Maerz et al., 2008). SO is an ascomycete-specific WW domain protein (Fleißner and Glass, 2007; Fleißner et al., 2005).

estrogen receptor is required for estrogen-induced activation of a MAP kinase signal transduction pathway (Lu et al., 2004). In *S. macrospora*, mutations in the *ham-3* ortholog (*pro11*) result in a mutant unable to complete sexual development; full fertility was restored by expression of a mouse striatin cDNA (Poggeler and Kuck, 2004). These data suggest that HAM-2/Pro22, HAM-3/Pro11, and HAM-4 might physically interact in filamentous ascomycete fungi and that this interaction might be involved in vegetative hyphal fusion.

In the tips of hyphae within the mature colony, including chemotropic fusion hyphae, the position of the Spitzenkörper determines directional growth (Harris et al., 2005; Hickey et al., 2002; Virag and Harris, 2006). However, an obvious Spitzenkörper is not observed in germ tubes (Araujo-Palomares et al., 2007) or CATs (Roca et al., 2005b). The absence of a recognizable Spitzenkörper may be due to the reduced concentration of vesicles in the slow-growing germ tube and CAT tips, and this may relate to their slow extension rates. Nevertheless, germ tube and CAT tips probably possess key components of the hyphal tip growth machinery such as the polarisome and exocyst protein complexes that have been characterized in *S. cerevisiae*. The polarisome is responsible for directing cytoskeletal and other cell components towards sites of localized cell expansion at sites of growth, while the exocyst is involved in secretory vesicle docking and fusion with the plasma membrane (Harris et al., 2005; Virag and Harris, 2006). Chemotropic growth must involve the rapid transduction of chemoattractant signals perceived at the plasma membrane to the tip growth machinery (Spitzenkörper/polarisome/exocyst). This machinery responds rapidly and sensitively to direct secretory vesicles involved in wall synthesis to appropriate locations on the apical plasma membrane of CATs or fusion hyphae (Read, 2007). This is thought to involve the directed polymerization of actin microfilaments, along which secretory vesicles are transported towards sites of vesicle fusion within the tips of CATs and fusion hyphae.

Of possible significance here is that cytochalasin-A and latrunculin B, drugs that disrupt F-actin polymerization, perturb germling fusion (Rasmussen, 2007; M. G. Roca and N. D. Read, unpublished data).

Cell-Cell Adhesion, Cell Wall Breakdown, and Membrane Merger

The molecular basis of cell-cell adhesion, a shift from polar to isotropic growth, cell wall degradation, and plasma membrane merger during the final stages of hyphal fusion are little understood in filamentous fungi. Upon physical contact, the two Spitzenkörper of two fusion hyphae are juxtaposed at the point of contact (Hickey et al., 2002). The localization of the two Spitzenkörper in fusion hyphae resembles the prefusion complexes found during muscle myoblast fusion, in which vesicles line up at the sites of cell-cell contact, forming pairs across the apposing plasma membranes (Dworak and Sink, 2002).

In *S. cerevisiae*, mating-type-specific adhesins are expressed in response to pheromone, enabling the fusion partners to tightly adhere at their shmoo tips (reviewed by Lipke and Kurjan, 1992). However, *S. cerevisiae* genes encoding mating-type-specific agglutinins are not conserved in the genome of *N. crassa* (Glass et al., 2004), indicating that different proteins may be involved in cell-cell adhesion. Recent data from *N. crassa* demonstrate that glycosylphosphatidylinositol (GPI)-anchored proteins are required for hyphal fusion. Mutations in *gpig-1*, *gpip-1*, *gpip-2*, *gpip-3*, and *gpit-1* genes, which encode components of the *N. crassa* GPI anchor biosynthetic pathway, resulted in mutants with pleiotropic phenotypes and that were unable to undergo vegetative hyphal fusion, as assessed by heterokaryon formation (Bowman et al., 2006) (Table 1; Fig. 3). Chitinases, such as the GPI-anchored chitinase ChiA in *A. nidulans*, which localizes to the tips of germ tubes, at hyphal branching sites, and at hyphal tips (Yamazaki et al., 2008), might play a role in cell wall remodeling and degradation at sites of hyphal fusion during fusion pore formation.

In *S. cerevisiae*, one of the few proteins implicated in plasma membrane merger during mating is Prm1p; *prm1*Δ mutants show a ~50% reduction in mating cell fusion (Heiman and Walter, 2000). Deletions of the *PRM1* homolog in *N. crassa* (Δ*Prm-1;* mutations in *Prm-1* are ascus dominant) showed a ~50% reduction in germling fusion (Fleißner et al., 2009). In addition, *N. crassa* Δ*Prm-1* mutants have a similar reduction in the frequency of trichogyne-conidium fusion during sexual reproduction, as well as defects in crozier cell fusion (see "Relationship between Vegetative Hyphal Fusion and Sexual Development" below). These data suggest that in *N. crassa*, PRM1 is involved in cell fusion events during both the vegetative and sexual stages of the *N. crassa* life cycle and may thus be part of the general cell fusion machinery.

Other Proteins Involved in Vegetative Hyphal Fusion

A number of mutants have been found to be defective in vegetative hyphal fusion, but the precise stages at which they are blocked have yet to be determined (Table 1). These include strains containing mutations in two additional MAP kinase pathways predicted in filamentous ascomycete genomes (Lengeler et al., 2000; Xu, 2000). The first of these MAP kinase pathways is orthologous to the *S. cerevisiae* cell wall integrity MAP kinase pathway and includes a MAPKKK (Bck1p), two redundant MAPKKs (Mkk1p/2p), and a MAPK (Slt2p/Mpk1p). In *S. cerevisiae*, the polarized growth of mating projections involves new cell wall synthesis, which requires activation of a cell wall integrity MAP kinase, Mpk1p (Slt2p) (Buehrer and Errede, 1997); during pheromone-induced morphogenesis, Mpk1-GFP is localized at the shmoo tip (Changwei et al., 2007). In *F. graminearum*, mutations in the *MPK1* ortholog, *MGV1*, resulted in a mutant that fails to form heterokaryons via hyphal fusion (Hou et al., 2002). Similarly, in *N. crassa*, mutations in the *MPK1* ortholog, *mak-1*, and predicted upstream kinases, *mek-1* and *mik-1*, also result in strains that fail to undergo hyphal fusion (Maerz et al., 2008) (Table 1; Fig. 3). In *M. grisea* and *Colletotrichum lagenarium*, mutations in the MAP kinase gene orthologous to *MPK1* affect conidial germination, sporulation, ability to form appressoria, and plant infection (Kojima et al., 2002; Xu, 2000; Xu et al., 1998). Defects in vegetative fusion were not assessed in these mutants.

A third MAP kinase pathway predicted in filamentous ascomycete genomes is orthologous to the osmosensing MAP kinase pathway in *S. cerevisiae* and has been extensively studied in a number of filamentous ascomycete fungi (Furukawa et al., 2005; Vitalini et al., 2007; Zhang et al., 2002). In *N. crassa*, strains containing deletion mutations in the MAPKKK (*os-4*), the MAPKK (*os-5*), or the MAPK (*os-2*) genes show hyphal fusion defects (Maerz et al., 2008) (Table 1). Future studies will reveal the relationship, interaction, and function of these MAPK pathways in vegetative hyphal fusion (Fig. 3).

RELATIONSHIP BETWEEN FUSION DURING VEGETATIVE GROWTH AND SEXUAL DEVELOPMENT

Relationship between CAT Fusion and Hyphal Fusion in a Mature Colony

CAT fusion is being used as a model to study fundamental aspects of vegetative hyphal fusion because it is a much simpler and more experimentally amenable system than fusion within a mature colony (Read and Roca, 2006). Data obtained so far suggest that many features of CAT fusion are common to the fusion of hyphae in a mature colony. All germling fusion mutants identified so far are also defective in hyphal fusion in mature colonies (Fleißner et al., 2005; Roca et al., 2005b). However, there are differences between the two processes of hyphal fusion. First, there are morphological and developmental differences. CATs are short (Fleißner et al., 2005; Roca et al., 2005b), while fusion hyphae vary from being short peg-like structures to much longer, and often dichotomously branched hyphae (Hickey et al., 2002). Second, there are physiological differences. Cytoplasmic and organelle mixing between hyphae is usually very rapid between hyphae in the mature colony following fusion but is very slow between fused CATs (Roca and Read, unpublished). We speculate that there might be slight differences in the turgor pressures of fusion hyphae which result in the rapid bulk flow of cytoplasm and organelles (Hickey et al., 2002). It may be that the turgor pressure differential between fusing germlings is much less or nonexistent (Read and Roca, 2006). Further identification and characterization of hyphal fusion mutants should more clearly define similarities and differences between fusion of CATs and fusion hyphae and should determine how far CAT fusion can be used as a model for vegetative hyphal fusion in general.

Relationship between Vegetative Hyphal Fusion and Sexual Development

All of the fusion mutants so far identified in *N. crassa* have a pleiotropic phenotype and are affected in aspects of sexual development (Table 1). For example, the *N. crassa mak-2*, *mek-2*, and *nrc-1* mutants fail to form female reproductive structures (protoperithecia) or develop defective ones, suggesting that hyphal fusion may be important during the development of fruiting bodies (e.g., in the development of the protoperithecial or perithecial wall). Fusion mutants also show reduced growth rates and conidiation defects (Kothe and Free, 1998; Li et al., 2005; Maerz et al., 2008; Pandey et al., 2004; A. Lichius, K. M. Lord, and N. D. Read, unpublished results). Similar results have been observed with hyphal fusion mutants identified in other species (Craven et al., 2008; Hou et al., 2002; Rech et al., 2007; Vallim et al., 2000; Wei et al., 2003).

Two stages of sexual development in *N. crassa* and related species that involve hyphal fusion are mating-cell fusion and crozier cell fusion (see "Hyphal Fusion in a Mature Colony" above). Mechanistically mating cell fusion appears reminiscent of germling and hyphal fusion in mature colonies: cells communicate over a spatial distance, grow towards each other, and fuse. However, the molecular basis of vegetative and sexual cell communication may differ. In particular, pheromone, pheromone receptor, and G-protein mutants are defective in chemotropic interactions during mating but are apparently not defective in vegetative fusion (see "Chemoattraction" above). In contrast, mutations in *soft* (*so*) result in strains that lack chemotropic interactions between CATs and are defective in germling fusion and fusion between hyphae in the mature colony (Fleißner et al., 2005). Both the *N. crassa so* mutant and the *S. macrospora so* mutant (*pro40*) form protoperithecia (Engh et al., 2007), but further sexual development is blocked. However, in *N. crassa*, the *so* mutant shows normal trichogyne-conidium chemotropic interactions and undergoes normal mating-cell fusion (Table 1). In addition, fusion of crozier cells in fruiting bodies (perithecia) of both the *so* and the *ham-2* mutants are not affected (Fleißner et al., 2005; Xiang et al., 2002). These data support the hypothesis that cell-cell communication during vegetative hyphal fusion and fusion during sexual development employ different signaling molecules and respective receptors for chemotropic interactions. In contrast, the *N. crassa* Δ*Prm-1* mutants have normal chemotropic interactions during germling and mating cell fusion but show ~50% reduction in both germling and trichogyne-conidium fusion (Fleißner et al., 2009). These observations indicate that vegetative and sexual fusion may require common components of the machinery involved in plasma membrane merger. Future comparison of different types of hyphal fusion at different stages during the fungal life cycle will be important to distinguish molecular components universally involved in cell fusion from those that are specific to individual cell fusion pathways.

ROLES OF HYPHAL FUSION

Cooperation between Conidial Germlings

Cooperation among relatives is a ubiquitous phenomenon in ecological systems and involves the activities of one individual benefiting one or more other individuals (for a review, see Sachs et al., 2004). Germling fusion during colony establishment is an excellent example of cooperative behavior; cooperation within and between fungal individuals can affect fitness attributes of filamentous fungi (Pringle and Taylor, 2002). Most germling and hyphal fusion mutants show pleiotropic growth defects, indicating a role for many of these genes in processes in addition to vegetative hyphal fusion. Thus, effects of germling fusion on cooperation and colony development are difficult to assess. However, one fusion mutant, *so*, shows a wild-type maximal linear colony extension rate (Fleißner et al., 2005), although *so* mutants show a significant delay in achieving wild-type rates. These observations suggest that cooperation via germling fusion during colony establishment may result in the attainment of a maximal extension rate by the mature colony in a shorter period of time (Roca and Read, unpublished).

Maintenance of Physiological Homeostasis in a Mature Colony

Hyphal fusion results in a supracellular, syncytial state in a filamentous fungal colony. This interconnected organization enables translocation of cellular contents, such as organelles, metabolites, nutrients, or signaling compounds throughout the colony, presumably facilitating growth and reproduction (Buller, 1933; Rayner, 1996). In *N. crassa*, fusion is often associated with dramatic alterations in cytoplasmic flow; organelles, including nuclei, pass through fusion pores (Hickey et al., 2002). Such dramatic changes in cytoplasmic flow and movement of organelles suggest that filamentous fungi must adapt to the physiological consequences of hyphal fusion within a fungal colony. Anastomosis between hyphae within a single colony allows the cooperation of hyphae and enables fungi to establish complex functional units that show coordinated growth and exploration of their environment (Buller, 1933; Rayner, 1996). Cytoplasmic continuity can be restored by growth of hyphae through dead hyphal compartments, followed by hyphal fusion with living sectors (Buller, 1933). Self fusion between multiple colonies can allow them to act cooperatively in supporting one or more large fruiting bodies, such as toadstools (Buller, 1933). Thus, in general terms, vegetative hyphal fusion contributes significantly to the general homeostasis within a colony.

Heterokaryon Formation and Parasexuality

Anastomosis between hyphae of genetically different, but heterokaryon-compatible genotypes, can lead to genetic diversity via parasexual recombination and formation of novel genotypes (Pontecorvo, 1956; Swart et al., 2001). This process has been postulated to contribute to the high adaptability of fungi in species that lack sexual reproduction and genetic diversity generated via meiotic recombination. However, in nature, the formation of heterokaryons is restricted by heterokaryon incompatibility (also termed vegetative or somatic incompatibility) (see chapter 20; see also Glass and Dementhon, 2006; Leslie, 1993; Saupe, 2000; and Worrall, 1997). Thus, at least for filamentous ascomycete species, it is unclear how much gene flow and recombination occur within natural fungal populations as a consequence of hyphal fusion and heterokaryon formation.

Hyphal Fusion and Plant Pathogenesis

Hyphal fusion can also be important in the pathogenicity of some plant pathogens. Studies involving a number of plant pathogenic fungi have shown that genes encoding components of MAP kinases are essential for infection of host plants (Kojima et al., 2002; Lev et al., 1999; Takano et al.,

2000; Xu, 2000; Xu et al., 1998). These observations led to the hypothesis that cell fusion and plant infection might share common signaling pathways and that cell fusion might be a prerequisite for successful host colonization (Craven et al., 2008; Prados Rosales and Di Pietro, 2008). For example, mutation of *mak-2* MAPK orthologs in plant pathogenic fungi such as *M. grisea*, *C. lagenarium*, or *Cochliobolus heterostrophus* results in strains that are defective in appressorium formation and also fail to colonize host plants when inoculated through wound sites (Lev et al., 1999; Takano et al., 2000; Xu, 2000; Xu et al., 1998). In the non-appressorium-forming "ergot fungus" *Claviceps purpurea*, mutations in the *mak-2* ortholog similarly result in nonpathogenic strains that show an inability to infect through preformed lesions (Mey et al., 2002). For wild-type *C. purpurea*, strictly oriented growth along the pollen tube path to reach the base of the ovary is a prerequisite of successful host infection (Tudzynski and Scheffer, 2004). Mutations in the MAP kinase gene orthologous to *N. crassa mak-1* in *M. grisea* and *C. lagenarium* result in strains affected in conidial germination, sporulation, ability to form appressoria, and plant infection (Kojima et al., 2002; Xu, 2000; Xu et al., 1998); defects in vegetative fusion have not been determined in these mutants. It is unclear whether defects associated with pathogenesis in these mutants are a consequence of a lack of vegetative hyphal fusion or whether they relate to alternative roles of MAP kinase pathways in these fungal pathogens.

Recent studies of the interaction between *F. oxysporum* and tomato revealed that conidia germinating on the root surface readily fused with each other, forming a mycelial network that adhered to the plant surface. Strains containing mutations in genes encoding orthologs of *mak-2* or *so* (*fmk1* or *fso1*, respectively) were germling fusion defective. Interestingly, mycelia of the *fmk1* and *fso1* mutants were easily detached from the root surface, indicating a function for network formation in plant colonization. However, while the *fmk1* mutant was unable to infect the plant, *fso1* strains showed only slightly reduced virulence (Prados Rosales and Di Pietro, 2008), suggesting that germling fusion might contribute to infection but is not essential for pathogenicity. In contrast, inactivation of the *so* ortholog in *A. brassicicola* (*Aso1*) led to a mutant exhibiting hyphal fusion defects as well as a lack of pathogenicity on the host plant (cabbage). While the mutant was able to penetrate and initially colonize the host, it failed to invade plant tissue. It was suggested that hyphal anastomosis in *A. brassicicola* may play a role in facilitating transport of nutrients from the host plant throughout the invading colony (Craven et al., 2008). The extent to which anastomosis contributes to virulence and pathogenicity might very well depend on the individual infection strategies of different phytopathogenic species. Future analyses employing a variety of different host pathogen systems will be essential to fully reveal the roles of hyphal fusion during fungal pathogenesis.

COMPARISON OF HYPHAL FUSION WITH OTHER SYSTEMS INVOLVING CELL FUSION

Many of the processes required for hyphal fusion in filamentous fungi during vegetative growth are also required during cell fusion processes in general, including signaling by diffusible substances, directed cell growth or movement towards each other, attachment of the two cell types to one another, production and targeting of enzymes to the attachment site, and fusion of the plasma membranes of the interacting cells. Hyphal fusion in filamentous fungi is comparable to somatic cell aggregation and fusion events in other eukaryotic organisms. In cellular slime molds such as *D. discoideum*, amoebae exhibit a form of self signaling and show chemoattractive movement towards each other (Manahan et al., 2004). The adjustment of hyphal growth towards the fusion partner is comparable to cell polarization and shmoo formation during yeast mating (Kurjan, 1993), directed pollen tube growth towards the ovary (Higashiyama et al., 2003), or the extension and/or stabilization of filopodia during myoblast fusion (Chen and Olson, 2004). Cell fusion is involved in the fusion of multinucleate vegetative plasmodia of the acellular slime mold *Physarum polycephalum* resulting in the formation of larger plasmodia (Collins and Haskins, 1972). In colonial marine invertebrates, such as *Hydractinia* and *Botryllus*, fusion can occur between compatible colonies (Buss and Grosberg, 1990; Litman, 2006), while in mammals, examples of somatic cell fusion events that result in syncytia include myoblast fusion during muscle differentiation, fusion between osteoclasts in bone formation, and trophoblast fusion during placental development (Chen et al., 2007; Cross et al., 1994; Dworak and Sink, 2002; Jee and Nolan, 1963; Paululat et al., 1999; Shemer and Podbilewicz, 2003; Vignery, 2000). Understanding the molecular basis of hyphal fusion during vegetative growth in filamentous fungi may provide a paradigm for self-signaling and self-fusion mechanisms in eukaryotic microbial species, as well as provide a useful model for somatic cell fusion events in complex, multicellular species.

Biology and Genetics of Vegetative Incompatibility in Fungi

DUUR K. AANEN, ALFONS J. M. DEBETS, N. LOUISE GLASS, AND SVEN J. SAUPE

DEFINITION OF VEGETATIVE INCOMPATIBILITY

As an individual fungal colony grows in nature, it will interact with a range of organisms inhabiting the same niche, including other individuals belonging to the same species. Filamentous fungi have the ability to undergo somatic cell fusion. As a consequence, an encounter between two individuals belonging to the same species can lead to spontaneous heterokaryon formation. In most cases, however, when somatic cell fusion occurs between distinct natural isolates of a given species, the fusion cell is adversely affected to various extents. The adverse reaction ranges from a simple growth impairment to an acute cell death reaction. This phenomenon is known as vegetative (or heterokaryon) incompatibility (VI). VI can be envisioned as a conspecific somatic self/nonself recognition process analogous to other somatic allorecognition processes described in other phyla. Fusion between genetically distinct individuals is known to exist in protists, plants, and animals (Buss, 1982), but it is particularly common in fungi because they readily form hyphal anastomoses. Therefore, it is perhaps not surprising that allorecognition is so widespread among filamentous fungi. In Basidiomycetes, VI is typically expressed between secondary mycelia (i.e., stable-mating-type heterokaryons) but appears to be overridden in sexually compatible homokaryons (Rayner, 1991). In Ascomycetes, somatic incompatibility is expressed directly between homokaryotic mycelia, which generally outcross nonetheless, since somatic incompatibility is often suppressed during the sexual cycle.

As is detailed below, the VI reaction is triggered by genetic differences between fungal individuals and is defined by precise gene-to-gene interactions. Incompatibility is determined by the interaction of specific alleles at polymorphic loci termed heterokaryon incompatibility (*het*) genes. The *het* genes have been best studied in the Ascomycetes *Podospora anserina* and *Neurospora crassa* (Glass and Dementhon, 2006; Saupe, 2000). *het* genes control the cellular coexistence of genetically dissimilar nuclei by determining, on the basis of allelic or nonallelic interactions, whether cell death will occur. Stable heterokaryons form only when the strains are compatible at all *het* loci.

From a general point of view, VI can be viewed as an example of genome conflict. Different nuclear components lead to an adverse reaction when present in the same cell in a heterokaryon. As such, VI bears resemblance with phenomena like hybrid lethality or sterility (Burke and Arnold, 2001), hybrid necrosis in plants (Bomblies et al., 2007; Bomblies and Weigel, 2007), and speciation based on gene-to-gene interactions (Presgraves, 2007). Similar to VI, in all these phenomena the heteroallelism at polymorphic loci (in a heterokaryon, a zygote, or a meiotic progeny) cannot be tolerated and leads to detrimental cellular effects.

Fungi can have a very long life span (Smith et al., 1992) and may encounter many potentially dangerous viruses, bacteria, mites, insects, and nematodes, as well as other fungi of the same or other species. The study of VI has so far mainly focused on conspecific interactions, and VI has been considered to be a potential defense mechanism against disadvantages associated with somatic cell parasitism and cytoplasmic infections. However, a recent study suggests that the VI reaction may also be relevant during interactions with microbial parasites. The plant pathogen *Pseudomonas syringae* may have acquired a *het* gene as a potential virulence factor to trigger the VI reaction in *N. crassa* and utilize the fungus as a sole nutrient source (Wichmann et al., 2008). Interspecies host-pathogen interactions may be relevant for understanding the biological role, evolution, and maintenance of polymorphisms in VI genes in filamentous fungi (see below). This view is of particular relevance when one considers that other examples of genome conflicts are apparently a secondary consequence of gene divergence imposed by host-pathogen interactions (Bomblies and Weigel, 2007).

ASSAYS FOR VI

Vegetative compatibility between conspecific strains has been tested using different methods. When antagonistic alleles are expressed in the same cell (when introduced by anastomosis, transformation, protoplast fusion, or sexual crossing), the direct manifestations of VI can be studied at the macroscopic (barrage or abnormal growth) or microscopic (cell death) level. Alternatively, the differential consequences of anastomosis between compatible and incompatible pairings for stable heterokaryon formation (heterokaryon complementation of recessive markers) or heteroplasmon (e.g., exchange of suppressive mitochondrion-based senescence) can be used. It must be noted that some of the following methods are used more frequently than others.

Barrage Formation or Cell Death of Fused Cells

A barrage can often be seen on agar medium when incompatible colonies are confronted with one another (Fig. 1). The reactions may vary from dark lines between the colonies to a clear zone with lethal hyphal fusions. The barrage assay is convenient because it does not require any specific genetic marker and can be performed directly using wild-type isolates. It is thus very commonly used for directly analyzing natural populations and has been utilized in population studies of fungi, for example, *Ophiostoma ulmi* (Brasier, 1983), *Cryphonectria parasitica* (Anagnostakis, 1987), *P. anserina* (Bernet, 1967), and *Phomopsis subordinaria* (Meijer et al., 1994). It must be noted that the barrage reaction is often dependent on the experimental conditions. With *P. anserina*, for example, a clear barrage zone is formed on dung media whereas a white opaque zone is observed on synthetic media. With *N. crassa*, barrage formation occurs only on low-nutrient media (Micali and Smith, 2003). The absence of macroscopic antagonistic reactions is therefore not always a reliable indication of vegetative compatibility (Micali and Smith, 2003). In Basidiomycetes, demarcation lines are often observed between paired mycelia on agar media and on wood in nature (Worrall, 1997).

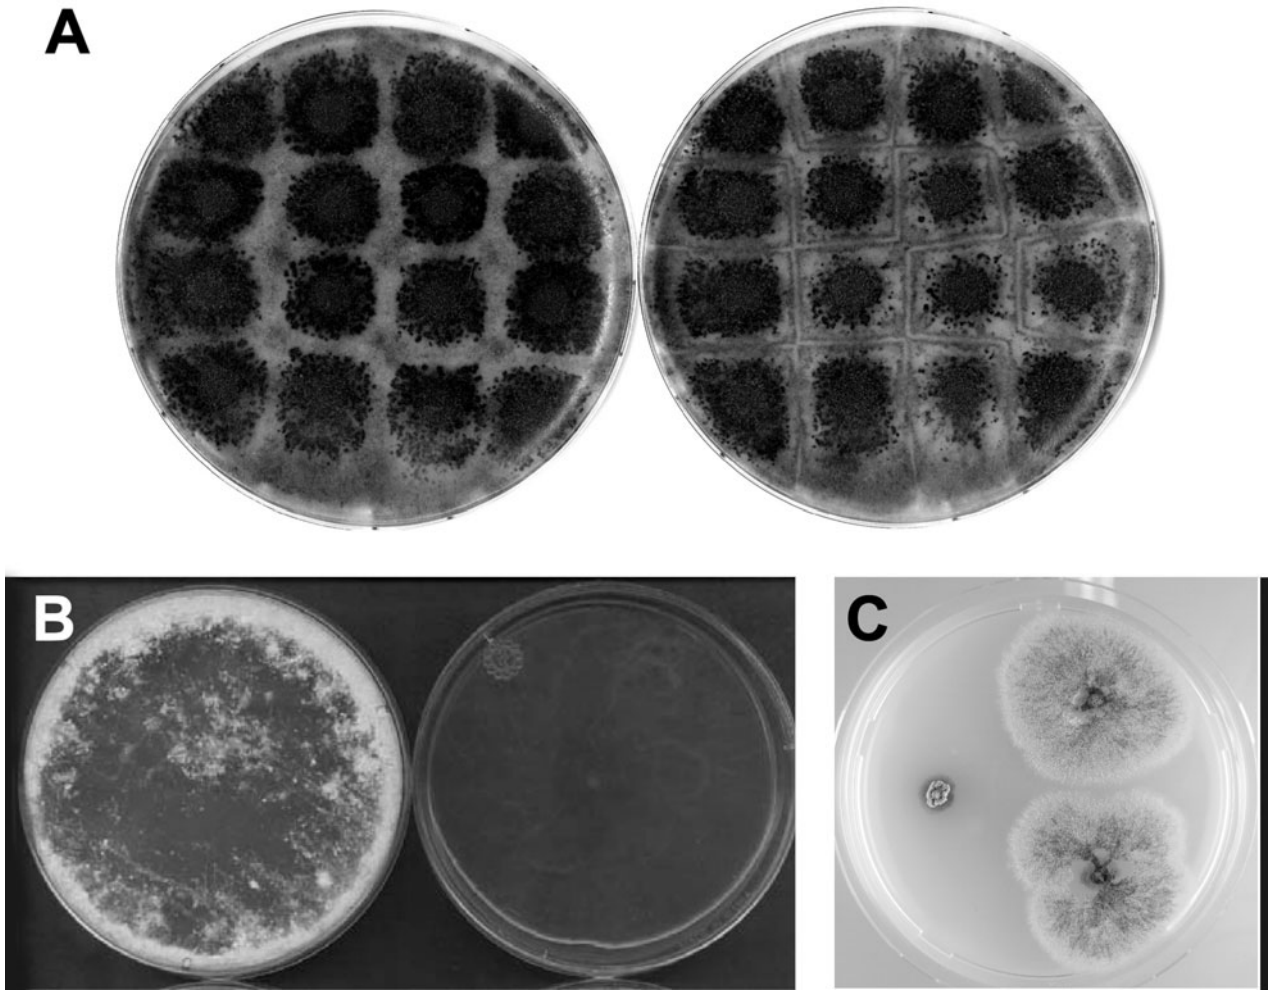

FIGURE 1 Incompatibility assays, barrage tests, and forced heterokaryon tests. (A) Barrage test in *P. anserina*. Strains on the left plate are compatible and show normal contact zones; the strains on the right plate are incompatible and show a barrage reaction, which on this medium appears as a clear zone lined by pigmented lines. (B) Forced heterokaryon test in *N. crassa*. The left plate contains compatible forced heterokaryon; the right plate *het-c/pin-c* shows incompatible heterokaryon. (C) Forced heterokaryon assay in *Aspergillus*. The inoculate on the left corresponds to an incompatible heterokaryon that fails to establish; the colonies on the right correspond to compatible heterokaryons with different spore color markers.

Microscopic observations of VI triggered by hyphal fusion between incompatible strains have revealed similar effects in different species: hyphal compartmentation, vacuolization, and cell death of the fused cells and often also of the neighboring cells (Aimi et al., 2002a, 2002b; Anagnostakis, 1984; Pinan-Lucarre et al., 2007). In *Rhizoctonia solani,* VI has indeed been based on lysis of anastomosed cells (Carling et al., 1994; Julian et al., 1996); lysis of the anastomosing and adjacent cells is seen when the anastomosing isolates are vegetatively incompatible.

Heterokaryon Formation

Two types of heterokaryons have been reported in filamentous ascomycete fungi. In the first type, heterokaryons are limited only to actual fusion cells and nuclei do not migrate between cells (Puhalla and Mayfield, 1974). Heterokaryons are continually re-formed by repeated fusion events within the mycelium and are visualized as vigorous growth in the contact zone. In the second type, in species such as *N. crassa* and *P. anserina*, heterokaryotic cells proliferate and almost all cells within the mycelium are heterokaryotic (Perkins, 1988).

Conidia from different auxotrophic mutant strains of *N. crassa* but from the same genetic background typically show complementation and grow readily on minimal medium (Beadle and Coonradt, 1944). However, when mutant strains from different genetic backgrounds are used, such complementation often does not occur, indicative of VI (Fig. 1). If the strains are incompatible, the forced heterokaryon fails to establish or displays growth retardation and aberrant morphology and shows evidence of cell death when examined microscopically. This principle of complementation of recessive marker alleles in a heterokaryon has been used in various ascomycete species and requires the introduction of genetic markers. For such studies, chlorate-resistant, nitrate-nonutilizing markers have been widely used. Such mutants can be isolated on the basis of chlorate resistance and classified for their ability to grow on various N sources (Cove, 1976). Nitrate-nonutilizing mutants have been used in heterokaryon tests to assay for compatibility groups among naturally occurring isolates in a number of different fungi. Alternatively, wild-type strains can be directly screened against tester strains that carry both a recessive auxotrophic and a dominant resistance marker, as has been demonstrated for *Aspergillus niger* (van Diepeningen et al., 1997). In *Aspergillus nidulans*, complementation of color mutations in asexual spores has been used as evidence for heterokaryosis (Grindle, 1963).

Introduction of Antagonistic *het* Alleles or Products into the Same Cell or Nucleus

Assays introducing antagonistic *het a*lleles or products into the same cell or nucleus have been performed in various ways and with different consequences. Cell death may occur when incompatible cytoplasm is directly introduced into the cell, e.g., by microinjection in *N. crassa* (Garnjobst and Wilson, 1956) or by maternal inheritance of the HET-s prion in *P. anserina* (Dalstra et al., 2005). More generally, VI is manifested as abnormal growth, morphology, and pigmentation after introduction of antagonistic *het* alleles, e.g., by transformation (Micali and Smith, 2006; Saupe et al., 1996a, 1996b) or protoplast formation (Dales and Croft, 1990). In pseudohomothallic species, such as *P. anserina* and *Neurospora tetrasperma*, outcrossing may result in incompatible combinations of *het* alleles in the sexual progeny leading to self-incompatible progeny, abortion, or loss of the heterokaryotic state of ascospores (Bernet, 1967; Pinan-Lucarre et al., 2007; Saenz et al., 2001). In *N. crassa*, loci involved in VI have been assessed by using strains containing chromosomal translocations (Perkins, 1997). When such strains are crossed to wild-type isolates, one-fourth of the progeny contain partial duplications for the translocated segment. If progeny have alternate *het* specificity in the duplicated segment, partial diploid progeny will show a typical VI phenotype (Mylyk, 1975; Perkins, 1988). Translocation strains have been useful in assessing specificity at single *het* loci in wild-type isolates of *N. crassa* (Wu et al., 1998). Similar to forced heterokaryons, ultrastructural studies of incompatible partial diploids in *N. crassa* show organelle degeneration, shrinkage of the plasma membrane, and septal plugging (Jacobson et al., 1998).

Transfer of Senescence

In several fungi, the transfer of cytoplasmic elements is not completely blocked by VI. However, there is a significant delay in the spread of highly suppressive lethal conditions, such as vegetative death in *A. nidulans* (Caten, 1972), mitochondrially based senescence in *P. anserina* (Marcou, 1961), and plasmid-based senescence in *Neurospora* (Debets et al., 1994). In compatible, but not in incompatible pairings of isolates, a mixed culture has the life span of the senescent strain. A VI test based on this principle has been used to assay field isolates of *Neurospora intermedia* (Debets et al., 1994).

The VI results of the barrage and heterokaryon assays do not systematically overlap. The relationship between barrage formation and VI shows concordance in *P. anserina* (Bernet, 1965). However, in *N. crassa, C. parasitica, Sclerotinia sclerotiorum, Rosellinia necatrix*, and *Tuber borchii* (Aimi et al., 2002a, 2002b; Ford et al., 1995; Micali and Smith, 2003; Sbrana et al., 2007; Smith et al., 2006), barrage formation was not necessarily associated with genetic differences at *het* loci. For instance, in *C. parasitica,* heteroallelism at one of the incompatibility loci (*vic4*) is detected in barrage assays but not in forced heterokaryon assays (Smith et al., 2006). In *N. crassa*, a barrage reaction occurs between strains identical at all major *het* loci, while barrages are not observed between strains with genetic differences at *het-6, het-c,* and *mat* (Micali and Smith, 2003). These observations suggest that, in some cases, barrage formation functions independently of VI.

Classification of Fungal Populations into vcgs

Incompatibility assays can be used to classify individuals in a fungal population into vegetative compatibility groups (vcgs). The number of different vcgs in populations can be considerable. One recent study on vcg diversity in native populations of the chestnut blight fungus, *C. parasitica*, indicated that in Japan and China almost every isolate belonged to a unique vcg (Liu and Milgroom, 2007). Another study, involving *Fusarium oxysporum*, identified 96 different vcgs in a sample of 128 isolates (Alves-Santos et al., 1999). In fungi that lack a sexual stage, have infrequent sexual recombination, or primarily inbreed, it is often inferred that strains belonging to the same vcg represent clonal derivatives from a common ancestor. Analysis of vcgs in populations is often used by plant pathologists to characterize the structure and dynamics of fungal populations.

GENETICS OF HETEROKARYON INCOMPATIBILITY

Two main types of genetic determinism of VI can be distinguished. In allelic systems, VI is determined by the interaction of two incompatible alleles of the same locus. In

nonallelic incompatibility, the VI reaction is caused by the interaction of specific alleles from distinct loci. The total number of *het* loci varies from species to species. In Ascomycetes it is usually around 10 (Anwar et al., 1993; Cortesi and Milgroom, 1998; Jinks et al., 1966; Perkins and Davis, 2000; Pinan-Lucarre et al., 2007). In Basidiomycetes, the number of VI loci is smaller, from one to four (Kauserud et al., 2006; Lind et al., 2007; Marcais et al., 2000; Worrall, 1997). For allelic systems, the number of allelic variants at a given locus is generally low (two or three alleles). The allelic systems are apparently the more common type of incompatibility systems. However, as is shown in the following section, the boundaries of this classification are somewhat blurred by the fact that more complex situations are also encountered; for instance, there are allelic systems in which the two allelic forms have totally different sequences or systems in which closely linked genes display nonallelic interactions that genetically appear allelic.

Genes involved in VI have been identified so far in only two species: *N. crassa* and *P. anserina*. Two categories of genes involved in VI have been characterized. The first category includes *het* genes that encode recognition function and are polymorphic between individuals. The second category includes downstream or upstream effector genes, in which mutations suppress or attenuate phenotypes associated with VI. The different incompatibility systems that have been characterized at the molecular level in *N. crassa* and *P. anserina* are shown in Fig. 2.

N. crassa

The Mating-Type Locus and the *tol* Suppressor

In *N. crassa*, the *mat A-1* and *mat a-1* mating-type genes are essential to define mating identity and for sexual reproduction. However, *mat A-1* and *mat a-1* function as a *het* locus during somatic cell fusions (Glass et al., 1988); heterokaryons between *A* and *a* strains are severely inhibited in their growth and aconidial and show cell death (Beadle and Coonradt, 1944; Garnjobst and Wilson, 1956; Pittenger, 1957). In other words, the result of the interaction between the *mat A-1* and *mat a-1* genes is completely different, depending on the cellular context in which it takes places.

The *mat a* and *mat A* mating-type alleles occupy the same locus in *a* and *A* strains, respectively, but are completely different in DNA and amino acid sequence; they are termed idiomorphs (Glass et al., 1988, 1990). The *mat A* idiomorph bears three different genes: *mat A-1*, *mat A-2*, and *mat A-3*. *mat A-1* specifies mating identity and is also required for postfertilization functions, while *mat A-2* and *mat A-3* operate only during postfertilization events (Ferreira et al., 1998, 1996). The *mat a* idiomorph contains a single gene, *mat a-1*, which is responsible for all mating and postfertilization

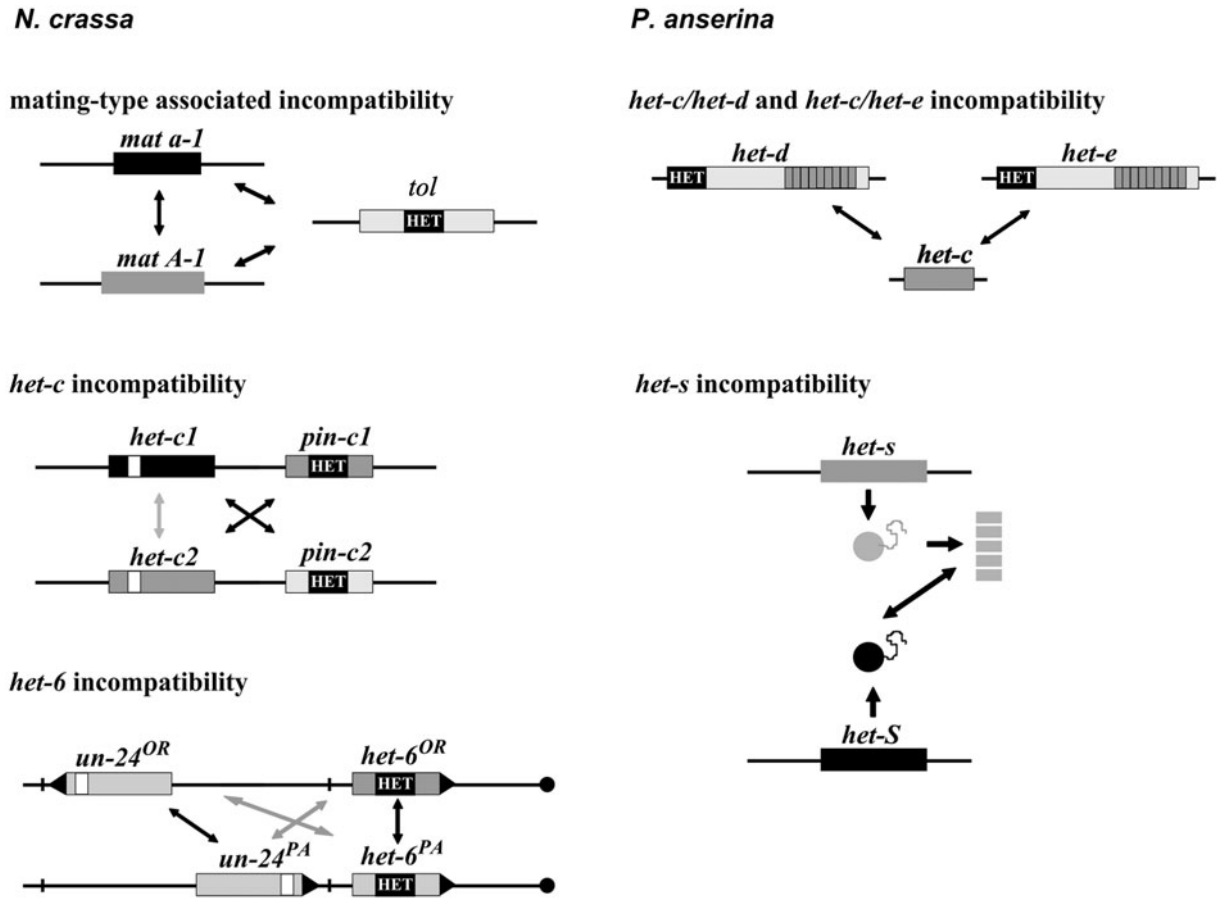

FIGURE 2 The different incompatibility systems characterized at the molecular level in *N. crassa* and *P. anserina*. The black double arrows represent incompatible interactions. The gray double arrows represent interactions that contribute to the VI response. The HET domain is represented by a black box. The specificity regions in *het-C* and *un-24* are represented by a white box. See the text for details.

functions (Staben and Yanofsky, 1990). The *mat a-1* and *mat A-1* gene pair confers the incompatibility function (Glass et al., 1990; Staben and Yanofsky, 1990). The MAT a-1 and MAT A-1 polypeptides are transcription factors displaying an HMG and an α-box, respectively. The mating and incompatibility functions are genetically separable in MAT a-1 and MAT A-1. Mutations or deletions that specifically affect only one of the functions have been described (Saupe et al., 1996a, and references therein). This observation led to the suggestion that MAT a-1 and MAT A-1 specify mating and somatic identity by distinct mechanisms.

This hypothesis is further supported by the fact that mutations at the unlinked *tol* locus suppress mating-type-associated incompatibility but do not affect mating capacity (Newmeyer, 1970) (Fig. 2). The *tol* gene encodes a 1,011-amino-acid polypeptide displaying a leucine-rich repeat (LRR) motif and a HET domain (Shiu and Glass, 1999). LRRs are protein-protein interaction domains consisting of repeated sequences. LRRs are encountered in a large number of proteins that are often involved in recognition functions, such as gene families associated with pathogen recognition in plants (DeYoung and Innes, 2006). As discussed below, the HET domain is a fungus-specific protein domain found in a variety of proteins involved in VI. *tol* is expressed in vegetative tissue but not in developing fruiting bodies, which could explain why the *mat a-1-mat A-1* interaction only leads to VI and cell death during the vegetative stage (Shiu and Glass, 1999).

The *het-c/pin-c* Locus

The *het-c/pin-c* system involves two adjacent genes located on LGII (Kaneko et al., 2006; Saupe and Glass, 1997; Saupe et al., 1996b). *het-c* encodes a plasma membrane protein with a large glycine-rich unstructured domain (Sarkar et al., 2002; Saupe et al., 1996b). Three distinct allelic types have been described for *het-c* (Saupe and Glass, 1997). The alleles differ in a highly polymorphic region of 34 to 48 amino acids. This region determines allelic specificity (Saupe and Glass, 1997; Wu and Glass, 2001). During the incompatibility reaction, a heterocomplex between alternate incompatibility polypeptides forms at the plasma membrane (Sarkar et al., 2002).

The adjacent gene *pin-c* (named for "partner for incompatibility with *het-c*") encodes a protein with a HET domain (Kaneko et al., 2006). Incompatibility between alternate *het-c* alleles can be suppressed by mutations in *pin-c*. Three different *pin-c* alleles have been described. The level of polymorphism between the *pin-c* alleles is extreme, ranging from 62 to 76% nucleotide identity, depending on the gene pair considered. *het-c/pin-c* gene pairs form three distinct haplotypes. The incompatibility function of these haplotypes is determined by three additive interactions: two nonallelic *het-c-pin-c* interactions and an additional allelic *het-c* interaction that contributes to the severity of the VI phenotype (Fig. 2) (Kaneko et al., 2006). Thus, this VI system, which at first glance is genetically an allelic system, is in fact based primarily on nonallelic interactions.

A screen for suppressors of *het-c/pin-c* incompatibility identified a gene called *vib-1* (for "vegetative incompatibility blocked"), which encodes a putative transcription factor showing homology to *Saccharomyces cerevisiae* Ndt80 (Dementhon et al., 2006; Xiang and Glass, 2002). Mutations in *vib-1* also suppress mating-type-associated incompatibility and incompatibility determined by the *het-6/un-24* system (Xiang and Glass, 2004). The suppressive effect is due to the fact that *vib-1* positively regulates expression of *pin-c*, *tol*, and *het-6* HET domain encoding genes. Expression of these genes is barely detectable in a Δ*vib-1* strain (Dementhon et al., 2006).

The *het-6/un-24* System

The third incompatibility system of *N. crassa* that has been characterized at the molecular level is the *het-6/un-24* system (Micali and Smith, 2006; Mir-Rashed et al., 2000; Smith et al., 2000a, 2000b). The *het-6* locus bears two tightly linked genes designated *het-6* and *un-24*, each having two allelic variants (Oakridge/OR and Panama/PA) (Fig. 2). In natural populations, only *het-6*^{OR} *un-24*^{OR} and *het-6*^{PA} *un-24*^{PA} allele combinations have been found; these allele combinations define the OR and PA haplotypes, respectively. The *het-6* gene encodes a protein with a HET domain, and *un-24* encodes the large subunit of ribonucleotide reductase, an essential enzyme of DNA metabolism. The sequence divergence between *het-6* alleles is considerable: the *het-6*^{OR} and the *het-6*^{PA} gene products share only 68% amino acid identity (Micali and Smith, 2006). In contrast, polymorphism in the *un-24* gene product is limited to a region located at the C terminus of the ribonucleotide reductase. The OR and PA haplotypes differ in overall genomic organization; the divergence between the haplotypes has been generated by a 18.6-kbp paracentric inversion (Micali and Smith, 2006). The existence of this inversion provides an explanation for severe linkage disequilibrium observed between *het-6* and *un-24*.

P. anserina

The het-c/het-d and *het-c/het-e* Systems

The *het-c*, *het-d*, and *het-e* genes of *P. anserina* define two nonallelic systems (*het-c/het-d* and *het-c/het-e*) (Bernet, 1965; Pinan-Lucarre et al., 2007). All three loci are multiallelic. The *het-c/het-d* and *het-c/het-e* incompatibilities also lead to sexual incompatibility, a situation not encountered for the *N. crassa* VI systems (Bernet, 1965). The *het-c* gene encodes a glycolipid transfer protein (GLTP) conserved in fungi, plants, and animals (Brown and Mattjus, 2007; Mattjus et al., 2003; Saupe et al., 1994). (Note that in spite of the confusing homonymy, *P. anserina het-c* and *N. crassa het-c* are not homologous.) *P. anserina het-c* is homologous to ACD11, a GLTP involved in programmed cell death (PCD) in higher plants (Brodersen et al., 2002). Het-c is required for proper ascospore delimitation and maturation (Saupe et al., 1994). *Het-d* and *het-e* are paralogues and encode large multidomain proteins (Espagne et al., 2002; Saupe et al., 1995). Both comprise an N-terminal HET domain followed by a central NACHT domain and a C-terminal WD-repeat domain. NACHT domains are regulatory NTP-binding domains involved in oligomerization and found in a variety of proteins controlling PCD and pathogen recognition processes (Leipe et al., 2004). NACHT proteins are part of a larger family, termed STAND, which includes other regulators of PCD, such as mammalian APAF-1 (Leipe et al., 2004). WD-repeats adopt a circular β-propeller fold forming a protein-protein interaction platform (Smith et al., 1999). *het-d* and *het-e* are in fact part of a large gene/pseudogene family in *P. anserina* that includes 10 members that share the NACHT and WD-repeat domains (Paoletti et al., 2007). Polymorphism in the *het-d* and *het-e* alleles lies in the WD-repeat domain, specifically at positions located at the protein-protein interaction surface (Espagne et al., 2002; Paoletti et al., 2007). Polymorphism in the HET-C GLTP localizes at the protein surface. It is probable that HET-C/HET-D and HET-C/HET-E incompatibility involves direct interaction of the

GLTP with the polymorphic positions of the WD-repeat of HET-D and HET-E.

Nonallelic incompatibility in *P. anserina* can be suppressed by mutations in the *mod-A* and *mod-B* genes (Barreau et al., 1998). Mutations in *mod-A* lead to partial suppression, while complete suppression of the *het-c/het-d* and *het-c/het-e* VI phenotype occurs only when mutations in *mod-A* and *mod-B* are associated.

The *het-s* System

The *het-s* allelic system is the only incompatibility system described so far for which no involvement of a HET domain has been detected. The *het-s* locus exists as two alleles, designated *het-s* and *het-S* (Rizet, 1952). HET-s and HET-S are proteins of 289 amino acids that differ at 13 amino acid positions distributed over the entire sequence, rather than being clustered in a discrete polymorphic region (Deleu et al., 1993; Turcq et al., 1991). Strains of the *het-s* genotype can exist as two alternate phenotypes, designated [Het-s*] and [Het-s] (Beisson-Schecroun, 1962; Rizet, 1952; reviewed by Saupe, 2007). [Het-s*] strains are compatible with [Het-S] strains, while [Het-s] strains are incompatible with [Het-S] strains. The [Het-s*] and [Het-s] phenotypes are metastable: [Het-s*] strains can acquire the [Het-s] phenotype spontaneously at a low frequency when subcultured. The [Het-s] phenotype can in turn be lost when mycelia are regenerated from propagules that contain very little cytoplasm. For instance, a fraction (~1%) of the mycelia that regenerate after plating of protoplasts from a [Het-s] strain have the [Het-s*] phenotype (Malato et al., 2007). The [Het-s] phenotype is contagious and cytoplasmically transmitted from a [Het-s] to a [Het-s*] strain. In other words, when a [Het-s*] strain is confronted with a [Het-s] strain, it is systematically converted to the [Het-s] phenotype. The [Het-s] phenotype then invades the mycelium at a high rate, reaching several millimeters per hour (Beisson-Schecroun, 1962).

The epigenetic properties and cytoplasmic inheritance of [Het-s] are explained by the fact that the *het-s*-encoded protein is a prion (Coustou et al., 1997). Prions are self-propagating protein particles responsible for fatal neurodegenerative diseases in mammals, but prions also exist in fungi, where they are detected as cytoplasmically transmitted, non-Mendelian genetic elements (Benkemoun and Saupe, 2006). The HET-s protein has two conformational states: a soluble monomeric form in [Het-s*] strains and an infectious aggregated form in [Het-s] strains (Coustou-Linares et al., 2001). In vitro studies showed that the aggregated prion form of HET-s corresponds to an amyloid polymer (Dos Reis et al., 2002; Maddelein et al., 2002; Ritter et al., 2005). Amyloids are fibrillar protein aggregates that display a so-called cross-β structure. HET-s is a two-domain protein with an N-terminal globular domain (spanning amino acid residues 1 through 220) and a C-terminal domain responsible for prion propagation and amyloid formation (Balguerie et al., 2003). This prion-forming domain (PFD) (residues 218 to 289) is unstructured in the soluble form of the protein and adopts a cross-β amyloid fold in the aggregated form (Balguerie et al., 2003). In spite of the tremendous technical difficulties associated with the structural characterization of amyloids, the structure of the HET-s PFD in the prion form was solved recently by solid-state nuclear magnetic resonance, making it the first prion protein to be characterized at that level of resolution (Wasmer et al., 2008). The HET-s amyloids display an exceptionally high level of order not generally found in other amyloids. The HET-s(218–289) displays a pseudorepeat structure with two layers of β-strand per monomer. The fold displays a triangular hydrophobic core leading to proper segregation of the polar residues and charged residues at the fibril surface, while apolar side chains are not exposed to the cellular milieu. This highly organized fold might provide an explanation for the fact that HET-s amyloid fibrils do not display any intrinsic toxicity in vivo.

HET-s and HET-S proteins differ both in the globular domain and in the region corresponding to the HET-s PFD (Balguerie et al., 2003; Turcq et al., 1991). Mutational analyses and chimeric gene constructions have revealed that polymorphisms relevant for specifying the incompatibility type actually reside in the globular domain (Balguerie et al., 2003; Deleu et al., 1993). Single point mutations in the globular domain of HET-S are sufficient to switch incompatibility specificity from [Het-S] to [Het-s]. In HET-S, both the globular domain and the region corresponding to the HET-s PFD are necessary for the incompatibility function. In the case of HET-s, the PFD is required for the incompatibility function, but large deletions in the globular domain do not affect incompatibility function (Balguerie et al., 2004). The mechanism underlying the incompatibility reaction in the *het-s* system remains unknown, in spite of the extensive structural characterization of the HET-s protein. A model compatible with the current data is that during the anastomosis of [Het-s] and [Het-S] strains, HET-s amyloid seeds trigger the conversion of HET-S to an amyloid form. In this model, in contrast to the HET-s amyloids, the HET-S amyloids would display an intrinsic toxicity that is dependent on the HET-S globular domain.

The *het-s/het-S* antagonism is also expressed during the sexual cycle (Bernet, 1965). *het-s* is a spore killer locus (Dalstra et al., 2003, 2005). In a *het-s* female × *het-S* male cross performed at 18°C, in a fraction of the asci, the two ascospores of *het-S* genotype abort, leading to an excess in *het-s* progeny over the expected Mendelian ratio. The *het-s* allele thus behaves as a meiotic drive element when the HET-s protein is in the prion state in the female parent. The *het-s* system provides an example of a genome conflict that can lead to different outcomes depending on the cellular and developmental context in which the antagonistic interaction occurs.

The molecular characterization of the *het*-genes summarized here has revealed that, in contrast to the situation suggested by formal genetic analyses, at the molecular level, VI nonallelic interactions (in the sense of interaction of distinct proteins rather than polymorphic variants of the same protein) are the rule, rather than the exception (Kaneko et al., 2006).

The HET Domain and the Modular Concept of Incompatibility

Five of the six incompatibility systems characterized so far include a gene bearing a HET domain (*tol* in mating-type incompatibility, *pin-c* in *het-c* incompatibility, *het-6* in the *un-24 het-6* haplotype, and *het-d* and *het-e* in the *het-c/d/e* system) (Fig. 2). The only exception to date is the *het-s* prion system, which apparently relies on a very specific toxicity mechanism related to the amyloid-forming ability of the involved proteins. No other VI system displays *het-s*-like epigenetic characteristics, again suggesting that *het-s* is an exception.

The HET domain spans about 200 amino acids and is defined by three conserved blocks of 15 to 30 amino acids with invariant tryptophan residues in each block (Smith et al., 2000b) (Pfam entry, P06985). Constitutive overexpression of the isolated HET domain of the HET-E protein leads to induction of a cell death reaction that is cytologically related

to the VI cell death response (Paoletti and Clave, 2007). Importantly, this cell death reaction is independent of *het-c* (the normal partner of *het-e* in VI) and can be suppressed as the *bona fide het-c/het-e* VI response by mutations in the *mod-A* and *mod-B* genes. These data are consistent with a modular conception of VI, with one protein module involved in the recognition step per se and a second protein module responsible for triggering the VI-associated cell death response. In the *het-c/het-e* system, the recognition module would be constituted by the polymorphic WD-repeat domain and the HET-C protein, while the HET domain of HET-E would correspond to the cell death execution domain. It has been proposed that the transduction of the recognition step into activation of the HET death domain might be based on a mechanism related to the one found in other STAND proteins, like the mammalian APAF-1 apoptosis-inducing factor (Paoletti and Clave, 2007). In APAF-1, the CARD death domain interacts with the WD-repeats until binding of cytochrome *c* to the WD-repeats leads to exposure of the CARD death domain.

The HET domain is found only in members of the Pezizomycota, and all genomes from sequenced Pezizomycota species possess at least one protein with a HET domain (Fig. 3). Fifty-five HET domain proteins are found in the *N. crassa* genome, while 129 are found in *P. anserina*. This number of HET domain genes far exceeds the number of *het* loci that have been characterized genetically in these species. It is thus very unlikely that all these HET domain proteins are involved in VI. It has been proposed that HET domain genes have undergone massive expansion in members of the Pezizomycota to serve different functions in recognition or host defense mechanism, whose exact nature remains unknown (Fedorova et al., 2005). Although Basidiomycetes have VI systems (Worrall, 1997), no HET domain genes have been identified in any basidiomycete genome sequenced so far. This observation suggests that Basidiomycetes have devised an alternative evolutionary solution to the problem of somatic nonself recognition.

CELL BIOLOGY OF VEGETATIVE INCOMPATIBILITY

Compatible Fusions

Hyphal fusion is a ubiquitous phenomenon in filamentous fungi (Glass and Fleißner, 2006; Glass et al., 2004; see also chapter 19), including filamentous basidiomycete, ascomycete, and zygomycete species (Buller, 1933; Gregory, 1984; Rayner, 1996; Giovannetti et al., 1999, 2001; Griffin and Perrin, 1960). Similar to cell fusion in other organisms, the process of hyphal fusion in filamentous fungi requires cell recognition, adhesion, cell wall breakdown, and membrane merger. In *N. crassa*, hyphae at the periphery of the colony exhibit negative autotropism and are refractory to fusion (Trinci, 1984). Within the interior of a colony, hyphae often show positive chemotropic responses (homing) associated with hyphal fusion events (Buller, 1933; Hickey et al., 2002). Both hyphal tip growth and the formation of lateral branches are associated with a membrane-dense organelle, the Spitzenkörper (Girbardt, 1957; Hickey et al., 2002; Lopez-Franco and Bracker, 1996; Riquelme and Bartnicki-Garcia, 2004; Riquelme et al., 1998). During hyphal fusion, the Spitzenkörper of the fusion hyphae are always juxtaposed (Hickey et al., 2002). Phenotypic aspects of compatible hyphal fusion are similar among filamentous fungi, including *T. borchii* (Sbrana et al., 2007), *C. parasitica* (Newhouse and MacDonald, 1991), and the basidiomycetes *Phanerochaete velutina* and *Stereum hirsutum* (Ainsworth and Rayner, 1986). Chemotropic interactions and rare fusion events between different fungal species have also been reported (Köhler, 1930).

Incompatible Fusions

If two fungal colonies of the same species undergo hyphal fusion but have genetic differences at *het* loci, most frequently, the heterokaryotic fusion cell is compartmentalized and dies or is inhibited in its growth. The triggering of hyphal compartmentation and death following hyphal

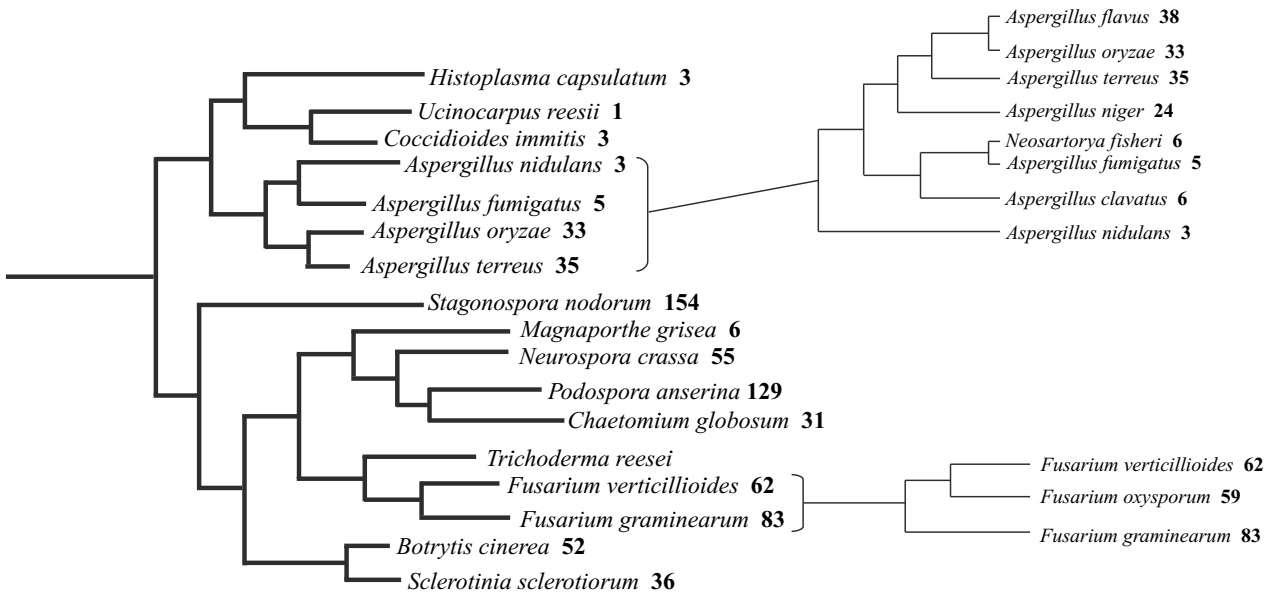

FIGURE 3 Distribution of HET domain proteins in the genomes of sequenced Pezizomycota species. For each species, the number of HET domain proteins in the genome is given on the right. The phylogenetic tree was modified from Fitzpatrick et al., 2006, to include the additional species that have been more recently sequenced.

fusion between *het*-incompatible individuals is morphologically similar among different fungi (Aimi et al., 2002a, 2002b; Ainsworth and Rayner, 1986; Beisson-Schecroun, 1962; Biella et al., 2002; Garnjobst and Wilson, 1956; Newhouse and MacDonald, 1991; Rizet, 1952). Common features include septal plugging, vacuolization of the cytoplasm, organelle degradation, and shrinkage of the plasma membrane from the cell wall. Microscopic characteristics of cell death associated with incompatible fusions are similar to VI in forced heterokaryons, partial diploids, and transformants (Glass and Dementhon, 2006; Perkins, 1988). The frequency of cell death in forced heterokaryons and partial diploid progeny is characteristic of a particular *het* interaction in *N. crassa*, with approximately 30% of the hyphal compartment dying in *het-c/pin-c* interactions, while a smaller percentage of cell death was observed in incompatible *mat* heterokaryons (Xiang and Glass, 2002, 2004).

One of the earliest events associated with an incompatible fusion event is the rapid plugging of septa in the heterokaryotic fusion cell and often in surrounding cells. Presumably, septal plugging prevents transfer of deleterious cytoplasmic elements following the fusion event. In filamentous ascomycete fungi, loss of cytoplasm in injured hyphae is restricted by the fast and efficient sealing of the central pores of hyphal cross walls, or septa, by a peroxisome-derived organelle called the Woronin body (Jedd and Chua, 2000; Markham and Collinge, 1987). The Woronin body is only occasionally associated with plugged septa in incompatible hyphal compartments (Fleissner and Glass, 2007). However, a protein required for hyphal fusion in *N. crassa*, SOFT, localizes to septal plugs in incompatible hyphal compartments (Fleissner and Glass, 2007; Fleissner et al., 2005). These data suggest that some components of the hyphal fusion machinery may also be involved in VI. Some VI interactions may also lead to the progressive loss of one of the nuclear types of the heterokaryon (Pittenger and Brawner, 1961); such unstable heterokaryons do not show growth inhibition, hyphal compartmentation, or death. It is likely that the instability of a nuclear partner in a heterokaryon occurs by biochemical and genetic mechanisms distinct from those of VI.

One of the phenotypic aspects associated with VI is vacuolization of incompatible hyphal compartments, which eventually burst (Glass and Kaneko, 2003). In filamentous fungi, vacuoles contain numerous proteases and degradative enzymes, which are released into the cytoplasm upon lysis of the vacuoles. In *P. anserina*, cell death is associated with the induction of genes involved in autophagy (Baehrecke, 2005; Pinan-Lucarre et al., 2003, 2005, 2007). In other eukaryotic systems, autophagic PCD has been shown to have biochemical and molecular features distinct from those of apoptotic PCD (Bursch, 2001). In *P. anserina*, a strain containing a deletion of *PaATG1*, the *Podospora* orthologue of the *S. cerevisiae* ATG1 gene, which is involved in the early steps of autophagy in yeast, abolished autophagy in *P. anserina*, but VI was not affected (Pinan-Lucarre et al., 2005, 2007). In fact, cell death by VI occurred more quickly in the *ΔPaATG1* mutants, suggesting that the induction of autophagy during VI may have a protective role.

PCD in Filamentous Fungi

Ultrastructural changes in dying cells during VI are consistent with features associated with PCD in multicellular eukaryotes (Konopleva et al., 1999). A number of biochemical assays have been used to assess cellular changes associated with apoptosis in filamentous fungi, including terminal deoxynucleotidyltransferase-mediated dUTP-biotin nick end labeling (TUNEL) for DNA degradation, annexin-fluorescein isothiocyanate binding for the presence of phosphatidylserine on the outer leaflet of the plasma membrane, and 2,7′-dichlorodihydrofluorescein diacetate for reactive oxygen species (ROS) production. Based on these assays, an apoptosis-like phenomenon occurs in filamentous fungi and in unicellular fungi, such as *S. cerevisiae*, in response to treatment with hydrogen peroxide, phytosphingosine, antifungal proteins (PAF), amphotericin B, and farnesol (Castro et al., 2008; Chen and Dickman, 2005; Cheng et al., 2003; Jin and Reed, 2002; Leiter et al., 2005; Ludovico et al., 2005; Mousavi and Robson, 2004; Semighini et al., 2006) and entry into stationary phase and asexual sporulation in *Aspergillus* sp. (Mousavi and Robson, 2003; Thrane et al., 2004). In *A. nidulans*, resistance to PAF and farnesol was associated with a dominant-interfering mutation in the α-subunit of G protein, $fadA^{G203R}$ (Leiter et al., 2005) or mutations in the Gβ subunit (Δ*sfaD*), respectively (Semighini et al., 2006). Interestingly, in *P. anserina* mutations in the *mod-D* gene, which encodes the α-subunit of a heterotrimeric G protein orthologous to *fadA*, suppress growth defects associated with some VI interactions. These observations suggest a connection between PCD induced by exposure to environmental toxins and VI.

In *N. crassa*, the cytology of hyphal fusion compartments between incompatible strains that differ in *het* specificity (*mat*, *het-c*, or *het-6*) showed extensive nuclear degradation and TUNEL-positive nuclei (Marek et al., 2003) and elaboration of ROS (Hutchison et al., 2009). In *S. cerevisiae*, ROS and TUNEL-positive nuclei have been associated with PCD in response to a variety of environmental treatments, some of which require a metacaspase gene, *YCA1* (Khan et al., 2005; Madeo et al., 2002; Mazzoni and Falcone, 2008). Caspases are proteases in animal cells that are activated during apoptosis and are involved in proteolytic cleavage of proteins important to the death process. These observations suggest that some aspects of PCD in *S. cerevisiae* are similar to that of metazoan apoptosis (Mazzoni and Falcone, 2008). *N. crassa* and other filamentous ascomycete fungi have two metacaspase orthologues; deletion of either or both of these predicted metacaspase genes had no effect on the frequency of cell death or on the phenotype of VI (Hutchison et al., 2009). These data suggest that even though some cytological events (such as ROS generation and nuclear degradation) are similar between VI and apoptosis, other currently unknown mechanisms are associated with the execution of death during VI.

In addition to nonself recognition between fungal individuals of the same species, nonself recognition also occurs between hyphae of different fungal species, such as between *P. anserina* and *Coprinopsis cinerea*. These interactions were associated with the generation of hydrogen peroxide and death of hyphae (Silar, 2005). It is likely that these mycelial interactions occur without hyphal fusion; fusion is rarely observed between species that are distantly related (Köhler, 1930).

EVOLUTIONARY ASPECTS

Kin selection theory (Hamilton, 1987) provides the most widely accepted explanation for the evolution of allorecognition (Buss and Green, 1985; Buss, 1987; Grafen, 1990; Rousset and Roze, 2007). Fusion between individuals has

potential costs and benefits. Potential benefits include increase in size, with associated increases in reproductive output and survivorship, while the costs involve the potential for competition among reproductive cells (Buss and Green, 1985). If fusion occurs between related individuals, the benefits of fusion may still apply, but the potential costs of reproductive competition are reduced by a fraction proportional to the relatedness with the fusing partner (Buss and Green, 1985). Kin selection theory thus predicts that the cost of fusion decreases as relatedness increases, hence favoring allorecognition.

Although not always explicitly, most explanations for the evolution of VI, and of nonself recognition (allorecognition) in general, have focused on this aspect: VI ensures that somatic growth exclusively benefits closely (clonally) related reproductive cells and thereby restricts the spread of selfish nuclei (or selfish cell lineages in organisms other than fungi) and also of harmful cytoplasmic elements, such as mycoviruses (for examples, see Hartl et al., 1975; Buss, 1987; Nauta and Hoekstra, 1994; Paoletti et al., 2007). Although this explanation makes intuitive sense, theoretical models have pointed out some complications. One complication of the evolution of allorecognition, first noted by Crozier (1986), is how selection directly affects the recognition genes used to estimate overall relatedness. If the short-term costs of VI are larger than the short-term benefits (or, relatively equivalent, if somatic fusion is reciprocally beneficial), positive-frequency-dependent selection on common *het* alleles will eliminate the genetic polymorphism required for VI. Furthermore, even though allorecognition can evolve as a protection against selfish nuclei or other cytoplasmic elements (Hartl et al., 1975), the number of vcgs in filamentous fungi is difficult to explain (Nauta and Hoekstra, 1994, 1996).

Patterns of *het* Gene Polymorphism and Signs of Balancing Selection

During the last decade, several studies have characterized the evolution of *het* loci. Some general features are emerging from these investigations. One remarkable attribute of *het* loci is that they are often completely unrelated between species and, furthermore, that homologues that function as *het* loci in one species can lack such function in other species (for examples, see Kerenyi et al., 2006; and Saupe et al., 2000). Saupe et al. (2000) found that the homologue of the *Neurospora het-c* gene probably does not function as a *het* locus in *P. anserina*, most likely because this species lacks the required polymorphism associated with nonself recognition. A second feature is that many *het* loci have other functions in addition to their role in VI. For example, in several ascomycete fungi, the two mating-type idiomorphs also confer VI (reviewed by Shiu and Glass, 1999; see above). Another example is the *het-c* locus of *P. anserina*, which also has a function during sexual reproduction (Saupe et al., 1994). A third feature of VI is that balancing selection maintains diversity of *het* loci and positive selection generates diversity in these genes in ascomycete species (Glass and Kaneko, 2003; Saupe, 2000; Paoletti et al., 2007). In *Neurospora* and related genera, balancing selection has even resulted in transspecies polymorphism (Wu et al., 1998; Powell et al., 2001, 2007); the three alleles of *het-c* were also found in nearly equal frequencies in population samples. Finally, some regions of the *het-c* sequence showed a high frequency of nonsynonymous substitutions. These features all strongly suggest that balancing selection has operated to maintain allelic diversity at *het-c*. Similarly, alternate *un-24/het-6* haplotypes were found in equal frequency in an *N. crassa* population isolated from a Louisiana sugarcane field along with a high frequency in nonsynonymous substitutions in the *het-6* alleles (Smith et al., 2000a, 2000b). However, balancing selection is not a general feature of all *het* loci (see Milgroom and Cortesi, 1999).

Structural features of *het* loci may guarantee a high mutation supply. For example, the *het-d* and *het-e* loci, involved in nonallelic VI in *P. anserina*, consist of repeated units (Paoletti et al., 2007). The high copy number of these repeats increases the probability of a mutation in one of the copies. In combination with positive selection and concerted evolution, this may enhance the mutation rate of this repeated element. RIP (repeat-induced point mutations), a fungus-specific hypermutation process acting specifically on repeated sequences, might further enhance the mutation supply of repeated sequences (Paoletti et al., 2007).

In summary, *het* genes are highly polymorphic, often have different cellular functions in addition to their role in VI, display signs of positive and balancing selection, and can have structural features that guarantee a high mutation supply.

The Consequences of Fusion and VI

As indicated earlier, somatic fusion has fitness consequences for both partners in an encounter. These fitness consequences can be caused by genetic differences between the partners or by nongenetic effects of fusion. A possible advantage caused by genetic differences between partners may derive from genetic complementation, leading to chimeric vigor (Buss, 1999). Furthermore, especially relevant for purely asexual fungi, somatic fusion may facilitate recombination via parasexuality (Pontecorvo, 1958). However, VI severely restricts the potential for heterokaryon formation, and therefore, the significance of parasexual recombination probably does not lie in recombination between divergent asexual clones as was suggested initially (Haldane, 1955). However, a recent paper has shown that parasexuality may nevertheless accelerate adaptive evolution, because mutation may generate sufficient variation to make genetic recombination effective (Schoustra et al., 2007).

Depending on how the reproduction between the two partners is divided, somatic fusion can also be advantageous for only one partner, at a cost to the other. Effectively, this means that one of the two partners parasitizes the other (Buss, 1987; Grosberg, 1988). Parasitic nuclear genes have been found in *N. crassa* (Pittenger and Brawner, 1961). The parasitic allele has a transmission advantage in the presence of its nonparasitic homologue but lowers the fitness of the individual in homozygous condition. Parasitism may be conditional on realized investment; if a mycelium has reached a certain size or invested in the production of sexual structures, fusion bears the risk that the investment will be exploited by another genotype ("resource plundering" [Debets and Griffiths, 1998]).

The second category is nongenetic consequences of fusion, which can be measured as the fitness outcomes of self fusion, i.e., fusion between genetically identical individuals. If the average costs and benefits of fusion cancel out, self fusion is neutral. A second possibility is that fusion is reciprocally beneficial, resulting in synergy. Several possibilities exist for synergy. Fusion between different individuals results in an instantaneous increase in the number of somatic cells. This can be mutually advantageous if the initiation of reproduction depends upon a critical size of an individual, which can be reached faster via fusion. If the risk of mortal-

ity is size dependent, an increase in size via fusion reduces this risk for both partners. Another potential advantage of fusion is that spatially separated substrates are more efficiently utilized (Buss, 1982; Rayner et al., 1984). Furthermore, if VI is costly, for example during barrage formation, fusion is automatically reciprocally beneficial, *relative* to VI.

The last possibility is that fusion results in a net loss of fitness. For example, fusion between an individual infected with a harmful horizontally transmitted virus and an uninfected individual will cause a net loss of fitness. Mycoviruses and other harmful cytoplasmic elements are widespread among fungi, so potentially they are a potent selective force. VI has indeed been shown to reduce the transmission of parasitic cytoplasmic elements (Brasier, 1986a, 1986b; Buck and Brasier, 2002; van Diepeningen et al., 1997), although it does not always fully prevent it (Caten, 1972; Anagnostakis and Day, 1979; Anagnostakis, 1983; Debets et al., 1994). For the invasive pathogen *Ophiostoma novo-ulmi*, strong evidence has been obtained that the specific acquisition of VI genes (and a MAT allele, which enabled sexual reproduction) from the related species *O. ulmi* has restricted the spread of cytoplasmic viruses (Paoletti et al., 2006).

Assumptions about the Consequences of Self Fusion Determine the Outcome of Theoretical Studies

The assumption about the consequences of somatic fusion with self is the main determinant for the evolutionary stability of kin recognition polymorphisms in theoretical models (Aanen et al., 2008). If self fusion is completely neutral, it is hard to explain the maintenance of kin-conditional fusion. It has been suggested that VI is selectively neutral (Nauta and Hoekstra, 1996; Saupe, 2000). However, this seems unlikely, given the widespread occurrence of allorecognition in other organisms, and also at other levels of biological organization.

The potential for selfish behavior of nuclei or cytoplasmic elements may possibly explain the evolution of conditional fusion (Hartl et al., 1975; Nauta and Hoekstra, 1994, 1996; Muirhead et al., 2002). However, theoretical modeling assuming a homogeneous population structure fails to explain the extreme level of polymorphism that is observed in most fungal species (Nauta and Hoekstra, 1994, 1996). Incorporating population subdivision, which means that competition occurs locally and not globally, may result in a higher total number of recognition alleles, but this remains to be studied.

If between-individual fusion is mutually advantageous (or, relatively equivalently, if VI is costly), VI is more difficult to explain. Crozier (1986) addressed this problem for sessile marine invertebrates, which behave aggressively to nonself, but the problem also applies to other allorecognition systems (see Rousset and Roze, 2007). Individuals bearing common *het* genes fuse more frequently and hence have a higher fitness than individuals bearing rare *het* genes. This means that *het* alleles are under positive-frequency-dependent selection and that *het* diversity will decrease. However, cheating genes are then likely to evolve in the population and become associated with common *het* alleles (Grafen, 1990). Under these circumstances, rare *het* alleles are more informative of close relatedness, which can lead to a lower frequency of cheater genes among bearers of rare alleles. This gives rare alleles an indirect advantage, which could stabilize the kin recognition system. Rousset and Roze (2007) have recently modeled the balance between these two effects, the direct benefit of a common marker and the indirect benefit of a rare marker. They concluded that under many circumstances the direct benefit of a common marker prevails, and, therefore, allorecognition polymorphisms disappear.

A possible solution for this theoretical problem, first suggested by Crozier (1986), is that selection for functions other than allorecognition maintains polymorphism (Crozier, 1986; Rousset and Roze, 2007). Some of the other functions of *het* loci in addition to allorecognition may lead to negative-frequency-dependent selection and thereby maintain diversity. One of the best examples is provided by the two mating-type alleles that also function as *het* alleles in several ascomycete fungi (see above). The mating-type genes are under strong balancing selection, since in heterothallic species both mating types are required for successful sexual reproduction. Genes associated with pathogen defense may also have been recruited for allorecognition functions (Fedorova et al., 2005), such as proteins involved in fungal allorecognition that share the HET domain. Parasite coevolution could stabilize polymorphism through negative-frequency-dependent selection, analogous to the major histocompatibility complex region in vertebrates. As mentioned above, the recently discovered homologue of the *Neurospora het-c* gene in the bacterium *P. syringae* also suggests that *het* genes may be involved in interspecies interactions (Wichmann et al., 2008).

It should be noted that if external selective forces are responsible for the *stability* of *het* polymorphism, it must still be beneficial to condition the *response* (cell death) on allotype (Grosberg and Quinn, 1989). If this were not the case, selection would work against VI. The fact that a recognition domain and an effector domain can be distinguished in the predicted products of most *het* loci (Paoletti and Clave, 2007; this chapter) supports this idea. In some cases, the effector is not even linked to the recognition locus (e.g., the *tol* locus, which is required for mating-type incompatibility in *N. crassa*).

Finally, if somatic fusion is associated with costs, selection will favor rare *het* alleles, because carriers of a rare allele will fuse less often. This will result in the maintenance of recognition polymorphism (Muirhead et al., 2002). It has been questioned, however, why the ability to fuse would not be lost altogether under these circumstances (Rousset and Roze, 2007). A possible reason is that fusion *within* the individual still provides an advantage (Nauta and Hoekstra, 1994). The significance of intraindividual fusion has indeed been shown by using a mutant of *N. crassa* that lacks the capacity to anastomose and exhibits slower and aberrant growth (Xiang et al., 2002) (see chapter 19). Similar observations have been made for other fungi (A. J. M. Debets, unpublished observations). Intraindividual fusion is believed to serve intraorganismal communication, redistribution of water and nutrients, and general homeostasis within a mycelium (Rayner et al., 1984).

Secondary Consequences of VI

So far, the consequences of VI that have been considered are believed to be primarily responsible for any selective explanations for the evolution of VI, such as a restriction of the spread of selfish nuclei and cytoplasmic elements. However, in addition to these primary effects of VI, there are other secondary consequences of VI. A consequence of nonallelic VI in the pseudohomothallic species *N. tetrasperma* and *P. anserina* occurs in the case of outcrossing, where a fraction of the spores are inviable due to the presence of incompatible nuclei in ascospore progeny. This process promotes inbreeding and may contribute to speciation.

In the pseudohomothallic species *P. anserina*, some loci involved in nonallelic somatic incompatibility also have a

function in sexual reproduction (Bernet, 1992). The same gene interactions that lead to VI between different mycelia lead to PCD during the transformation of vegetative tissue into reproductive tissue (Bernet, 1992). These loci are under selection to coevolve within an individual, and since *P. anserina* is secondarily homothallic, particular loci become associated for extended periods of time. This extended intraindividual coevolution between allelic pairs could also be a mechanism to stabilize polymorphisms (see above).

van der Gaag et al. (2003) found a possible link between VI and meiotic drive in *P. anserina*. They suggested that this link may be accidental, because of the expression of VI at the wrong moment (during the sexual cycle). However, if balancing selection acts on *het* loci, spore killer genes linked to different alleles might "hitchhike" along with these alleles (van der Gaag et al., 2003).

CLOSING REMARKS

VI in fungi as a paradigm for allorecognition in genetically tractable simple eukaryotic species holds great promise to gain a better understanding of the general principles that govern the evolution of nonself recognition systems. It also represents an attractive model for dissecting PCD mechanisms in fungi. Recent efforts have led to the emergence of a few important principles: first, the essentially nonallelic nature of the *het*-gene interactions, and second, the near systematic involvement of HET domain proteins. But although the main players are now characterized in a number of systems—and sometimes to a great extent—the exact modalities of the recognition step and its translation into a cell death reaction remain unclear. It is now also clear that *het*-genes are, as a rule, under a particular evolutionary regimen and experience balancing selection and positive diversifying selection. However, the exact nature of the selective forces that lead to these evolutionary signatures is still largely unknown. In that sense, the hypothesis that *het* systems are in some way related to heterospecific recognition and/or host defense mechanisms is particularly appealing.

Glucose

MARGARET E. KATZ AND JOAN M. KELLY

Glucose can provide a primary source of energy and metabolic intermediates for eukaryotic microorganisms. The yeast *Saccharomyces cerevisiae* has been considered the paradigm for eukaryotic cells. In yeast, extracellular glucose is transported by a range of high- and low-affinity transporters, and transport is regulated in response to carbon status. Nutrient sensing and signaling via pathways involving hexokinases, glucose transporter-like proteins that lack transport activity, and G-protein-coupled receptors have been characterized in yeast. Glucose is the preferred energy source; the genes that are required for the use of alternative carbon sources are not transcribed when glucose is available, and the key components of this transcriptional repression mechanism, including the Mig1p repressor protein, the Ssn6p-Tup1p corepressor complex, and the Snf1p kinase, have been extensively studied. Studies of multicellular filamentous fungi are only at an embryonic stage, but it is becoming clear that the situation is considerably more complex in filamentous fungi than in yeast, probably due to the restricted metabolic capacity of yeast due to strong selection for anaerobic fermentation of sugars to ethanol, rather than aerobic metabolism via the Krebs cycle as in filamentous fungi. A large number of sugar transporters have been predicted from the filamentous fungal genome projects, but functional data exist for only a small fraction of these proteins in Ascomycetes (*Aspergillus niger*, *Aspergillus nidulans*, *Neurospora crassa*, *Trichoderma harzianum*, and *Tuber borchii)* and Basidiomycetes (*Amanita muscaria* and *Uromyces fabae*). Similarly, the studies that have been performed with a few filamentous fungi have revealed that glucose sensing and signaling, as well as carbon catabolite repression, are achieved by different molecular mechanisms, not only between yeast and the filamentous fungi, but also between groups of filamentous fungi. Here we aim to review what is known about the regulation of glucose uptake and metabolism in filamentous fungi and to highlight the similarities with and differences from mechanisms in yeast.

GLUCOSE TRANSPORT

Fungal Glucose Transporters

Early work on glucose transport in filamentous fungi showed that there are two transport systems (Mark and Romano, 1971; Scarborough, 1970; Schneider and Wiley, 1971). Fungal glucose transporters are classified as high-affinity transporters if the K_m for glucose is in the micromolar range (e.g., <50 μM for high-affinity transporters from filamentous fungi) and low-affinity transporters if K_m for glucose is in the millimolar range. High-affinity glucose transporters are usually expressed during carbon starvation and are repressed by glucose. Low-affinity transporters are typically expressed when the concentration of glucose, or other hexoses, is high.

The identification and characterization of genes encoding hexose transporters in *S. cerevisiae* have shown that the assumption that there is one high-affinity transporter and one low-affinity transporter is incorrect. Multiple transporters contribute to each transport system (Özcan and Johnston, 1999). All of the fungal glucose transporters that have been characterized to date belong to the "Sugar (and other) Transporters" clan of the major facilitator superfamily (http://pfam.sanger.ac.uk/family?acc=PF00083). Major facilitator superfamily sugar transporters contain 12 transmembrane domains, which are thought to have arisen through a duplication of a six-transmembrane unit in prokaryotes. There is a longer cytoplasmic loop between the two sets of six transmembrane domains (Marger and Saier, 1993).

Glucose Transport in *S. cerevisiae*

S. cerevisiae contains a large number of proteins that can transport glucose across the yeast cell membrane, 17 of which (Hxt1 through Hxt11p, Hxt13 through Hxt17p, and Gal2p) belong to the yeast glucose transporter family (Fig. 1). These transporters differ in specificity for glucose, fructose, mannose, and galactose. They also differ in regulation in response

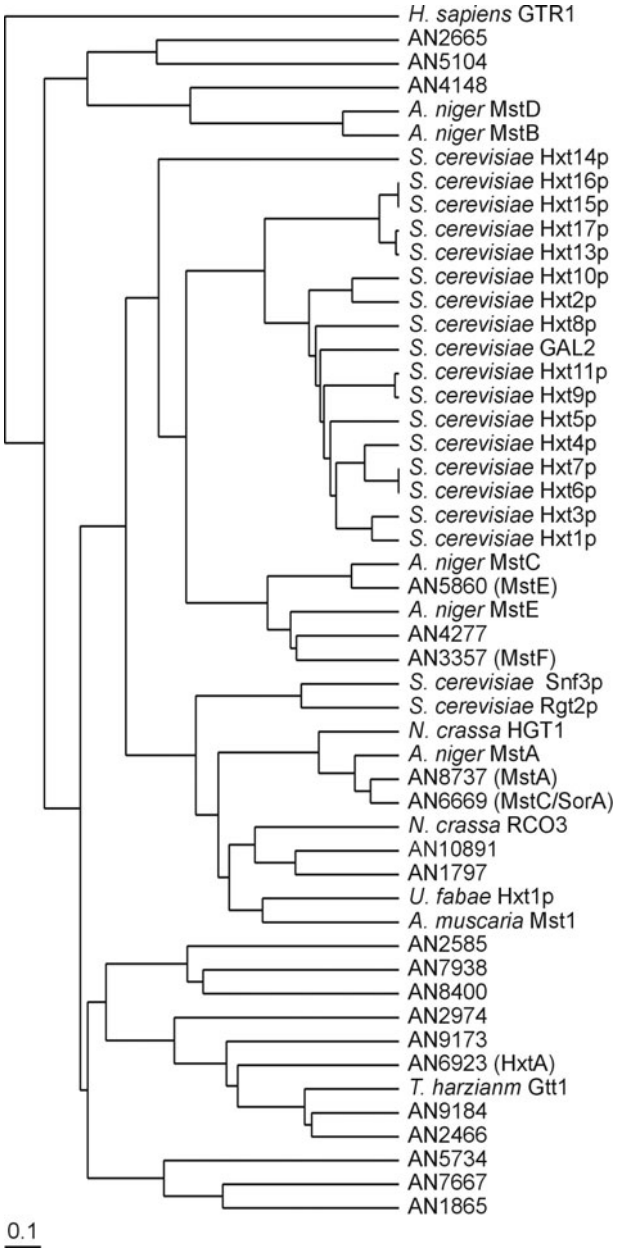

FIGURE 1 Phylogenetic tree of putative sugar transporters in *A. nidulans*. *A. nidulans* (AN) putative proteins that show similarity to fungal hexose transporters have been characterized in *A. muscaria* (Mst1), *A. nidulans* (HxtA and MstE), *A. niger* (MstA), *N. crassa* (HGT1 and RCO3), *S. cerevisiae* (Hxt1p through Hxt11p, Hxt13p through Hxt17p, and Gal2p). *T. harzianum* (Gtt1), and *U. fabae* (Hxt1p). The rooted tree was constructed using CLUSTAL (Thompson et al., 1994), PROTDIST and KITSCH (Felsenstein, 1996) through Biomanager at the Australian National Genome Information Service ((http://www.angis.org.au), and TREEVIEW (Page, 1996). The amino acid sequences used to construct the tree were obtained from the *Saccharomyces* Genome Database (http://www.yeastgenome.org/), NCBI (http://www.ncbi.nlm. nih.gov/), and the *Aspergillus* Comparative Database (http://www.broad.mit.edu/annotation/genome/aspergillus_group/MultiHome.html). The human glucose transporter GTR1 was included as an outgroup.

to glucose concentration, carbon starvation, osmotic pressure, and physiological status (Özcan and Johnston, 1999). In addition, yeast possesses two members of the yeast glucose transporter family, Snf3p and Rgt2p, which act as glucose sensors but do not transport glucose. The role of these two proteins in glucose sensing will be discussed in "Glucose Transporter Homologues" below.

Deletion of transporter genes *HXT1–7* prevents growth on glucose (Özcan and Johnston, 1999). However, Wieczorke and colleagues (1999) found that a strain that lacked *HXT1–17* and *GAL2* was still able to take up glucose. Deletion of an additional three maltose permease genes (*AGT2*, *MPH2*, and *MPH3*) was required to completely abolish glucose transport. Even this strain, lacking Hxt1–17p, Gal2p, Agt2p, and Mph2–3p, was able to grow in medium containing glucose as a sole carbon source if the *SNF3* regulator was absent, indicating that Snf3p represses one or more additional genes whose products act as hexose transporters (Wieczorke et al., 1999).

Glucose Transporters in Filamentous Fungi

Identification of Glucose Transporters

The genomes of filamentous fungi contain a large number of genes that are similar to yeast hexose transporter genes. *A. nidulans* contains 109 genes and *N. crassa* contains 45 genes which are predicted to encode proteins belonging to the sugar transporter clan of the major facilitator superfamily. In some cases these proteins are known to be involved in the transport of molecules other than sugars (e.g., AN1138 and quinate permease).

Only a few genes encoding glucose transporters have been analyzed in filamentous fungi (Table 1). It is likely that these genes represent only a small sample of the hexose transporter genes present in the genomes of multicellular fungi. The *A. nidulans* genome contains many proteins similar to known fungal glucose transporters. Phylogenetic analysis of some of these *A. nidulans* proteins is shown in Fig. 1. The tree shows that most of the yeast glucose transporters form a single group that is separate from the transporters identified in filamentous fungi. This suggests that yeast transporters may be adapted to a very specific set of environmental conditions, nutrient sources, and/or the unicellular state and may not be representative of the diversity of glucose transporters found in other fungi.

The *N. crassa rco-3* gene encodes a putative glucose transporter, but characterization of *rco-3* mutants suggests that, like *S. cerevisiae* Snf3p and Rgt3p, RCO-3 is involved in glucose sensing rather than glucose uptake (Madi et al., 1997). The role of RCO-3 in glucose sensing is covered in "Glucose Transporter Homologues" below.

Functional Analysis of Glucose Transporters

Because fungi possess multiple glucose transporters, it can be difficult to study the properties of the proteins encoded by individual genes. In some cases, such as the *N. crassa hgt-1*, *A. niger mst*A, and *A. nidulans mstE* genes, it has been demonstrated that disruption of a single transporter gene alters glucose uptake (Xie et al., 2004; vanKuyk et al., 2004; Forment et al., 2006). One strategy that can be used to demonstrate that a gene encodes a glucose transporter is to express the gene in a strain of *S. cerevisiae* that is unable to transport glucose. When the *U. fabae HXT1* gene is inserted in a yeast expression vector, it can complement the *S. cerevisiae hxt1–7*Δ deletion mutations and restore the ability to use glucose as a carbon source (Voegele et al., 2001). Using a similar strategy,

TABLE 1 Characterization of glucose transporters in filamentous fungi

Species	Protein	Location	Complementation in yeast	Affinity for glucose	Expression pattern	Phenotype of gene disruption mutant	Reference
A. muscaria	AmMST1	Hyphae	Yes	Unknown	Constitutively expressed in hyphae, upregulated in mycorrhizas and glucose concn of >5 mM	Unknown	Nehls et al., 1998
A. nidulans	HktA	Young cleistothecia and hyphae	No	High (proposed)	Expressed in response to carbon starvation and sexual development	No effect on growth or sexual development	Wei et al., 2004
A. nidulans	MstE	Conidial and hyphal membrane, septae, and vacuole	Not tested	Low	High during growth in glucose (and other repressing carbon sources)	No difference in growth; loss of low-affinity glucose transport	Forment et al., 2006
A. nidulans	SorA	Unknown	Not tested	High	Not tested	Loss of high-affinity glucose uptake, sorbose resistant	MacCabe et al., 2003; MacCabe et al., unpublished
A. niger	MstA	Unknown	Partial	High	High during carbon starvation and in presence of poor carbon sources. Repressed by high glucose concn.	No difference in growth; increased expression of *mstC*, reduced expression of *mstF*; reduced affinity for glucose	vanKuyk et al., 2004 Jørgensen et al., 2007
N. crassa	RCO-3	Unknown	Not tested	None?	Unknown	Reduced high- and low-affinity glucose uptake, defects in glucose repression, conidiation in the presence of glucose; sorbose and 2DOG resistant	Madi et al., 1997
N. crassa	HGT-1	Unknown	Not tested	High	High during carbon starvation, repressed by glucose	Reduced rate of high-affinity glucose uptake	Xie et al., 2004
T. harzianum	Gtt1	Unknown	No	High	High during carbon starvation, repressed by glucose.	Unknown	Delgado-Jarana et al., 2003
T. borchii	TBHXT1	Hyphae	Yes	High	Highest at 3 mM glucose concn and after prolonged starvation, lower at low and high glucose concn	Unknown	Polidori et al., 2007
U. fabae	Hxt1p	Haustorial plasma membrane	Yes	Medium	Unknown	Unknown	Voegele et al., 2001

vanKuyk and colleagues showed that the *A. niger mstA* gene can partially complement the growth defect of an *S. cerevisiae hxt1–7Δ gal2Δ* deletion mutant (vanKuyk et al., 2004). Nehls and colleagues showed that expression of *Amanita muscaria* AmMST1 could complement the growth defect of a *Schizosaccharomyces pombe* mutant unable to import glucose (Nehls et al., 1998). An alternative strategy was used by Delgado-Jarana and colleagues, when it was found that the *T. harzianum gtt1* gene did not complement *S. cerevisiae* mutants unable to use glucose (Delgado-Jarana et al., 2003). They showed that overexpression of the *gtt1* gene increased glucose uptake in *T. harzianum*. The *A nidulans hxtA* gene, which shows a high degree of similarity with *gtt1* (Fig. 1), also failed to restore glucose utilization to an *S. cerevisiae* hexose transport mutant (Wei et al., 2004).

Substrate Specificity of Transporters

Like yeast sugar transporters, the transporters from filamentous fungi have been shown to have multiple substrates. *A. niger* MSTA has a very high affinity for glucose (K_m, 25 μM) and mannose (K_m, 60 μM) but transports xylose and fructose with lower affinity (K_m, 300 μM and 4 mM, respectively) (vanKuyk et al., 2004). Experiments carried out with *S. cerevisiae* showed that *U. fabae* Hxt1p has a higher affinity for glucose (K_m, 360 μM) than for fructose (K_m, 1 mM). Mannose is also a substrate for Hxt1p, but galactose, trehalose, maltose, and sucrose are not (Voegele et al., 2001). The *T. borchii* TBHXT1 transporter has also been shown to have a higher affinity for glucose (K_m, 38 μM) than fructose (K_m, 16 mM) (Polidori et al., 2007). *A. niger* MstA, *U. fabae* Hxt1p, and *T. borchii* TBHXT1 have all been shown to be sugar/H^+ symporters.

Tissue-Specific Expression of Glucose Transporters

Several of the hexose transporters that have been characterized show tissue-specific expression. Voegele et al. (2001) identified a hexose transporter (Hxt1p) from the biotrophic plant pathogen *U. fabae*. They showed that the *hxt1* gene is expressed only in haustoria and the protein is found on the haustorial plasma membrane, which suggests that the Hxt1p transporter has a specific role in the uptake of sugars from plant cells. Expression of the AmMST1 glucose transporter is upregulated in the ectomycorrhizas that form when *A. muscaria* grows in association with plant roots, which suggests that it is also involved in the acquisition of plant-derived nutrients (Nehls et al., 1998). In contrast, the *T. borchii* gene, *Tbhxt1*, which encodes a high-affinity transporter, was not expressed at higher levels in ectomycorrhizas (Polidori et al., 2007). Another example of a transporter that shows tissue-specific regulation is the *A. nidulans* HxtA transporter, which is expressed during sexual development (Wei et al., 2004).

Regulation of Glucose Transport

Carbon Regulation

Most of the genes encoding fungal glucose transporters are either upregulated or repressed by glucose. The DNA-binding protein that mediates glucose repression in *Aspergillus* is encoded by the *creA* gene (Bailey and Arst, 1975; Dowzer and Kelly, 1991; Kulmburg et al., 1993) and is discussed further in "Mutations Leading to Carbon Catabolite Derepression" below. MacCabe et al. (2003) showed that the high-affinity glucose uptake system, which is repressed by glucose in wild-type strains, is derepressed in *A. nidulans* strains lacking a functional copy of the *creA* gene. In contrast, the low-affinity system is not induced by glucose in *creA* null mutants. Analysis of individual transporter genes has provided support for these findings. The *A. niger mstA* gene, which encodes a high-affinity glucose transporter, is expressed during carbon starvation and is repressed by high concentrations of glucose. In a *creA* null mutant, *mstA* expression is higher when glucose and other sugars are present but expression in response to carbon starvation is greatly reduced (vanKuyk et al., 2004). The *A. nidulans mstE* gene, which encodes a low-affinity glucose transporter, shows a completely different pattern of expression. The *mstE* transcript is at high levels during growth on glucose, fructose, mannose, sucrose, and other carbon sources that trigger CreA-mediated carbon catabolite repression and is low during growth on nonrepressing carbon sources (Forment et al., 2006). In a *creA30* loss-of-function mutant, expression of *mstE* was abolished.

Many of the high-affinity glucose transporters have been shown to be expressed at very high levels during carbon starvation. The *A. nidulans xprG* gene encodes a putative transcriptional activator that regulates the response of extracellular proteases to carbon starvation (Katz et al., 2006). Microarray analyses and glucose uptake assays suggest that XprG is also involved in the regulation of high-affinity glucose transport in *A. nidulans* (K. Sue and M. E. Katz, unpublished observations).

pH Regulation

The regulation of transporter gene expression by pH has also been investigated. Expression of the *A. niger mstA* gene is highest at pH 6 and lower at both pH 4 and pH 8 (vanKuyk et al., 2004). The transcription factor encoded by the *A. nidulans pacC* gene controls gene expression in response to environmental pH (Tilburn et al., 2005). Truncation of PacC, which has been shown to result in constitutive expression of PacC-regulated genes, led to a significant increase in *mstA* transcript levels (vanKuyk et al., 2004). The *T. harzianum gtt1* gene has also been shown to be regulated in response to pH, but in contrast to the *A. niger mstA* gene, expression was highest at acidic pH (Delgado-Jarana et al., 2003).

METABOLISM OF GLUCOSE IN FILAMENTOUS FUNGI

Glucose is a monosaccharide that is used to fuel cellular respiration in a range of organisms. Most aerobic filamentous fungi metabolize glucose primarily via oxidative phosphorylation, releasing carbon dioxide, water, and energy through a highly conserved series of reactions, although some can also ferment glucose to ethanol (Colvin et al., 1973), whereas *S. cerevisiae* preferentially ferments glucose to ethanol. Glucose may be available in the environment either directly or as the result of the breakdown of disaccharides and polysaccharides including sucrose, starch, and cellulose, or intracellularly, glucose can be generated de novo by gluconeogenesis (chapter 22).

Glycolysis and the Pentose Phosphate Pathway

When glucose is abundant, it is converted to pyruvate with the release of ATP, as shown generically in Fig. 2, although not all glucose is converted to pyruvate, as intermediates may be required in other pathways. A body of early research on each individual enzyme of glycolysis in a number of filamentous fungi exists, with each identified either by enzymatic, genetic, molecular biological, or comparative genomic means (Blumenthal, 1965). Examples

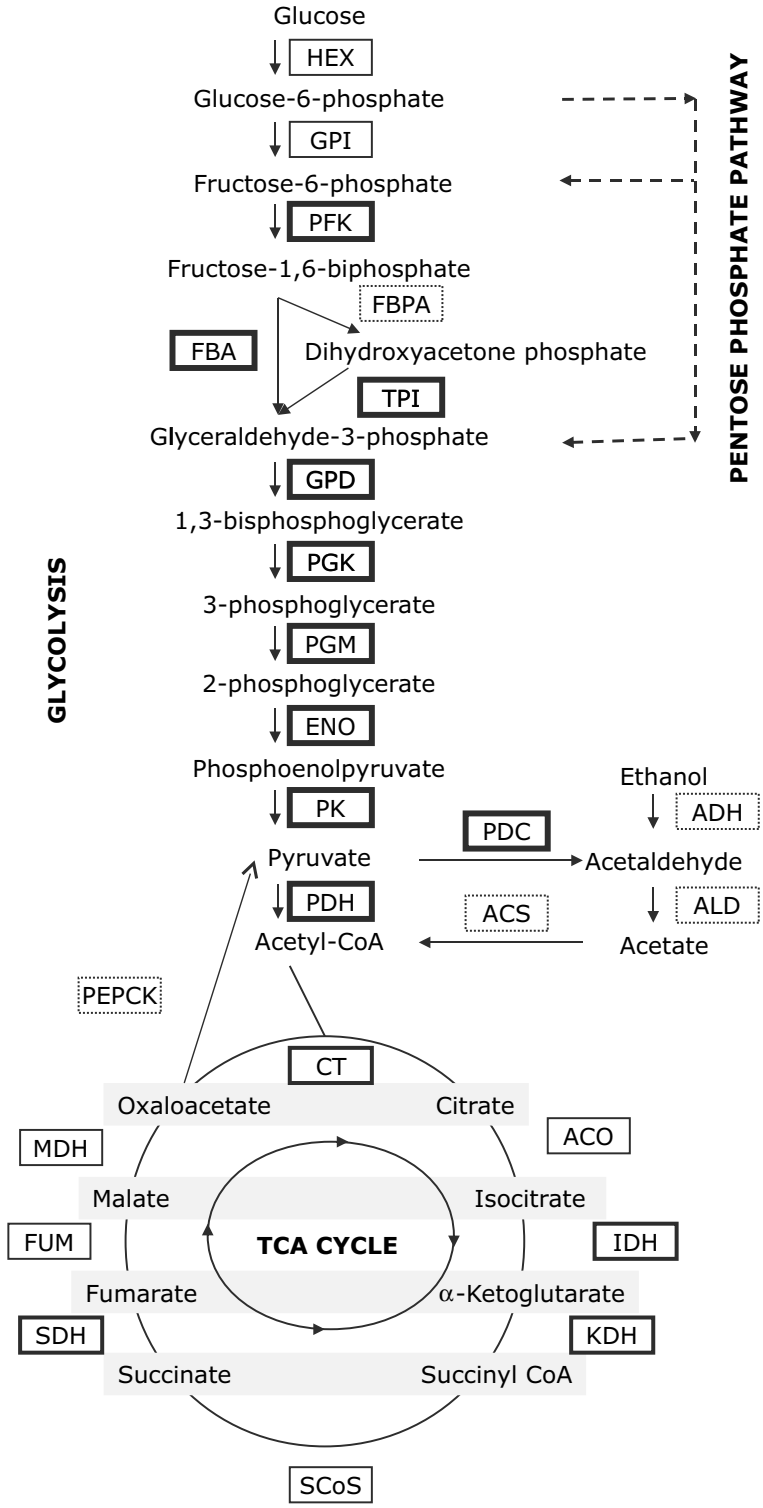

FIGURE 2 Enzymes of the glycolytic pathway and TCA cycle. In *A. oryzae*, genes encoding enzymes indicated in a solid box were increased, and those indicated in a dotted box decreased, in mycelia grown in glucose-rich compared to glucose-poor media (Maeda et al., 2004). Abbreviations: HEX, hexokinase/glucokinase; GPI, phosphoglucose isomerase; PFK, phosphofructokinase; FBA, fructose bisphosphatase; FBPA, fructose bisphosphate aldolase; TPI, triose phosphate isomerase; GPD, glyceraldehyde-3-phosphate dehydrogenase; PGK, phosphoglycerate kinase; PGM, phosphoglycerate mutase; ENO, enolase; PK, phosphoenolpyruvate kinase; PDC, pyruvate decarboxylase; ADH, alcohol dehydrogenase I; ALD, acetaldehyde dehydrogenase; ACS, acetyl-CoA synthase; PDH, pyruvate dehydrogenase; CT, citrate synthase; ACO, aconitase; IDH, isocitrate dehydrogenase; KDH, α-ketoglutarate dehydrogenase; SCoS, succinyl-CoA synthase; SDH, succinate dehydrogenase; FUM, fumarate dehydratase; MDH, malate dehydrogenase; PEPCK, phosphoenolpyruvate carboxykinase.

include hexokinase (Dunn-Coleman and Pateman, 1979; Flipphi et al., 2003; Klingmuller and Truper, 1965; Medina and Nicholas, 1957a, 1957b; Panneman et al., 1998; Ruijter et al., 1996), glucose-phosphate isomerase (Murayama and Ishikawa, 1975), aldolase (Mattoo and Roo, 1974), triosephosphate isomerase (McKnight et al., 1986), glyceraldehyde phosphate dehydrogenase (Punt et al., 1991), phosphoglycerate kinase (Clements and Roberts, 1985; Van Solingen et al., 1988; Vanhannen et al., 1989), phosphoglycerate mutase (Dunn-Coleman and Pateman, 1979; Johnson and Price, 1988; McAleese et al., 1988), enolase (Fischer et al., 1995; Kuwana and Tanaka, 1987; Machida et al., 1996; Toda et al., 2001; Verma et al., 1987), and pyruvate kinase (De Graaff et al., 1988, 1992; De Graaff and Visser, 1988; Kester et al., 1988; Kuwana and Tanaka, 1987; Schindler et al., 1993; Tsao and Madley, 1975).

Glucose can also be metabolized into pyruvate by the pentose phosphate pathway. The pentose phosphate pathway, which both acts in the conversion of hexose sugars and regenerates NADPH, is an alternative to glycolysis and relies on glycolysis to generate essential metabolites. Mutants that affect the pentose phosphate pathway have been isolated in *A. nidulans* (Hankinson, 1974). In *Penicillium chrysogenum*, the flux through the pentose phosphate pathway increases relative to the flux through glycolysis when the metabolism shifts from rapid growth without penicillin production to slow growth and high penicillin production (Jorgensen et al., 1995).

The Krebs Cycle

In aerobic fungi, pyruvate is primarily converted to acetyl coenzyme A (acetyl-CoA) via the pyruvate dehydrogenase complex (Bos et al., 1981; Harding et al., 1970; Song et al., 1978), and then to carbon dioxide and water, with the release of energy, via the Krebs cycle (Chandra and Shanmugasundaram, 1961; Flavell and Woodward, 1970a, 1970b). This is the key difference between the majority of filamentous fungi and *S. cerevisiae*, in that *S. cerevisiae* prefers fermentation at high glucose concentrations and represses genes for the tricarboxylic acid (TCA) cycle.

Genomic and Metabolic Flux Analyses

An integrated approach to the identification of metabolic pathways and networks, their regulation, and metabolic flux through the cycles has proved fruitful. For example, a stoichiometric model of central carbon metabolism was described using available information on *A. niger* metabolism, even before the fully annotated genome was available, by the integration of genomic, biochemical, and physiological data as well as extrapolation from closely related species (David et al., 2003). The primary metabolism of *P. chrysogenum* was also analyzed by advanced nuclear magnetic resonance measurements (Van Winden et al., 2003). David and colleagues (David et al., 2005, 2006) have reconstructed complete metabolic networks for *A. nidulans* growing on glucose, glycerol, and ethanol and shown that the shift from glucose to ethanol results in increased gluconeogenesis and decreased activity in the glycolytic and pentose phosphate pathways. Further, using ^{13}C-metabolic flux analysis, they have assessed the effects of the absence of CreA (see below) on metabolic flux and by calculation of the ratio between the enzymatic activity of key enzymes at the branch point of the glycolysis and pentose phosphate pathways found a 20% reduction through the pentose phosphate pathway under glucose conditions, whereas the addition of xylose resulted in a 40% increase and a reduction in glycolysis and the TCA cycle (David et al., 2005).

Expressed sequence tag and cDNA microarrays were used to investigate the fate of glucose in *Trichoderma reesei* compared to *S. cerevisiae* (Chambergo et al., 2002; DeRisi et al., 1997). In glucose-grown cultures of yeast and *T. reesei*, critical genes encoding enzymes that control the direction of flow of primary metabolites differ in expression. The expression of genes involved in the TCA cycle and mitochondrial respiration are repressed in yeast, leading to pyruvate being channeled to acetaldehyde, but active in *T. reesei*, leading to the oxidation of pyruvate (Chambergo et al., 2002). A similar approach was taken with *Aspergillus oryzae*, whereby transcription profiles were compared between glucose-rich and glucose-depleted cultures, with genes encoding enzymes of the glycolytic and TCA cycles present at higher levels in glucose-rich cultures than in glucose-depleted cultures (Maeda et al., 2004). Unlike in *T. reesei*, the gene encoding an alcohol dehydrogenase that converts acetaldehyde to ethanol was also more highly expressed in glucose-rich cultures than in glucose-depleted cultures, indicating that fermentation to ethanol could occur alongside aerobic respiration (Maeda et al., 2004). In *N. crassa*, glucose-rich cultures were compared to glucose-starved cultures, and although expression of the gene encoding pyruvate decarboxylase was higher in glucose-rich cultures than in glucose-starved cultures, the expression of the alcohol dehydrogenase that converts acetaldehyde to ethanol was similar in glucose-grown and glucose-starved cultures (Xie et al., 2004). Colvin and colleagues demonstrated that some ethanol is produced in glucose-grown cultures, indicating that some fermentation occurs in addition to respiration via the Krebs cycle (Colvin et al., 1973).

The public availability of the complete genome sequences of many fungi (Galagan et al., 2005; Machida et al., 2005; Nierman et al., 2005) and advances in microarray technology have allowed the integration of in silico approaches to metabolic pathway analysis, to more fully describe the regulation of cellular metabolism. Although microarray analyses in filamentous fungi (Breakspear and Momany, 2007) have proved useful in studies of metabolism, they do not allow direct and indirect effects on transcription to be teased out, and they may not reflect actual enzyme activity, as this can be affected by translational and posttranslational events, including feedback inhibition and inactivation, and protein stability.

GLUCOSE SENSING

Glucose has a wide range of regulatory effects in fungi. Glucose-sensing mechanisms are responsible for detecting glucose levels and triggering these regulatory effects. The sensing of glucose and other sugars is also discussed in chapter 30.

Glucose Analogues

The use of glucose analogues has been used to determine whether glucose sensing in fungi requires uptake and/or further metabolism of glucose. The analysis of analogues that are not transported (e.g., L-glucose), are transported but not phosphorylated (e.g., 6-deoxy-D-glucose), or are phosphorylated but not metabolized further (e.g., 2-deoxy-D-glucose) has shown that phosphorylation of glucose is required to trigger glucose repression in *S. cerevisiae*

(reviewed by Rolland et al., 2001). This suggested that glucose sensing might involve one or more of the hexokinases and glucokinase that phosphorylate glucose. Carbon catabolite repression still occurs in *S. cerevisiae* mutants lacking phosphoglucoisomerase, the enzyme that catalyzes the second step in the metabolism of glucose, confirming that further metabolism of glucose was not necessary (Rose et al., 1991).

As in *S. cerevisiae*, 2-deoxyglucose (2DOG) has been shown to mimic glucose in triggering carbon catabolite repression in the filamentous fungi (Fraser et al., 2001; Hynes et al., 2007; Todd et al., 2003). However, 2DOG does not mimic carbon nutrient sufficiency. Fraser et al. (2001) have shown that AreA-mediated expression of the *fmdS* gene is blocked by carbon starvation even in the presence of 2DOG. Likewise, production of extracellular proteases in response to carbon starvation is only partially repressed by 2DOG (M. Katz, unpublished data). 2DOG also does not stimulate upregulation of the glucose-inducible *A. muscaria* glucose transporter, AmMST1 (Nehls et al., 1998).

Nonmetabolizable, toxic glucose analogues (e.g., sorbose and 2DOG) have been used to select mutants which are defective in glucose transport or phosphorylation in a number of filamentous fungi, including *A. nidulans* (Elorza and Arst, 1971), *Coprinus cinereus* (Moore, 1973), *N. crassa* (Klingmüller, 1967), *P. chrysogenum* (Barredo et al., 1988), and others. Analysis of these mutants has led to the identification of genes encoding glucose transporters including *A. nidulans sorA* (A. P. MacCabe, R. Gonzalez, L.Ventura, J. F. Forment, M. J. A. Flipphi, and D. Ramón, unpublished data) and hexokinases including *A. nidulans glkA* (Flipphi et al., 2003). Numerous studies have employed 2DOG to isolate mutants, which show increased production of fungal enzymes or citric acid (e.g., cellulase in *Trichoderma viride* [Farkas et al., 1981]).

Glucose Sensing in *S. cerevisiae*

In *S. cerevisiae*, three interconnected glucose-sensing mechanisms have been described (reviewed by Rolland et al., 2002, and Santangelo, 2006). These signaling pathways are briefly described in this section. Many of the proteins known to play a role in these pathways have been omitted. In addition to these pathways, which require phosphorylation of glucose, the induction of glycolytic genes requires further metabolism of glucose (Muller et al., 1995).

Hexokinase PII

The role of hexokinases in glucose sensing was confirmed in studies using strains carrying mutations in the three genes encoding sugar-phosphorylating enzymes: *HXK1*, *HXK2*, and *GLK2*. A functional copy of any one of these three genes is sufficient for growth on glucose (Maitra and Lobo, 1983). Hxk2p is required for long-term repression of gene expression by glucose (De Winde et al., 1996). The downstream target of the Hxk2p glucose sensor is the repressor Mig1p (see "CreA Repressor Protein" below).

The role of Hxk2p in triggering carbon catabolite repression has been and still is controversial (Santangelo, 2006). While phosphorylation of glucose is required for glucose repression, the regulatory function of Hxk2p does not require catalytic function (Hohmann et al., 1999). A fraction of Hxk2p is located in the nucleus, where it may play a direct role in glucose repression through interaction with Mig1p (Ahuatzi et al., 2007). There is also evidence that the Hxk2p signal may modulate the activity of the Snf1p kinase that regulates Mig1p activity (Sanz et al., 2000). Snf1p is a homologue of the mammalian cyclic AMP (cAMP)-dependent protein kinase AMPK, which plays an important role in sensing energy status (reviewed by Hardie, 2007).

Glucose Transporter Homologues

The response of glucose-repressible and glucose-inducible hexose transporters is mediated by two glucose transporter homologues, Snf3p and Rgt2p. Snf3p and Rgt2p are similar in structure to the Hxtp and Gal2p proteins (see "Glucose Transport in *S. cerevisiae*" above) but contain several hundred additional amino acids at the C terminus. Snf3p induces expression of high-affinity and medium-affinity glucose transporters in low levels of glucose, and Rgt2p induces expression of low-affinity glucose transporters when high levels of glucose are present (Özcan and Johnston, 1999). Both effects are mediated through Rgt1p, which can act as a repressor or activator of *HXT* transcription depending on glucose concentration (Özcan and Johnston, 1999).

cAMP

A third glucose-sensing system involves activation of AMP-dependent protein kinase A (PKA) through two signaling pathways that activate adenylate cyclase and stimulate production of cAMP in response to glucose: a G-protein-coupled receptor, Gpr1p, and Gα subunit, Gpa2p, and a second pathway involving Ras proteins and Cdc25p (Santangelo, 2006). PKA is involved in the control of glycolysis, gluconeogenesis, cell growth, and stress resistance (Rolland et al., 2002). PKA also regulates *HXT* gene expression through Rgt1p (Kim and Johnston, 2006). It has also been proposed that the signal generated by PKA regulates Mig1p-mediated carbon catabolite repression through modulation of Hxk2p activity (Santangelo, 2006).

Role of Hexokinases in Nutrient Sensing in Filamentous Fungi

Role of Hexokinases in Carbon Catabolite Repression

Hexose-phosphorylating enzymes have been shown to be important in glucose repression in *A. nidulans*, but different enzymes have overlapping roles. *A. nidulans* possesses two genes encoding catalytic hexokinases, *frA* (*hxkA*) and *glkA* (Flipphi et al., 2003; Ruijter et al., 1996). A functional copy of only one of the two genes is required for utilization of glucose as a carbon source. Unlike what is observed in *S. cerevisiae*, in which disruption of only one (*HXK2*) of the three hexokinase genes causes derepression, inactivation of both *frA* and *glkA* is necessary to cause derepression of genes subject to CreA-mediated carbon catabolite repression in *A. nidulans* (Flipphi et al., 2003). This suggests that glucose phosphorylation is required to trigger repression in *A. nidulans*, but neither HxkA nor GlkA appears to have a role similar to *S. cerevisiae* Hxk2p (Table 2).

Role of Hexokinases in Carbon Starvation

In *A. nidulans*, CreA-mediated carbon catabolite repression is triggered by glucose and other preferred carbon sources (see "CreA Repressor Protein" below). Derepression of CreA-regulated genes occurs during growth in medium containing poor carbon sources (e.g., glycerol).

TABLE 2 Comparison of glucose sensing in *S. cerevisiae* and filamentous fungi

Type of glucose sensor	Sensor(s) in yeast	Sensor(s) in filamentous fungi	Role of sensor(s) in filamentous fungi
Hexokinase	Hxk2p	HxkA, GlkA (*A. nidulans*)	No evidence for a direct role of a single hexokinase as in yeast but phosphorylation required to trigger CCR (Flipphi et al., 2003)
		HxkC, HxkD (*A. nidulans*)	No role in CCR; involved in the response to carbon starvation (Bernardo et al., 2007)
Transporter	Snf3p, Rgt2p	RCO-3 (*N. crassa*)	May perform similar function to yeast proteins but structure of RCO-3 differs; could have broader role in CCR than yeast proteins which regulate hexose transporters (Madi et al., 1997)
G-protein-coupled receptor	Gpr1p, Gpa2p (Gα3)	GPR-4, GCNA1–3 (Gα1–3) (*N. crassa*)	G-protein-coupled receptor GPR-4 is involved in cAMP signaling in response to glucose. Unlike in yeast, GPR-4 interacts with Gα1 rather than Gα3, and Gα1 through Gα3 are all involved in nutrient sensing.
		GanB (Gα3) (*A. nidulans*)	Involved in carbon sensing/cAMP signaling in germinating conidia (Lafon et al., 2005)
		BCG3 (Gα3) (*B. cinerea*)	Involved in carbon sensing/cAMP signaling in germinating conidia (Doehlemann et al., 2006)
		GasC (Gα3) (*P. marneffei*)	Required for conidial germination but not involved in nutrient sensing (Zuber et al., 2003)
		Gpa1 (Gα3) (*C. neoformans*)	Involved in cAMP signaling in response to glucose and production of melanin (Alspaugh et al., 1997)
		Gpr4 (*C. neoformans*)	Similar to *S. cerevisiae* Gpr1p but is not involved in glucose signaling (Xue et al., 2006)

However, there are a number of genes, including the regulator of conidiation, *brlA* (Skromne et al., 1995), which are repressed by poor carbon sources as well as by glucose and are only expressed at high levels during carbon starvation. This suggests that carbon catabolite derepression and carbon starvation are not equivalent. Glucose repression of some of the carbon-starvation-inducible genes has been shown to be CreA independent and occurs in strains lacking hexokinase and glucokinase catalytic activity (Katz et al., 2008).

In addition to catalytic hexokinases, some filamentous fungi possess a number of atypical hexokinases (Fig. 3). Genetic and biochemical evidence suggests that these hexokinase-like proteins, which lack some of the highly conserved amino acids in the ATP- and sugar-binding domains, are solely regulatory in function (Bernardo et al., 2007). Analysis of *A. nidulans* HxkC and HxkD (formerly XprF) indicates that these atypical hexokinases modulate the activity of the putative p53-like transcriptional activator, XprG, and are involved in the response to carbon starvation (Katz et al., 1996, 2000, 2006). Most or all of the HxkD protein is located in the nucleus, which is consistent with a direct role in gene regulation (Bernardo et al., 2007). In contrast, HxkC is associated with mitochondria. Mitochondrial hexokinases have been implicated in the control of programmed cell death in both mammals and plants (Kim and Johnston, 2006; Pastorino et al., 2002). Thus, HxkC may play a key role in triggering programmed cell death in response to carbon starvation in filamentous fungi.

Not all species of filamentous fungi appear to possess the signaling pathway defined by HxkC, HxkD, and XprG. The genome of only one basidiomycete, *Ustilago maydis*, has a gene encoding a protein with similarity to the family of Ndt80-like DNA-binding proteins to which XprG belongs (Table 3). In contrast, the zygomycetes contain many members of this class of protein and a correspondingly large number of hexokinases. Even within members of the same species (e.g., *Coccidioides immitis*) or the same genus (e.g., *Aspergillus* and *Fusarium*) the number of hexokinases and Ndt80-like proteins is variable.

Glucose Transporters in Glucose Sensing

Mutations in two glucose transporters from filamentous fungi have been shown to have regulatory effects. The *N. crassa rco-3* gene encodes a protein similar to sugar transporters in *S. cerevisiae* and other fungi (Madi et al., 1997). RCO-3 is longer than most yeast hexose transporters and like Snf3p and Rgt2p has an extended C terminus. However, the RCO-3 C terminus, which has a glutamine-rich region followed by an S/T-rich region, is not similar in sequence to the same regions in the yeast transporter homologues.

The *rco-3* gene was first identified through analysis of an *N. crassa* mutant that could conidiate in submerged cultures and in the presence of high levels of glucose, fructose, glycerol, and xylose (Madi et al., 1994). Both high- and low-affinity glucose transport is altered in mutants lacking the *rco-3* gene (Madi et al., 1997). In addition, derepression of *qa* expression occurs. The many regulatory effects seen in strains lacking functional RCO-3 led to the suggestion that RCO-3 functions as a glucose sensor (Madi et al., 1997).

Disruption of the *A. niger* gene encoding the high-affinity glucose transporter, MstA, results in altered expression of two other genes encoding putative hexose

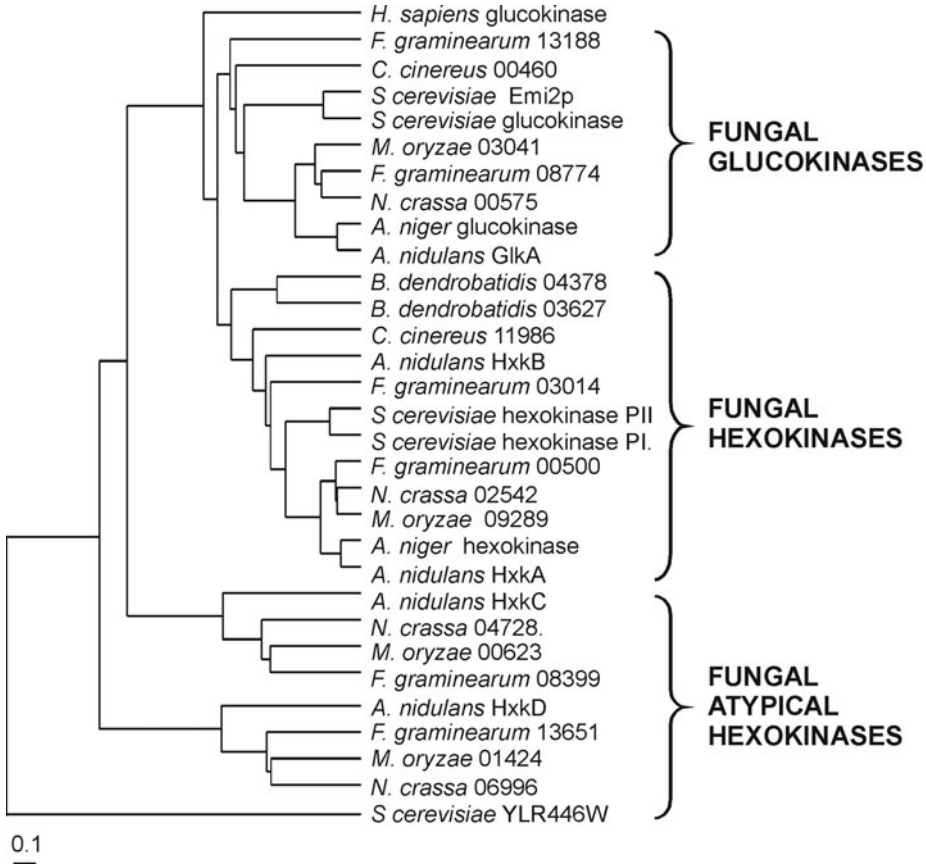

FIGURE 3 Phylogenetic tree of hexokinases and hexokinase-like proteins from *A. nidulans*, *A. niger*, *Batrachochytrium dendrobatidis*, *C. cinereus*, *Fusarium graminearum*, *Magnaporthe oryzae* (formerly *M. grisea*) and *N. crassa*. The rooted tree was constructed with amino acid sequences from the Fungal Genome Initiative at the Broad Institute (http://www.broad.mit.edu/annotation/fgi/) and sequences from *A. niger* (Panneman et al., 1996, 1998) by using CLUSTAL (Thompson et al., 1994), PROTDIST and KITSCH (Felsenstein, 1996) through Biomanager at the Australian National Genome Information Service (http://www.angis.org.au), and TREEVIEW (Page, 1996). Only two of the six sequences encoded by the *A. niger* genome were included (Panneman et al., 1996, 1998). Human glucokinase was included for comparison.

transporters (Jørgensen et al., 2007). Expression of *mst*C is increased, and expression of *mstF* is reduced. Unlike the *N. crassa rco-3* gene, the *mst*A gene has been shown to encode a glucose transporter (see "cAMP" above) and does not contain a C-terminal extension. Thus, it is likely that the effects on *mst*C and *mstF* expression are due to the change in glucose uptake of the *A. niger mst*AΔ gene disruption mutant.

G-Protein-Coupled Receptors/cAMP Signaling

In *S. cerevisiae*, the G-protein-coupled receptor Gpr1p and the class III Gα subunit (Gα3) Gpa2p are involved in the increase of cAMP in response to glucose (see "Role of Hexokinases in Carbon Starvation" above; see also chapter 30). G-protein-coupled receptors and Gα subunits that are involved in glucose sensing have been identified in a number of filamentous fungi (reviewed by Li et al., 2007). There are some differences in these signaling pathways in filamentous fungi, but in many cases the role of these proteins is similar to their role in *S. cerevisiae* (Table 2).

In *N. crassa*, the G-protein-coupled receptor GPR-4 plays a role similar to that of yeast Gpr1p (Li and Borkovich, 2006). However, GPR-4 appears to be coupled to a Gα1 (GNA-1) rather than a Gα3 heterotrimeric G protein as in yeast. Furthermore, analysis of *N. crassa* mutants lacking Gα1 (GNA-1), Gα2 (GNA-2), or Gα3 (GNA-3) suggests that all three are involved in carbon sensing.

The *A. nidulans* and *Botrytis cinerea* Gα3 subunits have been shown to be involved in carbon-nutrient sensing and cAMP signaling in germinating conidia (Doehlemann et al., 2006; Lafon et al., 2005). In both species, compared to what is observed in yeast, a broader range of carbon sources, including glycerol and acetate, may be sensed by this signaling pathway. As in *A. nidulans* and *B. cinerea*, the Gα3 subunit of *Penicillium marneffei* is required for germination of conidia but it is not involved in nutrient sensing (Zuber et al., 2003). The Gα3 subunit of *Cryptococcus neoformans* controls cAMP production in response to glucose (Alspaugh et al., 1997). It also regulates melanin production in response to glucose starvation.

TABLE 3 Number of genes encoding hexokinases in filamentous fungi

Species	Phylum	No. of genes[a]	
		Ndt80-like	Hexokinases
C. cinereus	Basidiomycota	0	2
Cryptococcus neoformans	Basidiomycota	0	2
Phanerochaete chrysosporium	Basidiomycota	0	2
Puccinia graminis	Basidiomycota	0	5
U. maydis	Basidiomycota	1	2
C. immitis H538.4	Ascomycota	1	5
Batrachochytrium dendrobatidis	Chytridiomycota	2	2
A. nidulans	Ascomycota	2	5
C. immitis RS	Ascomycota	2	5
A. oryzae	Ascomycota	2	6
Aspergillus flavus	Ascomycota	2	7
Magnaporthe grisae	Ascomycota	3	4
N. crassa	Ascomycota	3	4
S. sclerotiorum	Ascomycota	3	4
A. niger	Ascomycota	3	5
B. cinerea	Ascomycota	3	5
Fusarium graminearum	Ascomycota	3	6
Aspergillus fumigatus	Ascomycota	3	8
Fusarium oxysporum	Ascomycota	4	7
Phycomyces blakeleeanus	Zygomycota	5	7
Rhizopus oryzae	Zygomycota	7	11

[a]The number of genes was determined by searching fungal genomes at the Broad Institute (http://www.broad.mit.edu/annotation/fgi/) and DOE Joint Genome Institute (http://genome.jgi-psf.org/).

GLUCOSE AS A REGULATORY MOLECULE

Many filamentous fungi have pathways for the metabolism of a wide range of potential carbon sources, and mechanisms that allow maximum energy efficiency for the organism have evolved. In most cases, expression of genes for dispensable carbon pathways is regulated by both pathway-specific induction controls and carbon catabolite repression. Carbon catabolite repression is a global regulatory phenomenon found in a wide range of microbial organisms and results in transcriptional repression of genes encoding less readily metabolized carbon sources in the presence of glucose, xylose, or sucrose, but not in the presence of arabinose, glycerol, melibiose, and lactose. Mannose, sorbitol, maltose, fructose, mannitol, and galactose lead to intermediate levels of repression (Arst and Cove, 1973).

Analysis of the regulation of metabolic pathways that are involved in the metabolism of carbon sources has been conducted using a range of techniques. Initially growth testing, enzyme assays, and mutant analyses were used to deduce pathways and regulatory mechanisms, and with the event of molecular biological techniques the components of the pathways were analyzed at the mRNA and protein level. With the availability of genomic data and the development of microarray methodologies, a whole-genome approach has been taken to the analysis of gene expression patterns between different growth conditions or genotypes. Advances in proteomic and metabolomic analysis techniques are extending the genome-wide analyses to provide an integrated understanding of the regulation of metabolic flux in the cell.

Studies of the regulation of pathways that provide a carbon source to the cell have been valuable in uncovering induction and carbon catabolite repression mechanisms, and these include studies of the regulation of quinate utilization in both *N. crassa* and *A. nidulans* (Bailey and Arst, 1975; Geever et al., 1989; Lamb et al., 1996; Levett et al., 2000) and ethanol utilization in *A. nidulans* (Arst and Bailey, 1977; Bailey and Arst, 1975; Flipphi et al., 2001; Kulmburg et al., 1992a, 1992b; Lockington et al., 1985; Nikolaev et al., 1999; Pateman et al., 1983; reviewed by Flipphi and Felenbok, 2004). Many compounds provide both a carbon and a nitrogen source to the cell, and studies of the regulation of these pathways are valuable in that they potentially provide an opportunity to unravel the interaction between carbon catabolite repression and ammonium repression. These include the study of the regulation of acetamidase (Hynes and Davis, 2004) and the enzymes for L-proline catabolism (Scazzocchio et al., 1995) in *A. nidulans*.

Mutations Leading to Carbon Catabolite Derepression

FrA Hexokinase and GlkA Glucokinase

Hexose-phosphorylating enzymes have been shown to be involved in glucose repression in *A. nidulans*, but unlike in yeast, different enzymes have overlapping roles. Mutations in *frA1*, which encodes a hexokinase, were selected due to their toxicity on D-fructose medium (McCullough et al., 1977), and mutations in *glkA*, which encodes a glucokinase, were selected due to their resistance to 2DOG in glycerol medium (Flipphi et al., 2003). Mutations in individual genes do not affect growth on glucose, nor do they lead to carbon catabolite derepression (Arst et al., 1990; Roberts, 1963; Ruijter et al., 1996); however, strains containing both *glkA* and *frA* mutations, which completely lack both glucose and

fructose phosphorylation, show derepression, indicating that GlkA and FrA activities compensate for each other in carbon catabolite repression signaling (Flipphi et al., 2003).

CreA Repressor Protein

The first genetic screen that aimed to isolate mutants with reduced carbon catabolite repression involved the selection of phenotypic suppressors of the effects of *areA* null alleles in *A. nidulans* (Arst and Cove, 1973). AreA is a DNA-binding protein that is required for expression of genes subject to ammonium repression (Arst and Cove, 1973; Caddick, 2004). The regulation of nitrogen metabolism is discussed in chapter 23, and thus, only brief comments to allow understanding of the selection rationale are presented here. Strains lacking AreA cannot grow on most nitrogen sources when glucose is present, but they can grow on compounds that provide both a carbon and a nitrogen source, such as acetamide and proline. Genes encoding enzymes for acetamide or proline metabolism are regulated by both carbon catabolite repression and ammonium repression, and the relief of either allows expression (Arst and MacDonald, 1975; Hynes, 1970). The observation that strains lacking AreA can grow when acetamide or proline are the only sources of both carbon and nitrogen, but not when glucose is also present, was the basis for the selection of mutations that allowed growth of *areA* null strains on glucose plus proline medium due to reduced carbon catabolite repression (Arst and Cove, 1973; Arst, 1981; Bailey and Arst, 1975; Hynes and Kelly, 1977). The *creA* gene was also identified in screens that involved selection of phenotypic suppressors of the requirement for an alternative source of acetyl-CoA due to *pycA* (pyruvate carboxylase) and *pdhA* (pyruvate dehydrogenase) mutant phenotypes (Arst and Bailey, 1977; Bailey and Arst, 1975; Romano and Kornberg, 1968, 1969). In addition, *creA* mutations were present among phenotypic suppressors of toxicity on fructose medium due to a *frA* (hexokinase) mutation (Arst et al., 1990; McCullough et al., 1977; Ruijter et al., 1996).

Mutations were also identified in other filamentous fungi. An industrial strain of *T. reesei*, Rut-C30, that overproduces cellulolytic enzymes, was found to contain a mutation in *cre1*, the *T. reesei* equivalent of *creA* (Ilmen et al., 1996). Mutations in *creA* have also been isolated in *A. niger*, using a screen involving *areA* null alleles similar to one that was used in *A. nidulans* (Ruijter et al., 1997).

Mutations in *A. nidulans creA* result in various degrees of deregulated expression of a wide range of genes that would normally be repressed in the presence of glucose, with no clear hierarchy for derepression (Arst and Cove, 1973; Arst, 1981; McCullough et al., 1977; Scazzocchio et al., 1995; Shroff et al., 1996, 1997). Both enzyme assay data and transcript analysis indicated that *creA* mutations also lead to elevated levels of gene expression under both carbon catabolite-repressing and derepressing conditions, indicating roles for CreA under growth conditions generally regarded as repressing as well as under derepressing conditions, although there are confounding experimental difficulties in identifying conditions that are completely nonrepressing without causing starvation and thus triggering a cellular starvation response.

In addition to studies in which individual genes or pathways have been analyzed, the transcriptional effects of a *creA* null mutation have been analyzed on a genome-wide scale using microarray analysis of *creA* wild-type and mutant strains grown on repressing and derepressing carbon sources (Mogensen et al., 2006). Cluster analysis was used to identify eight groups of genes based on their response, ranging from those that were unaffected to those that were greatly affected, although whether they were direct or indirect targets of CreA cannot be determined using this approach (Mogensen et al., 2006). This analysis validated and extended the data available from the analysis of individual pathways using Northern blots. Although a wide range of pathways show a degree of deregulated expression in *creA* mutant strains, some pathways are unaffected by the absence of *creA*, indicating that CreA-independent mechanisms of carbon catabolite repression exist. Examples include extracellular lipase (Kawasaki et al., 1995), penicillin biosynthetic enzymes (Espeso and Penalva, 1994; Martin et al., 1999) in *A. nidulans*, and D-xylulose kinase (VanKuyk et al., 2001) in *A. niger*. Mutations in *creA* also affect colony morphology (Arst et al., 1990; Shroff et al., 1997) and sensitivity to toxic compounds including acriflavine and molybdate.

The *A. nidulans creA* gene encodes a Cys_2-His_2 DNA-binding protein of the zinc finger class (Dowzer and Kelly, 1989, 1991). CreA homologues have been identified in a number of filamentous fungi, and as a result, conserved domains and regions can be identified (Shroff et al., 1997). The CreA proteins from filamentous fungi exhibit a high degree of sequence similarity (Fig. 4), and the zinc finger regions are highly similar to the zinc finger region of Mig1p, the carbon catabolite repressor in yeast, as is the C-terminal Mig1p effector domain (Ostling and Ronne, 1988; Ostling et al., 1996); however, other regions of the proteins from filamentous fungi show far less sequence similarity to Mig1p.

Mutations isolated in vivo fall into two clear classes; some are missense mutations in the zinc finger region of the protein which affect amino acids that are conserved among zinc finger proteins and are predicted to alter (*creA204*) or prevent (*creA306*) DNA binding, and others are nonsense or frameshift mutations that result in a truncated protein. Thus, the mutations that lead to derepression either alter the DNA binding region or result in the absence of the effector domain due to truncation (Shroff et al., 1996, 1997). An *A. nidulans creA* null mutant (constructed using gene replacement techniques) exhibited strong morphological changes and a high level of derepression (Shroff et al., 1997). However, the *creA306* mutation led to an even more extreme phenotype, perhaps due to titration of proteins that interact with CreA. The highly cellulolytic *T. reesei* strain (Rut-C30) is predicted to express a nonfunctional, severely truncated form of *T. reesei* Cre1 (Ilmen et al., 1996) and shows high levels of expression of various cellulase family mRNAs under repressing conditions.

CreA binds a DNA consensus recognition sequence, 5′ SYGGRG 3′, and this core recognition sequence is usually present in pairs (Cubero et al., 2000; Kulmburg et al., 1993; Mathieu et al., 2000; Panozzo et al., 1998). The same core recognition sequence is bound by Mig1p (Nehlin and Ronne, 1990; Nehlin et al., 1991; Papamichos-Chronakis et al., 2004). The presence of core sequences does not necessarily indicate functional binding in vivo, and the consensus sequences are present in many promoters that are not regulated by CreA. In addition, in many promoters, including those for *alcA* and *alcR*, only a subset of potential consensus binding sites are functional, indicating the importance of residues outside the core consensus sequence (Mathieu et al., 2000; Panozzo et al., 1998), or perhaps position effects.

Although the zinc finger regions of CreA and Mig1p are highly conserved, the mechanism of glucose repression in *S. cerevisiae* and *A. nidulans* is quite different. It was thought that Mig1p acts by recruiting the corepressor complex, Ssn6p-Tup1p, to promoters that are under carbon catabolite repression control (Nehlin et al., 1991; Treitel and Carlson, 1995; Tzamarias and Struhl, 1995) and that cytoplasmic

TABLE 4 Comparison of mechanisms of regulation by major carbon catabolite repression proteins in fungi

Mechanism or effect	Organism (gene/protein)			
	S. cerevisiae (*MIG1*/Mig1p)	*A. nidulans* (*creA*/CreA)	*T. reesei* (*cre1*/Cre1)	*S. sclerotiorum* (*CRE1*/CRE1)
Amount of transcript in repressed versus derepressed conditions[a]	–[b]	Lower	Lower	Higher
Regulated nuclear localization[c]	Yes	No	–	Yes
Regulated localization required for CCR[d,e]	No	No	–	No
Snf1-like protein[f] involved in CCR	Yes	No	No	–
Ssn6p/Tup1p complex[g] involved in CCR	Yes	No	–	–

[a]Amount of *creA*/*cre1*/*CRE1* mRNA in mycelia grown under carbon catabolite-repressed conditions compared to carbon catabolite-derepressed conditions.

[b]–, not tested.

[c]Whether the intracellular location of the protein is different in mycelia grown under carbon catabolite-repressed compared with carbon catabolite-derepressed conditions.

[d]CCR, carbon catabolite repression.

[e]Whether regulated nuclear localization is required for CCR, as determined by artificial disruption of export of the protein from the nucleus or by overexpression experiments.

[f]See "Hexokinase PII" and "CreA Repressor Protein" in the text.

[g]See "CreA Repressor Protein" and "CreB Deubiquitinating Enzyme and CreC SD40 Protein" in the text.

translocation of Mig1p, triggered by its phosphorylation by Snf1 kinase in the nucleus, was a key regulatory step for releasing glucose repression (De Vit and Johnston, 1999; De Vit et al., 1997). However, glucose still regulates Mig1p-dependent repression in a mutant that no longer has nuclear export activity, indicating that Mig1p is regulated both by nuclear localization and by modification of its ability to repress transcription (De Vit and Johnston, 1999). Further, the Ssn6p-Tup1p complex is tethered to the promoter DNA of *GAL1* under both repressing and activating conditions, and Mig1p is not required for the Ssn6p-Tup1p complex to be tethered to the *GAL1* promoter (Papamichos-Chronakis et al., 2002). Although Mig1p is not essential for the binding of the Ssn6p-Tup1p complex to the promoter, it is important for Ssn6p-Tup1p-mediated glucose repression (Papamichos-Chronakis et al., 2002). Snf1p-dependent phosphorylation of Mig1p abolishes the interaction with Ssn6p-Tup1p and controls transcriptional repression or derepression, and it is the regulation of this interaction, not the Mig1p cytoplasmic localization, that is the molecular switch that controls transcriptional repression and derepression of *GAL1* (Papamichos-Chronakis et al., 2002). Phenotypic analyses of strains lacking the *A. nidulans* Tup1p homologue, RcoA, have shown that deletion of *rcoA* does not greatly affect carbon catabolite repression (Hicks et al., 2001), and it is unlikely that CreA acts by recruiting RcoA as part of a general repressor complex.

Not only is carbon catabolite repression different between yeast and filamentous fungi, even among filamentous fungi the various CreA homologues appear to effect repression using different molecular methods (Table 4). In *A. nidulans*, *creA* transcription is autoregulated and *creA* mRNA is present in higher amounts in strains grown in relatively derepressing carbon sources such as arabinose than in strains grown in medium containing repressing levels of glucose (Arst et al., 1990; Shroff et al., 1996). However, a strain containing a transgene expressed from a constitutive promoter is phenotypically similar to the wild type, and thus, this autoregulation appears not to be a critical step in the regulatory mechanism (Roy et al., 2008). The *T. reesei* homologue *cre1* showed similar autoregulation of transcription (Ilmen et al., 1996). A rapid transient increase in *creA* transcript occurred on the addition of either glucose or a nonrepressing monosaccharide to carbon-starved mycelium, but these were down-regulated on repressing carbon sources (Strauss et al., 1999). However, in *Acremonium chrysogenum, cre1* showed glucose-dependent transcriptional upregulation, and this was absent from a strain of *A. chrysogenum* that displayed enhanced production of the β-lactam antibiotic cephalosporin C, consistent with the interpretation that the deregulation of *cre1* is connected with the increased production rate in this strain (Arst et al., 1990; Ilmen et al., 1996; Jekosch and Kuck, 2000a, 2000b; Shroff et al., 1996; Strauss et al., 1999). In *Sclerotinia sclerotiorum*, *cre1* transcript levels were also positively correlated with glucose concentration (Vautard-Mey et al., 1999).

The role of phosphorylation in the repressor activity of Cre1 has been investigated in *T. reesei* (Cziferszky et al., 2002, 2003). Phosphorylation of the Ser^{241} residue of *T. reesei* Cre1 was found to be required for DNA binding. Ser^{241}

FIGURE 4 Conserved motifs within filamentous fungal carbon catabolite repressor proteins. Amino acid residues in *A. nidulans*, *S. sclerotiorum*, and *T. reesei* referred to in the text are underlined.

replaced by glutamic acid mimics phosphorylation, and Ser^{241} replaced by alanine allows binding without phosphorylation, and both these changes result in permanent carbon catabolite repression for cellobiohydrolyase I expression. On the other hand, a $Glu^{244}Val$ substitution leads to no phosphorylation, binding, or repression (Cziferszky et al., 2002). Snf1 kinase is not involved in phosphorylation of Cre1 in *T. reesei* (Cziferszky et al., 2002), and a casein kinase II target consensus surrounds Ser^{241}. However, in *S. sclerotiorum*, substitution of Ser^{266} in CRE1 (equivalent to Ser^{241} in *T. reesei*) by alanine leads to derepression (Vautard-Mey and Fevre, 2000). The *A. nidulans* CreA amino acid region $SHED^{262–265}$ corresponds to amino acids $SNDE^{241–244}$ in *T. reesei* and $SHEE^{266–269}$ in *S. sclerotiorum*. The observation that the *A. nidulans* strains containing deletions of this region are almost identical to the wild type with respect to repression and derepression indicates that this region is not essential for DNA binding or carbon catabolite repression in *A. nidulans* (Roy et al., 2008). In *Cochliobolus carbonum*, derepression of at least some carbon catabolite-repressible genes requires a Snf1p-like activity (Tonukari et al., 2000), but mutation of a *SNF1*-like gene in *A. nidulans* does not affect carbon repression (M. J. Hynes, personal communication).

By use of antibodies, CRE1 in *S. sclerotiorum* was detected at higher levels in glucose- and glycerol-grown mycelia than in pectin-grown mycelia, although there were no apparent differences in stability in the two media (Vautard-Mey et al., 1999; Vautard-Mey and Fevre, 2000). The subcellular localization of the protein varied with glucose concentration, and although the presence or absence of a potential serine phosphorylation site was correlated with repressor activity, it did not affect subcellular localization (Vautard-Mey et al., 1999; Vautard-Mey and Fevre, 2000). In *A. nidulans* strains expressing CreA:green fluorescent protein and exhibiting normal repression and derepression phenotypes, CreA:green fluorescent protein was present in the nucleus at high levels under both carbon catabolite-repressing and derepressing conditions. Thus, CreA activity is not regulated by subcellular localization in *A. nidulans* (Roy et al., 2008).

Strauss and colleagues showed that CreA was regulated at the posttranscriptional as well as the transcriptional level in *A. nidulans* (Strauss et al., 1999). They concluded that changes in activity of CreA could be due to covalent modification of the protein and/or protein degradation and noted the presence of a sequence similar to a consensus sequence involved in ubiquitination and proteasome-mediated degradation (Strauss et al., 1999). There is some evidence that at least a fraction of CreA in the cell is ubiquitinated (Kamlangdee, 2008), and Western blot analysis did not show significant differences in the total amount of CreA in cells grown under repressing or derepressing conditions, indicating that derepression does not require large-scale degradation of CreA (Kamlangdee, 2008).

SAGA complexes have been studied in yeast (reviewed by Baker and Grant, 2007), and they act through the coordination of multiple histone posttranslational modifications, including acetylation, methylation, ubiquitination, and phosphorylation. The Gcn5p subunit has histone acetyltransferase activity and acetylates histones. In *A. nidulans*, the relationship between transcriptional activation and nucleosome positioning has been investigated using the proline and ethanol regulons as a model (Garcia et al., 2004; Mathieu et al., 2005; Reyes-Dominguez et al., 2008). In the proline regulon, eight nucleosomes in the intergenic regulatory region are absent under inducing conditions, and they are partially restored under carbon- and nitrogen-repressing conditions when inducer is also present. CreA is required for partial nucleosome repositioning under repressing conditions, but not to establish the initial pattern. Trichostatin A, an inhibitor of deacetylases, results in total loss of nucleosome positioning under induced-repressing conditions (proline plus glucose), despite only a small derepression of *prnB*, indicating that CreA can repress independently of nucleosomes (Garcia et al., 2004). Transcriptional activation under derepressing conditions and chromatin remodeling were not affected in strains lacking GcnE and AdaB (essential components of the histone acetyltransferase), but the expression under induced-repressing conditions was affected along with the partial repositioning of histones under these conditions. This implies that nucleosome positioning, transcriptional activity, and histone acetylation are distinct rather than coupled processes and that GcnE and AdaB exert their function via CreA (Reyes-Dominguez et al., 2008).

CreB Deubiquitinating Enzyme and CreC WD40 Protein

Mutations in *creB* and *creC* were uncovered in some of the same screens that uncovered mutations in *creA*. Under glucose-repressing conditions, mutations in *creB* or *creC* result in a degree of deregulated expression of a subset of enzymes that would normally be subject to carbon catabolite repression. In the absence of repressing concentrations of glucose, these same alleles result in failure to express enzymes for the utilization of some carbon sources, such as quinate or proline (Arst, 1981; Hynes and Kelly, 1977; Kelly and Hynes, 1977). The effects of *creB* or *creC* mutations are pleiotropic, but there is no evidence of phenotypic heterogeneity among the alleles. Mutations in either gene increase sensitivity to acriflavine and decrease sensitivity to molybdate (Arst, 1981), and they have slight effects on colony morphology (Hynes and Kelly, 1977). *creB15* and *crec27* mutations greatly reduce uptake of proline or glutamate, but no effects could be measured on the uptake of glucose (Arst, 1981; Hynes and Kelly, 1977; Kelly, 1980). Biochemical studies have shown that mutations in *creB* and *creC* reduce external pH acidification, but the basis of this is not known, although it is known not to be due to defects in the plasma-membrane-bound H^+-ATPase (Abdallah et al., 2000; Espeso et al., 1995).

The *creB* gene encodes a ubiquitin-processing protease, upb, which is a member of the family defined by the human homologue UBH1 (Hansen-Hagge et al., 1998; Lockington and Kelly, 2001). The protein contains the six DUB (deubiquitination) homology domains common to this class of protein (D'Andrea and Pellman, 1998) and a carboxy-terminal extension (Lockington and Kelly, 2001). There are also high-scoring PEST sequences, which are usually implicated as signals for proteolysis and correlated with ubiquitination and rapid degradation (Rechsteiner and Rogers, 1996). The *creC* gene encodes a protein composed of a proline-rich region, a putative nuclear localization region, and five WD40 repeat motifs (Todd et al., 2000). Both CreB and CreC are conserved across eukaryotes. In *S. cerevisiae*, the Ssn6p-Tup1 general repressor complex is involved in carbon catabolite repression of genes regulated by glucose repression via the Mig1p DNA-binding protein, as well as in a number of other regulatory pathways (Treitel and Carlson, 1995; Tzamarias and Struhl, 1995). *S. cerevisiae* Tup1p shows weak sequence similarity to *A. nidulans* CreC within the WD40 repeat regions of each protein (Todd et al., 2000); however, Tup1p and CreC are not orthologous proteins, and *A. nidulans* RcoA is significantly more similar to Tup1p than is CreC (Hicks et al., 2001). Coimmunoprecipitation experiments

have shown that CreB and CreC are present in a high-molecular-weight complex in vivo, and each is not required for the presence of the other in the complex (R. A. Lockington, R. Murray, and J. M. Kelly, unpublished observations). CreB and CreC can be coimmunoprecipitated from mycelia grown under either carbon catabolite-repressing or carbon catabolite-derepressing conditions (Lockington and Kelly, 2002).

Some substrates of CreB have been identified. The quinate permease QutD is a ubiquitinated protein, and coimmunoprecipitation experiments have shown that it is a target of the CreB deubiquitinating enzyme (Kamlangdee, 2008). Further, levels of QutD are lower in a *creB* mutant strain than in a wild-type strain, indicating that deubiquitination by CreB is required to prevent protein turnover (Kamlangdee, 2008), and a failure to deubiquitinate ubiquitinated permeases is likely to be the underlying cause of the phenotypes of *creB* and *creC* mutations that are found under carbon-derepressing conditions. It is, however, not likely that these effects on permeases account for the all the derepression phenotypes due to these mutations, since the genes for ethanol utilization are partially derepressed in the mutants, and ethanol does not require a permease to enter the cell.

At least some of the pool of CreA, the carbon repressor protein, has also been found among proteins purified as ubiquitinated proteins; however, since there were no great differences in the total amount of CreA in cells grown under repressing or derepressing conditions, CreA activity is not regulated by wholesale degradation (Kamlangdee, 2008). Despite this, overexpression of CreA overcomes the defects in carbon catabolite repression seen in *creB* and *creC* mutant strains, and in coimmunoprecipitation experiments, a fraction of CreA precipitated with CreB, indicating that CreA is also a probable target of the CreB deubiquitinating enzyme (Kamlangdee, 2008).

Mutations Leading to Increased Carbon Catabolite Repression

CreD Arrestin Motif Protein

The *creC27* mutation results in hypersensitivity to fluoroacetamide in glucose medium due to derepression of acetamidase and acetyl-CoA synthetase, leading to the accumulation of toxic fluorocitrate. The *creD34* mutation was isolated as a suppressor of this hypersensitivity. *creD34* also suppresses some *creC27* phenotypes, such as derepression of alcohol dehydrogenase I, but not others, such as poor growth on quinate (Hynes and Kelly, 1977; Kelly, 1980). The *creD34* mutation also suppresses some of the phenotypic effects of the *creB15* mutation, and, weakly, of the *creA204* mutation (Hynes and Kelly, 1977; Kelly, 1980). In a wild-type background, the *creD34* mutation leads to increased resistance to acriflavine and reduced sensitivity to molybdate (the reverse of the phenotype due to *creA*, *creB*, and *creC* mutations) and to reduced utilization of some sugars and ω-amino acids. The CreD protein is highly similar to the Rod1p and Rog3p proteins from *S. cerevisiae*, and CreD was shown to interact with the ubiquitin ligase HulA, indicating that CreD is a component of a ubiquitination aspect of the glucose regulatory network that includes the CreB/CreC complex (Boase and Kelly, 2004).

AcrB

acrB mutant strains have a pleiotropic phenotype with respect to carbon source utilization. They show decreased ability to utilize a number of different sugars as sole carbon sources, including fructose, cellobiose, raffinose, and starch, in comparison to both the wild type and the *creD34* mutant strain, which may indicate a failure to derepress the enzymes required for their utilization (Boase et al., 2003). Mutations in *acrB* also lead to acriflavine resistance and sensitivity to molybdate (Boase et al., 2003; Boase and Kelly, 2004). The *acrB2* and *creD34* mutations also share other aspects of their mutant phenotypes, importantly suppression of aspects of the *creB15* and *creC27* mutant phenotypes such as allyl alcohol sensitivity. The effects on acriflavine resistance of the *acrB2* and *creD34* mutations are additive, and both genes encode proteins that, when mutated, can lead to tighter carbon catabolite repression (Boase and Kelly, 2004). That the *acrB2* mutation leads to suppression of the phenotypes due to the *creB* and *creC* mutations suggests that AcrB, like CreD, is involved in ubiquitination, since a failure to add ubiquitin to substrates could suppress the phenotypic effects of mutations that affect the removal of ubiquitin moieties. AcrB encodes a protein that contains three transmembrane domains and a coiled-coil region, with no highly similar proteins present in the genomes of yeast or higher eukaryotes (Boase et al., 2003). Thus, this represents a protein that performs a function that is either highly specific to filamentous fungi or is achieved by very divergent proteins in other organisms.

SUMMARY

There are significant differences in the mechanism(s) controlling gene expression in response to glucose in filamentous fungi and the well-characterized unicellular fungus *S. cerevisiae*. In addition, the few detailed studies of filamentous fungi that have been completed suggest that there are differences among these species as well. Similar DNA-binding proteins mediate carbon catabolite repression in filamentous fungi and *S. cerevisiae*. However, the regulation of the activity of this DNA-binding protein and its mechanism of action vary. Studies involving *A. nidulans* suggest that ubiquitination plays a role in carbon catabolite repression. The genes controlling this regulatory mechanism are not found in *S. cerevisiae*.

Little has been reported on the glucose-signaling mechanism that triggers changes in gene expression in filamentous fungi. Glucose phosphorylation has been shown to be necessary for glucose signaling in *A. nidulans*, but the role of hexokinases in glucose signaling in *A. nidulans* appears to differ from that of *S. cerevisiae*. A glucose transporter homologue (RCO-3), which may have a role in glucose signaling, has been identified in *N. crassa*, but the exact role of RCO-3 remains to be clarified. As in *S. cerevisiae*, G-protein-coupled receptors have been shown to have a role in sensing carbon nutrient status in filamentous fungi. The interaction of these signaling mechanisms has not been studied in filamentous fungi. Thus, an integrated picture of glucose signaling in filamentous fungi has yet to emerge.

Differences in the transport and metabolism of glucose also exist. *S. cerevisiae* possesses 17 closely related proteins that are capable of transporting glucose. Very few glucose transporters from filamentous fungi have been characterized. However, the transporters that have been identified appear to be more diverse in sequence. Further research will be required to determine how many different glucose transporters exist in filamentous fungi. The regulation of TCA cycle genes in response to glucose differs in *S. cerevisiae* and filamentous fungi, and as a consequence, the metabolism of glucose differs. In filamentous fungi, the expression of TCA

cycle genes is higher in glucose-rich medium and respiration rather than fermentation is favored. However, even among the few filamentous fungi that have been studied there are differences.

Given the central role of glucose in carbon metabolism and the diverse nutrient sources used by different fungi, it is not surprising that differences in glucose transport, glucose metabolism, glucose signaling, and carbon catabolite repression have arisen through selection. Most of the research on these pathways has been carried out with ascomycetes, and it is likely that additional differences will be discovered in other groups of fungi.

Cellular and Molecular Biology of Filamentous Fungi
Edited by K. A. Borkovich and D. J. Ebbole

22

Gluconeogenesis

MICHAEL J. HYNES

INTRODUCTION

Organisms require carbon substrates to generate energy and metabolites. The major pathways of carbon metabolism are glycolytic breakdown of sugars and the tricarboxylic acid (TCA) cycle for energy generation and the synthesis of biosynthetic intermediates. Filamentous fungi are able to use a very diverse range of compounds as carbon sources, consistent with growth in a variety of environments, including saprophytic growth on complex organic substrates, growth of pathogens in (or on) the host, and the use of storage compounds in reproductive spores. Growth on sugars requires glycolysis as well as the TCA cycle to generate energy and biosynthetic intermediates (chapter 21). Growth on carbon compounds metabolized via TCA cycle intermediates requires the net formation of sugars from TCA cycle intermediates in the process of gluconeogenesis—a reversal of glycolysis, in which TCA cycle intermediates are converted to sugars. This means that control of metabolism at the level of enzyme activity and enzyme synthesis in response to available carbon sources is absolutely vital to avoid futile cycling by glycolysis opposed by gluconeogenesis.

The availability of many annotated fungal genomes has revealed the complexities of carbon metabolic pathways and has highlighted our considerable ignorance of the function of many enzymes, their cellular localization, and the importance of the distribution of metabolites between cellular compartments. The impact of carbon metabolism on development and pathogenesis has been of increasing interest as fungal molecular genetics has developed. Furthermore, whole-genome analysis and attempts at systems biology approaches to metabolism afford opportunities for improvements in industrial uses of fungi.

A very thorough analysis of the state of knowledge regarding carbon metabolism in all filamentous fungi was published in 1986 (McCullough et al., 1986). This review now makes interesting reading in the light of the cloning and characterization of some of the genes discussed. In addition, the annotated genomes of fungi now available provide new information regarding the number of genes encoding isozymes, the possible cellular localization of enzymes, and the analysis of protein functions via molecular manipulations. For example, a particularly accurate and comprehensive annotation of relevant genes in *Aspergillus nidulans* has been published (David et al., 2006).

Michael J. Hynes, Department of Genetics, University of Melbourne, Parkville, Victoria 3010, Australia.

Gluconeogenesis

Gluconeogenesis is summarized in Fig. 1. There are two enzymes that are essential for growth on gluconeogenic carbon sources. Phosphoenolpyruvate carboxykinase (PEPCK) (EC 4.1.1.32) converts the TCA cycle intermediate oxaloacetate to phosphoenolpyruvate, bypassing pyruvate produced by pyruvate kinase at the end point of glycolysis. Fructose-1,6-bisphosphatase (FBP) (EC 3.1.3.11), the final, irreversible step in hexose monophosphate formation, converts fructose 1,6-bisphosphate to fructose 6-phosphate, bypassing the glycolytic enzyme phosphofructokinase. The interconversion of fructose 6-phosphate to fructose-2, 6-bisphosphate is affected by ATP and phosphoenolpyruvate, with fructose 2,6-bisphosphate levels promoting glycolysis and inhibiting gluconeogenesis by allosteric regulation (Kubicek-Pranz et al., 1990; Mlakar and Legisa, 2006). FBP but not PEPCK is required for the generation of sugars from glycerol. The other enzymes required are reversible and shared with glycolysis. As described below, additional anaplerotic reactions may be required for the use of particular carbon sources. These replenish carbon intermediates used in biosynthetic pathways and ensure that the TCA cycle is functional. The best known of these is the glyoxylate bypass necessary for growth on substrates generating acetyl coenzyme A (acetyl-CoA). This pathway requires the unique enzymes isocitrate lyase (ICL) (EC 4.1.3.1) and malate synthase (MAS) (EC 4.1.3.2) as well as shared activities with the TCA cycle: citrate synthase, aconitase, and malate dehydrogenase (Kunze et al., 2006).

Importance for the Lifestyle of Fungi

Saccharomyces cerevisiae is specialized, with a strong preference for growth on fermentable monosaccharides generating ATP via glycolysis and not by respiration. However, when operation of the mitochondrial TCA cycle is compromised, key enzymes are turned on by the retrograde response to produce intermediates for biosynthetic reactions (Liu and

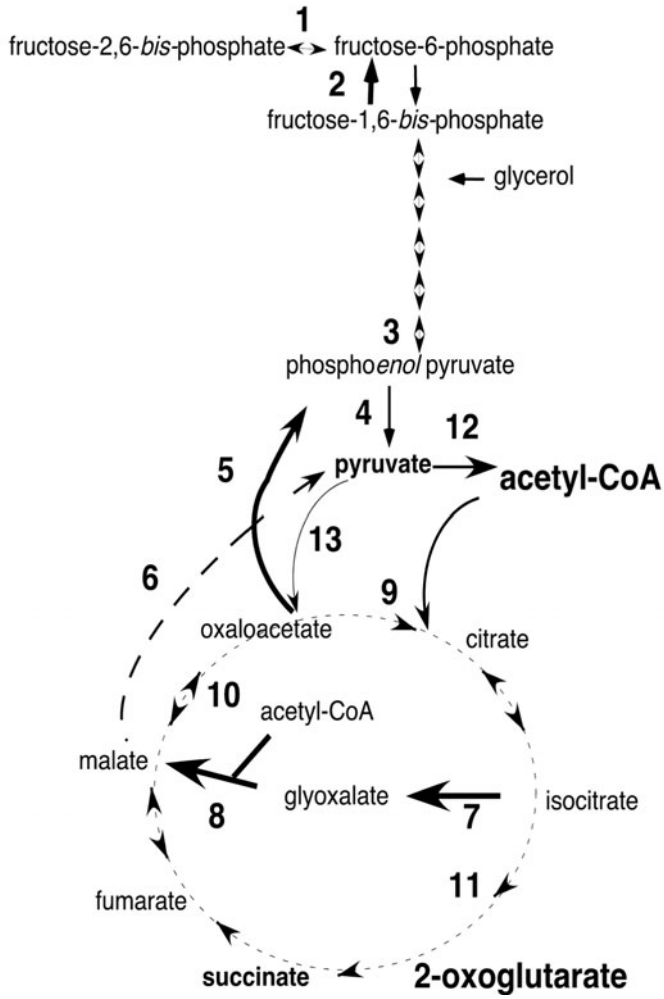

FIGURE 1 Outline of pathways for gluconeogenesis. Numbers in boldface represent key enzymes discussed in the text, as follows: 1, 6-phosphofructo-2-kinase and fructose-2,6-bisphosphatase; 2, fructose-1,6-bisphosphatase; 3, enolase; 4, pyruvate kinase; 5, phosphoenolpyruvate-carboxykinase; 6, malic enzyme; 7, isocitrate lyase; 8, malate synthase; 9, citrate synthase; 10, malate dehydrogenase; 11, isocitrate dehydrogenase; 12, pyruvate dehydrogenase; 13, pyruvate carboxylase. Reversible steps are shown with bidirectional arrows. For a full outline of relevant enzymes see Supplementary Figure S6 in David et al., 2006.

Butow, 1999). When glucose is exhausted, the metabolism switches to a respiratory mode in which the ethanol is consumed (Gancedo, 1998; Schuller, 2003). In contrast to filamentous fungi, *S. cerevisiae* can only use a limited number of substrates that result in the generation of TCA cycle intermediates as sole carbon sources (ethanol, acetate, and fatty acids), all of which result in the production of acetyl-CoA. Amino acids are not capable of acting as sole carbon sources but may be metabolized to fusel alcohols (Hazelwood et al., 2008). Some compounds are capable of acting as sole nitrogen sources but not as carbon sources, e.g., proline and γ-butyric acid (GABA).

In contrast, filamentous fungi are generally obligate aerobes, although *Neurospora crassa* is capable of considerable fermentation under high-glucose conditions (Xie et al., 2004) and under poor aerobic conditions fermentation is observed in *A. nidulans* (Lockington et al., 1997). Extremely slow growth on glucose, presumably via fermentation coupled with the alternative oxidase, has been observed in *A. nidulans* mutants lacking cytochrome *c* (Bradshaw et al., 2001). However, generally the TCA cycle is essential for growth on sugars and the retrograde response regulators of *S. cerevisiae* are apparently absent.

Consistent with growth on decaying plant material, fungi are capable of using a diverse range of gluconeogenic carbon sources, not just sources of acetyl-CoA but also amino acids and aromatic compounds (Hondmann and Visser, 1994; see also below). In the laboratory the ability to grow on particular carbon sources may be determined using defined media. In the real world, it is more likely that fungi grow on complex mixed carbon substrates with a consequent hierarchy of carbon utilization. It is also likely that mycelia undergoing carbon starvation in the wild are common, and survival depends on the breakdown of cellular components resulting in carbon sources requiring gluconeogenesis. Very little is known about the physiology of fungi under these circumstances. Of further relevance is fungal growth in fermenters with different growth-limiting parameters and substrates.

There has been increasing interest in the role of metabolism in processes such as spore formation and germination as well as pathogenesis. In asexual spores, mRNAs for gluconeogenic, glyoxylate cycle, and β-oxidation enzymes as well as peroxisomes are present, indicating that gluconeogenesis may be significant for spore survival and germination via the use of stored lipids (for examples, see Osherov and May, 2001; Osherov et al., 2002; Ebel et al., 2006; and Seong et al., 2008). Loss of citrate synthase and mutations affecting peroxisome function have been found to affect sexual development in *Podospora anserina* (Ruprich-Robert et al., 2002; Bonnet et al., 2006; see also chapters 15 and 33). Signaling by reactive oxygen species generated by NADPH oxidases is involved in both asexual and sexual reproduction in many fungi (Lara-Ortiz et al., 2003; Aguirre et al., 2005), and therefore the effects of growth on different carbon sources on NADPH levels are likely to alter development. In pathogenesis, infectious particles must germinate on host cell surfaces (often by the formation of specialized structures) or within host cells and initiate infection. Growth within host cells depends on available carbon substrates, and gluconeogenesis may be essential. Mutations affecting the glyoxylate cycle and fatty acid utilization can affect the pathogenicity and response to host cells of both plant and animal pathogens (Lorenz and Fink, 2002; Idnurm and Howlett, 2002; Solomon et al., 2004; Sexton and Howlett, 2006; Caracuel-Riosa and Talbot, 2007; Ibrahim-Granet et al., 2008). An example of particular relevance is afforded by infection by the rice blast pathogen *Magnaporthe grisea*, where turgor pressure required for leaf penetration by the appressorium depends on the conversion of lipids to glycerol via β-oxidation, the glyoxylate bypass, and gluconeogenesis (Wang et al., 2003, 2007; Caracuel-Riosa and Talbot, 2007). During infection by *Candida albicans* it has been shown that gluconeogenic enzymes are turned on (Barelle et al., 2006). Furthermore, the carbon substrate and the flux through central metabolic pathways affect the supply of essential intermediates for the production of signaling molecules such as oxylipins (Tsitsigiannis and Keller, 2007) as well as secondary metabolites such as antibiotics and mycotoxins (Maggio-Hall et al., 2005).

GLUCONEOGENIC CARBON SOURCES

Intermediary metabolites such as malate, pyruvate, and succinate are generally poor sole carbon sources, probably due to poor uptake. Other carbon sources metabolized to TCA cycle intermediates are excellent sole sources of carbon, and molecular genetic analysis of their mode of utilization has been performed for one or more filamentous ascomycete. These are summarized in Table 1. Using the *A. nidulans* sequence of a key indicator enzyme in a particular catabolic pathway for searches of the NCBI Uniprot database reveals that these pathways are conserved in filamentous ascomycetes (both pathogens and saprophytes) as well as in at least some basidiomycetes. The utilization of other weaker

[a]Intermediary metabolite(s) resulting from the specific catabolic pathway.

[b]*A. nidulans* genes used for blast-p searches on NCBI database (http://blast.ncbi.nlm.nih.gov/Blast.cgi). AN numbers are from http://www.broad.mit.edu/annotation/genome/aspergillus_group/MultiHome.html.

[c]Enzyme activity chosen as key indicator of the presence of the specific pathway.

[d]Even-numbered fatty acids result in acetyl-CoA, while odd-numbered fatty acids result in both acetyl-CoA and propionyl-CoA, which is metabolized as for propionate.

[e]Benzoate and quinate are metabolized via the protocatechuate pathway (Hondmann and Visser, 1994). A detailed analysis of genomes for the quinate pathway has been presented (Hane et al., 2007).

carbon sources has also been studied, e.g., isoleucine and valine (Maggio-Hall et al., 2007) and leucine and aromatic amino acids (Peñalva, 2001).

Different TCA cycle end products are produced dependent on the carbon source (Table 1), and this has a major effect on the requirement for particular enzyme activities. Catabolism that generates only acetyl-CoA leads to a requirement for the glyoxylate cycle to produce C4 compounds. The production of 2-oxoglutarate alone results in the need to produce acetyl-CoA, which is required for biosynthetic pathways as well as citrate synthesis from oxaloacetate via citrate synthase activity enabling maintenance of the TCA cycle. This situation does not arise in *S. cerevisiae*, for which only sources of acetyl-CoA are gluconeogenic carbon sources.

Substrates Metabolized via Acetyl-CoA

Genetic and biochemical analyses of acetate utilization in *N. crassa* and *A. nidulans* were among the first performed to study carbon catabolism in fungi (Flavell and Fincham, 1968; Armitt et al., 1976). Subsequently, ethanol utilization via alcohol dehydrogenase and acetaldehyde dehydrogenase to yield acetate has been studied in detail (Flipphi and Felenbok, 2004). Threonine catabolism also yields acetate via acetaldehyde, but the specific threonine catabolic pathway has not been extensively studied. Acetate is converted to acetyl-CoA by acetyl-CoA synthetase in the cytoplasm and enters the mitochondrion as acetyl-carnitine produced by carnitine-acetyltransferase for metabolism via the TCA cycle and the peroxisome for metabolism via the glyoxylate cycle (see below). Mutations in the genes for each of these enzymes lead to loss of growth on acetate and ethanol but not on fatty acids (Armitt et al., 1976; Connerton et al., 1990; Stemple et al., 1998; Hynes et al., 2006). In contrast, mutations in the genes encoding the glyoxylate cycle enzymes ICL and MAS abolish growth on even-numbered-chain-length fatty acids as well as acetate and ethanol (Armitt et al., 1976; Hynes et al., 2006, 2008).

Filamentous ascomycetes can grow on a range of fatty acids, both long and short chain. In *S. cerevisiae*, a complete pathway for long-chain fatty acid β-oxidation, together with accessory enzymes, results in the production of acetyl-CoA in peroxisomes (Hiltunen et al., 2003). Multiple enzymes for steps in β-oxidation are found in filamentous fungal genomes. Many of these are predicted to be peroxisomal, and in some cases this has been shown (Bonnet et al., 2006; Maggio-Hall and Keller, 2004; Fosså et al., 1995). Deletion of orthologs of the genes encoding some of these enzymes has been found to affect fatty acid utilization (Maggio-Hall and Keller, 2004; Klose and Kronstad, 2006; Wang et al., 2007). However, it is apparent that there is a high level of redundancy, and a complete genetic elaboration of this pathway has not been accomplished for any filamentous fungus. In addition, mutants affected in peroxisome functions or proliferation exhibit phenotypic defects during growth on fatty acid media (Klose and Kronstad, 2006; Wang et al., 2007; Bonnet et al., 2006; Hynes et al., 2008). Unlike *S. cerevisiae*, filamentous fungi can use short-chain fatty acids, such as butyrate and hexanoate. A complete pathway for their conversion to acetyl-CoA in mitochondria has been discovered in *A. nidulans* (Maggio-Hall and Keller, 2004; Hynes et al., 2008). Using the sequence of the ScdA protein AN0824 (Maggio-Hall et al., 2007) to search fungal protein databases revealed that this pathway is likely to be conserved in filamentous fungi but not in hemiascomycetes, with the interesting exception of *Yarrowia lipolytica*. It is also clear that peroxisomes are required, and it has been suggested that there is a peroxisomal pathway for conversion of short-chain fatty acids to acetyl-CoA (Hynes et al., 2008). No mutants affected in this pathway have been discovered so far.

Substrates Metabolized via Propionyl-CoA

Propionate is a carbon source for fungi and has been shown to be converted to propionyl-CoA (Zhang et al., 2004). The metabolism of propionyl-CoA via the mitochondrial methyl-citrate cycle has been well studied in *A. nidulans* and *Aspergillus fumigatus*, and the relevant enzymes are conserved in other fungi (Brock, 2005; Brock and Buckel, 2004; Brock et al., 2000; Maerker et al., 2005; Ebel et al., 2006). Methyl-citrate synthase combines propionyl-CoA with oxaloacetate to form methylcitrate, which isomerizes to methylisocitrate, which is then cleaved to succinate and pyruvate. The production of these end products ensures that the glyoxylate cycle is not required.

The last step of β-oxidation of odd-numbered chain fatty acids will result in the production of propionyl-CoA as well as acetyl-CoA. In the case of valerate (C_5), a single round of β-oxidation will produce propionyl-CoA and acetyl-CoA. Valerate is a good carbon source for *A. nidulans* and does not require the defined mitochondrial short-chain pathway (Hynes et al., 2008). Propionyl-CoA has toxic effects due to inhibition of pyruvate dehydrogenase and succinyl-CoA synthetase (Brock and Buckel, 2004). This is particularly observed when this metabolite accumulates in methylcitrate synthase-deficient strains. In addition, polyketide secondary metabolite synthesis is inhibited (Brock, 2005).

Substrates Metabolized via Glutamate

Transamination of amino acids yields glutamate, and the corresponding keto acid and glutamate itself can serve as a sole carbon source. NAD-dependent glutamate dehydrogenase yields ammonium as well as 2-oxoglutarate. This enzyme is also essential for the use of amino acids metabolized via glutamate as either nitrogen or carbon sources (Arst et al., 1975; Kinghorn and Pateman, 1976). Release of ammonium is necessary to enable glutamine synthesis for nitrogen metabolism, while 2-oxoglutarate can enter the TCA cycle as a gluconeogenic carbon source. Consistent with this, PEPCK and FBP are required for the use of amino acids as carbon, but not nitrogen, sources in the presence of glycolytic carbon sources (Armitt et al., 1976; Hynes et al., 2007).

Proline, a very good sole carbon source for *A. nidulans*, is metabolized directly to glutamate. The genes for proline utilization (*prn*) are present in a cluster that includes *prnD* and *prnC*, encoding the two enzymes required for conversion of proline to glutamate; *prnX*, a gene of unknown function in proline utilization; *prnB*, specifying a proline permease; and *prnA*, encoding a pathway-specific activator (Gómez et al., 2002). A comparison with other fungal genomes at the Broad Institute website (http://www.broad.mit.edu/annotation/fungi/fgi/) indicates that the genes are conserved in other filamentous ascomycetes. However, there are two unlinked clusters in *Aspergillus oryzae* and *A. fumigatus*, and neither of these includes a permease gene. Clustering is not observed in *N. crassa* or *M. grisea*. The same pathway is found in *S. cerevisiae*, where the genes are scattered and are only involved in the use of proline as a nitrogen source (Des Etages et al., 2001).

The omega amino acid GABA is converted to 2-oxoglutarate and succinic-semialdehyde by a specific

transaminase required for growth on GABA as a carbon or nitrogen source (Richardson et al., 1989). Succinic-semialdehyde is metabolized to succinate by a dehydrogenase (Arst, 1976).

Aromatic Acids

The *qa* cluster of genes in *N. crassa* is required for growth on quinate, a product of lignin degradation, and has been the subject of classical studies in the laboratory of Case and Giles (Giles et al., 1985). A similar cluster has also been studied in *A. nidulans* (Grant et al., 1988), and related clusters are found in the genomes of other ascomycetes (Hane et al., 2007). A quinate permease, together with three enzymes, is specifically required for quinate utilization. The resulting protocatechuic acid, which is also a product of benzoate degradation, is then converted to succinate and acetyl-CoA by an additional seven steps encoded by dispersed genes (Hondmann and Visser, 1994).

CELLULAR LOCALIZATION OF METABOLITES AND ENZYMES

General Considerations

A critical problem in understanding carbon metabolism is the distribution of metabolites and enzymes between cellular compartments: the cytosol, mitochondrion, and peroxisomes. In general, both glycolysis and gluconeogenesis occur in the cytoplasm, while the TCA cycle is mitochondrial. Peroxisomes are required for fatty acid degradation and play a role (albeit ambiguous) in the glyoxylate cycle (see below). Peroxisomes have been generally defined as microbodies containing catalase, while glyoxysomes are microbodies lacking catalase but containing glyoxylate cycle enzymes. There is no clear case for distinguishing between the two classes (at least in fungi), as the same set of peroxisomal proteins (peroxins) are necessary for biogenesis and function. *N. crassa* peroxisomes lack catalase as well as other enzymes, such as acyl-CoA oxidase, generating reactive oxygen species, while *A. nidulans* has peroxisomal catalase and acyl-CoA oxidases (Schliebs et al., 2006; Kawasaki and Aguirre, 2001; K. Reiser and M. J. Hynes, unpublished data). It can also be noted that metabolites such as acetyl-CoA and methyl group donors must also be provided to nuclei for processes such as histone modifications, and this might be reflected in specific effects of growth substrates or mutations affecting primary metabolism on developmental stages. An indication of significant confusion in this area is illustrated by the different cellular localizations portrayed for the same reaction in metabolic diagrams in the literature. Our ignorance of the complexities of cellular localization poses significant difficulties for attempts to develop models and systems biology approaches to metabolism.

The classical approach to enzyme localization has involved cell fraction and enzyme assays. This has allowed the distribution of activities between the particulate (mitochondria) and soluble fractions (for an example, see Osmani and Scrutton, 1983). However, discrimination between isozymes (either resulting from different forms of the same gene product or the products of different genes) is not possible using this method. In addition, the biological significance of low-level activities in a fraction is not readily assessed. Annotated genomes now permit the isozyme complexity issue to be resolved, and cell biology approaches using tagged proteins allow a more accurate definition of cellular localization. However, detailed studies of each gene product, including analysis of the phenotypic effects of enzyme mislocalization, are required for a full understanding.

A further complicating factor is competition for the same substrate by enzymes in a compartment. In *S. cerevisiae*, TCA cycle enzymes form a complex in the mitochondrion and cytoplasmic malate dehydrogenase physically interacts with PEPCK and FBP, favoring flux through gluconeogenesis (McAlister-Henn and Small, 1997; Gibson and McAlister-Henn, 2003).

Distribution of Metabolites

The shuttling of metabolites between mitochondria, cytosol, and peroxisomes is crucial for gluconeogenesis. TCA cycle intermediates generated by specific catabolic pathways in the cytoplasm or peroxisomes must enter the mitochondria for further metabolism. Cytoplasmic PEPCK requires cytoplasmic oxaloacetate as a substrate. There are 34 members of the mitochondrial carrier superfamily responsible for the transport of metabolites through the mitochondrial membrane in *S. cerevisiae*, and many of these have been studied (Palmieri et al., 2000). Incredibly, the *A. nidulans* genome encodes 105 proteins annotated with this domain (http://www.broad.mit.edu/annotation/genome/aspergillus_group/MultiHome.html), while *N. crassa* has 101 such proteins (http://www.broad.mit.edu/annotation/genome/neurospora/Home.html), and some of these are predicted to be dicarboxylic carriers relevant to gluconeogenesis. Apart from the acyl-carnitine carrier (see below), the only known relevant predicted protein is the product of the *acuL* gene, originally identified as an *A. nidulans* acetate utilization mutant (Armitt et al., 1976). AcuL is an ortholog of the *S. cerevisiae* Acr1/Sfc1 succinate/fumarate transporter that is required for mitochondrial trafficking of succinate generated by the glyoxylate cycle. Consistent with this, AcuL is mitochondrial and required for growth on ethanol and fatty acids (M. J. Hynes, M. A. Davis, and R. B. Todd, unpublished observations).

The extent to which the single membrane of peroxisomes generally acts as a barrier to the flow of metabolites is not known (Tabak et al., 2008). No motifs that are signatures of carrier proteins involved in peroxisomal transport have been recognized. In *S. cerevisiae*, ABC half-transporters for fatty-acyl-CoA transport and acyl-CoA synthetase-coupled transport of free fatty acids are known (van Roermund et al., 2004). Furthermore, the ATP transporter Ant1 is proposed to be required for ATP import and maintenance of a proton gradient across the peroxisomal membrane (Palmieri et al., 2001; van Roermund et al., 2004). Mutations in a gene predicted to encode the orthologous protein in *A. nidulans* have been isolated; such mutant strains are unable to grow on fatty acids but able to grow on acetate (Hynes et al., 2008). There is the further relatively unexplored possibility of direct transport of metabolites between peroxisomes and mitochondria without passing through the cytoplasm.

The enzymatic generation of the appropriate reducing power in the form of NADH/NADPH in the different compartments is an important factor in the ability to use carbon sources. In *S. cerevisiae*, there are three genes encoding NADP-dependent isocitrate dehydrogenases, each of which is located in just one of the three compartments (Haselbeck and McAlister-Henn, 1993). In contrast, in *A. nidulans* a single gene encodes enzymes for each compartment, with the cytoplasmic enzyme probably being important for 2-oxoglutarate formation, while the mitochondrial and peroxisomal forms produce NADPH (Szewczyk et al., 2001). *S. cerevisiae* has a specific peroxisomal NAD-dependent

malate dehydrogenase for generating NADH (Kunze et al., 2002), while filamentous fungi do not have an equivalent enzyme with a peroxisomal targeting sequence.

Enzyme Localization in Mitochondria

The process of protein import into mitochondria has been well studied. There are established programs for the prediction of N-terminal mitochondrial targeting signals for proteins (for examples, see http://www.cbs.dtu.dk/services/TargetP/ and http://psort.ims.u-tokyo.ac.jp/), and the predicted TCA cycle enzymes of filamentous fungi contain these. However, these predictions are not absolute; for example, in *S. cerevisiae* fumarase is produced as a single protein targeted to both mitochondria and the cytoplasm (Sass et al., 2001; Regev-Rudzki et al., 2008). In *A. nidulans*, significant cytoplasmic activity is found (Osmani and Scrutton, 1983), and this is consistent with this enzyme converting fumarate to malate for gluconeogenesis in the cytoplasm. In other cases separate genes encode differentially localized isozymes. *S. cerevisiae* has three genes for NAD-malate dehydrogenase (Roth and Schüller, 2001), while in *A. nidulans* two genes are predicted to encode enzymes with no obvious targeting sequences in addition to the mitochondrial enzyme.

Enzyme Localization in Peroxisomes

Peroxisomal enzymes are localized in the matrix and are imported as folded proteins synthesized in the cytoplasm (Tabak et al., 2008). Import is carried out by peroxisomal membrane complexes comprising specific peroxins, the products of *pex* genes (chapter 15). In fungi there are two classes of peroxisomal matrix proteins: those containing a C-terminal PTS-1 sequence, which require the specific receptor Pex5 for import, and those containing an N-terminal PTS2 recognized by Pex7 (Brocard and Hartig, 2006; Petriv et al., 2004). Other peroxins such as Pex1, Pex6, and Pex13 are necessary for the import of both kinds of protein. Three C-terminal amino acids of the form S/A R/K L/M are the most common signatures of PTS1 proteins. However, there are variants of these, and the overall context of the 12 C-terminal amino acids can affect targeting (Brocard and Hartig, 2006). Conservation of C-terminal sequences in proteins from different species provides opportunities for assessing the likelihood of peroxisomal localization. In addition, cryptic internal PTS1 sequences have been found in proteins dependent on Pex5-mediated localization (for an example, see Klein et al., 2002). The PTS2 consensus (R/K L/V/I X5 H/Q L/A/F/I) close to the N terminus is found in the minority of proteins dependent on Pex7 for targeting (Petriv et al., 2004). An internal sequence conserved in the ICL of filamentous ascomycetes, but not in hemiascomycetes or plants (Gainey et al., 1992), has been found to be necessary for targeting in *A. nidulans*. The targeting is Pex7 dependent, thereby constituting a rare case of a cryptic PTS2 signal (Hynes et al., 2008).

Acetyl-CoA Metabolism and Peroxisomes

There are many aspects of the distribution of metabolites and enzymes required for growth on sources of acetyl-CoA that are poorly understood (for a detailed discussion see Kunze et al., 2006). Growth on acetate or ethanol results in the formation of acetyl-CoA in the cytoplasm via acetyl-CoA synthetase, while β-oxidation of fatty acids results in the synthesis of peroxisomal acetyl-CoA. Acetyl-CoA must then be metabolized via the TCA cycle in the mitochondrion and by the glyoxylate cycle.

It is clear that acetyl-CoA entry into mitochondria occurs as acetyl-carnitine formed by reversible carnitine acetyltransferase activities. A cytoplasmic enzyme (encoded by *facC* in *A. nidulans*) is required for growth on acetate, but not on fatty acids (Stemple et al., 1998). A second carnitine acetyltransferase (encoded by *acuJ* in *A. nidulans*) contains both mitochondrial and peroxisomal targeting (PTS1) sequences and is needed for growth on fatty acids as well as acetate (Stemple et al., 1998; Hynes et al., 2006; Bhambra et al., 2006; Ramos-Pamplona and Naqvi, 2006). An acylcarnitine carrier protein (encoded by *acuH* in *A. nidulans*) is required for transport of acetyl-carnitine into mitochondria, where it is converted to acetyl-CoA by carnitine acetyltransferase (De Lucas et al., 1999). It has been suggested that the peroxisomal membrane is impermeable to acetyl-CoA, but not to acetyl-carnitine (Elgersma et al., 1995; van Roermund et al., 1995, 1999; Swiegers et al., 2001). However, AcuH is mitochondrial, but not peroxisomal, and is required for growth on both fatty acids and acetate (De Lucas et al., 2001). This raises the possibility that acetyl-carnitine generated in peroxisomes by β-oxidation and carnitine acetyltransferase activity is directly transferred to mitochondria and not via the cytoplasm. We have recently shown that mislocalization of peroxisomal AcuJ to the cytoplasm by mutation of the PTS1 sequence results in an inability to grow on fatty acids without affecting growth on acetate (M. J. Hynes and S. L. Murray, unpublished data).

It should be noted that there are redundant pathways for the transfer of acetyl groups into mitochondria in *S. cerevisiae*: via acetyl-carnitine and via citrate formed by peroxisomal citrate synthase (Cit2) (Elgersma et al., 1995; van Roermund et al., 1995, 1999; Swiegers et al., 2001). The acetylcarnitine pathway is essential for growth on acetate and fatty acids in *C. albicans* as for filamentous ascomycetes (Zhou and Lorenz, 2008; Strijbis et al., 2008), while the citrate pathway is essential in plants (Pracharoenwattana et al., 2005).

The enzyme activities necessary for the glyoxylate cycle are distributed among mitochondria, cytoplasm, and peroxisomes. Citrate synthase and aconitase are required for the formation of isocitrate using acetyl-CoA and oxaloacetate produced from malate by malate dehydrogenase. Both citrate synthase and aconitase activities are primarily mitochondrial in *A. nidulans* (Osmani and Scrutton, 1983). In contrast, in *S. cerevisiae* there are both mitochondrial (Cit1) and peroxisomal (Cit2) citrate synthases and a minor, but significant, cytoplasmic aconitase activity (Regev-Rudzki et al., 2008). Interestingly, predicted citrate synthase enzymes in all *Aspergillus* spp. contain a PTS1 sequence as well as a mitochondrial targeting sequence. The significance of this is not clear. In *S. cerevisiae*, mitochondrial, peroxisomal, and cytoplasmically localized malate dehydrogenases are encoded by three separate genes (Roth and Schüller, 2001), while both cytoplasmic and mitochondrial isozymes are predicted in filamentous ascomycetes.

The unique glyoxylate cycle enzymes, ICL and MAS, are generally regarded as peroxisomal in fungi. MAS contains a PTS1 sequence. ICL from some, but not all, fungi, also possesses potential PTS1 sequences, while it seems likely that filamentous ascomycetes have a cryptic internal PTS2 sequence (Kunze et al., 2006; Hynes et al., 2008). However, in *S. cerevisiae*, ICL is cytoplasmic, while MAS, which has a PTS1, is peroxisomal in the presence of oleate but not acetate and mislocalization of MAS does not affect growth on oleate (Kunze et al., 2002). This indicates that peroxisomal localization is not essential. In filamentous fungi, peroxisomal localization of ICL and MAS is also not absolutely

required, because *pex* mutants affected in peroxisome biogenesis have been found to grow on acetate (Hynes et al., 2008). Furthermore, we have shown that mislocalization of MAS does not affect growth on either fatty acids or acetate (Hynes et al., 2008). This indicates the potential for the flow of metabolites between peroxisomes and the cytoplasm.

The specific situation for acetyl-CoA is of interest. It has been proposed that this can only exit or enter the peroxisome as acetyl-carnitine (Elgersma et al., 1995). However, the cytoplasmic carnitine acetyltransferase (FacC) is not required for growth of *A. nidulans* on fatty acids (Stemple et al., 1998; Hynes et al., 2006), and therefore, conversion of exported acetyl-carnitine to acetyl-CoA in the cytoplasm is not necessary. It is difficult to avoid the conclusion that acetyl-CoA produced by β-oxidation can exit the peroxisome for metabolism via the glyoxylate cycle and does not require conversion to acetyl-carnitine. However, import of acetyl groups into mitochondria is absolutely dependent on conversion of acetyl-CoA to acetyl-carnitine.

REGULATION OF GENE EXPRESSION

The regulation of genes required for growth on gluconeogenic carbon sources in response to the diauxic shift has been well studied in *S. cerevisiae*. However, the ability of filamentous fungi to grow on a wider range of gluconeogenic carbon sources means that different strategies for controlling gene expression are required. Although there are some related regulatory proteins involved in these control mechanisms, there appear to be fundamental differences among these groups of fungi.

Gluconeogenesis in *S. cerevisiae*

The extensive changes in gene expression accompanying growth on nonfermentable carbon sources are determined by the Snf1 master kinase that is activated when glucose levels are low (Gancedo, 1998). The resulting phosphorylation of the Cys2His2 zinc finger repressor protein Mig1 and the transcriptional activators Adr1, Cat8, and Sip4 turn on a large number of genes, including those for ethanol breakdown, the glyoxylate bypass, and gluconeogenesis (Schuller, 2003). Different genes are dependent to varying extents on the individual activators binding to carbon source response elements (CSREs) (Young et al., 2003; Tachibana et al., 2005). To add further complexity, yet another Snf1-dependent activator of gluconeogenesis, Rsd2, has recently been identified as binding to at least some CSRE elements (Soontorngun et al., 2007). Intriguingly, this protein is related to AcuM in *A. nidulans* and, furthermore, two other genes (YBR239C and YJL103C) specify proteins similar to AcuK (see below). In *S. cerevisiae*, all of the central genes required for gluconeogenic growth, including the glyoxylate cycle, are controlled transcriptionally by a lack of fermentable carbon sources rather than by induction by specific substrates. This is summarized in Fig 2.

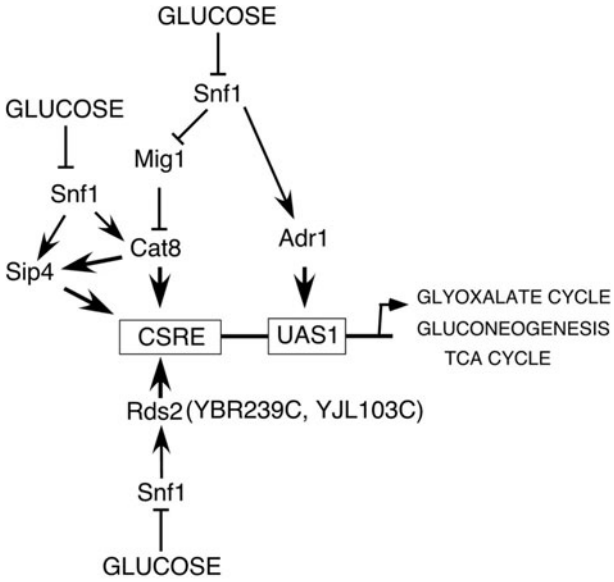

FIGURE 2 The logic of transcriptional regulation of gluconeogenic carbon source utilization in *S. cerevisiae*. The absence of glucose is the key signal. This results in the Snf1 kinase becoming active, leading to the removal of the repressor Mig1 from the nucleus and the activation of the transcriptional activators Cat8, Adr1, Sip4, and Rsd2 (and perhaps YBR239C and YJL103C) by phosphorylation. These activators regulate the transcription of a large number of genes involved in the utilization of carbon sources including both glyoxalate cycle and specific gluconeogenic genes. Each regulated gene is dependent to varying extents on two or more of the activators. The CSRE core element is CCAN5CCG, while the UAS1 consists of two half-sites, TTGGRG. In addition, Adr1, in conjunction with Oaf1 and Pip2, activates genes required for fatty acid utilization (Hiltunen et al., 2003). Based on data from Schuller (2003); Young et al. (2003); Tachibana et al. (2005); and Soontorngun et al. (2007).

Regulation in Filamentous Ascomycetes

Generally, specific catabolic pathways are controlled by pathway-specific induction using transcriptional activators—most commonly with Cys6 Zn binuclear cluster DNA binding domains. Examples of these are presented in Table 1, and the specific growth properties of loss-of-function mutations in these regulatory genes is shown in Table 2. Carbon catabolite repression of these pathways is mediated by conserved orthologs of the C2H2 Zn finger CreA repressor (Dowzer and Kelly, 1991; see also chapter 21). Commonly, repression of both structural genes (often permeases) and/or the pathway-specific transcription factor occurs. An example is provided by the ethanol system in *A. nidulans*, where both alcohol dehydrogenase (*alc*A) expression and *alcR* are subject to CreA-mediated repression (Flipphi and Felenbok, 2004). Therefore, specific pathways resulting in the formation of gluconeogenic substrates are expressed only if glucose is absent and inducer is present (Fig. 3).

There are fundamental differences with *S. cerevisiae*: deletion of genes for the Snf1 AMP kinase does not have pleiotropic effects on alternative carbon source utilization (for an example, see Yi et al., 2008), and obvious orthologs of Adr1 are absent from filamentous fungi. *A. nidulans* FacB and *N. crassa* Acu15, Zn(2)Cys(6) proteins, are related to Cat8 and Sip4 with similar DNA binding domains (Todd et al., 1997, 1998; Bibbins et al., 2002). However, in response to acetate, these proteins specifically regulate genes required for acetate utilization, i.e., acetyl-CoA synthetase, carnitine acetyltransferases, and the glyoxylate cycle enzymes ICL and MAS (Todd et al., 1998; Stemple et al., 1998; Bibbins et al., 2002; Hynes et al., 2006), and in contrast to Cat8 and Sip4, not those for gluconeogenesis. Mutations in *facA* and *facC* result in reduced FacB-mediated acetate induction, while an *acuJ* mutation enhances

TABLE 2 Carbon source utilization in loss-of-function regulatory gene mutants in *A. nidulans*[a]

Regulatory gene[b]	Carbon source						
	Glucose	Quinate	Ethanol	Acetate	Fatty acids	Proline	GABA
qutA	+	−	+	+	+	+	+
alcR	+	+	−	+	+	+	+
facB[c]	+	+	−	−	+	+	+
farA	+	+	+	+	−	+	+
prnA	+	+	+	+	+	−	+
amdR	+	+	+	+	+	+	−
acuK	+	−	−	−	−	−	−
acuM	+	−	−	−	−	−	−

[a]+, source is utilized; −, source is not utilized.

[b]See Table 1.

[c]Note that *facB* mutations affect growth on ethanol because ethanol is metabolized via acetate.

induction, indicating that acetyl-carnitine accumulation in the cytoplasm may be an important signal (Stemple et al., 1998). Mutations in two additional genes in *A. nidulans* specifically result in elevated levels of ICL in sucrose-grown cultures independently of FacB, but the function of these is not known (McCullough and Shanks, 1993).

In *S. cerevisiae*, fatty acid β-oxidation and peroxisome functions, but not ICL and MAS, are transcriptionally regulated by Oaf1 and Pip2 in response to long-chain fatty acids (Rottensteiner et al., 2003; Hiltunen et al., 2003). Completely different Zn(2)Cys(6) transcription factors, highly conserved in filamentous ascomycetes, not only transcriptionally control induction of these activities by fatty acids but also regulate other functions (e.g., the glyoxylate cycle enzymes and the peroxisomal/mitochondrial carnitine acetyltransferase) required for growth on both acetate and fatty acids separately from the specific acetate regulator, FacB (Hynes et al., 2006). FarA is required for induction by both short- and long-chain fatty acids, while FarB and ScfA are only necessary for short-chain induction. FarA and FarB orthologs were originally discovered as cutinase transcription factors involved in cutinase induction in *Nectria haematococca* (Li et al., 2002) and bind to a core CCGAGG sequence found upstream of many genes involved in the utilization of sources of fatty acids and in peroxisomal biogenesis and metabolism. FarA, but not FarB, orthologs are found in some hemiascomycetes such as *C. albicans* and *Y. lipolytica*, and CCGAGG sequences are present in the

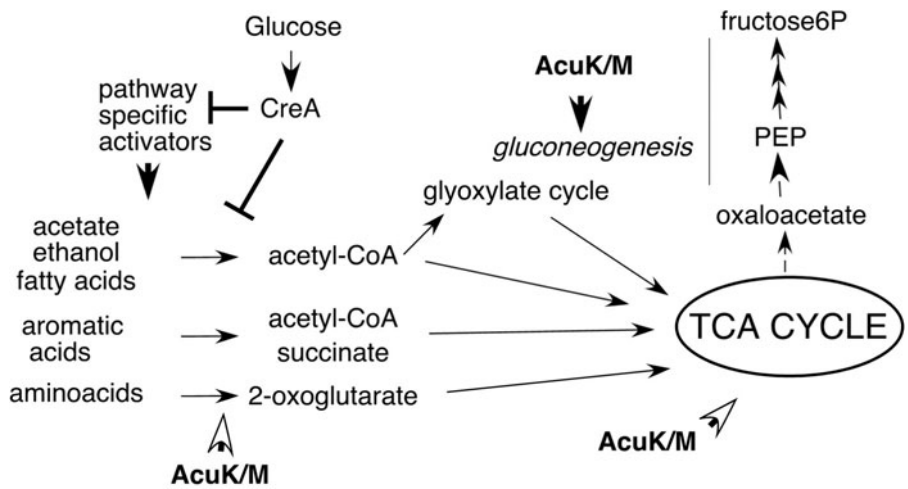

FIGURE 3 Proposed logic for transcriptional regulation of gluconeogenic carbon source utilization in *A. nidulans*. In the presence of glucose, the CreA repressor turns off the expression of the specific genes required for the utilization of each carbon source directly and/or by repression of the synthesis of a specific activator. However, this activator also requires an inducer for activity resulting in the genes for the specific pathway being turned on. Pathway-specific activators are given in Table 1. The specific pathways result in the production of TCA cycle intermediates. The AcuK/AcuM heterodimer is required for expression of the unique genes of gluconeogenesis as well as for at least some of the reversible glycolytic/gluconeogenic genes and is also proposed to increase the levels of at least some TCA cycle enzyme genes in response to the accumulation of TCA cycle intermediates. Black arrows indicate confirmed targets, while open arrows are proposed.

5′ end of relevant genes in these species (Hynes et al., 2006). This represents an extremely clear case of transcriptional rewiring within the Hemiascomycetes.

In filamentous ascomycetes, the genes for gluconeogenesis are regulated independently of the particular carbon source by a central control that reflects the buildup of TCA cycle intermediates and the requirement for hexose synthesis. Two key transcription factors required for this process have been identified in *A. nidulans* (Hynes et al., 2007). The *acuK* and *acuM* genes, which were originally identified as mutants unable to utilize acetate (Armitt et al., 1976), also affect growth on all carbon sources requiring gluconeogenesis (Table 2). Consistent with this, *acuK* and *acuM* mutations result in loss of induction of *acuF* (PEPCK) and *acuG* (FBP) by sources of TCA cycle intermediates such as acetate and proline. The *acuK* and *acuM* genes encode related transcription factors with similar Zn(2)Cys(6) DNA binding domains. Furthermore, database searches reveal that these genes are conserved in filamentous ascomycetes. Unexpectedly, we found that enolase (encoded by *acuN*), which is required for both gluconeogenesis and glycolysis, is expressed from two transcription starts: one controlled by glycolytic carbon sources and one by gluconeogenic carbon sources (Hynes et al., 2007). This raises the possibility that other genes encoding the reversible enzymes of glycolysis/gluconeogenesis are subject to dual control. This will not be observed in microarray experiments comparing glucose and gluconeogenic carbon source grown cultures (for an example, see David et al., 2006) if expression levels are similar on both glycolytic and gluconeogenic carbon sources. Detailed promoter analysis is necessary to resolve this for other glycolytic/gluconeogenic genes.

Recent work has identified binding sites for AcuK and AcuM. Electrophoretic mobility shift experiments with *Escherichia coli*-expressed maltose binding protein fusions have shown binding to DNA probes from the 5′ untranslated regions of *acuF*, *acuG*, and *acuN*, but only when both AcuK and AcuM proteins are present. Mutation of identified binding sites in an *acuF-lacZ* reporter has confirmed the in vivo significance of this binding. The minimal consensus sequence is a direct repeat, CCGN7CCG, and it appears that AcuK and AcuM bind cooperatively to activate expression (Y. Suzuki, M. A. Davis, and M. J. Hynes, unpublished observations). There is a striking conservation of both the sequence and position of these sites shown by in silico comparisons of the 5′ sequences of orthologous genes from other *Aspergillus* spp. The consensus site is also found in the 5′ untranslated regions of orthologous genes from more distantly related ascomycetes. The pattern of conserved 5′ sites also indicates the wide range of genes possibly subject to AcuK/M control. Upregulation of TCA cycle enzymes during growth on acetate was reported for *A. niger* and *A. nidulans* many years ago and in recent microarray experiments during growth on ethanol (Galbraith and Smith, 1969; McCullough et al., 1977; David et al., 2006). Genes for TCA cycle enzymes (e.g., orthologs of *S. cerevisiae SDH1*, *KGD1*, and *LPD1*), carboxylic acid mitochondrial transporters, NAD-dependent glutamate dehydrogenase and some glycolytic enzymes all have conserved sites in closely related species. It is clear that AcuK and AcuM play a central role in the rearrangement of metabolism during adaptation to growth on gluconeogenic carbon sources.

Intriguingly, the *N. crassa* orthologs (Aod2 and Aod5) of AcuK and AcuM have been found to regulate the alternative oxidase in response to antimycin inhibition of electron transport through complex III (Chae et al., 2007; see also chapter 13).These proteins have also been shown to bind cooperatively in vitro to CCGN7CCG sequences.

As in most Zn(2)Cys(6) proteins, the DNA-binding domains of AcuK and AcuM are N terminal, and conserved central domains (Pfam 04082) are present. Extensive stretches of amino acids at the C-terminal end of both proteins are conserved in the orthologs from other species. These contain similarities to PAS domains (pfam 00989) found in prokaryotic and eukaryotic proteins of diverse functions, including transcription factors, and act as sensors of various biological signals including light, oxygen, redox, and energy. Mutation of conserved residues in the PAS domains of the *N. crassa* Aod2 and Aod5 proteins eliminate induction of the alternative oxidase, thereby showing the importance of these domains (Chae et al., 2007). Interestingly the similar proteins found in *S. cerevisiae* (Rsd2 and the products of YBR239C and YJL103C; see above) also have C-terminal PAS domains. This raises the possibility that signaling to the transcription factors might reflect the required balance between TCA cycle flux and ATP generation by the electron transport chain. In addition, accumulation of TCA cycle intermediates results in induction of gluconeogenic gene expression in *A. nidulans*. The *acuF* mutation leads to increased expression of both *acuF-lacZ* and *acuG-lacZ* reporters and increased induction by malate, a weak source of induction in wild-type backgrounds (Hynes et al., 2007). This indicates that accumulation of oxaloacetate results in induction. However, oxaloacetate itself may not result in induction, since the reversible malate dehydrogenase and fumarase steps in the TCA cycle might lead to accumulation of fumarate. The nature of signaling to these gluconeogenic transcriptional activators remains to be determined. It is not clear why two transcription factors are needed, and it is possible that each protein responds to a different signal. Some genes might be regulated by homodimers of just of one of the proteins.

It is clear that AcuK and AcuM (and their orthologs in other fungi) play a major role in reprogramming metabolism in response to growth on gluconeogenic carbon sources. The full range of genes regulated needs to be addressed by microarray studies in wild-type and mutant backgrounds grown with different carbon sources. The relationship with additional control mechanisms operating during asexual and sexual development and in pathogenic infections is also of considerable interest.

SUMMARY

There is an increasing awareness of the complexities of carbon metabolism in fungi and of its importance for growth and development. The ability to use the sequenced genomes of many fungal species to identify and compare genes encoding metabolic enzymes provides many new opportunities for a fuller understanding. Furthermore, the availability of genome-wide approaches—microarrays, chromatin immunoprecipitation, proteomics, metabolomics, and systems biology—will allow a greatly increased expansion of knowledge. However, as discussed in this chapter, the complexities revealed by annotated genomes as well as recent studies should not be underestimated. These include (i) the occurrence of multiple genes encoding an enzyme activity; (ii) different proteins with different cellular localization signals encoded by a single gene; (iii) the possibilities for developmental and tissue-specific expression of pathways; (iv) the generation of substrates required for the production of signaling compounds and secondary metabolites; (v) the requirement for

counteracting metabolic stress (e.g., reactive oxygen species) during growth on particular substrates; and (vi) the situation in the real world, where mixed and limiting nutrients must be used, often in competition or cooperatively with other microbes, or where growth and development of pathogens on and in the host must occur. Clearly, detailed manipulations of individual genes, as well as whole-pathway analysis, are necessary.

It should also be noted that a comprehensive coverage of all aspects of the metabolism of gluconeogenic carbon utilization has not been attempted here. The role of many enzymes not discussed is ambiguous, and studies of the phenotypes of appropriate deletion mutants on a range of carbon sources, as well as of the effects of protein mislocalization, are necessary.

Despite the extensive analyses of carbon metabolism in *S. cerevisiae* that have been performed, there have been recent indications of unexplored complexities, as shown by the discovery of the role of the Rsd2 protein in transcriptional control (Soontorngun et al., 2007). The specialized physiology of *S. cerevisiae* is not always a good model for carbon metabolism in other fungi, not only in filamentous fungi but also in other hemiascomycetes. Therefore, an equivalent level of detailed analysis is needed in a wide range of fungi. Nevertheless, the discovery of the conserved AcuK and AcuM transcription factors as key regulators of the switch to growth on gluconeogenic carbon sources is a beginning to an understanding. In the filamentous ascomycetes, most is known about the laboratory models *A. nidulans* and *N. crassa*, the pathogens *M. grisea* and *A. fumigatus*, and the industrial species *A. niger* and *A. oryzae*. A broad attack on understanding metabolism in these organisms might be most rewarding. However, other organisms have provided particularly intriguing examples of specific relationships between metabolism and development, as exemplified by the work with *P. anserina* (chapters 15 and 33). Much less research on fundamental metabolism in other fungal phyla—the Zygomycetes and the Basidiomycetes—has been done, and these organisms have not been considered here. This is an important priority, as are investigations of mycorrhiza-plant metabolic interactions.

Nitrogen Metabolism in Filamentous Fungi

MERYL A. DAVIS AND KOON HO WONG

Nitrogen is an essential component of most biological macromolecules. The availability of nitrogen for assimilation into these compounds is therefore necessary for the growth, development, and reproduction of all living organisms. In the natural world, the fungi play a vital role in the recycling of nutrients through the degradation of organic material and the assimilation of environmental nitrogen. The metabolic versatility of the fungi is extraordinary, and their capacity to scavenge nitrogen is an important element in their success in occupying diverse environmental niches as free-living species and as opportunistic or obligate pathogens of plants and animals.

Among the filamentous fungi, the genetic basis of nitrogen metabolism has been most intensively studied in the model ascomycetes *Aspergillus nidulans* and *Neurospora crassa* by utilizing the excellent classical and molecular genetic systems provided by these species. Much of our current knowledge is based on classical genetic analysis of mutants affected in specific aspects of the enzymology or the regulation of nitrogen metabolism. These studies provided a foundation for the subsequent molecular genetic analysis (for reviews see Marzluf, 1981, 1997; and Caddick, 2004). Studies undertaken with other filamentous fungi reinforce many of the key aspects established in the model species. However, there are also instances where significant differences across species provide fascinating insights into the evolutionary divergence of nitrogen metabolism within the filamentous fungi. With the recent availability of multiple fungal genome sequences, it is now possible to look at the extent to which the fundamental processes of nitrogen metabolism and their underlying regulation are conserved. In this review, the molecular genetics of the ammonium assimilatory pathways is considered as the starting point for the biosynthesis of complex nitrogenous macromolecules. While ammonium or glutamine are the preferred nitrogen sources for fungi, their absence results in a need to synthesize catabolic enzymes in order to scavenge nitrogen from alternative sources. The switch from anabolism to catabolism requires the relief of nitrogen metabolite repression, a global control system that modulates the expression of large sets of nitrogen-catabolic enzymes. Recent studies suggest some diversity in the complex molecular mechanisms underlying this regulation among different fungal groups. Finally, we review the details of several nitrogen-catabolic systems to illustrate the metabolic and regulatory strategies employed by fungi in the acquisition of nitrogen metabolites.

Meryl A. Davis and Koon Ho Wong, Department of Genetics, The University of Melbourne, Parkville, Victoria 3010, Australia.

NITROGEN ASSIMILATION

Simple nitrogen-containing compounds released from the breakdown of more-complex substrates can provide sole sources of nitrogen for incorporation into new nitrogenous cellular components. The major route for the assimilation of ammonium in most fungi is via NADP-dependent glutamate dehydrogenase (NADP-GDH). This enzyme catalyzes the reductive amination of 2-oxoglutarate to produce glutamate and is a key step in linking the nitrogen and carbon cycles of the cell (Fig. 1). In *A. nidulans* and *N. crassa*, the NADP-GDH enzyme is encoded by the *gdhA* and *am* genes, respectively. Mutants lacking this activity are leaky glutamate auxotrophs and grow poorly when ammonium or sources of nitrogen assimilated via ammonium are the sole nitrogen source (Arst and MacDonald, 1973; Kinghorn and Pateman, 1975a; Kinnaird and Fincham, 1983). While animal GDHs can use either NAD or NADP as cofactors, fungal enzymes are usually NAD or NADP specific (Goldin and Frieden, 1971). In *A. nidulans* and *N. crassa*, a distinct NAD-linked GDH enzyme (encoded by the *gdhB* gene in *A. nidulans*) catalyzes the oxidative deamination of glutamate, forming 2-oxoglutarate and ammonium (Arst et al., 1975; Kinghorn and Pateman, 1976; Vierula and Kapoor, 1989). Unlike *gdhA* mutants, *gdhB* mutants are able to grow on ammonium as a sole nitrogen source but are unable to use glutamate or substrates metabolized via glutamate as sole carbon and nitrogen sources (Arst et al., 1975; Kinghorn and Pateman, 1976). The synthesis of these two GDH enzymes is regulated in an opposite fashion, consistent with their roles in either glutamate synthesis or catabolism. NAD-GDH activities are high in the presence of its substrate glutamate and under nitrogen or carbon limitation conditions, whereas NADP-GDH activities and *gdhA* transcript levels are high on ammonium and low in the presence of glutamate or under carbon-limited

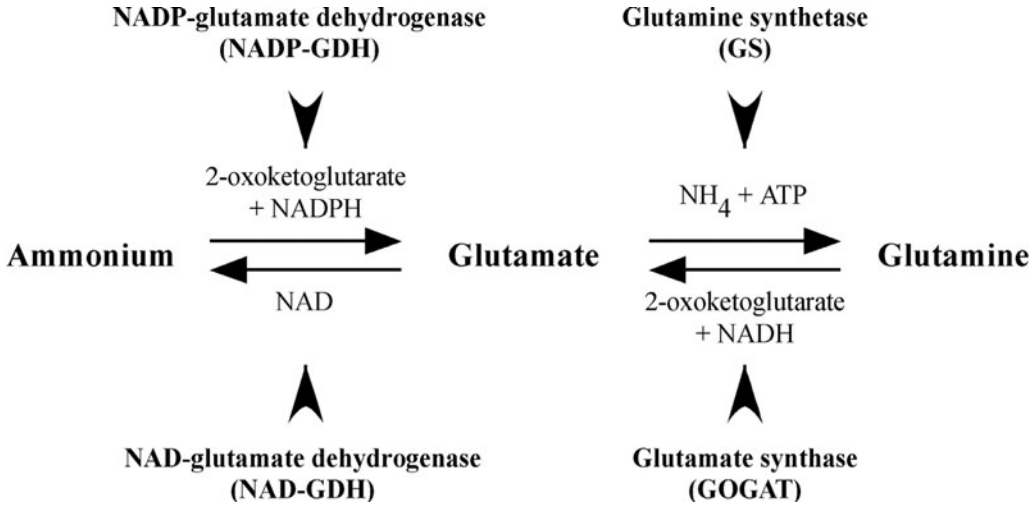

FIGURE 1 Ammonium assimilation pathway in fungi. Ammonium can be assimilated by NADP-GDH to form glutamate or by the GOGAT cycle through the action of GS and GOGAT to form glutamine and glutamate for the biosynthesis of nitrogenous molecules. The interconversion of ammonium, glutamate, and glutamine catalyzed by NADP-GDH, GS, GOGAT, and NAD-GDH is central to nitrogen metabolism.

conditions (Pateman, 1969; Kinghorn and Pateman, 1973, 1974; Hynes, 1974; Arst et al., 1975; Dantzig et al., 1979; Hernández et al., 1983; Hawkins et al., 1989).

Ammonium can also be assimilated by the GS-GOGAT cycle (Fig. 1) through the condensation of glutamate and ammonium to form glutamine catalyzed by glutamine synthetase (GS) and the conversion of glutamine and 2-oxoglutarate into two molecules of glutamate by glutamate synthase (GOGAT, NADPH-dependent glutamine:2-oxoglutarate amidotransferase). GS is encoded by the *gln*A gene in *A. nidulans* and the *gln-1* gene in *N. crassa*, while in *Fusarium (Gibberella) fujikuroi*, *gln*A-*Gf* is the GS structural gene (MacDonald, 1982; Cornwell and MacDonald, 1984; Margelis et al., 2001; Teichert et al., 2004). Mutants lacking this enzyme activity are unable to grow in the absence of glutamine, indicating that this is the sole route of glutamine biosynthesis. While GS mutants are strict glutamine auxotrophs, mutants of *A. nidulans* or *N. crassa* lacking GOGAT activity encoded by the *glt*A or *en-am* genes, respectively, do not have a discernible phenotype. The contribution of this enzyme to nitrogen assimilation is only apparent in double mutants lacking both NADP-GDH and GOGAT activities, where the residual capacity of *gdhA* or *am* mutants to grow on ammonium is abolished (Romero and Davila, 1986; Macheda et al., 1999). While NADP-GDH generally provides the major route of ammonium assimilation, in certain fungi the GS-GOGAT cycle is of more physiological importance (for an example, see Morel et al., 2006).

The molecular mechanisms controlling expression of the enzymes of nitrogen assimilation have not been well defined. Studies of NADP-GDH expression thus far suggest that multiple regulatory proteins modulate *A. nidulans gdhA* and *N. crassa am* gene expression. Dissection of the *am* gene promoter revealed two functionally important upstream regions, designated US*am*α and US*am*β (Frederick and Kinsey, 1990). The US*am*α site was shown to bind a heteromeric complex, AAB, homologous to the HAP CCAAT binding complex of *Saccharomyces cerevisiae* (Chen and Kinsey, 1994; Chen et al., 1998). In *A. nidulans*, high-level expression of *gdh*A also requires the activity of the CCAAT binding complex encoded by the *hapB*, *hap*C, and *hapE* genes (Steidel et al, 1999). In addition, regulatory proteins encoded by *A. nidulans* and *Aspergillus oryzae are*A and the *N. crassa nit-2* genes are required for wild-type levels of NADP-GDH activity on ammonium (Dantzig et al., 1979; Calderón and Martínez, 1993; Christensen et al., 1998). AreA and Nit2 are GATA transcription factors and function as global regulators of nitrogen metabolite repression (see "Global Regulation of Nitrogen Catabolism" below). The role of these transcription factors in activating NADP-GDH synthesis on ammonium is interesting. AreA and Nit2 activate nitrogen-catabolic gene expression under conditions of nitrogen limitation, and neither protein is active at catabolic gene promoters under nitrogen-sufficient conditions. However, they clearly have a role activating NADP-GDH synthesis in cells grown on ammonium as the sole nitrogen source. At least in the context of the *gdhA* promoter, the activity of AreA may depend on interaction with two $Zn(II)_2Cys_6$ transcription factors: TamA, an AreA coactivator, and LeuB, the *A. nidulans* homologue of *S. cerevisiae* Leu3 (Davis et al., 1996; Small et al., 2001; Polotnianka et al., 2004). The phenotypes of *tamA* and *leuB* loss-of-function mutants indicate that both gene products play a significant role in *gdhA* expression in *A. nidulans*, and *tamA* mutations have been associated with altered ammonium assimilation (Kinghorn and Pateman, 1975b, 1976; Arst et al., 1982; Davis et al., 1996; Polotnianka et al., 2004). TamA has been shown to interact with AreA and LeuB by yeast two-hybrid analysis, and TamA can recruit AreA to promoters when fused to a heterologous DNA binding domain (Small et al., 1999; Polotnianka et al., 2004). These studies suggest that all three proteins may function in a complex at the *gdhA* promoter. LeuB has an additional role in the regulation of leucine biosynthesis and *leuBΔ* mutants are leaky leucine auxotrophs (Polotnianka et al., 2004). *S. cerevisiae* Leu3 regulates *GDH1*, encoding NADP-GDH, and the activity of Leu3 is modulated by levels of α-isopropylmalate, an intermediate in leucine biosynthesis

(Sze et al., 1992; Hu et al., 1995). Similar regulation of LeuB activity would provide a mechanism to adjust glutamate synthesis via NADP-GDH in response to intracellular amino acid levels during growth on ammonium.

GLOBAL REGULATION OF NITROGEN CATABOLISM

When provided with a choice of nitrogenous substrates, most fungi will preferentially metabolize ammonium and glutamine. However, in the absence of these readily assimilated nitrogen sources, filamentous fungi can reclaim nitrogen from a wide range of alternative sources in their environment through the synthesis of various nitrogen-catabolic enzymes. The synthesis of these enzymes is regulated by a global regulatory control mechanism—nitrogen metabolite repression—that modulates the expression of catabolic genes in response to nitrogen availability. In addition, the expression of genes in certain catabolic pathways requires induction by their substrates mediated by pathway-specific transcriptional activators (for examples, see Andrianopoulos and Hynes, 1990; Burger et al., 1991a, 1991b; Fu et al., 1995; Suarez et al., 1995; Gómez et al., 2002). The nature of the signal(s) of nitrogen sufficiency is not established, but studies of *A. nidulans* and *N. crassa* using mutants lacking NADP-GDH or GS activity indicate that endogenous levels of glutamine or its derivatives are used as signaling molecules to monitor the nitrogen status in the cell (Kinghorn and Pateman, 1973; Dunn-Coleman and Garrett, 1980; Dantzig et al., 1978; Margelis et al., 2001).

The major fungal nitrogen regulatory protein is a GATA transcription factor required to promote expression of nitrogen-catabolic genes when nitrogen is limiting. These proteins contain a single C-terminal $CX_2CX_{17}CX_2C$ DNA binding domain related to the mammalian GATA zinc finger proteins that bind a core 5′-GATA-3′ DNA sequence (Fu and Marzluf, 1990a, 1990b; Kudla et al., 1990; see also Scazzocchio, 2000). In *A. nidulans* and *N. crassa*, the global nitrogen regulator is encoded by the *areA* and *nit-2* genes, respectively, and loss-of-function mutants are unable to use nitrogen sources other than ammonium or glutamine (Marzluf, 1997) (see Fig. 4A). The functional conservation of these genes was initially demonstrated by the complementation of an *areA* mutant using the *N. crassa nit-2* gene (Davis and Hynes, 1987). Homologous genes have been identified in various *Aspergillus* and *Penicillium* species, as well as a number of fungal pathogens by the characterization of loss-of-function mutants and/or heterologous complementation of either *areA* or *nit2* mutants (Haas et al., 1995; Froelinger and Carpenter, 1996; Christensen et al., 1998; Hensel et al., 1998; MacCabe et al., 1998; Screen et al., 1998; Gente et al., 1999; Tudzynski et al., 1999; Chang et al., 2000; Perez-Garcia et al., 2001; Pellier et al., 2003; Yamada et al., 2006). AreA homologues are highly conserved within the *Aspergillus* species and their close relatives, whereas NIT-2 and its homologues in species more closely related to *N. crassa* are diverged from AreA, consistent with the phylogenetic relationship between these species (Table 1). However, alignment of these fungal homologues reveals that there are several short conserved sequences throughout the protein, in addition to the extended amino acid conservation in the region of the GATA DNA binding domain, where AreA and NIT-2 differ by a single conservative amino acid substitution (Fu and Marzluf, 1987; Kudla et al., 1990; Wong et al., 2008).

Signals generated during growth under nitrogen-sufficient conditions serve to prevent these GATA factors from activating catabolic gene expression. How the activity of these regulatory proteins is modulated under different conditions remains an important question. While in *S. cerevisiae* the target of rapamycin cascade regulates the response to nitrogen status of the cells, the target of rapamycin kinase appears to play a more minor role in nitrogen regulation in filamentous fungi (Fitzgibbon et al., 2005; Teichert et al., 2006; Schönig et al., 2008). Both transcriptional and posttranscriptional controls have been shown to influence the levels and activity of AreA in response to nitrogen availability (Fig. 2). The last nine residues at the extreme C terminus of AreA and NIT-2 are absolutely conserved, and similar conserved regions are identified in the comparison of fungal AreA homologues. Detailed studies in *N. crassa* showed that these residues, together with residues in the NIT-2 GATA finger, interact with the negatively acting protein NMR (Dunn-Coleman et al., 1981; Fu et al., 1988; Young et al., 1990; Xiao et al., 1995; Pan et al., 1997). Loss-of-function *nmr* mutations result in derepression of nitrogen-catabolic gene expression, and deletion of the equivalent *A. nidulans nmrA* gene or C-terminal truncation of AreA also leads to a partial insensitivity to repression (Debusk and Ogilvie, 1984; Jarai and Marzluf, 1990; Stankovich et al., 1993; Platt et al., 1996a, 1996b; Andrianopoulos et al., 1998). It is not known whether the interaction with NmrA inhibits AreA activation and/or DNA binding under nitrogen-sufficient conditions. However, structural studies indicate that binding of the AreA zinc finger to GATA sequences and to NmrA is mutually exclusive, suggesting that NmrA may function to inhibit AreA DNA binding (Kotaka et al., 2008). NmrA contains a Rossmann fold identified in other corepressor proteins and preferentially binds oxidized rather than reduced nicotinamide dinucleotides (Stammers et al., 2001; Zhang et al., 2002; Lamb et al., 2003, 2004; Thio et al., 2004; Thoden et al., 2007). While nucleotide binding to NmrA may have a redox-sensing function, recent analysis of the crystal structure of the AreA zinc finger complexed with NmrA indicated that the conformation of the complex was not altered in the presence or absence of $NAD(P)^+$ (Kotaka et al., 2008). In vivo studies have shown that overexpression of *nmrA* is sufficient to inhibit AreA activity, even under conditions of complete nitrogen starvation (Wong et al., 2007). Thus, the AreA-NmrA interaction does not require a signal generated during nitrogen sufficiency, highlighting the levels of NmrA relative to AreA as the critical factor. NmrA levels are elevated under nitrogen-sufficient compared with nitrogen starvation conditions, and this is achieved through regulated expression of *nmrA* by the bZIP transcription factor MeaB (Polley and Caddick, 1996; Lamb et al., 1997; Wong et al., 2007). Therefore, the activity of MeaB may be the determining factor in the control of *nmrA* expression and the signals of nitrogen sufficiency may trigger changes in MeaB conformation and/or dimerization that ultimately regulate AreA activity.

Homologues of NmrA and MeaB are unique to the filamentous ascomycete fungi. Comparison of the overall similarity of the NmrA homologues reveals an extremely high level of amino acid conservation in the Eurotiomycetes (Table 1). While this comparison suggests that NmrA homologues in the Sordariomycetes and Leotiomycetes have significantly diverged from NmrA, direct alignment of the predicted proteins shows that these contain highly conserved 'core' NmrA sequences, including the NAD-binding domain flanked by nonconserved N-terminal and C-terminal

TABLE 1 Conservation of nitrogen regulators in filamentous ascomycetes[a]

Species	AreA		NmrA		MeaB	
	% Identity	% Similarity	% Identity	% Similarity	% Identity	% Similarity

[a]The protein sequences of AreA, NmrA, and MeaB orthologues from fungi belonging to Eurotiomycetes, Sordariomycetes, and Leotiomycetes within the Ascomycota lineage (Fitzpatrick et al., 2006) are identified by blastp and tblastn searches (Altschul et al., 1997) using the respective *A. nidulans* sequence from the respective fungal genome sequence database in Broad Institute (http://www.broad.mit.edu/annotation/fgi/) and DOE Joint Genome Institute (http://genome.jgi-psf.org/Trire2/Trire2.home.html). The orthologous AreA, NmrA, and MeaB sequences from various fungi are compared to the respective orthologue in *A. nidulans*, using the Needle program in Biomanager, Australian National Genome Information Service (ANGIS, http://www.angis.org.au). Accession numbers are listed below when possible; otherwise, the gene locus (GL) number in the respective genome sequence database is indicated. Accession numbers or gene locus numbers for AreA are as follows: *A. flavus* (GL, AFL2G_10206.2); *A. oryzae* (O13415); *A. terreus* (EAU32648); *A. niger* (CAA68196); *N. fischeri* (EAW15479); *A. fumigatus* (EAL85842); *A. clavatus* (EAW08915); *C. immitis* (EAS27400); *U. reesii* (GL, UREG_06018.1); *H. capsulatum* (GL, HCAG_05031.1); *M. grisea* (Q01168); *N. crassa* (P19212); *C. globosum* (EAQ89860); *T. reesei* (GL, 76817); *F. graminearum* (GL, FGSG_08634.3); *F. oxysporum* (GL, FOXG_03165.2); *F. verticillioides* (GL, FVEG_02033.3); *B. cinerea* (GL, BC1G_09852.1); and *S. sclerotiorum* (GL, SS1G_05040.1). See supplementary materials from Wong et al., 2007, for accession numbers of NmrA and MeaB orthologues, except for those of *C. immitis* (NmrA, EAS31008; MeaB, GL, CIMG_03780.2); *U. reesii* (NmrA, GL, UREG_03933.1; MeaB, GL, UREG_07503.1); *H. capsulatum* (NmrA, EDN02584; MeaB, GL, HCAG_01916.1); *T. reesei* (NmrA, GL, 74375; MeaB, GL, 73417); *F. oxysporum* (NmrA, GL, FOXG_01593.2; MeaB, GL, FOXG_02277.2); and *F. verticillioides* (NmrA, GL, FVEG_07953.3; MeaB, GL, FVEG_05452.3). Asterisks (*) indicate sequences that contain potential annotation errors. The EAS27400; GL, HCAG_05031.1; CIMG_03780.2; and HCAG_01916.1 sequences have been manually reannotated.

extensions (Wong et al., 2007). It appears that the acquisition (or loss) of these additional sequences occurred prior to the separation of Eurotiomycete and Sordariomycete groups. These additional sequences are dispensable for function in *N. crassa* (Jarai and Marzluf, 1990). Homologues of *meaB* are also present in other fungal genomes (Table 1). The predicted proteins encoded by these genes are well conserved, particularly in the DNA binding and dimerization domains (Wong et al., 2008).

Sequence conservation, supported by cross-species complementation studies, suggests that the roles of AreA, NmrA, and MeaB in nitrogen regulation are likely to be largely conserved. However, there are interesting differences even between *A. nidulans* and *N. crassa* that point to some divergence in nitrogen regulation within the filamentous fungi. In *N. crassa*, the levels of *nit-2* mRNA and NIT-2 protein are not regulated (Tao and Marzluf, 1999). In contrast, in *A. nidulans* AreA levels are modulated through autogenous control of *areA* transcription and differential stability of the *areA* transcript (Langdon et al., 1995; Morozov et al., 2000). Deadenylation of the *areA* transcript promotes accelerated turnover of the *areA* transcript under nitrogen-sufficient conditions compared to nitrogen-limiting conditions. This regulated transcript stability is determined by the intracellular levels of glutamine and requires sequences located in the 3′ untranslated region of the *areA* mRNA (Morozov et al, 2000, 2001). Similar 3′ untranslated region sequences have been identified in the *areA* homologues of all *Aspergillus* species, *Penicillium chrysogenum*, *P. roqueforti*, and *P. urticae* but not in *N. crassa* and other Sordariomycetes (Haas et al., 1995; Morozov et al., 2000; Wong et al., 2008). A further difference between *A. nidulans* and *P. chrysogenum* compared to *N. crassa* lies in the proposed function of a second GATA factor that contains an N-terminal GATA domain and a C-terminal leucine zipper domain. These proteins, AreB in *A. nidulans* and NreB in *P. chrysogenum*, are proposed to have a negative role in the regulation of nitrogen-catabolic enzymes (Haas et al., 1997; Conlon et al., 2001). However, a loss-of-function repeat-induced point mutation generated in the *N. crassa* homologue, *asd-4*, prevents sexual development

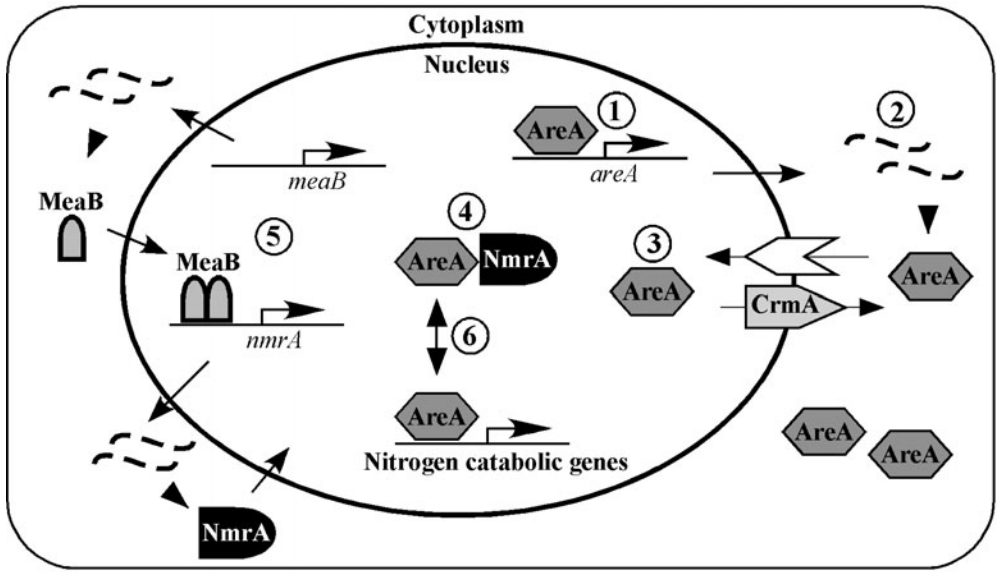

FIGURE 2 Components of nitrogen regulation in *A. nidulans*. The expression of genes subject to nitrogen metabolite repression is regulated by changes in the levels and transcriptional activity of AreA in response to the nitrogen status of the cells (see the text). The levels of *areA* mRNA are influenced by autoregulation of *areA* transcription (1) and differential stability of the *areA* mRNA (2) such that the transcript is degraded more rapidly under nitrogen-sufficient conditions than when nitrogen is limiting or absent. The levels of AreA available to activate transcription within the nucleus are determined by a balance between nuclear import and export (3). Under conditions of nitrogen starvation, AreA accumulates in the nucleus due to a block in CrmA-dependent nuclear export. Once inside the nucleus, the transcriptional activity of AreA is influenced by interaction with the NmrA corepressor (4). The extent to which AreA activity is inhibited by NmrA under nitrogen-sufficient conditions is determined indirectly by the bZIP transcription factor MeaB (5). Under nitrogen-sufficient conditions, MeaB activates *nmrA* expression, leading to increased levels of NmrA and greater inhibition of AreA activity. Thus, the activity of AreA is determined by the relative levels of AreA and NmrA (6), with active AreA predominating under nitrogen-limiting or nitrogen starvation conditions.

without affecting nitrogen-regulated gene expression (Feng et al., 2000). More examples of species-specific variation in aspects of nitrogen regulation in the fungi may emerge as more species are investigated. Already, studies involving the plant pathogen *Fusarium fujikuroi* have revealed some interesting differences with both glutamine and the GS enzyme itself, suggested to play a role in nitrogen regulation (Teichert et al., 2004). In addition, while the *F. fujikuroi nmrA* homologue (*nmr-GF*) can complement both *A. nidulans nmrA* and *N. crassa nmr-1* mutants and *F. fujikuroi* AreA and Nmr have been shown to interact by yeast two-hybrid analysis, deletion of the *nmr-GF* gene does not lead to significant derepression and overexpression does not reduce expression of nitrogen-catabolic enzymes in *F. fujikuroi* (Mihlan et al., 2003; Schönig et al., 2008).

Although *A. nidulans* AreA and *N. crassa* NIT-2 are viewed as global nitrogen regulators, the range of activities under their control may extend beyond nitrogen metabolism. The *F. fujikuroi areA* homologue, in addition to a role in nitrogen control, also regulates certain genes involved in secondary metabolite biosynthesis unrelated to nitrogen metabolism, and *P. chrysogenum* NREA binds to sequences in the promoters of genes involved in penicillin biosynthesis (Tudzynski et al., 1999; Haas and Marzluf, 1995). Screening of *F. verticillioides* microarrays has revealed additional AreA target genes involved in carbohydrate and energy metabolism in *F. fujikuroi* (Schönig et al., 2008). A recent study involving *Magnaporthe grisea* has also highlighted the need for a broader understanding of the integration of nitrogen metabolism with other aspects of cellular metabolism. This study demonstrated that expression of *NMR1*, the *M. grisea* homologue of *nmrA*, is regulated by the trehalose 6-phosphate synthase protein (Tps1) as part of a regulatory complex integrating carbon and nitrogen metabolism through regulation of the pentose phosphate pathway and intracellular NADPH levels (Wilson et al., 2007).

NITRATE ASSIMILATION

The assimilation of nitrate requires the nitrate reductase and nitrite reductase enzyme activities and results in the release of ammonium (Fig. 3). Nitrate is plentiful in soils and can potentially provide a readily accessible source of nitrogen. The acquisition by the filamentous ascomycetes of the nitrate assimilation genes from the oomycetes has been proposed to be an important factor for the success of this group of fungi in soil (Slot and Hibbett, 2007).

The biochemistry of nitrate assimilation is one of the best-studied pathways in fungi and in plants, and the enzymes are highly conserved in structure and function (Crawford and Arst, 1993). Nitrate is actively transported into the cells of *A. nidulans* by two high-affinity nitrate transporters, encoded by *ntrA* and *ntrB*. These genes have redundant functions, and loss of both functions is required

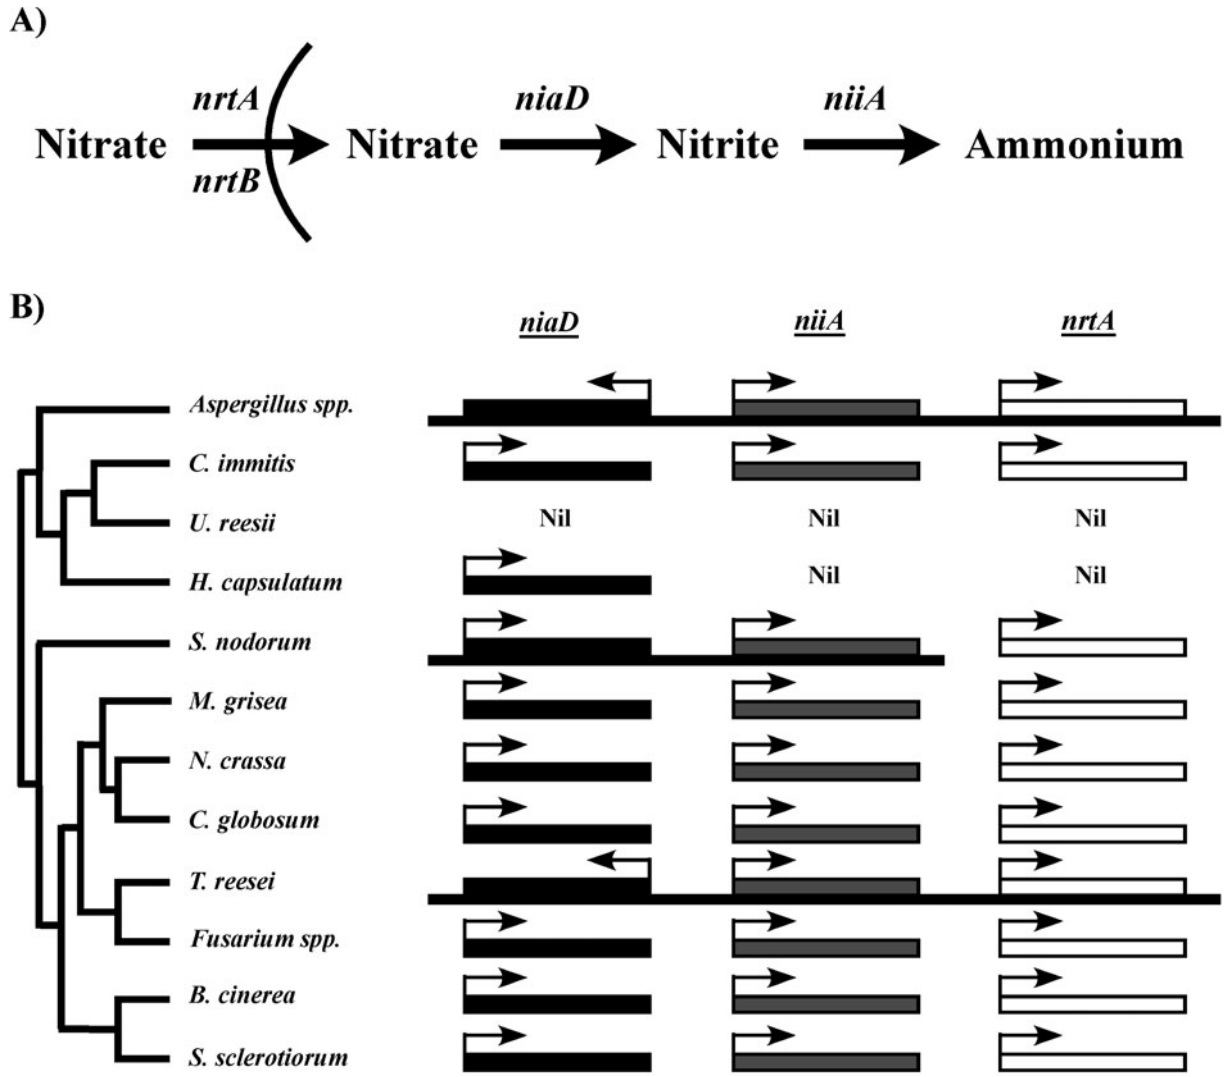

FIGURE 3 Genomic arrangement of nitrate-assimilatory genes in sequenced fungal genomes. (A) In the nitrate-assimilatory pathway, nitrate is transported into the cell by nitrate permeases (encoded by *nrtA* and *nrtB* in *A. nidulans*). Endogenous nitrate is catabolized by nitrate reductase (encoded by *niaD* in *A. nidulans*) to nitrite, which in turn is converted by nitrite reductase (encoded by *niiA* in *A. nidulans*) to ammonium for synthesis of nitrogen-containing biomolecules. (B) Evolution of the nitrate-assimilatory gene cluster in filamentous fungi. The phylogenetic relationships of the various fungi are shown on the left (Fitzpatrick et al., 2006). The *niaD*, *niiA*, and *nrtA* orthologues were identified by blastp and tblastn searches (Altschul et al., 1997) against the respective genome databases, using the *A. nidulans* NiaD, NiiA, and NrtA sequences. The relative orientation of the open reading frames of *niaD* (black rectangles), *niiA* (grey rectangles), and *nrtA* (white rectangles) orthologues in various fungi is indicated by arrows. Thick lines connecting the rectangles indicate that the genes are linked. Nil means that sequence with high similarity could not be found in the respective genome sequences by blastp and tblastn searches. "*Aspergillus spp.*" includes *A. nidulans*, *A. fumigatus*, *A. flavus*, *A. clavatus*, *A. terreus*, *A. oryzae*, *A. niger*, and *Neosartorya fischeri*. "*Fusarium spp.*" includes *F. graminearum*, *F. oxysporum*, and *F. verticillioides*.

to prevent growth on nitrate (Unkles et al., 1991, 2001). Once inside the cell, nitrate is converted to nitrite by a two-step reduction reaction catalyzed by the NADPH-nitrate reductase enzyme. Nitrate reductase structural gene mutants (*niaD* in *A. nidulans* and *nit-3* in *N. crassa*) exhibit specific loss of the ability to use nitrate as a sole nitrogen source. The functional enzyme is a homodimer, with each subunit associated with three cofactors: molybdenum pterin, iron heme, and flavin (Campbell and Kinghorn, 1990). The molybdenum cofactor is shared with the xanthine dehydrogenase enzyme, and its synthesis requires the products of the *cnx* genes (Unkles et al., 1997). The second step in the nitrate assimilatory pathway, the reduction of nitrite to ammonium, is catalyzed by the nitrite reductase enzyme encoded by the *niiA* gene in *A. nidulans* and the *nit-1* gene in *N. crassa* (Marzluf, 1997). The functional importance of the structural domains that coordinate with the cofactors of NiaD and NiiA is indicated by the high levels of

sequence conservation between NiaD and NiiA and their respective orthologues in various other filamentous fungi.

The arrangement of the structural genes in the nitrate assimilation pathway is interesting. In *A. nidulans* the *niaD*, *nii*A, and *nrt*A genes are located together in the genome, and *niaD* and *nii*A are transcribed bidirectionally from a common 1.2-kb intergenic region (Johnstone et al, 1990; Punt et al., 1995). The respective orthologues in various *Aspergillus* species are also present in similar arrangements and orientations. The clustering of these genes may have advantages in coordinating the expression of the two structural genes to efficiently process nitrate into ammonium and to balance the levels of expression of these activities to prevent accumulation of the toxic intermediate nitrite. However, this genomic arrangement is unlikely to be essential for nitrate assimilation, as these genes are found in unlinked loci in many other ascomycetes analyzed (Fig. 3). The presence of the nitrate cluster in the basidiomycete *Ustilago maydis* indicates that this genomic arrangement is the ancestral form and that disassembly of the cluster has occurred in most analyzed ascomycetes. Interestingly, partial rearrangement of the cluster has taken place in *Stagonospora nodorum*, in which the *niaD* and *nii*A orthologues have retained linkage with a different orientation to the ancestral form, while the *nrt*A orthologue is found in a different locus. A similar situation has been described in *Leptosphaeria maculans* (Williams et al., 1995). Furthermore, there appears to be a lack of correlation between the presence and arrangements of the nitrate assimilation genes in various analyzed fungi and their phylogenic relationships (Fig. 3). In the case of *Uncinocarpus reesii*, the nitrate assimilatory genes have been lost entirely, while *Histoplasma capsulatum* has retained only the *niaD* orthologue. In combination, these observations suggest that multiple independent evolutionary events have modified the ancestral nitrate assimilation cluster in the Ascomycota lineage.

The majority of filamentous ascomycetes have lost the clustering arrangement of the nitrate assimilation genes. In the Sordariomycetes lineage, it is puzzling to note that all members have unlinked nitrate assimilation genes, with the exception of *Trichoderma reesei*. Recently Slot and Hibbett (2007) provided evidence that *T. reesei* had regained the complete nitrate gene cluster through horizontal gene transfer from an ancestor of the basidiomycete *U. maydis* after the loss of ability to assimilate nitrate in the Trichoderma lineage. This reacquisition of the cluster was proposed to be advantageous to *T. reesei* in exploiting a new nutritional niche.

The regulated expression of the nitrate-assimilatory genes is conserved in *A. nidulans* and *N. crassa*, despite their nonconserved genomic arrangement. These genes are expressed only in the absence of ammonium and/or glutamine and in the presence of nitrate. This expression is dependent on the activity of the global nitrogen regulator AreA or Nit2, respectively (associated with the relief of nitrogen metabolite repression), while nitrate induction is mediated by the pathway-specific transcriptional activator, NirA in *A. nidulans* and NIT-4 in *N. crassa*. NirA and NIT-4 contain a conserved N-terminal $Zn(II)_2Cys_6$ binuclear cluster DNA binding domain, bind to similar target sites, and are functionally interchangeable (Yuan et al., 1991; Hawker et al., 1991; Burger et al., 1991a, 1991b; Strauss et al., 1998). Both AreA/NIT-2 and NirA/NIT-4 are necessary for expression of the nitrate-assimilatory genes, and these transcription factors have been shown to directly interact. This association is necessary for DNA binding and for changes in the chromatin state of *niaD-nii*A promoter region that accompanies induction (Feng and Marzluf, 1998; Chiang and Marzluf, 1995; Muro-Pastor et al., 1999; Narendja et al., 2002; Berger et al., 2006). Detailed studies have shown that, in the presence of nitrate, NirA accumulates in the nucleus as a result of nitrate-induced disruption of nuclear export (Bernreiter et al., 2007). However, nuclear retention alone is not sufficient for NirA function and NirA binding requires both nitrate and an active AreA (Berger et al., 2006; Bernreiter et al., 2007). Recent studies have shown that AreA-dependent changes in histone H3 acetylation in response to intracellular glutamine levels, as well as NirA-mediated chromatin remodeling of the *nii*A-*niaD* promoter, are associated with transcription of the nitrate assimilation genes (Berger et al., 2008). Together, induction and nitrogen repression ensure that the nitrate-assimilatory genes are expressed only under conditions in which nitrate breakdown would provide a needed source of nitrogen. A further subtlety in regulation of these genes was revealed by the finding that the stability of the *niaD* and *nii*A transcripts is influenced by nitrate and glutamine availability. Nitrate acts to stabilize these transcripts, reinforcing the transcriptional regulation, and this occurs even in the presence of glutamine, ensuring that nitrate and the toxic intermediate nitrite are removed from the cells (Caddick et al., 2006).

AMINO ACIDS AS NITROGEN SOURCES

The natural habitat of many fungi is the soil, where they play a vital role in the recycling of organic material. Decaying plant and animal material potentially provides a rich source of nutrients, and fungi produce both extracellular and intracellular proteases to break down proteins, releasing amino acids for biosynthesis and as nutrient sources (for examples, see Cohen, 1973; vanKuyk et al., 2000; and Billon-Grand et al., 2002). However, not all amino acids are equally good nitrogen sources and different fungal species exhibit different capacities to extract nitrogen from these substrates (Arst and Cove, 1973; Davis et al., 2005) (Fig. 4). The variation in growth patterns, particularly between closely related species, may reflect differences in the level of synthesis of specific catabolic enzymes and/or permeases. In *A. nidulans* in particular, growth testing on solid media provides a simple and effective qualitative measure of the level of nitrogen-catabolic gene activities. The catabolism of certain amino acids, such as proline and arginine, provides a good source of nitrogen metabolites and supports strong growth in *A. nidulans*, whereas other amino acids, such as histidine and leucine, are very poor sources of nitrogen for the wild-type organism (Fig. 4). Here we consider the pathway of proline catabolism and contrast that with the breakdown of histidine to illustrate different ways in which nitrogen compounds are used.

Proline is broken down to glutamate by two dedicated proline catabolic enzymes encoded by the *prnD* gene (proline oxidase) and the *prn*C gene (L-Δ^1–pyrrolie-5-carboxylate dehydrogenase). The *prn*C and *prnD* genes are contained within a cluster of genes that also encode a specific proline permease (*prnB*) and a transcription factor (*prn*A) that mediates proline induction of the *prn* genes (Jones et al., 1981; Hull et al., 1989). The degradation of proline can provide both a nitrogen source and a carbon and energy source for *A. nidulans*, and the synthesis of these enzymes is regulated by two global regulatory mechanisms: nitrogen metabolite repression mediated by AreA (see "Global Regulation of Nitrogen Catabolism" above) and carbon catabolite repression controlled by the CreA transcriptional repressor (Cubero and Scazzocchio, 1994). The function of CreA is described in detail in chapter 21. A key target of these regulatory proteins is

FIGURE 4 Growth of *A. nidulans* and *N. crassa* on various amino acids as nitrogen source. (A) *A. nidulans* wild-type, *areA*Δ, and *areA102* strains were grown at 37°C for 2 days on ANM solid media (Cove, 1966) containing 1% glucose and ammonium (NH_4), glutamine (Gln), glutamate (Glu), alanine (Ala), nitrate (NO_3), proline (Pro), γ-amino butyric acid (GABA), arginine (Arg), uric acid (UA), or histidine (His) at a final concentration of 10 mM as the sole nitrogen source. (B) Wild-type *A. nidulans* was grown on solid ANM minimal media (Cove, 1966) containing 1% glucose and the indicated amino acid at a concentration of 10 mM. The relative levels of growth after 2 days at 37°C are ranked from strongest (++++) to weakest (−/+). Wild-type *N. crassa* was grown on liquid Vogel's medium lacking NH_4 and NO_3 with 2% sucrose and the indicated amino acid at a concentration of 10 mM. The relative strength of growth is determined by dry mass weight after 3 days of growth at 30°C (Facklam and Marzluf, 1978). The *N. crassa* data are grouped and expressed with symbols as follows: ++++, >30 mg; +++, <30 mg; ++, <15 mg; +, 5 mg; −/+, <2 mg. ND, not determined.

the promoter of the *prnB* gene. Induction is a prerequisite for expression of the *prn* genes, and regulation of the PrnB permease controls the level of proline uptake and, hence, inducer availability (Cubero et al., 2000; Gómez et al., 2003). Proline induction is mediated by the positively acting $Zn(II)_2Cys_6$ transcription factor PrnA (Sharma and Arst, 1985; Cazelle et al., 1998). PrnA contains a tripartite nuclear localization sequence and is constitutively localized in the nucleus (Pokorska et al., 2000; Gómez et al., 2002). Proline is required for the binding of PrnA as a dimer to either

CCGG-N-CCGG or CCGG-6/7N-CCGG repeats and chromatin rearrangements associated with activation of gene expression (Gómez et al., 2002; García et al., 2004). Therefore, the combination of AreA, CreA, and PrnA controls ensures that the proline-catabolic enzymes are strongly expressed under conditions in which proline is available and a source of carbon and/or nitrogen is required by the cells.

In contrast to proline, histidine is an extremely poor nitrogen source and is not a carbon source for wild-type *A. nidulans* (Polkinghorne and Hynes, 1982) (Fig. 4). However, strains carrying the *areA102* mutation can grow strongly on histidine as a sole nitrogen source (Arst and Cove, 1973; Hynes, 1975; Polkinghorne and Hynes, 1982). This difference in phenotype between the wild type and this mutant strain is due to a single amino acid substitution (Leu^{683}-Val) in the GATA DNA binding domain of the AreA transcription factor, which alters the relative affinity of the protein for different promoters and consequently changes expression of its target genes (Kudla et al., 1990; Ravagnani et al., 1997; Starich et al., 1998a, 1998b; Gorfinkiel et al., 1993; Xiao and Marzluf, 1993). The *areA102* mutation is highly pleiotropic, leading to reduced growth on some nitrogen sources and stronger growth on other nitrogen sources, as well as histidine (Arst and Cove, 1973; Hynes, 1975; Diallinas et al., 1995; Davis et al., 1996, 2005). The phenotype of this mutant illustrates how changes in catabolic-gene expression are reflected in the ability of the organism to use particular substrates as nitrogen sources.

The *sarA* gene was identified by mutations that abolished the strong growth of *areA102* strains on histidine and a number of other amino acids but did not reverse the other *areA102* phenotypes (Polkinghorne and Hynes, 1975). This gene was found to encode an L-amino acid oxidase enzyme that is able to release ammonium directly from a wide range of amino acid substrates, producing H_2O_2 and a keto derivative of the amino acid (Davis et al., 2005). Synthesis of the *A. nidulans* L-amino acid oxidase activity requires only AreA function and relief of nitrogen metabolite repression, with no apparent requirement for induction. A similar activity with similar substrate specificity had been identified in *N. crassa*, although the *N. crassa* enzyme encoded by the *lao* gene appeared to require induction (Thayer and Horowitz, 1951; Sikora and Marzluf, 1982; Neidermann and Lerch, 1990, 1991). The level of the L-amino acid oxidase is rate limiting for the catabolism of histidine in *A. nidulans*, as additional copies of the *sarA* gene are sufficient to increase growth of the wild type on this and other amino acids that are substrates (Davis et al., 2005). It is not obvious why higher levels of this activity are not produced by the wild type to maximize the potential yield of nitrogen from histidine and other amino acids. One possibility is that elevated levels of activity and the associated generation of H_2O_2 may impose oxidative stress on the cell. Interestingly, L-amino acid oxidase is a component of snake venom, and H_2O_2 generation contributes to its toxicity (Torii et al., 2000). Under laboratory conditions, increased *sarA* copy number and/or elevated *sarA* expression in *areA102* strains increases growth on these substrates, without any apparent detrimental effects, although even subtle differences may be significant in a natural competitive environment (Davis et al., 2005).

A recent search of the *A. nidulans* genome with the *sarA* sequence revealed the unexpected presence of a closely related paralogue of *sarA* (K. H. Wong, unpublished data). The coding region of the second *A. nidulans* gene is 54% similar to the SarA protein, and the predicted flavin adenine dinucleotide binding domain present in other enzymes of this type is conserved. In comparison, the *N. crassaa* and *Fusarium*

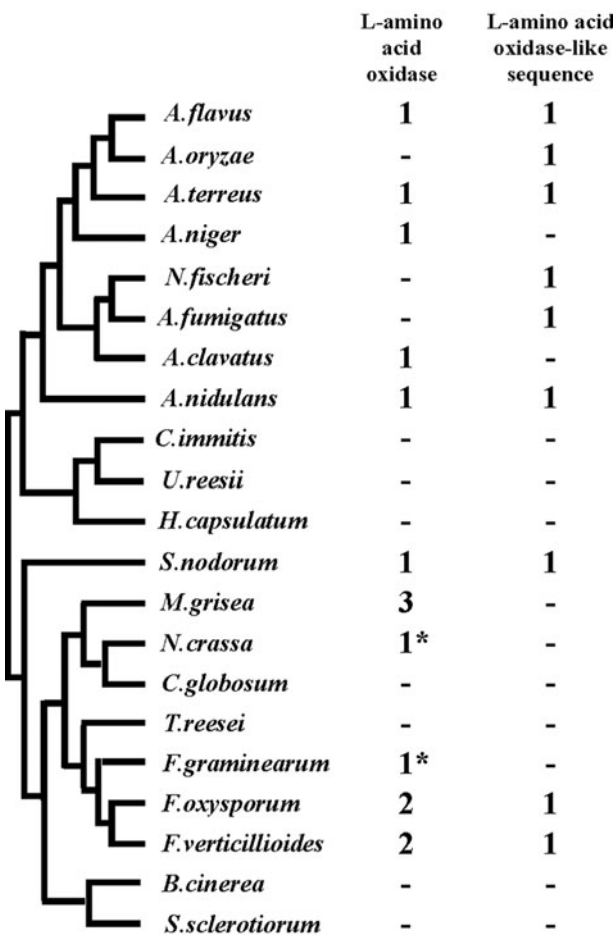

FIGURE 5 Evolution of L-amino acid oxidase in filamentous fungi. The phylogenetic relationships of the various filamentous ascomycetes are indicated on the left (Fitzpatrick et al., 2006; Broad Institute website [http://www.broad.mit.edu/annotation/genome/aspergillus_group/]). L-Amino acid oxidase and related sequences in various fungi were obtained by blastp and tblastn searches (Altschul et al., 1997) of the respective fungal genome database (Broad Institute [http://www.broad.mit.edu/annotation/fgi/]), using the A. nidulans sequences (L-amino acid oxidase, SarA [accession number, AAT84085], and L-amino acid oxidase-like sequence [accession number, EAA64973]). A minus sign (−) represents the absence of any orthologous sequence. An asterisk (*) indicates that the identified sequence was almost equally similar to both L-amino oxidase and L-amino oxidase-like sequences but has a slightly higher percentage of identity and similarity to the indicated sequence. Accession numbers or gene locus (GL) numbers of L-amino acid oxidase sequences are as follows: *A. flavus* (GL, AFL2G_08801.2); *A. terreus* (EAU31805); *A. niger* (CAK45753); *A. clavatus* (EAW12261); *S. nodorum* (EAT79476); *M. grisea* (EDK01261); *N. crassa* (CAD21325); *F. graminearum* (FGSG_13802.3); *F. oxysporum* (GL, FOXG_15820.2 and FOXG_15290.2); and *F. verticillioides* (GL, FVEG_13289.3 and FVEG_12615.3). Accession numbers or GL numbers of L-amino acid oxidase-like sequences are as follows: *A. flavus* (GL, AFL2G_11781.2); *A. oryzae* (BAC55901); *A. terreus* (EAU36894); *N. fischeri* (EAW19737); *A. fumigatus* (EAL86792); *S. nodorum* (EAT82237); *F. oxysporum* (GL, FOXG_05815.2); and *F. verticillioides* (FVEG_03694.3).

graminearum genomes contain a single L-amino acid oxidase orthologue that is intermediate in sequence similarity between the *A. nidulans* SarA and SarA-like sequences (Fig. 5). Searching other fungal genomes for similar sequences, it was found that within the *Aspergillus* genus some species contain only a *sarA* orthologue (e.g., *A. niger*), some possess only the *sarA*-like orthologue (e.g., *A. oryzae*), and some contain orthologues of both *A. nidulans* genes (Fig. 5). Looking beyond this group, some species appear to completely lack either of these genes, whereas others contain multiple copies of the *sarA* orthologue (Fig. 5). The intriguing result from this analysis is the complete absence of any relationship between the presence or absence of *sarA*-related sequences and the phylogeny of these fungi. These genes have been retained, amplified, or entirely lost apparently at random in particular species. It would be very interesting to correlate these differences with the ability of the different fungi to use amino acids such as histidine as nitrogen sources and the various ecological niches that these fungi occupy.

CONCLUDING REMARKS

The free-living lifestyle of many fungi means that the availability and quality of sources of nitrogen are unpredictable and, therefore, the requirement for nitrogen must be met by catabolizing a diverse range of nitrogenous substrates. The synthesis of an equally diverse array of catabolic enzymes is subject to global nitrogen regulation by a class of proteins characterized by a single GATA DNA-binding domain. This motif is present in a number of eukaryotic transcription factors, and indeed there are multiple GATA factors in fungi (Wong et al., 2008). In the filamentous fungi, only one of these factors is responsible for activating catabolic gene expression, and its transcriptional activity is finely modulated in response to the nitrogen requirements of the cells. In the natural world, not only are potential nitrogen sources of variable quality, but also it may not be uncommon for organisms to encounter environments completely devoid of an external source of nitrogen. Studies of *A. nidulans* have shown that complete nitrogen starvation triggers elevated AreA-dependent expression of certain nitrogen-catabolic genes and enhanced nuclear accumulation of AreA (Fraser et al., 2001; Todd et al., 2005). The nitrogen starvation response presumably facilitates the recycling of intracellular nitrogenous compounds and the rapid breakdown of nitrogen sources as they become available. Nitrogen starvation is also likely to be a factor in the initial phases of infection by pathogenic species, where the fungi must penetrate the host tissue before gaining access to intracellular host resources. Furthermore, the growth of the pathogen within the host requires the efficient utilization of these resources and nitrogen limitation can trigger infection-specific gene expression in certain plant pathogenic fungi (for a review, see Snoeijers et al., 2000). The regulatory circuits that control the levels of nitrogen-anabolic or -catabolic enzymes are able to sense and respond to specific signals that reflect the nutritional needs of the cells and the types of nitrogen sources available in a particular environment.

With the availability of multiple fungal genome sequences for analysis, it is becoming clear that there have been extensive changes and rearrangements in the genomes of fungi during their evolution. In some cases it is possible to trace these changes back in evolutionary time by using the phylogeny of the filamentous fungi. In other instances, the connection between evolutionary history and the current state of the genome is less obvious. It is likely that the metabolic versatility of the fungi and the extent to which certain enzymes or pathways have been acquired, conserved, or lost during evolution reflect the diverse environments that this group of organisms have successfully colonized and exploited.

Amino Acids and Polyamines: Polyfunctional Proteins, Metabolic Cycles, and Compartmentation

ROWLAND H. DAVIS

General metabolism consists of a network of biochemical systems variously linked by enzymes, substrate traffic, and regulatory features. As biochemical genetics took form in the 1940s, beginning with Beadle's and Tatum's methodological breakthrough with the ascomycete *Neurospora* (Beadle and Tatum, 1941), anomalies and complexities began to accumulate that would not fit into the easy comfort of the "one gene, one enzyme" hypothesis. Many of these complexities lay in amino acid and nucleotide pathways. The metabolic pathways themselves are now both well known and widely shared among prokaryotes and eukaryotes. This chapter focuses on three unusual aspects of certain of these pathways: polyfunctional proteins, metabolic cycles, and compartmentation. These features are not unique to fungi, but some of the most detailed analyses originated in fungal systems and have been applied successfully in studies of many other eukaryotes (Davis, 2000).

PATHWAY ANALYSIS

Translation of Eukaryotic mRNAs

At the outset, it should be recognized that a major difference between prokaryotes and eukaryotes lies in the translation of mRNAs. In prokaryotes, multicistronic mRNAs are translated such that each encoded protein is released as it is completed. The stop codon(s) of the proximal sequence is followed by a short untranslated sequence, and ribosomes can initiate translation of the next reading frame at an internal start codon. In eukaryotes, 40S ribosomes bind a 5′ cap of the mRNA and usually initiate at the first AUG codon they encounter as they scan the 5′ upstream sequence. As a general rule, eukaryotic mRNAs have only one coding sequence. However, a number of eukaryotic mRNAs may contain one or more quite short coding sequences between the cap and the main coding sequence. These have evolved to modulate the frequency of initiation of the main coding sequence downstream. In these cases, the small subunit of the ribosome remains attached and scanning, allowing reinitiation at the main coding sequence if proper conditions are met (e.g., whether the 40S ribosome binds the eukaryotic initiation factor 2 [eIF-2] that allows it to recognize the AUG of the main coding sequence). Many of the cases described below are exceptional in that several enzymes might be encoded in an mRNA, but they take the form of multiple domains of a single polypeptide, translated from beginning to end in a single coding sequence.

Rowland H. Davis, Department of Molecular Biology & Biochemistry, University of California, Irvine, Irvine, California 92697-3900

Aromatic Amino Acids

The study of aromatic amino acid biosynthesis in *Neurospora crassa* (Fig. 1) provided some of the earliest insights into unusual genetic relationships among related metabolic enzymes. Emerging from this was the appreciation of polypeptide aggregation and gene fusion. When these studies got under way, biochemists became aware of important differences between gene and enzyme organization in eukaryotes and prokaryotes, the latter studies developing at the same time.

The ARO Protein

The *aro* complex of *N. crassa* (Fig. 1) is a set of five genes encoding five enzymes that catalyze the synthesis of chorismic acid from 3-deoxy-D-arabinoheptulosonate phosphate (DAHP) to enolpyruvyl shikimate phosphate (EPSP) (Welch and Gaertner, 1980; reviewed by Davis, 2000). The latter is the precursor of chorismic acid, a common precursor of the aromatic amino acids tryptophan, phenylalanine, and tyrosine. Early mutational studies of *N. crassa* defined four "genes," *aro-1*, *−2*, *−4*, and *−5*, all tightly linked to one another on chromosome II. These were represented by point mutations, which all fell on a linear map of the cluster. Enzymic studies revealed the specific deficiencies in the mutants, but one enzyme of the five required for the overall conversion, dehydroquinase, was not represented by mutation. Among the many phenotypically Aro$^-$ mutants were those with multiple deficiencies, and some of these actually lacked dehydroquinase. Later, a dehydroquinase activity of the quinic acid catabolic pathway (C-dehydroquinase) was shown to be active in many Aro$^-$ mutants and would

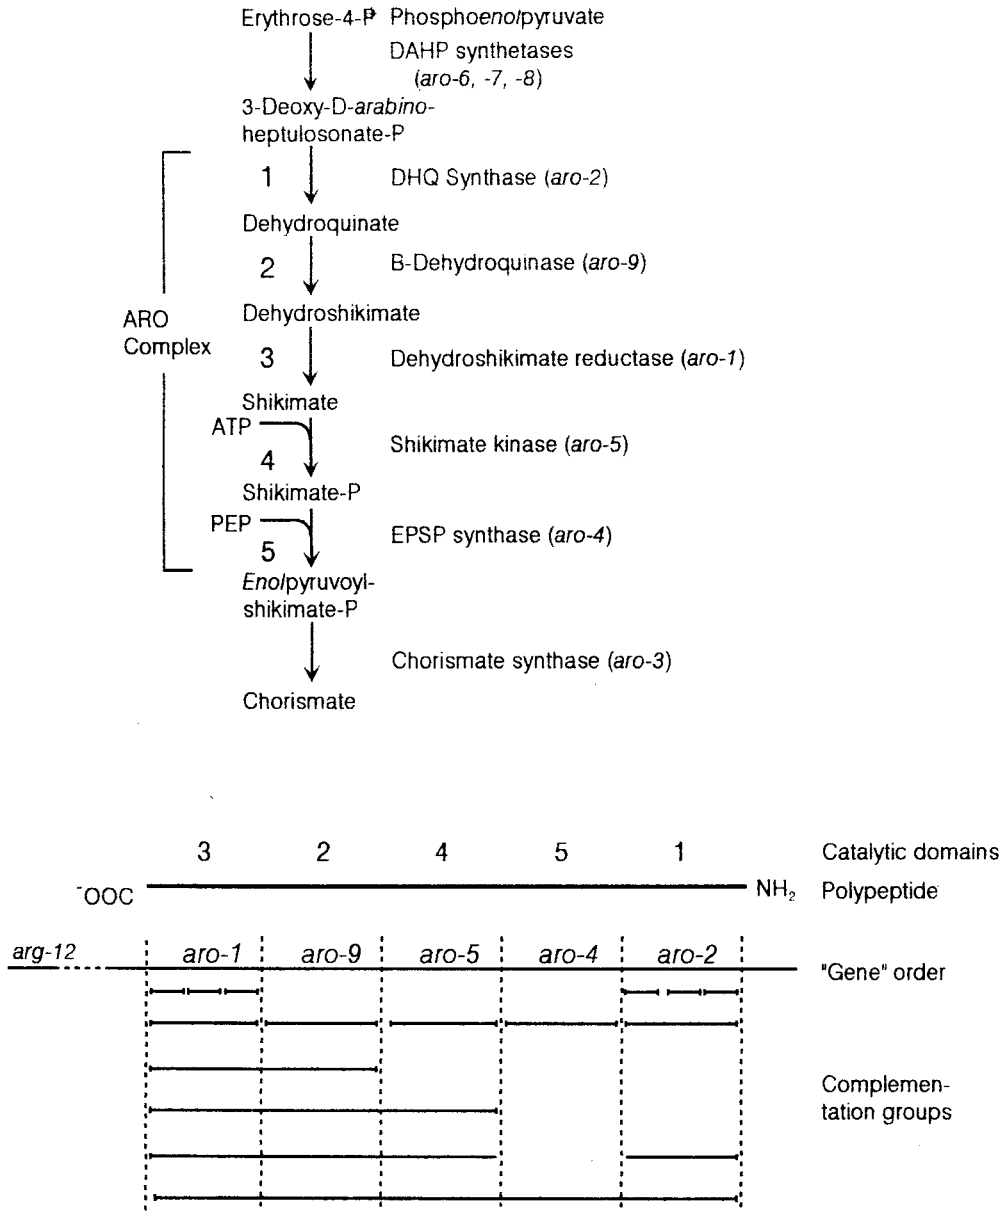

FIGURE 1 Pathway of chorismate synthesis in *N. crassa* (top), showing the metabolic positions of *aro* mutations. The organization of the ARO gene complex on linkage group IIR (bottom) shows the order of the catalytic domains (1 through 5) and of the corresponding component elements of the complex (aro-1, -2, -4, -5, and -9). The complementation groups are represented by lines that group mutants that will not complement; lines that do not overlap signify that complementation will take place between members of the different groups. Note that the translational polarity in this figure is oriented right (N terminal) to left (C terminal). Redrawn from Rines et al., 1969, and reprinted from Davis, 2000.

bypass any deficiency for the biosynthetic enzyme (B-dehydroquinase). Using mutants for the catabolic enzyme, investigators were able to isolate mutations, called *aro-9*, deficient in the B-dehydroquinase. These mutations lay in the *aro* cluster along with the other four *aro* mutations that catalyzed the overall DAHP-EPSP conversion. It was curious, but no more than that, that the map order of the "genes" did not follow the order of the enzymes in the pathway. The *aro* cluster was one of the first genetic systems that was finally recognized as encoding a multidomain protein.

A separate enzyme converting EPSP to chorismic acid is encoded by an unlinked, monofunctional gene, *aro-3*. Finally, the synthesis of DAHP itself, the first substrate dedicated to aromatic amino acid synthesis, is made by any of three isozymes encoded by the genes *aro-6*, *−7*, and *−8*. The three isozymes are individually and allosterically regulated by the cognate end products tryptophan, phenylalanine, and tyrosine, respectively.

Three aspects of these studies, one genetic and two biochemical, have become familiar in other systems involving

multidomain proteins. First, the earliest hypothesis concerning gene-enzyme relations was that the five enzyme activities of the *aro* complex were products of an operon, modeled on the *Escherichia coli lac* operon. At the time, this was reasonable, since few multidomain proteins of eukaryotes had been described in genetic terms. The salient features supporting this model were the tight genetic clustering, the multiple deficiencies of some mutants that suggested multicistronic deletions, and the polarity of some mutations. The last characteristic emerged from a study of complementation among mutants, in which nested overlaps were found: some mutants lacked all five enzymes, some four, some three or fewer, each "deletion mutation" able to complement particular single mutants with its remaining activities. In the *lac* system, mutations with such phenotypes arose either from deletions or from nonsense mutations that blocked progress of ribosomes past the mutant stop codon, with the ribosome failing to reach distal parts of the mRNA before it was degraded. The operon model for the *aro* system was quickly abandoned, as anomalies in the complementation pattern arose, and as analysis of mutant extracts showed that various of the enzyme activities could not be separated by biochemical techniques. The investigators then proposed that the enzymes, as they were being synthesized or after they were synthesized, remained or became obligatorily aggregated, a condition required for the activity of some or all of their activities. Indeed, it was suggested that the complex was a conductor for all of the intermediates of the overall reaction, in which these intermediates did not leave the protein.

The second aspect of the study of the ARO protein complex had to do with more-detailed biochemical studies of the system after 1975. Two groups of investigators applied emerging methods for stabilization of labile proteins (Lumsden and Coggins, 1978; Gaertner and Cole, 1977). Both succeeded in isolating a purified, homogeneous polypeptide, which, as a dimer, catalyzed the entire DAHP-EPSP conversion. The five activities were "domains," as the present language has it, of a single protein encoded by a single, long mRNA. The prior separability of individual enzyme activities and their variable associations with proteins of different molecular weights could be interpreted as interdomain cleavages by proteases or selective inactivation of individual domains. This example of a multidomain protein became a model for others, to be discussed hereafter.

The third aspect of interest in the *aro* gene cluster lay in the catalytic properties of the ARO complex, a property designated "catalytic facilitation" (Welch and Gaertner, 1976). Using the pure ARO protein, the rate of EPSP synthesis in vitro when shikimate, the penultimate substrate, was added directly was compared to the rate of EPSP synthesis when DAHP, the initial substrate, was added. The latter rate was much more rapid, with little lag time of product formation. Two interpretations were possible here. One was that shikimate (and perhaps other intermediates) produced by the complex lay in a compartment shielded from the ambient solution, as previously suggested by Giles' group (see above). The second was that providing the initial substrate of the complex, DAHP, might allosterically change the conformation of later enzyme domains, lowering their K_ms and thus facilitating their catalytic efficiency in nominally low concentrations of intermediate substrates. Some compelling evidence for the latter interpretation was presented, but the two views are not mutually exclusive.

DAHP Synthetases

As noted above, phenylalanine, tyrosine, and tryptophan each feedback inhibit a cognate DAHP synthetase, and each synthetase can individually form DAHP for the common ARO complex. This was one reason mutations for the three synthetases were isolated late in these studies: two synthetases had to be feedback inhibited in order to select auxotrophic mutants lacking the third.

Phenylalanine and Tyrosine

The EPSP produced by the ARO complex is used by the enzyme chorismate synthase to form chorismate, the proximal precursor common to all the aromatic amino acids (Fig. 1). The enzyme, deficient in *aro-3* mutants, is a flavoprotein with an intrinsic flavin reductase. Chorismate is a substrate for chorismate mutase, encoded by the *pt* (phenylalanine + tyrosine) gene to form prephenate (Fig. 2). This is used by

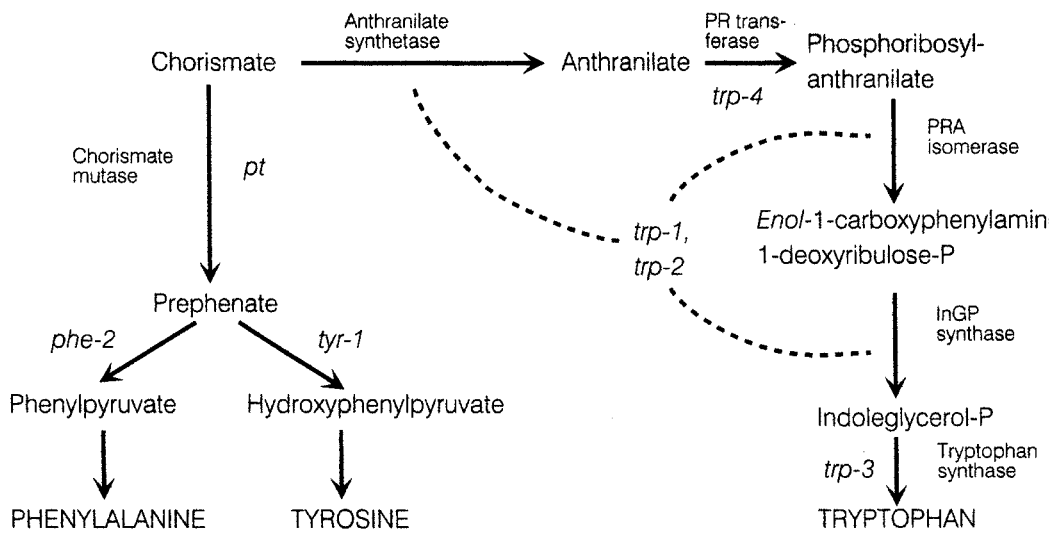

FIGURE 2 Tryptophan, phenylalanine, and tyrosine synthesis in *N. crassa*, showing the metabolic positions of various genes. Note that the complex of *trp-1* and *trp-2* gene products catalyzes three nonsequential reactions. Not all substrates are shown; for details of the tryptophan synthase reaction, see Fig. 3. Reprinted from Davis, 2000.

separate enzymes, one encoded by the *phe-2* gene to form phenylpyruvate (the α-keto precursor of phenylalanine), and the other encoded by the *tyr-1*gene to form hydroxyphenylpyruvate (the α-keto precursor of tyrosine). The two α-keto precursors are converted to the respective amino acids by general transaminases using glutamate.

Tryptophan Synthesis

Tryptophan synthesis depends upon two multidomain proteins, one of them aggregated to a third. The pathway from chorismate to tryptophan has been studied in detail in *N. crassa*, and complementary studies on tryptophan catabolism, which is a part of a potential metabolic cycle, have been performed. Tryptophan in *N. crassa* is a precursor for nicotinic acid and nicotinamide (see Davis, 2000).

Chorismate is used by anthranilate synthase to form anthranilate (Fig. 2), the dedicated substrate for tryptophan. Anthranilate is converted to phosphoribosylanthranilate (PRA) by condensation with 5-phosphoribosyl-1-pyrophosphate (PRPP), a reaction catalyzed by a transferase. PRA is then metabolized to *enol*-1-carboxyphenylamino-1-deoxyribulose-phosphate (CDRP). CDRP is converted to indole-glycerol phosphate and thence to tryptophan. Two polypeptides, specified by the *trp-1* and *trp-2* loci, form an $\alpha_2\beta_2$ heterotetramer required in three reactions in the pathway, the first of which is the anthranilate synthase reaction. The other two activities are the third and fourth reactions, which convert PRA to indole-glycerol phosphate. The last compound is converted to tryptophan via indole, a reaction considered separately below.

The *trp-2* product (the α subunit of anthranilate synthase) can catalyze anthranilate formation alone if ammonia is provided as the N donor. However, the biological reaction uses glutamine as an N donor, and the use of this substrate requires aggregation with the *trp-1* product (the β subunit), which contributes the glutamyltransferase activity via its G domain. In addition, the *trp-1* product has the enzymatic domains for third and fourth reactions; therefore, this subunit is trifunctional if the G domain is taken into account. As in the case of the ARO protein, catalytic facilitation was detected by finding a higher rate of indoleglycerol phosphate formation using PRA rather than CDRP as the initial substrate.

Clearly, gene fusions have taken place in this system if one compares the fungal and bacterial gene organizations. In the latter, most activities are catalyzed by separable proteins. Some fusions may have been selected for catalytic facilitation; others may be fortuitous but not essential (Crawford, 1989). We will revisit this matter in later examples.

Tryptophan Synthase

Tryptophan synthase of *Neurospora* is a multidomain enzyme encoded by the *trp-3* gene. Recognition of the multidomain nature of the enzyme came early, with the observation that mutants carrying some alleles of this gene accumulated indole, while others could use indole as a tryptophan source. Analysis of the enzyme reaction in vitro showed that the overall reaction from indoleglycerol phosphate to tryptophan was indeed the sum of two partial reactions, one forming indole and the other using it. Further analysis demonstrated that the two half-reactions were catalyzed by separate sites on the enzyme (Fig. 3). This was concordant with the more detailed studies of the enzyme of *Salmonella enterica* serovar Typhimurium, in which separate α and β peptides, products

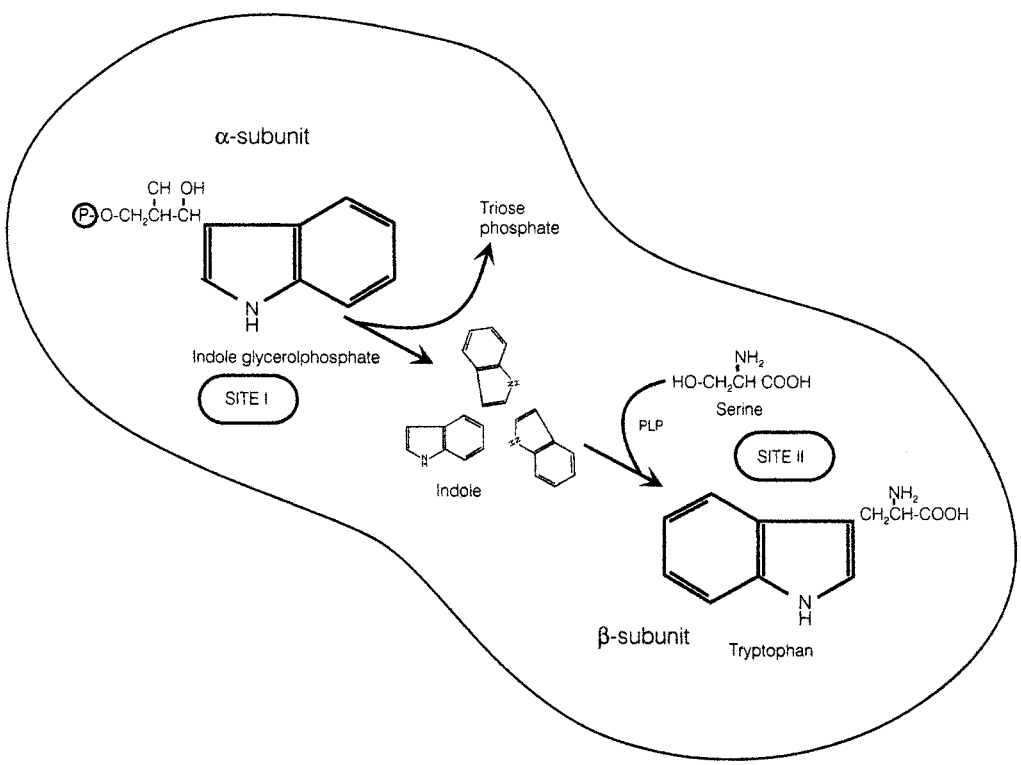

FIGURE 3 The tryptophan synthase partial reactions at sites I (reaction 2) and II (reaction 3). The intermediate indole diffuses between sites I and II, largely confined within the protein. Reprinted from Davis, 2000.

of distinct genes of an operon, carried the corresponding reaction sites (Crawford, 1989). Studies of the reaction in vitro showed that indole appeared not to be a free intermediate of the overall reaction in *N. crassa* but that it was reversibly and noncovalently enzyme bound. Ultimately, structural studies of the *S. enterica* serovar Typhimurium enzyme revealed a tunnel for indole to move from its site of release in the first reaction to the substrate binding site of the second reaction (Burns et al., 1990). An arrangement of fused enzyme domains ensures high local concentration of indole without the need to flood the cell with it. The localization of intermediates in the cell both by multifunctional polypeptides and by enzyme aggregates undoubtedly greatly relieves the solvent capacity of the cell as well as improving the efficiency of enzyme reactions.

A 1:1 stoichiometric ratio of polypeptides that aggregate may be achieved in bacteria by operon organization of the components and in eukaryotes by gene fusion. It is curious that in the case of tryptophan synthase, the order of the two subunits' genes (*trpB* and *trpA* for the β and α subunits, respectively) is reversed in the N-C-terminal order in *N. crassa* (α−β). Artificially fusing the bacterial polypeptides in the α−β order yields an effective enzyme, since the indole tunnel can be achieved in this arrangement if the linking sequence is sufficiently long (Burns et al., 1990).

The Tryptophan Cycle

Tryptophan catabolism, initiated by tryptophan pyrrolase, is notable only for the fact that one of the later products is anthranilic acid, a substrate of the biosynthetic pathway. Copious recycling of anthranilate is minor, however. Some of the immediate products of catabolism, such as indole pyruvate (by deamination), *N*-formylkynurenin, kynurenin, and anthranilate itself, may be excreted, to be used by the biosynthetic pathway only when the catabolic substrate, tryptophan, is exhausted from the medium (Matchett et al., 1968).

Histidine

The histidine pathway consists of 10 steps. In enteric bacteria, all are catalyzed by separate enzymes encoded by an operon. In the fungi *N. crassa*, *Aspergillus nidulans*, and *Saccharomyces cerevisiae*, apparent protein fusion has created a multifunctional gene. In *N. crassa*, this is the *his-3* gene, encoding a polypeptide with three enzyme activities (Minson and Creaser, 1969). The overall pathway starts with phosphoribosylpyrophosphate (required in purine, pyrimidine, and tryptophan biosynthesis), which is converted in the first dedicated step to phosphoribosyl-ATP. The second and third steps, in which phosphoribosyl-AMP and then phosphoribosylformiminoAICAR-phosphate are made, are catalyzed by the *his-3* gene product. These reactions are followed by six further steps, the last of which is histidinol dehydrogenase, the third reaction catalyzed by the *his-3* product. Thus, the activities of this protein are not sequential and can hardly channel intermediates within or on a protein. While this argues against a channeling interpretation, it may allow enzyme-bound phosphoribosyl-AMP to be directed to the next reaction. Moreover, the histidinol dehydrogenase step may be more efficient if the enzyme is part of the larger protein than if it is not (Minson and Creaser, 1969), a possible form of catalytic facilitation. The fact that all reactions are catalyzed by separate enzymes in *S. enterica* serovar Typhimurium suggests that the fungal system has evolved by gene fusion.

Isoleucine and Valine

The precursors of the isoleucine and valine pathways are α-ketobutyrate and pyruvate, respectively (Fig. 4). α-Ketobutyrate is derived from threonine in the threonine dehydratase reaction, and pyruvate is generally available in the cell. From this point on, three enzymes, acetohydroxy acid synthase, a reductoisomerase, and a dehydratase, catalyze the formation of the α-keto precursors of isoleucine (α-keto-β-methyl valerate) and valine (α-ketoisovalerate). These α-keto precursors in turn become isoleucine and valine through activities of general transaminase(s), using glutamate as an amino donor. While the use of the same enzymes for two pathways serves efficiency, it complicates control of the synthesis of the individual amino acids. Feedback mechanisms come into play here; isoleucine inhibits threonine deaminase, while valine inhibits the acetohydroxy acid synthase, but not enough to block isoleucine synthesis. Interestingly, the enzymes are mitochondrial, allowing many of these reactions to proceed in a restricted volume.

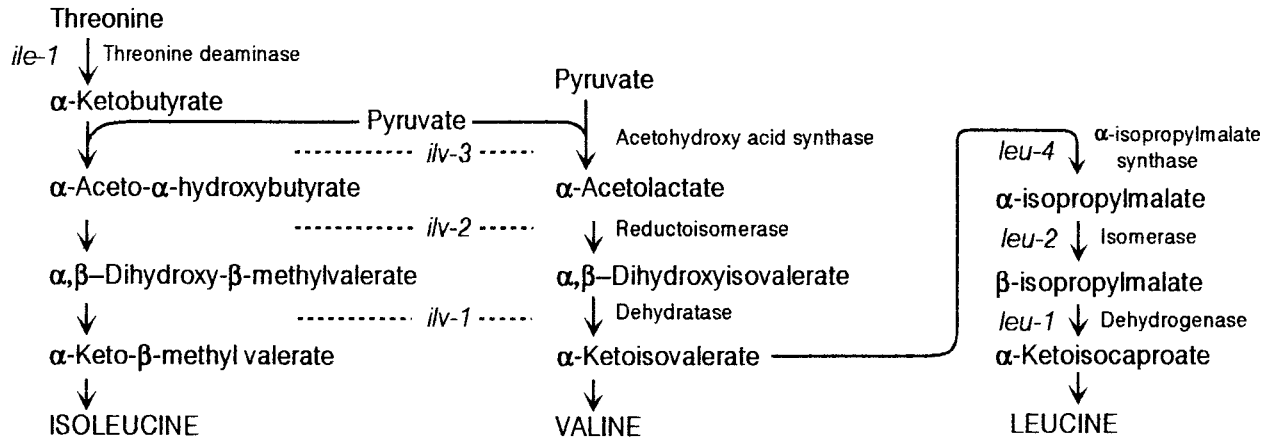

FIGURE 4 Isoleucine, valine, and leucine biosynthesis in *N. crassa*, showing the metabolic positions of mutations. Note that the *ilv-3* (acetohydroxy acid synthase), *ilv-2* (reductoisomerase), and *ilv-1* (dehydratase) genes encode single enzymes that carry out reactions in both the isoleucine and valine pathways. Reprinted from Davis, 2000.

Leucine

A complication also prevails in the aliphatic amino acid pathway: α-ketoisovalerate is the precursor of the leucine pathway (Fig. 4). In excess, valine might therefore partially block leucine as well as valine synthesis. However, the added valine becomes a leucine precursor through the reversible transaminase reaction that provides the required α-ketoisovalerate.

It is of some interest that the leucine pathway, initiated with the synthesis of α-isopropylmalate from α-ketoisovalerate, displays substrate induction of the next two enzymes by positive regulation at the gene level (Gross, 1965). This is true of both yeast and *N. crassa* and requires a specific leucine regulatory protein, encoded by the *leu-3* gene in the latter species. This protein, when bound to α-isopropylmalate, binds the DNA of the enzyme-coding genes and activates transcription. Although other minor allosteric regulatory features have been described in aliphatic amino acid biosynthesis, the ones noted here exemplify the interplay of regulatory mechanisms that must supplement the phenomenon of common enzymes involved in the synthesis of enzymes of three pathways. This theme is played out in other systems. For instance, as noted above, the synthesis of DAHP in the common pathway to tryptophan, tyrosine, and phenylalanine (see above) involves distinct DAHP synthetases, each feedback inhibited by one of the ultimate end products.

METABOLIC COMPARTMENTATION AND CONTROL

As biochemists and geneticists began to appreciate more fully the complexity of metabolism in the 1940s and 1950s, the cellular organization of pathways that might promote efficiency took shape as a new subject. The recognition of feedback inhibition and regulation of gene activity were the first steps in this appreciation. The sense that these mechanisms might generally smooth metabolic traffic within eukaryotic cells derived from studies of bacteria, in which the interplay of these regulatory mechanisms adjusted the synthesis of metabolites to cellular needs and called forth the synthesis of enzymes needed only episodically. Indeed, regulatory mechanisms similar to those in bacteria did prevail in eukaryotes, but several other mechanisms were discovered and pursued in fungal research programs.

Among these was the detection of enzymes with the same function, each dedicated to a specific pathway. The case of three enzymes for DAHP synthesis for aromatic amino acids has been discussed above. A more interesting case involves a second feature of eukaryotic systems, metabolic compartmentation. A well-studied example is that of the two carbamoyl phosphate synthetases, CPS-A and CPSase-P, dedicated to arginine and pyrimidine synthesis, respectively. This case involves both suitable feedback control mechanisms and a means of confining their common product to their respective pathways. Another, described below, is found in the role of mitochondria and vacuoles in managing general arginine and polyamine metabolism.

Carbamoyl Phosphate Synthesis

The simple, unstable intermediate carbamoyl phosphate is required for both arginine and pyrimidine syntheses. In arginine synthesis, it is used in the ornithine carbamoyltransferase (OTCase) reaction to form citrulline. In pyrimidine synthesis, it is a substrate for aspartate carbamoyltransferase (ATCase) and used to form carbamoyl aspartate (Fig. 5). The discovery of an enzyme that catalyzed the formation of carbamoyl phosphate from CO_2, ammonia, and ATP in mammalian liver (Jones et al., 1955) was followed by studies of its role in ammonia detoxification through use by OTCase

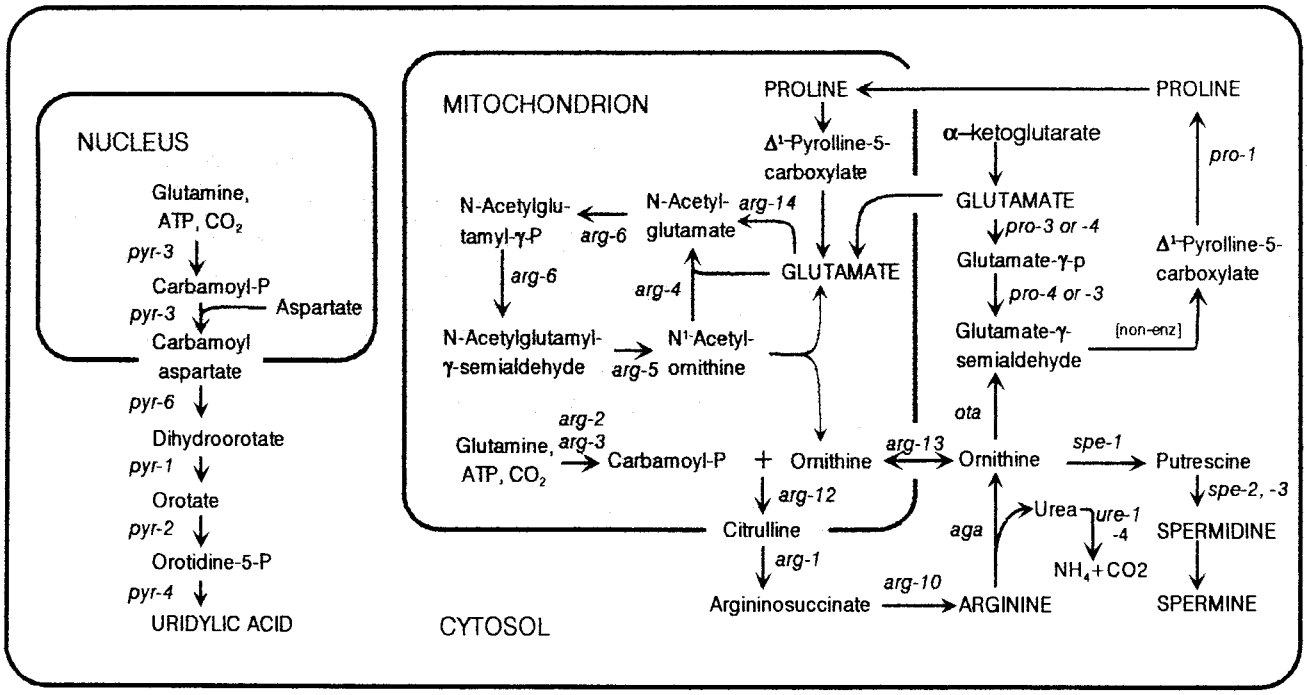

FIGURE 5 The pathways of pyrimidine, arginine, proline, and polyamine synthesis in *N. crassa*, showing the localization of enzymes and the metabolic positions of mutations. See Table 1 for gene-enzyme assignments. Reprinted from Davis, 2000.

and the urea cycle. Until 1962, the actual substrates and indeed several of the biosynthetic CPSases of nonureotelic organisms, including the fungi and bacteria such as *E. coli*, were unknown. While the CPSases then known could use ammonia as an N donor, the in vivo N donor was actually the amido nitrogen of glutamine (Levenberg, 1962). These enzymes were equipped with a small glutaminase subunit or peptide capable of delivering the amido nitrogen of glutamine to the other catalytic sites of the enzyme.

Arginine-Pyrimidine Relationships

Many bacteria have only one biosynthetic CPSase, CPSase I, responsible for the synthesis of this compound. In *E. coli*, pyrimidine nucleotides feedback inhibit CPSase I and ATCase. In order that carbamoyl phosphate remain available for arginine synthesis in conditions of excess pyrimidines, the ornithine accumulated upon feedback inhibition by pyrimidine nucleotides relieves the inhibition of CPSase I sufficiently to satisfy the needs of the arginine pathway. Mutations eliminating the enzyme activity had, as expected, a dual requirement for arginine and pyrimidines. Despite a wealth of mutations in the arginine and pyrimidine pathways isolated in *Neurospora* and yeast in the 1940s and 1950s, none having a dual nutritional requirement was found. Complications attended the mutational analysis of the two pathways, one being suggestive of interactions between arginine and pyrimidine mutations in double mutants. Another was an important difference between yeast and *Neurospora* in the phenotypes of similar CPSase mutants, once they had been recognized as such. The evolution of this problem has been described in detail elsewhere (Davis, 2000).

After considerable difficulty in interpreting the gene interactions noted above, it became clear that two CPSase enzymes existed in *Neurospora*, yeast, and finally, almost all eukaryotic organisms. These enzymes were path specific, at least in terms of their regulatory responses, and were designated CPSase-P and CPSase-A for the pyrimidine and arginine-specific proteins, respectively. Much later, *Bacillus subtilis* was shown to have two path-specific CPSases, each regulated appropriately by the end product of the respective pathway. In this bacterium and in yeast, both CPSases contribute to a common pool, such that a deficiency of one CPS does not block growth; the remaining CPSase can serve both pathways.

The case of *Neurospora* was quite unusual, however. It appeared that the carbamoyl phosphate made by each CPSase was channeled to its own pathway. Mutations of each CPSase imposed a requirement for its own end product. This implied a segregation not only of the two enzymes but also of their products. This channeling, however, was overcome if the use of carbamoyl phosphate in the functional pathway was mutationally blocked by a carbamoyl transferase deficiency (Fig. 6). This was the basis of considerable confusion in the early days but a key to the discovery that two CPSase enzymes existed in the organism.

Carbamoyl Phosphate in Pyrimidine Synthesis

The apparent segregation of the products of each CPSase evoked the question of how a small molecule like carbamoyl phosphate was channeled to a specific pathway. The early genetics of pyrimidine mutants showed that within a single gene, *pyr-3*, one found not only CPSase-P-deficient mutations (later collectively named *pyr-3*M) but also ATCase-deficient mutations (*pyr-3N*). The map positions of the two kinds within the *pyr-3* gene showed some overlap, suggesting that the two sorts of mutations affected a single protein encoding both enzyme activities. The two

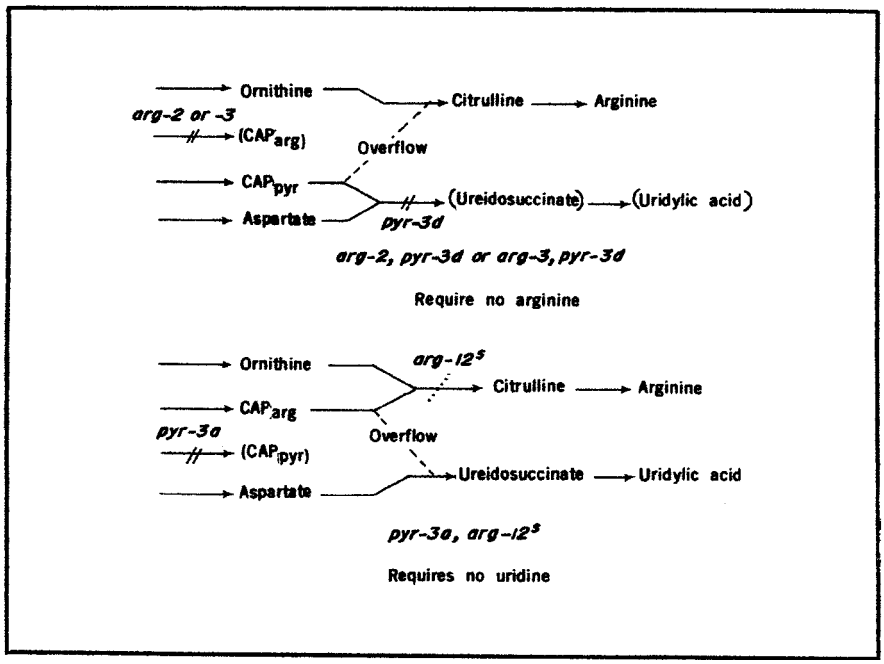

FIGURE 6 Carbamyl phosphate (CAP) overflow between pathways in two types of double mutants of *Neurospora*. Mutations *pyr-3d* (top) and *arg-12*^{s} (bottom) block CAP utilization in one pathway and thereby relieve nutritional requirements imposed by CPS mutants in the other. Parenthesized compounds are not synthesized. CAP is arginine or pyrimidine specific. Reprinted from Davis, 1972.

types complemented one another, but neither complemented with a third type, designated *pyr-3MN*, assumed to lack both functions.

The proposal that a single protein carried both enzyme activities was later proven directly by purification of a bifunctional protein. This was consistent with genetic complementation results, later amplified by showing that *pyr-3M*-type mutations were interspersed with *pyr-3MN*-type mutations at one end of the map; *pyr-3N*-type mutations were found only at the other end. This suggested that the CPSase-P domain was N terminal and the ATCase domain was C terminal (Radford, 1969).

A bifunctional CPSase-P-ATCase protein could in principle (as in the case of tryptophan synthase) retain carbamoyl phosphate between its production by the CPSase-P domain and its use by the ATCase domain. Later work involving yeast provided evidence that this channeling mechanism actually took place in vitro (Lue and Kaplan, 1970), but some doubt has developed about its efficiency. However, a histochemical localization of the protein of *Neurospora*, which liberates the phosphate moiety of carbamoyl phosphate in the second reaction, showed that the reaction product (as a lead precipitate) accumulated in the nucleolus. Later experiments with yeast suggested that this localization might be artifactual and that the bifunctional protein lies in the cytoplasm (Benoist et al., 2000). One therefore cannot with certainty attribute channeling of carbamoyl phosphate of the pyrimidine pathway to its binding the CPSase-P-ATCase protein or to confinement within the nucleus or nucleolus. The path segregation issue was made moot by later analysis of CPSase-A (see below).

Later Steps of Pyrimidine Synthesis

The pyrimidine pathway is common to almost all organisms, including bacteria. The product of ATCase is carbamoyl aspartate, in which a carbamoyl group is transferred to the α-amino group of aspartate. Carbamoyl aspartate is cyclized by the enzyme dihydroorotase to form dihydroorotate; this intermediate is dehydrogenated to form orotate. This is then brought to the nucleotide level by a phosphoribosyl transfer from PRPP. The orotidylic acid formed is decarboxylated to form uridylic acid, which enters general pyrimidine nucleotide metabolism. A few matters of interest here apply to the fungi. First, the dihydroorotate dehydrogenase step is catalyzed by an enzyme on the outside of the mitochondrial inner membrane, a location also found for the mammalian enzyme. Finally, in higher eukaryotes, but not in yeast, the apparent gene fusion of the CPSase-P-ATCase domains implied by the fungal systems in comparison to bacteria is extended in mammals by further fusion of the dihydroorotase. In addition, in mammals, the last two enzymes (phosphoribosyltransferase and decarboxylase) are fused as a bifunctional enzyme.

Arginine-Specific Carbamoyl Phosphate Synthesis

CPSase-A is a heterodimer of two polypeptides encoded by unlinked genes. One, the rather small subunit encoded by the *arg-2* gene, is a glutaminase that yields the amide nitrogen of glutamine as the N donor in the reaction. The other is a larger CPSase polypeptide, encoded by the *arg-3* gene, that uses this moiety, together with ATP and CO_2, to form carbamoyl phosphate. The two polypeptides enter the mitochondrion independently from the cytoplasm and aggregate to form the unstable, mature enzyme. The mitochondrial membrane provides an effective barrier to the exit of normal levels of carbamoyl phosphate to the cytoplasm and nucleus. This was indicated by direct measurement of the arginine-specific carbamoyl phosphate pool remaining in a pyrimidine-starved CPSase-A-deficient *pyr-3M* mutant. In complementary fashion, the mitochondrial membrane blocks entry of small amounts of the pyrimidine-specific carbamoyl phosphate as well, again inferred from the pyrimidine-specific CAP pool remaining in arginine-starved *arg-3* mutants.

The same is not true for yeast. CPSase-P and OTCase are located in the cytoplasm in yeast, thereby obviating channeling of carbamoyl phosphate by the mitochondrial membrane, to be discussed hereafter. As in *B. subtilis*, the carbamoyl phosphate from either pathway of yeast enters a common, cytoplasmic pool, available to both OTCase and ATCase.

Early genetic studies of *Neurospora* turned up a mutation, *arg-12^s*, that overcame the nutritional requirement of a *pyr-3M* (CPS-P-deficient) mutation. The double mutant grew as well as wild-type strains on minimal medium. The *arg-12^s* mutation reduced OTCase activity by over 90%, but the remaining activity supported a normal rate of arginine synthesis. In the double mutant, both ornithine- and arginine-specific carbamoyl phosphates accumulate, and the latter is diverted to ATCase. Similarly, the ATCase deficiency of *pyr3-N* mutants diverts accumulated pyrimidine-specific carbamoyl phosphate to OTCase (Fig. 6). This indicates that at high levels, carbamoyl phosphate of either pathway can penetrate the mitochondrial membrane at a sufficient rate to support the demands of a CPSase-deficient pathway. Each CPSase enzyme is controlled by the end product of its own pathway: UTP feedback inhibits CPSase-P, and arginine severely represses the synthesis of the *arg-2* product. The best indication of the latter is that the double mutant above (*arg-12^s pyr-3M*) acquires a pyrimidine requirement if it is grown in the presence of arginine. These control mechanisms, together with those peculiar to *S. cerevisiae*, are discussed in an integrated treatment of the arginine pathway below.

These studies illustrate, in addition to the possible advantages of enzyme-bound intermediates, another mechanism of metabolic organization, namely, the localization of enzymes and/or substrates within membrane-bound organelles. This contributes to a finer control of metabolite distribution and obviates the need for pancellular concentrations of metabolites sufficient to meet the K_m requirements of individual enzymes.

Ornithine and Arginine Biosynthesis

Arginine synthesis requires many enzymes, organized in two major segments (Fig. 5 and Table 1). A thorough review of arginine metabolism is available (Davis, 2000). The first segment is a cyclic pathway that begins with the synthesis of acetylglutamate from glutamate and acetylcoenzyme A and ends with the deacetylation of acetylornithine to form ornithine. In the latter reaction, the acetyl group is conserved by a transacetylase (ornithine-glutamate acetyltransferase), which, with another molecule of glutamate, regenerates acetylglutamate.

In the second segment of arginine synthesis, ornithine, once released as such, is transformed to citrulline and thence to arginine, most of which is used in protein synthesis in fungal cells grown in minimal medium. A potential problem develops under other conditions. The enzyme arginase catabolizes arginine to ornithine and urea if arginine is provided in excess. Both products of the arginase reaction are further catabolized. The ornithine is transformed

TABLE 1 Gene-enzyme assignments in the arginine, proline, pyrimidine, and polyamine pathways

Gene[a]	Enzyme	Gene ID[b]
aga	Arginase	NCU02333.3
arg-1	Argininosuccinate synthetase	NCU02639.3
arg-2	Carbamoylphosphate synthetase (arginine specific, CPS-A): small subunit	NCU07732.3

to glutamate (via proline), and urea is broken down by urease to carbon dioxide and ammonia. The problem lies in ornithine being a common intermediate of both arginine biosynthesis and degradation, setting up a potential futile cycle. The problem is solved in unusual and different ways in *Neurospora* and yeast, which are now discussed.

The ornithine-arginine pathway attracted the attention of early biochemists for its role in ammonia detoxification in mammals by way of urea synthesis and excretion. Other organisms, including many fungi, have no need for ammonia detoxification and can store and use arginine as a nitrogen source. The first major work on arginine synthesis in the fungi, owing to the large numbers of *Neurospora*, yeast, and *Aspergillus* Arg^- mutants that appeared in early genetic studies, offered a good example of the one gene, one enzyme relationship (Srb and Horowitz, 1944). The quite different patterns of arginine metabolism in fungi and mammals called for a comprehensive study of arginine metabolism in the context of fungal physiology.

Two themes will be followed. The first began with the discovery that all arginine-synthetic enzymes, including OTCase in *N. crassa*, are located in the mitochondrion. This poses the question of how cytosolic arginine might exert, if at all, allosteric control of early enzymes of the pathway, specifically CPSase-A and acetylglutamate synthase and/or acetylglutamyl kinase (Fig. 5). The second theme flows from the discovery that the cells of many fungi (as studied in detail in *Neurospora*) store a great deal of free arginine and ornithine in vacuoles and possess an active arginase. No arginine is catabolized unless it enters cells through the cell membrane or is released from the vacuoles. The role of the vacuole in sequestering arginine and ornithine serves to protect both amino acids from catabolism in the cytosol. In addition, vacuolar sequestration and the properties of the mitochondrial membrane prevent the entry of ornithine arising during arginine catabolism into the biosynthetic pathway in the mitochondrion.

Control of Ornithine Synthesis

The rate-limiting steps in arginine synthesis in minimal medium are the formation of ornithine and carbamoyl phosphate, both of which are controlled in unusual ways. No enzyme of the arginine pathway, except one, the small polypeptide of CPSase-A, is significantly repressed by arginine below levels found in cells grown in minimal medium. Except for CPSase-A, most enzymes are elevated only two- to threefold upon arginine starvation. Allosteric control is exerted only on early enzymes of the acetylglutamate cycle.

Figure 5 shows that cytosolic glutamate enters the mitochondrion, where it may be used by acetylglutamate synthase (the *arg-14* product) and by acetylornithine-glutamate transacetylase (the *arg-5* product). The first of these enzymes, although absolutely essential for arginine synthesis, has low activity and serves to maintain the level of acetylglutamate

during growth and against losses through deacetylation of later intermediates. The transacetylase, on the other hand, maintains the cycle, regenerating acetylglutamate from acetylornithine during each turn.

Acetylglutamate is committed to the synthesis of ornithine by a third enzyme, acetylglutamate kinase, encoded by a distinct domain of the *arg-6* gene (Fig. 5). No arginine is produced endogenously in the presence of excess arginine in the cytosol, owing to inhibition of acetylglutamate synthase and acetylglutamate kinase. The transacetylase is not inhibited by arginine. Investigation of the *arg-14* and the *arg-6* genes revealed unusually complex mechanisms of enzyme synthesis, transport into the mitochondrion, processing of enzyme precursors, and protein interactions enabling feedback control of ornithine synthesis.

As noted above, acetylglutamate kinase is encoded by a multifunctional gene, *arg-6*. This gene also encodes the next enzyme, *N*-acetylglutamate phosphate reductase. These two activities produce acetylglutamyl semialdehyde, the precursor of acetylornithine and ornithine.

The *arg-6* mRNA is translated into a 96-kDa polyprotein, in which the kinase and reductase domains are connected by a 200-amino-acid peptide (Parra-Gessert et al., 1998). The propolypeptide precursor contains an N-terminal mitochondrial targeting sequence and an N-terminal cleavage site just before the N terminus of the mature kinase domain. However, several other internal cleavage sites are found toward the C-terminal end of the connector segment, allowing cleavage of the polyprotein between the two domains as, or just after, it enters the mitochondrion. The mature kinase is an octamer of 51-kDa polypeptides; the reductase is a dimer of two 40-kDa polypeptides. Whether the two enzymes aggregate in the mitochondrion is not known, but curiously, an engineered, uncleaved polyprotein that remains intact in the mitochondrion is catalytically active for the overall reaction.

The acetylglutamate synthase gene, *arg-14*, encodes a 73-kDa protein. It is unusual in having little homology to the bacterial acetylglutamate synthases, unlike the two domains of the *arg-6* protein. It has low abundance in *N. crassa*, in keeping with its quasicatalytic role in maintaining substrate for the acetylglutamate cycle (Yu et al., 1996).

Mutations that eliminate the *arg-6* gene product and certain others that render it inactive also eliminate acetylglutamate synthase activity. This suggests a physical interaction of the *arg-6* and *arg-14* products (Kim and Weiss, 1995). Considerable attention has been devoted to this matter (Glansdorff and Xu, 2007; Abadjieva et al., 2001). One idea is that the kinase and synthase must aggregate to stabilize and impart activity to the synthase. Another is that the kinase and/or reductase proteins have a role in the maturation of the synthase. Finally, because feedback-insensitive mutations of the kinase also affect the sensitivity of the synthase to arginine, arginine can evidently negatively control both enzymes. These matters have been explored in somewhat more detail in the yeast arginine pathway. There, the yeast synthase and kinase do indeed associate physically, and the association is required for synthase activity and stability.

Mutations in the *arg-6* gene rendering acetylglutamate kinase feedback insensitive result in the synthesis of excess ornithine, but this is not accompanied by excess arginine formation (Weiss and Lee, 1980). This reflects a bottleneck arising at the synthesis of carbamoyl phosphate and the diversion of excess ornithine through the catabolic ornithine aminotransferase reaction to proline (Fig. 5).

A remaining question is whether, and if so, how, arginine enters the mitochondrion to exert feedback inhibition. Tests with purified mitochondria reveal that a facilitated diffusion mechanism permits the equilibration of arginine, ornithine, and lysine across the mitochondrial membrane (Yu and Weiss, 1992). This function is probably carried out by the product of the *arg-13* gene in *N. crassa* and the *arg-11* gene of *S. cerevisiae* (Glansdorff and Xu, 2007). Moreover, the three amino acids are mutually competitive and the system has a rather high K_m for each of them. Under circumstances in which cytosolic arginine is low in concentration, little enters the mitochondrion. Under conditions of arginine excess, arginine enters the mitochondrion and can inhibit the early enzyme reactions. Moreover, under these conditions, excess cytosolic arginine blocks the entry of ornithine into the mitochondria and thus its wasteful use in the anabolic pathway. This is one of the few cases in which an organellar membrane has been recruited as a site of feedback inhibition.

In passing, one may note here another element of metabolic organization, namely, derivatization of substrates. Both proline and ornithine syntheses use glutamate as the initial substrate. However, the acetylglutamate cycle effectively isolates glutamate destined for ornithine synthesis via acetylglutamate semialdehyde from the glutamate used for proline synthesis via glutamate semialdehyde.

Control of Arginine-Specific Carbamoyl Phosphate Synthesis

A second question emerged with the discovery of continued carbamoyl phosphate synthesis after addition of arginine to cells grown in minimal medium or to cells previously starved for arginine. Under the latter conditions, CPSase-A is highly derepressed, and carbamoyl phosphate accumulates in mitochondria, where much of it is turned over within the organelle (Davis and Ristow, 1987). Some is diverted to pyrimidine synthesis, a point we can appreciate in phenotypic terms: the double-mutant strain *pyr-3a*, *arg-12*^{s} has no pyrimidine requirement, as noted above. The most striking observation is that if arginine is added to such cells grown in minimal medium, at least two entire doublings take place before a pyrimidine requirement asserts itself, despite the fact that the amount of carbamoyl phosphate accumulated prior to adding arginine can account for little additional growth. Therefore, added arginine does not directly feedback inhibit CPS-A in vivo, consistent with in vitro results. Instead, control by arginine is exerted at the level of enzyme formation. Control is exerted almost wholly on the formation of the small glutaminase subunit of the enzyme, the product of the *arg-2* gene. The larger CPS polypeptide (the *arg-3* product, assayable with ammonia as an N donor) is relatively nonrepressible.

The reduced synthesis of the small polypeptide of CPS-A under conditions of arginine excess is only threefold below those seen in cells grown in minimal medium, but the mechanism of control is unusual. In *N. crassa* and in yeast, the 5′ leader of the mRNA for this protein has a 24-amino-acid upstream open reading frame (uORF). The sequence is translated, and in *N. crassa* excess arginine causes the peptide to bind ribosomes that have translated it. This results in the ribosomes stalling at the uORF termination codon (Wang et al., 1998; Fang et al., 2004), and the same is true for yeast (Gaba et al., 2005). Elimination of the uORF abrogates the negative control of synthesis of the *arg-2* protein by arginine. Arginine-starved cells synthesize the *arg-2* product at a 10-fold-higher rate than

cells grown in minimal medium, not only through relief of the inhibition by the uORF product but also through positive action of the cross-pathway control system on transcription of the *arg-2* gene (see hereafter).

The picture developed here suggests that the continued synthesis of carbamoyl phosphate under conditions of excess arginine might have evolved to the benefit of the organism. With long-term conditions of repression, carbamoyl phosphate accumulates to a point where turnover stabilizes the amount. Carbamoyl phosphate synthesis never stops, owing to the incomplete repression of the small subunit of CPSase-A. Thus, when arginine drops in its concentration and ornithine synthesis immediately resumes, citrulline synthesis will also resume quickly by virtue of residual carbamoyl phosphate and its carbamoyl phosphate synthesis, even as production of the small subunit of CPSase-A resumes at a normal rate.

A quite extraordinary difference exists between the control of arginine synthesis in yeast and the fungal system described above. First, in yeast both CPSase-A and OTCase reside in the cytosol, not in mitochondria. Like the *Neurospora* enzyme, CPSase-A of yeast is not feedback inhibited by arginine, but merely repressed. Second, arginase is induced considerably by arginine addition to yeast cells, unlike the arginase of *Neurospora*, which is constitutive and is induced only threefold at most (Davis, 1986). Third, while ornithine synthesis is controlled similarly to what is observed in *Neurospora*, the ornithine arising through arginase activity would appear in the cytosol, where it might enter the biosynthetic pathway through OTCase. The unusual feature displayed by yeast is the inhibition of OTCase by arginase (Penninckx et al., 1974). The two enzymes, both homotrimers, actually bind in a 1:1 stoichiometric ratio and accomplish a rapid cessation of citrulline synthesis, despite the continued availability of carbamoyl phosphate and ornithine. The cytosolic location of CPSase-A and OTCase and the unusual manner of control of citrulline synthesis are exceptional. *S. cerevisiae* and facultatively anaerobic yeasts display these features, but control in other yeasts and in filamentous fungi resembles that used in *N. crassa*.

The Role of the Vacuole

The understanding of vacuoles of filamentous fungi has peculiar origins. Vacuoles appear in older cells of mycelia in most species and are named as such by resemblance to those of yeast cells and, by extension, to plant cell vacuoles. However, many inclusions of fungal cells had been defined after electron microscopy revealed them, and most were much smaller than what had previously been called the vacuole. Further, even the large yeast vacuole undergoes fragmentation and reconstitutions during cell division in some strains and conditions. The isolation of poorly defined "protease particles" in other studies involving *N. crassa* led to some speculation that they might be vacuoles. The term "vacuole" became somewhat vague as investigators sought adequate and distinctive criteria for the organelle. The most important development in this process came as a surprise from studies of young, rapidly growing germlings of *N. crassa*, in which no vacuoles could be seen by light microscopy or were recognizable in electron micrographs. These studies led finally to isolation from germlings, and purification to homogeneity, of very small vacuoles (Vaughn and Davis, 1981). This allowed development of criteria for their identification, understanding of their osmotic sensitivity, active transport across the vacuolar membrane, discovery of a distinct vacuolar ATPase that regulates its internal pH, an inventory of vacuolar contents, and the physiological role of the vacuole in nitrogen, polyamine, and phosphate metabolism (Davis, 1986). These vacuoles, in their contents and biochemical markers, closely resembled those of yeast except for their size. For an excellent review of the fungal vacuole, see Klionsky et al., 1990.

The interest in the role of the vacuole in arginine metabolism emerged from the observation that arginase, a cytosolic enzyme, produces no urea whatsoever in cells grown in minimal medium despite the existence of a very large cellular arginine pool in even very young cells (nominally about 25 mM in cell water). Indeed, no urea accumulates in cells or the medium of a culture of a ureaseless mutant over many generations. Studies of cellular ornithine, also at high levels in the cells, demonstrated that little of it was catabolized by ornithine aminotransferase, a cytosolic enzyme. During the studies that demonstrated the mitochondrial location of arginine enzymes, sorbitol was used as an osmotic stabilizer of the organelle. Continued studies with extracts of gently disrupted, sorbitol-stabilized cells, followed by differential centrifugation, showed that over 95% of free arginine and ornithine sedimented with a dense, osmotically sensitive particle, distinct from mitochondria. The new particle also contained large amounts of inorganic polyphosphate, the major counterion to the basic amino acids and one of the key attributes of the vacuole of yeast. Indeed, the density of the particles could be attributed to the polyphosphate content and the osmotic loss of vacuolar water during sedimentation in the sucrose density gradient (Weiss, 1973). Plainly, the vacuolar location of arginine and ornithine, which were tightly retained during vacuole isolation, rendered the amino acids unavailable for catabolism (Davis, 1986).

An understanding of the mechanisms that influenced arginine metabolism required knowledge of the quantitative distributions of arginine and ornithine in different cellular compartments. For instance, what are the concentrations of these amino acids in relation to the substrate affinities of the enzymes in the same compartment? Part of the regulatory repertory of the cell consists of the control of the fluxes across the vacuolar and mitochondrial membranes. Analysis of these matters took advantage of radioactive arginine or its intermediates, added to cells at tracer levels. Even at tracer levels, arginine and ornithine are taken up readily through high-affinity uptake systems. The labeled compounds added are so high in specific radioactivity that they do not alter the chemical concentration of the cognate compound in the cells. In exponentially growing cells, chemical determinations can measure the amounts and rates of change of relevant components such as protein and free amino acid pools (including intermediates) independently of tracer addition. Measurement of radioactivity in these compounds, once isolated and assayed, allows one to determine the specific radioactivities (counts per minute per nanomole) of all components. After the addition of radioactive arginine or ornithine, sampling at short intervals allows one to compare the specific radioactivity (counts per minute per micromole) of *new* products of each enzyme reaction with those of the nominal substrates of the enzymes in the cell. Any differences can be attributed to a different distribution in the cell of the metabolically active pool and the remainder of the same compound (Subramanian et al., 1973; Karlin et al., 1976). The arginine, polyamine, and proline pathways are extremely favorable for these studies. The end products are relative dead ends (mostly in the form of protein amino acid for arginine and its intermediates, or

vacuolar pool for arginine and ornithine), and no radioactivity is lost in competing reactions. Unlike many previous experiments in this area, sampling intervals were extremely short (5 to 10 s). This allowed the detection of early and revealing changes in specific radioactivities of each metabolite as the metabolic system proceeded to steady state.

The outcome of these studies is summarized in Fig. 7. In minimal medium, less than 1% of the cellular ornithine lies in the cytosol in exponentially growing mycelia, a steady state maintained by reversible efflux of ornithine from the mitochondria and the uptake of ornithine into, and its release from, the vacuole as the cells grow. In the cytosol, small amounts of ornithine are used for polyamine synthesis (see hereafter) or "leakage" through the catabolic enzyme, ornithine aminotransferase, to the proline pathway. (Catabolism of ornithine proceeds through proline, any excess of which is further catabolized to glutamate.) Similarly, about 1% of the cellular arginine lies in the cytosol, where it is used by arginyl-tRNA synthetase or is taken up by the vacuole. None, as mentioned, is catabolized under these conditions. The concentrations of ornithine and arginine in the mitochondrion and the cytosol are attuned to the measured substrate affinities of the relevant enzymes.

More-refined studies of the fluxes of arginine and ornithine across the mitochondrial and vacuolar membranes in vivo revealed that one-third to one-half of the arginine synthesized by the cell passes through the vacuole on its way to incorporation into proteins (Fig. 7). More dramatic is the determination that one-half of the ornithine made in the mitochondrion and later used by the mitochondrial OTCase actually passes through the cytosol (including entry into, and exit from, the vacuole). This determination was made from specific radioactivity measurements of citrulline synthesized in the mitochondrion: only one-half of the ornithine produced by ornithine-glutamate acetyltransferase is immediately used by OTCase.

The next question is how the vacuolar pools of ornithine and arginine are managed and used during conditions of arginine starvation and excess. Experiments using a prototrophic strain, first grown in the presence of arginine and then transferred to a medium without arginine, yielded insight into the role of the vacuole. Under the initial conditions, an expanded vacuolar pool of arginine forms, ornithine is displaced from the organelle, and considerable hydrolysis of arginine by arginase takes place in the cytosol, providing continued availability of ornithine for catabolism. The amount of ornithine entering the mitochondria becomes severely reduced, owing to inhibition of the entry of ornithine by arginine.

The transition of arginine-replete cells to arginine-free medium is followed by a rapid cessation of arginine and ornithine catabolism and a very slow resumption of ornithine and arginine synthesis. Growth proceeds at the expense of vacuolar arginine, which can continue for at least a doubling of dry weight. In a strain having a feedback-insensitive ornithine pathway, however, ornithine synthesis resumes

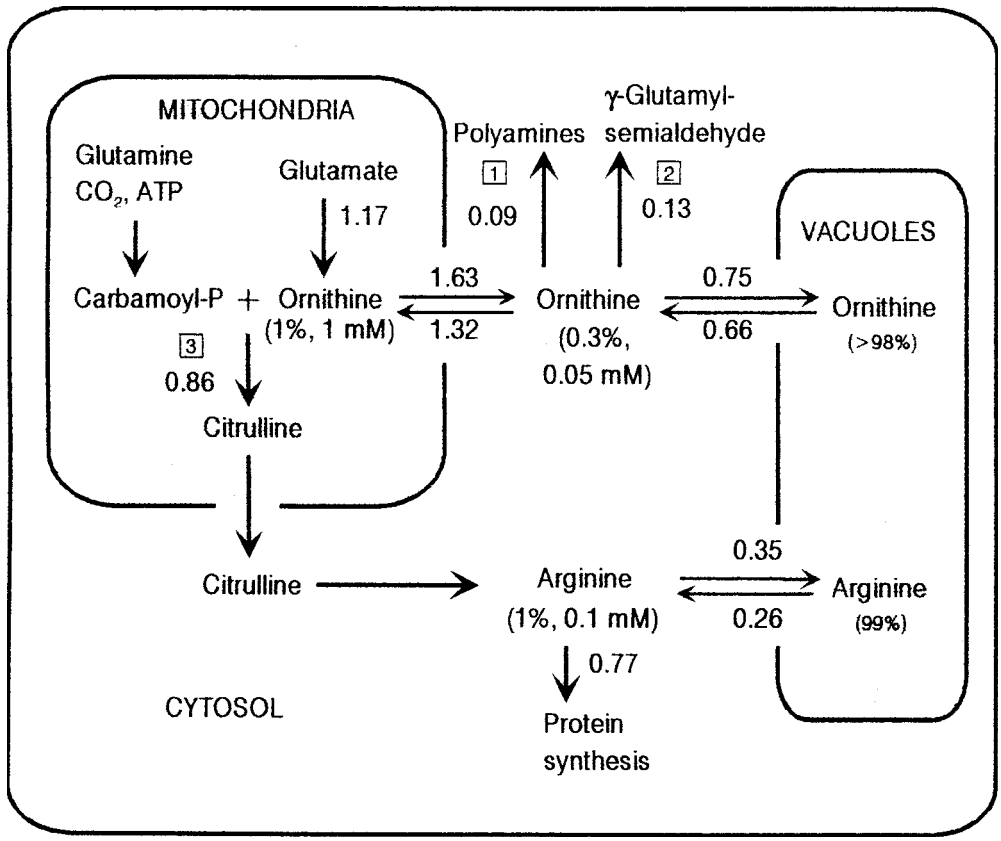

FIGURE 7 Steady-state flux of arginine and ornithine in exponential cultures of *N. crassa* grown in minimal medium. Values are in nanomoles per minute per milligram, dry weight, of mycelium. Boxed numbers identify ornithine decarboxylase (1), ornithine transaminase (2), and ornithine carbamoyltransferase (3). Based on Karlin et al., 1976, and reprinted from Davis, 2000.

rapidly (Goodman and Weiss, 1986). This suggests that in the wild-type strain, feedback inhibition of ornithine synthesis in arginine-replete cells is maintained until the vacuolar pool returns to normal. Indeed, in the transition from arginine-replete to arginine-free conditions, cytosolic arginine concentration quickly diminishes to a level unable to support catabolism of arginine or ornithine but remains high enough to exert continued feedback inhibition. At steady state in arginine-free conditions, feedback inhibition is finally relieved. These and other observations demonstrate that the vacuole plays a major role in adjusting cytosolic arginine concentrations despite large variations in vacuolar arginine content.
